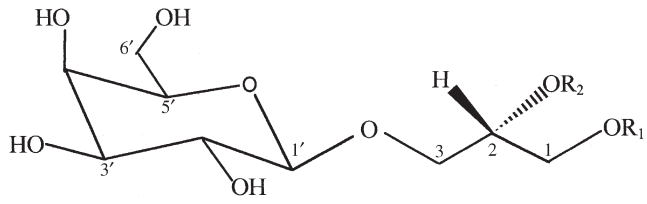
To define the locations of these fatty acid residues in diacylgalactolipid **1**, we applied enzymatic hydrolysis (3). The lipase-catalyzed hydrolysis of **1** using Lipase type XIII (Sigma, St. Louis, MO) afforded 1-*O*-deacylated galactolipid **1a** and 9*Z*,12*Z*-octadecadienoic acid, the latter being identified with an authentic sample by GC–MS and $^1$H NMR. Detailed comparisons of the $^1$H and $^{13}$C NMR spectra of **1a** and **1** showed that the signals due to both $H_2$-1 and C-1 were observed at higher fields than those in **1** (Table 1). These data strongly suggested that 9*Z*,12*Z*-octadecadienoic acid residue was on C-1 of the diacylgalactolipid **1**. Alkaline treatment of 1-*O*-deacylated galactolipid **1a** provided (2*R*)-3-*O*-β-D-galactopyranosylglycerol **1b** and methyl hexadecenoate, the latter exhibiting a molecular ion peak at *m/z* 268 corresponding to $C_{17}H_{32}O_2$ and a different spectrum from that of methyl 9*Z*-hexadecenoate in GC–MS. The geometry of the double bond in methyl hexadecenoate was supposed to be *Z* from the coupling constant of olefinic protons [δ 5.42 (1H, *ddd, J* = 10.7, 7.5, 7.0 Hz); 5.33 (1H, *m*)]. Therefore, methyl hexadecenoate was supposed to be an isomer of methyl 9*Z*-hexadecenoate in the double bond position.



**1**: $R_1$ = *9Z,12Z*-octadecadienoyl, $R_2$ = *4Z*-hexadecenoyl
**1a**: $R_1$ = H, $R_2$ = *4Z*-hexadecenoyl
**1b**: $R_1$ = $R_2$ = H

**SCHEME 1**

Treatment of methyl hexadecenoate with DMDS and iodine afforded the disubstituted adduct, resulting from the addition of a molecule of DMDS to a double bond (6,7). The expected adduct showed a molecular ion peak at *m/z* 362 and the fundamental fragments *m/z* 215 and 147, which unequivocally demonstrated the cleavage of the carbon-carbon bond between the two methylthio groups. This characteristic cleavage of the bond between the two carbon atoms linked to sulfur indicates the original position of the double bond and at the same time allows an unequivocal identification of the derivative.

Based on the above evidence, the structure of the diacylgalactolipid **1** was assigned as (2*S*)-3-*O*-β-D-galactopyranosyl-1-*O*-(9*Z*,12*Z*-octadecadienoyl)-2-*O*-(4*Z*-hexadecenoyl)glycerol (Scheme 1).

## ACKNOWLEDGMENTS

# Triple-Bonded Unsaturated Fatty Acids Are Redox Active Compounds

**Douglas A. Peterson[a,*], Helen L. Reeve[b,d], Daniel Nelson[a], Stephen L. Archer[c], and E. Kenneth Weir[a,b,d]**

**ABSTRACT:** Unsaturated fatty acids with triple bonds are used as inhibitors of unsaturated fatty acid metabolism or cytochrome P450 reactions because they are believed to be chemically inert. In this paper we use *in vitro* cytochrome C reduction to show that two commonly used triple-bonded unsaturated fatty acids are in fact potent electron transfer agents and could affect the multiple cellular systems that are redox-modulated.

Paper no. L8547 in *Lipids 36*, 431–433 (April 2001).

Electron transfer plays an essential role in mitochondia, oxidases, and many other physiological systems. It has been shown that organic acids with double bonds, aside from being metabolized to a series of products, such as prostaglandins and leukotrienes, are also potent electron transfer agents, and indeed this property has been hypothesized as the reason for their being necessary for the function of the electron transport system (1).

Organic acids with triple bonds have been used in biological systems as inhibitors of unsaturated fatty acid metabolism or cytochrome P450 reactions because they are thought to be chemically inert under physiologic conditions (2,3). Because organic acids with triple bonds possess pi electrons, which play a pivotal role in electron transfer, we felt these compounds might also act as electron transfer agents, making them important redox modulators. Pi electrons have been shown to enhance electron transfer in DNA as well as unsaturated fatty acids (1,4). Since they are true catalysts in this reaction they must act by lowering the activation energy for the electron transfer. Two such organic acids with triple bonds, 5,8,11,14-eicosatetraynoic acid (ETYA), a nonmetabolizable arachidonic acid analog, and 17-octadecyonic acid (17-ODYA), a cytochrome P450 inhibitor, were evaluated to examine their potential for redox activity. We assessed the hypothesis that ETYA and 17-ODYA would enhance electron transport as measured by cytochrome C reduction. Organic acids with double bonds, oleic and arachidonic acids, were studied for comparison.

## MATERIALS AND METHODS

ETYA, 17-ODYA, and cytochrome C were obtained from Sigma Chemical Co. (St. Louis, MO). Oleic and arachidonic acids were obtained from Nu-Chek-Prep (Elysian, MN).

A dose-response curve of the reduction of cytochrome C by ferrous iron in the presence of 17-ODYA was obtained (Fig. 1). Each reaction was carried out in 50 mM tris (hydroxy-methyl) aminomethane (TRIS) pH 7.4 and contained 25 μM cytochrome C. A baseline absorbance was taken at 550 nM, ferrous iron (120 μM) was added as an electron donor, and readings were taken at 550 nM at indicated time points. All reactions were carried out at 25°C. Each reaction was carried out in triplicate.

A dose-response curve of the reduction of cytochrome C by ferrous iron in the presence of ETYA was also obtained (Fig. 2). Each reaction was carried out in 50 mM TRIS pH 7.4 and contained 25 μM cytochrome C. A baseline absorbance was taken at 550 nM, ferrous iron (120 μM) was

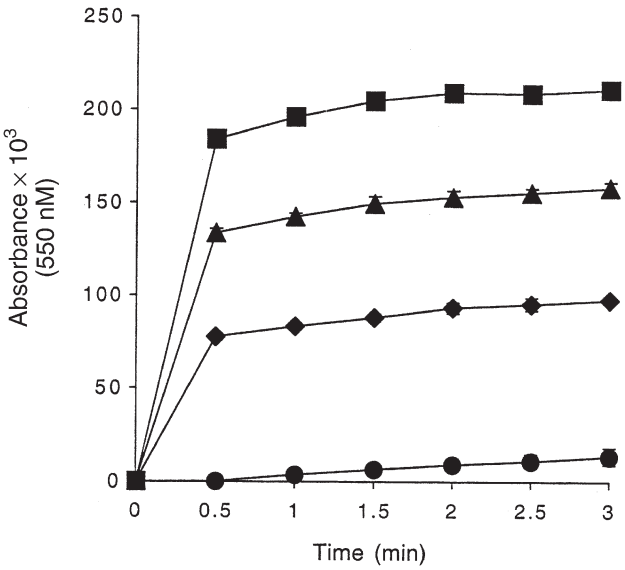

**FIG. 1.** Dose-response curve of acceleration of reduction of cytochrome C by ferrous iron in the presence of 17-octadecyonic acid (17-ODYA). Absorbance was measured at 550 nm. **FIG. 4.** Dose-response curve of acceleration of reduction of cytochrome C by ferrous iron in the presence of arachidonic acid. Absorbance was measured at 550 nm. Each data point is mean ± SEM of three separate experiments (some error bars hidden by symbols). ●, Blank; ◆, 22.5 μM; ▲, 45 μM; ■ 112 μM; ○, 225 μM.

The effect of arachidonic acid on cytochrome C reduction was studied in an identical manner (Fig. 4).

## RESULTS AND DISCUSSION

The dose-response levels indicate that both triple bond organic acids, 17-ODYA and ETYA, are effective electron transfer agents. They are somewhat less potent than double-bonded organic acids with the same degree of unsaturation, i.e., 17-ODYA vs. oleic acid or ETYA vs. arachidonic acid. Because of this property, they could affect any of the multiple cellular systems that have evidence of redox modulation. These include receptor activation (5–10), control of ion channels and pumps (11–17), G protein signaling (18–19), and transcription factor activation (20). Although the concentrations used in this study are slightly higher than the 10 μM used when they are given as inhibitors (2–3), it is known that these fatty acids are lipophilic and concentrate to much higher levels in membranes. Certainly, 20 μM 17-ODYA had a marked effect in terms of promoting the reduction of cytochrome C. It is of interest to note that at higher concentrations (40 μM) ETYA inhibits (as does arachidonic acid) DNA synthesis and in some cell systems produces morphologic changes in the mitochondria similar to those seen with oxidant stress (21,22). If ETYA is acting as an electron transfer agent and molecular oxygen as an electron acceptor, either directly or indirectly *via* a metal, this could produce those morphologic changes. We have previously shown that arachidonic acid can transfer electrons to molecular oxygen (23).

It is important to recognize that the effect of any molecule that is redox active, in addition to having other mechanisms

of action, must be interpreted with caution when evaluating cellular processes.

REVIEW

# Fatty Acid Composition of Pinaceae as Taxonomic Markers

**Robert L. Wolff[a,*], Olivier Lavialle[b], Frédérique Pédrono[a], Elodie Pasquier[a], Laurent G. Deluc[a,c], Anne M. Marpeau[c], and Kurt Aitzetmüller[d]**

[a]ISTAB, [b]ENITA, Laboratoire de Mathématiques Appliquées, [c]LCSV, Institut du Pin, Université Bordeaux 1, Talence, France; and [d]BAGKF, Münster, Germany

**ABSTRACT:** Following our previous review on *Pinus* spp. seed fatty acid (FA) compositions, we recapitulate here the seed FA compositions of *Larix* (larch), *Picea* (spruce), and *Pseudotsuga* (Douglas fir) spp. Numerous seed FA compositions not described earlier are included. Approximately 40% of all *Picea* taxa and one-third of *Larix* taxa have been analyzed so far for their seed FA compositions. Qualitatively, the seed FA compositions in the three genera studied here are the same as in *Pinus* spp., including in particular the same Δ5-olefinic acids. However, they display a considerably lower variability in *Larix* and *Picea* spp. than in *Pinus* spp. An assessment of geographical variations in the seed FA composition of *P. abies* was made, and intraspecific dissimilarities in this species were found to be of considerably smaller amplitude than interspecific dissimilarities among other *Picea* species. This observation supports the use of seed FA compositions as chemotaxonomic markers, as they practically do not depend on edaphic or climatic conditions. This also shows that *Picea* spp. are coherently united as a group by their seed FA compositions. This also holds for *Larix* spp. Despite a close resemblance between *Picea* and *Larix* spp. seed FA compositions, principal component analysis indicates that the minor differences in seed FA compositions between the two genera are sufficient to allow a clear-cut individualization of the two genera. In both cases, the main FA is linoleic acid (slightly less than one-half of total FA), followed by pinolenic (5,9,12-18:3) and oleic acids. A maximum of 34% of total Δ5-olefinic acids is reached in *L. sibirica* seeds, which appears to be the highest value found in Pinaceae seed FA. This apparent limit is discussed in terms of regio- and stereospecific distribution of Δ5-olefinic acids in seed triacylglycerols. Regarding the single species of *Pseudotsuga* analyzed so far *(P. menziesii),* its seed FA composition is quite distinct from that of the other two genera, and in particular, it contains 1.2% of 14-methylhexadecanoic (anteiso-17:0) acid. In the three genera studied here, as well as in most *Pinus* spp., the $C_{18}$ Δ5-olefinic acids (5,9-18:2 and 5,9,12-18:3 acids) are present in considerably higher amounts than the $C_{20}$ Δ5-olefinic acids (5,11-20:2 and 5,11,14-20:3 acids).

Paper no. L8716 in *Lipids 36,* 439–451 (May 2001).

Abbreviations: Ag-TLC, argentation thin-layer chromatography; anteiso-17:0, 14-methylhexadecanoic; FA, fatty acid; FAME, fatty acid methyl ester; GLC, gas–liquid chromatography; NMR, nuclear magnetic resonance; TAG, triacylglycerol; UPIFA, unsaturated polymethylene-interrupted fatty acid.

Many attempts have been made to gain some insight into the phylogenetic interrelationships of conifers, because they are the most prominent components of the extant flora, with a very long history and particularly rich fossil record, beginning in pre-Permian time (1). The family Pinaceae already presented a significant history prior to the Late Triassic period (180 million years ago; 2,3). As we were involved in the systematic study of conifer (and more generally gymnosperm) seed fatty acid (FA) compositions, we noted that these data could be of some use as new, original, and supplementary chemometric markers for the taxonomy of this plant group (4–9).

All conifer seeds contain lipids that include part of a series of FA that were considered until recently as "unusual" (10), Δ5-unsaturated polymethylene-interrupted FA (Δ5-UPIFA). These FA have been shown in the meantime not only to be common constituents of seed oils from all Coniferophyte families but also to be characteristic of some Cycadophyte families (10–12). In gymnosperms (Coniferophytes and Cycadophytes), Δ5-UPIFA have the structures 5,9-18:2 (taxoleic); 5,11-18:2 (ephedrenic); 5,9,12-18:3 (pinolenic); 5,9,12,15-18:4 (coniferonic); 5,11-20:1; 5,11,14-20:3 (sciadonic), and 5,11,14,17-20:4 (juniperonic) acids, all ethylenic bonds being in the *cis* configuration. In addition to seeds, these FA also occur in the leaf and wood lipids of Coniferophytes and likely of some Cycadophytes (10,13–16).

The family Pinaceae (Coniferophytinae) contains a total of 11 or 12 genera: *Abies*, *Cathaya*, *Cedrus*, *Keteleeria*, *Larix*, *Nothotsuga*, *Picea*, *Pinus*, *Pseudolarix*, *Pseudotsuga*, *Tsuga*, and *Hesperopeuce*, the latter with an ill-defined taxonomic position (also considered a *Tsuga* species) (17,18). Among these genera, *Pinus* is the largest and most heteromorphic genus. The seed FA compositions available for the most common pine species, totaling approximately one-half of extant species, have been recently reviewed (8). The genera *Larix* and *Picea* are closely related to *Pinus*, although their relationships are still poorly understood. *Pinus*, *Larix*, and *Picea* are sometimes put together along with *Cathaya* and *Pseudotsuga* into a "Pinoid" group, as opposed to an "Abietoid" group that embraces *Abies*, *Cedrus*, *Tsuga*, *Nothotsuga*, *Pseudolarix*, and *Keteleeria* (19). But other subfamily arrangements have been proposed, e.g., Pinoideae (*Pinus*), Laricoideae (*Larix*, *Pseudolarix*, *Cedrus*), and Abietoideae (*Abies*, *Cathaya*, *Keteleeria*, *Picea*, *Pseudo-*

*tsuga*, *Tsuga*); Pinoideae (*Pinus*), Piceoideae (*Picea*), Laricoideae (*Larix*, *Cathaya*, *Pseudotsuga*), Abietoideae (all other genera) (20); or more recently (21), Pinoideae, encompassing three tribes [Pineae (*Pinus*), Abieteae (*Cathaya*, *Picea*, *Tsuga*, *Cedrus*, *Keteleeria*, and *Abies*), and Lariceae (*Larix*, *Pseudotsuga*)], and Pseudolariceae (*Pseudolarix*). Clearly, there is a lack of general agreement as regards to the intergeneric relationships among Pinaceae.

In this study, a compilation of data available on *Picea*, *Larix*, and *Pseudotsuga* seed FA compositions is made, including numerous unpublished seed FA compositions. Species examined here represent approximately 40% of *Picea* and almost one-half of *Larix* species and varieties. Despite the fact that the three genera present rather similar seed FA compositions, principal component analysis and discriminant analysis allow distinction between them, improving our previous analysis of Pinaceae genera (5). This allows preliminary conclusions to be drawn on general features of the quantitative distribution of Δ5-UPIFA and other constituent seed FA in *Picea*, *Larix*, and *Pseudotsuga*.

## EXPERIMENTAL PROCEDURES

*Seeds, oil extraction, and FA methyl ester (FAME) preparation*. Most seeds were purchased from Lawyer Nursery, Inc. (Plains, MT), F.W. Schuhmacher Co., Inc. (Sandwich, MA), and Sandeman Seeds (Pulborough, Great Britain). *Picea abies* seeds from 15 different French orchards and indigenous stands and one location in Poland were kindly donated by Vilmorin S.A. (La Ménitré, France). Seeds were kept at 4°C until use. Lipid extraction, always performed by starting with 10-g samples taken from 15 ± 5 g of powdered seeds, and FAME preparation were performed as described in detail elsewhere for other gymnosperm seeds (4–7). All FAME preparations were made in duplicate and each solution was analyzed once by gas–liquid chromatography (GLC). Generally, FAME were prepared within 24 h after lipid extraction and immediately analyzed.

*Analytical GLC*. All FAME preparations were analyzed by GLC in a Carlo Erba 4130 chromatograph (Carlo Erba, Milano, Italy) equipped with a DB-Wax column (30 m × 0.32 mm i.d., 0.5 μm film; J&W Scientific, Folsom, CA). The oven temperature was 190°C, and the inlet pressure of the carrier gas (helium) was 140 kPa. Occasionally, to confirm some identifications, a CP-Sil 88 column (50 m × 0.25 mm i.d., 0.2 μm film; Chrompack, Middelburg, The Netherlands) was operated with temperature programming in a Carlo Erba HRGC chromatograph from 150 to 185°C at 4°C/min with $H_2$ at 100 kPa. The injector (split mode) and flame-ionization detector were maintained at 250°C for both columns. Quantitative data were calculated by SP 4290 integrators (Spectra Physics, San Jose, CA). In some instances, particularly to detect potential late-eluting components but also to confirm identifications, a Silar 5 CP (50 m × 0.25 mm i.d., 0.2 μm film; Chrompack), fitted in a Hewlett-Packard HP 5890 gas chromatograph (Avondale, PA), was used in the temperature program mode (isothermal for 1 min at 165°C; from 165 to 205°C at a rate of 1°C/min; isothermal at 205°C for 60 min). Nitrogen was the carrier gas, and the injector and detector temperatures were maintained at 230 and 260°C, respectively (22).

*Identification of FAME peaks*. The seed lipids from selected conifer species (23,24) or Ranunculaceae species (25) were used as sources of Δ5-olefinic acid methyl esters with known structures to identify FA from seed lipids by GLC, either by coinjection, comparison of the equivalent chain lengths (DB-Wax column), or retention times (CP-Sil 88 and Silar 5 CP).

*Data analysis*. Principal component analysis was performed with the program STATBOX (Grimmer, Paris, France). The classifications of *Picea* spp. were performed with the program XLSTAT (copyright T. Fahmy, Paris, France). To compare the variability of intra- and interspecific seed FA compositions of *P. abies* and *Picea* spp., respectively, ascending hierarchical classifications were computed using the Ward method. This method consists in minimizing the loss of intraclass inertia at each step. The results are presented as dendrograms (see below) in which the aggregation level can be interpreted as a dissimilarity index between the objects (i.e., *Picea* species, or *P. abies* locations).

## RESULTS AND DISCUSSION

*Comments on Δ5-UPIFA and other FA*. Regarding the genera studied here, most Δ5-UPIFA were initially structurally characterized in *L. kaempferi* [reported as *L. leptolepis* (26)] seed lipids by mass spectrometry coupled with GLC, further in *P. jezoensis* (27), and later supported by GLC in the same two *Larix* species (15). The presence of the 5,9-18:2 and 5,9,12-18:3 acids was recently confirmed by similar techniques in the seeds from *P. glauca engelmannii* ("interior spruce," a hybrid) and *P. glauca* (28). All Δ5-UPIFA reported in the seeds have also been characterized in the leaves of many *Picea* and *Larix* species (14), as well as in the wood of *P. abies* (13,16).

Detailed comments on the resolution of individual FA, including Δ5-UPIFA, have been presented elsewhere (8). All FA reported in the present study are baseline resolved except for *cis*-vaccenic acid, which is not completely resolved from oleic acid. Qualitatively, with respect to both the $C_{18}$ and the $C_{20}$ acid series, the routinely observed FA in the seed lipids from the genera *Picea*, *Larix*, and *Pseudotsuga* are exactly the same as in the genus *Pinus* (8).

The minor FA eluting from 12:0 to 15:0, as well as those eluting after 22:0 acid, are not reported individually in the present study and are included in the category "others" in the tables. On the other hand, the anteiso-17:0 (14-methylhexadecanoic) and 17:1 acids (likely the Δ9 isomer) are included. Anteiso-17:0 acid was unambiguously characterized by mass spectrometry in *Larix leptolepis* (26) as well as in *Pinus* seed lipids (29). In contrast, the 19:0 and "branched" 19:0 acids identified by mass spectrometry in the former species [each accounting for 0.2% of total FA (26)] have not been reported by other authors and are not included in the present study. It is likely that these acids are masked by other more important FA,

owing to similar GLC behavior. No unsaturated $C_{22}$ acids have been reported in *Larix* or *Picea* seed lipids, but a 13-22:1 acid occurs in *Pseudotsuga menziesii* [0.1% (30)].

It is worthwhile to mention the presence of anteiso 19:1, anteiso 5,9-19:2, anteiso 9,12-19:2, and anteiso 5,9,12-19:3 acids, the latter three acids totaling *ca.* 1.8% of total polyunsaturated acids in *P. abies* wood extracts (13). These acids, to our knowledge, have not yet been identified in conifer seeds, although occasionally we noted small unknown peaks in the chromatographic zone where these branched acids are supposed to elute (in the neighborhood of 9,12-18:2 and 9,12,15-18:3 acids). A better insight into these rare minor FA can be obtained by "bidimensional" chromatography that associates GLC and argentation thin-layer chromatography (Ag-TLC) of FAME. The latter analytical procedure, applied to total FAME, allows their fractionation according to the number of ethylenic bonds (provided they all are in the *cis*-configuration) with, however, subtle effects linked to their position along the hydrocarbon chain and to the chain length.

When such isolated fractions are concentrated *ca*. 10 times prior to further GLC analysis, a considerable number of minor components are then observable on chromatograms (results not shown). For *L. decidua* seed lipids (Deluc, L.G., and Wolf, R.L., unpublished results), the anteiso-19:0 acid can be located on chromatograms of the saturated fraction. It accounts for approximately 0.3% of total FA. However, this branched FA, on chromatograms of unfractionated FAME, elutes under the main 9,12-18:2 acid, and cannot be quantitated. In the same way, there are indications of an anteiso-19:1 acid in the 1Δ Ag-TLC fraction (*ca*. 0.3% of total FA) that co-elutes with the 5,9,12-18:3 acid under routine analytical conditions. Such overlaps are the limitations in the accuracy of data presented here, but they should be of very minor importance as regards to our conclusions.

A word should be added concerning juniperonic acid, which apparently does not occur in any significant amounts in *Larix* and *Picea* seed FA when total (4,5, current paper), neutral, or polar (15) lipids are analyzed under routine analytical conditions. Minor amounts (<0.1%) of this FA would, however, occur in one case. On the other hand, applying the bidimensional chromatographic procedure described above to FAME prepared from *L. decidua* seeds allowed unambiguous characterization of juniperonic acid, as well as of its putative metabolic precursor, 11,14,17-20:3 acid, but in trace amounts only, even after concentration of the fraction. Under such conditions, no arachidonic or eicosapentaenoic acids, recently characterized in the seeds and leaves of species from the Araucariaceae family (31,32), could be observed in the species analyzed here. It should, however, be noted that arachidonic acid was reported to be present in the cambium zone of *L. sibirica* (cited in Ref. 33; original article in Russian), though other detailed and thorough studies of *P. abies* wood extracts did not mention such an occurrence (13,16).

*Comments on* Picea*,* Larix*, and* Pseudotsuga *classification and nomenclature.* Several proposals have been made regarding subdivisions of the genus *Picea*, essentially based on morphological characters, e.g., the shape and structure of needles, buds, and cone-scales (34,35). Except for Liu (34), who divided the genus *Picea* into two subgenera (*Omorika* and *Picea*), other systems use "sections," "series," or "phyla." However, according to Wright (36) or Debazac (35), any divisions of the genus *Picea* are unlikely to correspond to well-differentiated evolutive phyla, owing to the large occurrence of natural hybridization. This may be illustrated by the gradual morphological transition from one species to another in the wild, e.g., from *P. abies* to *P. obovata* (*P.* × *fennica*). *Picea abies* can also cross, naturally or experimentally (more or less successfully), with morphologically similar species, separated by wide ranges that, however, are connected by "intermediate" species (Asia: *P. montigena*, *P. likiangensis*, *P. koyamae*), or with morphologically distinct species with neighboring (Europe; *P. orientalis*) or widely separated (North America; *P. mariana*, *P. rubens*, *P. sitchensis*) ranges (36). It was recently (37) inferred from nuclear ribosomal 18S sequence analysis that *P. rubens* and *P. mariana* (North America) are more closely related to the European species *P. omorika* (limited to a small area in Bosnia-Herzegovina) than to other North American *Picea*. Thus, even geographical grouping (35) is questionable.

With respect to *Larix*, tentative divisions of the genus have also been suggested, based primarily on female cone morphology and anatomy (38), but recent chloroplast and nuclear ribosomal DNA fragment analyses were not consistent with such classifications (39,40). Rather, they gave some molecular evidences for clades linked to geographical locations (e.g., *Larix* spp. from Eurasia vs. *Larix* spp. from North America), a situation that would also hold for *Pseudotsuga* (40). However, several *Larix* species can hybridize with one another, e.g., *L. laricina* (North America), *L. decidua* (Europe), and *L. kaempferii* (Japan) (41). The hybrid between the two latter species is known as *L. eurolepis* (35).

Consequently, owing to the lack of agreement, no classifications of the genera *Picea*, *Larix*, and *Pseudotsuga* are adopted here.

Latin as well as trivial names given in Tables 1–3 are from a compilation of descriptions by Wright (36), Debazac (35), and Liu (34), and from tree-seed seller catalogs, corrected wherever possible for synonymy according to Farjon (42). Names reported in original references but not "officially" recognized by Farjon (42) have been modified, e.g., *L. leptolepis* in Takagi and Itabashi (15) and Wolff *et al*. (4) is reported here as *L. kaempferi*. Spelling of names in original references or in tree-seed seller catalogs may also differ from Farjon's recommendations (42), when they are still in usage, e.g., *P. omorika*, instead of *P. omorica*. A few varieties, e.g., *P. pungens* var. *glauca*, or *L. decidua* var. *sudetica*, recognized by foresters or horticulturists but not mentioned by Farjon (42), have also been kept unchanged. For *Pseudotsuga*, some infrageneric taxa are diversely regarded as valid species [e.g., Debazac (35)] or varieties. The nomenclature retained here is mostly that of Farjon (42), but supplementary varieties recognized by tree-seed sellers are also included in Table 3 (e.g., *P. menziesii* var. *caesia*).

*The meaning of seed FA compositions as chemotaxonomic markers*. A study of the variability of the seed FA composition of *P. abies* as a possible function of the geographical origin of the seeds was conducted. For this purpose, seeds from 15 *P. abies* stands located in different regions of France and growing at different altitudes were analyzed. Two lots from each origin were extracted, and each lipid extract was used to prepare FAME for further GLC analysis. The results are

graphically expressed as dendrograms in Figure 1. Intraspecific dissimilarities between *P. abies* from different French stands are visibly of minor importance as compared to interspecific dissimilarities between other *Picea* species. Tillman-Sutela *et al*. (43), who conducted a similar study on *P. abies* from 10 locations in Finland, reached a similar conclusion on the near invariability of *P. abies* seed FA compositions.

It can be inferred from these observations that the seed FA composition of *P. abies* is almost unaffected by edaphic or climatic growing conditions. The very minor differences noted for *P. abies* between France and Finland (Table 4) may as well be linked to differences in analytical procedures and equipment. A similar conclusion regarding the invariability of seed FA was drawn in a study conducted with *Pinus sylvestris* (8). Considering larger distribution areas (Eurasia instead of France), however, showed some small but significant variations for a few FA in *P. sylvestris* seeds from France eastward to Mongolia (8). However, *P. sylvestris* is very heteromorphic [150 "variants" have been described (44)], and at least three varieties are recognized (42). Moreover, the crossability of *P. sylvestris* with Asian pines of the *Sylvestres* subsection is poorly known, and seed FA variations may be linked to introgressions.

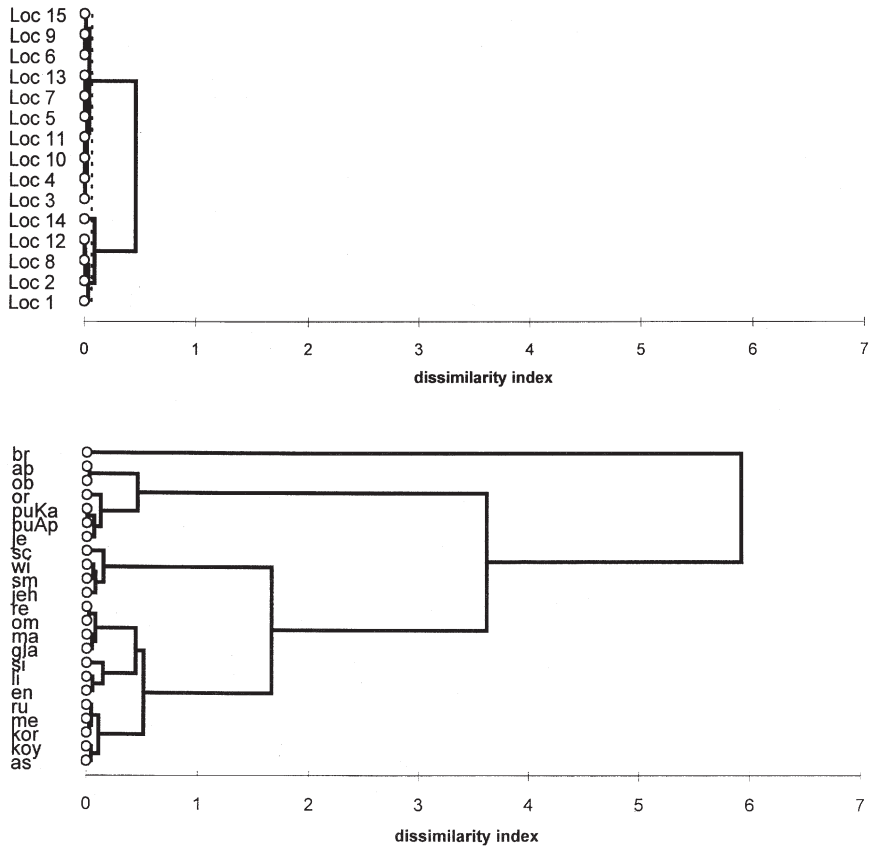

**FIG. 1.** Intraspecific dissimilarity for *Picea abies* from different locations (Loc) in France (upper dendrogram) and interspecific dissimilarity for *Picea* spp. (lower dendrogram). Abbreviations for species correspond to those listed in Table 4.

*Seed FA compositions of* Picea *spp*. Within the Pinaceae family, *Picea* is one of the largest genera (*ca*. 34 species, Table 1) being second to *Abies* and third to *Pinus*. This genus is reported to be rather heteromorphic, but subjected to natural cross-pollination (see above). *Picea* and *Pinus* are most often considered as sister groups, despite a gap of 20 to 70 million years in their fossil history (3,34). *Picea* spp. seeds are rather small, *ca*. 3–6 mm in length [weight of 1000 seeds, 2–9 g (35)]. The oil content is high, in the range 30–40% on a wet weight basis (results not shown). *Picea* spp. seed FA compositions are displayed in Table 4. It is immediately observable that the compositions of species analyzed so far show remarkable similarities. As regards to the species number and the limited variability in seed FA compositions, *Picea* spp. are in sharp contrast with *Pinus* spp. (8).

Total saturated acids in *Picea* spp. are approximately 5% of total FA (data not shown), which is less than in most *Pinus* spp. (*ca.* 10% in most instances). However, in both genera, the prevalence order of individual saturated FA is 16:0 > 18:0 > 20:0 > 22:0, as in *Pinus* spp. As mentioned above, a few branched-chain saturated acids occur. The main visible one is anteiso-17:0 acid, in the narrow range 0.10–0.26%, which is within the range found in most *Pinus* spp. This acid might be an important chemotaxonomic marker, as it does not occur in all conifer families.

The most common unsaturated FA is linoleic acid, with oleic acid being second. Linoleic acid accounts on average for 47.6%, varying in the narrow range 45.3–50.5% of total FA, whereas the corresponding values for oleic acid are 16.5% and 11.4–19.2%, respectively. α-Linolenic acid is a minor component that does not exceed 0.4%. These rankings are similar to those found in most pines (8). The level of *cis*-vaccenic acid in *Picea* seed lipids is relatively high as compared to that in *Pinus* spp. of the *Strobus* subgenus, but not clearly distinct from that occurring in several sections of the *Pinus* subgenus (8).

When considering the distribution profile of Δ5-UPIFA, similarities among the majority of pines are apparent. In particular, the $C_{18}$ Δ5-UPIFA are present in considerably greater proportions than the $C_{20}$ Δ5-UPIFA. Some pine species are not considered here for comparison purposes, e.g., those from the *Parrya* section, or those from the "Mediterranean coast and island" group (45), for reasons discussed elsewhere (mostly because of their exceptionally low total Δ5-UPIFA content) (8). Within the $C_{18}$ Δ5-UPIFA series, the 5,9,12-18:3 acid is always higher than the 5,9-18:2 acid, in the ranges 20.8–26.2%, and 2.1–3.7%, respectively, in *Picea* spp. In *Pinus* spp., the corresponding ranges are somewhat larger (after exclusion of the above-mentioned species, and some others) (8). The minor $C_{20}$ Δ5-UPIFA 5,11-20:2 and 5,11,14-

20:3 acids are always less than 0.09 and 1.24%, respectively, which resemble values found in the haploxyl pine subsection *Strobus*. With regard to sums of Δ5-UPIFA (including the metabolically related 7,11,14-20:3 acid) in *Picea* spp., they are in the range 25.0–30.4% (mean, 28.2%), which are values commonly found in many species of several subsections of the subgenus *Pinus* (e.g., practically all pine species of subsections *Sylvestres*, *Oocarpae*, and *Contortae*), but more seldom in the *Strobus* subgenus (e.g., in *P. strobus*). Bishomopinolenic (7,11,14-20:3) acid, the elongation product of pinolenic acid, is in the range 0.09-0.17%, which would correspond to an elongation rate of the latter acid of 0.6%. This FA is a usual minor component of Pinaceae seed lipids (46).

*Seed FA compositions of* Larix *spp*. This genus apparently has a rather short evolutionary history. No fossil records are known before the Middle or Late Eocene periods (38) or even the Oligocene period (3), and the number of admitted species, not taking into account varieties, is presently limited to 12 (Table 2). As for *Picea* spp., *Larix* spp. seeds are rather small, *ca*. 3–8 mm in length [weight of 1000 seeds, 2–12 g (35)]. Their oil content, relative to the weight of undehulled seeds, varies in the range 9–20% (results not shown).

The seed FA compositions of *Larix* species (Table 5) show remarkable similarities within the genus, and a striking resemblance with *Picea* spp. (*cf.* Table 4). The main FA is 9,12-18:2 acid in both cases, being slightly higher on average in *Larix* spp. than in *Picea* spp., 47.6 vs. 43.3%, respectively. Corresponding values for the second important common FA, 9-18:1 acid, are closer, 16.5 and 17.6%, respectively. The contents of total as well as of individual linear saturated acids in *Larix* spp. are identical to those in *Picea* spp. However, *Larix* and *Picea* spp. fundamentally differ when considering the amount of anteiso-17:0 acid, which in *Larix* is twice that in *Picea* spp. (0.36 vs. 0.18%, respectively).

As for *Picea* spp. and most *Pinus* spp., the $C_{18}$ Δ5-UPIFA are present in *Larix* spp. in higher proportions than the $C_{20}$ Δ5-UPIFA, with 5,9,12-18:3 acid being higher than 5,9-18:2 acid. In *Larix* spp., the range for taxoleic acid is narrower than in *Picea* spp. (2.2–2.6%), and pinolenic acid varies within limits that are definitely higher than in *Picea* spp., 25.8–30.7% vs. 20.8–26.2%. The elongation rate of the latter acid would be higher in *Larix* than in *Picea* spp. (0.9%), leading to a higher percentage of bishomopinolenic acid (mean, 0.24%).

*Seed FA compositions of* Pseudotsuga. Most recent authors (19–21,41,47,48) agree that *Pseudotsuga* is the closest relative to *Larix* within the Pinaceae family. The two genera also share a particular pollination mechanism not observed in other Pinaceae genera (49). This is why this genus is included in the present study. From fossil records, *Pseudotsuga* would have differentiated at the onset of the Cenozoic, slightly earlier than *Larix* (21).

Complete data for *Pseudotsuga* seed FA unfortunately are limited to two analyses of one single species, *P. menziesii*, of unknown variety (possibly the most common one, var. *menziesii*), which are not in full agreement (Table 6). No gross differences with the two preceding genera are noted for linear saturated acids. However, *P. menziesii* appears exceptional as regards to its high anteiso-17:0 acid content, *ca*. 1.2%, which seems unique among Pinaceae genera (29). Older data (50) for Douglas fir seeds indicated the presence of an unknown FA eluting between the 16:1 isomers and 18:0 acid, likely (in retrospect) the anteiso-17:0 acid, in amounts similar to those reported here. Some *Abies* and *Cedrus* species have seed FA containing as high as 0.8–0.9% of anteiso-17:0 acid (29). Whereas the contents of $C_{18}$ Δ5-UPIFA are relatively low, in particular pinolenic acid, the $C_{20}$ Δ5-UPIFA are relatively high, at least when compared to *Picea* and *Larix* species. Based on its seed FA composition, *P. menziesii* thus appears quite distinct from *Larix* spp., but not much more than from *Picea* spp. Obviously, complementary data are needed for *P. menziesii* varieties and for the three other species before a definitive conclusion can be drawn.

*Principal component analysis*. To assess whether the differences noted above between *Picea* and *Larix* spp. seed FA compositions were sufficient to distinguish the two genera on this biochemical basis, data were processed using principal component analysis. For this purpose, data for the species listed in Tables 4 and 5 were used. However, values for the very minor 17:0, 17:1, and 5,11,14,17-20:4 acids were not included as variables in calculations. Figure 2 shows the first two components which explain, respectively, 36.0 and 16.4% of the total inertia. Axis 1 clearly separates the two genera *Picea* and *Larix*. The most explanatory variables correlated with axis 1 can be divided into two groups, of which six are representative of *Larix* spp. These are the 5,9,12-18:3 and its elongation product 7,11,14-20:3; 9,12,15-18:3 and its Δ5-desaturation product 5,9,12,15-18:4; 5,11-20:2; and anteiso-17:0 acids. On the other hand, five FA are representative of *Picea* spp.: 9,12-18:2, its elongation product 11,14-20:2; the Δ5-desaturation product of the latter FA; 5,11,14-20:3; 5,9-18:2; and 20:0 acids.

As part of this study, axis 2 is not relevant to discriminate *Picea* and *Larix* spp. FA correlated with this axis lead to the separation of different species inside both genera. In particular, *P. breweriana* and *L. sukaczewii* are individualized because of a larger proportion of 18:0, 9-18:1 (*P. breweriana*), and 16:0 acids, and a small proportion of 7,11,14-20:3 acid (*L. sukaczewii*). Interestingly, *P. breweriana* is reported to have no close relatives, being locally endemic to southwest Oregon and northwest California in montane to subalpine forests of the Siskiyou Mountains (35). On the other hand, *L. sukaczewii* is reported to be relatively close to *L. sibirica* (35), but their seed FA compositions are rather different (see, e.g., the sums of Δ5-olefinic acids in Table 5). Farjon (42) even considers that *L. sukaczewii* is synonymous with *L. sibirica*, a view that is not supported by our results

*Concluding remarks*. *Picea* species, in contrast to *Pinus* spp., are mostly indistinguishable from one another on the basis of their seed FA compositions. Interspecific variations are even less important than in the *P. sylvestris* complex, which supports the view of Wright (36) that "taxonomically the genus (*Picea*) is more nearly comparable to a single se-

[a]Initial nomenclature modified to fit recent recommendations. Abbreviations of origins, Ap. and Ka., Apache and Kaibab National Forests, Arizona. Data for *P. abies* from France and Finland are the means of values obtained from 15 and 10 different locations, respectively. Original data for Finland were given as mol% and have been recalculated as wt%.
[b]Two isomers, 7- and 9-16:1 acids.
[c]14-Methylhexadecanoic, or anteiso-17:0 acid.
[d]Sum of Δ5-olefinic acids, including the 7,11,14-20:3 acid.
[e]Minor and unidentified components.
[f]Abbreviations refer to Figures 1 and 2.
[g]Not detected or not reported.
[h]Reported as *Pinaceae jezoensis*.
[i]Reported as 16:2n-6.
[j]Trace amounts.
[k]Reported as 16:3n-3.

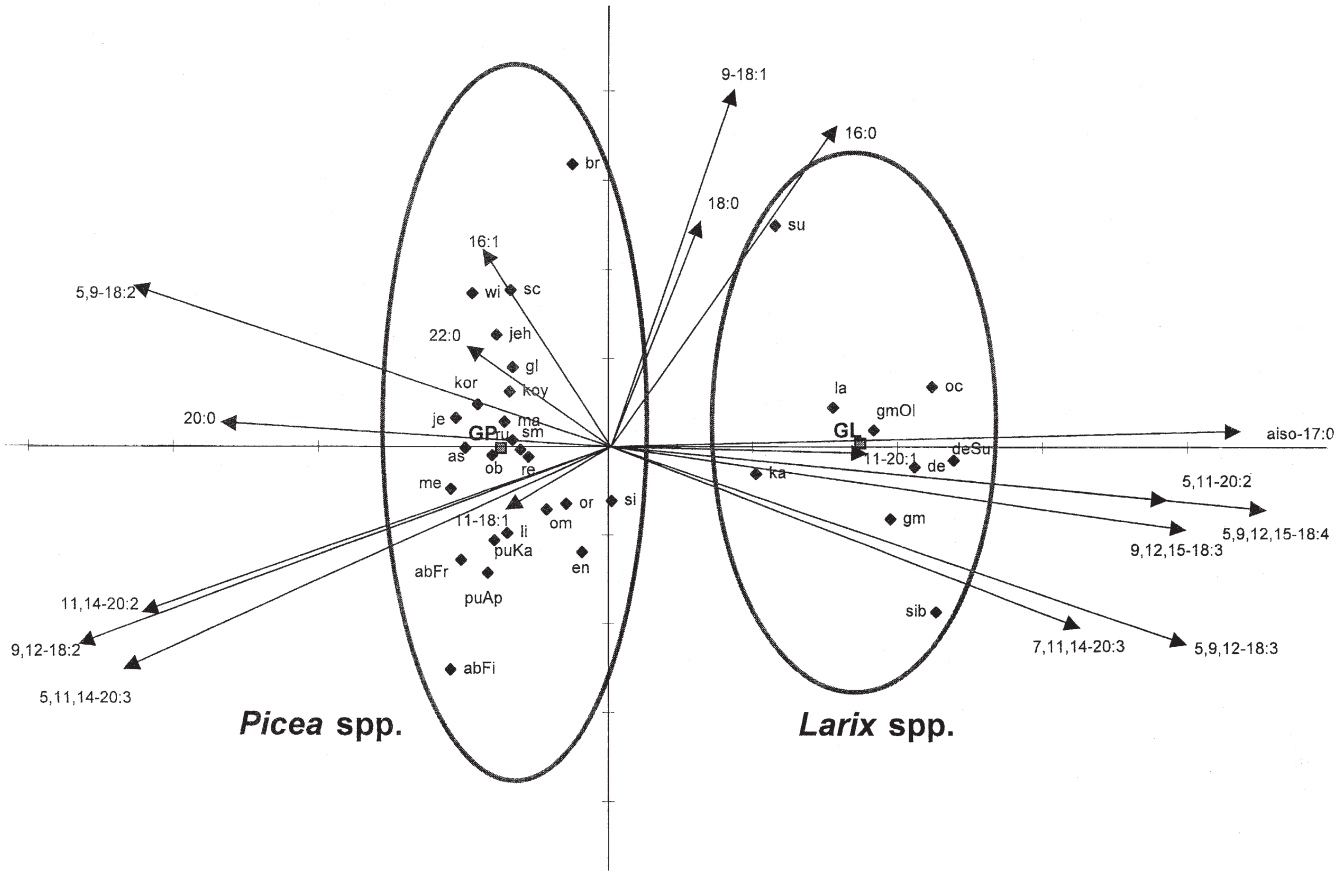

**FIG. 2.** Principal component analysis of *Picea* and *Larix* species and varieties. Abbreviations for species correspond to those listed in Tables 4 and 5. GP and GL, gravity centers.

ries in pine, maple, or ash than to any one of these complete genera." Apparently, the same holds for *Larix* spp. Although *Picea* and *Larix* spp. present on average rather similar seed FA compositions, multicomponent analysis quite clearly distinguishes these two genera. Moreover, our previous statistical analyses of *Picea*, *Larix*, and *Pinus*, though based on a smaller number of species in each genus, showed that *Picea* and *Larix* consistently differed from *Pinus* (5).

This study also confirms our previous observation that total Δ5-UPIFA cannot be higher than one-third of total FA in Pinaceae seeds (51,52). This indeed occurs in the genus *Larix*, for which GLC data were confirmed by $^{13}C$ nuclear magnetic resonance (NMR) spectroscopy (53). A probable explanation for this feature may be the stereospecificity of acylation of these acids to the glycerol backbone of triacylglycerols (TAG). It was shown for a great number of conifers, including some *Larix* and *Picea* species, that Δ5-UPIFA were enriched in the α (external) positions as compared to the β (internal) position of TAG (11). By applying a new regiospecific analysis method (54) that uses GLC of dibutyroyl derivatives of monoacylglycerols generated from TAG by partial deacylation with a Grignard reagent, levels of less than 5% of Δ5-UPIFA (a value close to the limit of detection by $^{13}C$ NMR spectroscopy) were shown to occur in the *sn*-2 position of TAG from *L. gmelinii* var. *olgensis* and *P. shrenkiana* seeds (Destaillats, F., Angers, P., Wolff, R.L., and Arul, J., unpublished data). Somewhat lower values were reported for *P. jezoensis* (15) and *L. decidua* (55). No data, however, are available yet for *P. menziesii*. In a smaller number of cases, including *L. decidua*, stereospecific analysis of conifer seed TAG has shown that Δ5-UPIFA are esterified mostly (*ca.* 90%) to the *sn*-3 position (56), independently of the chain length and the number of ethylenic bonds. Other studies on the seed TAG distribution profile of two *Pinus* species, *P. koraiensis* (57,58) and *P. pinaster* (57), have shown that TAG molecular species containing two or three Δ5-UPIFA are scarce or absent. It is thus probable that Δ5-UPIFA are mostly restricted to the *sn*-3 position of TAG, with the consequence that they cannot be higher than one third or so of total FA.

Incidentally, it should be noted that *Sciadopitys verticillata* (Sciadopityaceae) seed lipids contain in small amounts 2-monoacylglycerols, part of which are esterified with sciadonic acid (59). This would suggest that Δ5-olefinic acids can indeed esterify the *sn*-2 position of TAG, although it cannot be excluded that 2-sciadonoyl-glycerol is an artifact that derives from *sn*-3 monoacylglycerols through isomerization, e.g., during oil extraction.

**ABSTRACT:** The importance of low-density lipoprotein (LDL) in the etiology of atherosclerosis is well recognized. We have established a reproducible stenosis model in hypercholesterolemic hamsters, and the process of arterial stenosis by thrombus or neointima was studied and compared with that in normal hamsters. The level of plasma LDL was 4.6 times higher in hamsters fed a high-cholesterol diet than in hamsters fed normal food. Endothelial injury in right common carotid arteries was induced using a modified catheter. Arterial blood flow was monitored continuously using a Doppler flow probe. Arterial patency after the initiation of injury in high-cholesterol hamsters was significantly changed as compared with that of normal hamsters. Neointima was observed 2 wk after the vascular injury. The neointimal area of high-cholesterol hamsters was significantly larger than that of normal hamsters. To characterize the stenosis in hypercholesterolemic hamsters, we measured platelet aggregation, thrombin time, activated partial thromboplastin time, and proliferating smooth muscle cells (SMC) *in vitro* and *in vivo*. The half-maximal inhibitory concentration value for platelet aggregation induced by thrombin or collagen, the DNA synthesis stimulated by platelet-derived growth factor (PDGF)-BB, and 5-bromo-2-deoxy-uridine labeling indices (proliferating index of SMC *in vivo*) in high-cholesterol hamsters were each significantly higher than the comparable value from normal hamsters. However, specific binding of PDGF-BB in SMC was not different between the two types of hamsters. Furthermore, we investigated the inhibitory effects of probucol or losartan on neointima formation using this model. Probucol, but not losartan, significantly reduced the neointimal area in hypercholesterolemic hamsters. These findings indicated that high levels of plasma LDL strongly contributed to the development of thrombus and neointima formation *via* both up-regulation of platelet aggregation and the enhancement of SMC proliferation. This stenosis model may be useful for the investigation of hypercholesterolemia-associated cardiovascular diseases.

Paper no. L8606 in *Lipids 36,* 453–460 (May 2001).

Hypercholesterolemia increases the risk of developing cardiovascular diseases, and low density lipoprotein (LDL) plays an important role in atherosclerosis (1). Recent studies have shown that LDL stimulates endothelial cells to produce a variety of growth factors that induce the migration and proliferation of granulocytes, macrophages, and endothelial cells (2,3). These studies raise the possibility that increases in LDL content stimulate the production of factors that play an important role in the proliferation of cells and matrix elements found in both atherosclerosis and vascular neointima formation.

On the other hand, both platelets and LDL are intimately involved in the pathogenesis of atherosclerosis (2). Platelet function is directly influenced by lipoproteins, and platelets from patients with hypercholesterolemia display enhanced platelet reactivity (4). Each platelet processes specific high-affinity binding sites for LDL, ranging from 1000 to 8000 copies per platelet with a dissociation constant ($K_D$) value between 40 and 100 nmol/L (5,6). Moreover, the LDL-induced sensitization is accompanied by decreased angular movement in platelet membranes, possibly caused by increased cholesterol transfer (7), and platelets enriched with cholesterol show increased arachidonic acid release and thromboxane $B_2$ formation (8).

Until now, rabbits fed a high-cholesterol diet or Watanabe rabbits (9) have been the main animals used for the investigation of hypercholesterolemia or atherosclerotic lesions of vascular diseases. Other small animals that can be used for this type of study are exogenously hypercholesterolemic rats and hamsters. In rats, a few months are required to establish hypercholesterolemia after the start of a high-cholesterol diet (10,11). On the contrary, only a few weeks are necessary for hamsters to be hypercholesterolemic (11). Recently, we established a simple and reproducible vascular stenosis model in hamsters (12). We investigated the inhibitory effects of antiplatelet compounds (13–16), angiotensin-converting enzyme inhibitors (17), and an angiotensin II receptor antagonist (18) using this model. Vascular stenosis often accompanies injury to endothelial tissues. Progression of stenosis occurs by thrombus formation during the acute phase or neointima formation during the chronic phase after endothelial injury. Our previous observations clearly indicated that the inhibition of both platelet activation and smooth muscle cell (SMC) proliferation or migration strongly reduced the development of vascular stenosis after endothelial injury (13, 18). On the other hand, the likelihood of vascular occlusion in patients is enhanced by the additive effect of other risk factors, such as diabetes and hypercholesterolemia. Therefore, in the present study, this model was applied to examine the effect of plasma LDL levels on platelets and SMC in order to

define easily determined, clinically significant measures of vascular stenosis progression.

## MATERIALS AND METHODS

*Animals*. Male syrian hamsters (SLC, Sizuoka, Japan) weighing 60–80 g were selected and fed either a standard chow (RC4; Oriental Yeast Co., Ltd., Japan) or chow supplemented with 0.5% (w/w) cholesterol. An operation for vascular injury using a modified catheter was carried out 4 wk after the start of the diet regimen. The body weight of hamsters fed a high-cholesterol diet was not statistically significantly different from that of hamsters fed a normal diet (body weight: 120–130 g). All experiments were performed in accordance with institutional guidelines governing animal experimentation.

*Reagents.* Collagen for platelet aggregation was obtained from Nycomed Arzneimittela GmbH (Munich, Germany). [Methyl-$^{3}$H] thymidine and [$^{125}$I] platelet-derived growth factor (PDGF)-BB were purchased from Amersham Japan (Tokyo, Japan). Probucol and losartan are a kind gift from Otuka Co. Ltd. (Tokushima, Japan) and Banyu Co. Ltd. (Tokyo, Japan), respectively. The other chemicals were obtained from Sigma (St. Louis, MO).

*Induction of vascular stenosis and quantitation of neointima formation.* Four weeks after the start of either the regular or the high-cholesterol dietary regimen, hamsters were anesthetized by intraperitonial injection of 50 mg/kg sodium pentobarbital. In brief, the right common carotid artery and the right femoral artery were exposed, and an arterial injury to the right common carotid artery using a 2FG catheter (Portex Ltd., Kent, United Kingdom) with a roughened tip was performed according to the previously described technique (12). Another catheter (i.d. = 0.5 mm, o.d. = 0.8 mm, polyethylene sp3, Natume Co. Ltd., Tokyo, Japan) was connected to the right femoral artery for monitoring blood pressure and pulse rate using a pressure transducer (AP601G; Nihon Koden, Tokyo, Japan) during experiments on day 0 (initiation of vascular injury). Blood flow in the carotid artery was continuously monitored for 90 min on day 0 using a Doppler flow probe (model PDV-20; Crystal Biotech Co. Ltd., Tokyo, Japan) positioned proximally to the injured area of the carotid artery. Our previous histological observations revealed that a platelet-rich thrombus was obviously established when the blood flow was zero (12). After the recovery from anesthesia, animals were kept in individual cages. Three, 5, 7, and 14 d after vascular injury, hamsters ($n$ = 7 each) in each group were anesthetized and perfused transcardially with saline. The common carotid artery was excised, divided into several sections, and frozen. The tissue samples were cross-sectioned, and stained with hematoxylin (Sigma Chemical Co.) to determine the intimal area. Part of these samples were used for the stain of lipids using oil red. The total areas of the internal elastic lamina (IELA) and lumen (LA) were measured using a computerized image graphic analysis system. The measurement was performed in triplicate for each sample. The average of three intimal area (IA = IELA – LA) determinations was then expressed as a percentage of IELA.

*Measurement of serum cholesterol.* Blood samples (0.3 mL) from hamsters fed either a regular or a high-cholesterol diet were collected in each time period *via* the jugular vein after the animals had been anesthetized with ether. The samples were treated with 3.15% sodium citrate. High density lipoprotein cholesterol (HDL) and LDL cholesterol were determined by enzymatic assays of blood samples taken at 0 (before the start of diet), 2, 4, and 6 wk after the start of feeding regimens These measurement were performed with Nipro cholesterol determination kits (Nipro Co. Ltd., Osaka, Japan).

*Platelet aggregation.* At the end of the experiments, 4.0 mL of blood was collected from every hamster in each group by heart puncture into sodium citrate (3.15%, final concentration) and centrifuged for 10 min at 155 × $g$ to obtain platelet-rich plasma (PRP). Platelets were counted and adjusted to $4 \times 10^8$ cells/mL (final concentration), and then platelet aggregation was induced by collagen (1.0–10.0 μg/mL) or ADP (0.5–5.0 μM) using PRP. Washed hamster platelets were prepared as described previously (19). Washed platelet aggregation was induced by thrombin (0.0001– 0.3 unit/mL). Platelet aggregation was followed using an aggregometer (Aggrecorder II, DA-3220; Kyotodaiichi-Chemical, Kyoto, Japan) at 37°C with a stirring speed of 800 rpm. All measurements were performed in triplicate.

Ex vivo *anticoagulant studies.* After the separation of PRP for platelet aggregation, the remaining blood samples were further centrifuged for 10 min at 1550 × $g$ to obtain platelet-poor plasma (PPP). The activated partial thromboplastin time (aPTT) and thrombin time (TT) were determined using standard clinical laboratory procedures.

*Electron microscopic observation.* In separate experiments, several samples taken from hamsters fed a high-cholesterol or normal diet were used for histological observations by means of scanning or transmission electron microscopy. Hamsters were anesthetized and perfused transcardially with saline 2 wk after the initiation of vascular injury. The common carotid artery was excised and fixed with 2.0% glutaraldehyde in 50 mM sodium phosphate buffer for 30 min. Each segment was cut open longitudinally to allow visual inspection for scanning electron microscopy (SEM) or cross-sectioned for transmission electron microscopy (TEM) as described (12).

*Proliferation index of SMC* in vivo. Proliferating SMC were identified by *in vivo* DNA labeling with the thymidine analog 5-bromo-2-deoxy-uridine (BrdU) (12). BrdU (50 mg/kg) was injected subcutaneously 1, 8, 16, and 24 h prior to removal of the carotid artery. Following carotid artery removal 1, 3, 5, 7, or 14 d after injury from both control and cholesterol-supplemented hamsters ($n$ = 4, each time point), frozen cross sections were prepared from these arteries. BrdU-positive cells were detected with a murine monoclonal antibody (Sigma), followed by treatment with goat antimouse immunoglobulin-antibodies conjugated to peroxidase. The complexes were then stained with diaminobenzidine (DAB). The BrdU labeling index was calculated using the following formula: (nuclei stained positive by DAB)/(total nuclei stained by hematoxylin) × 100. Animals were sacrificed by an overdose of sodium pentobarbital at the end of the experiment.

*Cell culture and measurement of DNA synthesis*. Vascular SMC were isolated from the thoracic aorta of hamsters fed either a normal or supplemented diet. The cells were cultured over several passages using the method of Ross (20). SMC were grown to confluency in 7500-$mm^2$ culture flasks in Dulbecco's modified Eagle's medium [DMEM; Gibco BRL, Grand Island, NY; 5% fetal calf serum (FCS), 100 μg/mL streptomycin, 100 U/mL penicillin, 4 μmol/L glutamine] at 37°C under humidified 5% $CO_2$/95% air. The cells were then treated with 0.25% trypsin in phosphate-buffered saline (pH = 7.4), washed, and counted. A total of $8 \times 10^4$ isolated cells were cultured as above. Cell culture medium was replaced every 2 d. On day 8, cells were detached with trypsin and counted. The cultured cells were stimulated with 5% FCS or various doses of angiotensin II ($10^{-6}$–$10^{-8}$ M), thrombin (0.001–0.03 units/mL), vasopressin ($10^{-6}$–$10^{-8}$ M), endothelin I ($10^{-6}$–$10^{-8}$ M), or PDGF-BB (1.0–100 ng/mL) in 1 mL of DMEM at 37°C for 24 h. Six hours before harvest, the cells were pulse-labeled with [methyl-$^3$H]thymidine (0.5 μCi/dish). Incubation was terminated by adding 1 mL of 10% trichoroacetic acid, and radioactivity in the acid-insoluble materials was determined by using a Beckman LS-6000IC liquid scintillation spectrometer.

*[$^{125}$I]PDGF binding*. Cultured cells were subjected to a binding assay that was essentially as described (21). Briefly, the cells were treated at 37ºC in 10 mM HEPES-buffered Dulbecco's Eagle's medium (1.0 mL, pH = 7.4; Gibco BRL). The cells were incubated with or without a 1,000-fold molar excess of nonradioactive PDGF-BB for 20 min at 37ºC. At the end of the incubation, the cells were thoroughly washed with cold phosphate-buffered saline and solubilized using 0.1% sodium dodecyl sulfate (1.0 mL). The radioactivity of the lysate was then determined using a Wallac 1480 WIZARD 3″ automatic gamma counter (Turku, Finland).

*The effect of probucol or losartan on neointima*. To further define this stenosis model in pharmacological experiments, we investigated the effect of probucol or losartan using this model. Hamsters fed a high-cholesterol diet were divided into seven groups, a control group ($n$ = 10), three groups treated with probucol (twice a day, p.o.) at doses of 30.0, 60.0, or 120.0 mg/kg per day ($n$ = 6 each), and three groups treated with losartan (twice a day, p.o.) at doses of 2.0, 6.0, or 20.0 mg/kg per day ($n$ = 6 each). Oral administration of each compound was started 2 h before the initiation of endothelial injury by a modified catheter and continued for the next 2 wk. Fourteen days after vascular injury, the common carotid artery of hamsters in each group was treated as mentioned in the paragraph on quantitation of neointima formation. At the end of observation period, blood pressure was monitored for 10 min. A catheter (i.d. = 0.5 mm, o.d. = 0.8 mm, polyethylene sp3, Natsume Co. Ltd.) connected to a pressure transducer (AP601G; Nihon Koden) was inserted into the left femoral artery for 10 min. After the measurement of blood pressure, a blood sample was taken for platelet aggregation and measurements of coagulation factors (TT and aPTT).

*Statistics.* All data are presented as the mean ± SEM. The statistical significance of the data was determined by analysis of variance followed by the Student-Newman-Keuls test.

## RESULTS

*Alteration of plasma cholesterol levels.* The mean plasma LDL level in all animals before beginning a specific dietary regimen was <0.5 g/L. After 4 wk of a high-cholesterol diet, the LDL level had increased to ~2 to 2.5 g/L and remained elevated to the end of the observation period. In contrast, there was no significant difference in plasma HDL levels between hamsters fed normal and cholesterol-supplemented diets (Table 1).

*Acute thrombus formation and vascular patency.* Vascular patency is shown in Table 2. Blood flow in the carotid artery in normal hamsters ($n$ = 28) was interrupted in 6.4 ± 0.6 min after the initiation of vascular injury by a catheter. After the blood flow was zero, spontaneous cyclic reflow and reocclusion were observed in 21 hamsters during the observation period of 90 min. The other arteries were not reperfused during the observation period. In the group of high-cholesterol hamsters, the time to occlusion was significantly shortened to 4.8 ± 0.4 min and only four arteries showed spontaneous cyclic reocclusion and reflow during the observation period ($n$ = 28).

*Neointima formation in response to endothelial injury.* All hamsters developed concentric intimal lesions in response to endothelial denudation by a catheter. The ratios of time-dependent vascular stenosis by neointima formation are shown in Figure 1. In hamsters fed a high-cholesterol diet, the extent of vascular stenosis was significantly greater compared with that of hamsters fed a normal diet.

*Platelet aggregation and hemostasis analysis*. The half-maximally inhibitory concentration ($IC_{50}$) values for platelets induced to aggregate by collagen, ADP, and thrombin in ham-

[a]The values of the half-maximally inhibitory concentration for platelet aggregation induced by ADP, collagen (PRP), or thrombin (washed platelets) in hamsters fed a normal diet or a high-cholesterol diet. aPTT, activated partial thromboplastin time; TT, thrombin time. Data represent mean ± SEM. *$P < 0.05$; **$P < 0.01$.

sters fed a normal or a high-cholesterol diet are shown in Table 3. When platelets were induced by thrombin or collagen, the $IC_{50}$ values in high-cholesterol hamsters decreased compared with the values for hamsters fed a normal diet. In terms of hemostatic values, no significant difference was observed between normal and high-cholesterol hamsters. However, these values in high-cholesterol hamsters were slightly shortened as compared with those from normal ones.

*Histological observation.* According to observations obtained through TEM, foam cells and extracellular lipids in neointima were clearly observed in hamsters fed a high-cholesterol diet (Fig. 2). When neointima formation was established 2 wk after vascular injury, the vascular surface in injured area was not smooth; however, repaired endothelial cells were completely covered with neointima. Blood elements were not observed on vascular surfaces in hamsters fed a normal diet (Fig. 3A). On the other hand, platelets were locally adhered on neointimal vascular surfaces in hamsters fed a high-cholesterol diet 2 wk after vascular injury even if endothelial cells were recovered with the vascular surface in the injured area (Figs. 3B,3C).

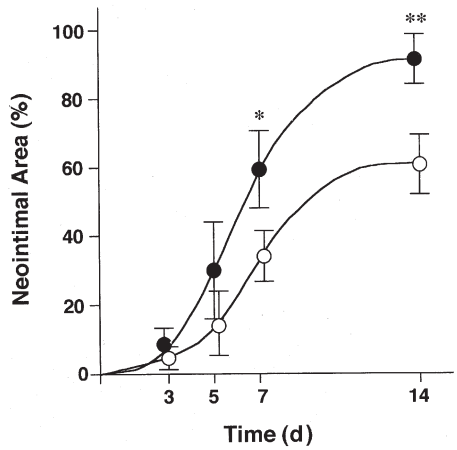

**FIG. 1.** The development of neointima in hamsters fed a normal or a high-cholesterol diet shown as percentage of luminal stenosis. Vascular injury occurred 4 wk after the start of regular (open circles) or high-cholesterol diet (closed circles), and neointima was measured 3, 5, 7, or 14 d after the vascular injury. *$P < 0.05$; **$P < 0.01$. The error bars represent SEM.

*Proliferation of SMC* in vivo. Figure 4 shows the percentage of proliferating SMC on days 1, 3, 5, 7, and 14 after vascular injury. The increased level of plasma cholesterol caused a significant increase in SMC proliferation, measured on days 1, 3, 5, and 7. These differences represented increases of 21.4, 27.3, 11.1, and 14.8% in proliferation index, respectively.

*Proliferation index* in vitro. The amount of DNA synthesis induced by various agonists is shown in Figure 5A. DNA synthesis is markedly increased in high-cholesterol hamsters when SMC are stimulated by FCS or PDGF. Dose-dependent alterations of DNA synthesis induced by PDGF are shown in Figure 5B. DNA synthesis in response to PDGF-BB stimulation of SMC in hamsters fed a high-cholesterol diet is significantly higher than in hamsters fed a normal diet. When SMC were stimulated by the other stimulation factors (thrombin, vasopressin, endothelin I, or angiotensin II), DNA synthesis was not changed in SMC from either group of hamsters.

*[$^{125}$I]PDGF binding in SMC.* The binding affinities in both groups of hamsters were unchanged (Fig. 6).

*Effects of probucol or losartan on neointima.* Figure 7 shows the inhibitory effects of probucol or losartan on neoin-

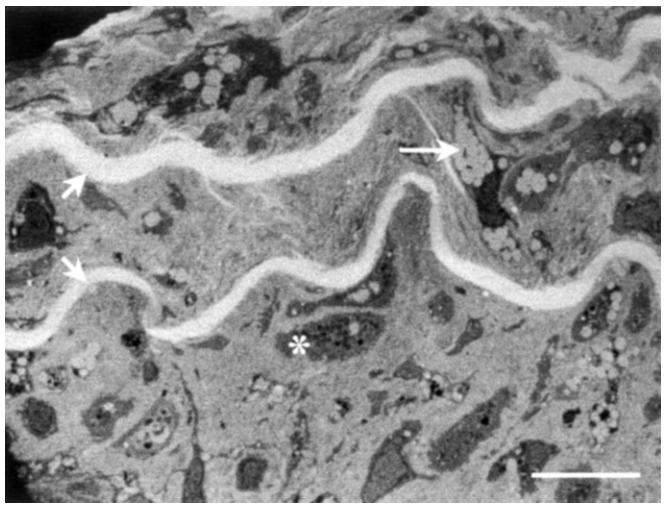

**FIG. 2.** A transmission electron micrograph of neointima formation 14 d after vascular injury in hamsters fed a high-cholesterol diet. Internal elastic lamina (IEL) can be clearly observed (small arrows) and lipid particles (large arrow) and foam cells (asterisk) are observed in media (during IEL) and newly formed intima. The scale bar indicates 200 μm.

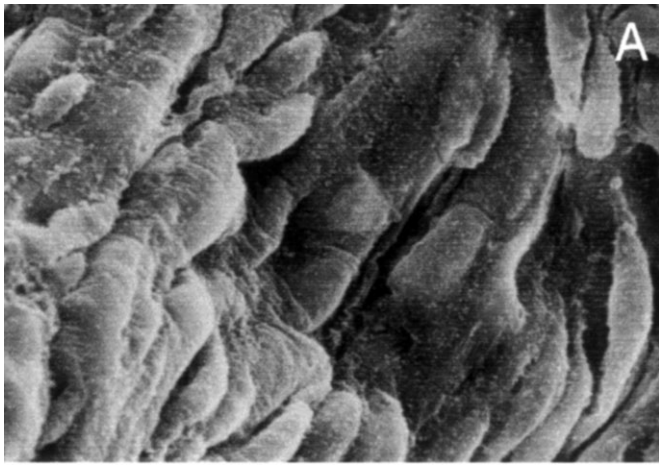

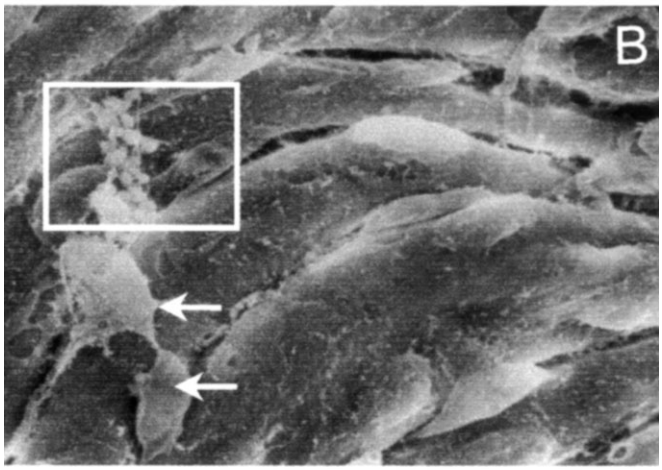

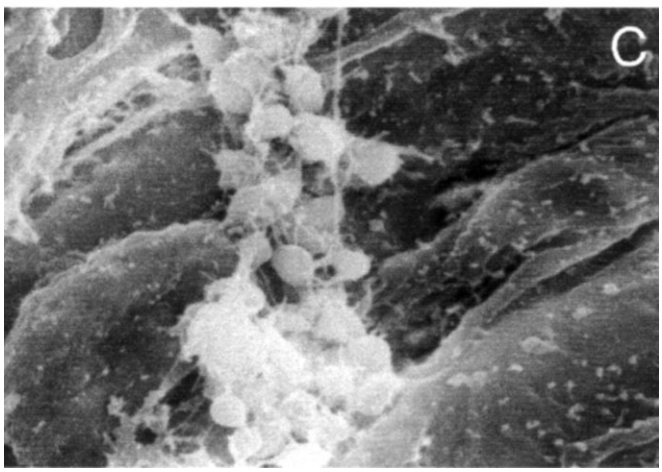

**FIG. 3.** Scanning electron micrographs from hamsters fed a normal or a high-cholesterol diet 14 d after the initiation of vascular injury. (A) Neointima formation on injured area. The luminal surface is entirely covered with newly formed endothelial cells, which are morphologically different from native ones and irregularly oriented. Blood elements are not observed in this area. (B) Locally activated platelets (a window) and monocytes (arrows) are adhered on irregularly oriented vascular surface. (C) A high magnification of a window of panel B. Adherent platelets consist of microthrombus formation.

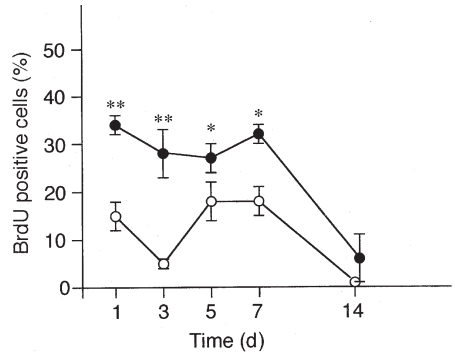

**FIG. 4.** Smooth muscle cell proliferation ($n = 4$, each time point) measured as the 5-bromo-2-deoxy-uridine (BrdU) index (%) following vascular injury in hamsters fed a normal (○) or a high-cholesterol diet (●). $^*P < 0.05$; $^{**}P < 0.01$ vs. control (normal hamsters). The error bars represent SEM.

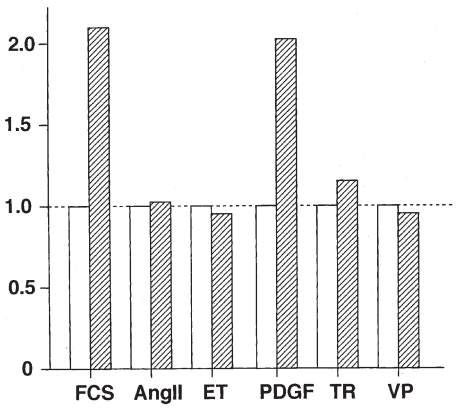

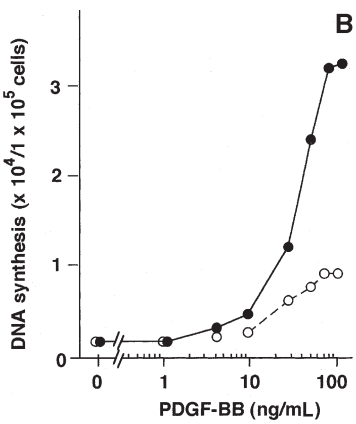

**FIG. 5.** The amount of DNA synthesis induced by various agonists (A) and dose-response line plot of DNA synthesis induced by platelet-derived growth factor (PDGF)-BB (B). (A) The cultured cells from either normally fed hamsters (open bars) or high-cholesterol-fed hamsters (hatched bars) were stimulated with 5% fetal calf serum (FCS), $10^{-6}$ M angiotensin II (AngII), 0.03 unit/mL thrombin (TR), $10^{-6}$ M vasopressin (VP), $10^{-6}$ M endothelin I (ET), or 30 ng/mL PDGF-BB (PDGF) in 1 mL of Dulbecco's modified Eagle's medium. Alteration of DNA synthesis in high-cholesterol hamsters shows a ratio vs. normal hamsters. (B) Dose-response line plot: DNA synthesis induced by PDGF-BB. Each plot presents data from hamsters with normal (open circle) or high-cholesterol diets (closed circles). Each point represents the mean of duplicate cultures.

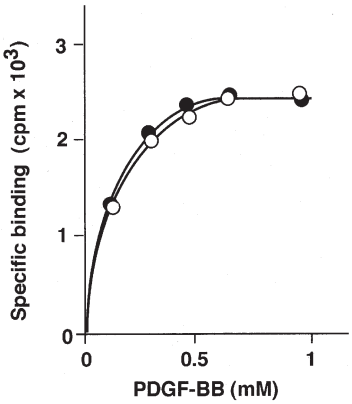

**FIG. 6.** Specific binding of PDGF-BB using explanted vascular smooth muscle cells from hamsters fed a normal or a high-cholesterol diet. Each plot presents data from hamsters with normal (open circle) or high-cholesterol diets (closed circles). Each point represents the mean of duplicate cultures. For abbreviation see Figure 5.

tima formation. The treatment with probucol at a dose of 120 mg/kg/d significantly reduced the neointimal area in hypercholesterolemic hamsters. However, losartan slightly decreased the neointimal area at the highest dose. Photomicrographs of typical neointima formation 2 wk after arterial injury of hamsters either treated with probucol at a dose of 120 mg/kg/d or not, are shown in Figure 8. Formation of neointima including a lot of lipids was observed in hamsters not treated with probucol. On the contrary, neointimal areas and points of lipid accumulation were clearly reduced by treatment with probucol. Platelet aggregation and coagulation factors were not different in hamsters fed a high-cholesterol diet compared with those fed a normal diet. Blood pressure was slightly decreased when the highest dose of losartan was used to treat hamsters.

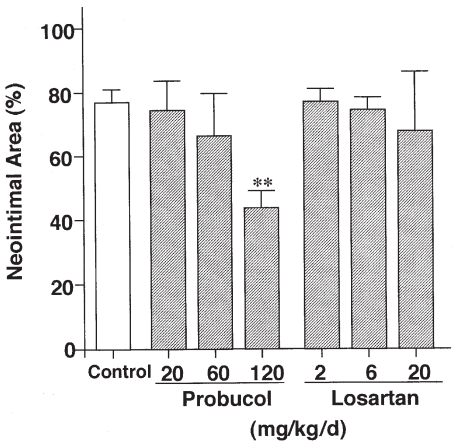

**FIG. 7.** This graph shows dose-dependent inhibition of neointima formation in hamsters fed a high-cholesterol diet by treatment with probucol or losartan. The compound was administered orally twice a day from 2 h before until 14 d after carotid artery injury; control ($n$ = 12) and treated animals ($n$ = 6) were analyzed at day 14. The ratio between neointimal area and the area within the internal elastic lamina was determined on three cross sections of carotid arteries. $^{**}P < 0.01$ vs. control. The error bars represent SEM.

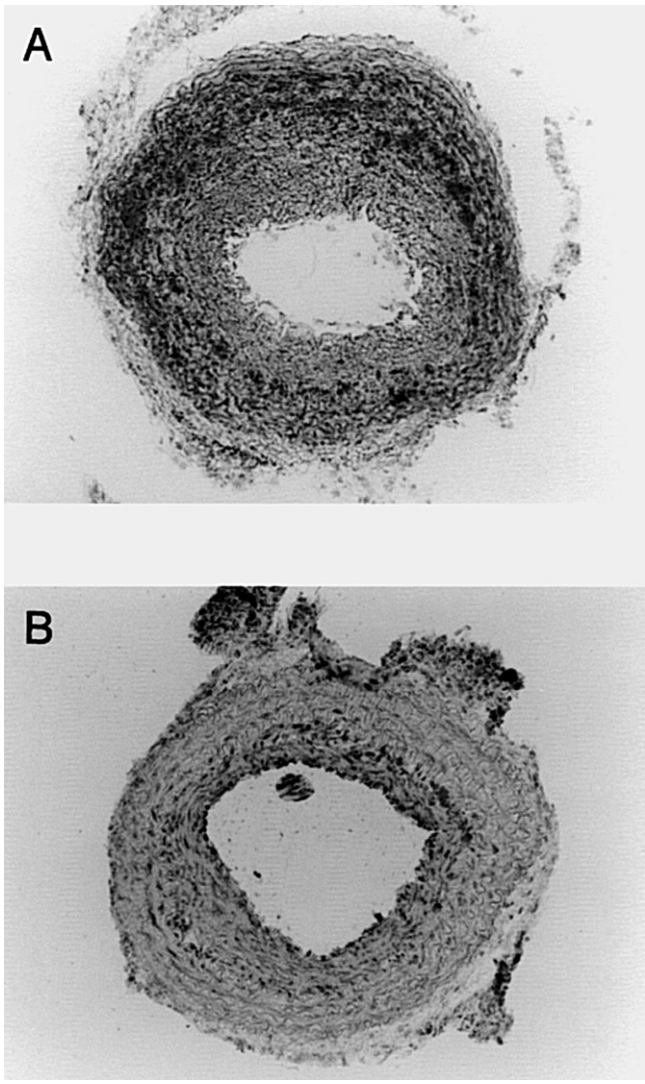

**FIG. 8.** Photomicrographs show neointima formation in damaged carotid arteries of hypercholesterolemic hamsters either treated with 120.0 mg/kg/d probucol (B) or not treated (A). Lipids were stained bright red. The tissue was counterstained with hematoxylin. A packed neointima was observed in both samples, however, the stenosis area in tissue from animals treated with probucol was diminished and lipids in stenosis clearly decreased.

## DISCUSSION

This study demonstrates that high plasma LDL levels in hamsters fed a high-cholesterol diet are associated with marked increases in the development of thrombus and neointima formation, as compared to normally fed hamsters, in injured carotid arteries, which we have established and used to demonstrate the inhibitory effects of several kinds of compounds on vascular stenosis (12–18). Furthermore, these phenomena are mainly characterized by the enhancement of platelet activation induced by thrombin and of SMC proliferation induced by PDGF-BB.

A high arterial LDL level is an important factor in the development of vascular stenosis. Several molecular mechanisms have been suggested to account for the correlation of elevated LDL serum levels with the development of chronic vascular

diseases (22,23). In our experiments, the plasma LDL level of hamsters fed a high cholesterol diet (2.24 ± 0.32 g/L) 2 wk after the start of the diet regime was 4.6 times higher than that of hamsters fed a normal diet (0.49 ± 0.02 g/L), but the HDL plasma level was not significantly different. These levels are similar to those found in pathologic conditions, such as familial combined hyperlipidemia (24), nephrotic syndrome (25) (LDL = 1.6 to 2.0 g/L), and especially homozygous familial hypercholesterolemia (LDL = 3.0 to 5.5 g/L) (26,27).

Vascular stenosis was related mainly to thrombus development in the acute phase or to neointima formation in the chronic phase after endothelial injury. In the present experiments, the development of thrombus formation of high-cholesterol hamsters *in vivo* was clearly accelerated, because the time to occlusion and vascular patency in high-cholesterol hamsters were significantly changed as compared with those of normal hamsters. This phenomenon was mainly attributable to up-regulation of platelet activation since $IC_{50}$ platelet aggregation values significantly decreased in high-cholesterol hamsters, but coagulation factors were not different in both hamsters. Our previous data indicated that platelets play a major role in the development of thombus formation since activated platelets adhere to injured vascular surfaces in the days immediately after injury (13,14). Moreover, LDL may induce a state of hypersensitivity in the platelets that contributes to the high rate of thrombosis formation observed in patients (7,28).

Our findings also showed that neointima formation in injured carotid arteries of hamsters fed a high cholesterol diet was significantly greater than in hamsters fed a normal diet. The number of proliferating SMC *in vivo* measured at each time point after vascular injury in hamsters fed a high-cholesterol diet was also significantly higher compared with hamsters fed a normal diet. LDL particles, trapped in the extracellular matrix of the vessel wall, are well known to undergo substantial structural and chemical modification in response to many kinds of stimuli (29). In our histological observations using TEM, lipid particles can be found in vascular neointima formation. Furthermore, to define the findings of increased neointima lesion in high-cholesterol hamsters, we studied the DNA synthesis using explanted SMC induced by various agonists. These results indicated that PDGF plays a key role in arterial stenosis by neointima after endothelial injury. When PDGF-BB were applied to SMC from hamsters fed a high-cholesterol diet, DNA synthesis increased markedly compared with synthesis in hamsters fed a normal diet. LDL is capable of increasing PDGF production and expression of PDGF receptors in human vascular SMC (30). Therefore, we performed binding experiments using $^{135}$I-labeled PDGF-BB on SMC from hamsters fed a high-cholesterol diet or a normal diet. The results indicated there were no differences in binding assay in SMC between hamster populations. According to these findings, we speculated that the responsibility of post-PDGF receptors, such as intracellular signaling, could play an important role in the enhancement of neointima formation in hypercholesterolemia. Moreover, PDGF is an α granule component (31) that is released during the platelet reaction induced by collagen or ADP (32), or when platelets adhere to sites of injured blood vessels, as seen in our findings using SEM. Therefore, up-regulation of sensitivity in platelets in high-cholesterol hamsters also plays a role in the enhancement of neointima formation. Indeed, our previous findings indicated that platelets play a significant role in the development of neointima formation since antiplatelet compounds improved SMC proliferation during the acute phase of vascular injury (13,14).

To define the utility of this model in pharmacological experiments, we used losartan and probucol to treat hamsters fed a high-cholesterol diet, because probucol inhibited aortic cholesterol accumulation (33) and reduced neointima formation (34) and losartan also reduced neointima formation (35). In these experiments, probucol significantly reduced the neointimal area and attenuated lipid formation in vascular SMC. Indeed, foam cell lesions in hypercholesterolemic hamsters were decreased by treatment with probucol (33). On the contrary, losartan did not show significant effects on neointima formation even though our previous study showed that losartan significantly reduced neointima formation in normal hamsters (18). These findings indicated that probucol greatly affects the development of neointima formation promoted by hypercholesterolemia, but not the inhibition of angiotensin II by losartan.

Finally, we speculate that the physiological importance of such responses to the development of neointima formation in hypercholesterolemia may be modeled as follows: First, after endothelial injury, activated platelets adhere to and aggregate at damaged endothelial surfaces. Next, these platelets are sensitized by high levels of plasma LDL. The production of locally secreted PDGF by activated platelets increases proliferation of SMC in the region of the injury. The continuous production of PDGF may play a very significant role in the amplified development of neointima in hypercholesterolemia. This is especially relevant since the other known stimulants (angiotensin II, vasopressin, or endothelin) did not increase DNA synthesis in SMC from high-cholesterol hamsters. This model is a sensitive one for pharmacological experiments.

In conclusion, high levels of plasma LDL lead to intimal hyperplasia *via* up-regulation of platelet aggregation and enhancement of proliferating SMC. Further research is necessary to determine whether this LDL-induced hyperplasia occurs in humans with elevated LDL levels. If so, antiplatelet and antithrombin drugs could be part of a new supportive therapeutic concept in the treatment of hypercholesterolemia-associated cardiovascular diseases. This model could be a useful tool for investigation of this field since hamsters are smaller and permit a reduction in the amount of drug required.

# Effects of Dietary Defatted Squid on Cholesterol Metabolism and Hepatic Lipogenesis in Rats

**Kazunari Tanaka[a,*], Ikuo Ikeda[b], Hiroko Yoshida[c], and Katsumi Imaizumi[b]**

[a]Laboratory of Nutrition Chemistry, Siebold University of Nagasaki, Nagasaki 851-2195, Japan, [b]Laboratory of Nutrition Chemistry, Faculty of Agriculture, Graduate School Kyushu University, Fukuoka 812-8581, Japan, and [c]Division of Food and Nutrition, Nakamura Junior College, Fukuoka 814-0198, Japan

**ABSTRACT:** Male Sprague-Dawley rats were fed a cholesterol-free (Exp. 1) or cholesterol-supplemented (Exp. 2) diet containing 20% casein (control group) or 15% defatted squid and 5% casein (defatted squid group), as protein, for 14 d. Serum and hepatic cholesterol concentrations were lower in rats fed defatted squid than in those fed casein in both cholesterol-free (–20%, $P < 0.05$ and –15%, $P < 0.05$, respectively) and cholesterol-supplemented (–25%, $P < 0.05$ and –15%, $P < 0.05$, respectively) diets. Hepatic triglyceride concentration was lower in the defatted squid than in the control groups in both cholesterol-free (–51%, $P < 0.05$) and cholesterol-supplemented diets (–38%, $P < 0.01$). The activities of cytosolic fatty acid synthase and the NADPH-generating enzymes, malic enzyme and glucose-6-phosphate dehydrogenase, in the liver were lower in the defatted squid than in the control groups in both cholesterol-free (–21%, $P < 0.01$, –33%, $P < 0.05$, and –33%, $P < 0.01$, respectively) and cholesterol-supplemented diets (–34%, $P < 0.05$, –57%, $P < 0.05$, and –67%, $P < 0.05$, respectively). The activity of mitochondrial carnitine palmitoyltransferase in the liver was comparable between the control and defatted squid groups. The activity of $Mg^{2+}$-dependent phosphatidate phosphohydrolase in the liver cytosol was lower in the defatted squid (–9%, $P < 0.05$) than in the control groups only in the cholesterol-free diet. Fecal excretion of total steroids was stimulated by the feeding of defatted squid in both cholesterol-free (+77%, $P < 0.005$) and cholesterol-supplemented diets (+29%, $P < 0.01$). These results suggest that the nonlipid fraction of squid exerts a hypocholesterolemic effect by increasing the excretion of total steroids in feces. The fraction also induces a triglyceride-lowering activity in the liver by decreasing hepatic lipogenesis.

Paper no. L8638 in *Lipids 36,* 461–466 (May 2001).

An inverse association between seafood consumption and death from coronary heart disease has been reported (1,2). This effect is ascribed primarily to reductions of serum triglyceride and cholesterol and to suppression of platelet aggregation by two n-3 polyunsaturated fatty acids (PUFA), eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids, occurring in seafoods (3–5). The Japanese frequently eat seafoods other than fishes, for example, shellfish, crustaceans, mollusks. Because these seafoods contain both n-3 PUFA and cholesterol, the effect of dietary seafoods on cholesterol metabolism is complicated. Childs *et al.* (6) reported that six seafoods—clam, oyster, scallop, crab, shrimp, and lobster—do not have a profound hypercholesterolemic effect in normal subjects. Recently, we observed (7,8) that dietary short-necked clam, shrimp, squid, and octopus reduced the concentrations of serum and liver cholesterol in mice. Squid and octopus are consumed mainly in Japan and are also eaten in the Far East, Southeast Asia, and Mediterranean area. The hypocholesterolemic effect of these seafoods was ascribed mainly to the increased output of fecal steroids. It was also observed that dietary seafoods, in particular squid, effectively reduced liver triglyceride concentrations in mice (8). However, mechanisms of the triglyceride-lowering action were not investigated in the study. The hypolipidemic effect of the seafoods are not necessarily attributable to the constituent n-3 PUFA, because the contents of n-3 PUFA in the seafoods apparently are too low to exert the cholesterol- and triglyceride-lowering action. However, information on the effect of the nonlipid fraction of seafoods other than fish on lipid metabolism is seldom obtained.

In the present study, the effect of delipidated squid on cholesterol and triglyceride metabolism was elucidated in more detail in Sprague-Dawley rats, in which knowledge of lipid metabolism is well established (9–13). In one study, cholesterol and sodium cholate were supplemented in the diets in order to investigate the effect of squid on hypercholesterolemia.

## MATERIALS AND METHODS

*Materials.* Fresh squid (*Tadarodes pacificus*) were obtained from a fish market. The tentacle of squid was removed. An edible fraction of squid was minced and lyophilized. Freeze-dried squid was defatted by a mixture of hexane/ethanol (4:1, vol/vol). Crude protein and fat contents in defatted squid, which were assayed by the Kjeldahl method and the Soxhlet method with diethyl ether, were 80.0 and 0.03%, respectively. Defatted squid contained 5.91% ash.

*Animals and diets.* Male Sprague-Dawley rats, 4 wk old and weighing about 110 g (Seac Yoshitomi, Co., Fukuoka, Japan),

were housed individually and kept in an air-conditioned room at 22–25°C in a 12 h light/12 h dark cycle (0800 to 2000). They were given one of the four experimental diets shown in Table 1 and water *ad libitum* for 14 d. The level of dietary protein in the experimental diets was adjusted to 20% on an isonitrogenous base. Since the nutritional value of squid is somewhat low, 15% defatted squid protein and 5% casein were served as the protein source in the defatted squid diet. Casein was the sole protein source in the control diet. Corn oil was added at the 5% level. In Experiment 1, the diets did not contain cholesterol, but in Experiment 2, 0.5% cholesterol and 0.125% sodium cholate were supplemented in the diets. The other experimental conditions were the same between the experiments. Feces were collected for 2 d at the end of experiments. After 7 h of fasting, rats were killed by withdrawing blood from the abdominal aorta, and livers were immediately excised.

All animal studies were carried out under the guidelines for animal experiments in Faculty of Agriculture, Graduate School of Kyushu University (Fukuoka, Japan) and Law No. 105 and Notification No. 6 of the government of Japan.

*Lipid analyses.* Serum lipids were assayed enzymatically using commercial kits (Cholesterol C-II Test, Triglyceride G-Test, Phospholipid B-Test; Wako Pure Chemicals, Osaka, Japan; and HDL-C · 2-Daiichi; Daiichi Chemicals, Tokyo, Japan). Liver lipids were extracted by the method of Folch *et al.* (15), and concentrations of cholesterol, triglyceride, and phospholipid were measured as described elsewhere (16). Fecal neutral and acidic steroids were measured by gas–liquid chromatography using an OV-17 (Chromatotec, Tokyo, Japan) column (17) and an AN-600 (Chromatotec) column (18), respectively.

*Measurements of lipogenic enzyme activity.* The enzyme activities of fatty acid synthase (FAS) (19), glucose-6-phosphate dehydrogenase (G6PDH) (20), malic enzyme (21), phosphatidate phosphohydrolase (PAP) (22), and carnitine palmitoyltransferase (CPT) (23) were determined as described.

*Statistical analysis.* Data were inspected by Student's *t*-test.

## RESULTS

There were no differences in body weight gain, food intake, and relative liver weight between the control and the defatted squid groups in both cholesterol-free and cholesterol-supplemented diets (Table 2).

The concentration of serum cholesterol was significantly lower in rats fed defatted squid diet than in rats fed control diet in both the cholesterol-free and cholesterol-supplemented groups (–20 and –25%, respectively, $P < 0.05$) (Table 3). The concentration of high density lipoprotein (HDL)-cholesterol was higher in the control group than in the defatted squid group when cholesterol was added to the diets (+34%, $P < 0.05$). However, there was no difference in the very low density lipoprotein (VLDL)- and low density lipoprotein-cholesterol level between the control and defatted groups in both cholesterol-free and cholesterol-supplemented diets. The ratio of total cholesterol to HDL-cholesterol was comparable between the groups irrespective of the addition of cholesterol to the diets. The concentration of serum triglyceride was comparable between the control and defatted squid groups in both cholesterol-free and cholesterol-supplemented diets. There was no significant difference in the concentration of serum phospholipid between the corresponding groups.

The concentration of hepatic cholesterol was significantly lower in the defatted squid group than in the control group of cholesterol-free and cholesterol-supplemented diets (–15%, $P < 0.05$) (Table 4). Liver triglycerides were reduced in the defatted squid groups in cholesterol-free (–51%, $P < 0.05$)

[a]Mean ± SE of six rats.
[b]Significantly different from the control group at $P < 0.05$. Abbreviations: HDL, high density lipoprotein; VLDC, very low density lipoprotein; LDL, low density lipoprotein.

and in cholesterol-supplemented diets (–38%, $P < 0.01$). The concentration of liver phospholipid was the same between the groups in both experiments.

The activities of enzymes related to fatty acid synthesis—FAS, malic enzyme, and G6PDH—in liver cytosol were significantly lower in the defatted group than in the control group in both cholesterol-free (–21%, $P < 0.01$, –33%, $P < 0.05$, and –33%, $P < 0.01$, respectively) and cholesterol-supplemented diets (–34%, $P < 0.05$, –57%, $P < 0.05$, and –67%, $P < 0.01$, respectively) (Table 5). There was no difference in the activity of hepatic mitochondrial CPT, the rate-limiting enzyme of mitochondrial β-oxidation, between the control and defatted squid groups. The activity of $Mg^{2+}$-dependent PAP in liver microsomes, the rate-limiting enzyme of triglyceride synthesis, was comparable in cholesterol-free and cholesterol-supplemented diets, but the activity in cytosol was lower in the defatted group than in the control group in cholesterol-free diets (–9%, $P < 0.05$).

As shown in Table 6, fecal weight was higher in the groups fed defatted squid than in the control groups, and the difference was significant in the cholesterol-free diet (+29%, $P < 0.05$). Feeding of defatted squid significantly increased the excretion of neutral steroids in cholesterol-free diet (+86%, $P < 0.005$). In cholesterol-supplemented diet, the excretion of acidic steroids was significantly increased (+85%, $P < 0.0005$). Consequently, total steroid excretion was higher in the defatted squid groups than in the control groups in both cholesterol-free (+77%, $P < 0.005$) and cholesterol-supplemented diets (+29%, $P < 0.01$).

## DISCUSSION

The present study revealed that feeding the nonlipid fraction of squid affects both cholesterol and triglyceride metabolism differently compared with that of casein. Because a large portion (approximately 80%) of the nonlipid fraction is protein, the effect is considered to be mainly exerted by protein.

Dietary defatted squid lowered serum and liver cholesterol concentrations in both cholesterol-free (Exp. 1) and cholesterol-supplemented (Exp. 2) diets compared with the control diets. Because the excretion of neutral steroids into feces was higher in the defatted squid group of rats fed a cholesterol-free diet (Exp. 1), it is conceivable that intestinal absorption of cholesterol was inhibited in the defatted squid group. Therefore, the reduction of hepatic cholesterol in this group is ascribed to the reduced cholesterol absorption. In contrast, dietary defatted squid did not increase fecal excretion of neutral steroids, but it enhanced the excretion of acidic steroids in Experiment 2. Dietary cholesterol is known to stimulate bile acid synthesis in the liver (24). Madani *et al.* (25) reported that the activity of hepatic cholesterol 7α-hydroxylase, the rate-limiting enzyme in bile acid synthesis, was lower in rats fed soybean protein than in rats fed casein in a cholesterol-free diet, but the activity was higher in rats fed soybean protein than casein in a cholesterol-supplemented diet. Therefore, we think that defatted squid stimulates bile acid synthesis more than casein does in a cholesterol-supplemented diet, and hence more bile acids were secreted into the intestinal lumen and fecal output was enhanced. Because the increased

[b]Significantly different from the control group at $P < 0.05$. The activities of the fatty acid synthase, malic enzyme, and glucose-6-phosphate dehyrogenase were measured in the liver cytosol fraction. Carnitine palmitoyltransferase activity was measured in liver mitochondria.
[c]The assay was performed in the presence of 3.45 mM $MgCl_2$.

bile acid concentration in the lumen can accelerate micellar solubility of cholesterol, there is a possibility that it weakens the inhibitory effect of cholesterol absorption by defatted squid. This may be why the feeding of defatted squid did not accelerate fecal excretion of neutral steroids in Experiment 2. Although more studies will be necessary on this point, a similar inconsistency has been reported on the effect of soybean protein on fecal excretion of neutral and acidic steroids. That is, dietary soybean protein increased fecal excretion of neutral (26,27) or acidic (28,29) steroids or both (30,31).

Defatted squid lowered serum cholesterol concentration, without modifying the ratio of total cholesterol to HDL-cholesterol, compared with the control group in both cholesterol-free and cholesterol-supplemented diets. In our previous experiment in mice (8), defatted squid did not reduce the serum cholesterol concentration. Causes of the differences in the effect of defatted squid on serum cholesterol level between our previous and present experiments are obscure. However, since the decrease in liver cholesterol level followed the feeding of defatted squid in our previous study (8), serum cholesterol level may be reduced by the prolongation of the feeding period. Also, there is a possibility that the difference in species between mice and rats is involved.

Feeding of defatted squid reduced hepatic triglyceride concentration in the present and previous studies (8). There was no precise information on the effects of squid on hepatic lipogenesis. In the present results, since defatted squid suppressed the activities of FAS, malic enzyme, and G6PDH, it is considered that defatted squid reduced the rate of fatty acid synthesis more effectively than casein. Iritani *et al.* (32) reported that the activities of G6PDH, malic enzyme, and FAS in rat liver were lower in the feeding of plant proteins, soybean protein, and gluten than in the feeding of animal protein, casein, and fish protein. The present study has shown for the first time that squid protein suppresses hepatic fatty acid synthesis compared with casein. The activities of CPT, an indicator of mitochondrial β-oxidation, and $Mg^{2+}$-dependent PAP, the key enzyme in the synthesis of triglyceride (33), were not appreciably modified in rats fed defatted squid. Therefore, the reduction of hepatic triglyceride level in the feeding of defatted squid is thought to be mainly induced by the reduction of the activities of FAS and NADPH-generating enzymes.

Serum triglyceride was not influenced by the feeding of defatted squid in the present study. We previously observed that dietary EPA and DHA reduced hepatic triglyceride concentration by suppressing the activities of enzymes involving fatty acid synthesis in rat liver (12). In contrast to the present study, these n-3 PUFA also decreased serum triglyceride concentration. However, serum triglyceride concentration was not always determined only by fatty acid synthesis in the liver. The activity of lipoprotein lipase is also a major determinant of serum triglyceride concentration. We observed that dietary fish oil increased lipoprotein lipase activity in adipose tissue, suggesting that chylomicron- and VLDL-triglyceride clearance from serum is accelerated in fish oil feeding (13). Therefore, there is a possibility that the effect of defatted squid on lipoprotein lipase may be different from that of fish oil. Further investigation is necessary in this point.

In summary, the present studies suggest the possibility that nonlipid components of squid decrease serum and liver cholesterol and liver triglyceride levels through the stimulation of fecal steroid excretion and the suppression of hepatic lipogenesis in rats.

## ACKNOWLEDGMENTS

Part of this study was supported by a Grant-in-Aid for Scientific Research (C) (No. 10680169) from the Ministry of Education, Science, Sports and Culture and a grant from Siebold University of Nagasaki.

**ABSTRACT:** In this study, we investigated a change in the excretory content of 2,7,8-trimethyl-2(2′-carboxyethyl)-6-hydroxychroman (γ-CEHC), a γ-tocopherol (γ-Toc) metabolite, in rat urine and bile by using a new high-performance liquid chromatography–electrochemical detection (HPLC–ECD) method. In this determination, CEHC [α- and γ-CEHC, where α-CEHC = 2,5,7,8-tetramethyl-2(2′-carboxyethyl)-6-hydroxychroman] in the biological specimens were treated with 3 N methanolic HCl to hydrolyze conjugates and to promote esterification. The methylated samples were extracted by *n*-hexane/water (1:2). The analyses of the methyl esters of α-CEHC and γ-CEHC were performed by an HPLC–ECD using an ODS-3 column at 35°C. The mobile phase was acetonitrile/water (45:55, vol/vol) containing 50 mM sodium perchlorate. After rat urine and bile samples, respectively, were methylated as described above, methylated biliary metabolites were identified by liquid chromatography–mass spectrometry as methyl esters of γ-CEHC. Furthermore, we examined the differences in the excretion of γ-CEHC between rat urine and bile after an oral administration of γ-Toc or α- + γ-Toc by the above HPLC method. In the γ-Toc group, each vitamin E-deficient rat was given 0.5 mL of a stripped corn oil preparation containing 10 mg of γ-Toc. In the α- + γ-Toc group, the rat was given 10 mg of α-Toc and 10 mg of γ-Toc. The content of γ-CEHC in rat urine from the α- + γ-Toc group was increased more in comparison to the γ-Toc group at 18–36 h after oral administration. Moreover, the content of γ-CEHC in rat bile in the α- + γ-Toc group was increased more in comparison to the γ-Toc group at 6–18 h after oral administration. Therefore, we have suggested that γ-CEHC was shifted mainly to urinary excretion after γ-CEHC had been excreted into the bile. Furthermore, we assume that α-Toc may affect the metabolism of γ-Toc to γ-CEHC in the body.

Abbreviations: AsA, ascorbic acid; α-CEHC, 2,5,7,8-tetramethyl-2(2′-carboxyethyl)-6-hydroxychroman; γ-CEHC, 2,7,8-trimethyl-2(2′-carboxyethyl)-6-hydroxychroman; δ-CEHC, 2,8-dimethyl-2(2′-carboxyethyl)-6-chromanol; CEHC-Me, CEHC-methyl ester; ECD, electrochemical detection; HPLC, high-performance liquid chromatography; α-, γ-, or δ-Toc, α-, γ-, or δ-tocopherol; TOC-3, tocotrienol; TQ, tocopherylquinone; α-TTP, α-tocopherol transfer protein.

There are eight different naturally occurring forms of vitamin E: four tocopherols (Toc) (α-, β-, γ-, δ-) and four tocotrienols (Toc-3) (α-, β-, γ-, δ-). α-Toc is known to be a major antioxidant in protecting cellular membranes (1).

Orally administered Toc analogs (especially α- and γ-Toc) are absorbed equally well from the small intestine without discrimination. After uptake into the intestinal cells, Toc analogs are secreted into chylomicrons. Chylomicron remnants are subsequently catabolized during circulation by lipoprotein lipase. After uptake of chylomicron remnants by the liver, Toc analogs are discriminated by α-Toc transfer protein (α-TTP) in liver, which transports α-Toc, circulated in plasma, and then transported to each tissue. On the other hand, γ-Toc remains in liver. Hosomi *et al*. (2) examined the structural characteristics of vitamin E analogs required for recognition by α-TTP. Relative affinities (*RRR*-α-Toc = 100%) calculated from the degree of competition were as follows: β-Toc, 38%; γ-Toc, 9%; δ-Toc, 2%; α-Toc acetate, 2%, α-Toc quinone, 2%; *SRR*-α-Toc, 11%; α-tocotrienal, 12%; trolox, 9%. From these results, they proposed that the affinity of vitamin E analogs for α-TTP, which may determine their plasma levels, is a major determinant of their biological activity. The question has been raised regarding what happens to Toc remaining in liver. Kayden and Traber (3) pointed out that the different *RRR*-α-Toc remaining in liver (i.e., γ-Toc or *SRR*-α-Toc) will probably be excreted in the bile.

The following mechanism for α-Toc metabolism has been suggested: α-Toc is first oxidized to α-tocopherylquinone (-TQ); it is then reduced to α-tocopherylhydroquinone, then the side chain is degraded. Finally, these are found in urine as Simon metabolites, which were first found in rabbit urine (4), in which they are present mainly as glucuronide conjugates. However, in 1995, Schultz *et al*. (5) reported that 2,5,7,8-tetramethyl-2(2′-carboxyethyl)-6-hydroxychroman (α-CEHC) was the major urinary metabolite of α-Toc. They suggested that α-Toc can undergo ω-oxidation without cleavage of the chroman ring and that this pathway will be responsible for generation of the major urinary α-Toc metabolite in healthy humans. On the other hand, we also studied the metabolism of α-Toc stereoisomers in rats by using [5-methyl-

$^{14}$C] *SRR*- or *RRR*-α-Toc. According to these results, the *ca.* 73% of the total radioactivity of both groups was found to be present in α-CEHC when urine samples from rats receiving *SRR*-α-Toc were hydrolyzed with 3 N methanolic HCl and analyzed by HPLC (6). Furthermore, Wechter *et al.* (7) isolated a new endogenous natriuretic factor, LLU-α, from human urine, which was presumably a metabolite of γ-Toc. With respect to δ-Toc, Chiku *et al*. (8) reported that the major metabolite of δ-Toc treated with sulfatase was 2,8-dimethyl-2(2′-carboxyethyl)-6-hydroxychroman. Clearly, urinary metabolites of vitamin E analogs are mainly CEHC forms, but how CEHC forms *in vivo* is not clear. Determination of free-CEHC by using HPLC–electrochemical detection (ECD) after enzyme treatment (9,10) or of CEHC by using a coupled-column HPLC with a fluorometric derivatization (11) have been reported. We tried to establish a new way to convert CEHC into CEHC-methyl esters (CEHC-Me) in biological specimens by HPLC-ECD and to estimate the amounts of CEHC present in rat urine and bile. Furthermore, we examined the effect of α-Toc on γ-Toc metabolism *in vivo*.

## MATERIALS AND METHODS

*Materials. RRR*-α-Toc (α-Toc), *RRR*-γ-Toc (γ-Toc), α-CEHC, and 2,7,8-trimethyl-2(2′-carboxyethyl)-6-hydroxychroman (γ-CEHC) were donated by Eisai Co. (Tokyo, Japan).

*Animals.* Male Sprague-Dawley strain rats (3 wk of age) were purchased from Nippon Clea Co. (Tokyo, Japan). They were initially fed a commercial diet (CE-2; Nippon Clea Co.) for a week to allow them to adapt to the new environment. The rats were then fed a diet deficient in vitamin E (AIN-76; Eisai Co.) for 4 or 8 wk. This diet was composed of 23.68% sucrose, 23.68% glucose, 18.95% vitamin-free casein, 14.21% cornstarch, 4.74% filter paper, 3.32% mineral mixture, 0.95% vitamin mixture except vitamin E, 0.28% DL-methionine, 0.19% choline bitartrate, and 10% stripped corn oil. Animals were housed individually in cages at 22°C and 55% humidity with a 12-h light/dark cycle. The feed and water were supplied *ad libitum*.

*Experimental protocol using vitamin E-deficient rats (Experiments 1 and 2).* In Experiment 1, the vitamin E-deficient rats (fed the diet for 8 wk) were divided into two groups after 17 h of fasting: one was the γ-Toc group and the other the α- + γ-Toc group. Rats of the γ-Toc group ($n$ = 4) were each given orally 0.5 mL stripped corn oil containing 10 mg of γ-Toc, and rats of α- + γ-Toc group ($n$ = 4) were each given orally 0.5 mL stripped corn oil containing 10 mg each of α-Toc and γ-Toc. Rats were then housed individually in metabolic cages; urine was collected into flasks kept cool with dry ice. Urine was collected over 6-h intervals after administration for 48 h.

In Experiment 2, the vitamin E-deficient rats (fed the diet for 4 wk) were divided into two groups and then prepared by a method similar to the one described above. Under nembutal anesthesia, rats administered Toc were subjected to cannulation of bile duct; then the bile was collected into tubes cooled by dry ice. After surgery, bile collection was started at 3 h after oral administration and performed at 3-h intervals for 24 h. Samples of urine or bile were immediately lyophilized and stored at −20°C under nitrogen until CEHC determination. The present study was approved by the animal committee of Ochanomizu University.

*Hydrolysis of conjugated CEHC during acid methylation.* Urine was collected from a human volunteer after supplementation with all-*rac*-α-tocopherol (400 mg for 5 d). Because free-CEHC was completely converted to CEHC-Me by this method, the sample was divided: one was methylated by using this method after the conjugated CEHC had been converted to free-CEHC by treatment with β-glucuronidase; the other was methylated directly with this method. For enzymatic hydrolysis, we used a method of Lodge *et al*. (9). Human urine (2 mL) was hydrolyzed by the addition of 200 μL enzyme solution (4 mg β-glucuronidase in 450 μL of 0.1 M sodium acetate buffer, pH 4.5) and incubation for 4 h at 37°C. After enzyme treatment, samples were lyophilized immediately. This portion of the study was carried out under the guidelines established by the Center for Human Care of Ochanomizu University, Tokyo, Japan.

*Extraction of CEHC from the rat urine and bile.* We tried to establish a simultaneous determination of α- and γ-CEHC. We speculate CEHC are present as unconjugated and conjugated forms *in vivo* (5,8–10). Our methodology determined both unconjugated and conjugated CEHC in samples as CEHC-Me that replaced a conjugated substance or a part of carboxy group with methyl group by methylation. Replacing CEHC-Me can measure stability. Furthermore, the extraction and determination of this method are relatively simple and performed at low cost.

Purified water (10 mL) was added to the tube containing the lypophilized sample. From this was pippetted 0.5 mL into a centrifuge tube containing 0.1 mL of ascorbic acid (AsA) solution (0.5 g/mL) and 1 mL of EDTA solution (0.54 mM). This sample was immediately lyophilized again. After 2 mL of 3 N methanolic HCl had been added to each tube, the contents were methylated with shaking at 60°C for 1 h under $N_2$. After methylation, sample tubes were cooled in ice water, 6 mL of water was then added to each tube, and the medium was shaken vigorously with 3 mL of *n*-hexane for 1 min. This mixture was centrifuged at 3000 rpm for 5 min, and the upper layer was collected and evaporated. The residue was dissolved in 100 μL of 45% acetonitrile/water containing 50 mM sodium perchlorate for the determination by HPLC. Methylated CEHC in biological specimens was also identified by liquid chromatography–mass spectrometry (LC–MS).

*Chromatographic apparatus and conditions.* The HPLC system consisted of JASCO Intelligent HPLC Pump (PU-980), Intelligent Sampler (AS-950-10), Column Oven (860-CO), and integrator (870-IT) (JASCO Co., Tokyo, Japan). The electrochemical detector used was an LC-4C Amperometric Detector (BAS Co., Tokyo, Japan) applying a potential of +0.6 V vs. Ag/AgCl. The analysis of α- and γ-CEHC was performed at 35°C by using an ODS-3 column (5

μm, 250 × 2.1 mm i.d.; GL Science Inc., Tokyo, Japan). The mobile phase was acetonitrile/water (45:55, vol/vol) containing 50 mM sodium perchlorate (pH was adjusted to 3.6 with acetic acid) at a flow rate of 0.2 mL/min.

*Conditions of LC–MS.* LC–MS analysis was performed on a TSQ 7000 LC/APCI MS system (Thermo Quest K.K., Tokyo, Japan). Conditions were as follows: auxiliary gas flow, 10 units; sheath gas pressure, 70 psi; capillary temperature, 150°C; vaporizer temperature, 400°C; corona current, 5 μamps; scan time, 1 s. For LC, Irica PR-18T C18 column (5 μm, 250 × 2.0 mm; Irica Instruments Inc., Kyoto, Japan) was used. The mobile phase was 50% (vol/vol) acetonitrile/water at a flow rate of 0.2 mL/min.

*Statistical analysis.* All results were expressed as mean ± SD. Student's *t*-test was used for a comparison of γ-Toc group and α- + γ-Toc group. Differences were considered significant at $P < 0.05$.

## RESULTS

*Simultaneous determination of α- and γ-CEHC in biological specimens.* Figure 1 shows HPLC chromatograms of methylated α- and γ-CEHC standard. α- and γ-CEHC-Me were completely separated into two peaks by this method. The first peak was γ-CEHC-Me, and the second was α-CEHC-Me.

Calibration curves were prepared with solutions containing authentic samples of both α-and γ-CEHC. One-milliliter aliquots of 0.01, 0.02, and 0.05 μg methanolic α-CEHC (or γ-CEHC)/mL were methylated with methanolic HCl in the presence or absence of 10% methanolic AsA solution under $N_2$. The resultant products were analyzed by HPLC-ECD. For the calibration curves of α- and γ-CEHC-Me, the linear regression equation of α-CEHC-Me without AsA was $y = 1.73 \times 10^7 x - 8.49 \times 10^4$ (correlation coefficient: $r = 0.965$); that of γ-CEHC-Me without AsA was $y = 1.88 \times 10^7 x + 1.22 \times 10^4$ (correlation coefficient: $r = 0.991$). In contrast, the linear regression equation of α-CEHC-Me with AsA was $y = 2.06 \times 10^7 x - 2.40 \times 10^4$ (correlation coefficient: $r = 0.983$), that of γ-CEHC-Me with AsA was $y = 2.02 \times 10^7 x + 1.50 \times 10^4$ (correlation coefficient: $r = 0.992$) (Fig. 2). Accordingly, the standard solutions were methylated in the presence of 10% methanolic AsA solution under $N_2$. The resultant calibration curves were found to be optimal for analysis of the vitamin E metabolites. Also, samples were treated similarly to the procedure described above after lyophilization.

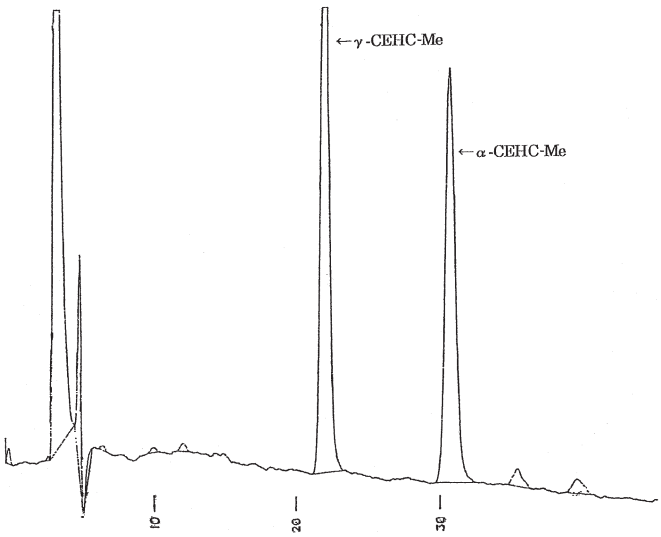

**FIG. 1.** High-performance liquid chromatogram of methylated α- and γ-CEHC standards. α- and γ-CEHC standards were treated with 3 N methanolic HCl, then extracted by *n*-hexane. α-CEHC, 2,5,7,8-tetramethyl-2(2′-carboxyethyl)-6-hydroxychroman; γ-CEHC, 2,7,8-trimethyl-2(2′-carboxyethyl)-6-hydroxychroman.

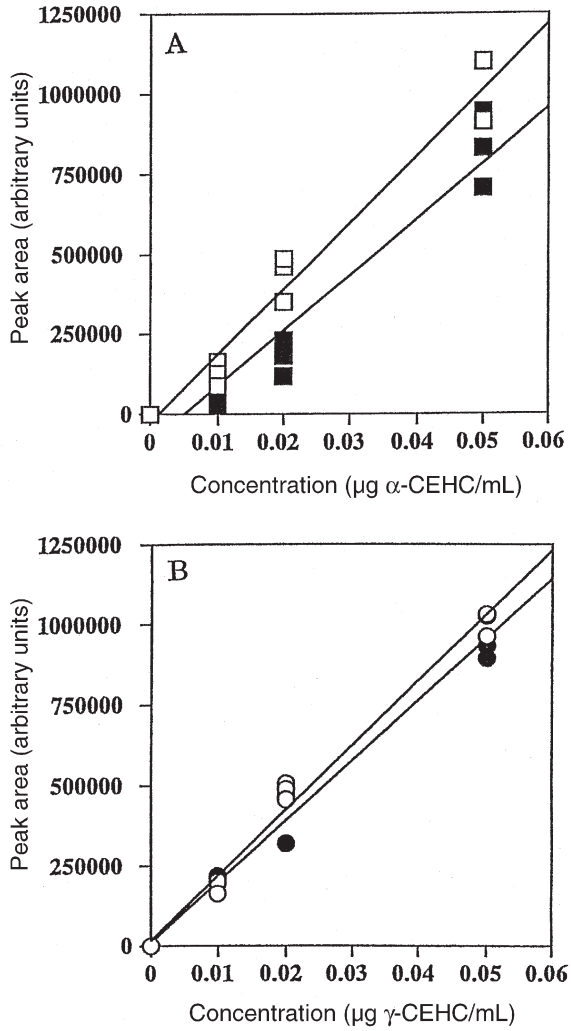

**FIG. 2.** Calibration curves of methylated α- and γ-CEHC. (A) Calibration curves of α-CEHC with AsA (□) and α-CEHC without AsA (■). (B) Calibration curves of γ-CEHC with AsA (○) and γ-CEHC without AsA (●). One milliliter of 0.01, 0.02, or 0.05 μg/mL of α- or γ-CEHC methanolic solution was treated with 3 N methanolic HCl. The extracted solutions were analyzed by high-performance liquid chromatography with electrochemical detection. AsA, ascorbic acid. See Figure 1 for other abbreviations.

Standard samples of α- and γ-CEHC were added to rat urine, and the analytical recoveries of α-and γ-CEHC-Me were measured by this method. A urine sample (0.5 mL) was

**TABLE 1**
**Comparison Between CEHC Methylated After Being Treated with Enzyme and CEHC Methylated Directly[a]**

| μg/mL urine | Methylation with enzyme[b] | Methylation without enzyme[c] | Without/with |
|---|---|---|---|
| α-CEHC-Me | 22.04 ± 1.09 | 22.56 ± 0.68 | 1.023 |
| (CV%) | (4.95) | (3.01) | |
| γ-CEHC-Me | 2.00 ± 0.11 | 2.03 ± 0.09 | 1.020 |
| (CV%) | (5.50) | (4.43) | |

[a]Values are means ± SD of five times. α-CEHC, 2,5,7,8-tetramethyl-2(2′-carboxyethyl)-6-hydroxychroman; γ-CEHC, 2,7,8-trimethyl-2(2′-carboxyethyl)-6-hydroxychroman; CEHC-Me, CEHC-methyl ester.
[b]Urine sample was methylated by using this method after conjugated CEHC was converted to free-CEHC by treatment with β-glucuronidase.
[c]Urine sample was methylated directly by using this method. For experimental details, see the Materials and Methods section.

pipetted into a centrifuge tube containing 1 mL of EDTA solution (0.54 mM). Then α-and γ-CEHC solutions (final concentration, 0.05 μg/mL) were added to each sample followed by 0.1 mL of AsA solution. These were lyophilized and methylated according to the method described above. The analytical recoveries of α- and γ-CEHC were then determined. Endogenous CEHC in rat urine without added standard were not detected by this method. According to this method of standard addition, the analytical recoveries of both α- and γ-CEHC were above 97%. Therefore it was found that free-CEHC was completely converted to CEHC-Me by this method.

*Hydrolysis of conjugated CEHC during acid methylation.* We next examined whether the conjugate is hydrolyzed completely during the acid methylation reaction. Table 1 shows the comparison between CEHC methylated after treatment with enzyme and CEHC methylated directly without treatment. The concentration of CEHC methylated directly in human urine equaled that of CEHC methylated after treatment by enzyme with respect to both α- and γ-CEHC. Therefore, we concluded that the conjugate is hydrolyzed and methylated completely by this method.

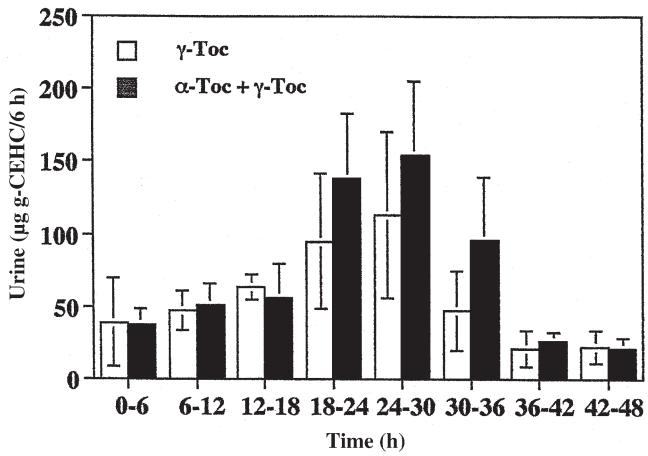

**FIG. 3.** Change in content of γ-CEHC in rat urine with time. Vitamin E-deficient rats were orally administered a single dose of 10 mg γ-Toc (□) or 10 mg α-Toc + 10 mg γ-Toc (■). Values are means ± SD of four rats. α- and γ-Toc, α- and γ-tocopherol. See Figure 1 for other abbreviation.

*γ-CEHC excretion in rat urine (Experiment 1).* We investigated changes of γ-CEHC concentration in rat urine (Fig. 3). It is highest at 24 to 30 h after administration in both the γ-Toc and the α- + γ-Toc groups. γ-CEHC content of rat urine in the α- + γ-Toc group was higher than that of the γ-Toc group from 18 to 36 h after administration. Therefore, we suggest that α-Toc may affect γ-Toc metabolism as evidenced in urine excretion.

*γ-CEHC excretion in rat bile (Experiment 2).* There is no report on the form of CEHC in bile. Therefore, the biliary metabolite of γ-Toc was identified by LC–MS. In Figure 4 are shown the mass spectra of the methylated biliary metabolite and methyl esters of the γ-CEHC standard. The molecular weight of the methylated biliary metabolite was 279, as was the methylated γ-CEHC standard. The methylated biliary metabolite was thus identified as γ-CEHC -Me, and it was clear that the metabolite excreted in rat bile has the basic structure of γ-CEHC. The urinary metabolite was also identified as γ-CEHC-Me by the same method (data not shown).

We next investigated changes in the γ-CEHC content in rat bile (Fig. 5). γ-CEHC content in rat bile was the highest from 6 to 12 h after administration of Toc for both the γ-Toc and the α- + γ-Toc groups. γ-CEHC content of rat bile from the α- + γ-Toc group was higher than that in the γ-Toc group from 6 to 18 h after administration. Therefore we suggest that γ-CEHC excretion is gradually shifted from bile to urine.

## DISCUSSION

In this study, we investigated the difference between γ-CEHC excretion in rat urine and in rat bile by using a new HPLC-ECD method. Stahl *et al.* (10) and Lodge *et al.* (9) reported the determination of α- and γ-CEHC in human serum and urine, respectively, by means of HPLC-ECD. These investigators measured the free-CEHC after its conjugated forms were hydrolyzed by enzymes. On the other hand, we measured the CEHC-Me after both the conjugated and unconjugated forms were methylated by 3 N methanolic HCl. By the methylation of CEHC, it is possible to stabilize them. In regard to the unconjugated form, the analytical recoveries of α- and γ-CEHC-Me were above 97% when the standard samples of α- and γ-CEHC were added to rat urine and then methylated. Therefore, we found that free-CEHC were converted to CEHC-Me quantitatively by using this method. We also found that conjugated CEHC were converted to CEHC-Me completely by using this method (Table 1). Furthermore, we had previously methylated an unlabeled α-CEHC standard with 3 N methanolic HCl, then injected the product into a high-performance liquid chromatograph (6). The α-CEHC standard had a retention time of 6.8 min. After methylation, the retention time was 16.7 min. On the other hand, the retention time of radioactive substances in urine after oral administration of *SRR*-α-[$^{14}$C]Toc was shifted completely to 16.7 min after methylation of these substances; moreover, this radioactive substance was identified as α-CEHC-Me by LC–MS (6). Therefore methylation with 3 N methanolic HCl hydrolyzes conjugates and promotes esterification.

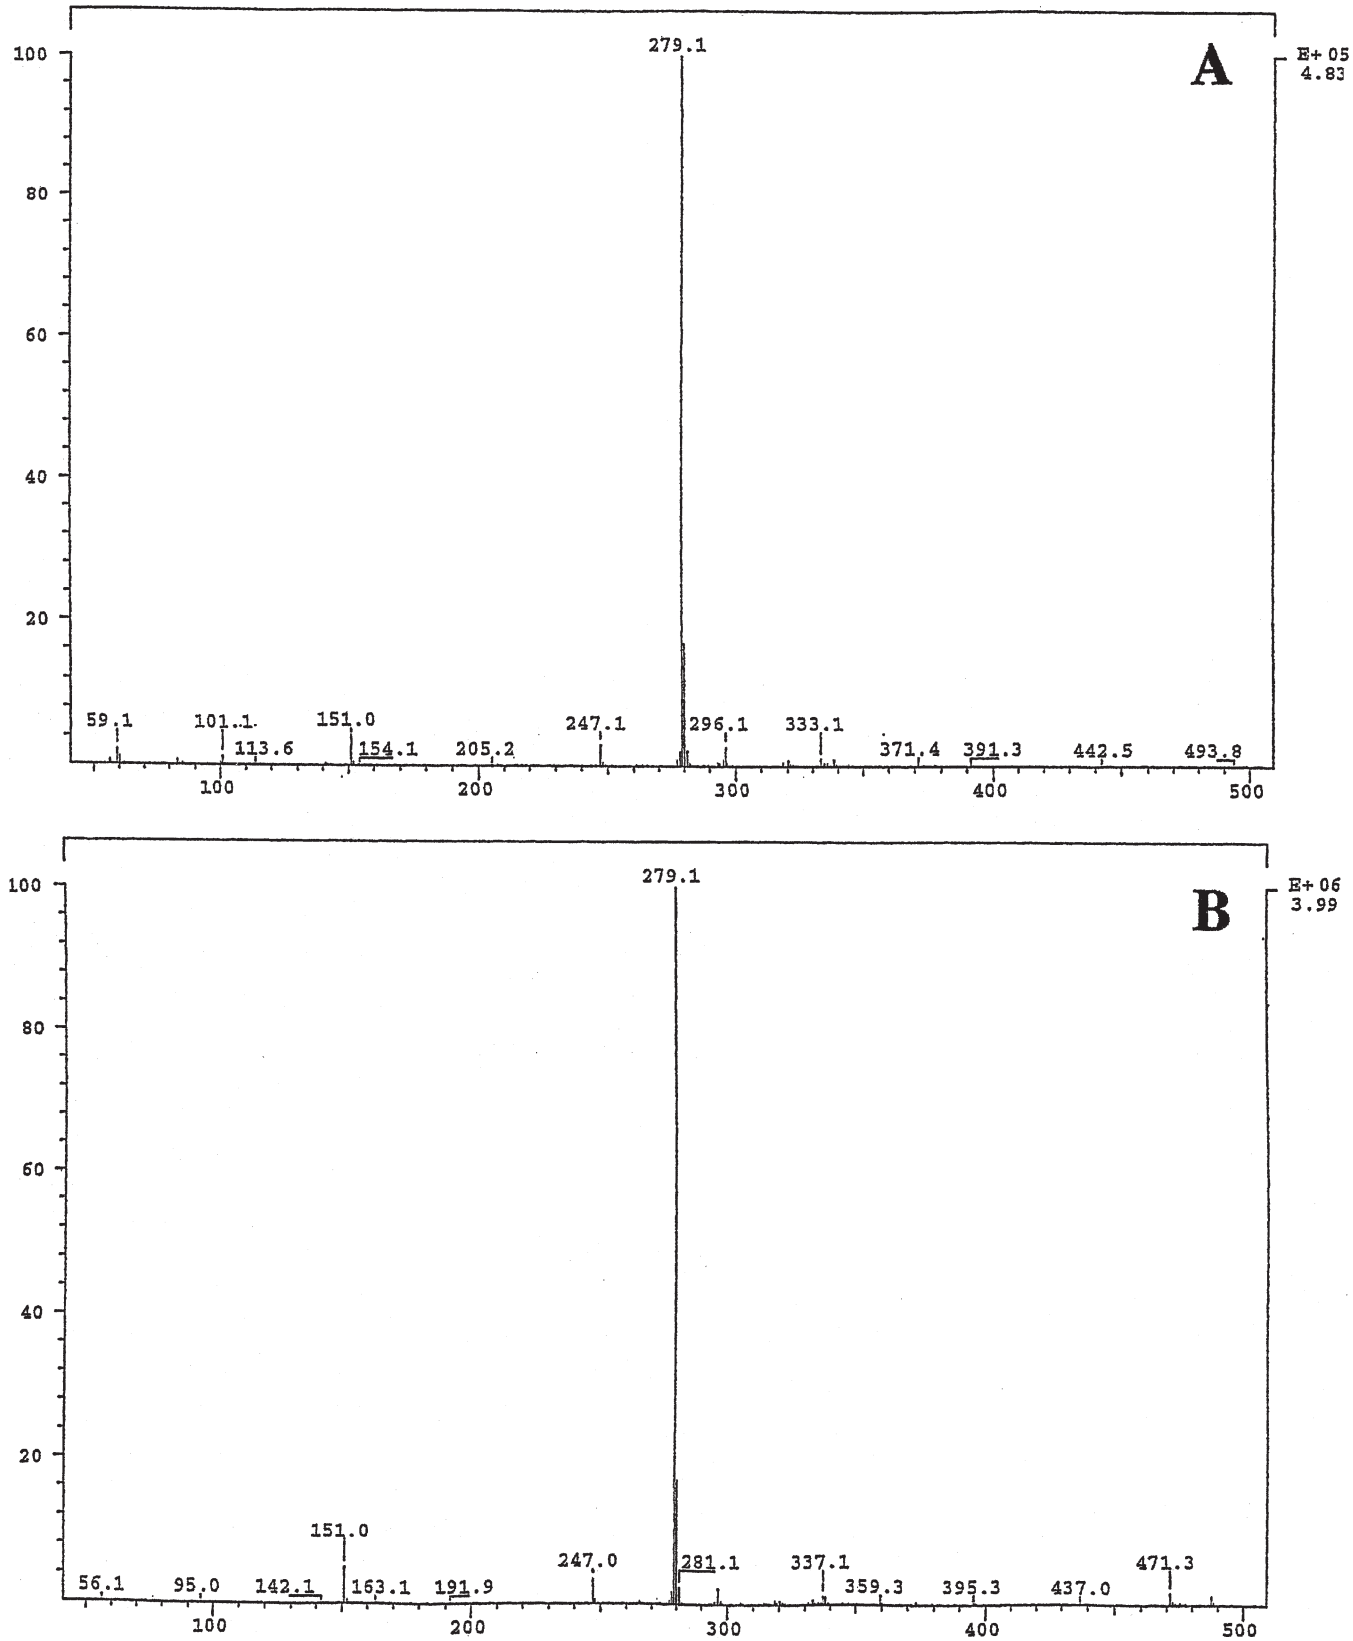

**FIG. 4.** Mass spectra of methylated biliary metabolite of tocopherol and γ-CEHC methyl ester. Bile samples were collected from 12 to 24 h after oral administration of γ-Toc (A) and γ-CEHC standard (B). These samples were treated with 3 N methanolic HCl (see the Materials and Methods section). For abbreviations see Figures 1 and 3.

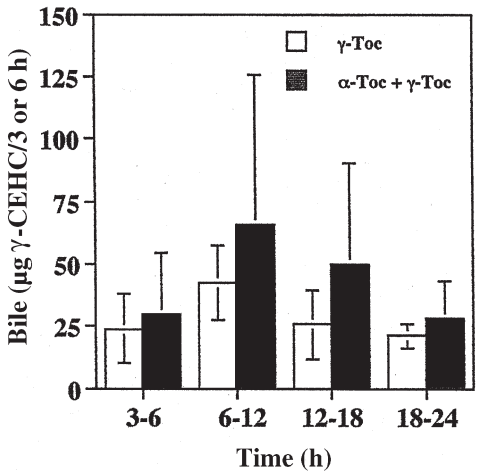

**FIG. 5.** Change in the content of γ–CEHC in bile with time. Vitamin E-deficient rats were orally administered a single dose of 10 mg γ-Toc (□) or 10 mg α-Toc + 10 mg γ-Toc (■). Values are means ± SD of four rats. For abbreviations see Figures 1 and 3.

Each urine and bile sample was collected into a flask being cooled with dry ice, followed immediately by lyophilization. This procedure is carried out to protect against the breakdown of the conjugated CEHC form. However, in the present study, all CEHC (conjugated and unconjugated forms) were converted into methyl ester form. Hereafter, unconjugated forms of CEHC will be measured by this method after methanolic extraction.

The γ-CEHC content in rat urine of both groups was at the highest level from 24 to 36 h after single-dose administration; then it declined to 48 h, and the metabolite may be excreted. The total amount of γ-CEHC excreted in rat urine until 48 h after oral administration was *ca.* 450 μg in the γ-Toc group and *ca.* 580 μg in the α– + γ-Toc group. Therefore we suggest that α-Toc may affect γ-Toc metabolism.

The γ-CEHC content in the bile of both groups was at the highest level from 6 to 12 h after administration; after that it decreased until 24 h after administration. According to these results, we assume that γ-CEHC was shifted to the urinary excretion after part of the γ-CEHC had been excreted into the bile. The total CEHC content of the urine and bile for 24 h was *ca.* 250 μg in γ-Toc group, and *ca.* 280 μg in the α- + γ-Toc group. The content of γ-CEHC in rat bile for 24 h after oral administration was *ca.* 130 μg in the γ-Toc group and *ca.* 190 μg in the α– + γ-Toc group. These results indicate that the content of γ-CEHC in urine was significantly higher ($P \leq 0.05$, *t*-test) than that for bile 24 h after oral administration. Therefore, γ-CEHC clearly was mainly excreted into the urine rather than into the bile.

Swanson *et al.* (12) presumed that γ-CEHC is present in conjugated form in human urine, mainly as glucuronide. On the other hand, Chiku *et al.* (8) presumed that δ-CEHC in a conjugated form in rat urine is found mainly as a sulfate. We assume that the CEHC conjugated form in bile is different from that in urine.

In summary, we focused on the effects of α-Toc on γ-Toc metabolism in the rat. We found that γ-Toc metabolism is affected by α-Toc *in vivo* and demonstrated that the presence of α-Toc accelerates the metabolism of γ-Toc to γ-CEHC.

# Absorption of Canthaxanthin by the Rat Is Influenced by Total Lipid in the Intestinal Lumen

**Richard M. Clark* and Harold C. Furr**

Department of Nutritional Sciences, University of Connecticut, Storrs, Connecticut 06269-4017

**ABSTRACT:** In this study the effect of luminal lipid on the absorption of canthaxanthin (CTX) was investigated using the lymph duct cannulated rat. Treatments were emulsions designed to deliver increasing amounts of olive oil (10, 30, 50, 70, or 90 mg/h) and CTX (12.5 nmol/h). Emulsions were continuously infused into the duodenum for 12 h, and lymph was collected during the final 6 h of infusion for analysis. As the amount of lipid in the emulsion increased, a linear increase in the absorption of CTX was observed. The recovery of CTX in the lymph when infused with 10 mg/h olive oil was 14.2 ± 1.2% and with 90 mg/h was 26.9 ± 5.7%. The efficiency of CTX absorption nearly doubled by increasing the amount of lipid infused with CTX. The correlation between lipid load and CTX absorbed was $r = 0.85$. We conclude that luminal lipid load affects CTX absorption.

Paper no. L8719 in *Lipids 36*, 473–475 (May 2001).

Because of the health benefits associated with the consumption of carotenoid-rich foods, factors influencing carotenoid absorption are of interest. The carotenoids are a class of lipophilic dietary components absorbed from the digestive tract with other dietary lipids. Numerous studies have shown that low-fat diets or the absence of dietary fat results in greatly reduced carotenoid absorption as measured by serum carotenoid and retinol levels (1–6). Therefore, dietary lipid appears to be a key factor influencing carotenoid absorption.

The presence of dietary lipid in the digestive tract promotes the release of bile salts into the intestinal lumen. This is crucial as carotenoids freed from the food matrix gain access to the intestinal brush border membrane by solubilization into bile salt micelles. In the absence of bile salt micelles, there is essentially no carotenoid uptake by enterocytes (7). Once bile salts are present at a concentration above the critical micelle concentration, it is not clear if additional lipid influences carotenoid absorption. A recent review suggests that the amount of dietary fat required to ensure carotenoid absorption is low and may only be 3 to 5 g per meal (8). This low level of dietary lipid appears to be enough to stimulate the release of bile salts into the intestinal lumen. It was further noted that dietary fat above the 3- to 5-g level did not enhance plasma concentrations of carotenoids (8). This would suggest that additional lipid has no effect on carotenoid absorption.

The objective of this study was to determine if increasing the lipid load in the intestine affects carotenoid absorption. The lymph duct cannulated rat, an animal model previously used in our laboratory to study the absorption of non-provitamin A carotenoids, was used (9–11). The carotenoid selected for study was canthaxanthin (CTX) because it is absorbed intact by the rat and has physical properties similar to other xanthophyll-type carotenoids.

## MATERIALS AND METHODS

*Animals and surgical procedure*. The animal protocol used in this study was approved by The University of Connecticut Institutional Animal Care and Use Committee. Male Holtzman albino rats obtained from Holtzman Laboratory Animals (Madison, WI) and weighing 250–300 g at the time of surgery were used. Prior to surgery the animals were housed individually in stainless-steel cages and fed a standard laboratory diet (Purina, Rodent Chow 5001; Purina Mills, St. Louis, MO) *ad libitum*.

Surgery included cannulation of the major mesenteric lymph duct and placement of a feeding tube into the duodenum as previously described (9). Immediately following surgery, the rats were placed in a warm dark environment and allowed to recover for approximately 36 h. During the recovery period the rats had access to water, and a glucose/electrolyte solution (Pedialyte; Ross Laboratories, Columbus, OH) was infused into the duodenum at 2.0 mL/h.

*Treatment emulsions.* On the day of the study a stock solution of CTX (Sigma Chemical, St. Louis, MO) was prepared in dichloromethane. The concentration of CTX was estimated using the extinction coefficient $E$ at 466 nm ($E^{1\%}_{1cm} = 2200$), and purity was verified by spectral characteristics and high-pressure liquid chromatography (HPLC).

Five treatment emulsions designed to deliver increasing amounts of olive oil (10, 30, 50, 70, or 90 mg/h) and 12.5 CTX nmol/h (Sigma Chemical) were used. The emulsions contained olive oil, CTX, and a buffer solution (115 mmol/L NaCl, 5.0 mmol/L KCl, 6.8 mmol/L $Na_2HPO_4$, and 16.5 mmol/L $NaH_2PO_4$), and 10 mmoL/L sodium taurocholate (Sigma Chemical). The emulsions were prepared by placing the olive oil in a round-bottomed flask with an appropriate amount of CTX stock solution. Sodium taurocholate and buffer were added to the olive oil/CTX mix and emulsified by

Abbreviations: CTX, canthaxanthin; HPLC, high-pressure liquid chromatography.

using a probe sonicator (Branson Sonifier, Model 185; Branson Sonic Power, Danbury, CT).

*Administration of treatment emulsions and collection of lymph.* Three rats per treatment were used. Treatment emulsions were intraduodenally infused at a rate of 2.0 mL/h for 12 h. During this time animals had free access to water and maintained a constant hydration state. After infusing the emulsion for 6 h, lymph was collected for analysis during the final 6 h of infusion. In an earlier study, we had observed that CTX in the lymph reached a plateau or steady-state transport into the lymph by 6 h of continuous intraduodenal infusion (9).

*Carotenoid analysis of lymph.* Prior to HPLC analysis, CTX was extracted from lymph. An aliquot of lymph and dichloromethane/methanol (2:1, vol/vol) containing an internal standard, ethyl-β-apo-8′-carotenoate (Fluka, Ronkonkoma, NY) were placed in a separatory funnel at a solvent-to-lymph ratio of 9:1 (vol/vol) and stored in the dark at 4°C for 4–6 h. The bottom phase was removed and saved. Methanol at 1.5 times and dichloromethane at 6 times the original lymph volume were added to the upper phase. The separatory funnel was again stored for several hours in the dark at 4°C. After phase separation the bottom phase was removed and combined with the original bottom phase. Solvent was removed from the extracted lipids in the combined bottom phase under reduced pressure and redissolved in 500 µL 2-propanol/dichloroethane (1:1 vol/vol). For analysis, aliquots of 20–40 µL were injected into the HPLC in triplicate.

Carotenoid separation by HPLC was with a Waters C18 Resolve column (15 cm × 3.9 mm; Millipore, Milford MA) with an Upchurch C18 guard column (Upchurch Scientific, Oak Harbor, WA) by the method of Barua *et al*. (12). An isocratic mobile phase consisting of acetonitrile/dichloromethane/methanol/*n*-butanol/ammonium acetate (90:15:10:0.1:0.1, by vol) was used at a flow of 1.0 mL/min. The CTX and ethyl-β-8′-carotenoate were identified based on a comparison of retention times with standards and quantified by peak areas at a wavelength of 450 nm. Standard curves for CTX and ethyl-β-8′-carotenoate were developed and used to calculate the concentrations of carotenoids. The recovery of ethyl-β-8′-carotenoate in the lymph averaged 90% and was used to correct for losses of CTX during analysis. Extractions with less than 80% recovery of the internal standard were rejected.

*Fatty acid analysis of treatment emulsions and lymph.* A 200-µL aliquot of the treatment emulsion or lymph was used for fatty acid analysis. Fatty acids in the aliquot were prepared for analysis by direct methylation in methanol/hexane (4:1, vol/vol) in the presence of acetyl chloride (13). A known amount of heptadecanoic acid was added as an internal standard. The fatty acid methyl esters were separated by gas–liquid chromatography on a Supelcowax 10 fused-silica capillary column (30 m, 0.53 mm i.d., Supelco, Bellefonte, PA), and identification of individual fatty acids was based on comparison of retention times with known standards. The total lipid concentration in the treatment emulsions and lymph was calculated based on the peak areas of the fatty acid methyl esters relative to the internal standard.

## RESULTS AND DISCUSSION

The results of the study are presented in Table 1. Lipid in the lymph, calculated from total fatty acid analysis, increased with the amount of lipid infused into the duodenum. Interestingly, when the lowest lipid load (10 mg/h) was infused, the total fatty acid recovered in the lymph averaged 14.5 with a range of 11.6 to 18.3 mg/h. The greater amount of fatty acids in the lymph was due to the absorption of endogenous lipid. Lymph contained myristic acid and arachidonic acid, two fatty acids not present in the treatment emulsion, and a greater proportion of stearic acid in lymph than in the emulsion. When the 90 mg/h lipid load was infused, there was a 93 ± 10.3% recovery of total fatty acids in the lymph. We did not observe any signs of malabsorption.

The absorption of CTX infused at a constant rate of 12.5 nmol/h significantly ($P < 0.05$) increased with the amount of lipid infused into the duodenum. At the lowest lipid load (10 mg/h), the efficiency of CTX absorption was 14.2 ± 1.2% and increased to 26.9 ± 5.7% when 90 mg/h lipid was infused. As seen in Figure 1, the relationship between the amount of lipid infused and the amount of CTX absorbed was linear. For each 10 mg/h increase in lipid intraduodenally infused, there was an additional 0.2 nmol/h CTX recovered in the lymph.

Few studies have directly measured carotenoid absorption. Nevertheless, reports measuring plasma and tissue concentrations have identified factors affecting carotenoid bioavailabil-

**TABLE 1**
**Recovery of Canthaxanthin and Total Fatty Acids in the Mesenteric Lymph of Rats[a]**

| | Lymph measurements | | | |
|---|---|---|---|---|
| Infused lipid (mg/h) | Fatty acids (mg/h) | Percent recovered | Canthaxanthin (nmol/h) | Percent recovered |
| 10 | 14.5 ± 1.2 | 145 ± 19.9 | 1.8 ± 0.2 | 14.2 ± 1.2 |
| 30 | 33.1 ± 2.2 | 110 ± 7.5 | 2.1 ± 0.2 | 16.7 ± 1.1 |
| 50 | 53.9 ± 8.0 | 108 ± 16.2 | 2.6 ± 0.3 | 20.9 ± 2.9 |
| 70 | 63.1 ± 5.7 | 90 ± 6.3 | 2.9 ± 0.5 | 22.8 ± 4.0 |
| 90 | 83.9 ± 7.2 | 93 ± 10.3 | 3.4 ± 0.7 | 26.9 ± 5.7 |

[a]Each value is the mean ± standard deviation from three individual rats. Canthaxanthin was infused into the duodenum at the rate of 12.5 nmol/h. "Infused lipid" is the sum of all fatty acids in the treatment emulsions as measured by gas chromatography.

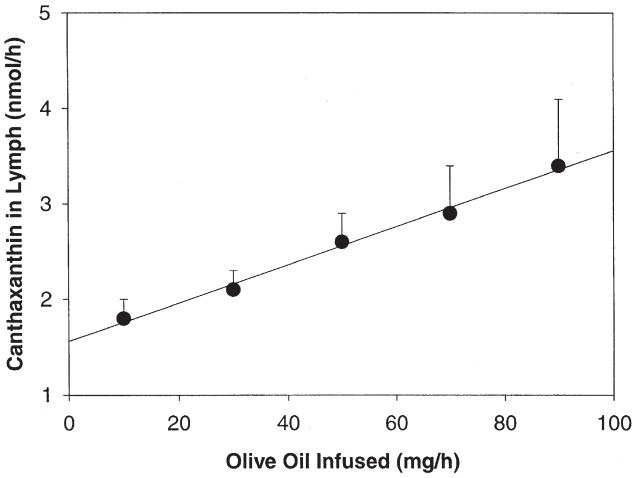

**FIG. 1.** Relationship between lipid load in the duodenum and canthaxanthin recovered in the mesenteric lymph. Canthaxanthin was continuously infused into the duodenum at a level of 12.5 nmol/h for 12 h. Lymph was collected from 6 to 12 h after the initiation of infusion and represents absorption under steady-state conditions. Each point is the mean ± SD from three individual rats. There was a significant ($P < 0.05$) linear relationship between the amount of lipid infused and the recovery of canthaxanthin in the lymph.

ity. A list of these factors have been used to form the mnemonic ***SLAMENGHI*** representing: ***S***pecies of carotenoids, ***L***inkages at the molecular level, ***A***mount of carotenoid, ***M***atrix, ***E***ffectors, ***N***utrient status, ***G***enetics, ***H***ost-related factors, and ***I***nteractions among these variables (14). One ***E***ffector of carotenoid absorption identified in several reports is the amount of dietary fat present (1–6). The precise manner by which dietary fat affects absorption is poorly understood. A key step in carotenoid absorption affected by dietary fat would be the transfer of carotenoid from the food matrix to the bile salt micelle for transport to the intestinal absorptive membrane.

In this study, bile salts and lipid were present in adequate amounts to ensure carotenoid absorption even at our lowest level of lipid infusion. As the lipid load in the duodenum increased there was a significant positive correlation with absorption of CTX into the lymph ($r = 0.85$, $P < 0.05$). This positive relationship may be explained by the increase in lipid digestion products being transferred from emulsion particles to bile salt micelles. We speculate that the greater amount of digested lipid in the bile salt micelle would result in an increased capacity to solubilize carotenoids in the micelle for transport to the brush border membrane and subsequent absorption.

We conclude that in the presence of adequate amounts of bile salts, absorption of carotenoid may further be improved by increasing the amount of lipid consumed. This is not consistent with the observation that increasing dietary fat above 3 to 5 g per meal did not enhance plasma concentrations of carotenoids (8). Additional work is needed to understand the luminal phase of carotenoid absorption.

# Cytotoxic Effect of Conjugated Trienoic Fatty Acids on Mouse Tumor and Human Monocytic Leukemia Cells

**Rikako Suzuki[a], Ryoko Noguchi[a], Tomoki Ota[b], Masayuki Abe[c], Kazuo Miyashita[a,*], and Teruo Kawada[d]**

[a]Laboratory of Biofunctional Material Chemistry, Division of Marine Bioscience, Graduate School of Fisheries Science, Hokkaido University, Hakodate 041-8611, Japan, [b]Hokkaido Food Processing Research Center, Ebetsu 069-0836, Japan, [c]Food Research Institute, Kaneka Co., Takasago, Hyogo 676-8688, Japan, and [d]Laboratory of Nutritional Chemistry, Division of Applied Life Science, Graduate School of Agriculture, Kyoto University, Kyoto 606-8502, Japan

**ABSTRACT:** The cytotoxicity of fatty acids from seed oils containing conjugated linolenic acids (CLN) was studied. Fatty acids from pomegranate, tung, and catalpa were cytotoxic to human monocytic leukemia cells at concentrations exceeding 5 μM for pomegranate and tung and 10 μM for catalpa, but fatty acids from pot marigold oil had no effect at concentrations ranging up to 163 μM. The main conjugated fatty acids of pomegranate, tung, catalpa, and pot marigold were *cis*(*c*)9,*trans*(*t*)11,*c*13-CLN (71.7%), *c*9,*t*11,*t*13-CLN (70.1%), *t*9,*t*11,*c*13-CLN (31.3%), and *t*8,*t*10,*c*12-CLN (33.4%), respectively. Therefore, the cytotoxicities of fatty acids from pomegranate, tung, and catalpa were supposed to be due to 9,11,13-CLN isomers. To elucidate the cytotoxicity of these CLN, we separated each CLN isomer from the fatty acid mixtures by high-performance liquid chromatography and analyzed its cytotoxicity. The cytotoxicities of *c*9,*t*11,*c*13-CLN, *c*9,*t*11,*t*13-CLN, and *t*9,*t*11,*c*13-CLN were much stronger than that of *t*8,*t*10,*c*12-CLN. Therefore, the higher cytotoxicity of fatty acids from pomegranate, tung, and catalpa than those from pot marigold would be derived from the different activities of 9,11,13-CLN and 8,10,12-CLN. Since there was little difference in the cytotoxicities of *c*9,*t*11,*c*13-CLN, *c*9,*t*11,*t*13-CLN, and *t*9,*t*11,*c*13-CLN, it is suggested that the *cis/trans* configuration of 9,11,13-CLN isomers had little effect on their cytotoxic effects. The mechanism of the cytotoxicity of the four fatty acids above may involve lipid peroxidation, because the order of toxicity of the fatty acids was consistent with their susceptibility to peroxidation in aqueous phase. This was supported by the decrease in the cytotoxicity of the fatty acids by addition of butylated hydroxytoluene.

Paper no. L8575 in *Lipids 36,* 477–482 (May 2001).

Many papers have been published on the potent beneficial health and biological effects of conjugated linoleic acids (CLA) (1–7). Preliminary studies indicate that CLA is a powerful anticancer agent in the rat mammary tumor model with an effective range of 0.1–1% in the diet (8). The effect of CLA on various human cancer cell cultures has also been examined. CLA inhibited the growth of lung, breast, and colorectal cancer but had no effect on the glioblastoma cell line (9,10). Although the mechanisms for the anticancer effect of CLA have not been fully elucidated, these results suggested that the conjugated diene system may be responsible for this cytotoxic effect.

On the other hand, previous studies showed the occurrence of other types of conjugated polyunsaturated fatty acids (PUFA) in natural products (11–14), and some reports have appeared on the biological properties of these PUFA (15–18). Cornelius *et al.* (15) reported the strong cytotoxic effect of conjugated octadecatetraenoic acid [*cis*(*c*)9,*trans*(*t*)11,*t*13,*c*15-18:4; α-parinaric acid] from garden balsam seed oil on human leukemia cells. They also found that lipid peroxidation was involved in this effect. The cytotoxic effect of conjugated PUFA on human tumor cells also has been found in α-linolenic acid (LN), eicosapentaenoic acid, and docosahexaenoic acid after base treatment (17,18). Furthermore, Dhar *et al.* (16) reported that *c*9,*t*11,*t*13-18:3 from karela seed oil acted as antioxidant in rat tissues.

Conjugated PUFA including CLA usually constitute less than 1% in natural products, however, some kinds of seed oils have much higher contents (40–80%) of conjugated linolenic acids (CLN) (14). α-Eleostearic (*c*9,*t*11,*t*13-CLN), punicic (*c*9,*t*11,*c*13-CLN), catalpic (*t*9,*t*11,*c*13-CLN), and calendic (*t*8,*t*10,*c*12-CLN) acids are reportly found in tung seed oil (68%), pomegranate seed oil (83%), catalpa seed oil (42%), and pot marigold seed oil (62%), respectively.

This paper reports a study of the cytotoxic effect of CLN found in these seed oils. Igarashi and Miyazawa (17) reported the cytotoxicity of alkaline isomerized α-linolenic acid (LN) and tung oil fatty acids on human tumor cells. Isomerized linolenic acid (IsoLN) was a mixture of unreacted linolenic acid and CLN having conjugated dienoic and trienoic double bonds. Tung oil fatty acids were also a mixture of α-eleostearic acid and nonconjugated fatty acids. To better understand the cytotoxicity of CLN, it is important to elucidate the cytotoxic effect of each positional and geometrical CLN isomer. Thus, we separated each CLN isomer from fatty acid mixtures of these seed oils by high-performance liquid chro-

matography (HPLC) and analyzed its cytotoxic effect on tumor cells.

## EXPERIMENTAL PROCEDURES

*Oil sources for CLN with conjugated trienes*. Raw materials for preparation of fatty acids containing a particular CLN isomer were tung (*Aleutrites fordii*) seed oil for *c*9,*t*11,*t*13-CLN, pomegranate (*Punica granatum*) seed oil for *c*9,*t*11,*c*13-CLN, catalpa (*Catalpa ovata*) seed oil for *t*9,*t*11,*c*13-CLN, and pot marigold (*Calendula officinalis*) seed oil for *t*8,*t*10,*c*12-CLN (14). Each seed oil, except for tung, was obtained by extraction of ground seeds with *n*-hexane at room temperature. Tung oil was a bottled commercial product.

*HPLC separation of CLN isomer from seed oil methyl esters.* Each seed oil containing CLN was transesterified to its methyl esters with 0.5 M sodium methoxide in methanol. Each CLN isomer was separated from the mixed methyl esters by preparative reversed-phase HPLC (Shimadzu LC 10A system; Shimadzu Seisakusho, Kyoto, Japan) using a mixture of acetonitrile/water (50:10, vol/vol), a flow rate of 8.0 mL/min, a column of 5 μm C-18 (25.0 × 2.0 cm, YMC-pack R&D ODS; YMC, Kyoto, Japan), sample loads of 90–100 mg, and an ultraviolet detector set at 235 nm. Each isomer isolated by HPLC was characterized by capillary gas chromatography (GC) and compared with the reference fatty acid methyl esters from the original seed oil containing the particular CLN isomer (14). The isolated CLN methyl ester showed a purity greater than 99%. The GC analysis was performed on a Shimadzu GC-14B (Shimadzu Seisakusho) equipped with a flame-ionization detector and a capillary column [Omegawax 320 (30 m × 0.32 mm i.d.) or SP-2380 (100 m × 0.25 mm i.d.); Supelco, Bellefonte, PA].

*Isomerization of ethyl α-linolenate*. Ethyl α-linolenate (99+% purity) was purchased from Sigma (St. Louis, MO). The ethyl ester was catalytically isomerized. Potassium *t*-butoxide (Nacalai Tesque, Kyoto, Japan) was used as a catalyst for the isomerization of double bonds in linolenate ester so as to produce conjugation. Reaction was done by stirring linolenate (0.5–1.5 g) with catalyst in dimethylformamide (50 mL) at 30°C for 1 h. After incubation, the reaction mixture was neutralized with 2 N HCl. The reaction products were extracted with *n*-hexane and fractionated by silicic acid column chromatography, eluting with *n*-hexane, diethyl ether/*n*-hexane (5:95, vol/vol), and diethyl ether/*n*-hexane (20:80, vol/vol), respectively. Isomerized ethyl ester was eluted with diethyl ether/*n*-hexane (5:95, vol/vol).

*Fatty acid preparation*. Seed oils, methyl esters of CLN isomer isolated by HPLC, and isomerized α-linolenate were saponified with 0.2 N KOH at room temperature under nitrogen overnight, and unsaponifiable matter, such as tocopherols, was removed by diethyl ether extraction. After acidifying the aqueous solution with 1 N HCl, free fatty acid was extracted with diethyl ether and purified on a silicic acid column (Silicagel 60; Merck, Darmstadt, Germany), eluting with *n*-hexane and a mixture of diethyl ether/*n*-hexane solution (5:95, 10:90, 20:80, 30:70, and 40:60, vol/vol). Free fatty acid was eluted with diethyl ether/*n*-hexane (20:80 and 30:70, vol/vol). This chromatographic purification was done just before use of each fatty acid. The refined free fatty acid sample gave only a single spot on the thin-layer chromatogram with normal-phase silica plates (Merck) developed with diethyl ether/*n*-hexane/acetic acid (40:60:1, by vol). The peroxide value of the free fatty acid was less than 1.0 as determined by the colorimetric iodine method (19). The composition of conjugated dienes and trienes in IsoLN was evaluated by the AOCS Official Method Cd 7-58 (20). CLA (99+% purity; mixture of 9,11- and 10,12-18:2) was obtained from Nu-Chek-Prep (Elysian, MN). Nonconjugated fatty acids, linoleic acid (LA; 99+% purity) and LN (99+% purity), were obtained from Sigma (St. Louis, MO).

The fatty acid composition of seed oils was analyzed by capillary GC after conversion to methyl esters by heating in a sealed tube at 50°C for 1 h with 0.5 M sodium methoxide in methanol. The capillary GC analysis was performed as described above.

*Cell culture conditions*. Dulbecco's modified Eagle's medium (DMEM) and RPMI 1640 medium were obtained from Nissui Pharmaceutical (Tokyo, Japan). Fetal bovine serum was obtained from Sanko Chemical (Tokyo, Japan). Penicillin-streptomycin solution was obtained from Sigma. Water-soluble tetrazolium solution (WST-1) was obtained from Dojindo (Kumamoto, Japan).

Mouse fibroblast cell (A31) and its transformed cell (SV-T2) were obtained from Japan Health Sciences Foundation (Tokyo, Japan). The cells ($3 \times 10^4$/mL) were grown in plastic tissue culture dishes in DMEM (10 mL) containing 10% fetal bovine serum, 0.12% $NaHCO_3$, 100 units/mL penicillin, and 0.1 mg/mL streptomycin at 37°C in a humidified $CO_2$ (5%) incubator.

Human monocytic leukemia cells (U-937) were also obtained from the Japan Health Sciences Foundation (Tokyo, Japan). U-937 cells ($1 \times 10^5$/mL) were grown in plastic flasks in RPMI 1640 medium (10 mL) with 10% fetal bovine serum, 0.12% $NaHCO_3$, 100 units/mL penicillin, and 0.1 mg/mL streptomycin. Cells were maintained at 37°C in a humidified $CO_2$ (5%) atmosphere.

The percentage of viability of these cells after incubation was determined by WST-1 assay (21), which is a modification of the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) dye reduction (MTT) assay based on the tetrazolium salt/formazan system. Cells preincubated as described above were seeded at a density of $2 \times 10^3$ cells/well in 96-well microplates and cultured in 100 μL medium/well for 24 h. Each fatty acid was dissolved in 10 μL of 1% dimethyl sulfoxide solution and then added to the culture. Butylated hydroxytoluene (BHT), as an antioxidant, was added to the fatty acid with mixing. After 21 h of incubation, 10 μL of WST-1 solution was added to each well, and the plate was incubated for a further 3 h. Cell viability was then measured spectrophotometrically (Microplate reader, Emax; Molecular Devices, Sunnyvale, CA) and was expressed as a

percentage of the viability obtained in control cultures, which were incubated without the addition of free fatty acids.

*Oxidative stability of free fatty acids in emulsion*. Each fatty acid was mixed homogeneously with Triton X-100 (Nacalai Tesque) in chloroform. After removing the chloroform by gently sweeping with nitrogen, a 0.05 M phosphate buffer (pH 7.4 at 37°C) was added to the mixture. Emulsification was carried out in an ice bath for 3 min with a sonicator (5202 PZT; Ohtake Works, Tokyo, Japan). Oxidative stability was evaluated by analyzing oxygen consumption. For continuously monitoring oxygen uptake by the oxidation of fatty acids in the solution, a model 5300 biological oxygen monitor (YSI, Yellow Springs, OH) was used. As soon as the 2,2′-azobis(2-amidinopropane)dihydrochloride (AAPH) solution had been added to the substrate solution, the reaction vessel was charged with 3 mL of the reaction solution, and the concentration of dissolved oxygen in the solution was measured. AAPH was obtained from Wako Pure Chemical Ind. (Osaka, Japan). The final concentrations of the substrate fatty acids, Triton X-100, and AAPH were 1.08 mg/3 mL, 0.1 wt%, and 1.0 mM, respectively.

## RESULTS AND DISCUSSION

Igarashi and Miyazawa (17) examined the cytotoxic effect of two kinds of alkaline IsoLN on human tumor cells and showed that the IsoLN consisted of conjugated triene (22.5%) and conjugated diene (47.5%), which was as cytotoxic as tung oil fatty acid, whereas IsoLN consisting of conjugated triene (17.0%) and conjugated diene (66.7%) had little effect. From these results, they demonstrated that the cytotoxicity of IsoLN was attributable to its conjugated triene structure. However, there was little difference in the content of conjugated triene in the two kinds of IsoLN, and more data are required to conclude that conjugated trienoic acid is more cytotoxic than conjugated dienoic acid.

Thus, in this experiment, we prepared two kinds of alkaline IsoLN (IsoLN-1 and -2) with significant differences in the ratio of conjugated diene to conjugated triene and compared the cytotoxic effects of these CLN with other 18-carbon PUFA, namely LA, CLA, and LN. IsoLN-1 and IsoLN-2 were prepared by the alkaline isomerization of ethyl α-linolenate in dimethylformamide followed by the saponification of the isomerized linolenate, but the concentrations of catalyst (potassium *t*-butoxide) and substrate used for IsoLN-1 preparation (17.4 and 34.7 mM, respectively) were different from the case of IsoLN-2 (104.4 and 104.4 mM, respectively). Table 1 shows the compostion of conjugated dienes and trienes in each IsoLN. The change in isomerization conditions produced two kinds of IsoLN (IsoLN-1 and -2) containing different ratios of conjugated trienes to conjugated dienes. For cell viability assay, IsoLN-1 was used in conjunction with a mixture of IsoLN-2 + LN prepared such that IsoLN-1 and IsoLN-2 + LN contained the same overall concentration of conjugated fatty acids (Table 1).

Although LA and LN had no cytotoxic effect on U-937 cells, conjugated fatty acids (CLA, IsoLN-1, IsoLN-2 + LN) reduced cell viability at concentrations up to 324 μM for CLA, 327 μM for IsoLN-1, and 41 μM for IsoLN-2 + LN (Fig. 1). This result indicates the higher cytotoxic effect of conjugated trienes than conjugated dienes and confirms the earlier report (17).

**TABLE 1**
**Composition of Conjugated Dienes and Conjugated Trienes in IsoLN-1, IsoLN-2, and IsoLN-2 + LN[a]**

| Fatty acids | Conjugated dienes (%) | Conjugated trienes (%) | Total conjugated fatty acids (%) |
|---|---|---|---|
| IsoLN-1 | 45.3 | 3.7 | 49.0 |
| IsoLN-2 | 51.6 | 35.6 | 87.2 |
| IsoLn-2 + LN | 28.6 | 19.7 | 48.3 |

[a]IsoLN, isomerized linolenic acid; LN, α-linolenic acid.

As described above, the importance of the conjugated triene structure in the cytotoxicity to tumor cells is confirmed; however, there are many kinds of positional and geometrical isomers of CLN in alkaline IsoLN, and the difference in the cytotoxicity of each CLN isomer remains to be elucidated. Some seed oils contain high contents of different types of CLN isomer (14), and it is interesting to compare the cytotoxic effects of these seed oil fatty acids. The fatty acid profiles of seed oils containing CLN are shown in Table 2. The percentages of the main components are generally in harmony with those described previously (14).

Figure 2 shows the inhibitory effect of these fatty acid mixtures containing CLN on mouse normal (A31) and tumor (SV-T2) cells. Fatty acids from pot marigold had no effect on either cell line, but other kinds of fatty acids from seed oils were cytotoxic to SV-T2 cells at concentrations exceeding 41 μM for pomegranate and tung, and 81 μM for catalpa, respectively. Fatty acids from pomegranate and tung were also cytotoxic to A31 cells at concentrations exceeding 81 and 163 μM, respectively. As shown in Table 2, free fatty acids from

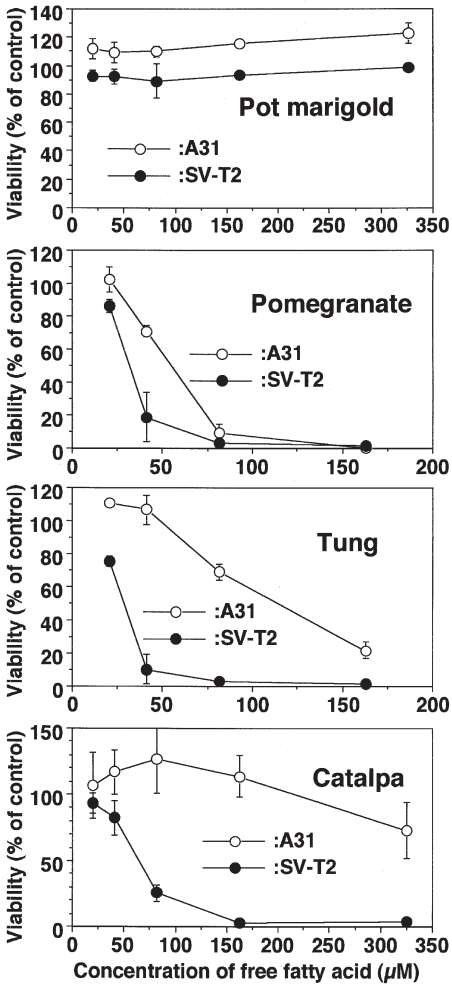

**FIG. 2.** Cytotoxic effect of fatty acids from four kinds of seed oils on A31 and SV-T2 cells. Cells were incubated in Dulbecco's modified Eagle's medium (DMEM) at 37°C in a humidified $CO_2$ (5%) atmosphere. Viability was assessed spectrophotometrically by using WST-1 reagent. Each point is the mean ± SD of three values obtained from separate cultures. For abbreviation see Figure 1.

tung, pomegranate, and catalpa contained different types of geometrical 9,11,13-CLN isomers, whereas CLN from pot marigold contained only 8,10,12-isomers, suggesting that the cytotoxic effect of 9,11,13-CLN would be strong, but that of 8,10,12-CLN would be relatively weak.

The same result was obtained by the determining the viability of human monocytic leukemia cell (U-937) (Fig. 3). The fatty acids from seed oils of pomegranate, tung, and catalpa showed strong cytotoxic effects on U-937 cells, but those from pot marigold oil had a relatively low cytotoxicity. When the cytotoxic effect of free fatty acids from seed oils of pomegranate, tung, and catalpa were compared, pomegranate and tung oils were more effective than catalpa oil. This difference was considered to be due to the different level of total 9,11,13-CLN isomers of these oils (Table 2).

To elucidate the difference in the cytotoxic effect of each CLN isomer, we separated CLN isomer by HPLC from a fatty acid mixture of seed oil and analyzed its cytotoxicity to tumor cells SV-T2 and U-937 (Fig. 4). As expected, the effects of *c*9,*t*11,*c*13-CLN, *c*9,*t*11,*t*13-CLN, and *t*9,*t*11,*c*13-CLN were stronger than that of *t*8,*t*10,*c*12-CLN. Therefore, it was confirmed that 9,11,13-CLN isomers were more cytotoxic than 8,10,12-CLN isomer on tumor cells. The results in Figure 4 also indicated that the cytotoxic effects of three different 9,11,13-CLN isomers were almost the same, suggesting that the *cis*/*trans* configuration of the 9,11,13-CLN isomers had little effect on their effects. Cornelius *et al.* (15) reported that *c*9,*t*11,*t*13,*c*15-18:4 was toxic to U-937 cells at concentrations of 5 μM or less. The toxicity of 9,11,13-CLN on U-937 cells found in this study was comparable to that of *c*9,*t*11,*t*13,*c*15-18:4. These results suggest that the conjugation at 9,11,13-positions of 18-carbon fatty acids may be important for their expression of cytotoxicity.

The mechanism of the cytotoxicity of conjugated fatty acids is supposed to involve lipid peroxidation because the toxic action can be blocked by the addition of antioxidants (15,18). The cytotoxicity of each 9,11,13-CLN isomer was

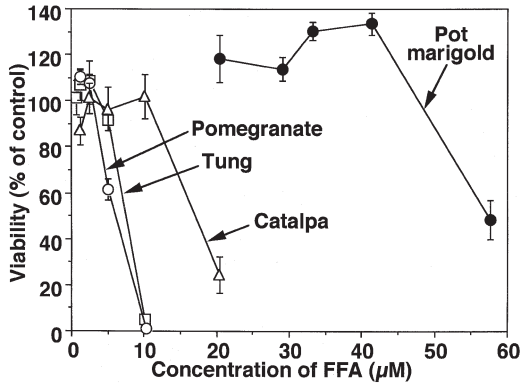

**FIG. 3.** Cytotoxic effect of fatty acids from four kinds of seed oils on U-937 cells. Cells were incubated in RPMI 1640 medium at 37°C in a humidified $CO_2$ (5%) atmosphere. Viability was assessed spectrophotometrically by using WST-1 reagent. Each point is the mean ± SD of three values obtained from separate cultures. For abbreviation see Figure 1.

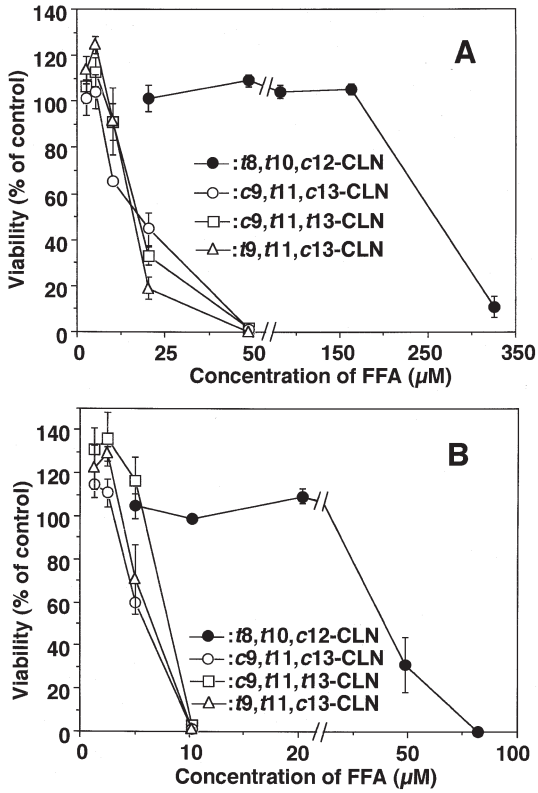

**FIG. 4.** Cytotoxic effect of each conjugated linolenic acid (CLN) isomer on SV-T2 cells (A) and on U-937 cells (B). Cells were incubated in DMEM medium for SV-T2 cells and in RPMI 1640 medium for U-937 cells at 37°C in a humidified $CO_2$ (5%). Viability was assessed spectrophotometrically by using WST-1 reagent. Each point is the mean ± SD of three values obtained from separate cultures. For abbreviation see Figure 2.

also completely inhibited by the addition of quarter molar ratio of BHT as an antioxidant to fatty acid (data not shown), confirming that lipid peroxidation is responsible for the cytotoxicity of conjugated fatty acids.

Furthermore, the possible contribution of lipid peroxidation in the greater cell toxicity exerted by 9,11,13-CLN compared with 8,10,12-CLN may be explained by the different oxidative stability of these CLN isomers. Figure 5 shows the oxidative stability of four kinds of CLN isomers and LN in an aqueous phase. As shown in Figure 5, the stabilities of three kinds of 9,11,13-CLN isomers were the same, but lower than that of *t*8,*t*10,*c*12-CLN isomer, suggesting that the difference in the cytotoxicity of 9,11,13-CLN and 8,10,12-CLN found in Figure 4 would be due to the different susceptibilities of these CLN isomers to peroxidation.

The oxidative stabilities of other kinds of fatty acids used in this study also showed a good correlation between the oxidizability of these fatty acids and their cytotoxic activities. Figure 6A shows that the oxidative stabilities of free fatty acids from pomegranate and tung were almost the same and were lower than that from catalpa, but the stability of pomegranate fatty acids was much greater than for catalpa fatty acids. On the other hand, when the oxidative stabilities of LA, LN, CLA, and IsoLN were compared (Fig. 6B), IsoLN-2 +

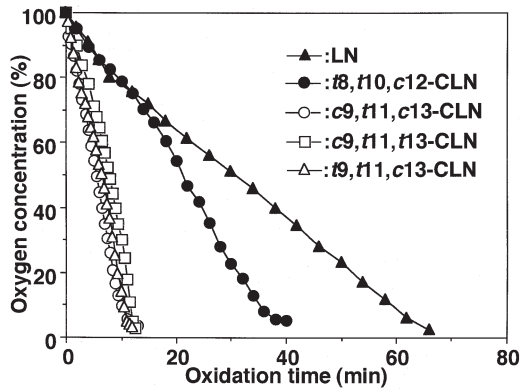

**FIG. 5.** Comparison of oxidative stabilities of CLN isomers and LN in an aqueous dispersion. Fatty acids (1.08 mg/3 mL) were incubated with 2,2′-azobis(2-amidinopropane)dihydrochloride (AAPH) (1.0 mM) in 3 mL of a phosphate buffer containing 0.1 wt% of Triton X-100. Oxidation was monitored by measuring oxygen uptake during oxidation. For other abbreviations see Figures 1 and 4.

LN was oxidized most rapidly, followed by IsoLN-1 and CLA, LN and LA. These orders in oxidative stabilities (Fig. 6) agreed with those of cytotoxicity on U-937 cells (Figs. 1 and 3).

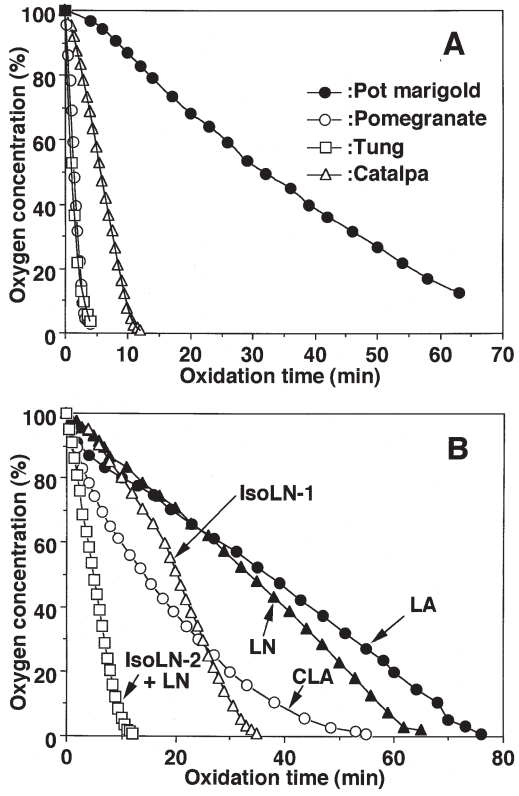

**FIG. 6.** Comparison of oxidative stabilities of free fatty acids from seed oils (A) and conjugated and nonconjugated 18-carbon fatty acids (B) in an aqueous dispersion. Fatty acids (1.08 mg/3 mL) were incubated with AAPH (1.0 mM) in 3 mL of a phosphate buffer containing 0.1 wt% of Triton X-100. Oxidation was monitored by measuring oxygen uptake during oxidation. For abbreviation see Figure 5.

# Effect of Sesamin on Mitochondrial and Peroxisomal β-Oxidation of Arachidonic and Eicosapentaenoic Acids in Rat Liver

**Rumi Umeda-Sawada*, Megumi Ogawa, Mayumi Nakamura, and Osamu Igarashi**

Institute of Environmental Science for Human Life, Ochanomizu University, Tokyo 112-8610, Japan

**ABSTRACT:** The effects of dietary sesamin on the hepatic metabolism of arachidonic (AA) and eicosapentaenoic (EPA) acids, were investigated with respect to their β-oxidation and secretion as triacylglycerol (TG). For 2 wk, rats were fed three types of dietary oils: (i) corn oil (control) group; (ii) EPA group: EPA ethyl esters/rapeseed oil = 2:3; (iii) AA group: AA ethyl esters/palm oil/perilla oil = 2:2:1, with or without 0.5% (w/w) of sesamin. Dietary sesamin significantly increased the activities of hepatic mitochondrial and peroxisomal fatty acid oxidation enzymes (mitochondrial carnitine acyltransferase I, acyl-CoA dehydrogenase, and peroxisomal acyl-CoA oxidase). Dietary EPA increased mitochondrial carnitine acyltransferase I and peroxisomal acyl-CoA oxidase. Dietary AA, however, had an effect on peroxisomal acyl-CoA oxidase only. In whole liver and the TG fraction, EPA and AA concentrations were significantly increased by dietary EPA and AA, respectively, and were decreased by dietary sesamin. In hepatic mitochondria and peroxisomes, EPA concentration was increased by dietary EPA, but AA was not changed by dietary AA. The addition of dietary sesamin to the EPA-supplemented diet significantly decreased the EPA concentration compared to concentrations found with consumption of dietary EPA alone. These results suggest that sesamin increased β-oxidation enzyme activities and reduced hepatic EPA and AA concentrations by degradation. The stimulating effect of sesamin on β-oxidation, however, was more significant in the EPA group than in the AA group. Hepatic AA concentration was altered by the joint effect of sesamin through esterification into TG and the stimulation of β-oxidation.

Paper no. L8725 in *Lipids 36*, 483–489 (May 2001).

Sesamin (a mixture of sesamin and episesamin, 47:53, w/w) is found in sesame seeds and sesame seed oil. It has multiple biological functions such as antioxidative activity (1,2), anticarcinogenicity (2) and antihypertensive effects (3,4) in rats, and alleviation of hepatic injury caused by alcohol or carbon tetrachloride (5) in mice. Sesamin also affects lipid metabolism, inhibits cholesterol absorption from the intestine, reduces 3-hydroxy-3-methyl-glutaryl CoA reductase activity in liver microsomes (6,7), and affects the incorporation of linoleic acid (LA) into lipid subfractions (8) in rats. It also increases the concentration of dihomo-γ-linolenic acid (DGLA) by inhibiting Δ5-desaturase activity in the *Mortierella alpina* fungus and rat liver microsomes (9,10). In human studies, sesamin has been reported to have hypocholesterolemic effects (11).

In our previous studies, we reported that sesamin inhibited Δ5 desaturation from DGLA (n-6) to arachidonic acid (AA, n-6), but not from 20:4n-3 to eicosapentaenoic acid (EPA, n-3) in cultured rat hepatocytes (12) and in rats (13). We also found that sesamin inhibits extreme changes of the n-6/n-3 ratio *in vivo* through the reduction of polyunsaturated fatty acid (PUFA) concentration in rat liver (13,14). This regulating effect is especially significant in the presence of high amounts of EPA (13) and AA (14), which are PUFA as well as precursors of eicosanoids. An investigation of the concentrations of serum triacylglycerol (TG) and ketone bodies (14) revealed that the reduction of hepatic PUFA concentration may have occurred because sesamin intervenes in PUFA degradation (β-oxidation) and esterification into TG. Ashakumary *et al.* (15) reported that sesamin increased the activity and gene expression of hepatic fatty acid oxidation enzymes. However, the combined actions of sesamin and different classes of long-chain PUFA (AA, n-6, and EPA, n-3) on the enzyme activities involved with fatty acid oxidation in rats have not yet been investigated.

In this study, we focused on the effects of dietary sesamin on the hepatic metabolism of AA and EPA with respect to their oxidation and secretion as TG. In particular, to investigate the effects of sesamin, AA, and EPA on fatty acid oxidation, we determined the activities of hepatic mitochondrial and peroxisomal fatty acid oxidation enzymes. The fatty acid composition of TG and mitochondrial and peroxisomal fatty acid concentrations were also investigated.

## MATERIALS AND METHODS

*Chemicals.* Sesamin (a mixture of sesamin and episesamin, 47:53,w/w), prepared from refined sesame oil and purified by the method of Fukuda *et al.* (16), was donated by Suntory Ltd. (Osaka, Japan). The sesamin included equivalent amounts of sesamin and episesamin as a result of the deodorization process (16). AA ethyl esters (purity >99%) were also donated by Suntory Ltd. EPA ethyl esters (purity >95%) were donated by Q.P. Co. (Tokyo, Japan). Corn oil, rapeseed oil,

Abbreviations: AA, arachidonic acid; AIN, American Institute of Nutrition; ALA, α-linolenic acid; ANOVA, analysis of variance; DGLA, dihomo-γ-linolenic acid; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EPA, eicosapentaenoic acid; GLA, γ-linolenic acid; LA, linoleic acid; PUFA, polyunsaturated fatty acid; TG, triacylglycerol.

and palm oil were provided by Nisshin Oil Co. (Tokyo, Japan). Palmitoyl-CoA, linolenoyl-CoA, arachidonoyl-CoA, and L-carnitine were purchased from Sigma Chemical (St. Louis, MO). *N*-Ethylmaleimide, 4-aminoantipyrine, and FAD were purchased from Nakarai Tesque (Kyoto, Japan). Phenazinemethosulfate, horseradish peroxidase, tris(hydroxymethyl) amino methane, EDTA, and Triton X-100 were purchased from Wako Pure Chemical Industries Ltd. (Osaka, Japan). 2,6-Dichlorophenolindophenol and bovine serum albumin fraction V (essential fatty acid-free) were purchased from Sigma Chemical.

*Animals and diets.* All experiments were approved by the Animal Experimentation Ethics Committee of Ochanomizu University (Tokyo, Japan). Five-week-old male Wistar rats were purchased from Nippon Clea Co. (Tokyo, Japan). The rats were initially fed on a commercial diet (CE-2, Nippon Clea Co.) for a week. Weighing an average of 198 g, the animals were then divided into six groups of five animals each. They were housed individually in an air-conditioned room at 23 ± 1°C with a 12-h light-dark cycle and were given experimental diets (20 g/d, 1–7 d; 25 g/d, 8–14 d) and water *ad libitum* for 2 wk. The basal diet prepared under standards given by the American Institute of Nutrition (AIN) (17) was provided by Eisai Co. (Tokyo, Japan) and contained the following percentage of ingredients (weight basis): casein, 20; glucose, 25; sucrose, 25; cornstarch, 15; filter paper, 5; AIN mineral mixture, 3.5; AIN vitamin mixture, 1; choline bitartrate, 0.2; DL-methionine, 0.3. The test diets were prepared by mixing 5% (w/w) experimental oil mixtures with the basal diet. Three kinds of oil mixtures were prepared: (i) control group: corn oil only; (ii) EPA group: EPA ethyl esters/rapeseed oil = 2:3; (iii) AA group: AA ethyl esters/palm oil/perilla oil = 2:2:1. Each diet was then split into two types: with or without 0.5% (w/w) of sesamin. The dietary oils of EPA and AA groups are the same as those in our previous studies (13,14). The concentration of EPA or AA ethyl esters was about 40% (w/w) in each dietary oil, respectively. The fatty acid compositions of these oils are shown in Table 1.

**TABLE 1**

[a]Values are expressed as weight percentages. EPA, eicosapentaenoic acid; AA, arachidonic acid.

*Enzyme assays.* At the termination of the experimental period, livers of rats were excised under nembutal anesthesia. Three grams of each liver were homogenized with 7 vol of 0.25 M sucrose and centrifuged at 500 × *g* for 10 min. The supernatant was recentrifuged at 9,000 × *g* for 10 min. The supernatant was centrifuged twice at 39,000 × *g* for 10 min to isolate the fraction including peroxisomes which were then finally suspended in 0.25 M sucrose containing 1 mM EDTA and 10 mM Tris-HCl (pH 7.3). The precipitate suspended in 0.25 M sucrose containing 1 mM EDTA and 10 mM Tris-HCl (pH 7.3) was centrifuged twice at 9,000 × *g* for 10 min to isolate the mitochondrial fraction. It was washed twice with 0.25 M sucrose containing 1 mM EDTA and 10 mM Tris-HCl (pH 7.3) and then resuspended in the same medium. The activities of succinate dehydrogenase, the marker enzyme of mitochondria, in the two fractions were measured. The enzyme activity was found in the mitochondrial fraction, but not in the fraction including peroxisomes (data not shown). Therefore, mitochondria were not contaminated in the fraction including peroxisomes. Carnitine palmitoyltransferase I activities in mitochondrial fraction were measured by the method of Markwell *et al.* (18), using palmitoyl-CoA as a substrate. Acyl-CoA dehydrogenase activities in the mitochondrial fraction were measured by the method of Dommes and Kunau (19) by using palmitoyl-CoA, linolenoyl-CoA, and arachidonoyl-CoA as substrates. Acyl-CoA oxidase activities in peroxisomal fraction were measured by the method of Hashimoto *et al.* (20), using palmitoyl-CoA, linolenoyl-CoA, and arachidonoyl-CoA as substrates. Protein was measured by the method of Lowry *et al.* (21).

*Lipid analyses.* Lipids were extracted from livers of the rats by the method of Folch *et al.* (22). TG extracted from the liver was separated by thin-layer chromatography by the method of Skipski *et al.* (23). As an internal standard, margaric acid (17:0) was added to the lipid extracts, which were then methylated by using HCl-methanol as described in our previous paper (24) to measure the content of fatty acids in tissues. The fatty acid methyl esters were then measured by gas–liquid chromatography (PerkinElmer AutoSystem GC, Palo Alto, CA) on a Rascot Silliar 5CP capillary column (0.25 mm × 50 m; Nihon Chromato Works Ltd., Tokyo, Japan) as described previously (24).

*Statistical analysis.* All results are shown as means ± SD. The significance of the differences in mean values was evaluated by a Student's *t*-test and an analysis of variance (ANOVA). After ANOVA, a Bonferroni-Donn *post-hoc* test was used. Analyses were performed by using a Stat View (System 4.02) computer package (Abacus Concepts, Inc., Berkeley, CA).

## RESULTS

*Growth parameters and tissue weights.* No significant differences in food intake and body weight gain were observed among all groups. We concluded that the administration of sesamin and the three kinds of dietary oils had no influence on the growth of rats. Dietary sesamin significantly increased the liver weight of rats (control + sesamin, 4.06 ± 0.26; EPA + sesamin, 4.57 ± 0.20; AA + sesamin, 4.42 ± 0.19 g/100 g body weight vs. control, 3.20 ± 0.06; EPA, 3.02 ± 0.12; and AA, 3.15 ± 0.14 g/100 g body weight, respectively). The difference between the with and without-sesamin groups was statistically significant ($P < 0.05$).

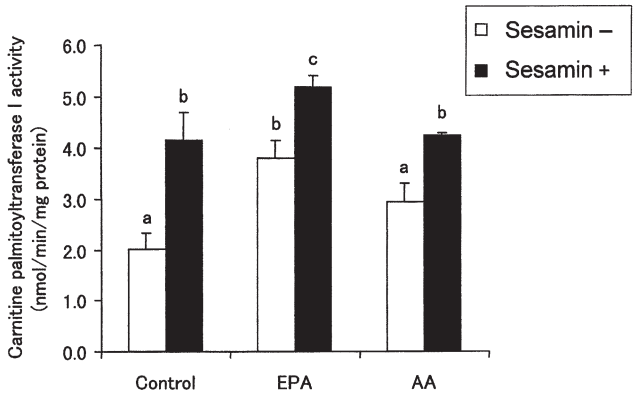

**FIG. 1.** Effect of dietary sesamin, eicosapentaenoic acid (EPA), and arachidonic acid (AA) on mitochondrial carnitine palmitoyltransferase I activity in rat liver. Values are means ± SD of five determinations made on separate animals. The significance of differences between the dietary treatments was analyzed by an analysis of variance. Bars with different superscript letters are significantly different ($P < 0.05$).

*Activities of fatty acid oxidation enzymes in rat liver.* Mitochondrial carnitine palmitoyltransferase I activities in rat liver are shown in Figure 1. Dietary sesamin significantly increased the enzyme activities in all dietary oil groups. Dietary EPA also increased enzyme activity, but dietary AA had no significant effect. The highest enzyme activity was observed in the combination of EPA with sesamin.

Mitochondrial acyl-CoA dehydrogenase activities in rat liver are shown in Figure 2. Dietary sesamin significantly increased the enzyme activities, using every substrate (palmitoyl-CoA; 16:0-CoA, linolenoyl-CoA; 18:3-CoA, and arachidonoyl-CoA; 20:4-CoA) in all dietary oil groups. When a 16:0-CoA (saturated fatty acid-CoA) was used as a substrate, dietary sesamin increased the activities less than twofold compared with the no-sesamin group. But when a 18:3-CoA (n-3 PUFA-CoA) was used, dietary sesamin increased the activities 4.4-fold in the control group, 2.4-fold in the EPA group, and 3.4-fold in the AA group. When a 20:4-CoA (n-6 PUFA-CoA) was used, dietary sesamin increased the activities 4.1-fold in the control group, 4.2-fold in the EPA group, and 4.6-fold in the AA group. One may compare the enzyme activity levels of 16:0-CoA, 18:3-CoA, and 20:4-CoA; a conclusion would be that either chain length, or degree of unsaturation, or both, could relate to their increased suitability as substrates. Dietary EPA and AA had no effect on the enzyme activity.

Peroxisomal acyl-CoA oxidase activities in rat liver are shown in Figure 3. When a 16:0-CoA was used as a substrate, dietary sesamin increased the enzyme activities about fourfold in all dietary oil groups. Furthermore, EPA and AA also significantly increased the activities. The effect of sesamin on increasing the activity was much greater than for EPA or AA. When 18:3-CoA was used, dietary sesamin increased the activities 3.2-fold in the control group, 4.5-fold in the EPA group, and 2.9-fold in the AA group, compared with the no-sesamin group. When 20:4-CoA was used, the activities in the EPA + sesamin and AA + sesamin groups were significantly higher than in the control group. The effectiveness of enzyme activity is in the order of 16:0-CoA > 18:3-CoA > 20:4-CoA, similar to mitochondrial acyl-CoA dehydrogenase.

*Liver fatty acid levels.* The fatty acid concentrations of liver are shown in Table 2. In the control group, dietary sesamin tended to decrease LA (18:2n-6) and α-linolenic acid (ALA; 18:3n-3) but significantly increased DGLA (20:3n-6). Dietary EPA significantly increased EPA (20:5) and docosapentaenoic acid (DPA, 22:5n-3) but decreased AA (20:4) compared with the control group. In the EPA group, dietary sesamin significantly decreased n-3 PUFA: ALA, EPA, and DPA. On the contrary, dietary sesamin increased the n-6 PUFA, DGLA, and AA. Dietary AA significantly increased the AA compared with the

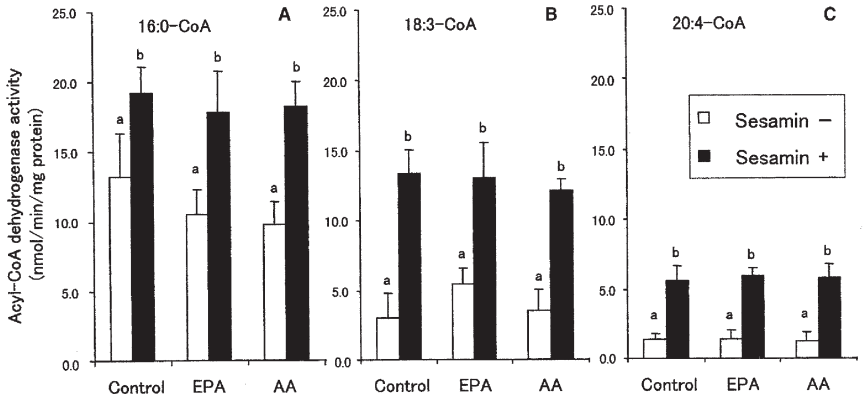

**FIG. 2.** Effect of dietary sesamin, EPA, and AA on mitochondrial acyl-CoA dehydrogenase activity in rat liver. Values are means ± SD of five determinations made on separate animals. The significance of differences between the dietary treatments using the same substrate (16:0-CoA, 18:3-CoA, or 20:4-CoA) was analyzed by analysis of variance. Bars with different superscript letters are significantly different ($P < 0.05$). (A) 16:0-CoA, palmitoyl-CoA; (B) 18:3-CoA, linolenoyl-CoA; (C) 20:4-CoA, arachidonoyl-CoA. See Figure 1 for abbreviations.

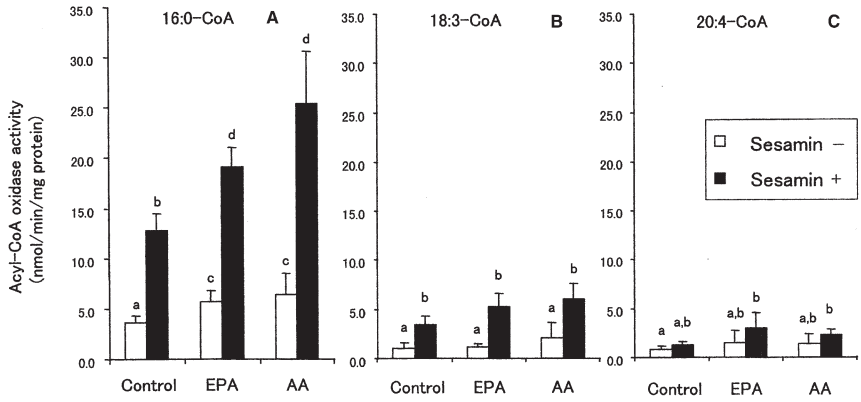

**FIG. 3.** Effect of dietary sesamin, EPA, and AA on peroxisomal acyl-CoA oxidase activity in rat liver. Values are means ± SD of five determinations made on separate animals. The significance of differences between the dietary treatments using the same substrate (16:0-CoA, 18:3-CoA, or 20:4-CoA) was analyzed by an analysis of variance. Bars with different superscript letters are significantly different ($P < 0.05$). (A) 16:0-CoA, palmitoyl-CoA; (B) 18:3-CoA, linolenoyl-CoA; (C) 20:4-CoA, arachidonoyl-CoA. See Figures 1 and 2 for abbreviations.

control group. In the AA group, dietary sesamin significantly decreased AA to the control group level. Furthermore, dietary sesamin also decreased n-3 PUFA: ALA, EPA, and DPA. EPA concentration in the EPA group was reduced to about one-fifth and AA concentration in the AA group to about one-half by the administration of sesamin.

The fatty acid composition of liver TG is shown in Table 3. In the control group, dietary sesamin significantly increased AA but decreased ALA. Dietary EPA significantly increased EPA, DPA, and docosahexaenoic acid (DHA, 22:6n-3), but decreased AA, compared with the control group. In the EPA group, dietary sesamin decreased EPA and DHA and increased AA. Dietary AA significantly increased the n-6 PUFA: AA and DPA (n-6) compared with the control group. In the AA group, dietary sesamin decreased γ-linolenic acid (18:3n-6), AA, and 22:4n-6. In the AA group, dietary sesamin had no effect on n-3 PUFA compositions. EPA composition in the EPA group was reduced to about one-fifth and AA composition in the AA group to about one-half by the administration of sesamin.

The mitochondrial fatty acid concentration in liver is shown in Table 4. In the control group, dietary sesamin had no effect on mitochondrial fatty acid concentration. Dietary EPA significantly increased EPA, but decreased AA. In the EPA group, dietary sesamin significantly decreased EPA, but increased AA. Dietary AA had no effect on mitochondrial AA concentration.

The peroxisomal fatty acid concentration in liver is shown in Table 5. In the control group, dietary sesamin had no effect on peroxisomal fatty acid concentration. Dietary EPA significantly increased EPA, but decreased AA. In the EPA group, dietary sesamin significantly decreased EPA, but increased AA. Dietary AA had no effect on peroxisomal AA concentration.

## DISCUSSION

In our previous studies, sesamin inhibited the extreme change of n-6/n-3 PUFA ratio *in vivo* (13,14). This regulating effect was remarkable when an excessive amount of EPA (13) or

AA (14), was given, and the reduction of hepatic PUFA concentration may have occurred because sesamin acts at some point between PUFA degradation (oxidation) and esterification (14). To reveal the mechanism of sesamin's effect, we examined changes in the hepatic fatty acid β-oxidation enzyme activities, the fatty acid composition of TG, and mitochondrial and peroxisomal fatty acid concentrations. This study was an extension of our previous studies on the effect of sesamin on fatty acid metabolism; therefore, the fatty acid compositions of experimental oils were the same as those in our previous studies (13,14).

Fatty acids are incorporated into cells and degraded *via* the β-oxidation pathway in mitochondria and peroxisomes. Acyl-CoA can be directly incorporated into peroxisomes, but in mitochondria, acyl-CoA is first changed to acylcarnitine by carnitine acyltransferase I before passage through the mitochondrial inner membrane. Acyl-CoA dehydrogenase is the first enzyme in mitochondrial β-oxidation, and that of peroxisomal β-oxidation is acyl-CoA oxidase. To investigate the capacity for fatty acid oxidation in each organelle (mitochondria and peroxisomes), we determined the activities of these three enzymes.

Dietary sesamin increased all three enzyme activities (Figs. 1–3). The increasing levels of mitochondrial enzymes

(carnitine acyltransferase I and acyl-CoA dehydrogenase) by sesamin were less than twofold, but those of peroxisomal enzyme (acyl-CoA oxidase) were about fourfold, using 16:0-CoA as a substrate. Several studies have demonstrated that fibric acid derivatives such as clofibrate and bezafibrate enhance peroxisomal β-oxidation (25–27). These compounds are peroxisome proliferators and hypolipidemic drugs, and they affect lipid metabolism and decrease TG and cholesterol levels in serum (28,29). In this study, we demonstrated that sesamin significantly increased peroxisomal β-oxidation enzyme activity; therefore, sesamin may have a function similar to fibrate derivatives. Although this study had not investigated the dose-related effect of sesamin on the enzyme activities, Ashakumary *et al.* (15) reported that sesamin increased hepatic fatty acid oxidation enzyme activity dose-dependently [from 0.1 to 0.5% (w/w) of sesamin in the diet]. The amount of sesamin consumed by the rats in our present study was approximately equal to ingestion of 20 g/d sesamin by an adult human.

The activities of carnitine acyltransferase I, which take place when fatty acids are incorporated into mitochondria, were increased by dietary EPA, but not by dietary AA (Fig. 1). A difference was found between EPA and AA in incorporating into mitochondria. In mitochondrial fatty acid content (Table 4), EPA concentration was increased by dietary EPA, but the AA was not changed by dietary AA. The addition of dietary sesamin to the EPA-supplemented diet significantly decreased the EPA concentration compared to concentrations found with consumption of dietary EPA alone. The activities of peroxisomal acyl-CoA oxidase were significantly increased by dietary EPA or AA, and no difference was noted in either increasing ratio (Fig. 3). In peroxisomal fatty acid concentration (Table 5), dietary EPA increased EPA concentration, and dietary sesamin inhibited it. Dietary AA, however, had no effect on peroxisomal AA concentration. In fatty acid concentration in whole liver (Table 2), EPA and AA concentrations were significantly increased by dietary EPA and AA, respectively, and dietary sesamin decreased them. In liver TG (Table 3), the same results were demonstrated as in the whole liver. However, dietary sesamin reduced AA concentration to about half the amount, and EPA concentration to one-fifth. These results suggested that dietary EPA stimulated mitochondrial and peroxisomal β-oxidation enzyme activities in the liver; furthermore, dietary sesamin promoted β-oxidation of EPA. On the contrary, dietary AA had no effect on mitochondrial and peroxisomal AA concentration, despite the significant increase of AA in liver TG. These results suggested that AA may at first have been incorporated into TG as an AA pool, and excess AA was subsequently degraded *via* β-oxidation mainly in peroxisomes when an excessive amount of AA was administered. Sesamin increased mitochondrial and peroxisomal β-oxidation enzyme activities and reduced fatty acid concentrations in the whole liver, but there were differences between the reduction processes of EPA and AA. In the stimulation of fatty acid β-oxidation by sesamin, EPA may be degraded *via* the β-oxidation pathway instead of esterified into TG and phospholipids. On the other hand, AA concentration in the liver can be maintained by a balance between esterification of AA into TG and peroxisomal β-oxidation.

In conclusion, the present study demonstrated that sesamin increased β-oxidation enzyme activities and reduced hepatic EPA and AA concentrations by the degradation of extra EPA and AA. That is why sesamin regulates the extreme change of n-6/n-3 PUFA ratio. The stimulating effect of sesamin on β-oxidation, however, was more notable with the high intakes of EPA than of AA, and the reduction rate of EPA was higher than AA. In the excessive intake of AA, AA concentration was regulated by the joint effect of sesamin through the esterification into TG and a stimulation of β-oxidation by sesamin. It was demonstrated that sesamin stimulated mitochondrial and peroxisomal fatty acid degradation, and the reduction process of AA was different from EPA in liver.

# Correlation of Fatty Acid Unsaturation of the Major Liver Mitochondrial Phospholipid Classes in Mammals to Their Maximum Life Span Potential

**Manuel Portero-Otín, Maria Josep Bellmunt, Maria Cristina Ruiz, Gustavo Barja[1], and Reinald Pamplona***

Metabolic Physiopathology Research Group, Department of Basic Medical Sciences, Faculty of Medicine, University of Lleida, Lleida 25198, Spain

**ABSTRACT:** Free radical damage is considered a determinant factor in the rate of aging. Unsaturated fatty acids are the tissue macromolecules that are most sensitive to oxidative damage. Therefore, the presence of low proportions of fatty acid unsaturation is expected in the tissues of long-lived animals. Accordingly, the fatty acid compositions of the major liver mitochondrial phospholipid classes from eight mammals, ranging in maximum life span potential (MLSP) from 3.5 to 46 yr, show that the total number of double bonds is inversely correlated with MLSP in both phosphatidylcholine (PtdCho) and phosphatidylethanolamine (PtdEtn) ($r = 0.757$, $P < 0.03$, and $r = 0.862$, $P < 0.006$, respectively), but not in cardiolipin ($P = 0.323$). This is due not to a low content of unsaturated fatty acids in long-lived animals, but mainly to a redistribution between kinds of fatty acids on PtdCho and PtdEtn, shifting from arachidonic ($r = 0.911$, $P < 0.002$, and $r = 0.681$, $P = 0.05$, respectively), docosahexaenoic ($r = 0.931$ and $r = 0.965$, $P < 0.0001$, respectively) and palmitic ($r = 0.944$ and $r = 0.974$, $P < 0.0001$, respectively) acids to linoleic acid ($r = 0.942$, $P < 0.0001$, for PtdCho; and $r = 0.957$, $P < 0.0001$, for PtdEtn). For cardiolipin, only arachidonic acid showed a significantly inverse correlation with MLSP ($r = 0.904$, $P < 0.002$). This pattern strongly suggests the presence of a species-specific desaturation pathway and deacylation-reacylation cycle in determining the mitochondrial membrane composition, maintaining a low degree of fatty acid unsaturation in long-lived animals.

Paper no. L8661 in *Lipids 36*, 491–498 (May 2001).

Several lines of evidence indicate that mitochondria and oxidative damage can be implicated both in pathological responses and in the aging process (1). The available comparative studies indicate that maximum life span potential (MLSP) is inversely related to mitochondrial free radical production (2,3) and mitochondrial DNA oxidative damage (4,5). Although these very important characteristics are consistent with free radical–oxidative stress theories of aging (6,7), additional factors related to other macromolecules also can lead to a low level of oxidative damage in long- *vs.* short-lived animal species.

Among cellular macromolecules, polyunsaturated fatty acids (PUFA) exhibit the highest sensitivity to oxidative damage. It is accepted that their sensitivity increases as a power function of the number of double bonds per fatty acid molecule. Since both oxygen consumption and reactive oxygen species formation occur predominantly in mitochondrial membranes, a low degree of fatty acid unsaturation in these membranes may be advantageous, in oxidative stress terms, by decreasing their sensitivity to lipid peroxidation. This would also protect other molecules against lipoxidation-derived damage. In line with this, it has been suggested that in long-lived species a low degree of total tissue and mitochondrial fatty acid unsaturation (low double-bond content) is accompanied by a low sensitivity to lipid peroxidation and a low concentration of the lipoxidation-derived adducts malondialdehyde-lysine and $N^{\varepsilon}$-(carboxymethyl)lysine in several tissues and mitochondrial proteins (8–12). Independent experiments have also demonstrated a negative correlation between sensitivity to lipid autoxidation and MLSP in brain and kidney homogenates from different mammalian species (13).

Mitochondria from different mammalian tissues are similar with respect to their phospholipid distribution (14). The major phospholipids, phosphatidylcholine (PtdCho) and phosphatidylethanolamine (PtdEtn), together account for about 70–80% of total phospholipids; cardiolipin constitutes 10–20% of total mitochondrial phospholipids.

Phospholipids play multiple roles in mitochondria including establishing a permeability barrier, providing the matrix for the assembly and function of a wide variety of catalytic processes, acting as donors in the synthesis of macromolecules, and actively influencing the functional properties of membrane-associated processes. The wide range of processes in which specific involvement of phospholipids has been documented explains the need for diversity in phospholipid structure and fatty acid composition (15).

In this work, the fatty acid compositions of the phospho-

Abbreviations: AA, arachidonic acid; ACL, average chain length; DBI, double bond index; DHA, docosahexaenoic acid; GC–MS, gas chromatography–mass spectrometry; LA, linoleic acid; MLSP, maximum life span potential; MSE buffer, mannitol, sucrose, and EGTA at pH 7.4; MUFA, monounsaturated fatty acids; PtdCho, phosphatidylcholine; PtdEtn, phosphatidylethanolamine; PUFA, polyunsaturated fatty acid; SFA, saturated fatty acids; TLC, thin-layer chromatography; UFA, unsaturated fatty acids.

lipids PtdCho, PtdEtn, and cardiolipin from liver mitochondria of eight mammalian species ranging in MLSP from 3.5 to 46 yr were analyzed. The results obtained show that the degree of fatty acid unsaturation is inversely correlated with MLSP in PtdCho and PtdEtn, while there is no relationship between cardiolipin composition and MLSP.

## MATERIALS AND METHODS

*Chemicals.* Phospholipid standards were obtained from Avanti Polar Lipids (Alabaster, AL); fatty acid methyl ester standards, from Sigma (St. Louis, MO); gas chromatography columns, from Teknokroma (Teknokroma SCCL, Barcelona, Spain); silica gel thin-layer chromatography (TLC) plates, from Whatman (Fisher, Cincinnati, OH); other reagents were purchased from Sigma unless otherwise specified. All chemicals were of analytical grade.

*Animals and diets.* All animals, namely, mouse (*Mus musculus, n* = 6), hamster (*Critecus critecus, n* = 4), guinea pig (*Cavia porcellus, n* = 4), rabbit (*Oryctolagus cuniculus*, *n* = 6), sheep (*Ovis aries, n* = 6), pig (*Sus scrofa, n* = 5), cow (*Bos taurus, n* = 4), and horse (*Equus caballus, n* = 5), whose MLSP vary from 3.5 to 46 yr, were adult specimens with an age at 15–30% of their MLSP (equivalent to an age ranging from 0.5 to 6 yr). The recorded values of MLSP (in yr) were: mouse, 3.5; hamster, 4; guinea pig, 8; rabbit, 13; sheep, 20; pig, 27; cow, 30; and horse, 46 (16). The animal care protocols were approved by the University of Lleida Animal Experimentation Ethics Committee. Mice, hamsters, guinea pigs, and rabbits were killed by decapitation. Sheep, pigs, cows, and horses (farm animals) were sacrificed at the abattoir. Samples of diet administered during the adult life of the animals were obtained at the sacrifice.

*Mitochondrial isolation.* Tissue samples were taken from the main hepatic lobe and were immediately processed. Mitochondrial fractions were isolated by standard methods of homogenization and differential centrifugation as previously described (8). Liver samples (2–3 g) were briefly and gently homogenized with a loose fitting pestle hand-operated glass-glass homogenizer in 10 mL of MSE buffer (225 mM mannitol, 75 mM sucrose and 1 mM EGTA, pH 7.4) containing 5 mg of nagarse, a bacterial proteinase (EC 3.4.21.14) from Fluka (product no. 82518, Sigma Co.), and 25 mg of albumin. After standing for 1 min, 25 mL of additional MSE buffer containing 25 mg of albumin was added, and homogenization was gently performed again with a tighter-fitting pestle. The homogenates were centrifuged for 3 min at 1,500 × *g* (5°C) in a RC5C Sorvall centrifuge. The supernatants were centrifuged 10 min at 9,800 × *g,* the pellets were resuspended, and the procedure was repeated two more times. All procedures were performed at 0–4°C.

The purity of the mitochondrial fractions was tested by determining 5′-nucleotidase (as marker for plasma membrane), peroxidase (for peroxisomes), glucose-6-phosphatase (for endoplasmic reticulum), acid phosphatase (for lysosomes), and cytochrome c oxidase (for mitochondria) activities according to published methods (17). Based on the specific activities of the different markers, our mitochondrial preparations contains approximately 1% of nonmitochondrial subcellular membranes.

*Lipid extraction and phospholipid classes separation.* Lipids from mitochondria were extracted into chloroform/methanol (2:1 vol/vol) by the method of Folch *et al.* (18) in the presence of 0.01% butylated hydroxytoluene. The phospholipid classes were separated by TLC on silica gel plates. Development with *n*-hexane/1,2-dichloroethane/methanol/formic acid (16:14:4:1 by vol) was performed, followed by 1,2-dichloroethane solvent system (19). Fractions were made visible by spraying with 0.02% 8-anilino-1-naphthalenesulfonic acid in ethanol. The bands on the plates corresponding to major mitochondrial phospholipids (PtdCho, PtdEtn, and cardiolipin), identified by comparison with authentic standards, were scraped, transferred to screw-capped tubes, and transesterified.

To quantify the percentages of major phospholipid classes, lipid samples were separated on Silica gel 60A LK6D TLC plates (Whatman, Clifton, NJ), by using the solvent system described above. Separated lipid fractions were detected using a 10% cupric sulfate in 8% phosphoric acid solution, followed by charring at 160°C for 20 min, and were quantified by scanning densitometry using a Shimadzu CS-9001PC dual-wavelength flying spot scanner (Shimadzu Europe GmbH, Duisburg, Germany).

*Fatty acid analysis.* Mitochondrial phospholipid fatty acids were transesterified in 2.5 mL of 5% methanolic HCl at 75°C for 90 min. The resulting methyl esters were extracted by adding 2.5 mL *n*-pentane and 1 mL saturated NaCl. The *n*-pentane phase was separated and evaporated under $N_2$, and the fatty acid methyl esters were redissolved in 100 μL of carbon disulfide. One microliter was submitted to gas chromatography–mass spectrometry (GC–MS) analysis. GC separation was performed on an SP2330 capillary column (30 m × 0.25 mm × 0.20 μm) in a Hewlett-Packard 6890 Series II gas chromatograph (Hewlett-Packard, S.A., Barcelona, Spain). A Hewlett-Packard 5973 mass spectrometer was used as detector in the electron-impact mode. The injection port was maintained at 220°C, and the detector at 250°C; the temperature program was 2 min at 100°C, then 10°C/min to 200°C, then 5°C/min to 240°C, and finally hold at 240°C for 10 min. Identification of methyl esters was made by comparison with authentic standards and on the basis of mass spectra. Results are expressed as mol%.

*Calculations and statistics.* The average chain length is calculated as ACL= $[(\Sigma\ \%\text{Total}_{16} \times 16) + \cdots + (\Sigma\ \%\text{Total}_{n} \times n)]/100$ (*n* = carbon atom number); the double bond index as DBI = (Σ %Monoenoic × 1) + (Σ %Dienoic × 2) + (Σ %Trienoic × 3) + (Σ %Tetraenoic × 4) + (Σ %Pentaenoic × 5) + (Σ %Hexaenoic × 6); saturated fatty acids as SFA = Σ % (16:0 + 18:0); unsaturated fatty acids as UFA = Σ % (16:1 + 18:1 + 18:2 + 18:3 + 20:3 + 20:4 + 22:6); monounsaturated fatty acids as MUFA = Σ % (16:1 + 18:1); polyunsaturated fatty acids as PUFA = Σ % (18:2 + 18:3 + 20:3 + 20:4 + 22:6); n-3 polyunsaturated fatty acids as PUFAn-3 = Σ % (18:3 + 22:6); and finally, n-6 polyunsaturated fatty acids as PUFAn-6 = Σ% (18:2 + 20:3 + 20:4).

Regression equations were obtained by nonlinear regression analyses with the curve estimation statistic by SPSS/PC software for Windows (SPSS, Chicago, IL). These regressions were determined and tested for significance using the mean values for each species. The 0.05 level was selected as the point of minimal statistical significance. Values in tables and figures are expressed as mean ± SEM.

## RESULTS

The fatty acid composition of the diets of the different animal species showed that the DBI of the dietary fats was not correlated with MLSP (Table 1). From analytical TLC, mitochondrial phospholipid distribution was calculated. In all the mammalian species studied in this work, the major phospholipid was PtdCho, in the range of 40–50%, followed by the PtdEtn fraction in the range of 23–35%. Cardiolipin was present in the range of 14–21%. Phospholipid distribution among species was not correlated with MLSP (data not shown). The complete fatty acid composition and indexes related to the degree of unsaturation, the chain length, or to the main fatty acid types or series of the major liver mitochondrial phospholipids, namely, PtdCho, PtdEtn, and cardiolipin, are shown in Tables 2, 3, and 4. Summaries of correlations between MLSP and fatty acid composition or fatty acid indexes of different phospholipid classes from liver mitochondria in the mammalian species are included in Tables 2, 3 and 4.

Neither the ACL nor the percentage of total MUFA shows statistically significant correlation with MLSP in any of the phospholipid classes analyzed. In contrast, total SFA and UFA contents show highly significant correlations with MLSP, in a negative and positive way, respectively, for PtdCho and PtdEtn, whereas no relationship was observed for the cardiolipin fraction. The decrease in the percentage of SFA with increases in MLSP is due to the negative correlation of palmitic acid (16:0) with MLSP in both PtdCho and PtdEtn (Figs. 1A, 1B); in contrast, no significant correlations were observed with cardiolipin. In the PtdCho and PtdEtn fractions docosahexaenoic acid (22:6n-3, DHA) was negatively correlated with maximum longevity, whereas the contrary was true

[a]For footnotes and abbreviations see Table 2.

for linoleic acid (18:2n-6, LA) (Figs. 1A, 1B). Cardiolipin also showed a significant negative correlation with MLSP in the arachidonic acid (20:4n-6, AA) content, while LA was not affected. As result of this fatty acid redistribution, the total content of double bonds showed significant negative correlations with MLSP in PtdCho and PtdEtn, and was not affected in cardiolipin (Fig. 2).

## DISCUSSION

In agreement with previous comparative studies of mitochondria in mammals and birds (8–12) we found in this investigation that the number of fatty acid double bonds of the major phospholipid classes from liver mitochondria is negatively correlated with MLSP, i.e., the fatty acids of mitochondrial PtdCho and PtdEtn of long-lived mammals have a lower degree of unsaturation than those of short-lived ones. This is due to the redistribution between components of the polyunsaturated n-3 and n-6 fatty acid series, shifting from the highly unsaturated DHA and AA in short-lived animals to the less unsaturated LA in long-lived ones. This leads to a low DBI in the mitochondrial PtdCho and PtdEtn of long-lived animals. Further, since ACL may be seriously altered by the redistribution between DHA/AA and LA fatty acids, the decline in 16:0 and rise in 18:0 with increases in MLSP may be considered as an adaptation to maintain this parameter. In contrast, the cardiolipin fatty acid composition and fatty acid indexes show that only AA and palmitoleic acid (16:1) shows a signifi-

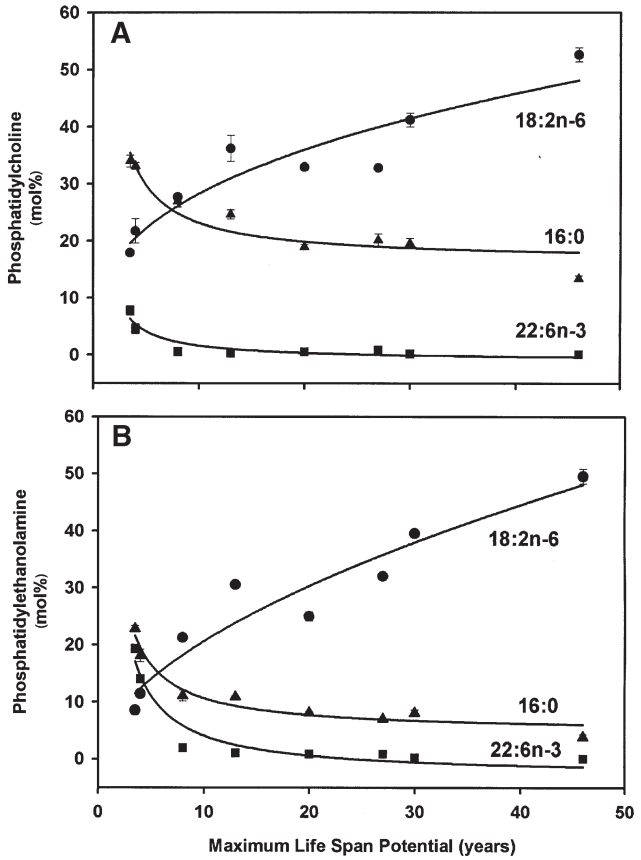

**FIG. 1.** Relationship between maximum life span (MLSP) and mol% of linoleic acid (18:2n-6), mol% of docosahexaenoic acid (22:6n-3), and mol% of palmitic acid (16:0), in liver mitochondrial phosphatidylcholine (A) and phosphatidylethanolamine (B). Regression equations: In A, for phosphatidylcholine, (i) 18:2n-6 (mol%) = 12.65 · MLSP $^{0.348}$, $r = 0.93$; $P < 0.0008$; (ii) 22:6n-3 (mol%) = –0.931 + (25.35/MLSP), $r = 0.93$, $P < 0.0008$; (iii) 16:0 (mol%) = 16.53 + (66.17/MLSP), $r = 0.94$, $P < 0.0004$. In B, for phosphatidylethanolamine, (i) 18:2n-6 (mol%) = 5.72 · MLSP$^{0.555}$, $r = 0.96$; $P < 0.0002$; (ii) 22:6n-3 (mol%) = –2.91 + (70.05/MLSP), $r = 0.96$, $P < 0.0001$; (iii) 16:0 (mol%) = 4.76 + (58.93/MLSP), $r = 0.97$, $P < 0.0001$. Values are means ± SEM.

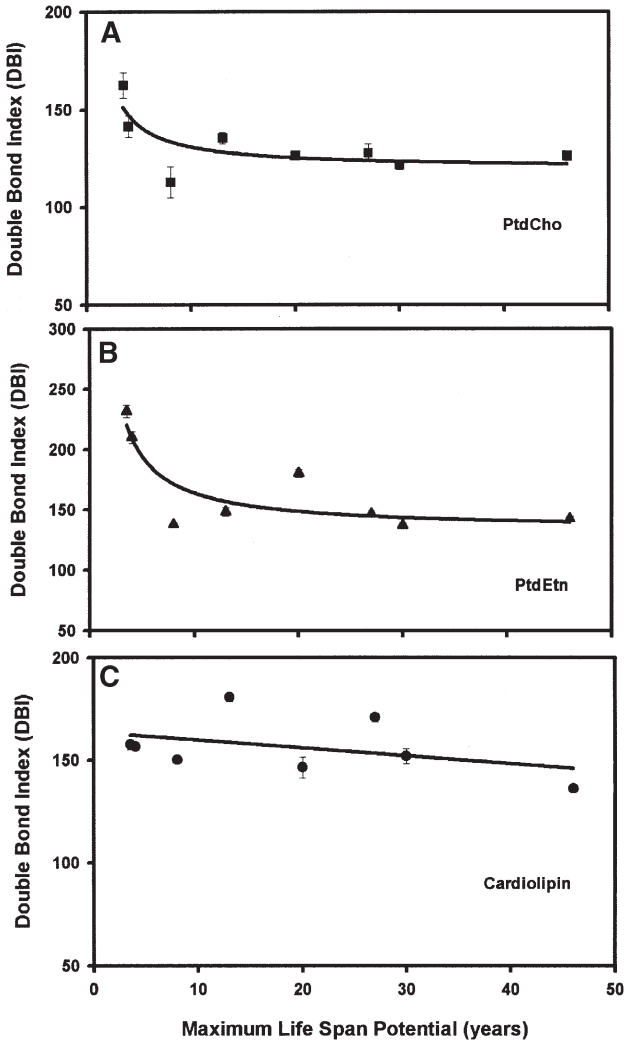

**FIG. 2.** Relationship between maximum life span potential (MLSP) and double bond index (DBI) of liver mitochondrial phosphatidylcholine (PtdCho, A), phosphatidylethanolamine (PtdEtn, B), and cardiolipin (C) in mammalian species. Regression equations: (A) $DBI_{PtdCho} = 119.81 + (110.81/MLSP)$, $r = 0.75$, $P < 0.03$; (B) $DBI_{PtdEtn} = 133.25 + (304.95/MLSP)$, $r = 0.86$, $P < 0.006$; (C) $DBI_{Cardiolipin} = 163.53 - 0.38 \cdot MLSP$, $r = 0.40$, $P = 0.323$. Values are means ± SEM.

cant negative correlation with MLSP. Similarly, previous studies in different tissues, subcellular fractions, or species usually showed that the low degree of fatty acid unsaturation of long-lived animals is obtained by analogous redistributions between types of PUFA without decreasing the total PUFA or UFA content (8–12). These results were later confirmed by another independent laboratory (20). While this had never been described as a function of MLSP, two previous comparative reports exist in mammals in relation to body size (21,22). In the first one (21), DHA decreased sharply as body size increased in the order mouse–rat–rabbit–man–whale, which is also an order of increasing MLSP although the authors did not comment on this. In the second report (22), DBI was found to correlate negatively with body size in the heart, skeletal muscle, and kidney cortex of five species, mouse–rat–rabbit–sheep–cattle, whereas in the liver the negative trend did not reach statistical significance and in the brain a low DBI was observed only in cattle. The fatty acids mainly responsible for these differences were again DHA and AA, which decreased as body size increased, and LA, which showed progressively larger levels in animals of larger size.

These results suggest that cellular and/or subcellular mechanisms exist to bring about the observed distinctive distribution of acyl groups in the mitochondrial membrane phospholipids among different mammals. Two mechanisms may be implied in determining the fatty acid profile observed in the major liver mitochondrial phospholipid classes: (i) the fatty acid desaturation pathway and (ii) the deacylation–reacylation cycle. With respect to (i), these results might be explained by the metabolic characteristics of the recently postulated mitochondrial desaturation pathways (23), which would make the n-6 and n-3 fatty acids available *in situ* to phospholipid acyltransferases in order to remodel the phospholipid

acyl groups and lead to the postulation of a constitutively decreased species-specific desaturase activity in the long-lived animals. Furthermore, since fatty acid composition differs between the zwitterionic (PtdCho and PtdEtn) and anionic (cardiolipin) phospholipids, perhaps there is differential remodeling activity among mammals. With respect to (ii), in order to maintain the appropriate molecular species composition of the different phospholipids, the deacylation–reacylation of mitochondrial phospholipids based on the presence of both phospholipase $A_2$ and acyl-CoA:lysophospholipid acyltransferase activities may be species-specific and rate-limiting for the molecular remodeling of PtdCho, PtdEtn, and cardiolipin in liver mitochondria. The conservation among mammals of the cardiolipin DBI probably reflects its importance as modulator of the activity of a number of mitochondrial membrane enzymes involved in the oxidative generation of ATP (24). Furthermore, special attention must be addressed to the decreased AA content in cardiolipin with MLSP. A recent report demonstrates that AA interaction with the mitochondrial electron transport chain promotes generation of reactive oxygen species (25). The lower AA content in long-lived species is consistent with the lower rate of free radical production in these animal species (26).

The presence of constitutively whole membrane remodeling activities in long-lived animals can explain why feeding corn oil (rich in LA) to primates (marmoset monkeys, *Callithrix jacchus*) increases mainly LA (to 30% of total fatty acids) instead of AA (to only 10% of total) in their tissues (27), whereas in short-lived rodents dietary LA leads to strong increases in AA. Similarly (28), members of human monastic communities that chronically consume only corn oil as the main dietary fat source (67% rich in LA) have lipid profiles with around 30% LA but only 9% AA in their high density lipoproteins (29). Moreover, the diets of all the animals studied contain LA and linolenic acid (18:3n-3), the precursors in the n-3 and n-6 series, but do not contain AA and/or DHA. Nevertheless, the DHA levels reached 8 and 20% in mice, but were only 0.12 and 0.07% in horses, for PtdCho and PtdEtn, respectively. In any case, the double-bond content of the diets was not correlated to MLSP.

Concerning the physiological meaning of the decrease in the degree of unsaturation in long-lived animals, there are various possibilities. Other authors have proposed (22) that mammals of large body size have a low DBI to decrease their metabolic rates, because the lower the DBI of a membrane, the lower is its permeability to ions (ion pumping is one of the main determinants of metabolic rate). The permeability to $Na^+$ and $K^+$ in liver hepatocytes (30) and to $H^+$ in inner mitochondrial membranes (31) also correlates negatively with body size. Although this possibility may be true for mammals of different sizes, it cannot explain the low DBI from birds because they have a metabolic rate similar to or higher than that of mammals of similar size. But the studied birds and the mammals of large body size share a common trait; they have a long life span. We thus hypothesized that the low phospholipid DBI of long-lived homeotherms (mammals or birds) could have been selected during evolution to decrease membrane lipid peroxidation and its peroxidative consequences to other cellular macromolecules including proteins (32–34) and DNA (35). In agreement with this, a low degree of total tissue and mitochondrial fatty acid unsaturation, accompanied by a low sensitivity to lipid peroxidation and a low concentration of the lipoxidation-derived adducts malondialdehydelysine and $N^{\varepsilon}$-carboxymethyllysine in tissue and mitochondrial proteins have been described (8–12). A negative correlation between sensitivity to lipid autoxidation and MLSP in brain and kidney homogenates from different mammalian species has also been described (13). Furthermore, during aging, a modification of fatty acid unsaturation and oxidative damage in membranes occurs, which is prevented by food restriction (36–41). Thus, the low fatty acid unsaturation of long-lived mammals of large body size would protect their tissues against oxidative damage while at the same time it could contribute to lower their metabolic rates. But the more general relationship in all homeotherms is that between DBI and MLSP, not between DBI and metabolic rate, because the low DBI of birds does not fit with their very high metabolic rates. Undoubtedly, other factors must be responsible for the high metabolic activity of these last animals.

The influence of fatty acid unsaturation on the transition temperature, and hence in the membrane fluidity, is well known (42). Whereas strong increases in lipid fluidity are observed after introduction of the first double bonds to a saturated fatty acid, progressively smaller effects are observed after the introduction of additional double bounds. Thus, the change in PUFA composition from the highly unsaturated AA and DHA to the less unsaturated LA found in the present work in PtdCho and PtdEtn from long-lived animals may allow them to decrease their double bond content without greatly changing their membrane fluidity. The membrane fluidity is a parameter needed for a proper function of mitochondrial membrane proteins such as enzymes, ion pumps, or electron carriers (43,44).

Thus, it may be proposed that, during evolution, a low degree of fatty acid unsaturation in liver mitochondria may have been selected for in long-lived mammals in order to protect their tissues against oxidative damage while maintaining an appropriate environment for membrane function.

Faculty of Applied Biological Science, Hiroshima University, Higashihiroshima 739-8528, Japan

**ABSTRACT:** Two cDNA encoding red sea bream DE-1 and DE-2 phospholipases $A_2$ ($PLA_2$) were cloned from the hepatopancreas of red sea bream, *Pagrus (Chrysophrys) major*. The cDNA of DE-1 $PLA_2$ encoded a mature protein of 125 amino acid residues with an apparent signal peptide of 20 residues and propeptide of 5 residues, and that of DE-2 $PLA_2$, a mature protein of 126 amino acid residues with an apparent signal peptide of 17 residues and propeptide of 6 residues. Comparison of the predicted amino acid sequences for mature DE-1 and DE-2 $PLA_2$ showed that both proteins contain 14 cysteines including Cys 11 and 77 and a pancreatic loop, which are commonly conserved in group IB $PLA_2$; however, the identity in amino acid sequence between DE-1 and DE-2 $PLA_2$ was low (47%). A previous report concerning the cDNA cloning of red sea bream gill G-3 $PLA_2$ and the present results represent the first cloning and sequencing of three distinct isoforms of group IB $PLA_2$ in a single fish species, red sea bream. Reverse transcription-polymerase chain reaction analysis showed that DE-1 $PLA_2$ mRNA was expressed in the hepatopancreas, pyloric ceca, intestine, spleen, gonad, stomach, and kidney, whereas gill G-3 $PLA_2$ mRNA was expressed only in the gills and gonad. The expression of DE-2 $PLA_2$ mRNA was detected in all of the tissues analyzed. These results indicate that three distinct isoforms of group IB $PLA_2$, DE-1 and DE-2 $PLA_2$ in hepatopanceas and gill G-3 $PLA_2$, are expressed in a tissue-specific manner in red sea bream.

Paper no. L8702 in *Lipids 36,* 499–506 (May 2001).

Phospholipase $A_2$ (phosphatide 2-acyl hydrolase, EC 3.1.1.4) ($PLA_2$) comprises a diverse family of enzymes that catalyze the hydrolysis of a fatty-acyl ester bond at the *sn*-2 position of glycerophospholipids to liberate free fatty acids and lysophospholipids. $PLA_2$ plays a central role in cellular processes as diverse as phospholipid digestion and metabolism, host defense, and signal transduction (1–3). Secretory $PLA_2$ ($sPLA_2$) are $Ca^{2+}$-dependent, low molecular mass enzymes (13–18 kDa) with five to eight disulfide bridges and a broad specificity for the phospholipid headgroup and fatty acids (3). At present, they are classified into six groups, I, II, III, V, IX and X, depending on the primary structure characterized by the number and positions of cysteine residues (2). Group IB $PLA_2$ has been referred to as pancreatic-type $PLA_2$ because it is abundant in the pancreatic juice in many mammals (4,5). However, group IB $PLA_2$ mRNA and protein have been recently found in nondigestive organs, including the spleen, lung, kidney, and ovary (6–16). The discovery of specific receptors for group IB $PLA_2$ from various mammalian tissues and cells has led to the notion that group IB $PLA_2$ evokes various biological responses by binding to the receptor in addition to its digestive function (17–19). This implies a physiological role for group IB $PLA_2$ in nondigestive tissues and cells, in addition to the function of digestive lipolysis in the digestive system.

Compared with the amount of information available on mammalian group IB $PLA_2$, little is known about the primary structure and enzymology of fish $PLA_2$. $PLA_2$ has been partially purified or purified from rainbow trout *(Salmo gairdneri)* liver (20,21) and cod *(Gadus morhua)* muscle (22,23), but its primary structure has not yet been determined. Zambonino Infante and Cahu (24) recently obtained a cDNA clone encoding group IB $PLA_2$ from seabass *(Dicentrarchus labrax)* and found that the mRNA level of $PLA_2$ in seabass larvae increased in culture with diets containing higher lipid levels. Previously, we detected $PLA_2$ in the pancreatic acinar cells and secretory materials of certain epithelial cells in the pyloric ceca of red sea bream, by immunohistochemical analysis using an antiserum against *Naja naja* venom $PLA_2$ (25). We have further purified six low molecular weight $Ca^{2+}$-dependent $PLA_2$ from the pyloric ceca (26), hepatopancreas (27,28) and gills (29), and classified hepatopancreas DE-1 and DE-2 $PLA_2$ and three gill G-1, G-2 and G-3 $PLA_2$ as group I $PLA_2$, based on the analysis of N-terminal amino acid sequence and enzyme properties. In addition, we have very recently cloned a cDNA encoding red sea bream gill G-3 $PLA_2$ and classified gill G-3 $PLA_2$ as a group IB $PLA_2$, based on the amino acid sequence deduced from nucleotide sequence of the cDNA (29). On the other hand, the primary structure of red sea bream hepatopancreas DE-1 and DE-2 $PLA_2$ remains to be established. In the present paper, we describe the cloning and sequencing of the cDNA for red sea bream hepatopancreas DE-1 and DE-2 $PLA_2$ as well as the three distinct isoforms that exist in a single fish species, red sea bream. We further investigated the distribution of mRNA for hepatopancreas DE-1, DE-2 $PLA_2$, and gill G-3 $PLA_2$ in various tissues by reverse transcription-polymerase chain reaction (RT-PCR) to better understand the structure–function relationship of the three isoforms.

[1]The sequences of DE-1 and DE-2 $PLA_2$ and β-actin presented in this article have been submitted to DDBJ/EMBL/GenBank with accession numbers AB050632, AB009286, and AB050670, respectively.

## MATERIALS AND METHODS

*Extraction of poly (A)$^+$ RNA.* The hepatopancreas and other tissues were removed immediately from freshly killed red sea bream and were stored in liquid nitrogen. Total RNA was extracted from the hepatopancreas using Isogen (Nippon Gene, Tokyo, Japan), and poly (A)$^+$ RNA was isolated using Oligotex-dT30 Super (Roche Japan, Tokyo, Japan), according to the manufacturer's protocol.

*cDNA amplification of DE-2 PLA$_2$.* Primers P-1 (5′-GC(A/G/C/T)TT(A/G/C/T)AATCAGTTTTG(A/G/C/T)CA-GATGAT-3′) and P-2 (5′-CGGTCGCAGTTGCAGATGAA-3′) were derived from possible cDNA sequences corresponding to a part of the amino acid sequence of red sea bream hepatopancreas DE-2 PLA$_2$ (28), ALNQFRQM (1st–8th in Fig. 1), and that of the conserved amino acid sequences of mammalian pancreatic PLA$_2$ (30), FICNCD (96th–101th in Fig. 3), respectively. Hepatopancreas total RNA (1 μg) was reverse-transcribed using P-2 primer, 1 mM deoxynucleoside triphosphate (dNTP) and 0.25 units of Rous-associated virus (RAV)-2 reverse transcriptase (Takara, Tokyo, Japan) in a reaction buffer [50 mM Tris-HCl, 75 mM KCl, 8 mM $MgCl_2$, 10 mM dithiothreitol (DTT), pH 8.3] at 50°C for 15 min, and then denatured at 99°C for 5 min. After the addition of P-1 primer and 2.5 units of Taq DNA polymerase (Takara) to the reaction buffer (10 mM Tris-HCl, 50 mM KCl, 1.5 mM $MgCl_2$, pH 8.3), PCR was carried out for 28 cycles of 30 s denaturation at 94°C, 30 s annealing at 60°C, and 90 s extension at 72°C. Then the PCR product was purified with 2% agarose gel and sequenced. From the nucleotide sequence of the internal cDNA, the new primers P-3 [5′-CTAG-GATCCGCAATAGCAGCCATAGTCAGC-3′, complementary to nucleotides (nt) 136–159 in Fig. 1], P-4 (5′-CATCT-GTCCAGATCATCCACGGGTGTG-3′, complementary to nt 174–200 in Fig. 1), and P-5 (5′-CTGTCTAGATGCTGC-CAAGTGCACGA-3′, identical to nt 196–215 in Fig. 1) were designed for 5′- and 3′-end amplifications. The 5′RACE (rapid amplification of cDNA ends) method was performed using 5′-AmpliFINDER™ RACE Kit (Clontech, Palo Alto, CA). For 5′-end amplification of PLA$_2$ cDNA, a single-stranded cDNA was synthesized with 2 μg of red sea bream hepatopancreas poly (A)$^+$ RNA, 25 units of avian myeloblastosis virus (AMV) reverse transcriptase, and primer P-4. The resulting 5′-end PLA$_2$ cDNA was ligated with an AmpliFINDER anchor using T4 RNA ligase and was then amplified with 10 mM dNTP, P-3 primer, AmpliFINDER anchor primer, and 2.5 units of AmpliTaq DNA polymerase in a reaction buffer (10 mM Tris-HCl, 50 mM KCl, 2 mM $MgCl_2$, 0.1% (wt/vol) gelatin, pH 8.3). For PCR, 28 cycles of 45 s denaturation at 94°C, 45 s annealing at 60°C, and 2 min extension at 72°C were carried out. Then the PCR product was separated on 1% agarose gel, and the DNA of expected size was isolated and sequenced. For 3′-end amplification of PLA$_2$ cDNA, red sea bream hepatopancreas total RNA (1 μg) was used to prepare first-stranded cDNA with an RNA PCR kit (Takara), employing 10 mM dNTP, Oligo $(dT)_{20}$ adaptor primer (Takara), and 20 units of Moloney murine leukemia virus (MMLV)reverse transcriptase. The resulting dT primed single-stranded cDNA was amplified with 2.5 units of Taq polymerase (Takara), Oligo $(dT)_{20}$ adaptor primer, and P-1 primer as described above. After the first PCR, the products were used as a template for the second PCR. The primers used in the second PCR were P-5 primer, Oligo $(dT)_{20}$ adaptor primer, and 0.5 units of Ex Taq polymerase (Takara), and the PCR conditions were the same as those used in the first PCR. Then the PCR product was separated and sequenced.

*cDNA amplification of DE-1 PLA$_2$.* Primers P11, 5′-TGG-CA(A/G)TT(C/T)GGIAA(C/T)ATGATICA-3′, and P2a, 5′-GC(A/G)GCCTT(C/T)CTGTCGCACTC(A/G)CA-3′,were derived from possible cDNA sequences corresponding to a part of the amino acid sequence of red sea bream hepatopancreas DE-1 PLA$_2$ (28), WQFGNMIQ (3rd–10th), and that of conserved amino acid sequences of mammalian pancreatic PLA$_2$ (30) and red sea bream DE-2 PLA$_2$, CECDRKAA (98th–105th in Fig. 1), respectively. The cDNA amplification of DE-1 PLA$_2$ by PCR was performed essentially as described previously (29). One microgram of red sea bream hepatopancreas poly (A)$^+$ RNA was used to prepare first-stranded cDNA with an RNA PCR kit (Takara) employing 20 units of MMLV reverse transcriptase. An internal cDNA fragment encoding PLA$_2$ was generated by PCR from first-stranded cDNA of red sea bream hepatopancreas using primers P11 and P2a, 0.5 mM dNTP, and 1.25 units of *Pyrococcus kodakaraensis* KOD1 (KOD Dash) (Toyobo, Tokyo, Japan) in a reaction buffer (20 mM Tris-HCl, 7.5 mM DTT,1.8 mM $MgCl_2$, pH 8.3). After an initial denaturation for 160 s at 94°C, 30 cycles of amplification were carried out with 30 s denaturation at 94°C, 10 s annealing at 58°C, and 30 s extension at 74°C. Then the PCR product was separated on 2% agarose gel, and the DNA of an expected size was isolated and sequenced. From the determined nucleotide sequence of the internal cDNA, new primers AP11 (5′-GGAAGGTCAGCGACAGCCGTGCATCCAGG-3′, complementary to nt 247–275 in Fig. 2) and P15 (5′-GACGTG-GATGCGTGCTGTAAGG-3′, identical to nt 190–211 in Fig. 2) were designed for 5′- and 3′-end amplifications, respectively. First-stranded and second-stranded cDNA were synthesized with 1 μg of red sea bream hepatopancreas poly (A)$^+$ RNA and Marathon cDNA Amplification kit (Clontech) according to the manufacturer's instruction. The resulting second-stranded cDNA was precipitated and ligated to a Marathon cDNA adaptor using T4 DNA Ligase for 40 min at room temperature. The 5′-end amplification of PLA$_2$ cDNA was carried by PCR with adaptor-ligated double-stranded cDNA, adaptor primer (5′-CCA TCCTAA TAC GAC TCA CTA TAG GGC-3′), AP11 primer, and 1.25 units of KOD Dash (Toyobo) in the above reaction buffer. PCR conditions were: an initial denaturation for 160 s at 94°C, followed by 30 cycles of amplification, with 30 s denaturation at 94°C, 10 s annealing at 58°C, and 30 s extension at 74°C. The resulting PCR products were subcloned into pGEM-T vector (Promega, Madison, WI) and transformed into JM109 cells,

and positive clones were selected on LB/ampicillin/IPTG/X-Gal plates according to the manufacturer's protocol. Plasmid DNA was purified from positive clones with QIAprep Spin Miniprep Kit (Qiagen, Tokyo, Japan) and sequenced. For 3′-end amplification of $PLA_2$ cDNA, PCR was carried out with adaptor-ligated double-stranded cDNA, adaptor primer, P15 primer, and 1.25 units of KOD Dash, and the resulting PCR products were subcloned into pGEM-T vector as described above and sequenced.

*Sequencing of PCR products.* The sequences of DNA fragments were determined with an Applied Biosystems 373A DNA sequencer using the Dye terminator cycle sequencing kit (PerkinElmer, Norwalk, CT), according to the manufacturer's protocol.

*RT-PCR.* Total RNA was isolated from the hepatopancreas, pyloric ceca, intestine, spleen, gill, gonad, heart, brain, stomach, kidney, and muscle of three fishes (200 g in body weight) using Isogen. Three micrograms of total RNA was used as the template to synthesize the first-stranded cDNA using oligo $(dT)_{20}$-M4 adaptor primer (5′-GTTTTCCCAGTCACGACTTTTTTTTTTTTTTTTTTTT-3′) and MMLV reverse transcriptase, RNase H Minus (Point mutant) (Promega). The cDNA fragments containing coding and noncoding regions of DE-1, DE-2, and gill G-3 $PLA_2$ cDNA were amplified by PCR from the first-stranded cDNA. The primers used were: DE-1 $PLA_2$, 5′-GCCTTATGGCAGTTTGGGAACA-3′ (identical to nt 76–97 in Fig. 2) and 5′-CTCTAACTTCAACAAATCAGG-3′ (complementary to nt 540–560 in Fig. 2); DE-2 $PLA_2$, 5′-GCACTCAACCAGTTCAGACAG-3′ (identical to nt 70–92 in Fig. 1) and 5′-TAGTAGGGAATGATGGATGGC-3′ (complementary to nt 572–592 in Fig. 1); gill G-3 $PLA_2$ (29), 5′-GCTATATGGCAGTTTGGGGACA-3′ (identical to nt 73–94) and 5′-ATGCTGAACTGATTGGACACA-3′ (complementary to nt 1009–1029). A pair of primers (5′-CGGGATCCACTACCTCATGAAGATCCTG-3′ and 5′-CCGCTCGAGTTGCTGATCCACATCTGCTG-3′) specific for red sea bream heart β-actin gene (DDBJ, accession number AB050670) was used for amplifying a 478 base pair (bp) fragment of red sea bream β-actin as an internal control. PCR conditions were: an initial denaturation for 2 min at 94°C, followed by 35 cycles of amplification, with 30 s denaturation at 94°C, 5 s annealing at 56°C for DE-1 and DE-2 $PLA_2$ and at 60°C for gill G-3 $PLA_2$, and 10 s extension at 74°C. The reaction products were electrophoresed on a 1% agarose gel.

## RESULTS

*Isolation and characterization of cDNA clones for DE-1 and DE-2 $PLA_2$.* Total RNA and poly $(A)^+$ RNA were prepared from the hepatopancreas of red sea bream. Primers for PCR were designed according to the amino-terminal amino acid sequence of purified hepatopancreas DE-2 $PLA_2$ and the highly conserved amino acid sequences among mammalian pancreatic $PLA_2$. A full-length cDNA clone was isolated by RT-PCR and RACE methods. The nucleotide sequence of the DE-2 $PLA_2$ cDNA included a 447 bp open reading frame that encoded a prepropeptide of 23 amino acids, followed by a mature protein of 126 amino acids (Fig. 1). The calculated molecular mass and isoelectric point of the mature protein were 14,422 Da and 4.16, respectively. The sequence AATAAA, which is the conserved sequence of a polyadenylation signal, was found 23 bp upstream of the poly A tail. The nucleotide sequence of the DE-1 $PLA_2$ cDNA included a 450 bp open reading frame that encoded a putative prepropeptide and mature protein of 25 and 125 amino acids, respectively (Fig. 2). The calculated molecular mass and isoelectric point of the mature protein were 13,634 Da and 5.63, respectively. The 3′-noncoding region contained two putative polyadenylation signals located 17 and 34 bp upstream of the poly A tail. The nucleotide sequences of DE-1 and DE-2 $PLA_2$ encoded no putative sites of N-glycosylation (Asn-X-Ser/Thr, where X is any amino acid) (Figs. 1 and 2).

**FIG. 2.** Nucleotide and deduced amino acid sequences of red sea bream hepatopancreas DE-1 $PLA_2$ (DE-1 $PLA_2$). The predicted prepro-segment is boxed and a possible initiator methionine is shown in **bold**. The putative polyadenylation signals are underlined and shown in **bold**. An asterisk shows the termination codon.

and prepropeptide of red sea bream hepatopancreas DE-1 and DE-2 $PLA_2$ with the sequences of red sea bream gill G-3 $PLA_2$, seabass *(D. labrax)* $PLA_2$, human and porcine group IB $PLA_2$, and *N. naja atra* group IA $PLA_2$ are presented in Figures 3 and 4, respectively (6,24,29,31,32). In amino acid sequence, DE-1 and DE-2 $PLA_2$ have characteristics in common with mammalian pancreatic type, group IB $PLA_2$, including the presence of Cys11 and 77 and the alignment of other Cys residues; residues of N-terminal helix Gln4, Phe5, and Ile9, and the presence of the absolutely conserved active-site His48, Tyr52, Tyr73, and Asp101; the "pancreatic loop" of residues 63–67 that are conserved in group IB $PLA_2$; and the conserved sequence of the calcium-binding segment Tyr25-Gly35, except for the substitution of Trp for Tyr 28 in DE-1 $PLA_2$ (Fig. 3). Insertion of lysine doublet at positions 82 and 83 was found in DE-2 and seabass $PLA_2$. The degree of identity for amino acid sequence between red sea bream hepatopancreas DE-1 and DE-2 $PLA_2$ was low (47%) (Table 1). DE-2 PLA2 shows high identity to gill G-3 $PLA_2$ (65%), and DE-1 $PLA_2$ shares higher identity to seabass $PLA_2$ (87%). SignalP computer analysis (33) for the potential cleavage positions in the signal sequence suggested that DE-1 and DE-2 $PLA_2$ contain five and six residues of propeptide preceding the mature enzyme, respectively (Fig. 4). In addition, signal peptide sequences of DE-1 and DE-2 $PLA_2$ were homologous to those of gill G-3 and seabass $PLA_2$, respectively. A phylogenetic tree was derived from an alignment of known protein sequences between fish $PLA_2$ and secretory $PLA_2$, using the CLUSTAL W program (34) and Tree view (35). The sequences of mouse group IIA, IIC, IID, IIE, IIF and V $PLA_2$, and rat group X $PLA_2$ were obtained from the DNA Data Bank of Japan. The others are the following: porcine (31), cow (36), dog and rat (37), human (38), guinea pig (39), horse (40), and rabbit (41) pancreatic group IB $PLA_2$, *Oxyuranus scuttus scutatus* OS 1 group IB″ $PLA_2$ and OS 2 group IA $PLA_2$ (42), *Notechis scutatus scutatus* II-1 and II-5 (43,44), *Pseudochis australis* (45), *Pseudonaja texistilis* (46), *Haemachatus hemachatus* (47), *N. melanoleuca* DE II and DE III (48,49), *N. naja naja* (50), *N. naja atra* (32) and *N. naja kaouthia* (51) group IA $PLA_2$, and *Bitis gabonica* group IIB $PLA_2$ (52). Subdivision of snake venom and mammalian group I and group II $PLA_2$ shown in Figure 5 are based on the proposals of Danse *et al.* (42) and Valentin *et al.* (15). This tree shows that fish $PLA_2$ were placed in the branch of mammalian group IB $PLA_2$ but were separated into two subgroups, red sea bream DE-1 and gill G-3 $PLA_2$, and DE-2 and seabass $PLA_2$, respectively. DE-2 and seabass $PLA_2$ are more distantly related to mammalian group IB $PLA_2$ than DE-1 and gill G-3 $PLA_2$.

*RT-PCR.* The mRNA expressions of hepatopancreas DE-1 and DE-2 $PLA_2$ and gill G-3 $PLA_2$ were compared among various tissues of red sea bream by RT-PCR. As shown in Figure 6, amplification of β-actin mRNA produced a band of 478 bp, providing a positive control. The expected cDNA of DE-1 $PLA_2$ (483 bp) was amplified in the hepatopancreas, pyloric ceca, intestine, gonad, spleen, stomach, and kidney. The DE-2 $PLA_2$ cDNA (522 bp) was detected in the hepatopancreas, pyloric ceca, intestine, spleen, gill, gonad, heart, brain, stomach, kidney, and muscle, suggesting that this $PLA_2$ isoform is ubiquitously expressed. On the other hand, gill G-3 $PLA_2$ (957 bp) was expressed only in the gills and gonad.

**TABLE 1**
**Identity (%) of Amino Acid Sequence in Mature Protein Among Fish, Mammalian, and Snake Venom Group I Phospholipase $A_2$ ($PLA_2$)[a]**

| Group I $PLA_2$ | DE-2 | G-3 | Seabass | pGIB | nGIA |
|---|---|---|---|---|---|
| DE-1 | 46.7 | 64.5 | 47.5 | 48.4 | 48.4 |
| DE-2 | | 54.5 | 87.3 | 54.0 | 48.8 |
| G-3 | | | 54.5 | 53.2 | 48.7 |
| Seabass | | | | 57.3 | 47.2 |
| pGIB | | | | | 52.8 |

[a]DE-1, red sea bream hepatopancreas DE-1 $PLA_2$; DE-2, red sea bream hepatopancreas DE-2 $PLA_2$; G-3, red sea brim gill G-3 $PLA_2$; seabass, seabass group 1B $PLA_2$; pGIB, porcine pancreatic group IB $PLA_2$; nGIA, *Naja naja naja* venom group 1A $PLA_2$.

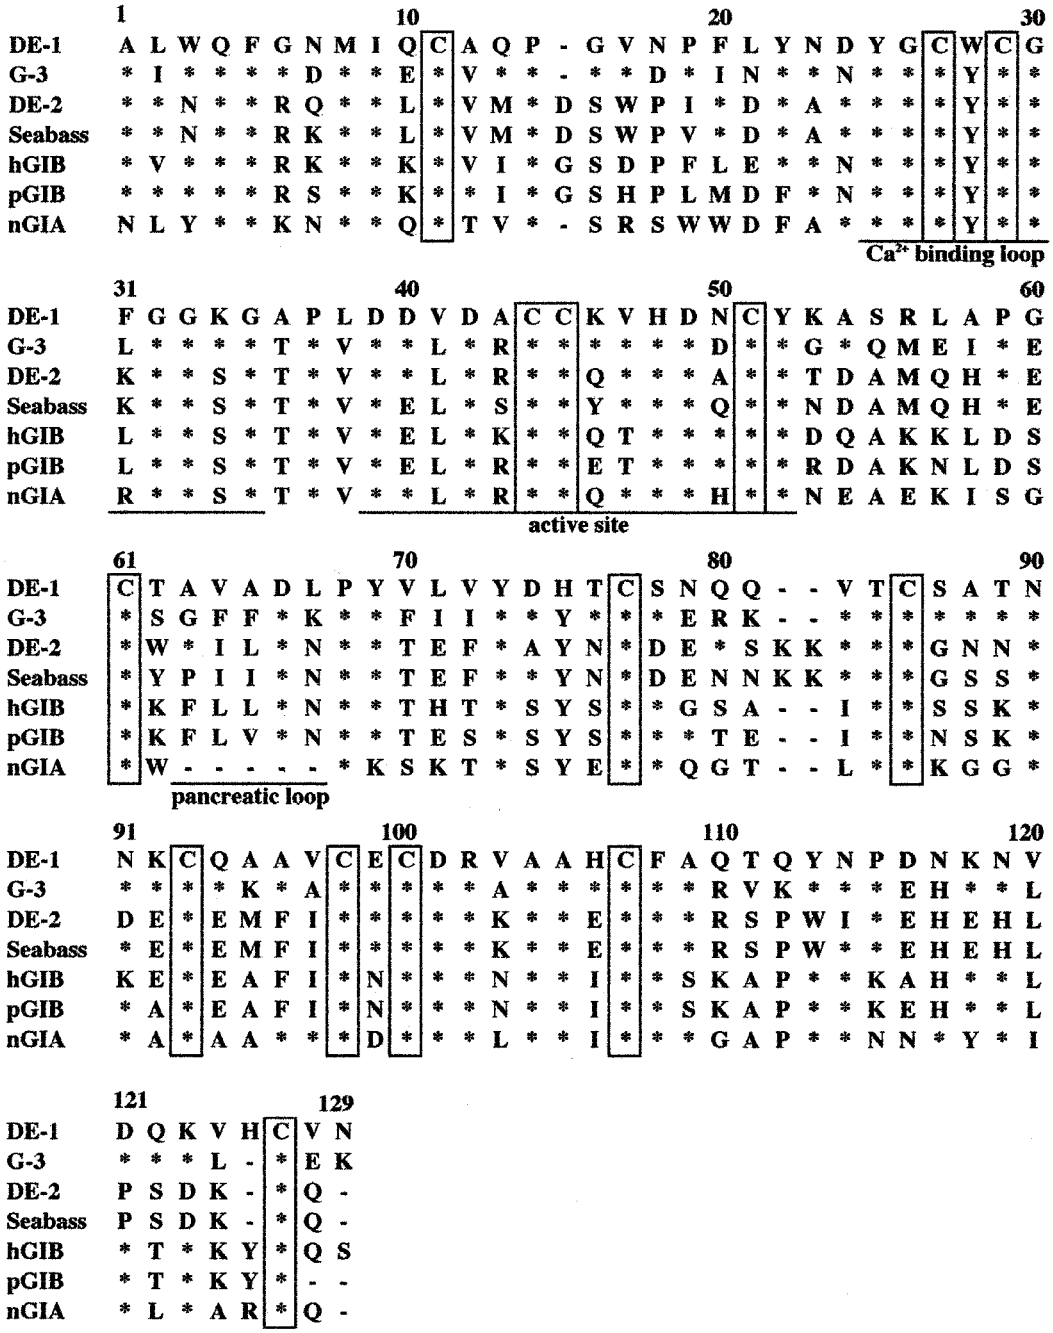

**FIG. 3.** Alignment of the amino acid sequences of red sea beam hepatopancreas DE-1 and DE-2 $PLA_2$, gill G-3 $PLA_2$ and seabass $PLA_2$ with mammalian and snake venom group I $PLA_2$. Sequences of mature $PLA_2$ proteins are shown: DE-1, red sea bream hepatopancreas DE-1 $PLA_2$; DE-2, red sea bream hepatopancreas DE-2 $PLA_2$; G-3, red sea bream gill G-3 $PLA_2$; seabass, seabass group IB $PLA_2$; hGIB, human pancreatic group IB $PLA_2$; pGIB, porcine pancreatic group IB $PLA_2$; nGIA, *Naja naja atra* venom group IA $PLA_2$. Asterisks indicate the amino acid residues identical to those of red sea bream hepatopancreas DE-1 $PLA_2$. Cysteines that are conserved among all $PLA_2$ are indicated in boxes.

Thus, the three distinct isoforms of red sea bream group IB $PLA_2$, DE-1, DE-2 and G-3 $PLA_2$, were expressed in a tissue-specific manner.

## DISCUSSION

Group I $PLA_2$ include mammalian pancreatic $PLA_2$ and those forms from elapid and hydrophid snake venoms. This group possesses 14 cysteines including a disulfide bridge formed by Cys 11 and 77 and can be further subdivided to group IA and group IB $PLA_2$, based on the presence or absence of the pancreatic loop (30,42). In a previous report, we showed that red sea bream hepatopancreas contains two enzymatically distinct group I $PLA_2$ isoforms, DE-1 and DE-2 $PLA_2$ (28). In the present study, we reported the complete amino acid sequences of red sea bream hepatopancreas DE-1 and DE-2 $PLA_2$, as deduced from their cDNA sequences. From the comparison of amino acid sequences of mature mammalian and snake

**FIG. 4.** Alignment of amino acid sequences in signal peptides and propeptides of red sea beam hepatopancreas DE-1 and DE-2 $PLA_2$, gill G-3 $PLA_2$, and seabass $PLA_2$ with mammalian and snake venom group I $PLA_2$. The potential cleavage site of the signal peptidase is indicated with a question mark. For abbreviations see Figure 3.

venom group I $PLA_2$, DE-1 and DE-2 $PLA_2$ were found to contain 14 cysteines including Cys 11 and Cys 77 and a pancreatic loop of residues 63–67, which are commonly conserved in group IB $PLA_2$ (Fig. 3). In addition, both DE-1 and DE-2 $PLA_2$ are predicted to have five and six propeptides preceding the mature protein, respectively (Fig. 4). These results indicate that red sea bream hepatopancreas DE-1 and DE-2 $PLA_2$ belong to the mammalian pancreatic type, group IB $PLA_2$, similar to red sea bream gill G-3 $PLA_2$ (1). This work and a previous report (1) represent the first cloning and sequencing of three distinct isoforms of group IB $PLA_2$ in a single fish species.

From the results of phylogenetic tree, fish $PLA_2$ were classified into the branch containing mammalian group IB $PLA_2$; however, they were further divided into two subgroups, DE-1 and gill G-3 $PLA_2$, and DE-2 and seabass $PLA_2$, respectively. In addition, signal peptide sequences of DE-1 $PLA_2$ and DE-2 $PLA_2$ are also homologous to those of gill G-3 $PLA_2$ and seabass $PLA_2$, respectively. As DE-2 and seabass $PLA_2$ are more distantly related to mammalian group IB $PLA_2$ than DE-1 and gill G-3 $PLA_2$, a duplication event would have occurred to generate DE-1 and gill G-3 $PLA_2$ and another subgroup, DE-2 and seabass $PLA_2$, similar to mammalian group IB $PLA_2$.

From the result of RT-PCR analysis, both DE-1 and DE-2 $PLA_2$ were expressed in digestive tissues such as the hepatopancreas, pyloric ceca, and intestine. In mammals, pancreatic type group IB $PLA_2$ were synthesized as the prepro-$PLA_2$ and were processed with signal peptidase in the rough

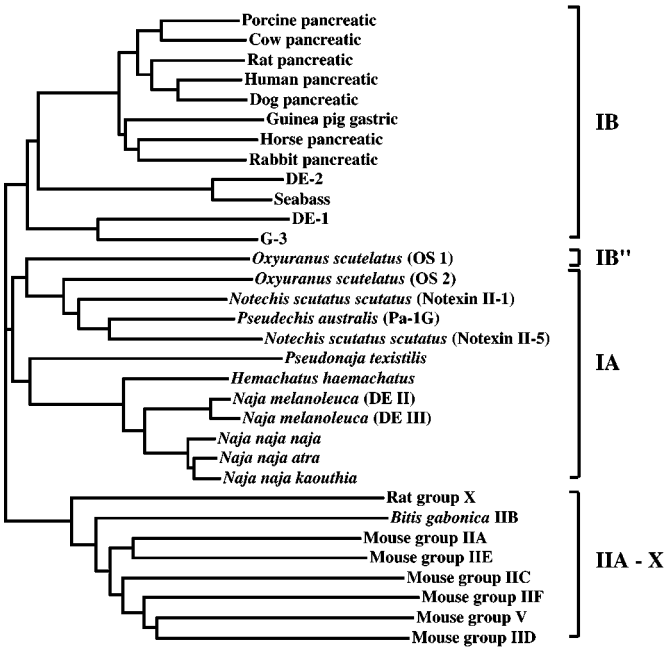

**FIG. 5.** Phylogenetic tree of fish group IB $PLA_2$, and mammalian and snake venom secretory $PLA_2$. $PLA_2$ belonging to the same group are denoted as IB, IB″, IA, and IIA-X, as described in the text.

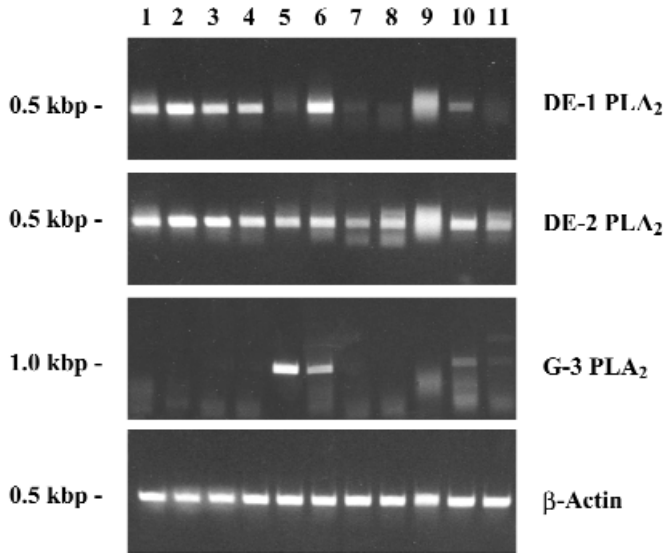

**FIG. 6.** Reverse transcription-polymerase chain reaction (RT-PCR) analysis for the tissue distribution of hepatopancreas DE-1 and DE-2 $PLA_2$ and gill G-3 $PLA_2$. Total RNA from various tissues of red sea bream were used as templates for RT-PCR. DE-1, DE-2 and G-3 $PLA_2$ were amplified with a single round of PCR as described in the Materials and Methods section. β-Actin was used as an internal standard. The calculated size of the transcript detected is indicated at the left. 1, Hepatopancreas; 2, pyloric ceca; 3, intestine; 4, spleen; 5, gill; 6, gonad; 7, heart; 8, brain; 9, stomach; 10, kidney; 11, muscle.

endoplasmic reticulum of pancreatic acinar cells (5). They were then stored as an inactive proPLA$_2$ in the zymogen granules. After being secreted in the intestinal lumen, proPLA$_2$ was activated by limited tryptic proteolysis and digest dietary phospholipids. As described above, red sea bream hepatopancreas DE-1 and DE-2 PLA$_2$ have prepro sequences; both preproPLA$_2$ may be processed and secreted in the digestive tract from the hepatopancreas, pyloric ceca, intestine, and stomach, similar to mammalian pancreatic group IB PLA$_2$. Red sea bream hepatopancreas DE-1 and DE-2 PLA$_2$ were expressed also in the nondigestive tissues; DE-1 PLA$_2$ was expressed in the spleen and gonad, and DE-2 PLA$_2$ in spleen, gill, gonad, heart, brain, kidney, and muscle. These results may indicate that DE-1 and DE-2 PLA$_2$ have different physiological functions in the nondigestive tissues and cells of red sea bream, except for the digestion of dietary phospholipids. Mammalian group IB PLA$_2$ are expressed in spleen, lung, and gonad of human (14), rat (8), and mouse (15,16). At present, two main types of PLA$_2$ receptor, M-type and N-type, have been identified in mammals. Group IB PLA$_2$ elicits a variety of biological responses, including cell proliferation, cell migration, hormone release, and eicosanoid production by interacting with the M-type receptor in various tissues and cells (17,53). In addition, neurotoxic snake venom PLA$_2$ and bee venom PLA$_2$ are said to bind to the N-type receptor, which is abundantly distributed in the brain (19). From the above results, it is reasonable to consider that the PLA$_2$ receptor, reacted specifically to group IB PLA$_2$, exists also in red sea bream. However, it still remains unclear whether DE-1 and DE-2 PLA$_2$ express as a funtional enzyme in the above tissues. Although PLA$_2$ activity was detected in the spleen, gonad, heart, kidney, and muscle (29), we do not yet analyze the distribution of both enzymes in these tissues. In order to demonstrate the above question, it is necessary to investigate the distribution of DE-1 and DE-2 PLA$_2$ by immunoblotting and immunohistochemistry. We are now trying to make recombinant DE-1 and DE-2 PLA$_2$, for preparing monoclonal antibodies and for the analysis of PLA$_2$ receptor.

Gill G-3 PLA$_2$ was expressed only in the nondigestive tissues, gills, and gonad, as shown by RT-PCR analysis (Fig. 6). However, we had found previously that PLA$_2$ activity in the gills was extremely high compared with that in the gonad (29). In addition, gill PLA$_2$ was detected only in the gills, especially the mucous cells and pavement cells located on the surface of gill epithelia, by immunoblotting and immunohistochemistry using monoclonal antibody raised against gill PLA$_2$ (Uchiyama, S., Fujikawa, Y., Uematsu, K., Matsuda, H., Aida, S., and Iijima, N., unpublished data). These aspects indicate that gill PLA$_2$ is mainly expressed in the gills and the expression of gill PLA$_2$ is extremely low in the gonad.

**ABSTRACT:** Fifty-five triterpenoids consisting of 19 tetracyclic, 32 pentacyclic, and 4 incompletely cyclized triterpenoids, and 2 sterols, mostly isolated from various plant and fungal materials, were examined for their inhibitory effects on a purified human immunodeficiency virus type 1 (HIV-1) reverse transcriptase. Twenty triterpenoids and one sterol showed inhibitory effects with 50% inhibition concentration ($IC_{50}$) values less than 5.0 μM. Among these cycloartenol ferulate ($IC_{50}$ = 2.2 μM), 24-methylenecycloartanol ferulate (1.9 μM), lupenone (2.1 μM), betulin diacetate (1.4 μM), and karounidiol 29-benzoate (2.2 μM) inhibited most effectively. Some of the triterpenoids and sterols may be potential new lead compounds to find still more potent HIV-1 reverse transcriptase inhibitors.

Paper no. L8532 in *Lipids 36*, 507–512 (May 2001).

Reverse transcriptase (RT) is a key enzyme of the human immunodeficiency virus (HIV), catalyzing the RNA-dependent and DNA-dependent synthesis of double-stranded proviral DNA. Since the replicative cycle of HIV is interrupted by RT inhibitors, the inhibition of HIV RT is considered as a useful approach in the prophylaxis of acquired immunodeficiency syndrome (AIDS). Several nucleoside HIV RT inhibitors, including AZT (3′-azido-2′,3′-dideoxythymidine), DDC (2′,3′-dideoxycytidine), and DDI (2′,3′-dideoxyinosine), have been developed and are clinically used in AIDS patients (1). Furthermore, a number of natural (flavonoids, tannins, and alkaloids) and synthetic {tetrahydro-5-methylimidazo-[4,5,1-jk][1,4]benzodiazepin-2(1*H*)-one (TIBO) and piperazine derivatives} nonnucleoside-type compounds with diverse molecular structures have been reported as being HIV RT inhibitory (2–4). However, the efficiency of both nucleoside and nonnucleoside RT inhibitors is limited by the high rate of the virus mutation, which rapidly leads to the emergence of drug-resistant viral strains (5). Compounds possessing potent anti-HIV activity with novel structures and modes of action are urgently needed to add to the existing anti-HIV agents.

Abbreviations: AIDS, acquired immunodeficiency syndrome; DMSO, dimethylsulfoxide; DTT, dithiothreitol; HIV, human immunodeficiency virus; methyl-dTTP, methyl thymidine 5′-triphosphate; RT, reverse transcriptase; TPA, 12-*O*-tetradecanoylphorbol-13-acetate.

Triterpene alcohols (3-monohydroxy triterpenoids) and sterols occur in all major groups of organisms, from fungi to humans, accompanied by their oxygenated derivatives (6,7). These compounds constitute minor but ubiquitous components of our diet including edible fats and oils. In the course of our research on the pharmacological aspects of triterpenoids and sterols, we have demonstrated that various compounds of these classes possess considerable activity against 12-*O*-tetradecanoylphorbol-13-acetate (TPA)-induced inflammatory ear edema in mice and tumor promotion in mouse skin (8–13). In continuing our study, we were especially interested to evaluate the inhibitory effects on HIV-1 RT of various types of triterpenoids and sterols, since we recently found that oleanolic acid (**32**), an olanane-type triterpenoid, isolated from the methanol extract of *Salvia officinalis* (Labiatae) has HIV-1 RT inhibitory effect (14). In this paper, we report the inhibitory effect against HIV-1 RT of 55 triterpenoids with various structural types and two stigmastane-type sterols.

## MATERIALS AND METHODS

*Chemicals and materials.* HIV-1 RT was purchased from Seikagaku Co. (Osaka, Japan), methyl-[$^3$H] thymidine 5′-triphosphate (methyl-dTTP, specific activity: 1.63 TBq/mmol; radioactive concentration: 37 MBq/mL) from Amersham Pharmacia Biotech (Tokyo, Japan) and scintillation fluid Aquasol-2 from NEN Research Products (Boston, MA). Poly(rA), primer$(dT)_{15}$, and unlabeled dTTP were obtained from Sigma Aldrich Japan (Tokyo, Japan), and DEAE-cellulose paper discs (DE81, 2.3 cm) from Whatman International, Ltd. (Maidstone, England). Sources of the 55 triterpenoid and 2 sterol samples used in this study for the HIV-1 RT assay are shown in Table 1.

*Assay of HIV-1 RT activity.* Inhibitory activity was measured in a way similar to that described previously by Ono *et al.* (15). The reaction mixture consisted of 2.0 μL of 1 M Tris-HCl (pH 8.3), 0.4 μL of 1 M dithiothreitol (DTT), 1.5 μL of 2 M KCl, 0.3 μL of 1 M $MgCl_2$, 0.2 μL of 5 mg/mL poly(rA) · p$(dT)_{15}$, 1.0 μL of 3.7 MBq/mL methyl-[$^3$H]dTTP, 0.5 μL of 10 mM dTTP, 2.5 μL of glycerol, 1.6 μL of $H_2O$, and 10 μL of 5 U/mL HIV-1 RT. A test sample was dissolved in 0.2 mM dimethylsulfoxide (DMSO), and 20 μL of this solution was added to the reaction mixture in a final volume of

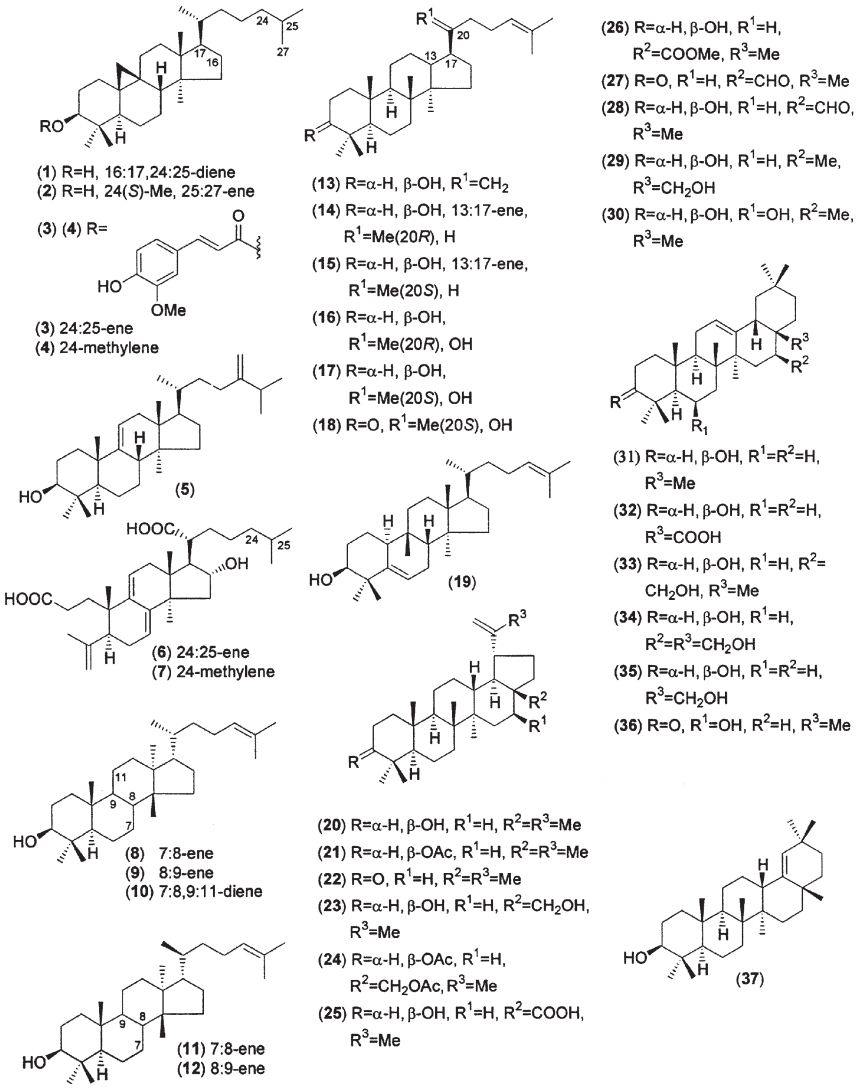
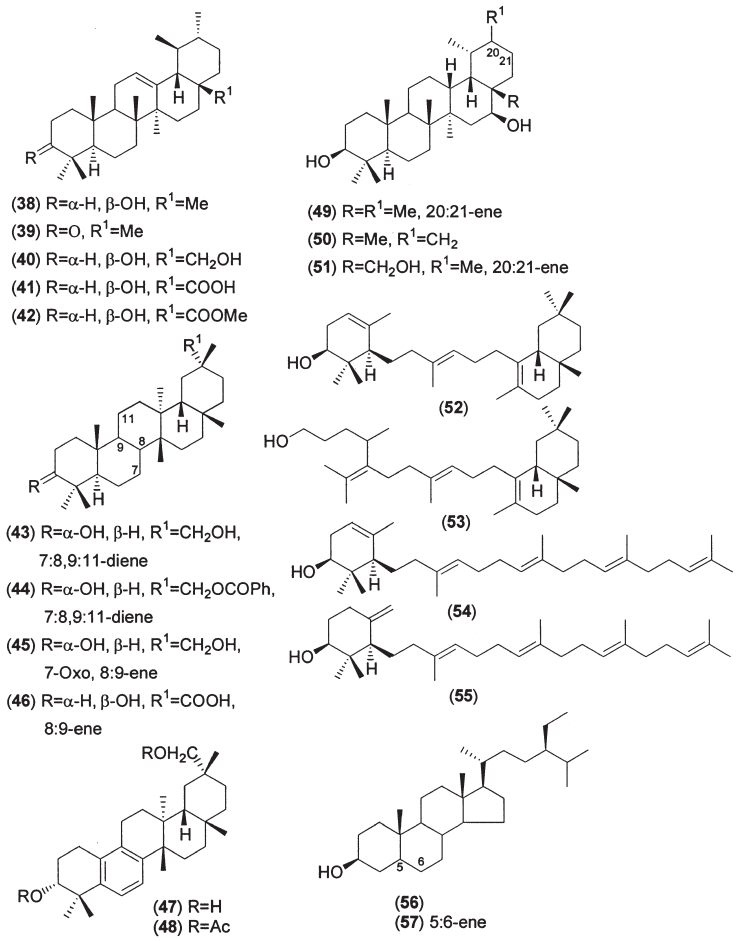


**SCHEME 1**

40 μL. The enzyme was added immediately prior to incubation. The reaction was allowed to proceed for 30 min at 37°C and terminated by immersion in ice and addition of 20 μL of 0.2 M EDTA·2Na. A portion (50 μL) of each assay was applied to DEAE-cellulose discs, kept at room temperature for 10 min, and washed batchwise with 5% $Na_2HPO_4$ (eight times), $H_2O$ (two times), 99% ethanol (two times), and diethyl ether (two times). The discs were dried, and their radioactivities were counted in a scintillation fluid.

The HIV-1 RT inhibition was measured as the inhibition



**SCHEME 1 (continued)**

of the incorporation of [$^3$H]-labeled substrate (dTTP) into a polymer fraction in the presence of a tested compound as follows:

$$\text{inhibition (\%)} = [1 - (\text{cpm test/cpm control})] \times 100 \qquad [1]$$

The control assay was performed by adding 0.2 mM DMSO containing no test sample, and its count was *ca.* 19,000 cpm. The assay was undertaken at the concentrations of 20, 10, 4, and 0.8 μg/mL for each sample, and the inhibition was the mean value from the duplicated experiments. The 50% inhibitory concentration ($IC_{50}$) values were calculated by interpolation from the linear regression curve.

## RESULTS AND DISCUSSION

Table 1 summarized the inhibitory effect against HIV-1 RT of 55 triterpenoids consisting of four cycloartanes (**1**–**4**), three lanostanes (**5**–**7**), three euphanes (**8**–**10**), two tirucallanes (**11**,**12**), six dammaranes (**13**–**18**), one cucurbitane (**19**), eleven lupanes (**20**–**30**), seven oleananes (**31**–**37**), five ursanes (**38**–**42**), six multifloranes (**43**–**48**), three taraxastanes (**49**–**51**), four incompletely cyclized triterpenoids (**52**–**55**), and two stigmastane-type sterols (**56**,**57**). Chemical structures of these triterpenoids and sterols are given in Scheme 1. Although seven (**2**, **7**, **18**, **34**, **36**, **55**, **57**) and eleven (**5**, **6**, **16**, **17**, **28**, **37**, **50**–**54**) compounds showed no or weak inhibitory effect [$IC_{50} \geq 45$ μM (20 μg/mL)], respectively, 20 triterpenoids, including oleanolic acid (**32**), and a sterol, stigmastanol (**56**), exhibited significant inhibitory effects with $IC_{50}$ smaller than 5.0 μM, among which cycloartenol ferulate (**3**) ($IC_{50}$ = 2.2 μM), 24-methylenecycloartanol ferulate (**4**) (1.9 μM), lupenone (**22**) (2.1 μM), betulin diacetate (**24**) (1.4 μM), and karounidiol 29-benzoate (**44**) (2.2 μM) were the most inhibitory compounds.

Whereas betulinic acid (**25**; $IC_{50}$ = 7.9 μM), a lupane-type triterpenoid, oleanolic acid (**32**; 3.1 μM) (14), and ursolic acid (**41**; 6.4 μM) were shown to possess potent inhibitory effect against HIV-1 RT in this and in our recent studies (14), some synthetic derivatives of **25** (4,16–21), **32** (19), and **41** (22) have been reported to show strong anti-HIV-1 activity by inhibiting HIV-1 replication in H9 lymphocyte cells (16–19,22) and in CEM 4 and MT-4 cells (20,21) without affecting HIV-1 RT (16–21) and protease activities (20,21). Mechanistic

studies have revealed that betulinic acid derivatives interfere with HIV-1 entry in the cells at a postbinding step (20,21). Several other triterpenoids have been described as antiviral compounds. Glycyrrhizin, an oleanane-type triterpenoid saponin, displays some limited activity against a whole range of viruses including HIV-1 (4,23). Salaspermic acid, a friedelane-type triterpenoid, and related compounds (24) and suberol, a $C_{31}$ lanostane-type triterpenoid (25), inhibit HIV-1 in H9 cells in the upper micromolar range. Triterpenoids **25**, **32**, and ursolic acid (**41**) (26), and ganoderic acids, which are lanostane-type triterpenoids from *Ganoderma lucidum* (27), inhibit HIV-1 protease activity. Nigranoic acid, an A-ring-seco-cycloartane triterpenoid, is one of the few examples evaluated for its HIV-1 RT inhibitory activity, although it shows low $IC_{50}$ value (74 μg/mL) (28).

Various types of triterpenoids, *viz.*, cycloartanes, euphanes, tirucallanes, dammaranes, and multifloranes, and a stigmastane-type sterol, in addition to triterpenoids of lupane-, oleanane-, and ursane-types, have been demonstrated in this study to possess potent HIV-1 RT inhibitory effect, and these triterpenoids and sterols might be new compounds to find still more potent HIV-1 RT inhibitors and anti-HIV-1 drugs although one should be cautious in extrapolating from cell-free enzymatic assays to the mode of action of these compounds in intact cells (29).

## ACKNOWLEDGMENT

The authors gratefully acknowledge support for this research by a grant "Research and Development of Nanoscience" from the Ministry of Education, Science, Sports and Culture to promote multidisciplinary research project.

# A Novel Sphingophosphonolipid Head Group 1-Hydroxy-2-aminoethyl Phosphonate in *Bdellovibrio stolpii*

**Yoko Watanabe[a], Masaharu Nakajima[b], Tsutomu Hoshino[c], Koka Jayasimhulu[d], Elwood E. Brooks[d], and Edna S. Kaneshiro[e,*]**

[a]Department of Medical Technology, School of Health Sciences, Faculty of Medicine, Niigata University, Niigata 951-8518, Japan, [b]Department of Analytical Chemistry, Niigata College of Pharmacy, Niigata 950-2081, Japan, [c]Department of Applied Biological Chemistry, Faculty of Agriculture, Niigata University, Ikarashi-2 Niigata 950-2181, Japan, and Departments of [d]Chemistry and [e]Biological Sciences, University of Cincinnati, Cincinnati, Ohio 45221

**ABSTRACT:** Members of the bacterial genus *Bdellovibrio* include strains that are free-living, whereas others are known to invade and parasitize larger Gram-negative bacteria. The bacterium can synthesize several sphingophospholipid compounds including those with phosphoryl bonds as well as phosphonyl bonds. In the present study, the dominant sphingophosphonolipid component was isolated by column chromatography, and the long-chain bases, fatty acids, and polar head groups were identified by thin-layer and gas–liquid chromatographic procedures. The definitive structural identity of the sphingolipid was established by nuclear magnetic resonance and mass spectrometry of hydrolysis products and the intact compound. The compound was identified as *N*-2′-hydroxypentadecanoyl-2-amino-3,4-dihydroxyheptadecan-1-phosphono-(1-hydroxy-2-aminoethane).

Paper no. L8697 in *Lipids 36,* 513–519 (May 2001).

Members of the genus *Bdellovibrio* are small, comma- or crescent-shaped bacteria, commonly found in soil. Although many species are free-living, most are characterized by their predatory behavior. They can attack other larger bacteria, and proliferate as parasites in the intraperiplasmic space of various Gram-negative species (1–5). Obligate and facultative parasitic strains have been reported. Much of the lipids in parasitically grown organisms are scavenged from the host bacterium, but the parasite synthesizes its own distinct array of lipids (2,3) and like eukaryotic cilia and flagella (6), the bacterial flagellar domain differs in lipid composition compared to the rest of the cell surface membrane (7). The free-living and facultative parasitic strains can be grown in the laboratory under axenic culture conditions, thus biochemical analysis of these organisms eliminates the potential of contamination by host lipids (5).

Sphingolipids have been reported in all groups of eukaryotic organisms thus far analyzed, and they occur in the membranes as phosphosphingolipids, glycosphingolipids, and inositolsphingolipids (8–20). Sphingolipids, their precursors and metabolic products (e.g., sphingosine, sphingosine-1-phosphate, and ceramide) play important roles in transmembrane signaling and appear to be important in mammalian cell proliferation, differentiation, aging, and apoptosis (21–24). There is evidence that sphingolipid metabolism within host cell membranes augments the ability for invasion by pathogens (25,26). It has been suggested that sphingolipids may play a role in the attack and invasion processes of *Bdellovibrio* (5).

Sphingolipids are not widely distributed among the prokaryotes (27,28), and have been mainly studied among organisms in the genus *Sphingomonas* (27). To date, there is a single report of sphingophosphonolipids in *Bdellovibrio*. Steiner *et al*. (5) compared the phospholipids of two strains of *B. stolpii (B. bacteriovorus)* to determine whether phospholipids in the predator cell membrane could play a role in the attack phase. Two strains, UKi2 (a facultative parasite) and UKi1 (a free-living strain derived from the same obligate parasite parent), were both grown axenically under the same culture conditions. Three sphingophospholipids were detected in UKi2 but not in UKi1. The most abundant of the three was designated as compound 9, and the other two, compounds 8 and 11. These components were identified as sphingolipids by their resistance to alkaline hydrolysis, and by several chromatographic properties. Based on reactions to differential hydrolysis, it was tentatively concluded that compound 11 was a sphingolipid with a phosphoryl bond, and this minor lipid component was not further characterized. The two major sphingolipids compounds 8 and 9 were tentatively identified as sphingophosphonolipids. $C_{17}$ dihydrosphingosine and phytosphingosine were identified as the long-chain bases (LCB) of compounds 8 and 9, respectively. Both contained a similar mixture of α-hydroxy fatty acids, dominated by a branched $C_{15}$ hydroxy fatty acid.

Phosphonolipids appear rare as naturally occurring compounds. Most reports of this group of lipids have been from studies of the ethanolamine glycerophosphonolipids and sphingophosphonolipids in the ciliated protozoa *Tetrahymena* and *Paramecium* (29–32). The discovery of sphingophosphonolipids in a bacterium was a novel and significant finding (5), hence it is important that definitive structural characterizations of these *Bdellovibrio* lipids be elucidated. present study, we obtained the definitive structural identity of the major *B. stolpii* sphingolipid component, compound 9 (5) employing mass spectrometry (MS) and nuclear magnetic resonance (NMR) spectroscopy.

## MATERIALS AND METHODS

*Organism. Bdellovibrio stolpii* (ATCC 27052) was the same strain previously analyzed for sphingolipids (5). It was grown axenically in 2-L flasks containing 660 mL of 1% (wt/vol) Bactopeptone and 0.3% (wt/vol) yeast extract (Difco, Becton Dickinson, MD). The cultures were grown at 30°C without shaking until stationary phase was achieved. Cultures were centrifuged at 10,000 × *g* for 5 min, and the cell pellet was washed with physiological saline and recentrifuged.

*Lipid extraction and purification of the major sphingolipid component.* The cell pellet was immediately extracted with chloroform/methanol (2:1, vol/vol) and stored at −35°C. The lipids from 18 L of culture were pooled, water (0.25 vol) was added to the extract, and the lower organic layer was recovered and evaporated using a rotary evaporator. The residue was dissolved in the minimum amount of $CHCl_3$/MeOH (2:1, vol/vol). The sample was placed in an ice bath, and acetone (3 vol) added. After standing overnight at 4°C, it was centrifuged, and the acetone-insoluble pellet containing the phospholipids was dissolved in $CHCl_3$.

Adsorption column chromatography of the phospholipid fraction was performed to isolate the major sphingophosphonolipid. The phospholipid fraction (approximately 1 g) in $CHCl_3$ was loaded onto a 1.5 × 30.0-cm glass column containing Iatrobeads (6RS-8060, Iatron Laboratories, Tokyo, Japan) and eluted with (i) 70 mL $CHCl_3$; (ii) 70 mL of $CHCl_3/CH_3OH$, 95:5; (iii) 70 mL $CHCl_3/CH_3OH$, 4:1; (iv) 140 mL $CHCl_3/CH_3OH$, 3:2; (v) 70 mL $CHCl_3/CH_3OH$, 2:3; (vi) 70 mL $CHCl_3/CH_3OH$, 1:4; (vii) 70 mL $CHCl_3/CH_3OH$, 1:9; and (viii) 70 mL $CH_3OH$. After thin-layer chromatography (TLC) analysis of all the fractions, those containing the major sphingophosphonolipid were pooled and dried.

The sample was resuspended in *n*-propanol/*n*-propylamine/$H_2O$ (80:5:3, by vol), applied to a second Iatrobeads column, and the sphingophosphonolipids were eluted using the same solvent system. After analyzing each fraction by TLC, the fractions containing only the major sphingphosphonolipid were pooled and dried to approximately 0.5 mL. The purified sphingophosphonolipid was recrystallized from 5 mL of ethyl acetate/methanol (3:2, vol/vol). Approximately 200 mg of the purified sphingophosphonolipid were obtained from 54 L of bacterial cultures, representing approximately 2 kg wet wt of cells.

*Analysis of fatty acid, polar head group (PHG), and LCB.* The purified sphingophosphonolipid was hydrolyzed with $CH_3OH/H_2O$/HCl (11:2.6:1, by vol) at 80°C overnight (11–13), and the fatty acid methyl esters (FAME) were extracted into *n*-hexane for analysis by gas–liquid chromatography (GLC) and MS. The remaining material was dried under $N_2$ and dissolved in approximately 2 mL $H_2O$. The pH was then adjusted to 10.0–11.0 (with 1 M NaOH), and the LCB were extracted into $CHCl_3$ and concentrated under $N_2$. The LCB were purified on an Iatrobeads column, eluting with $CHCl_3/CH_3OH/H_2O$/25% $NH_4OH$ (70:17.5:1.5:0.25, by vol). The LCB fractions were identified by TLC, pooled, and dried under $N_2$. The LCB was acetylated in $CH_3OH$/acetic anhydride (4:1, vol/vol) and analyzed by GLC–MS. Alternatively, it was converted to its *O*-trimethylsilyl (TMS) derivative with *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) (Tokyo Kasei Co., Tokyo, Japan) and analyzed. The acetylated TMS LCB derivative was subjected to GLC–MS analysis and compared with derivatized authentic dihydrosphingosine, sphingosine, and phytosphingosine (Sigma, St. Louis, MO).

The remaining water phase was neutralized with 1 M acetic acid, dried, redissolved in approximately 2 mL of $H_2O$; and the polar head group (PHG) was purified by cation exchange chromatography (Amberlite IR-120B). Ethanolamine- and phosphorus-positive fractions were pooled, lyophilized, and an aliquot was derivatized with BSTFA.

The ceramide moiety was obtained by treating the intact sphingophosphonolipid with HF (33). Fast-atom bombardment (FAB)-MS was obtained by the JEOL Company (Tokyo, Japan).

*TLC.* Phospholipids were separated by Silica Gel 60 high-performance TLC (HPTLC; Merck, Darmstadt, Germany) using $CHCl_3/CH_3OH/H_2O$ (60:35:8, by vol). After the solvent reached 5 cm from the top of the plate, it was dried, then re-developed with $CHCl_3/CH_3OH$/acetic acid (90:2:8, by vol). Development in the second dimension was with *n*-propanol/*n*-propylamine/$H_2O$ (80:15:5, by vol). The solvent system for LCB analysis was $CHCl_3/CH_3OH/H_2O$/25% $NH_4OH$ (70:17.5:1.5:0.25, by vol).

The PHG was analyzed by cellulose TLC (Avicel, Asahi-Kasei, Tokyo, Japan) using authentic 2-aminoethylphosphonic acid (2-AEP, Sigma) as standard. After one-dimensional development with either 88% phenol/$H_2O$ (4:1, vol/vol), isobutyric acid/$H_2O$/25% $NH_4OH$ (66:33:1, by vol), or butanol/acetic acid/$H_2O$ (5:3:1, by vol), plates were stained for ethanolamine (ninhydrin) and phosphorus (34).

*GLC–MS, FAB-MS, and liquid secondary ion MS (LSIMS) analysis.* The hydrolysis products were analyzed by GLC–MS as FAME, the PHG TMS, and the LCB N-acetylated TMS (11) using a Hewlett-Packard 5890 Series II GLC equipped with an HP-1 capillary column and interfaced with a 5971 mass selective detector. The initial 2-min column temperature of 100°C was increased at 10°C/min for 15 min and held at 250°C for 10 min. The helium carrier gas flow rate was 1.0 mL/min. The MS electron-impact (EI) source and transfer line temperatures were 280 and 190°C, respectively.

The underivatized ceramide was analyzed by FAB-MS on a JEOL MS700 mass spectrometer. 3-Nitrobenzyl alcohol was the matrix. Spectra were recorded in a positive ion mode at an accelerating voltage of 6.0 kV. The intact sphingophosphonolipid was analyzed by LSIMS on a Kratos MS-890 mass spectrometer (Kratos, Manchester, United Kingdom) in the positive ion mode. The sample on a glycerol matrix was bombarded with cesium ions, transferring a proton to the intact molecule.

*$^{31}P$, $^{13}C$, $^{15}N$, and $^{1}H$ NMR analysis of the PHG.* The PHG dissolved in $D_2O$ was analyzed by NMR spectroscopy (Bruker DMX600 spectrometer) by one- and two-dimensional (1-D and 2-D) analyses. Chemical shifts were estimated from the external TMS for proton and carbon, from 85% $H_3PO_4$ for $^{31}P$, and from 90% formamide (112.4 ppm) for $^{15}N$.

## RESULTS

*The phospholipid composition of* B. stolpii. The major phospholipid components of *B. stolpii* UKi2, identified by 2-D HPTLC, were phosphatidylethanolamine, phosphatidylglycerol, diphosphatidylglycerol, and three sphingophospholipids. The total phospholipid profile in organisms analyzed in the present study was similar to that reported in the earlier study of the UKi2 strain. After alkaline hydrolysis, three phosphorus-containing sphingolipids were left intact. The sphingolipid, with similar chromatographic properties as the component designated as compound 9 by Steiner *et al*. (5), was also identified as the dominant sphingolipid in this study.

*Analysis of hydrolysis products: N-linked fatty acids.* The alkali-stable, acid-labile amide-linked fatty acids in the purified sphingophosphonolipid preparation were analyzed as their methyl ester derivatives by GLC and quantified by integration of peak areas obtained by using a total ion current detector. Results were reported as retention time in min (wt%): 8.741 (3.4); 9.755 (3.8); 10.938 (89.6); 11.305 (3.3). By EI-MS, the molecular ion was observed at *m/z* 272. The fragmentation pattern resulting from cleavage between the C-1 and C-2 positions produced the dominant *m/z* 213 ion (Figs. 1,2). This indicated the presence of a hydroxyl group neighboring the carboxyl group. The structure of the major fatty acid in this preparation was shown by MS to be the straight-chained $C_{15}$ α-hydroxy fatty acid. The other FAME components were at too low a concentration for MS analysis. This sphingophosphonolipid, which had previously been isolated by TLC and analyzed for its fatty acid composition, had 68% iso-branched α-hydroxy $C_{15}$ fatty acid and 13% of an unbranched α-hydroxy-$C_{15}$ fatty acid (5). The apparent disparity can be explained by the large-scale column chromatographic procedures used in the present study. Since some fractions containing other sphingolipids were discarded, the isolated population was enriched with the molecular species with the straight-chain $C_{15}$ α-hydroxy fatty acid.

*Analysis of hydrolysis products: LCB.* The N-acetylated TMS-derivatized LCB fraction was analyzed by GLC and found to contain a single major component (not shown). The GLC-EI-MS analysis of the N-acetylated TMS derivative of the LCB ($C_{17}$ phytosphingosine) did not indicate the molecular ion, but an ion at *m/z* 546 corresponding to [$M^{+\cdot}$ – 15] typical of TMS derivatives (loss of a TMS methyl group). Other ions detected were *m/z* 456 (loss of trimethylsilanol), 387 (loss of $C_1$ and $C_2$ with the attached N-acetyl and the TMS), 286 [285 + H] ($C_4$ through $C_{17}$ including the silylated hydroxyl group at $C_4$), 276 ($M^{+\cdot}$ – 285), 218 (loss of the amino acyl group at $C_2$ from the *m/z* 276 ion), 187 (loss of *O*-TMS from *m/z* 276 ion), 174 ($C_1$ and $C_2$ with their derivatives), 132 ($C_1$ with its TMS group and $C_2$ with an $NH_2$ group), and 73 (TMS). The fragmentation pattern and the mass spectrum are typical of the derivatized phytosphingosine (11).

*Analysis of hydrolysis products: PHG.* The TMS derivative of the polar head group was analyzed by cellulose TLC and by GLC–MS. A single TLC component was detected in the sample after staining the plate with ninhydrin. By using three different solvent systems, the polar head group from the *B. stolpii* sphingophosphonolipid migrated at a slower rate than authentic 2-AEP or phosphorylethanolamine, indicating that the former was more polar (Table 1). It eluted earlier than 2-AEP on an amino acid analyzer (data not shown), further demonstrating that they were distinct compounds. The GLC retention time of the TMS derivative of 2-AEP was 8.8 min. In contrast, the TMS derivative of *B. stolpii* sphingophosphonolipid head group eluted at 8.2 min.

Analysis by GLC–MS of the TMS-derivatized head group did not show the molecular ion at *m/z* 429, but the ion representing ($M^{+\cdot}$ – 15, loss of TMS methyl group) was observed at *m/z* 414. The mass of the derivative indicated the presence of four TMS groups, which is only possible if there is a hydroxyl group on C-2. This fragmentation pattern clearly demonstrated that, unlike 2-AEP, a hydroxyl group was present in the head group of the *B. stolpii* sphingophosphonolipid. Other important ions observed included the ions at *m/z* 328 [327 + H] (loss of C-2 and TMS amine group), and 204 (oxygen and *N*-TMS aminoethanol, which further indicates that there must be a hydroxyl group at C-1, and that C-1 is directly linked to the phosphorus).

The $^{1}H$, $^{13}C$, $^{15}N$, and $^{31}P$ NMR spectra of the PHG (dissolved in $D_2O$, pH 4.6) were obtained. Three protons were found at 3.27 (multiplet of eight peaks, $H_a$), 3.08 (multiplet of eight peaks, $H_b$), and 3.87 ppm (multiplet of six peaks because $J_{bc}$ and $J_{cf}$ are equivalent in value) in the $^{1}H$ NMR spectrum (Fig. 3A). However, the multiple splits of each proton were collapsed to a multiplet of four peaks ($H_a$, $J_{ab}$ = 13.2 Hz and $J_{ac}$ = 3.3 Hz), multiplet of four peaks ($H_b$, $J_{ab}$ = 13.2 Hz and $J_{bc}$ = 10.0 Hz), and the multiplet of four peaks ($H_c$, $J_{ac}$ = 3.4 Hz and $J_{bc}$ = 10.0 Hz), respectively, by $^{31}P$ decoupling experiments (data not shown). The protons $H_a$ and $H_b$ are nonequivalent; both protons are bonded to $C_d$ and exhibit a large H-H coupling constant of 13.2 Hz. The $H_c$ proton at 3.87 ppm

**TABLE 1**
**Thin-Layer Chromatographic Migrations of the Hydrolyzed Polar Head Group of the Major *Bdellovibrio stolpii* Sphingophosphonolipid**

| Head group | $R_f$ A[a] | $R_f$ B[b] | $R_f$ C[c] |
|---|---|---|---|
| Authentic phosphorylethanolamine | 0.42 | 0.50 | 0.19 |
| Authentic 2-aminoethylphosphonate | 0.32 | 0.53 | 0.27 |
| Head group of *B. stolpii* sphingophosphonolipid | 0.19 | 0.47 | 0.06 |

[a]88% phenol/water (4:1, vol/vol).
[b]Isobutyric acid/water/25% $NH_4OH$ (66:33:1, by vol).
[c]Butanol/acetic acid/water (5:3:1, by vol).

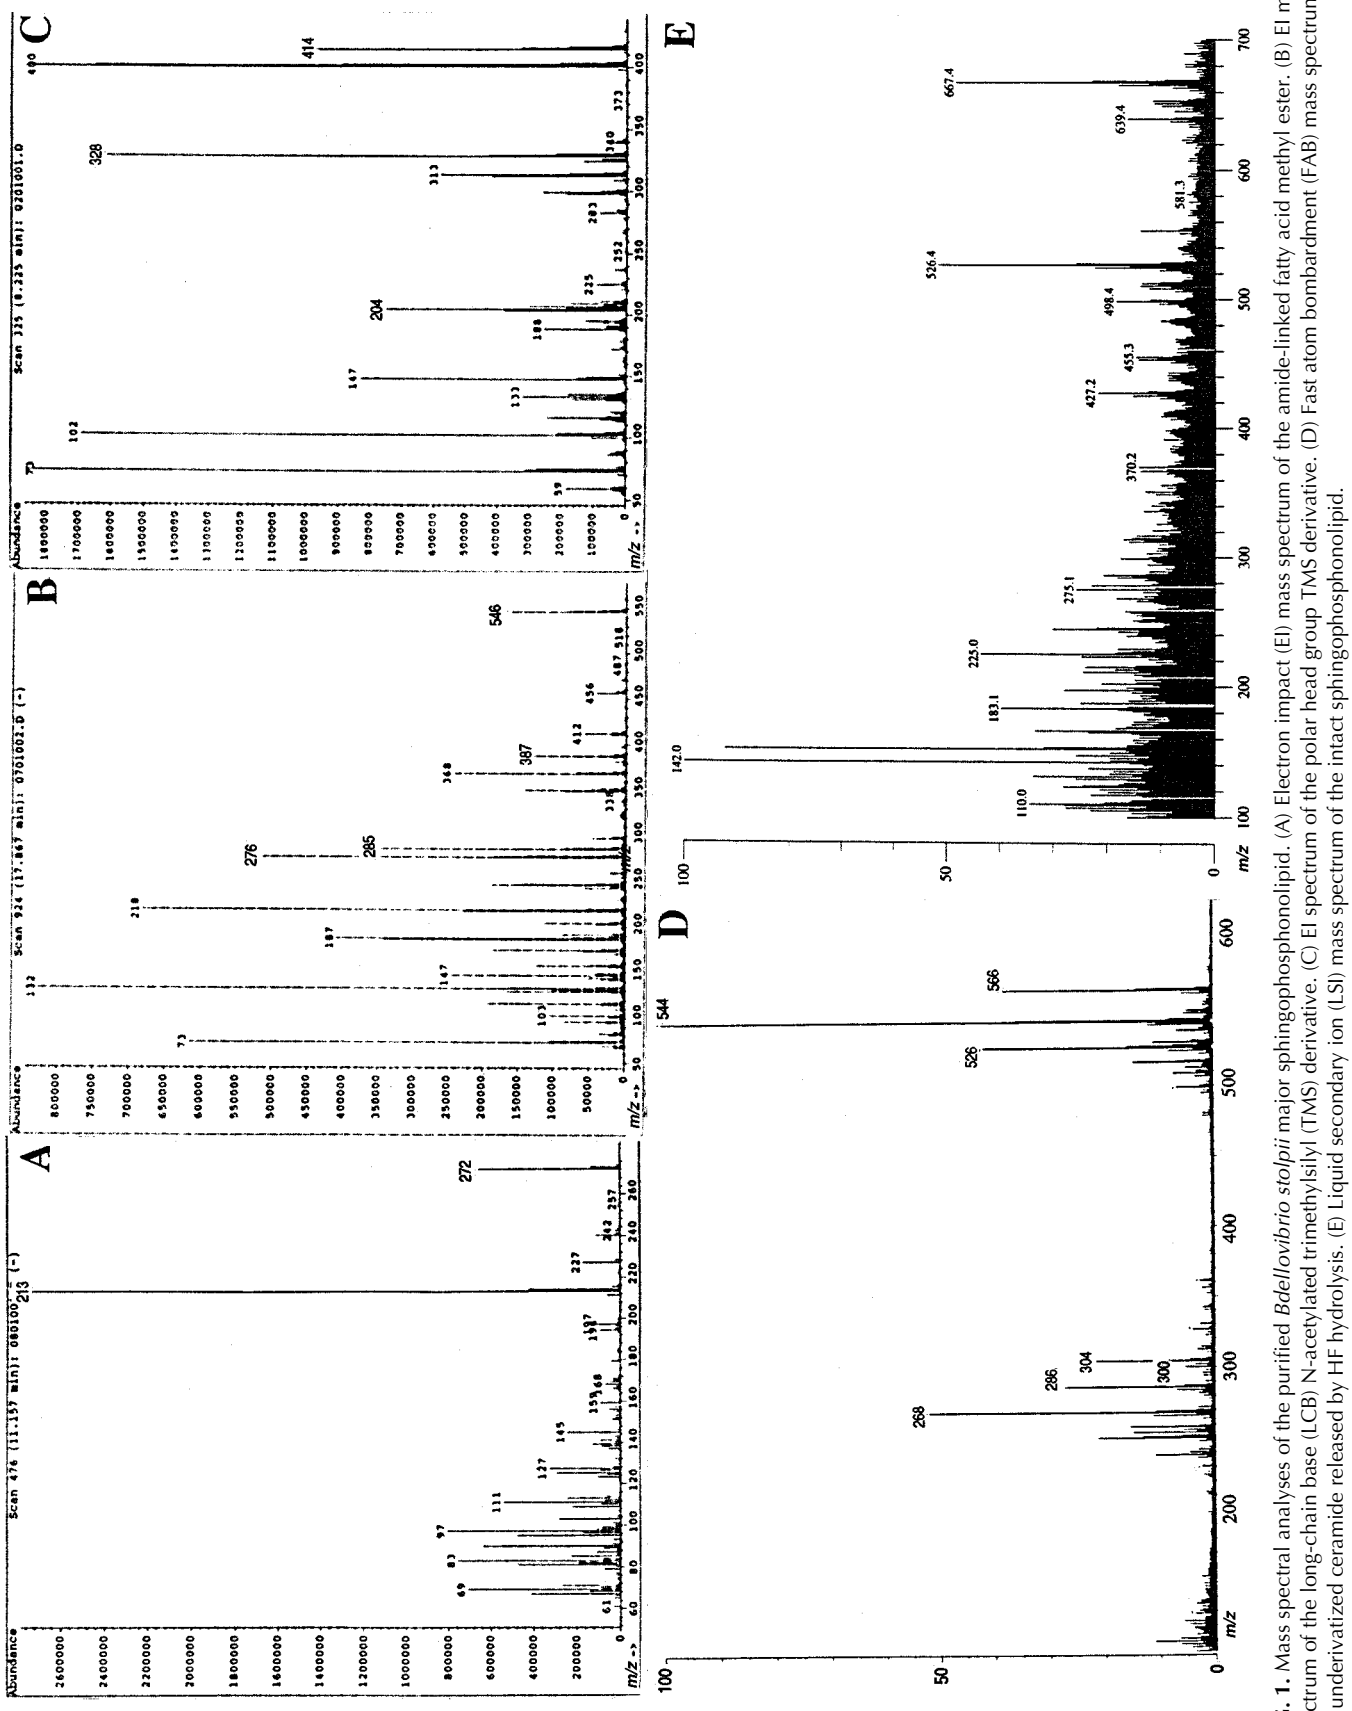

**FIG. 1.** Mass spectral analyses of the purified *Bdellovibrio stolpii* major sphingophosphonolipid. (A) Electron impact (EI) mass spectrum of the amide-linked fatty acid methyl ester. (B) EI mass spectrum of the long-chain base (LCB) N-acetylated trimethylsilyl (TMS) derivative. (C) EI spectrum of the polar head group TMS derivative. (D) Fast atom bombardment (FAB) mass spectrum of the underivatized ceramide released by HF hydrolysis. (E) Liquid secondary ion (LSI) mass spectrum of the intact sphingophosphonolipid.

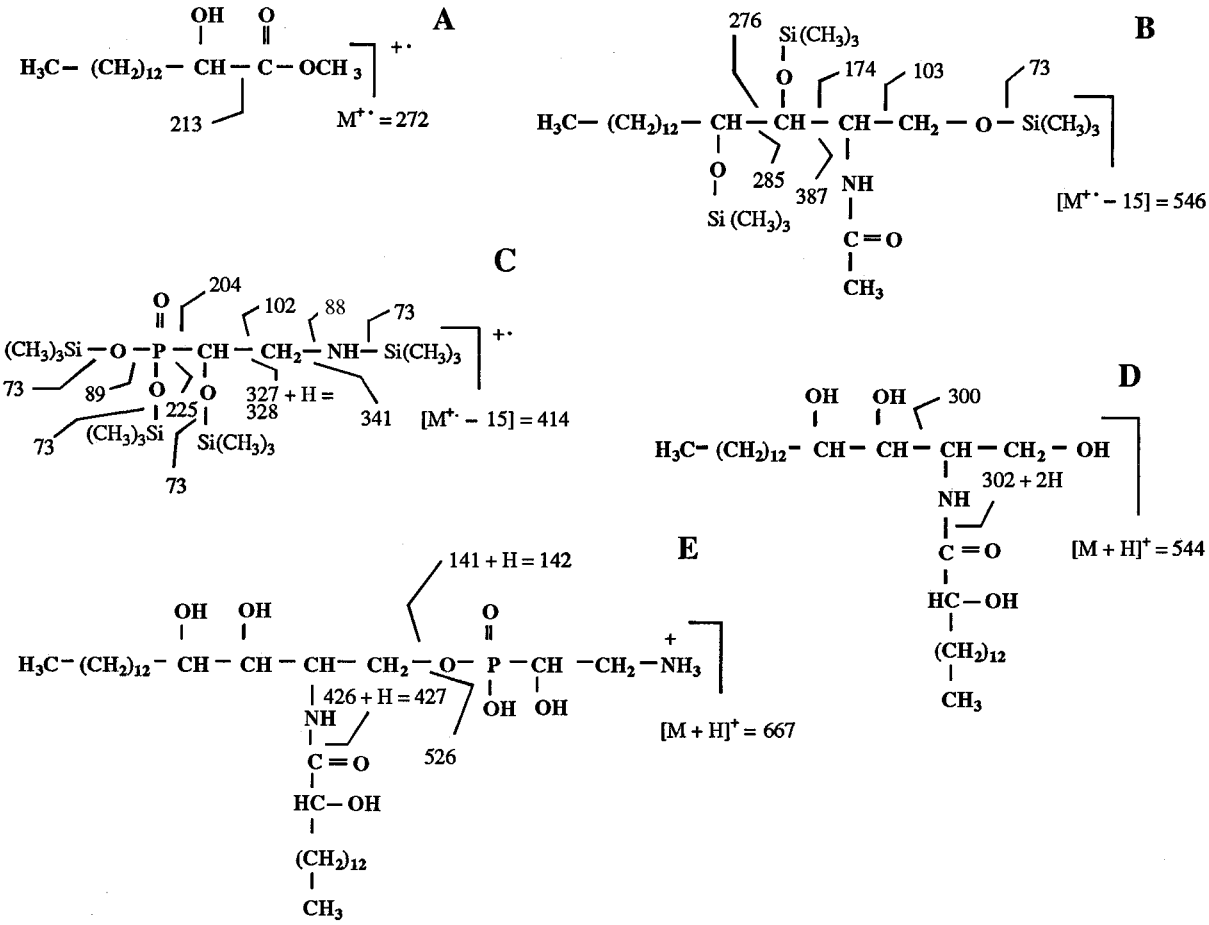

**FIG. 2.** Fragmentation patterns of samples shown in Figure 1. (A) The amide-linked fatty acid methyl esters indicate it is an α-hydroxy 15-carbon straight-chain acid. (B) The N-acetylated LCB TMS derivative was identified as C-17 phytospingosine. (C) The polar head group TMS derivative indicated it was ethanolamine with a direct P–C bond and a hydroxyl group at C-1. (D) FAB mass spectrum of the underivatized ceramide moiety verified the structural assignments of the fatty acid and LCB. (E) LSI mass spectrum of the underivatized intact sphingophosphonolipid verified the structural assignments of the fatty acid ($C_{15}$ α-hydroxy *n*-fatty acid), LCB ($C_{17}$ phytosphingosine), and the polar head group (1-hydroxy-2-aminoethyl phosphonate). For abbreviations see Figure 1.

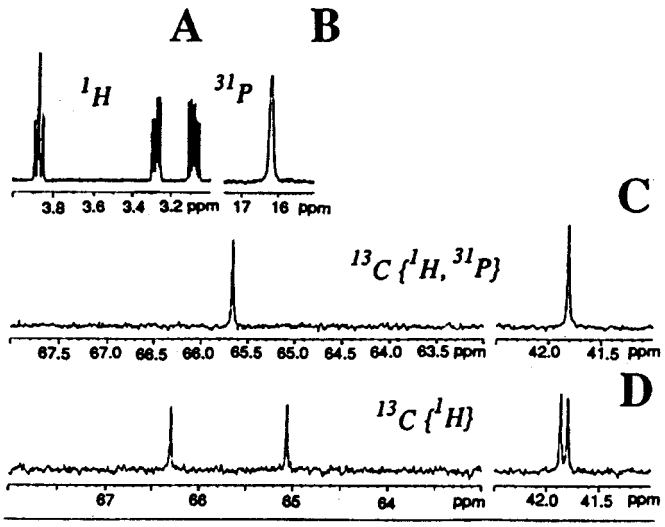
resonated at a lower field, compared to those of $H_a$ and $H_b$. This suggested that $H_c$ is bonded to carbon $C_e$, which is also bonded to the hydroxy group. All other protons in the head group were not observed due to the isotopic exchange with deuterium atoms of the $D_2O$ solvent.

The proton-decoupled $^{13}C$ NMR spectrum showed four signals, with two peaks centered at 65.7 and 41.8 ppm. A double-decoupled experiment (in which both the $^1H$ and $^{31}P$ were decoupled from $^{13}C$) showed that the $C_e$-$P_f$ coupling constants were $J_{c_e}P_f$ = 155.1 Hz and $J_{c_d}P_f$ = 8.8 Hz (Figs. 3C,3D). The large coupling constant of 155.1 Hz indicated that $C_e$ is bonded to $P_f$. The chemical shifts of 65.7 and 41.8 ppm are also suggestive of the presence of $C_e$-OH and $C_d$-N centers, respectively. The $^{31}P$ NMR spectrum showed a single peak with a chemical shift of 16.2 ppm (Fig. 3B) corresponding to the chemical shift of the alkylphosphonic acid reference standard. $^{15}N$ showed a single peak at 26.0 ppm.

The detailed analyses by 2D-NMR including $^1H$-$^{13}C$, $^1H$-$^{15}N$, and $^1H$-$^{31}P$ heteronuclear multiple bond correlation (pulse-field gradient mode) made clear the position of each atom in the PHG, as shown in Figure 3E. The chemical shifts and coupling constants of $^1H$, $^{13}C$, $^{15}N$, and $^{31}P$ are summarized in Figure 3. The NMR data, together with those obtained from the other analyses presented in this paper, unequivocally demonstrated that the PHG of the major *B. stolpii* phosphonosphingolipid is 1-hydroxy-2-aminoethylphosphonic acid.

*Analysis by FAB-MS and LSIMS.* The FAB-MS analysis of underivatized ceramide released by HF digestion showed the $(M + H)^+$ ion at 544 Da. The fragmentation pattern confirmed the assignments of the LCB and the fatty acid moieties. The ion at *m/z* 566 is the result of the addition of a sodium ion to the molecule. The ion at 526 Da is due to the loss of $H_2O$ from the $(M + H)^+$ ion. The ion at 304 Da is due to the protonated LCB phytosphingosine (Figs. 1,2).

The LSIMS analysis of the intact underivatized molecule demonstrated that the ion at *m/z* 667 $(M + H)^+$ was intense. The fragment ion at *m/z* 142 $(141 + H)^+$ corresponds to the polar head group, and the ion at *m/z* 526 (667 − 141) corresponds to ceramide [loss of the polar head group from $(M + H)^+$]. This analysis demonstrated that it is a phosphonolipid,



| Observed Chemical Shifts (ppm) | | Observed Coupling Constants (Hz) |
|---|---|---|
| $H_a$ | 3.27 | $J_{ab} = 13.2, J_{ac} = 3.3, J_{H_aP_f} = 6.5$ |
| $H_b$ | 3.08 | $J_{ab} = 13.2, J_{bc} = 10.0, J_{H_bP_f} = 6.3$ |
| $H_c$ | 3.87 | $J_{ac} = 3.4, J_{bc} = 10.0, J_{H_cP_f} = 10.0$ |
| $C_d$ | 41.8 | $J_{C_dP_f} = 8.8$ |
| $C_e$ | 65.65 | $J_{C_eP_f} = 155.1$ |
| $P_f$ | 16.2 | |
| $^{15}N_g$ | 26 | |

Analyses of 2-D NMR

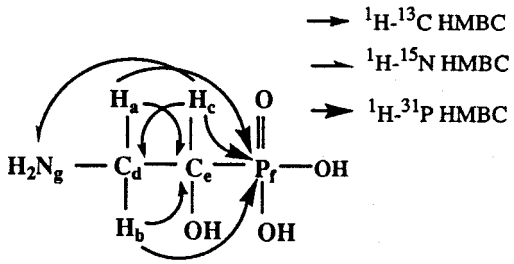

**FIG. 3.** Nuclear magnetic resonance (NMR) spectra of the polar head group. (A) Proton NMR spectrum showing peaks at 0.87 ppm for $H_c$, 3.37 ppm for $H_a$, and 3.08 ppm for $H_b$. (B) $^{31}P$ NMR spectrum. The single peak present was at 16.2 ppm, the chemical shift for a direct P–C bond. (C) The decoupled $^{13}C$ spectrum showing the single peak of $C_e$ (bonded to $P_f$) at 65.65 ppm and the single peak of $C_d$ (bonded to $N_g$) at 41.8 ppm. (D) The coupled $^{13}C$ spectrum showing two peaks at 65.05 ppm and 66.3 ppm from $C_e$ (bonded to $P_f$), and two peaks between 41.8 ppm and 41.9 ppm from $C_d$ (bonded to $N_g$). (E) Summary of analyses by two-dimensional (2-D) NMR showing coupling between atoms in the polar head group. HMBC, heteronuclear multiple bond correlation.

and that the C-1 of the ethanolamine head group is directly linked to phophorus and to a hydroxyl group.

Together, all data obtained from alkaline hydrolysis, TLC, GLC, MS analyses of hydrolyzed products and the intact compound, and NMR analysis of the polar head group, identified its structure as *N*-2′-hydroxypentadecanoyl-2-amino-3,4-dihydroxyheptadecan-1-phosphono-(1-hydroxy-2-aminoethane). It cannot be ruled out that other molecular species were present in the spot or band on TLC plates. This was the structure for the major component that was isolated by the purification procedures used in the present study.

## DISCUSSION

Sphingophosphonolipids have been isolated from various organisms (5,6,8,9,11,12,17,20,29–31), and occur as minor lipid components in mammals (32). In most cases, the PHG is 2-AEP, but 2-*N*-monomethyl-AEP has also been found (11,12). Steiner *et al.* (5) found that the isolated head group from the major sphingophosphonolipid of *Bdellovibrio* did not migrate as far as 2-AEP in the two paper chromatographic systems they used. They also noted that N-methyl derivatives of authentic standards of 2-AEP had $R_f$ values greater than underivatized 2-AEP, thus eliminating N-methyl derivatives as possible structures for the head group of the sphingophosphonolipid in this bacterium. The only previously reported identification of naturally occurring 1-hydroxy-2-AEP was a hydrolysis product of complex polysaccharides of the soil amoeba *Acanthamoeba castellanii* (35). Thus, this is the first report of a lipid with a phosphonoethanolamine head group containing a hydroxyl group. The definitive structure of the intact *B. stolpii* phosphonosphingolipid was here shown to be *N*-2′-hydroxypentadecanoyl-2-amino-3,4-dihydroxyheptadecan-1-phosphono-(1-hydroxy-2-aminoethane).

The lipids of many bacterial lipids can have high proportions of fatty acids with odd-numbered carbons (e.g., $C_{15}$, $C_{17}$); branched (iso, anteiso), or with an α- or 2-hydroxy group (36–39). There is evidence for high α-oxidation activity that could account for the high proportions of α-hydroxy fatty acids (36) in bacteria, including *Cornebacterium* (*Arthrobacter) simplex* grown on 1-octadecene and other hydrocarbons as the only sources of carbon (39). In *C. simplex*, radiolabeled palmitate was mainly incorporated into α-hydroxypalmitate. Furthermore, the fatty acid composition of lipopolysaccharide from intraperiplasmically grown *B. stolpii* (*bacteriovorus*) was found to be highly enriched in β-hydroxy fatty acids (7). The discovery of the hydroxylated ethanolamine head group in this *B. stolpii* sphingophosphonolipid suggests that oxidative reactions in aerobic bacteria may play greater roles in several metabolic pathways than earlier appreciated.

# New Glycosphingolipid Containing an Unusual Sphingoid Base from the Basidiomycete *Polyporus ellisii*

**Jin-Ming Gao[a,b], Lin Hu[a], Ze-Jun Dong[a], and Ji-Kai Liu[a,*]**

[a]Department of Phytochemisty, Kunming Institute of Botany, Chinese Academy of Sciences, Kunming 650204, People's Republic of China, and [b]College of Life Sciences, Northwest Science & Technology University of Agriculture and Forestry, Yangling, Shaanxi 712100, People's Republic of China

**ABSTRACT:** A new 9-methyl-sphinga-4,8-dienine-containing glucocerebroside (**1**), together with two additional known analogs, cerebrosides B and D, was isolated from the chloroform-soluble lipid fraction of the ethanol and chloroform/methanol extract of the fruiting bodies of the basidiomycete *Polyporus ellisii* Berk. and characterized. The structure and relative stereochemistry of the new compound were identified as (2*S*,3*R*,4*E*,8*E*)-1-(β-D-glucopyranosyl)-3-hydroxy-2-[(*R*)-2′-hydroxyheptadecanoyl]amino-9-methyl-4,8-octadecadiene by means of spectroscopic ($^1$H, $^{13}$C, and two-dimensional nuclear magnetic resonance; mass spectrometry) and chemical methods.

Paper no. L8736 in *Lipids 36,* 521–527 (May 2001).

Two groups of sphingolipids in higher mushrooms, or basidiomycetes, are distinguished from one another by the relation of their carbohydrate to the ceramide moiety. Classical glycosphingolipids (GSL) of the first group have their sugar portion linked directly to the ceramide by a glycoside link. In the second group, the glyco-inositol-phospho-sphingolipids, carbohydrate is coupled to the lipophilic portion of the molecule *via* an inositol phosphate. Sphingolipids, e.g., ceramides, sphingomyelin, cerebrosides and gangliosides, are important building blocks of the plasma membrane of eukaryotic cells. Their function is to anchor lipid-bound carbohydrates to cell surfaces and to create an epidermal water permeability barrier, as well as to participate in antigen–antibody reactions and transmission of biological information (1,2). Some are also anti-ulcerogenic, ionophoretic, antihepatotoxic, antitumor, immunostimulatory or stimulatory to axon growth (3–7). In the course of our investigation on the sphingolipid composition of higher mushrooms collected from Yunnan Province of the People's Repulic of China, we recently reported the occurrence of two antifungal glucocerebrosides from *Russula ochroleuca* (8), and two ceramides containing $C_{18}$-phytosphingosine from *R. cyanoxantha* (9) and *Armillaria mellea* (10).

In continuing our studies on basidiomycete-derived bioactive secondary metabolites, we investigated the chemical constituents of the mushroom, *Polyporus ellisii* Berk. (Polyporaceae). A new glucocerebroside (**1**) has now been isolated and described.

## EXPERIMENTAL PROCEDURES

*Chromatographic and instrumental methods.* Melting points were obtained on an XRC-1 apparatus (Sichuan University, Sichuan, People's Republic of China). Optical rotations were taken on a Horiba SEPA-300 automatic polarimeter (Horiba, Tokyo, Japan). The nuclear magnetic resonance (NMR; $^1$H, $^{13}$C, and two-dimensional NMR) spectra were acquired on Bruker AM 400 (Rheinstetten, Germany) and DRX-500 NMR instruments (Karlsruhe, Germany); tetramethylsilane was used as an internal standard, and coupling constants were represented in Hertz. Mass spectra were measured with a VG Autospec3000 mass spectrometer (VG, Manchester, England). Infrared (IR) spectra were obtained in KBr pellets on a Bio-Rad FTS-135 IR spectrophotometer (Bio-Rad, Richmond, CA). Gas chromatography–mass spectrometry (GC–MS) was performed with a Finnigan 4510 GC–MS spectrometer (San Jose, CA) employing the electron impact (EI) mode (ionizing potential 70eV) and a capillary column (30 m × 0.25 mm) packed with 5% phenyl/95% methylsilicone on 5% phenyl-dimethylsilicone (HP-5) (Hewlett-Packard, Palo Alto, CA). Helium was used as carrier gas; column temperature 160–240°C (rate of temperature increase: 5°C/min).

*Materials.* Column chromatography (CC) was performed on silica gel (200–300 mesh; Qingdao Marine Chemical Ltd., Qingdao, People's Republic of China) and Sephadex LH-20 gel (25–100 μm, Amersham Pharmacia Biotech AB, Uppsala, Sweden). Reversed-phase chromatography was carried out on LiChroprep$^R$ RP-8 (40–63 μm) (Merck, Darmstadt, Germany). Thin-layer chromatography (TLC) analysis was carried out on plates precoated with silica gel $F_{254}$ (Qingdao Marine Chemical Ltd.), and detection was achieved by spraying with 10% $H_2SO_4$ followed by heating. All solvents were distilled before use.

Fresh fruiting bodies of *P. ellisii* were collected from Ailao Mountains in Yunnan Province in August 1998 and identified by Professor P.G. Liu, X.H. Wang, Kunming Institute of Botany, Chinese Academy of Sciences, Kunming, Yunnan, People's Republic of China, where a voucher specimen (no. HKAS 32905) has been deposited.

*Extraction and isolation.* Dried fruiting bodies (228 g) of *P.*

*ellisii* were first extracted twice with 95% ethanol (1 L × 24 h × 2) for 48 h and then four times with chloroform/methanol (1:1, vol/vol; 0.5 L × 36 h × 4) at room temperature. The combined organic phase was concentrated *in vacuo*. The residue was suspended in water and partitioned with chloroform. The crude chloroform extract (7.6 g) was chromatographed on a reversed-phase (RP)-8 column, eluted with a gradient of methanol in water. The fraction (1.1 g), eluted with 200 mL methanol, was passed through vacuum liquid chromatography with a chloroform/methanol mixture containing increasing amounts of methanol to provide six fractions. Of these, the fraction eluted with chloroform/methanol (5:1, vol/vol) was further purified by chromatography on an RP-8 column by elution with methanol/water (85:15, 90:10, 95:5, vol/vol) and followed by separation on Sephadex LH-20 using methanol to produce compounds **2** (6 mg), **1** (20 mg), and **3** (8 mg).

*(2*S*,3*R*,4*E*,8*E*)-1-(β-*D*-glucopyranosyl)-3-hydroxy-2-[(*R*)-2′-hydroxyheptadecanoyl]amino-9-methyl-4,8-octadecadiene (**1**).* White amorphous powder (methanol); mp 154–156°C; $[\alpha]_D^{26}$ +4.9° (*c* 0.40, MeOH); IR (KBr) $\nu_{max}$ 3393 (OH), 2921, 2852 (C–H), 1650 (HNC=O), 1540 (NH), 1469, 1304, 1079 (C–O), 963 (*trans* C=C), 721 (methylenes) $cm^{-1}$; $^1H$ and $^{13}C$ NMR spectra are given in Table 1; EI–MS (70 eV) *m/z* (relative intensities, %) 724 $[M - OH]^+$ (0.5), 562 $[M - OH - 162]^+$ (4.8), 530 (2.8); negative fast atom bombardment-mass spectrometry (FAB-MS) *m/z*: 740 $[M - 1]^-$, 579 $[M - H - 162]^-$, 561 $[M - H - 179]^-$; negative high resolution FAB-MS *m/z* 740.5659 $[M - 1]^-$ (calcd. for $C_{42}H_{78}NO_9$, 740.5677).

*Acetylation of **1**.* Compound **1** (6.3 mg) was dissolved in pyridine (0.3 mL), and the mixture was treated with acetic anhydride (0.3 mL) and left standing overnight at room temperature. The reaction solution was then diluted with 2 mL of water and extracted with ethyl acetate (3 × 4 mL). The ethyl acetate extract was washed with brine and dried over $Na_2SO_4$, then evaporated to dryness under reduced pressure. The residue obtained was subjected to silica gel CC, with elution by petroleum ether/ethyl acetate (8:2, vol/vol) to give 7 mg of its peracetate derivative **1a**.

*(2*S*,3*R*,4*E*,8*E*)-1-*O*-(2,3,4,6-tetra-*O*-acetyl-β-*D*-glucopyranosyl)-3-*O*-acetyl-2-[(*R*)-2′-acetoxyheptadecanoyl]amino-9-methyl-4,8-octadecadiene (**1a**).* White powder solid. $[\alpha]_D^{26}$ +5.6° (*c* 0.36, $CHCl_3$); IR (KBr) $\nu_{max}$ 3369 (OH), 2925, 2856 (C–H), 1745 (C=O of ester), 1675 (C=O of amide), 1533

[a]Assignments were made by distortionless enhancement by polarization transfer (DEPT) and heteronuclear multiple quantum coherence (HMQC) analysis. HMBC, heteronuclear multiple bond coherence. COSY, correlation spectroscopy.

(N–H), 1467, 1376, 1234, 1125–1037 (glycosidic C–O), 977 (*trans* C=C), 889, 721 ($nCH_2$) $cm^{-1}$; $^1H$ NMR 500 MHz ($CDCl_3$), δ ppm 0.88 (6H, *t*-like, *J* = 6.7 Hz, 2 × Me), 1.25 (*s*, methylenes), 1.57 (3H, *s*, 19-Me), 2.05 (2H, *m*, H-3′), 1.95 (2H, *br t, J* = 7.8 Hz, H-10), 1.80 (2H, *m*, H-6), 2.06 (2H, *m*, H-7), 3.61 (1H, *dd, J* = 4.5, 10.3 Hz, H-1), 3.69–3.71 (1H, *m*, H-5″), 3.93 (1H, *dd, J* = 4.0, 10.3 Hz, H-1), 4.14 (1H, *dd, J* = 2.1, 12.3 Hz, H-6″), 4.24 (1H, *dd, J* = 4.6, 12.3 Hz, H-6″), 4.31 (1H, *m*, H-2), 4.48 (1H, *d, J* = 7.9 Hz, H-1″), 4.95 (2H, *m*, H-2″, H-3″), 5.08 (1H, *br t, J* = 9.7 Hz, H-8), 5.15 (1H, *dd, J* = 4.7, 7.1 Hz, H-2′), 5.19 (1H, *t, J* = 9.5 Hz, H-4″), 5.32 (1H, *dd, J* = 5.3, 6.8 Hz, H-3), 5.41 (1H, *dd, J* = 15.3, 7.4 Hz, H-4), 5.82 (1H, *dt, J* = 15.3 Hz, H-5), 6.36 (1H, *d, J* = 8.8 Hz, NHCO), 2.00 (*s*, MeCO), 2.02 (*s*, 2 × MeCO), 2.03 (*s*, MeCO), 2.09 (*s*, MeCO), 2.15 (*s*, MeCO); $^{13}C$ NMR 100 MHz ($CDCl_3$) δ ppm 14.0 (2 × Me), 15.9 (19-Me), 2 × 22.6, 24.7, 27.4, 28.0 (C-7), 29.3, 29.6 (all $CH_2$), 31.9 (C-6), 32.5 (C-3′), 39.7 (C-10), 67.2 (C-1), 50.8 (C-2), 74.0 (C-3), 73.2 (C-2′), 100.6 (C-1″), 71.3 (C-2″), 72.0 (C-3″), 68.4 (C-4″), 72.8 (C-5″), 62.2 (C-6″), 123.0 (C-8), 136.6 (C-9), 124.6 (C-4), 136.2 (C-5), 20.5 (4 × COMe), 20.9 (2 × COMe), 2 × 169.3, 3 × 169.6, 170.0, 170.4 (all COMe, NHCO); EI-MS (70 eV) *m/z* (relative intensities, %): 993 $[M]^+$ (2.0), 933 $[M - HOAc]^+$ (3), 874 $[M - HOAc - OAc]^+$ (1.0), 826 (1.5), 700 (0.5), 663 $[M - Glc(OAc)_4 + 1$, where glucose = $Glc]^+$ (0.5), 646 (2.8), 632 (1.2), 586 (2.2), 572 (2.2), 526 (1.0), 512 (0.5), 433 $[AcOCH^+CH_2OGlc(OAc)_4]$ (0.5), 390 $[H_2N^+{=}CHCH_2OGlc(OAc)_4]$ (15), 359 (1.8), 332 (17), 331 $[Glc(OAc)_4]^+$ (100), 276 $[C_{16}H_{28}CH{=}CH(NH_2)CH_2^+]$ (1.2), 271 (9), 229 (4), 211 (5), 170 (11), 169 (95.8), 145 (7.8), 139 (8.0), 127 (10.5), 109 (32.5), 81 (14), 60 (31.5).

*Methanolysis of **1***. Compound **1** (7.3 mg) was refluxed with 2.2 mL 0.9 M HCl in 82% aqueous methanol at 80°C for 18 h. The resultant reaction mixture was extracted with *n*-hexane, and the combined organic layer was dried over $Na_2SO_4$. Concentration of the hexane yielded a fatty acid methyl ester, which was purified by silica gel CC with *n*-hexane/ethyl acetate (9:1–7:3, vol/vol) to give a methyl ester of fatty acid **1b** (2.6 mg) and then analyzed by GC–MS.

*Methyl (2*R*)-2-hydroxyheptanoate (**1b**).* The retention time ($t_R$) of **1b** was 14.3 min; white solid. $[\alpha]_D^{25}$ –4.1° (*c* 0.061, $CHCl_3$) [lit. (11) $[\alpha]_D^{24}$ – 3.6° ($CHCl_3$)]; IR (KBr) $\nu_{max}$ 3400 (OH), 2934, 1740 (C=O), 1465, 1284, 720 (methylenes) $cm^{-1}$; $^1H$ NMR 400 MHz ($CDCl_3$) δ ppm 4.19 (1H, *dd, J* = 4.2, 7.4 Hz, H-2), 3.79 (3H, *s*, $COOCH_3$), 2.74 (1H, *bs*, OH), 1.76 (1H, *m*, H-3), 1.63 (1H, *m*, H-3), 1.25 (*br s*, methylenes), and 0.88 (3H, *t, J* = 7.0 Hz, terminal methyl); EI-MS (70 eV) *m/z* (relative intensities, %) 300 $[M]^+$ (2), 241 $[M - COOMe]^+$ (13.5), 189 (2.4), 149 (12.2), 83 (34), 69 (52.2), 57 (72.6), and 43 (100).

*2-Acetoamino-1,3-diacetoxy-9-methyl-4,8-octadecanediene (**1c**).* The aqueous methanolic layer was neutralized with saturated $NaHCO_3$, concentrated to dryness, and extracted with ether. The ether phase was dried over $Na_2SO_4$, filtered, and then concentrated to yield a long-chain base (LCB), which was heated with acetic anhydride/pyridine (1:1, vol/vol) for 1.5 h at 70°C. The reaction mixture was diluted with water and then extracted three times with ethyl acetate. The residue of the ethyl acetate fraction was chromatographed over silica gel using *n*-hexane/ethyl acetate (8:2, vol/vol) as eluents to furnish a peracetate of the LCB (**1c**, 1.4 mg) as white solid. $^1H$ NMR 500 MHz ($CDCl_3$) δ ppm 5.78 (1H, *m*, H-5), 5.67 (1H, *d, J* = 9.2 Hz, NHAc), 5.42 (1H, *m*, H-4), 5.29 (1H, *m*, H-3), 5.08 (1H, *m*, H-8), 4.42 (1H, *m*, H-2), 4.29 (1H, *dd, J* = 11.6, 6.0 Hz, H-1a), 4.05 (1H, *dd, J* = 11.6, 3.4 Hz, H-1b), 2.05, 2.08 (each 3H, *s*, 2 × OAc), 2.03 (3H, *s*, HNAc), 1.95–2.15 (6H, *m*, H-6, H-7, and H-10), 1.58 (3H, *s*, H-19), 1.21–1.63 (12H, *m*), 0.88 (3H, *t, J* = 6.1 Hz, $CH_3$); EI-MS (70 eV) *m/z* (relative intensities, %) 438 $[M + 1, 2]^+$, 396 $[M + 1 - Ac]^+$ (4), 378 $[M + 1 - HOAc]^+$ (5), 318 $[M + 1 - 2 \times HOAc]^+$ (7), 284 (5.2), 268 (38), 185 (24.5), 144 $[AcOCH_2CHNHAc + H]^+$ (43), 102 $[144 - Ac + 1]^+$ (48), 84 $[144 - HOAc]^+$ (97.5), 69 (68), 55 (100).

*1*-O-*Methyl-*D*-glucopyranoside*. The remaining water layer was evaporated *in vacuo*. The residue was then chromatographed on silica gel using chloroform/methanol/water (7:3:0.5, by vol) to afford methyl glucopyranoside. $[\alpha]_D^{27}$ + 74.2° (*c* 0.01, methanol), [literature (12) $[\alpha]_D^{25}$ + 77.3° (*c* 0.1, methanol)]; negative FAB-MS *m/z* 193 $[M - 1]^-$.

*(2*S*,3*R*,4*E*,8*E*)-1-(β-*D*-glucopyranosyl)-3-hydroxy-2-[(*R*)-2′-hydroxypalmitoyl]amino-9-methyl-4,8-octadecadiene (= cerebroside B) (**2**)*. White amorphous powder. $[\alpha]_D^{27}$ +5.1° (*c* 0.3, methanol) IR (KBr) $\nu_{max}$: 3380 (OH), 2960, 1650, 1540, 1000–1100, 720 $cm^{-1}$; negative FAB-MS *m/z* 726 $[M - 1]^-$, 564 $[M - 1 - 162]^-$; negative high resolution FAB-MS *m/z* 726.5561 $[M - 1]^-$ ($C_{41}H_{76}NO_9$, calcd. 726.55200). Methanolysis of **2** yielded a methyl 2-hydroxy palmitate (retention time 12.4 min) identified by GC–MS. The NMR (Table 2) and IR spectra of **2** were identical with those reported in the literature (8,18).

*(2*S*,3*R*,4*E*,8*E*)-1-(β-*D*-glucopyranosyl)-3-hydroxy-2-[(*R*)-2′-hydroxyoctadecanoyl]amino-9-methyl-4,8-octadecadiene (= cerebroside D) (**3**)*. White amorphous powder. $[\alpha]_D^{27}$ +4.8° (*c* 0.2, methanol); IR (KBr) $\nu_{max}$: 3385 (OH), 2960, 1650, 1541, 1000–1100, 721 $cm^{-1}$; negative FAB-MS *m/z* 754 $[M - 1]^-$, 592 $[M - 1 - 162]^-$. Methanolysis of **3** yielded a methyl 2-hydroxy stearate (retention time 16.2 min) identified by GC–MS. The NMR (Table 2) and IR spectra of **3** were identical with those reported in the literature (8,18).

## RESULTS AND DISCUSSION

The chloroform-soluble part of the ethanol and chloroform/methanol extract from the fruiting bodies of *P. ellisii* was separated by normal-phase followed by reversed-phase CC to give compounds **1**, **2**, and **3**. The structural elucidation of new compound **1** was as follows.

Compound **1** was obtained as white amorphous powder, $[\alpha]_D^{26}$ +4.9° (*c* 0.40, methanol). The molecular formula of $C_{42}H_{79}NO_9$ for **1** was determined by negative high resolution FAB-MS at *m/z* 740.5659 $[M - H]^-$ (calcd. 740.5677). In the negative FAB-MS, compound **1** exhibited significant frag-

[a]For abbreviation see Table 1.

ment peaks at *m/z* 740 $[M - H]^-$, 579 [M – H – 162 (glucosyl)]$^-$, and 561 $[M - 1 - 179]^-$. The IR spectrum of **1** showed absorption bands ascribable to hydroxyl at 3393 cm$^{-1}$, glycosidic (C–O) at 1037 cm$^{-1}$, a secondary amide at 1540 and 1650 cm$^{-1}$, and long aliphatic chains at 2921, 1469, and 721 cm$^{-1}$. The $^1$H and $^{13}$C NMR spectral data of **1** indicated the presence of a sugar, an amide, and long-chain aliphatic moieties, strongly suggesting the glycolipid nature of the molecule (Table 1).

To determine the number of hydroxyl groups, compound **1** was acetylated with acetic anhydride/pyridine at room temperature to give its peracetate derivative **1a**, which showed a molecular ion peak at *m/z* 993 $[M]^+$ in its EI-MS, consistent with the composition $C_{54}H_{91}NO_{15}$ for **1a**. The existence of a fragment ion peak at *m/z* 663 [M – 331 (tetraacetyl hexose)]$^+$ confirmed hexose as the sugar residue. Meanwhile, the EI-MS data of **1a** also displayed the diagnostic fragments of the sugar moiety at *m/z* 331 (base peak), 271, 229, 211, 169, and 109, due to an acetylated glucopyranoside (13). Compound **1a** showed six acetyl signals at δ 2.15 (3H, *s*), 2.09 (3H, *s*), 2.03 (3H, *s*), 2.02 (6H, *s*), and 2.00 ppm (3H, *s*) in the $^1$H NMR spectrum and at δ 20.5 (four *C*$H_3$CO), 20.9 (two *C*$H_3$CO) and at δ ppm 169.3 (two $CH_3$*C*O), 169.6 (three $CH_3$*C*O) and 170.0 (one $CH_3$*C*O) in the $^{13}$C NMR spectrum, respectively. In addition to a fragment ion at *m/z* 663 [M – Glc(OAc)$_4$ + 1]$^+$ **1a** also provided typical fragment ions at *m/z* 933 $[M - HOAc]^+$ and 874 $[M - HOAc - OAc]^+$, thereby confirming the presence of six hydroxyl groups in the original structure of **1**.

On methanolysis (6,9), compound **1** yielded a fatty acid methyl ester, a mixture of α- and β-anomers of methyl glucoside, and an LCB (Scheme 1). The methyl ester **1b** was identified as methyl 2′**-**hydroxyheptanoate by the help of GC–MS analysis, with a molecular ion peak at *m/z* 300, corresponding to the composition $C_{18}H_{36}O_3$. Comparison of the $^1$H NMR and optical rotation data ($[\alpha]_D^{27}$ – 4.5°) with those reported in the literature (11) led us to propose that the relative stereochemistry at C-2′ of the fatty acid methyl ester was *R*. That the optical rotation of the methyl glucoside, $[\alpha]_D^{27}$ +74.2° (determined on the methanolysis product from **1**), was close

to that of the authentic sample, $[\alpha]_D^{25}$ + 77.3° (12), indicated that glucose was present as its D-isomer.

In the $^1$H NMR spectrum of **1** an anomeric signal indicative of the sugar moiety was observed at δ 4.91, and the coupling constant (*d, J* = 7.8 Hz) of this signal suggested the β-configuration of a glucoside linkage. The six oxygenated carbon signals at δ 105.4 (CH), 78.3 (CH), 78.3 (CH), 74.9 (CH), 71.5 (CH), and 62.6 ($CH_2$) in the $^{13}$C NMR spectrum also supported the presence of the β-glucopyranoside moiety in **1** by comparison of the observed and reported chemical shifts (14). In addition, from the heteronuclear multiple bond correlation spectrum, the correlation between H-1″ [δ 4.91 (1H, *d*)] and C-1 [δ 69.9 ($CH_2$)] suggested that the glucose was attached to the C-1 position of the LCB.

The $^1$H NMR data (Table 1) of **1** revealed the presence of two terminal methyls at δ 0.86 (6H, *t, J* = 7.0 Hz), an allylic methyl group at δ 1.61 (3H, *s*, H-19), methylene protons at δ 1.25 (*br s*), an amide proton signal at δ 8.36 (*d, J* = 8.6 Hz), an anomeric proton at δ 4.91 (*d, J* = 7.8 Hz), and carbinol protons appearing as multiplets between δ 3.90 and 4.75. A signal appearing at δ 4.81 (*m*, H-2) was assigned as a methine proton vicinal to the nitrogen atom, clearly suggesting a branched cerebroside containing a 2-hydroxy fatty acid (6,15). Furthermore, **1** was considered to possess a normal type of side chains since the carbon signals due to the terminal methyl groups were observed at δ 14.0 (normal form) in the $^{13}$C NMR spectrum (16). The $^{13}$C NMR spectrum of **1** exhibited carbon signals at δ 175.5 (carbonyl carbon), 54.5 (CHNH, C-2), 22.7–31.9 (methylene carbons), 14.0 (two terminal methyls, C-18 and C-17′), and 15.9 (an allylic methyl group, C-19), which further support the branching glycolipid nature of the molecule. Four olefinic carbon signals observed at δ 124.0 (CH), 131.7 (CH), 132.2 (CH), and 135.6 (quaternary carbon) suggested that **1** possessed two double bonds. In the $^1$H-$^1$H homonuclear correlation spectroscopy spectrum, the correlation between H-4 and H-3, H-4 and H-5, H-5 and H-6, H-6 and H-7, H-7 and H-8 was observed. The above correlation analysis has thus unambiguously assigned the position of the two double bonds at C-4 and C-8, respectively. The analysis was further supported by HMBC spectrum of **1**, which displayed the correlation between H-6 and C-4, H-3 and C-5, H-7 and C-9, H-10 and C-8. On the other hand, the presence of an allylic methyl group (C-19) in the branched LCB was also confirmed by the HMBC spectrum in which the correlation between H-19 and C-8 was observed. The geometry of the C-4/C-5 alkene bond was determined to be *E* by the large vicinal coupling constant (*J* = 15.3 Hz) displayed between H-4 and H-5, as also evidenced by the $^{13}$C NMR chemical shift of the methylene carbon C-6 (δ 32.9) next to the olefinic carbon (15) and the signals of olefinic protons (H-4 and H-5) that appear in the vicinity of δ 5.95 as a multiplet (17). When C-7 methylene protons were irradiated in an nuclear Overhauser effect (NOE) difference experiment, an NOE enhancement of the C-19 methyl protons was observed, arguing that the C-8/C-9 double bond was also assigned *E*. Furthermore, the $^{13}$C NMR chemical shift of the C-19 methyl group (δ 15.9) in turn supported the assignment of this *trans* isomer, as demonstrated by comparison with the chemical shifts of the C-3 methyl groups in *E* (δ 15.4) and *Z* (δ 22.7) isomers of 3-methyl-3-hexene (18). It is thus clear that **1** possesses a branched sphingoid moiety with (4*E*,8*E*) geometry, 2-amino-1,3-dihydroxy-9-methyl-4,8-octadecanediene. In addition, treatment of the methanolysis product of **1** with acetic anhydride/pyridine at 70°C afforded production of a triacetyl LCB **1c**, which we suggest is 2-acetoamino-1,3-diacetoxy-9-methyl-4,8-octadecanediene on the bases of the molecular ion at *m/z* 438 and the $^1$H NMR spectrum, which are consistent with those of the synthetic model compound (19). All of the above spectral evidence further supported that **1** is a cerebroside composed of a (4*E*,8*E*)-2-amino-1,3-dihydroxy-9-methyl-4,8-octadecanediene, (2*R*)-2-hydroxy fatty acid, and β-D-glucopyranose.

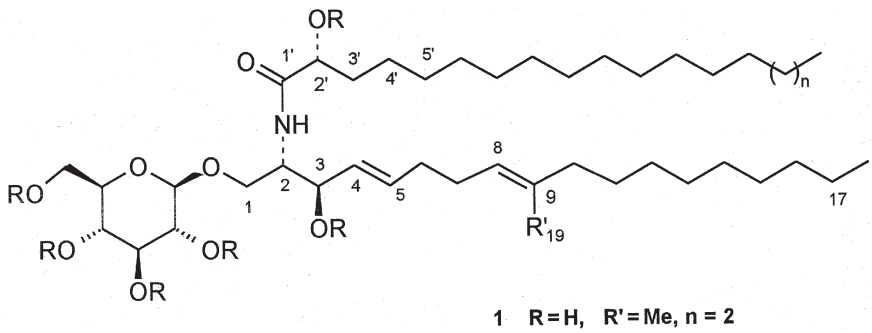
[a]*J* is given in Hz, in parentheses. δ are in ppm. For abbreviation see Table 1

The relative stereochemistry at C-2 and C-3 in **1** was presumed as 2*S*,3*R* (*erythro*) which was shown to be the same as that of the natural cerebrosides **4**, which are phallusides isolated from the ascidian *Phallusia fumigata* (11) and of synthetic glucosyl-(2*S*,3*R*)-sphingadienine **5** (20). The chemical shifts and coupling constants of H-1, H-2, H-3, and H-2′ in **1** and **1a** are in agreement with those of natural **4** and synthetic **5**, synthetic precursor of **5**, (2*S*,3*R*,4*E*,8*E*, 2′*R*)-2-(2′-acetoxyhexadecanoyl)amino-3-*O*-acetyl-1-*O*-(2,3,4,6-tetra-*O*-benzoyl-β-D-glucopyranosyl)-4,8-octadecadien-1,3-diol **6** (20) (Table 3). Moreover, the specific rotations of **1** ($[\alpha]_D^{26}$ +4.9°) and **1a** ($[\alpha]_D^{26}$ +5.6°) are also in accordance with those of natural **4** ($[\alpha]_D^{26}$ +7.0°) and synthetic **5** ($[\alpha]_D^{20}$ +5.4°) and **6** ($[\alpha]_D^{26}$ +8.8°). These data suggest that **1** has the same absolute configuration as that of natural **4** and synthetic **5** for the core structure at chiral centers 2, 3, and 2′. On the basis of the above evidence, the structure of **1** was therefore established as (2*S*,3*R*,4*E*,8*E*)-1-(β-D-glucopyranosyl)-3-hydroxy-2-[(*R*)-2′-hydroxyheptadecanoyl]amino-9-methyl-4,8-octadecadiene (Scheme 2).

Compounds **2** and **3** have the same $^1$H and $^{13}$C NMR (Table 3) data in addition to IR absorptions as **1**, indicating that both **2** and **3** are 9-methyl-sphinga-4,8-dienine-type cerebrosides possessing 2-hydroxy fatty acid and β-D-glucopyranose moieties. The molecular formulas of **2** and **3** were determined as $C_{41}H_{77}NO_9$ and $C_{43}H_{81}NO_9$, respectively, by negative high-resolution FAB-MS and $^{13}$C NMR data. Further methanolysis of both yielded the corresponding fatty acid methyl esters, namely, methyl 2-hydroxy palmitate and methyl 2-hydroxy stearate, which were identified by GC–MS. From the above evidence and comparison of the physicochemical properties with the reported data, compounds **2** and **3** were characterized as (2*S*,3*R*,4*E*,8*E*)-1-(β-D-glucopyranosyl)-3-hydroxy-2-[(*R*)-2′-hydroxypalmitoyl]amino-9-methyl-4,8-octadecadiene (= cerebroside B), and (2*S*,3*R*,4*E*,8*E*)-1-(β-D-glucopyranosyl)-3-hydroxy-2-[(*R*)-2′-hydroxyoctadecanoyl] amino-9-methyl-4,8-octadecadiene (= cerebroside D) (Scheme 2), respectively, which were previously obtained from a basidiomycete, *R. ochroleuca* (8) and an imperfect fungus *Pachybasium* sp. (18); both had antifungal activity.

Sphingolipids are ubiquitous membrane constituents of animals, plants, and also lower forms of life, the principal component of which is the LCB or sphingoid base. In nature, the most widely occurring sphingoid base is D-*erythro*-4(*E*)-sphyingenine, whereas branched (4*E*,8*E*)-sphingadienines having two double bonds in the hydrocarbon chain are minor sphingoid bases. The present study has demonstrated the presence in *P. ellisii* of a previously unrecognized cerebroside and two known cerebrosides, consisting of 9-methyl-4,8-sphingadienine in amide linkage with a hydroxy fatty acid and in β-glycosidic bond with glucose, respectively. The new cerebroside belongs to the first class of GSL (which have their sugar portion linked directly to the ceramide by a glycoside), and contains a fairly unusual dienic LCB with a methyl branch at C-9. This cerebroside has been found in a unique marine microorganism *Thraustochytrium globosum* (15), an



**1** R = H, R' = Me, n = 2

**3** R = H, R' = Me, n = 3
**5** R = H, R' = H, n = 1

**SCHEME 2**

imperfect fungus *Pachybasium* sp. (18), a pathogenic fungus *Fusicoccum amygdali* (21), and a marine animal sea anemone *Metridium senile* (22). The natural occurrence of molecules of this species from higher fungi has also been reported (8). Thus, the branched nonadecasphingadienine is presumed to be a characteristic component in cerebrosides from lower organisms. From the viewpoint of comparative biochemistry, it will be of considerable interest to elucidate fully its distribution and also to investigate the physiological significance of the 9-methyl branch, as well as the biosynthetic pathway.

It should be noted that the occurrence of structurally closely related sphingolipid derivatives in taxonomically remote species is very intriguing and may indicate the connection with a common producer, probably symbiotic microorganisms.

# Method to Produce 9(*S*)-Hydroperoxides of Linoleic and Linolenic Acids by Maize Lipoxygenase

**Harold W. Gardner* and Marilyn J. Grove**

Mycotoxin Research, NCAUR, ARS, USDA, Peoria, Illinois 61604

**ABSTRACT:** Seed from maize (corn) *Zea mays* provides a ready source of 9-lipoxygenase that oxidizes linoleic acid and linolenic acid into 9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid and 9(*S*)-hydroperoxy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid, respectively. Corn seed has a very active hydroperoxide-decomposing enzyme, allene oxide synthase (AOS), which must be removed prior to oxidizing the fatty acid. A simple pH 4.5 treatment followed by centrifugation removes most of the AOS activity. Subsequent purification by ammonium sulfate fractional precipitation results in negligible improvement in 9-hydroperoxide formation. This facile alternative method of preparing 9-hydroperoxides has advantages over other commonly used plant lipoxygenases.

Paper no. L8749 in *Lipids 36,* 529–533 (May 2001).

Oxylipin research often requires the use of 9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid [9*S*-HPODE; 9-HPODE is the abbreviation for stereochemically undefined 9-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid]. In our laboratory, 9*S*-HPODE was routinely produced by oxidation of linoleic acid by 9-lipoxygenase (9-LOX) from a tomato fruit extract (1). Although tomato fruit is readily available, this method has a few disadvantages. Extraction of the product by chloroform as outlined by the method often gives intractable emulsions, and a variety of carotenoids co-elute by chromatographic clean-up of 9*S*-HPODE. Further, the use of certain varieties of tomato has given us amounts of 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid as high as 15%. In addition, the 1-mM solution of linoleic acid recommended (280 mg/L) gives only partial conversion to 9*S*-HPODE.

Probably because potato is a readily available commodity, potato 9-LOX has often been used to form 9*S*-HPODE (2). Our laboratory has limited experience with potato 9-LOX, but some purification (2) would be required in view of the biotransformations of 9*S*-HPODE known to occur in crude potato extracts (3,4). Although recombinant 9-LOX cloned into bacteria are known, these cultures must be maintained.

Abbreviations: AOS, allene oxide synthase; CP–HPLC, chiral-phase high-performance liquid chromatography; EI, electron impact; FID–GC, flame-ionization detection–gas chromatography; GC–MS, gas chromatography–mass spectrometry; 9*S*-HPODE, 9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid; 9*S*-HPOTE, 9(*S*)-hydroperoxy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid; 9-LOX, 9-lipoxygenase; mes, 2-(*N*-morpholino)ethane sulfonic acid; OTMSi, trimethylsilyloxy; SP–HPLC, straight-phase high-performance liquid chromatography.

*Zea mays,* maize (corn), seed is another readily available commodity found worldwide. Although LOX from corn was the first 9-LOX identified (5), it has the disadvantage of possessing a highly efficient enzyme, allene oxide synthase (AOS, formerly known as hydroperoxide isomerase). AOS immediately transforms 9*S*-HPODE into 9,10- and 10,13-ketols. AOS can be mostly removed by selective ammonium sulfate precipitation to such an extent that 9*S*-HPODE can be isolated (6), but further improvement in the ease of preparation is desirable. The germs of other cereals, such as rice (7), barley (8) and wheat (9), contain 9-LOX; however, multistep partial purification of these 9-LOX is required.

In this report alternative methods are described to oxidize linoleic acid or linolenic acid into 9*S*-HPODE or 9(*S*)-hydroperoxy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid (9*S*-HPOTE), respectively, by facile procedures using either corn germ (embryonic axis plus scutellum) or whole corn seed.

## MATERIALS AND METHODS

*Materials.* The seed source was *Z. mays*, commonly known as maize (international terminology) or corn (U.S.A. terminology). Common field corn, otherwise known as "dent corn," was used. Corn seed preferably was from the most recent harvest. Ear corn, that is, "corn-on-the-cob," is recommended. The cob, upon which the kernels are attached, is a specialized receptacle with archaic origins from a stalk or tassel. In the past, corn was stored in bins as ear corn and permitted to air-dry. Recently, most corn grain is harvested by a combined picker/sheller, and occasionally this grain is dried with heated air. Although not proven, it is believed that ear corn may be a more reliable product, not unduly subjected to variable heat conditions. Ear corn was purchased from a local animal feed store, and then the seed was shelled from the cob by hand.

Almost all of the 9-LOX activity resides in the germ, whereas the endosperm has negligible activity (5). By weight, the germ makes up 10 to 14% of the total kernel and comprises several anatomically distinct tissues that are subcategorized by the general terminology of the embryonic axis plus the scutellum. The germ is identified as an oval depression on one side of the kernel that extends from the base of the kernel to about two-thirds upward. For a detailed explanation of germ tissue, consult the microscopic work of Wolf *et al.* (10). For those investigators who do not choose the tedium of hand-dissecting germ, an alternative method using whole corn kernels is outlined below (Procedure 3).

Linoleic and α-linolenic acids were obtained from Nu-Chek-Prep (Elysian, MN). 2-(*N*-Morpholino)ethane sulfonic acid (mes) buffer was purchased from Research Organics (Cleveland, OH) and was used as the K salt.

*Preparation of 9*S*-HPODE/9*S*-HPOTE: Procedure 1.* Acid treatment (pH 4.5) of a water extract of corn germ followed by centrifugation removed sufficient AOS activity to afford 9*S*-HPODE from 9-LOX activity. Hand-dissected corn germ (2 g of the embryonic axis plus scutellum) was homogenized using a Polytron homogenizer for 1 min at full speed with 20-mL deionized water. The homogenate was adjusted to pH 4.5 ± 0.2 with citric acid (~0.1 M). The acidified homogenate did not require an incubation time, and it was subjected to centrifugation at 10,000 × *g* for 30 min whenever convenient. The floating layer of lipid bodies was aspirated, and the supernatant was carefully decanted. To avoid minor amounts of suspended residue, the supernatant was filtered through a wad of cotton. The supernatant was adjusted to pH 6.5 with KOH (~0.1 M) giving 11–15 mL solution, which was brought up to 19 mL with 50 mM mes buffer at pH 6.5 (final reaction concentration of 10–20 mM mes). Linoleic/linolenic acid substrate (1 mL) (80 mM, 22.4/22.2 mg) and 2.24 wt% Tween 20 at pH 7 ± 0.2 were added to the buffered supernatant (final linoleic/linolenic acid concentration of 4 mM) in a 250-mL Erlenmeyer flask with vigorous magnetic stirring under a stream of pure oxygen for 30 min at room temperature. After reaction, the solution was adjusted to pH 4.5 with 1 M oxalic acid and immediately extracted with 60 mL chloroform/methanol (2:1, vol/vol). The chloroform layer was washed with 15 mL water and then was concentrated by rotary evaporator at about 37°C until nearly dry. The residue plus a small amount of solvent remaining was immediately taken up in about 1 mL of diethyl ether and was stored at –20°C for further processing. It is important to store hydroperoxides in the freezer dissolved in solvent. After chromatographic purification, methanol as a solvent is recommended for long-term storage.

A "control reaction" consisted of the identical treatment as Procedure 1, except the citric acid adjustment of the homogenate to pH 4.5 was omitted.

For preparation of substrate, either 112 mg linoleic acid or 111 mg linolenic acid plus 112 mg Tween 20 was stirred with 1 mL water. Enough 1 M KOH was added to achieve pH 12–13, at which point the solution should clarify. The solution was then acidified with 1 M citric acid to pH 7 to obtain a uniformly cloudy solution. This solution was then brought up to 5 mL with water (80 mM substrate).

*Preparation of 9*S*-HPODE: Procedure 2.* Corn germ was homogenized in water, adjusted to pH 4.5, centrifuged, and the pH of the supernatant was readjusted to 6.5 as in Procedure 1 described above. The supernatant was adjusted to 40% of $(NH_4)_2SO_4$ saturation and centrifuged at 10,000 × *g* for 30 min. This supernatant was adjusted to 60% $(NH_4)_2SO_4$ saturation and centrifuged as above. The pellet obtained (40 to 60% of saturation) was brought up to 19 mL with 50 mM mes buffer (pH 6.5). As described in Procedure 1, addition of 1 mL substrate (80 mM, 22.4 mg linoleic acid) containing 2.24 wt% Tween 20 commenced the reaction. The final reaction concentrations were 47.5 mM mes, 4 mM substrate, and 0.112 wt% Tween 20. Recovery of product was identical to Procedure 1.

*Preparation of 9*S*-HPODE: Procedure 3.* Whole corn kernels (15 g) were ground into a meal with an electric coffee grinder. The corn meal was homogenized with 25 mL water using a Polytron homogenizer (full speed for 1 min). The homogenate was adjusted to pH 4.5 with citric acid and centrifuged as in Procedure 1. As in Procedure 1, no particular incubation time at pH 4.5 was required. Usually 9–10 mL of supernatant was obtained which was diluted to 19 mL with mes buffer, pH 6.5. Substrate solution (1 mL) was added as before, and the reaction and recovery of product were the same as the other procedures. The final reaction concentrations were ~25 mM mes, 4 mM substrate, and 0.112 wt% Tween 20.

*Analytical methods.* Activity as a function of pH (4.5 to 8.25) was determined with 50 mM $KH_2PO_4/Na_2HPO_4$ buffer. Activity assays were accomplished by oxygen electrode (Gilson 5/6H oxygraph; Middleton, WI). Temperature was 25°C. Substrate was 1 mM linoleic acid emulsified with 0.028 wt% Tween 20.

In order to determine the yield of either linoleic or linolenic acid conversion, an aliquot of the extracted products was reduced by $NaBH_4$ in 1 mL methanol for 30 min. To extract products, 3 mL $CHCl_3/H_2O$ (2:1, vol/vol) was added, and the upper aqueous layer was adjusted to pH 4 with 1 M oxalic acid. The recovered $CHCl_3$ layer was washed with water, and the fatty acids extracted by $CHCl_3$ were esterified by diazomethane in diethyl ether/methanol (9:1, vol/vol) followed by formation of trimethylsilyloxy ethers (OTMSi) by pyridine/hexamethyldisilazane/trimethylchlorosilane (2:2:3, by vol) for 15 min. The reagent was evaporated, and the residue was taken up in hexane for determination of products by flame-ionization detection–gas chromatography (FID–GC) using a Hewlett-Packard model 5890 gas chromatograph (Palo Alto, CA). The capillary column used was an SPB-1 (dimethyl polysiloxane phase, 0.32 mm × 30 m, film thickness 0.25 μm) from Supelco (Bellefonte, PA). Temperature programming was from 160 to 260ºC at 5ºC/min with a hold at 260ºC for 5 min; He flow was 2 mL/min. The identity of the FID–GC peaks was confirmed by GC–mass spectrometry (MS) using a Hewlett-Packard Model 5890 gas chromatograph interfaced with a model 5971 mass-selective detector operating at 70 ev. The capillary column utilized was a Hewlett-Packard HP-5MS cross-linked 5% phenyl methyl silicone (0.25 mm × 30 m, film thickness 0.25 μm). Temperature programming was identical to the conditions used for FID–GC; He flow rate was 0.67 mL/min. The mixture containing 9*S*-HPOTE was also hydrogenated with $H_2$ and a catalyst (5% Pd on $CaCO_3$; Aldrich Chemical Co., Milwaukee, WI) for 1 h. The methyl ester/OTMSi derivative was produced as described above for analysis by GC–MS.

As outlined (11), regio- and stereoconfigurations were determined by straight-phase high-performance liquid chromatography (SP-HPLC) (regio-analysis) followed by stereo-

analysis by chiral-phase HPLC (CP-HPLC) of the methyl hydroxyoctadecadienoate derivative. The stereoconfiguration of 9*S*-HPOTE and 9*S*-HPODE was ascertained by an independent method of forming diastereomeric (–)-menthylcarbonyl derivatives (12) modified to use $KMnO_4$ in acetic acid in the place of oxidative ozonolysis (13). The (–)-menthylcarbonyl derivative of dimethyl 2-hydroxy-decanedioate from oxidative cleavage was separated into 2(*S*) and 2(*R*) isomers by GC (14).

## RESULTS

*Source of corn 9-LOX and pH optimum.* A full description of the source of maize (corn) used in the preparation of 9-LOX is outlined in the Materials and Methods section. In addition, a rationale is given for choosing between corn germ or whole corn kernels.

By use of the unpublished procedure of H.W. Gardner and D.D. Christianson, corn germ 9-LOX was purified 320-fold (reviewed in Ref. 15) in order to obtain a pH activity optimum at 6.5 (Fig. 1). Although LOX activity was shown to be very slight above pH 8.3, Veldink *et al.* (16) reported that a corn-germ preparation oxidized linoleic acid to mainly the 13(*S*)-hydroperoxide at pH 9. Whether this oxidation was promoted by higher pH or the result of another LOX isoenzyme is not known. In this method an optimum of pH 6.5 was maintained to favor the formation of 9*S*-HPODE.

*Procedure 1.* A simple water extraction of corn germ, adjustment to pH 4.5 with citric acid, and centrifugation removed most of the AOS activity. Thus, readjusting the pH with KOH and mes to the optimum pH 6.5 for corn 9-LOX and incubation with 4 mM linoleic acid afforded 9*S*-HPODE in good yield (70 ± 21%), while AOS-produced ketols amounted to only 4 ± 3% of the total (Table 1).

*Procedure 2.* After acidification and centrifugation by Procedure 1, further purification of corn 9-LOX with fractional precipitation between 40 and 60% of ammonium sulfate saturation resulted in an insignificant difference in yield of 9*S*-HPODE compared to Procedure 1 (Table 1).

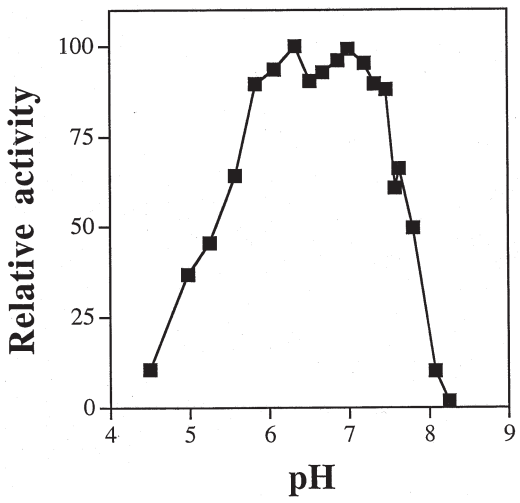

**FIG 1.** Corn-germ lipoxygenase activity (relative values) as a function of pH (50 mM $Na_2HPO_4/KH_2PO_4$ buffer).

**TABLE 1**
**Percentage Yield of 9-Hydroperoxide, Ketols, and Unreacted Linoleic Acid[a]**

| Procedure[b] | 9*S*-HPODE | Linoleic acid | α- Plus γ-ketols | Other[c] |
|---|---|---|---|---|
| 1 | 70 ± 21 | 22 ± 23 | 4.0 ± 3.4 | 3.7 ± 4.0 |
| 2 | 69 ± 25 | 15 ± 29 | 7.9 ± 8.8 | 7.1 ± 4.4 |
| 3 | 55 ± 17 | 31 ± 19 | 11 ± 20 | 1.9 ± 1.0 |
| Control[d] | 2.1 ± 0.2 | 18 ± 10 | 75 ± 7 | 4.7 ± 3.5 |

[a]Weight percentage determined by flame-ionization detection–gas chromatography of $NaBH_4$-reduced products after conversion to methyl esters/trimethylsilyloxy (OTMSi) ethers. Values are means and standard deviation (Procedure 1, $n = 6$; Procedure 2, $n = 4$; Procedure 3, $n = 5$; Control, $n = 2$). Each oxidation represents a 20 mL reaction containing 4 mM linoleic acid (22.4 mg linoleic acid). On a molar basis, the values would be modified by their molecular weight: 9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid (9*S*-HPODE) as methyl 9-OTMSi-octadecadienoate, 382 mg/mmol; linoleic acid as methyl linoleate, 294 mg/mmol; α- plus γ-ketols as methyl 9,10-diOTMSi- and 10,13-diOTMSi-octadecenoate, 472 mg/mmol.
[b]Procedure 1: homogenized corn germ adjusted to pH 4.5, centrifuged, decanted, and readjusted to pH 6.5. Procedure 2: same as Procedure 1, except additionally fractionated by $(NH_4)_2SO_4$ (40 to 50% of saturation). Procedure 3: same as Procedure 1, except whole corn meal replaced corn germ.
[c]"Other" were isomeric HPODE other than 9*S*-HPODE, as well as oxidized fatty acids more polar than ketols.
[d]"Control reaction," that is, a water extract of corn germ adjusted to pH 6.5 with 2-(*N*-morpholino)ethane sulfonic acid; no pH 4.5 treatment.

*Procedure 3.* A comparatively larger quantity of whole corn was pretreated by grinding into a meal before using whole corn meal in the place of corn germ by Procedure 1. This method resulted in slightly less oxidation of linoleic acid as expected (Table 1). However, it eliminated the time required to dissect the germ. Further purification of the whole-corn preparation by $(NH_4)_2SO_4$ precipitation (40–60% of saturation; method not listed) did not significantly improve the method (53 ± 16% 9*S*-HODE, 42 ± 16% linoleic acid, 1.3 ± 1.1% ketols).

*Regio- and stereoconfiguration of 9-LOX product.* As shown in Table 2, the stereoconfiguration of the 9-LOX product was predominantly 9*S*-HPODE (97%) as determined by SP-HPLC followed by CP-HPLC. Chemical determination of stereoconfiguration was confirmatory (Table 2).

*Formation of 9S-HPOTE.* The oxidation of linolenic acid by corn germ has not been reported previously. Procedure 1 afforded a yield of 9*S*-HPOTE of 69%, with the remainder being unreacted linolenic acid (27%), AOS-generated ketols (3%), and other fatty acids (1%). The electron impact–mass spectrum (EI–MS) of the methyl esterified, $NaBH_4$-reduced, OTMSi derivative was as follows in *m/z* [ion structure] (% ion intensity): 380 $[M]^+$ (0.6), 365 $[M - CH_3]^+$ (0.2), 311 $[M - CH_3CH_2CH{=}CHCH_2]^+$ (30), 290 $[M - TMSiOH]^+$ (3), 223 $[M - (CH_2)_7COOCH_3]^+$ (44), 157 (12), 154 (10), 143 (15), 130 (17), 108 (23), 103 (20), 73 $[TMSi]^+$ (100). Since EI–MS of the unsaturated derivative did not precisely locate the position of the hydroxyl, the product mixture was hydrogenated and then examined by EI–MS as the methyl ester/OTMSi derivative, affording the precise location of the hydroxyl at C-9: 371

[a]Stereoconfiguration of 13-hydroperoxides and (*E,E*)-isomers was not determined.
[b]Analysis by straight-phase–high-performance liquid chromatography (HPLC) and chiral-phase–HPLC of methyl hydroxyoctadecadienoates from triphenylphosphine reduction and methyl esterification of hydroperoxide products. For statistical analysis of linoleic acid products, $n = 8$.
[c]Analysis of stereoconfiguration of 9*S*-HPODE and 9(*S*)-hydroperoxy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid by a chemical/gas chromatography method (11). For abbreviation see Table 1.

$[M - CH_3]^+$ (2), 355 $[M - CH_3O]^+$ (3), 339 $[M - CH_3OH - CH_3]^+$ (6), 259 $[CHOTMSi(CH_2)_7COOCH_3]^+$ (100), 229 $[CH_3(CH_2)_8CHOTMSi]^+$ (76), 155 (15), 129 (9), 109 (10), 103 (10), 73 $[TMSi]^+$ (49).

The stereoconfiguration of 9*S*-HPOTE examined after triphenylphosphine reduction gave a chiral purity better than 99% 9(*S*) (Table 2).

## DISCUSSION

Although it was not specifically investigated, it is presumed that AOS precipitated after acid treatment. Because AOS is largely membrane-bound in corn seed, care should be taken to carefully aspirate the floating oil-body layer and decant and filter the supernatant after centrifugation. Accidental inclusion of precipitate may account for the variability in AOS-generated ketols in the products, which occasionally were higher than usual. An additional treatment with ammonium sulfate fractionation would give additional protection against AOS inclusion (6), but it can be seen from Table 1 that there was no significant improvement. The largest variability in yield was due to the relative percentages of unreacted substrate and hydroperoxide product because of inconsistent recovery of LOX activity.

*Chromatographic purification of 9S-HPODE.* SP–HPLC separation of fatty acid hydroperoxides has been reported using hexane/2-propanol/acetic acid eluting solvent (17). Although acetic acid in the solvent is satisfactory for analytical applications, it may be a problem in preparative applications. Strong acids are known to decompose linoleic acid hydroperoxides (18). Weak acids, such as acetic acid, are far less damaging, but should be a concern when they are concentrated by evaporation. For this reason, the use of a pH 4 silica is preferred in order to suppress ionization of the carboxylic acid without the use of organic acid. Such supports are available for ordinary column chromatography, such as SilicAR CC4 (Mallinckrodt, Phillipsburg, NJ) or silicic acid (100 mesh, Mallinckrodt). Normally, elution by a stepwise or gradient of 5 to 10% acetone in hexane is satisfactory (19), but we found that α-ketol has a propensity to migrate with 9*S*-HPODE in this solvent. However, a gradient of diethyl ether in hexane has been shown to be satisfactory in separating 9*S*-HPODE from α-ketol (5). This method excludes unreacted substrate and AOS-produced ketols but only partly separates hydroperoxide regio-isomers. Early-eluting 13-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid can be largely removed by discarding the very early portion of the eluting hydroperoxide peak. In our laboratory we usually apply 0.5–0.7 g crude oxidation product to a 2.5 cm i.d. column containing 50 g silicic acid. Very often losses, including those from selective collection of fractions, result in recovery of about 50% of the original hydroperoxide product. Appropriate scaleup of the reaction reported here would be required to obtain 0.5–0.7 g crude product; however, attention must be given to surface area and stirring in order to promote sufficient oxygen exchange.

SP–HPLC on silica columns is more easily accomplished with methyl esters. Because fatty acid hydroperoxides are decomposed by acid-catalyzed methylation, including alkali-catalyzed transmethylation, only diazomethane is suitable for methyl esterification. As originally reported by Chan and Prescott (20), purification of the methyl-esterified 9-HPODE was readily accomplished by SP–HPLC on silica columns using elution with hexane and 1% or less of either ethanol or 2-propanol.

# Synthetic Routes and Lipase-Inhibiting Activity of Long-Chain α-Keto Amides

**Antonia Chiou[a], Robert Verger[b], and George Kokotos[a,*]**

[a]Department of Chemistry, University of Athens, Panepistimiopolis, Athens 15771, Greece, and [b]Laboratoire de Lipolyse Enzymatique CNRS, UPR 9025, 13402 Marseille, France

**ABSTRACT:** Synthetic routes to primary and *N*-alkyl α-keto amides are presented in this paper. Primary α-keto amides may be prepared by using an aldehyde as starting material. Commercially available α-keto acids may be coupled in high yield with primary amines by the mixed carbonic anhydride method affording *N*-alkyl α-keto amides. Alternatively, *N*-alkyl α-keto amides may be prepared by coupling long-chain α-hydroxy acids with amino components, followed by oxidation with pyridinium dichromate or NaOCl in the presence of 4-acetamido-2,2,6,6-tetramethyl-1-piperidinyloxy free radical. The α-keto amide derivatives prepared according to these procedures were tested for their ability to form stable monomolecular films at the air/water interface. The inhibition of porcine pancreatic lipase by the α-keto amides, spread as mixed films with 1,2-dicaprin, was studied with the monolayer technique. Among the compounds tested in this study, methyl 2-[(2-ketododecanoyl)amino]hexadecanoate was shown to be the most potent inhibitor, causing a 50% decrease in lipase activity at a 0.09 molar fraction.

Paper no. L8677 in *Lipids 36,* 535–542 (May 2001).

Inhibitors of pancreatic lipase hold great promise as antiobesity agents, because nonhydrolyzed triacylglycerols cannot be absorbed through the intestine and thus cannot contribute to the energy intake of the body. The β-lactone-containing inhibitor tetrahydrolipstatin is already a registered drug for the treatment of obesity (1,2). On the other hand, synthetic inhibitors of lipases are of interest because they may contribute to a better understanding of the mechanism of lipase action (3–5). Alkyl phosphonates of simple or more complicated structure are the main representative class of such synthetic inhibitors (6–10).

The enzymatic mechanism as well as the catalytic site residues of pancreatic lipase are similar to those of serine proteases, consisting of a Ser-His-Asp triad. Many inhibitors of serine proteases consist of a substrate-like structure incorporating an activated carbonyl group at the site of the scissile amide bond. A number of reactive carbonyl groups, such as fluorinated ketones (11), α-keto esters (12), α-keto amides (13) and α-keto heterocycles (14), have been successfully used in the design of protease inhibitors.

Synthetic compounds containing electrophilic carbonyl groups, such as fatty alkyl trifluoromethyl ketones (15,16) and tricarbonyl derivatives of arachidonic and palmitic acids (17), have been reported to inhibit cytosolic phospholipase $A_2$ and calcium-independent phospholipase $A_2$, enzymes containing a Ser residue in their active site. Recently, we reported that a lipophilic α-keto amide inhibits pancreatic lipase (18). In this paper we describe synthetic routes to primary and *N*-alkyl α-keto amides. Furthermore, we present that long-chain α-keto amides of simple structure may inhibit pancreatic lipase.

Abbreviations: AcNH-TEMPO, 4-acetamido-2,2,6,6-tetramethyl-1-piperidinyloxy; COSY, correlation spectrometry; $Et_3N$, triethylamine; FAB, fast atom bombardment; HOBt, 1-hydroxybenzotriazole; IR, infrared; MS, mass spectrometry; NMM, *N*-methylmorpholine; NMR, nuclear magnetic resonance; PDC, pyridinium dichromate; PPL, porcine pancreatic lipase; THF, tetrahydrofuran; Tris, 2-amino-2-hydroxymethyl-1,3-propanediol; WSCI, 1-(3-dimethylaminopropyl)-3-ethyl carbodiimide.

## EXPERIMENTAL PROCEDURES

*Materials and methods.* 1,2-Dicaprin was purchased from Serdary Research Laboratory (London, Canada). 4-Acetamido-2,2,6,6-tetramethyl-1-piperidinyloxy free radical (AcNH-TEMPO) was purchased from Aldrich (Milwaukee, WI). Analytical thin-layer chromatography plates (silica gel 60 $F_{254}$) and silica gel 60 (70–230 mesh) were purchased from Merck (Darmstadt, Germany). Porcine pancreatic lipase (PPL) was purified at the laboratory using previously described procedures (19). Tetrahydrofuran (THF) was passed through a column of aluminum oxide and distilled from $CaH_2$. Isobutyl chloroformate was distilled and stored over $CaCO_3$. *N*-Methylmorpholine (NMM) and triethylamine ($Et_3N$) were distilled from ninhydrin. All other solvents and chemicals were of reagent grade and used without further purification. Melting points were determined on a Büchi 530 apparatus and are uncorrected. Infrared (IR) spectra were recorded on a PerkinElmer 841 spectrometer (Palo Alto, CA). $^1H$ nuclear magnetic resonance (NMR), $^{13}C$ NMR, distortionless enhancement by polarization transfer, correlation spectrometry (COSY) and $^{13}C$-$^1H$ COSY spectra were obtained in $CDCl_3$ using a Varian Mercury (200 MHz) or Varian Unity (300 MHz) spectrometer (Palo Alto, CA). Fast atom bombardment (FAB) mass spectra were obtained on a VG Analytical ZAB-SE instrument (Manchester, United Kingdom). Elemental analyses were performed on a PerkinElmer 2400 instrument. Monomolecular film experiments as well as enzyme kinetics experiments were performed with a KSV 2200 Barostat equipment (KSV-Helsinki, Finland).

*Synthetic procedures. (i) 2-Hydroxypentadecanenitrile (**2**).* To a stirred solution of tetradecanal (0.64 g, 3.0 mmol) in $CH_2Cl_2$ (4 mL), $NaHSO_3$ (0.47 g, 4.5 mmol) in water (1 mL) was added at room temperature. A white solid started to precipitate upon the addition. After stirring for 30 min at room temperature, $CH_2Cl_2$ was evaporated under reduced pressure, and water (3 mL) was added. To the resulting suspension, cooled at 0°C, a solution of KCN (0.29 g, 4.5 mmol) in $H_2O$ (1 mL) was added dropwise over a period of 3 h at 0°C. After

stirring at room temperature overnight, $CH_2Cl_2$ was added followed by extraction. The organic phase was washed with brine solution and dried ($Na_2SO_4$). The solvent was evaporated under reduced pressure, and the crude product was purified by column chromatography using petroleum ether 40–60°C/EtOAc (9:1, vol/vol) as eluent. Yield 0.545 g (76%); m.p. 53.5–55°C; $^1$H NMR (300 MHz) δ 4.5 (1H, *m*, CHCN), 2.4 (1H, *br*, OH), 1.8 (2H, *m*, C$H_2$CH), 1.6–1.3 (22H, *m*, 11 × $CH_2$), 0.9 (3H, *t, J* = 7 Hz, $CH_3$); $^{13}$C NMR (75 MHz) δ 120.03 (CN), 61.34 (*C*HCN), 35.18 [*C*$H_2$CH(OH)], 32.00, 29.72, 29.56, 29.43, 29.01, 24.62, 22.77 (*C*$H_2$CH$_3$), 14.20 ($CH_3$); IR (ν cm$^{-1}$, KBr): 3397 (O–H), 2254 (C≡N), 1074 (C–O); FAB-mass spectrometry (MS) *m/z* 262 (M + $Na^+$, 100%), 240 (M + $H^+$, 21%), 222 (21), 213 (97). Calc. for $C_{15}H_{29}NO$: C 75.26; H 12.21; N 5.82; MW 239.40. Found: C 75.12; H 12.51; N 5.93.

*(ii) 2-Hydroxypentadecanamide (**3**).* A suspension of compound **2** (0.48 g, 2.0 mmol) in concentrated hydrochloric acid (5 mL) was stirred at room temperature overnight. $CHCl_3$ (3 × 30 mL) was added, and the organic phase was washed with brine solution and dried ($Na_2SO_4$). The solvent was evaporated to a small volume and the white solid that precipitated after cooling was filtered and dried. Yield 0.345 g (67%); m.p. 151–152°C; $^1$H NMR (300 MHz) δ 4.5 (1H, *m*, C*H*CONH$_2$), 2.8 (1H, *m*, OH), 1.9–1.6 (2H, *m*, C$H_2$CH), 1.6–1.3 (22H, *m*, 11 × $CH_2$), 0.9 (3H, *t, J* = 7 Hz, $CH_3$); IR (ν cm$^{-1}$, KBr): 3384 and 3278 (NH, OH), 1639 (C=O), 1098 (C–O); FAB-MS *m/z* 280 (M + $Na^+$, 13%), 258 (M + $H^+$, 100%). Calc. for $C_{15}H_{31}NO_2$: C 69.99; H 12.14; N 5.44; MW 257.41. Found: C 70.22; H 12.43; N 5.63.

*General procedure for the amide bond formation* via *the mixed anhydride method.* To a stirred solution of the appropriate α-keto acid (1.0 mmol) in THF (5 mL) cooled at −10°C, NMM (0.11 mL, 1 mmol) and subsequently isobutyl chloroformate (0.13 mL, 1.0 mmol) were added dropwise. After stirring for 5 min at −10°C, an ice-cooled solution of the amino component (1.0 mmol) in THF (5 mL) was added dropwise. The reaction mixture was stirred for 1 h at −10°C and then at room temperature overnight. The solvent was evaporated and the residue was dissolved in EtOAc. The organic phase was washed with water, 0.5 N HCl, water, 5% $NaHCO_3$, brine solution, and dried ($Na_2SO_4$). The solvent was removed under reduced pressure and the residue was purified by column chromatography using petroleum ether 40–60°C/EtOAc (8:2, vol/vol) as eluent.

N-*hexadecyl-2-ketobutanamide (**7a**)*. Yield 0.296 g (91%); m.p. 49–50°C; $^1$H NMR (300 MHz) δ 6.9 (1H, *br*, CONH), 3.3 (2H, *m*, C$H_2$NH), 2.9 (2H, *q, J* = 7 Hz, C$H_2$CO), 1.6 (2H, *m*, C$H_2$CH$_2$NH), 1.3 (26H, *m*, 13 × $CH_2$), 1.1 (3H, *t, J* = 7 Hz, C$H_3$CH$_2$CO), 0.9 (3H, *t, J* = 7 Hz, $CH_3$). Calc. for $C_{20}H_{39}NO_2$: C 73.79; H 12.08; N 4.30; MW 325.54. Found: C 73.95; H 12.36; N 4.22.

N-*Hexyl-2-ketooctanamide (**7b**)*. Yield 0.210 g (87%); oil; $^1$H NMR (300 MHz) δ 6.9 (1H, *br*, CONH), 3.3 (2H, *m*, C$H_2$NH), 2.9 (2H, *t, J* = 7 Hz, C$H_2$CO), 1.5 (4H, *m*, C$H_2$CH$_2$CO, C$H_2$CH$_2$NH), 1.3 (12H, *m*, 6 × $CH_2$), 0.9 (6H, *m*, 2 × $CH_3$).

N-*hexadecyl-2-ketooctanamide (**7c**)*. Yield 0.328 g (86%); m.p. 60–61°C; $^1$H NMR (300 MHz) δ 6.9 (1H, *br,* CONH), 3.3 (2H, *m*, C$H_2$NH), 2.9 (2H, *t, J* = 7 Hz, $CH_2$CO), 1.5 (4H, *m*, C$H_2$CH$_2$NH, C$H_2$CH$_2$CO), 1.3 (32H, *m*, 16 × $CH_2$), 0.9 (6H, *m*, 2 × $CH_3$). Calc. for $C_{24}H_{47}NO_2$: C 75.53; H 12.41; N 3.67; MW 381.64. Found: C 75.70; H 12.78; N 3.42.

N-cis-*9-Octadecenyl-2-ketooctanamide (**7d**)*. Yield 0.367 g (90%); oil; $^1$H NMR (200 MHz) δ 6.9 (1H, *br*, CONH), 5.4 (2H, *m*, CH=CH), 3.3 (2H, *m*, C$H_2$NH), 2.9 (2H, *t, J* = 7 Hz, $CH_2$CO), 2.0 (4H, *m*, C$H_2$CH=CHC$H_2$), 1.6 (4H, *m*, C$H_2$CH$_2$NH, C$H_2$CH$_2$CO), 1.3 (28H, *m*, 14 × $CH_2$), 0.9 (6H, *m*, 2 × $CH_3$); $^{13}$C NMR (50 MHz) δ 199.47 (*C*OCONH), 160.09 (CONH), 129.92 and 129.68 (CH=CH), 39.28 ($CH_2$NH), 36.67 (*C*$H_2$CO), 32.55, 31.86, 31.47, 29.72, 29.66, 29.48, 29.35, 29.28, 29.22, 29.16, 28.89, 27.17, 27.12, 26.81, 23.13, 22.64 and 22.41 (*C*$H_2$CH$_3$), 14.06 and 13.95 ($CH_3$); FAB-MS *m/z* 409 (M + 2$H^+$, 100%), 269 (96).

*2-Keto*-N-*{2-[(2-ketobutanoyl)amino]ethyl}butanamide (**8a**)*. Yield 0.162 g (71%); m.p. 153–155°C; $^1$H NMR (300 MHz) δ 3.5 (4H, m, C$H_2$NH), 2.9 (4H, *q, J* = 7 Hz, $CH_2$CO), 0.9 (6H, *t, J* = 7 Hz, 2 × $CH_3$). Calc. for $C_{10}H_{16}N_2O_4$: C 52.62; H 7.07; N 12.27; MW 228.25. Found: C 52.94; H 7.12; N 11.95.

*2-Keto*-N-*{2-[(2-ketooctanoyl)amino]ethyl}octanamide (**8b**)*. Yield 0.269 g (79%); m.p. 121–122°C; $^1$H NMR (300 MHz) δ 3.5 (4H, *m*, C$H_2$NH), 2.9 (4H, *t, J* = 7 Hz, $CH_2$CO), 1.6 (4H, *m*, C$H_2$CH$_2$CO), 1.3 (12H, *m*, 6 × $CH_2$) 0.9 (6H, *t, J* = 7 Hz, 2 × $CH_3$). Calc. for $C_{18}H_{32}N_2O_4 \cdot 0.5H_2O$: C 61.86; H 9.52; N 8.02; MW 349.47. Found: C 62.22; H 9.62; N 7.73.

*General procedure for the deamination of lipidic α-amino acids.* To a stirred suspension of the lipidic α-amino acid (10 mmol) in 1 M $H_2SO_4$ (120 mL), a solution of $NaNO_2$ (1.45 g, 21 mmol) in water (38 mL) was added dropwise over a period of 2 h with heating at 80–90°C. The mixture was stirred for 3 h at 80–90°C and overnight at room temperature. It was then extracted with $Et_2O$ (4 × 200 mL), and the combined organic layers were washed with brine solution and dried ($Na_2SO_4$). The solvent was evaporated under reduced pressure, and the residue was purified by recrystallization from $CHCl_3$.

*2-Hydroxydodecanoic acid (**10a**)*. Yield 1.12 g (52%); m.p. 71–73°C; $^1$H NMR (200 MHz) δ 4.3 (1H, *m*, C*H*COOH), 1.8 (2H, *m*, C$H_2$CH), 1.3 (16H, *m*, 8 × $CH_2$), 0.9 (3H, *t, J* = 7 Hz, $CH_3$); IR (ν cm$^{-1}$, KBr): 3518 (OH), 3600–2500 (COOH), 1701 (C=O).

*2-Hydroxyhexadecanoic acid (**10b**)*. Yield 1.28 g (47%); m.p. 82–84°C. The NMR spectrum of **10b** was not obtained because of its low solubility in any of the deuterated solvents.

*General procedure for amide bond formation* via *the water-soluble carbodiimide method.* To a stirred suspension of the appropriate α-hydroxy acid (2.0 mmol) and amine (2.0 mmol) in $CH_2Cl_2$ (8 mL), $Et_3N$ (0.31 mL, 2.2 mmol) and subsequently 1-(3-dimethylaminopropyl)-3-ethyl carbodiimide (WSCI: 0.42 g, 2.2 mmol) and 1-hydroxybenzotriazole (HOBt: 0.27 g, 2.0 mmol) were added at 0°C. The reaction mixture was stirred for 1 h at 0°C and overnight at room temperature. The organic layer was washed with brine solution, dried ($Na_2SO_4$), and

evaporated under reduced pressure. The residue was purified by column chromatography using petroleum ether 40–60°C/EtOAc (3:2, vol/vol) as eluent.

N-*Hexyl-2-hydroxyhexadecanamide (**11a**)*. Yield 0.511 g (72%); m.p. 96–97°C; FAB-MS *m/z* 378 (M + $Na^+$, 5%), 356 (M + $H^+$, 100%). Calc. for $C_{22}H_{45}NO_2 \cdot 0.5H_2O$: C 72.47; H 12.72; N 3.84; MW 364.62. Found: C 72.49; H 12.90; N 3.55.

N-*Hexadecyl-2-hydroxyhexadecanamide (**11b**)*. Yield 0.525 g (53%); m.p. 94–96°C; $^1$H NMR (200 MHz) δ 6.4 (1H, *br*, CONH), 4.1 (1H, *m*, C*H*OH) 3.3 (2H, *m*, C$H_2$NH), 2.4 (1H, *br*, OH), 1.9–1.5 (4H, *m*, C$H_2$CHOH, C$H_2$C$H_2$NH), 1.3 (50H, *m*, 25 × $CH_2$) 0.9 (6H, *m*, 2 × $CH_3$); FAB-MS *m/z* 496 (M + $H^+$, 100%). Calc. for $C_{32}H_{65}NO_2 \cdot H_2O$: C 75.45; H 13.16; N 2.75; MW 513.90. Found: C 75.22; H 13.00; N 2.83.

N-cis-*9-Octadecenyl-2-hydroxyhexadecanamide (**11c**)*. Yield 0.699 g (67%); m.p. 80–81°C; $^1$H NMR (200 MHz) δ 6.5 (1H, *br*, CONH), 5.3 (2H, *m*, CH=CH), 4.1 (1H, *m*, C*H*OH) 3.3 (2H, *m*, C$H_2$NH), 2.6 (1H, *br*, OH), 2.0 (4H, *m*, C$H_2$CH=CHC$H_2$), 1.9–1.5 (4H, *m*, C$H_2$C$H_2$NH, C$H_2$CHOH), 1.3 (46H, *m*, 23 × $CH_2$), 0.9 (6H, *m*, 2 × $CH_3$); $^{13}$C NMR (50 MHz) δ 173.72 (CONH), 129.95 and 129.74 (CH=CH), 72.14 (CHOH), 39.12 ($CH_2$NH), 34.98 (*C*$H_2$CHOH), 31.91, 29.68, 29.65, 29.58, 29.54, 29.42, 29.35, 29.31, 29.25, 27.19, 26.88, 24.95, 22.67 (*C*$H_2$$CH_3$), 14.10 ($CH_3$). Calc. for $C_{34}H_{67}NO_2 \cdot 0.5H_2O$: C 76.92; H 12.91; N 2.64; MW 530.92. Found: C 76.92; H 13.08; N 2.68.

*Methyl 2-[(2-hydroxydodecanoyl)amino]hexadecanoate (**11d**)*. Yield 0.639 g (66%); m.p. 61–63°C; $^1$H NMR (200 MHz) δ 6.9 (1H, *d, J* = 8 Hz, CONH), 4.6 (1H, *m*, C*H*NH), 4.2 (1H, *m*, C*H*OH), 3.8 (3H, *s*, $COOCH_3$), 2.7 (1H, *br*, OH), 2–1.6 (4H, *m*, C$H_2$CHOH, C$H_2$CHNH), 1.3 (40H, *m*, 20 × $CH_2$), 0.9 (6H, *m*, 2 × $CH_3$); $^{13}$C NMR (50 MHz) δ 173.60 and 172.87 (CONH, *C*OOC$H_3$), 72.00 (CHOH), 52.34 (COO*C*$H_3$), 51.81 (CHNH), 34.87 and 32.36 (*C*$H_2$CHNH, *C*$H_2$CHOH), 31.89, 29.64, 29.58, 29.52, 29.38, 29.35, 29.16, 25.25, 24.81, 22.67 (*C*$H_2$$CH_3$), 14.11 ($CH_3$). Calc. for $C_{29}H_{57}NO_4 \cdot H_2O$: C 69.41; H 11.85; N 2.79; MW 501.78. Found: C 69.68; H 11.97; N 2.82.

*General procedures for the oxidation. (i) Procedure A: Oxidation using pyridinium dichromate (PDC)*. To a solution of α-hydroxy amide (1.0 mmol) in glacial acetic acid (5 mL), PDC (1.13 g, 3.0 mmol) was added. After stirring for 2 h at room temperature, the mixture was neutralized with 5% aqueous $NaHCO_3$ and extracted with EtOAc (3 × 15 mL). The combined organic layers were washed with brine solution and dried ($Na_2SO_4$). The solvent was evaporated under reduced pressure, and the crude product was purified by column chromatography using petroleum ether 40–60°C/EtOAc (9:1, vol/vol) as eluent.

*(ii) Procedure B: Oxidation using NaOCl/AcNH-TEMPO*. To a stirred solution of α-hydroxy amide (1.0 mmol) in a mixture of EtOAc/toluene/$CH_2Cl_2$ (1:1:0.1, by vol) (6 mL) was added a solution of NaBr (113 mg, 1.1 mmol) in water (0.5 mL), followed by AcNH-TEMPO (2 mg, 0.01 mmol), at 0°C. To the resulting biphasic system was added with vigorous stirring a solution of NaOCl (82 mg, 1.1 mmol) and $NaHCO_3$ (252 mg, 3.0 mmol) in $H_2O$ (3 mL) dropwise at 0°C over a period of 1 h. After stirring for 15 min at 0°C, EtOAc (15 mL) and water (5 mL) were added. The organic layer was washed first with 10% aqueous citric acid (10 mL) that contained KI (60 mg), then 10% aqueous $Na_2S_2O_3$ (10 mL), then brine solution (10 mL), and then it was dried ($Na_2SO_4$). The solvent was evaporated under reduced pressure and the crude product was purified by column chromatography using petroleum ether 40–60°C/EtOAc (9:1, vol/vol) as eluent.

*2-Ketopentadecanamide (**4**)*. Procedure A: Yield 0.179 g (70%); m.p. 114–116°C; $^1$H NMR (200 MHz) δ 2.9 (2H, *t, J* = 8 Hz, $CH_2CO$), 1.6 (2H, *m*, C$H_2$$CH_2$CO), 1.3 (20H, *m*, 10 × $CH_2$), 0.9 (3H, *t, J* = 7 Hz, $CH_3$); IR (ν $cm^{-1}$, KBr): 3401 (NH), 1717 (C=O), 1670 (CONH); FAB-MS *m/z* 278 (M + $Na^+$, 10%), 256 (M + $H^+$, 28%), 211 (19). Calc. for $C_{15}H_{29}NO_2$: C 70.54; H 11.45; N 5.48; MW 255.40. Found: C 70.81; H 11.34; N 5.33.

N-*Hexyl-2-ketohexadecanamide (**12a**)*. Procedure B: Yield 0.335 g (95%); m.p. 55–56°C; $^1$H NMR (200 MHz) δ 6.9 (1H, *br*, CONH), 3.3 (2H, *m*, C$H_2$NH), 2.9 (2H, *t, J* = 7 Hz, $CH_2CO$), 1.6 (4H, *m*, C$H_2$$CH_2$CO, C$H_2$C$H_2$NH), 1.3 (28H, *m*, 14 × $CH_2$), 0.9 (6H, *m*, 2 × $CH_3$); $^{13}$C NMR (50 MHz) δ 190.47 (*C*OCONH), 161.61 (CONH), 39.30 ($CH_2$NH), 34.05 (*C*$H_2$CO), 31.42, 29.11, 28.57, 25.21, 22.88, 22.40 (*C*$H_2$$CH_3$), 13.96 ($CH_3$); IR (ν $cm^{-1}$, KBr): 3330 (NH), 1722 (C=O), 1658 (CONH); FAB-MS *m/z* 376 (M + $Na^+$, 7%), 354 (M + $H^+$, 100%). Calc. for $C_{22}H_{43}NO_2$: C 74.73; H 12.26; N 3.96; MW 353.58. Found: C 74.78; H 12.06; N 3.87.

N-*Hexadecyl-2-ketohexadecanamide (**12b**)*. Procedure A: Yield 0.257 g (52%); $^1$H NMR (200 MHz) δ 6.9 (1H, *br*, CONH), 3.3 (2H, *m*, C$H_2$NH), 2.9 (2H, *t, J* = 7 Hz, $CH_2CO$), 1.6 (4H, *m*, C$H_2$$CH_2$CO, C$H_2$C$H_2$NH), 1.3 (48H, *m*, 24 × $CH_2$), 0.9 (6H, *m*, 2 × $CH_3$); $^{13}$C NMR (50 MHz) δ 190.54 (*C*OCONH), 160.12 (CONH), 39.32 ($CH_2$NH), 36.72 (*C*$H_2$CO), 31.91, 29.67, 29.64, 29.47, 29.43, 29.35, 29.22, 29.20, 29.06, 26.83, 23.21, 22.68 (*C*$H_2$$CH_3$), 14.10 ($CH_3$). N-cis-*9-Octadecenyl-2-ketohexadecanamide (**12c**)*. Procedure A: Yield 0.338 g (65%), Procedure B: Yield 0.493 g (93%); m.p. 55.5–57°C; $^1$H NMR (200 MHz) δ 6.9 (1H, *br*, CONH), 5.4 (2H, *m*, CH=CH), 3.3 (2H, *m*, C$H_2$NH), 2.9 (2H, *t, J* = 7 Hz, $CH_2CO$), 2.0 (4H, *m*, C$H_2$CH=CHC$H_2$), 1.6 (4H, *m*, C$H_2$$CH_2$CO, C$H_2$C$H_2$NH), 1.3 (44H, *m*, 22 × $CH_2$), 0.9 (6H, *m*, 2 × $CH_3$); $^{13}$C NMR (50 MHz) δ 199.49 (*C*OCONH), 160.10 (CONH), 129.94 and 129.71 (CH=CH), 39.29 ($CH_2$NH), 36.70 (*C*$H_2$CO), 31.89, 29.62, 29.57, 29.50, 29.41, 29.32, 29.22, 29.16, 29.05, 27.18, 27.14, 26.82, 23.19, 22.66 (*C*$H_2$$CH_3$), 14.08 ($CH_3$). Calc. for $C_{34}H_{65}NO_2$: C 78.55; H 12.60; N 2.69; MW 519.83. Found: C 78.70; H 12.56; N 2.71.

*Methyl 2-[(2-ketododecanoyl)amino]hexadecanoate (**12d**)*. Procedure B: Yield 0.477 g (99%); m.p. 46.5–47.5°C; $^1$H NMR (200 MHz) δ 7.4 (1H, *d, J* = 9 Hz, CONH), 4.5 (1H, *m*, C*H*NH), 3.8 (3H, *s*, $COOCH_3$), 2.9 (2H, *t, J* = 7 Hz, $CH_2CO$), 1.9–1.6 (4H, *m*, C$H_2$$CH_2$CO, C$H_2$CHNH), 1.3 (38H, *m*, 19 × $CH_2$), 0.9 (6H, *m*, 2 × $CH_3$); $^{13}$C NMR (50 MHz) δ 198.52

(*C*OCONH), 171.95 (*C*OOCH$_3$), 159.70 (CONH), 52.48 (COO*C*H$_3$), 52.14 (CHNH), 36.73 (*C*H$_2$CO), 32.24, 31.86, 29.62, 29.56, 29.52, 29.47, 29.41, 29.30, 29.07, 29.02, 25.20, 23.12, 22.66 (*C*H$_2$CH$_3$), 14.10 (CH$_3$). Calc. for $C_{29}H_{55}NO_4$: C 72.30; H 11.51; N 2.91; MW 481.75. Found: C 71.97; H 11.30; N 2.56.

*Monomolecular film experiments.* Surface pressure/area curves as well as inhibition experiments were performed with a Teflon trough. Before each experiment the trough was first washed with tap water, then gently brushed in the presence of distilled ethanol, washed again with plenty of tap water, and finally rinsed with double-distilled water. The lipidic film, from a solution in $CHCl_3$ (approximately 1 mg·mL$^{-1}$), was spread with a Hamilton syringe over an aqueous subphase composed of 2-amino-2-hydroxymethyl-1,3-propanediol hydrochloride (Tris/HCl) 10 mM, pH 8.0, NaCl 100 mM, $CaCl_2$ 21 mM, and EDTA 1 mM. The above buffer solution was prepared with double-distilled water and filtered through a 0.22 µm Millipore (Milford, MA) membrane. Before each utilization, residual surface-active impurities were removed by sweeping and suction of the surface (20). The force/area curves were automatically recorded upon a continuous compression rate at 4.8 cm·min$^{-1}$.

*Enzyme kinetics experiments.* The inhibition experiments were performed using the monolayer technique. The principle of this method has been previously described (20).

For the inhibition studies the method of mixed monomolecular films was used. This method involves the use of a zero-order trough, consisting of two compartments: a reaction compartment, where mixed films of substrate and inhibitor are spread, and a reservoir compartment, where only a pure film of substrate is spread. The two compartments are connected to each other by narrow surface channels. The aqueous subphase was composed of Tris/HCl 10 mM, pH 8.0, NaCl 100 mM, $CaCl_2$ 21 mM, and EDTA 1 mM. PPL (final concentration 4.0 ng·mL$^{-1}$) was injected into the subphase of the reaction compartment, where efficient stirring was applied. When, owing to the lipolytic action of the enzyme, the surface pressure decreased, a mobile barrier moving over the reservoir compartment compressed the film, thus keeping the surface pressure constant. The surface pressure was measured on the reservoir compartment with a Wilhelmy plate. The surface of the reaction compartment was 100 cm$^2$ and its volume 120 mL. The reservoir compartment was 14.8 cm wide and 24.9 cm long. The lipidic films were spread from a chloroform solution (approximately 1 mg·mL$^{-1}$). The kinetics were recorded for 20 min. In all cases linear kinetics were obtained. Each experiment was duplicated.

## RESULTS AND DISCUSSION

*Synthesis of various α-keto amides.* A number of primary and *N*-alkyl α-keto amides with small, medium, or long chains were synthesized following various routes. 2-Ketopentadecanamide (**4**) was prepared from tetradecanaldehyde (**1**) as described in Scheme 1. Addition of KCN to aldehyde **1** afforded cyanohydrin **2**, which was mildly hydrolyzed to 2-hydroxypentadecanamide (**3**). Oxidation of **3** using PDC afforded primary α-keto amide **4** in high yield.

Commercially available α-keto acids can be directly coupled with primary amines by the mixed carbonic anhydride method (21) in high yield. The mixed anhydrides of 2-ketobutanoic acid (**5a**) and 2-ketooctanoic acid (**5b**) with isobutyl chloroformate (**6a**,**b**) were prepared *in situ* and were used for coupling with hexylamine, hexadecylamine, *cis*-9-octadecenylamine, and 1,2-ethylenediamine to afford *N*-alkyl α-keto amides **7a–d** and **8a**,**b** (Scheme 2). The use of dicyclohexylcarbodiimide as a condensing agent in the presence of HOBt proved to be unsuccessful for the coupling of α-keto acids, leading to moderate yields.

However, long-chain α-keto acids are not commercially available. Thus, we developed a general method for the synthesis of *N*-alkyl α-keto amides using lipidic α-amino acids as starting material. The lipidic α-amino acids (22) are a class of compounds combining structural features of amino acids with those of fatty acids. They are nonnatural α-amino acids with saturated or unsaturated long side chains and can be prepared by classical methods in racemic form. New methods for the

**SCHEME 2**

enantiomeric synthesis of saturated (23) or unsaturated derivatives, like 2-aminoarachidonic acid (24), have been recently presented. 2-Aminododecanoic acid (**9a**) and 2-aminohexadecanoic acid (**9b**) were prepared as described in the literature (22) and deaminated by treatment with $NaNO_2$ under acidic conditions (Scheme 3). 2-Hydroxy acids **10a**,**b** were coupled with various amino components using WSCI (25) as a condensing agent in the presence of HOBt. Apart from linear saturated or unsaturated amines, methyl 2-amino hexadecanoate was used as amino component. The lipophilic *N*-alkyl α-keto amides **12a–d** were obtained by oxidation of **11a–d** with either PDC or NaOCl in the presence of catalytic amounts of AcNH-TEMPO free radical (26,27). In most cases PDC was an effective reagent for the oxidation, affording the products in good yields. However, the conversion of products with long aliphatic chains proceeded only in moderate yields. In these cases, the use of NaOCl in the presence of AcNH-TEMPO in a biphasic system of toluene, ethyl acetate, dichloromethane, and aqueous NaBr proved to be advantageous, affording the oxidized products in almost quantitative yields.

All intermediates and final products gave satisfactory analytical and spectroscopic data, which are described in detail in the experimental part. In the $^{13}C$ NMR spectra of the α-keto amide derivatives, two signals corresponding to carbon atoms of COCONH were clearly assigned. The carbon atom of the α-keto group was shifted at 199.5–190.5 ppm owing to the presence of the adjacent amide function. The signal of the amide group carbon atom appeared at 160 ppm, whereas in the case of α-hydroxy amides it was at 173 ppm. Furthermore, $^{13}C$ NMR spectra of α-hydroxy amides showed a signal at 72 ppm that was assigned to the carbon atom of the methine group.

*Force/area curves of the α-keto amides prepared.* The use of the monolayer technique, which is based upon surface pressure decrease due to film hydrolysis, is advantageous for the study of lipase inhibition, because with conventional emulsified systems it is not possible to control their "interfacial quality" (28). The monolayer technique is applicable to those cases of enzymatic studies where the lipid film forms a stable monomolecular film at the air/water interface and where the reaction products are freely water-soluble and dif-

**SCHEME 3**

fuse away rapidly into the aqueous phase (29,30). To determine the film stability and the interfacial properties of the compounds synthesized, we recorded their force/area curves at the air/water interface by a continuous compression.

Compounds **7a**,**c**, bearing a two- and a six-carbon atom chain, respectively, in the α-keto acid moiety and a 16-carbon-atom aliphatic chain in the amine moiety, were not able to form stable films. A chain of six carbon atoms in the amine moiety was not able to stabilize the film, even when a chain of 14 carbon atoms was present in the α-keto acid moiety (compound **12a**). Compounds **4**, **7b,** and **8a**,**b** were not proven able to form stable thin films, in agreement with the above findings.

*N*-Alkyl α-keto amides **7d**, and **12b–d** were proven able to form stable thin films. Figure 1 illustrates representative recordings of surface pressure dependency as a function of the molecular area of four different compounds spread over a buffered subphase at pH 8.0. The collapse pressures of compounds **12d** and **7d** are observed at surface pressure values of 20.9 and 13.2 $mN \cdot m^{-1}$, respectively. By comparing the force/area curves obtained for compounds **7d** and **12c**, one can notice a significant decrease in the molecular area, as the alkyl chain length in the α-keto acid moiety increases. An expanded film was obtained for compound **7d**, having a *cis* double bond in the amine moiety and an aliphatic chain of six carbon atoms in the α-keto acid moiety, which may be attributed to the presence of the double bond. However, in the case of compound **12c**, bearing the same unsaturated chain in the amine moiety and a chain of 14 carbon atoms in the α-keto acid moiety, the film was condensed. This indicates that in the latter case the predominant factor is the long saturated alkyl chain in the α-keto acid moiety, resulting in a different mode of molecular packing.

*Pancreatic lipase activity on mixed films containing α-keto amide inhibitors.* The α-keto amides, which formed stable monomolecular films at the air/water interface, were studied as potential inhibitors for PPL. There are at least five major reasons

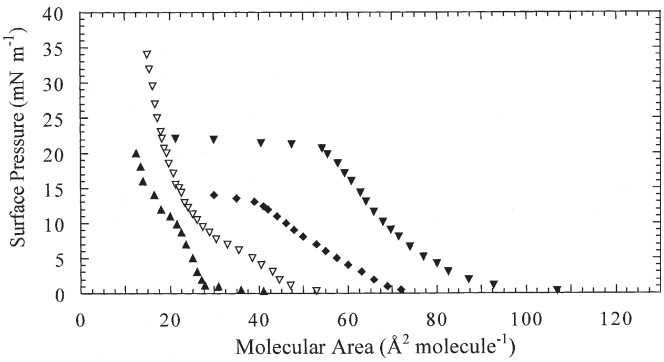

**FIG. 1.** Force/area curves of *N-cis*-9-octadecenyl-2-ketooctanamide (**7d**) (◆); *N*-hexadecyl-2-ketohexadecanamide (**12b**) (▽); *N-cis*-9-octadecenyl-2-ketohexadecanamide (**12c**) (▲); methyl 2-[(2-ketododecanoyl)amino]hexadecanoate (**12d**) (▼). The aqueous subphase was composed of Tris/HCl 10 mM, pH 8.0, NaCl 100 mM, $CaCl_2$ 21 mM, EDTA 1 mM. The continuous compression experiments were performed in the rectangular reservoir of the zero-order trough (20).

for using lipid monolayers as substrates for lipolytic enzymes (31): (i) It is easy to follow the course of the reaction by monitoring one of several physicochemical parameters characteristic of the monolayer film: surface pressure, potential, density, etc. (ii) Probably the most important reason is that it is possible with lipid monolayers to vary and control the "interfacial quality," which depends on the nature of the lipids forming the monolayer, the orientation and conformation of the molecules, the molecular and charge densities, the water structure, the viscosity, etc. (iii) Using the surface barostat balance, the lipid packing of a monomolecular film of substrate can be maintained constant during the course of hydrolysis, and it is therefore possible to obtain accurate pre-steady-state kinetic measurements with minimal perturbation caused by increasing amounts of reaction products. (iv) The monolayer technique is highly sensitive and very little lipid is needed to obtain kinetic measurements. This advantage can often be decisive in the case of synthetic or rare lipids. (v) Inhibition of lipase activity by water-insoluble substrate can be precisely estimated using the zero-order trough and mixed monomolecular films in the absence of any synthetic, nonphysiological detergent. The monolayer technique is therefore suitable for modeling *in vivo* situations.

The inhibition of PPL was studied using the monolayer technique (20) and mixed monomolecular films of lipase substrate (1,2-dicaprin) containing variable proportions of each inhibitor.

Depending upon the film stability and the collapse pressure of each compound, we chose the appropriate surface pressure at which the inhibition kinetics were performed. Compound **7d** was studied at 10 $mN \cdot m^{-1}$ and compound **12b** at 20 $mN \cdot m^{-1}$. Compound **12d** was studied at both 15 and 20 $mN \cdot m^{-1}$. PPL was active, and linear kinetics were recorded at 10, 15, and 20 $mN \cdot m^{-1}$.

The decrease in the enzymatic activity caused by the presence of each of the α-keto amide inhibitors mixed with 1,2-dicaprin monolayers at a molar fraction of 10% was measured. The remaining enzymatic activity of PPL was 65.1 ± 3.8% for compound **7d** and 70.2 ± 4.8% for compound **12b**. At this molar fraction, the remaining enzymatic activity found in the presence of compound **12d** was 47.6 ± 3.2% at a surface pressure of 15 $mN \cdot m^{-1}$ and 50.1 ± 3.7% at 20 $mN \cdot m^{-1}$. Since among the compounds tested, compound **12d** was the best inhibitor of PPL, it was further studied at various molar fractions. Remaining lipase activity was plotted as a function of the inhibitor **12d** molar fraction, at both 15 and 20 $mN \cdot m^{-1}$, and the results obtained are presented in Figure 2. The dotted line corresponds to surface dilution phenomena, which reflects the decrease in lipase activity that would be observed if a nonsubstrate, noninhibitor compound, that is, a so-called surface dilutor, were present in the monomolecular film. From these curves the $\alpha_{50}$ value, which is the inhibitor molar fraction present in 1,2-dicaprin monolayers that causes a 50% decrease in the enzymatic activity, was calculated. The $\alpha_{50}$ values were found to be 0.094 ± 0.022 at 15 $mN \cdot m^{-1}$ and 0.100 ± 0.018 at 20 $mN \cdot m^{-1}$, indicating that within the range of surface pressure investigated, there was a slight effect of surface pressure on inhibition.

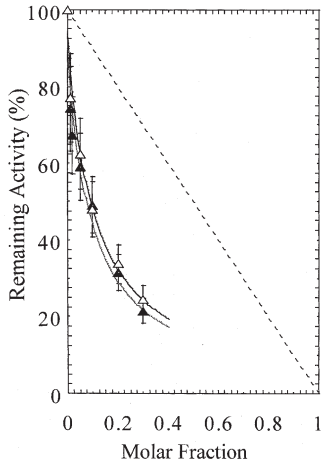

**FIG. 2**. Effect of increasing the concentration of **12d** on the hydrolysis rate by porcine pancreatic lipase of 1,2-dicaprin monolayer maintained at a constant surface pressure of 15 $mN \cdot m^{-1}$ (▲) or 20 $mN \cdot m^{-1}$ (▽). The aqueous subphase was composed of Tris/HCl 10 mM, pH 8.0, NaCl 100 mM, $CaCl_2$ 21 mM, EDTA 1 mM. The kinetics of hydrolysis were recorded for 20 min. For **12d** see Figure 1.

Although these values indicate a rather weak inhibition of pancreatic lipase, the α-keto amide **12d** exhibits a stronger inhibitory effect as compared to recently reported chiral acylglycerol analogs belonging to phosphonate-type inhibitors ($\alpha_{50}$ values 0.13–0.20) (32). Up to now, the best synthetic inhibitor of HPL reported in the literature is *O*-hexadecyl-*O*-(*p*-nitrophenyl) *n*-undecyl phosphonate, with an $\alpha_{50}$ value of 0.003 (10).

In the case of serine proteases, the mechanism of action of inhibitors containing electrophilic carbonyl groups most likely involves a nucleophilic addition of the active site serine hydroxyl group of the enzyme to the carbonyl group of the inhibitor, with formation of a metastable hemiacetal adduct that mimics the tetrahedral species involved in the enzymatic cleavage of peptide bonds. In the case of some proteases, X-ray (33,34) and $^{13}C$ NMR (35) studies have demonstrated the formation of such enzyme–inhibitor hemiacetal adducts. Based on the fact that the catalytic triad of lipases is homologous to that described in serine proteases as well as on their similar mechanism of action, the above findings may be extrapolated to lipases. Thus, the inhibitory effect of the α-keto amides on pancreatic lipase may be attributed to the interaction of the active-site serine hydroxyl group with the carbonyl group of the synthetic compound.

In conclusion, three synthetic routes to primary and *N*-alkyl α-keto amides were developed. α-Keto amides of simple structure, like compound **12d**, are able to inhibit pancreatic lipase, indicating that the α-keto amide group may be used as a reactive functionality in the design and synthesis of potent inhibitors of lipolytic enzymes.

COMMUNICATION

# Inhibition of Purified Pig and Human Liver Retinyl Ester Hydrolase by Pharmacologic Agents

**Rainer Schindler***

Department of Human Nutrition and Food Science, Christian-Albrechts-Universität zu Kiel, D-24116, Germany

**ABSTRACT:** Identification of inhibitors of retinyl ester hydrolase (REH) would help to elucidate its role in vitamin A metabolism *in vivo*. By using standard incubation conditions, the effects of 215 drugs as potential inhibitors of purified pig and human liver REH when acting on micellar substrate retinyl palmitate were evaluated at 16.7, 167, and 1670 μM. Out of the compounds tested, 103 were inhibitors of the pig liver enzyme. The most potent compounds, in order of decreasing activity, were chloral hydrate, lovastatin, phytomenadione, alimemazine, physostigmine, thioridazine, phenoxybenzamine, probucol, cinnarizine, cyclandelate, amiodarone, flupenthixol, and naftidrofuryl; this order is roughly similar to that of their inhibition of human liver REH. Of the 10 tricyclic ring-containing drugs tested, alimemazine was the most potent enzyme inhibitor. The concentrations necessary for 50% enzyme inhibition ranged from <2.6 up to >540 μM. Moreover, inhibitory kinetic studies showed that at least two pharmaceuticals, chloral hydrate and amiodarone, are potent REH inhibitors at therapeutically achievable serum concentrations. First-pass metabolites were inactive as REH inhibitors compared to that of the parent compounds, in the cases of chloral hydrate, lovastatin, and cyclandelate.

Paper no. L8432 in *Lipids 36*, 543–548 (May 2001).

The liver plays a central role both in the regulation of plasma retinol (vitamin A alcohol) concentration and in the maintenance of whole-body vitamin A homeostasis *via* delivery of retinyl esters in chylomicron remnants and the retinol–retinol-binding-protein complex (1,2). Once inside the hepatocytes, retinol molecules released by cellular processes, i.e., hydrolysis of gut-derived retinyl esters (1) or desorption from its carrier protein (2), enter the pool of free retinol. The major route of egress of vitamin A from this pool is into the retinyl ester storage compartment. The formation of esterified retinol takes place mainly in stellate cells (3,4) through the action of acyl-CoA:retinol acyltransferase (5) or lecithin:retinol acyltransferase (6), the resulting retinyl esters being found in the cytoplasm as large lipid droplets (3). In response to changes in hepatic retinol concentration, vitamin A balance across the liver is maintained by regulating the rates of hydrolysis and formation of retinyl ester.

In well-nourished populations, the amount of retinoids in plasma and bile reflects the intrahepatic formation of retinol, which is likely controlled by a number of factors including the activities and selectivities of the key enzymes in the pathway from retinyl ester to retinol. Several enzymes are able to catalyze such a reaction *in vitro* (see Ref. 7 for recent review). Among these ubiquitous retinyl ester-utilizing enzymes, we have recently (8) demonstrated the presence of a retinyl ester hydrolase (REH) (EC 3.1.1.-) in liver that is, in some aspects [e.g., primary structure, immunological behavior, specific activity, pH dependence, and sensitivity to bis-(4-nitrophenyl) phosphate] similar to liver microsomal esterase ES-4 (EC 3.1.1.1) but exhibits some distinct characteristics, including bimodal distribution of activity between cytosolic and membrane fraction, detergent {e.g., 3-[(3-cholamidopropyl)dimethylammonio]-1-propane sulfonate (CHAPS)}-dependent esterase activity against retinyl palmitate (a hydrophobic substrate molecule), and higher molecular mass. ES-4 (also called the pI 6.2/6.4 esterase or microsomal hydrolase) belongs to the nonspecific carboxylesterases supergene family. This is an extremely large family of enzymes that are involved in detoxification of many xenobiotics including drugs containing ester, thioester, and amide functional groups.

Although the function of REH in vitamin A metabolism remains incompletely understood, its existence in liver cytosol (9) suggests that this enzyme may act at the lipid-water interface of intracellular fat bodies to hydrolyze retinyl esters, a step in retinol mobilization (3,7). One method for studying the physiological role of an enzyme is through the use of inhibitors. However, no biocompatible inhibitors of soluble REH have yet been reported. Therefore, the purpose of this study was to evaluate a series of widely used drugs ($n$ = 215) as inhibitors for further characterizing this enzyme.

## EXPERIMENTAL PROCEDURES

Pig and human liver REH enzymes were prepared by methods described previously (8). Two hundred fifteen drugs from different pharmacological classes were studied in the pig REH assay system; only 18 of these substances were examined in both human and pig assay systems. The test compounds were purchased or generously obtained in their chemically pure form from the various manufacturers. Retinyl

Abbreviations: CHAPS, 3-[(3-cholamidopropyl)dimethylammonio]-1-propane-sulfonate; ES, nonspecific carboxylesterase; $IC_{50}$, inhibitor concentration giving 50% inhibition of enzyme activity; REH, retinyl ester hydrolase.

palmitate was a gift from Hoffman-La Roche (Basel, Switzerland), Triton X-100 was from Serva (Heidelberg, Germany), CHAPS was from Boehringer (Mannheim, Germany), and bovine serum albumin was from Sigma (Deisenhofen, Germany). Inorganic substances, organic solvents (e.g., dimethyl sulfoxide), and antioxidants (e.g., ascorbic acid and butylated hydroxytoluene) were purchased from Merck (Darmstadt, Germany). All chemicals and solvents were of analytical grade.

REH activity was determined by the method of Cooper and Olson (9). The standard mixture solution consisted of 2 mg/mL Triton X-100 and 100 mM CHAPS in 0.05 M Tris-maleate buffer, pH 8.0, in a total volume of 0.5 mL. The final concentration of the substrate retinyl palmitate in the assay was 0.05 mM. The reaction was started by adding the enzyme (170–220 μg protein/mL), and the mixture was incubated with gentle shaking for 60 min at 37°C. The incubations were terminated by addition of 0.5 mL ethanol. Liberated retinol was extracted with 2 mL *n*-hexane containing 0.1% (wt/vol) butylated hydroxytoluene. The organic phase was evaporated to dryness and dissolved in chloroform/methanol (1.5:4, vol/vol). The amount of retinol formed by REH was quantified fluorimetically (excitation at 325 nm, emission at 480 nm) by reversed-phase high-performance liquid chromatography, as described previously (8), by using a Bio-Tek Kontron (Neufahrn, Germany) Spherisorb ODS (5 mm × 25 cm) column eluted with methanol at a flow rate of 1.8 mL/min (8).

To test the effect of several drugs as potential inhibitors on purified human REH, the enzyme reaction was carried out according to the standard REH assay, except that 0.05 M Tris-maleate buffer, pH 8.0, was replaced with 0.05 M Tris-maleate buffer, pH 6.5 (10). In assays involving the drugs under investigation, the agents were incubated with the enzyme for 30 min before addition of the substrate. These experiments were performed in the presence of three different drug concentrations, 16.7, 167, and 1670 μM, and each inhibitor was evaluated in triplicate. All assay controls were adjusted for effects of solvents on enzyme activity. Solutions of the drugs were made fresh for each experiment. The property of each solvent that allowed solubilization of the drugs was apparently related to both its hydrogen ion concentration and polarity. Several drugs were readily solubilized by either 0.05 M Tris-maleate buffer, pH 6.0, or 0.05 M glycine-NaOH buffer, pH 9.5, but not by 0.05 M Tris-maleate buffer, pH 8.0. To examine the effects of these drugs on the activity of REH, the enzyme reaction was carried out according to the standard assay used, except that 0.05 M Tris-maleate buffer, pH 8.0, was replaced with one of the two buffers mentioned before. Water-insoluble drugs were dissolved in dimethyl sulfoxide, methanol, or ethanol and then diluted with the enzyme diluent. Final concentration of these organic solvents in assay mixture never exceeded 2% (by vol).

Drug concentrations for half-maximal inhibition of the REH activity ($IC_{50}$) were determined for the specified conditions. The inhibitor $IC_{50}$ values were calculated from individual concentration-effect curves as suggested by Hafner *et al.* (10).

Protein concentration was determined by measuring the absorbance at 595 nm by the Bradford dye-binding assay (11). The reference protein for all assays was bovine serum albumin. Retinol was prepared from retinyl palmitate by standard procedures (8). The concentration of pure retinol dissolved in petroleum ether was determined spectrophotometrically using an extinction coefficient of 1830 at 325 nm ($E_{325nm}^{1\%,1\ cm}$; Ref. 12).

## RESULTS

In a preliminary approach, 215 pharmacologic drugs from different chemical classes were tested, each at 16.7, 167, and 1670 μM, for their effects on REH activity. Numerous drugs ($n$ = 103) were able to inhibit the pig form of liver REH to various degrees. Only the 33 most active compounds are shown in Table 1. Under these conditions, the strongest inhibition observed in the micromolar range (at 167 μM) was by chloral hydrate and lovastatin, two distinctly different compounds.

To establish whether these findings would hold true for human liver REH, a number of compounds ($n$ = 18) listed in Table 1 were evaluated for their effects on this REH form, under the same conditions. All 18 drugs inhibited purified human REH activity, and chloral hydrate was again found to be most potent. For these drugs the rank order of potency for inhibition (number in parentheses following residual REH activity; Table 1) was similar to that seen with purified pig REH, with some notable exceptions; miconazole, diclofenac, and amiodarone exhibited human REH-selectivity, whereas flupenthixol and physostigmine exhibited pig REH-selectivity. However, the REH inhibitory effects of the drugs (Table 1) should be viewed as relative ranges of potency or selectivity rather than absolute rankings.

The results of inhibitory kinetic studies of pig liver REH are shown in Table 2. To evaluate whether the drug concentration used in these experiments and the calculated $IC_{50}$ values were comparable with the serum and tissue concentrations seen after therapeutic dosage, we compiled data for the test compounds from a review of the available literature (Table 2; Refs. 13–22). For all drugs, except two, for which data could be compared, their expected clinical serum concentration was below their $IC_{50}$ values for hepatic REH inhibition. Exceptions are chloral hydrate and amiodarone, whose $IC_{50}$ values are within the range found in human serum. However, some drugs will concentrate in the liver during long-term therapy, reaching tissue concentrations 4- to 11-fold higher than in plasma, as has been shown for drugs such as phytomenadione, probucol, and amiodarone (Table 2). Thus, mainly within the liver, regional concentrations of these drugs comparable to those producing REH inhibition in our *in vitro* experiments could occur in *in vivo* situations.

Among the pharmacologic agents tested, chloral hydrate was the most potent inhibitor, with an $IC_{50}$ value of 2.5 μM. This value is in the concentration range achieved clinically (Table 2). The aim of the next set of experiments was therefore to investigate whether chloral hydrate (a compound with

a short half-life) or its metabolites could interfere in hepatic vitamin A metabolism. In these experiments we tested directly for inhibition of REH activity by chloral hydrate, trichloroethanol, or trichloroacetic acid (13). Chloral hydrate and trichloroethanol were tested above or at the clinical peak plasma concentration found in the *in vitro* REH assay; REH activity was inhibited by 85% and >95% at chloral hydrate concentrations of 16.7 and 167 μM, respectively. In contrast, weak (<30%) inhibition of retinyl palmitate hydrolysis was observed by the degradation products, even at a concentration of 1670 μM. Thus, although chloral hydrate is a potent REH inhibitor *in vitro*, this is less likely to occur *in vivo* because chloral hydrate undergoes extensive first-pass metabolism to products without inhibitory potency on REH at clinically relevant concentrations. Similar observations were made comparing REH inhibition by lovastatin and cyclandelate with their metabolites (data not shown).

## DISCUSSION

Screening common pharmacologic agents for inhibition of hepatic REH has identified 103 as inhibiting REH activity to varying extents. In general, compounds containing amide bonds ($n$ = 25) were less potent as REH inhibitors than were ester-type drugs ($n$ = 16) (Table 1). Because the structures of these agents are very diverse, they may exert their effect through many different mechanisms. One mode of inhibition is *via* direct interaction with the catalytic site of the enzyme. An example of an active site-directed enzyme blocker is chloral hydrate, known to inhibit chicken liver carboxylesterase

(EC 3.1.1.1) (23). A mechanism has been proposed (25) whereby chloral hydrate is dehydrated in a rate-limiting step by the enzyme to form trichloroacetaldehyde, which rapidly adducts the protein *via* its active-site serine, yielding an inactive enzyme. It is to be expected that the same mode of inhibition could also take place with REH, another serine esterase. Physostigmine is a reversible inhibitor of acetylcholinesterase (EC 3.1.1.7) and other serine esterases (24). The REH inhibitory activity of physostigmine therefore is likely *via* carbamoylating the catalytic serine. Physostigmine also discriminates between carboxylesterase subtypes (25). For example, ES-4 (pI 6.2/6.4 esterase, closely related to REH) and ES-10 (pI 6.0/6.1 esterase) were significantly inhibited, but ES-3 (pI 5.6 esterase) was not inhibited at the concentration used. ES-4 also shares long-chain fatty acyl coenzyme A-splitting activity with acyl coenzyme A:cholesterol acyltransferase (EC 2.3.1.26; Refs. 25,26). However, isoforms of this enzyme are sensitive to inhibition by ester drugs, namely, cyclandelate and lovastatin (27,28), as is the case for REH. Lovastatin appears to function as an inhibitor of retinyl ester hydrolysis by acting as an alternative substrate; as an ester-type drug it requires carboxylesterase-mediated bioactivation in order to elicit pharmacological activity (29). It can be anticipated that acting as an alternative substrate also applies to the mode of inhibition of REH by naftidrofuryl, a known substrate for butyl cholinesterase (EC 3.1.1.8) (30). The same may be true for dilazep (not shown), which is a substrate for the human liver carboxylesterase subtypes pI 4.5 and pI 5.3 (31). On the other hand, metoclopramide, an amide-type drug, differentiates among carboxylesterases by inhibiting ES-2 (32) but not REH.

The REH inhibitory activities of erythromycin and alimemazine appear to proceed by a mechanism that was different from the anti-REH action of the active site-directed enzyme blockers. Erythromycin is an inhibitor and a substrate of CYP 3A4 (33). It contacts the enzyme at the catalytic site through hydrophobic interactions (34). By analogy, erythromycin may occupy the substrate-binding pocket of REH such that it interferes with the hydrolysis of retinyl palmitate. A similar mechanism of action may be operative in REH inactivation by alimemazine and related phenothiazine and thioxanthene neuroleptic drugs. In this context, it is interesting that insertion of a methylene group and rearrangement of another one in the triacylamine-containing side chain of alimemazine leads to ethopropazine. The latter compound is a reversible tricyclic inhibitor of acetylcholinesterase, and its main known mode of action is *via* blocking the access of the substrate to the esterolytic site (24).

The REH reaction occurs at a lipid-water interface, and it depends upon adsorption of the enzyme to the surface of the substrate-carrier. The interfacial binding site involved in the formation of enzyme-substrate-carrier complex may be part of a hydrophobic domain at or close to the active center of the enzyme. Lipophilic drugs thus may function as inhibitors of REH by binding to a nonpolar area of this enzyme. Likely candidates with submillimolar potency in REH assays that meet this description are phytomenadione (a carboxylase cofactor) and the nonsteroidal anti-inflammatory drug diclofenac (Table 1). The concept of diclofenac as a noncompetitive inhibitor of REH is supported by its high binding affinity to proteins (35). At the same time, we demonstrated that alkylating agents such as phenoxybenzamine, cyclophosphamide and chlorambucil are also powerful inhibitors of REH. At least one of these lipophilic compounds, chlorambucil, may also possess inhibitory activity by virtue of its ability to bind to proteins, but, unlike phytomenadione and diclofenac, it might act by irreversible formation of an enzyme-drug complex (36).

Inhibition of REH by some amphiphilic drugs may be due to rendering the substrate at the lipid-water interface less susceptible to the enzyme. Amiodarone, for example, is a cationic as well as an amphiphilic iodinated benzofuran derivative. These properties make the drug capable of entering into both lipophilic interactions with the substrate and electrostatic interactions with anionic interfaces, such as polar headgroup regions of substrate monolayer. Amiodarone could also inhibit enzymic activity by a direct interaction with the polypeptide chain at the interface or by modifications of surface charge, as amiodarone is an ionized amine at pH 7.4 (37). Moreover, amiodarone has a very long half-life (38) and extensive distribution to the liver and other organs, reaching tissue concentrations up to 11-fold higher than in plasma (Table

2). However, intracellular accumulation of large amounts of amiodarone is associated with the appearance of phospholipidosis and consequently fibrosis within the liver, both of which are likely secondary to drug-induced phospholipase inhibition (39,40). Thus, it is probable that amiodarone reaches intrahepatic concentrations adequate to inhibit not only phospholipase but also REH, as indicated by a comparison of its REH inhibitory potency ($IC_{50}$ of 380 μM) and its liver concentration (≤2500 μM) during long-term therapy (Table 2).

In summary, a screening of a range of common pharmacologic agents for inhibition of hepatic REH has led to the identification of numerous drugs as active compounds. Some of these agents may be useful tools for distinguishing among esterase enzymes and for probing their physiological relevance *in vivo*.

**ABSTRACT:** The incidence of atherosclerosis is increased in growth hormone (GH) deficient-individuals. Nonetheless, the antiatherogenic benefits of GH replacement therapy remain uncertain. In this study the effect of human recombinant growth hormone (hrGH) replacement therapy administered to GH-deficient adults on the plasma cholesteryl ester transfer protein (CETP) concentration and activity was analyzed. These findings were related to changes in the concentrations of the plasma lipoproteins. The hrGH was administered for 12 mon to human GH-deficient patients ($n$ = 13; 8 men, 5 women). During the study plasma lipoproteins were separated by ultracentrifugation, and plasma cholesterol esterification rate (CER), endogenous CETP activity, and CETP concentration were measured. GH replacement therapy transiently (at 3 mon) lowered plasma concentration of CETP and low density lipoprotein-cholesterol (LDL-C) and raised total triglycerides. Furthermore, hrGH permanently increased both the plasma lipoprotein(a) [Lp(a)] concentration, which is known as atherogenic, and the proportion of cholesteryl ester in the high density lipoprotein$_2$ ($HDL_2$) particles, which is potentially atheroprotective. The simultaneous decrease of the plasma CETP and LDL-C concentrations elicited by hrGH indicated a close relationship between LDL metabolism and the regulation of the CETP gene expression. Endogenous CETP activity and the CER were not modified because these parameters are regulated in opposite ways by plasma levels of triglycerides; that is, CER increased and CETP decreased.

Paper no. L8691 in *Lipids 36,* 549–554 (June 2001).

Patients with hypopituitarism are at a greater risk than normal subjects of developing premature cardiovascular disease, which has been related to growth hormone (GH) deficiency (1,2). Cardiovascular risk factors such as decreased plasma fibrinolytic activity, glucose intolerance and insulin resistance as well as increased abdominal adiposity and plasma levels of low density lipoprotein cholesterol (LDL-C) (3,4), together with carotid intima-media thickness (5) and abnormal carotid arterial wall dynamics (6), have been identified in these subjects. Nonetheless, the antiatherogenic benefits of human recombinant growth hormone (hrGH) replacement therapy remain uncertain. In hypopituitarism hrGH treatment has been shown to lower the plasma LDL-C level in several (4,7–10), but not all studies (4,11,12). This treatment often increases the serum lipoprotein(a) [Lp(a)] concentration (4,8–10,13, 14), a condition related to premature atherosclerosis (15), although it reduces visceral adiposity (4) and seemingly reverses early morphological and functional atherogenic changes in major arteries (11).

Reverse cholesterol transport (RCT) is a mechanism that protects against premature atherosclerosis. Accordingly, the liver excretes cholesterol removed from peripheral cells, including the arterial wall intima. Unesterified cell membrane cholesterol taken up by nascent high-density lipoprotein (HDL) particles is esterified by lecithin cholesterol acyltransferase (LCAT) and reaches the liver either directly or indirectly upon transfer of HDL-cholesteryl ester to apolipoprotein B (apoB)-containing lipoprotein. The latter pathway is mediated by cholesteryl ester transfer protein (CETP), which exchanges HDL-cholesteryl ester with triglycerides from apoB-containing lipoproteins, bringing about a net transfer of cholesteryl ester from HDL to LDL and very low density lipoprotein (VLDL) (16–18). Although plasma CETP activity depends more on the availability of donor- and acceptor-lipoproteins than on the CETP mass itself (19,20), cholesteryl ester transfer is negligible in the absence of CETP, a condition that raises plasma HDL-C concentration (21).

Evidence for an interrelationship between cholesterol metabolism and the regulation of plasma CETP levels is supported by the following observations: (i) in a variety of species, plasma CETP concentration and activity, as well as hepatic and peripheral CETP mRNA levels, increase in response to a high-cholesterol diet (22–24) whereas the number of hepatic LDL receptors decreases (25); (ii) subjects with family-related hypercholesterolemia have high plasma CETP concentrations (26,27); (iii) simvastatin (28) and cholestyramine (29), well-known hypocholesterolemic drugs, increase the expression of the hepatic LDL receptors and reduce the plasma CETP levels; and (iv) these receptors are induced by GH treatment (30).

Abbreviations: apoB, apolipoprotein B; CE, esterified cholesterol; CER, cholesterol esterification rate; CETA, cholesteryl ester transfer activity; CETP, cholesteryl ester transfer protein; DTNB, 5,5-dithio-bis-[2-nitrobenzoic acid]; EST, cholesterol esterification; GH, growth hormone; HDL, high density lipoprotein; HDL-C, HDL-cholesterol; hrGH, human recombinant growth hormone; IGF-1, insulin growth factor-1; LCAT, lecithin cholesterol acyltransferase; LDL, low density lipoprotein; LDL-C, LDL-cholesterol; Lp(a), lipoprotein(a); PLTP, phospholipid transfer protein; RCT, reverse cholesterol transport; TLC, thin-layer chromatography; UC, unesterified cholesterol; VLDL, very low density lipoprotein.

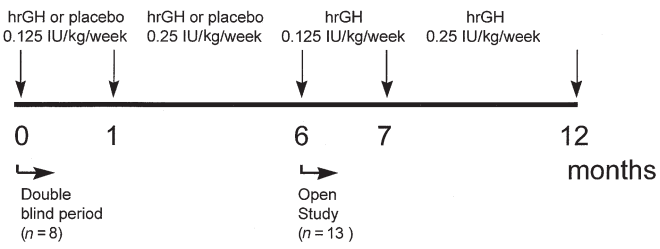
Tan *et al*. (31) showed that plasma CETP activity is increased in acromegalic patients. CETP concentration and activity in GH-deficient subjects have never been studied. Moreover, according to Rudling *et al*. (30), GH also lowers plasma LDL-C by raising the hepatic LDL receptor expression, which is an analogous mechanism to that of simvastatin (32) and of cholestyramine (33). Although CETP activity has recently been shown to diminish on GH replacement therapy (8), CETP plasma concentration has never been measured and its relation to the plasma lipoprotein concentration in this therapy is unknown.

## MATERIALS AND METHODS

*Subjects.* Thirteen (8 male, 5 female; mean age ± SD: 39 ± 9 yr) GH-deficient adults recruited for the protocol completed the study. The patients presented either GH deficiency or hypopituitarism resulting from pituitary adenoma, craniopharyngioma, or hypophysitis. GH deficiency was defined as a maximum stimulated serum GH level below 5 mU/L in response to insulin-induced hypoglycemia (blood glucose < 2.2 mmol/L) or to oral clonidine (100 µg). Patients with multiple pituitary deficiencies had been on stable replacement with thyroxin, cortisol, sex hormones, and with desmopressin when necessary, and maintained for at least 6 mon prior to entering the protocol. No subjects had received GH during the previous 12 mon or suffered from diabetes mellitus, renal, hepatic, or other secondary causes of hyperlipidemia. Informed consent was obtained from all patients, and the Ethics Committee of the Hospital das Clínicas of University of São Paulo Medical School approved the study.

*Study protocol.* Eight patients were submitted in the initial 6 mon to a double-blind treatment with either hrGH (Genotropin, Kabi-Pharmacia, Stockholm, Sweden) or an identically presented placebo. Thereafter, all of them ($n$ = 8) received hrGH in an open study for a further 6 mon. Another group consisted of five additional subjects that participated only in the open study, receiving hrGH for 6 mon. Therefore, 13 patients were on hrGH for at least 6 mon.

The dose of GH was 0.125 IU/kg/wk for the first month, and thereafter 0.25 IU/kg/wk, maximum of 4 IU/d. Because the study remained blinded throughout in the first group, the GH dose for all eight subjects was lowered during the seventh month, and reverted to the full dose thereafter (Scheme 1). GH or placebo was self-administered using the KabiPen (Kabi-Pharmacia) from 16 IU/mL vials as single subcutaneous injections 7 nights/wk at bedtime, and compliance was checked by vial counting. All analyses were carried out at the beginning of the study and then every 3 mon. The GH replacement effectiveness was properly assessed measuring the serum levels of insulin growth factor (IGF-1).



**SCHEME 1**

*Laboratory procedures.* After an overnight fasting period venous blood samples were drawn over 0.1% EDTA, and plasma was obtained after low-speed centrifugation. The following preservatives were added per milliliter of plasma: 2 mmol/L benzamidine (5 µL), 0.5% gentamycin and 0.25% chloramphenicol (20 µL), 25 mg phenylmethylsulfonylfluoride/28.7 mL dimethyl sulfoxide (0.5 µL), and aprotinin (10 µL). The LCAT inhibitor 5,5-dithio-bis-[2-nitrobenzoic acid] 0.1% (DTNB, 5.5 µL/mL) was added to samples used for cholesteryl ester transfer activity (CETA) and CETP measurements. An aliquot was used for precipitation of apoB-containing lipoproteins with dextran sulfate and magnesium chloride (34), and all samples were stored at –70°C until further analysis. All chemicals were purchased from Sigma (St. Louis, MO). Total and unesterified cholesterol and triglyceride levels were determined in duplicate using enzymatic diagnostic kits (Boehringer Mannheim, Buenos Aires, Argentina; and Merck, Darmstadt, Germany, respectively); lipoprotein cholesterol fractions were calculated by the Friedewald formula (35). Plasma apoB, apoA-1 and Lp(a) levels were measured by radioimmunoassay kits (Mercodia, Uppsala, Sweden), and plasma IGF-1 concentrations by the commercially available DSL kit (Diagnostic Systems Labs, Webster, TX).

*HDL-cholesterol esterification and transfer rates.* The HDL-cholesterol esterification rate (CER) and the cholesteryl ester transfer activity (CETA) were determined by the methods described elsewhere (36–39). Briefly, $^{14}$C-cholesterol (0.18 µCi; New England Nuclear, Boston, MA) diluted in ethanol (5 µL) was added to small Whatman-1 filter-paper disks in triplicate. The latter were then incubated at 4°C for 18 h with 30 µL of apoB-LP-free plasma containing HDL mixed with 70 µL of a buffer solution (Tris, 10 µmol/L; NaCl, 150 µmol/L; EDTA, 0.01%; $NaN_3$, 0.03%). Thereafter, incubations occurred in a water bath at 37°C for 30 min for the CER measurement. Aliquots were immediately submitted to thin-layer chromatography (TLC) on silica gel G and developed with hexane/ethyl ether/acetic acid (70:30:1, by vol). Both unesterified (UC) and esterified (CE) cholesterol spots were scraped into counting vials containing toluene/Triton X-100 solution with 1,4-bis [2-(5-phenyloxazole)] benzene and 2,5-diphenyloxazole (0.5:5, w/w), and radioactivity was measured in a beta scintillation counter (LS6000, Beckman Instruments, Fullerton, CA). LCAT activity (CER) was expressed as percent activity and calculated from the 30-min radioactivity values as $[^{14}\text{C-CE}/(^{14}\text{C-CE} + ^{14}\text{C-UC})] \times 100$.

Incubations identical to those employed for CER were also carried for 24 h; 80 to 90% of $^{14}$C-UC in HDL was then present in the esterified form ($^{14}$C-CE HDL) and was utilized for the endogenous CETP activity (CETA) analysis. Whole plasma from each patient (400 µL) with added DTNB was then admixed to the tube containing $^{14}$C-CE HDL. Aliquots in triplicate were then incubated at both 4 and 37°C for 4 h,

and apoB-LP was precipitated as previously described. The supernatant containing $^{14}$C-CE HDL was utilized for separation of $^{14}$C-CE by TLC as described above. The percentage of radioactive cholesteryl ester transferred from HDL to VLDL and LDL (CETA) was calculated, as [1 − ($^{14}$C-CE at 37°C/$^{14}$C-CE at 4°C)] × 100.

*Measurement of CETP concentration.* Plasma CETP concentration was measured at the Lipoprotein and Atherosclerosis Group, University of Ottawa Heart Institute, Ontario, Canada, using a solid-phase radioimmunoassay method (40).

*Lipoprotein composition.* Lipoprotein composition was determined only in the second group of patients ($n = 5$) that participated in the open protocol, on admission and after 3 and 6 mon of therapy. Fresh plasma density was adjusted to 1.21 g/mL with addition of KBr and submitted to discontinuous gradient ultracentrifugation (41) in a SW41 rotor, Beckman L8 ultracentrifuge (Beckman Instruments, Palo Alto, CA) at 196,000 × *g*, 4°C for 24 h. The VLDL ($d < 1.006$ g/mL), intermediate density lipoprotein ($1.006 < d < 1.019$ g/mL), LDL ($1.019 < d < 1.063$ g/mL), $HDL_2$ ($1.063 < d < 1.125$ g/mL), and $HDL_3$ ($1.125 < d < 1.21$ g/mL) obtained were stored at −70°C until further analysis. Total cholesterol, UC, and triglycerides were enzymatically measured, as described above. Protein was measured by the method of Lowry *et al.* (42) and phospholipids by the Bartlett method (43).

*Statistical analysis*. All data are presented as mean ± SD or median (range). Comparisons between baseline, placebo, and hrGH treatment values were done using analysis of variance for repeated measurements, followed by the Student-Neuman-Keuls multiple-range test or Friedman's test for repeated measurements, followed by Dunn's multiple comparisons test. All correlations were analyzed by the Spearman test.

## RESULTS

During the double-blind period hrGH was administered to 5 patients and placebo to 3 patients; thereafter, hrGH was administered to all 8 individuals. Consequently, hrGH was administered to 5 patients for 12 months. However, because 5 additional cases were added at the sixth month of the protocol, 13 subjects were on hrGH for 6 mon. None of the parameters analyzed differed between the basal and the placebo phase, and consequently, basal and placebo data are representative of the period before treatment. Several of the biochemical plasma parameters analyzed (Table 1), namely, total plasma cholesterol, HDL-C, apoB-LP and apoA1-LP, did not differ between the periods before and during hrGH treatment, and body weight remained stable throughout the study. Triglyceride levels rose transiently at 3 mon on hrGH therapy. The plasma level of Lp(a) was permanently raised by hrGH, and, confirming the efficacy of treatment, the IGF-1 levels were increased as well.

Plasma CETP and LDL-C concentrations fell significantly at 3 but not at 6 and 12 mon on hrGH replacement; total cholesterol and apoB lipoprotein followed the same trend, although not reaching significant differences.

As shown elsewhere (28), the CETA method is not sensitive for detecting small variations in the plasma CETP mass. Nonetheless, as expected (25) the endogenous CETA and CETP values correlated with each other ($r = 0.29$, $P < 0.05$). Endogenous CETA likely represents the CE content transferred from HDL to the triglyceride-containing particles because there is a strong inverse correlation between CETA, HDL-C level ($r = -0.68$; $P < 0.001$), and apoA1 concentration ($r = -0.64$; $P < 0.001$). This plasma triglyceride-depen-

[a]Calculated by the Friedewald formula, plasma biochemistry values, and parameters of cholesteryl ester metabolism before and during human recombinant growth hormone (hrGH) replacement treatment: 3–6 mon ($n = 13$) and 12 mon ($n = 5$). Because the latter was a small group, statistical analysis was not provided. Data as mean ± SD or as median (range).
[b]Statistically significant difference between the periods before and during hrGH: *$P < 0.05$ mean values compared by analysis of variance as measured by the Student-Newman-Keuls test; **$P < 0.05$ median values compared by Friedman, as measured by Dunn's test. LDL, low density lipoprotein; HDL, high density lipoprotein; apoB, apolipoprotein B; apoA1, apolipoprotein A1; Lp(a), lipoprotein(a); CETP, cholesteryl ester transfer protein; CETA, cholesteryl ester transfer activity; CER, cholesteryl esterification rate; IGF-1, insulin growth factor-1.

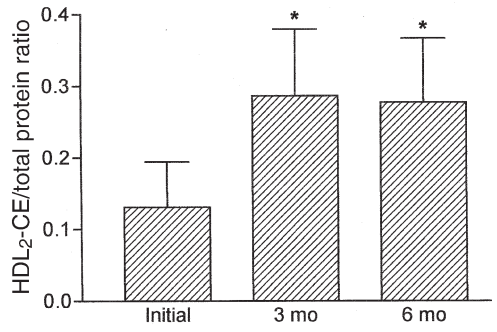

**FIG. 1.** Plasma lipoprotein composition ($HDL_2$-CE/total protein, mg/mg, mean ± SD as bar heights) obtained by ultracentrifugation from five patients. Initial values before human recombinant growth hormone (hrGH) compared by the Friedman test to 3 and 6 mon on hrGH therapy: $*P < 0.05$. None of the other lipoprotein fractions differed between control and treatment periods (data not shown). $HDL_2$, high density lipoprotein$_2$; CE, esterified cholesterol.

dent transfer process facilitates the LCAT-dependent rate of esterification of HDL-C because, as expected, CETA and CER values correlate with each other ($r = 0.35$; $P < 0.01$). According to this interpretation an inverse correlation between the HDL-C concentration and the CER value ($r = –0.33$; $P < 0.01$) was expected.

Although the *in vitro* measured endogenous CETA and CER were not modified on the hrGH therapy, the cholesteryl ester content of $HDL_2$ isolated by ultracentrifugation increased during hrGH (Fig. 1). Data on the composition of all other lipoprotein fractions separated by ultracentrifugation ($n = 5$) are not shown because they were not modified by the hrGH treatment.

## DISCUSSION

LDL-C concentration is known to increase in GH-deficient adults when compared to normal controls (3,4), however, the concentration of LDL-C does not differ between patients with active and controlled acromegaly (44). On the other hand, previous investigations on hrGH treatment of GH-deficient patients had shown LDL-C concentration as permanently lowered (4,7–10), not modified (4,11), or only transiently lowered (12). No clear explanations are found for these discrepant results since hrGH treatment lowered LDL-C permanently when administered either at high (7,10) or at low doses (8,9). In addition, LDL-C level failed to permanently respond to hrGH administration utilizing similarly low doses (11), as in the present report, or high hrGH dose (12).

Interestingly, the simultaneous, although transient, decrease of LDL-C and of CETP concentrations elicited by hrGH supports other studies that have suggested a close relationship between LDL metabolism and the regulation of the CETP gene expression: (i) plasma CETP levels are high in primary hypercholesterolemic subjects (26,27), and diminish upon the administration of cholestyramine (29), a nonabsorbable drug that stimulates the gene expression of the hepatic LDL receptors; (ii) cholesterol feeding increases both the transcription of the human CETP gene (23) and the plasma CETP concentration (24) and diminishes the number of hepatic LDL receptors (25); (iii) these receptors are induced by GH treatment (30).

Plasma triglycerides did not vary in the majority of the trials with hrGH replacement administered to GH-deficient adults. However, measurements were usually made at baseline and after 6 (4) or 12 mon of therapy (8). When measurements of triglyceride levels are carried out earlier along the treatment course, a transient rise has been observed (45). Furthermore, since GH replacement brings on a faster hepatic triglyceride synthesis rate (46), a transient rise in the plasma triglyceride concentration could represent a greater number of VLDL particles. However, along the treatment course a greater number of hepatic LDL receptors that recognize VLDL might have offset the faster plasma VLDL-triglyceride synthesis rate.

CETP concentrations measured by radioimmunoassay were also modified at 3 but not at 6 and 12 mon on hrGH. Endogenously measured CETA was not modified but this procedure is simultaneously dependent on the availability of VLDL-triglyceride, which takes up cholesteryl ester from HDL (16–18,47) and on the CETP concentration. Seemingly, the higher concentration of plasma triglycerides failed to raise the endogenous CETA value, possibly owing to the lower CETP concentration. In a recent study by Beentjes *et al.* (8), GH replacement lowered the exogenous CETA value after 12 mon, but CETP concentration was not measured. Interestingly, these authors also showed that the LCAT activity as well as the rate of cholesterol esterification (EST) was lowered by GH replacement. Incidentally, in their work phospholipid transfer protein (PLTP) activity was not modified although CETP is known to have substantial PLTP activity (17,48).

In view of our finding that the CETP concentration returned to normal after 6 mon, and remained stable in five patients at 12 mon (mean μg/mL = 2.30 ± 0.58), although statistical treatment of the latter data is not provided because it was a small group, we suggest that some other factor may have lowered the exogenous CETA at 12 mon in the Beentjes *et al*. study (8). Free fatty acids nonetheless could not be responsible for this effect because they increase in plasma on GH treatment (49) and are known to raise the CETA either directly (50) or indirectly, owing to their described role of suppressing a lipid transfer protein inhibitor (51,52).

Although the concentrations of plasma CETP and of $HDL_2$-CE are known to be reciprocally related (17), the level of the latter was not related to the concentration of CETP because CETP decreased transiently only, whereas $HDL_2$-CE remained elevated throughout the whole span of the hrGH replacement. Therefore, the concentration of $HDL_2$-CE is independently modified by hrGH by unknown mechanisms. The modification of the $HDL_2$-CE/protein ratio elicited by hrGH replacement shown in the ultracentrifuged plasma samples ($n = 5$) does not reflect the total plasma HDL-C concentration as measured after the precipitation of the apoB-containing lipoproteins reported in this and in another study (8), possibly because $HDL_2$ is a lesser fraction of the total HDL.

In the study by Beentjes *et al.* (8), lower rates of plasma EST were associated with diminished LCAT and CETA activities after 12 mon but not after 6 mon on a similar mean dose of hrGH replacement (2 U/d) as that utilized in our study (2.4 U/d). Interestingly, Lp(a) concentration was not modified in their study but has been reported as increased by GH treatment in our study and in most reports (4,9,10,13,14), including in active acromegalics (44). No obvious explanations are afforded for the discrepancy between all these reports and the data of Beentjes *et al.* (8).

In conclusion, this study shows, for the first time, that hrGH administration to GH-deficient subjects transiently reduces the plasma CETP concentrations and permanently raises the plasma $HDL_2$-CE/protein ratio. Confirming several other studies, we also demonstrated that hrGH permanently brings on a higher plasma Lp(a) concentration but only transiently lowers the plasma LDL-C level. Therefore, the relevance to atherosclerosis of hrGH replacement therapy cannot be predicted in the long run because, although a high Lp(a) plasma level is potentially harmful, the elevated $HDL_2$-CE/protein ratio could be beneficial.

## ACKNOWLEDGMENTS

The authors wish to acknowledge the contributions of Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP) for the financial support (Grant 95/2851-8) and the fellowship provided to A.J.F. Carrilho (93/2350-3), of Kabi-Pharmacia, Sweden, and of LIM (Clinical Investigation Laboratories) of the Hospital das Clínicas (Hospital of the University of São Paulo Medical School). The authors are in debt to Dr. Ruth McPherson at the University of Ottawa Heart Institute, Ontario, Canada, for the CETP mass measurements.

Hoffmann-La Roche Ltd., Division of Vitamins, CH-4070 Basel, Switzerland

**ABSTRACT:** Several studies have reported that feeding γ-linolenic acid (GLA) has resulted in no increase in arachidonic acid (AA) in newborns. This result was ascribed to the eicosapentaenoic acid (EPA)-rich fish oil used in these formulas. Docosahexaenoic acid (DHA) sources with only minor amounts of EPA are now available, thus the addition of GLA to infant formulas might be considered an alternative to AA supplementation. Sixty-six premature infants were randomized to feeding one of four formulas [ST: no GLA, no long-chain polyunsaturated fatty acids; BO: 0.6% GLA (borage oil); BO + FOLOW: 0.6% GLA, 0.3% DHA, 0.06% EPA; BO + FOHIGH: 0.6% GLA, 0.3% DHA, 0.2% EPA] or human milk (HM, nonrandomized) for 4 wk. Anthropometric measures and blood samples were obtained at study entry and after 14 and 28 d. There were no significant differences between groups in anthropometric measures, tocopherol, and retinol status at any of the studied time points. The AA content of plasma phospholipids was similar between groups at study start and decreased significantly until day 28 in all formula-fed groups, but not in the breast-fed infants [ST: 6.6 ± 0.2%, BO: 6.9 ± 0.3%, BO + FOLOW: 6.9 ± 0.4%, BO + FOHIGH: 6.7 ± 0.2%, HM: 8.6 ± 0.5%, where values are reported as mean ± standard error; all formulas significantly different ($P \leq 0.05$) from HM]. There was no significant influence of GLA or fish oil addition to the diet. GLA had only a very limited effect on AA status which was too small to obtain satisfactory concentrations (concentrations similar to breast-fed babies) under the circumstances tested. The effect of GLA on AA is independent of the EPA and DHA content in the diet within the dose ranges studied.

Paper no. L8539 in *Lipids 36,* 555–566 (June 2001).

The addition of suitable amounts of long-chain polyunsaturated fatty acids (LC-PUFA) to infant formulas, especially arachidonic (AA) and docosahexaenoic (DHA) acids, establishes concentrations of these fatty acids in infant plasma phospholipids equivalent to those found in breast-fed infants (1,2). Evidence is accumulating that the availability of appreciable LC-PUFA concentrations is associated with the neurological development of preterm (3) and term babies (4,5). This is ascribed to the importance of these fatty acids for membrane properties, as there are high relative concentrations of DHA in retina and brain (6). AA and other 20-carbon atom fatty acids [dihomo-γ-linolenic (DGLA) and eicosapentaenoic (EPA)] are important precursors for eicosanoids (7). Although functional effects of pure AA supplementation have not been investigated in humans, a stable supply of AA, as achieved by breast feeding (8), seems desirable for formula-fed babies. In rats negative effects of low AA plasma concentrations, induced by fish oil feeding, on postnatal development have been shown (9). Furthermore, AA status has been associated with infant growth (10,11).

An exogenous supply of LC-PUFA is required to achieve plasma concentrations equivalent to those found in breast-fed babies, although newborns already synthesize LC-PUFA endogenously from the essential precursors linoleic (LA) and α-linolenic acid during the first days after birth (12–14). Although the pathways of conversion have been elucidated, the question whether the low plasma and tissue concentrations found without dietary supplement are due to the high metabolic demand of LC-PUFA or to low conversion has not been answered (15). The pathways of n-3 and n-6 essential fatty acid conversion to AA and DHA share the enzymes for Δ-6, Δ-5 desaturation and chain elongation, but it is not yet known whether there are different variants of these enzymes (16). The initial step is a Δ-6 desaturation, which converts LA to γ-linolenic acid (GLA). There are strong indications that this is the rate-limiting step for the endogenous synthesis of AA (17). Based on this concept, an exogenous supply of GLA might increase the plasma concentration of n-6 LC-PUFA in infants, as was reported to occur in adults (18).

Many manufacturers produce infant formulas containing from 0.4 to 1.0% of fatty acids as LC-PUFA (19). Although fish oils are readily available as a source for n-3 LC-PUFA, the introduction of AA is a greater challenge. Egg phospholipids and single-cell oils are the primary AA sources used in infant formulas, but they are comparatively expensive or have not been approved for formula use in all countries. Alternatively, readily available sources of GLA-containing oils, e.g., borage, black currant seed or evening primrose oil, could be

Abbreviations: AA, arachidonic acid (20:4n-6); BO, borage oil; Chol, cholesterol; DGLA, dihomo-γ-linolenic acid (20:3n-6); DHA, docosahexaenoic acid (22:6n-3); EPA, eicosapentaenoic acid (20:5n-3); GLA, γ-linolenic acid (18:3n-6); HM, human milk; LA, linoleic acid (18:2n-6); LC-PUFA, long-chain polyunsaturated fatty acids (≥ 20 C atoms, ≥ 2 double bonds); MUFA, monounsaturated fatty acid; PUFA, polyunsaturated fatty acid; SAT, saturated fatty acid; ST, standard formula; TG, triglycerides.

added to the formulas (20). These oils have been considered safe in older children even in pharmacological doses (21).

Some studies investigated the influence of a GLA and n-3 LC-PUFA supply to term infants and found no positive effects on AA percentage in red blood cell phospholipids (22–24). Since formulas tested in these studies also contained fish oils rich in EPA, it appeared possible that the lack of a positive effect of the GLA supplement might have been due to an inhibiting effect of high EPA and DHA supply on AA synthesis (8,20). This is based on the observation that feeding n-3 LC-PUFA-rich marine oil caused increased concentrations of n-3 LC-PUFA and decreased AA concentrations in infants and adults (25,26). However, in term infants a formula containing 0.5% GLA only marginally increased the AA level, although EPA contributed only 0.07% to dietary fatty acids (22). DHA sources that contain only minor amounts of EPA are now readily available, thus we investigated the inclusion of a slightly higher dose of GLA into a preterm formula as an alternative to AA supplementation.

We compared four different formulas for preterm infants containing: (i) no GLA and no LC-PUFA, (ii) 0.6% GLA and no LC-PUFA, (iii) 0.6% GLA and 0.3% DHA combined with 0.06% EPA, and (iv) 0.2% EPA and 0.3% DHA plus 0.6% GLA. A nonrandomized reference group of breast-fed infants was also followed. While the majority of the previous infant studies analyzed red blood cells, which might have an attenuated and delayed response to dietary changes, we chose to analyze plasma phospholipids.

Since LC-PUFA supplementation of the diet decreased the tocopherol/lipid ratio in the erythrocytes of infants and the plasma vitamin E concentrations in adults (27,28) and since in newborns serious health risks have been associated with low vitamin E levels (29), we also analyzed plasma concentrations of lipid-soluble vitamins to detect potential influences of the various fatty acid supplies on the infants' antioxidative status (30).

## SUBJECTS AND METHODS

Premature infants were recruited for the study at the Children's Hospital Gyor (Hungary) from December 1994 to May 1997. Inclusion criteria were a birth weight below 1800 g and full enteral feeding with more than 120 mL milk/kg/d. Excluded from the study were any infants with serious metabolic or congenital anomalies; infants on artificial ventilation; infants with septic infections, gastrointestinal problems or metabolic diseases; and infants receiving any parenteral lipids during the study period. Systemic corticosteroid therapy during the study was only allowed for up to 3 d, otherwise subjects were excluded. According to the standard hospital protocol for parenteral nutrition, all participating infants were fed a 20% lipid emulsion based on soybean oil. Up to 10% of total energy intake from sources other than the corresponding study diet were permitted.

The study protocol was approved by the Ethical Committee of the Hungarian Medical Association. After explanation of the study protocol, written parental consent for participation was obtained for all infants before enrollment. If mothers provided HM, the infants were fed with breast milk. If mothers chose not to provide breast milk, the infants were randomized double blind to one of the four formula groups without further stratification. Randomization numbers were computer-generated (Roche, Basel, Switzerland) and allocated sequentially in the order of enrollment to the infants. Double blinding was achieved, as the identity of the dispensed formula was provided in a sealed envelope for each infant. Only in case of an immediately reportable adverse event was this envelope to be opened.

The study formulas were produced by Nutricia (Zoetermeer, The Netherlands) based on the low birth weight infant formula "Nenatal." The formulas delivered 80 kcal per 100 mL, and contained 11% (of energy) protein (whey/casein = 3:2), 40% carbohydrates (mainly lactose and polysaccharides), and 49% fat. The dietary fat (4.4 g/100 mL) was based on a blend of milk fat, coconut oil, soy oil, sunflower oil, and canola oil. These were the only fat components of the standard formula (ST), whereas the GLA content was increased by the addition of borage oil (BO). The two other formulas (BO + FOLOW, BO + FOHIGH) additionally contained fish oils differing in their EPA/DHA ratio (Hoffmann-La Roche Ltd., Basel, Switzerland). Both were composed to deliver 0.3% DHA but contained either 0.06% (BO + FOLOW) or 0.2% EPA (BO + FOHIGH). Table 1 shows the detailed fatty acid composition of the different formulas and of the breast milk fed (mean and standard error of individual samples), as analyzed in our laboratory. In the case of breast milk feeding, a 5-mL sample of breast milk was collected on days 0 and 14. All formulas contained 0.1 mg vitamin A and 1.3 mg vitamin E per 100 mL.

On the day of enrollment (study day 0), 2 wk later (study day 14), and 4 wk later (study day 28) anthropometric measures were recorded and blood samples were taken. At all time points a deviation of maximally 1 d from the date determined by the protocol was tolerated. Weight, length, and head circumference were measured according to standard hospital procedures. Blood samples (0.5 mL) were taken by venipuncture and immediately transferred into EDTA-containing tubes. Blood cells and plasma were separated by centrifugation at $1000 \times g$ for 5 min. A plasma aliquot of at least 200 μL was frozen immediately at −80°C for later analysis. Red blood cells were washed three times in 0.9% aqueous NaCl solution, hemolyzed, and stored at −80°C until analysis (data not shown). The remaining portion of the sample was used for the determination of routine laboratory parameters: alanine-amino-transferase, γ-glutamyltranspeptidase, total bilirubin, creatinine, total protein, glucose, carbamide-N, sodium, potassium, and calcium. For further assessment of possible adverse effects a series of hematological measures were performed, e.g., red blood cell count, hemoglobin, hematocrit, mean corpuscular volume, hemoglobin E, white blood cell count, platelet count, and hemogram. Pulse rate and blood pressure were also recorded.

As differences of 20% or greater in the primary study parameter, AA concentration in plasma phospholipids, were considered clinically important, the sample size was planned on the data of Decsi and Koletzko (31) who reported a rela-

[a]ST, standard formula; BO, borage oil; BO + FOLOW, borage oil + 0.3% DHA and 0.06% EPA; BO + FOHIGH, borage oil + 0.3% DHA and 0.2% EPA; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; SAT, saturated fatty acids; MUFA, monounsaturated fatty acids; TRANS, *trans* fatty acids; ND, not detected; LC-PUFA, long-chain polyunsaturated fatty acids.

tive standard deviation of 24% for AA. With 13 infants per group, the considered difference between groups was to be detected with 90% probability and a 5% risk of type I error.

*Analysis of plasma phospholipids*. After the addition of dipentadecanoyl-phosphatidylcholine as an internal standard, total lipids from 100 µL plasma were extracted into 2 mL hexane/isopropanol (4:1) and subsequently twice into 2 mL of hexane (32). Extracts were combined and dried under a stream of $N_2$. For application on silica gel plates (Merck KG, Darmstadt, Germany), the residue was taken up in chloroform/methanol (1:1). Phospholipids were isolated by development of the plates in *n*-heptane/diisopropylether/glacial acetic acid (60:40:3, by vol) (33). After visualization with 2,7-dichlorofluorescein, phospholipid-containing bands were scraped off and transferred into reaction vials. Synthesis of fatty acid methyl esters was performed by heating the phospholipids to 85°C for 45 min after dissolution in 1.5 mL 3M methanolic hydrochloric acid. After neutralization of the reaction mixture with carbonate buffer, methyl esters were extracted twice into 1 mL hexane and the combined extracts taken to dryness under nitrogen. For storage (–80°C) until gas chromatographic analysis, the samples were dissolved in 40 µL hexane (containing 2 g/L butylhydroxytoluene) and transferred into microvials.

Gas chromatography was performed on an HP5890 series II gas chromatograph (Hewlett-Packard, Waldbronn, Germany), equipped with a split/splitless injector (250°C, split ratio = 1:20, column head pressure 1.20 bar) and a flame-ionization detector (300°C). Separation of individual fatty acid methyl esters was achieved with a BPX70 column (SGE, Weiterstadt, Germany) with 60 m length and 0.32 mm inner diameter. The temperature program started at 130°C, increased at a rate of 3°C/min up to 200°C, and continued without delay up to 210°C at a rate of 1°C/min. For identification and determination of response factors, commercially available standards were used [Nu-Chek-Prep, Elysian, MN; Sigma, Deisenhofen, Germany; docosapentaenoic (n-6) acid methyl ester was a gift from Omega Tech, Boulder, CO]. Chromatographic data were recorded and evaluated using EZChrom Elite Ver. 2.1 software (Scientific Software Inc., Pleasanton, CA). Because of the small plasma volumes, samples were weighed in addition to volumetric dosage, and absolute plasma concentrations are given as mg fatty acid methyl ester per kg plasma.

*Analysis of milk lipids*. Milk samples were analyzed as previously described (34). Briefly, after the addition of 100 µL potassium oxalate (3.5%) solution, lipids from 1 mL milk were extracted into 3 mL of a mixture of ethanol/*tert*-butylmethylether/petrolether (1:1:1). To obtain quantitative recovery, a second extraction with 2 mL *tert*-butyl-methylether/petrolether (1:1) was performed. Extracts were combined and transferred into a preweighed vial; solvents were evaporated under nitrogen, and the remainder was dried in a desiccator overnight. Total lipid content could now be determined gravimetrically. For transesterification at 90°C for 60 min, the lipids were dissolved in 2 mL 1.5 M methanolic hydrochloric acid

and 1 mL hexane. After the addition of 2 mL water, the methyl esters were extracted into 2 mL of hexane and analyzed by gas chromatography as described for plasma samples.

*Analyses of vitamins A and E*. These analyses were performed as previously described from 100 µL plasma samples by high-performance liquid chromatography (35). After the addition of 100 µL ethanol to the samples, vitamins were extracted three times into 1 mL hexane and the combined extracts taken to dryness. For chromatography the extract was reconstituted in 100 µL mobile phase [acetonitrile/tetrahydrofuran/methanol/ammonium acetate (1%) = 684:220:68:28] containing tocol as standard for quantification. A high-performance liquid chromatography system (L6200 pump, AS 2000 autosampler, L4250 ultraviolet-visible detector, F-1050 fluorescence detector; Merck), equipped with a reversed-phase column (LiChrospher 100, RP-18, 25 cm long, Merck) was used for chromatography. With a flow rate of 0.65 mL/min, retinol, α-tocopherol and δ-tocopherol could be separated, while β- and γ-tocopherol coeluted. For retinol detection the photometer was set to 325 nm, and tocopherols were detected by their fluorescence at 330 nm after excitation at 298 nm. Data were recorded and evaluated with EZChrom Elite Ver. 2.1 software (Scientific Software Inc., Pleasanton, CA).

Total triglycerides (TG) and total cholesterol (Chol) were determined using a Vitros 250 autoanalyzer (Johnson & Johnson, Neckargmünd, Germany).

*Statistical analysis*. Data characterizing subjects are given as means ± standard deviations. One-way analysis of variance was used to detect statistically significant differences ($P \leq 0.05$) between groups. Analytical results for fatty acids and lipid-soluble vitamins are presented as means ± standard errors of the mean. Statistical evaluation of the results at the end of the study was performed by analysis of variance, including the corresponding values at study start as covariates. Differences between group means were taken as statistically significant if the 95% confidence interval (Scheffé method for correction of multiple testing) of differences between groups did not include 0. Coefficients of correlation were calculated according to Pearson and were taken as significant if $P$ was equal to or less than 0.05. Individual changes with time were investigated by paired $t$-tests (significance level 0.05). Calculations were performed using S Plus, Ver. 4.5 (Mathsoft Inc., Seattle, WA).

## RESULTS

Sixty-six infants with gestational ages between 25 and 37 wk were enrolled into the study. One infant from group ST was excluded from the study because of infectious disease. Thus the results from 65 infants who completed the study were evaluated. There were no statistically significant differences between the five dietary groups in clinical characteristics, body weight, length, head circumference, and postnatal age (Table 2). Although infants in groups BO and BO + FOHIGH tended to be older, there were no significant differences at study start and study end.

Infants presented very similar fatty acid compositions of plasma phospholipids across all groups at study start (Table 3). Saturated fatty acids (SAT) contributed almost one-half and *cis*-monounsaturated about 20% of the total. The only major difference at study start was a lower GLA content in the plasma phospholipids of the breast-fed group, although 0.15% GLA was detected in HM fat.

Tendencies indicating the statistically analyzed values at study end could already be observed for all investigated parameters at study day 14; thus there seemed to be a continuous trend during the whole study period.

[a]Common roman letter superscripts within a row indicate a significant difference ($P \leq 0.05$) between groups. For abbreviations see Table 1.

After 4 wk on the study diet, the percentage of SAT fatty acids decreased, while *cis*-monounsaturated fatty acids (MUFA) increased in all formula groups (Tables 3,4). In contrast, there were no changes in the breast-fed group, reflecting a higher percentage of SAT and a lower percentage of *cis*-MUFA in breast milk compared to the formula diets (Tables 3,4). The *trans* fatty acid content in the plasma lipids of breast-fed babies was almost twice as high as in all formula-fed groups, which corresponds to about 0.8% *trans* fatty acids in breast milk and no detectable *trans*-MUFA in formulas based on plant oil. Mead acid (20:3n-9) percentage decreased significantly over time in all formula groups, but not in HM-fed infants. In the diet, the percentage of the precursor oleic acid was higher in the formulas than in breast milk (43 vs. 31%), but traces of Mead acid were detectable only in breast milk.

At day 28, on the diets with 0.6% GLA there was no marked difference in phospholipid GLA content (0.1% in group ST vs. 0.15% in the other formula groups, not significant); only the breast-fed group showed a significant increase with time. No obvious difference was caused by additional dietary supply of n-3 LC-PUFA in the diet. The same trend was observed for the absolute concentrations, with all mean values below 2.5 mg/kg plasma. There were no significant differences in the content (absolute and relative) of DGLA, which is obtained by chain elongation of GLA. LA content increased significantly with time in all groups, but only the differences between groups ST and HM evolved to significance at day 28. The concentration of the elongation product of LA, 20:2n-6, like LA, showed no significant group differences, although only HM contained 20:2n-6. The content of the major n-6 LC-PUFA AA, which was very similar in all groups on day 0, decreased significantly until day 28 in all formula groups but not in the breast milk (0.5% AA) group, indicating that supplementation with GLA did not increase the AA content (Table 3). After 4 wk on the study diets, the AA percentage was significantly higher in the HM group, whereas no other group differences approached statistical significance. Absolute concentrations were only different between ST and HM (Table 4). The chain elongation product of AA (22:4n-6) was significantly lower in the formula-fed groups than in HM, but this cannot be ascribed to elongase activity since only breast milk contained 22:4n-6 (0.14%).

Addition of fish oil that was either high or low in EPA content did not further decrease n-6 LC-PUFA but markedly increased the DHA content in phospholipids (Tables 3,4). Mean EPA percentage was about twice as high in these groups as in all other groups, although EPA contributed only 0.06 and 0.15% to dietary fatty acids. Absolute concentrations of EPA were more than sixfold higher in the fish oil groups than in the HM group and twofold higher than in the other formula groups, respectively (Table 4). In contrast to EPA and DHA, the levels of the intermediate 22:5n-3 tended to be higher in HM infants, who received an exogenous supply (0.1%) of 22:5n-3. There was no significant difference between groups BO + FOLOW and BO + FOHIGH in any fatty acid concentration.

There was a marked influence of fish oil supply on the ratio of n-6 LC-PUFA to n-3 LC-PUFA. The ratios at day 28 were similar in breast-fed infants and in infants from groups ST and BO, whereas the n-6/n-3 LC-PUFA ratio dropped significantly ($P \leq 0.05$) from 6.27 ± 0.33 (M ± SE) to 4.23 ± 0.30 in BO + FOLOW and from 6.36 ± 0.36 to 3.97 ± 0.27 in BO + FOHIGH, respectively, and in BO it increased significantly from 5.72 ± 0.39 to 7.36 ± 0.48.

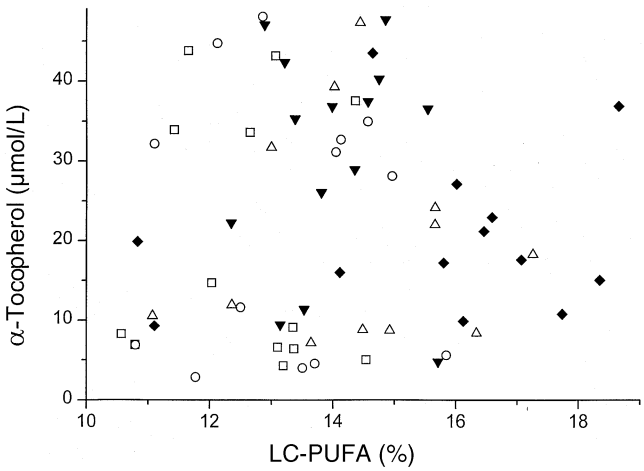

**FIG. 1.** Individual α-tocopherol concentrations (µmol/L) in relation to the percentage of LC-PUFA in plasma phospholipids (□ ST, ○ BO, △ BO + FOLOW, ▼ BO + FOHIGH, ◆ HM) showing neither a significant difference between groups nor a significant correlation for any of the groups. Abbreviations: LC-PUFA, long-chain polyunsaturated fatty acids; ST, standard formula; BO, borage oil; BO + FOLOW, borage oil + 0.3% docosahexaenoic acid (DHA) and 0.06% eicosapentaenoic acid (EPA); BO + FOHIGH, BO + 0.3% DHA + 0.2% EPA; HM, human milk.

The amount of antioxidative vitamins in the formulas (0.1 mg retinol and 1.3 mg tocopherol per 100 mL) resulted in plasma concentrations of retinol and α-tocopherol that were not different from breast-fed infants (Table 5). There was no detectable influence of LC-PUFA addition to the formulas on this parameter. In addition, there was no significant correlation between LC-PUFA percentage and α-tocopherol concentration (Fig. 1). Only for δ-tocopherol, which showed low concentrations in all infants and which is an isomer with low biological activity (36), could significant differences be observed between BO and HM as well as BO + FOHIGH and HM. The adjustment of α-tocopherol and retinol concentrations for Chol and TG by multiple regression according to Jordan *et al.* (37) did not reveal significant differences between groups (Table 5). In all groups there was a trend for α-tocopherol to increase with time, but it reached significance at day 28 only in groups BO and BO + FOHIGH.

## DISCUSSION

This study was designed to evaluate the influence of added GLA in preterm infant formula on the composition of n-6 LC-PUFA in infant plasma phospholipids. The added GLA resulted in dietary intakes of at least 32–34 mg/kg/d in groups BO, BO + FOLOW and BO + FOHIGH, which is close to the sum of GLA, DGLA, and AA typically ingested with breast

[a]Common roman letter superscripts within a row indicate a significant difference between groups; asterisk indicates a significant change ($P \leq 0.05$) from day 0 to day 28. Chol, cholesterol; TG, triglycerides; for other abbreviations see Table 1.

milk (38) and agrees reasonably well with the observed intake of about 43 mg/kg/d in the studied breast-fed infants.

The formulas showed a LA/α-linolenic acid ratio of about 11, which was markedly different from the mean ratio of 36 in human milk lipids, caused by the low α-linolenic acid content of human milk. The slightly higher LA content of 15.4% in breast milk compared to 13% in the formulas was not reflected by higher LA concentrations in the plasma phospholipids and is not assumed to cause an increase in AA, as the addition of LA to formulas showed only small effects on circulating AA (39).

There were no significant differences between groups with respect to plasma TG and total Chol concentrations, even though breast milk contains considerably more Chol than formulas for infants based on plant oil (40). This lack of a difference might be due to the fact that the infants were studied in the period when enteral feeding had just started. However, the concentrations were similar to values observed previously in newborn infants (41,42).

Total fatty acids in plasma phospholipids did not differ between groups or change with time and were well within the range of previously observed values in preterm infants of this age (36). AA levels were similar in all groups at study start, while there were clear differences between the formula groups and the breast milk group at the later time points, reaching significance at day 28. The decrease with time in infants not supplemented with AA is in agreement with earlier reports (36,43,44). The addition of GLA either alone or in combination with fish oil did not significantly improve the AA status as compared to the unsupplemented group. This confirms previous observations in studies where infant formulas had been supplemented with 0.5 or 0.3% GLA in addition to EPA and DHA (0.4 and 0.3%) or (0.6 and 0.4%), respectively, and either an unchanged or a decreased AA content in red blood cell lipids was observed (23,24). Thus, even in the absence of dietary n-3 LC-PUFA, an intake of up to 0.6% GLA failed to produce a significant increase of AA status. On the other hand, GLA supplementation in children and adults showed differing effects on AA status (18,45). Johnson *et al*. (18) reported a significant increase of total plasma AA percentage after 3 wk of GLA (1.5–6 g/d) intake, which corresponded to intakes ≥20 mg/kg/d assuming a body weight of 70 kg. Animal studies clearly showed that GLA is converted to AA (16), but whether there is an increase of AA concentrations in humans seems to depend on further factors. Stable isotope studies in term infants identified Δ-6 desaturation as the limiting step in the endogenous conversion of dietary LA to AA (13). The principal activity of the conversion of LA *via* GLA and DGLA to AA in neonates has been demonstrated *in vitro* (46) and *in vivo* (12–14), but the addition of the intermediate GLA to the diet does not seem to im-

prove the yield of AA. As it can be assumed that GLA has been efficiently absorbed (47), there must be some other physiological reason.

Although DGLA was delivered only in trace amounts with all tested formulas, DGLA showed plasma phospholipid concentrations in the GLA-containing formula groups that were higher than in the HM group, but lower values were present in the ST group, although differences were not significant (Table 3). It appears that 0.6% of GLA in the diet may well replace about 0.4% of DGLA, as provided with breast milk lipids (22), thus pointing toward rapid elongation. This is in accordance with other findings in neonates, healthy adults, and patients with atopic dermatitis (18,24,48). A further indication for an active fatty acid elongase in the studied preterm neonates is the finding that 20:2n-6, the elongation product of LA, was found in similar concentrations in all feeding groups, although only breast milk contained appreciable amounts of this fatty acid.

Phospholipid GLA concentrations did not respond to dietary GLA supply, which may be explained by the low affinity of GLA toward incorporation into phospholipids (49). Moreover, lipoprotein lipase preferentially hydrolyzes fatty acids with 16 or 18 carbon atoms from chylomicrons as compared to polyenoic fatty acids with 20 carbon atoms (50). There appears to be more uptake of the shorter fatty acids by tissues for oxidation, while a lower proportion is available for conversion to LC-PUFA or direct incorporation into phospholipids in the liver. This is in agreement with the observation of Leyton *et al*. (51) who reported that 27% of orally administered GLA in rats was oxidized to $CO_2$ within 24 h, while only 14% each of DGLA or AA were recovered in breath. Brouwer *et al.* (52) and Woltil *et al.* (53) reported that dietary GLA is preferentially incorporated into Chol esters in adults and that a significantly higher GLA content in plasma Chol esters of low birth weight infants was found when they were fed a formula with 0.3% GLA than when they were fed HM.

Obviously, dietary GLA was efficiently elongated to DGLA, possibly already in the intestine (54). Elongation products and remaining precursors reached the circulation after incorporation into chylomicrons, and it is possible that from these lipoproteins GLA was preferentially eliminated and oxidized. Thus only a negligible portion of GLA might have been available in the liver for conversion into AA and incorporation into phospholipids. Owing to the active elongation, the ingested GLA appears in the liver converted to DGLA, and might be handled similarly to dietary DGLA. After feeding deuterated DGLA to adults and measuring the concentration of deuterated AA in plasma, it was estimated that only a very low percentage of exogenous DGLA is converted to AA (55,56). The study by Emken *et al*. (56) offers a possible explanation for an inconsistent effect of GLA feeding on AA concentrations, as they noted that in subjects with an AA intake of 0.2 g/d, only about 2% of DGLA was desaturated, while this percentage increased to 18% with an AA intake of 1.7 g/d. In a larger group of subjects it was demonstrated that the high AA intakes were followed by elevated AA concentrations in all plasma lipid fractions and blood cells (57). Hence, the effect of GLA supplementation might depend on the current AA status. As there was no AA intake in the formula groups studied and AA concentrations were lower than those observed by Emken *et al.*, in combination with a possible immaturity of the desaturating enzyme system, these findings could explain the absence of an increase of AA after GLA supplementation.

This study also investigated the influence of fish oil supplementation on infant plasma phospholipid composition. The addition of 0.3% DHA established phospholipid DHA values similar to those found in the HM-fed group, and even exceeded them in a population with rather low HM contents of DHA. These findings are in accordance with published studies in term infants; e.g., Horby-Jorgensen *et al*. (24) reported 1.9% DHA in red blood cell phosphatidylcholine after feeding a formula with 0.3% DHA for 1 mon compared to 1.25% in an unsupplemented group. In preterm infants 0.2% DHA compared to 0% DHA in dietary fatty acids caused a concentration difference of about 5 mg/L in plasma total phospholipid DHA after 4 wk (25). In previous studies, dietary fish oil without simultaneous addition of preformed AA into the formula had led to AA concentrations below those of groups with LC-PUFA unsupplemented (25), which was explained by the competition of EPA and DHA for the incorporation into phospholipids (58) and an inhibitory effect of n-3 fatty acids on desaturase activities (59,60). It has been postulated that DHA and not EPA is the potent desaturase inhibitor in humans and that it mainly affects Δ-6 desaturation (61). The absence of a further AA decrease with DHA intake may be explained by the GLA supply in both fish oil-supplemented groups, thereby circumventing the Δ-6 desaturation step. Effects similar to those seen here were reported by Ward *et al*. (62) in brain phospholipids of artificially reared rat pups on diets varying in their GLA content from 0.5 to 3% and with either 0.5 or 2.5% DHA (62). They demonstrated that even 3% GLA in dietary lipids did not significantly increase AA content compared to 0.5% GLA. In contrast to our results, Makrides *et al*. (23) found a lower AA value of 10.2 ± 1.0% (mean ± SD) of total fatty acids from erythrocytes in term infants fed for 16 wk a formula with 0.58% EPA, 0.36% DHA, and 0.27% GLA compared to an unsupplemented control group (12.9 ± 1.3%), but they did not study a group fed the same dose of n-3 LC-PUFA but no GLA.

Tocopherol and retinol did not differ between groups on day 28 in either the absolute concentrations or in α-tocopherol and retinol concentrations after adjustment by multiple regression. At study day 0, 50% of the infants showed α-tocopherol concentrations below a level of 12.4 μmol/L, considered as the threshold for vitamin E sufficiency (63). This number decreased to 38% at day 28 with mean values for all groups from day 14 on above the threshold of sufficiency. Although there are suggestions to aim at much higher vitamin E concentrations, the intake in the formula-fed groups was 1.6 mg vitamin E/100 kcal (1.9 mg vitamin E/g PUFA), which is well above recommendations of the European Society for Pediatric Gastroenterology Hepatology and Nutrition (64).

In conclusion, our results are in line with previous findings (22,24,53,65) and show that addition of 0.6% GLA to formula diets does not increase AA content in plasma phospholipids of preterm infants and does not achieve values similar to comparable HM-fed infants. This effect does not seem to depend on the n-3 LC-PUFA content of the diet with the dose ranges studied. Although AA in the diet cannot be substituted by equimolar amounts of GLA, its addition may have other beneficial effects, e.g., increased high density lipoproteins (66). For the achievement of a LC-PUFA status similar to breast-fed infants, the supplementation of AA and n-3 LC-PUFA seems necessary.

## ACKNOWLEDGMENTS

The authors are grateful to Dr. Oross Istváné, Tóth Lászlóné, Dr. Kóbor Lászlóné, and Töröcsik Lászlóné for expert technical assistance. This study was supported in part by Deutsche Forschungsgemeinschaft, Bonn, Germany (Ko 912/5-2), and Hoffmann-La Roche Ltd., Basel, Switzerland. The experimental study formulas were kindly provided by Nutricia, Zoetermeer, The Netherlands.

# Effects of Δ5 Polyunsaturated Fatty Acids of Maritime Pine *(Pinus pinaster)* Seed Oil on the Fatty Acid Profile of the Developing Brain of Rats

**E. Pasquier[a,b], W.M.N. Ratnayake[a,*], and R.L. Wolff[b]**

[a]Nutrition Research Division, Food Directorate, Health Products and Food Branch, Health Canada, Ottawa, Ontario, Canada K1A 0L2, and [b]Laboratoire de Lipochimie Alimentaire, ISTAB, Université Bordeaux 1, Talence 33405 Cedex, France

**ABSTRACT:** Conifer (pine) seeds are a potential source of dietary oils, but their safety and nutritional properties are not well established. Conifer seed oils differ from common edible vegetable oils in having a series of unusual polyunsaturated fatty acids (PUFA) with a polymethylene-interrupted (PMI) double bond system and a double bond at the Δ5 position. A rat study was conducted to assess whether Δ5 PMI-PUFA of conifer seeds could alter the levels of n-6 and n-3 long-chain polyunsaturated fatty acids (LC-PUFA) in mothers' milk and the developing brain of fetuses and pups. Feeding maritime pine *(Pinus pinaster)* seed oil (MPO) diet with a Δ5 PMI-PUFA content of 1.4 g/100 g throughout pregnancy and lactation resulted in a large incorporation of Δ5 PMI-PUFA in mothers' milk (5.1 ± 0.5% of total fatty acids). The fetus (17 d old) and pup (22 d) brains, however, accumulated very little (0.6 and 0.4% of total fatty acids, respectively) Δ5 PMI-PUFA. Mother's milk and pup's brain of the MPO group contained normal levels of 20:4n-6, 22:4n-6, and 20:5n-3 compared to a reference group of rats fed a fat blend of sunflower, high-oleic sunflower, and canola oils. The level of 22:6n-3, however, was slightly but significantly ($P < 0.05$) higher in milk and pup brain of the MPO group. These results show that Δ5 PMI-PUFA of MPO exert no negative effect on the levels of n-6 and n-3 LC-PUFA in rat brain during its early development.

Paper no. L8708 in *Lipids 36,* 567–574 (June 2001).

Wolff *et al.* (1) recently proposed that seeds from conifer (pine) plants should be considered as a potential source of dietary oil for humans. Conifers are the most common naturally growing plant in the Northern Hemisphere, and their seeds contain about 65% triacylglycerol (TAG) oil. Currently, conifer seed oils are not directly used as dietary oils, but the seeds are consumed in some countries as condiments in food preparations. In China, seeds from *Biota orientalis* (a conifer species) are used for pharmaceutical purposes (2). Several animal studies have shown that conifer seed oils have a substantial lipid-lowering potential (3–5). These reports might imply that conifer seed oils are safe and provide health benefits to humans. However, more studies are needed to further explore the biological and nutritional effects of conifer seed oils before considering them as a safe dietary oil.

Conifer seed oils have a very unusual series of $C_{18}$- and $C_{20}$-polyunsaturated fatty acids (PUFA), in which the first double bond is in the Δ5 position and the next immediate double bond is at Δ9 or Δ11 (1), so that the first two double bonds are separated by two or four methylene ($CH_2$) units. The other subsequent bonds, however, are separated by one $CH_2$ unit. This pattern is in contrast to the usual PUFA of common vegetable oils and animal fats, in which the neighboring double bonds are always separated from each other by a single $CH_2$ unit. Since the first two double bonds of the unusual PUFA of conifer seed oils are separated by two or more $CH_2$ units, it is appropriate to name them as Δ5 polymethylene-interrupted PUFA and to abbreviate them as Δ5 PMI-PUFA. The Δ5 PMI-PUFA so far identified in conifer seed oils included 5,9-18:2 (taxoleic acid), 5,11-18:2 (ephedrenic acid), 5,9,12-18:3 (pinolenic acid), 5,9,12,15-18:4 (coniferonic acid), 5,11-20:2; 5,11,14-20:3 (sciadonic acid), and 5,11,14,17-20:4 (juniperonic acid) (1). The totals of these acids in different varieties of conifer seeds usually range from 5 to 35% of the total fatty acids, of which the major ones are sciadonic and pinolenic acids.

Results from the few studies on the biological effects of conifer seed oils suggest that sciadonic acid has an enormous potential to replace arachidonic acid (20:4n-6, or AA) in tissues and cells (6–9). Studies by Berger and coworkers (7,8) have shown that sciadonic acid is primarily incorporated in cardiac and hepatic phosphatidylinositol (PI) in the mouse. In hepatic PI, sciadonic acid replaced AA, resulting in a 50% reduction of the level of AA. Another study reported that sciadonic acid reduced the AA content of the PI fraction from a control value of 15.9 to 7% in a cultured cell system (9). This replacement of AA by sciadonic acid should be a concern in infant nutrition because AA, along with other $C_{20}$ and $C_{22}$ n-6 as well n-3 PUFA, particularly docosahexaenoic acid (22:6n-3, or DHA), is recognized as essential for the development of brain and retina (10). Insufficient supply of these

Abbreviations: AA, arachidonic acid; amu, atomic mass units; DHA, docosahexaenoic acid; DMOX, 2-alkalenyl-4,4-dimethyloxazoline; FAME, fatty acid methyl esters; GC, gas chromatography; GC–MS, gas chromatography–mass spectrometry; HOSF/SF/CO, high oleic sunflower/sunflower/canola oils; LC-PUFA, long chain-polyunsaturated fatty acids; MPO, maritime pine seed oil; MUFA, monounsaturated fatty acids; PMI-PUFA, polymethylene interrupted polyunsaturated fatty acids; PI, phosphatidylinositol; PL, phospholipid; PUFA, polyunsaturated fatty acids, SFA, saturated fatty acids; TAG, triacylglycerol; TLC, thin-layer chromatography.

fatty acids during the rapid development phase of the central nervous system, which occurs primarily during embryogenesis and neonatal periods, might result in poor visual acuity and cognitive function in later life (10).

The main objective of this study was to determine, using the rat as the experimental model, whether mothers' intake of sciadonic acid and other Δ5 PMI-PUFA from conifer seed oils during pregnancy and lactation has an effect on the proportions of AA, DHA and other $C_{20}$ and $C_{22}$ n-6 and n-3 PUFA in mothers' milk and the developing brain of fetuses and pups. In this study we utilized oil extracted from *Pinus pinaster* (maritime pine) seeds as the representative conifer seed oil. *Pinus pinaster* is one of the common conifer varieties growing in the Northern Hemisphere.

## EXPERIMENTAL PROCEDURES

*Animals and diets*. Twenty-day-old female Wistar rats (Charles River, Québec, Canada) were randomly assigned according to body weight (259 ± 11 g) to two dietary groups (A and B) with 10 females in each group. They were housed individually in metal cages in an air-conditioned room maintained at 22°C and 60% relative humidity with a 12 h day/12 h night cycle. The rats in group A were fed a semipurified diet containing a blend of high-oleic sunflower, sunflower, and canola oils (35:55:10) (HOSF/SF/CO) in the proportion of 10 g/100 g. The rats in group B were fed a similar diet but containing maritime pine seed oil (MPO, provided by Société Bertin, Lagny-le-Sec, France) in the same proportion. The fatty acid composition of the two diets (determined by gas–liquid chromatography, see below) is given in Table 1. Both diets contained similar levels of linoleic acid (45% of total fatty acids) and α-linolenic acid (1.3%). The Δ5 PMI-PUFA occurring in MPO were replaced by oleic acid in the HOSF/SF/CO diet. The diets were prepared according to the AIN-93 recommendations (American Institute of Nutrition) for rodent diets (11). Other dietary components were (g/100 g diet): casein, 22; cornstarch, 47.95; granulated sugar, 10; fiber (Alfa-floc), 5; mineral mixture AIN-93G, 3.50; vitamin mixture AIN-93-VX, 1; L-cystine, 0.30; and choline bitartrate, 0.25. Rats were allowed free access to water and food. Amounts of food consumed were recorded, and fresh food and water were provided once in 4 d. The animals were weighed weekly.

| 7,11,14-20:3 | ND | TR |

[a]HOSF, high-oleic sunflower oil; SF, sunflower oil; CO, canola oil; MPO, maritime pine seed oil; SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; Δ5 PMI-PUFA, polymethylene-interrupted polyunsaturated fatty acids; TR, trace amounts (≤0.05% of total fatty acids); ND, not detected.

After 16 d on the diet, the rats were allowed to mate by overnight pairing. At the 17th day of pregnancy, five rats from each group were killed by exsanguination while under 3% isoflurane anesthesia. Blood, liver, and breast tissues from the mother, and brains and fetuses were collected for lipid analysis. Blood (about 7 mL/rat) was withdrawn immediately from the aorta and stored in EDTA tubes. Tissue samples were frozen immediately in liquid nitrogen and stored at −70°C until analyses. All of the other rats were allowed to give birth, and the number of pups per mother and the birth weights of the neonates were recorded. A milk sample was collected on the 21st day after delivery. All the animals were killed on day 22 of lactation, and blood, liver, brain, and breast tissues were collected. Health Canada's guide for the care and use of laboratory animals was followed and the study protocol was approved by the Animal Care Committee of Health Canada.

*Fatty acid analysis.* Lipids from the tissue samples were extracted according to the Bligh and Dyer procedure (12). A small portion of the extracted lipid was separated into the various lipid classes by thin-layer chromatography (TLC) and the phospholipid (PL) and TAG fractions were collected. The dietary oils, tissue total lipids, PL, and TAG fractions were converted to fatty acid methyl esters (FAME) using $BF_3$/MeOH reagent according to the procedure of Morrison and Smith (13). The FAME were analyzed using a gas–liquid chromatograph equipped with a flame-ionization detector (Hewlett-Packard 5890 Series II, Avondale, PA) and a CP-Sil 88 capillary column (100 m × 0.25 mm i.d.; Chrompack, Middelburg, The Netherlands). The gas chromatography (GC) peaks for the FAME were identified by their relative retention times in comparison with FAME standards and with published data (14). The identifications were confirmed by calculating equivalent chain length and, for *P. pinaster* oil FAME, by argentation-TLC and GC–mass spectrometry (GC–MS) analyses of 2-alkalenyl-4,4-dimethyloxazoline (DMOX) derivatives of fatty acids (15–17). The GC–MS analyses were executed using a VG Analytical MS system, Model 7070 EQ (VG Analytical, Manchester, England), equipped with a 11/250 data system interfaced to a Varian GC, Model Vista 6000 (Varian Associates, Palo Alto, CA) operated at an ionization energy of 70 eV. GC separation of the DMOX derivatives was performed on the same CP Sil 88 column described for the FAME analysis.

*Hematologic measurements.* The complete blood count was measured using a Coulter Counter S-PLUS IV system (Coulter Electronics, Hialeah, FL) on whole blood samples collected in EDTA tubes.

*Statistical analysis*. Statistica software, version 6.0 (Statsoft, Tulsa, OK) was used to analyze the data. For each dietary group, means and standard deviations were calculated and the significant differences were assessed by Tukey's honest significant test. Differences were considered significant when $P$-value <0.05. All data in tables are reported as means and standard deviations.

## RESULTS

*General health parameters*. The adult female rats grew normally, and there were no significant differences in the body weights between the two dietary groups, measured at regular intervals during the feeding phase of the experiment (Table 2). The ratios of liver weight to total body weight also were similar. The effect of the diet on pup brain weight was assessed by calculating the pup brain weight to pup total body weight ratio. The values were not different between the two dietary groups. Daily food intakes by mothers in both groups were high but normal for pregnant and lactating mothers, and there was no difference between the two groups. Visual inspection at necropsy indicated no apparent tissue and organ abnormalities of both mothers and their pups. Litter sizes of HOSF/SF/CO (12.7 ± 4.6 pups) and MPO (16.0 ± 2.1 pups) groups were high but within the normal range for Wistar rats (3–18 pups), and the difference between the two groups was not significant.

*Hematologic indices*. The lactating mothers of the MPO group at 21 d postpartum had a leukocyte count of 7.42 ± 1.86 $\times 10^9$/L , which was significantly ($P = 0.0044$) higher than that of the lactating mothers in the HOSF/SF/CO group (3.95 ± 1.17 $\times 10^9$/L ). Mature female rats (125 d old) normally range between 6.8 and 15.7 $\times 10^9$ leukocytes/L (18). This suggests that the leukocyte count was normal in the MPO group but too low in the HOSF/SF/CO group. Platelet count was also significantly ($P = 0.0384$) lower in the HOSF/SF/CO group (6.98 ± 0.25 $\times 10^{10}$/L vs. 7.12 ± 0.29 $\times 10^{10}$/L for MPO). There were no significant differences ($P > 0.05$) in the other hematology indices (erythrocyte count, hemoglobin, mean corpuscular volume, mean corpuscular hemoglobin concentration, red cell distribution width, and mean platelet volume) between the two dietary groups (data not shown).

*Fatty acid composition of blood, liver, and breast tissue from 17-d-pregnant rats*. All the dietary Δ5 PMI-PUFA were detected in blood, liver, and breast tissue samples from the 17-d pregnant rats fed MPO (Tables 3–5). As expected, none of these Δ5 fatty acids was detected in the pregnant rats fed HOSF/SF/CO. The proportion of total Δ5 PMI-PUFA of the MPO group was higher in blood (6.8%) (Table 3) than in the liver total lipids (3.4%), liver PL (2.6%) (Table 4), and breast total lipids (3.9%) (Table 5). In all tissues 5,11,14-20:3 and 5,9,12-18:3 were the major Δ5 PMI-PUFA, whereas 5,9-18:2 and 5,11-20:2 were present in relatively lower proportions. In addition to these fatty acids, the MPO-fed rats showed the presence of 7,11,14-20:3. The proportion of this PMI-PUFA in blood and tissues was higher than in the PMO diet. This unusual PMI-PUFA was not detected in rats fed HOSF/SF/CO.

There were no notable differences found in the blood and tissue levels of n-3 and n-6 long-chain-PUFA (LC-PUFA) between the two dietary groups.

*Fatty acid composition of blood and liver of lactating mothers at day 22 of lactation*. Blood and liver of lactating mothers of the MPO group on day 22 after delivery (i.e., 63 d of feeding) also contained Δ5 PMI-PUFA (Tables 6 and 7). Here also, 5,9,12-18:3 and 5,11,14-20:3 were the major Δ5 PMI-PUFA. The PL and TAG fractions of liver contained similar proportions of total Δ5 PMI-PUFA (Table 7). However, 5,11,14-20:3 was primarily in the PL fraction, whereas 5,9,12-18:3 was mainly in the TAG fraction. As in pregnant rats, 7,11,14-20:3 acid was also detected in maternal blood and liver samples, but at considerably lower levels. As expected, none of these fatty acids was detected in the lactating mothers of the HOSF/SF/CO group. Blood and liver of the mothers fed the HOSF/SF/CO diet, compared to those of the

**TABLE 2**
**Body and Organ Weights of Mothers ($n = 5$) and 22-d-old Pups and Food Intakes by Mothers**

| | HOSF/SF/CO (g) | MPO (g) |

[a]Values in a row with different roman superscripts between HOSF/SF/CO and MPO groups are significantly ($P < 0.05$) different. For abbreviations see Tables 1 and 3.

MPO-fed mothers, contained significantly higher proportions of MUFA (primarily oleic acid). The proportion of 18:2n-6 in blood lipids was similar in both groups (Table 6); however, the liver TAG of the MPO rats showed a higher proportion of 18:2n-6 than those of the HOSF/SF/CO rats. In contrast, there was no difference in the 18:2 proportion in liver PL between the two dietary groups. The proportion of AA in blood and liver lipids was similar between the two groups. With regard to other LC-PUFA, 22:4n-6, 20:5n-3, 22:5n-3, and 22:6n-3 proportions were slightly higher in the MPO rats, whereas 22:5n-6 was slightly lower.

*Fatty acid composition of whole body and brain of 17-d-old fetus.* Significant accumulations of the Δ5 PMI-PUFA were observed in the fetal body and brain during pregnancy of the MPO group (Table 8). The proportion of total Δ5 PMI-PUFA in brain PL was 0.6% of total fatty acids, whereas the body total fat contained slightly higher proportions (1.4%). As in the pregnant and lactating mothers, 5,9,12-18:3 and 5,11,14-20:3 were the main Δ5 PMI-PUFA. The compounds 5,9-18:2 and 5,11-20:2 were almost absent in both the total body fat and brain. The 7,11,14-20:3 was present in proportions similar to those in maternal blood fat.

[a]Values in a row with different roman superscripts between HOSF/SF/CO and MPO groups are significantly ($P < 0.05$) different. For abbreviations see Tables 1 and 3.

The brain PL fraction of the MPO group showed a lower proportion of saturated fatty acids (SFA) than that of the HOSF/SF/CO group. This low proportion was compensated by large increases in total monounsaturated fatty acids (MUFA) (primarily oleic acid), 20:4n-6, and slight, but significant, increases of 22:4n-6 and 22:5n-6 acids in the MPO group. However, in fetal body total fat, there were no significant differences in these fatty acids between the two groups.

*Fatty acid composition of milk.* All of the dietary Δ5 PMI-PUFA were found in mothers' milk of the MPO group withdrawn on day 21 of lactation (Table 9). Compared with maternal blood fatty acid composition, there was a large incorporation of Δ5 PMI-PUFA with 18 carbon atoms into milk fat. The 7,11,14-20:3 was also incorporated, and its proportion reached 0.3% of total milk fatty acids. Major differences in the other fatty acids were also seen between dietary groups. The proportion of total MUFA was lower, whereas the proportions of total SFA and 18:2n-6 were higher in the MPO group than in the HOSF/SF/CO group. In addition, the MPO group contained slightly but significantly higher proportions

[a]Values in a row with different roman superscripts are significantly ($P < 0.05$) different. For abbreviations see Tables 1 and 3.

of 20:5n-3, 22:5n-3, and 22:6n-3. The proportions of 20:4n-6 and other n-6 LC-PUFA, however, were similar between the two groups. Consequently, the ratio of total n-6 LC-PUFA to total n-3 LC-PUFA was significantly higher for the HOSFO/SFO/CO group (1.70 ± 0.15) than for the MPO group (1.44 ± 0.06).

*Fatty acid composition of brain PL and blood total fat of 22-d-old pups*. All of the dietary Δ5 PMI-PUFA were found in blood of the pups from the MPO group, and they accounted for 9% of the total fatty acids (Table 10). In contrast, pup brain contained very little Δ5 PMI-PUFA (0.4% of total fatty acids). In pup blood, both 5,9,12-18:3 and 5,11,14-20:3 were found in important proportions but only 5,9-18:2 and 5,11,14-20:3 were detected in brain. The brain of the MPO group compared to the HOSF/SF/CO contained significantly higher proportions of 22:6n-3 and total n-3 LC-PUFA.

## DISCUSSION

The measurement of routine indicators of nutritional adequacy such as body and organ weights, and hematologic measurements demonstrated that consumption of MPO had no adverse effects on mothers' and pups' health.

*Δ5 PMI-PUFA levels in pregnant and lactating rats*. The fatty acid data show that feeding of pregnant and lactating rats with MPO results in the incorporation of Δ5 PMI-PUFA into blood followed by deposition into various tissues including breast and milk. The 5,9,12-18:3 and 5,11,14- 20:3 were the primary Δ5 PMI-PUFA detected in blood and tissues of pregnant and lactating rats. Of these two, 5,11,14-20:3 was more concentrated in the liver PL fraction, whereas 5,9,12-18:3 was concentrated in the liver TAG fraction. The specific incorporation of 5,11,14-20:3 in the PL fraction may indicate a special affinity, perhaps due to its structural similarity with AA. Nevertheless, no significant replacement of AA was observed in the liver PL of both pregnant and lactating rats, but we cannot exclude that this may have occurred in PI, which is quantitatively a minor lipid class in the liver (9). This point deserves further investigation.

*Δ5 PMI-PUFA in fetus and pups*. The 17-d-old fetal brain and whole body contained detectable levels of Δ5 PMI-PUFA, which shows that there is a transfer of these fatty acids from the mother to fetus during pregnancy. However, the lev-

[a]Values in a row with different roman superscripts between HOSF/SF/CO and MPO groups are significantly ($P < 0.05$) different. For abbreviations see Tables 1 and 3.

els detected in the fetus were considerably lower than those in mothers' blood. This indicates that there is a mechanism in the placenta for selectively slowing the passage of Δ5 PMI-PUFA from maternal blood to the fetus. An alternative explanation is that there is a preferential passage through the placenta for normal fatty acids particularly oleic acid and, n-6 and n-3 LC-PUFA. The proportions of these fatty acids were considerably higher in fetal than in maternal blood. These data would also suggest that Δ5 PMI-PUFA are not recognized as usual PUFA by the fetus during fatty acid transfer from the placenta, and therefore, Δ5 PMI-PUFA appear not to interfere with LC-PUFA during transport.

Among the different Δ5 PMI-PUFA, 5,9,12-18:3 and 5,11,14-20:3 acids were primarily incorporated into fetal tissues, and 5,9-18:2 and 5,11-20:2 acids were poorly incorporated. Between 5,9,12-18:3 and 5,11,14-20:3, the latter was more efficiently incorporated. For example, the ratio of 5,11,14-20:3 to 5,9,12-18:3 in pregnant mothers' blood was 1.12, and this ratio was increased to 1.80 and 1.31 in brain PL and whole body fat, respectively, of the 17-d-old fetus. This preferential incorporation might be explained by its structural closeness to 8,11,14-20:3 and 5,8,11,14-20:4. The primary difference between these three $C_{20}$-PUFA is the absence of a Δ8 bond in 5,11,14-20:3. This similarity might give 5,11,14-20:3 a slight advantage over 5,9,12-18:3 during placental transfer to the fetus. An alternative possibility concerning the lower incorporation of 5,9,12-18:3 in fetus may be related to the surprisingly high level of 7,11,14-20:3 in the same tissue; 7,11,14-20:3 is the two-carbon chain elongation product of 5,9,12-18:3, and its proportion in fetal whole body fat was twice that found in maternal blood. Whereas the ratio of 7,11,14-20:3 to 5,9,12-18:3 was 0.10 in the maternal blood, this ratio reached 1.57 and 1.11 in brain PL and whole body fat, respectively. This may indicate that 5,9,12-18:3 is elongated inside the fetal milieu to 7,11,14-20:3, and this would result in low levels of 5,9,12-18:3 in tissues. The fetal whole body fat compared to the fetal brain PL contained a higher proportion of Δ5 PMI-PUFA (1.4 vs. 0.6%). This may indicate that brain is relatively protected against incorporation of Δ5 PMI-PUFA. It may be that the blood–brain barrier restricts the passage of Δ5 PMI-PUFA.

The fatty acid data suggest that transfer of Δ5 PMI-PUFA from milk into pups was more efficient than the transfer of these fatty acids from pregnant mothers to the fetus. For example, the ratio of the proportion of Δ5 PMI-PUFA between fetal whole body fat and pregnant rats' blood total fat was 0.21, whereas it was 1.56 between pups' blood total fat and milk fat. This increased transfer of Δ5 PMI-PUFA from milk to pup is not surprising as digestion in the newborn relies mainly on lingual lipase because the bile salt levels fall below critical micellar concentration (19); under these conditions pancreative lipase is inactive. Lingual lipase preferentially cleaves the *sn*-3 position of TAG fatty acids present on dietary TAG, giving high free fatty acid levels. Free fatty acids are more readily absorbed than monoacylglycerol under conditions of low intestinal intraluminal levels of bile salts. Therefore, the location of LC-PUFA at the *sn*-3 position of milk TAG leads to their preferential release during gastric lipolysis (20). The Δ5 PMI-PUFA, particularly 5,9,12-18:3 and 5,11,14-20:3, because of their structural similarity to n-6 PUFA, should also be concentrated in the *sn*-3 position of milk TAG and, consequently, preferentially cleaved and well absorbed. It is necessary to study the Δ5 PMI-PUFA distribution in milk TAG to confirm the site of esterification as the *sn*-3 position, as was reported for conifer seed oil TAG structure (21).

Although pups' blood of the MPO group contained a large proportion of total Δ5 PMI-PUFA (9% of total fatty acids), pups' brain PL contained very little Δ5 PMI-PUFA (0.4%), and this level was slightly lower than in fetal brain PL (0.6%). This shows that the blood–brain barrier effectively inhibited the transfer of Δ5 PMI-PUFA to the brain during its development. A comparison between the Δ5 PMI-PUFA distribution of fetal and pups' brain PL presents some interesting biochemical features related to the metabolism of these fatty acids. The 5,11,14-20:3 is present at similar proportions in both fetal body total fat and brain PL, and 5,9-18:2 and 5,11-20:2 are nearly absent. But a noticeable difference is seen in the proportions of 5,9,12-18:3. This Δ5 PMI-PUFA is found in fetal brain PL (0.2% of total fatty acids), but it is almost absent in pups' brain PL. Nevertheless, pups' brain PL contained 7,11,14-20:3 at two times the level found in fetal brain PL (0.6 vs. 0.3% of total fatty acids). This might indicate that the process of chain elongation of 5,9,12-18:3 to 7,11,14-20:3 in brain is active during its development from the fetus to pup stage.

*Effect of diet on tissue levels of essential fatty acids*. The fatty acid data show that the consumption of Δ5 PMI-PUFA from MPO during pregnancy and lactation produces no drastic changes in the proportions of AA, DHA, and other n-6 and n-3 LC-PUFA in the various tissues of both pregnant rats and fetuses, including the brain. Moreover, the possible direct replacement of AA by 5,11,14-20:3 (sciadonic acid), which was suspected because this was reported in several previous studies (6–9) and because of the close structural similarity between AA and sciadonic acid, was not observed in this study. Previous studies had suggested that replacement of AA by sciadonic acid occurs mainly in PL fraction, but this was not evident from the fatty acid data of the present study. In contrast, PL from various tissues of this study showed no change in the AA level; and in some tissue PL, particularly from 17-d-old fetal brain, there was a slight but significant elevation of the proportion of AA as well as other n-6 LC-PUFA and DHA. The DHA proportion was also increased in 22-d-old pup brains from mothers treated with MPO. These increases in the proportions of n-3 and n-6 LC-PUFA may be beneficial for pups in developing their visual acuity and cognitive functions. The mechanism by which the dietary Δ5 PMI-PUFA can modify LC-PUFA proportions in brain, liver, and other tissues, however, remains unclear.

In summary, our study demonstrated that intake of sciadonic acid and other Δ5 PMI-PUFA from MPO by rats during pregnancy and lactation presents no adverse effects on the proportions of AA, DHA, and other $C_{20}$ and $C_{22}$ n-6 and n-3

PUFA in the developing brain of fetuses and infants. Moreover, the present study suggests that MPO would be helpful in increasing the n-3 and n-6 LC-PUFA levels in brain of fetus and infants and therefore their consumption might be beneficial for pregnant and lactating women.

# The Effect of Conjugated Linoleic Acid Isomers on Fatty Acid Profiles of Liver and Adipose Tissues and Their Conversion to Isomers of 16:2 and 18:3 Conjugated Fatty Acids in Rats

**J.-L. Sébédio*, E. Angioni[1], J.M. Chardigny, S. Grégoire, P. Juanéda, and O. Berdeaux**

INRA, Unité de Nutrition Lipidique, 21065 Dijon Cedex, France

**ABSTRACT:** Conjugated linoleic acid (CLA) is a collective term that describes different isomers of linoleic acid with conjugated double bonds. Although the main dietary isomer is 9*cis*,11*trans*-18:2, which is present in dairy products and ruminant fat, the biological effects of CLA generally have been studied using mixtures in which the 9*cis*,11*trans*- and the 10*trans*,12*cis*-18:2 were present at similar levels. In the present work, we have studied the impact of each isomer (9*cis*,11*trans*- and 10*trans*,12*cis*-18:2) given separately in the diet of rats for 6 wk. The 10*trans*,12*cis*-18:2 decreased the triacylglycerol content of the liver (–32%) and increased the 18:0 content at the expense of 18:1n-9, suggesting an alteration of the Δ9 desaturase activity, as was already demonstrated *in vitro*. This was not observed when the 9*cis*,11*trans*-18:2 was given in the diet. Moreover, the 10*trans*,12*cis*-18:2 induced an increase in the $C_{22}$ polyunsaturated fatty acids in the liver lipids. The 10*trans*,12*cis*-18:2 was mainly metabolized into conjugated 16:2 and 18:3, which have been identified. The 9*cis*,11*trans* isomer was preferentially metabolized into a conjugated 20:3 isomer. Thus, the 9*cis*,11*trans*- and the 10*trans*,12*cis*-CLA isomers are metabolized differently and have distinct effects on the metabolism of polyunsaturated fatty acids in rat liver while altering liver triglyceride levels differentially.

Paper no. L8692 in *Lipids 36,* 575–582 (June 2001).

Conjugated linoleic acid (CLA) is a collective term that describes several conjugated isomers of linoleic acid (1,2). CLA isomers have been reported to have beneficial properties with respect to some experimentally induced cancers (3–6) and to some parameters that are considered as cardiovascular risk factors (7,8). However, a recent paper by Munday *et al.* (9) showed that, even if feeding CLA resulted in a serum lipoprotein profile considered to be less atherogenic, the presence of CLA in the diet increased the development of aortic fatty streak. CLA have also been reported to be effective in preventing the catabolic effects of immune stimulation and to have beneficial effects on diabetic rats (10).

Moreover, CLA can induce a reduction of body fat in mice, chicks, and pigs (11–14). Feeding 4.2 g/d of CLA to humans (men and women) for 3 mon resulted in a reduction of body fat (15), but an increase in lipid peroxidation (16). On the contrary, a recent study by Zambell *et al.* (17) showed that feeding CLA capsules (3 g/d) for 64 d to healthy adult women did not result in any change in fat-free mass, fat mass or energy expenditure which contrasts with the findings in animals. However, the CLA isomers used in the different studies were different.

CLA are present in human food. They mainly occur in dairy products (18–24) but also in meat from ruminants (25), hydrogenated fats (26), and used frying oils (27). The main dietary CLA isomer is 9*cis*,11*trans*-18:2, whereas synthetic CLA mixtures contain many other 18:2 isomers with conjugated double bonds (1,2). These synthetic samples contain 9,11 dienes as well as 8,10, 10,12, and 11,13 *cis-trans*/*trans-cis* isomers, which are accompanied by some all-*cis* and all-*trans* isomers. Most of the experimental studies were carried out using such synthetic CLA mixtures, and the role of each isomer has not yet been clearly identified. A recent study (28) suggested a specific effect of the 10*trans*,12*cis*-18:2 isomer on body composition. Furthermore, Ip *et al.* (5) also showed that an enriched CLA butterfat, containing mainly the 9*cis*,11*trans* isomer, had a similar activity as a potent cancer-preventive agent to the commercial CLA mixture frequently used in animal models of chemically induced carcinogenesis.

The antioxidant role of CLA, which was a hypothesis of the mechanism of its action, has been reevaluated (29). Some studies suggest that dietary CLA may alter eicosanoid biosynthesis (30). Such data could also explain their action, but the mechanism is not clearly understood (21). It has been suggested that CLA alter the fatty acid composition of animal tissues when given in the diet (31). However, these studies were carried out using a mixture of CLA isomers and the precise effect of each major isomer has not been studied yet. In the present paper, we report data on the lipid profile and the fatty acid composition of liver lipids and the fatty acid composition of the adipose tissue from rats fed for 6 wk a diet containing 1% of either 9*cis*,11*trans*- or 10*trans*,12*cis*-18:2, which are the major isomers present in synthetic CLA mixtures utilized so far for animal studies. Metabolites of the CLA isomers were also identified in liver lipids and adipose tissue.

## MATERIALS AND METHODS

*Animals*. Twenty weanling male Wistar rats (IFFA Credo, L'Arbresle, France) were housed in individual stainless steel cages in an animal house maintained at 26 ± 1°C (light/dark: 12 h/12 h). They were randomly divided into four experimental groups of five animals which were fed a semisynthetic diet containing 6% (by weight) of lipids. The composition of the diet, in terms of dry weight (g/1000 g), was as follows: casein, 180; corn starch, 460; sucrose, 220; cellulose, 20; mineral mixture, 50 [The mineral mixture contained: $CaCO_3$, 12 g; $K_2HPO_4$, 10.75 g; $CaHPO_4$, 10.75 g; $MgSO_4 \cdot 7H_2O$, 5 g; NaCl, 3 g; MgO, 2 g; $FeSO_4 \cdot 7H_2O$, 400 mg; $ZnSO_4 \cdot 7H_2O$, 350 mg; $MnSO_4 \cdot H_2O$, 100 mg; $CuSO_4 \cdot 5H_2O$, 50 mg; $Na_2SiO_7 \cdot 3H_2O$, 25 mg, $AlK(SO_4)_2 \cdot 12H_2O$, 10 mg; $K_2CrO_4$, 7.5 mg; NaF, 5 mg; $NiSO_4 \cdot 6H_2O$, 5 mg; $H_3BO_3$, 5 mg; $CoSO_4 \cdot 7H_2O$, 2.5 mg, $KIO_3$, 2 mg; $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$, 1 mg; LiCl, 0.75 mg; $Na_2SeO_3$, 0.75 mg; $NH_4VO_3$, 0.5 mg, sucrose, 5.5 g]; vitamin mixture, 10 (The vitamin mixture contained: retinol acetate, 5000 IU; cholecalciferol, 1250 IU; DL-α-tocopherol acetate, 100 IU; phylloquinone, 1 mg; thiamine chlorhydrate, 10 mg; riboflavin, 10 mg; nicotinic acid, 50 mg; Ca-pantothenate, 25 mg, pyridoxin chlorhydrate, 10 mg; D-biotin, 0.2 mg; folic acid, 2 mg; cyanocobalamin, 25 µg; choline chlorhydrate, 1 g; DL-methionine, 2 g; *p*-aminobenzoic acid, 50 mg; inositol, 100 mg; sucrose, 5.5 g); oil, 50; free fatty acids, 10. Dietary lipids were made up of 5% of a mixture of high-oleic sunflower and linseed oils (98:2, w/w) and 1% of conjugated CLA as free fatty acid (FFA: experimental groups) or 1% of oleic acid (control group). The different experimental groups were fed either 1% of 9*cis*,11*trans*-18:2 (group 9*cis*,11*trans*), 1% of previously synthetized 10*trans*,12*cis*-18:2 (32,33) (group 10*trans*,12*cis*), or a synthetic commercial mixture of conjugated-18:2 isomers (group CLA mixture). The detailed fatty acid composition of each FFA moiety of the diets is presented in Table 1. The animals were fed for 6 wk *ad libitum* with free access to tap water. This experiment was carried out according to the French guidelines for animal studies.

*Lipid analyses.* At the end of the 6-wk experimental period, the animals were anesthetized with diethyl ether, exsanguinated, and the liver and adipose tissue were quickly excised, blotted on filter paper, and weighed. Liver and adipose tissue lipids were extracted using a mixture of chloroform and methanol (2:1, vol/vol) (34).

Quantitative lipid class analyses were carried out by the Iatroscan (Iatron, Tokyo, Japan) thin-layer chromatography–flame-ionization detection (TLC–FID) system using a mixture of hexane/diethyl ether/acetic acid (97:3:1, by vol) as solvent (35).

Liver lipid classes were fractionated into phospholipids (PL), cholesteryl esters (CE), and triacylglycerols (TAG) using $NH_2$ cartridges (Phase Separation Products, Saint Quentin en Yvelines, France) (36). The purity of each fraction was assessed by the TLC–FID method (35). PL were separated into classes by high-performance liquid chromatography (HPLC) as previously described (37).

Fatty acids from the total PL, PL classes, CE, and TAG of the liver as well as total lipids from adipose tissue were esterified using sodium methylate (1 M) followed by boron trifluoride in methanol (14%) according to Glass (38). Sphingomyelin was transformed into methyl esters as described by Kramer *et al.* (39)

The resulting fatty acid methyl esters were then analyzed by gas–liquid chromatography (GLC) using an HP 5890 series II gas chromatograph (Hewlett-Packard, Palo Alto, CA), equipped with an automatic HP 6890 injector, a BPX 70 fused-silica capillary column (50 m × 0.33 mm i.d., 0.25 µm film thickness; SGE, Melbourne, Australia) and a flame-ionization detector as previously described (40). Quantitative data were obtained using the WOW software (Thermo Separation Products, Les Ulis, France).

*Isolation of CLA metabolites.* The isolation of CLA metabolites was carried out using HPLC on FFA. Free fatty acids were obtained by a mild saponification as described by Banni *et al.* (41). Briefly, small aliquots (4 mg) of lipids extracted from the adipose tissue of rats fed the 10*trans*,12*cis*-18:2 isomer were dissolved in 5 mL of ethanol. Then 100 µL of EGTA (14.5 mg/mL $H_2O$), 1 mL of a 25% water solution of ascorbic acid, and 0.5 mL of 10 N KOH, were added. The solutions were left in the dark at room temperature for 16 h. The FFA were extracted by phase partition with 10 mL of *n*-hexane, 7 mL of $H_2O$, 350 µL HCl 36% (pH samples 3–4) and by centrifugation at 2000 rpm for 1 h. Hexane was evaporated, and the FFA were dissolved in 1 mL of $CH_3CN/CH_3COOH$ (100:0.14, vol/vol).

HPLC was carried out on a Waters system (Waters Co., Milford, MA) equipped with a model 600 pump and a model 996 photodiode array detector. FFA separations were carried out using a Nucleosil column (C18 5 µm, 250 × 4.6 mm; Interchim, Montluçon, France) and a mobile phase of $CH_3CN/H_2O/CH_3COOH$ (570:30:0.12, by vol) at a flow rate of 1.5 mL/min. The spectrum from 190 to 300 nm was used to detect conjugated fatty acids (234 nm) and nonconjugated fatty acids (200 nm). Data were processed by the Waters Millenium 2010 software. Peaks showing an absorption at 234 nm were collected for further GC–mass spectrometry (MS) analysis.

*Identification of conjugated fatty acid metabolites by GC–MS.* The identification of the metabolites of the 18:2 con-

**TABLE 1**

[a]Mainly include 16:0. CLA, conjugated linoleic acid.

jugated isomers was carried out on their 4-methyl-1,2,4-triazoline-3,5-dione (MTAD) adducts following the method of Dobson (42). Briefly, conjugated methyl esters (100 µg) and MTAD (200 µg) in dichloromethane (300 µL) were mixed in a test tube at 0°C by agitating for less than 10 s. The reaction was stopped by addition of 1,3-hexadiene. The mixture was evaporated to dryness and redissolved in dichloromethane for GC–MS analyses. GC–MS analyses were performed with an HP 5870 gas chromatograph coupled with an HP 5970 (Hewlett-Packard) quadrupole mass spectrometer. Fatty acid methyl ester MTAD adducts were analyzed on a HP5 bonded fused-silica capillary column (30 m, 0.25 mm i.d., 0.25 µm film thickness; Hewlett-Packard) using a splitless/split injector (290°C). The transfer line temperature was 290°C. Helium was used as carrier gas at a velocity of 35 cm/s. The oven temperature was 50°C (1 min)—20°C/min—260°C—3°C/min—290°C. Electron impact mass spectra were recorded at 70 ev between 100 and 500 amu in 700 ms.

An aliquot of the methyl ester of the HPLC fraction containing the 18:3 isomers collected from the adipose tissue of rats fed the 10*trans*,12*cis*-18:2 was converted into dimethyloxazoline derivatives (DMOX) and analyzed by GC–MS as previously described by Juaneda and Sébédio (43).

Briefly, 100 µL of 2-amino-2-methyl-1-propanol was added to the fatty acid methyl ester (up to 1 mg) in a screw-capped tube, purged with $N_2$, and sealed using a polytetrafluoroethylene cap. The reaction mixture was maintained at 170°C. The DMOX derivatives were analyzed on a BPX70 column using an HP 5890 coupled to an HP 5970 mass spectrometer.

*Statistical analysis*. Results are expressed as means ± standard deviation (SD). The values were compared using the PROC ANOVA and the Student-Newmann-Keuls or Dunnet test from SAS software (Cary, NC). *P* values of less than 0.05 were considered as significant.

## RESULTS

*Animals.* The CLA intake ranged from 179 mg/d for the 10*trans*,12*cis*-18:2 group to 186 mg/d for the animals fed the CLA mixture.

At the end of the experimental feeding period, the weights of the animals were not significantly different, 300 ± 10, 309 ± 15, 316 ± 9, 318 ± 6 g (means ± SEM) in groups fed the control, 9*cis*,11*trans*, 10*trans*,12*cis,* and the CLA mixture diets, respectively.

*Liver lipid classes.* The lipid content ranged from 48.2 mg/g of liver for the animals fed the 10*trans*,12*cis*-18:2 diet to 55.8 mg/g of liver for the animals fed the 9*cis*,11*trans* diet. No significant differences were observed between the control and the experimental groups.

The lipid composition of the livers from rats fed the 6-wk experimental diet is presented in Figure 1: the diacylglycerol (DAG), cholesterol, and FFA contents were not affected by the diet while the TAG content was decreased when the animals were fed the 10*trans*,12*cis* isomer (17.6%) compared to the control group (26.1%). This decrease was balanced by the

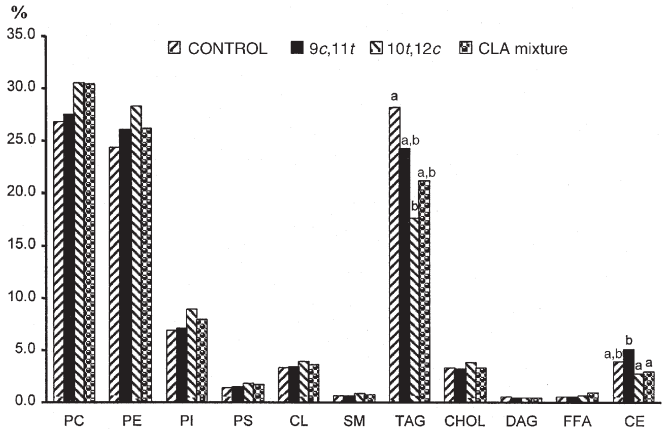

**FIG. 1.** Composition (%) of liver lipid classes. Bars having different superscripts are significantly different ($P < 0.05$, Newmann-Keuls test). Values are means of five determinations. PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; CL, cardiolipid; SM, sphingomyelin; TAG, triacylglycerol; CHOL, cholesterol; DAG, diacylglycerol; FFA, free fatty acid; CE, cholesteryl ester; CLA, conjugated linoleic acid.

PL content. The three CLA treatments did not induce any changes in the partition of the different PL classes.

*Fatty acid composition of the liver lipid classes*. Figure 2 shows the major fatty acid changes induced by feeding the three CLA diets compared to the control diet. In the TAG, the levels of 18:1n-9 were lower in the animals fed CLA compared to control animals. The presence of 10*trans*,12*cis*-18:2 in the diet resulted in a significant decrease of 16:1n-7 and 18:1n-9 in the TAG of the animals of this group. The CLA mixture had a similar effect as the 10*trans*,12*cis* isomer except for 18:0, which did not change, and 16:1n-7, which increased.

In the CE, the 10*trans*,12*cis* isomer induced a decrease in 16:1n-7 and an increase in 18:0. The presence of 9*cis*,11*trans*-18:2 in the diet resulted in a decrease in 20:4n-6. The CLA mixture raised the quantities of 16:0 and 18:0.

The major changes were observed in the PL, where the intake of 10*trans*,12*cis*-18:2 decreased the amounts of 16:0, both 18:1 isomers, and 20:4n-6 but increased 18:0 and all the $C_{22}$ polyunsaturated isomers. The presence of 9*cis*,11*trans*-18:2 in the diet resulted in an increase in the 16:0 and a decrease in the 20:4n-6 contents. The CLA mixture had the same effects as the 10*trans*,12*cis*-18:2 except for most of the $C_{22}$ polyunsaturated fatty acids (PUFA).

The CLA treatment did not induce any changes in the partition of the different PL classes (Fig. 1). A significant increase in the $C_{22}$ PUFA content after the intake of 10*trans*,12*cis*-18:2 (especially for 22:5n-6 and 22:5n-3) was only observed in phosphatidylcholine (PC) and phosphatidylethanolamine (PE) (Table 2). In PE, feeding the 10*trans*,12*cis* isomer or the CLA mixture resulted in a decrease of arachidonic acid.

*Conjugated fatty acids in liver lipid classes*. The highest incorporation of 9*cis*,11*trans*- and of 10*trans*,12*cis*-18:2 was observed in TAG and in CE (Table 3). Moreover, more 9*cis*,11*trans*- than 10*trans*,12*cis*-18:2 was observed in both

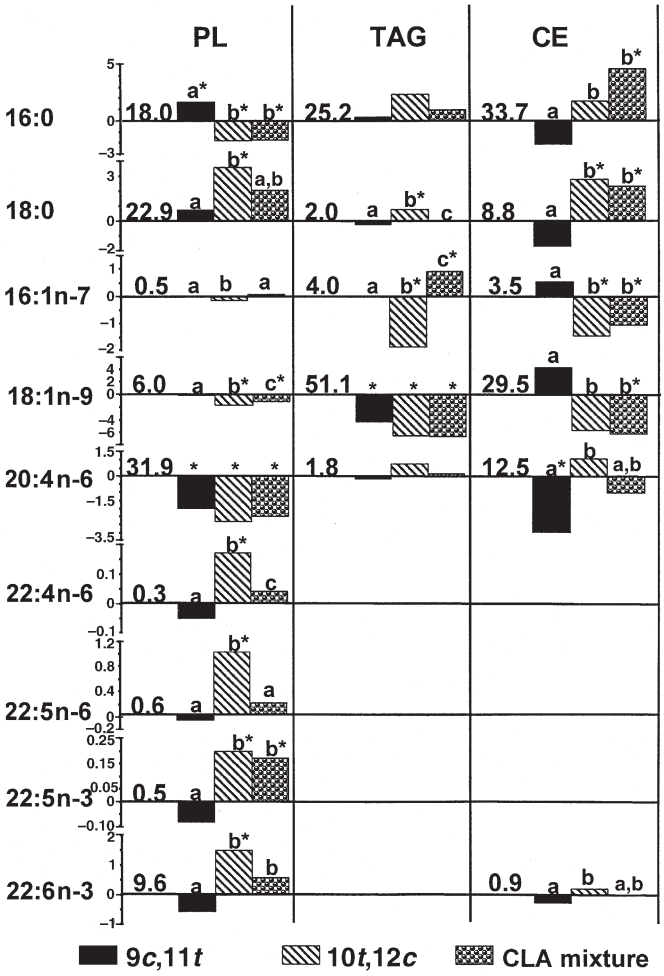

**FIG. 2.** Changes in main fatty acids compared to control in PL, TAG, and CE in liver from rats fed different CLA isomers. Bars having different superscripts are significantly different ($P < 0.05$, Newman-Keuls test). Asterisk (*) indicates statistically different from the control group ($P < 0.05$, Dunnett test). For abbreviations see Figure 1. Data reported as Δ%.

neutral lipid classes. The 18:3 and 20:3 conjugated isomers were only detected in the TAG, the main metabolite from the 10*trans*,12*cis*-18:2 being 6,10,12-18:3, whereas the 9*cis*,11*trans* isomer produced mainly the 8*cis*,11*cis*,13*trans*-20:3 conjugated isomer (see below for the identifications). The occurrence of conjugated 16:2 was only detected in the TAG from the animals fed the 10*trans*,12*cis*-18:2 diet. Detailed fatty acid analyses of the PL classes revealed that PC, PE, and cardiolipids (CL) contained appreciable amounts of CLA isomers (from 0.3 to 0.6% of the total fatty acids), whereas only trace amounts (less than 0.05%) were incorporated in phosphatidylinositol and phosphatidylserine. In PE and CL, the incorporation of the 9*cis*,11*trans* isomer was about twice that of 10*trans*,12*cis*-18:2, whereas similar quantities were found in PC (data not shown).

*Adipose tissue fatty acids*. The major fatty acids found in adipose tissue are reported in Table 4. Feeding the 10*trans*,12*cis*-18:2 isomer resulted in an increase in saturated fatty acids (14:0, 16:0, and 18:0) and 16:1n-9. The CLA mixture only increased the quantity of 14:0 and 16:1n-9. The 9*cis*,11*trans*-18:2 only decreased the quantity of 18:0. The extent of incorporation of 9*cis*,11*trans*-18:2 was twice that of the 10*trans*,12*cis* isomer. The 20:3 conjugated isomer was mainly detected in the adipose tissue of animals fed the 9*cis*,11*trans* diet and to a lesser extent in those from animals fed the CLA mixture.

*Identification of the 16:2 and 18:3 conjugated metabolites of the 10*trans,*12*cis-*18:2*. The identification of the 16:2 and 18:3 metabolites was carried out using the adipose tissue lipids of rats fed the 10*trans*,12*cis*-18:2 isomer. The fractions containing the 16:2 and the 18:3 conjugated isomers were isolated from the total lipids as reported in the Materials and Methods section. These were further converted into the MTAD adducts and into the DMOX derivatives.

The mass spectrum of the MTAD adduct with 16:2 is represented in Figure 3. There is a strong $M^+$ ion (*m/z* 379). The alkyl chain on one side of the ring ($M^+ - R_2$, *m/z* 236) and the other one on the other side of the ring ($M^+ - R_1$, *m/z* 308) permitted location of the position of the ring between C8 and C11 of the C16 chain, and therefore the location of the 8,10-dienoic system in the parent fatty acid. The two intense ions at *m/z* 348 and 276 were accounted for by the loss of a methoxy radical from the molecular ion and loss of methanol from the ion at *m/z* 308.

Similarly, the mass spectrum of the MTAD adduct of the 18:3 conjugated isomer showed a strong $M^+$ ion at *m/z* 405. Two characteristic fragments ($M^+ - R_1$ and $M^+ - R_2$) at *m/z* 236 and 334, respectively, indicated a 10,12-dienoic system (data not shown). Unfortunately, it was impossible to locate the last double bond on fragment $R_2$ using this type of derivatives. Examination of the DMOX derivative permitted us to

locate the double bond in the Δ6 position. Mass spectra of the DMOX derivative of the 18:3 isomer gave an intense molecular ion at *m/z* 331, an intense ion at *m/z* 152, and ions of about equal intensity at *m/z* 166 and *m/z* 167 (data not shown). A similar type of fragmentation has been reported for unsaturated fatty acids having the first double bond in the Δ6 position (42). The other two double bonds can be located by fragments at *m/z* 208 (C9) and 220 (C10) and fragments *m/z* 234 (C11) and 246 (C12).

## DISCUSSION

Most of the studies so far published on CLA have been carried out using commercial mixtures of isomers, where the 9*cis*,11*trans*- and the 10*trans*,12*cis*-18:2 were accompanied by different amounts of the other positional and geometrical isomers. In order to know the impact of the two major isomers on lipid metabolism, the 9*cis*,11*trans*- and the 10*trans*,12*cis*-18:2 were synthesized (32,33) and administered separately to rats.

The fatty acid composition of the liver lipid classes can be modulated by the dietary intake of CLA isomers, as was already reported using a mixture of CLA (31,44). Ingesting the 10*trans*,12*cis*-18:2 resulted in an increase of 18:0 with a commensurate decrease of 18:1n-9 in the three lipid classes, suggesting an inhibition of the Δ9 desaturase as already proposed by Li and Watkins (30) when feeding a CLA mixture. However, this effect is not observed with the 9*cis*,11*trans*-18:2, which indicates that only the 10*trans*,12*cis* isomer may be effective. These *in vivo* results confirm the data of Bretillon *et al.* (45) on the Δ9 desaturation of stearic acid using rat liver microsomes. These data are also consistent with those of Lee *et al*. (46) and Park *et al.* (47).

Ingestion of the 10*trans*,12*cis*-18:2 induced a decrease of

38% in the liver content of TAG compared to the control group, while a small but nonsignificant decrease was observed for the animals fed the 9*cis*,11*trans* isomer. The CLA mixture resulted in a decrease of 24% in TAG compared to the control group (Fig. 1). As the consumption of the 10*trans*,12*cis* isomer in the group fed the CLA mixture was half of that fed the pure isomer, it is obvious that the 10*trans*,12*cis* isomer is responsible for the decrease in the hepatic TAG content. However, this decrease could be due to either an increase in the secretion of TAG by the liver or a decrease in the TAG synthesis or both. The results presented here as well as *in vitro* data (45–47) indicate that the 10*trans*,12*cis* CLA isomer is able to decrease the Δ9 desaturase activity and mRNA expression. As this enzyme activity has been correlated to the TAG secretion in hepatocytes (48), one may speculate that this could be an explanation of our results.

Major changes were also observed when looking at the n-6 and n-3 long-chain PUFA. The 9*cis*,11*trans*-18:2 only decreased the arachidonic acid content in liver PL. The same effect was observed when feeding the 10*trans*,12*cis*-18:2 or the CLA mixture, but this decrease was balanced by an increase in the $C_{22}$ PUFA. This effect has been recently described (30) as a result of feeding a CLA mixture to rats. Again, 10*trans*,12*cis*-18:2 seems to be the isomer mainly responsible for the increase in long-chain PUFA, which could be due to stimulation of the peroxisomal fatty acid metabolism. Such an effect was not reported by Belury and Kempa-Steczko (31), who studied the effect of different levels of CLA added to a corn oil diet at the expense of dextrose. These modifications of the content in PUFA must be further studied to appreciate the impact of such alteration on eicosanoid synthesis.

The selectivity of incorporation of CLA isomers, which was already observed in total neutral lipids (31), has been found in both TAG and CE (Table 4). Interestingly, both the 9*cis*,11*trans* and the 10*trans*,12*cis* isomers are converted in long-chain metabolites, as previously reported (40). However, the present study using pure isomers has shown that the 9*cis*,11*trans* is converted in 18:3 and in 20:3 conjugated fatty acids, the latter being previously identified as the 8,11,13-20:3 (43). Injection of a synthesized 20:3 molecule on both $AgNO_3$-HPLC and GC revealed that this metabolite is the 8*cis*,11*cis*,13*trans* isomer (Berdeaux, O., personal communication). The 10*trans*,12*cis*-18:2 isomer is mainly converted into an 18:3 having double bonds in Δ6,10,12, whereas only smaller quantities of the conjugated 20:3 have been detected. The structure of this 20:3 was previously established as being an 8,12,14 isomer. Further work will have to be carried out to fully identify the 18:3 metabolite of the 9*cis*,11*trans* isomer, which is present only in small amount in liver TAG. Furthermore, the 10*trans*,12*cis* isomer can also be converted into a conjugated 16:2 fatty acid having the ethylenic position in Δ8 and Δ10. Similar peroxisomal metabolic pathways have already been described by Luthria and Sprecher (49) for linoleic acid, which was transformed into a 7,10-16:2 and 5,8-14:2. This 16:2 conjugated isomer was only found in liver lipids from animals fed the 10*trans*,12*cis*-18:2. This may suggest that the 9*cis*,11*trans* and the 10*trans*,12*cis* are metabolized differently through the peroxisomal β oxidation pathway.

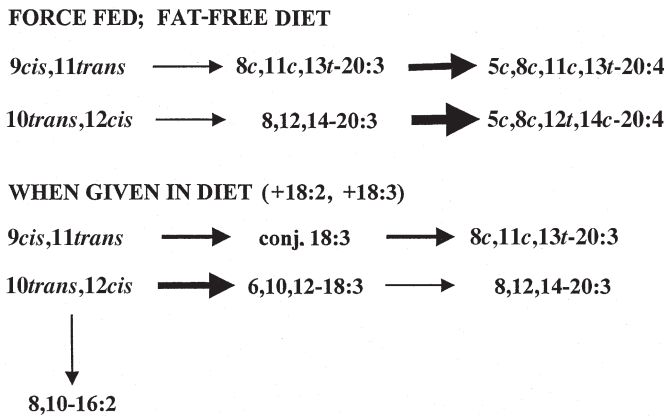

**FIG. 4.** Metabolism of the 9*cis*,11*trans*- and 10*trans*,12*cis*-18:2 isomers by fat-free-fed rats after force-feeding (40) and when given in an equilibrated semisynthetic diet for 6 wk (this study). The thickness of the arrows suggests the importance of the metabolic pathway.

All these results differ from our previous study (40) in which we force-fed CLA to rats consuming a fat-free diet (Fig. 4), where the two 20:4 conjugated isomers were the major metabolites of the 9*cis*,11*trans*- and 10*trans*,12*cis*-18:2 (50). In the present study, the animals received an equilibrated diet. Consequently, the biosynthesis of conjugated 20:4 isomer may be low, as already suggested by Banni *et al.* (41), who detected only the 20:3 conjugated metabolites from CLA in rats. Another possibility is that 20:4 may be formed and rapidly converted. Interestingly, the levels of metabolites from the 10*trans*,12*cis* CLA isomer indicate that its conversion is higher than that of the 9*cis*,11*trans* isomer. Synthesis of the labeled metabolites will permit study of the impact the 18:3 and 20:3 isomers may have on lipid metabolism.

## ACKNOWLEDGMENTS

Elisabetta Angioni was funded by a postdoctoral fellowship from INRA. This study was funded by INRA and a grant from the French Ministry of Research (No. 98G-0005). This work was part of a program included in a Concerted Action (PL 3671) financed by the Commission of the European Communities. The authors gratefully acknowledge Asgeir Saebo (Natural Lipids, Hovdebygda, Norway) for the generous gift of the CLA mixture.

# A Single Oral Administration of Conjugated Linoleic Acid Enhanced Energy Metabolism in Mice

**Koichiro Ohnuki, Satoshi Haramizu, Kasumi Oki, Kengo Ishihara, and Tohru Fushiki***

Laboratory of Nutritional Chemistry, Department of Applied Life Sciences, Graduate School of Agriculture, Kyoto University, Kyoto 606-8502

**ABSTRACT:** We investigated the effect of a single oral administration of conjugated linoleic acid (CLA) on energy metabolism in mice. Male Std ddY mice were orally administered CLA (5 mL/kg weight) or linoleic acid (5 mL/kg weight) (both solutions at concentrations of 73.5%) as a control. Oxygen consumption was significantly greater in the CLA-administered mice than in the control mice. Respiratory quotient was slightly lower in the CLA-administered mice than in the control mice. We calculated fat and carbohydrate oxidation from oxygen consumption and respiratory quotient. Fat oxidation in the CLA-administered mice was significantly higher than in the control mice, and there was no difference in carbohydrate oxidation. Serum concentrations of noradrenalin and adrenalin in the CLA administered mice were significantly higher than in the control mice. These results suggested that CLA enhanced sympathetic nervous activity and energy metabolism.

Paper no. L8666 in *Lipids 36,* 583–587 (June 2001).

Conjugated linoleic acid (CLA) refers to a group of positional and geometric isomers that are derived from linoleic acid. It is found in foods such as ruminant meats, pasteurized dairy products, and processed cheeses. The major dietary source of CLA for humans is beef or dairy products; beef tallow contains ~0.5% fatty acids as CLA (1). Interest in CLA is increasing because it has been found to have protective properties against cancer (2–8) and atherosclerosis (9,10).

Intake of CLA for several weeks has been reported to reduce body fat content. Adipose tissue of mice given a CLA-supplemented diet (0.5–1.5% CLA) weighed less (11–13). In addition, energy metabolism was higher in mice fed a CLA-supplemented diet than in mice fed a control diet for 6 wk (13).

We assumed that CLA promotes body fat consumption and followed the effect of CLA for 3 h after administration. We gave a diet supplemented with either CLA or linoleic acid (LA) to mice *ad libitum* in a preliminary study. With this method we were not able to evaluate the change in respiratory gas or body temperature after feeding, because the amount of food intake in the CLA group was markedly lower than in the LA group, and oxygen consumption and body temperature were similarly lower. Therefore, the mice were administered CLA *via* a stomach tube in the present study. We now report the effect of a single oral administration of CLA on oxygen consumption, body temperature, and blood components.

Abbreviations: CLA, conjugated linoleic acid; FFA, free fatty acid; HPLC, high-performance liquid chromatography; LA, linoleic acid; PPAR, peroxisome proliferator-activated receptor.

## MATERIALS AND METHODS

*Animals.* Five-week-old male Std ddY mice (mean body weight 25.5 ± 0.3 g; Japan Shizuoka Laboratory Center, Hamamatsu, Japan) were used. They were housed in standard cages (33 × 23 × 12 cm) under controlled conditions of temperature (22 ± 0.5°C), relative humidity (50%), and lighting (lights on from 1800 to 0600). Mice had free access to water and a stock diet (type MF; Oriental Yeast, Tokyo, Japan) containing (g/kg diet): water, 70; protein, 240; fat, 51; fiber, 32; carbohydrates, 545. The mice were allowed to adapt to the laboratory housing for at least 1 wk before respiratory gas measurement, surgery for telemetry transmitter implant, or blood sampling. The care and treatment of the experimental animals conformed to the guidelines of Kyoto University for the ethical treatment of laboratory animals.

*Materials.* We used unesterified safflower LA as a control and synthesized CLA from unesterified safflower LA. These two samples were synthesized from safflower oil by Linoleic Oils and Fats Co., Ltd. (Tokyo, Japan). The composition of samples was 17.4% palmitic acid, 2.3% stearic acid, 6.5% oleic acid, and 73.5% LA or CLA. The composition of CLA was 34.0% *cis*-9,*trans*-11 and *trans*-9,*cis*-11 CLA; 35.1% *trans*-10,*cis*-12 CLA; 2.5% *cis*-9,*cis*-11 and *cis*-10,*cis*-12 CLA; and 1.9% *trans*-9,*trans*-11 and *trans*-10,*trans*-12 CLA.

*CLA administration.* To avoid circadian variations in physical activity, experiments were carried out from 1100 to 1600, in the dark period when the mice were eating or moving most of the time. One group was administered LA and the other was administered CLA, both in compositions of 73.5% (5 mL/kg body weight) *via* a stomach tube, so the amount of administered LA or CLA was about 200 mg. Body temperature, activity, oxygen consumption, and respiratory quotient were measured when mice were sedentary (baseline values), and measurement was begun after oral administration. The blood samples was taken from mice at 1, 2, and 3 h after oral administration of LA or CLA.

*Respiratory gas analysis.* The instruments (all from Alco System, Tiba, Japan) used for the measurement of oxygen consumption and respiratory quotient in the mice consisted of six acrylic metabolic chambers, gas analyzers (model RL-600), and a switching system (model ANI6-A-S) to sample gas from each metabolic chamber. Mice ($n$ = 11) were separated into two groups of equal body weights; each mouse was placed into a metabolic chamber designed to measure respiratory gas. The details of methods were described in a previous report (14). Briefly, room air was pumped through the chambers and expired

air was dried in a thin cotton column and then directed to a gas analyzer. The amount of fat and carbohydrate oxidized were calculated from the value of oxygen consumption and respiratory quotient, using software for analysis. The data for each chamber were obtained every 7 min and stored on a spreadsheet. The instruments and software were obtained from Alco System (Tiba, Japan).

*Body temperature and activity.* Body temperature and activity were measured by a telemetry system as described elsewhere (15,16). Briefly, a telemetry transmitter was implanted in the peritoneal cavity of each mouse ($n$ = 8), and the mice were subsequently used for experiments for at least 1 wk. The mice were anesthetized with an intraperitoneal injection of sodium pentobarbital (Nembutal, 1 mg/kg). A 1.5- to 2-cm incision was made in the skin along the midline immediately caudal to the abdominal space. Subsequently, the abdominal wall was opened, and the transmitter was implanted in the peritoneal cavity. The instruments for the telemetry system were purchased from Data Science Inc. (St. Paul, MN).

*Serum components.* Mice ($n$ = 96) were divided into two groups so that the mean body weights were equal in both groups. Blood was taken from the heart of mice at 1-h intervals for 3 h after administration of CLA or control. Each mouse was used only once. Serum was obtained by centrifugation and stored at −20°C until measurement. Serum free fatty acids (FFA) were determined by the acyl CoA-synthetase and acyl CoA oxidase enzyme method with a commercial kit (NEFA C-Test; Wako Pure Chemical Industries, Kyoto, Japan). Glucose was assayed by a combination of mutase and glucose oxidase with a commercial kit (Glucose CII Test; Wako). Triglycerides were assayed with a commercial kit (Triglyceride G Test; Wako). Noradrenalin and adrenalin were assayed by a high-performance liquid chromatography (HPLC)-electrochemical detector.

*Statistical analysis.* Data are expressed as means ± SE. The effects of time, treatment, and time × treatment were evaluated by two-way repeated measures analysis of variance (ANOVA); for comparison between two groups at certain time points, Student's $t$ test was used. Statistics were calculated with the Stat View software package (Macintosh Version J 5.0; Abacus Concepts, Berkeley, CA). Probability levels of $<0.05$ were considered to indicate significance.

## RESULTS

Oxygen consumption and respiratory quotient obtained with the gas analyzer, and the amounts of fat and carbohydrates oxidized, which were calculated from these values, are shown

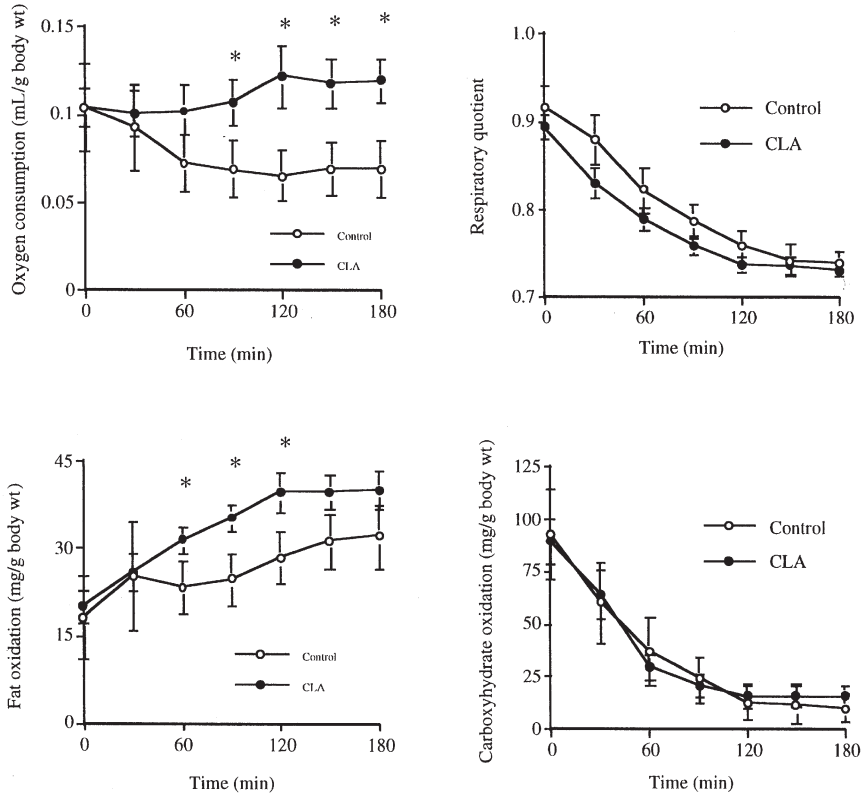

**FIG. 1.** Oxygen consumption (upper left), respiratory quotient (upper right), fat oxidation (lower left) and carboxyhydrate oxidation (lower right) in the mice administered conjugated linoleic acid (CLA) and linoleic acid (control). Values are means ± SEM ($n$ = 5 or 6) Oxygen consumption and fat oxidation were significantly higher in the CLA group than in the control group (time × treatment effect, $P < 0.05$ by two-way repeated measures analysis of variance). *Significantly different from control group ($P < 0.05$ by Student's $t$ test).

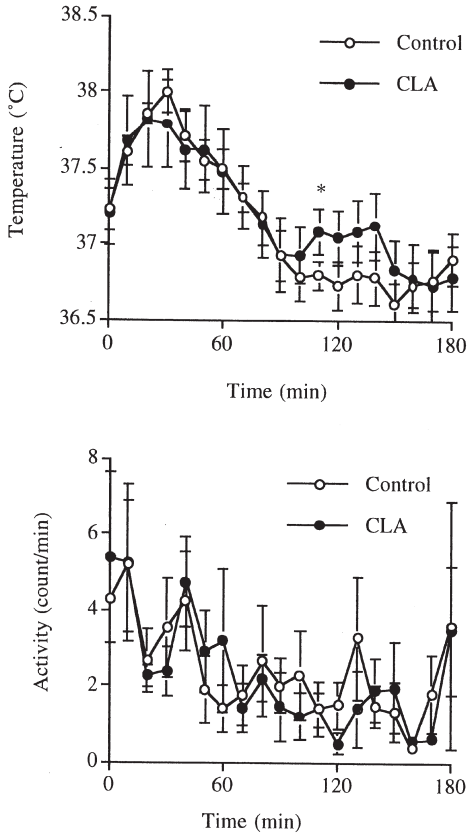

**FIG. 2.** Body temperature (upper panel) and locomotor activity (lower panel) of mice administered CLA or linoleic acid (control). Values are means ± SEM ($n$ = 6–8). *Significantly different from control group ($P$ < 0.05 by Student's $t$ test). For abbreviation see Figure 1.

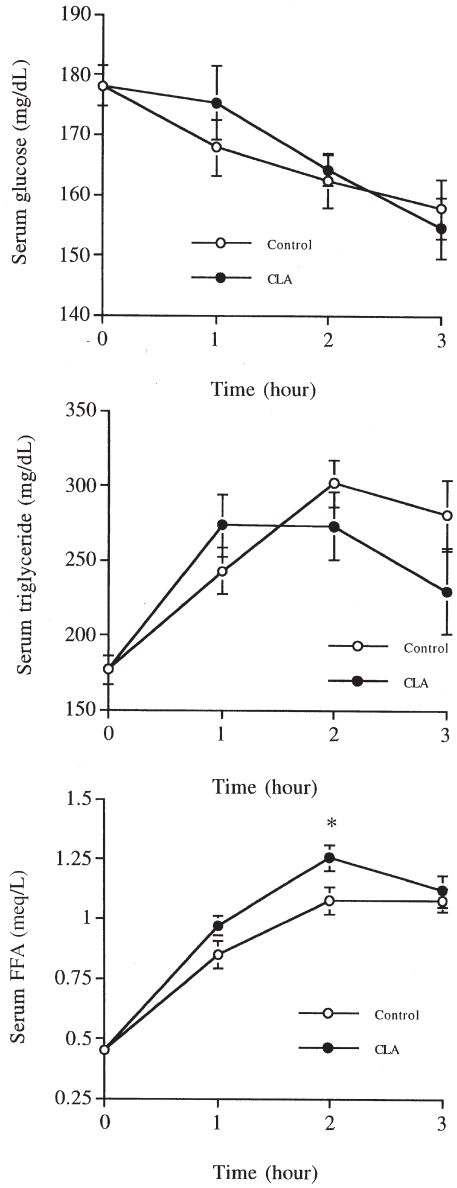

**FIG. 3.** The concentrations of serum glucose (top), serum triglyceride (middle), and serum free fatty acids (FFA) (bottom) in mice administered CLA and linoleic acid (control). Values are means ± SEM ($n$ = 7–15). The concentration of serum FFA was significantly higher in the CLA group than in the control group (time × treatment effect, $P$ < 0.05 by two-way repeated measures analysis of variance). *Significantly different from control group ($P$ < 0.05 by Student's $t$ test). For abbreviation see Figure 1.

in Figure 1. Oxygen consumption was significantly higher from 90–180 min after the administration of CLA as compared with the control group, and the fat energy consumption was significantly higher from 60 to 120 min after administration of CLA. The respiratory quotient in the CLA group was slightly lower than in the control group at 30 and 90 min after administration ($P$ < 0.1), and there was no difference between CLA and control at the baseline value and 3 h after administration ($P$ > 0.9).

Body temperature and activity after administration of CLA were measured using a telemetry system (Fig. 2). Body temperature tended to be higher 2 h after the administration of CLA, and was significantly different from the control group at 110 min.

Figure 3 shows the change of serum FFA, glucose, and triglyceride assayed with commercial kits after the administration of CLA or control. There was no difference between the two groups in the amounts of blood glucose and triglycerides. Serum FFA concentration tended to be increased, and was significantly higher 2 h after CLA administration in mice compared with the control group.

Figure 4 shows the changes in serum noradrenalin and adrenalin concentrations as assayed with an HPLC-electrochemical detector after the administration of CLA or control. The concentration of noradrenalin was significantly higher in the mice administered CLA compared to the control group. The concentration of serum adrenalin tended to increase after the administration of CLA and was significantly different from the control group at 2 h after the administration.

## DISCUSSION

CLA has been reported to suppress body fat accumulation in mice *via* enhancement of body fat metabolism (11,13). How-

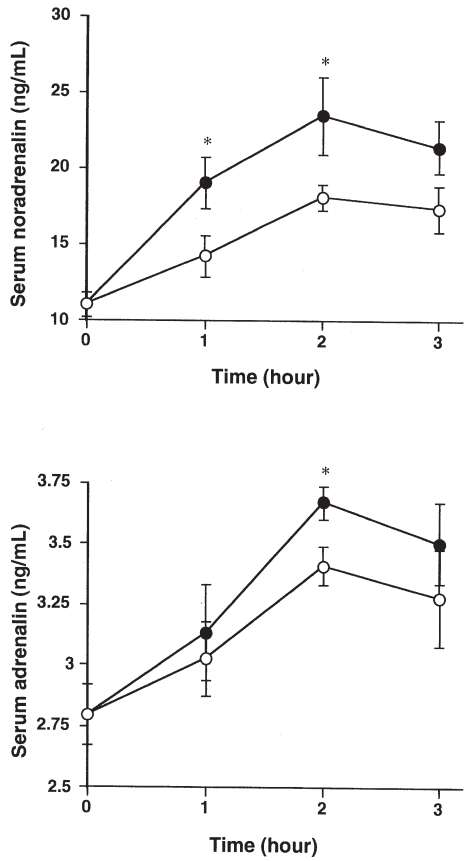

**FIG. 4.** The concentrations of serum noradrenalin (upper panel) and adrenalin (lower panel) of mice administered CLA or linoleic acid (control). Values are means ± SEM ($n$ = 6–8). The concentrations of serum noradrenalin and adrenalin were significantly higher in the CLA group than in the control group (time × treatment effect, $P < 0.05$ by two-way repeated measures analysis of variance). *Significantly different from control group ($P < 0.05$ by Student's $t$ test). For abbreviation see Figure 1.

ever, the mechanisms underlying the stimulation of body fat oxidation have not been elucidated.

The higher oxygen consumption of mice administered CLA *via* a stomach tube was consistent with the elevation of the body temperature. The energy source of this excess oxygen consumption was attributable to fat oxidation, as the results on respiratory quotients in Figure 1 (upper right panel) indicate. There was no difference in carbohydrate oxidation between the CLA and the control groups throughout the experimental period. Analyses and the measurement of sampled gases were carried out in a separate room to avoid exciting the mice.

Throughout the measurement of body temperature, locomotor activity of both groups of mice showed no difference, suggesting that the increment of body temperature was due not to excessive locomotion but to metabolic heat generation. The measurement of the body temperature was carried out in a separate room by using a temperature information telemetry system that was noninvasive and that caused less stress on the experimental animals.

The mechanisms for increased fat oxidation by CLA have been discussed in other reports. Park *et al.* (11) found that carnitine palmitoyltransferase, which catalyzes a rate-limiting process of β-oxidation of fatty acids in mitochondoria, was increased; and lipoprotein lipase activity in the adipose tissue was decreased. West *et al.* (13) reported that energy expenditure was significantly increased after 6 wk of CLA feeding. However, their studies were not intended to explain the cause of the excess metabolic rate associated with CLA feeding. Accumulation of the rapid increases in oxygen consumption and fat oxidation found in the present single administration of CLA would explain the consequent chronic increase in fatty acid β-oxidation and fat utilization reported by Park *et al.* (11) and West *et al.* (13).

In addition, we cannot rule out the possibility that the free CLA directly stimulated body fat oxidation. Belury *et al.* (17) reported that CLA administration activated peroxisome proliferator-activated receptor (PPAR)-α in the liver in mice. The induction of PPAR-α, which plays an important role in fat metabolism (18–20), may be a stimulus for increased fat oxidation by CLA. PPAR regulates acyl-CoA oxidase, cytochrome P4504A1, and liver fatty acid-binding protein. This may activate body fat oxidation. On the other hand, Hida *et al.* (19) reported that fish oil induces PPAR-γ in the organs and induces uncoupling proteins in brown adipose tissue, which causes enhanced energy expenditure by heat generation. Further studies are needed on CLA as a ligand for master regulators like PPAR.

Overall, CLA is expected to be useful in dietary therapy to prevent obesity by increasing energy expenditure. The present study demonstrates that the administration of CLA induces catecholamines, and it enhances not only use of fatty acids as a fuel but also directly stimulates fatty acid utilization *via* heat generation. It should be noted that the CLA used in this study was not pure, and it is possible that the different isomers have different metabolic effects. Further studies using pure reagents are needed to fully understand the metabolic specificity of these different isomers of CLA.

# Effect of Dietary Restriction on Age-Related Increase of Liver Susceptibility to Peroxidation in Rats

**Tae Il Jeon[a], Beong Ou Lim[a,b], Byung Pal Yu[c], Yoongho Lim[a], Eun Ja Jeon[a], and Dong Ki Park[a,*]**

[a]Department of Applied Biology and Chemistry, Konkuk University, Korea, [b]Graduate School of East-West Medical Science, Kyunghee University, Korea, and [c]Department of Physiology, The University of Texas Health Science Center, San Antonio, Texas

**ABSTRACT:** Dietary restriction (DR) increases life span and decreases age-related diseases in experimental animals. It has received a great deal of attention in connection with the relationship between aging, nutrition, and oxidative stress because oxidative injury in several organ systems is a prominent feature in aging. We investigated the possibility that DR can protect vulnerable liver lipids against age-related increases of peroxidation. Male Fischer 344 rats fed *ad libitum* (AL) or dietarily restricted (maintained on 60% of AL food intake) were killed by decapitation at 4 (young) or 12 mon (adult) of age. Phosphatidylcholine hydroperoxide (PCOOH) concentration of liver was determined using a chemiluminescent high-performance liquid chromatographic method. Liver PCOOH increased with age in adult rats, but less of an increase of PCOOH was seen in DR rats, which is consistent with results on production of thiobarbituric acid-reactive substances and oxygen-derived free radicals. No significant differences were found in liver superoxide dismutase and catalase activity between AL and DR groups of young and adult rats. Liver triglyceride and cholesterol contents were lower in DR than AL rats at 12 mon. Fatty acid compositions of phosphatidylcholine and phosphatidylethanolamine indicated that the ratio of (20:3n-6 + 20:4n-6)/18:2n-6, an index of linoleic acid (18:2n-6) desaturation, was lower in DR than in AL rats. We concluded that DR suppresses age-related oxidative damage in liver by modulating the amount of lipid as well as fatty acid composition.

Paper no. L8757 in *Lipids 36*, 589–593 (June 2001).

Aging can be characterized as an accumulation of deleterious changes that increase the risk of death. These changes can be attributed to both genetic and environmental factors (1), and they inevitably compromise an organism's ability to meet both internal and external challenges. Oxidative stress is causally related to irreversible damage due to endogenously generated free radicals (2,3). Under normal conditions, cells of aerobic organisms utilize reactive oxygen species (ROS) as physiological messengers. The redox balance is altered by the age-related decline in an organism's ability to counteract oxidative damage (4,5).

Reducing the caloric intake of laboratory animals while maintaining nutrition can increase their lifespans (6–8). Dietary restriction (DR) delays age-associated pathological and physiological changes and extends longevity. DR postpones the accumulation of damaging effects that accompany *ad libitum* (AL) food intake. One major mechanism by which DR retards the aging process is its remarkable ability to reduce oxidative damage (5,9). For example, Kim *et al*. (10) showed that DR decreases the malondialdehyde content of cardiac mitochondria, indicating a decrease in lipid peroxidation. DR feeding regimens enhanced the organism's ability to attenuate levels of harmful reactive free radicals in various organs (11,12). Oxidative stress-mediated injury is causally related to aging since ROS-caused damage accumulates with age (13,14). Although several previous studies reported a relationship between aging and lipid peroxidation, most examined thiobarbituric acid-reactive substance (TBARS) levels to indicate peroxidative status.

In the present study, we determined phospholipid hydroperoxide (PLOOH), a sensitive key indicator for oxidative injury, because phospholipids (PL) are important structural and functional components of the biological system (15,16), and are commonly recognized as a major target of lipid peroxidation. The technique we used to determine PLOOH was a chemiluminescence–high-performance liquid chromatography (CL-HPLC) method. Previous reports from this laboratory described a simple and continuous one-step flow injection system based on cytochrome c-amplified chemiluminescence for the assay of radical scavenging activity (17,18). The present study attempts to quantify age-associated changes of the lipid profile and the degree of attenuation on oxidative damage in DR.

The liver is an important metabolic organ, and is susceptible to a wide variety of disorders, possibly because it is constantly exposed to potentially harmful agents. It is generally recognized that oxidative end-products accumulate with age and therefore free radical-mediated damage to liver cells occurs. Thus, the liver was selected as a model organ for this study in recognition of the significant health benefits of DR.

## EXPERIMENTAL PROCEDURES

*Animals*. Specific-pathogen-free (SPF) male Fisher 344 rats were housed in plastic cages at the University of Texas Health Science Center with approval of the Institutional Animal Care and Utilization Committee. The SPF status of shipments of rats was verified and maintained as described by Yu *et al*. (19). Dietary restriction (60% of *ad libitum* fed) was begun at 6 wk of age as described by Yu *et al*. (20), and continued throughout life. Rats were weighed biweekly, and were killed by decapitation at 4 or 12 mon of age. The required tissues were then removed.

*Antioxidant activities measurement by the flow injection (FI)-CL system*. To determine changes in antioxidant activity in liver CL intensity was measured with a filter-equipped photon counting-type spectrophotometer (CLD-110; Tohoku Electronic Industry, Miyagi, Japan) connected to a pump (model 303; Gilson Medical Electronics S.A., Villiers-le-Bel, France) and a sample injection valve (model 7125; Rheodyne, Cotati, CA). The mobile phase was 50 mM phosphate buffer (pH 7.4) containing 50% methanol (for solvent-soluble samples), cytochrome c (10 mg/L), and luminol (2 mg/L). The flow rate was maintained at 1.0 mL/min with the pump. For the purpose of measuring the abilities of radical scavengers, a mixture of 0.06% $H_2O_2$ (5 μL) and sample solution (5 μL) was injected. The reduced CL intensity of the mixture compared to the CL intensity of 0.06% $H_2O_2$ (5 μL) enables analysis of radical-scavenging activity (17).

*Phosphatidylcholine hydroperoxides (PCOOH) measurement*. Total lipids were extracted from the liver by the method of Folch *et al*. (21). The CL-HPLC procedure for quantification of PCOOH concentration followed the method of Miyazawa *et al*. (15). Standard PCOOH was prepared by oxidation of PC using a method of Terao *et al*. (22).

*TBARS measurements*. TBARS were quantified as described by Buege and Aust (23) using 1,1,3,3,-tetraethoxypropane as a standard material (Sigma, St. Louis, MO).

*Antioxidant enzyme activities measurements*. Liver catalase activity was determined spectrophotometrically by observing the decomposition of hydrogen peroxide at 240 nm. One catalase unit is defined as the amount of enzyme required to decompose 1.0 μmol $H_2O_2$/min at pH 7.0 at 25°C (24,25). Total superoxide dismutase (SOD) activity was determined by monitoring the inhibition of reduction cytochrome c at 550 nm using xanthine and xanthine oxidase system. One SOD unit was defined as the amount of enzyme that inhibited reduction of cytochrome c by 50% (26).

*Analysis of lipids*. Liver total lipids were extracted and purified by the method of Folch *et al*. (21). PL, total cholesterol (TC), and triglyceride (TG) were measured as described by Gu *et al*. (27). PC and phosphatidylethanolamine (PE) were separated by thin-layer chromatography with chloroform/ethanol/water/triethylamine (30:35:6:35, by vol) as the developing solvent (28). The fatty acid composition of PC and PE were analyzed by gas–liquid chromatography (Varian, Palo Alto, CA) in an Omegawax 320 capillary column (30 m × 0.32 mm i.d., 0.25 μm film, Supelco, Bellefonte, PA) equipped with a flame-ionization detector (FID) after direct transmethylation with 14% $BF_3$ in methanol at 70°C (28). Chromatographic conditions were as follows: column temperature 200°C; carrier gas $N_2$ 30 mL/min; FID temperature 260°C; injector temperature 250°C. Fatty acid methyl esters were identified by comparing their retention times with those of standard methyl esters (Supelco).

*Statistics*. Differences between the means of the individual groups were assessed by one-way analysis of variance with Duncan's multiple range test (SPSS version 7.5, SPSS Institute, Chicago, IL). Differences of $P < 0.05$ were considered to be significant (29).

## RESULTS

DR decreased body weight of each group. DR rats had body weights lower than those of AL rats by 59.7 and 55.7% at 4 and 12 mon, respectively.

To determine the effect of DR on lipid peroxidation, PCOOH (as a representative PLOOH), TBARS production, and active oxygen-derived radical levels were examined in AL or DR rats at 4 and 12 mon. The liver peroxidation indices increased with age in AL rats. PCOOH and TBARS concentrations in livers of AL rats were 3 and 1.4 times higher in the 12-mon group than in the 4-mon group (top and middle panels, Fig. 1). Consistent with these results, the radical activity evaluated by FI-CL assay was significantly higher in the 12-mon group than in the 4-mon group ($P < 0.05$; bottom panel, Fig. 1). However, DR was associated with much less peroxidation in the 12-mon rats. Concentrations of PCOOH or TBARS in adult rat livers were 50 and 76% less, respectively, in the DR rats as compared to those of AL rats (top and middle panels, Fig. 1).

No significant differences were found in catalase and SOD activity between AL and DR groups (Fig. 2). These results demonstrate that lipid peroxidation products increase with age, while DR attenuates the extent of free radical damage.

We further analyzed lipid contents in each group as shown in Figure 3. The TC and TG concentrations of AL rats increased with age of rats (top and middle panels, Fig. 3). The TC and TG concentrations were significantly lower in the DR group than the AL group at 12 mon ($P < 0.05$). No significant difference was found in the PL concentration among all groups (bottom panels, Fig. 3).

The constituent fatty acids in PC and PE are indicated in Table 1. At 4 mon, PC showed an increasing trend of 18:2n-6 (linoleic acid). At 12 mon, a decreasing trend of 20:4n-6 (arachidonic acid) in DR rats was evident when compared to that of AL rats. Consequently, the ratio of (20:3n-6 + 20:4n-6)/18:2n-6, an index of linoleic acid desaturation, was lower in the DR group, and the proportion of 22:5n-6 in the DR group at 12 mon also decreased. A similar, but lesser degree of difference was observed in PE and there was a nonsignificant trend toward decreasing 22:6n-3 in the DR rats.

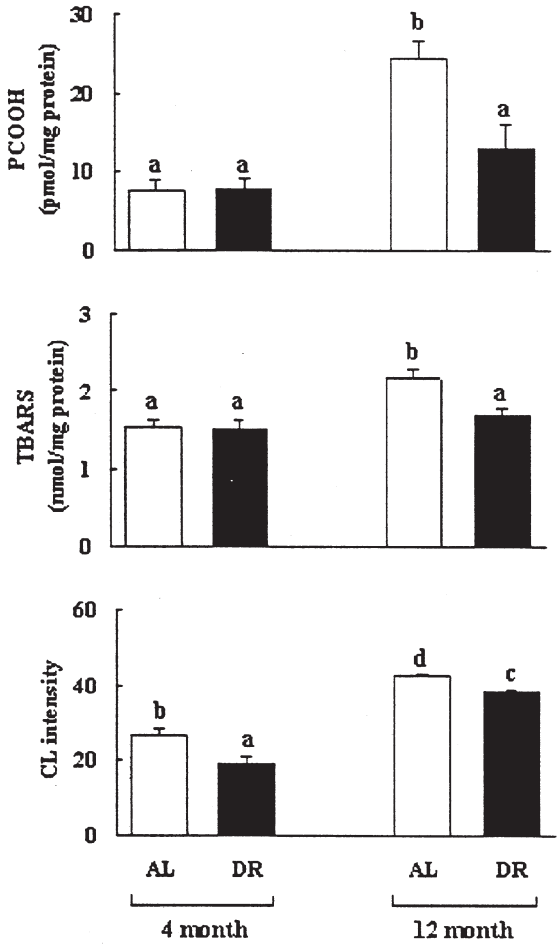

**FIG. 1.** Effects of dietary restriction (DR) on the amount of phosphatidylcholine hydroperoxide (PCOOH; top panel), thiobarbituric acid-reactive substances (TBARS; middle panel), and oxygen-derived radical activity (bottom panel) in the liver of rats between 4 and 12 mon. Each bar represents the mean ± SEM of five rats. Mean values with different superscripts are significantly different ($P < 0.05$). CL, chemiluminescent; AL, *ad libitum*-fed rats.

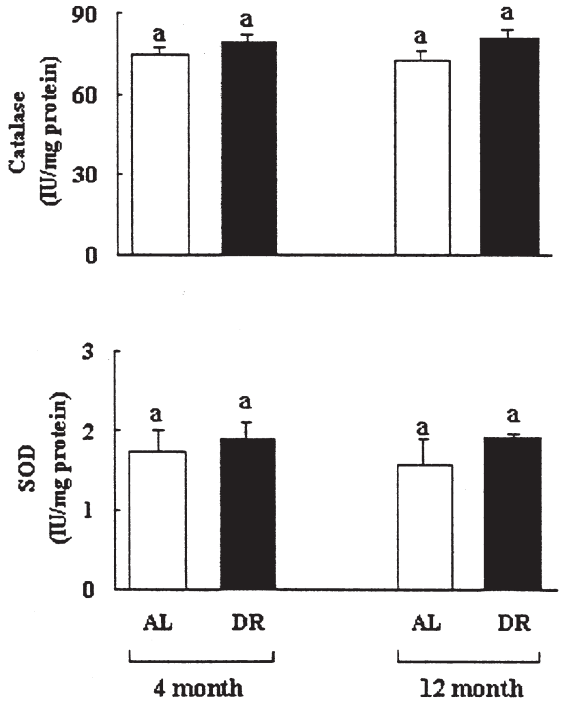

**FIG. 2.** Effects of DR on the cytosolic catalase activity (top panel) and superoxide dismutase (SOD) activity (bottom panel) in the liver of rats between 4 and 12 mon. Each bar represents the mean ± SEM of five rats. Mean values with different superscripts are significantly different ($P < 0.05$). For other abbreviations see Figure 1.

## DISCUSSION

In this study we demonstrated that indices of hepatic oxidative stress increased with age and were less prominent in DR rats. The index of linoleic acid desaturation and unsaturation degree of fatty acids in PC and PE was significantly reduced by DR. A number of investigators have previously examined the effect of DR with age on lipid peroxide concentrations, mostly using TBARS (13,30). They suggested that fatty acid unsaturation is a main factor in determining the sensitivity to lipid peroxidation. To evaluate the effect of DR on oxidative stress, we measured PCOOH as a sensitive marker of oxidative liver injury because of PC's vulnerability to peroxidation (31).

PLOOH was shown to increase significantly with age in AL rats (top panel, Fig. 1). Moreover, polyunsaturated fatty acid (PUFA) contents of 20:4n-6, 22:5n-6, and 22:6n-3 increased in 12-mon AL rats (Table 1) over those present at 4 mon (Table 2), implying an age-related increase of PUFA susceptibility to peroxidation. However, major PUFA amounts were markedly lowered by DR in adult rats, with lower TBARS and PCOOH levels than in AL rats.

The present study found that catalase and SOD activities were not significantly different between DR and AL rats (Fig. 2). Catalase and SOD activities at basal levels were not statistically different between the young and the adult groups. Interestingly, DR led to significant changes in cholesterol and TG levels, indicating that DR primarily modulates the reduction of neutral lipids, not PL (Fig. 3).

To further explore the notion that tissue lipid vulnerability is a crucial factor contributing to cellular oxidative status, constituent fatty acids in PC and PE were analyzed. The trends in fatty acid composition to increase toward peroxidizable PUFA with age are evident (Table 1). Among the most obvious modifications by DR have been the compositional changes related to membrane lipid composition, specifically the age-related membrane fatty acid composition (32). It has been proposed that the modulation of the fatty acid profile by DR results in lower age-related oxidative stress as a possible adaptive strategy (9,11,14). In our study, 18:2n-6 and 18:3n-3 increased in PE of DR rats, whereas the content of PUFA derivatives (20:4n-6, 22:5n-6, and 22:6n-3) is decreased (Table 2).

We conclude that DR protects liver against age-related increases in oxidative stress *in vivo* by modifying lipids and their composition to reduce peroxidizable substrates such as TG and PUFA. Our study strongly supports earlier data

# Overexpression of Acyl-CoA Binding Protein and Its Effects on the Flux of Free Fatty Acids in McA-RH 7777 Cells

**Yingying Yang, P. Haydn Pritchard, Jalal Bhuiyan, David W. Seccombe, and Mohammed H. Moghadasian***

Healthy Heart Program and Department of Pathology and Laboratory Medicine, St. Paul's Hospital and the University of British Columbia, Vancouver, British Columbia, Canada V6Z 1Y6

**ABSTRACT:** Overexpression of acyl-CoA binding protein (ACBP) was induced in a rat hepatoma cell line (McA-RH 7777) by stable integration of rat ACBP cDNA. The transfected cells (ACBP-27) had 3.5-fold higher concentrations of ACBP than control cells (14 vs. 4 ng/μg DNA). Both ACBP-27 and control cells were cultured in the presence of various concentrations of radiolabeled palmitic acid; and the effects of ACBP on lipogenesis and β-oxidation were studied. Incubation of the cells with 100 μM palmitic acid resulted in 42% greater incorporation of the fatty acid in ACBP-27 cells as compared to that in the control cells. This increased incorporation of the fatty acid was observed predominantly in the triglyceride fraction. Higher concentrations of palmitic acid (200 to 400 μM) were associated with a significant decrease in the production of $^{14}CO_2$ in the ACBP-27 cell line than in the control cells, while lower concentrations had no effect. Our data suggest a role for ACBP in the partitioning of fatty acids between esterification reactions leading to the formation of neutral lipids and β-oxidation. ACBP may play a regulatory role by influencing this important branch point in intermediary lipid metabolism.

Paper no. L8658 in *Lipids 36,* 595–600 (June 2001).

Acyl-CoA binding protein (ACBP) binds long-chain acyl-CoA esters with very high affinity; it is a ubiquitous protein that probably acts as a housekeeping protein with no pronounced built-in specificity (1). The role of long-chain fatty acyl-CoA esters in the regulation of metabolism and cell signaling has been reviewed by Faergeman and Knudsen (2). It has been reported that the free cytosolic concentration of acyl-CoA esters is very low (nanomolar range) under physiological conditions (2). ACBP is a 10-kDa protein found in various species including mammals (3–7), duck (8), frog (9), insects (10), yeast (11), and plants (12,13); ACBP is expressed in all mammalian tissues tested (14–17). Although the specific biological function of the protein in cells is presently unknown, a number of *in vitro* studies indicate that it is most likely involved in intracellular lipid transport and metabolism of acyl-CoA moieties (18–21). Jolly *et al.* (22) recently identified a novel role of ACBP in microsomal phosphatidic acid biosynthesis that is mediated primarily through the activity of glycerol-3-phosphate acyltransferase. ACBP has been shown to act in the generation of an intracellular acyl-CoA pool-former in yeast (18); it stimulates the synthesis of long-chain acyl-CoA esters by mitochondrial long-chain acyl-CoA synthetase (19) and regulates the activity of outer mitochondrial carnitine palmitoyl transferase (20,21). Previous studies have demonstrated that ACBP can mediate the transport of long-chain acyl-CoA esters immobilized on phospholipid-coated nitrocellulose membranes to mitochondria or microsomes for β-oxidation or glycerolipid synthesis (23), respectively. More recently, the *ACB1* gene encoding ACBP was disrupted in yeast, and the results strongly indicate that yeast ACBP is involved in the transport of newly synthesized acyl-CoA esters from the fatty acid synthetase to the site of glycerolipid synthesis and acyl-CoA desaturation (24). It is also known that the promoter region of the yeast ACBP gene contains two essential elements: one is necessary for expression of the yeast fatty acid synthetase genes (11), and the other element contains sequences corresponding to motifs known as the β-oxidation boxes (25).

ACBP synthesis is regulated by peroxisome proliferators (26–28). Both *in vitro* and *in vivo* studies have shown an increase up to twofold in the expression of rat hepatic ACBP mRNA and protein level after treatment with peroxisome proliferators (26–28). In our previous studies (21), we showed that the levels of ACBP in rat liver decrease with fasting and increase after consumption of a high-fat diet (21). These results indicate that liver ACBP responds to dietary changes and further support a role for this protein in lipid metabolism.

The aim of the present study was to investigate the effects of ACBP on hepatic fatty acid metabolism using a rat hepatoma cell line (McA-RH 7777) with increased expression of ACBP (ACBP-27).

## MATERIALS AND METHODS

*Construction of plasmid pNUT-ACBP and stable integration of ACBP cDNA into McA-RH 7777 cells.* Construction of plasmid pNUT-ACBP was achieved by inserting rat ACBP cDNA into the mammalian expression vector pNUT as previously described (29,30). This was carried out by removal of

Abbreviations: ACBP, acyl-CoA binding protein; BSA, bovine serum albumin; DMEM, Dulbecco's modified Eagle medium; FABP, fatty acid binding protein; LCAT, lecithin: cholesterol transferase; TLC, thin-layer chromatography.

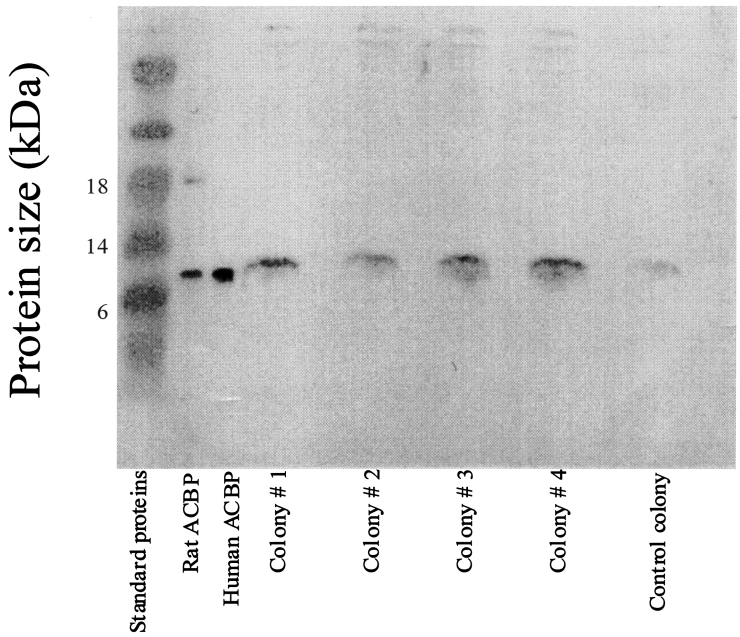

**FIG. 1.** Western blot analysis indicating overexpression of acyl-CoA binding protein (ACBP) (at ~10 kDa size) by ACBP gene-transfected colonies 1–4 as compared to control colony which was transfected with vector only.

the lecithin:cholesterol acyltransferase (LCAT) cDNA from pNUT-LCAT (31) using restriction sites *Xho*I and *Bam*HI.

McA-RH 7777 cells (American Tissue Culture Collection, Rockville, MD) were cotransfected with pNUT-ACBP (or pNUT for construction of the control cell line) using the vector pSV2neo; this vector carries a neomycin resistance gene. Transfection mixtures were made in a 3-mL polypropylene tube as follows: 10 μg/plasmid DNA was suspended in 0.45 mL sterile water, and 0.5 mL HEPES-buffered saline, pH 6.95, was added slowly while mixing with 0.05 mL 2.5 M $CaCl_2$. After 30 min of incubation at room temperature, 1 mL of the above-mentioned transfection mixtures was added to each culture dish containing McA-RH 7777 cells at approximately 50% confluency cultured in Dulbecco's modified Eagle medium (DMEM; Gibco BRL, Burlington, Ontario, Canada) containing 10% fetal bovine serum, 10% horse serum, and 1% antibiotic-antimycotic (Geneticin, Sigma, Oakville, Ontario, Canada). The dishes were incubated overnight at 37°C under 5% $CO_2$ concentrations. Subsequently, the medium was refreshed and 0.1 mL Geneticin (50 mg/mL) was added to give a final Geneticin concentration of 500 μg/mL. Dishes were continuously incubated, and the medium was changed every 2–3 d until the majority of the cells sloughed off. After 2 wk of culturing in the presence of Geneticin, virtually none of the parent cells had survived. Macroscopic colonies of surviving cells were harvested and further cultured using multiwell culture plates. These colonies were subsequently transferred to single dishes for further growth. The cells were then collected and screened for the production of ACBP by Western blotting and radioimmunoassay methods (21). ACBP content was expressed relative to DNA content, which was determined according to the method of Labarca and Paigen (32). Briefly, cell homogenates in which deoxyribonucleoprotein structure of chromatin was dissociated were incubated with Hoeschst H 33258 (American Hoechst Corp, currently Hoechst Marion Roussel, Cincinnati, OH). This method has been shown to enhance the fluorescence seen with binding of reagent (Hoeschst H 33258) with DNA (32). Figure 1 shows overexpression of ACBP in ACBP gene-transfected cells as compared to controls. It should be noted that we used only vector (pNUT) transfected cells as control colonies (Fig. 1) vs. ACBP gene-transfected colonies (colonies #1–4 in Fig. 1). One of the ACBP gene-transfected colonies (ACBP-27) was chosen for further study on the basis of its augmented ACBP content. ACBP antibody was generated as previously described (21). Briefly, ACBP was coupled to thyroglobulin and injected into rabbits. The antibody generated against ACBP was purified and used in cross-reactivity studies to determine its specificity; it showed negligible cross reactivity with purified rat liver FABP, bovine serum albumin (BSA), or rat serum albumin (21).

*Determination of the effects of constitutively expressed ACBP on the metabolic flux of free fatty acid.* Cell lines expressing various amounts of ACBP were grown to approximately 80% confluence in 24 multiwell plates and subsequently incubated for 4 h with various concentrations of [U-$^{14}$C]palmitic acid (Amersham Life Science, Arlington Heights, IL) in HEPES-buffered saline containing 2 mg/mL BSA, 36% DMEM, and 0.72% Geneticin. In the labeled medium, there was approximately $2 \times 10^7$ dpm [U-$^{14}$C]palmitic acid/mL of the medium. Therefore, the specific

activities were 4.2, 1.74, 1.13, 0.87, and 0.71 μCi/μM for 100, 200, 300, 400, and 500 μM palmitic acid concentrations, respectively. Two hundred microliters of either labeled or nonlabeled media was added to each well, three wells for each medium. Subsequently, two overlapping glass microfiber filters saturated with 3.5 N NaOH were placed on top of each well for trapping $^{14}CO_2$. The multiwell plates were then wrapped with plastic wrap and covered with a glass plate secured with an approximately 1-kg weight to prevent $CO_2$ leakage. The above unit was incubated at 37°C. After 4 h incubation, the filters were removed from each well, dried, and the trapped radioactivity was determined by scintillation counting and the incorporation of radiolabeled palmitic acid into $^{14}CO_2$ calculated from the specific activity. Subsequently, the medium was removed and each well was rinsed three times with phosphate-buffered saline (1 mL) to remove unincorporated label. Lipids were then extracted by adding a mixture of methanol and water (methanol/water; 1:0.8 vol/vol) to each well. The monolayer was scraped free and transferred to a glass tube, followed by addition of chloroform (2 mL) and glacial acetic acid (0.05 mL) to each tube. After mixing well, the samples were pelletted by centrifugation and dried under nitrogen. An aliquot of the pellet was used for radioactivity determination and another aliquot was resuspended in chloroform and the lipid fractions were determined using thin-layer chromatography (TLC). Lipid fractions were identified by $R_f$ values, and the radioactivity associated with each fraction was calculated by scintillation counting.

*TLC*. A TLC standard mixture was prepared containing oleic acid, diolein, triolein, and phosphatidylcholine. An aliquot (0.075 mL) of this standard mixture was added to each of the dried lipid extracts and mixed thoroughly. The mixture was applied to TLC plates (20 × 20 cm) that were subsequently developed in hexane/diethylether/acetic acid (90:60:1.5 by vol). This solvent system separated the extractable lipids into four fractions, namely, free fatty acids, diglycerides, triglycerides, and phospholipids. Each fraction was visualized with $I_2$ vapor, and areas of the plates corresponding to various fractions were cut and transferred directly into counting vials. Radioactivity was determined by scintillation counting.

*Statistics*. A two-tailed Student's *t*-test for unpaired data was used to assess the differences between the two groups of cells. Differences were considered significant at $P < 0.05$. Data are expressed as means ± standard deviation.

## RESULTS

*Overexpression of ACBP.* Transfected cells with either pNUT-ABCP (ACBP-27) or pNUT (control cells) were incubated in Puregen cell lysis solution for 10 min. ACBP and DNA analyses were performed as previously described (21). ACBP-27 cells had 3.5 times more ACBP than control cells (14 vs. 4 ng/μg DNA).

*Effects of ACBP on the incorporation of palmitic acid into lipids and the substrate dose-response relationship*. A series of studies were carried out to establish optimal conditions for assessing the oxidation of palmitic acid using the McA-RH 7777 cell line. Control cells were grown to confluence in multiwell plates in culture media containing 100 μM [U-$^{14}$C]palmitate. Our preliminary studies indicated a linear relationship between incubation time (from 1 to 5 h) and the incorporation of uptaken radiolabeled palmitate into radiolabeled $CO_2$ (Fig. 2). Regression analysis showed a strong positive relationship ($R^2 = 0.997$) between the incubation time and the mean of three in-

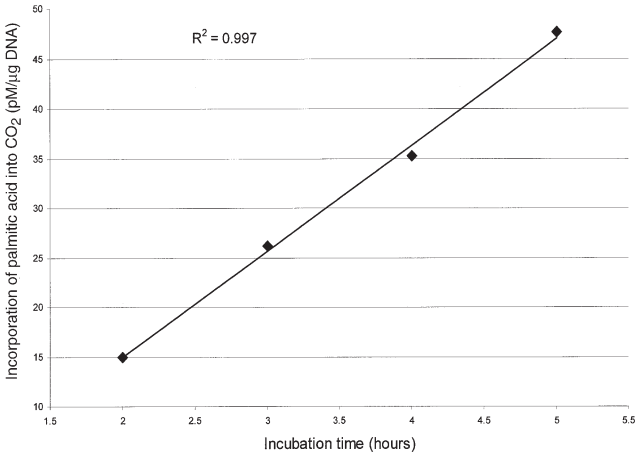

**FIG. 2.** The effects of incubation time on the incorporation of [U-$^{14}$C] palmitic acid into $^{14}CO_2$ in control cells. The cells were grown to confluence in a medium containing 100 μM palmitate (specific activity 3.27 μCi/μM). The incorporation of [U-$^{14}$C]palmitic acid into $^{14}CO_2$ was determined as described in the Materials and Methods section. Results are expressed as means ± standard deviation of triplicate cultures.

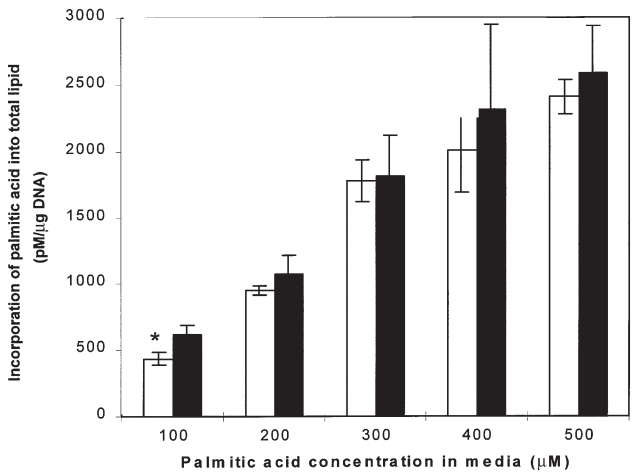

**FIG. 3.** The effects of ACBP on the flux of [U-$^{14}$C]palmitic acid into total lipid and the substrate dose-response relationship. ACBP-27 (solid bars) and control cells (open bars) were incubated for 4 h under varying concentrations of palmitic acid. The lipids were subsequently extracted, and the incorporation of label was determined as outlined in the Materials and Methods section. The data are means ± standard deviation of triplicate cultures. * Indicates significantly different from control levels ($P < 0.02$). For abbreviation see Figure 1.

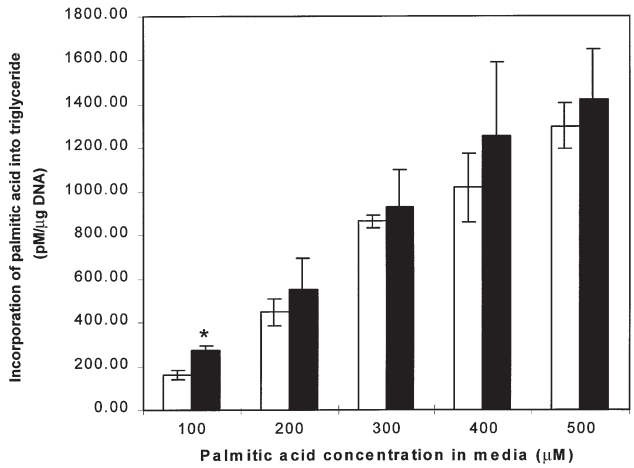

**FIG. 4.** The effects of ACBP on the flux of [U-$^{14}$C]palmitic acid into triglycerides and the substrate dose-response relationship. ACBP-27 (solid bars) and control cells (open bars) were incubated with varying concentrations of palmitic acid for 4 h. Lipids were extracted and separated as described in the Materials and Methods section. The data are means ± standard deviation of triplicate cultures. * Indicates significantly different from controls ($P < 0.01$). For abbreviation see Figure 1.

dependent measurements of generated $CO_2$ (Fig. 2). The 4-h incubation time point was on the linear line and resulted in production of more than 50% of total radiolabeled $CO_2$ measured during the 2–5 h period of incubation (Fig. 2). These criteria were used to choose an incubation time of 4 h.

Cells with increased expression of ACBP (ACBP-27) were grown in the presence of various concentrations of radiolabeled palmitic acid, and the incorporation of label into extractable lipids was monitored after 4 h of incubation. The pattern of incorporation was compared to that obtained in the control cells. Incorporation of palmitic acid into lipids is shown in Figure 3. Although there was a general trend for a greater incorporation of palmitate into extractable lipids in ACBP-27 cells compared to control cells, the difference between the two groups of cells was statistically significant ($P < 0.02$) only at the lowest concentration of fatty acid tested (100 μM). At this concentration, ACBP-27 cells had a 42% greater incorporation of the radiolabel into total extractable lipids than the control cells. The total lipid increase at this concentration was mainly due to an increase in triglycerides; ACBP-27 cells had a 71% greater incorporation of label into triglycerides compared to that in control cells (Fig. 4). Similarly, ACBP-27 cells had a 25% increase (on average) in the incorporation of label into phospholipids when compared to control cells.

*Effects of ACBP on the flux of palmitic acid into β-oxidation and the substrate dose-response relationship.* A similar set of experiments was conducted to examine the effects of the up-regulated ACBP on the flux of [U-$^{14}$C]palmitic acid into β-oxidation as monitored by incorporation of label into $^{14}CO_2$. Incubation with palmitic acid resulted in a significant decrease in the production of $^{14}CO_2$ in ACBP-27 cells as compared to control cells (Fig. 5). This effect appeared to be dose-dependent; ACBP-27 cells produced 51, 47, and 39% lower $^{14}CO_2$ when incubated with 200, 300, or 400 μM of palmitic acid, respectively, as compared to corresponding controls.

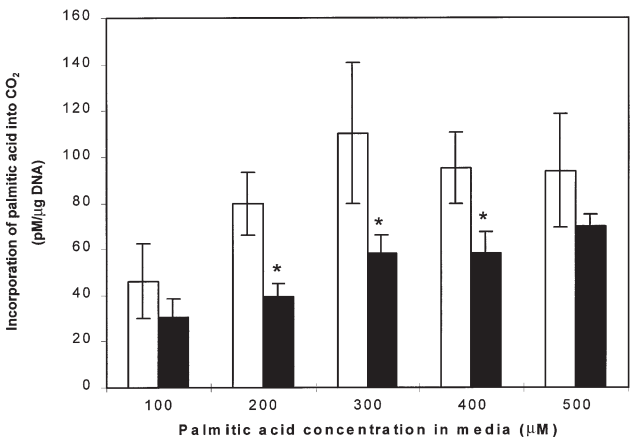

**FIG. 5.** The effects of (ACBP) on the flux of [U-$^{14}$C]palmitic acid into β-oxidation and the substrate dose-response relationship. β-Oxidation of palmitic acid was monitored by trapping of $^{14}CO_2$ during a 4-h incubation time as described in the Materials and Methods section. The data are means ± standard deviation of triplicate cultures. * Indicates significantly different from controls ($P < 0.05$). For abbreviation see Figure 1.

## DISCUSSION

Previous studies have indicated that ACBP stimulates the synthesis of long-chain fatty acyl-CoA (19). It was suggested that ACBP was able to accomplish this by removing newly synthesized long-chain fatty acyl-CoA moieties from the mitochondrial membrane and thereby reducing the negative feedback inhibition by this substrate on the activity of mitochondrial long-chain fatty acyl-CoA synthetase (19). Other studies have suggested that ACBP may facilitate transportation of long-chain acyl-CoA esters to microsomes and mitochondria for glycerolipid synthesis or β-oxidation (23). In previous studies, we showed that tissue levels of ACBP were increased in response to a high-fat diet and were decreased with fasting in the rat (21). Tissue levels of ACBP showed a positive correlation with liver triglycerides in these studies. All of these data suggest a role for ACBP in intermediary regulation of lipid metabolism.

The present studies employed a hepatic cell line in which the expression of ACBP was up-regulated to examine the effects of this protein on the metabolism of palmitic acid *in vitro*. Our data suggest that at a low concentration of palmitic acid, ACBP enhances the incorporation of [U-$^{14}$C]palmitic acid into the synthesis of lipids (particularly triglycerides). This is in accordance with the observations of Rasmussen *et al.* (19), who demonstrated that the saturation of ACBP with long-chain acyl-CoA ester abolished the stimulatory effects of ACBP on the activity of acyl-CoA synthetase. Coincident with the increased label incorporation into synthesis of triglyceride was a decrease in the incorporation of $^{14}CO_2$. As is evident in Figure 5, oxidation of the fatty acid significantly decreased at palmitic acid concentrations of 200, 300, and

400 μM. Since ACBP can influence the flux of fatty acids between esterification into neutral lipids and β-oxidation it may play an important regulatory role in lipid metabolism by influencing this important branch point in intermediary metabolism. Recently, Jolly *et al.* (22), showed that both liver fatty acid-binding protein (L-FABP) and ACBP stimulate microsomal incorporation of the monounsaturated oleoyl-CoA and polyunsaturated arachidonoyl-CoA by 8- to 10-fold, and 2- to 3-fold, respectively. On the other hand, both proteins (L-FABP and ACBP) inhibit microsomal utilization of saturated palmitoyl-CoA by over 60% (22). It has been reported that ACBP protects long-chain fatty acyl-CoA from microsomal acyl-CoA hydrolase activity in the following order: palmitoyl-CoA > oleoyl-CoA > arachidonoyl-CoA (22).

As the relative molar ratio of FABP to ACBP is approximately 8:1 (1,3,33–35), it could be argued that the role of ACBP is likely to be more significant at lower concentrations of long-chain fatty acyl-CoA. FABP may contribute additional function under conditions in which long-chain fatty acyl-CoA levels have exceeded the binding capacity of ACBP. In our studies, ACBP-27 constitutively expressed a 3.5-fold increase in the cellular levels of ACBP when exposed to a low concentration of palmitic acid, which was associated with an enhanced incorporation of radiolabel into total lipids (particularly triglycerides). However, at higher concentrations of palmitic acid the increased incorporation into neutral lipid was not significant. The binding capacity of ACBP may have been exceeded under these conditions.

Although the ACBP gene belongs to the class of housekeeping genes that are ubiquitously expressed, the level of expression for this protein differs markedly among different tissues and cell types (36,37). ACBP is highly expressed in secretory cells such as hepatocytes and steroid-producing cells. This protein is regulated by peroxisome proliferators. The addition of peroxisome proliferators to a rat hepatoma cell line results in an increase in ACBP mRNA (26–28). Several studies indicate that fatty acids and/or acyl-CoA may activate the peroxisome proliferator-activated receptors (38). This in turn would be expected to activate the ACBP gene (38). It may be through this mechanism that intracellular levels of free fatty acids are able to influence key regulatory steps for directing an appropriate metabolic response by the cells. Further studies are required to elucidate the regulatory role of ACBP in intermediary lipid metabolism.

# Metabolism of Very Long Chain Polyunsaturated Fatty Acids in Isolated Rat Germ Cells

**Kjetil Retterstøl[a,*], Thien N. Tran[a], Trine B. Haugen[b], and Bjørn O. Christophersen[a]**

[a]Institute of Clinical Biochemistry, Andrology Laboratory, and [b]Department of Gynecology and Obstetrics, National Hospital, University of Oslo, N-0027 Oslo, Norway

**ABSTRACT:** Which cell type is responsible for the high levels of very long chain polyunsaturated fatty acids in testis and whether this fatty acid pattern is a result of a local synthesis are not presently known. In this study, fatty acid conversion from 20:4n-6 to 22:5n-6 and from 20:5n-3 to 22:6n-3 was investigated in isolated rat germ cells incubated with [1-$^{14}$C]-labeled fatty acids. The germ cells elongated the fatty acids from 20- to 22-carbon atoms and from 22- to 24-carbon atoms but had a low Δ6 desaturation activity. Thus, little [$^{14}$C]22:5n-6 and [$^{14}$C]22:6n-3 were synthesized. When Sertoli cells were incubated with [1-$^{14}$C]20:5n-3 for 24 h, an active fatty acid elongation and desaturation were observed. *In vivo* germ cells normally have a higher content of 22:5n-6 or 22:6n-3 than Sertoli cells. An eventual transport of essential fatty acids from Sertoli cells to germ cells was thus studied. Different co-culture systems were used in which germ cells were on one side of a filter and Sertoli cells on the opposite side. When isolated pachytene spermatocytes or round spermatids were added to the opposite side of a semipermeable filter, approximately 1 nmol [$^{14}$C]-22:6n-3 crossed the filter. Little of this was esterified in the germ cells. Similarly, in using [1-$^{14}$C]20:4n-6 in identical experiments, very little [$^{14}$C]22:5n-6 was esterified in germ cells on the opposite side of the filter. Although the very active synthesis of 22:5n-6 and 22:6n-3 observed in Sertoli cells suggests a transport of these compounds to germ cells, this was not experimentally determined.

Paper no. L8509 in *Lipids 36,* 601–606 (June 2001).

n-6 Fatty acids are essential for normal testicular development and fertility (1). The testis and sperm of rats and several other rodents have a high content of docosapentaenoic acid (22:5n-6) (2), whereas in humans (3,4), monkeys (5), and pigs (6) docosahexaenoic acid (22:6n-3) is the dominant fatty acid in testis. A selective n-3 deficiency does not reduce rat fertility (7). However, reduced motility of human spermatozoa has been associated with a declining content of 22:6n-3 in the phospholipids (PL) of the spermatozoa (8).

The germ cells are in close connection with the Sertoli cells. They are located within the seminiferous tubules undergoing mitotic and meiotic divisions, differentiating from diploid spermatogonia (DNA = 2C) to spermatocytes (4C) and finally to spermatozoa (1C), which are released. The content of very long unsaturated polyenes is higher in germ cells than in Sertoli cells both in rat (9) and in monkey (5). Whether the germ cells themselves are able to synthesize the very long unsaturated polyenes from linoleic and α-linolenic acid or whether they must be provided with these fatty acids, e.g., from the Sertoli cells is unknown. Several authors have proposed transport of long polyenes from the Sertoli cells to the germ cells, but such a transport has not yet been determined (10–13).

The aim of the present work was to study the fatty acid metabolism in isolated rat germ cells and eventually the transport of fatty acids from Sertoli cells to germ gells. In the present study centrifugal elutriation followed by application of a Percoll density gradient (14) allowed measurements on highly purified round spermatids (RST) and pachytene spermatocytes (PS). The formation of 22:5n-6 and 22:6n-3 from labeled fatty acid precursors was studied in the light of the revised pathway of the synthesis of these fatty acids (15,16). Sertoli and germ cells were co-cultured to study a possible fatty acid transfer between the different cell types.

## MATERIALS AND METHODS

*Chemicals.* The labeled fatty acids were obtained from American Radiolabeled Chemicals Inc. (St. Louis, MO) and the unlabeled fatty acids were from Sigma Chemicals Co. (St. Louis, MO).

*Animals.* Weanling Sprague-Dawley rats were obtained from Møllegaard Laboratory (Ry, Denmark). After separation from their mother, the rats were given a standard rat diet from Grimstone Aldbrough (Hull, UK). The experimental procedures were approved by the local ethical committee.

*Preparation of isolated germ cell suspensions.* Germ cells were isolated from seminiferous tubules of 32-d-old rats. A cell suspension was obtained by consecutive treatment with collagenase, trypsin, and DNase (17,18). The cells were fractionated into PS and RST by centrifugal elutriation followed by separation in density gradients of Percoll (19). By this method purified populations of PS (87–96% purity as evaluated by flow cytometry of the DNA content) and RST (90–95% purity) were obtained (data not shown). The cells were diluted in minimum essential fatty acid medium, and labeled fatty acid substrates were added. More than 90% of the cells were viable, as measured by resistance to uptake of Trypan blue, and more than 80% remained viable after the 24-h incubation period. The cell

Abbreviations: BSA, bovine serum albumin; FFA, free fatty acids; HBSS, Hanks' balanced salt solution; PL, phospholipid; PS, pachytene spermatocytes; RST, round spermatids; TAG, triacylglycerol.

density in the germ cell suspension was (0.4–1.4) × $10^6$ cells/mL, and the corresponding mean protein concentration was 0.34 mg/mL. Of this preparation, 5.0 mL was used for incubation in NUNC (Roskhilde, Denmark) 50-mL cell culture flasks. The suspensions contained 1.5% (wt/vol) essentially fatty acid-free bovine serum albumin (BSA). Radiolabeled fatty acid (20 nmol) with a specific activity of approximately 55 mCi/mmol was added to each flask.

*Preparation of enriched Sertoli cell suspensions.* The testes were removed, decapsulated, and cut into small pieces in $Ca^{2+}$- and $Mg^{2+}$-free Hanks' balanced salt solution (HBSS). The tissue was then incubated in HBSS containing 0.25% trypsin and 0.2 mg/mL DNase for 15 min at 34ºC in a shaking water bath (120 cycles/min). Subsequently the tubule fragments were allowed to sediment for 5 min, the medium was aspirated, and the pellet was re-suspended in HBSS containing soybean trypsin inhibitor (0.4 mg/mL). The tubule fragments were washed three times in HBSS (with $Ca^{2+}$ and $Mg^{2+}$) by sedimentation at unit gravity for 5 min and then incubated for 30 min in 50 mL HBSS containing 50 mg collagenase for 15 min at 34ºC in a shaking water bath (120 cycles/min). The cells were pelleted by centrifugation at room temperature for 2 min at 15 × *g* and dispersed in HBSS containing 1.25% BSA, followed by centrifugation. The pellet was resuspended in HBSS and filtered through a premoistened 100-µm nylon mesh. The filtrate was centrifuged for 2 min, and the final pellet resuspended in Earle's minimal essential medium supplemented with 2 mM L-glutamine, penicillin ($10^6$ IU/L), streptomycin (25 mg/L), and fungizone (2.5 mg/L). More than 90% of the cells were viable, as measured by resistance to uptake of Trypan blue. After 24 h of incubation, the viability varied from 80 to 95%. The Sertoli cells were isolated essentially as described by Dorrington *et al*. (20).

*Sertoli and germ cells in co-culture.* Costar's (Skipholt, The Netherlands) Transwell cell culture flasks with a growth area of 44 $cm^2$ and a 3.0 µm pore size polycarbonate membrane was used for co-culture experiments. The cell density using the Costar system was (0.8–1.6) × $10^6$ cells/mL in the Sertoli cell suspensions and (0.5–1.4) × $10^6$ cells/mL in the germ cell suspensions. Sertoli cell densities within this range have been used in several other studies (21). Below the membrane 12.5 mL of cell suspension or of medium only was used and 8.5 mL of cell suspension or medium only above the membrane. Some experiments were performed using Falcon cell culture inserts (3.0 mL cell suspension under the membrane and 2.0 mL over) with a membrane pore size of 0.45 µm (Cyclopore®, Whatman, Maidstone, United Kingdom).

*Analytical methods.* Lipids were extracted (22), and aliquots were separated on silica gel 60H thin-layer plates (Merck, West Point, PA) with hexane/diethylether/acetic acid (70:29:1 by vol) and scanned in an imager scanner from Packard (Downers Grove, IL). The PL were isolated using the same thin-layer chromatography system and eluted with 2 × 2 mL $CHCl_3$/MeOH/acetic acid/water 50:39:1:10, by vol. The PL were further separated into phosphatidylinositol, phosphatidylserine, phosphatidylcholine, and phosphatidylethanolamine on Whatman LK5 thin-layer plates with $CHCl_3$/MeOH/40% aqueous methylamine (120:40:10, by vol) as solvent. The Whatman LK5 thin-layer plates were scanned in a Packard Instant Imager Scanner, and the PL classes were then eluted with 2 × 2-mL $CHCl_3$/MeOH/acetic acid/water 50:39:1:10, by vol.

Aliquots of the total lipids of the cell suspensions, the isolated cells, and the isolated mediums, as well as the PL and the triacylglycerol (TAG) fractions, were transmethylated ($BF_3$-methanol), and the fatty acids were separated with reversed-phase high-performance liquid chromatography (isocratically) on a Supelcosil LC-18 (250 × 4.6 mm) reversed-phase column (Supelco, Bellfonte, PA). The mobile phase was acetonitrile/water (80:20, vol/vol) 2.0 mL/min, or acetonitrile/water (90:10, vol/vol) 0.75 mL/min delivered by a LC-9A Shimadzu apparatus (Kyoto, Japan). Radioactivity was measured in a flow detector A-100 (Radiomatic Instruments & Chemical, Tampa, FL). The fatty acids were identified by comparison with retention times from $^{14}C$-labeled fatty acid standards and with retention times from previous experiments.

The naturally occurring concentration of nonesterified free fatty acids in the sera of the Wistar rats used was approximately 400 µM as measured by capillary gas chromatography with 17:0 as internal standard using a SP-2340 capillary column (30 m × 0.32 mm; Supelco) and a Hewlett-Packard 5890 series II gas chromatograph (Palo Alto, CA) with a flame-ionization detector and helium as carrier gas.

Determination of radioactive acid-soluble products and of radioactive $CO_2$ (as a measure of the rate of oxidation of carbon in the number 1 position) was essentially performed as described by Christiansen (23) and by measuring the labeling of the water phase of the Folch *et al.* extraction (22). The cellular protein was determined (24).

*Statistics*. Mann-Whitney rank test was used, and the *P*-values were Bonferroni-corrected when multiple comparisons were performed.

## RESULTS

*Elongation, desaturation, and retroconversion.* The germ cells were able to perform the elongation reaction from 20- to 22- and from 22- to 24-carbon atom fatty acids (Fig. 1). The fatty acid substrates were elongated to a different degree, and [1-$^{14}C$]20:4n-6 was elongated less than [1-$^{14}C$]20:5n-3. By contrast, [1-$^{14}C$]22:4n-6 and [1-$^{14}C$]22:5n-3 were elongated to an almost equal degree (Fig. 1). The PS were more active in elongating the fatty acids than the RST (Fig. 1 B–D). Little of the labeled fatty acid substrates was Δ6-desaturated, and very small amounts of [$^{14}C$]22:5n-6 and [$^{14}C$]22:6n-3 were synthesized.

*Oxidation and uptake of fatty acid substrate in the lipid fractions.* The fatty acid substrates were esterified to a different degree in PL and TAG (Fig. 2). More [1-$^{14}C$]20:5n-3, [1-$^{14}C$]22:5n-3, and [1-$^{14}C$]22:4n-6 were oxidized or esterified in TAG than [1-$^{14}C$]20:4n-6, [1-$^{14}C$]22:5n-6 and [1-$^{14}C$]-22:6n-3 (Fig. 2). The sum of [1-$^{14}C$]20:5n-3, [1-$^{14}C$]22:5n-3, and [1-$^{14}C$]22:4n-6 that were esterified in TAG was higher than that of [1-$^{14}C$]20:4n-6, [1-$^{14}C$]22:5n-6, and [1-$^{14}C$]22:6n-3,

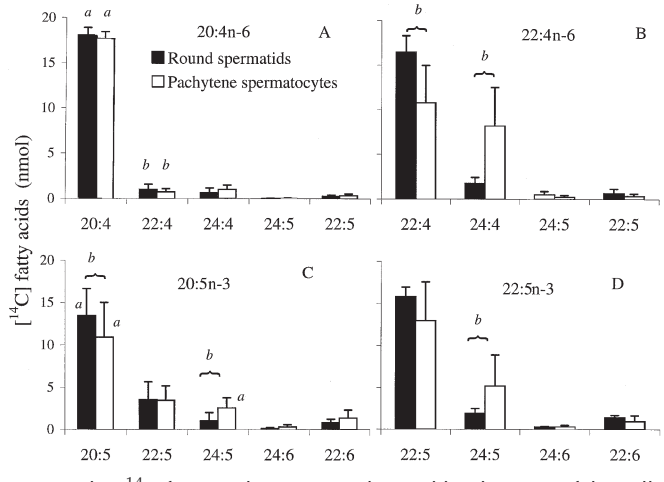

**FIG. 1.** The [$^{14}$C]fatty acid patterns in the total lipid extract of the cells plus media in combination. Germ cells were incubated in NUNC cell culture flasks (Roskhilde, Denmark) with 20 nmol [1-$^{14}$C]-labeled 20:4n-6 (A), 22:4n-6 (B), 20:5n-3 (C), and 22:5n-3 (D) in round spermatids or pachytene spermatocytes as indicated in the legend to panel (A). The [$^{14}$C]-labeled metabolites from the different fatty acid substrates are indicated below each bar. The results are given as the mean of 3–10 (mean 5.4) incubations with 1 SD indicated as T-bars. *a* = $P < 0.05$ when comparing the intermediates formed from [1-$^{14}$C]20:4n-6 with the analog metabolites from [1-$^{14}$C]20:5n-3. *b* = $P < 0.05$ comparing the intermediates formed from round spermatids with the amounts formed from pachytene spermatocytes.

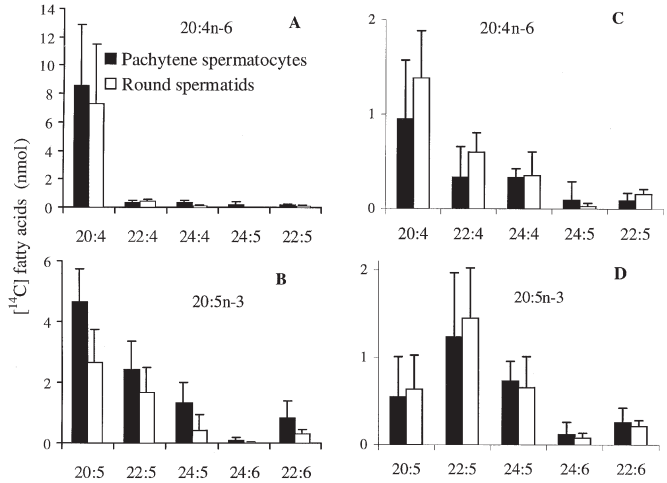

**FIG. 3.** The [$^{14}$C]fatty acid pattern in the phosopholipid (A and B) and triacylglycerol (C and D) fraction after 24 h of incubation with 20 nmol [1-$^{14}$C]20:4n-6 (A,C) or [1-$^{14}$C]20:5n-3 in germ cell suspension (B,D). Key for round spermatids and pachytene spermatocytes are indicated in panel A. NUNC cell culture flasks were used. The [$^{14}$C]-labeled fatty acid metabolites are indicated under the bars. The amounts of the substrates and intermediates recovered are given as a mean of 3–6 (mean 4.5) incubations. T-bars = 1 SD. For manufacturer see Figure 1.

both in PS (rank sum 373 vs. 92, $n_1 = 13$, $n_2 = 17$, $P < 0.0001$) and in RST (rank sum 182 vs. 122, $n_1 = 11$, $n_2 = 13$, $P < 0.01$). The proportion of fatty acid substrates that had been elongated was higher in the TAG fraction than in the PL fraction (Fig. 3). With [1-$^{14}$C]22:5n-6 and [1-$^{14}$C]22:6n-3 as substrates, no products from elongation were detected (data not shown).

Phosphatidylcholine was the major PL class in which the labeled fatty acids were esterified, followed by phosphatidylethanolamine (Fig. 4).

In using PS 1.9–7.1 nmol as nonesterified free fatty acid (FFA) substrates was recovered (depending on the fatty acid substrate used) and in using RST this fraction was 6.3–11.8 nmol. The FFA consisted almost exclusively of the substrate

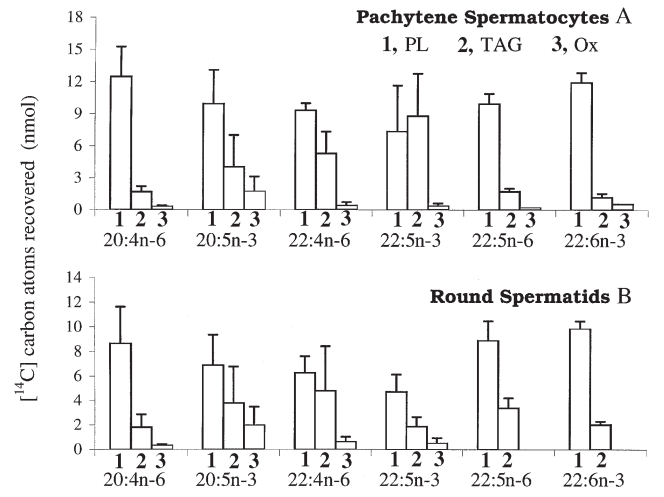

**FIG. 2.** [$^{14}$C]-Incorporation in the phospholipid fraction (PL) and in the triacylglycerol fraction (TAG), and oxidation (Ox) measured by the amount of radioactive acid-soluble products and carbon dioxide formed after 24 h of incubation. Pachytene spermatocytes (A) and round spermatids (B) were incubated with [1-$^{14}$C]fatty acid substrates in NUNC cell culture flasks. The substrates used (20 nmol) are indicated below each cluster of bars. The mean values of 2–10 (mean 4.2) incubations are given. T-bars = 1 SD. For manufacturer see Figure 1.

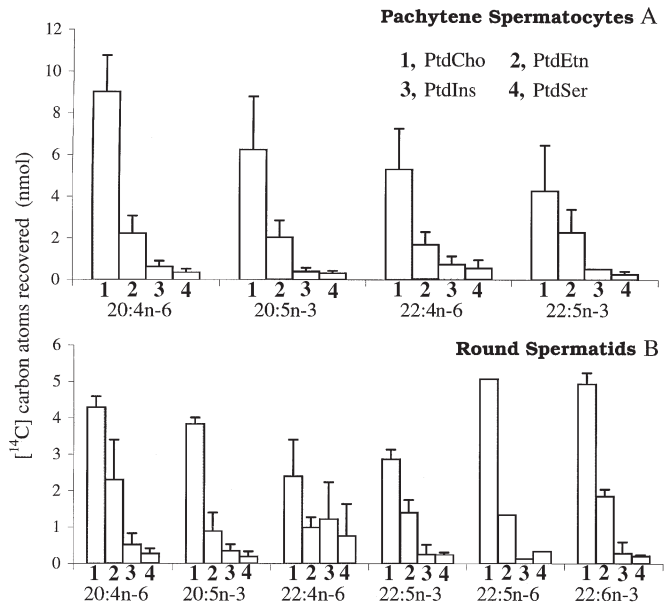

**FIG. 4.** Esterified [$^{14}$C]fatty acids in various phospholipid classes in pachytene spermatocytes (A) and round spermatids (B) after 24 h of incubation in NUNC cell culture flasks. PtdCho = phosphatidylcholine, PtdEtn = phosphatidylethanolamine, PtdIns = phosphatidylinositol, PtdSer = phosphatidylserine. The substrates are indicated below each cluster of bars. The mean amount (nmol) from 2 to 6 (mean value 3.4) incubations are given. T-bars = SD. For manufacturer see Figure 1.

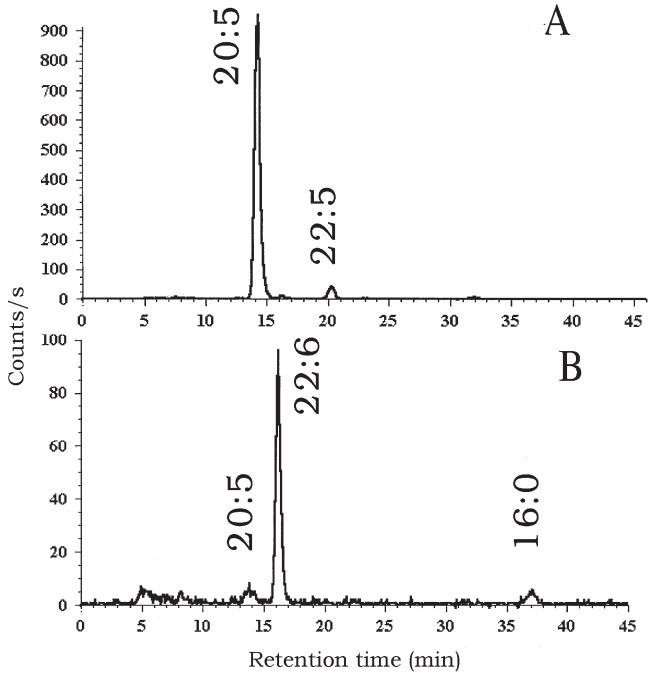

**FIG. 5.** Examples of reversed-phase high-performance liquid chromatograms after incubation with [1-$^{14}$C]20:5n-3. Panel A shows the free fatty acid fraction after incubating round spermatids with [1-$^{14}$C]20:5n-3 for 24 h in absence of Sertoli cells. Panel B shows the labeled fatty acids found in the free fatty acid fraction at the germ cell-side of a 3.0-μm pore membrane when Sertoli cells were incubated with [1-$^{14}$C]20:5n-3 at the opposite side for 24 h. A Costar two-chamber system was used as described in the Material and Methods section.

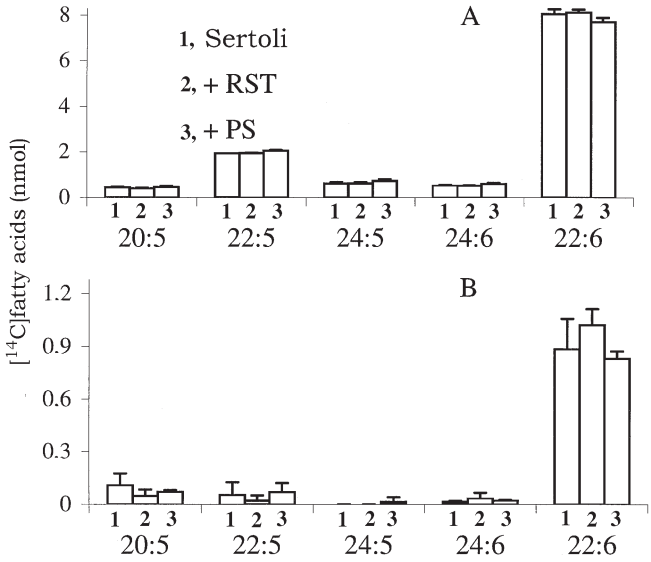

**FIG. 6.** Sertoli and germ cells co-cultured at each side of a 3.0-μm pore membrane using a Costar two-chamber system. The Sertoli cell suspension was incubated with 20 nmol [1-$^{14}$C]20:5n-3 for 24 h at the top of the membrane. Germ cells [pachytene spermatocytes (PS) or round spermatids (RST)] were thereafter incubated at the other side of the membrane and were co-cultured for 48 h. The labeled fatty acids in the lipid extract of cells plus medium at the Sertoli-side of the membrane are shown in panel A and at the germ cell-side of the membrane in panel B. The different [$^{14}$C]-labeled fatty acids are indicated below each bar-cluster. The co-cultures are explained in the legend to panel A. Sertoli = Sertoli cells incubated without germ cells at the other side of the membrane; +RST = Sertoli cells at one side of the membrane and round spermatids at the other; +PS, Sertoli cells with pachytene spermatocytes at the opposite side of the membrane.

used (Fig. 5A) and probably represented the fatty acids that were not taken up by the germ cells. In contrast, [$^{14}$C]22:6n-3 accounted for almost all the FFA when incubating Sertoli cells with [1-$^{14}$C]20:5n-3 (Fig. 5B).

*Studies on a possible transport of fatty acids from Sertoli to germ cells.* A Costar two-chamber incubation system with a polycarbon filter (3.0 μm pores) was used. The Sertoli cell suspension was incubated with [1-$^{14}$C]20:4n-6 or [1-$^{14}$C]-20:5n-3 for 24 h before the germ cells were added to the opposite side of the filter. By doing this preincubation, almost all of the labeled fatty acids were esterified in the Sertoli cells. In the lipid extract from cells plus medium at the Sertoli cell-side of the filter, some [$^{14}$C]22:5n-3, [$^{14}$C]24:5n-3, and [$^{14}$C]24:6n-3 were found, but [$^{14}$C]22:6n-3 dominated after incubation with [1-$^{14}$C]20:5n-3 (Fig. 6A). The conversion of [1-$^{14}$C]20:4n-6 to [1-$^{14}$C]22:5n-6 was less efficient than that of the n-3 analog (data not shown), as described previously. When incubating Sertoli cells with 20 nmol [1-$^{14}$C]22:4n-6, the amounts of labeled 22:4n-6, 24:4n-6, 22:5n-6, and 22:5n-6 found as FFA were 0.4 ± 0.1, 0.1 ± 0.0, 0.1 ± 0.0, and 0.5 ± 0.1 nmol, respectively. When using [1-$^{14}$C]22:5n-3, 1.1 ± 0.0 nmol of [$^{14}$C]22:6n-3 was found in the FFA fraction, which accounted for more than 90% of the labeled fatty acids present there. The labeled fatty acid pattern in the Sertoli cell suspension was not influenced by the presence of germ cells on the contrary side of the filter, and the amounts of [$^{14}$C]-22:6n-3 that crossed the filter from the Sertoli cell side to the germ cell side were independent of the presence of germ cells (Fig. 6). The small amount of [$^{14}$C]22:6n-3 that crossed the filter was mainly found as FFA and was not esterified (data not shown). We conclude that no active transport of labeled fatty acids from Sertoli to germ cells occurred.

## DISCUSSION

Isolated rat germ cells were able to elongate labeled fatty acids from 20- to 22- and from 22- to 24-carbon fatty acids, but little 22:5n-6 and 22:6n-3 were formed from labeled fatty acid precursors. This suggests a low Δ6 desaturation activity in the isolated germ cells, which is very different from the active Δ6 desaturation activity previously observed in rat Sertoli cells (Fig. 6) (26).

Labeled 20:4n-6 and 22:5n-6, two fatty acids which are normally present in significant amounts in rat germ cells, were good substrates for esterification in the PL fraction of the germ cells and little of these acids was oxidized. This was also the case with labeled 22:6n-3. On the contrary, labeled 20:5n-3, 22:4n-6, and 22:5n-3 fatty acids, which are normally present in very small amounts in rat germ cells, were better substrates for esterification in TAG, and partly also for oxida-

tion. The degree of fatty acid esterification in PL may partly contribute to the fatty acid pattern observed in testis of normal rats. The TAG fraction contained a higher degree of elongated fatty acid substrates than the PL. This was similar to previous findings in isolated rat seminiferous tubules (27) and rat Sertoli cells (25), suggesting that the TAG fraction is important in the metabolism of testicular fatty acids.

The limited synthesis of 22:5n-6 and 22:6n-3 observed in the germ cells in the present study was in contrast to the high content of these fatty acids previously observed in germ cells *in vivo* (28). However, the present study shows that Sertoli cells are very active in metabolizing polyunsaturated fatty acids as compared with isolated germ cells. Thus, the Sertoli cells may provide the germ cells with these polyenes. A small amount of [$^{14}$C]22:6n-3, synthetized by Sertoli cells, was released into the incubation medium as FFA and recovered in similar concentrations on both sides of the filter separating germ cells and Sertoli cells. However, [$^{14}$C]22:6n-3 did not accumulate in the germ cells (Fig. 6), and thus a transport of labeled fatty acids from Sertoli cells to germ cells was not observed. The experimental conditions may have an influence on this. The low extracellular concentration of labeled 22:6n-3 and 22:5n-6 (0.1 μM) possibly was too low for [$^{14}$C]22:6n-3 to be efficiently esterified in the germ cells. A cell-to-cell contact may also be obligate for an eventual fatty acid transport to occur, since *in vivo,* germ cells are in close contact with Sertoli cells throughout all steps of the development (during certain stages of their maturation they are actually embedded within the Sertoli cell cytoplasm).

When labeled 18:2n-6 and 20:4n-6 were injected in testis in a previous study, the fatty acids were primarily taken up and metabolized by Sertoli cells, suggesting an important role of the Sertoli cell in the lipid metabolism of testis (29). Further, the results from the present study show that isolated germ cells were inactive in metabolizing labeled polyunsaturated fatty acid, in contrast to Sertoli cells. Together these indicate that Sertoli cells do play a major role in testicular fatty acid metabolism, but it is not demonstrated if there is a transfer of fatty acids from Sertoli cells (or other cells types, e.g., in the vesicula seminalis) to the germ cells. It is possible that the high proportion of 22:5n-6 or 22:6n-3 found in germ cells *in vivo* may partly be due to the loss of most cytoplasm from germ cells along with their maturation (30), possibly altering the fatty acid content, both quantitatively and qualitatively.

In conclusion, the present study showed that isolated rat germ cells were inefficient in synthesizing 22:5n-6 and 22:6n-3 and had a low Δ6 desaturation activity. The rat Δ6 desaturase gene was recently cloned (31), and future studies thus may confirm the major metabolic differences between Sertoli and germ cells observed in the present study on the mRNA level of some key enzymes.

## ACKNOWLEDGMENT

We are grateful to Anne-Marie Lund and Siri Tverdal for excellent technical work.

# Oleate Acutely Stimulates the Secretion of Triacylglycerol by Cultured Rat Hepatocytes by Accelerating the Emptying of the Secretory Compartment

**Victor A. Zammit* and David L. Lankester[1]**

Cellular Biochemistry, Hannah Research Institute, Ayr KA6 5HL, Scotland, United Kingdom

**ABSTRACT:** The acute effects of addition of oleate on the rate of triacylglycerol (TAG) secretion by cultured rat hepatocytes were studied by monitoring the use of endogenous ($^{14}$C-prelabeled) acyl moieties and exogenous ($^{3}$H-labeled) oleate for the synthesis of secreted TAG simultaneously. Inclusion of exogenous oleate in the medium stimulated the secretion of the endogenous $^{14}$C-labeled acyl moieties by 55–100%. To find out whether the stimulation was due to increased endogenous TAG mobilization or an increased rate of processing of TAG within the endoplasmic reticulum (ER) secretory machinery, use was made of the inhibition of apolipoprotein B (apoB) synthesis (but not degradation) by $Ca^{2+}$ mobilization from the ER. Inhibition of apoB synthesis stopped entry of acyl moieties (from endogenous and exogenous sources) into the secretory pathway. However, even when entry of acyl moieties into the secretory pathway was totally inhibited, exogenous oleate was still able to stimulate (twofold) the secretion [$^{14}$C]TAG, indicating that oleate stimulates the emptying of prelabeled TAG from the secretory compartment at a point distal to apoB synthesis and nascent particle formation. These data indicate that exogenous oleate, besides providing additional acyl moieties for incorporation into secreted TAG, stimulates the secretion of endogenous TAG in a manner (i) that is independent of effects on apoB synthesis and/or degradation and (ii) that involves the enhanced processing of TAG resident within the ER secretory pathway.

Paper no. L8705 in *Lipids 36,* 607–612 (June 2001).

Triacylglycerol (TAG) secretion by hepatocytes is affected by several factors, including the availability of fatty acids and of apolipoprotein B (apoB) for assembly into very low density lipoprotein (VLDL) particles. Through the phosphatidate pathway, exogenous fatty acids are incorporated into diacylglycerols (DAG), which are then partitioned between either the synthesis of cytosolic TAG or, after permeation through the endoplasmic reticulum (ER) membrane, into TAG destined for secretion (1). Within the ER, TAG occur within apoB-containing nascent lipoprotein particles in the rough ER (rER), and as apoB-free TAG droplets within the smooth ER (sER) (2). Addition (fusion) of TAG from this sER pool to the nascent particles (step two of lipidation) at regions of fusion between the rER and sER membrane populations results in the full-sized VLDL particles that are secreted (3,4). Cytosolic TAG undergo a continuous cycle of lipolysis (5) [mostly to DAG (6,7)] and resynthesis. DAG formed through cytosolic TAG lipolysis also contribute to the synthesis of ER lumenal (secreted) TAG (6). Therefore, DAG required for TAG synthesis are contributed both directly through the phosphatidate pathway and from the hydrolysis of cytosolic droplet TAG (1,8).

In freshly prepared rat or rabbit hepatocytes, in which the endogenous cytosolic TAG stores are depleted during the cell isolation procedure, the rate of TAG secretion is almost totally dependent on the addition of oleate (9,10). However, in cultured rat hepatocytes, in which the accumulation of cytosolic TAG is maximized by preculture for up to 24 h with fatty acids, the rate of TAG secretion is less dependent on added fatty acids (11), and the DAG and acyl moieties formed by hydrolysis of cytosolic TAG make a major contribution (about 80%) toward the synthesis of secreted TAG, even in the presence of exogenous oleate (7). Therefore, it appears that in addition to the ability of oleate to stimulate TAG secretion directly, by providing additional acyl moieties, it also stimulates secretion of endogenous acyl groups through an unknown mechanism. The secretion of TAG occurs within VLDL particles, the nascent form of which are produced by rapid but partial lipidation of newly synthesized apoB. Therefore, an experimental approach that distinguishes between the stimulation of the supply of acyl moieties and DAG proximal to apoB synthesis, and of the rate of secretory steps distal to apoB synthesis would be useful in identifying the site of oleate action.

One such approach is provided by the inhibition of TAG secretion when intracellular (ER) $Ca^{2+}$ stores are mobilized (12). The mechanism of this inhibition has not been studied, although it has been suggested that ER lumenal $Ca^{2+}$ is required for the correct folding of apoB (12). However, because ER $Ca^{2+}$ mobilization is known to inhibit protein synthesis (13,14), we considered it possible that TAG secretion may be inhibited as the result of the inhibition of apoB synthesis. If this could be shown to be the case, it would provide the opportunity experimentally to investigate the effect of the addition of exogenous oleate on the rate of TAG secretion by hepatocytes at a step(s) distal to apoB synthesis (and step 1 lipidation). Therefore, in the present study we combined the use of this approach to the

previously described dual-labeling technique for the quantification of the utilization of endogenous and exogenous acyl moieties for the synthesis of secreted TAG (7) to study the mechanism of the effect of exogenously added oleate on TAG secretion by cultured rat hepatocytes. The data show that exogenous oleate stimulates the rate of secretion of a pool(s) of TAG resident within the secretory pathway.

## MATERIALS AND METHODS

*Preparation and culture of hepatocytes.* Hepatocytes were isolated from female Wistar rats (200–220 g) by a two-step collagenase perfusion protocol, as described previously (7). They were plated onto 6-cm diameter plastic dishes and allowed to attach in 3 mL of Earls balanced salts solution (EBSS) containing 10 mM HEPES (pH 7.4) and supplemented with new-born calf serum, amino acids, and antibiotics for 4 h, as described previously (7). The medium was then removed, and fresh serum-free EBSS medium was added, supplemented with 0.75 mM oleate complexed to albumin (final concentration 1%), 1 mM pyruvate, 10 mM lactate, 10 nM dexasmethasone, and antibiotics. When [$^{14}$C]-oleate was added the final specific radioactivity of the fatty acid was 0.035 μCi/μmol. After 18 h, the medium was removed and the cells were washed. Fresh medium containing different supplements, as indicated, was added, and the cellular and secreted radiolabeled lipids were quantified for the periods indicated, also as described previously (7).

*Measurement of TAG secretion rates from exogenous and endogenous sources*. The respective contributions of exogenous and endogenous acyl moieties to the secreted TAG were quantified, after extraction and separation of lipids, as described by Lankester *et al*. (7). Cellular TAG were quantified at each experimental time-point so as to obtain the specific activity of endogenous acyl moieties. Secretion rates were expressed in terms of nanomoles of fatty acid equivalent, so that utilization of endogenously generated oleoyl moieties would be directly comparable to that calculated for exogenously added oleate. Preliminary experiments established that all the secreted TAG were associated with VLDL; therefore, routinely no separation of the lipoprotein particles was performed. Incorporation of [$^{3}$H] and [$^{14}$C] labels into cellular and secreted phospholipid was also measured. Routinely, secretion of labeled phospholipid was very low and was negligible compared to that of TAG. Acid-soluble oxidation products, which under these conditions represented >95% of the total oxidation products, were measured after acid precipitation of the fatty acid substrate from solution (7).

*Measurement of apoB synthesis and degradation rates.* Hepatocytes cultured for 18 h as described above were washed and incubated in 3 mL of methionine-free EBSS medium. For the measurement of the rate of synthesis of apoB, the medium was then replaced by 1 mL of methionine-free supplemented medium to which was added 0.75 nmol of [$^{35}$S]methionine (1.14 mCi/μmol); the incorporation of label into cellular protein was allowed to proceed for 20 min, at which time the cells were solubilized by addition of 1.5 mL of a solution containing 100 mM NaCl, 5 mM EDTA, 10 mM $K_2HPO_4$, 1% Triton X-100, 0.5% deoxycholate, 0.1% sodium dodecylsulfate (SDS), and protease inhibitors: 1 μg each of antipain, leupeptin, 5 μg *N*-acetyl-Leu-Leu-Nle-CHO and 1 mM 4-(2-aminoethyl)benzenesulfonylfluoride•HCl. The cell extract was sonicated for 30 s and incubated at 40°C for 30 min to complete solubilization. Aliquots (20 μL) of the solubilized cells were acidified with trichloroacetic acid to precipitate total protein. After being washed twice with cold 95% acetone/water, the precipitated protein pellets were used to quantify incorporation of $^{35}$S into total protein.

ApoB was immunoprecipitated from the rest of the solubilized cell material by incubation with sheep anti-rat apoB antibody (4 h at 0°C) followed by incubation (4°C for 18 h) with donkey anti-sheep IgG antiserum. The immune precipitates were dissolved in medium containing 62 mM Tris-HCl (pH 6.8), 8 M urea, 16 mM dithiothreitol, 2% SDS, and 10% mercaptoethanol, aided by sonication. ApoB48 and apoB100 were separated by SDS-polyacrylamide gel electrophoresis as described in Reference 15. Quantification of the radioactivity associated with intact apoB48 and apoB100 was performed by phosphorimage analysis.

*Materials.* Culture media and amino acid, vitamin, and antibiotic solutions were obtained from Gibco (Irvine, Scotland). TAG assay kits were obtained from Sigma (Dorset, United Kingdom). Radiochemicals were obtained from NEN Life Science Products (Hounslow, United Kingdom).

## RESULTS AND DISCUSSION

*Effect of exogenous oleate on the use of endogenous acyl moieties for TAG secretion*. When cells were precultured overnight with [$^{14}$C]oleate, they accumulated [$^{14}$C]TAG and phospholipid intracellularly (7,16). After washing and re-incubation with fresh medium from which oleate was absent, the cells secreted [$^{14}$C]-labeled TAG linearly for at least 3 h (basal rate; Fig. 1A). Addition of oleate (0.75 mM) to the fresh incubation medium at the start of this 3 h period increased the rate of secretion of endogenous ($^{14}$C-labeled) moieties within TAG by 55% (Fig. 1A). In addition, when the exogenously added oleate was $^{3}$H-labeled, it too contributed acyl moieties (about 20% of the total, Fig. 1B) toward TAG secretion (Fig. 1B). Consequently, the overall rate of TAG secretion (from endogenous and exogenous acyl moieties) was increased twofold by the addition of oleate (compare filled symbols in Figs. 1A and 1B), with more than half the stimulation being due to the enhanced secretion of endogenous, prelabeled acyl moieties.

*Secretion of TAG after depletion of ER $Ca^{2+}$*. Depletion of the thapsigargin-sensitive $Ca^{2+}$ store of the ER resulted in inhibition of the utilization of both endogenous and exogenous acyl moieties for TAG secretion (Fig. 2A,B, respectively). However, the pattern of inhibition was different for the two sources. Secretion of [$^{14}$C]oleoyl moieties continued for at least 30 min, after which it was totally inhibited. By contrast,

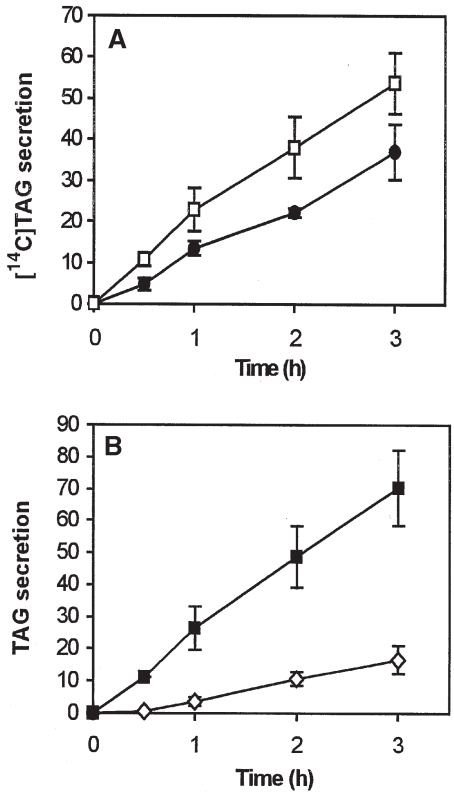

**FIG. 1.** The effect of oleate addition on the secretion of endogenous oleoyl chains within triacylglycerol (TAG). In (A) hepatocytes were cultured for 18 h in the presence of 0.75 mM [$^{14}$C]oleate. They were then washed and incubated for 3 h in fresh medium in the absence (●) or presence (□) of 0.75 mM 9,10[$^{3}$H]oleate. In (B) the rate of appearance of $^{3}$H-labeled acyl chains (◇) within secreted TAG is shown together with total ($^{14}$C- plus $^{3}$H-labeled) TAG secretion (■). Values are expressed as nmol fatty acid per mg of cell protein and are means (± SEM) for three separate preparations, each of which was analyzed in duplicate.

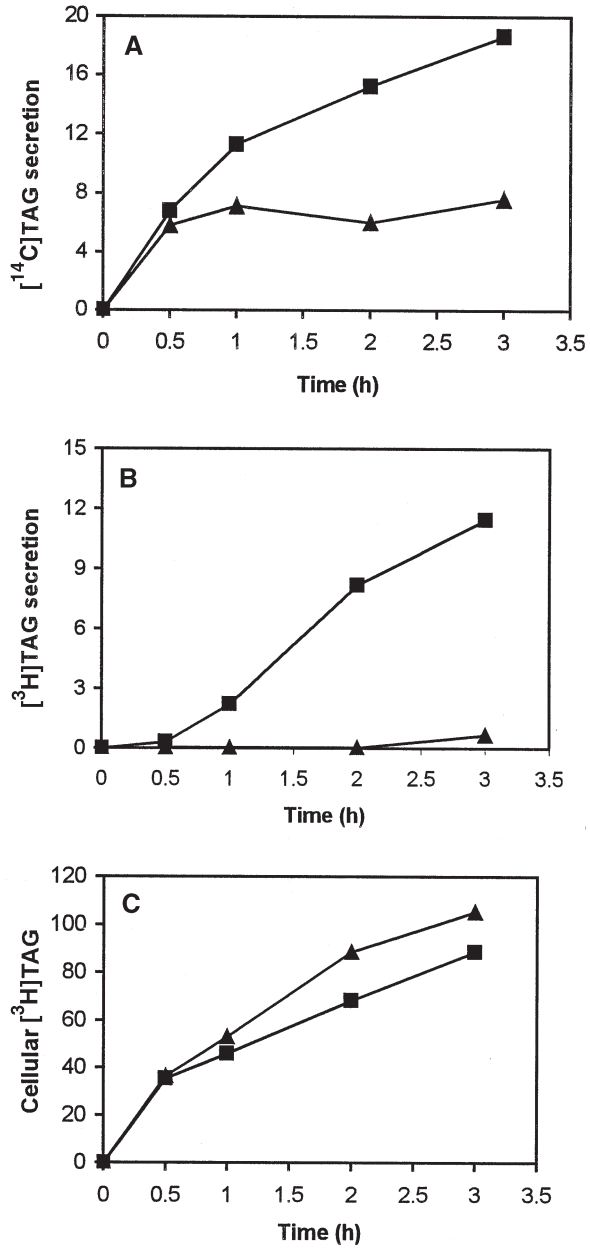

**FIG. 2.** The effects of thapsigargin on the time courses for the secretion and intracellular accumulation of TAG. Cells were prelabeled with [$^{14}$C]oleate for 18 h, washed, and incubated for the indicated times with 0.75 mM [$^{3}$H]oleate in the presence (▲) or absence (■) of thapsigargin. (A) Secretion of $^{14}$C-labeled TAG; (B) secretion of $^{3}$H-labeled TAG; (C) accumulation of $^{3}$H-labeled TAG within the cell. They are from an experiment representative of three similar experiments performed on separate cell preparations. See Figure 1 for abbreviation.

secretion of [$^{3}$H]oleoyl moieties was totally inhibited immediately upon addition of thapsigargin at zero time. Importantly, however, this was achieved without inhibition of TAG synthesis from exogenous [$^{3}$H]oleate (Fig. 2C), which in fact showed a small stimulation, presumably because acyl groups were diverted from TAG secretion to cytosolic TAG accumulation (7). These combined data indicated that depletion of ER $Ca^{2+}$ inhibited the further formation of new lipoprotein particles without inhibiting either (i) the secretion of TAG already within the secretory pathway or (ii) the cellular synthesis of TAG. Thus, the continued secretion of $^{14}$C-labeled TAG for 30 min after addition of thapsigargin is suggested to represent the emptying, from the ER, of secretion-competent [$^{14}$C]TAG pools already present within the secretory compartment prior to the addition of thapsigargin. These intra-ER pools of prelabeled TAG would have included TAG within the nascent apoB-containing particles present within the rER, and non-apoB-associated TAG within the lipid globules of the sER (2–4). The abrupt cessation of [$^{14}$C]TAG secretion after 30 min suggests that, when one or the other of these pools became exhausted, secretion ceased. Since synthesis of TAG was not affected by addition of thapsigargin (Fig. 2C), it would be expected that synthesis of non-apoB-associated TAG within the sER would not have been affected and that this apoB-free pool of TAG would not have become limiting. It is likely therefore that it was the availability of apoB-associated (nascent particle) TAG within the rER that became exhausted after the 30-min time. The time required to empty this pool (approximately 30 min; see Fig. 2A) is of the same order

as that required for assembly of VLDL particles (17). In cells precultured overnight with [$^{14}$C]oleate, the secretion-competent pool of TAG resident within the ER that continued to be secreted after addition of thapsigargin may be calculated to represent approximately 3% of the total cellular TAG.

Thapsigargin inhibits the $Ca^{2+}$-ATPase of the ER (18,19) and therefore produces complete depletion of the relevant pool of $Ca^{2+}$. To verify that inhibition of entry of acyl moieties in newly secreted TAG was proportional to the inhibition of a parameter affected by $Ca^{2+}$ mobilization, we tested conditions that mobilize the ER $Ca^{2+}$ pool suboptimally, as described previously (14). These conditions included additions of hormones and agonists that activate ER $Ca^{2+}$ mobilization, as well as 2,5-di(*tert*-butyl)-1,4-benzohydroquinone (tBuBHQ), another inhibitor of the ER $Ca^{2+}$-ATPase (20), in the presence or absence of extracellular $Ca^{2+}$ (Figs. 3,4). The data in Figure 3 show that submaximal depletion of this pool resulted in partial inhibition of the entry of exogenous [$^3$H]oleate into the secretory pathway. The competition between synthesis of cellular (cytosolic) TAG and of secretory TAG for a common intermediate—suggested to be cytosolic DAG (7)—is indicated by the inverse relationship between the graded effects of $Ca^{2+}$ mobilization on the two parameters (Fig. 3A,B). Qualitatively similar inhibition of [$^{14}$C]TAG secretion was also observed (not shown).

*Role of the inhibition of apoB synthesis in the inhibition of TAG secretion by $Ca^{2+}$ mobilization*. The observation that submaximal $Ca^{2+}$ mobilization from the ER resulted in a graded inhibition of the entry of exogenous oleate into the secretory pathway (Fig. 3A) suggested that the inhibition of TAG secretion was due to the inhibition of apoB synthesis, especially since it is well-established that $Ca^{2+}$ mobilization from the ER inhibits the initiation of protein synthesis (21). When the initial rates of incorporation of [$^{35}$S]methionine into apoB48 and apoB100 were measured, inhibition of TAG secretion was found to be proportional to inhibition of apoB synthesis (Figs. 4A–D). This relationship was particularly strong between the rate of incorporation of [$^{35}$S]methionine into apoB48 and the rate of TAG secretion (Fig. 4A,B) as would be expected from the fact that, under the present culture conditions, more than 80% of total apoB secreted was as apoB48 (22). In contrast to [$^3$H]oleate incorporation into secreted TAG, a residual amount of secreted endogenous $^{14}$C-label was insensitive to the inhibition of apoB synthesis (Fig. 4A,C) as would be expected if this residual secretion of [$^{14}$C]TAG were due to the emptying of the $^{14}$C-labeled TAG already present within the ER before the addition of thapsigargin. Importantly, in parallel experiments $Ca^{2+}$ mobilization (in the presence or absence of exogenous oleate) was shown not to affect apoB degradation (data not shown). One may conclude that under conditions of constant apoB degradation, modulation of the rate of apoB synthesis is able to exert strong control over the rate of TAG secretion by becoming rate-limiting for the formation of nascent particles. The observation that both apoB synthesis and [$^3$H]TAG secretion were fully inhibited in the presence of thapsigargin (Fig. 4B,D) explains the instantaneous inhibition of the incorporation of exogenous [$^3$H]oleate into secreted TAG upon addition of the $Ca^{2+}$-ATPase inhibitor at zero-time (Fig. 2B) as expected if, under these conditions, no further nascent particle formation occurred.

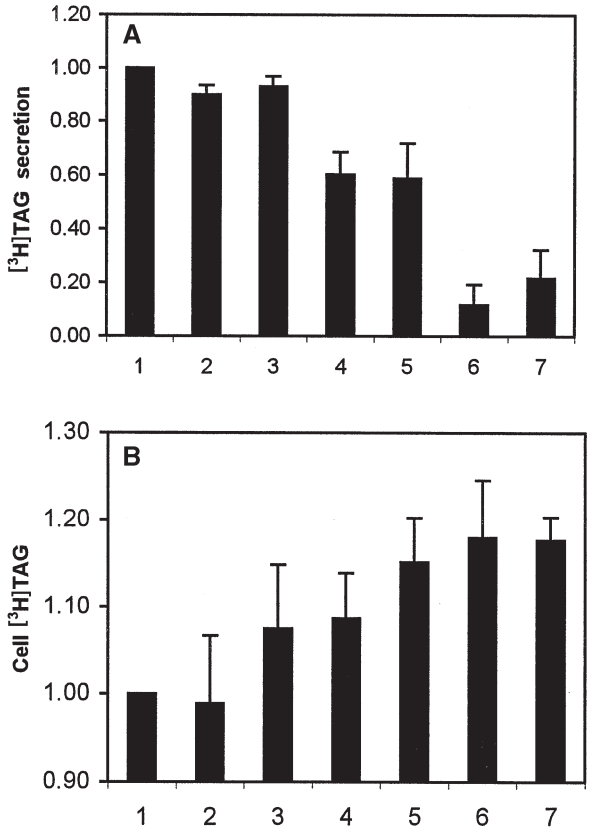

**FIG. 3.** The effect of increasing the degree of $Ca^{2+}$ mobilization in cultured rat hepatocytes on the incorporation of $^3$H-labeled acyl chains into (A) secreted TAG and (B) cellular TAG. Hepatocytes were cultured for 18 h in the presence of 0.75 mM oleate. They were then washed and incubated for 3 h in medium containing 0.75 mM 9,10[$^3$H]oleate. The incorporations of the label into (A) secreted and (B) cellular TAG were measured after 3 h. The acyl chain equivalents (nmol fatty acid/mg cell protein) secreted or accumulated were calculated from the specific activity of exogenous [$^3$H]oleate; see the Materials and Methods section. Values are expressed relative to those of paired control incubations and are means (±SEM) for four separate hepatocyte preparations. Those for control incubations have been set at unity. Conditions were: (1) Control medium, (2) plus 10 nM glucagon, (3) 100 nM vasopressin, (4) 10 nM glucagon plus 100 nM vasopressin, (5) 1 nM phenylephrine plus 10 nM glucagon, (6) 25 μM 2,5-di(*tert*-butyl)-1,4-benzohydroquinone or (7) 100 μM thapsigargin. All dishes had a final concentration of 0.1% dimethylsulfoxide, which was used as solvent for some of the additions. For other abbreviation see Figure 1.

There was a degree of selectivity in the inhibition of [$^{35}$S]-methionine incorporation into apoB48 or apoB100, in that the inhibition of incorporation into total protein was much smaller for any condition tested (approximately 30% of that into the apoB proteins). This may have arisen partly from the fact that $Ca^{2+}$ mobilization inhibits protein synthesis initiation but not peptide chain elongation (23). Therefore, $Ca^{2+}$ mobilization would be expected to have a disproportionate effect on [$^{35}$S]-

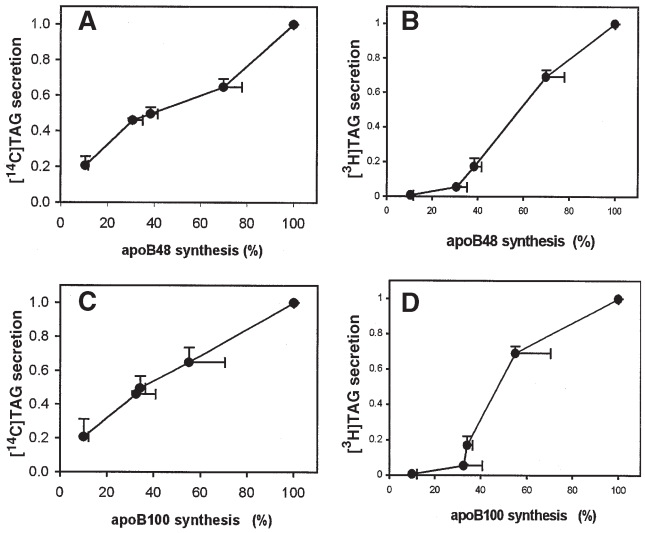

**FIG. 4.** Dependence of TAG secretion on the rate of apoB48 and B100 synthesis in cultured rat hepatocytes subjected to different extents of $Ca^{2+}$ mobilization. In parallel experiments either TAG secretion rates from endogenous ($^{14}C$) and exogenous ($^{3}H$) acyl sources were measured over 3 h or the initial rate of [$^{35}S$]methionine incorporation into apoprotein B48 (apoB48) and apoB100 was quantified under various conditions (control, plus glucagon and phenylephrine, minus calcium chloride, plus EGTA, plus thapsigargin; see legend to Fig. 3). The relationships of the rates of secretion of [$^{14}C$]TAG (A,C) and of [$^{3}H$]TAG (B,D) to the syntheses of apoB48 (A,B) or apoB 100 (C,D) are shown. Values are expressed relative to the rates observed for paired incubations performed in control media, which are set to unity. Data are means (±SEM) for three separate cell preparations. Where the error bars do not show they lie within the symbol.

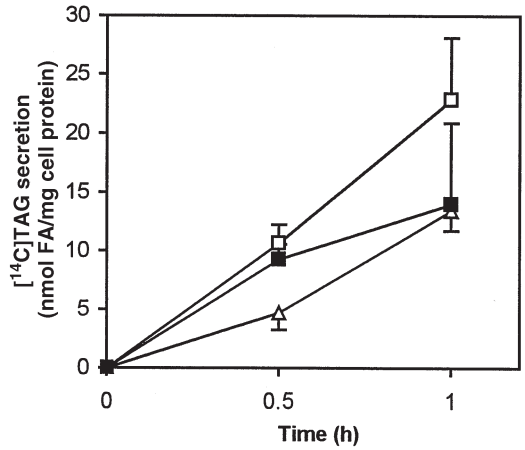

**FIG. 5.** Effect of exogenously added oleate on the rate of TAG secretion from endogenous acyl moieties in the presence or absence of thapsigargin. Cells were prelabeled by culture for 18 h in the presence of 0.75 mM 1[$^{14}C$]oleate. They were then washed and incubated for the times shown either in the absence (△, basal secretion) or the presence of 0.75 mM oleate and either in the absence of thapsigargin (□) or in its presence (100 μM, ■). Data are means (±SEM) for three separate cell preparations. FA, fatty acid; for other abbreviation see Figure 1.

methionine incorporation into larger proteins (e.g., apoB48 and apoB100) with longer chain-elongation times (22).

*Effect of exogenous oleate on the secretion of TAG present within the secretory pathway.* The inability of $Ca^{2+}$ mobilization to inhibit the secretion of [$^{14}C$]TAG already within the secretory pathway while inhibiting the synthesis of apoB enabled us to test the effect of exogenous oleate on the rate of emptying of secretion-competent TAG from the secretory pathway. Figure 5 shows time courses for the secretion of prelabeled, endogenous [$^{14}C$]-labeled moieties within TAG in the presence and absence of exogenous oleate added at zero time. In the absence of thapsigargin, the addition of exogenous oleate markedly stimulated the rate of secretion of [$^{14}C$]TAG (Fig. 1). In the presence of thapsigargin, the initial rate of [$^{14}C$]TAG secretion was equally stimulated (compare 30-min time-points in Fig. 5). Because addition of thapsigargin inhibited entry of acyl groups into the secretory pathway (Fig. 2B) the stimulation of [$^{14}C$]TAG secretion occurred under conditions in which (i) the exogenous oleate itself made no contribution toward overall TAG secretion and (ii) new apoB synthesis was maximally inhibited (Fig. 4). Thus, these data show that the stimulation by exogenous oleate of the rate of secretion of endogenous acyl chains involved a stimulation in the rate of processing, or emptying, of [$^{14}C$]TAG through the secretory pathway. That exogenous oleate did not affect the size of the secretion-competent pool of [$^{14}C$]TAG thus emptied (compare lower two curves in Fig. 5), but only the rate at which it was secreted, suggests that the accelerated emptying of the [$^{14}C$]TAG resident within the ER was not due to recruitment of additional TAG stores within the ER. Instead, accelerated emptying may have been due to indirect activation of the emptying of the ER by an increase in the concentration of an effector metabolite of oleate (e.g., oleoyl-CoA) within the ER lumen rather than to a direct mass-action effect. Previous studies ruled out the possibility that such a metabolite could act by altering the stability of apoB in rat hepatocytes (24), as confirmed in ths study, but other processes, such as second-step lipidation of the nascent particles by the non-apoB-associated TAG within the sER, may be affected by a metabolite generated from exogenous oleate. The identity of such a putative effector is currently under study.

Even when the contribution of cytosolic droplet TAG lipolysis is abolished—by inhibition of the entry of acyl moieties into the secretory pathway that accompanies the inhibition of apoB synthesis—exogenous oleate still stimulates TAG secretion from endogenous sources distal to apoB synthesis and therefore to nascent particle assembly. We conclude that this (these) pool(s) of TAG occur(s) within the secretory pathway itself. That this TAG secretion continued for the same time that it takes to assemble and secrete VLDL particles and that the total amount of TAG secreted was the same, irrespective of its rate of secretion (Fig. 5), suggest that the amount of TAG secreted, after inhibition of apoB synthesis, is determined by the amount of secretion-competent apoB already present within the ER before mobilization of $Ca^{2+}$ occurs.

# Necrosis and Apoptosis in Lymphoma Cell Lines Exposed to Eicosapentaenoic Acid and Antioxidants

**Hilde Heimli, Hanne S. Finstad, and Christian A. Drevon***

Institute for Nutrition Research, University of Oslo, Norway

**ABSTRACT:** The present study is focused on the role of oxidative stress in the induction of either necrosis or apoptosis by eicosapentaenoic acid (EPA) in the lymphoma cell lines Raji and Ramos, respectively. To investigate the different death modes induced by EPA, we assessed the importance of some antioxidants and reactive oxygen species in the two cell lines. We observed that different antioxidants counteracted the necrotic effect of EPA on Raji cells to a different extent, and that vitamin E counteracted EPA-induced accumulation of superoxide anion in this cell line. On the contrary, no effects of antioxidants were observed on development of apoptosis induced by EPA in Ramos cells, and vitamin E did not counteract EPA-induced accumulation of superoxide anions in Ramos cells. Moreover, apoptosis was partly inhibited by transcription inhibitors (actinomycin D) and protein synthesis inhibitors (cycloheximide), suggesting dependency upon new protein synthesis prior to apoptosis. Kinase inhibitors (staurosporin and calphostin C) did not alter the EPA-induced apoptosis. The observed cellular accumulation of superoxide anion following EPA incubation may be important for induction of necrosis in Raji cells. In contrast, none of the other investigated parameters indicated a role of oxidative stress promoted by EPA in the induction of apoptosis in Ramos cells.

Paper no. L8516 in *Lipids 36,* 613–621 (June 2001).

Cross-sectional epidemiological studies suggest that n-3 fatty acids may protect against development of cancer in colon, breasts, and the prostate gland (1,2). Furthermore, reductions in tumor growth and metastasis have been observed in animals fed n-3 fatty acids (3–5). These effects may be due to reduced cell multiplication, as observed in several cancer cell lines derived from breast, colon, prostate, and lung incubated with polyunsaturated fatty acids (PUFA) (6–9). In some of these studies different sensitivity to PUFA has been reported (9–11). This was also observed when we studied the sensitivity of 14 different leukemia/lymphoma cell lines to incubation with PUFA (12). In 10 of these cell lines, reduced cell multiplication was observed with 30–60 μM of arachidonic acid (AA, 20:4n-6), eicosapentaenoic acid (EPA, 20:5n-3), or docosahexaenoic acid (22:6n-3), whereas four cell lines were resistant to PUFA. The sensitivity to fatty acids was specific for PUFA as none of the cell lines was sensitive to oleic acid (18:1n-9) or stearic acid (18:0) (13). The reduction in cell number with PUFA could be due to modulation of cell differentiation and proliferation as well as to induction of apoptosis or necrosis. In the promyelocytic HL-60 cell line, differentiation was accompanied by both apoptosis and necrosis after incubation with EPA or AA (13). In Raji cells EPA induced necrosis, whereas apoptosis predominantly was observed in Ramos and U937-1 cells based on data obtained by staining with propidium iodide (PI) and Hoechst 33342 (HO342) and flow cytometry (12,14). Thus, the same bioactive molecule (EPA) induces different biological responses in different cell types. We also have reported that addition of a single dose of vitamin E counteracted necrosis induced by EPA in Raji cells, whereas vitamin E had no effect on EPA-induced apoptosis in Ramos cells (12).

Although growth inhibition of several tumor cell lines has been observed, the molecular mechanisms by which PUFA execute their anticarcinogenic effects still are unknown (10,12,15). Oxidation products of PUFA may contribute to some of the reported effects, whereas deficiencies in cellular antioxidant defense systems may enhance the sensitivity of tumor cells (16). Cells are equipped with a repertoire of antioxidant enzymes, e.g., superoxide dismutase, catalase and glutathione peroxidase, as well as small antioxidant molecules that are mostly derived from fruits and vegetables, including tocopherols, flavonoids, carotenoids, ubiquinol and glutathione (17). Potentially lethal cellular injury can occur if these defense systems are overwhelmed. Accumulation of reactive oxygen species due to incubation with PUFA may cause lipid peroxidation, which may result in a range of products that can be deleterious to cells. Whereas massive amounts of oxidized lipid products are thought to cause gross structural or metabolic damage, moderate amounts may initiate a stress signal cascade inducing cellular death programs leading to apoptosis (18). Lipid peroxidation has been linked to a variety of diseases, including atherosclerosis, ischemia-reperfusion injury, cancer (19), and degenerative disorders like Alzheimer's and Parkinson's diseases and Down's syndrome (20–22) In addition to reactive oxygen species, several other mediators of apoptosis have been identified, e.g., CD95 ligand and receptor, damaged DNA, and ceramide (23–25). The different signals promoting apoptosis may utilize common pathways including caspases (26). During the apoptotic process a series of stereotypic mor-

phological changes occur, like condensation and fragmentation of nuclear chromatin and decrease in cell volume and alteration in the plasma membrane, which cause recognition and phagocytosis of apoptotic cells. In contrast, the necrotic process promotes cell swelling and bursting before release of cell content, which may induce inflammatory response.

The aim of the present study is to elucidate mechanisms by which EPA causes cell death, using Raji and Ramos cells as models for necrosis and apoptosis. We describe the effect of EPA and antioxidants in relation to necrotic and apoptotic cell death. Our experiments demonstrate that EPA-induced necrosis may be counteracted by antioxidants up to 24 h after addition of EPA. On the contrary, we found no effect of antioxidants on EPA-induced apoptosis. Our experiments furthermore indicate that selenium-induced glutathione peroxidase (GSHPx) and protein kinase are not essential for EPA-induced apoptosis.

## MATERIALS AND METHODS

*Materials.* EPA, fatty acid-free bovine serum albumin (BSA), PI, HO342, vitamin E, vitamin C, butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), propyl gallate, *N*-acetyl-cysteine (NAC), *N-tert*-butyl-2-sulfo-phenylnitrone (SPBN), sodium selenite, dihydroethidium (DHE), and 2,7-dichlorofluorescein diacetate were purchased from Sigma Chemical Co. (St. Louis, MO). Phosphate-buffered saline (PBS), RPMI-1640, fetal calf serum (FCS), L-glutamine, and gentamycin were bought from BioWhittaker (Walkersville, MD). Other chemicals were analytical grade from commercial suppliers. Fujichrome Provia 400 professional color reversal film was supplied from Fuji (Tokyo, Japan). The In Situ Cell Detection kit Fluorescein was purchased from Boehringer Mannheim (Mannheim, Germany).

*Cells*. The leukemic cell lines Raji and Ramos were purchased from BioWhittaker, and cultured in suspension in RPMI-medium supplemented with 10% heat-inactivated FCS, l-glutamine (2 mmol/L), and gentamycin (0.1 mg/mL). Cells were incubated with fatty acids complexed to BSA at a molar ratio of 2.5:1 and then added to regular RPMI medium. The cells were routinely kept in logarithmic growth at 0.2–1.2 $\times 10^6$ cells/mL. For experiments, cells were seeded at a density of $0.3 \times 10^6$ cells/mL. Cell count experiments were performed in duplicate by use of a Coulter Z1 counter (Coulter Electronics Limited, Luton, Bedfordshire, United Kingdom). Cell cultures incubated without fatty acids were used as control in all cell-count experiments and defined as 100%. The effect of certain compounds on cell number was presented as percentage of control. A concentration of 0.1% ethanol, used in the experiments with vitamin E and BHT, affected neither cell viability nor cell multiplication.

*Cell viability*. For microscopic analyses of cell viability (27) 1 mL of the cell cultures was first incubated with 10 µL of PI (0.5 mg/mL) in the dark for 30 min. Thereafter, 10 µL of HO342 (1 mg/mL) was added to the same cultures and incubated for another 30 min in the dark. Staining with PI indicated leaky plasma membranes since this dye cannot cross intact cell membranes. HO342, however, crosses intact as well as distorted plasma membranes and stains the nuclei in all cells; it stains most strongly nuclei with DNA-damage. After staining, the cells were sedimented at $514 \times g$ for 5 min in a swing-out rotor, and the medium was removed. After washing in PBS and resedimentation, the cell pellets were resuspended in 10 µL of pure FCS. Drops of the cell suspensions were placed on a microscope slide and air-dried before at least 200 cells were counted in a Leitz Ortholux II fluorescence microscope (Leica, Wetzlar, Germany). The cells were photographed with Fujichrome Provia 400 professional color reversal film with an MPS 48/52 camera (Leica Mikroskopie und Systeme, Wetzlar, Germany). The film was exposed as 800 ISO, but developed as 400 ISO. DNA fragmentation was quantified by terminal deoxynucleotidyl transferase (TdT)-mediated dUTP-biotin nick end labeling (TUNEL) using the In Situ Cell Death Detection kit and a FACScan Flowcytometer (Becton Dickinson, San Jose, CA) (28). Five thousand cells from each culture were analyzed.

*Detection of superoxide anion*. Superoxide anion was quantified by DHE in a final concentration of 0.01 µg/mL. After adding the staining solution, the cells were incubated for 15 min at room temperature under an aluminum foil tent before the cells were fixed in 2% paraformaldehyde. Red fluorescence from oxidized ethidium was visualized by fluorescence microscopy (FACScan Flowcytometer) in a total of 10,000 cells per sample. Data were processed using Consort 32 Lysis II software (Becton Dickinson). The percentage of ethidium-positive cells was determined by flow cytometry.

*Determination of GSHPx activity*. GSHPx activity was determined by an assay that couples the reduction of peroxides and the oxidation of glutathione with the reduction of oxidized glutathione by glutathione reductase, using NADPH as a cofactor. Hydroperoxide reduction was followed by a decrease in NADPH absorbance at 340 nM (29).

*Statistics*. Student *t*-test was used to determine the significance level of differences between sample groups. The level of significance was set to $P \leq 0.05$. Results are presented as means ± standard deviation (SD).

## RESULTS

*Antioxidants counteract EPA-induced necrosis in Raji cells, but not EPA-induced apoptosis in Ramos cells.* Raji and Ramos cells were incubated with one of the following antioxidants: 10 µM BHT, 50 µM vitamin E, 20 µM BHA, 100 µM SPBN, 100 µM vitamin C, 1 mM NAC, or 5 µM propyl gallate prior to the addition of 30 µM EPA. Another dose of the respective antioxidants was added to the cells after 12 and 24 h. The cell numbers were counted after 12, 24, and 48 h, and cellular viability was determined after 48 h. EPA in an amount of 30 µM promoted 40% reduction in cell number of Raji cells after 48 h of incubation. Furthermore, EPA induced leaky cell membranes and no sign of nuclear condensation as evaluated by PI and HO342 (12). This indicates necrosis rather than apoptosis (Fig. 1A,B). The reduction in cell num-

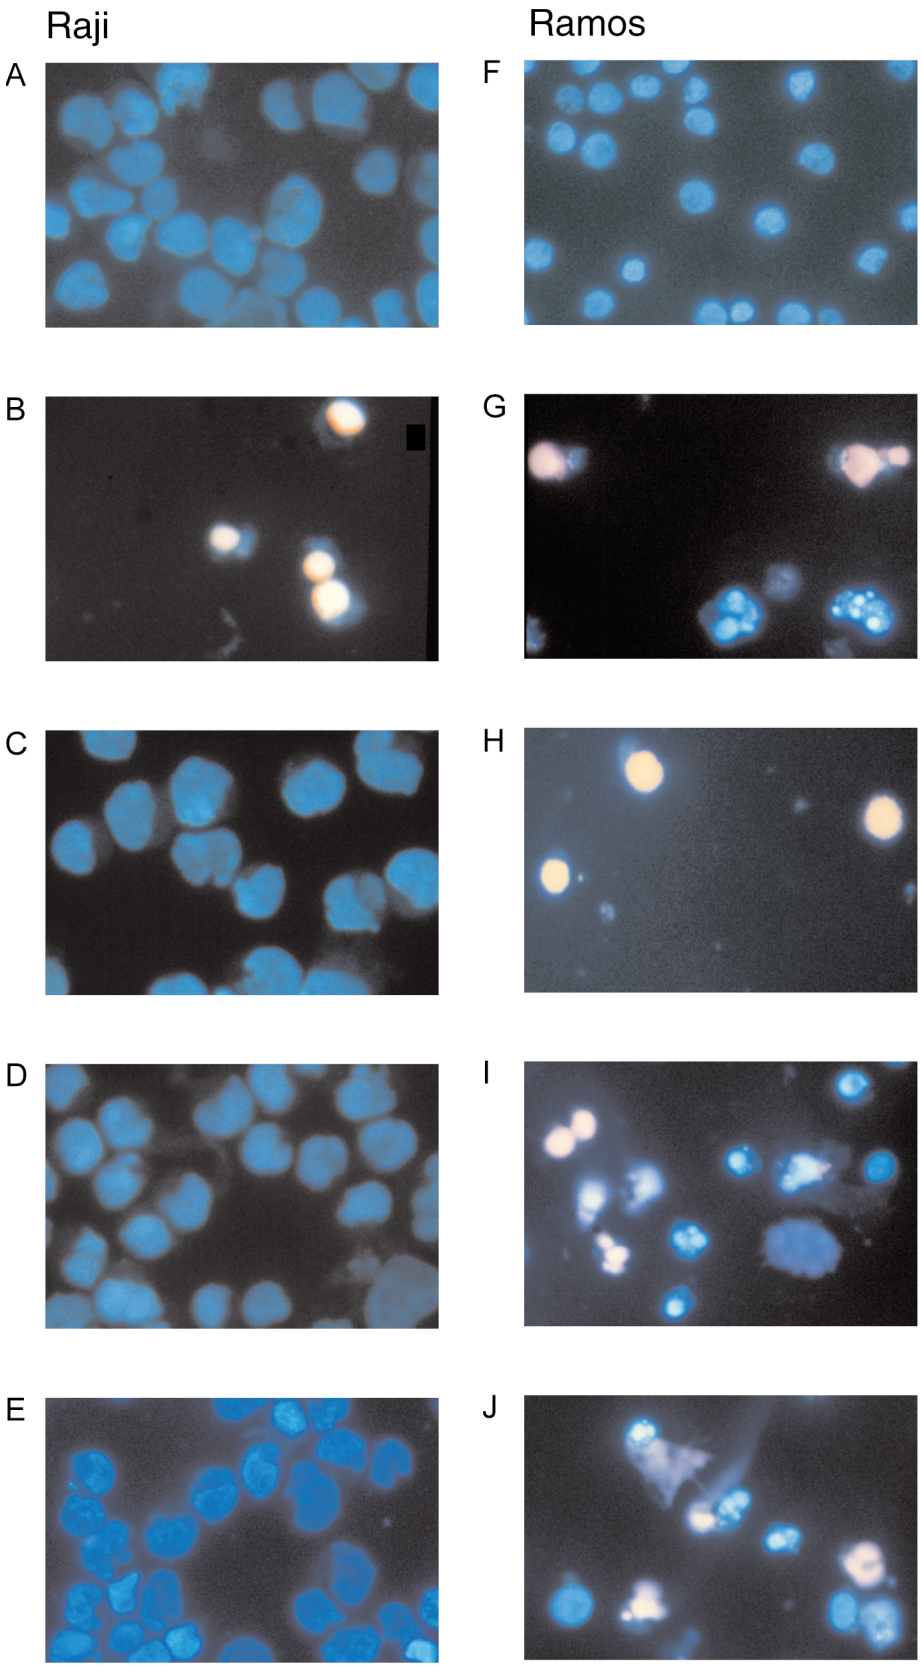

**FIG. 1.** Effect of eicosapentaenoic acid (EPA) with and without antioxidants on Raji (A–E) and Ramos (F–J) cell integrity. Propidium iodide (PI) and Hoechst 33342 (HO342) fluorescence were monitored after 48 h incubation in control cells (A,F), 60 μM EPA (B,G), 100 μM vitamin C + 60 μM EPA (C,H), 50 μM vitamin E + 60 μM EPA (D,I) and 10 μM butylated hydroxytoluene (BHT) + 60 μM EPA (E,J). PI and HO342 associate with DNA and emit red and blue light, respectively, when exposed to ultraviolet (UV) light. Staining with PI indicates leaky plasma membranes since this dye cannot cross intact cell membranes. HO342, however, crosses intact as well as distorted plasma membranes and stains the nuclei in all cells. When HO342 associates with condensed chromatin found in apoptotic cells, the blue color becomes more intense (almost white in the photos). One set of photographs from three separate experiments is shown to provide a qualitative impression about the cellular viability after 48 h.

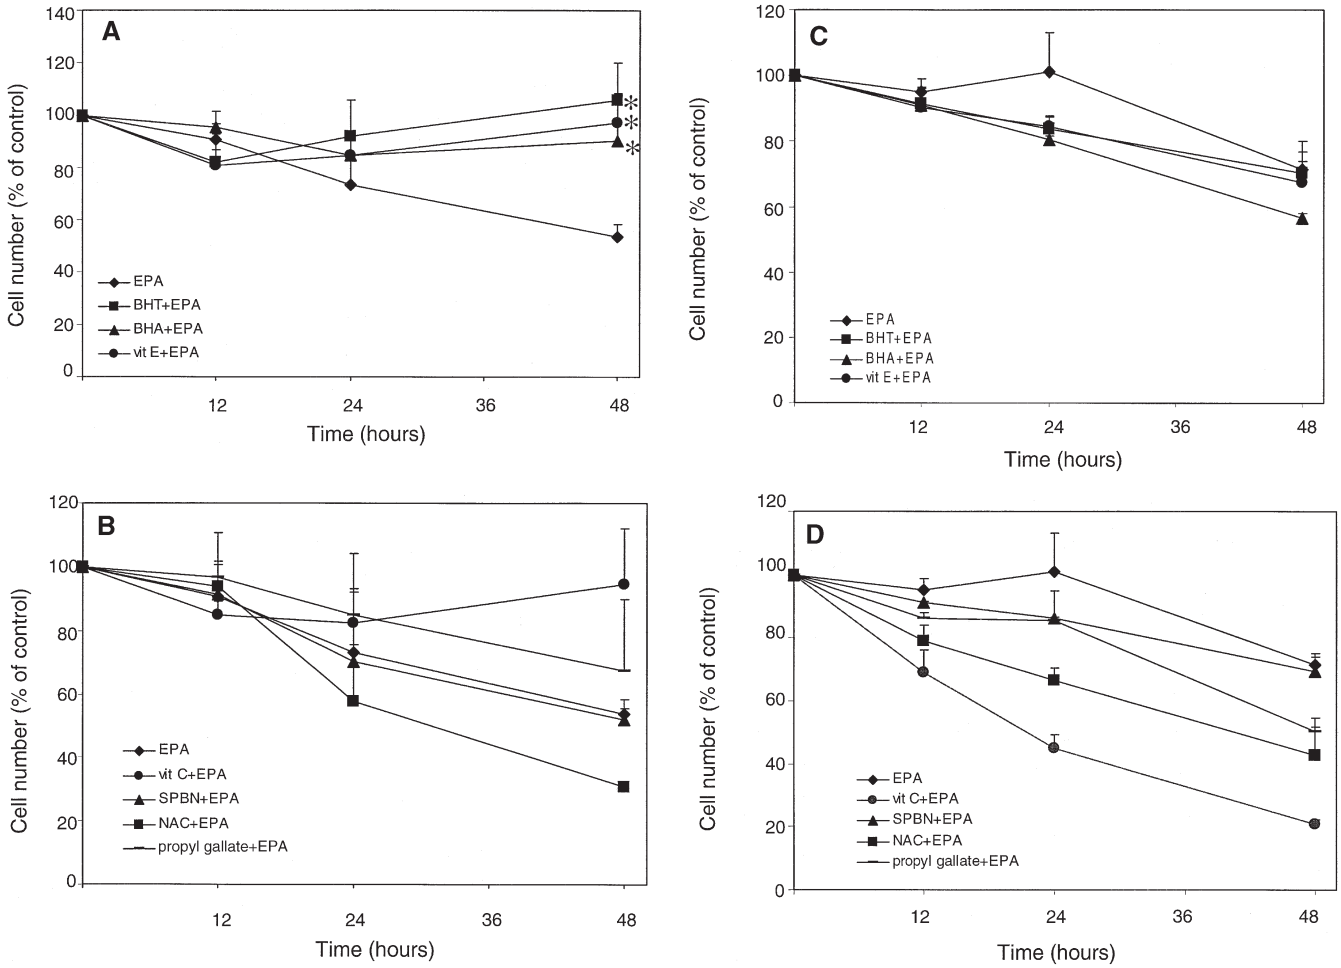

**FIG. 2.** Effect of antioxidants on number of Raji cells (A,B) or Ramos cells (C,D) incubated with EPA. In addition to 30 μM EPA, cells were incubated with water-soluble antioxidants [B,D; 100 μM *N-tert*-butyl-2-sulfophenylnitrone (SPBN), 100 μM vitamin C (vit C), 1 mM *N*-acetylcysteine (NAC) or 5 μM propyl gallate], and lipid-soluble antioxidants [A,C; 10 μM BHT, 50 μM vitamin E (vit E), or 20 μM butylated hydroxyanisole (BHA)]. The antioxidants were added at 0, 12, and 24 h after addition of EPA. Cell numbers were counted at all time points and are presented as percentages of control cells. Data represent means ± SD from triplicates of three separate experiments ($n = 3$). Absolute values for Raji control cells (100%) were 0.38 ± 0.08, 0.57 ± 0.09, and 1.36 ± 0.13 million cells/mL after 12, 24, and 48 h, respectively. For Ramos control cells the absolute values were 0.46 ± 0.11, 0.62 ± 0.17 and 1.44 ± 0.45 million cells/mL. For abbreviations see Figure 1. $^*P \leq 0.05$ compared to EPA-treated cells.

ber and viability of Raji cells was counteracted by BHT, vitamin E, BHA, vitamin C, and to some extent by propyl gallate (Fig. 2A,B). Two of the tested antioxidants did not oppose the EPA-induced reduction in cell number; SPBN had no effect, whereas NAC reduced the cell number more than EPA alone.

The following experiments were limited to the lipid-soluble antioxidants BHT and vitamin E, and the water-soluble vitamin C. The antioxidants were incubated with increasing concentrations of EPA. Incubation of vitamin E or BHT counteracted the effect of 30–60 μM EPA (Fig. 3), whereas vitamin C was less effective than the other antioxidants in counteracting 45 and 60 μM of EPA in Raji cells as evaluated by cell counting. By staining with PI and HO342 to investigate cell integrity, the counteractive effect of vitamin E, vitamin C, and BHT on EPA-incubated Raji cells is clearly demonstrated in Figure 1A–E. It should be noted that there is little difference between the effects of 30 and 60 μM EPA on the number of cells.

In contrast to the marked effects of antioxidants on the EPA-induced necrosis in Raji cells, the antioxidants BHT, vitamin E, and vitamin C had no influence on the apoptotic effect of 60 μM EPA in Ramos cells after 48 h incubation (Fig. 1F–J). Moreover, we found that the lipid-soluble antioxidant BHA did not affect the apoptotic effect of EPA on Ramos cells when counting the cells (Fig. 2C). Incubation of the water-soluble antioxidants SPBN, vitamin C, propyl gallate, and NAC in combination with EPA caused an even greater reduction in cell number compared to Ramos cells incubated with EPA alone (Fig. 2D).

*Effects of vitamin E on EPA-induced necrosis in Raji cells.* We investigated whether the effect of vitamin E differed with preincubation of Raji cells with EPA. Thus, vitamin E (50 μM) was added either at the same time as EPA or after 12 or 24 h incubation. We found that vitamin E added at 12 and 24 h after EPA administration reduced the EPA-induced necrosis to the same extent as when vitamin E was added at the same time as EPA (Fig. 4).

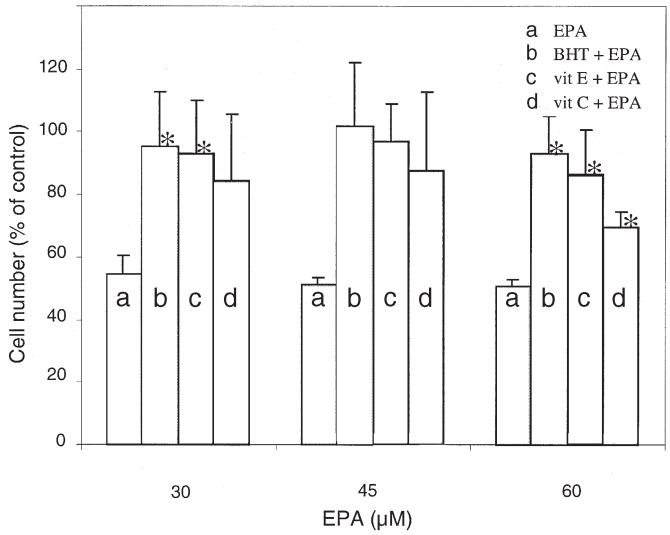

**FIG. 3.** Effect of antioxidants on Raji cells incubated with different concentrations of EPA. BHT (10 μM), vitamin E (50 μM), or vitamin C (100 μM) was added to Raji cells prior to the addition of 30, 45, or 60 μM EPA. The respective antioxidants were added at 0, 12, and 24 h after addition of EPA. Cell numbers were determined after 48 h incubation, and presented as percentages of control cells. Data represent means ± SD from three separate experiments performed in triplicate ($n = 3$). Absolute values for control cells (100%) were 0.45 ± 0.10, 0.56 ± 0.08, and 1.44 ± 0.17 million cells/mL after 12, 24, and 48 h, respectively. For abbreviations see Figure 1. *$P \leq 0.05$ compared to EPA-treated cells.

Furthermore, we wanted to investigate whether preincubation with vitamin E prevented EPA-induced cell death. Therefore, Raji cells were incubated with vitamin E (50 μM) for 1 h, then washed twice and reincubated in the presence of EPA (30 μM) for 48 h. We found that the cell number was 89 ± 21% ($n = 3$) in Raji cells preincubated with vitamin E before addition of EPA, whereas the cell number in EPA-administered cells was 43 ± 14% ($n = 3$) as compared to control cells.

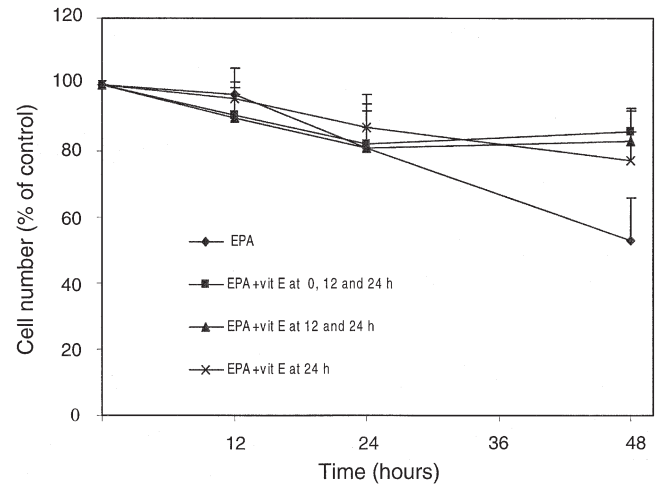

**FIG. 4.** Effect of preincubation of Raji cells with EPA before vitamin E administration. Vitamin E (50 μM) was added either three times (0, 12, and 24 h), two times (12 and 24 h), or one time (24 h) after incubation with EPA (60 μM). Data represent means ± SD from three separate experiments performed in triplicate ($n = 3$). Absolute values for control cells (100%) were 0.34 ± 0.09, 0.78 ± 1.15, and 1.92 ± 0.32 million cells/mL after 12, 24, and 48 h, respectively. For abbreviation see Figure 1.

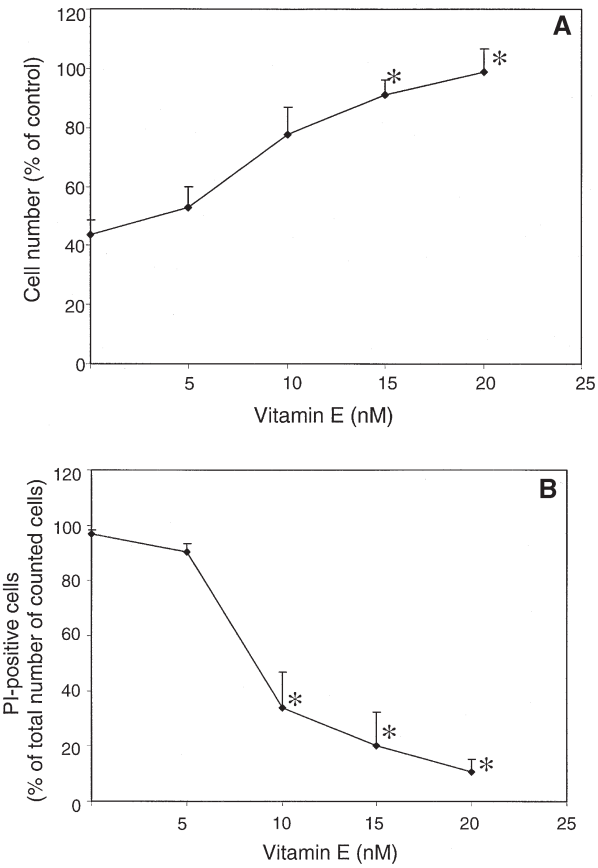

**FIG. 5.** Effect of EPA and different concentrations of vitamin E on number (A) and (B) integrity of Raji cells. Vitamin E was added at 0, 12, and 24 h after incubation with 30 μM EPA. Cell numbers and cell integrity were determined after 48 h incubation, and presented as percentage of control cells (incubated without EPA). Data represent means ± SD from three separate experiments performed in duplicate ($n = 3$). Absolute values for control cells (100%) in part A were 1.39 ± 0.18 million cells/mL. PI, propidium iodide; for other abbreviation see Figure 1. *$P \leq 0.05$ compared to EPA-treated cells.

To determine the concentration of vitamin E necessary to prevent EPA-induced necrosis, Raji cells were incubated with 5–20 nM prior to addition of 30 μM EPA. Vitamin E prevented the reduction in cell numbers in a dose-dependent manner as well as the development of necrosis promoted by EPA (Fig. 5A,B).

*Superoxide anion in necrotic and apoptotic cells incubated with EPA.* The opposing effect of antioxidants on EPA-induced cell death may indicate an elevated level of intracellular reactive oxygen species. This would be consistent with the report that PUFA interfere with cell signal systems by enhancing the level of reactive oxygen species (10). To address this issue, 50 μM vitamin E was added to Raji and Ramos cells prior to addition of 60 μM EPA. DHE, which fluoresces after oxidation by superoxide anion, was added 12, 24, and 48 h after starting the incubation with EPA. In Raji cells incubated with EPA, 95% of the cells were fluorescent after 48 h incubation. The appearance of fluorescence was completely prevented by vitamin E in cells incubated with EPA (Fig. 6A), indicating that vitamin E acts as an expected antioxidant. Incubation of Ramos cells with 60 μM EPA alone caused 40%

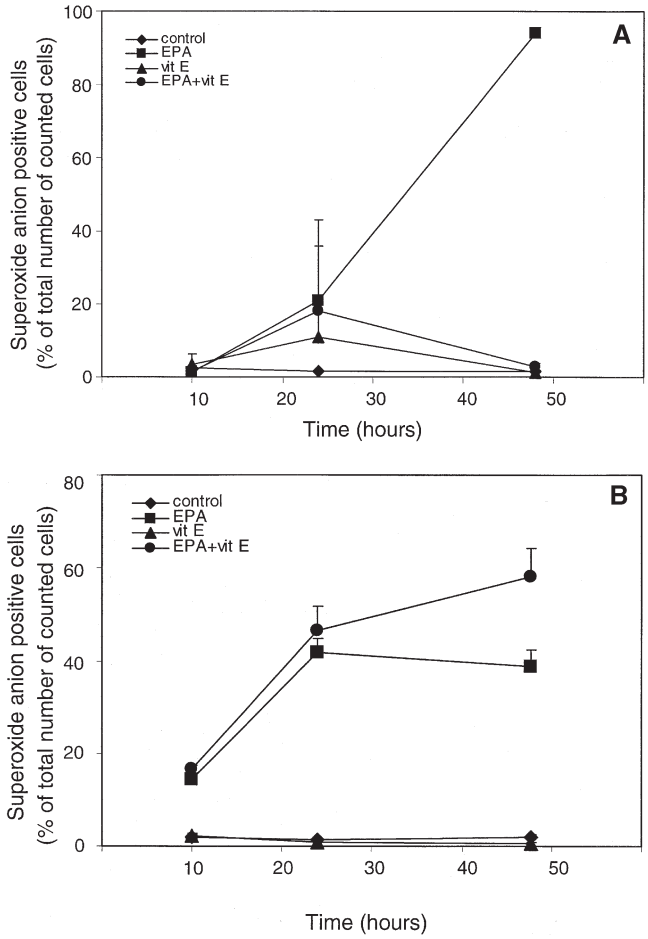

**FIG. 6.** Effect of EPA on superoxide anion level in Raji (A) and Ramos cells (B). Cells were incubated with either control medium, 60 μM EPA, 50 μM vitamin E, or 60 μM EPA + 50 μM vitamin E. Superoxide anion level was measured by flow cytometry after 10, 24, and 48 h. Data represent means ± SD from three separate experiments. For abbreviation see Figure 1.

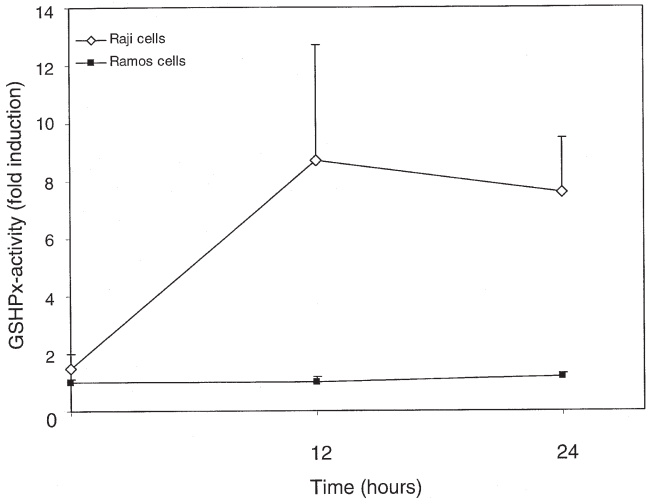

**FIG. 7.** Glutathione peroxidase (GSHPx) activity in cells incubated with 60 μM EPA. Raji and Ramos cells were incubated with 60 μM EPA up to 24 h. GSHPx activity was measured in homogenates of cells, and the data are presented as related to the levels in cells incubated with control medium. Data represent means ± SD from three separate experiments. For other abbreviation see Figure 1.

fluorescent cells, whereas the combination of vitamin E and EPA led to 60% fluorescence (Fig. 6B). These findings indicate that EPA may induce accumulation of superoxide anion in cells undergoing necrosis as well as apoptosis. Addition of vitamin E, however, only prevented development of necrosis and had no significant effect on development of apoptosis.

These experiments showed that we successfully counteracted EPA-induced accumulation of superoxide anion and the onset of necrosis by antioxidants in Raji cells. However, in Ramos cells antioxidants were unable to oppose EPA-induced apoptosis and the accumulation of superoxide anion. Nevertheless, it is possible that local changes in the concentration of reactive oxygen species are influenced by EPA. Therefore, we further evaluated the effects of EPA on glutathione and protein kinase C in Ramos cells.

*Increased GSHPx activity in Raji cells, but not in Ramos cells incubated with EPA*. To further investigate the effects of antioxidant defense mechanisms, we examined the effect of EPA on GSHPx activity. GSHPx uses glutathione as a substrate, and enhanced enzyme activity may protect against cell death caused by PUFA (16). GSHPx is also enhanced by oxidative stress (30,31). Thus, Raji and Ramos cells were treated with 60 μM EPA for 12 and 24 h. This resulted in an eightfold induction of GSHPx activity in Raji cells, whereas no such effect was measured in Ramos cells (Fig. 7). In addition, Raji and Ramos cells were incubated with sodium selenite (pretreatement of 250 nM for 24 h) to induce increased GSHPx activity and then incubated with EPA for another 12 h. This resulted in a 2.5-fold increase in GSHPx activity compared to control cells, whereas there was no protection against EPA-induced cell death (data not shown).

*Inhibitors of transcription and protein synthesis reduced EPA-promoted apoptosis*. Inhibition of either protein or RNA synthesis may prevent or delay apoptosis in different cell types (33,34). We examined whether EPA-induced apoptosis in Ramos cells could be influenced by inhibition of protein synthesis or transcription. Ramos cells were incubated with different concentrations of cycloheximide or actinomycin D, with or without 60 μM EPA. The inhibitors were added 30 min prior to EPA, and after incubation for 24 h cells were HO342-stained to assess apoptosis. Cycloheximide (at 100 nM) and actinomycin D (at 2.4 nM) reduced the apoptotic effect of 60 μM EPA by 21 and 40%, respectively. In addition to microscopic evaluation, we quantified DNA fragmentation by TUNEL-assay using flow cytometry when combining 60 μM EPA and 110 nM cycloheximide. We found that 79% of the cells exhibited fragmented DNA, in accordance with microscopic analyses. That is, with cycloheximide as inhibitor 79 ± 9% of cells showed condensed/fragmented DNA in comparison with EPA-incubated cells (±SD), and with actinomycin D the comparable value was 60 ± 2%.

*Protein kinase C inhibitors did not affect EPA-induced apoptosis*. Protein kinase C activation may reduce as well as promote apoptosis (35). Because PUFA may activate protein

kinase C (36,37) we examined whether inhibition of protein kinases could reduce EPA-induced apoptosis. Calphostin C is an inhibitor of protein kinase C and staurosporin is a potent inhibitor of several types of kinases. Calphostin C (1 nM–1 μM) as well as staurosporin (0.5 nM–0.5 μM) failed to reduce EPA-induced apoptosis in Ramos cells (data not shown).

## DISCUSSION

We observed that EPA caused oxidative stress in the two cell lines Raji and Ramos as evaluated by detection of superoxide anion, but the two cell lines differed in response to antioxidants after incubation with EPA. We demonstrated that several antioxidants effectively reduced the necrotic effect promoted by EPA in Raji cells (Fig. 2A,B). Moreover, vitamin E added up to 24 h after administration of EPA counteracted the effect of EPA in Raji cells. The small amount of vitamin E (20 nM) needed to reduce EPA-induced cell death may be explained by the relative accessibility of vitamin E *in vitro* as compared to the *in vivo* situation. Vitamin E was dissolved in ethanol in our experiments, whereas plasma vitamin E is associated with lipoprotein particles *in vivo* (38). In addition, the amount of cells compared to the number of vitamin E molecules is higher *in vivo* than in our *in vitro* experiments, which also may contribute to the observed effects of low vitamin E concentrations.

Antioxidants counteracted EPA-induced necrosis in Raji cells, suggesting formation of reactive oxygen species by EPA. This is in accordance with other reports suggesting that n-3 fatty acids and their lipid peroxidation products cause cell death in tumor cell lines (10,39). Electron "leakage" from mitochondria during normal oxidase action may give rise to oxidants such as superoxide anion, which *per se* can oxidize biological substrates but cannot trigger lipid peroxidation by abstraction of allylic hydrogens (40). However, superoxide anion may reduce hydrogen peroxide and thereby give rise to hydroxyl radicals, which are extremely strong and indiscriminant oxidants able to abstract allylic hydrogens. Hydroxyl radicals will abstract electrons from molecules located in close vicinity to the place of generation (site-specific reaction) (41). Since it is very difficult to measure hydroxyl radicals, the level of superoxide anion was measured to clarify the difference in response to EPA and antioxidants in Raji and Ramos cells. We found that vitamin E counteracted EPA-induced accumulation of superoxide anion in Raji cells, but not in Ramos cells. In fact, vitamin E further increased the level of superoxide anion in EPA-incubated Ramos cells, indicating that vitamin E in this case may act as a pro-oxidant (42). Several experiments were performed to further investigate whether reactive oxygen species had a role in EPA-induced apoptosis in Ramos cells. Glutathione is the most abundant nonprotein antioxidant in mammalian cells. Depletion of cellular glutathione has been described for oxidative and alkylating agents, tumor necrosis factor-α, and the CD95 ligand axis in different cell types (43). Cells depleted of glutathione either undergo apoptosis or become more sensitive to death-inducing agents (44–46). Glutathione plays a critical role in the cellular defense against oxidative stress by directly reacting with free radicals and reactive oxygen, or as a substrate for the enzyme GSHPx. Furthermore, GSHPx is reported to be enhanced by oxidative stress (30,31). This may explain the increase in GSHPx activity in Raji cells, which is in accordance with our observations that antioxidants counteract the effect of EPA in these cells. However, the GSHPx activity in Ramos cells was not elevated by EPA, which supports our findings that antioxidants had no effect on EPA-induced cell death in Ramos cells. The low activity of cellular selenium-dependent GSHPx may explain the sensitivity to PUFA of some tumor cell lines, and the availability of selenium may be critical for the activity of this enzyme (16). Although incubation with selenium increased the activity of GSHPx, we observed no effect on EPA-induced apoptosis. This indicates that cell death in Raji and Ramos cells is influenced more by other processes than the activity of cellular GSHPx.

Oxidative stress may trigger CD95 ligand expression, contributing to apoptosis (32). However, increased superoxide anion level in Ramos cells incubated with EPA exhibited no alteration in cellular expression of CD95 ligand (Heimli, H., and Drevon, C.A., unpublished data).

Previous studies have shown that inhibitors of macromolecular synthesis may oppose or promote apoptosis in some circumstances (34,47). The inconsistent effects of these agents on apoptosis may reflect the diverse mechanisms preceding apoptosis in different cell types. Our results show that inhibitors of transcription or protein synthesis partly inhibit apoptosis induced by EPA. This implies that Ramos cells exposed to EPA depend on translation/transcription before onset of apoptosis. This is in accordance with the report that apoptosis in lymphoid and colorectal cancer cells depends on new protein synthesis (48).

To further unravel the relations between fatty acids and apoptosis, we inhibited protein kinase C, since EPA or other PUFA may affect the activity of these proteins (36). Furthermore, protein kinase Cδ is specifically cleaved during apoptosis to a catalytically active fragment that is associated with nuclear fragmentation and cell death (49). However, there was no effect on EPA-induced apoptosis by kinase inhibitors, suggesting that activation of kinases is not necessarily involved in apoptotic processes caused by EPA.

In conclusion, antioxidants opposed EPA-induced elevation of superoxide anion and necrosis in Raji cells at different time-points, indicative of a slow structural or metabolic reversible damage caused by oxidized products. However, apoptosis induced by EPA in Ramos cells is probably not initiated by oxidative stress since vitamin E and other antioxidants, had no effect on either apoptosis or lowering EPA-induced elevation of superoxide anion.

# Effect of 4-Hydroxy-2(*E*)-nonenal on Soybean Lipoxygenase-1

**Harold W. Gardner[a,*] and Nigel Deighton[b]**

[a]Mycotoxin Research, NCAUR, ARS, USDA, Peoria, Illinois 61604, and [b]Scottish Crop Research Institute, Invergowrie, Dundee DD2 5DA, Scotland

**ABSTRACT:** The oxidation of linoleic acid by soybean lipoxygenase-1 (LOX-1) was inhibited in a time-dependent manner by 4-hydroxy-2(*E*)-nonenal (HNE). Kinetic analysis indicated the effect was due to slow-binding inhibition conforming to an affinity labeling mechanism-based inhibition. After 25 min of preincubation of LOX-1 with and without HNE, Lineweaver-Burk reciprocal plots indicated mixed noncompetitive/competitive inhibition. Low concentrations of HNE influenced the electron paramagnetic resonance (EPR) signal of 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid (13-HPODE)-generated $Fe^{3+}$-LOX-1 slightly, but higher concentrations completely eliminated the EPR signal indicating an active site hindered from access by 13-HPODE. HNE may compete for the active site of LOX-1 because its precursor, 4-hydroperoxy-(2*E*)-nonenal, is a product of LOX-1 oxidation of (3*Z*)-nonenal. Also, it was an attractive hypothesis to suggest that HNE may disrupt the active site by forming a Michael adduct with one or more of the three histidines that ligate the iron active site of LOX-1.

Paper no. L8721 in *Lipids 36,* 623–628 (June 2001).

In the animal kingdom it is generally acknowledged that 4-hydroxy-2(*E*)-nonenal (HNE) originates from lipid peroxidation of n-6 polyunsaturated fatty acids (1). Recently, specific autoxidative pathways from both 9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid (9-HPODE) and 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid (13-HPODE) have been defined (2). Once formed, HNE has been documented to act as a lipid signal (3). Involvement of HNE in mammalian pathologies is diverse, including Alzheimer's disease (4), Parkinson's disease (5), cancer (6), atherosclerosis (7), sporadic amyotrophic lateral sclerosis (8), and alcoholic liver disease (9).

In plants, a metabolic pathway has been found in faba beans and soybeans that involves a sequence of 9-lipoxygenase oxidation of linoleic acid to 9-HPODE, hydroperoxide lyase cleavage of 9-HPODE to give 3(*Z*)-nonenal, and lipoxygenase and hydroperoxide peroxygenase action on 3(*Z*)-nonenal to produce HNE (10–12). However, there is evidence that the last step of oxidation of 3(*Z*)-nonenal readily occurs by autoxidation, even with plant enzymes (13). Since soybean lipoxygenase-1 (LOX-1) oxidized 3(*Z*)-nonenal stereospecifically to 4(*S*)-hydroperoxy-2(*E*)-nonenal, it is obvious that HNE can access the active site of LOX-1 and other lipoxygenase isozymes (12). Three essential histidines ligate the iron active site of LOX-1 (14). It has been shown that HNE forms a Michael adduct with histidine residues (15,16), thereby implying that HNE can react with and cause suicide inhibition of LOX-1 by compromising the active site. In addition, it has been shown that HNE can react with other amino acid residues, such as cysteine (17) and lysine (18), which also can contribute to the inactivation of LOX-1. The literature abounds with other examples of enzyme inactivation or activation by HNE. Those enzymes inactivated include glucose-6-phosphate dehydrogenase (19), microsomal cytochrome P450 (20), $Na^+$-$K^+$-ATPase (21), aldose reductase (22), cytochrome C oxidase (23), α-ketoglutarate dehydrogenase (24), pyruvate dehydrogenase (24), plasma membrane ($Ca^{2+}$ + $Mg^{2+}$)-ATPase (25), glutathione peroxidase (26), and glyceraldehyde-3-phosphate dehydrogenase (27). Interestingly, multicatalytic proteinase, which clears cells of oxidized protein, is inhibited by HNE-cross-linked protein (28), implying a mechanism for accumulation of age-related lipofuscin. Enzymes activated by HNE are those involved in lipid signaling, phospholipase D (29), and phosphoinositide-specific phospholipase C (30).

In this work we demonstrate that HNE inactivates LOX-1 by a mixed noncompetitive/competitive mechanism and that at least part of the competitive mechanism may be due to the decomposition of HNE in buffer.

## MATERIALS AND METHODS

*Materials.* HNE was synthesized by a modification of a previously described method (31). Instead of oxidizing 3,4-epoxynonan-1-ol to the aldehyde by periodinane, the oxidation of Ratcliffe and Rodehorst was used (32), making certain to wash the ethyl ether solution of product HNE with NaOH, HCl, and $NaHCO_3$ solutions as prescribed by the method. The product HNE was somewhat less pure than that obtained with periodinane. Thus, HNE was purified by silicic acid (100 mesh; Mallinckrodt, Phillipsburg, NJ) column chromatography (40 g, column i.d. 2.5 cm) by sequentially eluting with 300 mL each of 7.5, and 10% acetone in hexane. HNE eluted between 200 and 300 mL in 95.5% purity. Linoleic acid was obtained from Nu-Chek-Prep (Elysian, MN). LOX-1 was isolated as previously described (33) and was stored at 3°C as a suspension in 2.3 M $(NH_4)_2SO_4$; protein concentration was 34.5 mg/mL. 13-HPODE was prepared by the method of Gardner (34).

*Time-dependent inactivation of LOX-1 by HNE.* The oxygen electrode assay (Gilson 5/6H oxygraph, Middleton, WI)

Abbreviations: cmc, critical micelle concentration; EPR, electron paramagnetic resonance; HNE, 4-hydroxy-2(*E*)-nonenal; 9-HPODE, 9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid; 13-HPODE, 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid; LOX-1, soybean lipoxygenase-1.

was completed in a 2.4-mL cell held at 25˚C. The cell was filled with 0.1 M potassium borate buffer (pH 9.86) containing 0.36 μg LOX-1/mL. For zero-time measurement, 10 μL of HNE dissolved in methanol and 10 μL linoleic acid substrate (240 mM) in methanol were injected into the cell in rapid sequence. The final concentration of linoleic acid was 1 mM. Various concentrations of HNE were tested, 10 μL of 4.8, 15, 24, 30, 60, 120, and 240 mM in methanol per 2.4 mL cell, giving final concentrations of 0.02, 0.0625, 0.1, 0.125, 0.25, 0.5, and1 mM, respectively. For the measurements requiring precise timed incubation of HNE with the LOX-1 borate solution, a batch solution was prepared [24 mL 0.1 M potassium borate buffer (pH 9.86) containing 0.36 μg LOX-1/mL was stirred with 100 μL of methanolic HNE solution at the various concentrations described above]. The batch solution was incubated at 25°C for the prescribed time of 5.5, 11, 17, 30, 55, and 90 min, after which 2.4 mL was transferred to the oxygen electrode cell and 10 μL of 240 mM methanolic linoleic acid was injected into the cell to start the oxygen uptake measurement.

The control measurements were the same as described above, except the same volume of methanol replaced the methanolic HNE solution.

*Lineweaver-Burk kinetic analyses of HNE inhibition.* LOX-1 activity assays were measured by oxygen electrode without or with HNE inhibitor after preincubation for exactly 25 min at 25°C by adding either 0.417% methanol (10 μL methanol/2.4 mL LOX-1 solution) or 0.417% methanolic HNE solution (methanolic HNE tested were 30, 60, and 120 mM, giving 0.125, 0.25, and 0.5 mM final concentration, respectively). The LOX-1 solution was 0.97 μg LOX-1/mL in 0.1 M potassium borate (pH 9.86). After the 25-min preincubation, 2.4 mL was transferred to the oxygen electrode cell and 10 μL methanolic linoleic acid was injected to start the reaction. Methanolic linoleic acid was injected at concentrations of 24, 12, 8, 6, 4.8, or 4 mM giving final concentrations of 0.1, 0.05, 0.0334, 0.025, 0.02, or 0.01667 mM, respectively, all of which are below the critical micelle concentration (cmc) of linoleic acid at pH 9.86 (35). As many as 10 replicates were determined for the "without HNE" activities, and "with HNE" activities were replicated four to eight times. Lineweaver-Burk reciprocal data were plotted and interpreted according to Dixon and Webb (36).

*Electron paramagnetic resonance (EPR) analysis of $Fe^{3+}$-LOX-1 in presence of HNE.* A LOX-1 stock solution (109 μM) in potassium borate buffer (0.1 M, pH 9.9) was prepared. To 120 μL aliquots of this enzyme stock, dilute solutions of HNE in ethanol (20 μL) were added such that the final concentrations of HNE were 0, 0.21, and 1.57 mM. These solutions were incubated for 1 h (25°C), at which point the enzyme was oxidized through addition of a 37 μL aliquot of 13-HPODE (2 mM) in methanol. Samples were immediately frozen in liquid nitrogen and EPR spectra acquired at 77 K in a quartz finger Dewar flask. The samples (177 μL) analyzed as follows: LOX-1 (74 μM), 13-HPODE (418 μM), and HNE = 0, 0.17, and 1.24 mM. All spectra were acquired on a Bruker ESP-300E X-band spectrometer. Key parameters were center field 130 mT, sweep width 100 mT, microwave power 63 mW, modulation amplitude 1.2 mT, and sweep time 80 s.

*Analyses of HNE decrease in buffered solutions.* HNE was trapped as the benzoxime and analyzed by flame-ionization detection gas chromatography as the trimethylsilyloxy ether as described (10). Methanolic HNE (15 μL of 60 mM HNE) was added to 3 mL 0.1 M potassium borate buffer (pH 9.86) or 3 mL potassium borate buffer containing 1.04 mg LOX-1. These solutions were incubated at 25°C, and 0.5 mL aliquots were taken at 0, 10, 40, 90, and 120 min to make the *O*-benzoxime derivative of HNE. Aliquots were added to 0.1 mL reagent containing 50 mM *O*-benzylhydroxylamine-HCl in 100 mM Na piperazine-*N,N′*-bis-(2-ethanesulfonate) (pH 6.5) and 0.4 mL methanol. After permitting the reagent to react for 10 min, 27.5 μg methyl nonadecanoate was added as an internal standard, and the derivative was extracted with 1 mL chloroform. The chloroform extract was evaporated with a stream of nitrogen and reacted with trimethylchlorosilane/hexamethyldisilazane/dry pyridine (3:2:2, by vol). After 10 min, the reagent was evaporated with a stream of nitrogen and taken up in 100 μL hexane for gas chromatographic analysis as reported previously (11). Values were relative based on 100% HNE content at zero time.

## RESULTS AND DISCUSSION

An examination of the persistence of HNE in 0.1 M borate buffer (pH 9.86) revealed the loss of HNE (Table 1) with the appearance of seven unidentified compounds having a greater retention time by gas chromatography. The four main compounds had related mass spectra indicating that they were isomeric. The disappearance of HNE was not markedly affected by the presence of LOX-1, which was not too surprising as the concentration of LOX-1 was many orders of magnitude less than HNE. That is, HNE was present at 0.3 mM, and LOX-1 was only at 0.011 μM. Since HNE was present at only 57% of its original concentration after 40 min, the potential effect of HNE on LOX-1 was diminished at longer times. However, during short incubation times, when the rate of inhibition was greatest (Fig. 1), the amount of HNE was only slightly depleted. At 5.5 and 11 min, the amount of HNE was projected to be about 95 and 91%, respectively, at which time the rate of inhibition was the greatest.

**TABLE 1**
**Loss of HNE with Time When Incubated in 0.1 M Potassium Borate Buffer (pH 9.86) at 25°C With or Without LOX-1[a]**

| | Percentage, relative to zero time | |
|---|---|---|
| Time (min) | Without LOX-1 | With LOX-1 |
| 0 | 100 | 100 |
| 10 | 86.4 | 92.8 |
| 40 | 57.3 | 55.7 |
| 90 | 27.3 | 25.1 |
| 120 | 26.3 | 18.8 |

[a]The concentrations of 4-hydroxy-2(*E*)-nonenal (HNE) and soybean lipoxygenase-1 (LOX-1) were 0.3 mM and 0.35 mg/mL, respectively.

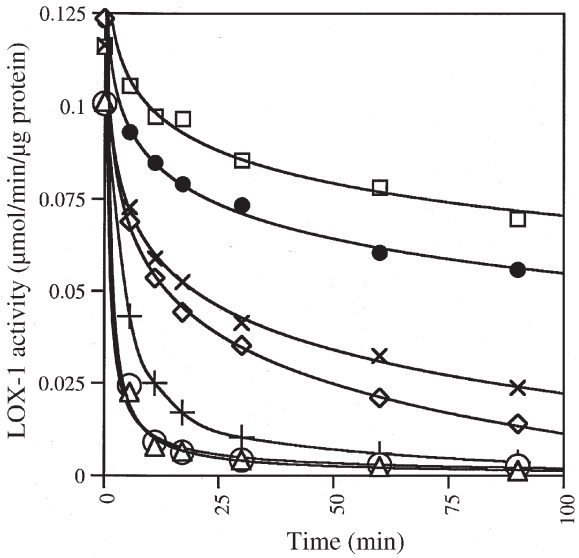

**FIG. 1.** Time-dependent inactivation of soybean lipoxygenase-1 (LOX-1) activity by various concentrations of 4-hydroxy-2(*E*)-nonenal (HNE). □, Control containing methanol only in place of methanolic HNE; ●, 0.02 mM HNE; ×, 0.0625 mM HNE; ◇, 0.125 mM HNE; +, 0.25 mM HNE; ○, 0.5 mM HNE; △, 1 mM HNE. All points represent mean values of replicates. The range in coefficient of variation in percentages was as follows: control, 13 to 18 ($n$ = 19); 0.02 mM HNE, 3 to 31 ($n$ = 4); 0.0625 mM HNE, 5 to 18 ($n$ = 3); 0.125 mM HNE, 9 to 36 ($n$ = 3); 0.25 mM HNE, 10 to 26 ($n$ = 3); 0.5 mM HNE, 0 to 28 ($n$ = 3); and 1 mM HNE, 22 to 81 ($n$ = 3).

It was determined that HNE in concentrations ranging between 20 μM and 1 mM was an effective inhibitor of LOX-1 activity as assayed with 1 mM linoleic acid (Fig. 1). Previous studies with other enzymes showed that the effective concentrations of HNE required for inhibition ranged from a low for cytochrome P450 (0.24 μM to 0.8 mM) (20) and $Na^+$-$K^+$-ATPase (1 μM to 1 mM) (21) to a high for glucose-6-phosphate dehydrogenase (1 to 8 mM) (19). Other enzymes were reported to be effective at HNE concentrations between the foregoing values; thus, the inhibition of LOX-1 by 20 μM to 1 mM was comparable to the effect on many other enzymes. Interestingly, we did not see inhibition when HNE and linoleic acid were added simultaneously; that is, no significant slowing of the rate was seen over the course of the assay of 4 to 5 min. This result indicated that linoleic acid was a more effective competitor for the active site than HNE. However, when HNE was incubated with LOX-1 for a period of time in the absence of linoleic acid, subsequent activity with linoleic acid substrate was markedly reduced. After the data shown in Figure 1 were compensated for the control, the loss of activity was found to be complete after about 17 min of incubation with HNE.

The data presented in Figure 1 are indicative of a slow-binding inhibitor. As outlined by Copeland (37), slow-binding inhibitors are categorized into three types, which can be distinguished by kinetic analysis. The data derived from Figure 1 best fit the "affinity labeling and mechanism-based inhibition" according to Scheme 1, where E, enzyme; $k$, rate constant; and [I], inhibitor.

$$E \underset{k_4}{\overset{k_3[I]}{\rightleftharpoons}} E[I] \xrightarrow{k_5} E\text{-}I$$

**SCHEME 1**

For this type of inhibitor the rate equation is:

$$k_{obs} = \frac{k_5[I]}{K_i + [I]} \quad [1]$$

where $k_{obs}$, apparent (observed) rate constant; $K_i$, apparent concentration of inhibitor required to reach the half-maximal rate of inactivation, and [I], inhibitor concentration.

Since this rate equation is reminiscent of the Michaelis-Menton equation, a reciprocal plot of $k_{obs}$ vs. [I] ideally should give a linear plot. After correcting for the control, exponential extrapolation of the rate of inactivation obtained during the first 11 min (Fig. 1) $k_{obs}$ was derived from $0.693/t_{1/2}$ min. The rate for 1 mM HNE was omitted as being too rapid to obtain reasonable data. The linear reciprocal plot shown in Figure 2 with a nonzero intercept conforms to the inhibitor type shown in Scheme 1. The intercept with the $y$-axis gave the 1/maximal rate of $k_5$, or the maximal rate of inactivation, $k_{inact.}$, that is, $1/k_{inact.} = 5$ or $k_{inact.} = 0.2$ min$^{-1}$. Intersection of the plot with the $x$-axis gave $-1/K_i = -1/3.4$ or $K_i = 0.294$ mM. This type of inhibition is reasonable in view of the fact that HNE is known to form Michael adducts with cysteine (17), lysine (18), and histidine (15,16). It is noted that LOX-1 possesses three essential histidines that ligate the iron active site. It is known from the literature that 4(*S*)-hydroperoxy-2(*E*)-nonenal is a LOX-1 product of 3(*Z*)-nonenal oxidation (12); thus, it seems reasonable that the smaller and structurally related HNE should be capable of accessing the active site.

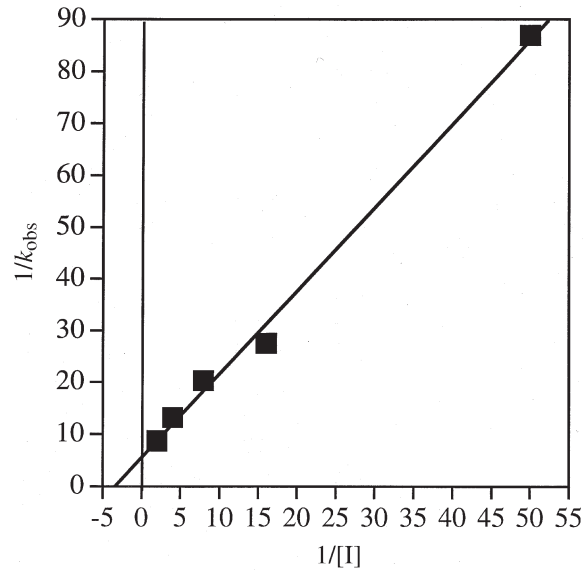

**FIG. 2.** Reciprocal plot of apparent (observed) rate constant, $k_{obs}$ (min$^{-1}$), as a function of inhibitor [I] concentration (mM). Intercept with the $x$-axis is equivalent to $-1/K_i$, and the intercept with the $y$-axis is $1/k_{inact}$ (reciprocal of the maximal rate of inactivation). Derived from the data shown in Figure 1.

For this reason, Lineweaver-Burk kinetic analyses of the inhibitor effect of HNE were completed to confirm the foregoing assessment. In order to determine these data, LOX-1 was preincubated with HNE for 25 min, a time determined to be safely beyond the effective time required for inhibition; however, after 25 min the concentration of HNE was reduced to about 75% of its original value by decomposition in buffer. Also, all activity assays had to be completed below the cmc concentration of linoleic acid, because the true substrate of LOX-1 has been determined to be monomeric linoleic acid, not substrate trapped in micelles (38). This severely restricts the usable range of substrate concentrations, but reasonable data can be collected by the use of replicates. Thus, the $K_M$ of LOX-1 was determined to be 23 μM (Fig. 3), which compares with 15 ± 3 μM reported by Schilstra *et al*. (39). Reciprocal plot analyses in the presence of various concentrations of HNE revealed mixed competitive/noncompetitive inhibition at the two lowest concentrations of HNE tested. Since 3(*Z*)-nonenal served as a substrate of LOX-1 and 4(*S*)-hydroperoxy-2(*E*)-nonenal was a product (12), it was expected that HNE would occupy the active site of LOX-1. The competitive aspect of HNE can be readily explained. The noncompetitive nature of the inhibition was expected due to the slow-binding kinetic analysis outlined above. Surprisingly, at the highest inhibitor concentration tested (0.5 mM), where one would expect the greatest degree of noncompetitive inhibition, the plot showed an almost classical competitive inhibition. In fact, the trend toward competitive inhibition occurred as the inhibitor concentration progressively increased.

This observation of classical competitive inhibition at 0.5 mM HNE does not have a straightforward explanation. Some competitive inhibition could be caused by decomposition products of HNE, which would afford higher concentrations after 25 min preincubation with 0.5 mM HNE. To test this possibility, HNE was preincubated in buffer for 2 to 4 h before testing for its effect on LOX-1 activity. Pretreated HNE was then incubated with LOX-1 for 10 min prior to adding 1 mM linoleic acid. Preincubated HNE, 0.5 and 1 mM, inhibited LOX-1 at 17 and 58%, respectively, compared to controls. Little significant difference in activity could be seen with the time of preincubation between 2 and 4 h. By contrast, a 10 min exposure of LOX-1 to HNE (not preincubated in buffer) at 0.5 and 1 mM inhibited activity 73 and 85%, respectively. As seen in Table 1, the amount of HNE remaining after 2 h preincubation in buffer was less than 25%. It is conceivable that the inhibition observed with preincubation is partly due to residual HNE, but the lack of significant effect over time is suggestive of the contribution from degraded HNE. It is conceivable that the competitive aspect of the Lineweaver-Burk plots observed at higher HNE concentrations was due to degraded HNE from 25 min preincubation of HNE. Nevertheless, some degree of mixed competitive/noncompetitive inhibition should be expected.

Disruption of the active site was supported by EPR results. An EPR signal of LOX-1 was generated by oxidizing native $Fe^{2+}$-LOX-1 to $Fe^{3+}$-LOX-1 by exposing the enzyme to its product, 13-HPODE, followed by immediate liquid $N_2$ freezing (Fig. 4). In the presence of low HNE concentrations (0.21 mM incubation concentration, 0.17 mM after 13-HPODE addition) the EPR signal from oxidized LOX-1 was slightly affected. A 22% decrease in peak-to-peak width of the $g_\perp$ (g = 6) signal was observed: 11.3mT in the absence of HNE and 8.8 mT in the presence of HNE. In view of the half-maximal inhibitor concentration ($K_i$) for HNE of 0.294 mM (Fig. 2), this result was not unreasonable. When the concentration of HNE was increased (1.57 mM incubation concentration, 1.24 mM after 13-HPODE addition), the EPR signal completely disappeared. Since 1.24/1.57 mM HNE is substantially greater than $K_i$, complete inhibition was anticipated; however, the relatively low HNE/LOX-1 incubation ratio of 21 may have depleted the actual HNE concentration by noninhibitory reactions with LOX-1 to some extent. In the present EPR study, the HNE/LOX-1 incubation ratio of 21 compared to literature HNE/protein ratios of 15–143 that were utilized to modify histidine residues (15). From these observations it was concluded that HNE caused the active site to be sufficiently hindered to prevent oxidation of $Fe^{2+}$-LOX-1 to $Fe^{3+}$-LOX-1 by 13-HPODE.

A potential physiological function of HNE is suggested by the results. It is well known that pathogens activate the oxylipin pathway (e.g., Ref. 40). More specifically, Deighton *et al*. (41) found that HNE accumulates at levels as high as 19,000 pmol/g tissue at the site of fungal infection of sweet peppers. In certain experiments HNE was found at even higher levels of 30,000 pmol/g (Deighton, N., unpublished data). Because of HNE reaction with protein and/or glutathione, it is plausible that the amount produced was actually higher. The concentrations found by Deighton translate

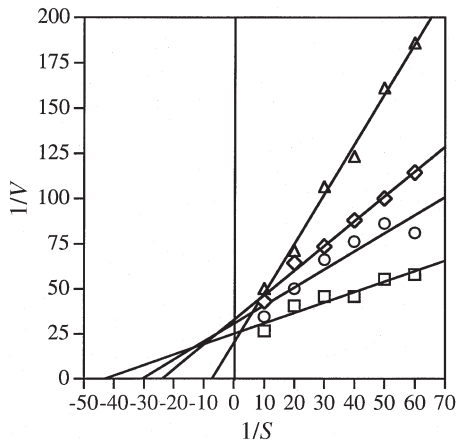

**FIG. 3.** Lineweaver-Burk reciprocal plots of LOX-1 activity with and without HNE inhibitor. Preincubation with or without HNE was 25 min at 25°C before measurement of activity with linoleic acid. Reciprocals are activity, *V*, in μmol/min/μg LOX-1, and linoleic acid substrate, *S*, in mM. □, Activity without HNE; ○, activity with 0.125 mM HNE ◇, activity with 0.25 mM HNE; and △, activity with 0.5 mM HNE. All points are mean values of replicates. The ranges in coefficient of variation in percentages were as follows: "without HNE," 14 to 35 ($n$ = 10); 0.125 mM HNE, 9 to 22 ($n$ = 4); 0.25 mM HNE, 11 to 24 ($n$ = 6); 0.5 mM, 7 to 22 ($n$ = 4). For abbreviations see Figure 1.

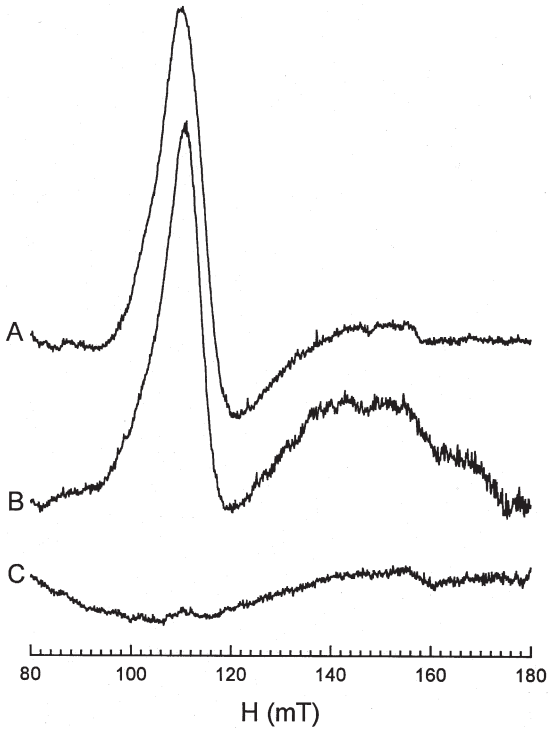

**FIG. 4.** Electron paramagnetic resonance spectra of oxidized LOX-1. The enzyme was oxidized by 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid in the absence (A) and presence of HNE at 0.17 (B) and 1.24 mM (C). For abbreviations see Figure 1.

to 0.019 to 0.03 mM, which brackets the lowest concentration of HNE tested in this study (Fig. 1). Thus, it seems possible that the downstream oxylipin HNE, and possibly related oxylipins, may serve to switch off the lipid signal pathway through inactivation of one of the initiating enzymes. Because linoleic acid effectively competes for the active site, this "feedback suicide" of LOX is suggested to occur only after substrate depletion.

Further research is planned to locate the specific site of LOX-1 inactivation by HNE.

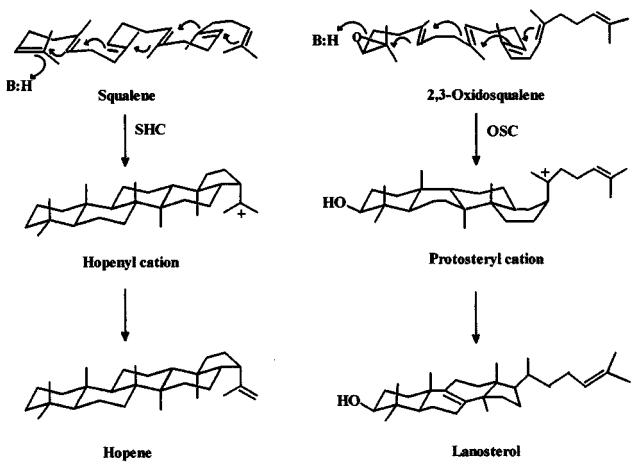
# Vinyl Sulfide Derivatives of Truncated Oxidosqualene as Selective Inhibitors of Oxidosqualene and Squalene-Hopene Cyclases

**Maurizio Ceruti[a], Gianni Balliano[b], Flavio Rocco[b], Paola Milla[b], Silvia Arpicco[b], Luigi Cattel[b], and Franca Viola[b,*]**

[a]Dipartimento Farmacochimico, Tossicologico e Biologico, Università di Palermo, 90123 Palermo, Italy, and [b]Dipartimento di Scienza e Tecnologia del Farmaco, Università di Torino, 10125 Torino, Italy

**ABSTRACT:** Various vinyl sulfide and ketene dithioacetal derivatives of truncated 2,3-oxidosqualene were developed. These compounds, having the reactive functions at positions C-2, C-15 and C-19 of the squalene skeleton, were studied as inhibitors of pig liver and *Saccharomyces cerevisiae* oxidosqualene cyclases (OSC) (EC 5.4.99.7) and of *Alicyclobacillus acidocaldarius* squalene hopene cyclase (SHC) (EC 5.4.99.-). They contain one or two sulfur atoms in α-skeletal position to carbons considered to be cationic during enzymatic cyclization of the substrate and should strongly interact with enzyme nucleophiles of the active site. Most of the new compounds are inhibitors of the OSC and of SHC, with various degrees of selectivity. The methylthiovinyl derivative, having the reactive group at position 19, was the most potent and selective inhibitor of the series toward *S. cerevisiae* OSC, with a concentration inhibiting 50% of the activity of 50 nM, while toward the animal enzyme it was 20 times less potent. These results could offer new insight for the design of antifungal drugs.

Paper no. L8718 in *Lipids 36,* 629–636 (June 2001).



**SCHEME 1**

2,3-Oxidosqualene cyclases (OSC) (EC 5.4.99.7) are membrane-associated enzymes that catalyze the cyclization of (3*S*)-2,3-oxidosqualene (OS) to lanosterol in mammals and yeasts and to cycloartenol in higher plants. OSC have been purified and cloned from different species: *Candida albicans*, *Saccharomyces cerevisiae*, *Schizosaccharomyces pombe* among the fungi; higher plants; the rat, the pig, and man (1–14 and references therein).

Squalene-hopene cyclase (SHC) (EC 5.4.99.-) catalyzes the cyclization of squalene to hopene and hopanoids, a class of pentacyclic, sterol-like triterpenes present in many bacterial membranes (2,10,15,16). The two enzymes show many similarities in their substrate cyclization mechanism (Scheme 1). Both enzymes are able to generate carbocationic species by protonation of either a carbon double bond (SHC) or an epoxide (OSC). The formation of the final product in both enzymes is a highly complex and specific process rising from a progression of partially cyclized carbocationic intermediates.

For the formation of lanosterol, as final product of OSC, the pentacyclic C-20 protosteryl cation undergoes rearrangement through a series of 1,2-methyl and hydride shifts, while hopene, the final product of SHC, arises from the loss of the H-29 proton directly from the hopenyl C-22 cation, without skeletal rearrangement. Possibly this is a consequence of the fact that SHC behaves as a more primitive enzyme (16,17). SHC from *Alicyclobacillus acidocaldarius* has recently been overexpressed in *Escherichia coli*, purified, and crystallized (10,18,19). It shows a 17–27% identity with the cloned OSC and a molecular weight of 71,500 Da, and it contains several repeats of a highly conserved motif rich in aromatic amino acids, the QW motif, also present in OSC (20). SHC is so far the only suitable model for studying the mechanism of triterpene cyclization from a structural standpoint. Indeed, all information available about the oxidosqualene cyclization mechanism is inferred from mutagenesis experiments and inhibition studies, since no OSC have been crystallized (21–23).

For many years we have been studying OSC inhibitors. Initially we obtained effective inhibitors of OSC by mimicking the carbocationic intermediates formed during cyclization

Abbreviations: CIMS, chemical ion mass spectrometry; EIMS, electron ionization mass spectrometry; HRMS, high-resolution mass spectrometry, $IC_{50}$, concentration of inhibitor that reduces the enzymatic conversion by 50%; IR, infrared; 29-MOS, 29-methylidene-2,3-oxidosqualene; NMR, nuclear magnetic resonance; OS, 2,3-oxidosqualene; OSC, 2,3-oxidosqualene-lanosterol cyclase; SHC, squalene-hopene cyclase; THF, tetrahydrofuran.

of OS, designing squalene-derived structures in which the positively charged carbocation was replaced by a nitrogen (1, 24–26). Another strategy that has been adopted is to intercept the enzymatic active-site nucleophiles with a stable allylic cation, resulting in an irreversible covalent modification of OSC. Following this strategy, Prestwich (21,27–29), Corey (23), and our (30,31) groups synthesized various series of 2,3-oxidosqualenoid dienes and vinyl epoxides, some of which were found to be selective and time-dependent inhibitors of yeast or animal OSC. Finally, various series of sulfur-containing oxidosqualene derivatives, in which sulfur has replaced carbons C5, C6, C8, C9, C10, C11, C13, C14, C15, C16, C18, C19, or C20 (squalene numbering), have been synthesized (22,32–36). Some of these compounds are potent inhibitors of OSC, particularly of the *C. albicans* enzyme.

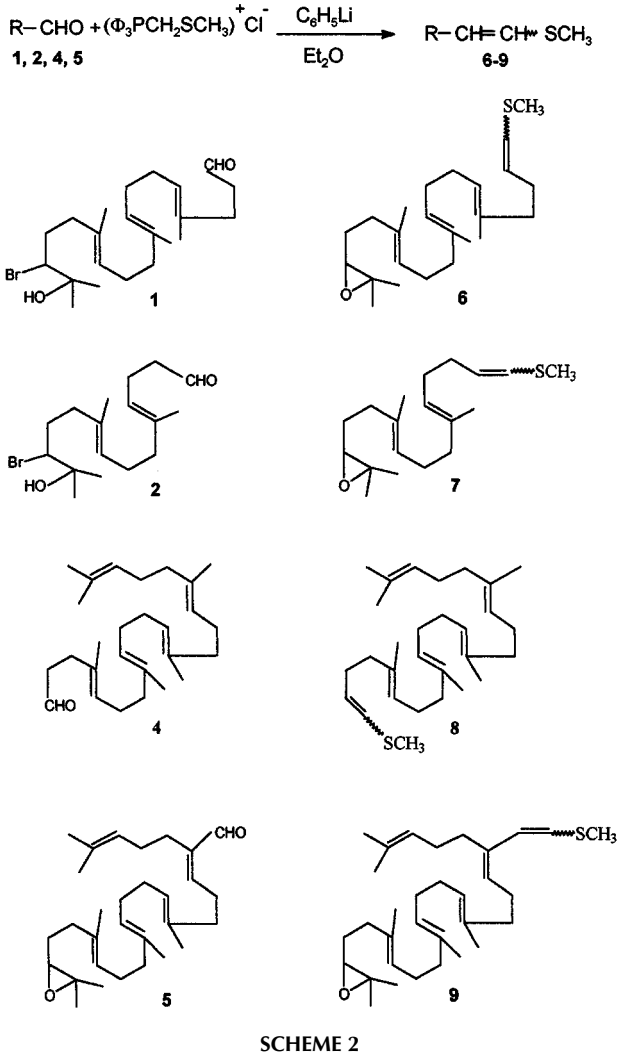
We thus believed that the synthesis of a new class of truncated vinyl sulfide derivatives of OS and of squalene, having the reactive functions at crucial positions 2, 15 and 19, together with other related compounds, might afford new derivatives with better selectivity toward the animal, yeast, or bacterial enzyme. These derivatives should give new insight into the function and the reactivity of the nucleophiles of the active site of the various OSC (and of SHC) that stabilize the C-2, C-13 and C-20 cationic intermediates.

## MATERIALS AND METHODS

*Chemicals.* The $^1$H nuclear magnetic resonance (NMR) spectra were recorded on either a JEOL EX 400 (JEOL, Inc., Peabody, MA) or a Bruker AC 200 instrument (Karlsruhe, Germany) in $CDCl_3$ solution at room temperature, with $SiMe_4$ as internal standard. Mass spectra were obtained on a Finnigan MAT TSQ 700 spectrometer (San Jose, CA). Infrared (IR) spectra were recorded on a PE 781 (PerkinElmer, Wellesley, MA) spectrophotometer. Microanalyses were performed on an elemental analyzer 1106 (Carlo Erba Strumentazione, Milano, Italy). The reactions were monitored by thin-layer chromatography (TLC) on $F_{254}$ silica gel precoated sheets; after development, the sheets were exposed to iodine vapor. Flash-column chromatography was performed on 230–400 mesh silica gel. Tetrahydrofuran (THF) and diethyl ether were dried over sodium benzophenone ketyl. All solvents were distilled prior to flash chromatography.

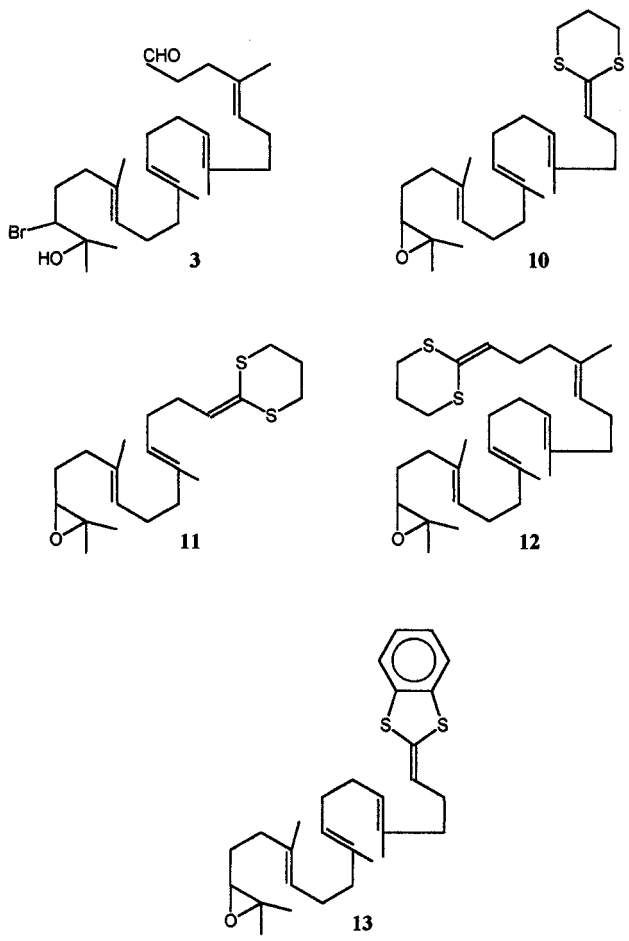
Squalene, lanosterol, and polyoxyethylene 9 lauryl ether were obtained from Sigma Chemical Co. (St. Louis, MO). [$^{14}$C]Squalene and [$^{14}$C]-(3*S*)-2,3-oxidosqualene were obtained through biological synthesis by incubating a pig liver $S_{10}$ fraction with [2-$^{14}$C]mevalonolactone (NEN, Boston, MA).

$C_{22}$ squalene aldehyde monobromohydrin **1** (Scheme 2) was obtained as previously reported (37,38). $C_{17}$ and $C_{27}$ squalene aldehyde monobromohydrins **2** (Scheme 2) and **3** (Scheme 3) were obtained using the same method as reported for **1**, starting from the corresponding $C_{17}$ and $C_{27}$ aldehydes. $C_{27}$ squalene aldehyde **4** (Scheme 2) was obtained as previously described (24). $C_{30}$ squalene aldehyde epoxide **5** (Scheme 2) was obtained as previously described (30).



**SCHEME 2**

*(5*E*,9*E*,13*E*)-17,18-Epoxy-5,10,14,18-tetramethyl-1-methylthio-1,5,9,13-nonadecatetraene (**6**, Scheme 2).* In a two-necked flask, anhydrous diethyl ether (5 mL) and phenyllithium (1.6 M solution in hexane, 2.40 equiv, 360 μL, 0.58 mmol) were added and stirred at room temperature under dry nitrogen. (Methylthiomethyl)triphenylphosphonium chloride (1.20 equiv, 104 mg, 0.29 mmol), dissolved in anhydrous diethyl ether (3 mL), was then added, and the red solution turned to pale yellow. After stirring for 10 min at room temperature, $C_{22}$ squalene aldehyde monobromohydrin **1** (1.0 equiv, 100 mg, 0.24 mmol), in anhydrous diethyl ether (2 mL), was added and left for 30 min under stirring. The mixture was then poured into cold diethyl ether/saturated aqueous NaCl (1:1, 50 mL) and extracted with diethyl ether (3 × 30 mL). The combined extracts were washed with saturated brine (1 × 30 mL), dried with anhydrous sodium sulfate, and evaporated *in vacuo*. The resulting oil was purified by flash chromatography with petroleum ether/diethyl ether, 97:3, to give 32 mg (35% yield from **1**) of compound **6**, as a mixture (about 1:1) of 1*E* and 1*Z* isomers, as a colorless oil. $^1$H NMR ($CDCl_3$): δ 1.26 and 1.30 (2 *s*, 6 H, epoxidic $CH_3$), 1.56–1.68



SCHEME 3

*2-[(4*E*,8*E*,12*E*,16*E*)-20,21-Epoxy-4,8,13,17,21-pentamethyl-4,8,12,16-docosatetraenylidene]-1,3-dithiane (**12**, Scheme 3).* Compound **12** was obtained starting from aldehyde **3** using the same method as described for **10**, in 32% yield. $^1$H NMR ($CDCl_3$): δ 1.26 and 1.30 (2 *s*, 6 H, epoxidic $CH_3$), 1.58–1.68 (*m*, 14 H, allylic $CH_3$ and $CH_2$-epoxide), 2.00–2.35 (*m*, 20 H, allylic $CH_2$ and $SCH_2CH_2CH_2S$), 2.70 (*t*, 1 H, epoxidic CH, *J* = 6.2 Hz), 2.85 (*t*, 4 H, $SCH_2CH_2CH_2S$, *J* = 5.9 Hz), 5.00–5.20 (*m*, 4 H, vinylic CH), 5.95 (*t*, 1 H, fulvenic CH, *J* = 7.2 Hz); IR (liquid film): 2965, 2930, 2860, 1725, 1680, 1450, 1380 cm$^{-1}$; EIMS *m/z* 502 (0.2), 349 (0.2), 281 (0.5), 268 (0.2), 239 (0.3), 145 (100); CIMS (isobutane) *m/z* 503 (100), 485 (18); HRMS *m/z* 502.3305 (calc. for $C_{31}H_{50}OS_2$ 502.3303). Anal. ($C_{31}H_{50}OS_2$) C, H, O, S.

*2-[(4*E*,8*E*,12*E*)-16,17-Epoxy-4,9,13,17-tetramethyl-4,8,12-octadecatrienylidene]-1,3-benzodithiole (**13**, Scheme 3).* In a two-necked flask, 2-dimethoxyphosphinoyl-1,3-benzodithiole (39) (1.05 equiv, 79 mg, 0.30 mmol) was dissolved in anhydrous THF (3 mL) and stirred at room temperature under dry nitrogen. The reaction mixture was cooled at –80°C and *n*-butyllithium (1.6 M solution in hexane, 2.50 equiv, 455 µL, 0.73 mmol) was added, while the solution turned to yellowish orange. After stirring for 10 min at room temperature, $C_{22}$ squalene aldehyde monobromohydrin **1** (1.0 equiv, 120 mg, 0.29 mmol) in anhydrous THF (2 mL) was added and left for 10 min at –80°C and for a further 2 h at room temperature, under stirring. The mixture was then poured into cold diethyl ether/saturated aqueous NaCl (1:1, 50 mL) and extracted with diethyl ether (3 × 30 mL). The combined extracts were washed with saturated brine (1 × 30 mL), dried with anhydrous sodium sulfate and evaporated *in vacuo*. The resulting oil was purified by flash chromatography on a column that had been eluted with petroleum ether/isopropylamine, 99:1 until the eluate was basic, and then it was eluted with petroleum ether/isopropylamine, 99.9:0.1 to give 38 mg (28% yield from **1**) of compound **13**, as a colorless oil. $^1$H NMR ($CDCl_3$) δ 1.26 and 1.30 (2 *s*, 6 H, epoxidic $CH_3$), 1.54–1.64 (*m*, 11 H, allylic $CH_3$ and $CH_2$-epoxide), 2.02–2.18 (*m*, 14 H, allylic $CH_2$), 2.70 (*t*, 1 H, epoxidic CH, *J* = 6.2 Hz), 5.02–5.24 (*m*, 4 H, vinylic CH and fulvenic CH), 7.26–7.55 (*m*, 4 H, aromatic CH); IR (liquid film) 2970, 2930, 2860, 1450, 1380 cm$^{-1}$; EIMS *m/z* 468 (0.3), 315 (1.8), 251 (2.2), 203 (1), 179 (100); CIMS (isobutane) *m/z* 469 (70), 347 (90), 345 (100), 329 (90); HRMS *m/z* 468.2522 (calc. for $C_{29}H_{40}OS_2$ 468.2520). Anal. ($C_{29}H_{40}OS_2$) C, H, O, S.

*Enzymatic assays*. Solubilized and partially purified pig liver and yeast OSC were obtained as previously described (37,40). The enzymatic activity was determined by incubating 2,000 cpm of [$^{14}$C]-(3*S*)-2,3-oxidosqualene and evaluating the amount of lanosterol formed, as previously described (40). [$^{14}$C]-(3*S*)-2,3-Oxidosqualene and [$^{14}$C]squalene were obtained by biological synthesis by incubating 1 µCi of [$^{14}$C]mevalonolactone with an $S_{10}$ supernatant of a pig liver homogenate (25 mg of proteins) in the presence of the OSC inhibitor U-18666A (1), following the method of Poják (41). Recombinant squalene hopene cyclase was provided by Prof. Karl Poralla (Universität Tübingen, Germany).

For enzymatic activity determination of SHC, 10 µM squalene and 2,000 cpm of [$^{14}$C]squalene were dissolved in ethanol in the presence of polyoxyethylene 9 lauryl ether (final concentration 0.05%) in test tubes. The solvent was evaporated under nitrogen; and the enzyme (3 µg) in 1 mL of citrate buffer, 0.1 M, pH 6.0, containing 0.1% polyoxyethylene 9 lauryl ether, was added to the test tubes and incubated for 30 min at 55°C. The reaction was stopped by adding 1 mL of methanolic KOH and heating at 80°C for 30 min in a water bath. After extracting with 2 mL of petroleum ether, the solvent was evaporated. The extracts were redissolved in a small amount of $CH_2Cl_2$ and spotted on TLC plates developed with petroleum ether. The conversion of squalene to labeled hopene was analyzed by radio-TLC scanner (Packard System 2000 Imaging Scanner; Hewlett-Packard, Palo Alto, CA), and the percentage of transformation was calculated by integration. Alternatively, bands corresponding to squalene and hopene were scraped off and counted with a liquid scintillator (Beckman LS500 TD; Beckman Instruments, Fullerton, CA). In these conditions, the amount of diplopterol formed was negligible (less than 1%) and it was ignored.

$IC_{50}$ values (the concentration of inhibitor that reduced the enzymatic conversion by 50%) were determined by adding the inhibitors, as ethanolic solution, to the mixture of nonradiolabeled and labeled substrates and by incubating with SHC, as described.

Time-dependent inactivation of OSC was determined at 35°C as previously described (31). Time-dependent inactivation of SHC was determined at 55°C by adding the inhibitors to the enzyme solution in the absence of substrate. Aliquots

were withdrawn at suitable intervals, and diluted 50-fold by transfer to test tubes containing nonradiolabeled and labeled substrate squalene (10 μM) and polyoxyethylene 9 lauryl ether (0.1%) in 0.1 M citrate buffer, pH 6. Residual activity was determined by comparison to an enzyme solution preincubated in the above conditions. Second-order inactivation constants were determined from *t*/2 values obtained in the time-dependent inactivation experiments.

## RESULTS AND DISCUSSION

As mentioned in the introduction, the Oehlschlager group has developed various nontruncated sulfide analogs of OS by following different strategies (32–35). One approach involved the development of OS analogs containing a sulfur atom at positions normally occupied by carbons of OS considered to be cationic during enzymatic cyclization. In another approach, sulfur substituted a carbon of a double bond of OS adjacent to a position considered to be cationic during OS cyclization. These derivatives are supposed to bind the enzyme and to be cyclized, generating sulfonium intermediates. These two classes of thia analogs therefore lack one double bond in the squalene skeleton. Another approach was the development of analogs of OS usually containing a sulfur atom in α-skeletal position to carbons considered to be cationic during OS cyclization. These compounds are supposed to cyclize enzymatically and the carbocation formed is stabilized by the adjacent sulfur, strongly interacting with enzyme residues normally stabilizing the natural carbocation.

Our previous findings showed that compounds having a truncated squalenoid structure and a correctly located reactive group adjacent to a double bond involved in the cyclization are potent and selective inhibitors of the eukaryotic OSC (17,30,31). Several of these squalenoid derivatives, with a 2,3-oxide function, are able to inhibit bacterial SHC. Squalene is the natural substrate of the bacterial enzyme, but the 2,3-oxidosqualene is also a substrate of SHC *in vitro* (42,43). We have now developed truncated vinyl sulfide derivatives of OS and other new derivatives and compared their activity on the animal, yeast and bacterial enzyme.

In Table 1, the $IC_{50}$ inhibition values obtained testing OSC activity with a solubilized and partially purified pig liver OSC and a microsomal suspension of *S. cerevisiae* are compared with those obtained with a purified recombinant SHC of *A. acidocaldarius*. Most of the compounds tested, as expected, are effective inhibitors of both OSC and SHC. The most promising result was obtained with compound **6** (Scheme 2), which shows an $IC_{50}$ of 50 nM for yeast OSC and for SHC: this is among the best activities described to date for *S. cerevisiae* OSC inhibition and one of the best for bacterial SHC. On *S. cerevisiae* OSC, compound **6** is 240-fold more effective than compound **9**, the homologous compound bearing a lateral chain, and 30-fold more effective than the shorter analog **7**. The $IC_{50}$ of compound **6** toward pig OSC is 1 μM, which is one-fifth and one-half of the activity shown by compounds **7** and **9**, respectively. Therefore, compound **6** is not only very active but also specific for yeast OSC, as it is 20 times less active toward the animal enzyme. This result strongly supports the existence of peculiar differences between animal and fungal OSC in the modality of assisting the cyclization process by the active site, although a great homology exists between yeast and animal cyclases both in the amino acid sequence and in the mechanism of cyclization.

**TABLE 1**
**Inhibition Values ($IC_{50}$) of Pig Liver and *Saccharomyces cerevisiae* Oxidosqualene Cyclase (OSC) and Squalene-Hopene Cyclase (SHC) by Vinyl Sulfide Derivatives of Truncated Oxidosqualene**

| | $IC_{50}$ (μM)[a] | | |
|---|---|---|---|
| Compound[b] | OSC (pig liver) | OSC (*S. cerevisiae*) | SHC (*A. acidocaldarius*) |
| **6** | 1 | 0.05 | 0.05 |
| **7** | 5 | 1.5 | 0.5 |
| **8** | 100 | 50 | 3.1 |
| **9** | 2.2 | 12 | 9 |
| **10** | 0.35 | 0.17 | 10 |
| **11** | 6 | 2.5 | 0.6 |
| **12** | >100 | 35 | 25 |
| **13** | 12 | 3.5 | 0.9 |

[a]$IC_{50}$, inhibitor concentration reducing enzymatic conversion by 50%; *A. acidocaldarius, Alicyclobacillus acidocaldarius.*
[b]For compound structures, see Scheme 2 and 3.

The differences seem mainly to concern the formation or stabilization of the C-20 carbocation, since the shorter inhibitors, designed to affect the formation or the stabilization of the C-13 carbocation, do not show important differences of activity between pig and yeast OSC. A similar pattern of inhibition was observed with the 29-methylidene-2,3-oxidosqualene (29-MOS) and hexanor-29-MOS derivatives (21,27–30): (18*Z*)-29-MOS was a very potent irreversible inhibitor of pig and rat OSC, but failed to inactivate yeast OSC, while the (18*E*)-hexanor-29-MOS, lacking the side chain, was a potent and time-dependent inhibitor of yeast OSC.

With the exception of compound **6** toward yeast OSC and SHC, the activity of the other methylthio derivatives **7** and **9** is in the micromolar range for both OSC and SHC. Another interesting finding about this new series of compounds concerns compound **10** (Scheme 3): this dithiane derivative is a very effective inhibitor of both pig and yeast OSC ($IC_{50}$ = 0.35 and 0.17 μM, respectively) and less effective as an SHC inhibitor ($IC_{50}$ = 10 μM). The shorter derivative **11** and the benzodithiole derivative **13** are less active toward OSC and more active toward SHC, and derivative **12**, bearing a terminal dithiane, is a poor inhibitor of both OSC and SHC. The activity of **11** toward SHC is similar to that of other truncated derivatives, such as compound **7** or the (18*E*)-hexanor-29-MOS, previously studied by us (17). SHC seems to be more affected than OSC by possible interactions with the process of formation or stabilization of the C-13 carbocation, since insertion in the substrate analogs of functionalities in the vicinity of this position is very effective for inhibition. Compound **8** is a very poor inhibitor of OSC and a fairly good inhibitor of SHC, thus confirming our previous finding that the substrate analogs need a 2,3-epoxide ring to behave as OSC

inhibitors. Obviously, the epoxide is not necessary for SHC, as the activity toward **8** on SHC is comparable to the other derivatives of this series.

Theoretical studies (44,45) have shown the excellent properties of sulfur in stabilizing the electron-deficient α-carbon, due to its good π- and σ-donor properties. These new compounds, once cyclized by the enzyme, should therefore form a more stable carbonium ion, because of the adjacent sulfur. This intermediate should react, or at least strongly interact, with enzyme residues normally stabilizing the natural carbocations of the cyclizing substrate. Stabilization by sulfur is obviously greater in the α-carbon of ketene dithioacetals, such as compounds **10** and **11**, that, if cyclized by the OS enzyme, should afford a highly delocalized thiocarbenium ion interacting with the adjacent nucleophiles of the enzyme active site. Finally, the benzo-1,4-dithiafulvene derivative **13**, if cyclized by the enzyme, should afford a stable heteroaromatic 1,3-benzodithiolium ion, which might react with the enzyme nucleophiles or directly afford the cyclized fulvene through elimination of the adjacent proton (39).

In order to get further insight into the mechanism of inhibition by the more active compound **6,** it would be interesting to study the time-dependency of inhibition on *S. cerevisiae* OSC, but the low specific activity found in yeast microsomes does not allow the dilution necessary to test the residual activity after preincubation. We are currently planning to look for a more active and suitable source of yeast enzyme. Recently it has been shown that most OSC activity in yeast is present in the cellular compartment of lipid particles (46). Work is in progress to prepare a lipid particle fraction and to test whether this source of enzyme activity is more suitable to study time-dependency of the more interesting inhibitors on yeast.

So far, time-dependency has only been studied with pig liver OSC and with SHC. SHC was not inhibited in a time-dependent manner up to a concentration of **6** that was 10-fold higher than the $IC_{50}$.

Pig liver OSC was inhibited in a time-dependent manner only at inhibitor concentrations five times higher than the $IC_{50}$: after 5 min of preincubation in the presence of the inhibitor, the residual activity was 60% of the controls, and after 20 min it was reduced to 35% of the controls, as shown in Figure 1. The second-order inactivation constant, $k_{inact}/K_I$, calculated from the $t_{1/2}$ values, was 0.011 $mM^{-1}$ $min^{-1}$. This time-dependent inhibition of pig liver OSC showed a pattern similar to that found with a β-hydroxysulfide derivative of truncated OS that we had previously studied (31). Also in this case, the inhibition might be due to the formation of partially cyclized carbocationic intermediates able to bind the enzyme irreversibly or to form a tightly bound ionic complex of the sulfonium ion with the nucleophilic residues of the active site.

The formation of a 6.6.5 fused tricyclic cation that is responsible for OSC inactivation by (18 *E*)-29-MOS was suggested by Abe *et al.* (47). After incubating SHC with labeled (18*Z*)-29-MOS, a partially cyclized metabolite was isolated (36).

We were not able to show the presence of metabolites of compound **6** by high-performance liquid chromatographic analysis of the incubation mixture. Compound **6** is a very efficient inhibitor, and therefore only traces of metabolites could be formed. It is possible that a large amount of the enzyme is necessary to produce detectable amounts of metabolites of a very effective inhibitor.

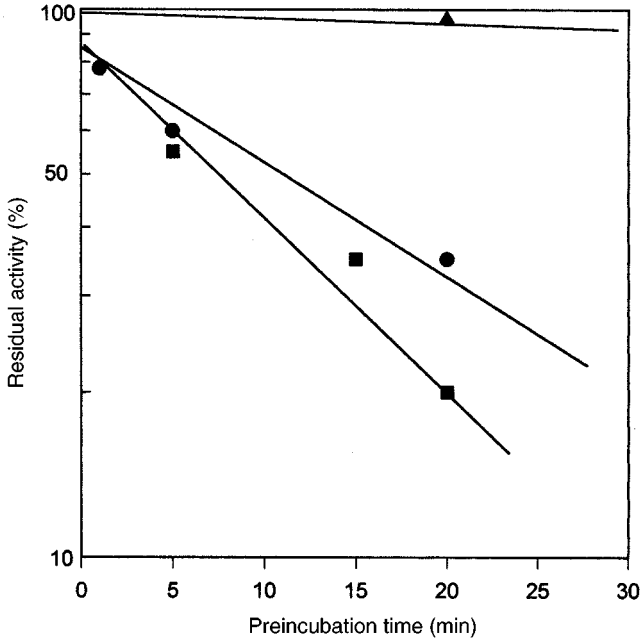

**FIG. 1.** Time-dependent inhibition of pig oxidosqualene cyclase by compound **6** at concentrations of 0.2 (–▲–), 5 (–●–), and 20 μM (–■–).

The high activity and specificity of the methyl sulfide derivative **6** toward yeast OSC, if confirmed with pathogenic fungi, could offer interesting prospects for designing new antifungal drugs.

## ACKNOWLEDGMENTS

This work was supported by the Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST) (40%) and by the Università degli Studi di Terino (60%). Thanks are due to Professor Karl Poralla for supplying the recombinant SHC enzyme.

# Composition of the Silk Lipids of the Spider *Nephila clavipes*

**Stefan Schulz***

Institut für Organische Chemie, Technische Universität Braunschweig, D-38106 Braunschweig, Germany

**ABSTRACT:** A detailed analysis of the lipids of spider silk is given for the first time. Extracts of the silk from the golden orb weaver, *Nephila clavipes*, were studied by gas chromatography, mass spectrometry, and chemical derivatizations. The major group of the lipids consisted of methyl-branched 1-methoxyalkanes (methyl ethers) with up to four methyl groups in the chain (chain length between $C_{28}$ and $C_{34}$), which are unique to spiders. The position of the methyl branches was determined by conversion into cyanides, which allowed easy location of methyl branches. The second-largest group included alkanes with a wide structural variety; 2-methyl-branched, even-numbered hydrocarbons predominated. A general numerical method for the estimation of retention indices of alkanes and their derivatives is presented. Further components of the web included alkanols and alkanediols, fatty acids, and glyceryl ethers. Some comments on the biosynthesis of these compounds are also given.

Paper no. L8714 in *Lipids 36*, 637–647 (June 2001).

The chemical composition and structure of spider silk is currently under intensive study because of its unique properties like tensile strength and elasticity (1–4). Most of this work has been done on silk of the golden orb weaver, *Nephila clavipes* (Arachnida: Araneae). Although the proteins of the fiber have been investigated in detail, other components of the webbing have not received much attention. The presence of lipids on the silk of some spiders has been reported by us (5,6). The purpose of the present study was to analyze the silk lipids of *N. clavipes* for the first time.

## MATERIALS AND METHODS

*Silk*. *Nephila clavipes* was fed *Drosophila melanogaster* and *Calliphora erythrocephala* flies. The large sexual dimorphism between male and the larger female spiders facilitated the collection of female silk only. Silk was obtained from freshly built webs (<2 d old) produced by female specimens living freely in a rearing room under subtropical conditions. The spiders were not fed during web production in order to reduce the possibility of contamination of the silk with lipids of insect prey. Batches of silk (wet weight between 100 mg and 2 g) were immersed in 1 to 4 mL pentane or $CH_2Cl_2$ for several hours; the silk was removed and then the excess solvent was evaporated at room temperature. Dichloromethane exhibited greater efficiency in the extraction step especially with freeze-dried material, which tended to form hard clumps, but $CH_2Cl_2$ also extracted greater quantities of polar material such as ethanolamine. The silk extracts were then analyzed. For quantitative determinations silk batches were freeze-dried (Christ Alpha 1-2), weighed, extracted, freeze-dried again, and finally weighed to estimate the amount of lipids of the silk.

*Derivatization*. Transformation of methyl ethers into cyanides was performed with pentane or dichloromethane extracts of silk (7). The methyl ethers in the extracts were cleaved with $Me_3SiI$ and the resulting iodides were substituted with cyanide. Although substitution could have been performed with NaCN in dimethylsulfoxide at 50°C, cleaner extracts were obtained using tetraethylammonium cyanide at room temperature in $CH_2Cl_2$, because the solution of the iodides could be used directly without change of solvent. After extraction of excess reagent with water and evaporation of $CH_2Cl_2$, the residue was taken up in pentane. This procedure resulted in a clean, salt-free solution ready for analysis by gas chromatography–mass spectrometry (GC–MS) without formation of artifacts.

Methyl esters were obtained by oxidation of extracts with $RuO_4$ (5). Silylations were performed by adding 30 μL *N*-trimethylsilyltrifluoroacetamide (MSTFA) to an equal amount of extract. After 30 min at 50°C, excess reagent and solvent were evaporated with a gentle stream of nitrogen and the residue was taken up in pentane. Methylations of fatty acids were performed similarly, but with trimethylsulfonium hydroxide solution (Aldrich, Milwaukee, WI) instead of MSTFA. Under these conditions, wax esters are cleaved and alcohols are converted to 1-methoxyalkanes.

*Analysis*. Mass spectra (70 eV) were obtained with a VG 70/250 S mass spectrometer (Manchester, United Kingdom) coupled to a Hewlett-Packard HP 5890 A gas chromatograph (Palo Alto, CA) with on-column injection or a Hewlett-Packard MSD 5973 with splitless injection, both in electron impact (EI) mode with helium as the carrier gas. The gas chromatograph was a Carlo-Erba Fractovap 2101 (Milan, Italy) with on-column injection or a CE Instruments GC 8000 (Milan, Italy) with split/splitless-injection. Separations were performed on different 25-m BPX-5 (SGE; Melbourne, Australia) capillary columns with hydrogen as the carrier gas. The retention indices *I* were determined according to van den Dool and Kratz (8). Well-established procedures for identification of alkanes exist, which have been recently summarized in a general identification scheme based on mass spectra and retention indices (9). These were followed and modified, as

discussed in the text, when needed. Several identified compounds were compared with synthetic samples [1-alkanols, 1,3-diols, some 1-methoxyalkanes (5), and 2,6-dimethyloctacosane and 2,22-dimethyloctacosane].

## RESULTS

Two extractions with pentane yielded a lipid content of 2.14 and 2.27% for two samples (173.0 and 224.2 mg dry weight, respectively). An additional extraction with $CH_2Cl_2$ yielded another 2.6 and 4.01% of material, which also contained some nonlipidic compounds. From these experiments, the lipid content of the dry fiber was estimated to range between 3 and 5%. The GC–MS analyses of the $CH_2Cl_2$ or pentane extracts revealed the presence of three major classes of lipid: hydrocarbons, alcohols, and unique methyl-branched alkyl methyl ethers.

*Alkyl methyl ethers*. Long-chain ($C_{28}$ to $C_{34}$) alkyl methyl ethers (1-methoxyalkanes) made up between 50 and 80% of the silk lipids. The ethers were identified by characteristic ions at $m/z = 45$ ($CH_3OCH_2^+$) and $M^+ - 32$ ($M^+ - CH_3OH$) in their mass spectra, as well as their inertness toward MSTFA. Their gas chromatographic *I* and intensive ions arising from cleavage next to methyl groups pointed to multiple methyl branches in these ethers. The gas chromatograms of the crude and derivatized extracts showed one advantage of cyanide derivatization (Fig. 1). Owing to the later elution of the cyanides, other compounds present in the extract were better resolved, thereby allowing the identification of minor hydrocarbons that coeluted with some methyl ethers in the silk extracts.

The ethers from *N. clavipes* contained up to four methyl branches. As an example, the identification of 1-methoxy-16,20,24,28-tetramethylhentriacontane (compound **28** in Table 1) will be described (mass spectrum, Fig. 2A). The number of methyl groups along the chain was calculated by comparison of its retention index *I* (8) with calculated values $I_c$ for different structures according to Equation 1 (5,6), where *N* is the number of carbons in the chain times 100, FG is a functional group increment, Me is an increment for each methyl group according to its position relative to the end of the chain (see Table 2), and *S* is a steric increment for each 1,5-position of two methyl groups, which was determined to

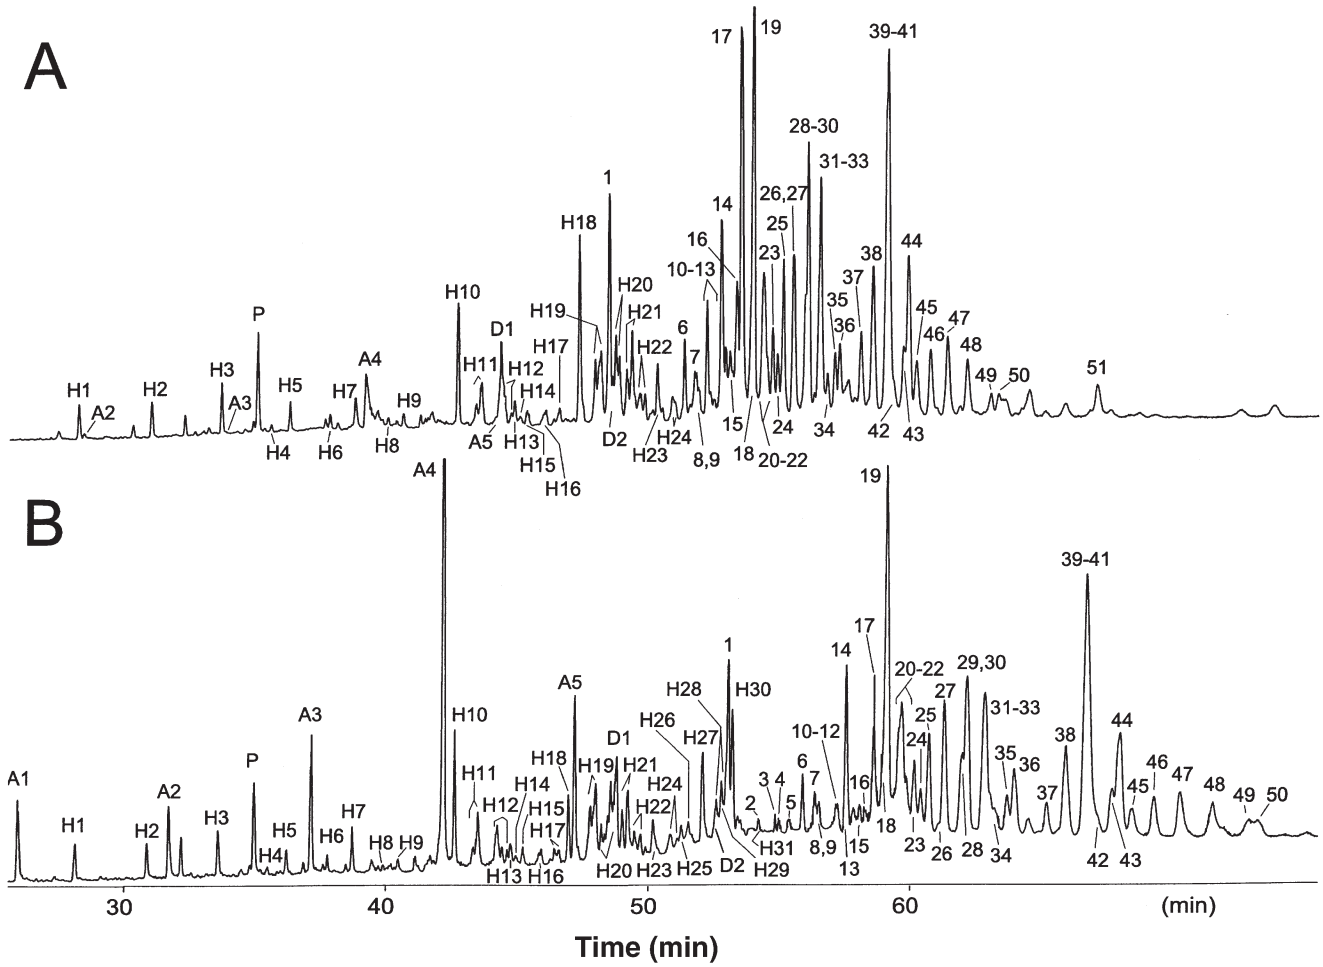

**FIG. 1**. Gas chromatograms of silk lipid extract from *Nephila clavipes* on a 25-m BPX-5 column (SGE, Melbourne, Australia). (A) Crude silk extract; (B) silk extract after transformation into cyanides. Prefixes of peak numbers denote chemical classes: H, hydrocarbon; A, alcohol; P, phthalate; D, diol.

be 5.[1] Normally, the calculated and measured values did not fall more than 10 units apart.

$$I_c = N + \mathrm{FG} + \Sigma\,\mathrm{Me}_i - \Sigma\,S \qquad [1]$$

A value of $I$ = 3465 was found for compound **28** (FG is 232 for methyl ethers), pointing to four or more methyl groups in

[1]The values were determined with $C_{29}$ and $C_{30}$ components. A slight decrease in increments [see Carlson *et al.* 9] has to be taken into account when applying the method to longer chains. A 1,7-arrangement of methyl groups often shows a similar factor $S$ especially in multimethyl-branched compounds. Note that this algorithm allows only rough estimation of the structure (9), especially the discrimination of several constitutional isomers with different chain length. More precise $I_c$ values can be obtained with molecular mechanics calculations (10), at the expense of considerably more effort.

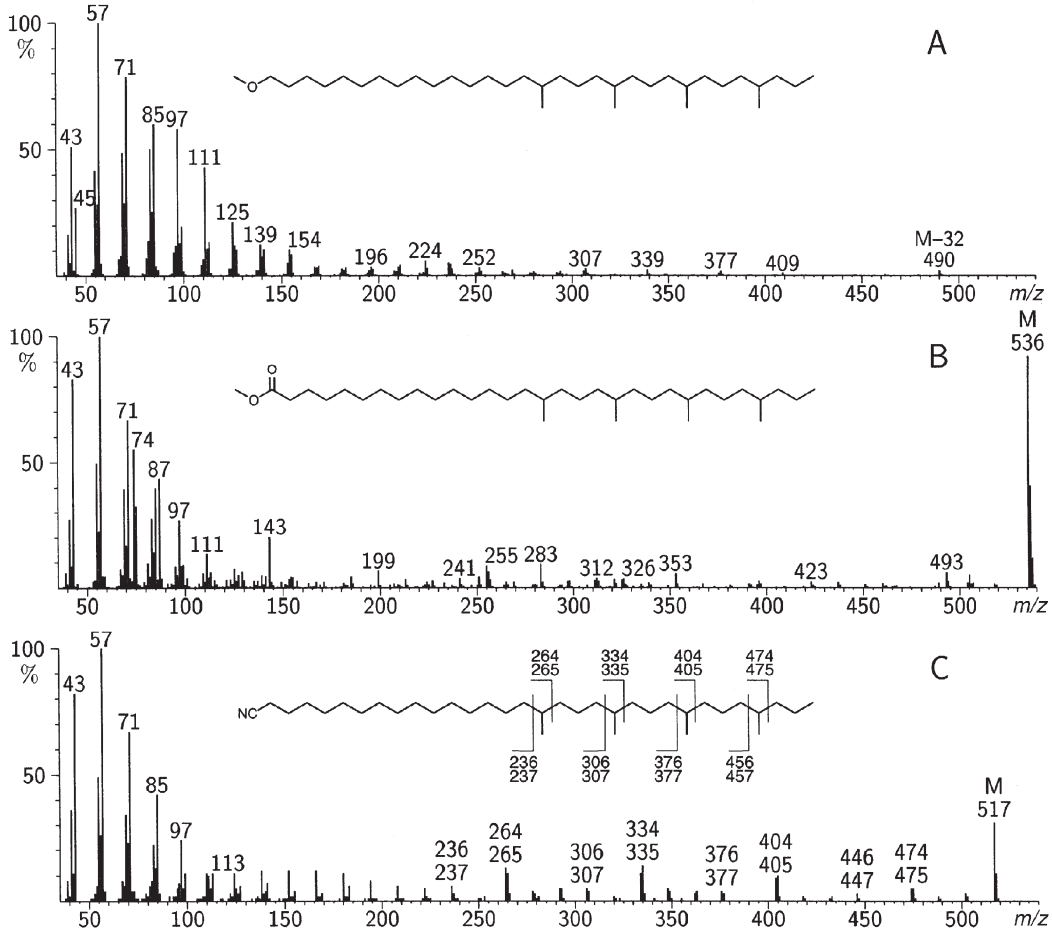

**FIG. 2.** Mass spectra of *Nephila clavipes* silk lipids and their derivatives. (A) 1-Methoxy-16,20,24,28-tetramethylhentriacontane (compound **28** in Table 1); (B) methyl 16,20,24,28-tetramethylhentriacontanoate; (C) 16,20,24,28-tetramethylhentriacontyl cyanide.

the molecule. The EI mass spectrum of the corresponding cyanide allowed easy location of the methyl groups, because chain cleavage predominantly occurs at branching points and preferably furnishes nitrogen-containing cations (7) (Fig. 2C). The original position of the methoxy group is thus evident. Because other fragment ions become more prominent below *m/z* = 115, location of methyl groups between C-2 and C-5 is ambiguous. To overcome this problem, the mass spectra of the corresponding methyl esters allow the localization especially at these positions (11), whereas multiple branchings within the chain are difficult to ascertain in the esters (Fig. 2B), especially when they occur as mixtures (12). The mass spectrum of the corresponding methyl ester of compound **28** exhibits no ions characteristic for methyl groups between C-2 and C-5, leading to the structural assignment of compound **28**. The value $I_c$ = 3461 for compound **28** correlates well with the observed one of 3465, while the respective cyanide (FG 458 for the cyanide group) differs slightly more: $I$ = 3681, $I_c$ = 3688. For comparison, mass spectra derived from 1-methoxy-18,22,26-trimethylhentriacontane (compound **25** in Table 1) are given in Figure 3. A total of 51 methoxyalkanes of *Nephila clavipes* silk were identified by this method and are tabulated in Table 1.

*Alkanes*. Alkanes constituted the second-largest group of compounds in the silk extracts; most of them were methyl-branched. The major components, 2-methyloctacosane and 2-methyltriacontane, were accompanied by a large number of dimethyl, trimethyl, and tetramethyl even- and odd-numbered alkanes (alkanes with an even or odd number of carbon atoms in the chain) as well as some *n*-alkanes (Fig. 1). The identification of even-numbered alkanes with several methyl branches is more difficult than those of the odd-numbered ones (9). As

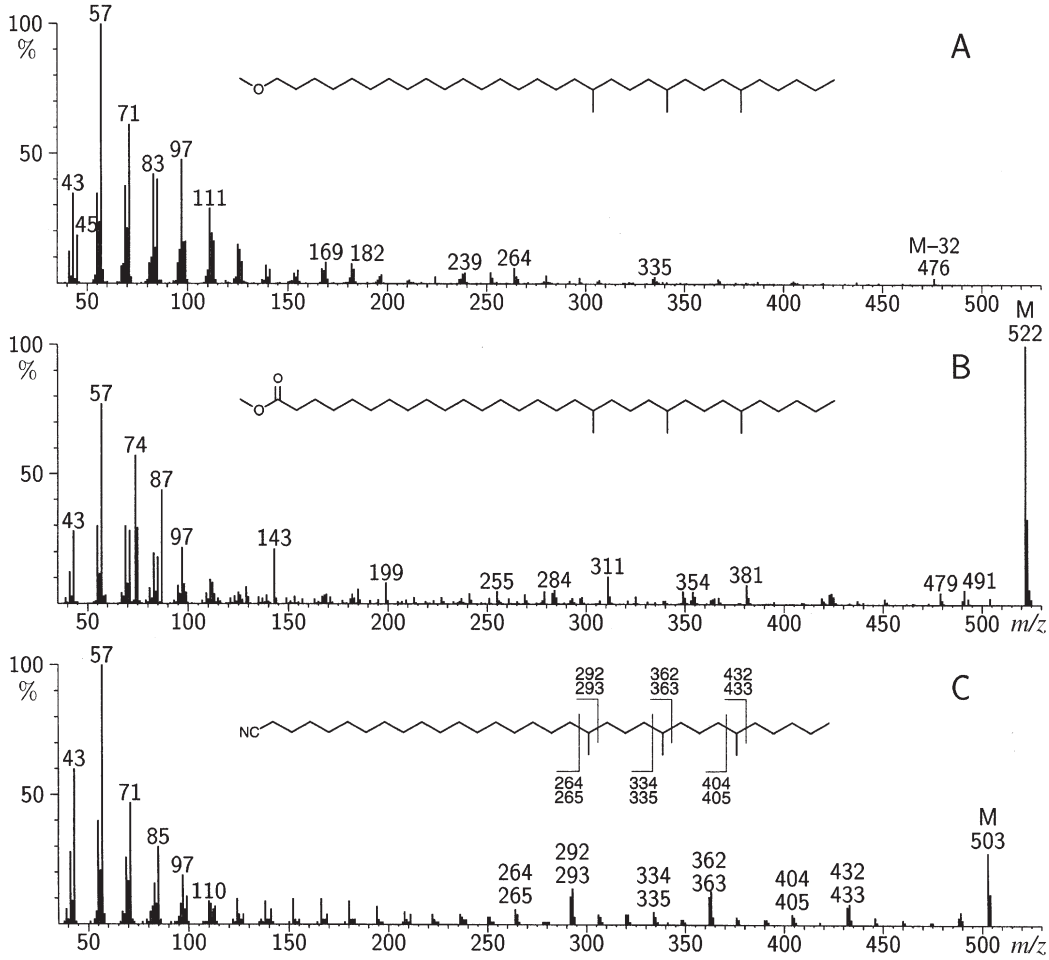

**FIG. 3.** Mass spectra of *Nephila clavipes* silk lipids and their derivatives: (A) 1-Methoxy-18,22,26-trimethylhentriacontane (compound **25** in Table 1); (B) methyl 18,22,26-trimethylhentriacontanoate; (C), 18,22,26-trimethylhentriacontyl cyanide.

pointed out by Pomonis *et al.* (13), but not always considered by later workers, the identification of 2-methylalkanes with an even-numbered carbon chain and additional methyl branches is often ambiguous. In the mass spectra, characteristic ions *a* arise from α-cleavage next to the methyl branch (Fig. 4).

Fragments containing no additional methyl branch also form an intense ion $a - 1$, resulting in characteristic double ions (14,15). Unfortunately, a methyl group at C-2 does not suppress the formation of the $a - 1$ ion (13), as do methyl groups in other positions. Therefore, for every set of ions, two possible structures exist, provided both represent biosynthetically reasonable structures. All multiply branched cuticular alkanes from arthropods identified so far possess at least three methylene units and an uneven number of them between the branches (14,16–18). An even number of spacer units can arise only in 2,X-branched odd-numbered alkanes, which are formed by an isobutyryl starter (derived from leucine) and incorporation of a propionate unit somewhere in the chain. The only compound of this type known so far is 2,5-dimethylheptadecane, a sex pheromone component of the moth *Lambdina fiscellaria* (19). Other reports of compounds not fulfilling the above rules are either not unequivocally supported by the presented data or are misinterpretations (14). Nevertheless, hydrocarbons possessing only a one-methylene spacer are reported from insects (18,20), but these are considerably smaller molecules than typical cuticular alkanes. In odd-numbered hydrocarbons usually only one structure fulfills the rules listed above, but in even-numbered alkanes often both structures are reasonable. Nevertheless, it should be noted that hydrocarbons not following the described biosynthetic requirements have been identified in other organisms, e.g. cyanobacteria (21).

The silk of *N. clavipes* contained a complex, difficult-to-elucidate pattern of hydrocarbons with many positional isomers. For example, the mass spectra from 2,6-dimethyloctacosane ($I$ = 2898, Fig. 4A) and 2,22-dimethyloctacosane ($I$ = 2899, Fig. 4B), which were available as synthetic reference compounds (Schulz, S., unpublished data), showed only small differences which could not be predicted. The presence of 2,6-dimethyloctacosane in the extracts was confirmed by its

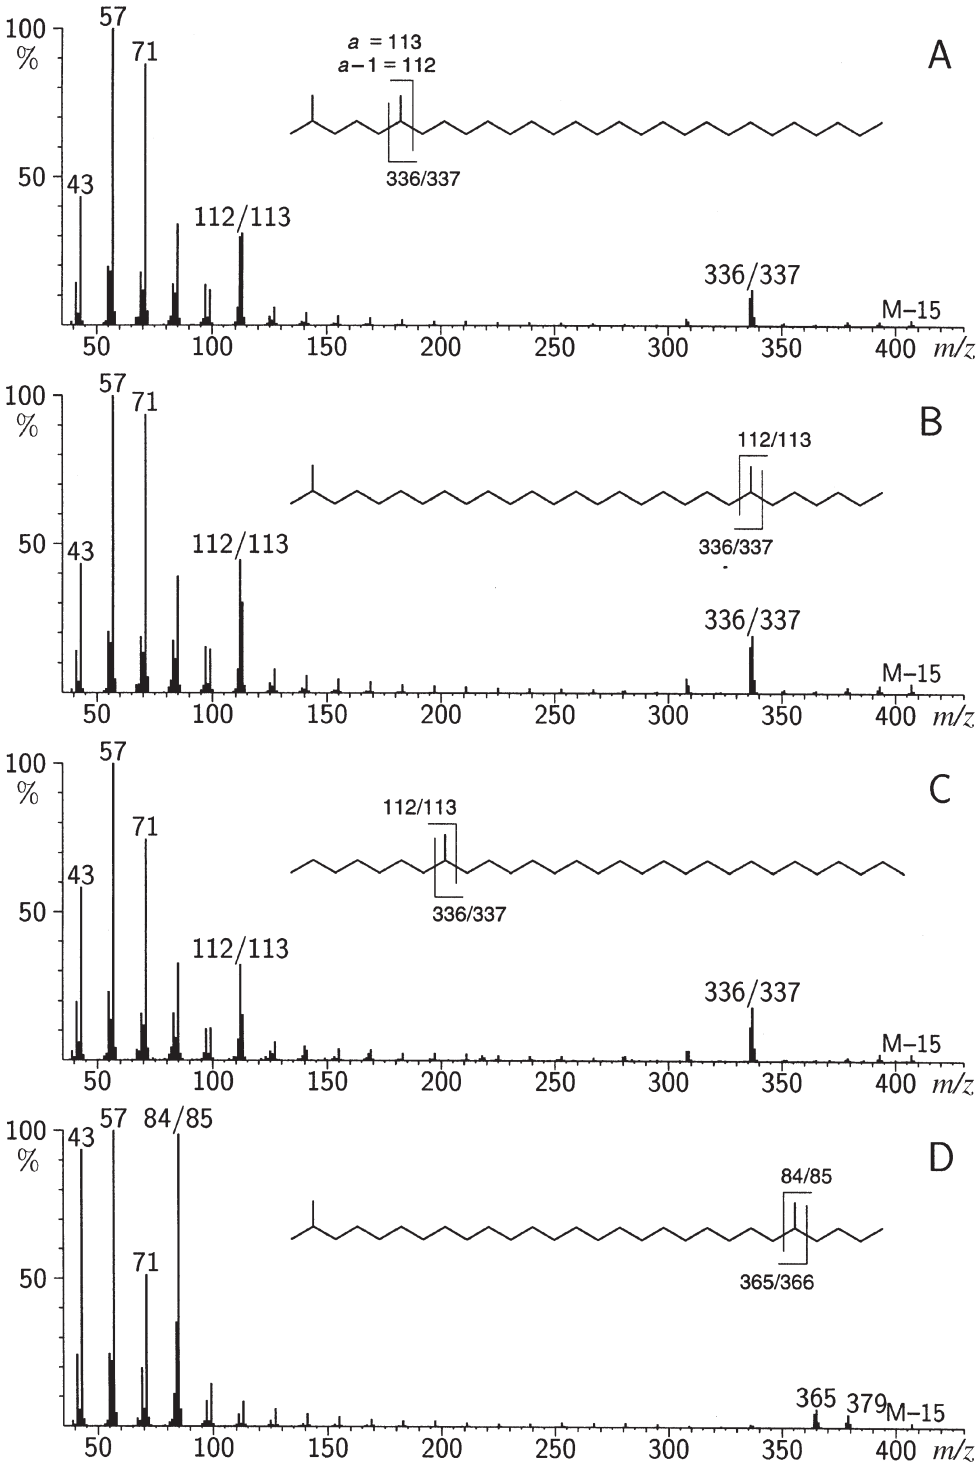

**FIG. 4.** Mass spectra of branched alkanes. (A), 2,6-Dimethyloctacosane (synthetic); (B), 2,22-dimethyloctacosane (synthetic); (C) 7-methylnonacosane (*Nephila clavipes*); (D) 2,24-dimethyloctacosane (*Nephila clavipes*).

mass spectrum, although the presence of the 2,22 isomer remains possible. The third compound with a similar spectrum, 7-methylnonacosane (Fig. 4C), also occurred in the extract but was readily identified because of its greater retention index ($I$ = 2936). We also found spectra with corresponding $I$ values consistent with the isomeric pairs 2,8-/2,20- ($I$ = 2293), 2,10-/2,18- ($I$ = 2291), 2,12-/2,16- ($I$ = 2289), and 2,14-dimethyloctacosane ($I$ = 2289). It cannot be stated with certainty whether only one or both compounds of these pairs were present in the silk. Additionally, 2,24-dimethyloctacosane ($I$ = 2903) was identified, for which no biosynthetically reasonable other structure exists (Fig. 4D). Obviously, a relatively random distribution of methyl branches on even-numbered carbon atoms occurred along the chain.

Identifications became more difficult with additional methyl groups in the chain, because complex overlayings of several isomers with identical or slightly different *I* were found. Although only two isomers (2,6,10- and/or 2,18,22-) dominated in the trimethyloctacosanes eluting at an *I* of 2921, three isomers are possible in the corresponding tetramethyloctacosanes at *I* = 2950, despite the fact that the 2-methyl group and the other branches are certainly located at opposite ends due to biosynthetic considerations. Otherwise, only one methylene unit would be found between two methyl branches (Fig. 5).

Both 2,16,20,24- and 2,14,20,24-tetramethyloctacosane are consistent with the observed mass spectrum. Both were probably present, because the characteristic $a - 1$ fragment occurred at *m/z* = 224 and at 252. These structures do not explain the intense ion at *m/z* = 295, which could be due to the presence of 2,14,18,24-tetramethyloctacosane, but the required corresponding ion at *m/z* = 183 was of relatively low abundance. Similar difficulties arose with the identification of other multibranched hydrocarbons. The major hydrocarbons identified in each peak are shown in Table 3 and were often accompanied by several unstated isomers. A more detailed description of the hydrocarbons of the silk and the cuticle of *N. clavipes* will be published elsewhere.

*Alcohols*. Straight-chain, even-numbered 1-alkanols ($C_{18}$ to $C_{26}$) were also present in the silk extracts. They sometimes exhibited considerable tailing during GC on apolar phases, depending on the inertness of the column. Therefore, silylation prior to analysis is the method of choice to improve peak shape. During the transformation of the ethers into cyanides the alcohols were also smoothly transformed, as can be seen for 1-tetracosanol (**A4** in Fig. 1). Because peak shape was improved, an additional silylation was not necessary. In addition to the 1-alkanols, the diols 1,3-docosanediol (compound **D1** in Fig. 1), 1,3-tetracosanediol (**D2**), and 1,3-hexacosanediol were present in the extracts. They were identified from their mass spectra by an intense ion at *m/z* = 75, representing $HO(CH_2)_2CHOH^+$, which was accompanied by characteristic ions at M – 1, M – 18, and M – 36 (Fig. 6A). These diols formed dicyanides under the conditions reported above. The mass spectrum of the dicyanide of the major 1,3-tetracosanediol showed an intense ion at *m/z* = 348 (M – 40, M – $CH_2CN$), indicative for the terminal cyano group, but the location of the second cyano group could not be readily derived from its spectrum. This ion was intense, because in contrast to the monocyanides it contained a cation-stabilizing cyano group.

During the analysis of the fatty acids of the extracts (see below), we found that trimethylsulfonium hydroxide not only formed methyl esters from fatty acids and esters but also methylated alcohols when the reaction took place at 50°C for 30 minutes. The resulting 1,3-dimethoxy compounds gave characteristic mass spectra, exhibiting ions at *m/z* = 103 ($CH_3OCH_2CH_2CHOCH_3^+$) and 339 ($C_{22}H_{44}OCH_3^+$) (Fig. 6C).

We also observed the occurrence of a GC peak in the underivatized extracts showing a very prominent base peak at *m/z* = 131 in its mass spectrum (Fig. 6D). This compound obviously was a reaction product of the diol with the GC phase, because the spectrum was consistent with 4-henicosyl-2,2-dimethyl-1,3-dioxa-2-silacyclohexane. The ion trace at 131 was enhanced after the peak until it reached the later-eluting parent diol. This behavior represented degradation of a compound on the column and was also observed after injection of synthetic diols. A standard BPX-5 (SGE) column containing dimethylsilane units was used, but this effect was also observed on similar phases from other suppliers. We have also encountered this phenomenon with other long-chain diols (22). To the best of our knowledge, this is one of the very few cases demonstrating the reaction of an apolar GC phase with a solute normally regarded as nonreactive.

*Other compounds*. Other silk components were fatty acids, wax-type esters, and 1-*O*-alkylglyceryl ethers. They were identified by their mass spectra or after derivatization with MSTFA or trimethylsulfonium hydroxide (23,24). The content of the fatty acids varied with the sample, but palmitic acid (16:0, 39% of all acids) was always the most prominent one, followed by 18:1 (17%), stearic acid (18:0, 15%), and 18:2 (8%) acids. Other acids found in lower amounts were 14:0 (3%), 13-Me-14:0 (1%), 15:0 (1%), 16:1 (4%), 17:0 (1%), 20:0 (2%), 22:0 (5%), and 24:0 (1%), while the acids 12:0, 13:0, 3-Me-13:0, 12-Me-13:0, 4-Me-14:0, 12-Me-14:0, 4-Me-15:0, 14-Me-14:0, 4-Me-16:0, 14-Me-16:0, 15-Me-16:0, 19:0, 21:0, and 23:0 occurred in amounts less than 1% of the total acids in the sample. Branching positions were determined by MS (11) and comparison of *I* values with those of authentic samples. The major wax-type ester was tetracosyl hexadecanoate, which was accompanied by tetracosyl octadecanoate. Both compounds always occurred in minor amounts. The three ether lipids 1-*O*-octadecyl-, 1-*O*-eicosyl-, and 1-*O*-docosylglycerol occurred as trace components.

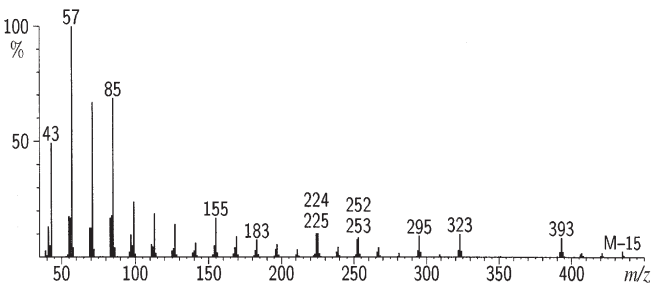

**FIG. 5.** Mass spectrum of the *Nephila clavipes* peak at *I* = 2950 consistent with 2,16,20,24- and/or 2,14,20,24- and/or 2,14,18,24-tetramethyloctacosane.

## DISCUSSION

The present study contains the first complete characterization of the silk lipids of a spider. Previously, only 1-methoxyalkanes from the silk of the linyphiid spider *Linyphia triangularis* had been characterized (5). The cuticular lipids of two spider species have also been analyzed. Although *Tegenaria*

[a]Bold numbers are compound assignments used in Figure 1, regular numbers indicate positions of methyl branches.
[b–n]Indices assign isomeric structures that would fit a given mass spectrum and retention time.
[o]Isomeric structure with n-1 methyl group instead C-2 methyl group also possible (see text).

*atrica* lipids are dominated by alkanes also found in insects (25–27), *Anelosimus eximus* contains unusual propyl esters of long-chain fatty acids together with alkanes (28). The current knowledge of cuticular and silk lipids of spiders has been reviewed (6). Previously we developed a method for identification of methyl ethers with up to two methyl branches (5). This method was improved and extended by replacing the final $LiAlD_4$ reduction step by substitution with cyanide (7). Comigrating alkanes are separated by this method from the resulting cyanides, which exhibit informative mass spectra.

The 1-methoxyalkanes, which are the major group of compounds in *N. clavipes* silk, contain up to four methyl branches in the chain. These methyl groups are located closer to the alkane end of the molecule and are most often arranged in a 1,5-pattern, with the exception of 1-methoxy-2,28-dimethyltriacontane (compound **17** in Table 1). This compound is also the only one with a methyl group at C-2, a prominent structural feature of the ethers from the silk of *L. triangularis* (5), which are less branched. No other ether occurs in both species, which are not closely related. The 1,5-arrangement of methyl substituents is the dominant pattern in di-, tri-, or tetramethyl alkanes from the insect cuticle (14,15,18).

The biosynthesis of the 1-methoxyalkanes, which have so far not been reported from organisms other than spiders, can be assumed to start from the alkyl end with the incorporation of methylmalonate instead of malonate units, leading to the methyl branches, as has been found in insects (16,18). The 4-methyl carboxylic acids present in traces might be suitable precursors for monomethyl-branched ethers. Elongation of these acids would lead to ethers containing a methyl group around C-20, a preferred location in the chain. Nevertheless, the putative precursors of the polymethyl-branched ethers, fatty acids with several methyl branches, could not be detected. Interestingly, α-oxidation or C-1 elongation seems to take place, because the structure of 3-methyltridecanoic acid cannot be explained by the known biosynthetic pathways (for a discussion on α-oxidation see Ref. 22). In the final steps, reduction and methylation furnish methyl ethers; a decarboxylation, which would lead to alkanes, does not occur. The unbranched, iso- and anteiso-branched fatty acids seem not to be involved in ether biosynthesis except for compounds **14** and **17**, which can be derived from anteiso-branched even-numbered fatty acids. The fact that methyl branches in the ethers always occur at even-numbered carbons points to an acetate starter unit for even-numbered ethers and a propionate starter for odd-numbered ethers, which do slightly prevail.

The hydrocarbons show a very broad range of structures: mono-, di-, tri-, and tetramethyl compounds. The predominating even-numbered 2-methylalkanes are formed most probably by a isobutyryl starter unit produced from valine (17). The other branches seem to be introduced relatively randomly, unlike in the ethers. These patterns indicate that the biosyntheses of hydrocarbon and ether chains are not closely related. Hydrocarbons with an odd number of carbon atoms in the chain usually predominate on the surface of arthropods (14,15,18). In contrast, major hydrocarbons of the silk lipids

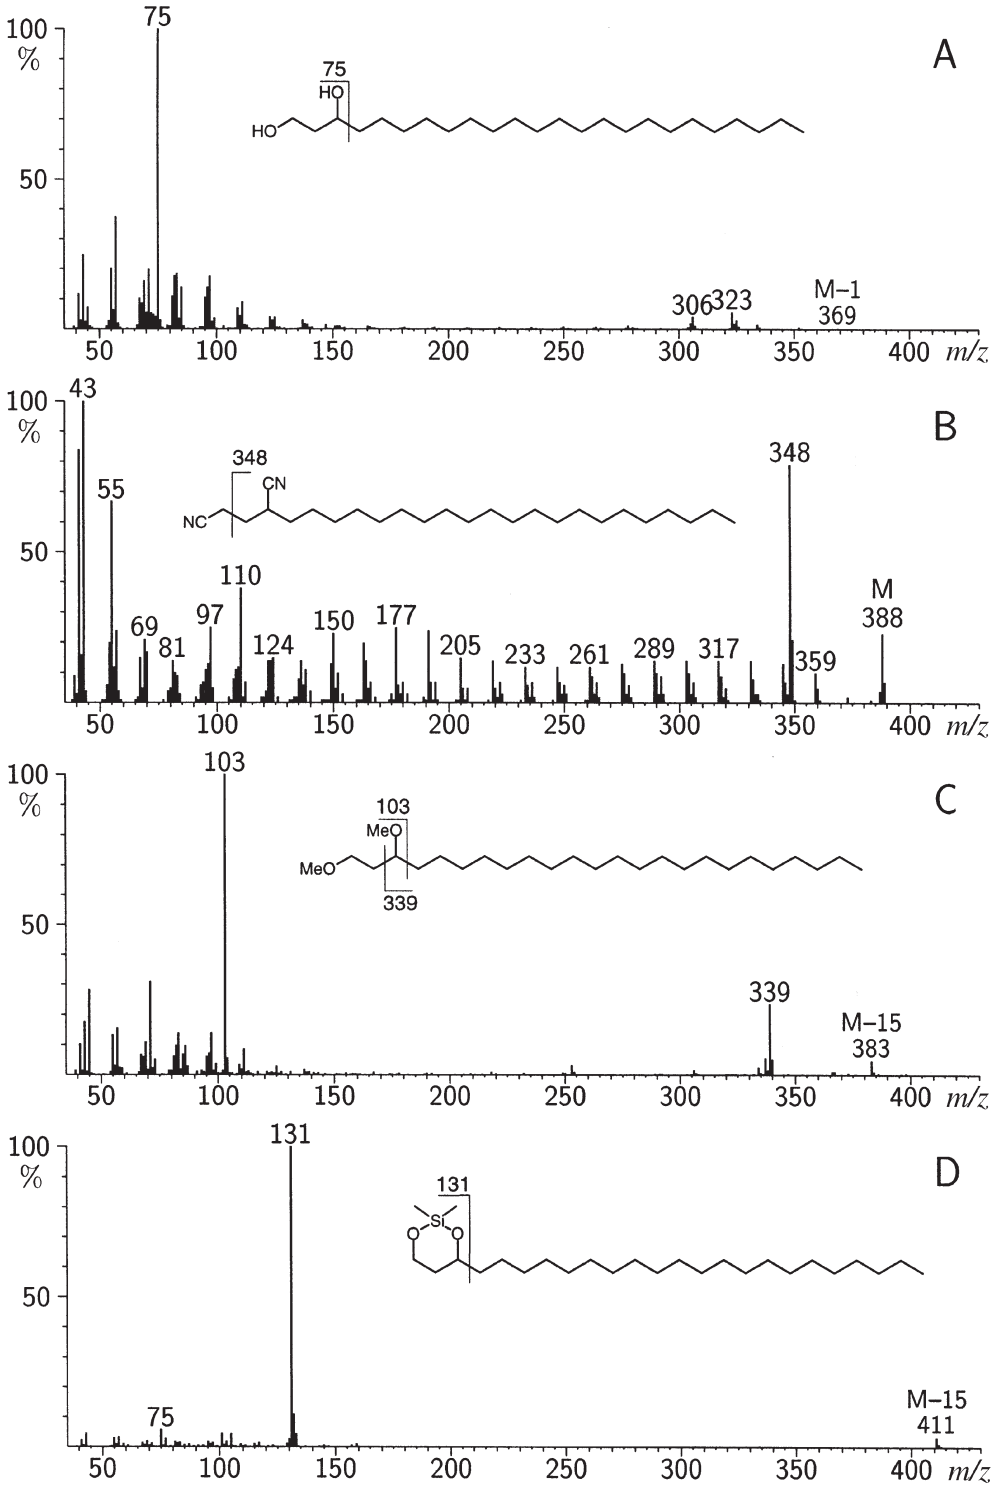

**FIG. 6.** Mass spectra of 1,3-tetracosanediol (A; compound **D2** in Fig. 1) from *Nephila clavipes*, its dicyanide derivative (B), the respective dimethyl ether (C), and its dimethylsiloxane derivative formed by reaction with the stationary phase (D).

of *N. clavipes* are even-numbered alkanes. This finding also points against a dietary uptake of the hydrocarbons, because the major alkanes of the flies used as food are odd-numbered 2-methyl and other alkanes (29,30).

The identified alcohols are not structurally related to the ethers. While the 1-alkanols have often been found in arthropod cuticle (18), the 1,3-diols are not known from any other arthropod so far. They have been recently identified in *Pa-*

*paver* leaf wax (31). Fatty acids and wax esters frequently occur in the cuticle of arthropods, while glycerol ether lipids have, to the best of our knowledge, not been reported before from such sources.

The function of the silk lipids remains unknown. Most of the lipids are likely to be present on the silk fiber, but the fact that prolonged extraction yields larger amounts of lipids may indicate involvement in the core fiber structure. The primary function may be regulation of the water content of the silk or protection of the protein-rich silk against degradation, e.g., by microorganisms or chemical agents. The lipids may also be used for communication, because males can recognize the webs of females by contact (32). Which one of the different silk types produced by *N. clavipes* (33) contains the most lipids is unknown, as is the origin of the lipids. Freshly drawn dragline silk from another *Nephila* species contains only relatively low amounts of lipids (Vollrath, F., and Schulz, S., unpublished data), suggesting that most of it is present in other silk types or is deposited from the spider while walking on the web. On the other hand, the cuticle lipids of the spider contain only small amounts of ethers and are dominated by hydrocarbons. Therefore, the possibility exists that the hydrocarbons are transferred from the cuticle during walking, while the ethers originate from another source, e.g., glands. 1-Methoxyalkanes have now been found in silk from three spider families: Araneidae, Linyphiidae, and Theridiidae (6). The reason for the production of more elaborate ethers as lipids instead of the more widespread alkanes is not clear. Probably some degree of polarity on one end of the molecule is needed for good interaction with the proteinaceous fiber or other silk compounds. The polarity of the head group of the long-chain compounds decreases from diol to 1-alkanol to ether to alkane.

The conversion of methyl ethers into cyanides proved to be an important tool for compound identification in this study. In addition to the ethers, primary and secondary alcohols were also cleanly transformed into cyanides. Esters of fatty acids can be transformed into alcohols prior to derivatization, as we have shown recently (28). On the other hand, attempts to determine the position of double bonds in unsaturated alcohols or ethers failed. No characteristic ions useful for the location of the double bond could be detected in the mass spectra of synthetic (*Z*)-9- and (*Z*)-11-octadecenyl cyanides.

## ACKNOWLEDGMENTS

I thank especially Harald Tichy and Rudolf Ehn, University of Vienna, for the supply of silk. I also thank Andreas Schmidt for technical assistance and the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support. Finally, I thank Fritz Vollrath for fruitful discussions in the early part of this study.

# Fullerenoid Lipids: First Synthesis of Structured Triacylglycerols Containing an Aza-[60]fullerene Unit

**Marcel S.F. Lie Ken Jie*, Sunny W.H. Cheung, and Janette C.M. Ho**

Department of Chemistry, The University of Hong Kong, Hong Kong, SAR, China

**ABSTRACT:** Some 1,2- and 1,3-diacyl glycerols (with acyl groups as stearyl, oleyl, linoleyl, or stearolyl) were synthesized by conventional methods. The diacyl glycerols were esterified with 6-bromo-hexanoic acid to give the corresponding bromo-triacylglycerols (of the type AAB and ABA containing a bromo group at the distal part of the hexanoate chain). The bromo function was transformed to an azide group by reaction of the bromo-triacylglycerols with sodium azide. The resulting azido-triacyl-glycerols were then reacted with [60]fullerene to give the requisite aza-fullerenoid triacylglycerol of the type ABA or AAB (45–62% yield based on the amount of [60]fullerene reacted). The nitrogen atom attached to the carbon cage formed a "[5,6]-open" type aza substructure, which was confirmed by the appearance of 31–32 signals in the region of $\delta_C$ 133–148 (carbon shifts of $sp^2$ carbons of the cage) in the $^{13}C$ nuclear magnetic resonance spectra. The spectroscopic and mass spectrometric properties of these novel fullerenoid triacylglycerols are reported.

Paper no. L8711 in *Lipids 36,* 649–654 (June 2001).

In the past 15 yr, the chemistry of the [60]fullerenes ("bucky balls") has been one of the most exciting challenges in chemical research (1–6). A number of potential medical applications of derivatives of [60]fullerene have been reported (7). For example: *p,p′*-bis(2-aminoethyl)-diphenyl-[60]fullerene is found to be a potent HIV protease inhibitor (8); a [60]fullerene derivative containing three methano-dicarboxylic acid groups is a strong antioxidant with neuroprotective abilities which is being targeted for controlling amyotrophic lateral sclerosis (Lou Gehrig's disease) (9).

Polyethylene glycol derivatives of [60]fullerene are potential photodynamic therapy agents, which are shown to cure mice induced with fibrosarcoma tumors (10). Most researchers have concentrated their efforts on the production of water-soluble [60]fullerene derivatives. Only a few have described [60]fullerene derivatives containing a fatty acid or ester moiety, such as the preparation of amphiphilic $C_{60}$ [(ethoxycarbonyl)decylene]fullerene and bis[(ethoxycarbonyl)decylene]-fullerene (11) and [60]fullerene bearing a triple-chain lipid (12). The structural and dynamic effects of some lipophilic [60]fullerene derivatives in phospholipid bilayers have also been reported (13).

We recently reported the syntheses of a number of [60]fullerenoid lipids: *viz*. dialkyl 1,2-[6,6]methano-[60]-fullerene dicarboxylates (14) and several fullerenoid-lipid molecules containing a triester system (15).

This paper reports the synthesis of the first structured triacylglycerols of the type ABA (compounds **1a–1d**) and AAB (compounds **2a–2d**), where the letter B represents an acyl group containing an aza-[60]fullerene cage and the letter A represents acyl groups derived from either stearic acid, oleic acid, linoleic acid, or stearolic acid (Schemes 1 and 2).

## MATERIALS AND METHODS

Infrared (IR) spectra were recorded on a Bio-Rad FTS-165 FT-IR spectrometer (Bio-Rad Inc., Hercules, CA). Samples were run as neat films for liquids on KBr discs. Ultraviolet (UV) spectra were recorded on a Hewlett-Packard Diode Array Spectrophotometer, model 8452A (Hewlett-Packard, Palo Alto, CA) of solutions in dichloromethane. Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker Avance $DPX_{300}$ (300 MHz) Fourier transform NMR spectrometer (Bruker, Fallanden, Switzerland) from solutions in deuteriochloroform ($CDCl_3$) with tetramethylsilane (TMS) as the internal reference standard. Chemical shifts are given in δ-values in ppm downfield from TMS ($\delta_{TMS}$ = 0 ppm). Mass spectral analyses [atmospheric pressure chemical ionization (APCI)] were carried out on Finnigan MAT-LCQ (Finnigan Corp., San Jose, CA).

Stearic acid, oleic acid, linoleic acid and 6-bromo-hexanoic acid were purchased from Aldrich Chemical Co. (Milwaukee, WI). Stearolic acid (9-octadecynoic acid) was prepared by bromination-dehydrobromination reaction of oleic acid as described elsewhere (16). [60]Fullerene was purchased from Materials and Electrochemical Research Corp. (Tucson, AZ).

*Synthesis of triacylglycerols (**1a–1d**) of type ABA containing an aza-fullerenoid acyl group at the β-position of the glycerol as exemplified by the synthesis of compound **1a** (Scheme 1).* 1,3-Dioctadecanoate glycerol (**4**) was synthesized starting from 1,3-dihydroxy-propan-2-one (**3**) as described by Jackson and Lundberg (17).

A mixture of compound **4** (2.0 g, 3.5 mmol), 6-bromo-hexanoic acid (0.67 g, 3.6 mmol), *N,N*-dicyclohexylcarbodiimide (DCC) (0.71 g, 3.67 mmol) and 4-dimethylaminopyridine

Reagents and conditions: (i) 3,4-dihydro-2*H*-puran, pyridinium-*p*-toluene sulfonate (PPTS), $CH_2Cl_2$, 25°C, 4 h; (ii) $KMnO_4$, 0–5°C, 2 h at room temperature and heated for 1 h at 100°C; (iii) DCC, DMAP, RCOOH, $CH_2Cl_2$, 25°C, 4 h; (iv) PPTS, EtOH, 55°C, 4 h; (v) DCC, DMAP, $Br(CH_2)_5COOH$, $CH_2Cl_2$, 25°C, 4 h; (vi) $NaN_3$, DMSO, 70°C, 4 h; (vii) [60]fullerene, chlorobenzene, reflux 12 h.

**SCHEME 2**

(DMAP) (50 mg) in $CH_2Cl_2$ (50 mL) was stirred for 4 h. The filtrate was evaporated under reduced pressure. *n*-Hexane (50 mL) was added to the residue, and the precipitate was filtered off. The filtrate was evaporated under reduced pressure. The residue was chromatographed on a silica gel column (100 g) using a mixture of diethyl ether/*n*-hexane (8:92, vol/vol, 250 mL) as eluent to give 2-(6-bromo-hexanoate)-1,3-dioctadecanoate glycerol (**5**, 1.9 g, 80%). Compound **5** (200 mg, 0.25 mmol) was stirred with sodium azide (24 mg, 0.36 mmol) in dimethylsulfoxide (DMSO: 20 mL) at 70°C for 4 h. The reaction mixture was cooled, and water (50 mL) was added. The mixture was extracted with diethyl ether (2 × 30 mL). The ethereal layer was washed with brine (30 mL) and water (30 mL) and then dried over $Na_2SO_4$. The filtrate was evaporated under reduced pressure to give 2-(6-azido-hexanoate)-1,3-dioctadecanoate glycerol as a colorless oil (**6**, 175 mg, 90%).

A mixture of compound **6** (83 mg, 0.11 mmol) and [60]fullerene (72 mg, 0.1 mmol) in chlorobenzene (90 mL) was refluxed in an oil bath for 12 h under an atmosphere of argon. The mixture was cooled, and the chlorobenzene was evaporated under reduced pressure. The residue was dissolved in toluene (10 mL) and separated by silica gel (120 g) column chromatography using *n*-hexane/toluene (1:1, vol/vol, 400 mL) to remove the unreacted [60]fullerene (50 mg). This was followed by elution with toluene (400 mL) to give the requisite compound **1a** as a viscous dark brown oil (24.5 mg, 60% based on the amount of [60]fullerene consumed). The yield of **1a–1d** in the last reaction sequence was 45–60% based on the amount of [60]fullerene reacted.

*Synthesis of triacylglycerols (**2a–2d**) of type AAB containing an aza-fullerenoid acyl group at the α-position of the glycerol as exemplified by the synthesis of compound **2a** (Scheme 2).* 1,2-Dioctadecanoate glycerol (**10**) was synthesized starting from allyl alcohol (**7**) as described by Mattson and Volpenhein (18)

Esterification of the diacylglycerol (**10**) with 6-bromohexanoic acid, followed by azidonation gave the corresponding azido-containing triacylglycerol (**11**). The latter compound was reacted with [60]fullerene as by the general method described above for the synthesis of compounds **1a–1d**. The yield of the requisite triacylglycerols, **2a–2d**, in the last step of the reaction sequence, ranged from 51–62% based on the amount of [60]fullerene reacted.

*2-(6-[2′,3′;5,6]-Aza-[60]fullerene-hexanoate)-1,3-dioctadecanoate glycerol (**1a**).* Dark brown oil, 60% yield (based on amount of [60]fullerene reacted); thin-layer chromatography (TLC) ($R_f$) = 0.2 (toluene); UV ($CH_2Cl_2$, $\lambda_{max}$ nm): 238, 260, 330; IR ($cm^{-1}$): 1743 (C=O, ester str.), 525 ($C_{60}$ cage); $^1H$ NMR ($CDCl_3$, $\delta_H$, *J*/Hz): 5.28 (*m*, β-H of glycerol, 1H), 4.13–4.36 (*m*, α-H of glycerol, 4H), 3.81 (*t, J* = 7.3, 6-*H* of fullerenoid β-acyl, 2H), 2.45 (*t, J* = 7.3, 2-*H* of fullerenoid β-acyl, 2H), 2.33 (*t, J* = 7.6, 2-*H* of 18:0, 4H), 2.05 (*qn, J* = 7.3, 5-*H* of fullerenoid β-acyl, 2H), 1.70–1.89 (*m*, 3-*H*, 4-*H* of fullerenoid β-acyl, 4H), 1.58–1.62 (*m*, 3-*H* of α-acyl 4H), 1.26–1.33 (*m*, $CH_2$, 56H), 0.88 (*t, J* = 6.7, $CH_3$, 6H); $^{13}C$ NMR ($CDCl_3$, $\delta_C$): 173.28 (C-1 of 18:0 at α-acyl), 172.61 (C-1 of fullerenoid β-acyl), [147.79, 146.77, 145.03, 144.72, 144.56, 144.46, 144.32, 144.28, 144.15, 144.11, 143.84, 143.64, 143.53, 143.39, 143.21, 143.10, 142.90, 142.79, 142.70, 142.64, 141.42, 140.78, 140.74, 139.21, 138.50, 138.03, 137.84, 137.27, 137.19, 136.20, 135.79, 133.71 ($sp^2$ C of cage)], 69.08 (β-C of glycerol), 62.07 (α-C of glycerol), 51.41 ($NCH_2$), 34.12 (C-2 of fullerenoid β-acyl), 34.08 (C-2 of 18:0 at α-acyl), 31.94 (C-16 of α-acyl), [29.73, 29.68, 29.52, 29.38, 29.32, 29.26, 29.16 ($CH_2$)], 26.74 (C-4 of fullerenoid β-acyl), 24.90 (C-3 of 18:0 at α-acyl), 24.73 (C-3 of fullerenoid β-acyl), 22.71 (C-17 of α-acyl ), 14.15 ($CH_3$); mass spectrometry (MS) (APCI) (*m/z* , relative intensity in parentheses, calc. $M^+$ *m/z* = 1456.835): 1458.1 ($M^+$, 100), 1430.0 (25), 722.2 (10).

## DISCUSSION

The synthesis strategies and the experimental conditions of the desired fullerenoid triacylglycerols (**1a–1d** and **2a–2d**) are shown in Schemes 1 and 2. The yield of the product obtained in the last step of the reaction sequence, i.e., between the corresponding key azido-containing triacylglycerols with [60]fullerene, was rather low (15–18%) when the calculation was based on the amount of [60]fullerene employed. However, in fullerene chemistry the yield of fullerenoid derivatives is normally calculated on the net amount of [60]-fullerene consumed during the reaction (19). Based on the net amount of [60]fullerene reacted, the yields of the final reactions described in Schemes 1 and 2 ranged from 45 to 62% and are considered to be reasonable and good.

The fullerenoid triacylglycerols (**1a–1d, 2a–2d**) obtained were viscous brown oils. Unlike [60]fullerene itself, these fullerenoid lipids dissolved readily in a wide range of organic solvents, including diethyl ether, *n*-hexane, chloroform, tetrahydrofuran, toluene, chlorobenzene, benzene, and tetrachloroethane. Compounds **1a** and **2a** did not solidify at room temperature despite the presence of two saturated acyl chains (18:0), which are esterified to the glycerol "backbone." Attempts to crystallize these derivatives from organic solvents have failed. The choice to use a short C-6 acyl group to link to a [60]fullerene unit *via* a nitrogen bridge was twofold. Firstly, this would ensure that the total length of this fullerene-containing acyl group was about the same as that of a medium- to long-chain fatty acyl group for future biological studies. Secondly, the $C_6$ acyl group could be readily identified by NMR spectroscopy, which would allow it to serve as an internal marker to facilitate the interpretation of the various spectra.

The presence of an aza-[60]fullerene unit in compounds **1a–1d, 2a–2d** was evident from the individual mass value of the molecular ion ($M^+$) and the appearance of the characteristic peak at *m/z* = 722 (ion fragment of a $C_{60}$) in the mass spectra (APCI). The [60]fullerene cage unit in these compounds gave rise to absorption bands in the UV spectra (bands at about 230, 260, and 330 nm from the conjugated C=C double bonds) and also by the appearance of a characteristic absorption band at 525 $cm^{-1}$ in the IR spectra. The TLC analysis showed a brown spot at $R_f$ = 0.2 when toluene was used as the developer (triolein gave an $R_f$ of 0.6 under same condition). The proton NMR confirmed the glycerol backbone structure of the compounds from the multiplets at $\delta_H$ 5.3 (methine proton) and $\delta_H$ 4.2 (methylene protons). In the case of compounds **1b**, **2b,** and **1c**, **2c**, which contain oleyl and linoleyl acyl groups, respectively, the shifts of the olefinic protons appeared at $\delta_H$ 5.3 as multiplets.

The $^{13}$C NMR spectroscopic analyses allowed the two types (ABA and AAB) of triacylglycerols to be clearly dis-

tinguished. In the case of compounds **1a–1d**, the ABA arrangement of acyl groups on the glycerol backbone was confirmed by the appearance of a pair of signals for the C-1 (in the region of $\delta_C$ 172–173), a pair of signals for the C-2 (at $\delta_C$ 34), and another pair of signals for C-3 (at $\delta_C$ 24) carbon atoms of the acyl groups. The more intense signal of these pairs of signals was attributed to the shifts of the carbon atoms of the two identical α-acyl groups. To support the ABA arrangement of acyl groups in compounds **1a–1d** further, the spectra showed two signals for the shifts of the methylene (at $\delta_C$ 62) and methine (at $\delta_C$ 68) carbon atoms of the glycerol. These pairs of signals confirm the ABA arrangement of the acyl group in compounds **1a–1d**.

The spectra of compounds **2a–2d**, which are of the type AAB, showed three signals of equal intensity for the C-1 (at $\delta_C$ 172–173), three signals for the C-2 (at $\delta_C$ 33–34), and three signals for the C-3 (at $\delta_C$ 24) carbon atoms of the acyl groups. Three distinct signals (at $\delta_C$ 68.8, 62.2 and 62.1) were also observed for the shifts of the methylene and methine carbon atoms of the glycerol structure. The pattern of these spectra was in agreement with carbon shift data for conventional structured triacylglycerols of the type ABA and AAB reported by Lie Ken Jie *et al.* (20,21).

Of great importance was the appearance of 31–32 signals in the region of $\delta_C$ 130–150 of the $^{13}C$ NMR spectra, which denoted the presence of a "[5,6]-open" aza substructure of the carbon cage. Similar "[5,6]-open" aza-fullerenes (also showing 31–32 signals in the carbon NMR spectra) were reported by Prato *et al.* (22) and Hawker *et al.* (23), when [60]fullerene was reacted with organic azides. The absence of signals in the $\delta_C$ 70–90 region of the $^{13}C$ NMR spectra (shift region for $sp^3$ hybridized carbon atoms when present in the [60]fullerene cage) supported the structure of compounds **1a–1d** and **2a–2d** as containing a [60]fullerene cage with a "[5,6]-open" aza substructure.

In this work we have demonstrated that structured triacylglycerols of the type ABA and AAB can be successfully synthesized to include an acyl chain with a "[5,6]open" aza-[60]fullerenoid unit tethered to the distal end of one of the acyl groups.

REVIEW

# Studies on Effects of Dietary Fatty Acids as Related to Their Position on Triglycerides

**J. Edward Hunter***

Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221-0172

**ABSTRACT:** This article reviews published literature on how the stereospecific structure of dietary triglycerides may affect lipid metabolism in humans. Animal studies have shown enhanced absorption of fatty acids in the *sn*-2 position of dietary triglycerides. Increasing the level of the saturated fatty acid palmitic acid in the *sn*-2 position (e.g., by interesterification of the fat to randomize the positions of the fatty acids along the glycerol backbone) has been shown in rabbits to increase the atherogenic potential of the fat without impacting levels of blood lipids and lipoproteins. In contrast, enhancing the level of stearic acid in the *sn*-2 position has not been found to affect either atherogenic potential or levels of blood lipids and lipoproteins in rabbits. Fatty acids other than palmitic and stearic have not been studied systematically with respect to possible positional effects. A limited number of human studies have shown no significant effects of interesterified fats on blood lipid parameters. However, it is unknown whether modifying the stereospecific structure of dietary triglycerides would affect atherogenicity or other long-term health conditions in humans. It is possible that incorporation of palmitic acid into the *sn*-2 position of milk fat is beneficial to the human infant (as a source of energy for growth and development) but not to human adults. Additional research is needed to determine whether processes like interesterification, which can be used to alter physical parameters of dietary fats (e.g., melting characteristics), may result in favorable or unfavorable long-term effects in humans.

Paper no. L8772 in *Lipids 36,* 655–668 (July 2001).

The purpose of this review is to determine, based on published literature, our current level of understanding about how the stereospecific structure of dietary triglycerides may affect lipid metabolism in humans. Of particular interest is whether altering the position of fatty acids on dietary triglycerides has an effect on blood lipid and lipoprotein levels. This review first highlights relevant experimental animal feeding trials as background and then focuses on recent human clinical studies that address this issue.

Human and animal studies conducted during the past 40–50 yr have established that different categories of dietary fatty acids have different effects on blood lipid and lipoprotein levels (1–5). Unsaturated fatty acids found primarily in fats derived from vegetable sources tend to lower total and low density lipoprotein (LDL) cholesterol when compared with saturated fatty acids. On the other hand, saturated fatty acids found primarily in animal fats tend to raise total and LDL-cholesterol when compared with unsaturated fatty acids. For example, linoleic acid, which is abundant in most liquid vegetable oils (e.g., soybean, corn, and safflower), has been associated with blood cholesterol lowering, whereas lauric, myristic, and palmitic acids, common in animal fats and certain vegetable oils (palm and coconut), have been associated with blood cholesterol raising. The saturated fatty acid stearic acid has been reported to have a neutral or lowering effect on total and LDL-cholesterol compared with other saturated fatty acids (6). The monounsaturated fatty acid oleic acid, compared with saturated fatty acids, appears to lower LDL-cholesterol level but to retain high density lipoprotein (HDL) cholesterol (7).

Despite these widely accepted generalizations, studies focusing on feeding high levels of specific saturated or unsaturated fatty acids can be difficult to interpret, because fats having similar ratios of unsaturated to saturated fatty acids may have dramatically different fatty acid compositions. For example, cocoa butter and milk fat have similar levels of saturation; however, the saturated fatty acids of cocoa butter (expressed as a percentage of total saturated fatty acids) are primarily palmitic (42.5%) and stearic (55%) acids, whereas milk fat contains a wider variety of saturated fatty acids including stearic (19%), palmitic (42%), myristic (16%), and medium- (MCFA) and short-chain fatty acids (SCFA) (≤ 12:0 = 23%). Other examples are beef tallow and palm oil, both of which contain about 51% saturated fatty acids. As a percentage of total saturated fatty acids, beef tallow contains about 38% stearic and 50% palmitic acids, whereas palm oil contains about 9% stearic and 88% palmitic acids (8).

In addition to overall fatty acid composition, the stereospecific distribution of fatty acids in a particular fat also should be considered when fatty acid effects are examined. Fatty acids can occupy any of three positions on the glycerol backbone, designated as *sn*-1, *sn*-2, and *sn*-3 (*"sn"* stands for "stereospecific numbering"). Table 1 (9–13) illustrates the positional distribution of fatty acids in the triacylglycerols of several natural oils and fats. Among animal fats, bovine milk fat and lard (pork fat) contain mainly saturated fatty acids in the *sn*-2 position, whereas tallow contains saturated fatty acids primarily in the *sn*-1 and *sn*-3 positions. Oils and fats of plant origin, such as soybean oil and cocoa butter, contain unsaturated fatty acids in the *sn*-2 position and saturated fatty acids in the *sn*-1 and *sn*-3 positions. In lard, oleic acid is mostly in the *sn*-1 and *sn*-3 positions, whereas in cocoa butter, oleic acid is almost entirely in the *sn*-2 position. In peanut oil and olive oil, oleic acid is more evenly distributed among all three positions. Estimates of the major triacylglycerol species found in a

[a]In this table, not all fatty acids are listed for each fat source. Also, each line represents the mol% of each fatty acid in position 1, 2, or 3. Most lines sum to *ca.* 100%; columns do not sum to 100%. The total percentage of a specific fatty acid at a specific position can be determined by dividing the mol% at that position by the total mol% for all three positions. For example, in cow's milk, the percentage of total 16:0 in position 1 is 36 mol%/79 mol% = 46%. References: 9–13. TG = triglyceride.

variety of natural fats and oils are listed in Table 2 (14). Most of these triacylglycerols have not been fully analyzed, and the specific stereoisomers have not been reported.

The stereospecific position of fatty acids on triglycerides plays a major role in the functionality of fats in food products. For example, in the case of lard, the presence of palmitic acid in the *sn*-2 position contributes to desirable flakiness of pie crusts when lard is used as a baking shortening. Also, in the case of cocoa butter, the unique positioning of palmitic, oleic, and stearic acids in two predominant triglyceride forms gives cocoa butter a sharp melting point just below body temperature. The way cocoa butter melts is one of the reasons for the pleasant eating quality of chocolate. The unique functionalities attributed to the location of specific fatty acids in fats, such as lard or cocoa butter, are difficult to duplicate in fat substitutes.

**TABLE 2**
**Principal TG Species of Natural Fats and Oils[a]**

| Fat or oil | Major TG species | | |
|---|---|---|---|
| Butterfat | PPB | PPC | POP |
| Lard | SPO | OPL | OPO |

| Olive oil | OOO | OOP | OLO |
| Canola oil | OOO | LOO | OOLn |

[a]Specific TG have been estimated from stereospecific fatty acid analyses. In many cases the stereospecific composition is uncertain. Abbreviations for acyl chains of TG: B = butyric (4:0); C = capric (10:0); D = dodecanoic (12:0); M = myristic (14:0); P = palmitic (16:0); S = stearic (18:0); O = oleic (18:1n-9); L = linoleic (18:2n-6); Ln = linolenic (18:3n-3). Reference: 14. See Table 1 for other abbreviation.

The relationship between triglyceride structure and metabolic behavior has been reviewed in several recent articles (8,9,14–16). The stereospecific position of fatty acids is important because it determines how triglycerides are digested. The process by which triglycerides are broken down *in vivo* was established by Mattson and Volpenhein (17). These investigators showed that during digestion in the gastrointestinal tract, pancreatic lipase, an enzyme highly specific for the *sn*-1 and *sn*-3 esters, catalyzes the formation of *sn*-2 monoglycerides and free fatty acids that are absorbed in the small intestine. The 2-monoglycerides are reacylated into new triglycerides that enter the lymph chylomicrons.

Fatty acids released from the *sn*-1 and *sn*-3 positions often have different metabolic fates than fatty acids retained in the *sn*-2 position. These metabolic fates depend on the fatty acid chain-length and stereospecific location on the triglyceride. SCFA and MCFA (≤10 carbon atoms) can be solubilized in the aqueous phase of the intestinal contents, where they are absorbed, bound to albumin, and transported to the liver by the portal vein. Longer-chain fatty acids, such as palmitic and stearic, have low coefficients of absorption because of melting points above body temperature and because of their ability to form calcium soaps.

**TABLE 3**
**Positional Distribution of Fatty Acids in Native and Interesterified Peanut Oil[a]**

| | | Fatty acid (mol%) | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| Source | Position | 16:0 | 16:1 | 18:0 | 18:1 | 18:2 | 20:0 | 22:0 | 24:0 |
| Native peanut oil | 1 | 19.9 | 0.1 | 3.5 | 47.5 | 26.1 | 0.3 | 0.1 | |
| | 2 | 2.2 | 0.1 | 1.0 | 50.8 | 46.2 | | 0.1 | |
| | 3 | 12.8 | 0.2 | 3.7 | 54.0 | 11.3 | 4.0 | 7.3 | 3.3 |
| Interesterified peanut oil | 1 | 11.8 | 0.1 | 2.7 | 50.8 | 27.8 | 1.4 | 2.6 | 1.1 |
| | 2 | 11.9 | 0.1 | 3.3 | 50.9 | 26.8 | 1.2 | 2.6 | 0.8 |
| | 3 | 11.9 | 0.1 | 2.1 | 50.3 | 27.9 | 1.4 | 2.6 | 1.6 |

[a]Each line represents the mol% of each fatty acid in position 1, 2, or 3. Most lines sum to *ca.* 100%; columns do not sum to 100%. The total percentage of a specific fatty acid at a specific position can be determined by dividing the mol% at that position by the total mol% for all three positions. Reference: 18.

Thus, fats with long-chain fatty acids in the *sn*-1 and *sn*-3 positions of triacylglycerols may exhibit different absorption patterns from fats with these fatty acids in the *sn*-2 position.

The role of stereospecific location of dietary fatty acids can be studied using a process called interesterification (sometimes referred to as randomization), in which the positions of the fatty acids on the glycerol backbone are rearranged. Interesterification is accomplished by catalytic methods at relatively low temperature and permits the exchange of fatty acids both within and between triacylglycerols. The process may be enzymatic (i.e., highly controlled) or chemical (i.e., relatively uncontrolled). The food industry uses interesterification (largely chemical) to modify the melting and crystallization behavior of fats. Also, the hardening of a liquid oil by interesterifying it with a solid fat offers an alternative to the use of partial hydrogenation in the manufacture of margarines and spreads. This exchange of fatty acids results in their randomization among all three stereospecific positions. Thus, a naturally occurring fat having oleic acid primarily in the *sn*-2 position after interesterification could have oleic acid roughly equally distributed among the *sn*-1, *sn*-2, and *sn*-3 positions.

The interesterification (randomization) process does not change the degree of unsaturation or the isomeric state of the fatty acids, as they transfer in their entirety from one position to another. Interesterification thus allows investigators to compare nutritional effects of diets that are identical in fatty acid composition but different in triacylglycerol composition. Randomization of naturally occurring fats could have implications regarding cardiovascular health. This is because randomization alters not only physical properties of fats (e.g., melting characteristics) but also their absorption properties. Table 3 (18) illustrates the percentage of fatty acids in the *sn*-1, *sn*-2, and *sn*-3 positions in native and interesterified peanut oil. Interesterification resulted in a roughly equal distribution of all fatty acids at all three positions of the triglyceride.

## BACKGROUND

*Fat absorption and metabolic clearance studies involving interesterified fats, structured triglycerides, and natural fats.* Studies with interesterified fats have found that altering the fatty acid composition at the *sn*-2 position affects the amount of fat absorbed. Filer *et al*. (19) reported that infants fed formulas containing randomized lard (i.e., having less palmitic acid in the *sn*-2 position than in native lard) excreted six times as much fat as infants fed native lard. This meant that the interesterified lard was less readily absorbed than its native counterpart. Lien and coworkers (20) fed rats combinations of coconut oil and palm olein either in their native state or interesterified. In a mixture of 25:75 coconut oil/palm olein, 93% of the palmitic acid was in the *sn*-1 and *sn*-3 positions in the native fats, and 65% of the palmitic acid was in the *sn*-1 and *sn*-3 positions in the interesterified fats. Interesterification significantly decreased fecal excretion of saturated fatty acids, suggesting that increasing the amount of palmitic acid in the *sn*-2 position could increase its absorption. Renaud and coworkers (21) fed rats diets containing either palm oil (58% of palmitic acid at *sn*-1 and *sn*-3), lard (65% of palmitic acid at *sn*-2), or their interesterified counterparts. Fecal excretion of palmitic acid was greatest in the diets containing high amounts of palmitic acid at the *sn*-1 and *sn*-3 positions (native palm oil and interesterified lard). Interesterification of lard decreased the incorporation of palmitic acid into plasma lipids and decreased total plasma triglycerides, consistent with reduced absorption of palmitic acid.

The specific positioning of 16:0 at the 2-position of human milk triglycerides has been suggested as one of the reasons for the high efficiency of absorption of fat from human milk (19,22). Support for this hypothesis has been provided by studies showing better absorption of total dietary fat or 16:0 by infants fed formula with 16:0 esterified to the *sn*-2 position rather than to the *sn*-1 or *sn*-3 positions of the dietary triglycerides (19,23). However, because of the proposed role of the milk enzyme bile salt-stimulated lipase, which in newborn infants is apparently responsible for the hydrolysis of 2-monoglycerides to free glycerol and fatty acid (24), the contribution of *sn*-2 16:0 to the total amount of milk fat being absorbed remains uncertain.

All of these studies demonstrated that modifying the dietary triglyceride structure to increase the level of palmitic acid in the *sn*-2 position led to increased absorption of palmitic acid.

The chain length of a fatty acid affects its transport and metabolism. Triglycerides containing fatty acids having a chain length of more than 10 carbon atoms are transported by the lymphatic system, whereas MCFA (having 10 or fewer carbon atoms) are transported by the portal vein to the liver, where they are metabolized rapidly. Carvajal *et al.* (25) recently conducted a study to determine if the positional distribution of MCFA in a synthetic dietary fat influences the lymphatic transport of dietary triglycerides and the chemical composition of chylomicrons in rats. In this study, rats with

cannulated thoracic ducts were fed diets containing one of four types of synthetic triglycerides: (i) *sn*-1(3) MCFA-*sn*-2 linoleic acid, (ii) interesterified *sn*-1(3) MCFA-*sn*-2 linoleic acid, (iii) *sn*-2 MCFA-*sn*-1(3) linoleic acid, or (iv) interesterified *sn*-2 MCFA-*sn*-1(3) linoleic acid. Lymph was collected, and lymph chylomicron triglycerides were analyzed for total fatty acid composition and triacylglycerol structure.

The positional distribution of MCFA in the dietary fat had no significant effect on lymph flow, triglyceride output, or lipid composition of the chylomicrons. The positional distribution of *sn*-2 fatty acids in the synthetic triglycerides was largely maintained in the chylomicron triglycerides. These results indicated that fatty acids with chain lengths <10 in the dietary triglycerides are transported by the lymphatic system, and the positional distribution is preserved in chylomicron triglycerides.

Kubow pointed out in his review (9) that although animal and human infant data suggest the role of molecular structure of triacylglycerols in influencing saturated fatty acid absorption, there are questions in the human adult regarding the relevance of positional distribution of saturated fatty acids on their absorption. It has been suggested that human adults can absorb efficiently most dietary fatty acids whether in nonesterified or monoacyl form, despite the apparent limited capacity of newborn infants to absorb saturated fatty acids in their nonesterified form. Kubow noted that studies on the efficiency of absorption of free fatty acids by human adults have been inconsistent and that the role of positional distribution in this regard needs further investigation.

Early events in the metabolic processing of dietary triglycerides may have an important impact on the risk of chronic diseases such as coronary heart disease. By using structured triglycerides containing predominantly stearic and oleic acids, Summers *et al.* (26) assessed the possibility that the initial removal of fatty acids from chylomicron triglycerides might be fatty acid-specific. The hypothesis was that a stearoyl chain at the *sn*-2 position of chylomicron triglyceride might hinder lipoprotein lipase action and thus clearance of stearic acid. A group of 14 healthy women (aged 29–70 yr, median age 49 yr) consumed meals in random order containing 60 g of either of two structured triglycerides containing predominantly stearic or oleic acids at the *sn*-2 position, i.e., SOO or OSO (S = stearic acid, O = oleic acid). Systemic concentrations and arteriovenous differences across adipose tissue were measured for plasma triglyceride and nonesterified fatty acids for up to 6 h after the meals.

The stereospecific structure of the ingested triglyceride was largely preserved in chylomicron triglycerides. Systemic concentrations of total and individual nonesterified fatty acids were not significantly different after ingestion of the two fats. The composition of nonesterified fatty acids released from adipose tissue changed after the meal to reflect the composition of the ingested triglyceride; however, no significant differences were observed between the two test meals. No detectable monoglycerides were released from adipose tissue after either test meal. The investigators concluded that there is no release of monoglyceride nor preferential uptake or release of fatty acids from chylomicron triglycerides according to the nature or position of the fatty acid within the triglyceride. Thus the data suggest that lipoprotein lipase processes *sn*-2 saturated fatty acids and *sn*-2 unsaturated fatty acids in a similar fashion.

A similar study using vegetable oils instead of structured triglycerides was conducted by Abia *et al.* (27). The purpose of this study was to determine whether two oils with equal levels of oleic acid but with different compositions of other fatty acids and triglyceride molecular species could produce different responses in the triglyceride molecular species of the "triacylglycerol-rich lipoprotein" fraction in the postprandial state. (The "triacylglycerol-rich lipoprotein" particles referred to by Abia *et al*. included chylomicrons, very low density lipoprotein, and their remnants.) Normolipidemic men ($n$ = 8; average age = 27 yr) consumed three meals in random order on separate occasions: control meal, control meal plus 70 g virgin olive oil (VOO), and control meal plus 70 g high-oleic sunflower oil (HOSO). Plasma total triglyceride and triacylglycerol-rich lipoprotein levels were measured for 7 h after ingestion. Triglyceride molecular species and *sn*-2 positional fatty acids within these molecular species were analyzed in the triacylglycerol-rich lipoprotein fraction.

Plasma total triglyceride concentrations in response to both oils were the same. Triglyceride molecular species from the triacylglycerol-rich lipoprotein fraction derived from VOO were found to disappear from the circulation more quickly than those from the triacylglycerol-rich lipoprotein fraction derived from HOSO. On the other hand, the triacylglycerol-rich lipoprotein triglycerides derived from either VOO or HOSO ingestion were reported to contain unexpectedly high percentages of the saturated fatty acids palmitic and stearic acids in the *sn*-2 position. The triacylglycerol-rich lipoprotein triglycerides derived from VOO contained 22% palmitic acid and 12% stearic acid (expressed as a percentage of total fatty acids) in the *sn*-2 position; those derived from HOSO contained 32% palmitic acid and 28% stearic acid in the *sn*-2 position. These results seem highly unlikely considering that natural vegetable oils such as olive oil typically have less than 2% saturated fatty acids in the *sn*-2 position (Table 1) and that *sn*-2 fatty acids are largely preserved in chylomicron triglycerides (9,14,26). Abia *et al*. (27) offered no explanation as to how the *sn*-2 position of the triacylglycerol-rich lipoprotein triglycerides they analyzed could have been substantially enriched with saturated fatty acids. As a result, the conclusion of Abia *et al.* (27) that the *sn*-2 positional distribution of saturated stearic and palmitic acids into the triglyceride molecules of the triacylglycerol-rich lipoprotein fraction may be important determinants of postprandial lipemia in normolipidemic men does not seem justified.

In contrast to the results of Abia *et al.*, Summers *et al*. (26) reported that the *sn*-2 fatty acid composition of triglyceride molecular species of the chylomicron triglyceride fractions they evaluated was largely unaffected by the nature or the position of stearic and oleic acids within the dietary triglycerides.

*Experimental animal studies involving interesterified fats*. Modifying the structure of dietary fats by interesterification has been found to affect not only the absorption characteristics of certain fats but also their atherogenic potential in ani-

mals. It should be noted, however, that while several different native and interesterified fats have been compared in animal studies, only two fatty acids have been studied for their possible positional effects, primarily palmitic, and to a lesser extent, stearic. Relevant studies are highlighted below.

Kritchevsky and Tepper (28) used randomized fats to compare the atherogenic potential of specific saturated fatty acids in rabbits. Special fats were prepared by randomizing corn oil with pure trilaurin, trimyristin, tripalmitin, and tristearin, yielding oils of similar iodine value but differing in the predominating saturated fatty acids. Rabbits were fed for 8 wk on diets consisting of chow augmented with 2% cholesterol and 6% special fats. Other groups of rabbits were fed diets in which corn oil or randomized corn oil was used as the cholesterol vehicle. In four experiments with cholesterol-containing diets, the four different saturated fats were more atherogenic than either native or randomized corn oil. The palmitic acid-rich fat was somewhat more atherogenic than the other special fats. Average serum cholesterol levels were lower in the special fat groups than they were in the rabbits fed corn oil. The investigators suggested that the presence in the diets of relatively large amounts of unsaturated fatty acids may have masked the specific hypercholesterolemic effects of the saturated fatty acids. This study did not compare the atherogenic potential of native vs. randomized fats but rather used randomization to enhance the absorption of specific saturated fatty acids.

In a subsequent study, Kritchevsky and coworkers (29) fed rabbits diets containing 2% cholesterol and 6% specific fat for 8 wk. The special fats included peanut oil, randomized peanut oil, and corn oil. In two of three experiments, the average serum cholesterol level of the randomized peanut oil group was greater than those of the other two groups, and in one experiment it was lower than those of the other two groups. Nevertheless, the average serum cholesterol values for the three experiments were very similar among the three treatment groups (Table 4). Despite this similarity in serum cholesterol levels among the three groups, the native peanut oil group had consistently more atherosclerosis than the randomized peanut oil or corn oil groups (Table 4).

While randomization of peanut oil reduced significantly its atherogenic properties, Kritchevsky *et al.* (30) indicated that native and randomized peanut oil have similar rates of lipolysis and that rats fed the two oils absorb and transport lipids in a similar manner. These authors noted further that peanut oil differs from other oils in having a relatively high lectin content and that the randomization process markedly reduces the lectin content as well. (Lectins are glycoproteins with high affinity binding to cellular carbohydrate residues.) A followup study by Kritchevsky *et al.* (30) suggested that peanut oil's endogenous lectin (rather than its triglyceride structure) may contribute significantly to its atherogenic properties in rabbits.

Kritchevsky and coworkers conducted a series of experiments in which native and randomized fats were compared for their effects on blood lipids and atherosclerosis. In one study (31) rabbits were fed diets containing 14% native or randomized lard or tallow and 0.5% cholesterol for 60 d to determine if

[a]I = interesterified (randomized) oil.
[b]NR = not reported.
[c]In the studies by Kritchevsky *et al.,* average atherosclerosis represents the severity of atherosclerosis [(aortic arch + thoracic aorta)/2] graded visually on a 0–4 scale. In the study by Nicolosi *et al.* (footnote *d*), average atherosclerosis represents aortic fatty streak area expressed as $\mu m^2/mm^2 \times 100$.
[d]Unpublished data of R.J. Nicolosi, T. Wilson, and C. Lawton, used with permission. For a given study, the absence of superscripts for total cholesterol, total TG, or atherosclerosis values indicates these respective values were not significantly different from each other: *Significantly different from other groups, $P < 0.05$. **Significantly different from other groups, $P < 0.01$. To convert serum cholesterol units from mg/dL to mM, divide by 38.67. To convert serum TG units from mg/dL to mM, divide by 88.54. See Table 1 for other abbreviation.

these two animal fats have different atherogenic potentials and if randomization of the fats might affect atherogenesis. Lard contains more linoleic acid and less stearic acid than tallow. Both lard and tallow contain *ca.* 24% palmitic acid (16:0). However, in lard over 90% of the palmitic acid is in the *sn*-2 position of the triglyceride, whereas only 15% of the palmitic acid in tallow is in the *sn*-2 position. The fats were randomized so that every component fatty acid was present at each triglyceride carbon at *ca.* one-third of its total concentration. The randomized tallow and lard had 8.5 and 7.6% of their component 16:0 (i.e., about one-third of their total 16:0 concentration) at the *sn*-2 position, respectively. Total cholesterol levels were not significantly different among the four groups. However, rabbits fed native lard exhibited significantly more atherosclerosis than those rabbits fed native tallow (Table 4). The atherogenicity of diets containing either randomized lard or tallow was virtually the same and less than that of the diet containing native lard. Randomization of tallow led to somewhat more palmitic acid in the *sn*-2 position and slightly (but not significantly) increased the severity of atherosclerosis compared to native tallow. On the other hand, randomization of lard caused reduction in the amount of palmitic acid in the *sn*-2 position and a significant decrease in the severity of atherosclerosis. This study showed that the level of 16:0 at the *sn*-2 position of a triglyceride influences its atherogenicity in rabbits.

Another study compared the atherogenic potential in rabbits of feeding native and randomized cottonseed oil (32). Cottonseed oil contains about 24% palmitic acid, of which only 2% is present at the *sn*-2 position. After randomization, one-third of the palmitic acid of cottonseed oil was at the *sn*-2 position. Rabbits were fed semipurified diets containing 14% native or randomized cottonseed oil and 0.10% cholesterol for 90 d. The rabbits fed the randomized cottonseed oil had significantly more severe atherosclerosis than those rabbits fed the native cottonseed oil. Plasma cholesterol and triglyceride levels were similar in the two groups (Table 4). It was suggested that the increased atherogenicity of the randomized cottonseed oil may reflect the increased absorbability of fats with palmitic acid at the *sn*-2 position.

A further study by Kritchevsky *et al.* (33) compared the atherogenic effects of refined, bleached, and deodorized (RBD) palm oil with those of randomized RBD palm oil. The RBD palm oil contained 41.2% palmitic acid, of which 2.6% was at the *sn*-2 position. In the randomized palm oil, 13.6% palmitic acid was at the *sn*-2 position. The randomized palm oil was significantly more atherogenic for rabbits than was the RBD palm oil, consistent with other findings of Kritchevsky *et al.* that increasing the amount of palmitic acid at the *sn*-2 position of a fat led to an increased atherogenic effect.

Four synthetic fats whose triglyceride structures were SOS, SSO, POP, and PPO (S = stearic acid, P = palmitic acid, O = oleic acid) were evaluated for their atherogenic potential in rabbits (34). The fats were fed in semisynthetic diets containing 15% fat, of which 58% was the synthetic fat, 24% was sunflower oil, and 18% was high-oleic safflower oil. All of the diets contained 0.05% cholesterol and were fed for 20 wk. The blood lipid levels (total cholesterol, % HDL, and triglycerides) were similar in all four groups. Average atherosclerosis was similar in rabbits fed SOS compared to SSO (2.4 or 28% of stearic acid in the *sn*-2 position, respectively); however, it was much greater in rabbits fed PPO compared to POP (Table 4). The authors noted that these findings confirmed their earlier observations that randomization of fats affects their atherogenicity but not their lipidemic effects. Specifically, fats bearing palmitic acid (but not stearic acid) in the *sn*-2 position have increased atherogenicity compared to fats with palmitic acid in the *sn*-1 or *sn*-3 positions. The mechanism of this effect was suggested to be related to greater absorption of the atherogenic fat.

An important observation in these studies by Kritchevsky *et al*. (28,29,31,32,34) was that feeding diets containing interesterified fats compared with native fats resulted in differences in atherogenicity that would not have been predicted from the blood lipid and lipoprotein levels of the animals. In all of these studies, there were no consistent differences in blood lipid or lipoprotein levels as a result of feeding an interesterified fat compared with the corresponding native fat. On the other hand, the feeding of interesterified fats compared with native fats showed significant differences in the development of atherosclerosis (Table 4). With the exception of peanut oil, the more atherogenic fats were those in which there was a higher level of palmitic acid in the *sn*-2 position compared with the *sn*-1 or *sn*-3 positions. Thus, native lard (with palmitic acid primarily *sn*-2) was more atherogenic than interesterified lard (31), and interesterified cottonseed oil (having more palmitic acid *sn*-2) was more atherogenic than native cottonseed oil (32). The increased atherogenicity of native peanut oil compared with randomized peanut oil (29) may have been more closely related to a higher level of lectin in the native oil than to a change in triglyceride structure.

It has been reported that the presence of a saturated fatty acid in the *sn*-2 position of a triglyceride slows its removal from the bloodstream (35). Thus, the *in vivo* residence of a fat with palmitic acid in the *sn*-2 position would be increased and the probability of its deposition increased. Kritchevsky *et al.* (32) suggested that the combination of enhanced absorption and persistence in the circulation of fats with palmitic acid in the *sn*-2 position adds up to increased availability and exposure to the aorta, even when levels in the blood do not differ.

Nicolosi, Wilson, and Lawton (personal communication) have conducted atherogenicity studies in which hamsters were fed for 6 wk on native or randomized tallow, lard, or peanut oil as part of semipurified diets. Consistent with results of Kritchevsky *et al*., Nicolosi *et al.* found no differences in various blood lipid parameters after feeding the native compared to the randomized oils. However, in contrast to the atherogenicity results of Kritchevsky *et al.* (in which atherogenicity increased when the level of palmitic acid in the *sn*-2 position of the dietary fat increased), Nicolosi *et al.* found no differences in atherogenicity after feeding the native compared to the randomized fats. This difference in atherogenicity results between the studies of Nicolosi *et al.* and Kritchevsky *et al.* may be related to a difference in responsiveness between the species used, hamsters compared to rabbits.

Innis and coworkers have conducted several experiments with piglets to evaluate the effect of dietary triacylglycerol structure on fatty acid absorption and on the composition and distribution of plasma lipoprotein fatty acids. In a fatty acid absorption experiment, Innis *et al.* (36) fed similar concentrations of palmitic acid (27–31%) to piglets, either in the form of sow's milk (55% of palmitic acid in *sn*-2) or in a formula containing interesterified triglycerides (from palm, sunflower, and canola oils; 70% of palmitic acid in *sn*-2). The piglets fed sow's milk or the interesterified fat showed increased incorporation of palmitic acid into plasma triglycerides and cholesterol esters 4 h after feeding compared with piglets fed palm oil (4% of palmitic acid in *sn*-2). These results were consistent with those of Lien *et al*. (20), who reported increased absorption of palmitic acid in rats if the palmitic acid was in the *sn*-2 position.

In a plasma lipoprotein study, Innis and Dyer (37) fed piglets formula containing synthesized triacylglycerols (32% 16:0 in the *sn*-2 position) or palm olein (4.2% 16:0 *sn*-2). These results were compared with those of piglets fed sow's milk (55% 16:0 in the *sn*-2 position). The formulas were made without or with cholesterol added to a level similar to that in human and sow's milk. The piglets were fed from birth until 18 d after birth. Plasma cholesterol and triacylglycerol levels were significantly higher in piglets fed milk than in piglets fed either the palm olein formula (with or without cholesterol) or the synthesized triacylglycerol formula (with or without cholesterol). In considering piglets fed either the palm olein or the synthesized triacylglycerol formula, plasma cholesterol levels were similar for these treatment groups without added cholesterol [1.98 ± 0.11 vs. 1.83 ± 0.17 mmol/L (76.6 vs. 70.8 mg/dL), respectively] or with added cholesterol [2.50 ± 0.06 vs. 2.11 ± 0.09 mmol/L (96.7 vs. 81.6 mg/dL), respectively]. These treatment differences (either with or without cholesterol) were not reported to be significantly different from each other. Also, plasma triacylglycerol levels were similar for the piglets fed either the palm olein or the synthesized triacylglycerol formula (with or without cholesterol).

Feeding sow's milk resulted in higher levels of total 16:0 in chylomicron triacylglycerols compared with feeding the palm olein or synthesized triacylglycerol formula. Also, feeding formula with 16:0 at the triglyceride *sn*-2 position or feeding sow's milk resulted in higher levels of 16:0 in the *sn*-2 position of chylomicron triacylglycerols than when palm olein was fed. This suggested that dietary triacylglycerol *sn*-2 position fatty acids are conserved during digestion, absorption, and reassembly into chylomicron triacylglycerols. The increased 16:0 at the *sn*-2 position of chylomicron triacylglycerols in piglets fed synthesized triacylglycerols was accompanied by lower chylomicron triacylglycerol arachidonic and docosahexaenoic acids than in piglets fed formula with palm olein. The authors suggested that there may be an interaction between the positional distribution of saturated fatty acids on the dietary triacylglycerols and the transport of n-6 and n-3 fatty acids. The nature of such an interaction, however, is unknown.

In a subsequent study, Innis *et al*. (38) investigated whether piglets fed formula with randomized oils (16:0 equally distributed among all positions of the triglycerides) influenced growth or the distribution of fatty acids in plasma and liver lipids compared with piglets fed formula with native oils or sow's milk. After feeding from birth until 18 d after birth, piglets fed formula with palm olein randomized with canola oil (co-randomized) had higher weight gain per liter of formula intake and higher 16:0 in the chylomicron triglyceride *sn*-2 position than piglets fed formula with randomized or native palm olein oil blended with canola oil. Also, piglets fed sow's milk had higher plasma total and HDL-cholesterol levels than piglets fed the formula with native oils, randomized palm olein, or co-randomized palm olein with canola oil. The investigators concluded that the fatty acid distribution of formula triglycerides is an important determinant of pathways of 16:0 absorption, and consequently of plasma lipid fatty acids in formula-fed piglets.

A study by Renaud *et al*. (21) using rats indicated that it is mostly dietary fatty acids in the *sn*-2 position that are able to influence lipemia and platelet reactivity and to be transformed by desaturation and elongation to longer-chain unsaturated fatty acids. Interesterification of lard resulted in significantly lower plasma triglyceride levels. Feeding interesterified lard was associated with reduced palmitic acid in plasma total lipids, and this was consistent with the decrease in palmitic acid in the *sn*-2 position compared with native lard. In addition, dietary levels of specific fatty acids in the *sn*-2 position, namely linoleic, palmitic, and oleic, were directly related to plasma levels of arachidonic (20:4n-6), palmitoleic (16:1n-7), and eicosatrienoic (20:3n-9) acids, respectively.

In summary, a key finding of many animal studies has been that randomization procedures have little or no impact on blood lipid and lipoprotein levels except in very young animals, such as piglets. In spite of this finding, however, randomization that increases the level of palmitic acid in the *sn*-2 position appears to increase the risk of atherosclerosis in susceptible species such as rabbits, whereas procedures that decrease the level of palmitic acid in the *sn*-2 position appear to decrease atherosclerosis risk. The increased risk of atherosclerosis from palmitic acid in the *sn*-2 position may be related to the combination of enhanced absorption and less active removal from the circulation of palmitic acid. This, in turn, could lead to increased exposure of the aortic tissue to this fatty acid and possibly to increased fat deposition. Other fatty acids that have been studied following randomization (e.g., stearic acid) have not shown the same properties with respect to atherosclerosis. Studies with randomized peanut oil, in sharp contrast to studies involving other randomized vegetable oils, have shown that increasing the level of long-chain saturated fatty acids in the *sn*-2 position (or reducing peanut oil's lectin content) appears to decrease the risk of atherosclerosis.

## HUMAN CLINICAL STUDIES INVOLVING INTERESTERIFIED FATS

*Selection of human studies for review*. The focus of this section is to assess from published literature how altering dietary triglyceride structure may affect blood lipids and lipoproteins in humans. The rabbit atherosclerosis studies discussed previously are not directly applicable to humans; however, such studies are

of interest because human studies cannot readily assess the atherogenic potential of a dietary component. Human studies were selected for review if they: (i) compared effects of feeding native (nonrandomized) fats with those of feeding interesterified (randomized) fats or (ii) used synthetic fats in which the positions of fatty acids on the triglycerides differed from those normally found in native fats and oils. Most of the studies utilized conventional food diets. Feeding periods lasted at least 3 wk, which is considered adequate to observe changes in blood lipid and lipoprotein levels. Of interest is whether there is a threshold level of fat in the diet at which there is no effect regardless of the position of the fatty acid on dietary triglycerides. On the other hand, the studies reviewed in this paper had design differences, such as the amount of total fat in the diet or the amount of test fat in the diet, which make comparisons difficult. These design differences are pointed out in the text.

*Human studies involving effects of interesterified fats on blood lipids and lipoproteins.* Four recent human studies have evaluated effects on blood lipids and lipoproteins of feeding native fats compared with interesterified fats. Key results from these studies are summarized in Table 5. Relevant study details are noted below.

Zock *et al.* (39) fed 60 normocholesterolemic male and female subjects (average ages = 29 yr for the men; 32 yr for the women) each of two diets containing 40–41% energy as fat in a crossover design for 3 wk. One diet contained a margarine high in conventional palm oil, and the other a margarine high in an interesterified palm oil. The conventional palm oil had 82% of the palmitic acid in the *sn*-1 and *sn*-3 positions and 18% in the *sn*-2 position. In contrast, the interesterified palm oil (derived by interesterification of palm oil with sunflower oil fatty acids) had 35% of the palmitic acid in the *sn*-1 and *sn*-3 positions and 65% in the *sn*-2 position. Regarding stearic acid, 78% was in the *sn*-1,3 positions and 22% in the *sn*-2 position in the conventional palm oil diet, and 72% was in the *sn*-1,3 positions and 28% in the *sn*-2 position in the modified palm oil diet. Following the modified palm oil diet, considering all subjects, there were nonsignificant ($P > 0.13$) increases of 0.06 mmol/L (2.3 mg/dL), 0.03 mmol/L (1.2 mg/dL), and 0.04 mmol/L (1.5 mg/dL) in total, HDL-, and LDL-cholesterol, respectively, compared with the conventional palm oil diet. The small increases in total and LDL-cholesterol were significant in the men but not in the women. Overall, a large difference in dietary fatty acid configurations had little effect on blood lipid and lipoprotein concentrations. Considering the hypercholesterolemic nature of palmitic acid, these results suggested that the position of palmitic acid on the triglyceride is not significant with respect to its effect on blood lipid and lipoprotein levels.

Nestel *et al.* (40) fed 27 moderately overweight hypercholesterolemic men (average age 49 yr) diets containing one of three special margarines. One margarine was high in linoleic acid and moderate in *trans* fatty acids (TFA); one was high in a palm oil blend; and one contained an interesterified form of the high palm oil blend. The test margarine high in linoleic acid and moderate in TFA and the margarine high in the noninteresterifed palm oil blend had palmitic acid primarily in the *sn*-1 and *sn*-3 positions. The margarine made with the interesterified palm oil blend had palmitic acid roughly evenly distributed among the *sn*-1, *sn*-2, and *sn*-3 positions. The positional distribution of stearic acid was approximately the same in both the noninteresterified and interesterified fat blends (i.e., *sn*-2 = 11–12% of total fatty acids; *sn*-1,3 = 9% of total fatty acids in both fat blends). The fat content of the diets was about 35% energy. Total, LDL-, and HDL-cholesterol values were not different after subjects consumed either the high palm oil blend margarine or the interesterified palm oil blend margarine. These levels, however, were significantly higher ($P < 0.002$) than those seen after the high-linoleic, moderate *trans* blend. Blood triglyceride levels were not affected by any of the three dietary treatments. Overall, the process of interesterification did not influence the plasma lipid and lipoprotein response.

In a further study, Nestel *et al.* (41) compared the effects of feeding a stearic acid-rich, structured fat (Salatrim™; 18:0 = 66% total fatty acids; 18:0 randomly incorporated into the *sn*-1, *sn*-2, and *sn*-3 positions) with those of feeding a palmitic acid-rich fat. The triglycerides of the palmitic acid-rich diet had both palmitic and stearic acids primarily in the *sn*-1 and *sn*-3 positions. The fats were incorporated into margarines, cookies, and muffins and fed to 15 hypercholes-

**TABLE 5**

[a]Data shown from Zock *et al.* (39) and Nestel *et al.* (41) are for combined male and female subjects. Meijer and Weststrate (42) did not report combined data for their male and female subjects. TC, total cholesterol; LDL-C, low density lipoprotein-cholesterol; HDL-C, high density lipoprotein-cholesterol. See Table 1 for other abbreviation.

terolemic men and women (average age = 51 yr) for 5 wk each in random order. A low-fat diet (21% energy as fat) was fed for 2 wk as a baseline "run-in" treatment. The test diets contained 41–42% energy as fat. The fat intake provided by the test fats was *ca.* 25% energy. Total cholesterol levels were not significantly different from each other after feeding the low-fat, high-stearic, or high-palmitic diets, but they were significantly lower ($P < 0.001$) than that measured during the habitual diet period before the study started. HDL-cholesterol and triglyceride levels were not significantly different among the three diet treatments. Overall, a similar increase in the intake of stearic and palmitic acids to ensure a high fat intake led to total- and LDL-cholesterol levels that did not differ significantly from those during the period of a low fat diet. The authors attributed the lack of difference between the palmitic and stearic treatments to the small difference in the palmitic and stearic acid contents of the diets (around 5% total energy for each). Also, the lack of difference in LDL-cholesterol between the palmitic and low-fat diets was consistent with results previously reported by these authors.

Meijer and Weststrate (42) fed 60 healthy male and female subjects (average ages = 34 yr for the men and 37 yr for the women) a blend of commonly consumed vegetable fats. Half of the subjects received a control (untreated) fat blend, and half received an interesterified fat blend. The control and interesterified fat blends had the same fatty acid composition, but differed primarily in the triglyceride distributions of palmitic, stearic, and oleic acids. In the control fat, palmitic and stearic acids were primarily in the *sn*-1 and *sn*-3 positions, and oleic acid was primarily in the *sn*-2 position. In the interesterified fat, these fatty acids were roughly evenly distributed among the *sn*-1, *sn*-2, and *sn*-3 positions. Both fat blends were fed at two energy levels (4 and 8% energy) in margarine. At either energy level, the fat blends were consumed according to a crossover design for two periods of 3 wk. The total dietary fat level was 34% energy. Neither the type of fat blend nor the energy level at which the fat blends were consumed resulted in significant changes in blood lipid levels or in various clinical chemical and hemostasis parameters. The investigators concluded that the inclusion of interesterified vegetable fat blends in the diet of healthy people does not influence fasting blood lipids, blood enzymes, or hemostasis parameters in an adverse way compared with a non-interesterified fat blend with the same fatty acid composition.

While the position of selected fatty acids on dietary triglycerides has been reported not to affect blood lipid levels of human adults, there appears to be an impact in infants. A study by Nelson and Innis (43) evaluated whether the position of 16:0 in human milk and infant formula triglycerides influences the position of fatty acids in postprandial plasma chylomicron triglycerides. These investigators fed full-term infants formula with 25–27% total 16:0 with either 39% of the 16:0 (synthesized triglyceride) or 6% of the 16:0 (standard formula) esterified at the *sn*-2 position of the triglycerides from birth to 120 d of age. Some infants were breast-fed (23% total 16:0, 81% at the *sn*-2 position). Palmitic acid (16:0) is predominantly esterified in the *sn*-2 position of human milk triglycerides but in the *sn*-1 and *sn*-3 positions in the oils used in infant formulas. Infants fed the synthesized triglyceride formula, standard formula, or breast milk had 15.8, 8.3, and 28.0%, respectively, 16:0 in the chylomicron triglyceride *sn*-2 position. These results suggested that 50% or more of the dietary triglyceride *sn*-2 16:0 is conserved through digestion, absorption, and chlylomicron triglyceride synthesis in breast-fed and formula-fed infants. Total plasma cholesterol levels were higher in the breast-fed infants than in both groups of formula-fed infants, and both groups of formula-fed infants had the same total cholesterol levels. Plasma triglyceride levels were the same among all three groups. Infants fed the synthesized triglyceride formula had significantly lower HDL-cholesterol and apolipoprotein (apo) A-I concentrations than infants fed the standard formula or who were breast-fed. On the other hand, the plasma apo B levels of infants fed the synthesized triglyceride formula were significantly higher than those of infants fed the standard formula and were not different from those found in the breast-fed infants.

In summary, consumption of interesterified fats by adult humans appears to have no significant effect on blood lipid and lipoprotein parameters compared with consumption of native fats (Table 5). On the other hand, one study with human infants indicated that feeding a synthesized triglyceride formula (with an increased level of palmitic acid in the *sn*-2 position) led to decreased HDL-cholesterol and apo A-I and increased apo B concentrations compared with feeding a standard formula (with less palmitic acid in the *sn*-2 position). In contrast, breast-fed infants (who consumed milk with a higher level of palmitic acid in the *sn*-2 position compared with the synthesized triglyceride formula) had higher HDL-cholesterol and apo A-1 concentrations than did the infants fed the synthesized triglyceride formula. Also, in view of the limited number of studies that have been conducted in which effects of native and interesterified fats have been compared, it is not possible to determine whether the degree of randomization or the level of fat in the diet has influenced the outcome of the study. In addition, the limited number of available studies does not permit any conclusions to be drawn about whether there is a threshold level of total fat in the diet at which there is no effect, regardless of the position of the fatty acid on the dietary triglycerides.

## HUMAN STUDIES INVOLVING EFFECTS OF SPECIFIC FATTY ACIDS ON BLOOD LIPIDS AND LIPOPROTEINS

Effects of specific fatty acids on blood lipids and lipoproteins have been evaluated using interesterified fat blends but without comparing directly the effects of a native fat with those of the corresponding interesterified fat. In a study to assess the cholesterol-raising potential of specific saturated fatty acids in humans, McGandy *et al*. (44) fed male subjects (aged 41–56 yr) a number of synthesized fats with an excess of a specific saturated fatty acid. The test fats were prepared by interesterifying natural fats with either trilaurin, trimyristin, tripalmitin, or almost fully hydrogenated soybean oil (85% stearic acid) in a ratio of 3:1. (Thus, interesterification was used to enrich the test fats with specific fatty acids, not to study positional effects.) The results obtained with the interesterified fats (in

which the tested saturated fatty acid was randomized among the three positions) conflicted with studies using naturally occurring fat sources. McGandy *et al*. found that the stearic acid interesterified fat showed a similar hypercholesterolemic effect compared with the palmitic or myristic acid fats.

Previous work by Hegsted *et al.* (3), in contrast to that of McGandy *et al*. (44), found that stearic acid fed as cocoa butter (with stearic acid primarily in the *sn*-1 and *sn*-3 positions) was neutral with respect to blood cholesterol raising. Hegsted *et al.*'s study was designed to compare various native fats that are different in degree of saturation and chain length. This study did not include interesterified fats. McGandy *et al*. suggested that the difference in cholesterolemic action of stearic acid in the two studies may have been related to the position of stearic acid on the triglycerides being fed. McGandy *et al.*'s work also contrasted with that of Grande and coworkers (45), who found no differences in either plasma total cholesterol or triglyceride levels in human adults fed native cocoa butter compared with an interesterified fat blend having the same fatty acid composition as cocoa butter but no added cocoa butter *per se*. In the interesterified fat blend, stearic and palmitic acids were randomized among the *sn*-1, *sn*-2, and *sn*-3 positions. This work suggested that the positions of stearic and palmitic acids on the triglycerides did not affect blood lipid levels. [These early (1965 and 1970) studies did not report levels of HDL- and LDL-cholesterol because analytical methods for blood lipoproteins were not well established at that time.]

Positional effects of stearic acid also can be considered by comparing studies conducted by Judd *et al*. (46) and Kris-Etherton *et al*. (47). Judd *et al.* (46) fed 50 normocholesterolemic men (average age = 42 yr) a series of six diets for 5 wk each to study effects of individual fatty acids on blood lipid and lipoprotein levels. Across diets, 8% energy was replaced as follows: (i) carbohydrate (CHO; 1:1 simple to complex); (ii) oleic acid (OL); (iii) TFA; (iv) stearic acid (STE); (v) TFA (4% energy) plus STE (4% energy); or (vi) the saturated fatty acids lauric, myristic, and palmitic (LMP). The CHO diet contained 30% energy as fat, and the other diets about 39% energy as fat. For four of the six diets (CHO, OL, TFA, and LMP), the fats were not modified to rearrange the positions of the fatty acids on the triglycerides. In these fats, STE and palmitic acid were primarily in the *sn*-1 and *sn*-3 positions. The high-stearic fat used in the STE and TFA/STE diets was randomized, so STE in these diets would have been equally distributed among the *sn*-1, *sn*-2, and *sn*-3 positions. Compared with the CHO control diet, the STE diet had no effect on LDL-cholesterol, but it lowered HDL-cholesterol. Also, the STE diet showed a directional (but not significant) increase in plasma triglyceride level compared with the CHO diet. Compared with the LMP diet, the STE diet did not change LDL-cholesterol, but it lowered HDL-cholesterol and raised the plasma triglyceride level. Plasma triglycerides were highest after the STE diet [1.134 mM (100.4 mg/dL)] and lowest after the OL diet [0.878 mM (77.7 mg/dL)]. [This study by Judd *et al*. (46) has been submitted for publication and at present is published only in abstract form.]

The study by Kris-Etherton *et al*. (47) compared the effects on blood lipids and lipoproteins of feeding either one milk chocolate bar or a high-carbohydrate snack per day as part of a National Cholesterol Education Program/American Heart Association (NCEP/AHA) Step 1 diet. Following a 21-d run-in period on the NCEP/AHA Step 1 diet (29% calories as fat), Kris-Etherton *et al.* fed 42 normocholesterolemic men (aged 21–35 yr) the same diet with the addition of either one milk chocolate bar per day (total dietary fat = 34% energy) or a high-carbohydrate snack per day (total dietary fat = 29% energy) for 27 d. Although the intakes of individual saturated fatty acids (except for stearate) were the same for subjects consuming the high-carbohydrate snack compared with the milk chocolate bar, subjects consuming the milk chocolate bar had greater intakes of oleic acid (11.4 energy %) than those consuming the high-carbohydrate snack (9.2 energy %). For subjects consuming the milk chocolate bar, HDL-cholesterol levels were 0.08 mmol/L (3.1 mg/dL) higher ($P < 0.01$), and plasma triglyceride levels were 0.06 mmol/L (5.3 mg/dL) lower ($P < 0.05$) compared with subjects consuming the high-carbohydrate snack. In contrast, Judd *et al.* found that subjects consuming the high-stearate diet had HDL-cholesterol levels that were 0.04 mmol/L (1.5 mg/dL) lower ($P \leq 0.01$) and triglyceride levels that were not significantly different compared with those of subjects consuming the high-carbohydrate diet.

The inconsistency in responses of HDL-cholesterol and triglyceride levels to increased intake of STE in the Judd *et al.* study compared to the Kris-Etherton *et al.* study may be related to differences in triglyceride structure and dietary levels of fat and STE between the two studies. In the STE diet used by Judd *et al.*, STE was randomized (i.e., distributed equally among the *sn*-1, *sn*-2, and *sn*-3 positions), whereas the cocoa butter used in the milk chocolate bars in the study by Kris-Etherton *et al.* was not randomized (STE primarily in the *sn*-1 and *sn*-3 positions). Also, the STE diet used by Judd *et al.* contained higher levels of total fat (39 vs. 34% energy) and of STE (about 38 vs. 17 g/d, based on a caloric intake of around 3000 kcal/d) compared with the milk-chocolate-bar-supplemented diet used by Kris-Etherton *et al.* Furthermore, the stearate and carbohydrate exchange was 8 energy % in the Judd *et al.* study but much lower (2.8 energy %) in the Kris-Etherton *et al.* study. Thus, much more STE would have been available for absorption in the Judd *et al.* study than in the Kris-Etherton *et al.* study. It is possible that the effect of dietary STE on blood lipid and lipoprotein levels depends not only on its level in the diet but also on whether it has been randomized on the dietary triglycerides.

Also in contrast to the study by Judd *et al.*, Nestel *et al.* (41) found no difference in HDL-cholesterol or triglyceride levels after feeding a high-STE diet (STE intake ≈ 43 g/d in a diet containing 2500–2600 kcal/d and randomly incorporated into the *sn*-1, *sn*-2, and *sn*-3 positions) compared with feeding a high-carbohydrate diet (baseline diet; fat = 21% energy). Three recent human studies (6,48,49) have indicated that a high-stearate diet (nonrandomized; i.e., STE, primarily *sn*-1 and *sn*-3) tended to lower or conserve HDL-cholesterol levels without raising triglyceride levels compared with a high-palmitate diet. Bonanome and Grundy (6) fed three liquid for-

mula diets, each containing 40% energy from fat (17% energy from palmitic, STE, or oleic acids), to hypercholesterolemic men for 3 wk each. The STE diet resulted in lower total, LDL-, and HDL-cholesterol compared with the palmitic acid diet but no change in triglyceride level. Snook *et al.* (48) fed premenopausal women each of three conventional food diets containing 40% energy from fat (13% energy from either myristic, palmitic, or stearic acid) for 5 wk. The STE diet resulted in lower total and LDL-cholesterol compared with the palmitic acid diet. HDL-cholesterol and triglyceride levels were the same after all three diets. Tholstrup *et al.* (49) fed three liquid formula diets, each containing 40% energy from fat (15% energy from either myristic plus lauric acids, palmitic acid, or STE) to male subjects for 3 wk each. The STE diet lowered total and LDL-cholesterol compared with both the palmitic and myristic acids plus lauric acid diets. HDL-cholesterol also was lower after the STE diet than after either the palmitic or myristic diet plus lauric acid diet. Triglyceride levels were the same after all three diets.

Zock [personal communication; presented at a special AHA conference (50)] has found that based on a meta analysis, high-stearate diets (having an average stearate content of 3.1% energy, range 0.7–16.5%) slightly decreased the total/HDL-cholesterol ratio when substituted for carbohydrates. The total fat content of the diets averaged 34.4% energy (range 4.5–53%). The high-stearate diets did not increase HDL-cholesterol levels as other saturated fatty acids did compared with carbohydrates. In this analysis, the stearate diets resulted in the same HDL levels as did the carbohydrate diets. Also, stearate diets significantly decreased plasma triglyceride levels compared with carbohydrate diets, and the decrease with stearate diets was to the same extent as that with other saturated fatty acid diets.

Aro *et al.* (51) compared effects of diets high in STE, TFA, or dairy fat for 5 wk on serum lipid and lipoprotein levels in 80 normocholesterolemic men and women (average age = 29 yr). As was the case with the study by Judd *et al.* (46), Aro *et al.* used a high-STE diet in which STE was provided in an interesterified fat blend. Thus STE in this fat was equally distributed among the *sn*-1, *sn*-2, and *sn*-3 positions. On the other hand, unlike the Judd *et al.* study, all three test diets used by Aro *et al.* provided 32–34% energy as fat and no lower-fat, high-carbohydrate diet was used. Thus a high-carbohydrate–high-STE comparison was not possible. Nevertheless, Aro *et al.* found that compared with the baseline dairy fat diet (high in saturated fatty acids), STE and TFA decreased total cholesterol levels similarly (13 and 12%, respectively). The STE and *trans* diets both reduced HDL-cholesterol, with the *trans* diet showing a larger decrease in HDL-cholesterol (17%) than the STE diet (11%). The STE diet decreased serum triglyceride levels by 10% ($P < 0.01$); however, triglyceride levels were unchanged by the *trans* diet. The authors concluded that dietary fats low in both saturated fatty acids and TFA should be favored for optimizing blood lipid and lipoprotein profiles.

Mascioli *et al.* (52) provided 30 healthy adult men and women (average age = 59 yr) baked goods (muffins or cookies) made with either of two fats: butter or an interesterified mixture of butter, medium-chain triglycerides (MCT), and safflower oil. The subjects followed each of two individualized meal plans incorporating either of the two fats in a crossover study design for periods of 5 wk each. The diets consisted of 36% energy as fat. In the butter diet, the levels of lauric, myristic, and palmitic acids in the *sn*-2 position exceeded the levels of these fatty acids in the *sn*-1,3 positions. In contrast, the level of STE in the *sn*-1,3 positions greatly exceeded that in the *sn*-2 position. In the diet containing the interesterified butter/MCT mixture, the saturated fatty acids were equally distributed among the *sn*-1, *sn*-2, and *sn*-3 positions. The investigators found that total-, LDL-, and HDL-cholesterol levels were not significantly different between the two dietary periods. Plasma triglyceride levels were significantly higher after feeding the interesterified butter-MCT mixture than after feeding butter [1.96 mmol/L vs. 1.75 mmol/L (174 vs. 155 mg/dL), $P < 0.05$]. These results were consistent with other cited reports that triglyceride levels increased when subjects consumed MCT. The authors concluded that an interesterified mixture of butter, MCT, and safflower oil compared with butter had no appreciable effect on plasma cholesterol concentrations but was associated with a modest rise in plasma triglycerides.

In addition, studies involving the feeding of high levels of STE as cocoa butter (47,53,54) or as shea butter (sheanut oil) (49,55) have not shown reductions in HDL-cholesterol or increases in triglyceride levels compared with baseline or control diets. In cocoa butter and shea butter, STE is primarily in the *sn*-1 and *sn*-3 positions, whereas in the study by Judd *et al.* (46), it was equally distributed among the *sn*-1, *sn*-2, and *sn*-3 positions. In the study by Judd *et al.*, STE was fed as part of a high-fat diet (39% energy as fat), which was similar to the levels of dietary fat in the studies involving cocoa butter and shea butter (34–40% energy). Thus, the effect of STE on certain blood lipid parameters may have been related to whether the fat had been structurally rearranged. As far as I am aware, human studies comparing effects of native vs. randomized cocoa butter or native vs. randomized shea butter have not been conducted.

In summary, responses among studies of blood lipids and lipoproteins to increased intake of specific fatty acids have been inconsistent. These inconsistencies may be related to differences in triglyceride structure and in dietary levels of the specific fatty acid and of total fat. Among dietary saturated fatty acids, high levels of STE fed in nonrandomized (i.e., native) form have been associated with no change in HDL-cholesterol (although at least one study showed an increase in HDL-cholesterol) and with decreased triglyceride levels compared with a high-carbohydrate diet. Compared with a high-palmitate diet, feeding high levels of stearate in nonrandomized form resulted in lowering or conserving HDL-cholesterol without raising triglycerides. Considering two studies in which STE was fed in randomized (i.e., interesterified) form, one study found the high-stearate diet to lower HDL-cholesterol without changing triglycerides compared to a high-carbohydrate diet, whereas the other study reported no differences in HDL-cholesterol or

triglyceride levels compared with a high-carbohydrate diet. Thus, the effect of dietary STE on levels of blood lipids and lipoproteins appears to depend on both the level of STE in the diet and whether STE has been randomized on the dietary triglycerides.

## IS THERE A RELATIONSHIP BETWEEN THE STEREOSPECIFIC POSITION OF A FATTY ACID AND ITS BIOLOGICAL EFFECTS?

This literature review has attempted to evaluate whether the stereospecific position of a fatty acid can be related to its biological effects. Based on studies conducted by Kritchevsky *et al.* (28,29,31,32,34), only two fatty acids, palmitic acid and, to a lesser degree, STE, have been evaluated in this regard. Based on these studies, it appears that fats with increased levels of palmitic acid in the *sn*-2 position may be more atherogenic to rabbits than those with palmitic acid largely in the *sn*-1 and *sn*-3 positions. For instance, randomized cottonseed oil was found to be more atherogenic to rabbits than native cottonseed oil (32). On the other hand, the stereospecific positioning of palmitic acid appears to have little effect on blood lipid and lipoprotein levels, as indicated by studies that showed no significant differences in blood lipids and lipoproteins after feeding native compared to interesterified fats (28,29,31,32,34). In addition, enhancing the level of STE in the *sn*-2 position has not been found to affect either atherogenic potential or levels of blood lipids and lipoproteins (34). Thus, to date, palmitic acid is the only fatty acid I am aware of with stereospecific positioning related to the atherogenicity of the test fat.

Similar studies on atherogenicity have not been reported with the other recognized cholesterolemic saturated fatty acids, namely, lauric and myristic. Furthermore, different species may vary in their responsiveness to dietary palmitic acid in the *sn*-2 position, considering that rabbits have shown atherosclerotic susceptibility (28,29,31,32,34) but hamsters have not (Nicolosi, R.J., Wilson, T., and Lawton, C., personal communication).

Studies with human adults conducted to date have not shown significant effects on blood lipid parameters of interesterified fats compared with native fats. On the other hand, one study with human infants (43) reported higher levels of HDL-cholesterol in infants fed breast milk (large amount of palmitic acid at the *sn*-2 position) compared with infants fed formulas with much less palmitic acid at the *sn*-2 position. More work is needed in order to establish whether a relationship exists between the stereospecific position of a fatty acid and its biological effects. Also it should be noted that comparisons of individual human studies involving the feeding of specific fatty acids frequently are complicated by many variables in the ways the studies were conducted. Such variables include level of fat (or fatty acid) in the diet, total calorie level of the diet, duration of feeding period, age of subjects, whether subjects were hypercholesterolemic or normocholesterolemic, and whether all foods were provided or only test foods were provided.

## RECOMMENDATIONS FOR FURTHER RESEARCH

Two areas of further research are recommended on effects of dietary fatty acids as related to their position on triglycerides. The first is to answer the fundamental question of whether there is a difference in the metabolic clearance and turnover of various fatty acids at the *sn*-2 compared to *sn*-1 and *sn*-3 positions of triglycerides. The second is to determine the relative hypercholesterolemic and atherogenic effects of fatty acids at the *sn*-2 compared with the *sn*-1 and *sn*-3 positions.

*Metabolic clearance and turnover of fatty acids at* sn-*2 vs.* sn-*1 and* sn-*3 positions.* Human studies could be conducted in which triglycerides with various fatty acids at the *sn*-2 compared with the *sn*-1 and *sn*-3 positions are fed. A single study would focus on a single fatty acid. Parameters such as the uptake of labeled (e.g., with deuterium) fatty acids into chylomicrons and the transport and metabolism of the fatty acids could be followed. Such studies would help to clarify whether the triglyceride position of a specific dietary fatty acid affects its uptake and metabolism.

*Relative hypercholesterolemic and atherogenic effects of fatty acids at the* sn-*2 position compared with the* sn-*1 and* sn-*3 positions.* (i) One study could compare in humans the effects of feeding a synthetic fat in which a cholesterolemic fatty acid (e.g., palmitic acid) or a noncholesterolemic fatty acid (e.g., STE) is completely in the *sn*-1 and *sn*-3 positions (little or none in the *sn*-2 position) with one in which the fatty acid is completely in the *sn*-2 position (little or none in the *sn*-1 and *sn*-3 positions). Human studies conducted to date on effects of native vs. interesterified fats have found no significant differences in various blood lipid and lipoprotein parameters. One possible explanation for this lack of differences may have been insufficient exaggeration of the level of fatty acid in the *sn*-1, *sn*-2, and *sn*-3 positions. Such a study could be conducted at both high and low-to-moderate levels of total dietary fat.

(ii) Another study could evaluate whether the stereospecific structure of triglycerides affects additional parameters (beside blood lipid and lipoprotein levels) that could be related to the promotion of atherosclerosis. Such parameters could include cellular adhesion molecules and postprandial triglyceride clearance and composition.

(iii) A long-term primate feeding study could be conducted to determine whether changing the positions of fatty acids on the trigylcerides (e.g., by interesterification) alters the atherogenicity of the fat. Studies with rabbits fed interesterified fats frequently have found that atherogenicity increased as the level of palmitic acid in the *sn*-2 position increased. Similar long-term studies conducted with primates might be more predictive of human atherosclerosis risk.

(iv) The n-3 fatty acids could be studied to determine if they have different physiological effects if incorporated into randomized fats compared with nonrandomized fats. Nawar (12) has noted that the long-chain polyunsaturated fatty acids characteristic of marine oils are preferentially located at the *sn*-2 position. In contrast, certain commercial preparations of n-3 fatty acids may have these fatty acids randomized on the triglycerides. Randomization might decrease the degree of

absorption of these n-3 fatty acids and thus modify their lipidemic properties.

## SUMMARY AND CONCLUSIONS

Animal studies have shown that altering the stereospecific distribution of certain fatty acids on dietary triglycerides can impact various biological parameters. The changes in specific biological parameters are thought to be related to the enhanced absorption of the fatty acid in the *sn*-2 position of the dietary triglycerides. Specifically, enhancing the level of the saturated fatty acid palmitic acid in the *sn*-2 position of a triglyceride (e.g., by interesterification of the fat to randomize the positions of the fatty acids along the glycerol backbone) has been shown to increase the atherogenic potential in rabbits of the fat without significantly impacting the levels of blood lipids and lipoproteins. In contrast, enhancing the level of STE in the *sn*-2 position has been found not to affect either atherogenic potential or levels of blood lipids and lipoproteins in rabbits. A limited number of human studies have shown no significant effects of interesterified fats on blood lipid parameters. However, it is not known whether modifying the stereospecific structure of dietary triglycerides would affect atherogenicity or other long-term health conditions in humans. It is possible that incorporation of palmitic acid in the *sn*-2 position of milk fat is of benefit to the human infant (as a source of energy for growth and development) but not to human adults. Additional research is needed to determine whether processes like interesterification, which can be used to alter physical parameters of dietary fats (e.g., melting characteristics), may result in favorable or unfavorable long-term effects in humans.

# Dietary Supplementation with Conjugated Linoleic Acid Increased Its Concentration in Human Peripheral Blood Mononuclear Cells, but Did Not Alter Their Function[1]

**D.S. Kelley[a,*], V.A. Simon[a], P.C. Taylor[a], I.L. Rudolph[a], P. Benito[a], G.J. Nelson[a], B.E. Mackey[b], and K.L. Erickson[c]**

**ABSTRACT:** The purpose of this study was to examine if conjugated linoleic acid (CLA) supplementation of diets would alter fatty acid (FA) composition and function of peripheral blood mononuclear cells (PBMC). Seventeen women, 20–41 yr, participated in a 93-d study conducted at the Metabolic Research Unit. The same diet (19, 30, and 51% energy from protein, fat, and carbohydrate, respectively) was fed to all subjects throughout the study. Seven subjects (control group) supplemented their diet with six daily capsules (1 g each) of placebo oil (sunflower) for 93 d. For the other 10 subjects (CLA group), the supplement was changed to an equivalent amount of Tonalin capsules for the last 63 d of the study. Tonalin provided 3.9 g/d of a mixture of CLA isomers (*trans*-10,*cis*-12, 22.6%; *cis*-11,*trans*-13, 23.6%; *cis*-9,*trans*-11, 17.6%; *trans*-8,*cis*-10, 16.6%; other isomers 19.6%), and 2.1 g/d of other FA. PBMC isolated on study days 30 and 90 were used to assess intracellular cytokines by flow cytometry, secreted cytokines, and eicosanoid by enzyme-linked immonosorbent assay, and FA composition by gas–liquid chromatography. After supplementation, total CLA concentration increased from 0.012 to 0.97% ($P < 0.0001$) in PBMC lipids, but it did not significantly alter the concentration of other FA. CLA supplementation did not alter the *in vitro* secretion of prostaglandin $E_2$, leukotriene $B_4$, interleukin-1β (IL-1β), or tumor necrosis factor α (TNFα) by PBMC simulated with lipopolysaccharide, and the secretion of IL-2 by PBMC stimulated with phytohemagglutinin. Nor did it alter the percentage T cells producing IL-2, interferon γ, and percentage of monocytes producing TNFα. The intracellular concentration of these cytokines was also not altered. None of the variables tested changed in the control group. Our results show that CLA supplementation increased its concentration in PBMC lipids, but did not alter their functions.

Paper no. L8741 in *Lipids 36,* 669–674 (July 2001).

Conjugated linoleic acid (CLA) is a mixture of 18:2 fatty acid isomers that have conjugated double bonds. One of the prominent isoforms of CLA, the 9-*cis* and 11-*trans* (9*c*,11*t*-18:2) isomer, is found naturally in beef and dairy products. This isomer has been commonly named rumenic acid, because it is formed by the microbes in the rumen from linoleic acid (18:2n-6) and *trans*-11-18:1 (1). Several other isomers of CLA are produced industrially during the processing of vegetable oils. The most abundant among these isomers include the 8*t*,10*c*-18:2, 10*t*,12*c*-18:2, and 11*c*,13*t*-18:2. In addition, there are several other minor isomers.

Trace amounts of different CLA isomers have been found in several human tissues, including adipose tissue, blood, milk, and bile (2–7). In animal models, the concentration of CLA in tissue (liver, heart, bone marrow, and spleen) lipids increased when the dietary intake of CLA was increased (8–12). Feeding diets containing CLA to animals also altered the production of prostaglandin $E_2$ ($PGE_2$), leukotriene $B_4$ ($LTB_4$), and cytokines by the splenocytes and peritoneal exudate cell (10,13–17).

The effects of dietary CLA on the fatty acid composition and functions of human or animal peripheral blood mononuclear cells (PBMC) have not been reported. The purpose of this study was to examine the effect of supplementing diets of healthy human adults with CLA on the fatty acid profile of the PBMC, and the *ex vivo* production of eicosanoids and cytokines. We examined the effect of feeding a mixture of CLA isomers on PBMC fatty acid profile, and *ex vivo* production of $PGE_2$, $LTB_4$, interleukin 2 (IL-2), interferon γ (IFN γ), and tumor necrosis factor α (TNF α). These indices were selected because CLA feeding in animal models altered these functions in splenocytes and peritoneal monocytes. Also they are relevant to other changes in immune functions reported in animal models (13–17). Supplementing diets of healthy women with a mixture of CLA isomers at 3.9 g/d for 63 d significantly increased the concentration of several CLA isomers in PBMC lipids, but it did not affect the production of eicosanoids and cytokines studied.

## METHODS AND MATERIALS

*Subjects and study design*. The study protocol was approved by the human use committees of the University of California, Davis, and the U.S. Department of Agriculture (USDA)

[1]Parts of data included here were published as abstracts for the Experimental Biology and AOCS 2001 meetings.

Abbreviations: CD, cluster designation; CLA, conjugated linoleic acid; CY5, cyanin 5; ELISA, enzyme-linked immunosorbent assay; FITC, fluorescein isothiocyanate; GC, gas chromatograph; Hu, human; IFN γ, interferon γ; IL, interleukin; LPS, lipopolysaccharide; $LTB_4$, leukotriene $B_4$; PBMC, peripheral blood mononuclear cells; PBS, phosphate buffered saline; PE, phycoerythrin; $PGE_2$, prostaglandin $E_2$; RDA, recommended daily allowance; TNFα, tumor necrosis factor α.

(Houston, TX). Healthy women ($n$ = 17) were selected to participate in two cohorts (9 and 8) of a 93-d metabolic research unit study after a physical and clinical evaluation by a physician. They were all nonsmokers and nondrug users and had body weights within 110–120% of the ideal body weight (1983, Metropolitan Life Insurance Co., New York, NY). The age, body weight, and body mass index (mean ± SEM) for the CLA and control groups were 27.0 ± 1.8 and 29.3 ± 2.6 yr, 63.1 ± 2.1 and 63.2 ± 4.3 kg, and 23.6 ± 0.5 and 21.9 ± 1.2, kg/m$^2$, respectively. The body weight of the subjects was maintained within 2% of the initial body weight throughout the study, by adjusting their caloric intake if necessary. All subjects lived at the metabolic suite of the Western Human Nutrition Research Center (San Francisco, CA) for the duration of the study, except when going for daily walks (2 miles, twice daily) or other scheduled outings. Subjects were under supervision when going out of the metabolic unit. They consumed only those foods prepared by the staff of the metabolic unit. For the first 30 d, all study participants were fed a stabilization diet supplemented with six capsules of a placebo (sunflower oil 6 g/d). For the next 63 d, subjects were divided into two groups; seven subjects remained on the placebo supplement for the entire period of the study (control group), while for the remaining 10 subjects, 6 g of Tonalin (providing 3.9 g/d of CLA isomers) replaced the placebo supplement. This CLA source was selected because it has been used in many animal studies, and the purified CLA isomers for human consumption were not available at the time the study was conducted. CLA concentration used in our study provided about 1.5% of the total energy intake and was comparable to the percentage energy from CLA in many animal studies.

The nutrient content of the diets was calculated using *USDA Handbook 8* (18); all known nutrients were at or above the recommended daily allowance (RDA) level, and were not different between the two diets. Diets contained 1 × RDA of vitamin E from natural foods and were supplemented with an additional 100 mg capsule of α-tocopherol (Bronson Pharmaceutical, St. Louis, MO) every 5 d. The proportions of energy from protein, fat, and carbohydrate in both diets were 19, 30, and 51%, respectively. Diets were fed with a 5-d rotating menu, comprised of three meals and a post-dinner snack. Specific menus were designed so that each of the saturated, monounsaturated, and polyunsaturated fats provided 10% of the total energy for both the control and intervention groups. Tonalin, a gift from Pharmanutrient, Inc. (Lake Bluff, IL), was the source of CLA. It was provided as capsules by replacing an equivalent amount of the placebo oil. Both Tonalin and placebo oil capsules were administered to the subjects before each meal (breakfast, lunch, dinner) under the supervision of the kitchen staff. CLA isomers made up 65 wt% of the total fatty acids present in Tonalin, while other fatty acids made up the remainder 35%. The major isomers of CLA present in Tonalin, expressed as percentage of total CLA were: *t*10,*c*12, 22.6%; *c*11,*t*13, 23.6%; *c*9,*t*11, 17.6%; *t*8,*c*10, 16.6%; other isomers 19.6%. Thus, the daily intake of different CLA isomers was: 881 mg of *t*10,*c*12; 920 mg of *c*11,*t*13; 686 mg of *c*9,*t*11; 647 mg of *t*8,*c*10; and 764 mg of other isomers. Placebo capsules were made from sunflower oil containing 72.6% linoleic acid and no detectable CLA. Other details regarding this study can be found in our previously published papers (19–22).

*Laboratory procedures*. Blood samples for PBMC fatty acid analysis were collected on study days 30 and 90, and for cytokine and eicosanoid production on study days 15, 22, 29, 78, 85, and 92. Samples were collected between 0700 and 0800, after a 12-h fast, by antecubital venipuncture into evacuated tubes without anticoagulants (for sera preparation) or containing heparin (all other uses).

*Isolation and culture of PBMC for cytokine and eicosanoid secretion.* PBMC were isolated using Histopaque-1077 as previously reported (23) and cultured with or without lipopolysaccharide (LPS, 1.0 mg/L) in 24-well flat-bottom culture plates ($5 \times 10^5$ PBMC/mL/well). The culture medium used was RPMI-1640, (Gibco, Grand Island, NY) containing 10% autologous serum and L-glutamine (2 mmol/L), penicillin (100 KU/L), streptomycin (100 mg/L), and gentamicin (20 mg/L). The tissue culture media were collected by centrifugation 24 h after stimulation with LPS and stored frozen at −70°C until the cytokine (IL-1β and TNFα) and eicosanoid ($PGE_2$ and $LTB_4$) concentrations were determined. For the stimulation of IL-2 synthesis, PBMC were cultured with PHA (10 mg/L) for 48 h, before collecting the cell culture media. These mitogen concentrations were found to cause maximal stimulation of cytokine production in our previous studies (23–25). Enzyme-linked immunosorbent assay (ELISA) kits for cytokine and eicosanoid assays were purchased from Cayman Chemical Company (Ann Arbor, MI).

*Intracellular cytokines*. The number of T cells producing IL-2 and INFγ was determined with a flow cytometer and reagents provided by Becton Dickinson (San Jose, CA) as previously reported (24). Briefly, the T lymphocytes were activated by mixing 500 µL sodium-heparin blood with 500 µL RPMI-1640, containing 10 µg brefeldin A, 25 ng phorbol 12-myristate 13-acetate (PMA), and 1 µg inomycin. After 4 h incubation at 37°C in 5% $CO_2$, the cells were recovered by centrifugation. The pellet was stained with either anti-human (Hu)-IL-2 PE or anti-Hu-IFNγ phycoerythrin (PE) and incubated for 30 min. The pellet was washed once with phosphate buffered saline (PBS) and resuspended in 1% paraformaldehyde. The number of IL-2 or IFNγ producing cells was analyzed with a flow cytometer by gating on the cluster designation (CD)3+ cells. The fluorescent geometric mean was also determined for these antigens. Isotype controls were run for both the stimulated and unstimulated control samples.

The number of monocytes producing TNFα was determined in a fashion similar to that used for the T cells producing IL-2, except that the cells were stimulated with LPS (1 µg/mL) instead of PMA and inomycin. Surface markers used for gating the monocytes were CD14 fluorescein isothiocyanate (FITC) and CD45 PE-CY5. After permeablization, anti-Hu-TNFα PE was added to the cell pellet. The number of cells expressing TNFα and the fluorescent geometric mean were determined.

In addition to determining the percentage of cells expressing specific cytokines, the amount of PE conjugated antibody bound per cell was determined using Becton Dickinson Phycoerythin Fluorescence Quantitation Kit. A standard curve was constructed plotting the log PE mean fluorescent intensity vs. the log of the number of PE molecules per bead. Assuming a 1:1 ratio of PE to monoclonal antibody, the antibody bound per cell was calculated by substituting the log fluorescent geometric mean of the PE-stained beads with the PE fluorescence expressed by the cells stained with the anti-Hu-TNFα PE antibody. The intracellular concentrations of cytokines are expressed as number of PE molecules/cell.

*PBMC isolation and fatty acid analysis*. The PBMC were isolated using Histopaque-1077 and purified as previously reported (23,24). Briefly, the isolated cells were washed with Dulbecco's PBS, resuspended in PBS, and layered over Histopaque-1077. The tubes were centrifuged to remove contaminating erythrocytes. PBMC were washed with PBS, mixed with LYMPHO-KWIK (One Lambda, Inc., Canoga Park, CA), and incubated for 15 min at 37°C. The PBMC were then overlaid with PBS and centrifuged. The cell pellet was washed with PBS and stored frozen at –20°C until fatty acid analysis. This isolation procedure removed most of contaminating platelets and erythrocytes and yielded cells containing 90–95% mononuclear cells as determined by differential cell counting.

Because of the limited sample size, the PBMC lipids were not extracted with chloroform/methanol, but were lyophilized and then transmethylated. In order to avoid isomerization of CLA isomers (26), the total lipids and CLA standards were transmethylated with 0.2 M sodium methylate (methoxide) for 10 min at 55°C followed by a reaction with 1 N hydrochloric acid in methanol for 15 min at 55°C (27). The fatty acid methyl esters (FAME) were extracted with hexane and purified by thin-layer chromatography as described elsewhere (28) before dilution and injection into the gas chromatograph (GC).

The FAME were analyzed by GC (model 6890; Hewlett-Packard, Palo Alto, CA) with a computer. An SP-2380 column (100 m × 0.25 mm i.d. × 0.2 mm film thickness; Supelco Inc., Bellefonte, PA) was used. The column was heated to 75°C for 4 min and then temperature-programmed at 13°C/min to 175°C, and held there for 27 min, followed by a second temperature program at 4°C/min to 215°C, and finally held there for 31 min. The total run time was 79.69 min. Fatty acids were identified by comparison of their retention times with authentic standards. If a GC peak was not clearly identified, then ion trap mass spectra were compared to mass spectra from NIST or mass spectra prepared in our laboratory (22).

*Data analysis*. The data from the two cohorts were combined for a repeated measure of analysis of variance using the SAS PROC MIXED procedure (29). Day, diet, and the interaction were considered the fixed effects, while cohort, diet × cohort, subjects within diet × cohort, and diet × cohort × day were the random effects. Period 1 (stabilization) vs. period 2 (intervention) × diet contrast was partitioned out of the day × diet effect. Pooled means ± SEM for the three measurements made at the ends of stabilization (days 15, 22, and 29) and intervention (days 78, 85, and 92) periods are shown in the Results section. For consistency with the fatty acid data, cytokines and eicosanoids data are also labeled as day 30 and day 90. Since none of the response variables in the control group changed from day 30 to day 90, data for this group are not shown. Paired *t*-test was used to evaluate the changes in the fatty acid composition data of PBMC. Changes in the parameters examined are considered significant for $P < 0.05$ unless stated otherwise.

## RESULTS

Both diets provided 19, 30, and 51% energy from protein, fat, and carbohydrates, respectively. The average daily caloric intake was approximately 2100 kcal (2117 ± 191, mean ± SD) and was not significantly different between the two groups. Fatty acid composition of the diets is shown in Table 1. Fatty acids other than CLA and linoleic acid were not significantly different between the two diets. The concentration of CLA in the control diet was below the detection limit, while the sum total of all CLA isomers in the CLA diet was 5.28% of the total fatty acids. The linoleic acid content of the control diet was about 5% higher than that in the CLA diet. This was because the placebo supplement contained sunflower oil with 73 wt% linoleic acid.

*Effect of CLA on fatty acid profile of PBMC*. The women in the CLA group received a placebo supplement until study day 30 and a CLA supplement from study day 31 to 93. The fatty acid profiles of the PBMC isolated on study day 30 and

[a]Data are mean ± SEM, $n = 5$. DMA, dimethyl acetal; CLA, conjugated linoleic acid.

day 90 for this group are shown in Table 2; comparisons between CLA concentrations on study days 30 and 90 are pictorially shown in Figure 1. The concentrations of all other fatty acids, except CLA, remained unchanged between study days 30 and 90, while that of CLA increased significantly ($P <$ 0.0001; Table 2 and Fig. 1). In the PBMC isolated on day 30, there were only trace amounts of CLA, and the sum of all CLA isomers was 0.12 wt% of the total fatty acids. The CLA isomers that were present included CLA1(9*c*,11*t*) + CLA2 (8*t*,10*c*), CLA 3 (11*c*,13*t*), and CLA4 (10*t*,12*c*) at 0.05, 0.03, and 0.04 wt%, respectively. Total concentration of CLA in PBMC on study day 90 increased to 0.97 wt%, which was an eightfold increase over its concentration on study day 30. Concentration of CLA as well as that of the other fatty acids in the PBMC from the control group remained unchanged between study days 30 and 90 (not shown).

*Effect of CLA supplementation on* in vitro *eicosanoid and cytokine secretion*. Concentrations of $PGE_2$ secreted by the LPS-stimulated PBMC from the CLA group on day 30 and day 90 were 22.7 ± 3.2, and 20.5 ± 2.7 (mean ± SEM) ng/million cells, respectively; corresponding values for $LTB_4$ secretion were 6.5 ± 2.4 and 10.3 ± 3.2 pg/million cells. Concentrations of neither of the two eicosanoids were different between day 30 and day 90. Likewise, the concentrations of these eicosanoids did not change from day 30 to day 90 in the control group (not shown). The concentrations of both these eicosanoids in the unstimulated PBMC from both dietary groups were below the detection limit of the ELISA assays used.

The concentrations (ng/mL) of IL-1β secreted by monocytes in response to LPS stimulation for the CLA group on day 30 and day 90 were 2.47 ± 0.47, and 2.98 ± 0.55, respectively; corresponding values for TNFα were 1.45 ± 0.13, and 1.27 ± 0.17, respectively. IL-2 secreted into the medium by T cells stimulated with phytohemagglutinin on days 30 and 90 was 0.28 ± 0.09, and 0.28 ± 0.12, respectively. Without stimulation, the concentrations of these cytokines secreted were not detectable. Thus, mitogen treatment caused a several-fold increase in the concentrations of the cytokines secreted by the monocytes and T cells, when compared to the corresponding values in the unstimulated cultures. However, CLA supplementation did not alter the concentrations of these cytokines secreted after mitogen stimulation. Nor did these cytokine concentrations change from day 30 to 90 in the control group (data not shown).

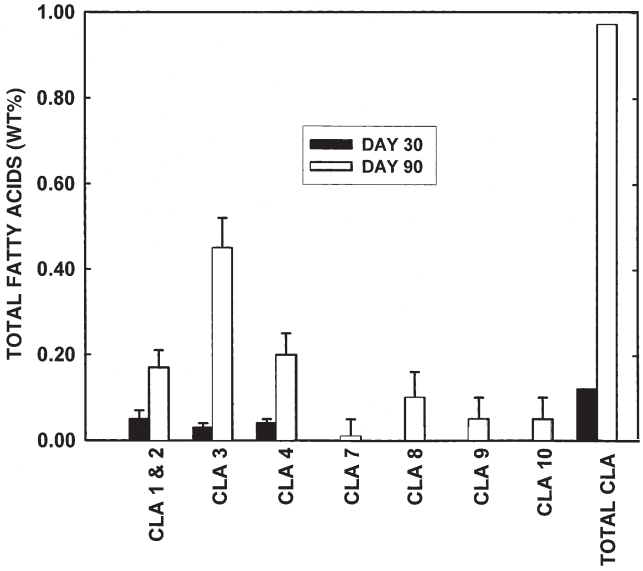

**FIG. 1.** Effect of conjugated linoleic acid (CLA) supplementation on CLA concentration of peripheral blood mononuclear cells. Data shown are the mean ± SEM ($n$ = 10) for study day 30 (end stabilization) and day 90 (end intervention). CLA supplementation significantly ($P < 0.05$) increased the concentration of all the CLA isomers. CLA 1 = 9*c*,11*t*; CLA 2 = 8*t*,10*c*; CLA 3 = 11*c*,13*t*; CLA 4 = 10*t*,12*c*; CLA 7 = 10*c*,12*c*; CLA 8 = 11*c*,13*c*; CLA 9 = 11*t*,13*t* + 8*t*,10*t*; CLA 10 = 9*t*,11*t* + 10*t*,12*t*.

**TABLE 2**
**Effect of CLA Supplementation on Fatty Acid Composition (wt%) of Peripheral Blood Mononuclear Cells[a]**

| Fatty acid | End stabilization (day 30) | End intervention (day 90) |
|---|---|---|
| 16:0 DMA | 2.22 ± 0.17 | 2.38 ± 0.06 |
| 16:0 | 16.35 ± 0.36 | 15.60 ± 0.36 |
| 18:0 DMA | 1.77 ± 0.12 | 2.10 ± 0.09 |
| 18:0 | 19.51 ± 0.33 | 19.23 ± 0.18 |
| 18:1n-9*t* | 1.37 ± 0.05 | 1.53 ± 0.09 |

| 9*c*,11*t*- + 8*t*,10*c*-18:2 | 0.05 ± 0.02 | 0.16 ± 0.01* |
| 11*c*,13*t*-18:2 | 0.03 ± 0.01 | 0.44 ± 0.02* |
| 10*t*,12*c*-18:2 | 0.04 ± 0.01 | 0.19 ± 0.01* |
| 11*c*,13*c*-18:2 | 0.00 ± 0.00 | 0.10 ± 0.01* |
| Other CLA | 0.00 ± 0.00 | 0.10 ± 0.01* |
| 18:2n-6 | 11.20 ± 0.23 | 11.12 ± 0.26 |
| 20:2n-6 | 1.12 ± 0.02 | 1.00 ± 0.03 |
| 20:3n-6 | 2.11 ± 0.16 | 1.95 ± 0.13 |
| 20:4n-6 | 19.99 ± 0.47 | 19.50 ± 0.51 |
| 24:1n-9 | 2.11 ± 0.14 | 2.22 ± 0.08 |
| 22:5n-3 | 1.79 ± 0.05 | 1.86 ± 0.07 |
| 22:6n-5 | 2.05 ± 0.14 | 2.00 ± 0.15 |
| Minors and unknowns | 7.41 | 7.78 |

[a]Data are mean ± SEM ($n$ = 10). *Significantly different between two periods ($P < 0.0001$). Minor fatty acids include those with concentration less than 1%, except CLA. For the control group, none of the fatty acids changed between days 30 and 90 (not shown). See Table 1 for abbreviations.

*Effect of CLA supplementation on the number of cells producing cyokines and their intracellular concentrations.* Percentages of T cells expressing IL-2 in the CLA group on days 30 and 90 were 40.3 ± 4.1 and 36.2 ± 4.4, respectively; corresponding values for IFNγ were 34.6 ± 4.2 and 26.5 ± 2.9, respectively. Percentages of monocytes expressing TNFα on day 30 and day 90 were 73.9 ± 3.9, and 78.9 ± 2.9, respectively. None of these percentages was different between day 30 and day 90, indicating that CLA did not alter the expression of these cytokines. Nor did CLA alter the intracellular concentrations of these cytokines, as determined by the PE molecules per cell (data not shown). On study day 30, the percentages of these cells that expressed TNFα, IL-2, and IFNγ were 73.9, 40.3, and 34.6, respectively. The corresponding values on study day 90 were 78.9, 36.2, and 26.5%, respectively. Thus, CLA supplementation did not alter the percentage of cells expressing these three cytokines. Nor did it alter the intracellular concentration of these cytokines as determined by the number of PE mole-

cules/cell, which was used to tag the specific monoclonal antibodies against these cytokines (data not shown). The percentage of cells expressing these cytokines and their intracellular concentrations did not change in the control group either between study day 30 or 90 (data not shown).

## DISCUSSION

CLA supplementation of the diets caused an eightfold increase (0.12 to 0.97 wt%) in its concentration in PBMC lipids. Although the concentrations of several CLA isomers increased, the largest increase occurred for the isomer 11*c*,13*t* (0.03 to 0.44%). This isomer represented 23.6% of all the CLA isomers in the diet but accounted for 45% of the total CLA in PBMC lipids. Since most of the health effects of CLA in animal models have been attributed to the 9*c*,11*t* and 10*t*,12*c* isomers, we do not know if this selective increase in 11*c*,13*t* isomer has any physiologic significance. We also do not know if this is due to increased transport or reduced metabolism of this isomer. Even if the concentration of CLA increased eightfold in PBMC lipids, it did not significantly reduce any of the other fatty acids in PBMC lipids.

In our study, CLA supplementation of the diets did not alter the *in vitro* production of $PGE_2$, $LTB_4$, IL1β, IL-2, and TNFα. Nor did it alter the intracellular concentrations of TNFα, IL-2, and IFNγ, or the number of PBMC positive for these cytokines. The lack of CLA effects on eicosanoid and cytokine production in our study is consistent with the lack of a change in the PBMC arachidonic acid, which is the precursor for these eicosanoids. Our results regarding $PGE_2$ production by the PBMC are consistent with those obtained with mice (14) and rat splenocytes (15), but are at variance with those obtained with rat peritoneal macrophages, where CLA feeding was reported to decrease $PGE_2$ production (10). Our results for $LTB_4$ production are at variance with others, who reported a decrease in its production by splenocytes from rats fed CLA-supplemented diets (15). The lack of an effect on IL-1β and TNFα production in our study is consistent with the results obtained with mice splenocytes (14) and rat peritoneal macrophages (10). CLA supplementation of the diets in our study did not alter the production of IL-2 and IFNγ. Our results regarding IL-2 production are not consistent with the increase reported in mice splenocytes (14,17).

We are not certain of the reasons for the difference in our results in humans with those of others in animal models. We had a small number of participants in our study, but based on our experience with the feeding of other fatty acids under metabolic unit conditions (23–25,30–32), the power to detect effects of CLA was more than adequate. Based on percentage energy from CLA, the amount we used was comparable to that used in animal studies. However, since animals eat several times more food per kg body weight than humans, the amount of CLA fed per day in our study was 5–10-fold less than that used in the animal studies. Considering that the average intake of CLA in the U.S. is only 100–200 mg/d (33), the amount of CLA used in our study was 20–40 times higher than the average daily intake. Amounts higher than those used in our study will also raise safety concerns. CLA supplementation in mice has been reported to cause an enlargement of livers and spleens, increase the circulating level of insulin, and decrease that of leptin (34,35). Most of the animal studies report that the CLA mixture used was an equal mixture of the *c*-9/*t*-11, and *t*-10/*c*-12 isomers, while in our study these two isomers represented only about 40% of the total CLA isomers. We believe the CLA mixture we supplemented was similar to those used in the animal studies; the discrepancy may be due to the analytical methods (27). Differences in species, cells studied, analytical methods, feeding regime, amount and the composition of CLA isomers, and duration of its feeding may have contributed to the disparate results. Inconsistencies exist not only between results from human and animal models but also between those obtained from different animal models.

In summary, our results show that CLA supplementation of human diets increased CLA concentration in PBMC lipids, but did not alter many of their functions investigated. These results, along with those previously published from this study that showed no change in a number of other indices of immune response, body composition, appetite, and blood lipids (19–22), do not indicate any health benefits to humans from feeding a mixture of CLA isomers. Future studies with purified isomers of CLA are needed to determine if there may be any health benefits of the individual isomers.

## ACKNOWLEDGMENTS

The authors appreciate the support provided by the Bioanalytical laboratory, and the dietary and nursing staff of the metabolic research unit in conducting this study. We thank the volunteers for their participation in the study, and Pharmanutrient, Inc. for donating the Tonalin oil.

# Fatty Acid Content of Plasma Lipids and Erythrocyte Phospholipids Are Altered Following Burn Injury

**Vera C. Pratt[a], Edward E. Tredget[c], M. Thomas Clandinin[a,b], and Catherine J. Field[a,b,*]**

Departments of [a]Agricultural, Food and Nutritional Science, [b]Medicine, and [c]Surgery, University of Alberta, Edmonton, Alberta, Canada T6G 2P5

**ABSTRACT:** The objective of this study was to examine compositional and quantitative changes in fatty acids of plasma components and red blood cell phospholipids (PL) immediately following and during recovery from burn injury. Subjects ($n$ = 10) with >10% total body surface area burn had blood drawn at specific timepoints (0 to >50 d) following burn injury. Fatty acid composition of red blood cell PL and plasma PL, cholesteryl esters (CE), and triglycerides was determined using gas–liquid chromatography after separating each fraction from extracted lipids by thin-layer chromatography. Total plasma PL and CE in burn patients were lower than in healthy control subjects with reduced 20:4n-6, n-6, and n-3 fatty acids and higher levels of monounsaturated and saturated fatty acids early after burn. CE levels remained half that of healthy control values up to 50 d post-burn. Red blood cell PL had decreased 20:4n-6 content and profiles similar to that of an essential fatty acid deficiency early after burn. These results suggest an impairment in lipoprotein and polyunsaturated fatty acid metabolism in the early post-burn period. Lower levels of 20:4n-6 and n-3 fatty acids in every plasma fraction suggest increased use of these fatty acids for wound healing and immune function following burn injury. Further work is needed to determine the ability of burn patients to utilize essential fatty acids in order to design nutritional intervention that promotes wound healing and immunological functions consistent with recovery in these patients.

Paper no. L8681 in *Lipids 36,* 675–682 (July 2001).

There are profound alterations in fatty acid metabolism following burn injury (1,2). Fatty acid oxidation rates, free fatty acid turnover, and lipolysis are elevated (3,4). In addition, plasma levels of 18:2n-6 (linoleic acid) and 20:4n-6 (arachidonic acid) are reduced (5) while saturated fatty acid (SFA) and oleic acid are increased, suggestive of an essential fatty acid deficiency (2,4). Diet is an important part of therapy for burn patients, and lipids must be included in the diet to provide energy, aid in the absorption of fat-soluble vitamins, and prevent essential fatty acid deficiency. Essential fatty acids are involved in wound healing (6,7) and serve important roles in immune functions (8). Dietary lipids have profound effects on immune functions and inflammatory processes through changing cellular membranes and altering substrate availability for the synthesis of lipid mediators such as prostaglandins (PG) (9–13) that may predispose patients to infection. Preventing infection and reducing inflammatory processes are important goals in the treatment of burn patients. Before diets designed to improve immune recovery in these patients can be formulated, an understanding about the metabolism of specific fatty acids, particularly the essential fatty acids involved in wound healing and immunological functions following burn injury, is needed. The objective of this study is to characterize quantitative and compositional changes in fatty acids in plasma components and red blood cells (RBC) immediately following and during recovery from burn injury.

## EXPERIMENTAL PROCEDURES

*Materials.* H-plates and G-plates were purchased from Analtech (Newark, DE). All solvents were purchased from VWR (Edmonton, Canada). Ficoll Hypaque gradients, bovine serum albumin (BSA) (Fraction V), chemicals for buffers, and all other lipid supplies, including standards, were purchased from Sigma Chemicals (St. Louis, MO).

*Subjects.* The burn study was approved by the University of Alberta Faculty of Medicine Research Ethics Board. The blood sampling on healthy subjects was approved by the Faculty of Agriculture, Forestry, and Home Economics Ethics Review Board. Subjects ($n$ = 10) were recruited from patients admitted to the Firefighter's Burn Treatment Unit at the University of Alberta Hospital (Edmonton, Canada). Patients who had >10% total body surface area (TBSA) burn and who gave informed consent were included in the study. Patients who were under the age of 18, overtly malnourished, had a history of alcohol or drug abuse, were taking immunosuppressive drugs, or had autoimmune disease were excluded. All subjects were previously healthy. Included in the study were 2 females and 8 males. Burns were a result of flame (8:10), hot tar (1:10), and electrical (1:10). Their age range was from 20 to 65 yr of age (mean = 40 ± 4 yr). The range of burn size was 12–90% [mean = 37 ± 5% TBSA]. Length of hospital stay ranged from 13 to 82 d (mean = 38 ± 9 d). All subjects survived their injuries. Subjects were resuscitated in Ringer's lactate (14) using the Parkland formula (15). All patients underwent wound excision and skin grafting of deep second- and third-degree wounds commenc-

Abbreviations: BSA, bovine serum albumin; CE, cholesteryl ester; MCT, medium-chain triglycerides; MUFA, monounsaturated fatty acids; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, prostaglandin; PI, phosphatidylinositol; PL, phospholipid; PS, phosphatidylserine; PUFA, polyunsaturated fatty acid; RBC, red blood cell; SFA, saturated fatty acid; TBSA, total body surface area; TG, triglyceride.

ing the first week of hospitalization. All subjects received similar wound-care treatment, analgesia, and antibiotic therapy using preestablished protocols.

Energy requirement for each subject was determined using the Harris Benedict equation with a stress factor based on injury severity. Continuous enteral feeding began within 24 h after injury and stopped when feeding complications persisted and 6 h prior to surgery. No patients received total parenteral nutrition. The enteral diet fed provided higher amounts of nitrogen and is especially designed for critical-care patients (Nitro-Pro™, Nutrition Medical, Minneapolis, MN). Nitro-Pro™ provided 5,188 kJ, 60 g protein (caseinates), 160 g carbohydrates (maltodextrin), 80% of the U.S. Department of Agriculture (USDA) recommended intakes for all minerals and water-soluble vitamins as well as 240% of the USDA recommended intake of vitamin C per 1000 mL formula. Pro-Mod™ (Ross Laboratories, Columbus, OH) was supplemented as an extra source of protein when required. The fat content of the diet was composed of half medium-chain triglycerides (MCT) and the other half corn oil for a total of 29% of total energy provided by fat. The fatty acid composition of the enteral diet fed is shown in Table 1. Regular blood draws on surgery days were taken the morning prior to surgery, thus avoiding the potential effects of blood or serum products provided during surgical procedures. A nonfasting blood sample was drawn from healthy volunteer subjects ($n$ = 8) recruited from the University of Alberta who gave informed consent.

*Sample collection.* A nonfasting venous blood sample (10 mL) was collected by the medical staff during the patient's regular blood work on the following timepoints after admission to the burn unit: within the first 12 d [(timepoint (t) 1], between 12 and 19 d (t2), between 20 and 35 d (t3), between 36 and 49 d (t4), and after 50 d (t5). For subjects with smaller burns or those who were discharged prior to 50 d, the final sample was obtained at the subject's first out-patient visit to clinic. When more than one sample was obtained within a time period, the results were combined and the mean reported.

*Serum collection.* Whole blood (3 mL) was layered on top of Ficoll Hypaque gradients and centrifuged as previously described (16). Serum was collected from the top and stored immediately at −70°C for plasma lipid analysis. After gradients were removed, the remaining RBC were washed once with Krebs-Ringer HEPES buffer with BSA (5 g/L). RBC were frozen immediately at −70°C for fatty acid analysis of phospholipids (PL).

*Fatty acid analysis*. A modified Folch method was used to extract lipids from RBC as previously described (17). Serum (500 µL) fatty acids were extracted using chloroform/methanol (2:1, vol/vol) as previously described (18). Individual PL from RBC and plasma were separated on H-plates (19), and serum lipid classes [PL, triglycerides (TG), and cholesteryl esters (CE)] were separated on G-plates as previously described (18). Bands corresponding to phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), and phosphatidylserine (PS) from RBC, and the PC, PE, and PI fractions from serum PL classes were visualized with 8-anilino-1-naphthalene-sulfonic acid and identified under ultraviolet light using appropriate standards. Bands were scraped and directly methylated. Internal standards were added to the TG and CE (20 µg of 15:0) bands, and they were saponified and methylated as previously described . The 17:0 standard was added to the scraped serum PL (10 µg of 17:0) followed by direct methylation.

Fatty acid methyl esters were prepared by methylation using 14% (wt/vol) $BF_3$/methanol reagent and separated by automated gas–liquid chromatography (Vista 6010; Varian Instruments, Georgetown, Canada) on a fused-silica BP20 capillary column (25 m × 0.25 mm internal diameter; Varian Instruments), as previously described (17). Peaks of fatty acid methyl esters were identified by comparisons with standards purchased from Supelco Canada and Sigma Chemical companies. Fatty acid contents of serum lipid classes were calculated using the area peak of the internal standard. Total PL, CE, TG, and their respective contents of saturated (SFA), monounsaturated (MUFA), polyunsaturated (PUFA), as well as the essential fatty acids and their elongation/desaturation products, were calculated on both a quantitative and percentage basis. Percentage fatty acids in RBC PL and major PL in serum were determined.

*Statistical analysis.* Data are reported as means ± SEM. Subjects were grouped into groups based on size of burn (large = >35%, $n$ = 5 and small = <35%, $n$ = 5), and when differences existed between these two groups, results are presented. When there were no differences between the two burn injury groups, all subjects were included in the analysis and the overall mean was presented. To determine differences between post-burn timepoints, a repeated measures analysis of variance was used to identify differences in fatty acids in each plasma fraction at the five post-burn time periods described above. The numbers of subjects sampled at each timepoint were as follows: t1, $n$ = 10; t2, $n$ = 10; t3, $n$ = 10; t4, $n$ = 8; t5, $n$ = 8. Subjects with burns >35% TBSA were sampled at each timepoint. When significant differences were identified, differences between time periods were identified using least square means. A Student's $t$-test was used to identify differences between post-burn timepoints and control values. All statistical analyses were conducted using the SAS statistical package (Version 6.12; SAS Institute, Cary, NC).

**TABLE 1**
**Fatty Acid Composition of Nitro-Pro™[a]**

| Fatty acid | g/1000 mL | Fatty acid | g/1000 mL |
|---|---|---|---|
| 8:0 | 14.62 | 18:0 | 0.42 |
| 10:0 | 5.76 | 18:1 | 4.64 |
| 12:0 | 0.21 | 18:2 | 11.58 |
| 14:0 | 0.02 | 18:3 | 0.32 |
| 16:0 | 2.29 | 20:0 | 0.07 |
| 17:0 | 0.02 | 22:0 | 0.02 |

[a]The clinical diet fed was composed of half medium-chain triglycerides and the other half corn oil for a total of 29% of total energy coming from fat. Mean linoleic and linolenic acid consumption per day coming from this diet was 24 ± 1 and 0.7 ± 0.1 g/d, respectively.

## RESULTS

*Dietary intake*. Continuous enteral feeds began within 24 h after injury and were generally well tolerated. Complications included diarrhea (2:10 subjects), emesis (2:10 subjects), and hyponatemia (1:10 subjects). Enteral feeds were stopped when feeding complications persisted and 6 h prior to surgery. Subjects consumed an average of 9,132 kJ/d during the in-patient period when enteral feeding provided the primary source of energy. The average intake of linoleic acid (18:2n-6) during the in-patient period was 24 ± 1 g/d (903 kJ/d, 10% energy), which approximates the intake of healthy, free-living North Americans who are estimated to consume 3–18% energy from linoleic acid (20). Mean linolenic acid (18:3n-3) consumption per day from the enteral feed diet was estimated at 0.7 ± 0.1 g/d. The enteral diet used did not contain long-chain n-3 fatty acids.

*Plasma total PL.* Percentages of 20:4n-6 and total n-6 in plasma PL were significantly lower at t1 compared to t5 (Table 2). Although not different on a relative percentage basis, quantitatively, the n-3 fatty acid content was lower at t1 (14.7 ± 1.9 μg/mL) and t2 (17.5 ± 2.2 μg/mL) than at t5 (25.1 ± 2.9 μg/mL; $P < 0.05$). The total percentage of MUFA in plasma PL was higher at t1 compared to t3, t4, and t5 (Table 2). The mean concentration of 20:3n-9 in plasma PL of the burn patients was 1.7 ± 1% (0.4–4.1%) and 0.1 ± 0.04% (undetectable–0.2%) in healthy subjects. The plasma concentration of 20:3n-9 did not differ significantly between post-burn timepoints. Compared to healthy control subjects, the relative proportion of total n-6 fatty acids was lower and SFA higher at all post-burn timepoints (Table 2). At t1 and t2, plasma PL exhibited lower percentage of 20:4n-6 and higher proportion of MUFA, compared to healthy control subjects. There were no significant differences in total plasma PL concentration between post-burn timepoints; however, at t1 and t2, the total plasma PL concentration was significantly less ($P < 0.03$) than healthy controls (Table 2).

*Major PL fractions*. There was no significant difference in the 20:4n-6 content in the major plasma PL fractions (PC = 6.7 ± 0.9%; PE = 14.8 ± 1.8%; PI = 16.9 ± 1.6%) between post-burn timepoints; however, PE and PI fractions contained less 20:4n-6 than control subjects (PE = 20.2 ± 2.2%; PI = 22.9 ± 1.9%; $n = 6$) at t1 and t2, and t1–t3 post-burn timepoints, respectively (data not illustrated). SFA content of the PI and PE fractions was significantly greater ($P < 0.03$) at t1 and t3 (PI = 47.5 ± 1.3%; PE = 40.9 ± 1.4%) as compared to control subjects (PI = 41.3 ± 2.3%; PE = 34.3 ± 1.5%). At all post-burn timepoints, PC and PE contained less percentage n-3 fatty acids than controls (Table 3).

*CE.* Proportions of 20:4n-6 and total n-6 fatty acids in plasma CE were significantly ($P < 0.04$) lower at t1 and t2 compared to t5 (Table 4). CE isolated at t5 contained significantly ($P < 0.03$) more n-3 fatty acids than any other post-burn timepoint (Table 4). The percentage of SFA was higher ($P < 0.04$) at t1 and t2 compared to t5. The mean concentration of 20:3n-9 in plasma CE was 0.7 ± 0.4% (ranging from undetectable levels to 1%) and that of healthy controls was 0.3 ± 0.1%. On a percentage basis, CE isolated from burn patients at t1, t2, and t3 contained significantly less ($P < 0.03$) n-6 fatty acids than control subjects (Table 4). The percentage SFA was higher than that of control subjects at sample points t1–t4. At every post-burn timepoint there was a lower concentration of CE in plasma and significantly ($P < 0.01$) lower amounts of 20:4n-6 (23.04 ± 4.1 μg/mL), n-6 (208.84 ± 26.4 μg/mL), and n-3 (5.75 ± 0.69 μg/mL) fatty acids compared to control values (data not illustrated).

*TG*. The total percentage n-6 fatty acids in plasma TG was lower at t1 than at t4 and t5 (Table 5). Total n-3 fatty acid content was lower ($P < 0.05$) at t2 compared to t5. The average concentration of 20:3n-9 in plasma TG of the patients was 1.3 ± 0.6% (ranging from undetectable levels to 5%) and did not differ significantly between post-burn timepoints. The level of 20:3n-9 in healthy controls was 0.2 ± 0.02%. Quantitatively, 20:4n-6 content at t1 (4.5 ± 0.9 μg/mL) was less ($P < 0.03$) than that of control subjects (8.5 ± 1.4 μg/mL). The n-3 fatty acid content at the first four timepoints (overall mean = 6.1 ± 0.6 μg/mL) was half that of control subjects (15.5 ± 2.6 μg/mL, data not illustrated, $P < 0.01$).

*Erythrocyte PL.* The fatty acid content of major n-6 and n-3 fatty acids for PC and PE, the major PL of RBC, during the post-burn period are depicted in Tables 6 and 7, respectively, and reference ranges of healthy adults reported in the literature are shown. In the PC (Table 6), PS (data not illustrated), and PI (data not illustrated) PL fractions of RBC, the relative percentage of 20:4n-6 was significantly ($P < 0.03$) lower at t1 than at t5. Every RBC PL fraction exhibited half the levels of n-3 fatty acids of reference values at all post-burn timepoints (data shown for PC and PE only in Tables 6 and 7). The fatty

acid, 20:3n-9 comprised <0.5% each RBC PL fraction, and the proportion of this fatty acid did not change significantly in any RBC fraction during the post-burn period (data not shown).

## DISCUSSION

The results of this study support the hypothesis that essential fatty acid metabolism is altered following burn injury. This study confirms other reports of reduced PL and CE levels following burn injury (5,21–25) and expands existing knowledge by demonstrating that n-6, particularly 20:4n-6, and n-3 fatty acids are reduced in the early post-burn period in plasma and erythrocytes. Reduced amounts of essential fatty acids in plasma suggest decreased availability from the diet or an increase in their utilization by the tissues.

A diet high in linoleic acid (18:2n-6) in healthy subjects would be expected to increase n-6 fatty acids in plasma (20). However, patients in this study exhibited lower n-6 and 20:4n-6 content early after burn injury when 18:2n-6 intake from the enteral diet was high. Despite the return of total plasma PL concentrations to values not different from healthy controls by t3, the content and relative percentage of n-6 and total PUFA in plasma remained low throughout the study. Low levels of 18:2n-6 and 20:4n-6 in total plasma lipid have previously been reported following burn injury (26), and this report confirms that this occurs in each of the lipid fractions that constitute the total plasma lipid pool. Low levels of 20:4n-6 in plasma PL and CE may suggest increased utilization of 20:4n-6 during the early post-burn period. Prostaglandins (PG) derived from 20:4n-6 have been reported to be increased post-burn (27,28) and have been implicated in immunosuppression associated with burn injury (29,30). Fatty acids in plasma have also been reported to occur in immune cell membranes (20) and would potentially affect PG synthesis and wound healing (31).

The n-3 content of each plasma fraction was reduced in the early post-burn period and in some cases persisted even 50 d after the initial injury. Reductions in the content of n-3 fatty acids observed in plasma TG (primarily from chylomicrons and very low density lipoprotein fractions) suggest reduced availability to tissues. The n-3 fatty acids are important in balancing the production of cyclooxygenase products derived from 20:4n-6 (32) and have also been demonstrated to reduce inflammatory responses (33–35). Increased SFA and MUFA were observed in all plasma fractions, which is consistent with increased lipolysis in these patients (36,37).

Mead acid (20:3n-9) is rarely produced, and its presence

in plasma is believed to be an indicator of essential fatty acid deficiency. Although there appeared to be higher levels, compared to the healthy subjects, of this fatty acid in the plasma of patients early after burn injury, the levels did not change significantly with recovery from burn injury. This is suggestive of essential fatty acid deficiency, at least in some patients after burn injury. However, elevated MUFA and SFA levels and reduced PUFA levels, particularly 20:4n-6, is a more consistent observation in this patient group. Clearly, metabolism is altered, and the observations reported in this study are likely a combined result of changes in absorption (38), assimilation (22,39–42), oxidation (26), and transport (43) of essential fatty acids that are reported to occur after burn injury.

Quantitative and compositional differences between patients and control subjects in this study suggest impairments in fatty acid assimilation and/or lipoprotein metabolism. It is unknown if the decrease in plasma components hinders utilization of essential fatty acids by tissues or if there is increased tissue utilization causing depletion in the plasma. Lipoproteins differ in CE, TG, and PL constituents (44). Severe reductions in plasma concentrations of CE and PL early after burn observed in this study and supported by others (5,21–25) suggest a change in the relative proportions of the individual lipoprotein fractions or an overall reduction in their synthesis. Unfortunately, the isolation of lipoprotein fractions was not done in the present study. However, concentrations of low density lipoprotein and high density lipoprotein have been reported to be reduced following burn injury (22,25), which would proportionately reduce cholesterol and PL levels. Deficiencies in intestinal lipases (38), lipoprotein carrier proteins (43), carnitine (26), and liver functions (22,39–42) have been reported following burn injury and might contribute to altered lipid metabolism and the compositional and quantitative changes observed in the plasma lipid components in this study.

The fatty acid composition of RBC is frequently used as a means to estimate the composition of dietary fat and abnormalities in essential fatty acid metabolism (45,46). It is likely that a sufficient amount of 18:2n-6 was provided by the diet, as 18:2n-6 levels were relatively constant throughout the study and were similar to control values with the exception of a transient decrease at t2 in the PC fraction. In spite of this, all RBC PL fractions exhibited lower 20:4n-6 levels than reference values throughout the post-burn period (47,48). These observations are inconsistent with Diboune *et al.* (49), who observed increases in 18:2n-6 at 14 d and no change in 20:4n-6 levels when intensive-care patients were provided an enteral diet with similar MCT and linoleic acid content as the enteral diet provided in this study. Despite dietary intake consisting of higher amounts of PUFA than MUFA and SFA (apart from the rapidly oxidized MCT), RBC exhibited higher SFA and MUFA than PUFA early after burn and compared to reference values in their PL. These findings parallel the observations in the various plasma components. Low concentrations of 20:4n-6, 22:6n-3, and 18:2n-6 with high levels of SFA have been reported in total RBC lipids following burn injury (5). In the current study, 22:6n-3 levels remained lower than healthy controls at all post-burn timepoints. If subjects in this study were provided adequate amounts of 18:2n-6, slow conversion to 20:4n-6 is a possible explanation of low 20:4n-6 levels observed in all measured RBC PL fractions and plasma components. Reduced Δ-6-desaturase activity is supported by the observations of low levels of 22:5n-3, 22:6n-3, and 20:3n-6 at t1 compared to t5 (and controls) even though 18:3n-3 content of RBC was similar to healthy controls and exhibited little change throughout the post-burn period. This pathway is reduced by a large essential fatty acid intake (50–52) and with burn injury (53). Several aspects of RBC have been reported to be altered following burn injury (54–57), some of which are known to be affected by PL composition of the membrane (58,59).

This study demonstrates essential fatty acid metabolism to be altered in both plasma and RBC following burn injury and points to deficiencies in key enzymes involved in regulation of lipid metabolism. Every lipid-containing plasma component isolated exhibited lower n-6 and n-3 fatty acid content and higher SFA and MUFA content in early post-burn timepoints compared to later post-burn timepoints and those of control subjects. Decreased essential fatty acids in plasma may be suggestive of the increased use of these lipids in the synthesis of membrane lipids for wound healing and immune functions. Achieving the optimal balance of fatty acids for skin regeneration, immune competence, and inflammatory processes through provision of specific fatty acids through diet is a complex issue. Further work is needed to determine the ability of burn patients to utilize essential fatty acids and to design nutritional intervention that supports optimal wound healing and immunological functions consistent with recovery in these patients.

## ACKNOWLEDGMENTS

This work was supported by a National Sciences and Engineering Research Council of Canada grant to Catherine Field. Vera Pratt received a Thomas H. Smouse Memorial Fellowship from the American Oil Chemists' Society. The authors would like to gratefully acknowledge the assistance of Heather Shankowsky for coordination of blood samples, Carmelle Cooper for providing the dietary records, the Firefighter's Burn Treatment Center nurses for their assistance in obtaining blood samples and chart information, and Tony Weizerbicki and Nicola Wilson for their technical assistance.

# Regulation of Intestinal Apolipoprotein A-I Synthesis by Dietary Phosphatidylcholine in Newborn Swine

**Heng Wang[a], Jianhui Du[a], Song Lu[b], Ying Yao[b], Felicia Hunter[a], and Dennis D. Black[b,*]**

[a]Arkansas Children's Hospital Research Institute, University of Arkansas for Medical Sciences, Little Rock, Arkansas 72202, and [b]Children's Foundation Research Center of Memphis at Le Bonheur Children's Medical Center, University of Tennessee Health Science Center, Memphis, Tennesee 38103

**ABSTRACT:** Phospholipid (PL) from both dietary sources and biliary secretions may be important in the regulation of intestinal apolipoprotein (apo) synthesis. We previously demonstrated the up-regulation of apo A-I secretion by phosphatidylcholine (PC) in a newborn piglet intestinal epithelial cell line. We hypothesized that dietary PC increases small intestinal apo A-I synthesis *in vivo* in the newborn piglet. Two-day-old female swine were fed by gavage for 48 h. Diets consisted of a formula containing 51% of calories as triacylglycerol providing 180 kcal/kg/24 h. The experimental group (+PC, $n = 7$) received 1 g/L added soybean PC, and the control group (–PC, $n = 7$) received no added PC. At the end of the study period, jejunal apo A-I, B, and A-IV synthesis was measured, and apo A-I mRNA levels were quantitated. Jejunal mucosal PL content and serum lipids and apo B and A-I levels were measured. Jejunal apo A-I synthesis was almost twice as high in the +PC group as compared to the –PC group with no difference in apo A-I mRNA levels. Jejunal content of PL was higher in the +PC group than in the –PC group. There were no differences in jejunal apo B and A-IV synthesis or serum levels of lipids and apo-lipoproteins between the two groups. Dietary PC supplementation in newborn swine up-regulated jejunal apo A-I synthesis. Apo A-IV synthesis, which is sensitive to fatty acid flux, was not significantly increased, which suggests a specific effect of PC on apo A-I synthesis. Lumenal PC may be important in the regulation of intestinal apo A-I synthesis in the neonate.

Paper no. L8723 in *Lipids 36*, 683–687 (July 2001).

Phospholipid (PL), specifically phosphatidylcholine (PC), has been shown to be important in intestinal chylomicron assembly and secretion in the adult rat, probably by providing a polar lipid surface coat for the lipoprotein particle (1–3). PC from both the diet and biliary secretions may also be important in the regulation of intestinal lipoprotein synthesis and secretion in the neonatal mammal, which is dependent on a high-fat breast milk diet to support rapid growth and development. In addition to regulating lipoprotein synthesis and secretion, lumenal PC may also be important in the regulation of apolipoprotein (apo) synthesis and secretion. Apo-lipoprotein are peptides that bind to the surface of lipoprotein particles and are crucial for the assembly, secretion, and subsequent metabolism of the particles (4). Apo A-I is the major apo-lipoprotein of plasma high density lipoproteins (HDL), as well as a major protein component of intestinal chylomicrons and very low density lipoproteins (VLDL), and is produced by both liver and intestine in the human, rat, and swine (5–9). Its major metabolic role is that of a cofactor for lecithin:cholesterol acyltransferase, the enzyme responsible for the production of HDL cholesteryl ester by the transfer of a fatty acid from PC to free cholesterol in HDL (10). We previously demonstrated up-regulation of apo A-I secretion by PC *in vitro* in a newborn piglet intestinal epithelial cell line (IPEC-1) (11). The present *in vivo* study was undertaken to determine if dietary supplementation with PC would regulate intestinal apo-lipoprotein synthesis in *vivo* in newborn swine, a model for the human infant.

## EXPERIMENTAL PROCEDURES

*Animals.* Two-day-old female domestic swine were obtained from Tyson Farms (Plummerville, AR). The animals were suckled by the sow during the first 2 d of life and were housed in groups of three to four in heated stalls with straw bedding. The experimental protocol was approved by the University of Arkansas for Medical Sciences Institutional Animal Care and Use Committee.

*Diets and feeding.* Animals were bolus-fed by gavage using an 8 French soft plastic feeding tube (Biosearch Medical Products, Somerville, NJ) five times per day for 48 h. Diets consisted of a fat-free formula base (Sowena; Merrick, Madison, WI) blended with lipids to contain 51% of calories as fat, 27% as carbohydrate, and 22% as protein, providing 180 kcal/kg/24 h. Of total lipid calories, 45% were from palm oil, 20% from soybean oil, 20% from coconut oil, and 15% from safflower oil. The experimental group (+PC, $n = 7$) received 1 g/L added refined soybean PC (1% free fatty acid content; ICN Pharmaceuticals, Inc., Costa Mesa, CA), and the control group (–PC, $n = 7$) received no added PC.

*Procurement of samples for determination of intestinal apolipoprotein synthesis.* At the end of the experimental feeding period, 2 h after the final feeding, the animals were anesthetized,

Abbreviations: apo, apolipoprotein; HDL, high density lipoprotein; PBS, phosphate-buffered saline; PC, phosphatidylcholine; PL, phospholipid; TCA, trichloroacetic acid.

and a 10-cm segment of proximal jejunum was isolated 10 cm distal to the ligament of Treitz by two ligatures. Radiolabeling was performed by instilling 1.0 mCi of L-[4,5-$^3$H]leucine (>120 Ci/mmol; Amersham, Arlington Heights, IL) into the segment. The segment was removed 9 min later and prepared for immunoprecipitation as described next. This labeling time has been shown to be optimal in similar experiments in the adult rat, and we used it previously in the piglet (6,8,9,12–14). A distal adjacent segment was snap frozen in liquid $N_2$ for later RNA extraction.

*Preparation of mucosal cytosolic supernatants for immunoprecipitation.* Radiolabeled intestinal segments were flushed with 50 mL of iced phosphate-buffered saline (PBS) (50 mmol/L phosphate, 100 mmol/L NaCl, pH 7.4)–20 mmol/L leucine, and the mucosa was scraped and homogenized on ice in 1 mL of PBS/1% Triton X-100/2 mmol/L leucine/1 mmol/L phenylmethylsulfonyl fluoride/1 mmol/L benzamidine, pH 7.4, as previously described (8). Aliquots of the homogenate were taken for measurement of trichloroacetic acid (TCA)-precipitable radioactivity. The remainder was pelleted at 105,000 × *g* for 65 min in a 50.3 Ti rotor (Beckman Instruments, Palo Alto, CA), followed by collection of the cytosolic supernatant. Although most intracellular apo-lipoprotein is membrane-associated, this technique was shown previously to result in extraction and solubilization of 84–94% of total recoverable apolipoprotein mass with no discernible effect of the state of lipid flux (12). All procedures were performed at 0–5°C, and the mucosal supernatant samples were stored at –80°C until analysis.

*Apo-lipoprotein immunoprecipitation.* Intestinal cytosolic supernatant fractions were subjected to specific immunoprecipitation of apo B, A-I, and A-IV under conditions of antibody excess as described (9,15). Aliquots of cytosolic supernatants were pre- incubated with washed IgG-SORB$^R$ (The Enzyme Center, Malden, MA) and subsequently reacted with excess rabbit polyclonal anti-swine apo-lipoprotein antiserum for 18 h at 4°C. Following a second addition of IgG-SORB$^R$ and extensive washing, the liberated immunocomplex was applied to either 5.6% (apo A-I, A-IV) or 4% (apo B) sodium dodecyl sulfate-polyacrylamide tube gels. After electrophoresis, gels were sliced into 2-mm slices and solubilized in Solvable$^R$ (DuPont, Boston, MA) at 50°C for 3 h, followed by the addition of Ultima Gold$^R$ scintillation fluid (Packard, Meriden, CT) and incubation overnight at room temperature. Liquid scintillation counting was performed in a Packard Model 2000 liquid scintillation counter (Packard, Downers Grove, IL). Apo-lipoprotein species were identified by comparison to stained co-electrophoresed apo. Apo-lipoprotein synthesis rates were expressed as the percentage of specific immunoprecipitated apoprotein counts as compared to total protein TCA-precipitable counts. Apo-lipoprotein synthesis was thereby expressed as a percentage of total protein synthesis.

*Apolipoprotein A-I mRNA quantitation.* Total RNA was extracted from the frozen jejunal samples by the method of Chomcyznski and Sacchi (16). Intactness of each RNA preparation was verified by agarose gel electrophoresis and visualization of ribosomal RNA subunits. RNA (10 µg) was applied to nitrocellulose filters using a slot blot apparatus (Hoefer, San Francisco, CA). Filters were serially hybridized with a swine apo A-I cDNA (17) and a murine β-actin cDNA (provided by Dr. L. Kedes, Stanford University, CA). Hybridization signals were quantitated using a Bio-Rad Model GS-525 Molecular Imager System and associated software (Bio-Rad, Hercules, CA). Apo A-I mRNA abundance was expressed as apo A-I mRNA/β-actin mRNA signal intensity ratios.

*Phospholipid quantitation.* Proximal jejunal mucosal homogenates and serum samples were subjected to lipid extraction followed by PL quantitation by the method of Bartlett (18).

*Serum lipid and apo-lipoprotein mass determination.* Serum total cholesterol, triacylglycerol, and HDL-cholesterol concentrations were measured using enzymatic assays (Sigma Chemical Co., St. Louis, MO). Serum apo B and A-I concentrations were measured by enzyme-linked immunosorbant assays as previously described (9).

*Statistics.* Student's unpaired *t*-test was used to compare the results from the control and PC-fed animals. Statistical significance was set at a two-tailed *P* value of <0.05.

## RESULTS

Figure 1 shows the PL content of jejunal mucosa from the two groups of animals. The group receiving PC added to their formula had almost twice as much PL in proximal jejunum as compared to the control group.

Jejunal synthesis of apo B, A-I, and A-IV in the two groups of animals is shown in Figure 2. There was no difference in apo B or A-IV synthesis between the two groups. However, jejunal apo A-I synthesis in the PC-supplemented animals was approximately twice that of the control group.

To determine whether the increase in jejunal apo A-I synthesis in the PC-supplemented group was accompanied by a concomitant increase in apo A-I mRNA levels, a slot blot hybridization assay was performed using β-actin as a control

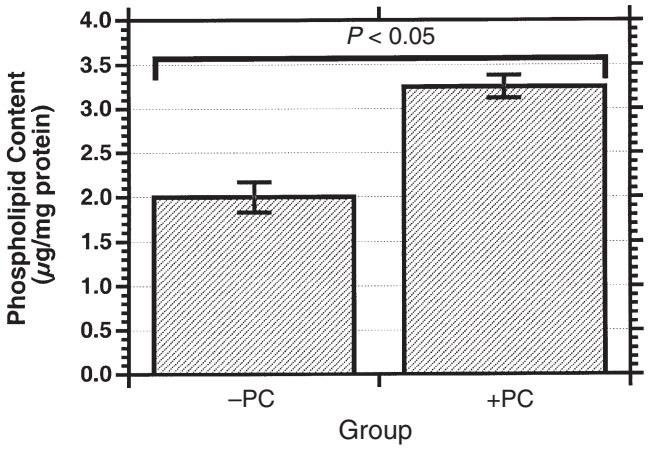

**FIG. 1.** Jejunal phospholipid content expressed as µg phospholipid/mg total mucosal protein in control animals (–PC group, *n* = 7) and animals receiving supplemental dietary phosphatidylcholine (+PC group, *n* =7). Bars represent the mean ± SEM of data from each group. The *P* values were determined using Student's unpaired *t*-test.

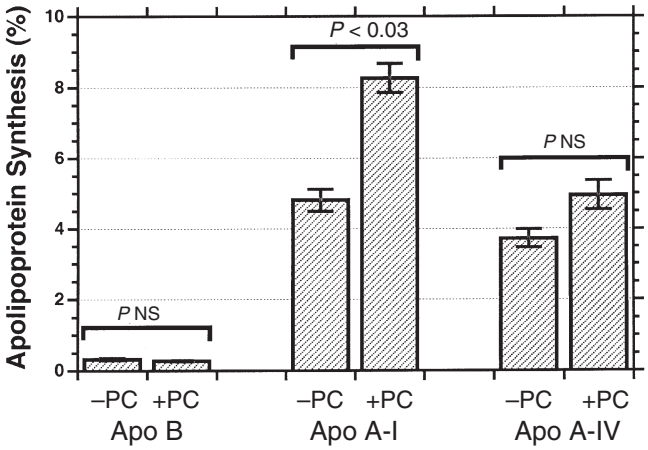

**FIG. 2.** Effect of dietary phosphatidylcholine supplementation on jejunal apolipoprotein (apo) synthesis expressed as a percentage of total protein synthesis in control animals (–PC group, $n = 7$) and animals receiving supplemental dietary phosphatidylcholine (+PC group, $n = 7$). Bars represent the mean ± SEM of data from each group. The $P$ values were determined using Student's unpaired $t$-test. NS, not significant.

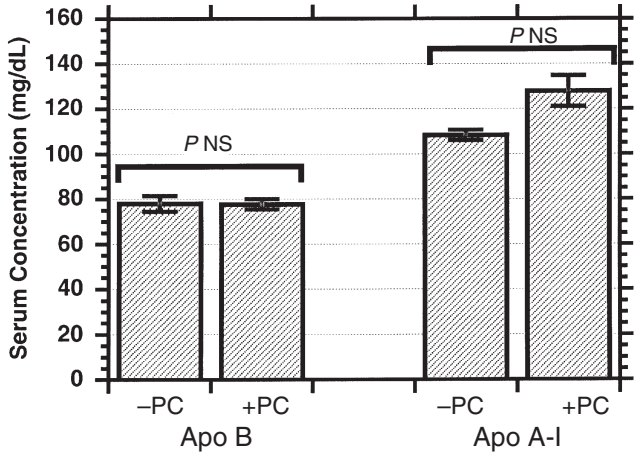

**FIG. 4.** Effect of dietary PC supplementation on serum apo B and A-I concentrations determined by enzyme-linked immunosorbent assays in control animals (–PC group, $n = 7$) and animals receiving supplemental dietary phosphatidylcholine (+PC group, $n = 7$). Bars represent the mean ± SEM of data from each group. The $P$ values were determined using Student's unpaired $t$-test. For abbreviations see Figures 1 and 2.

gene. Results are shown in Figure 3. There were no differences in apo A-I mRNA abundance between the two groups, which suggests that regulation occurs at the translational level.

Apo B and A-I levels were measured in serum samples taken from animals at the time of intestine harvest and euthanasia (Fig. 4). There were no differences in apo B levels. Apo A-I and HDL-cholesterol levels (Fig. 5) were slightly higher in the PC-supplemented group, but the differences did not reach statistical significance. No differences were noted between the two groups in serum total cholesterol, triacylglycerol, or PL (Fig. 5).

## DISCUSSION

In the present study, we report the up-regulation of apo A-I synthesis in newborn swine small intestine by dietary PC supplementation, as compared to a group of animals receiving the identical diet without added PC. This study was prompted by a previous study in a newborn swine intestinal epithelial cell line, IPEC-1, which demonstrated an increase in basolateral apo A-I secretion after incubation with PC in the apical culture medium compartment (11). In these cell culture studies, the regulation of apo A-I secretion appeared to occur at the posttranslational level, as compared to the present *in vivo* study, which demonstrates up-regulation of apo A-I expression at the translational level. The difference in the mechanism of apo A-I regulation (posttranslational vs. translational) between the *in vitro* and *in vivo* studies may be attributable to the timing of the exposure of the intestinal cells to the PC (24 h in

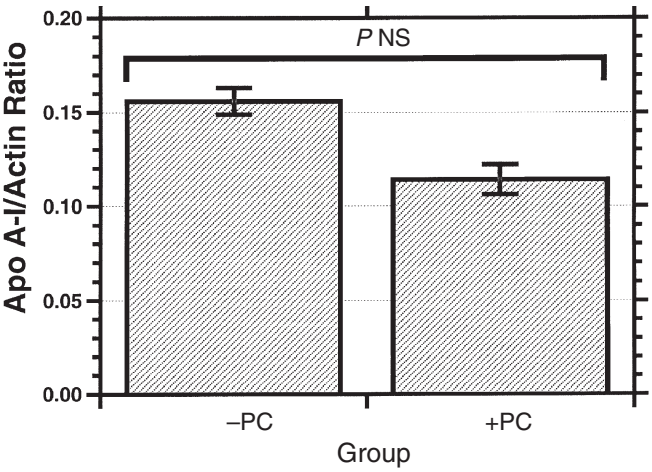

**FIG. 3.** Jejunal apo A-I mRNA abundance expressed as apo A-I to β-actin ratios determined by slot blot hybridization in control animals (–PC group, $n = 7$) and animals receiving supplemental dietary phosphatidylcholine (+PC group, $n = 7$). Bars represent the mean ± SEM of data from each group. The $P$ value was determined using Student's unpaired $t$-test. For abbreviations see Figures 1 and 2.

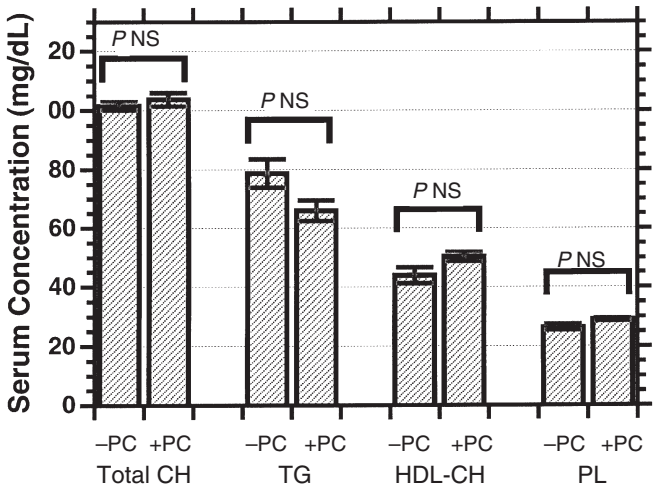

**FIG. 5.** Effect of dietary PC supplementation on serum total cholesterol (CH), triacylglycerol (TG), high density lipoprotein (HDL)-CH, and phospholipid (PL) concentrations in control animals (–PC group, $n = 7$) and animals receiving supplemental dietary PC (+PC group, $n = 7$). Bars represent the mean ± SEM of data from each group. The $P$ values were determined using Student's unpaired $t$-test. For other abbreviations see Figures 1 and 2.

the IPEC-1 cells studies and 48 h in the present piglet feeding study) or intrinsic differences in the model systems. Interestingly, the regulation of apo A-I secretion in IPEC-1 cells appeared to occur through a novel mechanism, which did not require the hydrolysis of PC to lysophosphatidylcholine or cellular uptake of either species, as verified using radiolabeled PC (11). Although developmental deficiency of phospholipase $A_2$, leading to the presence of significant amounts of intact lumenal PC, might exist in newborn swine in the present study, most of the lumenal PC was most likely digested to lysophosphatidylcholine and taken up by the enterocytes. Although this issue was not directly addressed in the present *in vivo* study, we did measure intestinal mucosal PL mass in jejunum of both experimental groups of animals at the end of the study and found a more than 1.5-fold increase in mucosal PL content in the group receiving PC supplementation. This increased mass of PL may have been present within the enterocyte and/or as a component of the cell membrane. This increased PL content may represent both exogenously and endogenously derived PL. Interestingly, in our previous studies in IPEC-1 cells, we observed that apical incubation with intact PC resulted in a striking up-regulation of cellular PL synthesis without uptake of the PC molecule (11). Although the mucosa was rinsed thoroughly at the time of harvest, it is also possible that at least a portion of the additional PL represents intact PC adherent to the brush border membrane.

Another issue is whether the increase in jejunal apo A-I synthesis with PC supplementation might be due to absorption of the fatty acid component of the PC molecule. We previously showed that 18-carbon unsaturated fatty acids can acutely upregulate apo A-I synthesis in newborn piglet jejunum (9). Soybean PC contains predominantly unsaturated fatty acids (18:1, 22%; 18:2, 54%; 18:3, 8%) (19). The added PC contributes approximately 2% to the total lipid mass in the experimental formula and represents an additional 1.8 kcal/kg/d to the total daily caloric intake (180 kcal/kg/d in the –PC group and 181.8 kcal/kg/d in the +PC group). If accounted for by differences in fatty acid content alone, it is doubtful that such a small difference in total fat caloric intake would make such a large difference in jejunal apo A-I synthesis. Furthermore, we previously showed that apo A-IV expression is a sensitive marker for intestinal epithelial fatty acid flux in newborn swine jejunum with a sevenfold increase in synthesis with a high-triacylglycerol diet containing predominantly polyunsaturated fatty acids, as compared to a very low-triacylglycerol diet (13). In a similar study with the same dietary composition and amount, jejunal apo A-I synthesis increased twofold in the animals receiving the high-triacylglycerol diet, as compared to the group receiving the low-triacylglycerol diet (9). In the present study, PC supplementation did not result in a significant increase in apo A-IV synthesis in the face of an almost twofold increase in apo A-I synthesis. This finding suggests that the increase in apo A-I synthesis is a specific effect of the PC molecule itself, rather than the esterified fatty acids.

Lumenal PC results in more efficient processing of absorbed fatty acids and monoglycerides that are reesterified by the monoglyceride pathway, resulting in greater transport of dietary lipid into lymph as chylomicrons (20–23). One possible mechanism for this effect is that the supplemental PC may improve the efficiency of fatty acid absorption by making more PL available to serve as a polar surface coat for nascent chylomicrons. Biliary PC is preferentially used, as compared to dietary PC, for this purpose (24). However, in the adult rat, lumenal PC seems to be inefficiently incorporated into chylomicrons, and enterocyte *de novo* PC synthesis cannot fully compensate for the lack of adequate PC for chylomicron assembly when the absorbed lipid load is high (3). Ultimately, adequate PC is not available to support maximal chylomicron triacylglycerol output unless there is dietary supplementation of PC (3). Therefore, in the present study, the efficiency of dietary lipid absorption may have been improved by the supplemental dietary PC, resulting in increased lipid absorption and resultant up-regulation of apo A-I synthesis. However, if this effect were of sufficient magnitude to increase apo A-I synthesis, it would also have been expected to result in significantly increased apo A-IV synthesis. Again, these findings suggest a specific effect of the supplemental PC on apo A-I synthesis.

Proximal intestinal synthesis of apo A-I increased almost twofold with PC supplementation. Also, serum levels of apo A-I and the lipoprotein associated with apo A-I, HDL, were slightly higher in the +PC group, but the differences did not reach statistical significance. This may be due to the fact that the serum levels of apo A-I are the net result of both synthesis and clearance from the plasma compartment. Therefore, the increased entry of apo A-I into the plasma compartment may be accompanied by increased clearance, resulting in no net significant change in the serum concentration.

Supplementation of a high-fat formula with soybean PC at a concentration of 1 g/L over a 48-h period in newborn swine resulted in an approximately twofold increase in jejunal apo A-I synthesis without a significant increase in apo A-I mRNA levels. The cellular mechanism of regulation of apo A-I translation by lumenal PC in the newborn enterocyte is currently under investigation in our laboratory. This effect of supplemental dietary PC may be beneficial to the newborn mammal.

# Studies of Phospholipid Metabolism, Proliferation, and Secretion of Stably Transfected Insulinoma Cells That Overexpress Group VIA Phospholipase $A_2$

**Zhongmin Ma, Alan Bohrer, Mary Wohltmann, Sasanka Ramanadham, Fong-Fu Hsu, and John Turk***

Mass Spectrometry Resource, Division of Endocrinology, Diabetes, and Metabolism, Department of Medicine, Washington University School of Medicine, St. Louis, Missouri 63110

**ABSTRACT:** A cytosolic 84 kDa Group VIA phospholipase $A_2$ ($iPLA_2\beta$) that does not require $Ca^{2+}$ for catalysis was cloned from Chinese hamster ovary (CHO) cells, murine P388D1 cells, pancreatic islet β-cells, and other sources. Proposed $iPLA_2\beta$ functions include participation in phosphatidylcholine (PC) homeostasis by degrading excess PC generated in CHO cells that overexpress CTP:phosphocholine cytidylyltransferase (CT), which catalyzes the rate-limiting step in PC biosynthesis; participation in biosynthesis of arachidonate-containing PC species in P388D1 cells by generating lysophosphatidylcholine (LPC) acceptors for arachidonate incorporation; and participation in signaling events in insulin secretion from islet β-cells. To further examine $iPLA_2\beta$ functions in β-cells, we prepared stably transfected INS-1 insulinoma cell lines that overexpress $iPLA_2\beta$ activity eightfold compared to parental INS-1 cells or to INS-1 cells transfected with an empty retroviral vector that did not contain $iPLA_2\beta$ cDNA. The $iPLA_2\beta$-overexpressing cells exhibit a twofold increase in CT activity compared to parental cells but little change in rates of [$^3$H]choline incorporation into or disappearance from PC. Electrospray ionization (ESI) tandem mass spectrometric measurements indicate that $iPLA_2\beta$-overexpressing cells have 1.5-fold higher LPC levels than parental INS-1 cells but do not exhibit increased rates of [$^3$H]arachidonate incorporation into phospholipids, and incorporation is unaffected by a bromoenol lactone (BEL) suicide substrate inhibitor of $iPLA_2\beta$. The rate of appearance of arachidonate-containing phosphatidylethanolamine species visualized by ESI mass spectrometry is also similar in $iPLA_2\beta$-overexpressing and parental INS-1 cells incubated with supplemental arachidonic acid, and this process is unaffected by BEL. Compared to parental INS-1 cells, $iPLA_2\beta$-overexpressing cells proliferate more rapidly and exhibit amplified insulin secretory responses to a protein kinase C-activating phorbol ester, glucose, and a cAMP analog. These findings suggest that $iPLA_2\beta$ plays a signaling role in β-cells that differs from housekeeping functions in PC biosynthesis and degradation in P388D1 and CHO cells.

Paper no. L8720 in *Lipids 36*, 689–700 (July, 2001)

Phospholipases $A_2$ ($PLA_2$) catalyze hydrolysis of the *sn*-2 fatty acid substituent from glycerophospholipid substrates to yield a free fatty acid and a 2-lysophospholipid (1–7). $PLA_2$ are a diverse group of enzymes, and the first well-characterized members have low molecular weights (*ca.* 14 kDa), require millimolar [$Ca^{2+}$] for catalytic activity, and function as extracellular secreted enzymes designated $sPLA_2$ (3,6). The first $PLA_2$ to be cloned that is active at $Ca^{2+}$ concentrations that can be achieved in the cytoplasm of living cells is an 85-kDa protein classified as a Group IV $PLA_2$ and designated $cPLA_2$ (3,5). This enzyme is induced to associate with its substrates in membranes by rises in cytosolic $Ca^{2+}$ concentrations in the submicromolar range, is regulated by phosphorylation, and prefers substrates with *sn*-2 arachidonoyl residues (5).

A second cytosolic $PLA_2$ has been cloned (8–10) that does not require $Ca^{2+}$ for catalysis; it is classified as a Group VIA $PLA_2$ and has been designated $iPLA_2$ (3,4). The $iPLA_2$ enzymes cloned from hamster (8), mouse (9), and rat (10) cells represent species homologs, and all are 84 kDa proteins containing 752 amino acid residues with highly homologous sequences. Each contains a GXSXG lipase consensus motif and eight stretches of a repeating motif homologous to a repetitive motif in the integral membrane protein-binding domain of ankyrin (8–10). Each of these $iPLA_2$ enzymes is susceptible to inhibition (8–10) by a bromoenol lactone (BEL) suicide substrate (11,12) that is not an effective inhibitor of $sPLA_2$ or $cPLA_2$ enzymes at comparable concentrations (4,11–14). It has been proposed that this enzyme now be designated $iPLA_2\beta$ to distinguish it from a membrane-associated, $Ca^{2+}$-independent $PLA_2$ that contains a peroxisomal targeting sequence and is designated $iPLA_2\gamma$ (15,16).

Proposed functions for $iPLA_2\beta$ include housekeeping roles in phospholipid metabolism. The first such role involves generation of lysophospholipid acceptors for incorporation of arachidonic acid into phosphatidylcholine (PC) of murine P388D1 macrophage-like cells (4,17,18). This proposal (4)

Abbreviations. BEL, bromoenol lactone suicide substrate; BSA, bovine serum albumin; CAD, collisionally activated dissociation; CHO, Chinese hamster ovary; $cPLA_2$, Group IV phospholipase $A_2$; CT,CTP:phosphocholine cytidylyltransferase; dBcAMP, dibutyryl cyclic AMP; dpm, disintegration per minute; ESI, electrospray ionization; FBS, fetal bovine serum; HPLC, high-performance liquid chromatography; $iPLA_2\beta$, Group VIA phospholipase $A_2$; KRB, Krebs-Ringer bicarbonate buffer; LPA, lysophosphatidic acid; LPC, lysophosphatidylcholine; MS, mass spectrometry; MS/MS, tandem mass spectrometry; NP-HPLC, normal-phase high-performance liquid chromatography; PBS, phosphate-buffered saline; PC, phosphatidylcholine; PE, phosphatidylethanolamine; $PLA_2$, phospholipase $A_2$; PMA, phorbol myristate acetate; $sPLA_2$, secretory phospholipase $A_2$; TLC, thin-layer chromatography.

derives from experiments involving inhibition of $iPLA_2$ activity in P388D1 cells with BEL (17) or with an antisense oligonucleotide (18). Inhibition of P388D1 cell $iPLA_2$ activity suppresses incorporation of [$^3$H]arachidonic acid into PC and reduces [$^3$H]lysophosphatidylcholine (LPC) levels in [$^3$H]choline-labeled cells (17,18). Arachidonate incorporation (17,18) reflects a deacylation/reacylation cycle (19,20) of phospholipid remodeling rather than *de novo* synthesis (21), and the level of LPC acceptors is thought to limit the rate of [$^3$H]arachidonic acid incorporation into P388D1 cell PC (17,18).

Recently, a second proposed housekeeping function for $iPLA_2\beta$ in PC homeostasis has been proposed from studies of cells that overexpress CTP:phosphocholine cytidylyltransferase (CT) (22,23), which catalyzes the rate-limiting step in PC biosynthesis *via* the Kennedy pathway. Cells that overexpress CT after transfection with CT cDNA in viral vectors exhibit increased rates of PC biosynthesis and degradation and little net change in PC accumulation (22,23). This suggests that PC degradative mechanisms are upregulated in response to CT overexpression in order to prevent excess PC accumulation and to maintain PC homeostasis. The increased PC degradation observed in CT-overexpressing cells is prevented by BEL, and immunoreactive $iPLA_2\beta$ protein and activity increase in such cells, suggesting that $iPLA_2\beta$ is upregulated in response to CT overexpression (22,23). If general, this could represent an important role for $iPLA_2\beta$ in cell biology because PC biosynthesis is involved in regulation of the cell cycle and apoptosis (24–27).

This model predicts that overexpression of $iPLA_2\beta$ might cause upregulation of CT as a compensatory response to maintain cellular PC homeostasis. To test this possibility, we have prepared INS-1 insulinoma cells that overexpress $iPLA_2\beta$ after stable transfection with a retroviral vector containing $iPLA_2\beta$ cDNA. We have measured CT activity in such cells and in parental INS-1 cells, and we have compared rates of [$^3$H]choline incorporation into and disappearance from PC in these cell lines. We have also measured LPC levels in the cells and compared rates of [$^3$H]arachidonic acid incorporation into PC and effects of BEL on this process. Because the glycerolipid composition of pancreatic islet β-cells may affect insulin secretion (28–31) and because signaling functions of $iPLA_2\beta$ have been proposed for some cells (32–47), including β-cells (48–59), we have also examined rates of cellular proliferation and insulin secretion in response to stimulation with secretagogues in $iPLA_2\beta$-overexpressing and parental INS-1 cells.

## EXPERIMENTAL PROCEDURES

*Materials.* Enhanced chemilumiescence detection reagents and 1-palmitoyl-2-[$^{14}$C]linoleoyl-*sn*-glycero-3-phosphocholine (55 mCi/mmol) were purchased from Amersham (Piscataway, NJ). PC standards were obtained from Avanti Polar Lipids (Birmingham, AL), and arachidonic acid was from Nu-Chek-Prep (Elysian, MN). BEL $iPLA_2$ suicide substrate (*E*)-6-(bromomethylene)tetrahydro-3-(1-naphthalenyl)- 2H-pyran-2-one was purchased from Cayman Chemical (Ann Arbor, MI). Tissue culture media (CMRL-1066, RPMI, and minimal essential minimum), penicillin, streptomycin, Hank's balanced salt solution, and L-glutamine were purchased from Gibco (Grand Island, NY). Fetal bovine serum (FBS) was obtained from Hyclone (Logan, UT) and Pentex bovine serum albumin (BSA; fatty acid free, fraction V) from ICN Biomedical (Aurora, OH). ATP, ampicillin, and kanamycin were obtained from Sigma Chemical (St. Louis, MO). Krebs-Ringer bicarbonate buffer (KRB) contained 25 mM HEPES (pH 7.4), 115 mM NaCl, 24 mM $NaHCO_3$, 5 mM KCl, and 1 mM $MgCl_2$.

*Cell culture.* INS-1 insulinoma cells provided by Dr. Christopher Newgard (University of Texas, Dallas, TX) were cultured as described (60) in RPMI 1640 medium containing 11 mM glucose, 10% fetal calf serum, 10 mM HEPES buffer, 2 mM glutamine, 1 mM sodium pyruvate, 50 mM β-mercaptoethanol, 100 U/mL of penicillin, and 100 µg/mL of streptomycin. RetroPack PT 67 cells (Clontech, Palo Alto, CA) were maintained in Dulbecco's modified Eagle's medium (4.5 mg/mL glucose) containing 10% FBS, 4 mM L-glutamine, 100 U/mL of penicillin, and 100 µg/mL of streptomycin.

*Preparation of recombinant retrovirus containing the cDNA encoding the rat pancreatic islet $iPLA_2\beta$.* A retroviral system (61,62) was used to stably transfect INS-1 cells with $iPLA_2\beta$ cDNA and achieve overexpression. To construct the retroviral vector, full-length rat pancreatic islet $iPLA_2\beta$ cDNA, was excised from pBK-CMV-$iPLA_2\beta$ vector and subcloned into the retroviral vector pMSCVneo at the recognition sites for restriction endonucleases EcoR I and Xho I. The construct containing the $iPLA_2\beta$ cDNA (pMSCVneo-$iPLA_2\beta$) was transfected into Clontech RetroPack PT 67 packaging cells with a GenePORTER transfection system according to the manufacturer's instructions (Gene Therapy Systems, San Diego, CA). Upon transfection of packaging cells, pMSCVneo integrated into the genome and expressed a transcript containing viral packaging signal, a neomycin resistance gene that confers resistance to the selection agent G418, and $iPLA_2\beta$ cDNA. This transcript is recognized by viral proteins in packaging cells. Introduction of pMSCVneo-$iPLA_2\beta$ into PT 67 cells resulted in production of high-titer, replication-incompetent, infectious virus particles that were released into the culture medium, collected, and used to infect INS-1 cells.

*Infection of INS-1 cells with recombinant retroviral particles and selection of stably transfected cells that overexpress $iPLA_2\beta$.* INS-1 cells were plated on 100-mm petri dishes at a density of 3–5 × $10^5$ per plate 12–18 h before infection. Freshly collected, retrovirus-containing medium was passed through a 0.45-µm filter and added to INS-1 cell monolayers. Polybrene (final concentration 4 µg/mL) was added to culture medium, and medium was replaced after 24 h of incubation. To select stably transfected cells that expressed high levels of $iPLA_2\beta$, retrovirally infected cells were cultured with G418 (0.4 mg/mL) for 1–2 wk. After G418-resistant colonies be-

came apparent, cell culture was continued for several days. Individual colonies were transferred to a 48-well plate for expansion of clonal cells.

*Assay of INS-1 cell iPLA$_2$ activity.* Seeded INS-1 were washed with phosphate-buffered saline (PBS) and detached by trituration. Cells were collected by centrifugation and disrupted by sonication (Vibra Cell High Intensity Processor, (Sonics & Materials, Inc., Danbury, CT) five 1-s pulses, amplitude 12%) in homogenization buffer (250 mM sucrose, 40 mM Tris-HCI, pH 7.1, 4°C). Homogenates were centrifuged (15,000 × *g*, 45 min, 4°C) to yield a cytosolic supernatant. Protein content was measured with Coomassie reagent (Pierce, Rockford, IL) against BSA standard. $Ca^{2+}$-independent PLA$_2$ activity in aliquots of cytosol (25 μg protein) was assayed by ethanolic injection (5 μL) of 1-palmitoyl-2-[$^{14}$C]linoleoyl-*sn*-glycero-3-phosphocholine (final concentration 5 μM) in assay buffer (40 μM Tris, pH 7.5, 5 mM EGTA, total volume 200 μL). Assay mixtures were incubated (5 min, 37°C, with shaking) and reactions terminated by adding butanol (0.1 mL) and vortexing. After centrifugation (2,000 × *g*, 5 min), products in the butanol layer were analyzed by silica gel G thin-layer chromatography (TLC) in petroleum ether/ethyl ether/acetic acid (80:20:1). The TLC plate region containing free fatty acid was identified with iodine vapor and scraped into a scintillation vial. Released [$^{14}$C]fatty acid was measured by liquid scintillation spectrometry, and PLA$_2$ specific activity was calculated from the disintegrations per minute (dpm) of released fatty acid and protein content as described (48).

*Assay of INS-1 cell CT activity.* CT activity was measured in whole cell lysates prepared from parental and transfected INS-1 cells. Cell homogenates were prepared in 10 mM HEPES buffer, pH 7.4, containing 0.34 M sucrose, 10 μg/mL leupeptin, 10 μg/mL aprotinin, and 1 mM phenylmethyl sulfonyl fluoride (assay homogenization buffer). Cells were sonicated on ice and then centrifuged (1000 × *g*, 20 min) to remove unbroken cells. CT activity was measured essentially as described (63). The assay depends on conversion of [*methyl*-$^{14}$C] phosphorylcholine to [$^{14}$C]CDP-choline. Substrate and product were separated by TLC on silica plates with methanol/0.5% sodium chloride/ammonium hydroxide (50:50:1) as mobile phase. The phosphorylcholine and CDP-choline bands were identified based on comigration with standards, and the radiolabel in each band was measured by liquid scintillation spectrometry.

*Rate of incorporation of [methyl-$^3$H]choline into PC*. INS-1 cells were plated at 2 × 10$^6$ cells per well in six-well plates and cultured overnight. The following day, cells were incubated with 0.5 μCi/mL [*methyl*-$^3$H]choline. After various incubation periods, lipids were extracted by the method of Bligh and Dyer (64). The organic layer of the extraction, which contained the lipids, was analyzed by TLC on silica plates with chloroform/methanol/ammonium hydroxide (65:25:5) as the mobile phase. PC was identified based on comigration with standards, and associated radiolabel was measured by liquid scintillation spectrometry. Raw data were corrected for extraction and counting efficiencies, normalized to cell protein content, and expressed as $^3$H dpm/μg protein.

*Rate of loss of [$^3$H]pc from cells prelabeled with [methyl-$^3$H]choline.* INS-1 cells were plated at 2.5 × 10$^6$ cells per well in six-well plates and metabolically labeled by incubation with 1.5 μCi/mL [*methyl*-$^3$H]choline for 60 h. Medium was then removed, and cells were washed twice with fresh medium containing 100 mM unlabeled choline. Cells were then incubated in that medium for various periods, and lipids were extracted by the method of Bligh and Dyer (64) and analyzed by TLC to isolate PC as described above. The [$^3$H]PC content was determined by liquid scintillation spectrometry, normalized to cell protein content, and expressed as a fraction of the [$^3$H] dpm/μg protein value observed in the time zero sample obtained immediately after completion of prelabeling with [$^3$H]choline.

*Measurement of INS-1 cell LPC mass and molecular species.* To determine INS-1 cell LPC mass, cells (10$^6$ per condition) were washed twice with and then resuspended and incubated (30 min, 37°C) in KRB medium containing 5.5 mM glucose and 0.1% BSA. Cells were then placed in fresh medium and incubated (30 min, 37°C). Cells were then washed twice with PBS and extracted by the method of Bligh and Dyer (64) with the modifications that 150 mM LiCl in water was aqueous phase and that the chloroform phase contained 17:0-LPC internal standard (300 pmol per condition). Concentrated extracts were analyzed by silica gel G TLC on heat-activated (30 min, 80°C) plates with chloroform/methanol/ammonium hydroxide (65:30:0.8) to separate LPC ($R_f$ 0.38), lysophosphatidylethanolamine ($R_f$ 0.46), and PC ($R_f$ 0.60). LPC was extracted by the method of Bligh and Dyer (64) with the modification that 150 mM LiCl in water was aqueous phase and analyzed by electroscopy ionization tandem mass spectroscopy (ESI/MS/MS).

*Incubation of INS-1 cells with radiolabeled arachidonic acid.* INS-1 cells were washed three times in KRB medium containing 5.5 mM glucose and 0.1% BSA, resuspended in that medium, and preincubated for 30 min at 37°C. The cells (2 × 10$^5$ per condition) were then placed in fresh KRB medium that contained 5.5 mM glucose, 0.1% BSA, and 2.5 mM $CaCl_2$ and incubated (30 min, 37°C) after addition of vehicle only (control) or BEL (10 μM). After the preincubation and loading steps described above, fatty acid incorporation experiments were initiated by adding [$^3$H]arachidonic acid (final concentration 0.5 μCi/mL, 5 nM) to the medium, and incubation was performed for 10–60 min at 37°C. INS-1 cells were then washed three times in KRB medium containing 5.5 mM glucose and 0.1% BSA to remove unincorporated [$^3$H]arachidonate. Cellular lipids were then extracted by the method of Bligh and Dyer (64) and analyzed by TLC or high-performance liquid chromatography (HPLC). The lipid phosphorus content of Bligh-Dyer extracts was measured as described (29).

*Chromatographic analyses of phospholipids*. Incorporation of [$^3$H]arachidonate or unlabeled arachidonate into INS-1 cell phospholipids was determined after TLC (15,16) or HPLC (50,51,57). TLC was performed on silica gel G plates

with hexane/diethyl ether/acetic acid (70:30:1). Phospholipids remain at the origin and are resolved from diglycerides ($R_f$ 0.21–0.24), free fatty acids ($R_f$ 0.58), and triglycerides. Phospholipid head-group classes were separated by normal phase (NP)-HPLC (46,47,53) analyses on a silicic acid column (LiChrosphere Si-100, 10 μm, 250 × 4.5 mm; Alltech, Deerfield, IL) with the solvent system hexane/2-propanol/(25 mM potassium phosphate, pH 7.0)/ethanol/acetic acid (367:490:62:100:0.6) at a flow of 0.5 mL/min for 60 min and then 1.0 mL/min. Retention times of standard phospholipids were: phosphatidylethanolamine (PE), 11 min; phosphatidic acid (PA), 20 min; phosphatidylinositol (PI), 27 min; phosphatidylserine (PS), 38 min; and PC, 102 min. Molecular species of PE were analyzed by ESI mass spectrometry (MS).

*Incubation of INS-1 cells with arachidonic acid to induce phospholipid remodeling.* INS-1 were cells cultured in RPMI medium supplemented with penicillin, streptomycin, fungizone, and gentamicin at a concentration of 0.1% (wt/vol) each. Cells ($1.2 \times 10^6$ per condition) were treated (30 min, 37°C) with vehicle only or with BEL (10 μM). Medium was then removed and replaced with fresh medium containing no supplements other than those described above or containing arachidonic acid (final concentration 70 μM), and cells were cultured at 37°C for various periods. After 0, 4, 8, or 18 h, cells were washed twice with PBS, suspended in homogenization buffer, and disrupted by sonication. One aliquot of homogenate was used to measure protein content, and the remainder was extracted by the method of Bligh and Dyer (64). The extract was concentrated and analyzed by NP-HPLC to separate phospholipid head-group classes.

*ESI/MS analyses of INS-1 cell lipids.* LPC and PC species were analyzed as $Li^+$ adducts by positive ion ESI/MS/MS (57,65), and PE species were analyzed as $[M - H]^-$ ions by negative ion ESI/MS (66) on a Finnigan (San Jose, CA) TSQ-7000 triple-stage quadrupole mass spectrometer with an ESI source controlled by Finnigan ICIS software. Phospholipids were dissolved in methanol/chloroform (9:1, vol/vol) containing LiOH (2 nmol/μL), infused (1 μL/min) with a Harvard syringe pump, and analyzed under described instrumental conditions (57,65,66). For tandem MS, precursor ions selected in the first quadrupole were accelerated (32–36 eV collision energy) into a chamber containing argon (2.3–2.5 mtorr) to induce collisionally activated dissociation (CAD) and product ions analyzed in the final quadrupole. Identities of PE species in the total ion current profile were determined from their tandem spectra (66). To quantitate LPC species, constant neutral loss scanning was performed to monitor LPC $[M + Li]^+$ ions that undergo loss of 59 (trimethylamine) upon CAD (57). Quantitation was achieved by comparing the intensity of the ion for 17:0-LPC internal standard (*m/z* 516) to intensities of ions for the endogenous species 16:0-LPC (*m/z* 502) and 18:0-LPC (*m/z* 530) (57). Standard curve experiments in which a constant amount of 17:0-LPC and varied amounts of 16:0-LPC and 18:0-LPC were added to a series of tubes and analyzed as $Li^+$ adducts by ESI/MS/MS indicated that this method is linear over a wide range that included levels in INS-1 cells.

*Determination of INS-1 cell proliferation rate.* INS-1 cells were seeded into six-well plates at a density of $0.3 \times 10^6$ cells/well and cultured at 37°C in the incubation medium described above. After various intervals, cells from one well were detached with trypsin/EGTA solution, and the number of cells in the suspension was determined with a hemocytometer.

*Determination of insulin secretion by INS-1 insulinoma cells.* Culture medium from INS-1 cells seeded in 24-well plates was removed, and the cells were washed twice in KRB medium and incubated (1 h, 37°C, under an atmosphere of 95% air/5% $CO_2$) in KRB medium (1 mL). Medium was then removed and replaced with KRB medium containing glucose (0-18 mM) with or without phorbolmyristate acetate (PMA) (1 μM) or dibutyryl cAMP (dBcAMP) (1 mM). After addition of final incubation medium, cells were incubated (2 h, 37°C) under the atmosphere described above, and medium was then removed for measurement of insulin by radioimmunoassay (67). Cells were then detached from the plate, and their acid-ethanol extractable insulin was determined by radioimmunoassay (68). Secreted insulin was expressed as a fraction of total cellular insulin content (69).

*Statistical analyses.* Student's *t*-test was used to compare two groups, and multiple groups were compared by one-way analysis of variance with *post-hoc* Newman-Keul's analyses.

## RESULTS

*Comparison of CT activities in control INS-1 cells and in INS-1 cells that overexpress iPLA$_2$β after stable retroviral transfection.* Transfection of INS-1 insulinoma cells with a retroviral construct containing the rat iPLA$_2$β cDNA followed by selection of G418-resistant cells resulted in the isolation of a stably transfected clone that expressed eightfold more iPLA$_2$β activity than parental INS-1 cells (Fig. 1, left set of bars). The iPLA$_2$β-overexpressing (iPLA$_2$-X) cell line also exhibited a twofold increase in specific activity of CT compared to parental INS-1 cells (Fig. 1, right set of bars). The magnitude of the increase in CT activity is thus substantially less than the increase in iPLA$_2$β activity in the transfected cells, but both effects are statistically significant. We also prepared an INS-1 cell line that was stably transfected with an empty retroviral vector that did not contain iPLA$_2$β cDNA, and we prepared a second iPLA$_2$β-overexpressing cell line by methods used to prepare the first such line. Properties of the second iPLA$_2$β-overexpressing line were similar to those of the first line, and properties of the line stably transfected with empty retroviral vector were similar to those of nontransfected parental cells (not shown).

*Comparison of rates of [$^3$H]choline incorporation into and loss from PC in control INS-1 cells and in INS-1 cells that overexpress iPLA$_2$β.* In stably transfected CHO cells that overexpress CT, rates of [$^3$H]choline incorporation into PC are increased, and, in cells in which the PC pool is prelabeled with [$^3$H]choline, rates of disappearance of [$^3$H]choline from PC are also higher in CT-overexpressing cells than in parental

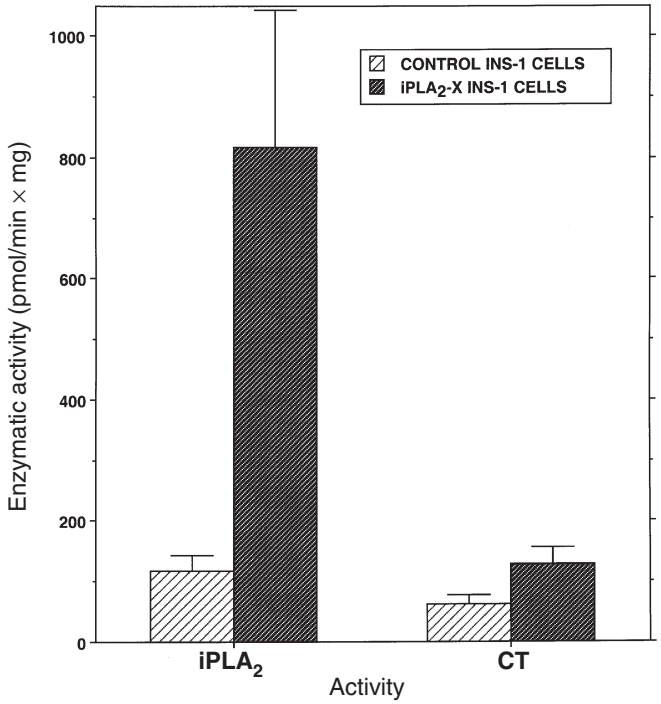

**FIG. 1.** Overexpression of iPLA$_2$β in INS-1 insulinoma cells stably transfected with iPLA$_2$β cDNA in a retroviral vector and effects on expression of CTP:phosphocholine cytidylyltransferase (CT) activity. A clonal INS-1 cell line was isolated after stable transfection with a retroviral vector containing iPLA$_2$β cDNA, and levels of iPLA$_2$β activity (left set of bars) and CT activity (right set of bars) were compared to those of parental INS-1 cells. PLA$_2$ activity was measured in the absence of [$Ca^{2+}$] and presence of EGTA and 1 mM ATP. Light bars reflect activity from parental cells (control INS-1 cells), and dark bars bars reflect activity from the clonal INS-1 cell line transfected with iPLA$_2$ cDNA in the retroviral construct (iPLA$_2$-X INS-1 cells). Mean specific activity values are displayed, and standard errors of the mean are indicated ($n$ = 6). The differences in specific activity between control and iPLA$_2$-X INS-cells were statistically significant ($P < 0.05$) both for iPLA$_2$ and for CT. Abbreviations: iPLA$_2$β, Group IV A phospholipase A$_2$; PLA$_2$, phospholipase A$_2$.

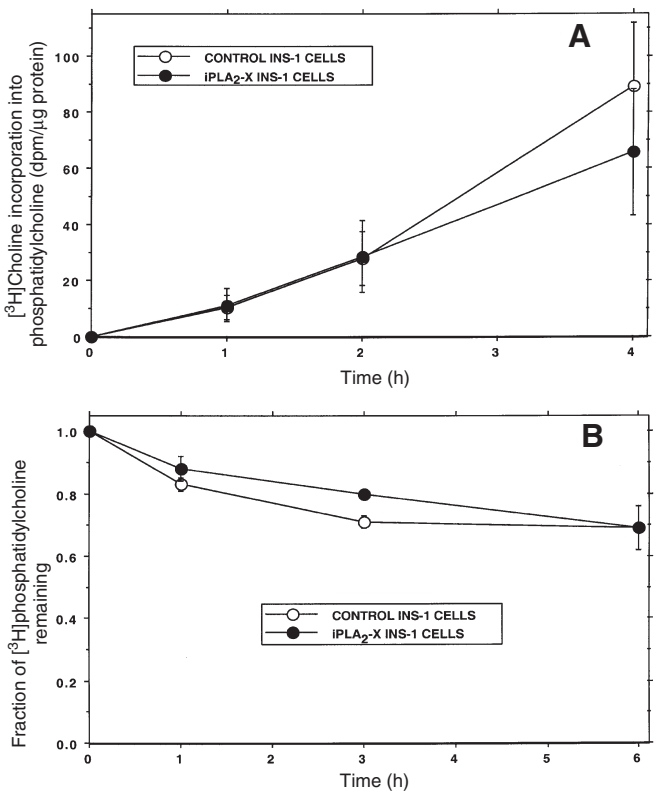

**FIG 2.** Rate of [$^3$H]choline incorporation into and disappearance from phosphatidylcholine (PA) in control and iPLA$_2$β-overexpressing INS-1 cells. The rates of [$^3$H]choline incorporation into PC (panel A) of control (open symbols) and iPLA$_2$β-overexpressing (closed symbols) were measured and expressed as [$^3$H] dpm per μg of cell protein. In panel B, control (open symbols) and iPLA$_2$β-overexpressing INS-1 cells were prelabeled with [$^3$H]choline for 60 h and then incubated in medium containing unlabeled choline for 1 to 6 h. At the end of the incubation, lipids were extracted, and PC was isolated by thin-layer chromatography. The [$^3$H] content was determined by liquid scintillation spectrometry, normalized to cell protein content, and expressed as a fraction of the time zero value. In both panels, mean values are displayed and standard errors of the mean are indicated ($n$ = 4). For abbreviations see Figure 1.

CHO cells upon incubation in medium with unlabeled choline (23). In similar experiments with INS-1 cells, iPLA$_2$β-overexpressing cells did not exhibit an increased rate of [$^3$H]choline incorporation into PC compared to parental cells (Fig. 2A) and did not exhibit accelerated [$^3$H]PC loss after prelabeling with [$^3$H]choline and subsequent incubation in medium with unlabeled choline (Fig. 2B). Effects of iPLA$_2$β overexpression in INS-1 cells thus do not mimic effects of CT overexpression in CHO cells with respect to rates of [$^3$H]choline incorporation into and disappearance from PC, even though the activities of iPLA$_2$β and CT increase together.

*Comparison of LPC levels in control INS-1 cells and in INS-1 cells that overexpress iPLA$_2$β.* Overexpression of iPLA$_2$β in INS-1 cells caused a modest increase in LPC levels (11.53 ± 0.45 nmol/μmol lipid phosphorus) compared to parental cells (7.97 ± 0.92 nmol/μmol lipid phosphorus), as measured by ESI/MS/MS (Fig. 3). The compound 17:0-LPC, which is not an endogenous constituent of INS-1 cells, was added as an internal standard to cell lipid extracts, and LPC species were isolated by TLC and analyzed as $Li^+$ adducts by ESI/MS/MS scans for constant neutral loss of 59 (loss of trimethylamine), which yields a much superior signal-to-noise ratio compared to the ESI/MS total ion current (57). The contents of endogenous 16:0-LPC (*m/z* 502), 18:0-LPC (*m/z* 530), and 18:1-LPC (*m/z* 528) were quantitated relative to the 17:0-LPC internal standard (*m/z* 516) by reference to a standard curve. The 1.5-fold increase in LPC content observed in iPLA$_2$β-overexpressing INS-1 cells compared to parental cells is substantially smaller than the eightfold increase in iPLA$_2$β activity.

*Comparison of rates of [$^3$H]arachidonate incorporation into PC in control INS-1 cells and in INS-1 cells that overexpress iPLA$_2$β.* It has been proposed that cellular content of LPC generated by iPLA$_2$β limits the rate of incorporation of arachidonic acid into PC during phospholipid remodeling and that iPLA$_2$β plays a housekeeping role in the biosynthesis of arachidonate-containing PC species (17,18). Because such a role of iPLA$_2$β might be readily apparent in cells that overexpress

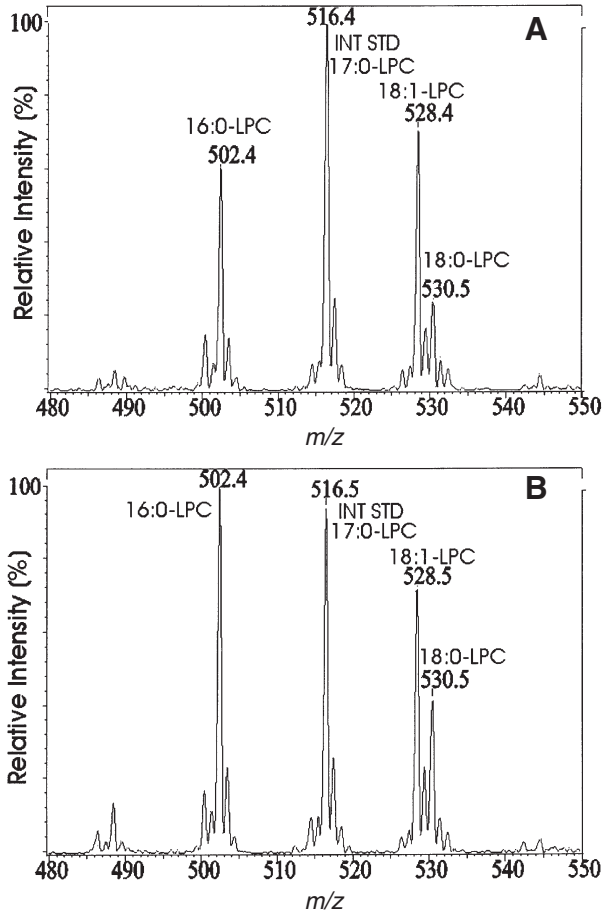

**FIG. 3.** Quantitation of lysophosphatidylcholine (LPC) molecular species by electroscopy ionization tandem mass spectrometry (ESI/MS/MS) in control and iPLA$_2$β-overexpressing INS-1 cells. After incubations described in the Experimental Procedures section, lipids were extracted from control (panel A) and iPLA$_2$β-overexpressing (panel B) INS-1 cells and mixed with 17:0-LPC internal standard. LPC species were isolated by thin-layer chromatography (TLC) and analyzed as $Li^+$ adducts by ESI/MS/MS scans for constant neutral loss of trimethylamine. Internal standard is represented by the ion at *m/z* 516, and endogenous LPC species are represented by ions at *m/z* 502 (16:0-LPC), 528 (18:1-LPC), and 530 (18:0-LPC). Quantities of endogenous species were determined from peak height ratios relative to the internal standard by interpolation from a standard curve. For abbreviations see Figure 1.

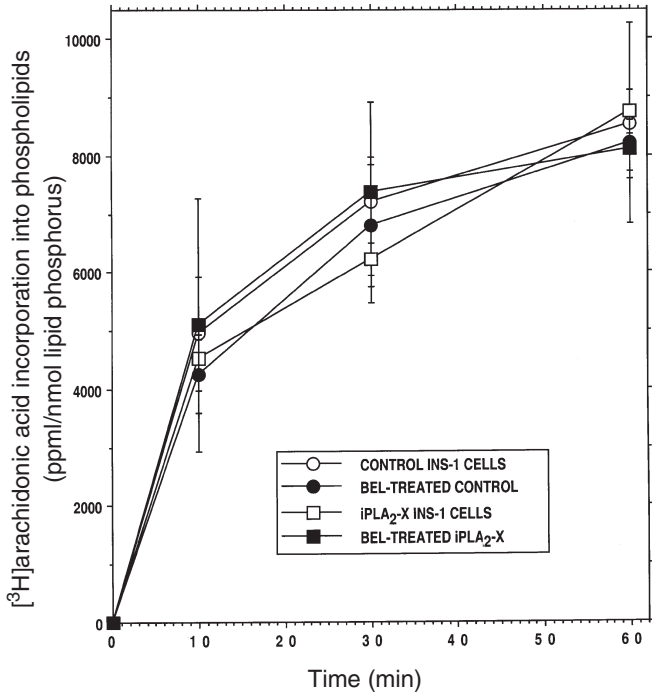

**FIG. 4.** Rates of [$^3$H]arachidonic acid incorporation into phospholipids of control and iPLA$_2$β-overexpressing INS-1 cells and effects of the iPLA$_2$β inhibitor bromoenol lactone (BEL). Control (circles) and iPLA$_2$β-overexpressing (squares) INS-1 cells were pretreated with 10 μM BEL (closed symbols) or BEL-free vehicle (open symbols), washed, and incubated in medium containing [$^3$H]arachidonic acid for various periods. At the end of the incubation, lipids were extracted and analyzed by TLC to isolate phospholipids from fatty acids and neutral lipids. The $^3$H content of the phospholipid band was determined and expressed as a ratio to the lipid phosphorus content of the lipid extract. Mean values are displayed, and standard errors of the mean are indicated ($n$ = 4). For abbreviations see Figures 1 and 3.

the enzyme, we examined rates of [$^3$H]arachidonic acid incorporation into phospholipids of iPLA$_2$β-overexpressing and parental INS-1 cells before and after treatment with the iPLA$_2$β inhibitor BEL (Fig. 4). Neither overexpression of iPLA$_2$β nor its inhibition with BEL significantly affected rates of incorporation of [$^3$H]arachidonic acid into INS-1 cell phospholipids (Fig. 4), arguing against a general role for iPLA$_2$β in biosynthesis of arachidonate-containing PC species. These radiochemical data are consistent with ESI/MS measurements of rates of appearance of arachidonate-containing PC species in INS-1 cells incubated with supplemental arachidonic acid (57).

*Comparison of rates of appearance of arachidonate-containing ethanolamine phospholipid molecular species during culture with arachidonic acid in control INS-1 cells and in INS-1 cells that overexpress iPLA$_2$β.* After initial incorporation of arachidonic acid into PC, it is subsequently transferred in part to PE species in islets and INS-1 cells (57) and in other cells by the action of a CoA-independent transacylase (70,71). With INS-1 cells that are incubated with supplemental arachidonic acid, this process is reflected by a time-dependent increase in the contribution of arachidonate-containing species to the ESI/MS total ion current for PE lipids (Fig. 5). When grown in culture medium without supplemental arachidonic acid, PE lipids from iPLA$_2$β-overexpressing (Fig. 5A) and parental INS-1 cells exhibit virtually identical ESI/MS profiles that include ions at *m/z* 700 (16:0p/18:1-PE), 714 (16:1/18:1-PE), 716 (16:0/18:1-PE), 722 (16:0p/20:4-GPE), 742 (18:1/18:1-PE), 744 (18:0/18:1-PE), 750 (18:0p/20:4-PE), 766 (18:0/20:4-PE), and 790 (18:0/22:6-PE). The designation "p" denotes a plasmalogen, which is identified by acid lability of the species represented by the corresponding ion in the ESI/MS spectrum (66). Identities of the *sn*-1 and *sn*-2 substituents were determined by CAD and tandem MS (66).

When either iPLA$_2$β-overexpressing or parental INS-1 cells are incubated with supplemental arachidonic acid, the contribution of the arachidonate-containing species 18:0/20:4-PE (*m/z* 766) rises progressively with time, and it becomes the predominant component of the mixture by 18 h (Figs. 5B,C). The chain-elongation product 18:0/22:4-PE also becomes a

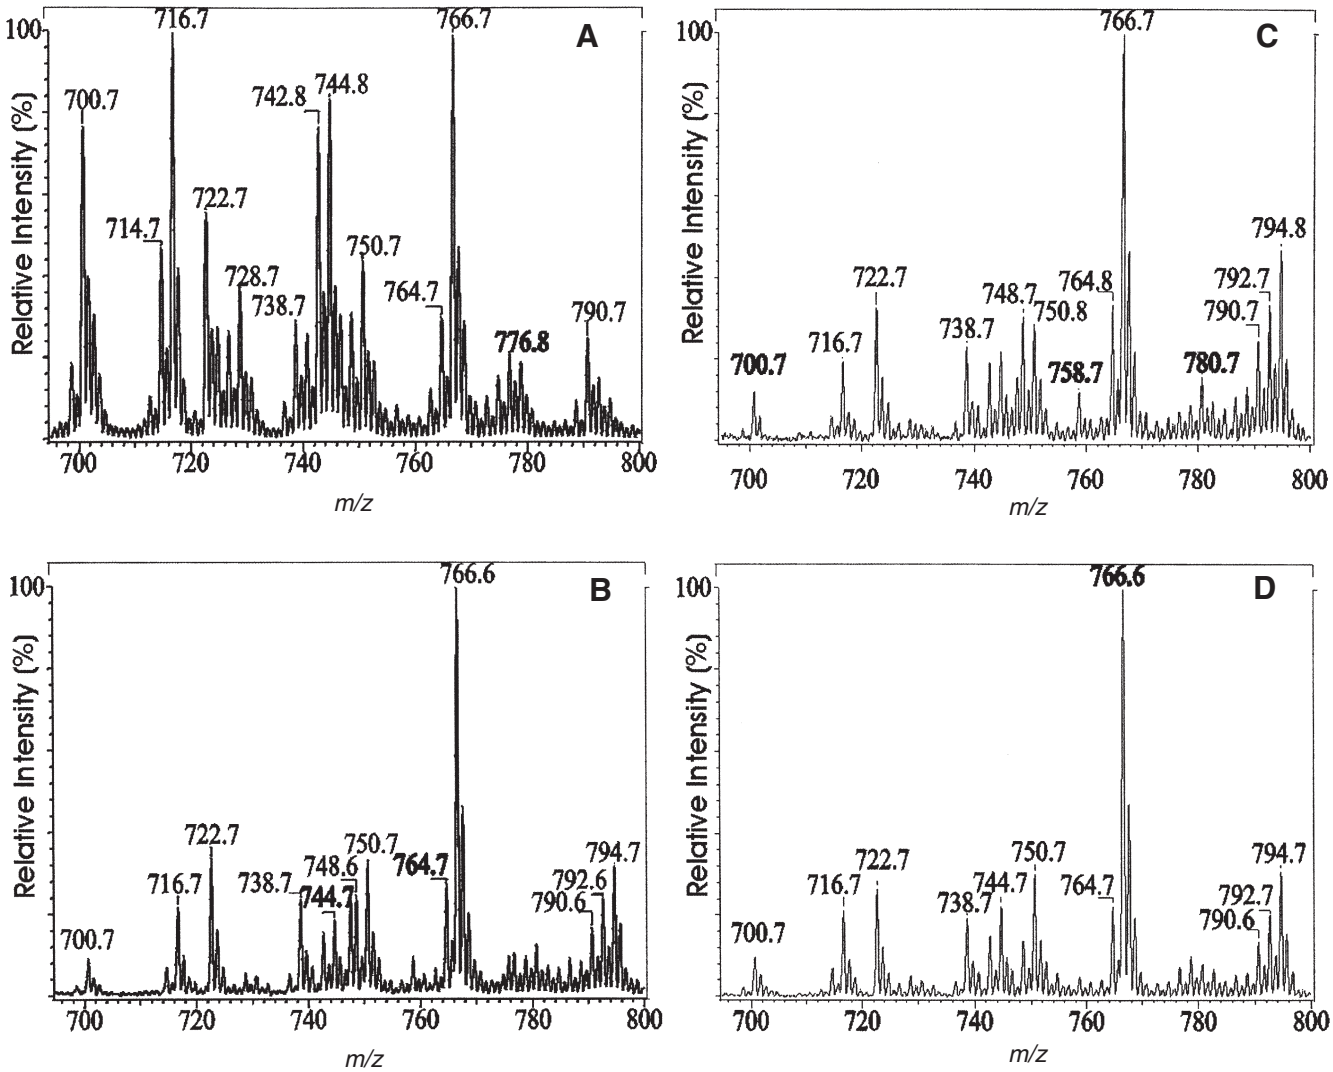

**FIG. 5.** Electrospray ionization mass spectrometry (ESI/MS) analyses of changes in phosphatidylethanolamine (PE) molecular species in control and iPLA$_2$β-overexpressing INS-1 cells incubated with supplemental arachidonic acid and effects of the iPLA$_2$β inhibitor BEL. Control (panel C) and iPLA$_2$β-overexpressing (panels A, B, and D) INS-1 cells were treated with 10 μM BEL (panel D) or with BEL-free vehicle (panels A, B, and C) and then incubated with supplemental arachidonic acid for various periods. At the end of the incubations, lipids were extracted and analyzed by normal-phase high-performance liquid chromatography to isolate PE species, which were analyzed by ESI/MS as $[M - H]^-$ ions. Identities of species represented by ions in the ESI/MS total ion current were determined by collisionally activated dissociation and tandem MS. Tracings displayed are representative of four separate experiments in which time points at 0, 2, 6, and 18 h were examined in quintuplicate. For abbreviations see Figures 1 and 4.

prominent component of the mixture, and the relative abundances of 18:1-containing species (e.g., *m/z* 700, 716, and 742, 744) decline, resulting in a simplified appearance of the spectrum. Neither the rate nor the extent of these effects differed between iPLA$_2$β-overexpressing and parental INS-1 cells (Figs. 5,C), and treatment of the cells with the iPLA$_2$β inhibitor BEL also failed to affect this process (Fig. 5D). The data in Figures 4 and 5 thus indicate that neither overexpression of iPLA$_2$β nor its inhibition with BEL affects the initial incorporation of arachidonate into phospholipids or its subsequent transfer among phospholipid classes in INS-1 cells.

*Comparison of rates of proliferation for control INS-1 cells and for INS-1 cells that overexpress iPLA$_2$β.* During the course of experiments with iPLA$_2$β-overexpressing INS-1 cells, it became apparent that their proliferation rate exceeded that of the parental cell line (Fig. 6). Between 70 and 270 h after application to culture plates, cell numbers for iPLA$_2$β-overexpressing cells increased 2.3-fold more rapidly than that for parental cells, and this property persisted on serial passage in culture.

*Comparison of insulin secretory responses of control INS-1 cells and of INS-1 cells that overexpress iPLA$_2$β.* Enhanced rates of proliferation of insulinoma cells are often associated with reduced insulin secretion (72), but iPLA$_2$β-overexpressing INS-1 cells exhibited greater insulin secretory responses to the protein kinase C-activating phorbol ester PMA and to the cAMP analog (dBcAMP) than did parental INS-1 cells (Fig. 7). The effect of PMA to promote insulin secretion was largely independent of medium glucose concentration (Fig. 7A), but insulin secretory responses to dBcAMP increased

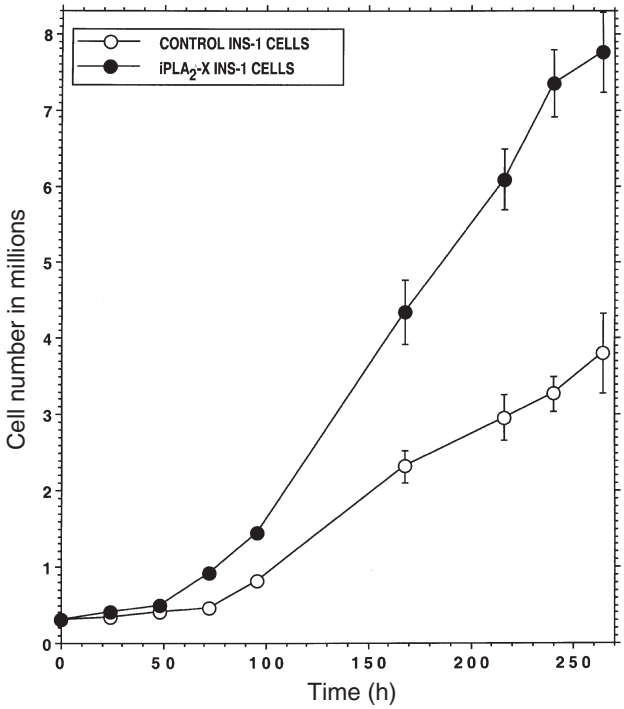

**FIG. 6.** Rates of proliferation of control and iPLA$_2$β-overexpressing INS-1 cells. INS-1 cells were seeded into six-well plates at a density of 0.3 × $10^6$ cells/well and cultured at 37°C. After various intervals, cells from one well were detached with trypsin/EGTA solution, and the number of cells in the suspension was determined with a hemocytometer. Mean values for cell number are displayed, and standard errors of the mean are indicated ($n = 6$). Values for iPLA$_2$β-overexpressing INS-1 cells were significantly higher ($P < 0.05$) than those for control INS-1 cells at all time points after 50 h. For abbreviations see Figure 1.

progressively with the glucose concentration over the range 0 to 11 mM (Fig. 7B). The iPLA$_2$β-overexpressing cells also exhibited greater insulin secretory responses to glucose alone than did the parental cells.

## DISCUSSION

Many potential functions for Group VIA PLA$_2$ (iPLA$_2$β) have been proposed (17,18,22,23,32–59) since it was first cloned (8–10). Among these are two housekeeping roles in PC biosynthesis. Cells that overexpress the rate-limiting enzyme in the Kennedy pathway of PC biosynthesis, CT, after transfection with CT cDNA exhibit increased rates of both PC biosynthesis and degradation with little net change in PC accumulation (22,23). It has previously been reported that CHO cells that overexpress CT activity by seven- to tenfold, compared to parental cells, after stable transfection with CT cDNA in a viral vector exhibit about a two- to threefold increase in iPLA$_2$β activity (23). This suggests that upregulation of PC degradative mechanisms occurs in response to CT overexpression to prevent excess accumulation of PC. Because CT overexpression in CHO cells is associated with increased iPLA$_2$β activity and immunoreactive protein and because the iPLA$_2$β inhibitor BEL retards PC degradation in CT-overexpressing cells, it has been proposed that iPLA$_2$β limits cellular PC accumulation and that its expression is coordinately regulated with that of CT (22,23). We find that overexpressing iPLA$_2$β in INS-1 insulinoma cells stably transfected with iPLA$_2$β cDNA in a retroviral vector is associated with a modest increase in CT activity, but we do not observe the increases in rates of [$^3$H]choline incorporation into or disappearance from PC that occur in CHO cells that overexpress CT. Our findings indicate that, while iPLA$_2$β and CT activity might be coordinately regulated in the same direction, the magnitudes of increases in the two activities are not proportional. Effects of increased expression of iPLA$_2$β and CT may thus depend on the context of the cell-type in which overexpression occurs.

Overexpressing iPLA$_2$β in INS-1 cells is associated with a modest increase in LPC levels, and another housekeeping function proposed for iPLA$_2$β is to generate LPC acceptors for arachidonate incorporation into PC during phospholipid remodeling in murine P388D1 cells (17,18). Although such a role for iPLA$_2$β cannot be demonstrated in pancreatic islets or parental INS-1 cells (57), it is considered possible that this function of iPLA$_2$β may be more readily demonstrable in cells that overexpress the enzyme. We find that neither iPLA$_2$β overexpression nor its inhibition with BEL affects the rate of [$^3$H]arachidonic acid incorporation into INS-1 cell phospholipids, and this is consistent with ESI/MS measurements of the rate of appearance of arachidonate-containing PC species in parental INS-1 cells incubated with supplemental arachidonic acid (57). We also find that neither iPLA$_2$β-overexpression nor its inhibition with BEL affects transfer of arachidonate into PE, as visualized by ESI/MS, in INS-1 cells incubated with supplemental arachidonic acid, and this is consistent with radiochemical studies in pancreatic islets and parental INS-1 cells (57). These findings indicate that iPLA$_2$β is not required for initial incorporation of arachidonic acid into phospholipids or its subsequent transfer among phospholipid head-group classes in β-cells.

It is possible that iPLA$_2$β plays different roles in distinct cell-types and that the function of the enzyme depends on stimulation condition or maturation state. Species of mRNA encoding at least four distinct products of the human iPLA$_2$β gene have been observed, and they are differentially represented among distinct human cell-types (35,39,73,74). The active form of iPLA$_2$β is an oligomer of interacting subunits that associate *via* their ankyrin-repeat domains (8), and distinct iPLA$_2$β gene products form hetero-oligomers with different properties (35). iPLA$_2$β is also subject to proteolytic processing that can increase its catalytic activity (43), and its amino acid sequence contains consensus sites for several posttranslational modifications (74). These findings suggest that iPLA$_2$β gene products might participate in complex regulatory networks that could affect several cell biological properties.

We find that iPLA$_2$β-overexpressing INS-1 cells proliferate more rapidly than parental cells, as reflected by the rate of increase in cell number (Fig. 6). Corresponding increases in the rate of [$^3$H]thymidine incorporation into DNA are observed (Bohrer, A., and Turk, J., unpublished observations),

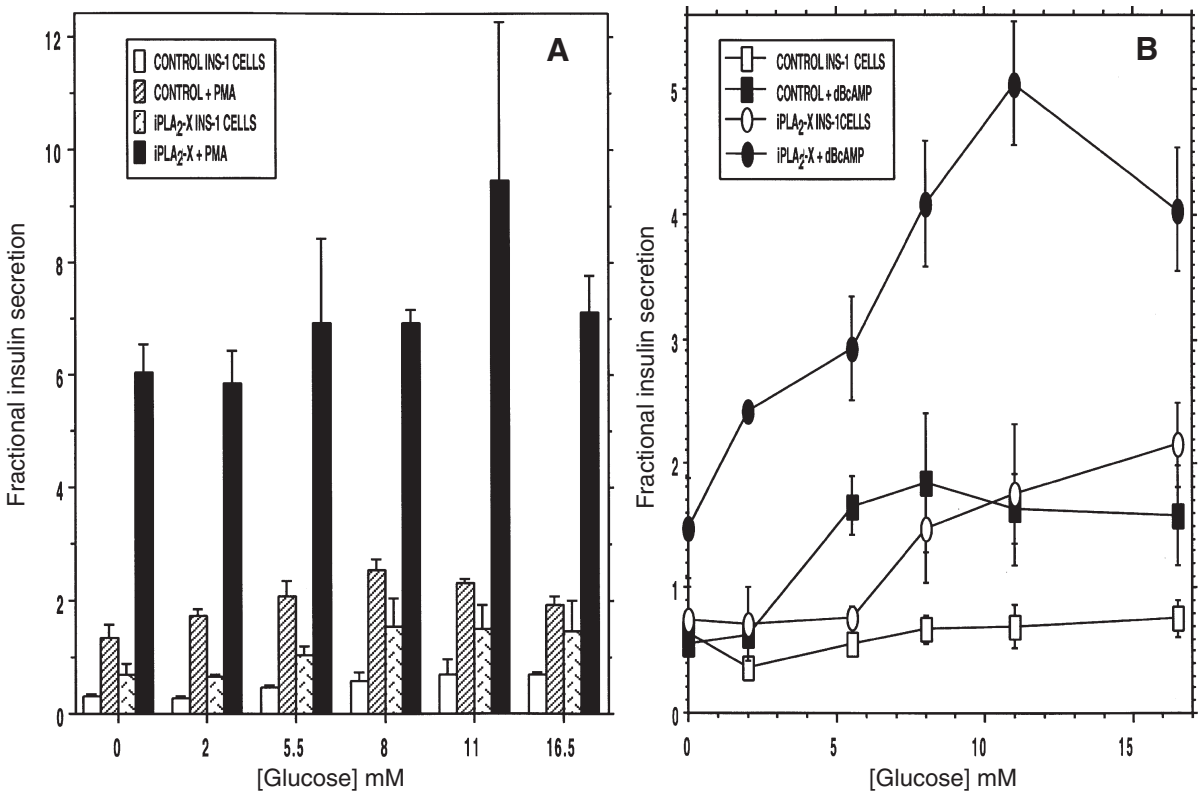

**FIG. 7.** Effects of the protein kinase C-activating phorbol myristate acetate (PMA) ester, glucose, and dibutyryl-cyclic AMP (dBcAMP) on insulin secretion from iPLA$_2$β-overexpressing and control INS-1 cells. Insulin secretion was measured after a 2-h incubation of INS-1 cells in medium containing glucose at concentrations between 0 and 16.5 mM without or with 1 μM PMA (panel A) or without or with 1 mM dBcAMP (panel B). Insulin secreted into the medium was normalized to cell insulin content to yield fractional secretion values. Mean values are displayed, and standard errors of the mean are indicated ($n = 4$). Secretion values for iPLA$_2$β-overexpressing cells were significantly higher ($P < 0.05$) than those for control cells in each comparison in panel A, for each comparison of cells treated with dBcAMP in panel B, and for each comparison at a glucose concentration higher than 5.5 mM in panel B. For other abbreviations see Figure 1.

and iPLA$_2$β inhibition has been reported to reduce [$^3$H]thymidine incorporation and rates of proliferation in lymphocyte lines (75). The bases for these phenomena have not yet been established, but the amino acid sequence of iPLA$_2$β contains a bipartite nuclear localization signal (74). It is thus possible that iPLA$_2$β might affect nuclear events involved in cell division. A favored substrate of iPLA$_2$β is PA, which it converts to lysophosphatidic acid (LPA) (8). LPA is a potent mitogen (75,77), and enhanced proliferation may occur if cellular LPA levels rise as a consequence of iPLA$_2$β overexpression. We are now attempting to quantify INS-1 cell LPA content, but this is technically difficult because of the low LPA levels in cells. Interconversions of LPA, an inverted cone-shaped lipid, and arachidonate-containing species of PA, which are cone-shaped lipids, have been demonstrated to be involved in membrane fission and fusion events in neurosecretion (78,79). Both brain and islets express high levels of iPLA$_2$β, and it is the vastly predominant brain cytosolic PLA$_2$ (80–82). Neurons in brain and β-cells in islets are both electrically active secretory cells that exhibit many biochemical similarities (83), and iPLA$_2$β may play similar signaling roles in secretory events in these cells.

Enhanced rates of proliferation of insulinoma cell lines are often associated with reduced insulin secretory responses (72), but iPLA$_2$β-overexpressing INS-1 cells both proliferate more rapidly and exhibit more robust insulin secretory responses to secretagogues than do parental INS-1 cells. Glucose also stimulates both β-cell proliferation and insulin secretion (84), and common signaling mechanisms, possibly including iPLA$_2$β, may be involved in these two responses. Both phorbol esters and cAMP-elevating agents are known to potentiate insulin secretory responses to glucose in insulinoma cell lines (60,85) and in purified β-cells prepared from dispersed cells from native islets by fluorescence-activated cell sorting (86,87). Products of iPLA$_2$β action may be involved in the interactions of these signaling pathways.

We have not examined the possibilities that enhanced insulin secretory responses to cAMP analogs and phorbol esters in iPLA$_2$β-overexpressing cells reflect increased expression of protein kinase A, protein kinase C, or critical target molecules for these enzymes. We do not observe changes in expression of the Group IVA PLA$_2$ (cPLA$_2$) in iPLA$_2$β-overexpressing INS-1 cells at the level of mRNA or immunoreactive protein (Ma, Z., and Turk, J., unpublished observations), but we cannot exclude compensatory changes in expression of other PLA$_2$ enzymes.

The observation that overexpressing iPLA$_2$β in β-cells enhances their proliferation and amplifies their insulin secretory

responses could prove useful in β-cell engineering. Recently, use of modified immunosuppressive regimens has permitted successful transplantation of human islets in seven consecutive patients with insulin-dependent diabetes mellitus, and each patient remained normoglycemic a year after transplantation without exogenous insulin (88,89). Widespread application of this therapy is precluded by limited availability of donor organs, and β-cell lines that are engineered to proliferate readily in culture but to retain regulated insulin secretion could represent an alternative source of cells for transplantation (72,89). Beta cells with improved secretory responses and other properties have been engineered by introducing genes in viral vectors and by clonal selection strategies (60,90–94). Identifying additional genes whose products affect β-cell proliferation and secretion may permit further progress, and our findings suggest that iPLA$_2$β gene products may be useful in constructing engineered β-cell lines.

## ACKNOWLEDGMENTS

This work was supported by grants from the National Institute of Health (R37-DK-34388, P41-RR00954, PO1-HL57278, P60-DK20579, P30-DK56341), the Juvenile Diabetes Foundation, and the American Diabetes Association. We thank Dr. Christopher Newgard (University of Texas-Southwestern, Dallas, TX) for providing the parental INS-1 cell line and Denise Kampwerth for assisting with the manuscript.

# Metabolism of an Oxysterol, 7-Ketocholesterol, by Sterol 27-Hydroxylase in HepG2 Cells

**Malcolm A. Lyons[1] and Andrew J. Brown***

Cell Biology Group, Heart Research Institute, Sydney, New South Wales 2050, Australia

**ABSTRACT:** 7-Ketocholesterol (7K) is a quantitatively important oxysterol in both atherosclerotic lesions and macrophage foam cells. We reported recently that radiolabeled 7K delivered to rodents in a modified lipoprotein or chylomicron remnant-like emulsion, both cleared predominantly by the liver, was rapidly excreted into the intestine as water-soluble products, presumably bile acids. Herein, we aimed to elucidate the early or initial reactions in 7K metabolism. The hypothesis was tested that sterol 27-hydroxylase, a mitochondrial cytochrome P450 and the first enzyme of the acidic bile acid pathway, is responsible for the initial metabolism of 7K by HepG2 cells, a human hepatoblastoma cell-line. The 27-hydroxylated product of 7K (27OH-7K) was shown to be the initial, lipid-soluble product of 7K metabolism. It was produced in mitochondrial incubations and whole cells and was readily released into the media from cells. Intact cells generated metabolites of 7K that had undergone conversion from lipid-soluble precursors to water-soluble products rapidly and extensively. Their production was ablated with cyclosporin A, a sterol 27-hydroxylase inhibitor. Furthermore, we demonstrated the effectiveness of two novel selective inhibitors of this enzyme, GW273297X and GI268267X. These inhibitors also ablated the production of water-soluble products by cells; and the inhibitor of choice, GW273297X, decreased the production of 27OH-7K in mitochondrial preparations. This is the first study to demonstrate that sterol 27-hydroxylase plays an important role in the metabolism of oxysterols such as 7K in liver cells.

Paper no. L8704 in *Lipids 36,* 701–711 (July 2001).

Cholesterol oxidation products (oxysterols) have been implicated in atherosclerosis since they were first discovered in atherosclerotic lesions some 50 yr ago. 7-Ketocholesterol (7K; cholest-5-en-3β-ol-7-one) is the most abundant nonenzymatically formed oxysterol detected in human atherosclerotic plaque and in human foam cells isolated from lesions (1,2). As with other oxysterols, 7K possesses a broad spectrum of potent biological effects *in vitro* (reviewed in Refs. 2–4), of which many are potentially pro-atherogenic. Despite the implications that 7K plays a role in atherogenesis, its source remains equivocal (4). It may be derived endogenously by free radical oxidation of cholesterol (5,6) and, indeed, is a major oxysterol in low-density lipoprotein (LDL), which is oxidized *in vitro* (7,8). Alternatively, it has been widely suggested that 7K may be derived exogenously from the diet (9), as it is the major oxysterol present in processed cholesterol-rich foods (10).

Of the estimated 300–500 mg of dietary cholesterol ingested daily by adult humans consuming a mixed Western diet, it has been estimated that as much as 1% of the cholesterol is oxidized (11). The most commonly detected oxysterols are the major cholesterol autoxidation products 7K, 7α-hydroxycholesterol (cholest-5-en-3β,7α-diol), 7β-hydroxycholesterol (7βOH, cholest-5-en-3β,7β-diol), cholesterol α-epoxide, and β-epoxide in foods that include eggs and egg products, meat and meat products, tallow, and dairy products (10,12–15). One example of a carefully executed measurement of 7K in three types of cheeses reported that 7K was consistently the most common oxysterol present, comprising 70% of that detected (10).

Studies in humans (16,17) and animals (18,19) have demonstrated that dietary oxysterols can indeed be absorbed by the intestine and then transported in chylomicrons. However, estimates of the extent to which oxysterols are absorbed vary greatly ranging from as little as 6% to 93% (20). There are also discrepancies for individual oxysterols between species. One study in humans reported that 7K was apparently absorbed preferentially even though it was not the most concentrated oxysterol in the test meal (17), whereas in rats, 7βOH was found to be absorbed to the greatest extent while 7K was least absorbed (19). On balance, however, it appears that oxysterols may not be absorbed as well as cholesterol (2).

Previous investigations showed that 7K can be metabolized *in vivo* to a host of water-soluble, bile acid-like products in rats (21,22), guinea pigs (21), and rabbits (23), although their identities were largely unknown. Recently, using a rat model, we confirmed these results and extended them using a novel mode of administration. In a dual-label approach, $^{14}$C-7K and $^{3}$H-cholesterol contained as steryl esters within a

Abbreviations: BTSFA plus 1% TMCS, *N*,*O*-bis(trimethylsilyl)trifluoroacetamide with 1% trimethylchlorosilane; CsA, cyclosporin A; DMEM, Dulbecco's modified Eagle's medium; GC–MS, gas chromatography–mass spectrometry; HPLC, high-performance liquid chromatography; $IC_{50}$, concentration level at which an enzyme's activity is inhibited by 50%; 7K, 7-ketocholesterol (cholest-5-en-3β-ol-7-one); LDL, low-density lipoprotein; 7βOH, 7β-hydroxycholesterol (cholest-5-en-3β, 7β-diol); 19OH, 19-hydroxycholesterol (cholest-5-en-3β-19-diol); 27OH, 27-hydroxycholesterol [(25R)-cholest-5-en-3β, 26-diol]; 27OH-7K, 27-hydroxy-7-ketocholesterol [(25R)-cholest-5-en-3β, 26-diol-7-one]; PBS, Dulbecco's phosphate buffered saline; TMS, trimethylsilyl; TMSOH trimethylsilylhydroxide; UV, ultraviolet.

modified lipoprotein vehicle were injected intravenously, thereby allowing us to compare the behavior of these two sterols directly. In that study, 7K was cleared from the liver and excreted into the intestine as water-soluble products (presumably bile acids) much more rapidly than cholesterol delivered simultaneously (24). We have reproduced these findings in a mouse study (25), in which 7K and cholesterol were delivered simultaneously in a chylomicron remnant-like emulsion. This vehicle models delivery of dietary oxysterols without the complications of intestinal absorption; once absorbed from the diet, oxysterols, including 7K, are incorporated into chylomicrons (17–19) and after lipolysis, their remnants are rapidly cleared by the liver (26–28). In that study, we showed that 24 h after injection, a substantial portion of the injected 7K-derived radioactivity had been excreted in the feces as water-soluble metabolites.

Conversion to bile acids is the major pathway for the excretion of cholesterol. Currently, there are two known pathways of bile acid biosynthesis: the "classical" and the "alternative" pathways (29–31). Since 7K and cholesterol have identical structures but for the addition of one oxygen functional group at C-7, it is conceivable that they may be catabolized by common elements of these pathways. However, owing to the C-7 hydroxyl group, it is unlikely that cholesterol 7α-hydroxylase, the rate-limiting enzyme of the classical pathway, will be able to act upon 7K. Furthermore, cholesterol 7α-hydroxylase is known to have very high substrate specificity and to be competitively inhibited by 7K (32–34). We hypothesized therefore that the initial step in the metabolism of 7K to bile acids (water-soluble products) is catalyzed by sterol 27-hydroxylase, an enzyme unimpeded by any functional groups on 7K, and the initial enzyme of the alternative pathway. We wished to test this hypothesis in a human cell-line that is known to express the two key enzymes of bile acid biosynthesis (cholesterol 7α-hydroxylase and sterol 27-hydroxylase) (35). Therefore, we employed the hepatoblastoma cell-line HepG2. These cells are known to synthesize the primary human bile acids (35–39) albeit in a pattern distinct from that of adult human liver (35–37,39). A cell-line was chosen over primary cultures since they are more readily available and maintained. Moreover, primary cultures of hepatocytes can still display substantial loss of liver-specific function (40).

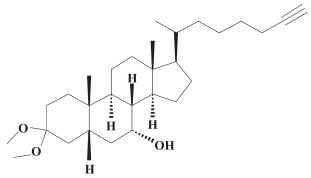
Herein we provide evidence, using the HepG2 human hepatoblastoma cell-line, that 7K is indeed metabolized by sterol 27-hydroxylase. This metabolism can be inhibited with a published inhibitor of sterol 27-hydroxylase, cyclosporin A (CsA) (41–44) and with two novel, more potent inhibitors that we report here for the first time.

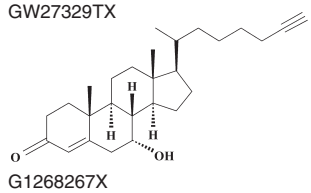
## EXPERIMENTAL PROCEDURES

*Materials.* All solvents were of high-performance liquid chromatography (HPLC) grade (EM Scientific, Kilsyth, Australia; Mallinckrodt, Mulgrave North, Australia; ICN Biomedical, Seven Hills, Australia). General reagents were of analytical reagent (AR) grade or higher and were supplied by Sigma-Aldrich (Castle Hill, Australia) or BDH (Kilsyth, Australia). The two compounds GW273297X and GI268267X (Scheme 1) were a generous gift of GlaxoSmithKline. All other reagents were of the highest grade commercially available and were obtained from the supplier indicated: 27-hydroxycholesterol [27OH; (25*R*)-cholest-5-en-3β,26-diol] (Steraloids, Wilton, NH); fetal bovine serum, L-glutamine, Dulbecco's modified Eagle's medium (DMEM) (Trace Biosciences, Castle Hill, Australia); bicinchoninic acid protein assay kit, *N*,*O*-bis(trimethylsilyl)trifluoroacetamide with 1% trimethylchlorosilane (BTSFA plus 1% TMCS) (Pierce, Sydney, Australia); complete protease inhibitor cocktail (Boehringer Mannheim, Castle Hill, Australia); $^{3}$H-7K (American Radiolabeled Chemicals, St. Louis, MO); $^{3}$H-cholesterol (Amersham Pharmacia Biotech, Castle Hill, Australia); liquid scintillation reagents (Canberra-Packard, Mt. Waverly, Australia); and benzoyl chloride, thin-layer chromatography plates (silica gel, 250 μm layer thickness, 5–17 μm particle size, 6 nm pore size), isocitrate, hydroxypropyl-β-cyclodextrin, CsA, Dulbecco's phosphate buffered saline (PBS), Triton X-100, 19-hydroxycholesterol (19OH, cholest-5-en-3β,19-diol), penicillin G, and streptomycin (Sigma-Aldrich).

*Synthesis of 27-hydroxy-7-ketocholesterol (27OH-7K).* 27OH-7K [(25*R*)-cholest-5-en-3β,26-diol-7-one] was synthesized by a modified version of the method described by Kan *et al.* (45), which was based on the methods of Chicoye *et al.* (46) and Parish *et al.* (47). In this method 27OH was used as the starting material rather than cholesterol. Briefly, to 5 mg 27OH, 30 μL benzoyl chloride was added to benzoylate and protect the hydroxyl groups, followed by 300 μL dry pyridine. The preparation was incubated at 60°C for 3 h and then underwent washing and extraction followed by oxidation and isolation as described previously (24). The product was purified by thin-layer chromatography with hexane/ethyl acetate (50:50, vol/vol) as the mobile phase and extracted from the silica with methanol/chloroform (20:80, vol/vol) followed by evaporation under vacuum.

*Characterization of 27OH-7K by gas chromatography–mass spectrometry (GC–MS) and ultraviolet (UV) spectroscopy.* 27OH-7K synthesized from 27OH and $^{14}$C-27OH-7K





**SCHEME 1**

biosynthesized by mitochondria (see below) were analyzed by GC–MS using a Hewlett-Packard (Agilent Technologies, Forest Hill, Australia) 5890 Series II gas chromatograph fitted with a BPX5 column (30 m, 0.25 μm film thickness; SGE, Ringwood, Australia) and a Hewlett-Packard 5989A mass spectrometer. The injector, GC–MS interface, and MS source were all set to 300°C. The temperature program was set at 180°C for 1 min, increased at a rate of 20°C per min to 250°C and 5°C per min to 300°C, and held at 300°C until the stop time at 25 min. The samples were prepared for GC–MS by conversion to the trimethylsilyl (TMS) ether derivatives using BTSFA plus 1% TMCS according to the manufacturer's instructions. A mixed oxysterol standard (5 nmol/μL per oxysterol) was injected (1.5 μL) at a split ratio of 12:1. Each of the 27OH-7K samples was injected in 2-μL volumes with the purge valve closed for 1 min. Normal-phase HPLC was conducted as described previously (8). Briefly, the system comprised a mobile phase of composition hexane/isopropanol/acetonitrile (94.1: 5.6: 0.3, by vol) run at 1.0 mL/min using a Shimadzu (South Rydalmere, Australia) LC-10AT pump, Shimadzu SIL-10A integrated sample cooler and auto-injector, and an Ultramex 3 silica column (3 μm, 150 × 4.6 mm, Phenomenex, Thornleigh, Australia) and 3-μm silica guard column (25 × 4.6 mm). Prior to use, the mobile phase was degassed under vacuum with sonication and continuously sparged with helium during analyses. UV spectra were collected using a Shimadzu SPD-M10AVP diode array detector for both the synthesized 27OH-7K and the $^{14}$C-labeled 27OH-7K produced by HepG2 mitochondria. A mixed oxysterol standard (100 nmol per oxysterol) was injected. Samples were evaporated under vacuum and redissolved in isopropanol/heptane (5:95, vol/vol) for normal-phase HPLC unless otherwise noted.

*Cell culture.* HepG2 cells were cultured in 75 cm$^2$ flasks in DMEM supplemented with 10% (wt/vol) heat-inactivated fetal bovine serum, 2 mmol/L L-glutamine, 50 U/mL penicillin G, and 50 U/mL streptomycin. Experiments were conducted with confluent cells. The viability of HepG2 cells was determined after 24 h incubation by assay of the release of intracellular lactate dehydrogenase as described previously (48).

*Assay for metabolism of 7K.* $^{14}$C-7K was synthesized as described previously and added to mitochondria as a saturated hydroxypropyl-β-cyclodextrin solution (45% wt/vol, 286 mmol/L) to test the sterol 27-hydroxylase activity toward 7K. Mitochondria were isolated from HepG2 cells according to the method of Winegar and colleagues (44). To a portion of mitochondrial suspension (500 μL), reaction mixture (100 μL) containing isocitrate (5 mmol/L) and isocitric dehydrogenase (1 U) was added and made up to volume (1.0 mL final) with potassium phosphate buffer (100 mmol/L, pH 7.7). At the appropriate time, the reaction was stopped by the addition of methanol (1.3 mL) and extracted by the addition of chloroform (2.7 mL). Samples were then evaporated under vacuum and prepared for either GC–MS or HPLC analysis.

$^3$H-7K in ethanol was added to the media of cell cultures. CsA was used at a final concentration of 10 μmol/L (41–44). GW273297X and GI268267X (Scheme 1) were used at final concentrations of 1.0 and 7.5 μmol/L, respectively. All three inhibitors were added in ethanol, and the final concentration of ethanol, including radiolabeled sterol, did not exceed 0.2% (by vol). At the appropriate time, medium was removed for lipid extraction and analysis of metabolic products in both the aqueous and nonpolar phases. The cells were washed three times in PBS at 37°C and extracted into 0.1% (by vol) Triton X-100 containing complete protease inhibitor cocktail or into 0.2 mol/L sodium hydroxide prior to lipid extraction and HPLC analysis. Mitochondrial and cellular protein concentrations were determined by the bicinchoninic acid method according to the manufacturer's instructions.

*7K metabolism determined by liquid scintillation and lipid analyses of media and cells by normal-phase HPLC.* To test the hypothesis that 7K is metabolized to bile acids or similar products, we determined the level of water-soluble radioactivity as a surrogate measure of bile acids. 7K and its initial metabolic product 27OH-7K (as demonstrated herein) are both chloroform-soluble, whereas bile acids partition into the aqueous phase when subjected to extraction by the method of Folch *et al.* (49) at neutral pH. Media and cells were extracted, and the two phases evaporated under vacuum to ensure removal of residual chloroform. Water-soluble samples were redissolved in water alone or 50% (by vol) methanol, scintillation fluid was added (Ultima Gold or Hionic Fluor, respectively) and samples assayed for radioactivity by liquid scintillation counting. Normal-phase HPLC was conducted as described previously (8) using the parameters indicated above. The system for radiometric detection comprised a Rheodyne manual injector (Rohnert Park, CA), LKB (Amersham Pharmacia Biotech) Bromma 2150 pump, LKB 2151 Variable Wavelength Monitor at 210 nm in series with a Canberra-Packard Series A-100 Radiomatic Flo-one Beta Radio-Chromatography Detector using Ultima-Flo M scintillant (scintillant to effluent solvent ratio of 2).

## RESULTS

*Synthesis and characterization of 27OH-7K.* The putative 27OH-7K was well resolved from other common oxysterols under the conditions employed for GC (Fig. 1A) and normal-phase HPLC (not shown). The other sterols (cholesterol, 7α-hydroxycholesterol, 7βOH, 7K, 19OH, and 27OH) analyzed by GC eluted at least 4 min earlier than 27OH-7K. This synthesized standard co-chromatographed on GC with a peak isolated from HepG2 mitochondria that had been incubated with $^{14}$C-7K (Fig. 1B). MS confirmed the structure of the product synthesized by oxidation of 27OH to be the 27OH-7K. The molecular ion (*m/z* 560) and three significant ions (*m/z* 545, 470, 129) (Fig. 1C) confirmed the finding of one previous publication . Other significant ions were found at *m/z* 455, 365, 269, 187, 174, 161, and 75. The fragment ions at *m/z* 545 (M – 15), 470 (M – 90), 455 (M – 15-90), and 365 (M – 15 – 2 × 90) were attributed to loss of methyl and TMS hydroxide (TMSOH) groups, and the fragment ion at *m/z* 269

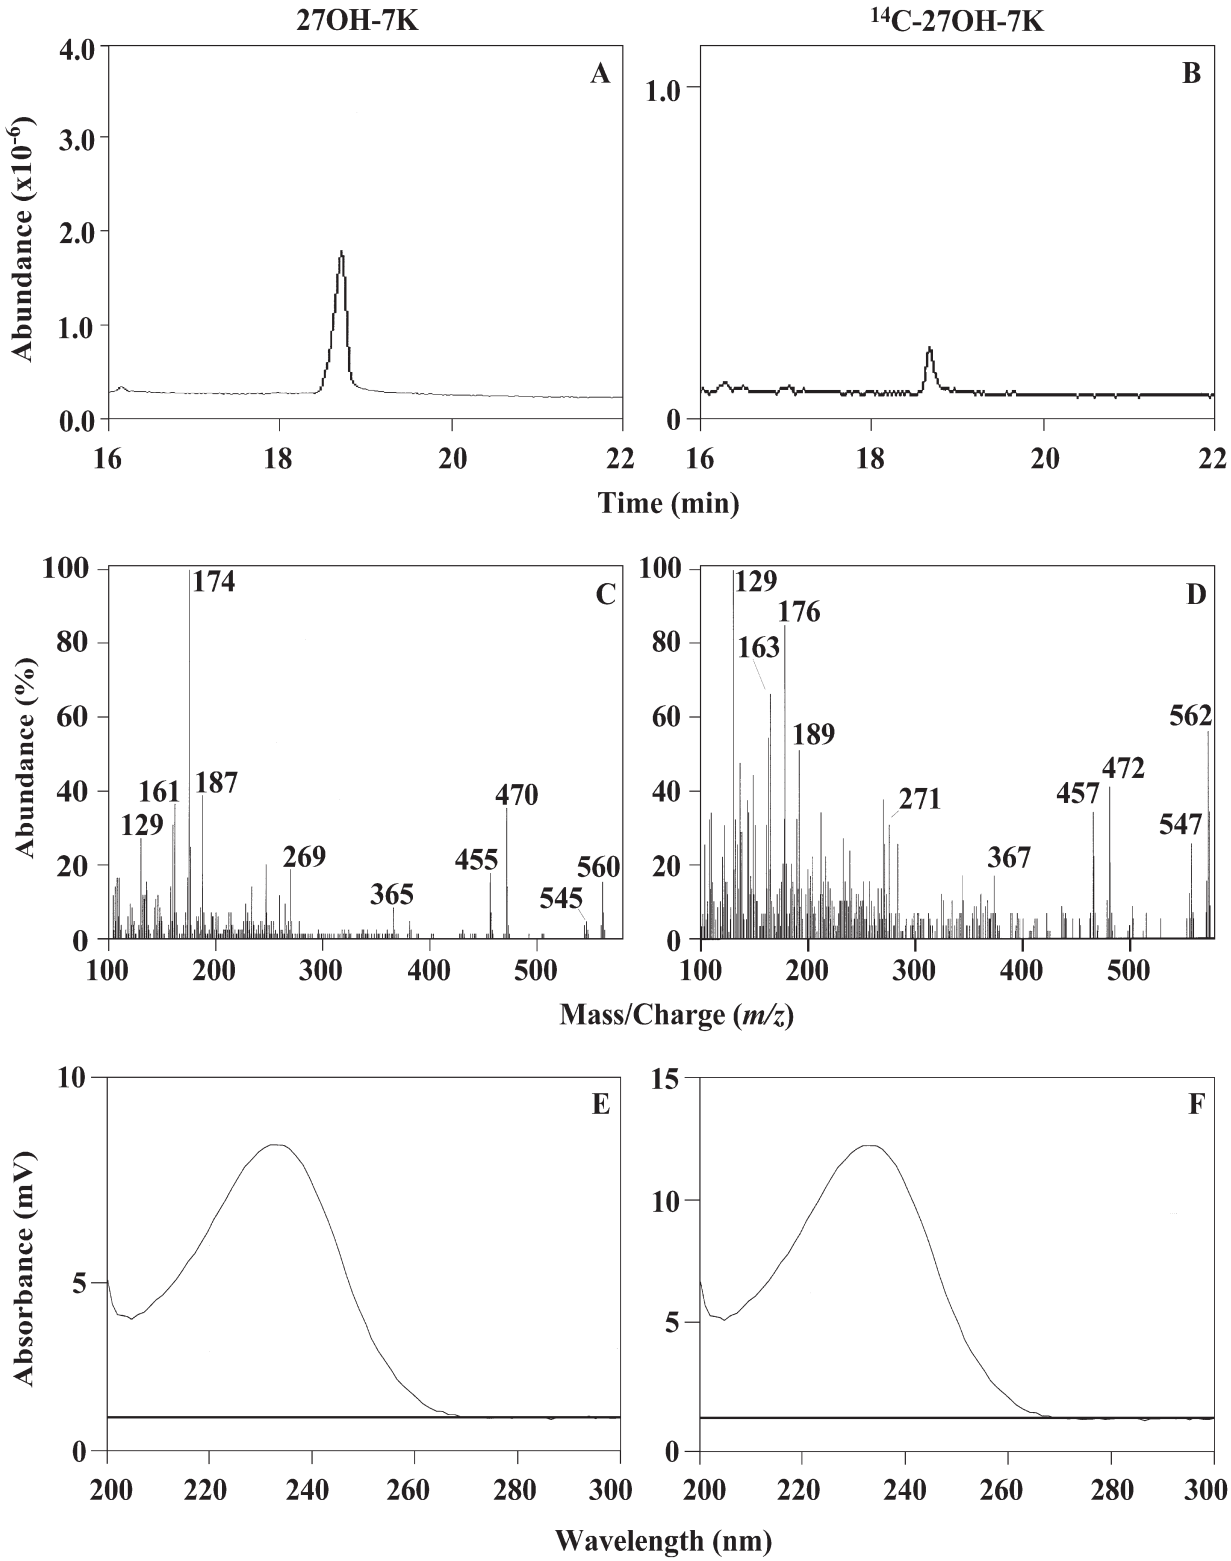


**FIG. 1.** Characterization of 27OH-7K synthesized from 27OH and $^{14}$C-27OH-7K biosynthesized by mitochondria from $^{14}$C-7K. Standard 27OH-7K was well-separated from other oxysterols when analyzed by gas chromatography–mass spectrometry (GC–MS) (panel A). $^{14}$C-27OH-7K generated by mitochondria had an identical retention time to synthetic 27OH-7K on both GC (panel B) and high-performance liquid chromatography (HPLC) (HPLC shown in Fig. 2). The MS data confirm the structure of standard 27OH-7K (panel C). The molecular ion was at *m/z* 560. $^{14}$C-27OH-7K had a similar mass spectrum (panel D) to the synthetic 27OH-7K, but the molecular ion and fragment ions above *m/z* 129 had mass M + 2 due to the $^{14}$C-label at C-4. Sterols were analyzed as their trimethylsilyl derivatives for GC–MS. The ultraviolet (UV) spectra of synthetic 27OH-7K (panel E) and $^{14}$C-27OH-7K (panel F) were indistinguishable and were collected using normal-phase HPLC employing a diode array detector. Methods are as described in the Experimental Procedures section. Abbreviations: 27OH, 27-hydroxycholesterol; 7K, 7-ketocholesterol; 27OH-7K, 27-hydroxy-7-ketocholesterol.

was attributed to the loss of the side chain as the TMS ether and loss of the second TMSOH. The peak generated by mitochondria had a comparable mass spectrum (Fig. 1D) to the standard 27OH-7K and had fragment ions corresponding to M + 2 compared with the synthesized 27OH-7K, for all ions of interest above *m/z* 129. The increase in fragment mass was attributed to the $^{14}C$ label at C-4. In addition, the synthesized standard (Fig. 1E) had an identical UV spectrum with the $^{14}C$-labeled compound (Fig. 1F). These data confirm the identity of the synthesized standard 27OH-7K and indicate that 7K can act as a substrate for sterol 27-hydroxylase in HepG2 mitochondria.

*Mitochondrial and cellular metabolism of 7K.* HepG2 cells were cultured to investigate the metabolism of 7K by human liver cells. After 24 h of incubation, no difference was found in the viability, as determined by lactate dehydrogenase release into the media, of control cells (72 ± 4%, mean ± standard deviation) vs. vehicle-treated cells (76 ± 4%, ethanol 0.2%, by vol). Sterol 27-hydroxylase, the enzyme of interest, is a mitochondrial cytochrome P450 enzyme (29,51) that is located on the inner membrane (52). For this reason we isolated mitochondria from HepG2 cells as a partially purified source of sterol 27-hydroxylase. The activity of this enzyme on cholesterol is such that it can initially introduce a hydroxyl group on the terminal carbon atom to produce 27OH. Thus, we determined the extent of metabolism of cholesterol and 7K by mitochondria through the measurement of 27OH and 27OH-7K, respectively. The primary pathway for excretion of cholesterol is *via* conversion to bile acids that are water-soluble. Therefore, extensive metabolism of the two sterols by intact cells was determined by the measurement of water-soluble radioactivity, where products of 7K were assumed also to be bile acid-like compounds or 7-oxo analogs of cholestenoic acid. The mitochondria, cells, and media were each subjected to lipid extraction and analyzed by normal-phase HPLC with radiometric detection. In a similar manner to GC, the standard 27OH-7K (Fig. 2A) co-chromatographed on normal-phase HPLC with $^{14}C$-27OH-7K produced by mitochondria (Fig. 2B). In addition to being detected in HepG2 mitochondria, 27OH-7K was also detected in whole HepG2 cells (Fig. 2C), and media (Fig. 2D). The relative levels were lower, however, when compared with the isolated mitochondria, a semipurified source of sterol 27-hydroxylase (*c.f.* Fig. 2B). Apart from 27OH-7K, two other chloroform-extractable products were identified by co-elution with authentic standards. These were 7K esters, detected in cells (Fig. 2C), and 7βOH, detected in cells and media (Figs. 2C,D). Both 7K esters (53) and 7βOH (21,22,50,54–58) have been documented previously as products of 7K. A number of other chloroform-extractable products were detected in both cells and media but remain unidentified. Two of these products made sizeable contributions to the products secreted into the media (Figs. 2D, 3B). The results of the radiometric characterization of $^{3}H$-7K metabolites are presented in Figure 3. The coefficient of variation for at least three independent experiments was typically less than 10% (e.g., Fig. 4B). Water-soluble products were formed early and extensively (Fig. 4A), comprising 19% of added radioactivity at 8 h, but the other products were negligible at 1 h (Fig. 3B), even in comparison with 27OH-7K which was readily detected. Thus, 27OH-7K, was the first lipid-soluble product detected in the system.

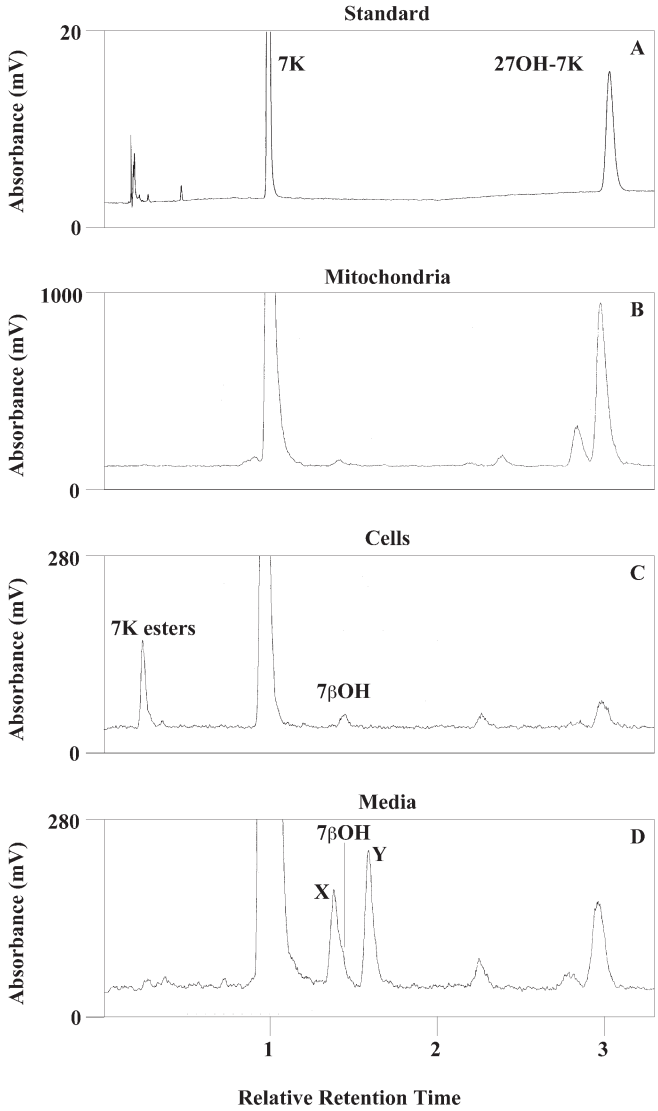

**FIG. 2.** Analysis of 7K metabolites generated by HepG2 mitochondria or intact HepG2 cells. Mixed unlabeled oxysterol standards, including synthesized 27OH-7K, were analyzed using UV detection at 234 nm (panel A) and 210 nm (not shown). Mitochondria were isolated from HepG2 cells and incubated with $^{14}C$-7K (delivered in β-cyclodextrin) in reaction mixture for 8 h then extracted, and the lipid fraction was subjected to normal-phase HPLC analysis with UV detection (not shown) and radiometric detection (panel B). Intact HepG2 cells were incubated with $^{3}H$-7K (delivered in ethanol) for 8 h, and the lipid fractions of the cells (panel C) and media (panel D) were subjected to analysis with radiometric detection. 7K esters and 7β-hydroxycholesterol (7βOH) were detected in cells by co-elution with authentic standards (not shown). Two unidentified chloroform-soluble compounds (peaks X and Y) were detected in the media sample. 7βOH appears as a shoulder on Peak X. Methods are as described in the Experimental Procedures section. Cells and media chromatograms are scaled to show metabolites generated and excreted by intact cells. For abbreviations see Figure 1.

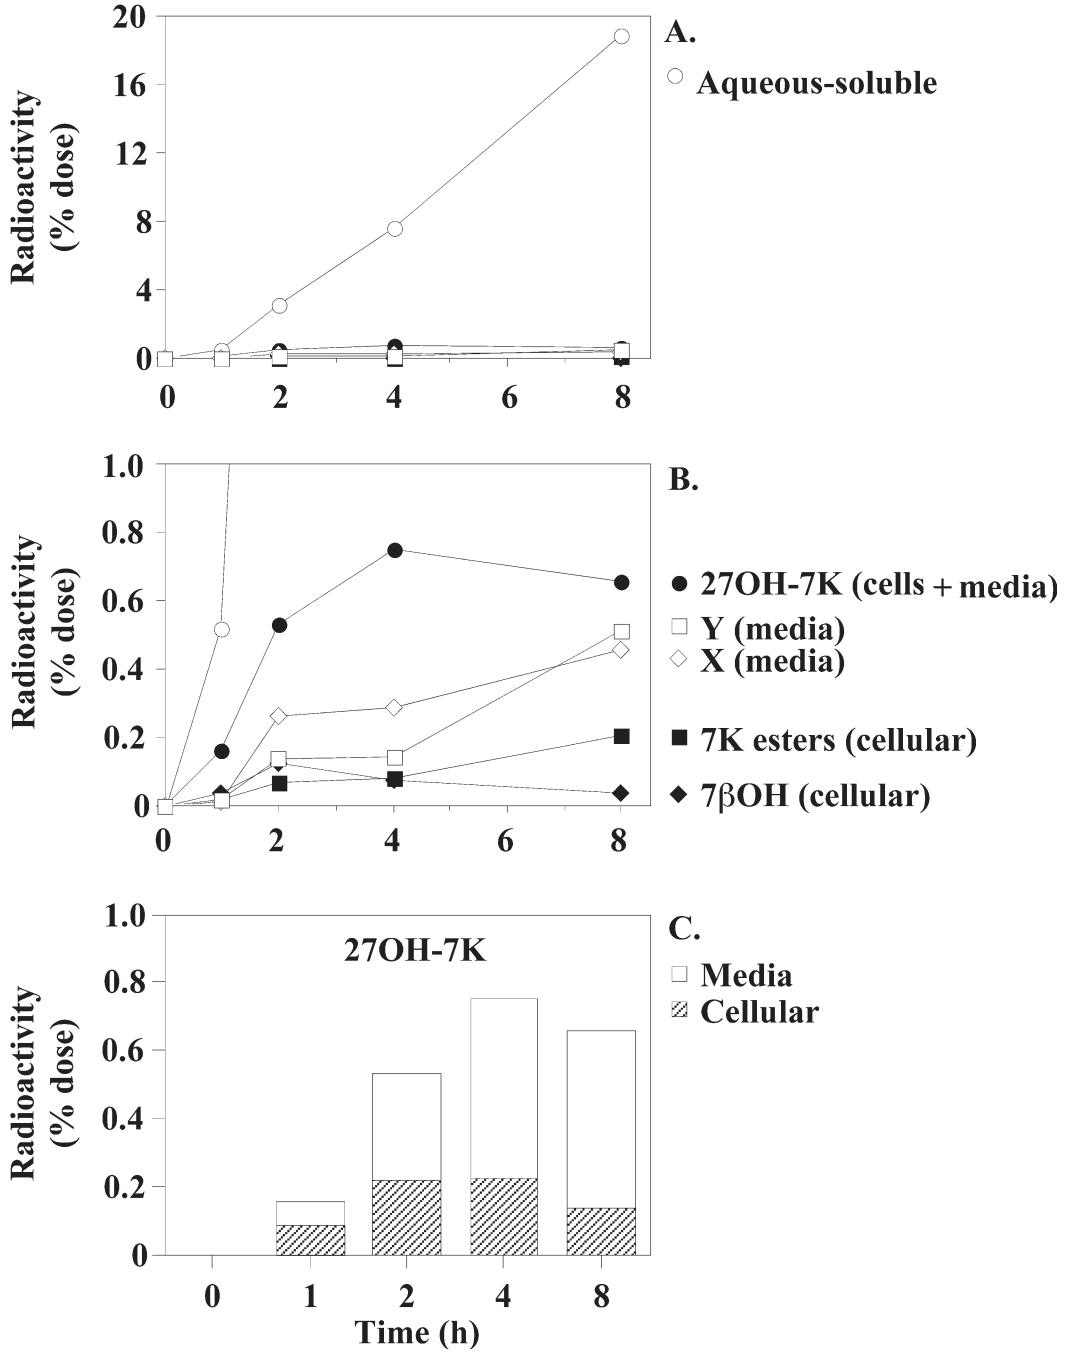

**FIG. 3.** Metabolism of 7K by HepG2 cells. $^{3}$H-7K was incubated with HepG2 cells for periods of up to 8 h. At the appropriate time, cells and media were subjected to lipid extraction. The lipid portions were analyzed by normal-phase HPLC with radiometric detection to detect 7K metabolites, and the aqueous portion (○) was assayed for radioactivity by liquid scintillation counting (panel A). Panel B is an enlargement of the data presented in panel A and shows that 27OH-7K (●, total in cells plus media) was the first lipid-soluble product detected. 7β-Hydroxycholesterol (◆) and 7K esters (■) were detected in the cellular extract. Two unidentified products (X and Y, ◇ and □, respectively) were detected in the media extracts. Panel C indicates the proportions of 27OH-7K detected in the media (open) and in cells (hatched). Data for water-soluble metabolites are representative of three or more experiments with a coefficient of variation <10%. Data for other metabolites in the system were based on a single determination from a pooled sample to achieve sufficient sensitivity for detection by radiometric HPLC. For abbreviations see Figure 1.

Although 27OH-7K is chloroform-extractable (quantitatively recovered, data not shown), it is a relatively polar sterol. It is therefore not surprising that in cell incubations, it was detected predominantly in the media. There was an increasing proportion of this product in the media with increased duration of incubation (Fig. 3C). By 8 h, ~80% of total 27OH-7K was found in the media, indicative of efficient excretion.

*Inhibition of sterol 27-hydroxylase with GW273297X and GI268267X.* In agreement with previous studies (41–44),

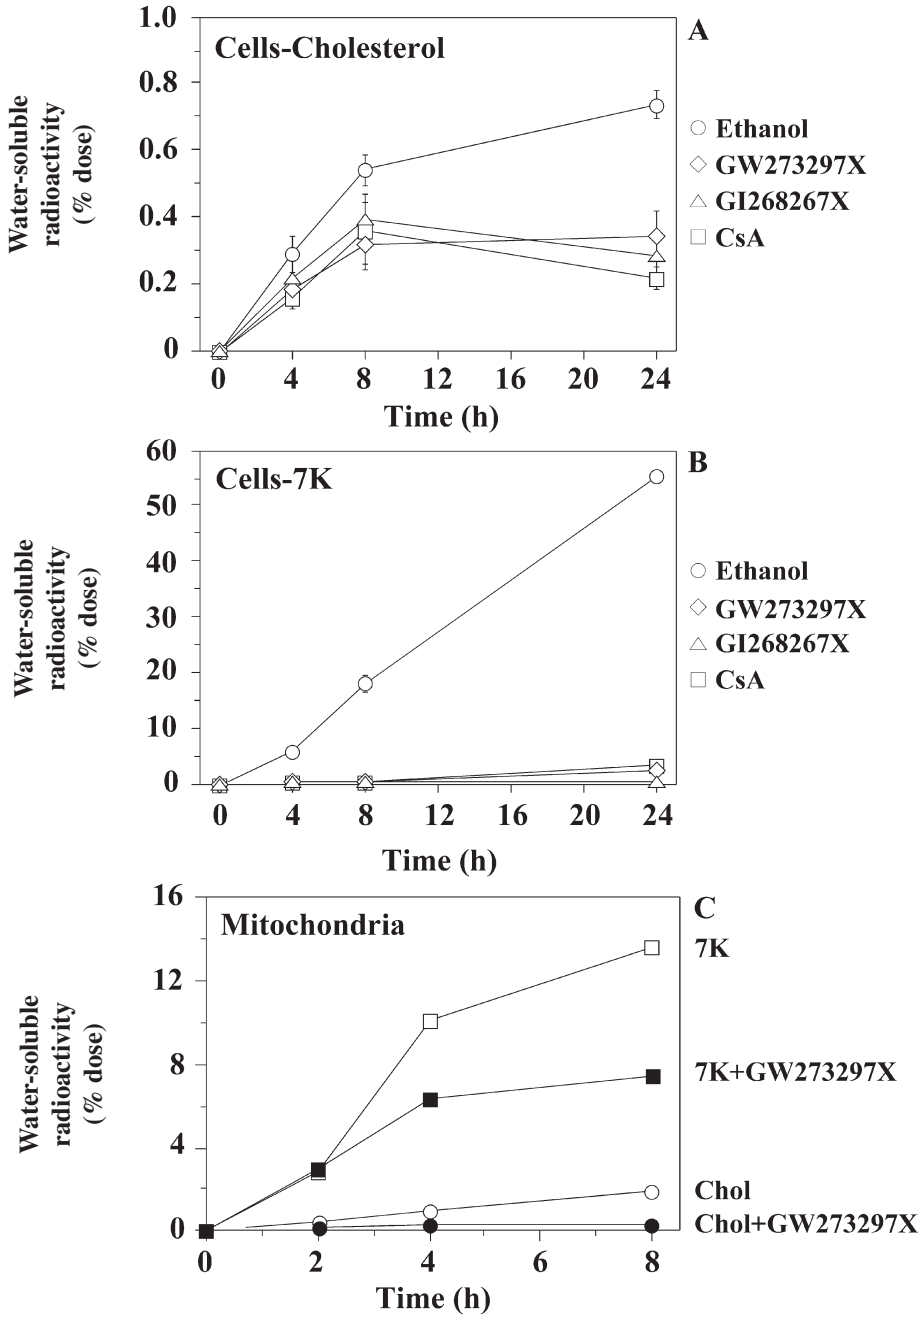

**FIG. 4.** Metabolism of 7K and cholesterol (Chol) by intact HepG2 cells and isolated mitochondria in the presence of inhibitors of sterol 27-hydroxylase. HepG2 cells were incubated for up to 24 h with $^{3}$H-cholesterol (panel A) or $^{3}$H-7K (panel B) in the absence (○, ethanol only, 0.2%, by vol, final concentration) or presence of cyclosporin A (CsA) (□, 10 μmol/L), GW273297X (◇, 1 μmol/L), or GI268267X (△, 7.5 μmol/L). Panel C: Because sterol 27-hydroxylase is a mitochondrial cytochrome P450, metabolism of $^{14}$C-7K (□,■) to 27OH-7K or $^{14}$C-cholesterol (○,●) to 27OH (by mitochondria isolated from HepG2 cells) was tested in the absence (open symbols) or presence (filled symbols) of GW273297X (1 μmol/L). Methods are as described in the Experimental Procedures. Panels A and B show data that are expressed as mean ± standard deviation ($n$ = 3).

sterol 27-hydroxylase activity directed toward cholesterol was inhibited with CsA (Fig. 4A). Inhibition of sterol 27-hydroxylase activity by GW273297X, GI268267X, and CsA was assayed using isolated mitochondria treated with $^{14}$C-cholesterol, and the 50% inhibition values ($IC_{50}$) were determined to be 40, 300, and 874 nmol/L, respectively (Winegar, D.A., unpublished data). GW273297X and GI268267X were used experimentally at final concentrations of 1.0 and 7.5 μmol/L, respectively, while CsA was used at 10 μmol/L as published previously (41–44). At concentrations up to 10 μmol/L, GW273297X and GI268267X were found not to inhibit cholesterol 7α-hydroxylase activity and thus were deemed specific for sterol 27-hydroxylase (Winegar, D.A., unpublished data).

*Inhibition of cellular and mitochondrial metabolism of 7K with CsA, GW273297X, or GI268267X.* The metabolism of cholesterol (Fig. 4A) to water-soluble products was inhibited by all three compounds tested (GW273297X, GI268267X, and CsA), although its absolute extent of metabolism was much less than that of 7K (Fig. 4B). The metabolism of 7K by HepG2 cells was also ablated by incubation with 10 µmol/L CsA (Fig. 4B). To further test whether 7K is metabolized by sterol 27-hydroxylase, we incubated HepG2 cells with two more potent, novel inhibitors of this enzyme, GW273297X and GI268267X. Incubation of HepG2 cells with 7K in the presence of these inhibitors also dramatically blocked the production of water-soluble metabolites over 24 h (Fig. 4B). Based on this result and the lower $IC_{50}$, later experiments were conducted using GW273297X as the inhibitor of choice. No difference was found in the viability (lactate dehydrogenase release) after 24 h of cells treated with 1 µmol/L GW273297X (76 ± 2%) vs. control or vehicle-treated (ethanol 0.2%, by vol) cells (72 ± 4%, 76 ± 4%, respectively, mean ± standard deviation).

Mitochondria were isolated from HepG2 cells to provide a partially purified source of the enzyme and were then incubated with $^{14}$C-7K or $^{14}$C-cholesterol solubilized in a cyclodextrin solution in the presence or absence of inhibitor. As already shown in Figure 2B, 27OH-7K was detected in mitochondrial incubations. GW273297X virtually abolished the production of 27-hydroxycholesterol and reduced the production of 27OH-7K by ~50% (Fig. 4C). Furthermore, we were able to show that mitochondria were able to produce low levels of water-soluble products in addition to their production of 27OH-7K (data not shown). GW273297X did not affect the net cellular uptake of 7K, although the overall proportion metabolized to other chloroform-extractable plus aqueous-soluble products was substantially reduced (Fig. 5).

*Metabolism of 7K vs. cholesterol by sterol 27-hydroxylase.* For the same amount of radiolabeled sterol added, cholesterol was metabolized to a far lesser extent than 7K by both intact HepG2 cells (Figs. 4A and 4B, respectively) and the mitochondrial fraction (Fig. 4C). After addition of equivalent amounts of $^{14}$C-7K or $^{14}$C-cholesterol to HepG2 mitochondria, the resultant 27OH had a specific activity that was one-tenth that of 27OH-7K, reflecting the contribution from endogenous cholesterol in the mitochondria. However, allowing for the specific activities, twice as much 27OH-7K was produced as 27OH on a mass basis (5.4 and 2.5 nmol/mg mitochondrial protein per 8 h, respectively), indicating a greater rate of action of sterol 27-hydroxylase on 7K compared to cholesterol.

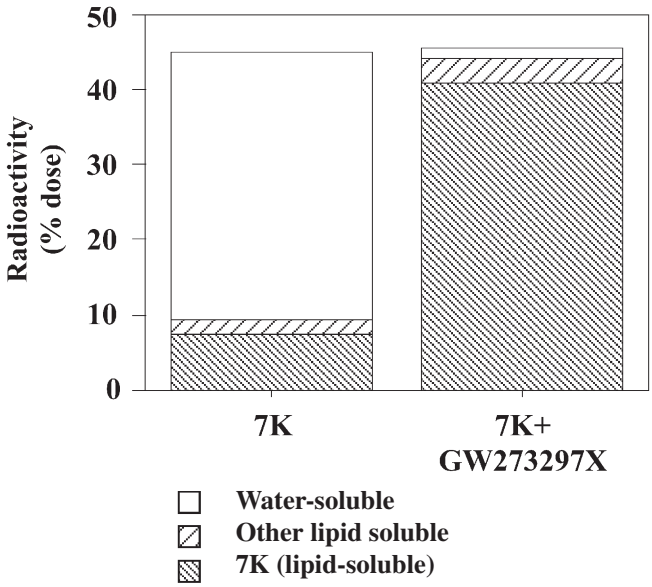

**FIG. 5.** Effect of GW273297X on the metabolic fate of 7K in intact HepG2 cells. HepG2 cells were incubated for 24 h with $^{3}$H-7K in the absence or presence of GW273297X (1 µmol/L). Cells and media were subjected to lipid extraction. The total water-soluble radioactivity (open) was measured by liquid scintillation counting while 7K (fine hatch) and other lipid-soluble radioactivity (coarse hatch) were determined by normal phase high-performance liquid chromatography with radiometric detection.

## DISCUSSION

We recently showed that metabolism of 7K, a quantitatively important oxysterol in the human diet and atherosclerotic lesions, occurred at a greater rate and to a greater extent than that of cholesterol delivered simultaneously to rats or mice. Therefore, our initial experiments were conducted to determine whether human cells were capable of similar metabolic processes. For these experiments we used the human HepG2 hepatoblastoma cell-line and clearly demonstrated that human liver cells are able to extensively metabolize 7K to water-soluble products and that this occurs at a greater rate than for cholesterol.

*7K serves as a substrate for sterol 27-hydroxylase.* The primary objective of this study was to test the hypothesis that 7K is at least initially metabolized by the defining enzyme of the alternative bile acid pathway, sterol 27-hydroxylase. Since sterol 27-hydroxylase is a mitochondrial cytochrome P450 enzyme, we isolated mitochondria from HepG2 cells to determine if 7K can serve as a substrate for this enzyme. The product, 27OH-7K, was identified in mitochondria incubated with 7K by comparison with a synthetic standard whose identity was confirmed by GC–MS and HPLC–UV spectroscopy. It was also detected in whole cell preparations, particularly in the media, along with other metabolic products that had been rapidly generated from 7K. 27OH-7K, however, was the first lipid-soluble product generated. This observation is consistent with the contention that sterol 27-hydroxylase catalyzes the initial catabolism of 7K since, intuitively, conversion of a lipids to a water-soluble product requiring a number of enzymatic steps would initially result in the generation of a more polar but lipid-soluble product. Furthermore, it highlights the speed by which 7K is acted upon by this metabolic pathway. Given the substrate availability, the fact that this product's generation reaches a plateau after 4 h further suggests that it is an intermediate product in the generation of water-soluble

products of 7K metabolism. It is likely also that this is the case for the unidentified products X and Y detected in the media of cells treated with 7K. In accordance with our results, two previous reports detected the 27-hydroxylated product when human fibroblasts (43) or human monocyte-derived macrophages (57) were treated with 7K. These data support the contention that the sterol 27-hydroxylase pathway is a mechanism designed to rid cells of excess sterols including this potentially harmful oxysterol.

*Inhibition of metabolism of 7K with CsA and two novel sterol 27-hydroxylase inhibitors, GI268267X and GW273297X.* Having established that 7K can be acted upon by sterol 27-hydroxylase in HepG2 cells, we further tested the hypothesis that 7K is metabolized by this pathway by using a previously published inhibitor of sterol 27-hydroxylase activity, CsA (41–44). However, CsA is better known for its effects as a potent immunosuppressant drug. Therefore, we also tested two novel inhibitors of sterol 27-hydroxylase, GW273297X and GI268267X, which are effective at lower concentrations than CsA ($IC_{50}$: 40 and 300 nmol/L vs. 874 nmol/L, respectively). These inhibitors, at lower concentrations, abolished the production of water-soluble products of 7K to the same extent as CsA. GW273297X also greatly diminished the production of 27OH-7K in mitochondria incubated with 7K.

The lower level of inhibition of 27OH-7K generation (Fig. 4C), compared with 27OH, may reflect the fact that 7K is able to move into and out of membranes at a greater rate than cholesterol (59). That is, simultaneous addition of inhibitor and sterol, as in this experiment, allowed a certain amount of 7K to be acted upon prior to the entry of the inhibitor into the mitochondrion. Mitochondria were able to produce small amounts of water-soluble products themselves. Presumably this is 3β-hydroxy-7-oxo-5-cholestenoic acid, the 7-oxo analog of cholestenoic acid that has been reported to be produced from 7K by fibroblasts in one previous publication (50). Since mitochondria can metabolize 7K to 27OH-7K (and even perhaps to the water-soluble carboxylic acid), and since inhibition of sterol 27-hydroxylase results in a substantial reduction of metabolism of 7K by both intact HepG2 cells and the mitochondrial fraction, the sterol 27-hydroxylase pathway is clearly an important mechanism for the metabolism of 7K.

In addition to 7K, a variety of other oxysterols have been detected in cholesterol-rich foodstuffs, predominantly those with their oxygen functional groups also present on the B-ring of the sterol (2). We speculate that sterol 27-hydroxylase may also be involved in the metabolism of other dietary oxysterols.

*Implications for dietary oxysterols.* Some oxysterols, including 7K, are absorbed from the diet and appear in triacylglycerol-rich lipoproteins in both rats (18,19) and humans (17). Thus far, however, investigations have been unable to demonstrate directly the accumulation in the artery wall of 7K derived from the diet or from intravenous administration (61,62). In light of the finding from this study that a human hepatocyte cell-line can efficiently metabolize 7K, it will be of great interest to see whether future studies can determine to what extent (if at all) dietary oxysterols contribute to the oxysterols found in atherosclerotic lesions.

This is the first study to identify the human mitochondrial sterol 27-hydroxylase as the enzyme responsible for the metabolism of 7K in liver cells. The initial 27-hydroxylated product of 7K was detected in both mitochondrial preparations and whole cell cultures. Indeed, this product was the first lipid-soluble metabolite produced by cells. The production of 27OH-7K was greatly attenuated by pharmacological inhibition in mitochondrial preparations and intact cultured cells. Sterol 27-hydroxylase also appears to be responsible for the further conversion of 27OH-7K to more polar compounds in a manner analogous to that proposed for cholesterol *via* 27OH because we have demonstrated an inhibition of metabolism of 7K to water soluble products by the human hepatic cell line HepG2 using three different inhibitors of sterol 27-hydroxylase. Moreover, we recently showed that macrophages from a patient with cerebrotendinous xanthomatosis, lacking functional sterol 27-hydroxylase, did not metabolize 7K to water-soluble products in contrast to control macrophages (57,58). Sterol 27-hydroxylase-dependent metabolism of 7K appears to operate in the whole human since we recently showed greatly elevated plasma concentrations of 7K in this same patient with cerebrotendinous xanthomatosis (58). In the absence of hepatic tissue from patients suffering from this rare condition, it would be of interest to repeat these studies in primary human hepatocytes employing the new inhibitors of sterol 27-hydroxylase introduced in this report. Given the continuing interest in oxysterols as physiological regulators of cholesterol homeostasis (63–65), it is noteworthy that Cali and Russell (51),who first cloned the human gene of sterol 27-hydroxylase, stated that "it is conceivable that the enzyme may play an equally important role in inactivating oxysterols." This study has for the first time identified the human mitochondrial sterol 27-hydroxylase as the enzyme responsible for the metabolism of an oxysterol (other than 27OH) in human liver cells and therefore strongly supports such a contention.

## ACKNOWLEDGMENTS

We thank Max Walker (Paris, France) and Nigel Ramsden (Stevenage, United Kingdom) from GlaxoSmithKline for providing the GW273297X and GI268267X inhibitors of sterol 27-hydroxylase, and Debbie Winegar, Jo Salisbury, Roy Hawke, Cliff Hyman, and Gordon Hodgson (GlaxoSmithKline, Research Triangle Park, North Carolina) for their work on the synthesis and characterization of these compounds. Also, thanks to Wendy Jessup for critically reading this manuscript. This project was supported by a grant from the American Egg Board.

**ABSTRACT:** Animal and human studies designed to examine the effects of α-linolenic acid (ALA) and linoleic acid (LA) supplementation on the fatty acid composition of plasma and tissues have demonstrated a marked difference in incorporation into phospholipids of these 18-carbon precursors of the long-chain polyunsaturates. Whereas tissue phospholipid levels are linearly related to dietary ALA and LA, the levels of tissue LA can be 10-fold higher than tissue ALA even when dietary levels are equivalent. There is some dispute whether this disparity is due to ALA being more rapidly metabolized to its products or substantially oxidized by the liver, or whether LA but not ALA is readily incorporated into cellular phospholipids. We examined the level of incorporation of polyunsaturated fatty acids into human respiratory epithelial cell lines (A549, 16HBE) by determining the dose-dependent incorporation of ALA and LA as free fatty acid (5–150 μg FFA/mL). Cell membrane phospholipid ALA and LA were both increased up to ~20–30% total fatty acids, with a concomitant decrease predominantly in monounsaturated membrane fatty acids, before significant toxicity was observed (50 μg/mL). Our data support the concept that rather than any inherent inability by human cells to incorporate ALA into membrane phospholipids, the lack of ALA content in human and animal tissues *in vivo* is due to the rapid metabolism or oxidation of this fatty acid in the liver.

Paper no. L8674 in *Lipids 36,* 713–717 (July 2001).

Numerous animal and human studies examined the effects of α-linolenic acid (ALA, 18:3n-3) and linoleic acid (LA, 18:2n-6) supplementation on the fatty acid composition of plasma and tissues. A common feature of these studies is the marked difference in the levels of these 18-carbon precursors of the long-chain polyunsaturates (LCPUFA) incorporated into plasma and tissue phospholipids. Whereas tissue phospholipid levels are linearly related to dietary ALA and LA, the levels of tissue LA can be 10-fold higher than tissue ALA even when dietary levels are equivalent (1–3). In humans, LA appears in high levels (15–30% total fats) in all plasma fractions and competes for incorporation with all long-chain (20- and 22-carbon) LCPUFA into cell membranes (4). In contrast, even when consumed in the same quantities, ALA appears in plasma fractions in only trace amounts (<3% total fats) (2), and there are no reports of ALA being incorporated in amounts comparable to LA into cell membrane phospholipids. A number of hypotheses have been proposed to explain this disparity. ALA may be more rapidly metabolized to its products or substantially oxidized by the liver (5,6).

LA is readily converted to arachidonic acid (AA) and incorporated into tissues in most rodent systems (7,8). Although ALA can be converted into eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), dietary supplementation studies have shown little direct association between high intakes of ALA and increased tissue DHA or EPA (2,9). However, dietary ALA has been shown to decrease AA levels dramatically in lung phospholipids independent of increases in cellular ALA or its metabolites (10).

Patients receiving high n-6/n-3 ratio diets have been shown to have significantly decreased lung function, whereas 50% of those on low n-6/n-3 diets experienced improved lung function (11). As epithelial cells have been shown to play a key role in the regulation of response to respiratory disease it is important to determine the capacity for change within the composition of cell membrane fatty acids of these cells and to what extent these changes may affect the expression of the lungs' natural defense mechanisms. As a first step toward this aim, the level of incorporation of the PUFA ALA and LA in human respiratory epithelial cell lines *in vitro* was examined.

## EXPERIMENTAL PROCEDURES

*Cell lines.* Two human transformed respiratory epithelial cell lines were used: alveolar (A549) and bronchial (16HBE). Both cell lines were maintained in continuous culture prior to each experiment. Culture media for the A549 cells (Dulbecco's modified Eagle's medium; DMEM) and 16HBE cells (RPMI 1640) contained 2 mM L-glutamine, 50 U/mL penicillin, 37.5 U/mL streptomycin, and 5 and 10% heat-inactivated fetal bovine serum (FBS), respectively. The fatty acid content of these base media was consistent regardless of the percentage of FBS added. This fatty acid content is summarized in Table 1.

*Free fatty acid (FFA) incorporation.* Cells were seeded into six-well plates at a density of $4 \times 10^5$ cells/mL. Triplicate wells were supplemented with a range of concentrations from 5–150 μg/mL of ALA or LA FFA (Nu-Chek-Prep Inc., Elysian, MN)

[a]The total lipid contribution of fetal bovine serum to the media in a 10% solution equals 17 μg/mL of which approximately 98% is phospholipid.
[b]ALA, α-linolenic acid; LA, linoleic acid; FFA, free fatty acid; total SATS, total saturated acids; total MONOS, total monounsaturated acids = sum of all monounsaturated fatty acids of chain length 11-24, as assessed by gas chromatography.

in 100% ethanol and incubated at 37°C in a 5% $CO_2$ humidified incubator until confluent (24–36 h). The amount of ethanol necessary to obtain these concentration ranges did not exceed 0.5% (vol/vol). Samples (6 mL) of each medium were reserved prior to and after each experiment for fatty acid analyses. At confluence all medium was removed from the wells, and triplicates were pooled and spun ($680 \times g$, 5 min) to pellet nonadherent cells. Triplicates of adherent cells were harvested with 0.25% trypsin/0.04% EDTA in phosphate-buffered saline (PBS), pooled, and added to the nonadherent cells before washing in PBS ($680 \times g$, 5 min). Total cells were then resuspended in 1.5 mL PBS for fatty acid extraction.

*Fatty acid analyses.* Cellular lipids were extracted with propanol/chloroform as described by Broekhuyse (12), and lipids in the culture media were extracted with methanol/chloroform as described by Bligh and Dyer (13). The phospholipid fraction of the cellular lipid extracts and the FFA, phospholipid, triglyceride, and cholesterol ester fractions of medium lipid extracts were separated by thin-layer chromatography using 3:1 petroleum spirit/acetone and 90:15:1 petroleum spirit/acetone/glacial acetic acid (+0.005% butylated hydroxyanisole), respectively. Lipids were transesterified in 1% $H_2SO_4$ in methanol for 3 h at 70°C as described previously (14). Fatty acid methyl esters were separated and quantified using a Hewlett-Packard 6890 gas chromatograph (Palo Alto, CA) and identified based on the retention time of authentic lipid standards (Nu-Chek-Prep Inc.).

*Cell viability.* The viability of cells post-FFA incubation was ascertained by the Cell Titer 96® $AQ_{ueous}$ One Solution Cell Proliferation Assay (Promega Corp., Madison, WI). Triplicate wells of a 96-well plate were seeded with $4 \times 10^4$ cells in 100 μL of each experimental FFA concentration in parallel to the FFA incubation experiment. At the time of cell harvesting from the six-well plates, an MTS tetrazolium compound [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium, inner salt] was added to each of the experimental wells and controls in the 96-well plate. The absorbance of colored formazan product produced through bioreduction by metabolically active cells was then read on an automatic plate reader at 490 nm. The viability index was determined by calculating the difference between the experimental wells and controls (no FFA).

*Statistical analysis*. Fatty acid data are presented as mean percentage ± SEM of the total fatty acids measured. The significance of fatty acid composition differences and cell viability index scores between ALA and LA supplementation concentrations was determined using one-way analysis of variance (ANOVA) followed by Bonferroni's *post-hoc* analysis using SPSS for Windows (SPSS Inc., Chicago, IL).

## RESULTS

*Incorporation of ALA and LA into respiratory epithelial cells.* Cell membrane phospholipid ALA and LA were increased dose dependently in both A549 and 16HBE cell lines up to a maximal level of incorporation (Fig. 1A–D). LA is readily incorporated into both cell lines at low FFA concentrations, reaching 50% of maximum at 5–10 μg/mL and maximal incorporation at 20–30 μg/mL (Figs. 1B,D). The incorporation of ALA reached 50% at 10–20 μg/mL with maximal incorporation being attained at ~30 μg/mL (Figs. 1A,C). From gas chromatograms, 88–107% of all added fatty acid could be accounted for as incorporated phospholipid or in the media as FFA. As ALA and LA FFA were recovered from the media at similar levels postincubation, the results indicate a slightly higher substrate requirement for equivalent incorporation of ALA than LA in both cell lines.

*Changes in cell membrane PUFA in response to increased ALA and LA incorporation.* The greatest change in membrane composition resulting from incubation with high levels (50 μg/mL) of ALA or LA was a large incorporation of these PUFA into both cell lines, offset by a decrease in monounsaturated fatty acid levels (Table 2). Decreases in the n-7 and n-9 fatty acids as well as a small decrease in DHA were also observed with incorporation of both PUFA in both cell lines. LA incorporation also caused a decrease in the membrane level of EPA and a resultant overall decrease in total n-3 fatty acids in both cell types. However, ALA incorporation resulted in an overall decrease in total n-6 fatty acids in only the A549 cell line.

At low levels of substrate (5 and 20 μg/mL), A549 cells were able to increase the cell membrane phospholipid content of the 20-carbon PUFA EPA and AA, presumably by endogenous synthesis, although this was not measured directly (Figs. 2A,B). The incorporation of EPA and AA by these cells decreased dose dependently with further increases in substrate ALA or LA.

16HBE cells were also capable of increasing cell membrane EPA in the presence of ALA, which was maintained at a constant level at increasing ALA doses (Fig. 2C). However, there was no change in cell membrane phospholipid AA con-

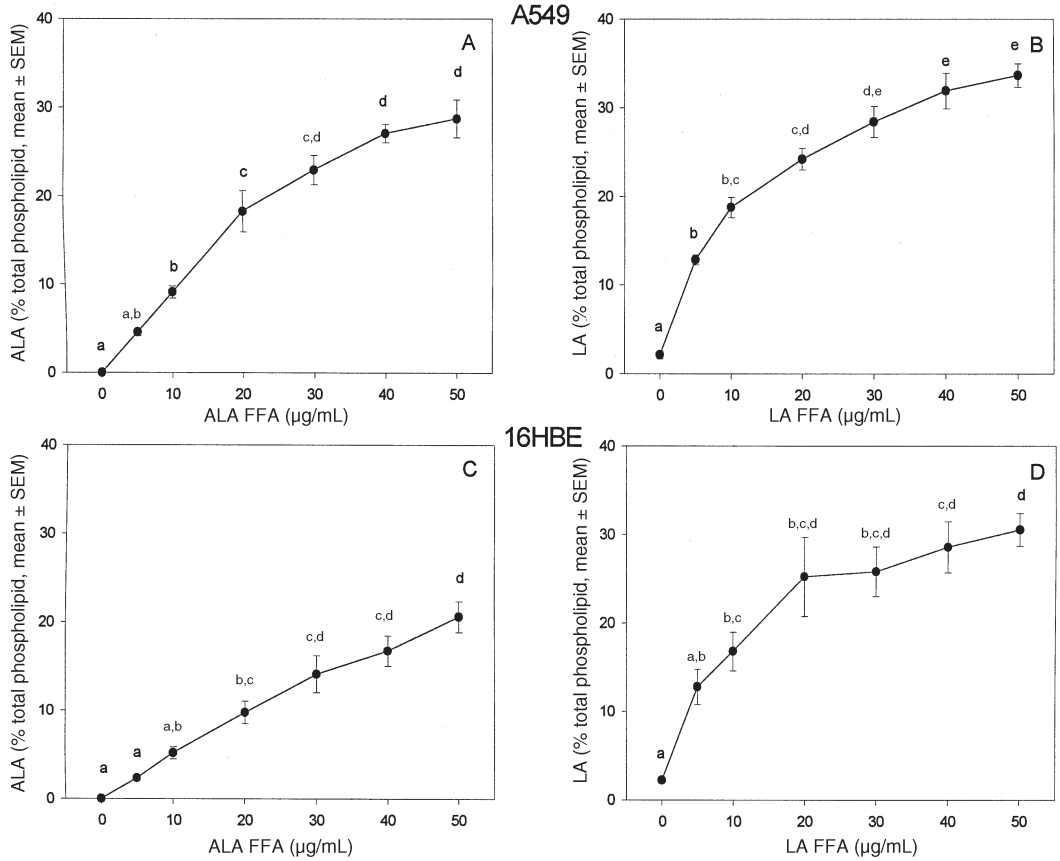

**FIG. 1.** Cell membrane phospholipid α-linolenic acid (ALA) (A,C) and linoleic acid (LA) (B,D) from respiratory epithelial cells A549 (A,B) and 16HBE (C,D) incubated with a range of concentrations of ALA or LA as free fatty acids (FFA). Results from three or four experiments are expressed as a relative percentage of the total fatty acids (mean ± SEM). Points with different superscripts indicate significant differences ($P < 0.05$).

tent in response to supplementation of media with any concentration of LA FFA (Fig. 2D).

*Cell viability.* No difference was seen in cell viability as measured by formazan production by cells grown in ALA or LA up to 50 µg/mL when compared with cells grown in control media (data not shown). There was, however, a significant decrease in cell viability at concentrations of both ALA and LA greater than or equal to 100 µg/mL in both cell lines. This was most likely due to a toxic effect of these high concentrations of FFA, as no toxicity to the maximal added ethanol 0.5% (vol/vol) was demonstrated.

## DISCUSSION

This is the first direct comparison of the incorporation of ALA and LA into human respiratory epithelium *in vitro*. The level of incorporation of LA attained in these experiments is comparable to that reported by Smith and colleagues (15) who showed an increase in LA to 28% of choline phosphoglyceride fatty acids by A549 cells after incubation with albumin-bound LA at a concentration of 85 µM (molar ratio albumin/fatty acid, 1:1). Similarly, ALA at 30 µg/mL has been shown to be readily incorporated into the phosphatidylethanolamine and phosphatidylcholine fractions of human Y79 retinoblastoma cells to a level of 20% with an increase in all other n-3 fatty acids except DHA (16). At lower concentrations of supplemental ALA (10 µg/mL), Y79 cells were able to metabolize and incorporate significant quantities of DHA. This elongation to the 22-carbon LCPUFA DHA or n-6 docosapentaenoic acid from the substrate ALA or LA was not observed in either the A549 or 16HBE respiratory cell lines.

Although ALA concentration did increase substantially in both respiratory cell lines, the incorporation into the A549 cells was higher than that into the 16HBE cells at the same supplemental ALA FFA concentration. This may be due to a decrease in ALA uptake in the presence of higher concentrations of FBS in the culture medium of the 16HBE cells (10%) compared with that of the A549 cells (5%) as observed previously by Tranchant and colleagues (17) in a Caco-2 human intestinal cell line. Alternatively, this may be a property of 16HBE cells.

Addition of ALA and LA to media resulted in small curvilinear effects on EPA and AA levels, respectively, in A549 cells (Figs. 2A,B). Y79 retinoblastoma cells in the presence of ALA showed a similar curvilinear effect of EPA and DHA production and incorporation with increasing ALA concentration (16). The explanation for this curvilinear response of 18-carbon precursors on 20-carbon metabolites is complex. This relationship may be a result of additional substrate for

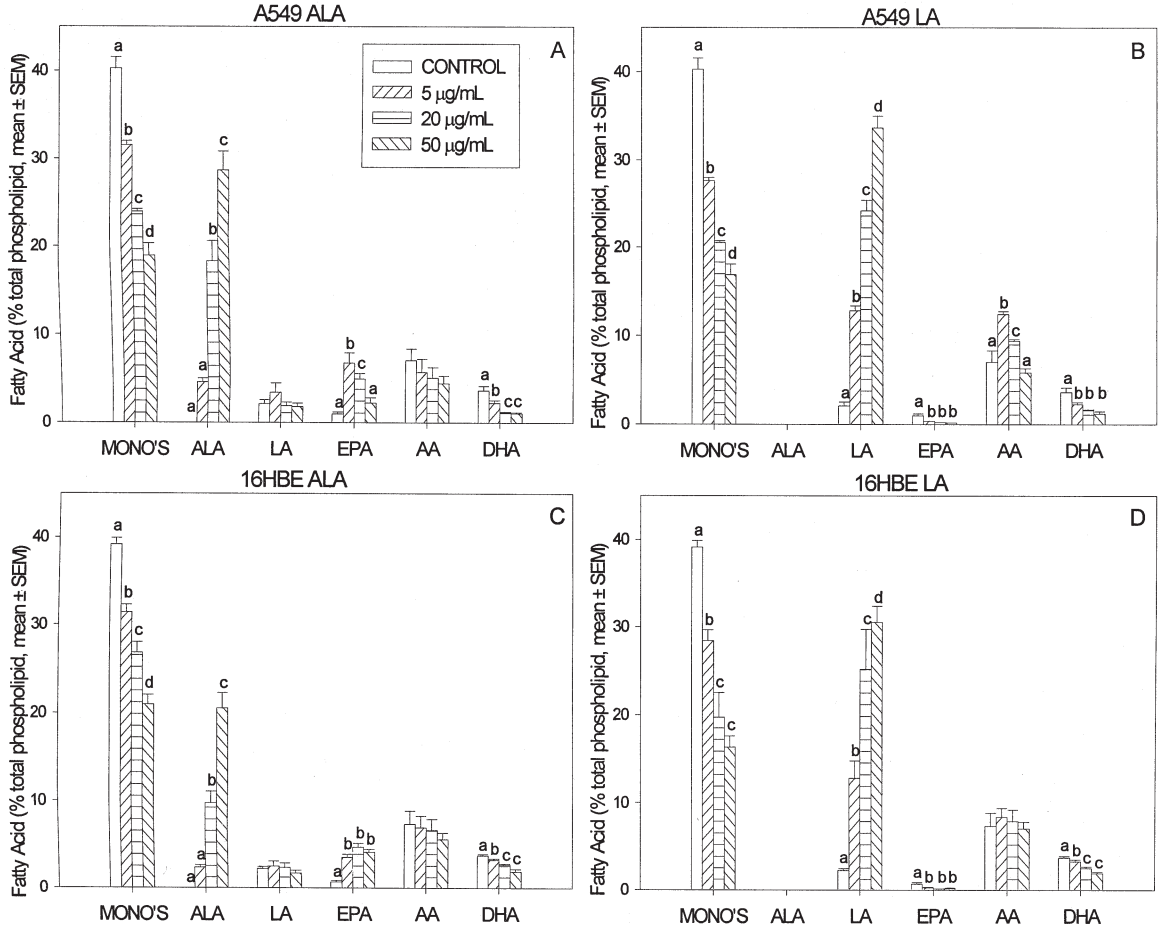

**FIG. 2.** Cell membrane phospholipid polyunsaturated fatty acids after incubation of respiratory cell lines A549 (A,B) and 16HBE (C,D) with differing concentrations of ALA and LA (C,D). Results from three or four experiments are expressed as a relative percentage of the total fatty acids (mean ± SEM). Points with different superscripts indicate significant differences ($P < 0.05$). MONO'S, monounsaturated fatty acids; EPA, eicosapentaenoic acid; AA, arachidonic acid; DHA, docosahexaenoic acid. For other abbreviations see Figure 1.

endogenous synthesis at lower ALA and LA levels offset by competition for incorporation between 18-carbon and 20-carbon fatty acids at the higher ALA and LA levels. Since neither metabolism nor incorporation was measured directly, these hypotheses remain untested. The 16HBE cells, while appearing to be unable to incorporate significant quantities of AA, maintain an increased level of EPA in their membrane even at increasing ALA levels. However, the effects on both 20-carbon LCPUFA are small relative to the changes in 18-carbon fatty acid incorporation achieved in both cell lines.

This study also demonstrates that for both alveolar and bronchial respiratory epithelial cells, incorporation of ALA and LA to levels of 20–33% of total phospholipid causes no measurable decrease in viable cell number and therefore in cell proliferation over the incubation period. There was, however, no stimulatory effect of LA on cell proliferation as shown by Schonberg and Krokan (18) in A549 cells and Usha and colleagues (19) with normal human respiratory epithelial cells incubated with concentrations of LA from 10–40 μM.

Our data support the concept that ALA is readily incorporated into membrane phospholipids, and the lack of incorporation in human and animal tissues *in vivo* may be due to the rapid metabolism or oxidation of this fatty acid to other n-3 PUFA in the liver. However, the relevance of these observations using transformed cell lines needs to be confirmed in normal epithelial cells.

This model provides the basis for examining the potential role for ALA and LA in the regulation of synthesis of mediators of immunity such as cytokines and eicosanoids in these respiratory epithelial cell lines.

# Modeling of α-Tocopherol Loss and Oxidation Products Formed During Thermoxidation in Triolein and Tripalmitin Mixtures

**T. Verleyen[a,*], A. Kamal-Eldin[b], C. Dobarganes[c], R. Verhe[a], K. Dewettinck[d], and A. Huyghebaert[d]**

[a]Department of Organic Chemistry, Coupure Links 653, 9000 Gent, Belgium, [b]Department of Food Science, Swedish University of Agricultural Sciences, 750 07 Uppsala, Sweden, [c]Instituto de la Grasa (CSIC), E-41012 Sevilla, Spain, and [d]Department of Food Technology and Nutrition, Coupure Links 653, 9000 Gent, Belgium

**ABSTRACT:** The degradation of α-tocopherol and the formation of α-tocopherol and triacylglycerol oxidation products at high temperatures (150–250°C) over a heating period (0–4 h) for a model system ranging between triolein and tripalmitin were modeled by use of an experimental design. The oxidation products of α-tocopherol formed under these conditions were α-tocopherolquinone (1.4–7.7%) and epoxy-α-tocopherolquinones (4.3–34.8%). The results indicate a very high susceptibility of α-tocopherol to capture peroxyl radicals upon oxidation, leading to the formation of polar tocopherol oxidation products. Both α-tocopherolquinone and epoxy-α-tocopherolquinones were not stable upon prolonged heating and were further degraded to other unknown oxidation products. The kinetics of α-tocopherol oxidation were significantly influenced by the triolein/tripalmitin ratio. By increasing the level of triacylglycerol unsaturation the rate of α-tocopherol recovery after heating increased significantly from 2.2 to 44.2% whereas in the meantime triacylglycerol polymerization increased from 0 to 3.7%.

Paper no. L8706 in *Lipids 36,* 719–726 (July 2001).

Vegetable oils have different susceptibilities toward oxidative degradation due to differences in fatty acid unsaturation and varying contents of antioxidants. Triacylglycerols rich in polyunsaturated fatty acids are especially prone to oxidation. Tocopherols are the most important natural antioxidants present in vegetable oils (1). The antioxidant properties of tocopherols at low temperatures have been ascribed to the easy hydrogen transfer from their phenolic hydrogen to a peroxyl radical. Hydrogen transfer produces a tocopheroxyl radical, which might combine with another lipid peroxyl radical in a series of termination reactions yielding nonradical oxidation products (2–4).

$$LOO^{\bullet} + TOH \rightarrow LOOH + TO^{\bullet} \quad [1]$$

$$LOO^{\bullet} + TO^{\bullet} \rightarrow TO\text{-}OOL \quad [2]$$

α-Tocopherol (**I**) (Scheme 1) is the main antioxidant for some major frying oils such as high-oleic sunflower, palm and olive oils. The number of studies dealing with the activity of **I** in the inhibition of oxidation reactions at low temperatures is extensive (e.g., 1,5,6), but studies at high temperatures are scarce (7–9). Rapid degradation of tocopherols under accelerated oxidation conditions (e.g., frying and microwave heating) has been reported (10,11).

Oxidation of **I** in model systems was shown to produce various oxidation products of which α-tocopherolquinone (**II**), 4a,5-epoxy-α-tocopherolquinone (**III**), 7,8-epoxy-α-tocopherolquinone (**IV**), α-tocopherol-α-tocopheroxyldimer (**V**), α-tocopherol-α-tocopherolquinonespirodimer (**VI**), α-tocopherolspirodimer (**VII**), and α-tocopherolspirotrimer (**VIII**) have been identified (1,12–17). However, little information is available on the identification and quantification of **I** degradation products formed during oxidation in a lipid matrix, and only **II** and epoxy-α-tocopherolquinone have been identified as the **I** oxidation products in heat-treated oils (18).

At the high temperatures of frying, it is of primary interest to know the evolution of **I** degradation in relation to the fatty acid oxidation process. Scattered research on the influence of triacylglycerol unsaturation on the **I** loss and triacylglycerol polymerization during frying is available. Tocopherols were reported to degrade faster in saturated than in unsaturated oils in simulated deep-frying experiments at 180°C but not at temperatures below 100°C (19–21). According to Reference 9, tocopherol losses were not different in fatty acid matrices of triolein (OOO) and trilinolein.

In this research, we studied the degradation of **I** at high temperatures in a model system of OOO and tripalmitin (PPP) using a statistical central composite design. Special emphasis was undertaken to study the oxidation products formed from both **I** and the triacylglycerols during the heating trials. The kinetics of **I** degradation and formation of identified oxidation products was studied as a function of the heating-time, heating-temperature, and composition of the triacylglycerol matrix.

## MATERIALS AND METHODS

*Materials and reagents.* Pure **I** and silica gel 60 for chromatography were purchased from Merck (Darmstadt, Germany), and technical-grade PPP and OOO were delivered by Sigma Chemical Company (St. Louis, MO). High-performance liquid chromatography (HPLC)-grade solvents (petroleum ether, hexane, 1,4-dioxane, tetrahydrofuran, and methanol) were

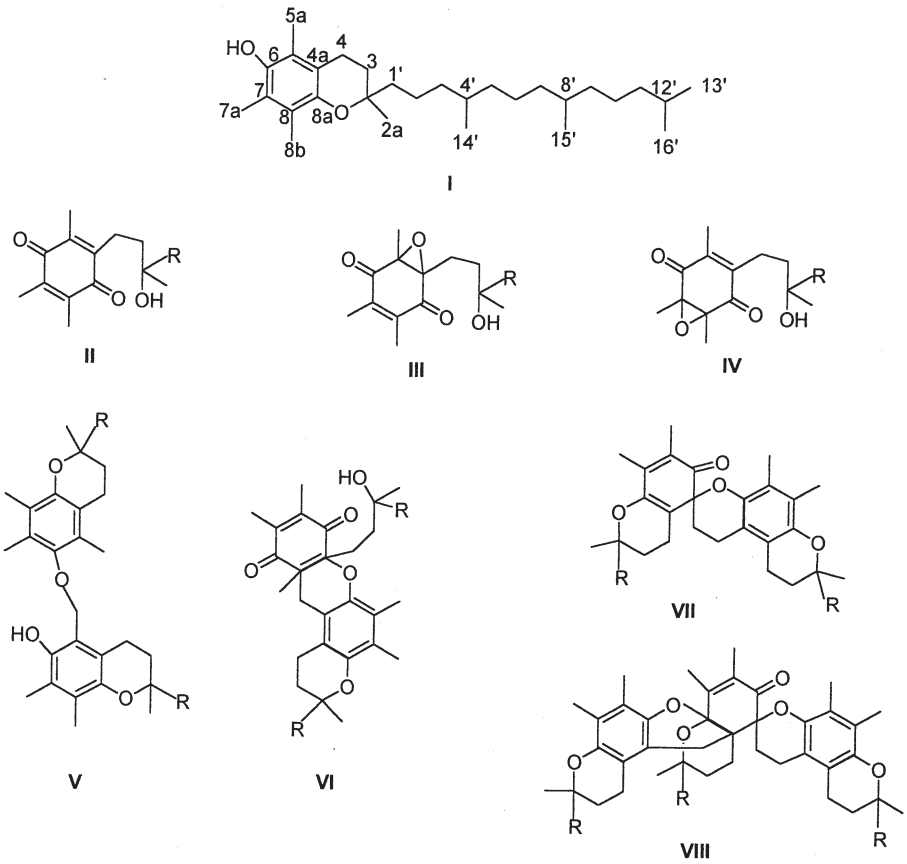
Abbreviations: FAME, fatty acid methyl ester; GC, gas chromatography; HPLC, high-performance liquid chromatography; HPSEC, high-performance size exclusion chromatography; IUPAC, International Union of Pure and Applied Chemistry; NMR, nuclear magnetic resonance; OOO, triolein; PPP, tripalmitin; UV, ultraviolet.



**SCHEME 1**

purchased from Merck. Water was distilled twice and additionally purified with activated char. All chemicals and reagents were of analytical grade and were used without further purification.

*Characterization of the technical OOO and PPP used in the study.* Technical-grade OOO and PPP were selected, owing to financial considerations, as the model triacylglycerols instead of highly purified standards. These materials were characterized by analysis of fatty acid composition, triacylglycerol distribution, and tocopherol content. Fatty acid composition was determined after derivatization to fatty acid methyl esters (FAME) with 2 N KOH in methanol according to the International Union of Pure and Applied Chemistry (IUPAC) Standard Method (22). Gas chromatography (GC) of FAME was performed on an HP 6890 chromatograph using HP Innowax capillary column (polyethylene glycol, 30 m × 0.25 mm internal diameter, film thickness 0.25 μm) (Hewlett-Packard, Avondale, PA) under the following temperature program: 180ºC (2 min), 4°C/min to 230°C. Samples were introduced to the column *via* a split injector (split ratio 1:40) at 250°C and the flow rate of hydrogen, used as carrier gas, was 1 mL/min. Temperature of both split injector and flame-ionization detector was 250ºC. The distribution of triacylglycerols was analyzed by GC on a fused-silica capillary column Restek RTX–65TG (35% dimethyl/65%diphenyl polysiloxane cross-bonded, 30 m length × 250 μm internal diameter, Hewlett-Packard) with programming from 300ºC (held for 1 min) to 360°C at 2ºC/min. The temperatures of the injector and detector were set at 370ºC. Samples were dissolved in hexane to a concentration of 1 mg/mL, and 1-μL portions were used for injection. The other fatty acids present in these samples (only identifiable components present in a concentration >1% are listed) are shown in Table 1. Technical-grade PPP (92.5% palmitate residues) contained small amounts of other saturated fatty acids, but the quality of technical OOO (73.1% oleate residues) was much inferior as it contained 5.8% linoleate residues, 8.5% saturated acyl residues, and 12.6% of a wide range of other acids present at <0.5% levels. We do not consider this quality problem as limiting to the conclusions of this study. No tocopherols could be detected in these materials.

*Synthesis of **I** oxidation products.* Several known oxidation products of **I** have been synthesized, purified, and authenticated as described below. Nuclear magnetic resonance (NMR) spectrometry was performed on a Jeol JNM-EX270 spectrophotometer (Tokyo, Japan). $^{1}$H NMR and $^{13}$C NMR spectra were recorded in deuterated solvents with tetramethylsilane as internal standard at 270 and 68 MHz, respectively.

α-Tocopherolquinone (**II**) was obtained by oxidation of **I** with ferric chloride (23,24), and **III** and **IV** were prepared according to a method modified from Csallany and Ha (25). Compounds **V** and **VI** were prepared by oxidation of **I** with *tert*-butylhydroperoxide (13,14), and compounds **VII** and **VIII** were prepared by oxidation of **I** with alkaline ferricyanide

[b]Main minor compounds are diacylglycerols.

(12,15,26–28). All spectral data of the components synthesized matched the spectral data reported in the literature cited.

*Thermoxidation of model triacylglycerol mixtures*. A full-factorial Central Composite Design was selected to study the influence of the factors (temperature, heating time, and fatty acid composition expressed as % OOO) on the degradation of **I** and the formation of identified oxidation products from **I** and triacylglycerols. Five levels (−2, −1, 0, +1, +2) were used for each of the three factors: OOO (0, 25, 50, 75, 100%), temperature (150, 175, 200, 225, 250°C), and heating time (0, 1, 2, 3, 4 h). The initial **I** content in the different triacylglycerol mixtures was 1000 ppm. For the heat treatment, oil samples (5 g) were weighed in tubes (22 mm i.d.) and placed in an oven preheated at the desired temperature. No air bubbling was applied during the heating, and the tubes were left open. After heating, the samples were transferred in glass tubes, purged with nitrogen and sealed until the time for analysis.

*HPLC analysis of **I** and its oxidation products.* The contents of residual **I** in thermoxidized oils were analyzed directly by normal-phase HPLC, and the content of **I** and its oxidation products was analyzed, after extraction and concentration in methanol, by reversed-phase HPLC.

Normal-phase HPLC was conducted on equipment consisting of compact Bischoff model 2250 HPLC pump (Leonberg, Germany) connected to a Midas version 1.3 auto-injector (Spark Holland BV, AJ Emmen, The Netherlands) and a LaChrom L-7480 fluorescence detector (Merck-Hitachi, Tokyo, Japan). Data were collected and processed by the software of Chromeleon version 4.12 (Gynkotek GmbH, Germering, Germany). HPLC separations were performed on an Alltima 5 μm, 250 × 4.6 mm i.d. silica column (Alltech, Deerfield, IL). The mobile phase, hexane/1,4-dioxane (96:4, vol/vol), was pumped at a flow rate of 1.5 mL/min. Fluorimetric detection of the **I** peak was performed at an excitation wavelength of 294 nm and an emission wavelength of 326 nm, and quantification of the amount of **I** was made using external standard calibration.

Enrichment of the residual **I** and polar **I** oxidation products was performed by extraction of oil samples (2 g) with hot methanol (3 × 8 mL) followed by centrifugation (18). Upon cooling of the combined methanol extracts, some crystals of co-extracted PPP were observed. The extract was evaporated to dryness and redissolved in methanol (1 mL). The clear methanol fraction was removed and analyzed by reversed-phase HPLC, whereas the PPP crystals were dissolved in hexane (1 mL) and analyzed for residual **I** content by normal-phase HPLC using fluorescence detection. A direct analysis of residual **I** by normal-phase HPLC allowed us to calculate the recovery of the **I** extraction procedure. The recovery factor for **I** was 35 ± 4.6% ($n$ = 20), which is rather low but was very reproducible.

Reversed-phase HPLC of **I** and its oxidation products was performed on an HP series 1100 chromatograph equipped with a diode array detector (Hewlett-Packard). Separations were performed on an Econosil C18 5 μm, 250 × 4.6 mm internal diameter column (Alltech). The solvent mixture and applied solvent gradient were optimized to obtain a good separation, within 17 min, of **III**, **IV**, **II**, and residual **I** starting with methanol/water (80:20, vol/vol) and increasing to 100% methanol within 4 min. The **III**, **IV**, and **II** were quantified by their ultraviolet (UV) maximal adsorption at 275 nm, whereas **I** was analyzed at a wavelength of 292 nm. Quantification of **I** and the identified oxidation products was performed using standard **I** and the synthesized oxidation products for external calibration. The contents of **I** and its oxidation products were calculated using the recovery factor of **I** determined by normal-phase HPLC (*vide supra*). In the study, all concentrations are expressed as percentages, relative to the initial **I** concentration of 1000 ppm.

*Quantification of total polymers.* Polymeric triacylglycerols were quantified by high-performance size exclusion chromatography (HPSEC) following the IUPAC Standard Method (22). Conditions applied for HPSEC were as follows: A Rheodyne 7725i injector (Cotati, CA) with a 10-μL sample loop and a Waters 510 HPLC pump (Waters Associates, Milford, MA), two 100 and 500 Å Ultrastyragel columns (Waters Associates), 25 × 0.77 cm internal diameter, packed with a porous, highly cross-linked styrenedivinylbenzene copolymer (<10 mm), connected in series, and a refractive index detector (Hewlett-Packard) were used. Tetrahydrofuran was the mobile phase with a flow of 1 mL/min, and sample concentration was around 50 mg/mL in tetrahydrofuran.

*Quantification and distribution of polar compounds.* Nonpolar and polar fractions from 50 mg of sample were separated by solid-phase extraction using monostearin as internal standard in 1-g Sep-Pak cartridges (Waters). The nonpolar fraction containing unoxidized triacylglycerols was eluted with 15 mL of *n*-hexane/diethyl ether (90:10, vol/vol), and the second fraction, comprising total polar compounds, was eluted with 15 mL of diethylether. The efficiency of the separation by adsorption chromatography was checked by thin-layer chroma-

tography using *n*-hexane/diethylether/acetic acid (80:20:1, by vol) for development of plates and exposure to iodine vapor to reveal the spots. The polar fraction obtained was dissolved in tetrahydrofuran to a concentration of 15 mg/mL for analysis by HPSEC using the conditions described above for the direct analysis of polymers. Quantification of polar compounds was achieved through the internal standard method (29). The experiments having a triacylglycerol composition with PPP concentration higher than 50% could not be analyzed as these samples were not soluble in the solvent used for the elution of unoxidized triacylglycerols (*n*-hexane/diethylether, 90:10, vol/vol), thus decreasing the efficiency of separation.

*Selection of experimental model equation.* A full-factorial Central Composite Design was selected to study the influence of the different factors (time, temperature, and triacylglycerol composition expressed as % OOO) on the responses (residual **I**, formation of **I** oxidation products, and total triacylglycerol polymer content). Establishment of the response surface quadratic models was done with Design Expert® (Stat-Ease, Minneapolis, MN) by evaluation of the analysis of variance. The best model (linear or quadratic) was selected by interpretation of the Sequential Model Sum of Squares, which was highly significant ($P < 0.0001$) and showed no lack of fit ($P > 0.05$). The complete quadratic model contains 10 different terms (linear, quadratic, and interaction terms), which makes handling the model equations very complicated in practice. Therefore, a reduced quadratic model was derived by elimination of the nonsignificant individual factors ($P > 0.05$).

## RESULTS AND DISCUSSION

In accordance with expectations, heating of the triacylglycerol mixtures caused a marked reduction in residual **I** level and increased the formation of total polar materials, mainly polymers and oxidized monomers, from triacylglycerols (Table 2). These results indicate a very fast degradation of **I** upon heating, giving rise to a recovery between 1.5 and 44.2% of **I**. Analytical data concerning triacylglycerol polymer content indicate a low total polymerization level ranging between 0.1 and 3.7%, except for samples containing 50 and 75% OOO heated at 250 and 225°C, respectively, where higher polymerization levels (>10%) were found. The results from the sample that did not receive heat treatment clearly indicate that the total polar fraction is mainly composed of diacylglycerols and free fatty acids initially present in the technical-grade OOO and PPP (Table 1). Depending on the experimental conditions, polymers and oxidized triacylglycerol monomers are formed to different extents, ranging between 0.2 and 11.1% and 0.6 and 6.1%, respectively.

Upon oxidation, **I** is known to degrade to a wide range of oxidation products (Scheme 1), but some are not easy to analyze owing to the lack of strong fluorescence of the chro-

manol structure. Direct analysis of these tocopherol oxidation products was therefore not possible, and an enrichment step was necessary. Enrichment was performed by extraction of residual **I** and its polar oxidation products with hot methanol (18). Several peaks were present in the reversed-phase HPLC chromatogram of the methanol extract (Fig. 1). The components eluting at 10.4, 10.7, 12.5, and 15.5 min were identified as **IV**, **III**, **II** and **I**, respectively, because their retention times matched those of **I** and chemically synthesized oxidation products. These results are in accordance with the report of Murkovic *et al.* (18), who found marked formation of epoxy-α-tocopherolquinones during thermoxidation. Identification of the other peaks was not possible, but these may include oxidation products from OOO.

As mentioned in the Materials and Methods section, a recovery factor of 35 ± 4.6% was determined for the methanol extractability of **I** using normal-phase HPLC. A good correlation ($R^2 = 0.9916$) was obtained between the residual **I** concentration analyzed by normal-phase and that analyzed by reversed-phase HPLC using the determined recovery factor. This indicates that the applied extraction procedure had a good reproducibility and was influenced neither by the con-

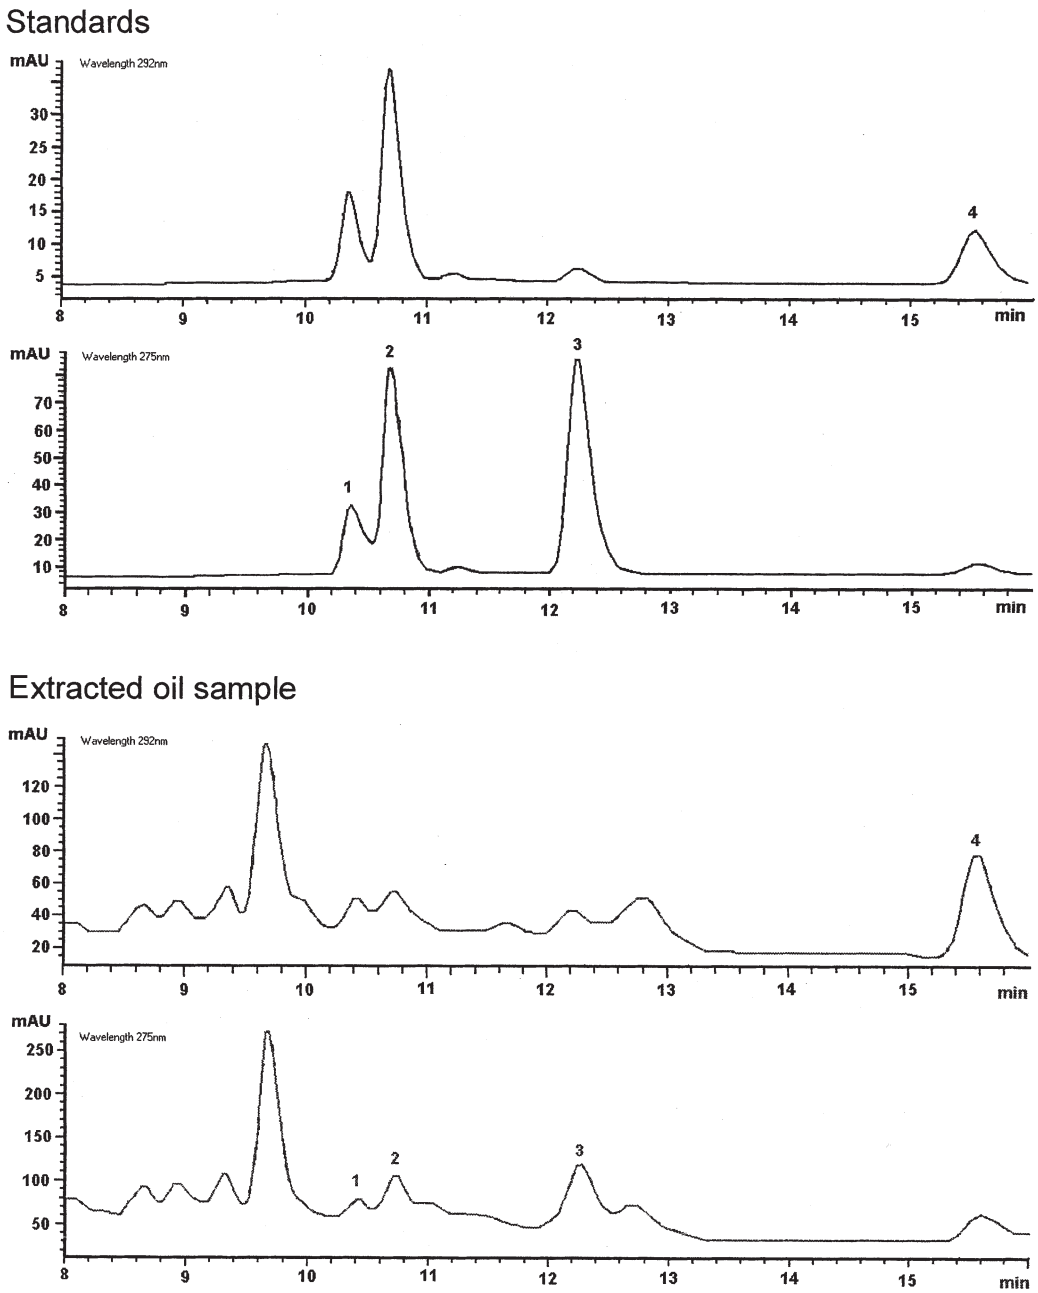

**FIG. 1.** Reversed-phase high-performance liquid chromatograms of standards and extracted oil samples with an ultraviolet detector at 275 nm for oxidation products and 292 nm for residual α-tocopherol. 7,8-Epoxy-α-tocopherolquinone (1), 4a,5-epoxy-α-tocopherolquinone (2), α-tocopherolquinone (3), and α-tocopherol (4).

centration of the oxidation products nor by the composition of the triacylglycerol matrix; this also allows further interpretation of the quantitative results. A similar recovery factor as determined for **I** was assumed for the **I** oxidation products. Although this assumption might not be perfectly right, only small variations in recovery factors were expected without major effects on the conclusions of this study. Epoxy-α-tocopherolquinones were the major identifiable **I** oxidation products present in the concentration range 4.3–34.6% of initial **I** concentration, whereas **II** was present in a much lower concentration range, 1.4–7.7%. Upon extraction of the oil with methanol, only the polar **I** oxidation products should be extracted leaving the nonpolar **I** oxidation products (**V**–**VII**) behind in the oil. Normal-phase HPLC analysis of the extracted oil residues with UV detection (250–292 nm) or fluorescence detection (excitation 294 nm, emission 326 nm) gave no positive detection of **V**, **VI**, **VII**, and **VIII**. Whether this result is due to the absence or instability of these products warrants further investigation.

The formation of **III**, **IV**, and **II** suggests these as degradation products of **I** peroxides formed at the 5, 7, and 8a positions, respectively. The origin of the peroxyl radicals that combine with α-tocopheroxyl to form the precursor adducts discussed above is not known since both peroxyl radicals and hydroperoxides are very unstable at these high temperatures. Moreover, the fast degradation of **I** in a reaction mixture containing only PPP (Experiment No. 20, Table 2) does not support participation of peroxyl radicals from fatty acid moieties. Degradation of **I** might have occurred by reaction of resonance forms of tocopheroxyl radicals with oxygen, although this reaction was found to have a very low rate at low temperatures (30). The predominance of **III** over **IV** is in accordance with the work of Nilsson *et al*. (31) showing increased reactivity at the 5- compared to the 7-position. Breakdown of these peroxides will generate alkoxyl radicals; in the case of 5- and 7-adducts, these radicals will cyclize to epoxy radical species with carbon-centered radicals at the 8a position, which capture oxygen and form 8a-hydroperoxyl derivatives. Further degradation of 8a-hydroperoxy-4a,5-epoxy-α-tocopherol, 8a-hydroperoxy-7,8-epoxy-α-tocopherol, and 8a-hydroperoxy-α-tocopherol will generate **III**, **IV**, and **II**, respectively.

The data in Table 2 were fitted into response surface quadratic models, and the "best" models (linear, quadratic) were selected by evaluating the Sequential Model Sum of Squares and choosing the significant model ($P < 0.0001$) having a good lack of fit test ($P > 0.05$). An overview of the lack of fit probabilities and the model correlation coefficients for the different analyses is listed in Table 3. As indicated by these results, within the range of the experimental study, the following models could be established:

$$\alpha\text{-tocopherol (\%)} = 187.88 - 43.57x - 1.22y + 0.25z + 3.87x^2 + 2.181 \times 10^{-3}y^2 + 7.200 \times 10^{-3}z^2 + 0.12xy - 0.13xz - 1.970 \times 10^{-3}yz \quad [3]$$

$$\text{total epoxy-}\alpha\text{-tocopherolquinones (\%) (4a,5- + 7,8-epoxy-}\alpha\text{-tocopherolquinone)} = -271.49 + 74.29x + 2.19y + 0.79z - 0.4x^2 - 4.196 \times 10^{-3}y^2 - 4.402 \times 10^{-3}z^2 - 0.34xy - 0.071xz - 7.549 \times 10^{-4}yz \quad [4]$$

$$\alpha\text{-tocopherolquinone (\%)} = -7.52 + 8.67x + 0.021y + 0.12z - 0.66x^2 - 5.368 \times 10^{-4}z^2 - 0.028xy \quad [5]$$

$$\text{triacylglycerol polymer (\%)} = 88.51 - 8.27x - 0.85y - 0.23z + 1.925 \times 10^{-3}x^2 + 0.047xy + 1.440 \times yz \quad [6]$$

where $x$ = thermoxidation time (h); $y$ = temperature (°C); $z$ = technical triolein (%).

By applying the above listed model equations the influence of the different factors on the kinetics of residual **I**, formation of **I** oxidation products, and triacylglycerol polymerization can be represented in perturbation graphs where one factor is varied within the established model borders while keeping the other two factors constant at their center point (Fig. 2). The time factor had a major influence on the degradation of **I** (Fig. 2A). After heating the triacylglycerol mixture containing 50% OOO for 1 h at 200°C, the **I** content decreased to 20%; after 3 h no residual **I** was present. Within the studied time interval, little influence of heating time on the concentrations of **III**, **IV**, and **II** was observed. This is indicative for an equilibrium between the formation of new epoxy-α-tocopherolquinone and their further degradation to unknown oxidation products. Murkovic *et al.* (18) reported a notable decrease in epoxy-α-tocopherolquinone concentration after 4 h heating at 220°C.

The influence of temperature on the degradation of **I** (Fig. 2B) can be evaluated by considering the decrease in residual **I** content, after heating the triacylglycerol mixture of 50% OOO for 2 h, at 175 and 225°C to 12.1 and 2.0%, respectively. By increasing the temperature above 175°C a gradual decrease in the epoxy-α-tocopherolquinone concentration is observed, whereas the level of **II** seems not to be affected by temperature. This indicates degradation of the epoxy-α-tocopherolquinone at high temperatures to unidentified oxidation products. At moderate

**TABLE 3**
**Overview of the Statistical Data of the Models Established for the Different Analyses**

| Analysis[a] | Model quadratic | Lack of fit | Correlation ($R^2$) |
|---|---|---|---|
| α-Tocopherol NP | ($P < 0.0001$) | 0.2365 | 0.9851 |
| α-Tocopherol RP | ($P < 0.0001$) | 0.0463 | 0.9706 |
| α-Tocopherol-quinone-epoxide | ($P < 0.0001$) | 0.2960 | 0.9814 |
| α-Tocopherolquinone | ($P < 0.0001$) | 0.3025 | 0.8658 |
| Total polymers | ($P < 0.0001$) | 0.0625 | 0.8881 |

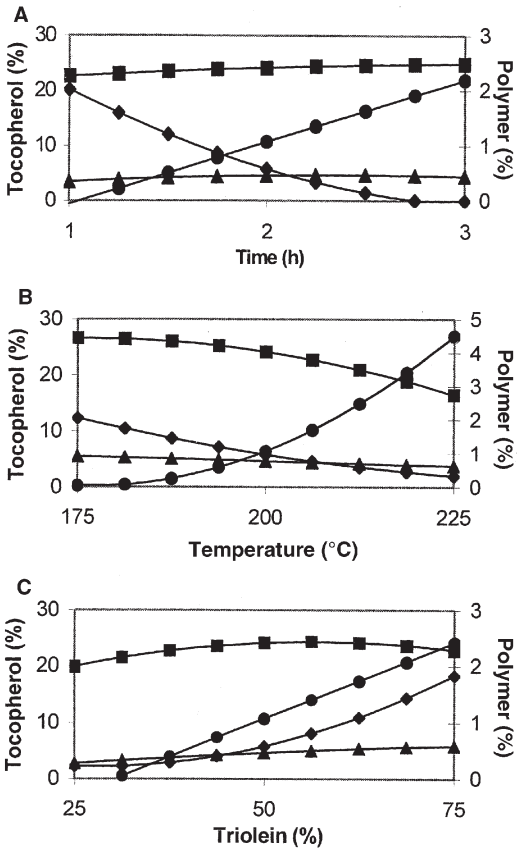

**FIG. 2.** Influence of time, temperature and triacylglycerol composition on evolution of α-tocopherol (◆), epoxy-α-tocopherolquinone (■), and α-tocopherolquinone (▲) concentrations relative to an initial α-tocopherol concentration of 1000 ppm; total triacylglycerol polymer content (●). (A) Temperature 200°C, triolein 50%; (B) time 2 h, triolein 50%; (C) time 2 h, temperature 200°C.

temperatures (175–200°C), low triacylglycerol polymer contents are formed (0–1%). However, small temperature increments above 200°C greatly accelerated the rate of polymerization, leading to a polymer content of 10.9% at 250°C.

The influence of the triacylglycerol composition on the degradation kinetics of **I** is very interesting (Fig. 2C). By increasing triacylglycerol unsaturation, the rate of **I** oxidation decreased although the triacylglycerol polymerization increased. When triacylglycerol mixtures containing 25:75, 50:50, 75:25, and 100:0 (w/w) of OOO/PPP were heated for 2 h at 200°C, the residual **I** concentrations were 2.2, 5.8, 18.3, and 44.2% and the total polymer percentages were 0, 0.3, 2.4, and 3.7%, respectively. These results are in agreement with Jorge *et al.* (19,20), who reported faster degradation of **I** in less unsaturated oils. These seemingly paradoxical results can be explained by considering involvement of peroxyl and alkoxyl radicals. As mentioned, the adduct products of α-tocopheroxyl and peroxyl radicals are unstable, and upon degradation they form the epoxy-tocopherones and tocopherolquinone after generation of alkoxyl radicals, which initiate new chain reactions. Alkoxyl radicals are not selective in their reactions, and unsaturated fatty acids will compete with **I** in these reactions. Saturated fatty acids, on the other hand, will stay inert, and only **I** will be oxidized by alkoxyl and peroxyl radicals. In line with this explanation is the finding of Barrera-Arellano (9) that **I** losses in OOO and trilinolein were independent of the fatty acid unsaturation, i.e., the difference in oxidizability between oleate and linoleate might not be sufficient to influence the rate of **I** oxidation significantly.

**TABLE 4**
**Model Calculated Values Indicating Interaction Between Variables (time, temperature, and OOO content)[a]**

| Time (h) | Temp. (°C) | Triolein (%) | Concentration (%) α-T | ETQ | TQ | TPol |
|---|---|---|---|---|---|---|
| Time and temperature (*x* and *y*) | | | | | | |
| 1 | 175 | 50 | 29.7 | 16.6 | 3.7 | 0.1 |
| 1 | 225 | 50 | 13.5 | 23.4 | 3.3 | 2.2 |
| 3 | 175 | 50 | 2.6 | 35.8 | 6.0 | 0 |
| 3 | 225 | 50 | 0 | 8.7 | 2.9 | 6.8 |
| Time and triolein % (*x* and *z*) | | | | | | |
| 1 | 200 | 25 | 13.5 | 16.6 | 1.6 | 0 |
| 1 | 200 | 75 | 35.9 | 23.1 | 4.7 | 1.3 |
| 3 | 200 | 25 | 0 | 22.4 | 2.6 | 0.8 |
| 3 | 200 | 75 | 8.51 | 21.8 | 5.7 | 3.5 |
| Temperature and triolein % (*y* and *z*) | | | | | | |
| 2 | 175 | 25 | 7.5 | 21.9 | 3.6 | 0 |
| 2 | 175 | 75 | 26.0 | 25.8 | 6.7 | 0.5 |
| 2 | 225 | 25 | 0 | 12.7 | 1.9 | 2.2 |
| 2 | 225 | 75 | 13.3 | 14.7 | 5.0 | 6.8 |

[a]OOO, triolein; α-T, α-tocopherol; ETQ, epoxy-α-tocopherolquinone; TQ, α-tocopherolquinone; TPol, total polymer content.

Interaction terms between time and temperature (*x* and *y*), time and triacylglycerol composition (*x* and *z*), and temperature and triacylglycerol composition (*y* and *z*) are present in the model equations for the levels of **I**, epoxy-α-tocopherolquinone, **II**, and triacylglycerol polymers. Owing to the presence of interaction terms, some of the previously observed effects will be highlighted at a position away from the center point. Some calculated values indicating these interactions are listed in Table 4. The slowest rate of tocopherol oxidation and lowest levels of oxidation products are found at low temperatures in an unsaturated triacylglycerol matrix. As indicated, temperature and triacylglycerol composition have a strong influence on the residual **I** content, whereas their influence on the level of epoxy-α-tocopherolquinone and **II** is much smaller. Extremely fast degradation of tocopherols is observed at high temperatures in a saturated triacylglycerol matrix. However, under these conditions the identified tocopherol oxidation products will quickly degrade to further unknown oxidation products. For unsaturated triacylglycerol levels, the polymerization is mainly determined by time and is strongly dependent on the applied temperature. At 200°C the linear increase in polymer content is 1.07%/h whereas at 225°C the linear increase in polymer content is 2.3%/h.

The results of this study suggest a very high susceptibility of **I** to oxidize during thermoxidation and to form **II**, **III,** and **IV** as oxidation products. The mechanism behind the conversion of **I** to oxygenated products is not fully understood and might in-

volve direct reaction with oxygen. Both **II** and **III**, **IV** were not stable, and upon prolonged heating at high temperatures a further degradation to other unknown oxidation products was observed. The rate of **I** oxidation decreased by competitive oxidation of unsaturated triacylglycerols and was significantly increased by elevated temperatures. At high temperatures, the protection provided to unsaturated fatty acids by **I** is reduced due to increased instability of this antioxidant. Further studies to confirm this hypothesis are under way in our laboratory.

**ABSTRACT:** The chain length and geometric isomerism of polyprenols from *Eucommia ulmoides* Oliver were analyzed using supercritical fluid chromatography. After intensive effort to establish separation conditions for geometric isomers, a phenyl-bonded silica gel-packed column was found that cleanly separated poly-*trans* and -*cis* prenols. The presence of long-chain poly-*trans* prenols (>9 mers) was confirmed for the first time in plants. *Trans* isomers were found in the leaf, seed coat, and root, but not in the bark and seed. Poly-*trans* prenols in this plant may act as intermediates for *trans*-polyisoprene biosynthesis.

Paper no. L8748 in *Lipids 36*, 727–732 (June 2001).

More than 2000 plant species are known to produce rubber (1). The latex of the Para rubber tree, *Hevea brasiliensis*, contains large amounts of polyisoprenes that can be processed to give elastic natural rubber. A woody plant, *Palaquium gutta*, produces hard rubber, or gutta-percha. It is assumed that polyisoprene is formed by a polymerization chain reaction between an allyl substrate, e.g., geranylgeranyl pyrophosphate, and a large number of isopentenyl pyrophosphate (IPP) molecules (2). However, chain-length regulation mechanisms and the geometry of the natural polyisoprene chains have not been fully elucidated.

Besides the rubber fractions, polyprenols with relatively small molecular weights, such as dolichols, are found in almost all organisms; the latter play an important role in glycoprotein biosynthesis (3). Interestingly, dolichols are found in a variety of organisms. We have been investigating polyisoprenoid biosynthesis. As the first step in studying rubber biosynthesis, it is necessary to characterize the polyprenol fraction, which contains low molecular weight polyisoprenoids. A detailed analysis of polyprenols provides many important clues to their biosynthesis, leading to understanding of rubber biosynthesis.

Polyprenols are linear polymers of $C_5$ isoprene units with a primary alcohol group at the terminal end. In 1956, solanesol was first isolated from tobacco as a novel unsaturated alcohol, and the geometry of all of the double bonds was elucidated to be *trans* (4). Many studies have been accumulated on the structure and the chain length of polyprenols (5–7). However, all of the structures of polyprenols so far reported are tri- or di-*trans* poly-*cis* except for the case of solanesol. Profiles of polyprenol contents in plants have been also analyzed from the chemotaxonomic point of view. The results indicate that individual plant species are characterized by the presence of a variety of polyprenols with different polymerization degrees and by the separation patterns.

In the course of elucidating polymerization mechanisms of polyisoprenoids in plants, we have established a new method for analyzing polyprenol fractions. To develop high-resolution analysis of polyprenols, a variety of chromatographic conditions were tested. Previously, Swiezewska *et al.* (8) reported a conventional polyprenol separation method using reversed-phase high-performance liquid chromatography (HPLC). Their findings showed that *Prunus kurilensis* has a broad distribution pattern of polyprenols with two distribution peaks centering at 19 and 34 mers. In comparison, *Cornus mas* has a unimodal and comparatively narrow distribution.

By using similar separation conditions with a $C_{18}$ reversed-phase column, polyprenols from rubber-producing plants were analyzed. Among the plants examined, the *n*-hexane-soluble fraction of the woody plant, *Eucommia ulmoides* Oliver (Hardy rubber tree), showed an unusual separation profile, suggesting the presence of polyprenol geometric isomers.

In this paper, we report the successful separation of polyprenol isomers by supercritical fluid chromatography (SFC), together with the characterization of the polyprenol components by means of spectral analyses.

## MATERIALS AND METHODS

*Materials.* Prenol C80-110 was purchased from Sigma Chemical Company and carbon dioxide (99.9%) from Daiwa Youzai (Osaka, Japan). Ethanol, for use as a modifier for SFC, was obtained from Wako Chemicals (Osaka, Japan) and was of >99.5% purity. For HPLC-analyses, HPLC grade methanol, 2-propanol, and *n*-hexane were used (Wako Chemicals). Water was purified with a Millipore Milli-Q system (Bedford, MA).

Plant samples of *E. ulmoides* were collected in July 2000 at the Hitachi Zosen Corporation experimental station (Habu 2264-1 Innoshima, Hiroshima, Japan).

*To whom correspondence should be addressed. E-mail: kobayashi@bio.eng.osaka-u.ac.jp

Abbreviations: HPLC, high-performance liquid chromatography; IPP, isopentenyl pyrophosphate; MS, mass spectrometry; NMR, nuclear magnetic resonance; SFC, supercritical fluid chromatography; UV, ultraviolet.

*Analysis by HPLC.* HPLC of polyprenols was performed on a reversed-phase column, Inertsil ODS-3 (250 × 4.6 mm i.d.; particle size, 5 μm; pore size, 100 Å; surface area, 450 $m^2$/g; GL Sciences, Tokyo, Japan), using a dual pump apparatus (Hitachi L7100; Hitachi, Tokyo, Japan), and an ultraviolet (UV) detector (set at 210 nm, L7420; Hitachi). A column oven (set at 40°C; L7300, Hitachi), a degasser (L7610, Hitachi), and a data station (SIC-480II data station; System Instruments, Tokyo, Japan) were used. For elution, a gradient was applied from an initial methanol 2-propanol/water mix (60:40:5, by vol) in pump A to 100% *n*-hexane/2-propanol (70:30, vol/vol) in pump B. The solvent flow rate was 1 mL/min and the end of the gradient was reached after 40 min.

*Analysis by SFC.* SFC analyses were performed on Inertsil ODS-3 (250 × 4.6 mm i.d.; particle size, 5 μm; pore size, 100 Å; surface area, 450 $m^2$/g; GL Sciences), Inertsil Ph-3 (250 × 4.6 mm i.d.; particle size, 5 μm; pore size, 100 Å; surface area, 450 $m^2$/g; GL Sciences) and Develosil C30-UG (250 × 4.6 mm i.d.; particle size, 5 μm; pore size, 140 Å; surface area, 300 $m^2$/g; Nomura Chemical, Aichi, Japan) columns using a Super-201 Chromatograph (JASCO, Tokyo, Japan). The system consisted of two pumps, one for delivery of liquid $CO_2$ as a mobile phase (flow rate = 3.0 mL/mim) and the other for delivering ethanol as a modifier. The ethanol flow rate (0.8 mL/min) was increased to 2.0 mL/min within the experimental time of 30 min. The fluid pressure was controlled at 19.6 MPa by back-pressure regulator. The column temperature was set to 130°C (ODS-3 column) and 100°C (Ph-3 column). Chromatograms were recorded using a UV detector (950-UV, JASCO) operating at a wavelength of 210 nm. For preparative SFC, Inertsil Ph-3 (250 × 10 mm i.d.; particle size, 5 μm; pore size, 100 Å; surface area, 450 $m^2$/g; GL Sciences) was used with the following flow rates for $CO_2$: 8.0 mL/min; ethanol: 2.3 to 5.5 mL/min within 30 min, and 5.5 mL/min thereafter.

*Evaluation of analysis.* The resolution ($R_s$) between octadecaprenol (prenol 18) and nonadecaprenol (prenol 19) was calculated using SIC-480II.

*Extraction and isolation of polyprenols from* E. ulmoides. *Eucommia ulmoides* leaf, bark, seed, seed coat, and root were heated in an oven at 95°C for 3 h and then ground for 1 min using a blender. The ground parts (2 g) were then treated with alkali (40 mL of 11.2% ethanolic potassium hydroxide containing 2% pyrogallol) for 2.5 h at 100°C. The saponifiable lipid was extracted with *n*-hexane, and then the resulting concentrate was weighed. The saponifiable lipid portion (5 mg) was loaded onto a Silica gel Sep-Pak column (Waters, Milford, MA). The column was washed thoroughly with 30 mL of *n*-hexane/ ethyl ether (98:2, vol/vol) and nonpolar lipids containing free polyprenols were eluted with 50 mL of *n*-hexane/ethyl ether (85:15, vol/vol). The samples for reversed-phase HPLC were pretreated with $C_{18}$ Sep-Pak (Waters). Polyprenols were eluted with *n*-hexane/2-propanol (7:3, vol/vol).

A large-scale preparation for spectral analysis was made by preparative SFC using samples 10–20 times larger than those at analytical scale.

*Nuclear magnetic resonance (NMR) and mass spectrometry (MS) measurements.* Mass spectra were determined in the field-desorption mode with a JMS-DX303 spectrometer (JEOL, Tokyo, Japan). $^1$H NMR spectra were obtained with a Varian Unity Inova 750 MHz NMR spectrometer (Varian, Oxford, United Kingdom) at 50°C in deuterated benzene, with trimethylsilane as an internal standard.

## RESULTS AND DISCUSSION

*SFC analysis of polyprenols from* E. ulmoides. *Eucommia ulmoides* Oliver (Hardy rubber tree) is an elm-like deciduous tree native to central and southern China that can grow to 18 m tall. This plant produces fibrous rubber, called *EU*-Rubber, which accumulates in all parts but the seed (Fig. 1). This unique rubber is thermoplastic and is similar to gutta-percha in term of chemical and physical properties (9). This information prompted us to examine the key intermediate compounds that play important roles in *EU*-Rubber biosynthesis.

We focused on the *n*-hexane-soluble components of the dried samples. Under alkaline hydrolysis condition, the polyprenol content was markedly increased, suggesting that the terminal alcohol was esterified. The crude sample obtained by silica gel chromatography was analyzed using a $C_{18}$ reversed-phase column. A unimodal separation profile was seen in the samples of bark and seed. Polyprenols with polymerization degrees of 15–21 were found in the bark and 15–23 mers in the seed (Fig. 2). However, in the leaf, seed coat, and root, overlapping peaks presumably corresponding to 15–20 mers, appeared as congested peaks around $R_t$ 20–25 min, which made it difficult to separate and identify components with closely similar structures (Fig. 3A).

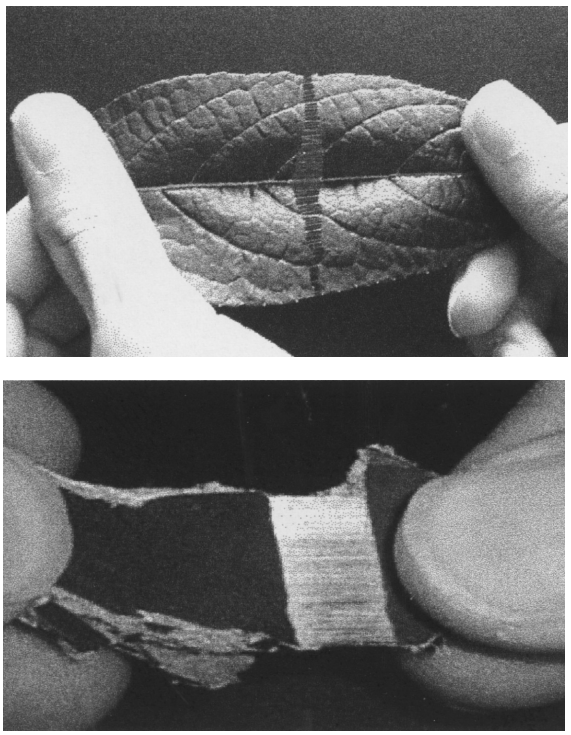

**FIG. 1.** Fibrous rubber of *Eucommia ulmoides.* (A) Leaf, (B) Bark.

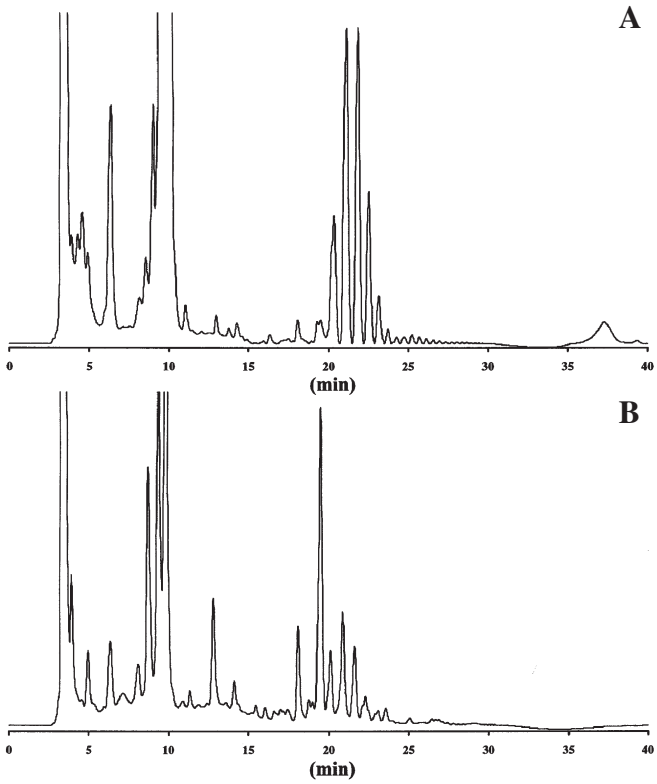

**FIG. 2.** Reversed-phase high-performance liquid chromatogram of polyprenol mixtures. (A) Bark sample, (B) seed sample. Conditions: programmed elution of methanol/propanol/water (60:40:5) to *n*-hexane/isopropanol (70:30) within 40 min, 1.0 mL/min, 40°C, ultraviolet detection at 210 nm. The determination of polymerization degree was made by cochromatography with authentic polyprenols.

We previously investigated the separation potential of SFC for waxy compounds and established a reliable separation condition (10). The resolution ($R_s$) of separation between the two peaks for prenol-18 and -19 was *ca*. two times larger than that using conventional reversed-phase HPLC.

SFC coupled with a $C_{18}$ reversed-phase column gave excellent baseline separation and enabled us to separate as many as 30 polyprenol components in the leaf sample (Fig. 3B). However, several polyprenols that eluted between $R_t$ 15 and 25 min were partly overlapped and were not satisfactorily separated. To improve separation, we investigated several reversed-phase columns and solvent systems. A reversed-phase column, Inertsil Ph-3, combined with supercritical carbon dioxide containing ethanol as a mobile phase, showed excellent separation (Fig. 4 B) and enabled us to conduct preparative SFC and obtain each component as a single compound. An improvement of the separation profiles by use of phenyl-type columns enabled us to confirm the presence of minor geometric isomers appearing as prominent peaks, each of which was eluted at equal time intervals in the leaf, root, and seed coat.

The Para rubber tree is known to produce *cis*-polyisoprene with a molecular weight of hundreds of thousands and to contain poly-*cis* prenols with polymerization degrees of more than 50 (11). These facts confirm that polyprenols play important roles in the *cis*-polyisoprene biosynthesis. It is also suggested that *E. ulmoides* should contain long-chain poly-*trans* prenols.

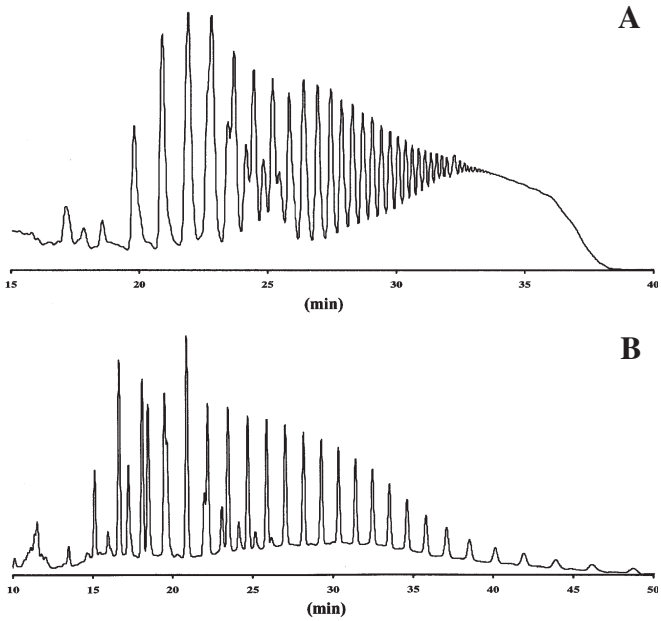

**FIG. 3.** Analysis of polyprenol mixtures from *Eucommia ulmoides* leaves by (A) reversed-phase high-performance liquid chromatography (HPLC) and (B) supercritical fluid chromatography (SFC). Conditions are described in the Materials and Methods section.

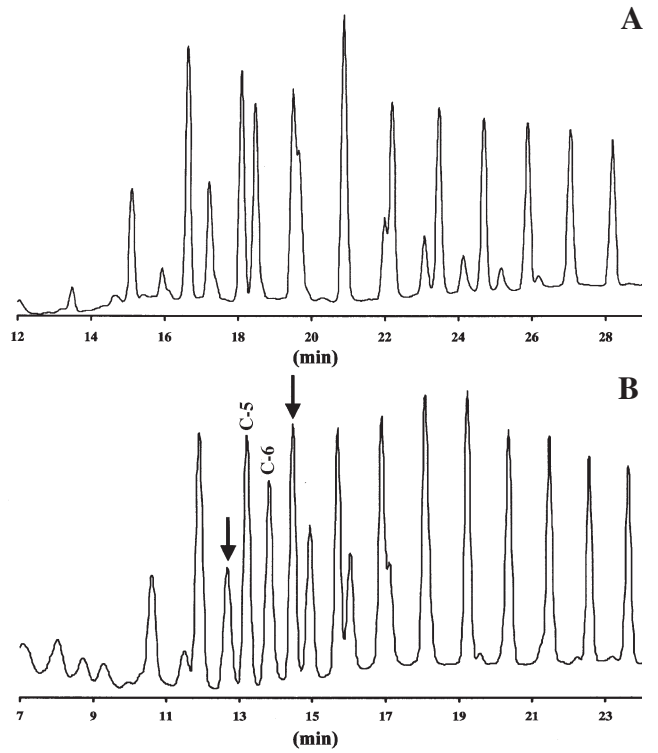

**FIG. 4.** Separation of polyprenols from *Eucommia ulmoides* leaves by SFC with (A) ODS-3 column, (B) Ph-3 column. Conditions: mobile phase ($CO_2$) flow, 3.0 mL/min; modifier (ethanol) flow, 0.8–2.0 mL/min within 30 min; top presssure, 19.6 MPa; detection, ultraviolet, 210 nm. The pair of peaks labeled with arrows were the same molecular weight. C-5: Compound 5, C-6: Compound 6. For abbreviation see Figure 3.

*Structural elucidation of polyprenols.* A detailed comparison of separation profiles allowed us to tentatively assign every other peak appearing at certain intervals to *trans* isomers. Only when the baseline peak separation of each component was achieved could we determine the number of isoprene units together with the content of the individual component in the leaf polyprenol fraction by spectroscopic analysis. Identification of the components of *E. ulmoides* supported the presence of unknown geometric isomers with all-*trans* double bonds.

Molecular weight analysis of the baseline-separated peaks was carried out by means of field desorption MS, and the same molecular weights were seen for the pair of peaks shown as arrows in Figure 4B, which indicated the presence of geometrical isomers.

In order to identify the geometry of the double bonds as well as the chain length of each component, every possible peak corresponding to *ca.* 10–30 mers of polyprenols was isolated using SFC. Two compounds (C-5 and C-6) from the leaf sample were separated by preparative SFC (Fig. 4B), and the collected samples were subjected to NMR analysis.

Geometric isomers can be identified by the assignment of methyl proton signals in $^1$H NMR. Methyl groups on *cis*- and *trans*-polyisoprene generally appear at different chemical shifts; *cis*: 1.76 ppm and *trans*: 1.64 ppm in benzene-$d_6$ (12). The α and ω end terminals can be assigned by high-resolution NMR.

In the $^1$H NMR spectrum of the collected sample (C-5), the signal at 1.635 ppm was assigned to the methyl groups in the central isoprene units of the *trans*-*trans*-*trans* sequence (Fig. 5; underlines indicate the observation site, i.e., the middle). The signals at 1.577 and 1.684 ppm were assigned to the methyls of the terminal dimethylallyl. The signals at 1.503 and 1.600 ppm correspond to the methyls of the *trans* (α)-terminal units, *trans*-α(*t*)-OH and *trans*-*trans*-α(*t*), respectively. These indicated that C-5 was an all-*trans* polyprenol, and this polyprenol had 15 isoprene units, as calculated from the integral value. This is the first report of the occurrence of a long- chain all-*trans* polyprenol, though solanesol (9 mers) from *Nicotiana*

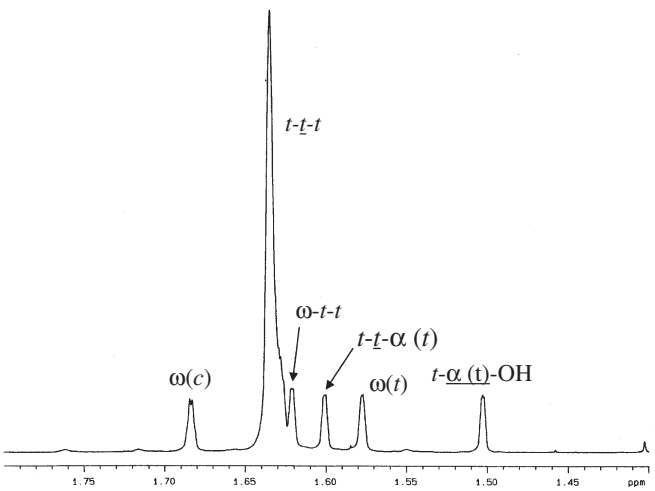

**FIG. 5.** $^1$H Nuclear magnetic resonance spectrum of C-5 in $C_6D_6$.

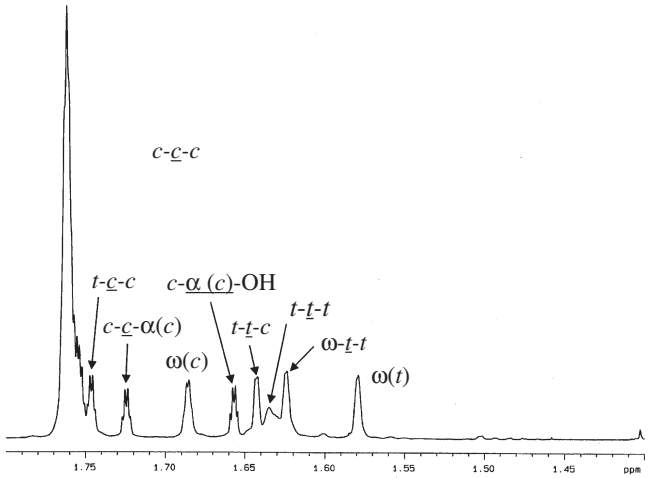

**FIG. 6.** $^1$H Nuclear magnetic resonance spectrum of C-6 in $C_6D_6$.

had previously been the only known all-*trans* polyprenol with polymerization degrees of more than five isoprene units.

In the $^1$H NMR spectrum of C-6, the methyls of the dimethylallyl terminal resonated at 1.579 and 1.685 ppm (Fig. 6). The signal at 1.762 ppm was assignable to the methyls in the central isoprene unit of the *cis*-*cis*-*cis* sequence. The signals at 1.746 and 1.724 ppm were from *cis* units. The signal at higher magnetic field (1.724 ppm) was due to the sequence *cis*-*cis*-*cis*(α), and the signal at lower magnetic field (1.776 ppm) was ascribable to the sequence *trans*-*cis*-*cis*, based on accumulated data (12). The signal at 1.657 ppm was assigned to *cis*-*cis*(α)-OH. The two signals at 1.624 and 1.642 ppm were from *trans* units, i.e., those in ω-*trans*-*trans* and *trans*-*trans*-*cis* sequences. By comparison with previously published data (12), the signal at 1.642 ppm was ascribable to a *trans*-*trans*-*cis* sequence, and the signal at 1.624 ppm to an ω-*trans*-*trans* sequence. Consequently, C-6 was identified as a tri-*trans* poly-*cis* prenol with 17 isoprene units.

Precise chain lengths were determined by field desorption-MS analysis, and the molecular weight of each peak was elucidated as shown in Table 1. The results suggested that *cis* and *trans* geometric isomers eluted at equal intervals. Based on NMR and MS analyses, the distribution of the chain length of the polyprenols was determined, as shown in Figure 7.

In *E. ulmoides*, polymerization degrees of poly-*cis* prenols are thus between 15 and 20 mers, and this is similar to those in other organisms (5,13). In contrast, *trans* forms showed a broad distribution range of 13 to 37 mers, or more.

Analyses of polyprenols that originated from the bark, seed, seed coat, and root were performed in a similar manner to the leaf sample analysis. Each sample had a characteristic distribution of polyprenols (Fig. 8). Both poly-*trans* and poly-*cis* prenols existed in the seed coat and root samples. In contrast, there was no poly-all-*trans* prenol in the seed and bark sample but rather tri-*trans* poly-*cis* prenols .

The poly-*trans* prenols had a broad distribution. However, the poly-*cis* prenols having peak maxima of 16 and 17 mers had a comparatively narrow distribution. In our previous study of *EU-*

Rubber, *trans*-polyisoprene was found in all parts except the seed (14). Our SFC analyses suggested that poly-*trans* prenols, presumed to be biosynthetic intermediates of *trans*-polyisoprene, occurred in all of the *EU*-Rubber-producing tissues except the bark, where only *EU*-Rubber with high molecular weights was found. In preliminary *in vitro* polymerization experiments using $^{14}$C-labeled IPP, radioactivities were found not only in the rubber fraction but also in the polyprenol fraction (low molecular weight polyisoprene fraction). This result strongly supported the idea that polyprenols are biosynthetic intermediates in polyisoprene biosynthesis. The lack of poly-*trans* prenols in the bark samples supports the presence of an effective polymerization process of the intermediate polyprenols, which quickly react with IPP to form fibrous structures. The chain elongation mechanism leading to higher molecular weight products might take place effectively in the bark, and thus, low molecular weight polyprenols do not remain in the bark. Our ongoing isotopic experiments should provide conclusive results for this point.

We have shown that the content and molecular weight distribution of *EU*-Rubber differ in the various parts of *E. ulmoides* and are site-specific (13). This study revealed that *trans* geometric intermediates were detected in all the tissues but the bark, and that the molecular weight distribution of polyprenols is tissue-specific, suggesting that the regulation mechanisms of polyisoprene elongation differ in these tissues. In order to elucidate the regulation mechanisms for the chain elongation and geometrical isomerization of polyisoprenes, an effective and precise analysis of the polyprenol and rubber fractions is essential.

Our SFC analytical method for polyprenol derivatives should be helpful in promoting biosynthetic work on rubber, since this technique is applicable to the separation of close structural relatives of rubber components other than polyprenols and lipophilic hydrocarbon analogs.

# Positional Distribution of Highly Unsaturated Fatty Acids in Triacyl-*sn*-glycerols of *Artemia* Nauplii Enriched with Docosahexaenoic Acid Ethyl Ester

**Yasuhiro Ando* and Yoshiaki Oomi**

Laboratory of Bioresources Chemistry, Division of Marine Biosciences,
Graduate School of Fisheries Sciences, Hokkaido University, Hakodate 041-8611, Japan

**ABSTRACT:** This paper presents the positional distribution of fatty acids in triacyl-*sn*-glycerols (TAG) of *Artemia* nauplii used in aquaculture as a live food for marine fish larvae. The nauplii were enriched with docosahexaenoic acid (DHA) ethyl ester (EE) in the form of gelatin-acacia microcapsules for 4, 18, and 24 h. TAG of the initial, enriched, and unenriched *Artemia* nauplii were subjected to stereospecific analysis. A remarkable increase of DHA content in the enriched *Artemia* TAG confirmed the view that DHA-EE is effectively assimilated and incorporated into the TAG fraction of *Artemia* nauplii. TAG of the nauplii enriched with 25 mg/L of DHA-EE contained DHA at concentrations of 5.9–6.8, 4.3–6.0, and 14.3–22.3 mol% in the *sn*-1, *sn*-2, and *sn*-3 positions, respectively. When the nauplii were enriched with 100 mg/L of DHA-EE, proportions of DHA in the *sn*-1, *sn*-2, and *sn*-3 positions were 5.2–8.6, 3.9–6.0, and 12.2–25.4 mol%, respectively. In all of the enriched *Artemia*, DHA was preferentially located in the *sn*-3 position followed in sequence by the *sn*-1 and *sn*-2 positions. The lower content of DHA in the *sn*-1 and *sn*-2 positions was consistent with low content of this acid in 1,2-diacyl-*sn*-glycerophospholipids. When fish larvae are reared on *Artemia* nauplii enriched with EE-type DHA oil, the larvae feed on DHA esterified in TAG with a positional distribution pattern similar to that of marine mammals (*sn*-3 >> *sn*-1 > *sn*-2) rather than that of fish or marine invertebrates (*sn*-2 >> *sn*-3 > *sn*-1).

Paper no. L8743 in *Lipids 36*, 733–740 (July 2001).

Longer-chain n-3 highly unsaturated fatty acids (HUFA) such as docosahexaenoic acid (DHA, 22:6n-3) and eicosapentaenoic acid (EPA, 20:5n-3) are essential dietary components for marine fish larvae (1–3). Various marine fish larvae exhibit high mortalities and abnormalities, such as underdeveloped swim bladders, scoliosis and depigmentation, when reared on diets either devoid or containing very low levels of n-3 HUFA (2,4). These essential fatty acids must be supplied in the diet to ensure good growth and survival of cultured marine fish larvae.

*To whom correspondence should be addressed.
E-mail: ando@pop.fish.hokudai.ac.jp

Abbreviations: DHA, docosahexaenoic acid; EE, ethyl ester; EPA, eicosapentaenoic acid; HPLC, high-performance liquid chromatography; HUFA, highly unsaturated fatty acids; MAG, monoacyl-*sn*-glycerols; PC, phosphatidylcholines; PE, phosphatidylethanolamines; TAG, triacyl-*sn*-glycerols; TL, total lipids.

*Artemia* nauplii are used in aquaculture as an important live food for fish larvae. However, the nauplii are an incomplete food source for many marine fish larvae because of their low level of essential n-3 HUFA and of DHA in particular (1,5–11). The nauplii are usually enriched with diets rich in n-3 HUFA, such as commercially available oil-based emulsions (e.g., Ref. 10), selected microalgae (11,12), algal-derived products (13), HUFA-modified yeast (9,11), or microparticulate diets (14,15), prior to being fed to fish larvae. Sargent *et al*. (1) reviewed recent procedures for optimizing the presentation of dietary HUFA to marine fish larvae in relation to the advantages and disadvantages of using single-cell eukaryotic organisms or purified fish oils as enrichment diet of live foods including *Artemia* nauplii.

Enrichment diets are evaluated mostly based on their capability to increase the content of n-3 HUFA in *Artemia* nauplii (e.g., 8–11,16–19). Enrichment of *Artemia* is often considered as a single filling of the gut with the enrichment diet. However, the increase in fatty acid content of *Artemia* nauplii after enrichment is due not only to a retention of the enrichment diet in the gut but also to an assimilation of fatty acids into lipid reserves as the result of ingestion, digestion, and metabolic conversions. Coutteau and Mourente (20) assessed lipid class compositions and their content of DHA and EPA in *Artemia* nauplii enriched with a lipid emulsion in which fatty acid ethyl ester (EE) provided a level of 30% n-3 HUFA. Enrichment of *Artemia* with the lipid emulsions resulted in an increase of triacyl-*sn*-glycerol (TAG) content. The low levels of EE recovered from *Artemia* after 24 h of enrichment with the emulsion containing EE demonstrated an efficient metabolic conversion into TAG. The TAG fraction concentrated >91% of the DHA and >64% of the total EPA present. These results showed that the n-3 HUFA and particularly DHA are effectively assimilated and incorporated into the TAG fraction during n-3 HUFA enrichment of *Artemia*. Takeuchi *et al*. (21) also concluded that fatty acid ethyl or methyl esters containing 43% of n-3 HUFA were very quickly converted to TAG and incorporated into the TAG fraction in *Artemia* nauplii. Recently, Navarro *et al.* (22) presented incontestable evidence of incorporation by using radiolabeled fatty acid EE for enrichment of *Artemia*.

The present study reveals positional distributions of n-3 HUFA in TAG of DHA-enriched *Artemia* nauplii, i.e., con-

tents of DHA esterified in the *sn*-1, *sn*-2, and *sn*-3 positions of TAG. The aim of this work was to characterize the mechanisms whereby ingested DHA is incorporated into TAG of *Artemia* nauplii and to determine the TAG form in which the essential DHA is available for fish larvae. For this purpose, EE of DHA (DHA-EE) with a high purity was selected as the simplest DHA-containing oil, and directly given to *Artemia* nauplii in the form of gelatin-acacia microcapsules.

## EXPERIMENTAL PROCEDURES

*Preparation of enrichment diet.* Gelatin-acacia microcapsules were used as DHA enrichment diet for *Artemia* nauplii, because fatty acid-related emulsifiers, such as Tween 80 (23,24) and natural phospholipids (17,18), are not necessary for their preparation.

The microcapsules were prepared by a method based on those described by Green and Schleicher (25) and Southgate and Lou (16) after some modifications as follows. A 10% (w/w) solution of gelatin (type A, from porcine skin, approx. 175 bloom; Sigma Chemical Co., St. Louis, MO) and a 10% (w/w) solution of acacia (gum arabic from acacia tree; Sigma Chemical Co.) were made up in distilled water at 40°C. Ten milliliters of these solutions were mixed and maintained at 40°C. DHA-EE (1 g; purity, >99%; Shiseido Co., Tokyo, Japan) was added to the gelatin-acacia solution, and the mixture was homogenized using a two-blade blender for 60 s. Distilled water (60 mL) was then added slowly to the homogenate drop by drop with constant stirring at 40°C. The mixture was poured into 500 mL of distilled water at 0°C, and the resulting microcapsule suspension was placed in a refrigerator for 2 h. The microcapsules had a mean diameter of 0.88 ± 0.47 μm ($n$ = 100; based on particle number) and were used in suspension without further treatment.

Artemia *enrichments. Artemia* cysts (Great Salt Lake, UT; Senju Seiyaku Co., Itami, Japan) were incubated in 2% (w/w) salinity artificial seawater at 25°C under continuous illumination and aeration for 24 h. Nauplii were separated from empty cysts, washed in a fresh portion of 2% salinity artificial seawater, and placed in clean, aerated 2% salinity artificial seawater. Enrichment was carried out with 24-h-old *Artemia* nauplii at a density of 100,000 nauplii/L in 10 L tanks containing well-aerated 2% (w/w) salinity artificial seawater at 20°C. Microcapsules containing DHA-EE were added to the tanks at 25, 50, and 100 mg/L on weight bases of DHA-EE. After the microcapsules were added to the culture tanks, enriched *Artemia* nauplii samples (2 L of the artificial seawater) were taken on a nylon mesh at 4, 18, and 24 h, washed in distilled water, weighed, and stored at –35°C for lipid analysis. Under the same conditions, unenriched *Artemia* samples were obtained after 4, 18, and 24 h starvation without adding the microcapsules. *Artemia* nauplii were also taken just before the start of enrichment as an initial sample.

*Isolation of TAG.* Total lipids (TL) were extracted from *Artemia* nauplii by the method of Bligh and Dyer (26). TAG were isolated from other lipids by preparative thin-layer chromatography on Silicagel 60G plates (0.5 mm thickness; Merck, Darmstadt, Germany) with hexane/diethyl ether (80:20, vol/vol) for development.

*Fatty acid analysis.* Fatty acid methyl esters were prepared by reacting 0.5 mg of TAG in a mixture of 1,2-dichloromethane (0.6 mL), methyl acetate (25 μL), and 1 M sodium methoxide/methanol solution (25 μL) at room temperature overnight. After adding acetic acid (9 μL) and removing the solvents, the products were taken up in hexane. Fatty acid methyl esters were analyzed by gas–liquid chromatography on a Shimadzu GC-14A gas chromatograph (Shimadzu Co., Kyoto, Japan) equipped with a capillary column Omegawax 320 (30 m × 0.32 mm i.d., 0.25 μm film thickness; Supelco Inc., Bellefonte, PA) and a flame-ionization detector. Column temperature was programmed from 180 to 240°C (1°C/min), and injector and detector temperatures were 250 and 260°C, respectively. Helium was the carrier gas. Peak area percentages were measured with a Shimadzu C-R6A integrator.

*Stereospecific analysis.* Positional distribution of n-3 HUFA in the TAG of *Artemia* nauplii was determined by stereospecific analysis of TAG. The method for stereospecific analysis of natural oil TAG (27–30) was used after modifications as follows. TAG (5 mg), mixed with trinonadecanoylglycerol (0.5 mg), were dissolved in 0.23 mL of dry diethyl ether, and ethyl magnesium bromide in dry diethyl ether (0.1 mL of 1 M solution) was added. The mixture was shaken for 25 s, and then 2 mL of acetic acid/diethyl ether (1:200, vol/vol) followed by water (1 mL) was added to stop the reaction. The ether layer was washed once with 2% aqueous sodium bicarbonate, then washed with water, and dried over anhydrous sodium sulfate. After removal of the solvent at ambient temperature, all of the products were dissolved in dry toluene (0.5 mL) and reacted with 3,5-dinitrophenylisocyanate (40 mg) in the presence of dry pyridine (5 μL) for 1 h at ambient temperature. Dry 1-propanol (20 μL) was added to stop the reaction, the bulk of the solvent was then removed in a stream of nitrogen, and the residual toluene solution filtered through a small cotton-wool plug. The resulting bis-3,5-dinitrophenylurethane derivatives of isomeric or enantiomeric 1-, 2-, and 3-monoacyl-*sn*-glycerols (MAG) were isolated from other products by high-performance liquid chromatography (HPLC) with a Shimadzu LC-6A pump, a Jasco 875-UV ultraviolet spectrophotometric detector (Japan Spectroscopic Co., Tokyo, Japan), and a Shimadzu C-R6A integrator. A column of Sumichiral OA-4100 (25 cm × 4.6 mm i.d., 5 μm particles; Sumitomo Chemical Co., Osaka, Japan) was used for isolation of *sn*-1- plus *sn*-2-MAG and *sn*-3-MAG fractions, and then one of Sumichiral OA-4000 (25 cm × 4.6 mm i.d., 5 μm particles) for separation of *sn*-1-MAG and *sn*-2-MAG fractions. Both HPLC separations were done with hexane/1,2-dichloromethane/ethanol (40:12:3, by vol) as mobile phase at a flow rate of 1.5 mL/min at –10°C. Detection was at 254 nm. Constituent fatty acids of the *sn*-1-, *sn*-2-, and *sn*-3-MAG derivative fractions were analyzed by reversed-phase HPLC without further derivatization. HPLC was done with a Hitachi L-6200 pump (Hitachi Co., Tokyo,

Japan), a Hitachi L-4200 ultraviolet spectrophotometric detector, and a Shimadzu C-R6A integrator. A column of Capcellpak C18 UG120 S-3 (15 cm × 4.6 mm i.d., 3 μm particles; Shiseido Co.) was used with acetonitrile and water as mobile phase at a flow rate of 1.0 mL/min. A linear gradient of 70% acetonitrile/30% water to 100% acetonitrile was generated over 90 min. Column temperature was held at 10°C for 35 min and then immediately changed to 30°C. Assignments of each fatty acid to the *sn*-1-, *sn*-2-, and *sn*-3-positions of TAG were obtained from the peak area ratio of each MAG molecular species relative to monononadecanoylglycerol, formed from the trinonadecanoylglycerol internal standard, and the fatty acid composition of each position was calculated on the basis of the assignments.

## RESULTS

*Contents of TL and TAG in* Artemia *nauplii.* Contents of TL and TAG in *Artemia* nauplii (dry-weight base) enriched with DHA-EE are shown in Table 1 together with those of initial and unenriched *Artemia*. Enrichment of *Artemia* with DHA-EE resulted in an increase of TL content from 20.2% (0 h) to 25.0–26.3% (4 or 18 h) and subsequent decrease to 20.3–22.6% (24 h). TAG content also increased from 7.7% (0 h) to 8.5–9.5% (4 h) and then decreased to 6.6–7.7% (24 h). Changes in TL and TAG contents were similar among the three enrichments with 25, 50, and 100 mg/L of DHA-EE with exception of a faster decrease of TL content observed for enrichment with 25 mg/L of DHA-EE. Unenriched *Artemia* showed a consistent decrease of TL content from 20.2 to 12.4%. This was due to a decrease of TAG content from 7.7 to 1.3%. Although the TAG content of enriched *Artemia* was not high compared with that of the initial sample, the enriched nauplii contained markedly higher amounts of TAG than the unenriched nauplii. Differences in TAG contents between the enriched and unenriched *Artemia* nauplii were 3.1–4.1% at 4 h, 5.6–6.4% at 18 h, and 5.3–6.4% at 24 h.

*Fatty acid compositions of* Artemia *nauplii TAG.* Table 2 shows the fatty acid compositions of TAG in *Artemia* nauplii. The principal fatty acids at more than 3 mol% of the total fatty acids were 16:0, 16:1n-7, 18:0, 18:1n-9, 18:1n-7, 18:2n-6, and 18:3n-3 in the initial and unenriched *Artemia* nauplii. Proportions of EPA (20:5n-3) and DHA (22:6n-3) were 1.9–2.4 and ≤0.2 mol%, respectively. Changes in the proportions of major fatty acids were similar among the *Artemia* enriched with DHA-EE at the three concentrations. In all of the enrichments, concentrations of DHA increased with enrichment period (especially 0–4 h), reached maxima after 18 h, and dropped slightly during 18–24 h. The maximal concentrations of DHA were 11.4, 12.2, and 13.2 mol% in the enrichment with 25, 50, and 100 mg/L of DHA-EE, respectively. The levels of EPA consistently increased from 2.4 to 4.1–4.2 mol% during the enrichment period. The levels of other major fatty acids such as 16:0, 16:1n-7, 18:1n-9, 18:1n-7, 18:2n-6, and 18:3n-3 decreased during the enrichment period (especially 0–18 h). In the unenriched *Artemia* TAG, fatty acid composition was almost steady, although slight decreases of 18:3n-3 and 18:2n-6 levels were observed during 0–24 h. Therefore, enriched *Artemia* showed significantly higher proportions of DHA and EPA than unenriched *Artemia*, and lower proportions of all other fatty acids.

*Positional distributions of fatty acids in TAG of* Artemia *nauplii.* Table 3 shows the positional distributions of principal fatty acids in TAG in *Artemia* nauplii enriched with DHA-EE at 25 and 100 mg/L together with those of initial and unenriched *Artemia*. TAG of *Artemia* enriched with 50 mg/L of DHA-EE were not subjected to stereospecific analysis, because of the similarity in positional distributions between the *Artemia* enriched with 25 and 100 mg/L of DHA-EE as described below.

In the initial *Artemia*, the predominant saturated and monounsaturated fatty acids (16:0, 18:0, and 18:1) were preferentially esterified in the *sn*-1 position followed in sequence by the *sn*-3 and *sn*-2 positions (i.e., *sn*-1 > *sn*-3 > *sn*-2 positions). The most prominent polyunsaturated fatty acid (18:3n-3) was concentrated in the *sn*-2 position followed in sequence by the *sn*-3 and *sn*-1 positions (i.e., *sn*-2 >> *sn*-3 > *sn*-1 positions), whereas 18:2n-6 was primarily located in the *sn*-2 and *sn*-3 positions (i.e., *sn*-2 ≈ *sn*-3 > *sn*-1 positions). EPA was esterified in the *sn*-2 position followed by the *sn*-3 position (i.e., *sn*-2 > *sn*-3 > *sn*-1 positions). The *sn*-1 position was high in 18:1 and 16:0 followed by 18:0 and 18:3n-3; the *sn*-2 position in 18:3n-3 and 18:1 followed by 18:2n-6; and the *sn*-3 position in 18:1, 18:3n-3, and 16:0 followed by 16:1n-7 and 18:2n-6.

In the unenriched *Artemia* TAG, the *sn*-1 position showed fatty acid compositions consistently similar to that in the initial *Artemia*. In the *sn*-2 position, 18:3n-3 decreased from 62.5 mol% to 59.1 mol% (24 h), and in contrast 18:1 increased from 10.2 mol% to 13.2 mole % (24 h). Decreases of 18:2n-6 and 18:3n-3 were also observed in the *sn*-3 position.

Enriched *Artemia* showed increases of DHA in all three positions of TAG. The nauplii enriched with 25 mg/L of DHA-EE contained DHA at concentrations of 5.9–6.8, 4.3–6.0, and 14.3–22.3 mol% in the *sn*-1, *sn*-2, and *sn*-3 posi-

[a]*Artemia* nauplii enriched with [b]25, [c]50, and [d]100 mg of DHA-EE per liter of rearing artificial seawater.
[e]Less than 0.1 mol%. For abbreviations see Table 1.

tions, respectively. When *Artemia* nauplii were enriched with 100 mg/L of DHA-EE, the proportions of this fatty acid in the *sn*-1, *sn*-2, and *sn*-3 positions were 5.2–8.6, 3.9–6.0, and 12.2–25.4 mol%, respectively. The increase of DHA in the *sn*-3 position was larger than that in the *sn*-1 and *sn*-2 positions. In all of the enriched *Artemia*, DHA was preferentially esterified in the *sn*-3 position. Smaller amounts of DHA were found in the *sn*-1 position followed by the *sn*-2 position. This acid was associated with the *sn*-3 >> *sn*-1 > *sn*-2 positions. During the enrichment with DHA-EE, the levels of EPA also increased in the three positions. This fatty acid increased from 0.7, 3.7, and 2.8 mol% (0 h) to 1.5–2.2, 3.9–5.0, and 3.2–5.1 mol% in the *sn*-1, *sn*-2, and *sn*-3 positions in *Artemia* enriched with 25 mg/L of DHA-EE, respectively. The nauplii enriched with 100 mg/L of DHA-EE had 1.6–2.3, 3.7–5.4, and 3.0–5.2 mol% of EPA in the *sn*-1, *sn*-2, and *sn*-3 positions, respectively. At the end of enrichment period (24 h), EPA was preferentially located in both the *sn*-2 and *sn*-3 positions followed by the *sn*-1 position. Distribution pattern of EPA after the 24-h enrichment (i.e., *sn*-2 ≈ *sn*-3 > *sn*-1 positions) was different from that of initial and unenriched *Artemia* (i.e., *sn*-2 > *sn*-3 > *sn*-1 positions).

Due to the considerable increase of DHA and EPA levels, some specific fatty acids changed in percentage in each position. In the *sn*-1 position, 16:0 decreased from 24.2 to 19.7 and 18.3 mol% during 18 h of enrichment with 25 and 100 mg/L of DHA-EE, respectively. The proportion of 18:1, the most prominent fatty acid in this position, was consistent. In the *sn*-2 position, 18:3n-3 showed a decrease from 62.5 to 55.5 and 53.8 mol% (18 h), whereas a slight increase was observed for 16:0. In the *sn*-3 position, all fatty acids other than DHA and EPA showed decreases during the 18-h enrichment.

## DISCUSSION

*Incorporation of DHA to* Artemia *nauplii TAG.* An increase of TL and TAG contents has been observed during enrichment of *Artemia* with DHA-containing EE (e.g., 18,20,21,31). In the study of Coutteau and Mourente (20), enrichment of *Artemia* with EE-type oil resulted in an increase of TL from 20.0 to 28.7% of dry matter due to the accumulation of neutral lipids, primarily TAG (from 8.2% in freshly hatched *Artemia* to 15.8% in 24-h enriched *Artemia*). McEvoy *et al.* (18) obtained, after 18-h enrichment with Super Selco (a com-

[a]Values for 16:1n-7, 18:0, and 18:1n-9 contain minor amounts of 20:4n-6, 20:1, and 18:1n-7, respectively. For abbreviations see Table 1.

mercially available enrichment diet consisting mainly of EE), a TL content in *Artemia* of 16.8% of which 11.4% (on a dry-weight basis) was TAG. These authors started their enrichment with 6-h-old *Artemia* that contained 12.3% of TL and 7.2% of TAG. Takeuchi *et al*. (21) reported two sets of data showing an increase of TL in *Artemia* from 33.0 and 24.4% to 45.2 and 31.9% and of TAG from 12.0 and 3.8% to 22.9 and 10.9% after 24 h of enrichment with EE-type oil, respectively.

The present study also showed increases of TL and TAG contents during the enrichment with DHA-EE in a manner similar to those reported (Table 1). The contents and increments of TL and TAG differed somewhat from those described above. Such variability can be explained by differences in populations and harvests of *Artemia*, starvation period before enrichment, and other enrichment protocols, such as duration, dosage, concentration and type for the enrichment diet, and physical and chemical conditions.

Coutteau and Mourente (20) also determined the distribution of DHA and EPA over the major neutral and polar lipid classes of n-3 HUFA-enriched *Artemia*. Over an 18-h enrichment period, the levels of DHA and EPA increased from 0.2 and 2.7% to 12.5 and 6.7% of total fatty acids in TAG, respectively. The TAG fraction contained 91 and 64% of the total amount of DHA (22.3 mg/g dry weight) and EPA (17.8 mg/g dry weight) present in the enriched *Artemia*, respectively. Navarro *et al.* (22) enriched *Artemia* nauplii for 24 h with radiolabeled fatty acid EE and analyzed the distribution of radioactivity in lipid classes of the enriched *Artemia*. At the end of the enrichment period, about 80% of radiolabeled DHA and EPA were recovered in the TAG fraction.

In the present study, the levels of DHA in *Artemia* TAG

[a,b]*Artemia* nauplii enriched with [a]25 and [b]100 mg of DHA-EE per liter of rearing artificial seawater. For abbreviations see Table 1.

drastically increased from 0.1 mol% in the initial to 11.4–13.2 mol% in 18-h enriched *Artemia* (Table 2). Distribution of DHA between TAG and other lipid classes was not known, because lipid class compositions and their content of DHA were not determined in the present study. In spite of the lack of this information, the drastic increase of DHA in TAG confirms the view that EE-type DHA is effectively assimilated and incorporated into the TAG fraction of *Artemia* nauplii (20–22).

In the enriched *Artemia* TAG, the levels of EPA also increased from 2.4 to 4.1–4.2 mol% (Table 2). *Artemia* nauplii have the ability to retroconvert DHA to EPA (22). The consistent increase of EPA demonstrates that the retroconversion took place during the enrichment with DHA-EE in the present study.

*Positional distribution of DHA characteristic of* Artemia *nauplii.* Brockerhoff *et al*. (32) studied the positional distribution of fatty acids in TAG of many aquatic animals and described the general tendencies observed for their distribution. In invertebrates, squid (liver), periwinkle (whole body), lobster (hepatopancreas), and scallop (hepatopancreas), polyunsaturated fatty acids were preferentially located in the *sn*-2 position, saturated acids, 16:0 and 18:0, in the *sn*-1 position, and longer-chain acids in the *sn*-3 position. In fish, the *sn*-1 position attracted saturated and monounsaturated acids; the *sn*-2 position polyunsaturated and shorter-chain acids; and the *sn*-3 position longer-chain acids. The *sn*-2 position was also rich in 16:0. In marine mammals, shorter-chain acids accumulated in the *sn*-2 position but the polyunsaturated fatty acids occupied the *sn*-3 position, and then the *sn*-1 position.

The distribution pattern of fatty acids in TAG of initial and unenriched *Artemia* nauplii (Table 3) was not very different from the general tendency for invertebrates. The total unsaturation of the *sn*-2 position was very high. The contents of n-3 HUFA were low in both the initial and unenriched *Artemia* TAG. Instead of EPA and DHA, a common polyunsaturated fatty acid, 18:3n-3, was prominent in the *sn*-2 position. Saturated fatty acids, 16:0 and 18:0, also showed a distribution pattern similar to the general tendency for invertebrates.

Brockerhoff *et al*. (32) pointed out the general tendency of DHA, 22:5, and EPA to be preferentially esterified in the *sn*-2 position in fish and invertebrate TAG, and in the *sn*-3 position in marine mammal TAG. Litchfield (33,34) discussed the relationships between the percentage of DHA esterified at each position and the total percentage of DHA in fish, invertebrates, and marine mammals and showed that the positional distribution of DHA can be predicted by the following proportionality equations: for fish and invertebrate TAG,

$$y_1 = 0.28x;\ y_2 = 2.06\ x;\ \text{and}\ y_3 = 0.66\ x \qquad [1]$$

and for marine mammal TAG,

$$y_1 = 0.94x;\ y_2 = 0.22x;\ \text{and}\ y_3 = 1.84x \qquad [2]$$

where $x$ shows the mole percentage of DHA in the total TAG and $0 < x < 30$; and $y_1$, $y_2$, and $y_3$ show the mole percentages of DHA in the *sn*-1, *sn*-2, and *sn*-3 positions, respectively. These relationships essentially indicate that about 10, 70, and 20% of DHA were esterified in the *sn*-1, *sn*-2, and *sn*-3 positions of fish and invertebrate TAG, and about 30, 10, and 60% of it were in the *sn*-1, *sn*-2, and *sn*-3 positions of marine mammal TAG.

Proportional distributions of DHA among the *sn*-1, *sn*-2, and *sn*-3 positions of the enriched *Artemia* nauplii TAG are shown in Table 4. The general tendency for fish and invertebrate TAG did not hold for *Artemia* nauplii. In the enriched *Artemia*, a preference of DHA for the *sn*-2 position was not observed. Less than 18% of DHA was esterified in the *sn*-2 position of the enriched *Artemia*, whereas 19–25 and 57–67% of this acid were located in the *sn*-1 and *sn*-3 positions, respectively. Such a distribution pattern resembles that reported for marine mammal TAG rather than invertebrates and fish TAG. The positional distribution of DHA in the DHA-enriched *Artemia* nauplii is found to be characterized by considerably higher assignment of DHA to the *sn*-3 position than to the *sn*-2 position, and therefore cannot be predicted by Litchfield's prediction rule (Eqs. 1,2; Refs. 33,34) for fish and aquatic invertebrates.

Owing to the enrichment of DHA and simultaneous retroconversion, the distribution pattern of EPA changed in the enriched *Artemia* nauplii (Table 3). Decreases in preference of this acid in the *sn*-2 position also support the view that the general tendency for fish and invertebrates does not hold for the DHA-enriched *Artemia*.

*Biosynthesis of DHA-containing TAG in* Artemia *nauplii*. The present study revealed the positional distribution of n-3 HUFA and other major fatty acids in TAG of *Artemia* nauplii. As far as the authors know, there has been no prior report on the positional distribution. In all of the *Artemia* nauplii en-

riched with DHA-EE, DHA was preferentially located in the *sn*-3 >> *sn*-1 > *sn*-2 positions of TAG. This distribution pattern was obvious even in the early period (4 h) of the enrichment. The increase of the DHA content in the enriched *Artemia* is attributable primarily to the increase of this acid in the *sn*-3 position of TAG.

Lesser amounts of DHA in polar lipids of enriched *Artemia* were also reported by Coutteau and Mourente (20). When the proportional distribution of DHA among major lipid classes was calculated from their data, phosphatidylcholines (PC) and phosphatidylethanolamines (PE) contained only 2.3 and 1.4% of this acid present in enriched *Artemia*, respectively. Czesny *et al*. (35) presented fatty acid profiles of neutral and polar lipid fractions of *Artemia* nauplii enriched with EE-type n-3 HUFA concentrate. The concentration of DHA in the polar lipid fraction (0.3 wt% of total fatty acids) was much lower than that in the neutral lipid fraction (5.0 wt% of total fatty acids). Preliminary experiments for the present study also showed low contents of DHA in polar lipids as follows: 1.0% of total fatty acids in PC fraction (28 wt% of TL) and 3.2% in PE (11%) vs. 8.9% in TAG (38%). Such low contents of DHA in 1,2-diacyl-*sn*-glycerophospholipids are consistent with the low content of this acid in the *sn*-1 and *sn*-2 positions of *Artemia* TAG. This consistency indicates that synthesis of DHA-containing TAG goes through the *sn*-3 glycerophosphate pathway in *Artemia* nauplii. Preference of exogenous DHA for the *sn*-3 position of TAG indicates that most of the DHA is esterified to 1,2-diacyl-*sn*-glycerols formed from 1,2-diacyl-*sn*-glycerophosphate at the final stage of the pathway.

This study revealed the incorporation of DHA in the *sn*-3 position of *Artemia* nauplii TAG in preference to the *sn*-1 and *sn*-2 positions. A lesser preference for the *sn*-1 and *sn*-2 positions confirms the fact that the preponderance of DHA is not incorporated into glycerophospholipids but into TAG. Glycerophospholipids have been found to be superior to TAG for fish larvae as a source of essential fatty acids and energy due to their better digestibility (36). However, without any modifications to present technology, it seems essentially difficult to boost DHA content in the phospholipids by enrichment with DHA-EE. When marine fish larvae are reared on *Artemia* nauplii enriched with EE-type of DHA oil, the larvae feed on DHA esterified in TAG with a positional distribution pattern similar to that of marine mammals rather than fish or invertebrates.

# Determination of Stereochemical Configuration of the Glycerol Moieties in Glycoglycerolipids by Chiral Phase High-Performance Liquid Chromatography

**Yoshinori Takahashi[a], Yutaka Itabashi[a,*], Minoru Suzuki[b], and Arnis Kuksis[c]**

[a]Graduate School of Fisheries Sciences, Hokkaido University, Hakodate 041-8611, Japan, [b]Graduate School of Environmental Earth Science, Hokkaido University, Sapporo 060-0810, Japan, and [c]Banting and Best Department of Medical Research, University of Toronto, Toronto, Ontario M5G 1L6, Canada

**ABSTRACT:** This study reports a simple and sensitive method for determining the absolute configuration of the glycerol moieties in glycoglycerolipids. The method is based on chiral phase high-performance liquid chromatography (HPLC) separations of enantiomeric di- and monoacylglycerols released from glycosyldi- and monoacylglycerols, respectively, by periodate oxidation followed by hydrazinolysis. The released di- and monoacylglycerols were chromatographed as their 3,5-dinitrophenylurethane (3,5-DNPU) and bis(3,5-DNPU) derivatives, respectively. The derivatives were separated on two chiral phases of opposite configuration, (*R*)- and (*S*)-1-(1-naphthyl)ethylamine polymers for diacylglycerols and *N*-(*R*)-1-(1-naphthyl)ethylaminocarbonyl-(*S*)-valine and *N*-(*S*)-1-(1-naphthyl)ethylamino-carbonyl-(*R*)-valine for monoacylglycerols. Clear enantiomer separations, which permit the assignment of the glycerol configuration, were achieved for *sn*-1,2(2,3)-diacyl- and *sn*-1(3)-monoacylglycerols generated from linseed oil triacylglycerols by partial Grignard degradation on all the chiral stationary phases employed. Using the method, we have determined the glycerol configuration in the glycosyldiacylglycerols (monogalactosyl-, digalactosyl-, and sulfquinovosyldiacylglycerols) and glycosylmonoacylglycerols (monogalactosyl-, digalactosyl-, and sulfoquinovosylmonoacylglycerols) isolated from spinach leaves and the coralline red alga *Corallina pilulifera*. The results clearly showed that the glycerol moieties in all the glycoglycerolipids examined have *S*-configuration (*sn*-1,2-diacyl- and *sn*-1-monoacylglycerols). The new method demonstrates that chiral phase HPLC provides unambiguous information on the configuration of the glycerol backbone in natural glycosyldi- and monoacylglycerols, and that the two-step liberation of the free acylglycerols does not compromise glycerol chirality.

Paper no. L8717 in *Lipids 36*, 741–748 (July 2001).

It is well known that monogalactosyldiacylglycerols (MGDG), digalactosyldiacylglycerols (DGDG), and sulfoquinovosyldiacylglycerols (SQDG) are major membrane constituents in plant chloroplasts and that they have also been found in terrestrial and marine organisms (1–3). In addition to various functions as membrane components, glycosyldi- and monoacylglycerols have recently been shown to have some pharmaceutical and biological activities (4–12).

The stereochemical configuration of the glycerol moieties in MGDG, DGDG, and SQDG can be assigned by physical methods, such as X-ray crystallography, $^{1}H$ and $^{13}C$ nuclear magnetic resonance (NMR) spectroscopy, optical rotatory dispersion, and circular dichroism (3). These techniques are powerful tools for determining the glycerol configuration, but they are not simple or practical to use. Recently, an enzymatic method, which uses diacylglycerol kinase from *Escherichia coli* and ATP, was reported for assigning the C2 configuration of the diacylglycerols released from $^{14}C$-labeled glycolipids (13). The method is sensitive and gives clear results as the enzyme has a high enantioselectivity for phosphorylating *sn*-1,2-diacylglycerols, but the radio-labeled compounds are somewhat troublesome to prepare and use. Thus, there is considerable interest in chromatographic methods.

Kim *et al*. (14) reported a highly sensitive method for determination of the absolute configuration of the glycerol moiety in glycosyldiacylglycerols by normal-phase high-performance liquid chromatography (HPLC) with fluorescent detection. The original glycosyldiacylglycerols were deacylated, methylated, and hydrolyzed to yield *sn*-1,2(2,3)-di-*O*-methylglycerols. The enantiomeric di-*O*-methylglycerols were reacted with (*S*)-(+)-2-*tert*-butyl-2-methyl-1,3-benzodioxol-4-carboxylic acid chloride, and the resulting diastereomeric derivatives were resolved on a conventional silica column. The method gives almost complete resolution of the diastereomeric derivatives at the level of a few picomoles, but the derivatization procedures including the synthesis of the chiral derivatization reagent seem to be complex and time-consuming. In addition, the method gives no information on the molecular species of glycosyldiacylglycerols.

We report here a simpler and more practical HPLC method for assigning the glycerol configuration in glycosyldi- and monoacylglycerols. The method is based on chiral-phase HPLC separations of enantiomeric di- and monoacylglycerols released from glycosyldi- and monoacylglycerols, respectively, by the frequently used periodate oxidation followed by hy-

Abbreviations: DGDG, digalactosyldiacylglycerol; DGMG, digalactosylmonoacylglycerol; DNPU, dinitrophenylurethane; ECN, equivalent carbon number; ESI, electrospray ionization; HPLC, high-performance liquid chromatography; MGDG, monogalactosyldiacylglycerol; MGMG, monogalactosylmonoacylglycerol; MS, mass spectrometry; NMR, nuclear magnetic resonance; SQDG, sulfoquinovosyldiacylglycerol; SQMG, sulfoquinovosylmonoacylglycerol; TLC, thin-layer chromatography.

drazinolysis. Although the enantiomer separations of di- and monoacylglycerols have already been reported by chiral and normal-phase HPLC (15–17), these methods have not been applied to the di- and monoacylglycerol moieties in glycosyldi- and monoacylglycerols.

## MATERIALS AND METHODS

*Chemicals.* Standard samples of MGDG, DGDG, and SQDG from plant leaves were obtained from Lipid Products (Redhill, United Kingdom). Silica gel 60 (70–230 mesh) for column chromatography, Silica gel 60 $F_{254}$ aluminum sheets for analytical thin-layer chromatography (TLC), and Silica gel $60F_{254S}$ plates for preparative TLC (20 × 20 cm, 0.25-mm thick) were obtained from Merck (Darmstadt, Germany). 3,5-Dinitrophenyl isocyanate was a product of Sumika Analysis Service (Osaka, Japan). Linseed oil was a commercial product from Nacalai Tesque (Kyoto, Japan). HPLC-grade solvents, *n*-hexane, dichloromethane and ethanol, were obtained from Kanto Chemicals (Tokyo, Japan). All other chemicals and solvents were of reagent grade or better quality and were also obtained from Kanto Chemicals.

*Isolation of glycosyldi- and monoacylglycerols from spinach leaves and* Corallina pilulifera. Spinach leaves were purchased from a local supermarket in Hakodate, Japan. The red alga *C. pilulifera* was collected in the intertidal zone of Oshoro Bay, Otaru, Hokkaido, Japan, during May to October 1997 and 1998. The leaf and algal lipids were extracted by the method of Bligh and Dyer (18) and with methanol (12), respectively. The leaf lipids (250 mg) were subjected to silica gel column chromatography, which facilitated further purification by TLC. The lipid classes were separated by sequential elution with chloroform, methanol, and water into four fractions: 1000 mL of chloroform (I), 300 mL of chloroform/methanol (9:1, vol/vol) (II), 300 mL of chloroform/methanol/water (65:25:4, by vol) (III), and 300 mL of chloroform/methanol/water (65:35:8, by vol) (IV). Fraction II contained MGDG, which were further purified by TLC with a solvent system of *n*-hexane/ethyl acetate/methanol/water (20:25:5:1, by vol). Fraction III contained both DGDG and SQDG, as did Fraction IV. Therefore, DGDG and SQDG were isolated from the combined Fractions III and IV by TLC with a solvent system made up of chloroform/methanol/water/ethyl acetate/2-propanol (5:2:1:5:5, by vol). The $R_f$ values of the MGDG, DGDG, and SQDG on TLC using these solvent systems were 0.35, 0.27, and 0.16, respectively, which were in good agreement with those of authentic standards. After spraying with 2′,7′-dichlorofluorescein reagent, bands were visualized under ultraviolet (UV) irradiation. The MGDG was recovered from the adsorbent with chloroform/methanol (2:1, vol/vol); DGDG and SQDG were recovered with chloroform/methanol/water (6:4:1, by vol). On analytical TLC, purified glycoglycerolipids showed characteristic dark red-colored spots when sprayed with an orcinol-sulfonic acid reagent and subjected to heating (19).

The methanol extracts (46 g) of *C. pilulifera* were partitioned between water and 1-butanol, and the organic phase was evaporated to dryness. The 1-butanol portion (6.1 g) was further partitioned between methanol and *n*-hexane. The methanol portion (42 mg) was separated into five fractions (V–IX) by preparative TLC with a solvent system of chloroform/methanol/water/ethyl acetate/2-propanol (5:2:1:5:5, by vol) to give MGDG ($R_f$ 0.61) (V), monogalactosylmonoacylglycerol MGMG ($R_f$ 0.39) (VI), DGDG ($R_f$ 0.27) (VII), SQDG ($R_f$ 0.16) (VIII), and a mixture of digalactosylmonoacylglycerol (DGMG) and sulfoquinovosylmonoacylglycerol SQMG ($R_f$ 0.10) (IX). Fraction IX was further separated into two portions by preparative TLC with a solvent system of 2-propanol/water/25% ammonia solution (72:11:17, by vol) to give SQMG ($R_f$ 0.39) and DGMG ($R_f$ 0.23). Structures of these glycosylmonoacylglycerols were confirmed by $^1H$ and $^{13}C$ NMR spectrometry, as described elsewhere (12).

*Release of di- and monoacylglycerols from glycoglycerolipids*. Glycosyldi- (MGDG, DGDG, and SQDG) and monoacylglycerols (MGMG, DGMG, and SQMG) were subjected to two consecutive reactions, periodate oxidation and fission of glycosidic linkage with 1,1-dimethylhydrazine, as described by Heinze *et al*. (20) for glycosyldiacylglycerols. The method releases free di- and monoacylglycerols from glycosyl diacylglycerols and monoacylglycerols, respectively. Briefly, glycoglycerolipid (3 mg) and $HIO_4{\cdot}4H_2O$ (46 mg) were dissolved in methanol (1 mL) and kept at room temperature for 90 min in the dark. Then chloroform (4 mL) and 0.45% NaCl solution (1.5 mL) were added and shaken vigorously. After brief centrifugation, the lower phase was evaporated under nitrogen gas. The residue was dissolved with 1,1-dimethylhydrazine (6.5 μL) in chloroform/water/2-propanol/acetic acid (6:7:2:3, by vol) and kept in the dark at 25°C for 4 h for DGDG and DGMG, and 20 h for MGDG, MGMG, SQDG, and SQMG. After adding *n*-hexane (3 mL), the mixture was washed twice with 50 mM $KH_2PO_4$ solution (2 mL) and dried over anhydrous $Na_2SO_4$. The residue obtained after removal of the solvent contained di- and monoacylglycerols released from glycosyldi- and monoacyglycerols, respectively.

*Preparation of derivatives.* The di- and monoacylglycerols released were immediately converted into their 3,5-dinitrophenylurethane (3,5-DNPU) derivatives without prior isolation from the reaction products to minimize acyl migration. The reaction products and 3,5-dinitrophenyl isocyanate (5 mg) were dissolved into dry toluene (0.5 mL) in the presence of dry pyridine (30 μL), and the solution was stirred at 30°C for 3 h (21,22). The reaction was quenched with methanol (1 mL). After removal of the solvent, the crude urethane derivatives were purified by TLC on silica gel GF (Merck), using *n*-hexane/1,2-dichloroethane/ethanol (40:10:3, by vol) for 3,5-DNPU derivatives of diacylglycerols (22) and *n*-hexane/1,2-dichloro-ethane/ethanol (40:15:5, by vol) for bis(3,5-DNPU) derivatives of monoacylglycerols as the developing solvents (23). Bands were visualized under UV irradiation, and the adsorbent containing the derivatives was scraped off and extracted with diethyl ether.

*Preparation of standard di- and monoacylglycerols from linseed oil triacylglycerols. sn*-1,2(2,3)-Diacylglycerols and *sn*-

1(3)-monoacylglycerols were generated by partial Grignard degradation from linseed oil triacylglycerols and were purified by boric acid TLC as described previously (24). The 3,5-DNPU and bis(3,5-DNPU) derivatives were prepared as described above.

*Mass spectrometry (MS).* Flow injection electrospray ionization (ESI)-MS was carried out in the negative ion mode with a LCQ ion-trap mass spectrometer (Thermo Separation Products, San Jose, CA). The 3,5-DNPU and bis(3,5-DNPU) derivatives of di- and monoacylglycerols dissolved in chloroform/methanol (2:1, vol/vol, *ca.* 0.1 mg/mL) were introduced directly into the ESI probe by flow injection (10 μL/min). The heated capillary temperature was 200°C and the spray voltage was 4.2 kV. The nitrogen sheath gas was set at 30 arb (arbitrary units) by the software. The mass spectrum was taken in the mass range 150–2000 *m/z*. The negative ESI-MS spectra of the two derivatives gave a prominent pseudomolecular ion $[M - H]^-$.

*Chiral-phase HPLC.* Chiral-phase HPLC was performed on a Shimadzu LC-6A instrument (Shimadzu, Kyoto, Japan) equipped with columns containing (*R*)- and (*S*)-1-(1-naphthyl)ethylamine (25 cm × 4.6 mm i.d.) packed with 5-μm particles (YMC-Pack A-K03 and A-L03, respectively; YMC, Kyoto, Japan) for 3,5-DNPU derivatives of diacylglycerols derived from MGDG, DGDG, and SQDG, and columns containing *N*-(*R*)-1-(1-naphthyl)ethylaminocarbonyl-(*S*)-valine (25 cm × 4 mm i.d., Sumichiral OA-4100; Sumika Chemical Analysis Service, Osaka, Japan) and *N*-(*S*)-1-(1-naphthyl)ethylaminocarbonyl-(*R*)-valine (25 cm × 4.6 mm i.d., Sumichiral OA-4100R) packed with 5-μm particles for bis(3,5-DNPU) derivatives of monoacylglycerols derived from MGMG, DGMG, and SQMG. The analyses were done isocratically using a mixture of *n*-hexane/dichloromethane/ethanol (40:10:1, by vol) for the diacylglycerol derivatives (22) and *n*-hexane/dichloromethane/ethanol (40:12:3, by vol) for the monoacylglycerol derivatives (21) as the mobile phases at a constant flow rate of 1 mL/min. The column temperature was kept at 10°C. Peaks were monitored with a Shimadzu SPD-6A variable wavelength detector set at 254 nm, and chromatograms were recorded on a Shimadzu Chromatopack C-R3A.

*Lipase hydrolysis and fatty acid analysis.* The positional distribution of fatty acids at the *sn*-1 and *sn*-2 positions in glycosyldiacylglycerol molecules was determined by specific hydrolysis with *Rhizopus delemar* lipase (Seikagaku Kogyo, Tokyo, Japan), as described by Fisher *et al*. (25). The fatty acids released from the *sn*-1 position and lyso-compounds were converted into methyl esters by heating at 90°C for 2 h in a 5% HCl/methanol solution. Fatty acid composition was determined by open-tubular gas chromatography on a Rascot Silar 5CP column (50 m × 0.25 mm i.d.; Nihon Chromato Works, Tokyo, Japan). The column temperature was 180°C isothermally. The injector and flame-ionization detector temperatures were set at 230°C. Hydrogen was used as the carrier gas at a constant flow of 1 mL/min. The split ratio was 1:50. Peaks were identified by comparison with known fatty acids from marine organisms (26).

## RESULTS AND DISCUSSION

The determination of absolute configuration of the glycerol moieties in glycoglycerolipids in their intact form has not been achieved by any HPLC modes including chiral-phase HPLC. The enantiomer separations of both *sn*-1,2(2,3)-diacylglycerols and *sn*-1(3)-monoacylglycerols, however, have already been established by chiral- and normal-phase HPLC (15–17). In this study therefore we applied the chiral-phase HPLC techniques to assign the glycerol configuration in the di- and monoacylglycerols released from glycosyldi- and monoacylglycerols. To obtain unambiguous conclusions, we employed two chiral stationary phases having opposite configurations in this study, which caused a reversal in the order of elution of enantiomeric di- and monoacylglycerols.

*Glycosyldiacylglycerols.* Figure 1 shows the chiral-phase HPLC profiles of the 3,5-DNPU derivatives of the diacylglycerols released from MGDG, DGDG, and SQDG of spinach leaves by periodate oxidation followed by hydrazinolysis, and of standard *sn*-1,2(2,3)-diacylglycerols generated from linseed oil triacylglycerols by partial Grignard degradation, on a column containing (*R*)-1-(1-naphthyl)ethylamine (A-K03). At 10°C, the linseed oil diacylglycerols were clearly resolved into two groups, representing the *sn*-1,2- and *sn*-2,3-enantiomers (Fig. 1D). Previous work established a faster elution of *sn*-1,2-enantiomers compared to *sn*-2,3-enantiomers on A-K03 (22). Each enantiomer group was split into six peaks, which were eluted in order of decreasing equivalent carbon numbers (ECN) of the molecules (22). When analysis was done at 28°C, some peak overlapping was observed between *sn*-1,2-enantiomers of low ECN values and *sn*-2,3-enantiomers of high ECN values, such as *sn*-1,2-dilinolenoylglycerol (18:3-18:3, ECN = 24) and *sn*-2,3-palmitoyloleoylglycerol (16:0-18:1, ECN = 32) (22). The separation factors of the *sn*-1,2- and *sn*-2,3-enantiomers at 10 and 28°C were 1.55 and 1.44, respectively. Apparently a lower column temperature employed in this study improved the enantiomer resolution. The effect of column temperature on the enantiomer resolution of diacylglycerols by chiral phase HPLC has been discussed elsewhere (27). The diacylglycerols released from the MGDG, DGDG, and SQDG of spinach leaves eluted within 20 min after injection with partial resolution of molecular species, all of which were *sn*-1,2-enantiomers (Figs. 1A–C). Any *sn*-2,3-enantiomers, if present, would appear after 20 min. Individual peaks were tentatively identified on the basis of the ECN concept, fatty acid compositions at the *sn*-1 and *sn*-2 positions in MGDG, DGDG, and SQDG molecules (Table 1), and a comparison of the molecular species separation obtained by reversed-phase HPLC for the intact MGDG and DGDG from spinach leaves (28). The major molecular species of the MGDG, DGDG, and SQDG were 18:3-18:3 (ECN = 24)/18:3-16:3 (ECN = 22), 18:3-18:3 (ECN = 24), and 16:0-18:3 (ECN = 28), respectively. Although no reverse isomer resolution was obtained for 18:3-16:3 and 16:0-18:3 under the HPLC conditions (29), it has been established that the 16:3 acid is mostly located at the *sn*-2 position and the 18:3 acid is

located at both *sn*-1 and *sn*-2 positions in the galactolipid molecules (2,3). Figure 2 shows the chiral phase HPLC profiles of the 3,5-DNPU derivatives of the diacylglycerol moieties in the spinach glycosyldiacylglycerols and of the linseed oil diacylglycerols on a column containing (*S*)-1-(1-naphthyl)ethylamine (A-L03), which has a configuration opposite to that of A-K03. Like the A-K03 column, the A-L03 column also gave complete resolution between the *sn*-1,2- and *sn*-2,3-enantiomers of the linseed oil diacylglycerols at 10°C, but with a reversal in the elution order (Fig. 2D). The enantiomeric diacylglycerols released from the MGDG, DGDG, and SQDG of spinach leaves also appeared in the *sn*-1,2-enantiomer region of the A-L03 column, but in a reversed order of elution (Figs. 2A–C). These results confirm that the glycerol moieties in the glycosyldiacylglycerols obtained from spinach leaves have *S* configuration (*sn*-1,2-diacylglycerols), as established previously (1). Furthermore, the results demonstrate that the periodate/methylhydrazine degradation does not compromise the chirality of the released acylglycerols.

Figure 3 shows the chiral-phase HPLC profiles of the 3,5-DNPU derivatives of diacylglycerols released from MGDG, DGDG, and SQDG of the red alga *C. pilulifera*, and of standard *sn*-1,2(2,3)-diacylglycerols generated from linseed oil triacylglycerols by partial Grignard degradation, on the A-K03 column. Like the spinach leaf diacylglycerols, the *C. pilulifera* diacylglycerols from the glycosyldiacylglycerols were eluted within 20 min after injection, and their elution orders were reversed from those seen on A-L03 (chromatograms not shown). These results clearly show that all the diacylglycerols released from the MGDG, DGDG, and SQDG of *C. pilulifera* consist only of *sn*-1,2-enantiomers (*S* configuration), which had not been established previously. On the basis of the ECN concept and the fatty acid composition of the *sn*-1 and *sn*-2 positions in the MGDG, DGDG, and SQDG molecules (Table 2), the partially resolved peaks were tentatively identified as follows: 16:0-18:1 (ECN = 32), 16:0-18:2 (ECN = 30), 20:5-16:0 (ECN = 26), 20:5-20:4 (ECN = 22), and 20:5-20:5 (ECN = 20) for MGDG (Fig. 3A); 16:0-18:1 (ECN = 32), 16:0-18:2 plus 16:1-

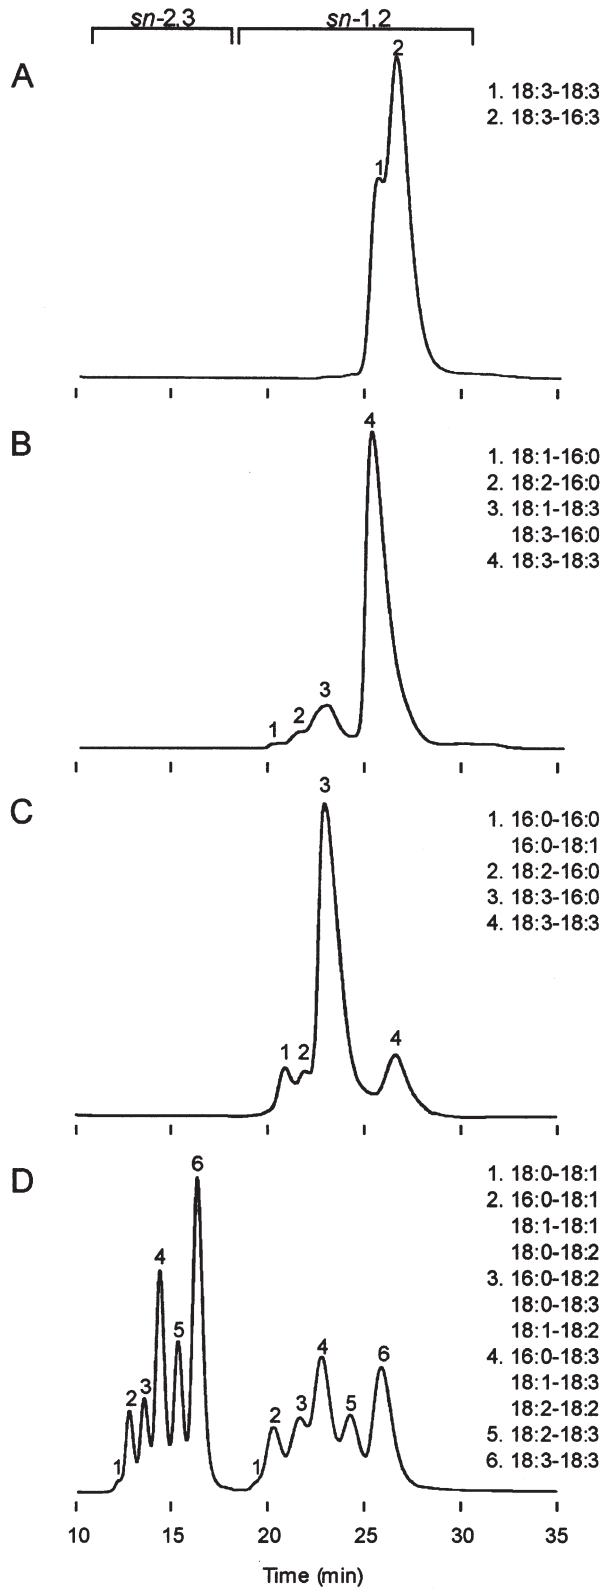

**FIG. 2.** Chiral-phase HPLC profiles of the 3,5-DNPU derivatives of diacylglycerols released from MGDG (A), DGDG (B), and SQDG (C) of spinach leaves, and of standard *sn*-1,2(2,3) diacylglycerols derived from linseed oil triacylglycerols by partial Grignard degradation (D) on a column containing (*S*)-1-(1-naphthyl)ethylamine polymer (A-L03; YMC). For abbreviations and manufacturer see Figure 1.

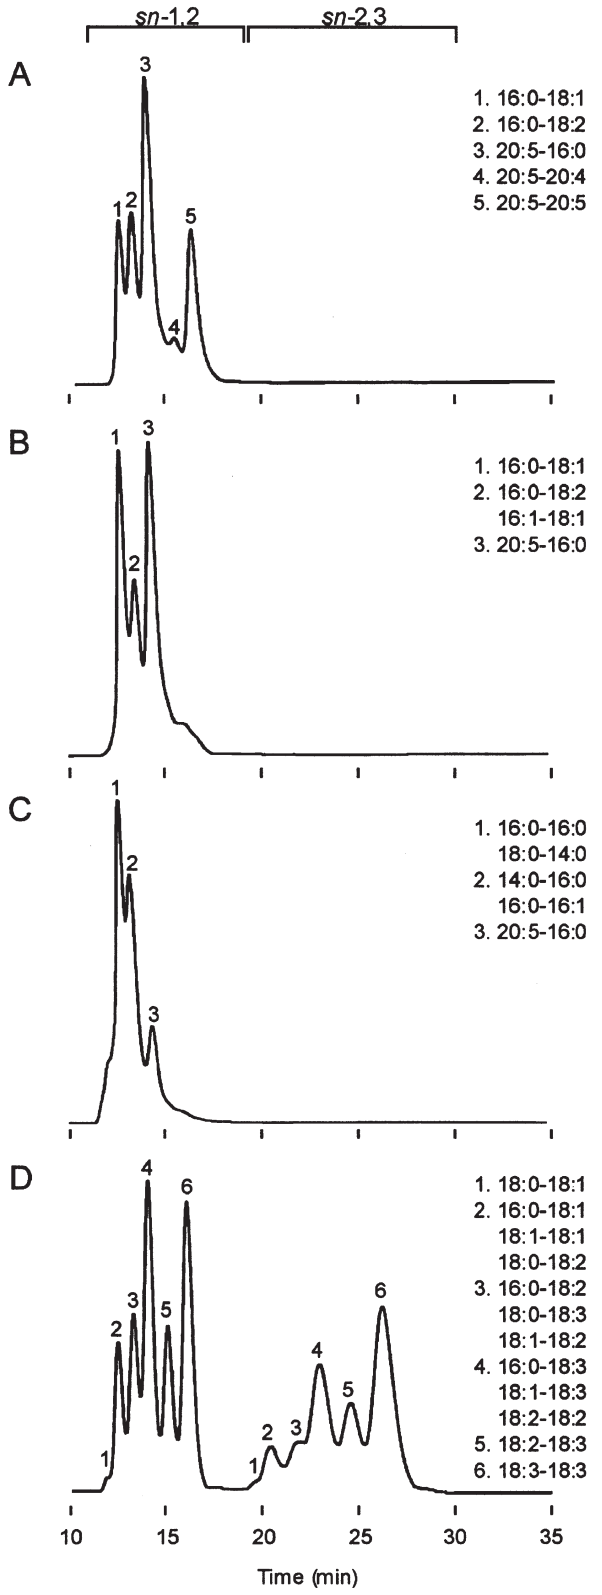

**FIG. 3.** Chiral-phase HPLC profiles of the 3,5-DNPU derivatives of diacylglycerols released from MGDG (A), DGDG (B), and SQDG (C) of the red alga *C. pilulifera*, and of standard *sn*-1,2(2,3) diacylglycerols derived from linseed oil triacylglycerols by partial Grignard degradation (D) on a column containing (*R*)-1-(1-naphthyl)ethylamine polymer (A-K03). For abbreviations and manufacturer see Figure 1.

18:1 (ECN = 30), and 20:5-16:0 (ECN = 26) for DGDG (Fig. 3B); and 16:0-16:0 plus 18:0-14:0 (ECN = 32), 14:0-16:0 plus 16:0-16:1 (ECN-30), and 20:5-16:0 (ECN = 26) for SQDG (Fig. 3C). The negative ESI-MS spectra of the 3,5-DNPU derivatives from MGDG, DGDG, and SQDG, which gave a prominent pseudomolecular ion $[M - H]^-$, also supported the occurrence of these molecular species. The molecular species of the glycosyldiacylglycerols in *C. pilulifera* are similar to those in the marine red alga *Porphyra yezoensis*, although the most predominant species of SQDG in the latter alga is 20:5-16:0 (30). The A-L03 column gave effective resolution of the reverse isomers of *sn*-1,2-diacylglycerols having very different pairs of acyl groups (29), but the occurrence of *sn*-1,2-palmitoyleicosapentaenoylglycerol (16:0-20:5) in the *C. pilulifera* glycosyldiacylglycerols could not be confirmed from the present chromatograms because of extensive overlapping among molecular species.

*Glycosylmonoacylglycerols.* The occurrence of the glycosylmonoacylglycerols (MGMG, DGMG, and SQMG) in the red alga *C. pilulifera* suggests hydrolysis of the glycosyldiacylglycerols by acyl hydrolases in the tissue. Notable amounts of free fatty acids, in which eicosapentaenoic acid was a major constituent, were also found in the algal lipids (31). The acyl hydrolase from the green alga *Dunaliella salina* chloroplasts preferentially attacks the *sn*-1 position of MGDG (32). The acyl hydrolase from potato tubers also attacks the *sn*-1 position in preference to the *sn*-2 position of MGDG (33). The enzymes from runner-bean leaves hydrolyze the acyl groups at both positions of MGDG and DGDG to form the corresponding galactosylglycerols and free fatty acids (34). The monoacylglycerols released from the MGMG, DGMG, and SQMG of *C. pilulifera* mainly consisted of *sn*-1-isomers (*sn*-1-monoacylglycerols, each 95%), which suggest that the enzymes preferentially hydrolyze the acyl group at the *sn*-2 position. In this study, however, we isolated the glycosylmonoacylglycerols from the alga using column chromatography and TLC on silicic acid, which could have isomerized some of the acyl groups at the *sn*-2 position to the *sn*-1 position (3). Therefore, the *sn*-1-isomers found in this study may contain appreciable amounts of the isomerized *sn*-2-isomers. The occurrence of both isomers in the red alga *C. pilulifera* suggests that acyl hydrolases in this tissue attack the *sn*-1 and *sn*-2 positions directly as already observed in higher plants and the green alga (32–34). In order to obtain clear HPLC chromatograms, small amounts of the *sn*-2-isomers (each 5%) were removed from the monoacylglycerols released from the MGMG, DGMG, and SQMG by silicic acid TLC after derivatization, and the remaining *sn*-1-isomers were used for determining the glycerol configuration. If the *sn*-2-isomers are not removed by TLC, they will interfere with the *sn*-1-isomers on OA-4100 and the *sn*-3-isomers on OA-4100R.

Figure 4 shows the chiral-phase HPLC profiles of the bis(3,5-DNPU) derivatives of the monoacylglycerols released from the MGMG, DGMG, and SQMG of the red alga *C. pilulifera* by periodate oxidation followed by hydrazinolysis, and of standard *sn*-1(3)-monoacylglycerols generated from linseed oil triacylglycerols by partial Grignard degradation, on a

[a]MGMG, monogalactosylmonoacylglycerol; DGMG, digalactosylmonoacylglycerol; SQMG, sulfoquinovosylmonoacylglycerol; for other abbreviations see Table 1.

column containing *N*-(*R*)-1-(1-naphthyl)ethylaminocarbonyl-(*S*)-valine (OA-4100). The linseed oil monoacylglycerols were clearly resolved into two groups, representing the *sn*-1- and *sn*-3-enantiomers (Fig. 4D). Previous study established faster elution of the *sn*-1-enantiomers when compared to the *sn*-3-enantiomers (23). Like the 3,5-DNPU of diacylglycerols, the bis(3,5-DNPU) derivatives of linseed oil monoacylglycerols were also eluted from the column according to their ECN values. Thus, the *sn*-1-enantiomers were partially resolved into four peaks, which were tentatively identified as follows: peak 1 (ECN = 18), monostearoylglycerol (18:0); peak 2 (ECN = 16), monopalmitoyl- (16:0) plus monooleoylglycerols (18:1); peak 3 (ECN = 14), monolinoleoylglycerol (18:2), and peak 4 (ECN = 12), monolinolenoylglycerol (18:3). All the monoacylglycerols released from the MGMD (Fig. 4A), DGMG (Fig. 4B), and SQMG (Fig. 4C) of *C. pilulifera* appeared in the *sn*-1-enantiomer region with partial resolution (MGMG and SQMG) or complete overlap (DGMG) of molecular species, which were attributed to 16:0 plus 18:1, 16:1 plus 18:2 and 20:5 (MGMG), 16:0 plus 18:1 (DGMG), and 16:0 plus 18:1 and 14:0 plus 16:1 (SQMG). Fatty acid compositions and negative ESI-MS spectra of each glycosylmonoacylglycerol also supported the peak identification (Table 2). No peaks were seen for the *sn*-3-enantiomers in the glycosylmonoacylglycerols (Figs. 4A–C). The bis(3,5-DNPU) derivatives of monoacylglycerols released from the *C. pilulifera* glycosylmonoacylglycerols and of the linseed oil monoacylglycerols were also resolved into two clearly distinguishable enantiomer groups but with a reversal in the elution order on a column containing *N*-(*S*)-1-(1-naphthyl)ethylaminocarbonyl-(*R*)-valine (OA-4100R), which has a configuration opposite that of OA-4100 (chromatograms not shown). Therefore, the results obtained with the two columns having opposite configurations clearly show that the glycerol moieties of all MGMG, DGMG, and SQMG of *C. pilulifera* have the *S*-configuration (*sn*-1-enantiomers), which had not been previously established.

In conclusion, this study reports the first successful application of chiral-phase HPLC to establishing glycerol chirality in complex natural glycosylacylglycerols. The method also provides information on the acyl group association in the glycosyldiacylglycerols. Further resolution of molecular species could be achieved by polar capillary gas–liquid chromatography or reversed-phase HPLC of the enantiomers isolated by chiral-phase HPLC, as well as by on-line mass spectrometry (17).

# Quantification of Key Odorants Formed by Autoxidation of Arachidonic Acid Using Isotope Dilution Assay

**Jianming Lin[1], Laurent B. Fay, Dieter H. Welti, and Imre Blank***

Nestec Ltd., Nestlé Research Center, CH-1000 Lausanne 26, Switzerland

**ABSTRACT:** Six odor-active compounds generated by autoxidation of arachidonic acid (AA) were quantified by isotope dilution assay (IDA), i.e., hexanal (**1**), 1-octen-3-one (**2**), (*E,Z*)-2,4-decadienal (**3**), (*E,E*)-2,4-decadienal (**4**), *trans*-4,5-epoxy-(*E*)-2-decenal (**5**), and (*E,Z,Z*)-2,4,7-tridecatrienal (**6**). Compound **1** was the most abundant odorant with about 700 mg/100 g autoxidized AA, which corresponds to 2.2 mol% yield. Based on the odor activity values (ratio of concentration to odor threshold), odorants **3** (fatty) and **5** (metallic) showed the highest sensory contribution followed by **1** (green), **2** (mushroom-like), **6** (egg white-like), and **4** (fatty). For the first time, reliable quantitative results are reported for odorants **1–6** in autoxidized AA, in particular odorant **6**, which is a characteristic compound found in autoxidized AA. Synthesis of deuterated **6**, required for IDA, is described in detail. The formation of odorants **1–6** by autoxidation of AA is discussed with respect to the quantitative data.

Paper no. L8774 in *Lipids 36,* 749–756 (July 2001).

Arachidonic acid (AA, 20:4) is found in membrane phospholipids of all mammalian tissues and plays a role in the regulation of functional properties like fluidity, permeability, and activity of membrane-bound enzymes. Although it is not an essential fatty acid, AA has recently been shown to correlate with both intrauterine growth of preterm infants (1,2) and growth in the first year of life (3). There is an increasing interest in the production of highly purified oils rich in AA for infant formulas (4).

As a polyunsaturated fatty acid, AA is very susceptible to oxidation with atmospheric oxygen and thus brings about losses in nutritional quality. Oxidative degradation also gives rise to flavor deterioration, i.e., formation of stale and rancid off-flavors. Off-flavor caused by lipid oxidation has been the subject of numerous studies, mainly on unsaturated lipids containing oleic, linoleic, and linolenic acids (5,6). However, little work has been published on volatile compounds formed by autoxidation of AA or methyl arachidonate. Depending on the starting material, reaction conditions, and analytical techniques used, various volatile compounds were identified, such as hexanal (7–10), 2-heptenal (7–9), 2,4-decadienal (8,10), 2,4,7-tridecatrienal (8), 1-octen-3-ol (9), 1-octen-3-one (9), pentane (10), and methyl 5-oxopentanoate (10).

The volatile composition of autoxidized AA has recently been characterized with focus on odor-active constituents (11,12). Hexanal (**1**), 1-octen-3-one (**2**), (*E,Z*)-2,4-decadienal (**3**), (*E,E*)-2,4-decadienal (**4**), *trans*-4,5-epoxy-(*E*)-2-decenal (**5**), and (*E,Z,Z*)-2,4,7-tridecatrienal (**6**) revealed high sensory relevance among the 19 odorants detected by gas chromatography–olfactometry (GC–O). The aroma properties of the most potent odorants were in good agreement with the overall aroma of autoxidized AA, described as green, metallic, egg white-like, fatty, and fishy.

It is well known that results obtained by GC–O only roughly estimate the sensory relevance of odorants, mainly because of discrimination during isolation of volatiles. The isotope dilution assay (IDA) has been shown to be a sensitive, accurate, and reliable quantification technique in flavor research (13–15). This method involves spiking food materials with known amounts of a labeled substance prior to sample preparation and analysis by gas chromatography–mass spectrometry (GC–MS). In this way, losses can be accounted for because whatever changes occur in the natural substance also occur in the labeled version. IDA has also been applied to lipid degradation products and off-flavor studies (14,16,17).

In this paper we report quantitative data of key odorants generated by autoxidation of AA, using the IDA technique for five aldehydes and one ketone. Synthesis of fourfold deuterated **6** is also described.

## EXPERIMENTAL PROCEDURES

*Materials.* The following chemicals were obtained commercially: AA (99%), ethylmagnesium bromide, palladium on $CaCO_3$ (Lindlar's catalyst) (Aldrich, Buchs, Switzerland); deuterium gas (Carbagas, Lausanne, Switzerland); neutral aluminum oxide ($Al_2O_3$), hexanal, cuprous chloride (CuCl), manganese (IV) oxide ($MnO_2$), phosphorus tribromide ($PBr_3$), pyridine ($H_2O$ <0.005%), tetrahydrofuran ($H_2O$ <0.005%) (Fluka, Buchs, Switzerland); 2,4-decadienal (*E,E*: 95%; *E,Z*: 5%; Fontarom, Cergy Pontoise, France); deuterated chloroform ($C^2HCl_3$, 99.8%, Dr. Glaser AG, Basel, Switzerland); diethyl ether ($Et_2O$), hexane, pentane, silica gel

Abbreviations: AA, arachidonic acid; CC, column chromatography; CI, chemical ionization; EI, electron ionization; GC, gas chromatography; GC–O, gas chromatography–olfactometry; HPET, hydroperoxyeicosatrienoic acid; HPETE, hydroperoxyeicosatetraenoic acid; HPOD, hydroperoxyoctadecadienoic acid; IDA, isotope dilution assay; IS, internal standard; MS, mass spectrometry; NMR, nuclear magnetic resonance; OAV, odor activity value; PCI, positive chemical ionization; RI, retention index; SIM, selected ion monitoring.

60, sodium carbonate ($Na_2CO_3$), sodium hydrogen carbonate ($NaHCO_3$), anhydrous sodium sulfate ($Na_2SO_4$), sulfuric acid ($H_2SO_4$) (Merck, Darmstadt, Germany); 2-octyn-1-ol, (*E*)-2-penten-4-yn-1-ol (Lancaster, Morecambe, England); and 1-octen-3-one (Oxford, Brackley, United Kingdom).

Silica gel 60 and neutral aluminum oxide were treated as reported by Ullrich and Grosch (18). *trans*-4,5-Epoxy-(*E*)-2-decenal (**5**) and (*E*,*Z*,*Z*)-2,4,7-tridecatrienal (**6**) were synthesized as described earlier (12,19). The labeled internal standards [5,6-$^2H_2$]-hexanal (***d*-1**), [1-$^2H_{1;2}$,2-$^2H_{1;1}$]-1-octen-3-one (***d*-2**), [3,4-$^2H_2$]-(*E*,*E*)-2,4-decadienal (***d*-4**), and [4,5-$^2H_2$]-*trans*-4,5-epoxy-(*E*)-2-decenal (***d*-5**) were synthesized as previously reported (19–21).

*Autoxidation.* AA (500 mg) was dissolved in freshly distilled $Et_2O$ (50 mL) and placed into a 250-mL flask. The solvent was removed with a stream of nitrogen to obtain a thin layer of the lipid material. The flask was filled with oxygen and sealed. After storing the sample in the dark for 48 h at room temperature, the flask was flushed with nitrogen (1 min). The peroxide value was measured using the Fe test (22), indicating the presence of about 60 mol% of total peroxides.

*Clean-up.* Nonvolatile components were removed by column chromatography (CC) for quantitative analysis. $Et_2O$ (2 mL) was added to the reaction mixture after autoxidation. The solution was spiked with labeled internal standards dissolved in pentane. The homogenized mixture was applied onto a glass column (20 × 1 cm) packed with $Al_2O_3$ in pentane/$Et_2O$ (2:1, vol/vol). The column was maintained at 10°C by a cooling jacket. Compounds without a carboxylic group were eluted with 150 mL pentane/$Et_2O$ (2:1, vol/vol). The effluent was collected and concentrated to 2 mL using a Vigreux column (50 × 1 cm).

In order to further purify the samples for quantification, the concentrated effluent obtained from CC with $Al_2O_3$ was applied to a glass column (20 × 1 cm, with cooling jacket) packed with silica gel 60 in pentane. Elution was performed stepwise with 50 mL pentane/$Et_2O$ (98:2, vol/vol) and 150 mL pentane/$Et_2O$ (85:15, vol/vol). Only the second fraction was collected and concentrated to 0.5 mL for GC–MS analysis.

*Capillary GC.* This was performed with a Carlo Erba Mega 2 (Fisons Instruments, *via* Brechbühler, Schlieren, Switzerland) equipped with a cold on-column injector and a flame-ionization detector held at 230°C. Fused-silica capillary columns of low (DB-5), medium (DB-1701), and high (DB-Wax, DB-FFAP) polarity were used (J&W Scientific MSP Friedli, Koeniz, Switzerland), both 30 m × 0.32 mm with a film thickness of 0.25 µm. Helium (80 kPa) was used as carrier gas. The temperature program was 35°C (2 min), 40°C/min to 50°C (1 min), 6°C/min to 180°C, 10°C/min to 240°C (10 min). Linear retention indices (RI) were calculated according to van den Dool and Kratz (23).

*GC–MS.* Qualitative analysis was performed on a MAT 8430 mass spectrometer ( Finnigan, Bremen, Germany). Electron ionization (EI) mass spectra were generated at 70 eV. Chemical ionization (MS–CI) was performed at 150 eV with ammonia as the reagent gas. Further details of the GC–MS system and chromatographic conditions were described elsewhere (20). Relative abundances of the ions are given in percentages.

Quantitative analysis was performed on a Finnigan SSQ 7000 mass spectrometer coupled with an HP-5890 gas chromatograph. CI was carried out at 200 eV with isobutane as reagent gas. Samples were introduced *via* splitless injection at 250°C on a DB-1701 capillary column (30 m × 0.32 mm, film thickness 0.25 µm; J&W Scientific). Helium (90 kPa) was used as carrier gas. Temperature program: 20°C (1 min), 70°C/min to 60°C, 6°C/min to 180°C, 10°C/min to 240°C (10 min). Each sample (2 µL) was injected at least twice. Quantitative measurements were carried out in full scan or, if necessary, in the selected ion monitoring (SIM) mode measuring characteristic ions listed in Table 1.

*Determination of isotopic purity.* This was calculated from GC–MS data as recently described for deuterated aldehydes (20). Clusters of ions representing the species from $[M + 3]^+$ to $[M - 2]^+$ of both the deuterated standard and nonlabeled reference compound were measured in the positive chemical ionization (PCI) mode on the SSQ 7000 using SIM and isobutane as reagent gas (24,25). The nondeuterated substance was analyzed for isotope correction of the labeled compound. The deuterium distribution was calculated according to Rohwedder (25).

**TABLE 1**
**Parameters Used in the Quantification of Six Lipid-Derived Odorants by Isotope Dilution Assay**

| Analyte | Internal standard (IS) | Selected ions (*m/z*)[a] | | Linearity[b] ($r^2$) | Linear range[b] (ratio analyte/IS) |
|---|---|---|---|---|---|
| | | Analyte | IS | | |
| **1** | [5,6-$^2H_2$]-Hexanal (***d*-1**) | 101 | 103 | 0.999 | 0.05–19.0 |
| **2** | [1-$^2H_{1;2}$,2-$^2H_{1;1}$]-1-Octen-3-one (***d*-2**) | 127 | 129/130[c] | 0.999 | 0.05–9.0 |
| **3** | [3,4-$^2H_2$]-(*E*,*E*)-2,4-Decadienal (***d*-4**) | 153 | 155 | 0.999 | 0.05–9.0 |
| **4** | [3,4-$^2H_2$]-(*E*,*E*)-2,4-Decadienal (***d*-4**) | 153 | 155 | 0.999 | 0.05–9.0 |
| **5** | [4,5-$^2H_2$]-*trans*-4,5-Epoxy-(*E*)-2-decenal (***d*-5**) | 153 | 155 | 0.999 | 0.05–9.0 |
| **6** | [4,5,7,8-$^2H_4$]-(*E*,*Z*,*Z*)-2,4,7-Tridecatrienal (***d*-6**) | 193 | 197 | 0.999 | 0.05–9.0 |

[a]Chemical ionization was applied using isobutane as reagent gas. The ion pairs measured generally were the species $[M + H]^+$, except for **5** and ***d*-5** where $[M + H - O]^+$ was monitored.
[b]Linearity and linear range were obtained from the calibration graphs using selected ions (see the Experimental Procedures section).
[c]***d*-2** was composed of two major isotopomers (21). The sum of both ions (*m/z* 129 and 130) was used for establishing the calibration graph.

*IDA.* Defined amounts of labeled internal standard (IS) in solution were added to autoxidized AA before isolation of volatiles by CC. Calibration curves were obtained using mixtures of defined amounts of analyte and labeled IS (14). As recently described for **5** and ***d*-5** (19), nine mixtures **1**/***d*-1** were used, i.e., from 0.5 + 9.5, 1 + 9, 2 + 8, 3 + 7, and 5 + 5 to 7 + 3, 8 + 2, 9 + 1, and 9.5 + 0.5. Calibration curves were established for the odorants **1**, **2**, **4**, **5,** and **6**, while (*E*,*Z*)-2,4-decadienal (**3**) was quantified using that of **4**. The parameters used in the IDA of the five odorants are summarized in Table 1. Samples for establishing the calibration curves and for quantification were injected twice.

*Nuclear magnetic resonance (NMR) spectroscopy.* The sample for NMR spectroscopy was prepared in a WILMAD 528-PP 5 mm Pyrex NMR tube (Textronica AG, Oberreit, Switzerland), using as solvent $C^2HCl_3$ (0.7 mL) from a sealed vial. The NMR spectra were acquired on a Bruker AM-360 spectrometer, equipped with a quadrinuclear 5-mm probe head, at 360.13 MHz for $^1H$ and at 90.56 MHz for $^{13}C$ under standard conditions (20). All shifts are cited in ppm from the internal trimethylsilane standard. Since nondeuterated (*E*,*Z*,*Z*)-2,4,7-tridecatrienal had been previously elucidated in detail (12), one-dimensional spectra ($^1H$ NMR, $^{13}C$ NMR, proton decoupled and nondecoupled, distortionless enhancement by polarization transfer 135) were sufficient to characterize its deuterated analog.

*Synthesis of [4,5,7,8-$^2H_4$]-(*E,Z,Z*)-2,4,7-tridecatrienal (***d-6***).* The synthesis procedure used for (*E*,*Z*,*Z*)-2,4,7-tridecatrienal (12) was adapted to obtain ***d*-6** by partial deuteration of intermediate **10** as shown in Scheme 1. Experimental details for the first two steps leading to **10** are described elsewhere (12).

*[4,5,7,8-$^2H_4$]-(*E,Z,Z*)-2,4,7-Tridecatrien-1-ol (***d-11***).* This was prepared by partial deuteration of **10** in $CH_3O^2H$ at room temperature under normal pressure with Lindlar's catalyst following the conditions recently described (12). Monitoring of the reaction by GC–MS indicated ***d*-11** as the major compound with some under- and over-deuterated by-products. The product mixture was used in the next step without purification. MS(EI) *m/z* (% relative abundance): 82 (100), 83 (66), 81 (60), 97 (58), 96 (46), 167 (45), 70 (42), 69 (41), 95 (38), 84 (37), 57 (36), 85 (35), 79 (35), 56 (35), 71 (34), 80 (33), 55 (27), 198 (25, $M^+$), 110 (21), 109 (21), 108 (19), 122 (17), 123 (15), 138 (8), 137 (8), 155 (5). MS(CI), ammonia *m/z* (% relative abundance): 181 (100, $[M + H - H_2O]^+$), 198 (20, $M^+$ or $[M + NH_4 - H_2O]^+$), 216 (10, $[M + NH_4]^+$).

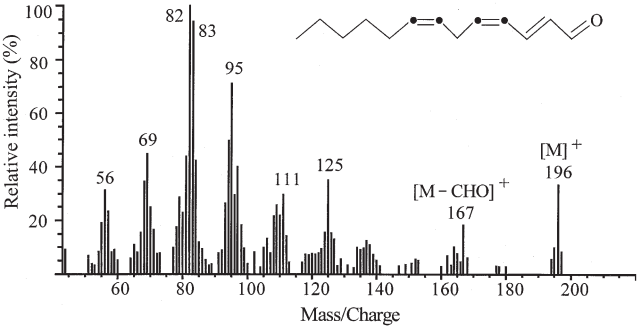

**FIG. 1.** Mass spectrum (electron ionization) of [4,5,7,8-$^2H_4$]-(*E,Z,Z*)-2,4,7-tridecatrienal (***d*-6**).

*[4,5,7,8-$^2H_4$]-(*E,Z,Z*)-2,4,7-Tridecatrienal (***d-6***).* The product mixture (1.0 g) containing ***d*-11** obtained in the previous step was oxidized with $MnO_2$ (10.0 g) in hexane. The oxidation, monitored by GC, was complete after 30 min. The target compound ***d*-6** was obtained with at least 80% (GC) purity by CC. GC: RI (DB-5) = 1581, RI (OV-1701) = 1731, RI (FFAP) = 2118, RI (DB-Wax) = 2105. MS(EI) of ***d*-6** is shown in Figure 1. MS(CI), ammonia *m/z* (% relative abundance): 197 (100, $[M + H]^+$), 214 (80, $[M + NH_4]^+$). The $^1H$ and $^{13}C$ NMR spectral data of ***d*-6** are given in Table 2.

## RESULTS AND DISCUSSION

*Synthesis of [4,5,7,8-$^2H_4$]-(*E,Z,Z*)-2,4,7-Tridecatrienal (***d-6***).* The IS ***d*-6** was synthesized in four steps (Scheme 1) in analogy to the nondeuterated compound **6** (12). Bromination of 2-octyn-1-ol (**7**) followed by coupling of the resulting 1-bromo-2-octyne (**8**) with the Grignard derivative of (*E*)-2-penten-4-yn-1-ol (**9**) gave rise to (*E*)-2-tridecen-4,7-diyn-1-ol (**10**). Partial deuteration of **10** using Lindlar's catalyst was employed to obtain all-*cis* configuration for the C4-C5 and C7-C8 double bonds in the resulting [4,5,7,8-$^2H_4$]-(*E,Z,Z*)-2,4,7-tridecatrien-1-ol (***d*-11**). The mild and neutral oxidant $MnO_2$ was used to oxidize the allylic alcohol ***d*-11** to the target compound (***d*-6**) without changing the *cis* configuration of the C4-C5 double bond, which is sensitive to acidity.

The MS–CI data *m/z* 197, 214 of ***d*-6** compared to *m/z* 193, 210 of **6** (12) indicated incorporation of four deuterium atoms in ***d*-6**. Ions *m/z* 197 and 214 represent the species $[M + H]^+$ and $[M + NH_4]^+$, respectively. The fragments *m/z* 196, 167, and 125 in the EI mass spectrum (Fig. 1) confirmed the presence of four deuterium atoms as compared to *m/z* 192, 163, and 121 in **6** (12).

Signals of the $^1H$ and $^{13}C$ NMR spectral data of ***d*-6** (Table 2) were assigned by comparison with the spectral data of **6** (12). The proton spectrum of ***d*-6** was almost identical to that of **6**, when the changes due to the deuteration were taken into account. The spectrum indicated approximately 95% deuterium substitution at each of the expected positions C4, C5, C7, and C8, and also that either two deuterium atoms or one

[a]Chemical shifts (δ) in ppm from internal trimethylsilane.
[b]$^1$H nuclear magnetic resonance (NMR) multiplicity abbreviations: *s* = singlet, *d* = doublet, *t* = triplet, *q* = quartet, *m* = multiplet, *d t* = doublet of triplets (with decreasing values of coupling constants). Quotes ("…") mean approximate description of the multiplet, *sl. br.* = slightly broadened by unresolved long-range couplings. The coupling constants *J* are directly extracted from the spectrum, after moderate Gaussian resolution enhancement, without equalizing the constants belonging to the respective coupling partners. The coupling partners are indicated by subscripts where there is no ambiguity. Since the $T_1$ relaxation times may be long in this richly deuterated molecule, minor integration errors are not excluded.
[c]$^{13}$C NMR multiplicity abbreviations: *s, d, t, q,* denominate quaternary, CH-, $CH_2$- and $CH_3$-carbons, respectively.
[d]Signal due to isotopomer(s) not deuterated at 4-C.
[e]Residual proton signals of threefold (or less) deuterated isotopomers.
[f]Due to residual protonated carbons.
[g]Dominant signal, accompanied by several small slightly broad singlet signals between 3.1 and 2.9 ppm, likely due to threefold (or less) deuterated isotopomers and/or double-bond stereoisomers.
[h]The proton signals of 11-$CH_2$ and 12-$CH_2$ are overlapping; see (12) for a more precise shift determination from a two-dimensional heteronuclear correlation experiment in the nondeuterated analog.

deuterium and one proton are found on a double bond, while the doubly protonated double bonds are negligible. The configuration of the double bonds was deduced from that of **6**. There, coupling constants of *ca.* 15.3, 10.6, and 10.6 Hz had been found for the $C_2$-$C_3$, $C_3$-$C_5$, and $C_7$-$C_8$ double bonds, respectively (12). This, together with the nuclear Overhauser effect results, had clearly indicated the *E,Z,Z* configuration.

For an incompletely deuterated substance, integration is complicated by the various isotopomers that occur. The 3-H signal of ***d*-6**, for example, was a superposition of two components. The dominating component (~95% of the integral area) was a doublet (due to the coupling to 2-H ) of approximate 1:1:1 patterns (the latter caused by the coupling to the quadrupolar deuterium atom replacing 4-H). This signal component represented four different isotopomers, since the majority of the molecules was at least threefold deuterated. The minor 3-H signal component (~5% integral area) was a doublet of doublets without deuterium coupling, standing for one isotopomer with 4-H instead of 4-$^2$H. The respective integral areas were estimated by simulation of the two overlapping components.

As was the case for **6**, the proton spectrum, e.g., of the aldehyde signal, indicated small amounts of various double-bond stereoisomers of ***d*-6** with a distribution similar to that of **6**, resulting in overinteger values of the aliphatic chain integrals (12). In view of these factors, we estimated the ***d*-6** content to be at least 82% of all (*E,Z,Z*)-2,4,7-tridecatrienal occurring in the solution. Integration of the aliphatic tail signals showed that (*E,Z,Z*)-2,4,7-tridecatrienal represented at least 80% of all 2,4,7-tridecatrienal present. GC analysis (data not shown) suggested that the stereoisomer (*E,E,Z*)-2,4,7-tridecatrienal is probably the second-most abundant 2,4,7-tridecatrienal in the product.

In the $^{13}$C NMR spectra of ***d*-6**, the typical isotope shifts with respect to **6** were found, and the minor signals of remaining nondeuterated carbons 4, 5, 7, and 8 were compatible with the corresponding residual proton integrals found in the $^1$H NMR spectrum.

The main reason for the isotopic impurities is the well-known phenomenon of deuterium scattering in catalytic deuteration (24). An accurate calculation of isotopic labeling is possible through correction of the data for the naturally occurring deuterium isotopes (24,25). This procedure indicated the following labeling pattern for ***d*-6**: $^2H_4$-**6** (84%), $^2H_3$-**6** (15.3%), $^2H_6$-**6** (0.5%), $^2H_2$-**6** (0.1%), and $^2H_5$-**6** (0.1%). As the isotopic purity is already considered in the calibration curve, mixtures of isotopomers do not preclude the application of IDA as long as the labeled molecules are stable with respect to deuterium/hydrogen exchange. This is the case for all labeled standards used in this study (19–21).

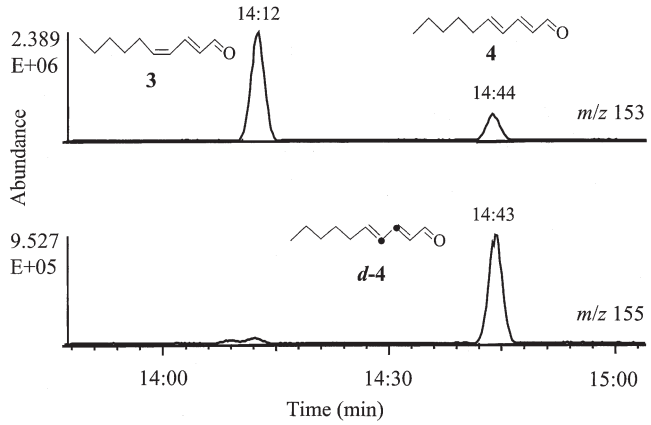

**FIG. 2.** Quantification of (*E,Z*)-2,4-decadienal (**3**) and (*E,E*)-2,4-decadienal (**4**) by isotope dilution assay using ***d*-4** as internal standard. The $[M + 1]^+$ ions *m/z* 153 of **3** and **4** and *m/z* 155 of ***d*-4** were measured by selective ion monitoring (SIM).

*IDA for the quantification of lipid-derived odorants.* Characteristic ion pairs of analyte and labeled IS were selectively monitored as shown in Figure 2 for odorants **3** and **4**. As they have almost identical chemical properties, ***d*-4** was used as IS for the quantification of both odorants. The SIM technique was preferably applied to labile compounds, such as odorant **5** (19), particularly if they occurred at low concentrations.

The calibration graphs obtained after plotting ion area ratio vs. amount area ratio showed typical second-order curves (Fig. 3A), particularly when the amount ratios were extended to values higher than 10. This is due to the natural $^{13}C$ abundance in the analyte, which coincided with the acquired ions of the deuterated IS, i.e., interference of natural isotope enrichment at higher mass or of the isotopic impurity at lower mass (26). To facilitate work within a linear range, we used only the lower part of the calibration curve, which showed excellent linearity (Fig. 3B). Therefore, the amount of IS added to the samples was adjusted to obtain an ion ratio falling in this linear range.

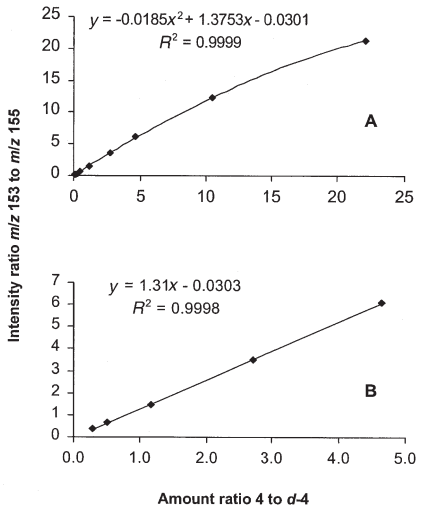

**FIG. 3.** Calibration curves obtained for the quantification of (*E,E*)-2,4-decadienal (**4**) by isotope dilution assay: (A) second-order curve and (B) linear range used in the quantification experiments.

The accuracy of the measured values compared to the theoretical values was checked according to the procedure recently described (26). Knowing the amount of analyte and labeled IS in the mixture, the theoretical enrichment of ***d*-IS** was calculated for each calibration point (data not shown) and expressed in mol% excess. The measured deuterium enrichment was plotted vs. theoretical deuterium enrichment resulting in linear curves as shown for **5** and ***d*-5** (19).

*Quantification of six odorants in autoxidized AA.* To obtain reliable quantitative data, concentrations of the potent odorants **1–6** were determined by IDA in the volatile fraction of autoxidized AA. Compound **1** with a green note was the most abundant odorant with about 7.4 g/kg autoxidized AA, which corresponds to 2.2% yield on a molar basis (Table 3). This is in good agreement with literature data reporting hexanal as the major volatile degradation product of autoxidized AA or methyl arachidonate (7,8,10). The concentrations of the remaining odorants varied from about 50 mg/kg AA for **5** (metallic) to nearly 400 mg/kg AA for **3** (fatty) with molar yields of less than 0.1%. The ratio hexanal to 2,4-decadienal was about 16:1, which is higher than those reported in the literature, i.e., 11:1 (7), 5:1 (10), and 1.4:1 (8).

As the concentrations of all of the volatile compounds identified in this study are far above their odor thresholds, they all contribute to the overall aroma of autoxidized AA. The odor activity values (OAV) were calculated as ratio of concentration to threshold. As summarized in Table 3, odorants **3** and **5** showed the highest OAV based on odor thresholds in air. They can be seen as the character impact odorants of autoxidized AA imparting metallic and fatty notes, which were found to be the main odor characters of the authentic sample (11). Data obtained on the basis of odor thresholds in oil indicated that in addition to **3** and **5**, odorants **1** and **2** significantly contribute with green and mushroom notes, respectively.

The significant contribution of **5** is due to its extremely low odor thresholds of 1.5 pg/L air (30) and 1.3 µg/L oil (14). Therefore, despite the lowest amounts found among the six impact odorants (Table 3), its sensory contribution is pronounced. Because of the low threshold value of **3**, particularly in oil (4 µg/L), and relatively high concentration, the sensory contribution of **3** to the overall aroma of autoxidized AA is of similar importance.

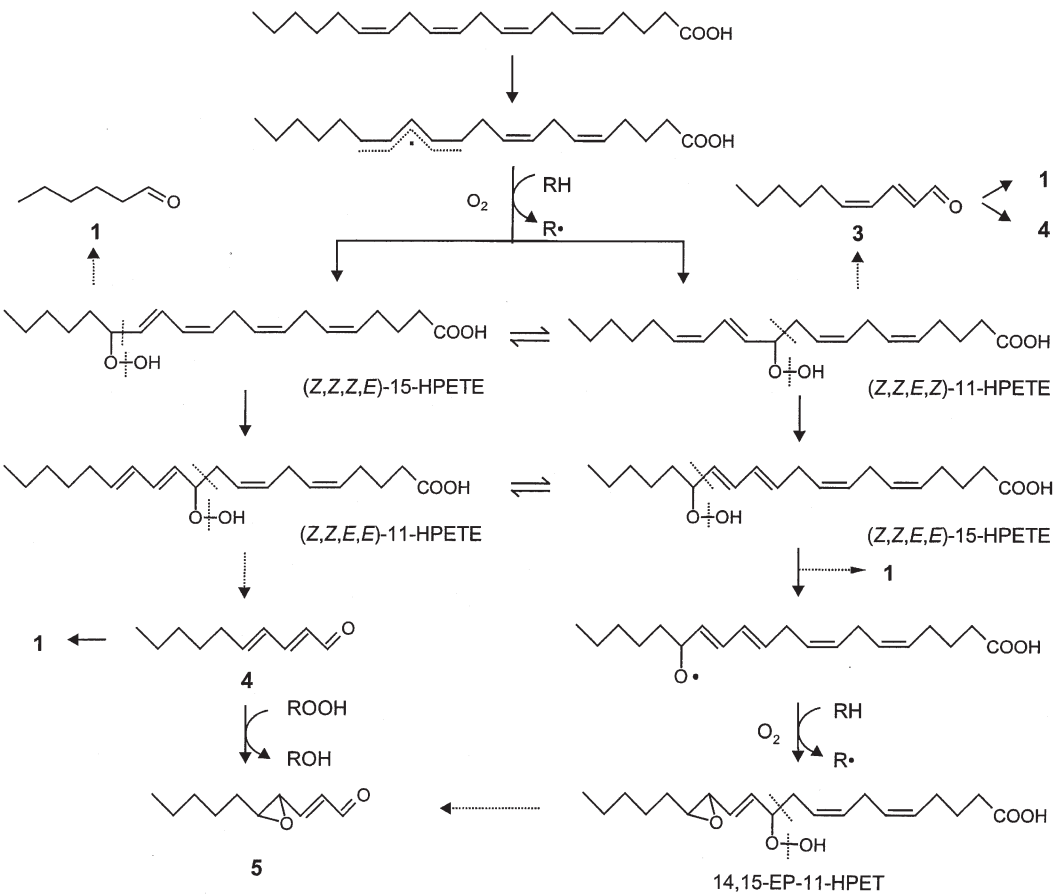
*Formation pathways.* Since AA belongs to the ω-6 fatty acid family, the formation of odorants with 10 carbon atoms and less can be explained in analogy to linoleic acid (6). Hexanal (**1**) is formed by β-cleavage of 15-hydroperoxy-5,8,11,13-eicosatetraenoic acid (15-HPETE) as shown in Scheme 2. It was found to be the major odor-active volatile degradation product in autoxidized AA with 2.2% molar yield (Table 3). Its abundance can be explained on the one hand by the relatively high yields of 15-HPETE (~35%) as reported by Yamagata *et al.* (32). On the other hand, odorant **1** is also known to be a secondary autoxidation product of 2,4-decadienal, compounds **3** and **4,** in Scheme 2 (33,34).

**TABLE 3**
**Odor Activity Values (OAV) of Potent Odorants Found in Autoxidized Arachidonic Acid (AA) Obtained by Calculating the Ratio of Concentration and Odor Thresholds in Air and Oil**

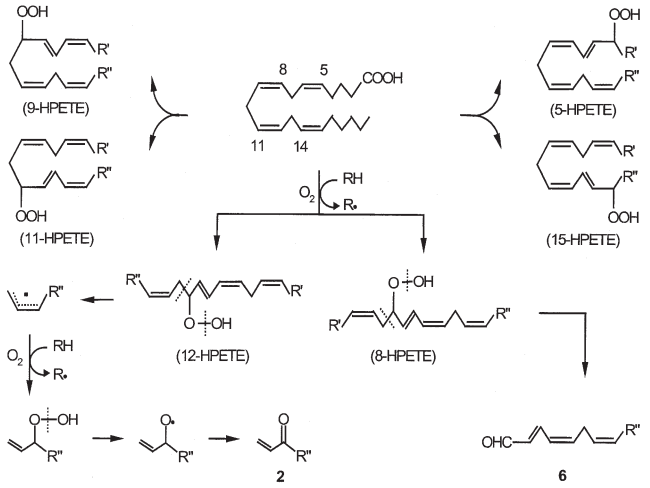
| Odorant | Aroma quality | Concentration (mg/kg AA) | Yield (mol%) | Odor threshold (ng/L air)[a] | OAV (air; × $10^6$) | Odor threshold (µg/L oil)[b] | OAV (oil) |
|---|---|---|---|---|---|---|---|
| **1** | Green | 7370 ± 520 | 2.2 | 30 | 245 | 300 | 24,570 |
| **2** | Mushroom-like | 70 ± 10 | 0.02 | 0.07 | 1000 | 10 | 7,000 |
| **3** | Fatty | 373 ± 7 | 0.07 | 0.01[c] | 37300 | 4 | 93,250 |
| **4** | Fatty | 96 ± 5 | 0.02 | 0.1 | 960 | 180 | 530 |
| **5** | Metallic | 47 ± 6 | 0.008 | 0.0015 | 31330 | 1.3 | 36,150 |
| **6** | Egg white-like | 131 ± 7 | 0.02 | 0.07[c] | 1870 | 180[d] | 730 |

[a]Odor thresholds in air were taken from the literature: **1** (27), **2** (28), **4** (29), **5** (30).
[b]Odor thresholds in oil were taken from the literature: **1** (14), **2** (14), **3** (31), **4** (14), **5** (14).
[c]Odor threshold was determined in this work (30).
[d]Odor threshold of **6** in oil was estimated to be similar to that of odorant **4**.

β-Cleavage of 11-(*Z*,*Z*,*E*,*Z*)-5,8,12,14-HPETE results in compound **3** with the *E*,*Z*-configuration of the double bonds (Scheme 2). In analogy, odorant **4** can be formed from 11-(*Z*,*Z*,*E*,*E*)-5,8,12,14-HPETE. The lower molar yields of **3** (0.07%) and **4** (0.02%) compared to **1** (2.2%) may be due to the lower amounts of the direct precursor 11-HPETE (~10%) formed by autoxidation of AA (32). The higher yields of **3** compared to **4** might be explained by the fact that **3** is directly formed from the primary precursor 11-(*Z*,*Z*,*E*,*Z*)-5,8,12,14-HPETE. In contrast, the precursor of **4**, 11-(*Z*,*Z*,*E*,*E*)-5,8,12,14-HPETE, must first be generated through isomerization of 11-(*Z*,*Z*,*E*,*Z*)-5,8,12,14-HPETE to 15-(*Z*,*Z*,*Z*,*E*)-5,8,11,13-HPETE. Following the mechanistic study of Porter and Wujek (35), the (*E*,*E*)-diene isomerization occurs after β-scission of $O_2$ from the 15-peroxyl radical (not shown in Scheme 2) leading to a pentadiene radical with 13,14 (*E*) and 11,12 (*Z*) conformation. Oxygenation of C-11 gives the desired 11-(*Z*,*Z*,*E*,*E*)-5,8,12,14-HPETE. Furthermore, aldehyde



**SCHEME 2**



**SCHEME 3**

**4** can also originate from **3**. However, **3** is stable at room temperature and in lipophilic media; isomerization to **4** occurs preferably upon heating or in aqueous solutions.

For the formation of **5**, we suggest 14,15-epoxy-11-hydroperoxy-5,8,12-eicosatrienoic acid (14,15-EP-11-HPET) (Scheme 2) as a key intermediate, in analogy to the formation of **5** from autoxidized linoleic acid (36). Alternatively, **5** can also be formed as a secondary oxidation product of 2,4-decadienal as recently reported by Gassenmeier and Schieberle (36). These authors demonstrated that **5** was preferentially formed from 9-hydroperoxy-10,12-octadecadienoic acid (9-HPOD) *via* 2,4-decadienal as the intermediate. Alternatively, **5** may also be formed by oxidation of **4** with peracids (not shown in Scheme 2).

Formation of **6** can be explained by β-cleavage of the corresponding 8-hydroperoxy-5,9,11,14-eicosatetraenoic acid (8-HPETE) as shown in Scheme 3. This is in analogy to the formation of (*E*,*Z*,*Z*)-2,4,7-decatrienal by autoxidation of linolenic acid (8,37). Similar to the formation of **2** in autoxidized linoleic acid from 10-hydroperoxy-8,12-octadecadienoic acid (10-HPOD), the mushroom-smelling odorant can also be generated from AA *via* the alkoxyl radical formed from 12-hydroperoxy-5,8,10,14-eicosatetraenoic acid (12-HPETE) as shown in Scheme 3, where R′ represents $CH_2$-$CH_2$-$CH_2$-COOH and R″ stands for $CH_2$-$CH_2$-$CH_2$-$CH_2$-$CH_3$ (8,37). However, the alkoxyl radical can also lead to 1-octen-3-ol (38) that was detected in autoxidized AA as well (11,12).

*Conclusions*. Quantitative characterization of the aroma composition of autoxidized AA by isotope dilution assay and calculation of the OAV suggest (*E*,*Z*)-2,4-decadienal and *trans*-4,5-epoxy-(*E*)-decenal as the character impact odorants, smelling fatty and metallic, respectively. These aroma notes are representative of the overall aroma of autoxidized AA. Hexanal seems to play an important role, particularly in oily media, due to its low odor threshold in oil. The quantitative data obtained for the six odorants are in good agreement with the possible formation mechanisms and the relative amounts of the corresponding hydroperoxides reported in the literature (32).

## ACKNOWLEDGMENTS

We are grateful to Francia Arce Vera and Sylviane Metairon for expert technical assistance and Dr. Elizabeth Prior for critical proofreading of the manuscript.

REVIEW

# Genomic and Functional Characterization of Polyunsaturated Fatty Acid Biosynthesis in *Caenorhabditis elegans*

**Johnathan A. Napier* and Louise V. Michaelson**

IACR-Long Ashton Research Station, Department of Agricultural Sciences, University of Bristol, Long Ashton, Bristol BS41 9AF, United Kingdom

**ABSTRACT:** The biosynthetic pathway for polyunsaturated fatty acids in the model animal *Caenorhabditis elegans* was examined in the context of the completed genome sequence. The genomic organization and location of seven desaturase genes and one elongase activity, all previously identified by functional characterization, were elucidated. A pathway for the biosynthesis of polyunsaturated fatty acids in *C. elegans* was proposed based on these genes. The role of gene duplication in enzyme evolution and proliferation is discussed.

Paper no. L8785 in *Lipids 36,* 761–766 (August 2001).

The successful completion of the *Caenorhabditis elegans* genome sequencing program (1) has been recognized not only as a major scientific achievement but also as ushering in the era of postgenomic biology for multicellular organisms. The knowledge of an entire genomic sequence provides new opportunities to determine and characterize the number of genes required by that organism to carry out various metabolic processes (1,2). One important and relatively simple metabolic pathway is that for polyunsaturated fatty acid (PUFA) biosynthesis (3). These fatty acids are essential components of the mammalian diet and serve as metabolic precursors for the eicosanoids (a collective group of $C_{20}$ molecules including prostaglandins and leukotrienes), which are important in the regulation of cellular processes (3,4). We examined the PUFA biosynthetic pathway in the model animal *C. elegans* with the aim of furthering our understanding of the genes required for this metabolic process.

The quantity and composition of the lipids (including PUFA) of *C. elegans* are well known (5,6). The total amounts of saturated and unsaturated fatty acids present in *C. elegans* cultured under a range of different temperatures have been determined (7), demonstrating the accumulation of $C_{20}$ PUFA. These include eicosapentanoic acid (EPA; $20{:}5\Delta^{5,8,11,14,17}$ or 20:5n-3), arachidonic acid (AA; $20{:}4\Delta^{5,8,11,14}$ or 20:4n-6), and dihomo-γ-linolenic acid (DHGLA; $20{:}3\Delta^{8,11,14}$ or 20:3n-6), which often occur in higher levels than in other organisms (>25% of total fatty acids). Therefore, PUFA biosynthesis in *C. elegans* (summarized in Fig. 1) serves as a good model system for the study of this biochemical pathway. In *C. elegans,* saturated 18-carbon fatty acids are desaturated to yield oleic acid ($18{:}1\Delta^{9}$; 18:1n-9) by a stearoyl CoA $\Delta^{9}$-desaturase enzyme, as in other animal (8) and fungal (9) systems. Further downstream, linoleic acid (LA; $18{:}2\Delta^{9,12}$; 18:2n-6) is desaturated by a $\Delta^{6}$-fatty acid desaturase to produce γ-linolenic acid (GLA; $18{:}3\Delta^{6,9,12}$; 18:3n-6), which is then $C_2$-elongated and further ($\Delta^{5}$-) desaturated to yield AA. The $\Delta^{6}$- and $\Delta^{5}$-fatty acid desaturases have previously been called "front-end" desaturases because they desaturate between preexisting double bonds and the carboxyl group, most usually between C-3 and C-7 (10). These enzymes appear to differ from "methyl-directed" desaturases (which insert double bonds sequentially toward the methyl end of the molecule) by the presence of an N-terminal domain related to cytochrome $b_5$ (11,12).

Another interesting observation regarding the fatty acid composition of *C. elegans* is that this organism is apparently capable of synthesizing LA (5–7). In the case of vertebrates, LA is classified as an essential fatty acid and must form part of the dietary intake to serve as a substrate for PUFA synthesis *via* endogenous desaturation and elongation (3). However, some biochemical evidence indicates that invertebrates maintain a capacity to synthesize LA from endogenous monounsaturated substrates (13–15).

The above observations allow the prediction of the number of enzymatic reactions required for PUFA biosynthesis in *C. elegans*. This number can then be compared with that determined by whole genome sequencing and functional characterization. The aim of this study is to discuss the various fatty acid desaturases present in *C. elegans* in the context of our current understanding of enzyme evolution and divergence.

## METHODOLOGY FOR GENOMIC CHARACTERIZATION

The complete *C. elegans* genome (1) (available at http://www.sanger.ac.uk/Projects/C_elegans/) was searched for desaturase-like sequences using the BLAST suite of programs (16). Information on genomic organization and location was extracted using the *C. elegans* ACEDB database (http://www.sanger.ac.uk/Projects/C_elegans/webace_front_end.shtml). Data on protein similarities were obtained from the WormPD database (http://www.proteome.com/

Abbreviations: AA, arachidonic acid; DHGLA, dihomo-γ-linolenic acid; ELO, elongation of fatty acids; EPA, eicosapentanoic acid; ER, endoplasmic reticulum; GLA, γ-linolenic acid; LA, linoleic acid; ORF, open reading frame; OTA, octadecatetraenoic acid; PUFA, polyunsaturated fatty acid.

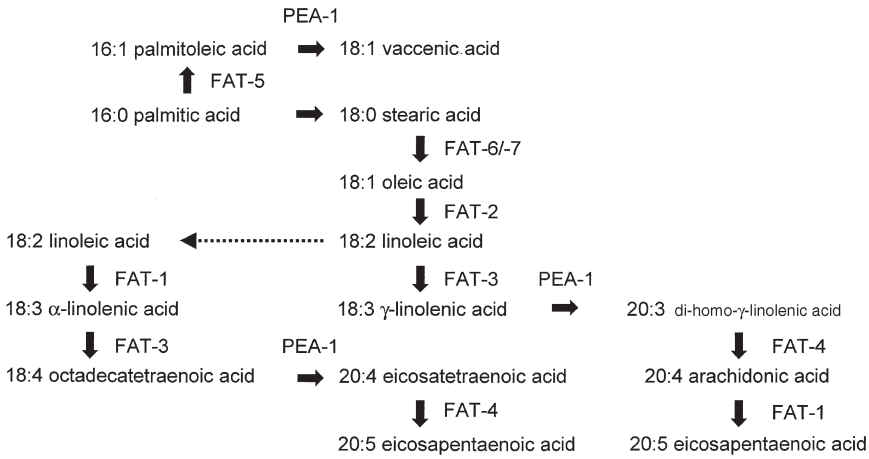

**FIG. 1.** A simplified schematic diagram of steps likely to be involved in the biosynthesis of polyunsaturated fatty acids in *Caenorhabditis elegans*. The names given to each enzyme reaction are shown in Table 1. Two alternative pathways for the synthesis of eicosapentanoic acid are shown, based on functional characterization of the enzymes involved. For clarity, the additional $\Delta^{12}$-desaturation of palmitoleic acid by FAT-2 is not shown. The enzymatic basis for the $C_2$ elongation of palmitic acid is presently unknown.

databases/index.html) (17). Phylogenetic data were produced using TreeView (http://taxonomy.zoology.gla.ac.uk/rod/treeview.html) on protein sequences aligned using GeneDoc (http://www.psc.edu/biomed/genedoc).

The work of Shanklin and others (reviewed in Ref. 18) has indicated that membrane-bound fatty acid desaturases are part of the larger group of class III di-iron-oxo enzymes. Desaturases in this class use either acyl-CoA or glycerolipid (i.e., fatty acids esterified to phosphatidylcholine) substrates. Sequence analysis of membrane-bound fatty acid desaturases from plant, fungal, and animal species (as well as related enzymes such as membrane-associated hydrocarbon hydroxylases) indicated that a number of motifs are absolutely conserved, most notably three short regions termed "histidine boxes," which are essential for the enzyme activity of fatty acid desaturases (19,20). Therefore, the presence of these short histidine box motifs (typically H-X-X-H-H) is indicative of the class of di-iron-oxo enzymes of which fatty acid desaturases are members, facilitating the identification of candidate fatty acid desaturase open reading frames (ORF).

*Functional characterization of fatty acid desaturases in* C. elegans. Our exhaustive searching of the entire *C. elegans* genome yielded (based on these conserved motifs and homology) seven ORF with similarity to fatty acid desaturases from other species. Moreover, recent functional characterization has defined the precise enzymatic role of these ORF, allowing us to classify the desaturases into three distinct groups, and provided a comprehensive description of the *C. elegans* genes involved in the PUFA biosynthetic pathway. Their individual roles in PUFA biosynthesis are summarized in Table 1 and described in detail next. The majority of these ORF have been characterized by Browse and colleagues (21), and we have used their gene nomenclature. The role of each ORF in *C. elegans* PUFA biosynthesis is also shown in Figure 1.

*(i) Group 1 (stearoyl CoA-like desaturases).* The three members of this group encode fatty acid desaturases related

**TABLE 1**
**Classification of *Caenorhabditis elegans* Open Reading Frames Involved in Polyunsaturated Fatty Acid Biosynthesis[a]**

| Enzymatic reaction | Gene ID | Designated name | Group | Locus | Number of introns | Comments |
|---|---|---|---|---|---|---|
| Palmitoyl $\Delta^9$-desaturase | W06D12.3 | FAT-5 | 1 | V, 16.43 cM | 2 | |
| Stearoyl $\Delta^9$-desaturase | VZK822l.1 | FAT-6 | | IV, 5.41 cM | 4 | |
| Stearoyl $\Delta^9$-desaturase | F10D2.9 | FAT-7 | | V, 1.33 cM | 4 | |
| $\Delta^6$-Desaturase | W08D2.4 | FAT-3 | 2 | IV, 4.44 cM | 6 | Tandem gene pair <1 Kb apart |
| $\Delta^5$-Desaturase | T13F2.1 | FAT-4 | | IV, 4.43 cM | 7 | |
| $\Delta^{12}$ $\omega^6$-Desaturase | W02A2.1 | FAT-2 | 3 | IV, 8.79 cM | 2 | Genes <6 Kb apart |
| $\Delta^{15}$ $\omega^3$-Desaturase | Y67H2B.a | FAT-1 | | IV, 8.68 cM | 2 | |
| $\Delta^6$-Fatty acid elongase | F56H11.4 | PEA-1 | | IV, 4.30 cM | 3 | Part of a tandem gene pair <2 Kb apart |

[a]The enzymatic reactions encoded by the seven open reading frames identified as desaturases from the completed *C. elegans* genome. The Sanger Centre's gene identifier code is given, as is the current designated name and our group classification; details of the $C_{18}$-elongating activity are also shown. Chromosomal location, map position in centiMorgans, and intron number are also indicated.

to the stearoyl CoA class of microsomal desaturases (8,9). These three genes, W06D12.3, VZK822l.1, and F10D2.9, have been designated FAT-5, FAT-6, and FAT-7, respectively (21). Functional characterization *via* heterologous expression of the ORF in yeast has indicated that while FAT-6 and FAT-7 are stearoyl $\Delta^9$-desaturases, they also desaturate palmitic acid (21). However, FAT-5 displays a strict substrate preference for palmitic acid and shows negligible activity toward stearate (21). FAT-6 and FAT-7 are 92% identical at the amino acid level and 78–80% identical to FAT-5.

*(ii) Group 2 (front-end desaturases).* This group consists of two genes, W08D2.4 and T13F2.1, which have been designated FAT-3 and FAT-4, respectively. We demonstrated that FAT-3 encodes the $\Delta^6$-fatty acid desaturase responsible for the synthesis of GLA from LA (22). We also showed that FAT-4 encodes the $\Delta^5$-fatty acid desaturase responsible for the final desaturation step in the synthesis of AA (23) (Fig. 1). These enzymes carry out "front-end" desaturation (10) and, like $\Delta^5$- and $\Delta^6$-desaturases from other systems (24–26), differ from the other *C. elegans* desaturases in the presence of an N-terminal cytochrome $b_5$ domain. Both the *C. elegans* $\Delta^5$- and $\Delta^6$-desaturases show sequence homology to higher plant $\Delta^6$-fatty acid desaturases (27) and also to plant sphingolipid long chain base desaturases (28). The similarity between the amino acid sequences of FAT-3 and FAT-4 is 66%.

*(iii) Group 3 ($\omega^{3/6}$-desaturases).* This group consists of two genes, Y67H2B.a and W02A2.1, respectively designated FAT-1 and FAT-2. The encoded enzymes are related to higher plant $\omega^3$ fatty acid desaturases such as the *Arabidopsis thaliana* FAD3 microsomal $\Delta^{15}/\omega^3$ desaturase (29). Spychalla *et al.* (30) reported the functional analysis of FAT-1 in transgenic *Arabidopsis* plants. FAT-1 was shown to encode a $\omega^3$-fatty acid desaturase with specificities for both $C_{18}$ and $C_{20}$ carbon unsaturated substrates (30), though the very small amounts of ALA in *C. elegans* (5,7) may indicate a preference for $C_{20}$ fatty acids. The dual $C_{18/20}$ substrate preference of FAT-1 provides two alternative pathways for the order of desaturation required for EPA synthesis (Fig. 1). FAT-2 displays a high degree of sequence identity (72%) to FAT-1 and has been shown to encode a $\Delta^{12}/\omega^6$ fatty acid desaturase that desaturates both 16:1 and 18:1 substrates. This latter reaction is therefore responsible for the synthesis of LA (31), confirming the predicted presence of this enzyme in invertebrates (15,31). No overlap in enzymatic function of the two desaturases was observed (30,31).

*Identification of other enzymes involved in PUFA biosynthesis.* The synthesis of PUFA such as AA and EPA requires the $C_2$ elongation of $C_{18}$ PUFA. This reaction is catalyzed by a multifunctional elongase complex that consists of four distinct enzymatic reactions (condensation, keto-reduction, dehydration, and enoyl-reduction). Of these four reactions, the (first) condensation step is considered to be rate-limiting. We recently functionally identified a *C. elegans* ORF (F56H11.4) that directs $C_{20}$ PUFA production when expressed in yeast (32). This elongating activity shows specificity for $\Delta^6$-desaturated $C_{18}$ PUFA [e.g., GLA and octadecatetraenoic acid ($18{:}4\Delta^{6,9,12,15}$ or 18:4n-3)], although it has some activity toward palmitoleic acid (the product of FAT-5), resulting in the production of vaccenic acid. Since vaccenic acid is a relatively large component of *C. elegans* total fatty acids (7), our observations may help to explain its abundance. The precise biochemical function within the elongase of F56H11.4 has not yet been elucidated, though this ORF shows some limited homology to the yeast ELO (elongation of fatty acids) gene family, required for medium and very long chain saturated fatty acid elongation (33). F56H11.4 is a member of a small gene family that appears to have undergone gene duplication, as determined by the presence of conserved intron-exon junctions within tandem gene pairs (32). In view of our functional characterization of F56H11.4 (32), we have designated this ORF PEA-1 for PUFA-elongating activity. Moreover, we have also co-expressed PEA-1 with FAT-3 and FAT-4 in yeast, successfully reconstituting the PUFA biosynthetic pathway (32).

*Common motifs and domain structures.* A comparison of the primary sequences of the *C. elegans* desaturases that comprise Groups 1–3 indicates only very limited sequence homology (restricted to the histidine box domains), as represented by the phylogenetic tree shown in Figure 2. However, the amino acid sequences of the seven fatty acid desaturase still share a number of similarities. First, the predicted ORF encode membrane proteins that have a similar topology (as judged by hydrophobicity plots; data not shown). This topology includes an even number of putative transmembrane spans, thereby placing the N- and C-termini of the proteins on the same membrane face; most probably the cytosolic face of the endoplasmic reticulum (ER). Thus, the three highly conserved histidine boxes present in all the desaturases are likely to be exposed to the cytosol, as opposed to the ER lumen. This predicted topology is in good agreement with models for desaturases from other species (18). It is also likely that the cytochrome $b_5$ domain of the Group 2

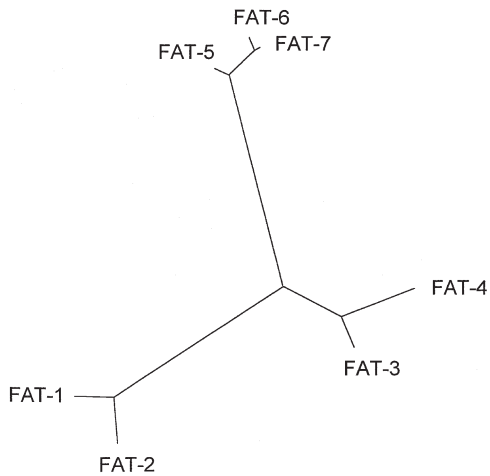

**FIG. 2.** A phylogenetic tree of the similarity between the seven *C. elegans* desaturase open reading frames. Deduced amino acid sequences were aligned and subjected to phylogenetic analysis *via* PHYLIP and TreeView. The degree of similarity between sequences is proportional to their distance apart.

front-end desaturases (FAT-3 and FAT-4) is present on the cytosolic side of the ER membrane. This would allow this domain to interact with other components of the electron transport chain (i.e., cytochrome $b_5$ reductase), which are predicted to be required for full enzymatic function. The proposed topology of the *C. elegans* desaturases is given further support by the presence of C-terminal ER-recycling/retention motifs in their amino acid sequences. This is most obvious in FAT-4 (motif K-K-I-A-stop) and FAT-7 (K-K-S-I-M-stop). Although these examples are from different groups of fatty acid desaturases, it is clear that they conform well to the consensus retention sequence for ER membrane proteins (K-K-$X_{2-3}$-stop) (34). Other studies in yeast have shown that the di-lysine C-terminal signal must be located on the cytoplasmic face of the ER in order to function (35), thus agreeing with the proposed topology. Interestingly, the PEA-1 elongating activity also contains an even number of transmembrane spans and a di-lysine retention motif (32). Perhaps more intriguingly, this ORF also contains a histidine box motif, though the precise function of this sequence is as yet unclear.

*Genomic organization of* C. elegans *desaturase genes.* Comparison between the locations of the genes encoding the PUFA biosynthetic enzymes revealed that several are in close proximity to each other (Table I). We initially observed this with the two front-end desaturases of Group 2 (22,23), where the stop codon of the $\Delta^5$-desaturase (FAT-4) is 990 bp upstream of the initiating methionine of the $\Delta^6$-desaturase (FAT-3). Although such proximity is consistent with polycistronic transcription (which accounts for 25% of all transcripts in *C. elegans*) (36), Watts and Browse demonstrated that the mRNA for these two fatty acid desaturases are transcribed from distinct operons (37). A similar level of proximity was observed for the two desaturases of Group 3, in which the FAT-1 $\omega^3$-desaturase is <6 Kb upstream of the $\Delta^{12}$-desaturase (FAT-2) (31). Furthermore, these desaturases (together with FAT-6 and PEA-1) map to a single region (4.3–8.79 cM) at the top of chromosome IV. Whether there is any evolutionary significance to the localization of all the enzymatic activities (i.e., stearoyl CoA-desaturase, $\Delta^{12}$-desaturase, $\Delta^6$-desaturase, elongating activity, $\Delta^5$-desaturase, and $\omega^3$-desaturase) required for PUFA biosynthesis to a region of <4 Mb in a genome of 97 Mb remains to be determined.

C. elegans *fatty acid desaturases display conserved intron-exon junctions*. It is likely that the number of desaturases in *C. elegans* has increased as a result of gene duplication, and certainly gene duplication in general was observed at an early stage in the *C. elegans* genome sequencing program (exemplified in Ref. 38). However, although there are many annotated examples of presumptive gene duplications present in the databases, there are considerably fewer examples of functional characterization of these tandem gene products. In that respect, our work showing that tandemly arranged genes have precise and distinct enzyme activities (e.g., $\Delta^5$- and $\Delta^6$-desaturases) is relevant. The conserved intron-exon junctions in these genes indicate that they may have resulted from a duplication event, as reflected by a level of identity between the two (spliced) gene transcripts of 60% (23,37). The last two intron-exon junctions of these two desaturases are perfectly conserved, even though the sizes of the respective introns differ between the two genes. It may also be significant that the last intron-exon junction is within the third histidine box and that both these desaturases have a glutamine for histidine substitution in this domain. Thus, these two front-end desaturases have not only an N-terminal cytochrome $b_5$ domain but also a variant third histidine box, which itself is bisected by a conserved intron. However, within these two genes we did not detect the presence of common elements in either the promoters or the untranslated regions of transcripts.

Similarly, the two $\omega^{3/6}$-desaturases in close proximity to each other (FAT-1 and FAT-2) also contained conserved junctions between the penultimate and last exons, despite variations in intron size (31). However, the position of this conserved intron is distinct from that present in the front-end desaturases in that it does not span the third histidine box. It is likely that the two $\omega^{3/6}$-desaturases have also arisen as a result of gene duplication (31). Thus, for both front-end and methyl-directed desaturases, duplications have likely resulted in the evolution of distinct and, more importantly, nonoverlapping enzyme activities.

Although the three genes of the stearoyl CoA-desaturase Group 1 are not tandemly located or in close proximity, conserved intron-exon junctions are also observed. For example, FAT-6 and FAT-7 contain four identical intron-exon junctions, even though they are located on different chromosomes. This identity may indicate that these two genes resulted from a gene-duplication event followed by subsequent chromosomal translocation. In addition, there are conserved intron-exon junctions between FAT-6/-7 and FAT-5 (one between exons 2 and 3 of FAT-6/-7 corresponding to one between exons 1 and 2 of FAT-5 and another between exons 3 and 4 of FAT-6/-7 homologous to one between exons 2 and 3 of FAT-5).

*Gene duplication: functional redundancy or enzyme divergence?* One obvious perspective on gene duplication events is that they are an evolutionary mechanism for generating discrete new enzymatic activities. In the case of essential genes, duplication must be considered a prerequisite to any alteration in function (39). Interestingly, in the cases of the *C. elegans* desaturases described previously, there appears to be no overlap or functional redundancy between enzyme activities contained within the two presumptive gene duplicatations (FAT-1/2 and FAT-3/4). It is an interesting yet open question as to whether the ancestral progenitors of these pairs encoded a discrete single enzyme activity similar to that of one of the current tandem pair enzymes, or whether the activity of the ancestors broadly encompassed the current activities of both members. Such questions also have implications in terms of the evolution of the PUFA-derived eicosanoids, and their roles in a wide range of important cellular processes (3). Another open question is why functional redundancy exists in the stearoyl CoA desaturases and whether there is any selective advantage in this. The fact that these enzymes catalyze the primary desaturation reaction in the biosynthesis of unsaturated fatty acids may also be a relevant consideration.

The recent advances toward the completion of the human genome sequence have also provided further insights into the genomic organization of fatty acid desaturases involved in PUFA biosynthesis. Remarkably, the *Homo sapiens* $\Delta^5$- and $\Delta^6$-fatty acid desaturases are also in close proximity, even in this much more complex genome (40). However, in the case of these two human front-end desaturases, the genes are in opposite 5′ to 3′ orientations and are separated by ~63 Kb (40). Perhaps a more intriguing question is why these desaturase genes (from worm to human) have remained in proximity to each other, and it will therefore be important to determine if this apparent synteny is related to coordinated transcriptional regulation. Tandem clusters of membrane proteins have been observed in a number of (prokaryote) genome sequences (41), though the reasons for these phenomena are not clear.

## CONCLUSION

Genome sequencing programs, as exemplified by the completion of the *C. elegans* genome project, provide a very powerful tool for the investigation of metabolic diversity and evolution. However, our studies on *C. elegans* PUFA desaturases indicate that, in the absence of functional characterization, assignment of enzyme activity *via* homology alone is potentially misleading. Moreover, the fact that gene duplication does not necessarily result in partial or complete functional redundancy, but instead can generate distinct enzyme activities (even in a pathway of primary metabolism) indicates the need for comprehensive functional characterizations of predicted gene products. At a more applied level, the investigation of important metabolic processes such as PUFA synthesis will help elucidate appropriate targets for the improvement of human health and nutrition. It will also be important to determine the role discrete *in vivo* changes in PUFA metabolism have on the whole organism, and, in that respect, *C. elegans* provides an excellent experimental system for study. In particular, RNA-mediated interference provides a powerful tool for the confirmation and dissection of enzymatic functions within the nematode (42).

## ACKNOWLEDGMENTS

IACR-Long Ashton Research Station receives grant-aided support from the Biotechnology and Biological Sciences Research Council (BBSRC) of the United Kingdom. We are very grateful to Dr. John Browse (Washington State University) for sharing information prior to publication and providing the FAT-1 gene for study. We would also like to thank Dr. David J. Chitwood for his encouragement and advice in the editing of this manuscript.

ARTICLE

# Conjugated Linoleic Acid Supplementation in Humans: Effects on Fatty Acid and Glycerol Kinetics

**Kirsten L. Zambell, William F. Horn, and Nancy L. Keim***

USDA/Western Human Nutrition Research Center, Department of Exercise Science, University of California, Davis, California 95616

**ABSTRACT:** Recent studies with mouse adipocytes have shown that dietary conjugated linoleic acid (CLA) may reduce body fat by increasing lipolysis. The present study examined the effect of CLA supplementation on fatty acid and glycerol kinetics in six healthy, adult women who were participating in a controlled metabolic ward study. These women were fed six CLA capsules per day (3.9 g/d) for 64 d following a baseline period of 30 d. The subjects were confined to a metabolic suite for the entire 94-d study, where diet and activity were controlled and held constant. The rate of appearance (Ra) of glycerol, which indicates lipolytic rates, was similar at baseline and after 4 wk of CLA supplementation at rest (1.87 ± 0.21 and 2.00 ± 0.39 μmol/kg/min, respectively) and during exercise (7.12 ± 0.74 and 6.40 ± 0.99 μmol/kg/min, respectively). Likewise, the Ra of free fatty acids (FFA) was not significantly different after 4 wk of dietary CLA at rest (2.72 ± 0.06 and 2.74 ± 0.12 μmol/kg/min, respectively) or during exercise (6.99 ± 0.40 and 5.88 ± 0.29 μmol/kg/min, respectively). CLA supplementation also had no effect on the percentage of FFA released from lipolysis that were re-esterified. The apparent rate of FFA re-esterification was 65.2 ± 4.2% at rest and 32.1 ± 3.44% during exercise. Four weeks of CLA supplementation had no significant effect on fatty acid or glycerol metabolism in healthy, weight-stable, adult women.

Paper no. L8576 in *Lipids 36*, 767–772 (August 2001).

Conjugated linoleic acid (CLA) is a group of linoleic acid isomers found naturally in foods such as grilled ground beef (1) and some dairy products (2). CLA is reported to have anticarcinogenic properties (3–5) and to be protective against atherosclerosis (6) in animal models fed supplemental CLA. Recently, dietary CLA has been shown to reduce body fat in mice (7–11).

Studies with adipocytes have been performed to determine the mechanism by which CLA reduces body fat in mice. Adipocytes (3T3-L1) exposed to exogenous CLA showed reduced lipoprotein lipase activity, reduced levels of triglyceride and glycerol inside the cells, and increased glycerol levels outside the cells (8,10). These data suggest that CLA may reduce body fat by affecting key enzymes involved in lipid mobilization and storage. However, lipolysis has not been measured directly.

Abbreviations: CLA, conjugated linoleic acid; FFA, free fatty acids; GC, gas chromatography; MS, mass spectrometry; Ra, rate of appearance; RQ, respiratory quotient; $VCO_2$, carbon dioxide production; $VO_2$, oxygen consumption.

Evidence on the effect of CLA supplementation on body fat in humans is contradictory. In a recent study, adults taking CLA supplements for 12 wk had reduced body fat mass (12). In contrast, we reported that body fat did not decrease significantly when adult women took CLA supplements for 9 wk (13). One factor that might have contributed to these discordant findings is the magnitude of the error associated with the measurement of human body composition. Generally, with the methods used in these studies, the standard error of estimate for body fat mass is about 1.5 kg (14,15). Thus, changes in fat mass on the order of 1–2 kg are difficult to measure with confidence. For this reason, longer periods of supplementation are needed to determine the impact of CLA on body composition in humans. Further, it is important to identify metabolic changes attributable to CLA that occur sooner and could serve as the basis of a long-term change in body fat. Accordingly, as part of our study, we measured the effect of CLA supplementation (3.9 g/d/person) on fatty acid and glycerol kinetics in a subset of six healthy women taking the CLA supplements. The dosage of CLA used was approximately fourfold higher than the average amount consumed in a typical diet containing meat and dairy products (2). However, this amount is similar to that used in previous animal and human studies, and it is within the reasonable range for a healthy, nonvegan adult. Stable isotopes of palmitate and glycerol were used to measure the rate of appearance (Ra) of free fatty acids (FFA) and glycerol as well as whole body lipolysis and apparent re-esterification in the resting state and during moderate activity.

## MATERIALS AND METHODS

*Subjects.* Seventeen women, 24–41 yr of age, completed the entire 94-d study. Subject selection criteria included being a healthy nonsmoker, premenopausal with normal menstrual cycles, and free of any abnormal physiological conditions or diseases. Prior to being selected for the study, all subjects completed medical and dietary histories, physical examinations, urinary tests for pregnancy, resting electrocardiograms, and standard batteries of blood tests. A subset of six women from the CLA supplement group participated in the stable isotope tracer studies. This subset was similar to the original group of 10 women in the CLA group (Table 1). Participation was by informed consent. The study protocol was approved by the Human Subject Committees of the U.S. Department of Agriculture and the University of California, Davis.

**TABLE 1**
**Comparison of Subject Characteristics in the CLA Subset and CLA Total Group**

| Subject | Age (yr) | BMI[a] (kg/m$^2$) | Body fat (%) | Change in body fat with CLA[b] (kg) |
|---|---|---|---|---|
| #29*[c] | 31 | 24.2 | 33.3 | –1.49 |

[a]BMI, body mass index; CLA, conjugated linoleic acid.
[b]Data from Reference 13.
[c,*]Denotes those subjects in the stable isotope infusion protocol subset.

Subjects lived in the metabolic suite at the Western Human Nutrition Research Center, 24 h/d, 7 d/wk for 94 d of the study. Times for meals and daily outdoor walks were standardized. While in the metabolic suite, the lifestyle was predominantly sedentary, but activity was provided in the form of walking 2 mi twice a day.

*Experimental design.* This study was part of a randomized, blind, and placebo-controlled study conducted with two cohorts totaling 17 subjects and has been described previously (13). Six of the 17 subjects participated in the stable isotope infusion study. The six were not randomly selected, but rather chosen because venous access was good, enabling the placement of the catheters, essential for the infusion of isotope and blood sampling. On day 31, following 30 d of baseline, subjects were randomly assigned to either the group receiving the sunflower oil placebo or the group receiving supplemental CLA (3.9 g/d) for the final 64 d of the study.

CLA capsules were obtained from Pharmanutrients, Inc. (Lake Bluff, IL). CLA constituted approximately 65% of the total fatty acids in the capsule (~3.9 g), with the remainder consisting mainly of oleic acid. Isomer composition of the CLA was determined by gas chromatography and found to be 22.6% *trans*-10, *cis*-12; 23.6% *cis*-11, *trans*-13; 17.6% *cis*-9, *trans*-11; 16.6% *trans*-8, *cis*-10; 7.7% *trans*-9, *trans*-11 and *trans*-10, *trans*-12; and 11.9% other isomers. The placebo capsule contained 72.6% linoleic acid, with the remainder consisting mainly of palmitic, stearic, and oleic acids with no detectable CLA isomers. The capsules used were identical in appearance and were packaged in the same manner.

*Dietary intake.* The subjects' diets were equivalent to the American Heart Association's Step II Diet containing the Recommended Dietary Allowance for all known nutrients and 30% of calories from fat. The energy intake of each subject was estimated using the Harris-Benedict equation. During the baseline period, the energy intake was adjusted if body weight changed by ±3% over time. Dietary fat consisted of saturated, monounsaturated, and polyunsaturated at 10% each for both placebo and intervention groups with saturated fat, linoleic acid, and other n-6 polyunsaturated fats held constant among the two groups. The cholesterol content of the diets was 250–300 mg/d.

*Infusion protocol.* The stable isotope infusion protocol was performed at the end of the baseline period and during the fourth week of intervention. These timepoints for testing were chosen so that the subjects would be in the same phase of their menstrual cycles for both tests. In order to measure palmitate and glycerol kinetics, a Teflon catheter was placed into an antecubital vein for [1-$^{13}$C]palmitate and glycerol-$d_5$ infusion. A second sampling catheter was inserted in a dorsal hand vein of the contralateral arm. The heated hand technique was used to obtain arterialized blood samples (16). The subjects rested for 1 h after catheter placement. After a blood sample was drawn to determine background enrichment, primed constant infusions of glycerol-$d_5$ and [1-$^{13}$C]palmitate were started according to Romijn *et al.* (17). In conjunction with the infusion protocol, indirect calorimetry was used to estimate fat oxidation rates. The gas exchange measurements were made with an automated respiratory gas exchange system (model 2900; SensorMedics, Anaheim, CA) and collected between 30 and 50 min of rest and exercise. The system was calibrated with standard gas mixtures, and the calibration was verified at intervals throughout the collection periods. Subjects wore inflatable facemasks that were connected to the gas analyzers *via* a tubing assembly.

The glycerol and palmitate tracers (99% enriched) were purchased from Cambridge Isotope Inc. (Andover, MA), and the infusates were prepared by the Parenteral Solutions Laboratory, University of California, San Francisco. The palmitate infusate contained 200 mg [1-$^{13}$C]palmitate and 100 mL 25% human albumin mixed with 0.9% sterile saline in a 500-mL bag and was infused at 92 and 184 mL/h at rest and during exercise, respectively. The glycerol infusate contained 128 mg glycerol-$d_5$ in 100 mL 0.9% sterile saline and was infused at 15 and 30 mL/h at rest and during exercise, respectively. The glycerol bolus injection contained 72 gm glycerol-$d_5$ in 15 mL 0.9% saline. The exact infusion rate in each experiment was determined by measuring the concentrations in the infusates. After 65 min of infusion at rest, treadmill walking was initiated, and the isotope administration was doubled for both palmitate and glycerol to minimize changes in substrate isotope enrichment. The infusion was terminated after 50 min of walking.

*Blood sampling.* Blood was taken at 50, 55, 60, and 65 min after the beginning of the infusion to measure resting kinetics. During walking at 60% of the maximal oxygen consumption ($VO_2$max), blood was taken after 5, 15, 25, 35, 40, 45, and 50 min of exercise. All samples were placed in 3-mL vacutainers containing lithium heparin and placed on ice. Plasma was separated by centrifugation shortly after sampling

and subsequently frozen for future analysis of palmitate and glycerol enrichment.

*Sample analysis.* FFA were extracted from plasma using heptane/isopropanol (30:70) and isolated by thin-layer chromatography (20 × 20 cm silica gel GF; Alltech, Deerfield, IL) and derivatized to their methyl esters. Palmitate and total FFA concentrations were measured by gas chromatography (GC)/flame-ionization detection (model 6890; Hewlett-Packard, Fullerton, CA) using pentadecanoic acid as an internal standard. A 100-m SP 2380 capillary column (Supelco, Bellefonte, PA) was used with the following temperature program: initial temperature of 150°C for 0 min, increase 2°C/min up to 170°C and hold for 5 min, increase 4°C/min up to 190°C and hold for 30 min.

GC/mass spectrometry (MS) (Hewlett-Packard 6890) was used for analysis of isotopic enrichments of palmitate. A 20-m fused DB-1 silica column (Fisher Scientific, Pittsburgh, PA) was used with electron ionization and the following temperature program: initial temperature of 70°C for 0 min, increase 25°C/min up to 250°C, hold for 2.8 min. Ions of *m/z* 270 (M + 0) and 271 (M + 1) were selectively monitored. Plasma samples were analyzed for glycerol concentration and enrichment by Metabolic Solutions, Inc. (Nashua, NH). A known amount of [2-$^{13}$C]glycerol was added as an internal standard to the samples analyzed for glycerol concentration. The trimethylsilyl derivative of glycerol was formed according to Beylot *et al.* (18) and analyzed in a Hewlett-Packard 5890 gas chromatograph coupled to a 5898A mass spectrometer using electron ionization and the following temperature program: initial temperature of 100°C for 0 min, increase at 5°C/min up to 120°C, then 30°C/min up to 300°C. Ions of *m/z* 205 (M + 0), 206 (M + 1, internal standard) and 208 (M + 5) were selectively monitored. Glycerol analysis was not performed on the plasma samples taken at 50 min of resting or at 5, 15, and 25 min of walking.

*Calculations.* Fat oxidation was calculated from oxygen consumption ($VO_2$), carbon dioxide production ($VCO_2$), and nitrogen excretion using the equation of Frayn (19). Nitrogen excretion rate was assumed to be 0.01 g/min. This estimate was based on the assumption that subjects were in nitrogen balance and included a value for dietary nitrogen intake adjusted for typical fecal and insensible nitrogen loss.

The palmitate Ra and glycerol Ra were calculated by the dilution technique (20). The Ra (μmol/kg/min) is equal to the isotope infusion rate (μmol/kg/min) divided by the molar excess followed by subtraction of the isotope infusion rate. FFA Ra was calculated by dividing the palmitate Ra by the fractional contribution of palmitate to the total FFA concentration, as determined by GC.

Triglyceride-fatty acid cycling was calculated using the equation of Wolfe *et al.* (21). The difference between three times the glycerol Ra (total fatty acids released) and the rate of total fatty acid oxidation (determined by indirect calorimetry) will give the apparent rate of re-esterification, since re-esterification is the only other fate of fatty acids released by lipolysis. Re-esterification is described as apparent because re-esterification may be underestimated due to intracellular FA oxidation.

*Statistical methods.* Values are reported as means ± SEM. The probability level for significance was set at $P < 0.05$. All statistical analyses were performed using the Statistical Analysis System (Version 6.12, SAS Institute Inc., Cary, NC), using one-way analysis of variance to estimate the effect of time (baseline vs. intervention) on the outcome variables.

## RESULTS

*Substrate concentrations.* The average plasma FFA concentrations during rest were not significantly different after 4 wk of CLA supplementation compared to baseline (0.23 ± 0.01 and 0.25 ± 0.01 mmol/L, respectively; Fig. 1). During exercise, plasma FFA concentrations increased relative to resting values. The average plasma FFA concentration during exercise was not significantly different after 4 wk of CLA supplementation (0.29 ± 0.03 mmol/L) from the baseline (0.35 ± 0.04 mmol/L). Four weeks of CLA supplementation had no significant effect on glycerol concentrations at rest (0.04 ± 0.01 and 0.04 ± 0.01 mmol/L, respectively) or during exercise (0.24 ± 0.03 and 0.21 ± 0.03 mmol/L; Fig. 1).

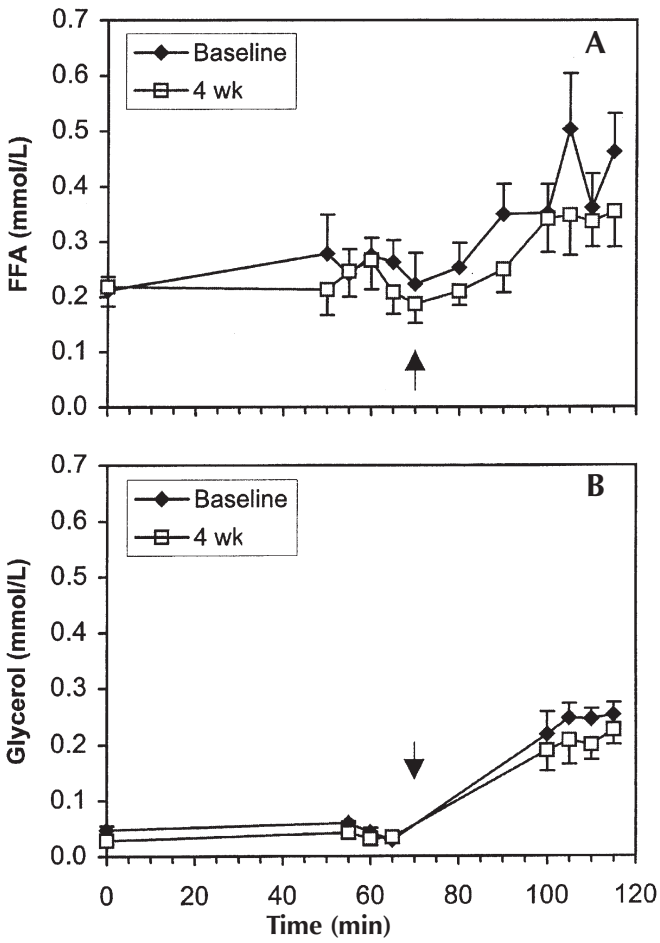

**FIG. 1.** Plasma free fatty acids (FFA) (A) and glycerol (B) concentrations at baseline and week 4. The arrow indicates the onset of treadmill walking at 60% maximal oxygen consumption ($VO_2$max). No significant differences were detected between baseline and week 4 in the average resting or average walking values for either FFA or glycerol concentrations. Error bars represent SEM ($n$ = 6).

*Rate of appearance.* After 4 k of CLA supplementation, the resting FFA Ra was unchanged compared to baseline (2.72 ± 0.06 and 2.74 ± 0.11 μmol/kg/min, respectively; Fig. 2). With exercise, the FFA Ra increased twofold over resting values; however, there was no significant difference between baseline and week 4 values (7.11 ± 0.40 and 5.89 ± 0.29 μmol/kg/min, respectively). The glycerol Ra was similar at baseline and after 4 wk of CLA supplementation during rest (1.87 ± 0.21 and 2.00 ± 0.39 μmol/kg/min, respectively) and during exercise (7.12 ± 0.74 and 6.40 ± 0.99 μmol/kg/min; Fig. 2).

*Triglyceride-fatty acid cycling.* Four weeks of CLA supplementation had no significant effect on apparent fatty acid re-esterification rates at rest or during exercise (Fig. 3). With the onset of exercise, the rate of re-esterification declined at both timepoints.

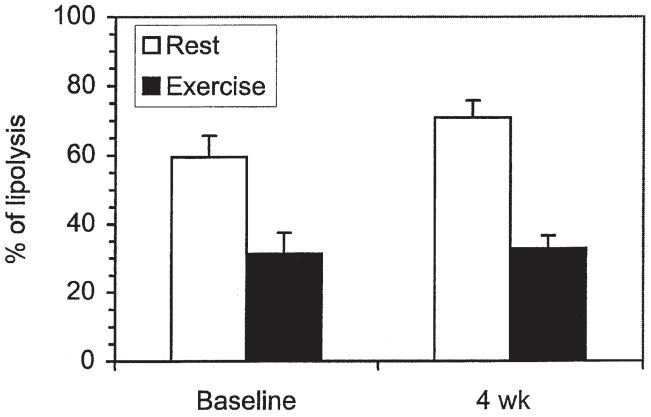

**FIG. 3.** Apparent re-esterification rates as a percentage of lipolysis at baseline and week 4. Error bars represent SEM ($n$ = 6).

## DISCUSSION

Four weeks of daily CLA supplementation in six healthy, adult women had no significant effect on lipolytic rates (glycerol Ra), FFA release from adipose tissue (FFA Ra), or apparent FFA re-esterification rates under conditions of rest or during exercise at 60% $VO_2$max. This is the first report of fatty acid and glycerol kinetics in CLA-supplemented subjects. Earlier work with adipocytes suggested that CLA reduced body fat by increasing lipolysis and decreasing fat deposition (8,10). When 3T3-L1 adipocytes were exposed to exogenous CLA, decreased levels of esterified and free glycerol were observed inside the cell while glycerol release from the cell was increased up to twofold. These data are in contrast with the present data in which the glycerol Ra was similar during the baseline and after 4 wk of CLA supplementation.

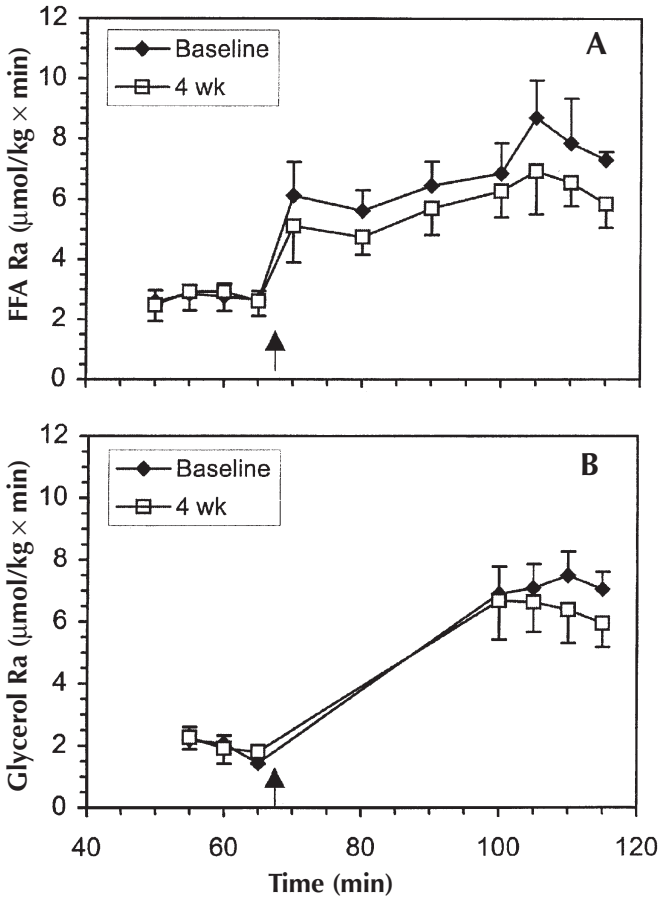

**FIG. 2.** FFA rate of appearance (Ra) (A) and glycerol Ra (B) values at baseline and week 4 . The arrow indicates the onset of treadmill walking at 60% $VO_2$max. No significant differences were detected between baseline and week 4 in the average resting or average walking values for either FFA Ra or glycerol Ra. For other abbreviations see Figure 1. Error bars represent SEM ($n$ = 6).

After 6 wk of dietary CLA supplementation in mice, West *et al.* (11) found that CLA appeared to block the normal day–night difference in the respiratory quotient (RQ). In untreated animals, the nighttime RQ was significantly greater than the daytime RQ, whereas in the CLA-supplemented animals there was no significant difference between the day and night values. The authors attributed the decrease in nighttime RQ to the promotion of fat oxidation by CLA *via* an increase in lipolysis and/or a decrease in fat deposition. The current study did not show any effect of CLA on lipolytic rates, but fat deposition (lipoprotein lipase activity) was not measured. Results from our indirect calorimetry studies indicated that the resting and exercising RQ did not decrease and the fat oxidation rates did not increase after 4 wk of CLA supplementation in the six women who participated in the infusion protocol. Similarly, there was no indication of increased fat oxidation after 8 wk of supplementation in all 10 subjects receiving CLA or in the 7 subjects receiving the placebo capsules (13).

Previous work examining the effect of dietary CLA on body composition, energy expenditure, and fat oxidation in mice was performed using weanling or adolescent animals that were still growing. There are data to suggest that CLA may affect the adipocytes of growing animals differently from those of adults (22,23). It is possible that CLA only affects lipid metabolism in young animals and exerts no effect in adults. Unfortunately, no studies are currently available reporting the effect of dietary CLA on fatty acid and glycerol kinetics in an adult animal model.

CLA supplementation also had no significant effect on the release of FFA from adipose tissue at rest or during exercise. The FFA Ra is not a good indicator of lipolysis since FFA can be re-esterified into triglycerides without ever leaving the adipocyte. FFA that are released into the plasma also may be re-esterified in the liver. Any FFA released by lipolysis that is not oxidized will be re-esterified in either the liver or the adipose tissue. Four weeks of CLA supplementation had no effect on apparent FFA re-esterification rates under any condition tested. At rest, 60–70% of the released FFA were re-esterified in the CLA group. The increase in fat oxidation associated with the onset of exercise resulted in a decline in the apparent re-esterification rate to approximately 30%. These rates of FFA re-esterification agree well with previous results in males where re-esterification rates were approximately 70% at rest and 25% during the first hour of exercise at 40% $VO_2$max (21). This combination of a decrease in FFA re-esterification and an increase in FFA Ra in response to exercise allows for an increase in plasma FFA for oxidation. However, dietary CLA had no significant effect on the FFA Ra or apparent re-esterification rates during rest or exercise.

It should be noted that the CLA supplement used in the present experiment was not pure and included a number of isomers along with the presumed biologically active form for body composition, energy expenditure and lipolytic changes, *trans*-10, *cis*-12 (9,10). In the present study, the *trans*-10, *cis*-12 isomer was the most abundant isomer, along with the *cis*-11, *trans*-13 (~23% of total CLA isomers for each), in the CLA supplement. However, we failed to show any effect of CLA on fatty acid and glycerol kinetics after 28 d of supplementation or on body composition after 64 d of supplementation in normal-weight women (13). In a recent study (12), 12 wk of CLA supplementation in overweight and obese adults resulted in a significant reduction in body fat mass. Although the authors stated that the CLA supplement contained equal parts of the *cis*-9, *trans*-11 and *trans*-10, *cis*-12 isomers, they failed to report what percentage of the total CLA isomers were *trans*-10, *cis*-12. Therefore, it is difficult to compare our data with those of the study mentioned above. In addition, CLA may affect overweight or obese individuals differently from normal-weight humans.

In conclusion, 4 wk of supplemental CLA had no effect on lipolytic rates, FFA release by lipolysis, or apparent FFA re-esterification rates in six healthy, adult women. These findings are consistent with our observation that body fat did not change in response to the CLA supplementation period of 64 d. A higher dose of the *trans*-10, *cis*-12 isomer of CLA may be needed to alter lipid metabolism in humans.

## ACKNOWLEDGMENTS

We would like to thank co-investigators Gary Nelson and Darshan Kelley for supporting this collaboration; Paloma Benito for study oversight; Carlene Gibbons for study coordination; Teresa Barbieri for technical support; Ilona Ellingwood and nursing staff for expert assistance in infusion setup and sampling; Kathy Bourdet for dietary planning; Vickie Jen and dietary staff for meal preparation; Ginny Gildengorin for statistical consultation; Dr. Lou Tommatsu for infusate preparation; and Richard Neese, Scott Turner and Mark D. Fitch for MS consultation.

# Conjugated Linoleic Acid Supplementation in Humans—Metabolic Effects

**Annika Smedman* and Bengt Vessby**

The Unit for Clinical Nutrition Research, Department of Public Health and Caring Sciences/Geriatrics, Uppsala University, Uppsala, Sweden

**ABSTRACT:** Supplementation with conjugated linoleic acid (CLA) induces a number of physiological effects in experimental animals, including reduced body fat content, decreased aortic lipid deposition, and improved serum lipid profile. Controlled trials on the effects of CLA in humans have hitherto been scarce. The aim of this study was to evaluate the effects of supplementation with CLA in healthy humans on anthropometric and metabolic variables and on the fatty acid composition of serum lipids and thrombocytes. Fifty-three healthy men and women, aged 23–63 yr, were randomly assigned to supplementation with CLA (4.2 g/d) or the same amount of olive oil during 12 wk in a double-blind fashion. The proportion of body fat decreased (–3.8%, $P < 0.001$) in the CLA-treated group, with a significant difference from the control group ($P = 0.050$). Body weight, body mass index, and sagittal abdominal diameter were unchanged. There were no major differences between the groups in serum lipoproteins, nonesterified fatty acids, plasma insulin, blood glucose, or plasminogen activator inhibitor 1 (PAI-1). In the CLA group the proportions of stearic, docosatetraenoic, and docosapentaenoic acids increased in serum lipids and thrombocytes, while proportions of palmitic, oleic, and dihomo-γ-linolenic acids decreased, causing a decrease of the estimated Δ-6 and Δ-9 and an increase in the Δ-5 desaturase activities. These results suggest that supplementation with CLA may reduce the proportion of body fat in humans and that CLA affects fatty acid metabolism. No effects on body weight, serum lipids, glucose metabolism, or PAI-1 were seen.

Paper no. L8595 in *Lipids 36*, 773–781 (August 2001).

Conjugated linoleic acid (CLA) is the common name of a group of fatty acids found in dairy products and meat from ruminants (1). CLA is an octadecadienoic acid (18:2) with two conjugated double bonds, predominantly found in the 9 and 11 or 10 and 12 positions. Each of the double bonds can be in *cis* or *trans* conformation. Lately, CLA has received considerable attention due to its metabolic and chemoprotective properties in experimental animals. These effects include reduced body fat content, improved serum lipid profile, decreased aortic lipid deposition, enhanced glucose metabolism and inhibited tumorigenesis (2,3). Whereas there are a large number of data from animal experiments, there are hitherto few reports on the effects of CLA in humans with inconclusive results (4–6).

The aim of the present study was to investigate the effects of CLA supplementation in humans under doubly-blinded placebo-controlled conditions and evaluate the effects on anthropometric variables, body composition, serum lipids, and fatty acid composition of serum lipids and thrombocytes. We previously reported the effects of CLA on lipid peroxidation in humans (7), which was also evaluated in this trial.

## MATERIALS AND METHODS

*Subjects.* Fifty-three healthy subjects, 27 men and 26 women, between 23 and 63 yr of age were included and randomly assigned to either a CLA-treated group or a control group before entering the study. Table 1 shows baseline characteristics of the participants. At the baseline there were no statistical differences between the groups with regard to the variables in Table 1. All subjects gave their informed consent, and the study was approved by the Ethical Committee of the Faculty of Medicine at Uppsala University.

*Study design.* During the initial 2 wk all subjects were given control capsules containing olive oil. For the following 12 wk, in a double-blind design, the subjects in the CLA group were given capsules containing 4.2 g/d of CLA while the control group continued taking capsules containing the corresponding amount of the control oil consisting of olive oil. The CLA capsules contained 75.9% CLA with equal amounts of the CLA isomers *cis*-9,*trans*-11 and *trans*-10,*cis*-12, respectively, and only minor amounts of other isomers. In addition to CLA, the capsules contained small amounts of oleic acid (18:1n-9) (14.0%), palmitic acid (16:0) (4.4%), stearic acid (18:0) (1.5%), and linoleic acid (18:2n-6) (0.4%). All capsules were provided by Natural Ltd. A/S (Oslo, Norway). The examinations and blood samplings were done in the morning after an overnight fast. The main investigations, on which the calculations were based, were on the first and the last days of the trial. Minor examinations were performed during the fourth and eighth weeks of the trial. The participants were requested not to change their habits regarding diet and physical activity and to abstain from any dietary supplementation with vitamins, minerals, or fatty acids prior to and during the study.

[a]Apo, apolipoprotein; BMI, body mass index; HDL, high density lipoprotein cholesterol; LDL, low-density lipoprotein cholesterol; NEFA, nonesterified fatty acids; PAI-1, plasminogen activator inhibitor 1; SAD, sagittal abdominal diameter; SD, standard deviation; TG, triglycerides; VLDL, very low density lipoprotein cholesterol; WHR, waist to hip.

*Dietary assessment.* On three occasions, before start and during the fifth and ninth weeks of the test period, the subjects were asked to perform 3-d weighed dietary records, including two weekdays and one weekend day. Dietary data from the registrations were computerized using the personal computer software MATs (MATs program version 4_03e, Rudans Lättdata, Västerås, Sweden). Calculations were made using the Swedish National Food Administration Food Database 2_97, PC version (Swedish National Food Administration, Uppsala, Sweden). The mean dietary intake at baseline is shown in Table 2. The fat provided by the CLA and control capsules was not included in the calculations of intakes.

*Anthropometric measurements.* Body weight was determined to the nearest kilogram and height to the nearest centimeter, wearing light indoor clothing and no shoes. The body mass index (BMI) was calculated as the body weight in kilograms divided by the square of the height in meters. The waist circumference was measured midway between the lowest rib and the iliac crest and the hip circumference at the widest part of the hip; and from these the waist-to-hip ratio was calculated. The sagittal abdominal diameter was measured as the height of the stomach when lying on the back on a firm bed with the knees bent. The percentage body fat was calculated from the three-compartment model based on measurement of skin fold thickness, measured with Harpenden skin fold calipers (John Bull, British Indicators Ltd., St Albans, Great Britain), and body water volume was estimated by a multifrequency bioelectric impedance analyzer Hydra 4200 (Xitron Technologies Inc., San Diego, CA) as described by Forslund *et al.* (8).

*Fatty acid composition of serum lipids.* The extraction, separation, and methylation of the plasma lipids were performed as described in detail by Boberg *et al.* (9). In short, plasma lipids were extracted with chloroform. Butylated hydroxytoluene and $NaH_2PO_4$ were added prior to evaporation under nitrogen. Phospholipids, triglycerides, and cholesterol esters were separated by thin-layer chromatography. The lipids esters were transmethylated with methanol and $H_2SO_4$. The fatty acid methyl esters were separated with gas chromatography using a Hewlett-Packard GC system (Avondale, PA) consisting of an HP 5890 Series II GC apparatus, HP 7673 automatic sampler, HP 3365A Series II Chemstation integrator software, and a 50 m × 0.25 mm CP-Sil 88 Chrompack capillary column, with helium as carrying gas. Standards from Nu-Chek-Prep (Elysian, MN) were used for identification of the individual fatty acids and as a control of the GC system. The technique used is not optimal for resolving different CLA isomers. Thus, the peaks identified as CLA when using a reference standard (Sigma Chemical, St. Louis, MO) were added, and the sum of the total CLA is presented here as CLA. The proportions of fatty acids are given as the relative percentage of the sum of the fatty acids analyzed. The desaturase

[a]Assessed using a 3-d weighed dietary record. SD, standard deviation; E%, energy percentage; CLA, conjugated linoleic acid.

activities were assessed by calculating product to precursor ratios as follows: 20:4n-6/20:3n-6 for Δ-5 desaturase, 18:3n-6/18:2n-6 for Δ-6 desaturase in triglycerides and cholesterol esters, 20:3n-6/18:2n-6 for Δ-6 desaturase in phospholipids and thrombocytes, and 18:1n-9/18:0 for Δ-9 desaturase activities.

*Fatty acid composition of the thrombocytes.* Blood was drawn using minimal venous pressure. A $16 \times g$ butterfly cannula was used to collect blood drop by drop. Thrombocyte clot was received through gentle centrifugation $120 \times g$ for 20 min, washed in saline, and dissolved with a Polytron mixer. From the dissolved clot the total platelet lipids were extracted with chloroform/methanol, including butylated hydroxytoluene. The fatty acid composition was analyzed as in the serum lipids.

*Serum lipoprotein analyses.* Serum lipoproteins (very low density lipoprotein, VLDL; low density lipoprotein, LDL; and high density lipoprotein, HDL) were isolated by a combination of preparative ultracentrifugation (10) and precipitation with a sodium phosphotungstate and magnesium chloride solution (11). Triglyceride and cholesterol concentrations in serum and in the isolated lipoprotein fractions were measured by enzymatic methods in a Monarch 2000 centrifugal analyzer. The concentrations of apolipoprotein A-I (Apo A-I) and apolipoprotein B (Apo B) were measured by immunoturbidimetry in a Monarch apparatus. Apolipoprotein(a) [Apo(a)] was determined by a Coda Automated EIA automatic enzyme-linked immunosorbent assay analyzer (Bio-Rad Laboratories, Hercules, CA) using Mercodia Apo(a) reagents (Mercodia AB, Uppsala, Sweden). Serum free fatty acids were measured by an enzymatic colorimetric method (Wako Chemicals, Neuss, Germany).

*Glucose and insulin.* Blood glucose was measured by the glucose dehydrogenase method (Gluc-DH; Merck,

Darmstadt, Germany). Plasma insulin was analyzed using an enzymatic-immunological assay (Enzymmun; Boehringer Mannheim) in an ES300 automatic analyzer (Boehringer Mannheim, Germany).

*Plasminogen activator inhibitor-1 (PAI-1) activity.* The amount of active PAI-1 was analyzed in citrate plasma using a commercially available bioimmunoassay (Chromolize PAI-1 kits; Biopool AB, Umeå, Sweden).

*Statistical analyses*. Two groups of subjects including 25 persons each was calculated to give a power of 80% to detect a difference in serum or LDL cholesterol of 9% if $P < 0.05$. For analyses of differences between the changes in the two groups, unpaired *t*-tests were used. Changes within each group were analyzed using paired *t*-tests. Variables with a skewed distribution ($W < 0.95$ in Shapiro-Wilk's *W* test for normality) were logarithmically transformed prior to the *t*-test. Variables that were not normally distributed after logarithmic transformation were analyzed using Wilcoxon Mann-Whitney two-sample test. Results with a *P*-value less than or equal to 0.05 were considered as significant. Percent change was calculated as [(mean value after − mean value before)/mean value before] × 100. The main statistical analyses were performed according to protocol, i.e., excluding participants with a low compliance (who had taken less than 80% of the prescribed number of capsules). Additional analyses were also made according to intention to treat, i.e. all subjects were included irrespective of their degree of compliance. Results from the latter analyses are shown in the text when differing from analyses according to the protocol. The statistical analyses were performed using the software systems Statistical Analysis System and STATA (Stata Corporation, College Station, TX).

## RESULTS

*Compliance and tolerance.* All participants fulfilled the trial. The compliance, counted as percentage of eaten capsules out of those prescribed, was more than 91% in 46 of the participants, between 81 and 90% in three, and 80% or less of the capsules in three of the participants. The participants with a compliance of 80% or less were excluded from the main statistical analyses. The capsules were well tolerated, and only a few subjects reported mild diarrhea at some occasions. No effect on serum levels of the liver enzymes aspartate amino transferase and alanine amino transferase was found. Fifty out of the 53 subjects completed the three 3-d weighed dietary registrations. The participants did not statistically change their dietary intake during the study with regard to energy, fat, carbohydrates, or protein (data not shown).

*Anthropometry.* As shown in Table 3 there was no significant change in body weight, BMI, waist-to-hip ratio, and sagittal abdominal diameter. The proportion of body fat was reduced by 3.8% in the CLA group, $P = 0.0006$ ($P = 0.05$ for difference between the groups) (Table 3). When analyzing according to intention to treat (including all participants), reduction of body fat in the CLA group was 3.7%, $P < 0.001$ ($P = 0.07$ for difference between the groups). There was no relation between change in body fat and the proportion of body fat at start (data not shown).

[a]$n = 50$ unless otherwise stated. BMI, body mass index; SAD, sagittal abdominal diameter; WHR, waist-to-hip ratio.
[b]Percentage change is calculated as: [(value after – value before)/value before] × 100, using mean values.
[c]Logarithmically transformed prior to *t*-test.
[d]Analyzed using Wilcoxon Mann-Whitney two-sample test.

*Serum lipids and apolipoproteins.* As shown in Table 4, an increase in Apo B was observed in the CLA-treated group ($P = 0.009$) with a significant difference between the two groups ($P = 0.044$). Within the control group we observed a decreased LDL triglyceride concentration ($P = 0.033$) and a significant difference between the groups ($P = 0.039$). When including all participants in the statistical analyses, there were no significant differences between the changes in serum lipid and apolipoprotein concentrations in the two groups.

*Plasma variables.* There was a borderline significant difference between the changes of fasting blood glucose in the groups ($P = 0.053$), as shown in Table 4. When including all participants, there were no significant differences between the two groups with regard to changes in fasting glucose, insulin, nonesterified fatty acids, or PAI-1.

*Fatty acid composition of serum lipids and thrombocytes.* In the serum phospholipids the proportion of stearic acid (18:0), docosatetraenoic acid (22:4n-6), and docosapentaenoic acid (22:5n-3) increased, and palmitic acid (16:0), oleic acid (18:1n-9), γ-linolenic acid (18:3n-6) ($P = 0.065$), and dihomo-γ-linolenic acid (20:3n-6) decreased in the CLA group, as compared to the control group (Table 5). The fatty acid composition in the thrombocytes changed with an increase of docosapentaenoic acid (22:5n-3) and a decrease of oleic acid (18:1n-9) and dihomo-γ-linolenic acid (20:3n-6) as shown in Table 5. The changes of fatty acid composition of serum cholesterol esters and triglycerides were similar to the changes of the serum phospholipids (data not shown). The changed proportions of the fatty acid composition in the serum lipids correspond to an increase in the estimated Δ-5 desaturase activity (20:4n-6/20:3n-6) in the CLA group as com-

pared to the control group, whereas the estimated activities of Δ-6 desaturase (18:3n-6/18:2n-6 in triglycerides and cholesterol esters and 20:3n-6/18:2n-6 in phospholipids) and Δ-9 desaturase (18:1n-9/18:0) decreased as compared to the control group (data not shown). Also in the thrombocytes, there was an increase in Δ-5 (20:4n-6/20:3n-6) and decrease in Δ-6 (20:3n-6/18:2n-6) estimated activities in the CLA group as compared to the control group while Δ-9 (18:1n-9/18:0) was unchanged (data not shown). No changes were seen in the activity of Δ-9 desaturase calculated as the ratio between 16:1n-7 and 16:0 in any of the compartments analyzed.

The effects of CLA and control supplementation on any of the parameters analyzed were not significantly different in men and women and were not changed when including mean fat intake in the statistical analyses as a possible confounder (data not shown)

## DISCUSSION

In this study the proportion of body fat in the subjects given CLA decreased significantly within the CLA-treated group by 3.8% with a borderline significant decrease as compared to the control group ($P = 0.050$). BMI, body weight, waist-to-hip ratio, and sagittal abdominal diameter were unchanged (Table 3).

Hitherto, there are two published studies on the effects of CLA on human body composition (4,6). In the study by Zambell *et al*., where healthy normal weight women were fed 3 g of CLA, consisting of minor amounts of several different isomers, no effect on body weight or composition was found (4). Contrastingly, Blankson *et al.* (6) observed a decreased body fat mass in overweight or moderately obese men and women when supplementing with 3.4 or 6.8 g of a CLA preparation with equal proportions of the *cis*-9,*trans*-11 and *trans*-10,*cis*-12 isomers. The diverging results between the two studies mentioned and the present could possibly be due to the different amounts and isomer compositions of the CLA preparation because different isomers and different study designs have been hypothesized to have different effects (12,13). It could also be due to the different study designs. Another interesting possibility is that there might be diverging effects of CLA in obese compared to normal-weight subjects. There could possibly also be gender and/or genetically determined difference. CLA supplementation to animals has been observed to reduce body fat (14). Little work has been done on the mechanisms of action of CLA on energy metabolism and the explanations of the effects are as yet not known. CLA has been suggested to affect the rate of *de novo* lipogenesis and/or the rate of lipolysis. Increased lipolysis and decreased lipoprotein lipase activity have been observed *in vitro* in adipocytes when CLA was added to the medium (14). An increased carnitine palmitoyltranferase activity giving an increased fatty acid oxidation in adipose and skeletal muscle tissue was found in mice after CLA supplementation (14). However, no effects on energy expenditure or fat oxidation was observed after CLA supplementation in healthy women (4).

In the present study, we observed an increase in Apo B and LDL triglycerides in the CLA group when compared to the control group (Table 4). Within the CLA group there were increases in total and LDL cholesterol, although not different from the changes in the control group, as also observed in a recent study of healthy women (15). In another study, reduc-

tions of total, HDL, and LDL cholesterol, but no changes in triglycerides and lipoprotein(a), were seen within the treatment groups after CLA treatment (6). CLA has, in studies of experimental animals, been suggested to affect serum lipoprotein concentrations. In a recent study in hamsters, the levels of total, LDL, and HDL cholesterol decreased and triglycerides increased after treatment with a mixture of CLA isomers (16). Other animal studies have shown decreased plasma LDL cholesterol (17), decreased total and non-HDL cholesterol and triglycerides (18), and decreased levels of total cholesterol and triglycerides (19) after CLA supplementation. The diverging results between the present study in humans and earlier studies in experimental animals could be due to species differences, but should be further investigated.

Insulin and nonesterified fatty acid levels were unchanged after CLA supplementation in the present study, while there was a tendency to an increased glucose concentration in the CLA group as compared to the controls (Table 4). In another human study, no changes in insulin or glucose concentrations were observed (5). Belury and coworkers (20), on the other hand, have found that dietary CLA normalizes glucose tolerance and prevents the progression to hyperglycemia and diabetes in diabetic fatty fa/fa Zucker rat, with an effect similar to that of the insulin-sensitizing drug thiazolidindione. The insulin-sensitizing effects are suggested to be mediated *via* activation of peroxisome proliferator activator receptor (PPAR) γ and a subsequent stimulation of adipocyte differentiation. In the same study, they also found a reduction of plasma nonesterified fatty acid concentration after CLA supplementation. This effect was assumed to be caused by an increased β-oxidation, *via* an activation of hepatic PPAR γ.

The PAI-1 activity was not significantly changed in any of the groups. PAI-1 has been found to be elevated in obesity, hypertension, glucose intolerance, insulin resistance, and type 2 diabetes, all included in the metabolic syndrome (21). In the adipose tissue of humans, mice, and rats, relatively high levels of PAI-1 have been detected, with increasing amounts in obese subjects (22). One could anticipate a decreased PAI-1 activity in the CLA supplemented group as body fat was reduced in this group and as PAI-1 levels have been observed to decrease when reducing body fat or body weight (21,23), but no such effect was seen in the present study.

In contrast to our findings (Table 5), no changes in the fatty acid composition of plasma lipids, thrombocytes, or adipose tissue were observed in another study of the effects of CLA in humans (15,24). The authors suggested that this could be due to a low number of participants ($n = 17$), but it could also be due to the lower amounts of several different isomers. In two studies of CLA feeding to rats, different tissues showed decreased proportions of dihomo-γ-linolenic acid (20:3n-6) and increased docosatetraenoic (22:4n-6) and docosapentaenoic acid (22:5n-3) (25,26), as also observed in the present study. However, in the rats the proportions of γ-linolenic (18:3n-6) and arachidonic acid (20:4n-6) decreased, which was not observed in the present study. Decreased proportions of linoleic (27) and arachidonic acid (25,27) were found in mouse liver and rat mammary gland after supplementation with CLA. In the present study the proportions of linoleic acid (18:2n-6) were unchanged, possibly indicating that CLA is not displacing linoleic acid to any larger extent or is not metabolized in the same way, as suggested by Banni *et al.* (25). The decrease in oleic acid (18:1n-9) can be interpreted as a decreased Δ-9 activity, as observed previously after CLA supplementation in experimental animals (28,29). A decrease in the activity of Δ-9 desaturase has been suggested to be due to an inhibitory effect of CLA on the mRNA expression of stearoyl-CoA desaturase, an enzyme catalyzing the Δ-9 desaturation (28,29). The estimated Δ-5 desaturase activity increased in the CLA group compared to the control group. The Δ-5 desaturase activity in humans has been suggested to be inversely related to the proportion of body fat (30), insulin levels (31), and risk for myocardial infarction (32). The Δ-6 desaturase activity (18:3n-6/18:2n-6) decreased after CLA treatment, as observed earlier in *in vitro* rat liver microsomes (29). The increased proportion of docosapentaenoic acid (22:5n-3) and the unchanged docosahexaenoic acid (22:6n-3) supports the indications of decreased Δ-6 desaturase activity.

Although the method used here was not optimal for analysis of the different CLA isomers, the proportions of total CLA increased in serum phospholipids (Table 5), cholesterol esters, and triglycerides (data not shown) in the CLA-treated group as compared to the control group. This supports earlier findings in humans (15) and animals (25). The fact that the proportions of CLA increased only in the CLA-treated group could be regarded as a verification of compliance.

The altered fatty acid profile of the serum lipids and thrombocytes, especially the decreased proportions of dihomo-γ-linolenic acid (20:3n-6) and increased activity of Δ-5 desaturase may lead to an altered eicosanoid metabolism. We have elsewhere reported on increased urinary levels of 8-iso-prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and 15-keto-dihydro-$PGF_{2\alpha}$ in humans after CLA supplementation (7). In some contrast to this Kavanaugh *et al.* (33) reported reduced $PGE_2$ levels in CLA-treated mice.

The intake of CLA in 123 Swedish men and women was estimated to be on average 160 mg/d (*cis*-9,*trans*-11) (34). CLA intakes in German men and women was estimated to 430 and 350 mg/d (*cis*-9,*trans*-11), respectively (35), and in 12 American men and women CLA intake was 127 mg/d (*cis*-9,*trans*-11) (36).

Of the known isomers of CLA, *cis*-9,*trans*-11 is the most abundant in natural food products (1). The two isomers considered most biologically active are *cis*-9,*trans*-11 and *trans*-10,*cis*-12. For example, *trans*-10,*cis*-12 has been suggested to be responsible for body composition changes in mice (37) and affect lipid metabolism in hamsters (16), and it has been observed to reduce milk fat synthesis in dairy cows (38). In the present study we used a mix of equal proportions of *cis*-9,*trans*-11 and *trans*-10,*cis*-12. It would be interesting to investigate the metabolic effects of the individual isomers.

The participants in the present study consisted of a rather heterogeneous group of healthy, nonobese, normolipidemic

men and women aged 23 to 63 yr. It is possible that the moderate changes seen after supplementation with CLA might be due to the heterogeneity of the group and to difficulties in changing physiological parameters within the normal range. The magnitude of a possible effect of CLA on, for example, body composition was unknown when designing the study. Thus the number of participants needed was estimated by a calculation of statistical power based on a change of serum lipid concentrations comparable to what has been seen when changing the fatty acid quality of the diet. Possibly, a larger number of participants is needed to detect changes in nonobese subjects. It would be interesting to study the effects of CLA supplementation in subjects with, for example, hyperlipidemia or abdominal obesity. An interesting view of this study is that the participants were weight-stable adult humans, as opposed to several studies where CLA has been given to growing animals. Judging from the effect on body composition in the present study and from the effects observed in growing animals, it could be hypothesized that CLA may be useful in inhibition of weight gain rather than in weight reduction *per se*.

These results indicate that supplementation with CLA for a limited period of time may cause reduction of the proportions of body fat and alter the fatty acid metabolism in healthy humans. However, CLA appeared to have no major effects on body weight, serum lipids, glucose metabolism, or PAI-1 in this group of subjects, in apparent contrast to results of earlier studies in animals. Whether the low concentrations of CLA naturally occurring in milk fat could have metabolic effects when eaten habitually for a long time still remains to be investigated.

## ACKNOWLEDGMENTS

For their invaluable help in the performance of this trial we are most grateful to the participants, to Lars Berglund for advice regarding statistical analyses, to Siv Tengblad, Barbro Simu, and Eva Sejby who performed the biochemical analyses, to Liisa Byberg who analyzed the PAI-1 activity, and to the staff at the metabolic ward. The capsules were kindly provided by Natural Lipids A/S, Oslo, Norway. The study was supported by research grants from The Swedish Medical Research Council (27X-13083) and The Swedish Dairy Foundation.

# Serum Cholesterol Predictive Equations with Special Emphasis on *Trans* and Saturated Fatty Acids. An Analysis from Designed Controlled Studies

**Hanne Müller[a,1], Bente Kirkhus[b,1], and Jan I. Pedersen[a,c,*]**

[a]University College of Akershus, 1340 Bekkestua, Norway, [b]Mills DA, 0506 Oslo, and [c]Institute for Nutrition Research, University of Oslo, 0316 Oslo, Norway

**ABSTRACT:** The effects of dietary *trans* fatty acids on serum total and low density lipoprotein (LDL) cholesterol have been evaluated by incorporating *trans* fatty acids into predictive equations and comparing their effects with the effects of the individual saturated fatty acids 12:0, 14:0, and 16:0. *Trans* fatty acids from partially hydrogenated soybean oil (*TRANS* V) and fish oil (*TRANS* F) were included in previously published equations by constrained regression analysis, allowing slight adjustments of existing coefficients. Prior knowledge about the signs and ordering of the regression coefficients was explicitly incorporated into the regression modeling by adding lower and upper bounds to the coefficients. The amounts of oleic acid (18:1) and polyunsaturated fatty acids (18:2, 18:3) were not sufficiently varied in the studies, and the respective regression coefficients were therefore set equal to those found by Yu *et al.* [Yu, S., Derr, J., Etherton, T.D., and Kris-Etherton, P.M. (1995) Plasma Cholesterol-Predictive Equations Demonstrate That Stearic Acid Is Neutral and Monounsaturated Fatty Acids Are Hypocholesterolemic, *Am. J. Clin. Nutr. 61*, 1129–1139]. Stearic acid (18:0), considered to be neutral, was not included in the equations. The regression analyses were based on results from four controlled dietary studies with a total of 95 participants and including 10 diets differing in fatty acid composition and with 30–38% of energy (E%) as fat. The analyses resulted in the following equations, where the change in cholesterol is expressed in mmol/L and the change in intake of fatty acids is expressed in E%: Δ Total cholesterol = 0.01 Δ(12:0) + 0.12 Δ(14:0) + 0.057 Δ(16:0) + 0.039 Δ(*TRANS* F) + 0.031 Δ(*TRANS* V) – 0.0044 Δ(18:1) – 0.017 Δ(18:2,18:3) and ΔLDL cholesterol = 0.01 Δ(12:0) + 0.071 Δ(14:0) + 0.047 Δ(16:0) + 0.043 Δ(*TRANS* F) + 0.025 Δ(*TRANS* V) – 0.0044 Δ(18:1) – 0.017 Δ(18:2,18:3). The regression analyses confirm previous findings that 14:0 is the most hypercholesterolemic fatty acid and indicate that *trans* fatty acids are less hypercholesterolemic than the saturated fatty acids 14:0 and 16:0. *TRANS* F may be slightly more hypercholesterolemic than *TRANS* V or there may be other hypercholesterolemic fatty acids in partially hydrogenated fish oil than those included in the equations. The test set used for validation consisted of 22 data points from seven recently published dietary studies. The equation for total cholesterol showed good prediction ability with a correlation coefficient of 0.981 between observed and predicted values. The equation has been used by the Norwegian food industry in reformulating margarines into more healthful products with reduced content of cholesterol-raising fatty acids.

Paper no. L8429 in *Lipids 36*, 783–791 (August 2001).

The effects of dietary fatty acids on serum cholesterol are an important criterion when nutritional properties of fat products are evaluated. Since the 1950s, several equations have been

Abbreviations: COCO, coconut oil; E%, energy percentage; HDL, high density lipoprotein; LDL, low density lipoprotein; MUFA, monounsaturated fatty acids; PALM, palm oil; PHFO, partially hydrogenated fish oil; PHSO, partially hydrogenated soybean oil; PUFA, polyunsaturated fatty acids; RMSEP, root mean square error of prediction; SAFA, saturated fatty acids; *TRANS*, *trans* fatty acids; *TRANS F*, *trans* fatty acids from PHFO; *TRANS V*, *trans* fatty acids from PHSO.

published that predict the effects of saturated fatty acids (SAFA), polyunsaturated fatty acids (PUFA), and monounsaturated fatty acids (MUFA) on serum total and low density lipoproteins (LDL) cholesterol levels in groups of individuals (1–10). The equations are fairly similar (Table 1) and indicate that SAFA increase serum cholesterol levels whereas PUFA have a lowering effect.

It should be noted that most of these equations predict changes in response to groups of fatty acids. Furthermore, they do not include *trans* fatty acids. To be of practical use to predict changes in response to commercial fat blends it is desirable to incorporate regression coefficients for individual dietary fatty acids including *trans* fatty acids. *Trans* fatty acids are formed during partial hydrogenation of liquid oils, a process that has been used by the food industry for many years to obtain edible fat blends with desired melting point behavior. During the last few years the European margarine industry has moved rapidly toward development of products virtually free of *trans* fatty acids. To avoid ending up with less healthful products by simply replacing *trans* fatty acids with cholesterol-raising SAFA one has to consider the effect of all individual fatty acids present in the products and choose the blends of raw materials with the most favorable fatty acid composition.

The aim of the present study was therefore to establish the cholesterolemic effects of *trans* fatty acids and compare them with the hypercholesterolemic effects of the SAFA 12:0, 14:0, and 16:0. Based on four strictly controlled dietary studies, *trans* fatty acids were incorporated into predictive equations by constrained linear regression analysis, utilizing prior knowledge about the regression coefficients for individual saturated and unsaturated fatty acids (11,12). We introduced *trans* fatty acids from two commonly used raw materials in Norway, partially hydrogenated soybean oil (PHSO) and partially hydrogenated fish oil (PHFO). *Trans* fatty acids from these raw materials differ with regard to both chain length and number of *trans* bonds. Hence, regression equations were developed that consider the effects of individual SAFA and *trans* fatty acids as well as MUFA and PUFA. Such equations are potentially useful for the food industry to optimize the fatty acid composition in edible fat products.

## MATERIALS AND METHODS

*Dietary studies.* The equations were based on results from four strictly controlled dietary studies conducted at the University College of Akershus, Norway, during the period 1993–1998 (13–15; Müller H., Lindman, S.A., Brantsæter, A.L., and Pedersen, J.I., unpublished results). They were Latin-square designed studies, or crossover studies where each individual consumed the diets in random order. Thus, each individual acted as his or her own control, and the variability among the individuals could be eliminated. The number of individuals was sufficient to assess significant differences in total and LDL cholesterol (13–15). As shown in Table 2 all participants had similar characteristics. However, in the first study (13) only young men participated, whereas in the last three studies only women participated.

All four studies were carried out following the same procedure. The meals were prepared at the college and the diets in each separate study differed only in the source of test margarine used for spreading, baking, and cooking. The test fats were incorporated into the menus in several foods including bread, buns, porridge, and sauces for dinner. The fat from the background diet was calculated to supply 6–8% of energy (E%), while the test fat was planned to provide the remaining fat energy, resulting in a total fat intake of about 30–38 E% (Table 3). The fatty acid composition of the diets and the content of dietary cholesterol were analyzed in duplicate portions by gas–liquid chromatography (Table 3).

A wide range of raw materials was used to produce the test fats: PHSO, PHFO, butter, palm oil (PALM), coconut oil (COCO), soybean oil, rapeseed oil, and sunflower oil. Since the main goal was to assess the effects of *trans* fatty acids and compare them with the effects of individual SAFA, diets enriched in PHSO and PHFO were tested twice with two separate groups of individuals (Table 3). In Study 1, PHSO and PHFO were tested against each other and butter (high in 14:0 and 16:0); in Study 2, PHFO was tested against PALM (high in 16:0); and in Study 3, PHSO was tested against PALM. Diets high in PUFA were tested against PHSO and PALM in Study 3, and against COCO (high in 12:0 and 14:0) in Study 4.

Blood samples were taken at the end of each test period of 3 wk duration in Studies 1, 3, and 4, and 2 wk in Study 2. Serum cholesterol was measured by enzymatic methods (16). Serum high density lipoprotein (HDL) cholesterol was measured by an enzymatic technique after precipitation of the LDL fraction with dextran sulfate and magnesium (16). LDL cholesterol concentrations were calculated using the equation of Friedewald *et al.* (17).

The four study protocols were approved by the Regional Committee for Ethics in Biomedical Research of Norway.

[e]Includes *trans,cis* and *cis,trans*. Abbreviations: PHSO, diets using margarines with a high content of *trans* fatty acids from partially hydrogenated soybean oil; PHFO, diets using a hard margarine with a high content of *trans* fatty acids from partially hydrogenated fish oil; PALM, diets using hard margarines containing vegetable oil, mainly palm oil; PUFA, diet using a soft highly polyunsaturated margarine; COCO, diet using a hard zero-*trans* margarine containing coconut oil.

*Regression analysis.* To be able to incorporate *trans* fatty acids into existing predictive equations that relate changes in intake of dietary fatty acids to changes in serum total and LDL cholesterol, we made use of constrained linear least-square regression (Optimization Toolbox in MATLAB, version 5.2; The Mathworks Inc., Natick, MA). This technique can be applied to regression modeling and optimization problems when the analyst possesses some knowledge about the regression coefficients, such as the signs and the ordering of the coefficients (11,12). Adequate constraints were added to the coefficients by using lower and upper bounds according to previous results in the literature. We assumed that the introduction of *trans* fatty acids did not severely influence the other coefficients. In other words, we allowed a slight adjustment of existing coefficients described in the literature while introducing *trans* fatty acids into the equations.

The data set with corresponding bounds is shown in Table 4. The table shows the differences in intake of the different fatty acids when changing from one diet to another (predictor variables, X). The corresponding difference in serum total and LDL cholesterol (response variables, Y) have been corrected for the effect of dietary cholesterol intake according to the the formulas of Hopkins (18) and Clarke *et al.* (9), respectively. However, except for Study 2 (14) the intake of cholesterol was similar for all diets within the same study and omission of the effect of dietary cholesterol had only a minor effect on the regression coefficients. The dietary studies with two diets yielded one data point, whereas the studies

[a]*TRANS* V, *trans* fatty acids from PHSO; *TRANS* F, *trans* fatty acids from PHFO. See Tables 1 and 3 for other abbreviations.

with three diets yielded three data points that represented the difference between any two groups. Hence, a total of eight data points were included in the analyses in order to estimate the coefficients for Δ12:0, Δ14:0, Δ16:0, Δ*TRANS* V, and Δ*TRANS* F. Because the amounts of MUFA and PUFA were not sufficiently and independently varied, their respective regression coefficients were set equal to those found by Yu *et al.* (8). Stearic acid (18:0) was not included in the regressions because it is considered to be neutral (1,2,5,6,9,10).

Estimates of the uncertainty variance of the regression coefficients were obtained using the "Jack-knife" (19). The method consists of leaving out one data point at a time and performing the regression analysis with the remaining data, resulting in eight single values of each coefficient for the calculation of the uncertainty variance. If a segment model differs greatly from the common model based on all data, it means that the data point left out seriously affects the common model by pressing some unique pattern of variation into the model parameters. Thus, the result shows the robustness of the common model against peculiarities in individual data points.

The predictive accuracy of the models is described by the root mean square error of prediction (RMSEP):

$$\text{RMSEP} = \left[ \frac{1}{N} \sum_{i=1}^{N} (y_{\text{obs}} - y_{\text{pred}})^2 \right]^{1/2} \quad [1]$$

which is a measure of the average difference between predicted ($y_{\text{pred}}$) and observed ($y_{\text{obs}}$) values. RMSEP can be interpreted as the average prediction error expressed in the same units as the original response (Y) variable.

The statistical packages SPSS Advanced Statistics, version 8.0 (SPSS Inc., Chicago, IL), were used for data analyses of the individual studies (Studies 1–4) and calculation of the Pearson correlation coefficient.

*Validation based on test set.* The serum cholesterol predictive equation was validated using a test set consisting of results from recently published Western studies (20–26) that fulfilled the requirements of well-controlled randomized cross-over or Latin-square design studies with normolipidemic or slightly hypercholesterolemic individuals (summarized in Table 5). The fat intake varied from 22 to 40 E%. All studies reported the fatty acid composition of the experimental diets, including *trans* fatty acids. The studies yielded 22 unique data points, each representing the difference between two diets within a study, i.e., changes in serum cholesterol that could be derived from other observed changes were omitted.

## RESULTS

All participants complied well. In Study 3, four overweight participants lost between 1.7–7 kg during the study and were therefore omitted from the regression analyses (Table 2).

*Serum total cholesterol.* Figure 1 presents the regression coefficients for the relation between variations in serum total cholesterol and variations in fatty acid intake, expressed as mmol/L per 1 E% change in fatty acid. The standard deviations were estimated by Jack-knifing. The coefficients were as follows: lauric acid (12:0) 0.01 ± 0.166, myristic acid (14:0) 0.12 ± 0.026, palmitic acid (16:0) 0.057 ± 0.019, *TRANS* V (18:1*t*, 16:1*t*) 0.031 ± 0.025, *TRANS* F (16:1*t*, 18:1*t*, 18:2*t*, 20:1*t*, 20:2*t*, 22:2*t*, 24:1*t*) 0.039 ± 0.022. The coefficients for oleic acid (18:1) and linoleic acid (18:2)/(α-linolenic acid (18:3) were set equal to the coefficients given by Yu *et al.* (8). Thus, the following equation was developed: Total cholesterol = 0.01 Δ(12:0) + 0.12 Δ(14:0) + 0.057 Δ(16:0) + 0.039 Δ(*TRANS* F) + 0.031 Δ(*TRANS* V) – 0.0044 Δ(18:1) – 0.017 Δ(18:2,18:3). The correlation coefficient between observed and predicted values was 0.996 and the RMSEP was 0.026 mmol/L (Fig. 2A).

*Serum LDL cholesterol.* There was a significant correlation (Pearson coefficient $r = 0.922$, $P < 0.01$) between serum total and LDL cholesterol in the four studies (Fig. 3). The regression coefficients for LDL cholesterol and their respective standard deviations were as follows: lauric acid (12:0) 0.01 ± 0.17, myristic acid (14:0) 0.071 ± 0.011, palmitic acid (16:0) 0.047 ± 0.032, *TRANS* V (18:1*t*, 16:1*t*) 0.025 ± 0.042, and

*TRANS* F (16:1*t*, 18:1*t*, 18:2*t*, 20:1*t*, 20:2*t*, 22:2*t*, 24:1*t*) 0.043 ± 0.028. The coefficients for oleic acid (18:1) and linoleic acid (18:2)/α-linolenic acid (18:3) were set equal to the coefficients given by Yu *et al.* (8). Thus, the following equation was developed: ΔLDL cholesterol = 0.01 Δ(12:0) + 0.071 Δ(14:0) + 0.047 Δ(16:0) + 0.043 Δ(*TRANS* F) + 0.025 Δ(*TRANS* V) – 0.0044 Δ(18:1) – 0.017 Δ(18:2,18:3). The correlation coefficient between observed and predicted values was 0.969, and the RMSEP was 0.079 mmol/L (Fig. 2B).

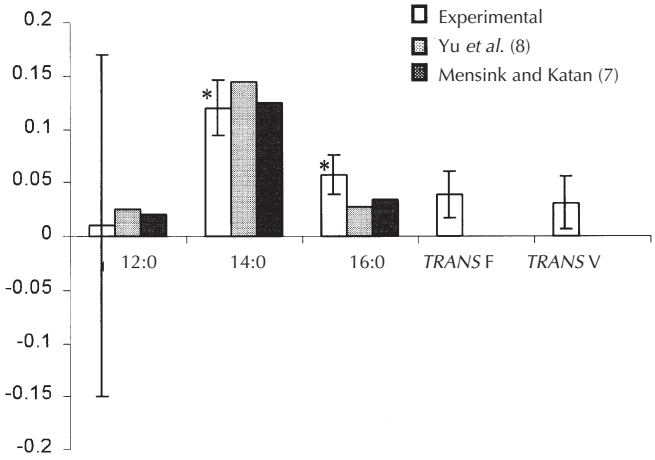

**FIG. 1.** Bar graph showing the coefficients of individual saturated and *trans* fatty acids obtained by constrained linear regression and expressed as mmol/L per energy% change in fatty acid intake. The standard deviations are calculated by Jack-knifing (*, regression coefficients are significantly different from zero, $P < 0.05$). Regression coefficients for individual saturated fatty acids published by Yu *et al.* (8) and Mensink and Katan (7) are shown for comparison.

*Test set validation.* Results from seven published dietary studies including diets with *trans* fatty acids (20–26) were used to test the prediction ability of the equation for total cholesterol. Based on the reported intake of individual fatty acids, the expected change in serum cholesterol was calculated and compared to the observed changes (Fig. 4). A significant correlation (Pearson coefficient $r = 0.981$, $P < 0.01$) between predicted and observed values was found (Fig. 4) with a RMSEP of 0.076 mmol/L, which shows that the equation gives good predictions not only of our dietary studies but also of a considerable number of studies performed in other laboratories.

## DISCUSSION

Recently, new interest is focused on the cholesterolemic effect of individual fatty acids rather than classes of fatty acids (7,8). The outcome of the regression analyses performed in the present study is in good agreement with previous studies (7,8), as demonstrated in Figure 1, and confirms that myristic acid (14:0) is more hypercholesterolemic than lauric acid (12:0) and palmitic acid (16:0). The present results also indicate that *trans* fatty acids are slightly less hypercholesterolemic than 16:0.

In most published equations (2,5–7,10) a regression coefficient is given only for the sum of 12:0, 14:0, and 16:0, and

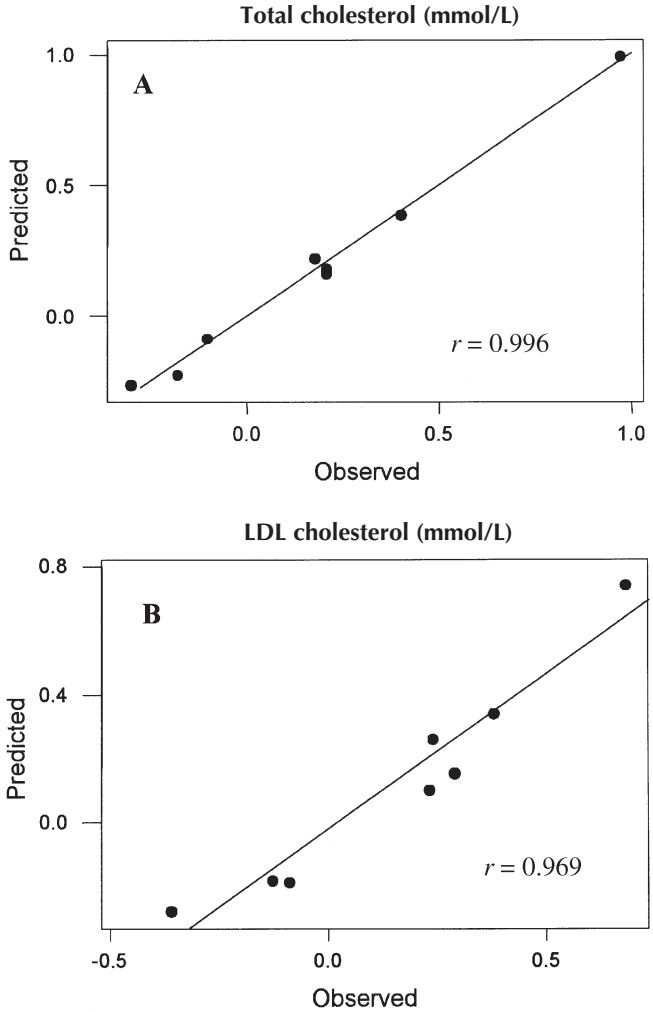

**FIG. 2.** Correlation between observed and predicted change in serum total cholesterol (A) and low-density lipoprotein (LDL) cholesterol (B) for data points included in the constrained regression analyses (Table 4). Pearson correlation coefficient between predicted and observed changes in total cholesterol is 0.996 ($P < 0.01$) and root means square error of prediction (RMSEP) = 0.026 mmol/L. Pearson correlation coefficient between predicted and observed changes in LDL cholesterol is 0.969 ($P < 0.01$) and RMSEP = 0.079 mmol/L.

*trans* fatty acids are not included. Since individual SAFA and *trans* isomers occur in different amounts in edible fats, those equations will not be applicable to every data set and may give erroneous predictions. The importance of splitting up the SAFA was also clearly demonstrated when we performed the constrained regression analyses with only one coefficient for total saturated fat. This resulted in much poorer models for both serum total cholesterol (RMSEP = 0.069 vs. 0.026 mmol/L) and LDL cholesterol (RMSEP = 0.112 vs. 0.079 mmol/L).

Our main goal was to incorporate *trans* fatty acids from PHSO and PHFO into predictive equations that would offer a valuable tool for the Norwegian food industry, particularly in the manufacture of margarine. We used constrained linear regression, a technique where lower and upper bounds can be added to the regression coefficients. The bounds were chosen

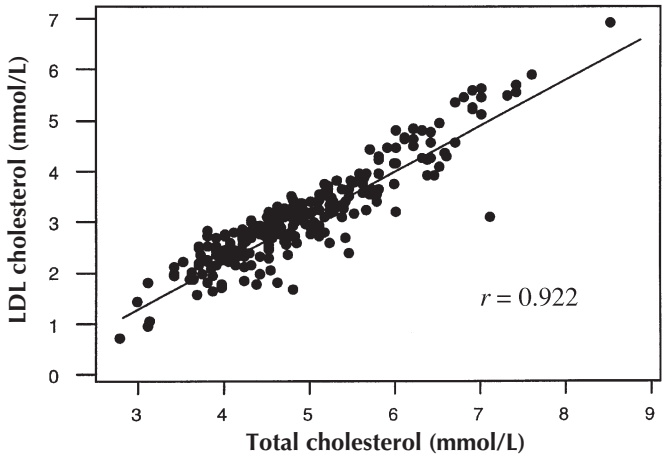

**FIG. 3.** Correlation between serum total cholesterol and low-density lipoprotein (LDL) cholesterol. Results from Studies 1–4 are included. The Pearson correlation coefficient between observed and predicted values is 0.922 ($P < 0.01$).

according to previously reported coefficients in the literature (7,8). The use of constrained regression is motivated by the need to utilize existing knowledge about the signs and ordering of the regression coefficients and the realization that regression estimates can be misleading when the X-variables are correlated.

As seen in Figure 1, there is a large uncertainty in the coefficient for lauric acid (12:0). The value of the coefficient is similar to the lower bound, which is lower than coefficients reported in the literature. This is due to the influence of the data point from Study 4 (COCO–PUFA), which seems to pull down the effect of 12:0. However, Study 4 is the only study where 12:0 is sufficiently varied and therefore it should be included. Caution must, of course, be taken when interpreting the standard deviations of coefficients that touch the bounds.

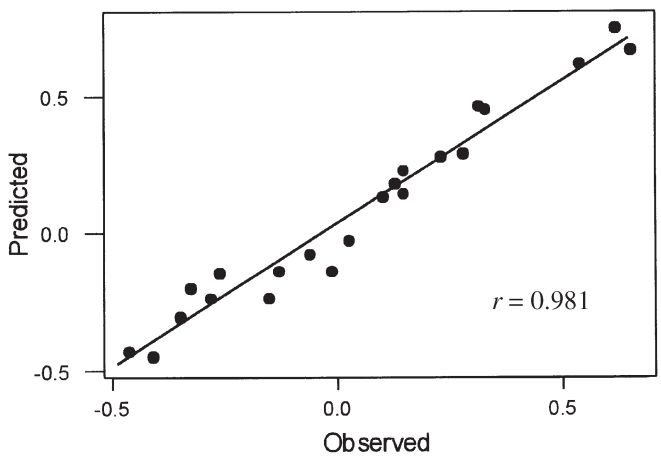

**FIG. 4.** Correlation between observed and predicted change in serum total cholesterol from seven studies (20–26) included in the test set (summarized in Table 5). The predicted values were calculated with Equation 1 given in the text. The Pearson correlation coefficient between observed and predicted values is 0.981 ($P < 0.01$). Root mean square error of prediction = 0.076 mmol/L.

Except for the coefficient for 12:0, this was not a problem as Jack-knifing showed that all estimated coefficients in the submodels were far from touching the upper and lower bounds. We therefore conclude that the coefficient for 12:0, although not significant, indicates that 12:0 does not raise serum total cholesterol as much as 14:0 and 16:0. This is in agreement with previously published data (7,8,27,28).

Cases with small data sets are often difficult to handle because there is little information for estimating a model, and each sample is unique. Furthermore, the fatty acids investigated should be varied independently of each other in order to assess coefficients that reflect a physiological role. This is difficult to do with natural oils where the different fatty acids are correlated to a greater or lesser extent. However, although our data are limited, they are precise, resulting from strictly controlled randomized cross-over studies reporting the fatty acid composition in duplicate portions of the experimental diets. Fat from the background diet supplied only 6–8%, and the observed effects were therefore due almost entirely to the test fat. In order to assess the effects of *trans* fatty acids, diets enriched in PHSO and PHFO were tested twice with two separate groups of individuals (Table 3), and this strengthens the results.

In the end it is the validation step that shows how good the regression model is. A nonrepresentative calibration set may introduce erroneous predictions of future data sets. In order to test predictive capability and validate our model for total serum cholesterol, we used a test set consisting of results from studies published from different laboratories in Western countries. We selected seven recently published papers from the literature that fulfilled the requirements of well-controlled studies reporting the complete fatty acid composition of the experimental diets. These were mainly studies including diets with *trans* fatty acids. Figure 4 demonstrates how well the equation predicts the results from these studies ($r = 0.981$, RMSEP = 0.076 mmol/L), suggesting that it may have a broader application. On the other hand, the equation gave rather poor predictions of the results from a study of Sundram *et al.* (29) where healthy Malaysians were exposed to *trans* fatty acids (PHSO). The authors report that the observed response to *trans* fatty acids differed from other studies and suggest that different ethnic background and habitual diet may explain the Malaysians' exceptional sensitivity to *trans*. Other contributing factors may be differences in the source and type of *trans* isomers and the way the *trans* content is measured. Some authors have also discussed the possibility of interactions, in particular between SAFA or *trans* and 18:2. In the present experimental diets the content of 18:2 varied from 8.6 to 36.2% (Table 3). Our data set is too small for incorporating interactions in the regression analyses. However, the precise predictions of the 11 studies (30 data points) in the calibration and test sets indicate that, if there are interaction effects, these are small compared with the main effects.

Possible differences between men and women in the response to dietary fatty acids would also affect the prediction ability. Both men and women participated in our studies (Table 2). Keys *et al.* (1,2) and Hegsted *et al.* (5,6) used data from middle-aged men in their regression analyses while others have used data from both men and women (7–10). Predictive equations from Yu *et al.* (8) indicate that the response to fatty acids are similar for women and men. However, some difference in HDL cholesterol response to diet between women and men cannot be excluded.

There are several reports showing that myristic acid (14:0) increases total cholesterol more than palmitic acid (16:0) (6,8,27,30). It should also be noted that in one study no difference was found in the cholesterol-raising effect of 14:0 and 16:0 (31), except that 14:0 resulted in an 8% higher HDL cholesterol level. In another study, the effect of 14:0 on serum total cholesterol was 1.5 higher than that of 16:0, and half of this increase was due to an increase in HDL cholesterol (30). The HDL cholesterol-increasing effect of 14:0 may explain why our regression coefficient for 14:0 is much larger for serum total than for LDL cholesterol. Constrained regression analysis of the present data failed to obtain a credible predictive equation for HDL. It is also apparent from Figure 2 that the developed equations predict serum total cholesterol (RMSEP = 0.026 mmol/L) better than LDL cholesterol (RMSEP = 0.079 mmol/L). There may be several reasons for this. Total serum cholesterol may simply be better described by a linear relationship between dietary intake of individual fatty acids than LDL and HDL cholesterol. Also, some fatty acids may have different effects on LDL and HDL cholesterol. Thus, as discussed above, 14:0 increases HDL cholesterol, while *trans* fatty acids have a decreasing effect (13,21, 23,26). Furthermore, unlike total cholesterol, LDL cholesterol is a calculated, not a measured, value and the methodological error is therefore probably greater. However, the regression coefficients for total and LDL cholesterol are in relatively good agreement with each other, and the correlation between total and LDL cholesterol is high (Fig. 3), indicating that changes in the level of total serum cholesterol were mainly due to changes in LDL cholesterol.

The effect of *trans* fatty acids on serum cholesterol has not been included in previously published predictive equations (2,5–10). However, Clarke *et al.* (9) give a regression coefficient of 0.038 mmol/L for 18:1 *trans* isomers, similar to our regression coefficient of *TRANS* F. It is now well established that *trans* fatty acids are hypercholesterolemic even if the exact increasing effect on serum total cholesterol is uncertain (3,21–23,32). Some have proposed that *trans* acids increase total and LDL cholesterol to a lesser extent than $C_{12}$, $C_{14}$, and $C_{16}$ saturated acids (22,32), while others have proposed that *trans* fatty acids and SAFA have similar effects on LDL cholesterol (33). The results of our study indicate that the effect of *TRANS* V is slightly lower than that of 16:0 on serum total and LDL cholesterol.

Very little is known about the effects of the very long chain saturated and *trans* fatty acids ($C_{20}$–$C_{24}$) in PHFO on serum lipoproteins (14). Several of these may be cholesterol increasing. The possible cholesterol-increasing fatty acids 14:1 *cis*, 16:1 *cis* (34), or 22:0 (35) were not included in our equation. Such fatty acids are present in hydrogenated fish oils, and

their effects will be reflected in the coefficient for *trans* fatty acids. This may explain why our regression coefficients for *TRANS* F from fish oil are higher than for *TRANS* V. Our model also indicates that *TRANS* F, unlike *TRANS* V increase LDL cholesterol more than total cholesterol. The explanation may be that *TRANS* F appear to decrease HDL cholesterol more than *TRANS* V (13).

Predictive equations such as those previously published (Table 2) or the one we have developed may certainly have their weaknesses and limited theoretical utility. This does not mean that they may be of no practical use. The equation for total serum cholesterol presented here has been used by a Norwegian food company to formulate a cholesterol-reducing margarine. When the margarine was tested against butter in an open clinical trial (36), the observed cholesterol-lowering effect corresponded reasonably well to the predicted effect (0.77 vs. 0.64 mmol/L, respectively). This study was not strictly controlled and Hopkins' formula (18) was used to correct for the difference in cholesterol content of margarine and butter. Together with the result from the test set validation, this confirms that the equation has practical applicability and can be used to formulate and nutritionally optimize fat products as well as evaluate already existing products on the market.

## ACKNOWLEDGMENTS

We gratefully acknowledge the cooperation of the participants in the four studies. We also wish to thank Dr. Kari Almendingen for having provided data from Study 1. Special thanks to Ola Eide, Director of Innovation, Mills DA, for his valuable ideas and support and Narinder Singh Sahni and Dr. Tormod Næs for valuable discussions regarding the statistical analyses. This study was supported by research grants from The Nordic Industrial fund, the Norwegian food company Mills DA, and the Norwegian Research Council.

# Comparative Bioavailability of Dietary α-Linolenic and Docosahexaenoic Acids in the Growing Rat

**Carine Poumès-Ballihaut[a,*], Bénédicte Langelier[a], Françoise Houlier[a], Jean-Marc Alessandri[a], Georges Durand[a], Christian Latge[b], and Philippe Guesnet[a]**

[a]Institut National de la Recherche Agronomique (INRA), Laboratoire de Nutrition et Sécurité Alimentaire, CRJ, 78352 Jouy-en-Josas Cédex, France, and [b]Blédina-sa, Groupe Danone, Villefranche-sur-Saône, France

**ABSTRACT:** Animal and human studies have indicated that developing mammals fed only α-linolenic acid (18:3n-3) have lower docosahexaenoic acid (22:6n-3) content in brain and tissue phospholipids when compared with mammals fed 18:3n-3 plus 22:6n-3. The aim of this study was to test the hypothesis that low bioavailability of dietary 18:3n-3 to be converted to 22:6n-3 could partly explain this difference in fatty acid accretion. For that purpose, we determined the partitioning of dietary 18:3n-3 and 22:6n-3 between total n-3 fatty acid body accumulation, excretion, and disappearance (difference between the intake and the sum of total n-3 fatty acids accumulated and excreted). This was assessed using the quantitative method of whole-body fatty acid balance in growing rats fed the same amount of a 5% fat diet supplying either 18:3n-3 or 22:6n-3 at a level of 0.45% of dietary energy (i.e., 200 mg/100 g diet). We found that 58.9% of the total amount of 18:3n-3 ingested disappeared, 0.4% was excreted in feces, 21.2% accumulated as 18:3n-3 (50% in total fats and 46% in the carcass-skin compartment), and 17.2% accumulated as long-chain derivatives (14% as 22:6n-3 and 3.2% as 20:5n-3 + 22:5n-3). Similar results were obtained from the docosahexaenoate balance (as % of the total amount ingested): disappearance, 64.5%; excretion, 0.5%; total accumulation, 35% with 30.1% as 22:6n-3. Thus, rats fed docosahexaenoate accumulated a twofold higher amount of 22:6n-3, which was mainly deposited in the carcass-skin compartment (68%). Similar proportions of disappearance of dietary 18:3n-3 and 22:6n-3 lead us to speculate that these two n-3 polyunsaturated fatty acids were β-oxidized in the same amount.

Paper no. L8435 in *Lipids 36*, 793–800 (August 2001).

Docosahexaenoic acid (DHA, 22:6n-3) is the main polyunsaturated fatty acid (PUFA) found in excitable membrane phospholipids of the mammalian brain and retina and is intensively deposited in these tissues during the brain growth spurt to ensure optimal visual and cognitive functions (reviewed in Ref. 1). In normal nutritional conditions, the 22:6n-3 requirement is covered by the dietary supply of both its essential precursor α-linolenic acid (ALA, 18:3n-3) and preformed 22:6n-3 (1). Several data suggest that this requirement is not fulfilled when only dietary 18:3n-3 is supplied. Indeed, infants fed formulas containing only 18:3n-3 have lower 22:6n-3 concentrations in their blood, liver, and brain phospholipids than breast-fed infants receiving both n-3 PUFA, even if formulas have a low ratio of linoleic acid (18:2n-6) to 18:3n-3 and/or a high 18:3n-3 content (reviewed in Refs. 2–4). Recent data obtained from artificially reared rat pups and young adult rats also indicate that a high dietary intake of 18:3n-3 is unable to sustain adequate neural and other tissue 22:6n-3 accretion (5,6). All these results suggest that the growing mammal has an insufficient metabolic capacity to biosynthesize an adequate amount of 22:6n-3 from its essential precursor, a hypothesis that has been confirmed in newborn infants by their extremely low *in vivo* conversion of deuterated 18:3n-3 to 22:6n-3 (7).

Limiting capacity to biosynthesize 22:6n-3 from 18:3n-3 might result from (i) a competitive inhibitory effect of 18:3n-3 on Δ6-desaturation of 24:5n-3 to 24:6n-3 in the new alternative pathway of Δ4-desaturation as some authors suggested (8), and/or (ii) a low bioavailability of dietary 18:3n-3 owing to its high *in vivo* rate of β-oxidation (9), recently confirmed by the indirect quantitative method of the whole-body fatty acid balance showing that 85% of the dietary 18:3n-3 consumed disappeared in the growing rat (10). In contrast, dietary 22:6n-3 is considered to be more bioavailable because it is a poor substrate for peroxisomal and mitochondrial β-oxidation pathways (11) and is preferentially acylated in membrane phospholipids. But to our knowledge, there are no *in vivo* quantitative data on the metabolic partitioning of dietary 22:6n-3 between its disappearance and body accumulation as 22:6n-3 and its derivatives.

Therefore, this study compared the overall partitioning of dietary 18:3n-3 and 22:6n-3 in the growing rat by quantifying (i) the amount of dietary 18:3n-3 and 22:6n-3 that disappeared, and (ii) the amount of 18:3n-3 and 22:6n-3 and their derivatives accumulated in the whole body and in different organ compartments. The whole-body fatty acid balance methodology was chosen, as it is relevant to determine these parameters specifically for PUFA and over a long period of time of dietary utilization. Moreover, it estimates indirectly the overall *in vivo* β-oxidation of PUFA as it is supposed that their disappearance is mainly attributable to this catabolic pathway, inasmuch as it is accepted that essential fatty acids are not synthesized *de novo* and that other catabolic processes

Abbreviations: ALA, α-linolenic acid 18:3n-3; ANOVA, analysis of variance; DHA, docosahexaenoic acid 22:6n-3; FAME, fatty acid methyl ester; LC, long-chain; PUFA, polyunsaturated fatty acid.

of PUFA, such as eicosanoid synthesis, are quantitatively minor (10,12). The dietary supply of 18:3n-3 and 22:6n-3 was chosen in order to satisfy the n-3 fatty acid requirement of the growing rat (200 mg/100 g diet, corresponding to 0.45% of energy) (13).

## MATERIALS AND METHODS

*Animals and diets.* All procedures involving animals followed official French regulations for the care and use of laboratory animals (nos. 87 848 and 03 056). Twelve 2-mon-old female rats were the offspring of Wistar female rats rendered deficient in n-3 fatty acids (second generation) by consuming a semisynthetic diet very low in 18:3n-3 (5 wt% of peanut oil providing 9 mg 18:3n-3/100 g diet) (14). They were mated over 4 d and then housed individually in a polycarbonate cage. One week before parturition, they were randomly divided into two dietary groups (6 females per group). The first group received an α-linolenate (ALA) diet containing about 200 mg 18:3n-3/100 g diet (0.45% of total dietary energy), which is sufficient to meet the n-3 requirements of the growing rat (13). This diet was obtained by mixing peanut and flaxseed oils (Table 1). The second group received a DHA diet that provided the same supply of n-3 fatty acids (200 mg/100 g diet), but only as 22:6n-3, by using a microalgae oil containing about 42 wt% 22:6n-3 and <0.1% 18:3n-3, 20:5n-3, and 22:5n-3 (Neuromins™ DHA oils, Martek Biosciences Corporation, Columbia, MD). As the fat blend included peanut oil, the DHA diet supplied a low 18:3n-3 content (0.2 wt%, i.e. 9 mg/100 g diet) (Table 1). This experimental rearing procedure was used to obtain female then male weaned young rats in the DHA group with low 18:3n-3 body stores, which is crucial for studying the 22:6n-3 balance. Both diets contained 5% fat (weight %) and satisfied the 18:2n-6 requirement of the growing rat (about 1.1 g 18:2n-6/100 g diet, i.e., 2.5% of total dietary energy) (13). They were prepared weekly and stored at 4°C to avoid oxidative damage of n-3 fatty acids. Fatty acid composition was monitored during storage of each preparation. During lactation, litter sizes were equalized to 8 pups.

At weaning, in each dietary group and for each litter, male pups of similar body weight were paired up. One rat was housed in a metabolic cage for a 5-wk balance period and continued to receive the same diet (6 rats per group), and the other was sacrificed by decapitation to quantify whole-body fatty acid partitioning (6 rats per group). Then, to avoid unbalanced dietary intake and different body weight gain between rats, all animals daily received the same amount of diet during the balance period, from 12 g on day 1 to 24 g on day 35. They were weighed and their food intake was recorded every day. Feces were also collected daily, freeze-dried and stored at –80˚C until analysis. At the end of the balance period, 8-wk-old rats were sacrificed by decapitation.

*Dissection and lipid analysis.* Before sacrifice, rats were fasted overnight. The major organs were carefully dissected as described by Cunnane and Anderson (10) for comparison purposes. Except for brain and liver, they were pooled as follows: viscera (gut, pancreas, spleen, testes, bladder, kidneys, heart, thymus, and lungs), internal fats (epididymal, mesenteric, omental, and perirenal adipose tissues), subcutaneous fats (all the subcutaneous adipose tissues that could possibly be removed), and remaining carcass (skin, muscles, the whole skeleton, and the head without the brain). Organ compartments were weighed, freeze-dried, reduced to powder with dry ice and stored at –80˚C until analysis.

Total lipids of the lyophilized organs, organ compartments, and feces were extracted by the procedure of Folch *et al.* (15) in the presence of 0.02% (wt/vol) butylated hydroxytoluene. To assess the effectiveness of this extraction procedure and quantify total fatty acids in each organ compartment, known amounts of diheptadecanoyl (17:0) phosphatidylcholine and trinonadecanoyl (19:0) glycerol (Sigma, St. Quentin Fallavier, France) were added as internal standards during extraction and represented approximately 10% of estimated total fatty acids. Total lipids were then transmethylated with 10% boron trifluoride (Fluka, Socolab, Paris, France) at 90°C for 40 min (16). Fatty acid methyl esters (FAME) were injected into a Carlo Erba gas

[a]The experimental diets contained (g/kg diet): lipids, 50; casein, 220; DL-methionine, 1.6; cellulose, 20; starch, 438.4; saccharose, 220; vitamin mixture, 10; mineral mixture, 40 (caloric density: 3970 kcal/kg or 16.61 MJ/kg). The vitamin mixture was a total vitamin supplement (United States Biochemical Corp., Cleveland, OH), and the mineral mixture was as follows (g/100 g): $CaHPO_4 \cdot 2H_2O$, 38.0; $K_2HPO_4$, 24.0; $CaCO_3$, 18.0; NaCl, 6.9; MgO, 2.0; $MgSO_4 \cdot 7H_2O$, 9.0; $FeSO_4 \cdot 7H_2O$, 0.86; $ZnSO_4 \cdot H_2O$, 0.5; $MnSO_4 \cdot H_20$, 0.5; $CuSO_4 \cdot 5H_2O$, 0.1; NaF, 0.08; $CrK(SO_4)_2 \cdot 12H_2O$, 0.05; $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$, 0.002; KI, 0.004; $CoCO_3$, 0.002; $Na_2SeO_3$, 0.002.
[b]Flaxseed and Neuromins™ DHA oils were purchased from Novance (Compiègne, France) and Martek Biosciences Corporation (Columbia, MD), respectively.
[c]ND, not detected.

chromatograph (HRGC 5300; Fisons Instruments, Arcueil-Cachan, France) equipped with an on-column injector, a flame-ionization detector, and a CP WAX 52 CB bonded fused-silica capillary column (50 m × 0.2 mm i.d. with 0.20 µm film thickness) purchased from Chrompack (Les Ulis, France). Hydrogen was used as carrier gas at a 1–2 mL/min flow rate. FAME with a C8 to C24 chain length and dimethyl acetals were identified by comparing equivalent chain lengths with those of commercial standards (Nu-Check-Prep Inc., Coger, Paris, France) and quantified by a computing integrator using the Nelson Analytical Program System (SRA, Gagny, France). The content of total fatty acids was corrected by the proportion of recovered internal standards. The fatty acid composition of the diets was determined by the same experimental procedure.

The whole-body fatty acid balance analysis was performed using the mode of expression of Cunnane and Anderson (10). The amount of dietary 18:3n-3 and 22:6n-3 that disappeared during the balance period was calculated as the difference between the total intake and the total amount of n-3 fatty acids excreted in feces and accumulated in the various organ compartments. The total amount of long-chain (LC) n-3 PUFA (20:5n-3, 22:5n-3, and 22:6n-3) accumulated in the whole body was used to determine the proportion of 18:3n-3 converted and accumulated in the ALA group, and the amount of both 20:5n-3 and 22:5n-3 was used to determine the proportions of 22:6n-3 retroconverted and accumulated in the DHA group. The same calculation method was used for the balance analysis of 18:2n-6. The sum of LC n-6 fatty acids (20:3n-6, 20:4n-6, 22:4n-6, and 22:5n-6) was used to determine the total proportion of linoleate converted.

*Statistics.* Results are means ± standard deviation for $n = 6$ individual animals analyzed independently. Differences in body weights, organ compartment weights, and fatty acid content in the various organ compartments between the two dietary groups were established by one-way analysis of variance. They were compared by the Scheffé test, with the level of significance set at $P < 0.05$ and $P < 0.01$ (StatView SE + Graphics™, Abacus Concepts Inc., ASD Meylan, France).

## RESULTS

*Dietary intake and growth.* The total amount of diet and fatty acids ingested during the 5-wk balance period and the body weights of the rats at the beginning and at the end of the balance period were similar in both groups (Table 2). No significant differences in weight of any of the organ compartments were found between the diet groups.

*n-3 Fatty acid balance.* The comparative effects of dietary 18:3n-3 and 22:6n-3 on the n-3 fatty acid balance are presented in Table 3. During the 5-wk balance period, the amounts of n-3 fatty acids ingested and accumulated in the whole body were similar between the two groups (about 1150 mg and 410–470 mg, respectively). Thus, taking into account the amount of n-3 fatty acid excreted, the disappearance of both dietary 18:3n-3 and 22:6n-3 was similar and represented about 700 mg. When expressed as a percentage of n-3 fatty acid intake, balance analysis revealed no significant difference between the groups: 0.5 to 0.7% of n-3 fatty acids consumed were excreted, 35 to 40% accumulated, and 58.9 to 64.5% disappeared. The DHA diet contained 18:3n-3 but in amounts too low (i.e., 9 mg per 100 g diet) to interfere with the 22:6n-3 metabolism. Indeed, rats fed this diet ingested only 49 mg of this fatty acid, of which 30 mg were deposited in their whole body (Fig. 1). Moreover, this diet supplied preformed 22:6n-3 and a high ratio of 18:2n-6 to 18:3n-3, which are known to strongly inhibit the desaturation–elongation rate

**TABLE 2**
**Ingestion, Body and Organ Weights of Rats Fed Either ALA or DHA[a]**

| | Dietary group | | | |
|---|---|---|---|---|
| | ALA | | DHA | |
| Amount ingested (g) | | | | |
| Diet | 534 ± 22 | | 548 ± 28 | |
| Total fatty acids | 25.4 ± 1.1 | | 26.0 ± 1.3 | |
| | Age (wk) | | | |
| | 3 | 8 | 3 | 8 |
| Body weight (g) | 52.9 ± 1.8 | 235.8 ± 19.0 | 51.9 ± 3.0 | 245.9 ± 17.8 |
| Organ compartments (g) | | | | |
| Brain | 1.4 ± 0.1 | 1.7 ± 0.3 | 1.5 ± 0.0 | 1.8 ± 0.1 |
| Liver | 1.8 ± 0.1 | 8.0 ± 1.1 | 1.8 ± 0.1 | 8.9 ± 1.1 |
| Viscera[b] | 5.0 ± 0.3 | 19.2 ± 3.4 | 5.2 ± 0.5 | 21.5 ± 2.1 |
| Internal fats[b] | 1.0 ± 0.3 | 8.3 ± 3.0 | 1.0 ± 0.2 | 10.1 ± 2.3 |
| Subcutaneous fats[b] | 2.2 ± 0.8 | 7.1 ± 2.1 | 2.1 ± 0.9 | 9.5 ± 3.2 |
| Remaining carcass[b] | 36.7 ± 1.3 | 168.8 ± 13.7 | 35.5 ± 1.6 | 173.1 ± 14.4 |

[a]Values (means ± standard deviation, $n = 6$). In both diets, the n-3 fatty acid amount was 200 mg/100 g diet. No significant effect of the diet ($P < 0.05$) by analysis of variance was noted for any of the parameters studied.
[b]Viscera was the pool of gut, pancreas, spleen, testes, bladder, kidneys, heart, thymus, and lungs. Internal fats were the pool of epididymal, mesenteric, omental, and perirenal adipose tissues. Subcutaneous fats corresponded to all the subcutaneous adipose tissues that were possible to collect. The remaining carcass corresponded to the pool of the skin, muscles, the whole skeleton, and the head minus the brain. For abbreviations see Table 1.

| Disappearance | 58.9 ± 5.0 | — | — | — | 64.5 ± 7.4 | — |

[a]Values are means ± standard deviation ($n$ = 6); in both diets, the n-3 fatty acid amount was 200 mg/100 g diet; * indicates a significant effect of the diet ($P < 0.01$) by analysis variation.
[b]LC-PUFA, long-chain polyunsaturated fatty acid: sum of 20:5n-3, 22:5n-3, and 22:6n-3.
[c]ND, not detected. For other abbreviations see Table 1.
[d]The whole-body content was the sum of the fatty acid amounts in the six organ compartments (brain, liver, viscera, internal and subcutaneous fats, remaining carcass).
[e]The whole-body accumulation was calculated as the difference between 8 and 3 wk of age in whole body content.
[f]In the ALA group the whole-body accumulation of total n-3 fatty acids included 18:4n-3 (22 mg mostly deposited in adipose tissues).
[g]18:3n-3 and 22:6n-3 disappearance was calculated as the difference between the dietary intake and the amount excreted in feces and accumulated in the whole body.
[h]In the DHA group, the amount of 18:3n-3 deposited in the whole body was not taken into account for the analysis of the 22:6n-3 fatty acid balance expressed as percentage of fatty acid intake.

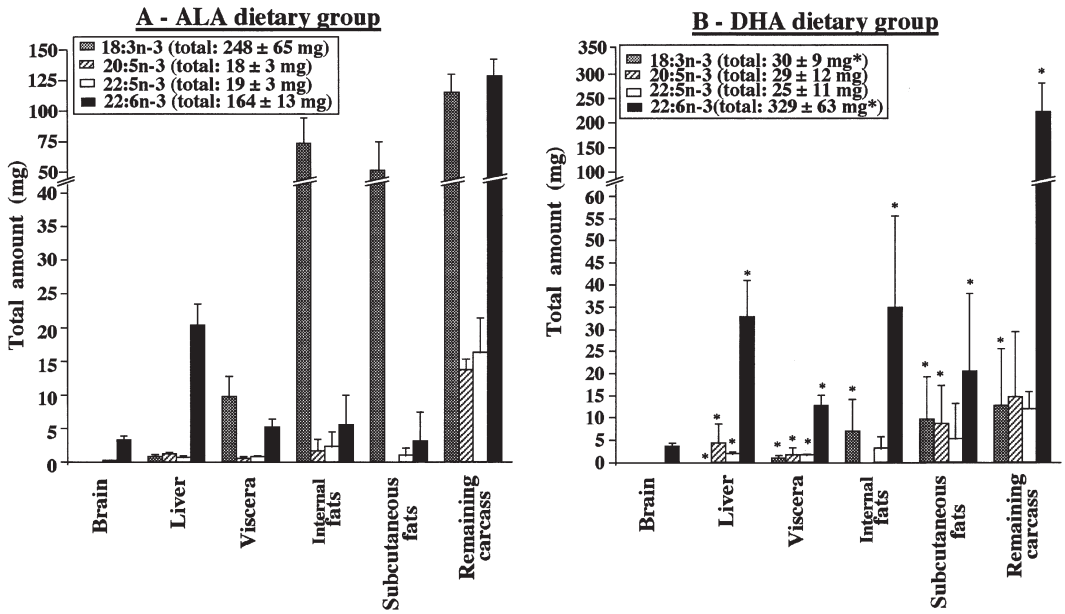

**FIG. 1.** Organ distribution of n-3 fatty acids deposited in the growing rat fed either α-linolenate (ALA) or docosahexaenoate (DHA). Values are means ± standard deviation ($n$ = 6). In both diets, the n-3 fatty acid amount was 200 mg/100 g diet. For each n-3 fatty acid, * indicates a significant effect of the diet, $P < 0.05$.

of 18:3n-3. So we can estimate that less than 1% of the total long-chain n-3 fatty acids deposited in rats fed DHA diet was biosynthesized from 18:3n-3.

In the ALA group, the amounts of both 18:3n-3 and the sum of its LC derivatives deposited in the whole body were similar (248 and 201 mg, respectively, i.e., 21 and 17% of the total intake) (Table 3), with 22:6n-3 as the main LC n-3 fatty acid derivative deposited (164 mg, i.e., 81.6%). However, their distribution between organ compartments differed (Fig. 1), 50% of accumulated 18:3n-3 was found in adipose tissues (29% in internal fats and 21% in subcutaneous fats) and 46% in the remaining carcass, whereas for 22:6n-3, 78% was deposited in the remaining carcass, 12% in the liver and only 5% in adipose tissues. In the DHA group, the total amount of 22:6n-3 accumulated in the whole body was twofold higher than in the ALA group (329 ± 63 mg vs. 164 ± 13 mg, $P < 0.01$), which corresponded to 86% of total deposited n-3 fatty acids and 30% of the total intake of 22:6n-3. This higher deposition was observed in all organ compartments. The distribution of 22:6n-3 among the six organ compartments was similar for the two groups except that the proportion found in adipose tissues was significantly higher in the DHA group (17%). The type of diet had no significant effect on the total amounts of 20:5n-3 and 22:5n-3 or on their organ distribution (Fig. 1). These fatty acids were found in equal amounts and accounted for 14 to 18% of total deposited n-3 LC-PUFA. They were mainly accumulated in the remaining carcass (81%) for the ALA group and in the remaining carcass (50%) and adipose tissues (34%) for the DHA group.

*n-6 Fatty acid balance.* The n-6 fatty acid balance was similar for the two groups, except that the amount of n-6 LC-PUFA deposited in the whole body was 22% lower for the DHA diet group (359 ± 60 mg vs. 459 ± 43 mg, $P < 0.01$) (Table 4). The percentage of dietary 18:2n-6 excreted was 0.5%, 46 to 51% was accumulated, and, by subtraction, 48 to 53% had disappeared. The main n-6 fatty acid deposited was 18:2n-6 (2407 to 2692 mg, i.e., 84 to 88% of total n-6 PUFA) and was principally found in the adipose tissues (47–51% with 28–30% in internal fats and 19–21% in subcutaneous fats) and the remaining carcass (44–48%) (Fig. 2). Of the n-6 LC-PUFA, 20:4n-6 was the main component deposited (324 mg in the ALA group and 243 mg in the DHA group) and represented 11% of total n-6 fatty acids deposited in the ALA group and significantly less in the DHA group (8%, $P < 0.01$) (Table 4). In both groups, the remaining carcass (50–61%, significant difference, $P < 0.01$), the liver (20–25%), and the viscera (11–13%) were the three major organs that accumulated 20:4n-6, contrary to brain, in which only 0.3 to 0.5% of total 20:4n-6 was deposited (Fig. 2). On the other hand, a significantly higher deposition of 20:3n-6 was observed in the whole body, mainly in the liver and viscera, in animals of the DHA group.

## DISCUSSION

*Whole-body balance of n-3 fatty acids.* During the 5-wk balance period, both n-3 fatty acids were readily absorbed (>99%). The high absorption of 22:6n-3 may have resulted from the predominant acylation of this fatty acid in the internal *sn*-2

**TABLE 4**
**Intake, Excretion, Accumulation, and Disappearance of n-6 Fatty Acids in the Growing Rat Fed Either ALA or DHA[a]**

[a]See footnotes in Table 3.
[b]Sum of 20:2n-6, 20:3n-6, 20:4n-6, 22:2n-6, 22:4n-6, and 22:5n-6.
[c]The whole-body content was the sum of the fatty acid amounts in the six organ compartments (brain, liver, viscera, internal and subcutaneous fats, remaining carcass).
[d]The whole-body accumulation was calculated as the difference between 8 wk and 3 wk of age in whole-body content.
[e]18:2n-6 disappearance was calculated as the difference between the dietary intake and the amount excreted in feces and accumulated in the whole body. For abbreviations see Table 1.

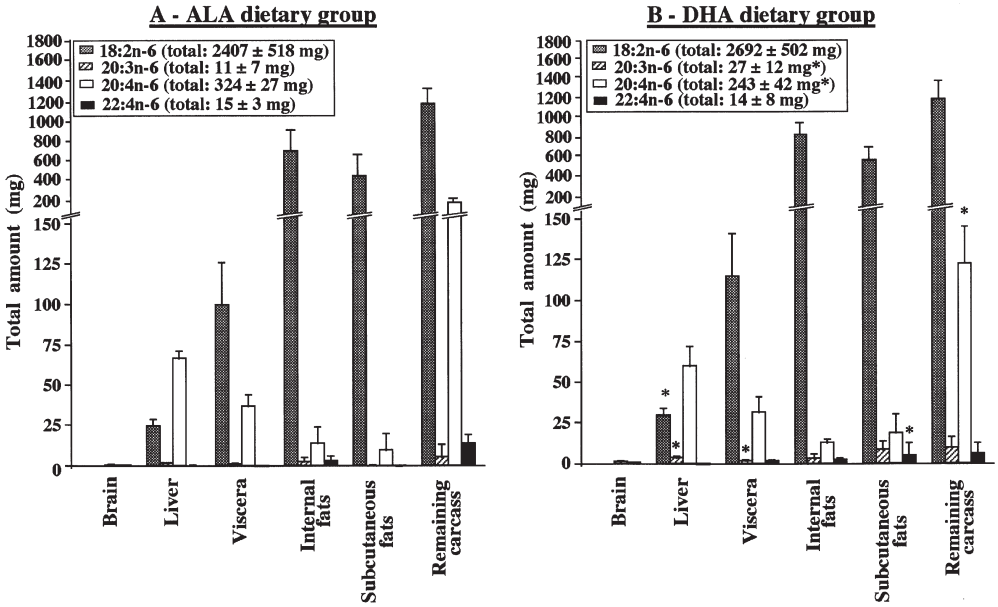

**FIG. 2.** Organ distribution of n-6 fatty acids deposited in the growing rat fed either ALA or DHA. Values are means ± standard deviation ($n = 6$). In both diets, the n-3 fatty acid amount was 200 mg/100 g diet. For each n-6 fatty acid, * indicates a significant effect of the diet, $P < 0.05$. For abbreviations see Figure 1.

position in algae-derived triglycerides (50% of the total 22:6n-3) (17), which seems to favor the efficiency of its digestion (18).

*In vivo* tracer studies have shown that the oxidation rate of 18:3n-3 is efficient in the growing rat (up to 65%) and is comparable to the one observed for the most highly oxidized fatty acid, lauric acid (12:0) (9). Using the fatty acid balance method, Cunnane and Anderson (10) suggested that the β-oxidation pathway is responsible for much of the whole-body utilization of dietary 18:3n-3 in the growing rat, as 85% of 18:3n-3 ingested disappeared. With the same method and a similar growth period in the rat, we confirmed these data but found here that only 59% of the 18:3n-3 dietary intake disappeared. This 30% relative decrease in 18:3n-3 disappearance could be explained by the 4.6-fold lower amount of dietary 18:3n-3 and twofold lower proportion of total fats in the diets in our study (19). Conversely, in the study the proportion of 18:3n-3 deposited in the whole body was higher (21% of the dietary intake vs. 10.9%) than that of total n-3 LC-PUFA (17% vs. 1.4%). However, expressed as total amount deposited daily, the whole-body deposition of n-3 LC-PUFA was very similar and represented around 3 mg. These observations are in acceptable agreement with the hypothesis that the bioavailability of 18:3n-3 to be converted to n-3 LC-PUFA (and mainly 22:6n-3) should be maintained, even if the energetic status or n-3 fatty acid dietary supply is insufficient (19). Altogether, our results are in accordance with the view that a large proportion of the ingested 18:3n-3 disappears, probably *via* β-oxidation, but our results do not support the notion that the biosynthesis pathway of n-3 LC-PUFA is quantitatively of minor importance.

We found that the disappearance of dietary 22:6n-3 was similar to that of 18:3n-3 (64.5% of the intake) and predominated over the n-3 fatty acid deposition. Although these data do not constitute conclusive proof, they argue for a high β-oxidation rate of 22:6n-3. This finding is unexpected because data from *in vivo* and *in vitro* radiotracer methodology show that the oxidation of LC-PUFA is generally low (9,11). But the new comprehensive view of the β-oxidation pathway of 22:6n-3 (first a peroxisomal retroconversion of 22:6n-3 to 20:5n-3 followed by a mitochondrial oxidation of 20:5n-3) and its regulation by dietary n-3 PUFA could partly explain it (reviewed in Ref. 20). Indeed, the presence of 22:6n-3 in dietary lipids induces an increase in the rate of peroxisomal β-oxidation of 22:6n-3 and activities of the key enzymes involved (21–24). Besides, the large disappearance of 22:6n-3 is consistent with the large deposition of its retroconverted products in organ compartments (14.1% of total n-3 fatty acids), either as 20:5n-3 or 22:5n-3, the 20:5n-3 elongation product (7.5 and 6.6% of total n-3 fatty acids, respectively). Studies conducted *in vitro* on rat liver and *in vivo* with or without labeled 22:6n-3 also showed an active retroconversion rate of 22:6n-3 in these two LC-PUFA (25,26).

Although dietary 18:3n-3 and 22:6n-3 disappeared in the same proportion, their partitioning between organ compartments was different, particularly their incorporation into adipose tissues. Adipose tissues were not of major importance in 22:6n-3 deposition (17% of the whole-body accumulation), whereas they represented the main storage compartment for 18:3n-3 (50%). This difference in incorporation may result from both differential uptake from blood lipids and release *via* lipolysis by adipocytes of 22:6n-3 and 18:3n-3 (27). n-3 Fatty acids stored in adipose tissues are considered a reservoir to cover body requirements, although the specific bioavailability of 22:6n-3 for other tissues, and particularly for nervous tissues, *via* its mobilization from adipose tissues is uncertain during suboptimal n-3 dietary supply (28).

*Whole-body balance of n-6 fatty acids.* In rats fed the ALA

diet, the proportion of dietary 18:2n-6 that disappeared was less than that of 18:3n-3. Moreover, and similarly as we noted above for 18:3n-3, it was 30% lower than that demonstrated by Cunnane and Anderson (10) (about 50% of the amount ingested in our study vs. 76%). However, in contrast to 18:3n-3, the 18:2n-6 dietary amount was the same, and only the proportion of lipids in our diet differed. So we may suggest that this lower partitioning toward disappearance of the two essential fatty acids resulted from the lower amount of total lipids in our diets. n-6 PUFA were mainly deposited as 18:2n-6 (84 to 88%) in adipose tissues (about 50% of total 18:2n-6 stored). In these tissues, the ratio of 18:2n-6 to 18:3n-3 was 50% higher than in dietary lipids (9:1 *vs.* 6:1) and thereby reflected the lower proportion of 18:2n-6 disappeared and converted to LC-PUFA than 18:3n-3. Thus, this ratio in adipose tissues reflects not only the dietary intake of 18:2n-6 and 18:3n-3 (29) but also the metabolic partitioning of these fatty acids. As regards the conversion activity of n-6 fatty acids, we found that 13.1 mg of 18:2n-6 was converted daily into n-6 LC-PUFA, i.e., 7.3% of the total dietary intake, a value higher than that found previously (9.8 mg/day, 3% of the dietary intake) (10). We assume that it likely resulted from the higher ratio of 18:2n-6 to 18:3n-3 used in our study (6:1 vs. 1.25:1), which could prevent the inhibition of 18:2n-6 desaturation–elongation induced by dietary excess of n-3 fatty acids.

The consumption of 22:6n-3 did not modify the whole-body metabolism of 18:2n-6, but it did alter the distribution of the n-6 fatty acids accumulated. Indeed, deposition of higher contents of 18:2n-6 and 20:3n-6 and lower contents of 20:4n-6 were noticed. Thus, the 20:3n-6/18:2n-6 and 20:4n-6/20:3n-6 ratios, which are indexes of Δ6- and Δ5-desaturation activities, respectively, were both decreased and thereby provided an indirect confirmation of the well-known inhibitory effect of dietary LC n-3 fatty acids on the activity of these enzymes (21).

The fatty acid balance analysis shows that disappearances of dietary 18:3n-3 and 22:6n-3 were comparable, which leads us to speculate that these two n-3 fatty acids were β-oxidized at similar rates. So further *in vivo* tracer studies measuring expired $CO_2$ in rats fed either 18:3n-3 or 22:6n-3 are needed, especially since an *in vitro* study did not confirm this hypothesis (30). The comparison of the data of Cunnane and Anderson (10) with that of the present study suggests that the amount of total fatty acids in the diet may influence the proportion of PUFA that disappeared and therefore implies that additional research on essential fatty acid partitioning in relation to energy balance is crucial to determine the n-6 and n-3 fatty acid requirements of humans, and notably of neonates.

# Hyperthyroidism Affects Lipid Metabolism in Lactating and Suckling Rats

**Silvia Mabel Varas[a], Graciela Alma Jahn[b], and María Sofía Giménez[a,*]**

[a]Laboratory of Biological Chemistry, Department of Biochemistry and Biological Sciences, Faculty of Chemistry, Biochemistry, and Pharmacy, National University of San Luis, 5700 San Luis, and [b]Laboratory of Reproduction and Lactation, CRICYT-CONICET, 5500 Mendoza, Argentina

**ABSTRACT:** Two per thousand pregnant women have hyperthyroidism (HT), and although the symptoms are attenuated during pregnancy, they rebound after delivery, affecting infant development. To examine the effects of hyperthyroidism on lactation, we studied lipid metabolism in maternal mammary glands and livers of hyperthyroid rats and their pups. Thyroxine (10 μg/100 g body weight/d) or vehicle-treated rats were made pregnant 2 wk after commencement of treatment and sacrificed on days 7, 14, and 21 of lactation with the litters. Circulating triiodothyronine and tetraiodothyronine concentrations in the HT mothers were increased on all days. Hepatic esterified cholesterol (EC) and free cholesterol (FC) and triglyceride (TG) concentrations were diminished on days 14 and 21. Lipid synthesis, measured by incorporation of $[^3H]H_2O$ into EC, FC, and TG, fatty acid synthase, and acetyl CoA carboxylase activities increased at day 14, while incorporation into FC and EC decreased at days 7 and 21, respectively. Mammary FC and TG concentrations were diminished at day 14; incorporation of $[^3H]H_2O$ into TG decreased at days 7 and 21, and incorporation of $[^3H]H_2O$ into FC increased at day 14. In the HT pups, growth rate was diminished, tetraiodothyronine concentration rose at days 7 and 14 of lactation, and triiodothyronine increased only at day 14. Liver TG concentrations increased at day 7 and fell at day 14, while FC increased at day 14 and only acetyl CoA carboxylase activity fell at day 14. Thus, hyperthyroidism changed maternal liver and mammary lipid metabolism, with decreased lipid concentration in spite of increased liver rate of synthesis and decreases in mammary synthesis. These changes, along with the mild hyperthyroidism of the litters, may have contributed to their reduced growth rate.

Paper no. L8550 in *Lipids 36*, 801–806 (August 2001).

Two per 1000 pregnant women have hyperthyroidism (HT) (1). Most of the symptoms of hyperthyroidism are attenuated during pregnancy, but the marked rebound after delivery has impact on infant development. Specific signs in the neonate include growth retardation, advanced bone age in relation to chronological age, and craniosynostosis (2). Hyperthyroxinemia and suppressed serum thyroid-stimulating hormone (TSH) in postnatal blood confirm the diagnosis (1). Similarly, in hyperthyroid rats, TSH secretion in the pituitary is suppressed, and serum and milk TSH concentrations are reduced as well (3).

Lactation is associated with widespread changes in whole-body lipid metabolism, the purpose of which is to direct lipids and lipid precursors to the mammary glands for milk-fat production (4,5). Fat is the major component of the milk, with 95% of this fat being triglycerides (TG) (4). Survival of all newborn mammals is dependent upon an adequate milk supply secreted from the mammary glands of the mother (6). Triiodothyronine ($T_3$) administration in physiological amounts is able to stimulate prolactin-induced synthesis of milk products and the enzymatic activities related to this process in differentiated rat mammary glands (7), but there is a paucity of studies concerning the effects of thyroid hormone excess on lactation and mammary gland function. Thyroid hormones affect a number of physiological processes including lipid, carbohydrate, and protein metabolism (8–10). Studies with litter-removed lactating rats have shown that hyperthyroidism depresses lipoprotein lipase (LPL) activity in mammary gland and white adipose tissue (7).

Rosato *et al.* (11,12) showed that the chronic administration of tetraiodothyronine ($T_4$) (100 μg/100 g body wt) produces marked changes in organ weight, lipid and protein content, and enzymatic activities (11) in virgin rats. These changes were markedly attenuated in pregnant rats near term (12) as well as in their fetuses (11), but the treatment produced advances in delivery and lactogenesis, with adverse effects on maternal behavior and milk release that resulted in death of the pups (12). The administration of 25 μg $T_4$/100 g body wt showed similar effects on delivery and pup mortality (13). Additionally, we previously showed that chronic administration of a lower dose of 10 μg/100 g body wt of $T_4$ in virgin females produced important changes in liver lipid metabolism (14).

In the present work, we investigated the effects of chronic administration of 10 μg $T_4$/100 g body wt on the lipid metabolism of the dams and their pups at days 7, 14, and 21 of lactation. This dose regimen was selected because it produced hyperthyroidism as measured by increases in circulating thyroid hormones and allowed the rats to nurse the litters until weaning.

## MATERIALS AND METHODS

*Chemicals and radioisotopes*. $[^3H]H_2O$ (3.70 GBq/g) and $[^{14}C]NaHCO_3$ (39.2 MBq/mmol) were purchased from Dupont, New England Company (Boston, MA). Lipid standards were acquired from Sigma Chemical Co. (St. Louis, MO). L-Tetraiodothyronine ($T_4$) was a generous gift from Glaxo (Buenos Aires, Argentina). All the other chemicals

Abbreviations: ACC, acetyl CoA carboxylase; Co, control rat; CPT-1, carnitine palmitoyltransferase 1; DTT, dithiothreitol; EC, esterified cholesterol; FAS, fatty acid synthase; FC, free cholesterol; HT, hyperthyroid rat = thyroxine-treated rat; LPL, lipoprotein lipase; $T_3$, triiodothyronine; $T_4$, tetraiodothyronine; TG, triglycerides; TSH, thyroid-stimulating hormone.

were of reagent grade and were obtained from Merck Laboratory (Buenos Aires, Argentina).

*Animals and experimental design.* Adult female Wistar rats bred in our laboratory, 3- to 4-mon-old, and weighing 190–210 g at the onset of treatment were used. The rats were housed in an animal room and kept in a 22–25°C controlled environment with a light-dark cycle of 12 h each. Rat chow and tap water were available *ad libitum*. Hyperthyroidism was induced by daily subcutaneous injection of $T_4$ (at a dose of 10 µg/100 g body wt) dissolved in 0.9% NaCl and alkalinized with NaOH to pH 9. The presence of spermatozoa in the vaginal smear the morning after caging with a fertile male during the night of proestrus was indicative of pregnancy and this day was counted as day 0 of pregnancy. Thyroxine-treated (= hyperthyroid; HT) or vehicle-treated (= control; Co) rats were made pregnant approximately 14 d after commencement of treatment and sacrificed on day 7, 14, or 21 of lactation at 0900–1000 by decapitation. The rats were injected during six ($L_7$), seven ($L_{14}$), and eight ($L_{21}$) weeks.

On day 1 of lactation, the number of pups in each litter was standardized to eight. Trunk blood of the dams and the pups was collected, and serum was separated by centrifugation and stored at –20°C until used. The livers from dams and pups and inguinal mammary glands from the dams were removed, washed in a cold saline solution, and stored at –70°C until they were analyzed. The values are means ± standard error of the means (SEM) for groups of eight lactating rats.

Blood and tissues of the pups were pooled for each litter and thus the values represent the means of the values for the litters. The body weights of the pups are the means ± SEM for eight litter means.

Animal maintenance and handling were performed according to the *NIH Guide for the Care and Use of Laboratory Animals* (NIH publication No. 86–23, revised 1985 and 1991) and the United Kingdom requirements for ethics of animal experimentation [Animals (Scientific Procedures) Act 1986].

*Serum determinations*. Serum $T_3$ and $T_4$ total concentrations were determined by a commercial enzyme-linked immunosorbant assay kit purchased from Boehringer, Mannheim, Germany.

*Tissue preparation and enzymatic assays.* Liver portions (1 g for 4 mL of buffer) were homogenized in an Ultra Turrax T25 homogenizer (Jahnke & Kunkle, Stauffen, Germany) in 0.5 M potassium phosphate buffer (pH 7) containing 10 mM EDTA and 10 mM D,L-dithiothreitol (DTT). The homogenates were centrifuged at 100,000 × *g* for 1 h to yield the cytosolic fraction in a Beckman model L8-80M ultracentrifuge with a Ty-80 rotor.

Cytosolic fatty acid synthase (FAS) activity was determined spectrophotometrically by a modified version of the method of Alberts *et al.* (15). The reaction mixture contained a 0.5 M potassium phosphate buffer (pH 6.6), 1 µmol each of EDTA and DTT, respectively, 100 nmol NADPH, and 0.05 mL of the cytosolic fraction. The reaction was started by adding 100 nmol of malonyl-CoA, and the final assay volume was 1.05 mL. The oxidation of NADPH at 30°C was monitored at 340 nm.

Acetyl CoA carboxylase (ACC) activity in liver or mammary cytosols was measured as described previously by Allred and Rochringer (16). The enzyme activity was measured using a reaction mixture that, in a final volume of 700 µL, contained 60 mM buffer Tris-acetate (pH 7.8), 100 mM potassium acetate, 3 mM DTT, 8.5 mM potassium citrate, 1 mM ATP, 0.6 mg/mL bovine serum albumin, 0.35 mM acetyl CoA, 8 mM magnesium acetate, 25 mM sodium bicarbonate, and 2 µCi [$^{14}$C]$NaHCO_3$. For blanks, acetyl-CoA was omitted. The mixture was preincubated 1 min at 37°C. Then 50 µL of the cytosolic fraction was added. After 1 min of incubation at 37°C, 50 µL of concentrated HCl was added to stop the reaction. A 200 µL aliquot was transferred into the scintillation vial and dried under cold air flow. The dried extract was resuspended with 200 µL 50% ethanol, and the radioactivity was measured in 10 mL of scintillation fluid in a Wallac LKB 1409 liquid scintillation analyzer. ACC activity was expressed as units per mg of protein, where 1 unit equals 1 pmol of [$^{14}$C]bicarbonate incorporated into malonyl-CoA per minute at 37°C. The protein concentration was determined by the method of Lowry *et al.* (17), using fraction V bovine serum albumin as standard.

*Lipid determinations*. The lipids from the hepatic or mammary tissue were extracted with chloroform/methanol (2:1) according to the method of Folch *et al.* (18). An aliquot of the lipid extracts was taken to determine total cholesterol, and another one to separate the different lipid fractions by thin-layer chromatography with an *n*-hexane/diethyl ether/acetic acid (80:20:1, by vol) solvent system. After eluting the scraped bands, aliquots were used for the mass determination according to the methods of Sardesai and Manning (19) for TG and of Zack *et al.* (20) after saponification (21) for free cholesterol (FC) and esterified cholesterol (EC). A recovery from thin-layer chromatography averaging 90% of cholesterol mass was obtained.

*Incorporation of $^3H$ from $H_2O$ into lipids*. The groups of lactating rats were fed *ad libitum* and then injected intraperitoneally with $^3H_2O$ (3.7 mBq/rat in 9 g/L of NaCl). They were killed 1 h later to ensure that the newly synthesized lipids in the liver and mammary gland had been labeled. One gram of the liver and mammary gland was extracted with 20 mL of chloroform/methanol (2:1) according to the method of Folch *et al.* (18). The radioactivity incorporated into the lipids was counted in the different lipid fractions that had been separated by thin-layer chromatography (see section above on lipid determinations). The results are expressed as pg $^3H$ incorporated/h/g of tissue.

*Statistical analyses.* Significant differences among means were considered at a level of $P < 0.05$ and identified by one-way analysis of variance and the Tukey test. In all cases, the variances were homogeneous.

## RESULTS

*Serum $T_4$ and $T_3$ concentrations in Co and HT lactating rats and their pups.* Serum $T_4$ and $T_3$ concentrations in the HT group of lactating rats were increased significantly compared with the Co group (Fig. 1).

The serum $T_4$ concentrations of the pups of the HT lactating dams were also increased significantly compared with the offspring of Co lactating dams on days 7 and 14 of neonatal

life, but not on day 21. The serum $T_3$ concentrations increased significantly on day 14 compared with the pups of the Co lactating dams, but no differences were observed on days 7 and 21 (Fig. 1).

*Body, liver weight, and total protein of liver and mammary gland in HT and Co lactating rats and their pups.* Table 1 shows that the liver weight of the HT mothers was increased significantly compared with Co only on day 7 of lactation. No differences were observed in body weight or in liver or mammary gland protein concentrations in any of the other studied days. The body weights of the pups of the HT lactating dams were decreased significantly compared with the Co on all the days of lactation. The total protein concentrations and liver weights on day 7 of lactation were lower than in the Co group, but no differences were observed on days 14 and 21 of lactation.

*TG, cholesterol concentrations, and activities of FAS and ACC in livers of the pups of HT and Co lactating rats.* The liver TG concentrations in the HT group were significantly decreased on days 14 and 21 of lactation when compared with the Co group, but no significant differences were observed on day 7 (Table 2). FC and EC concentrations were also significantly lower in the HT group on days 14 and 21, but no changes in cholesterol concentrations were observed on day 7 (Table 2).

As shown in Table 2, the FAS and ACC liver activities in the HT groups were higher than those of the Co on day 14 of lactation, while no differences were observed on the other days of lactation.

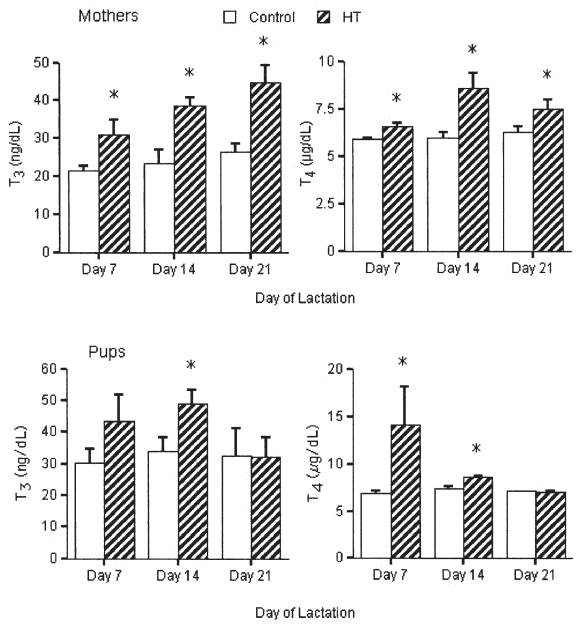

**FIG. 1.** Effects of hyperthyroidism on plasma thyroxine ($T_4$) and triiodothyronine ($T_3$) in lactating rats and their pups. Rats were made hyperthyroid (HT) by daily injections of $T_4$ at a dose of 10 µg/100 g body weight and mated 2 wk after beginning the treatments. Controls (Co) were injected with vehicle. The adult rats and their litters were sacrificed on days 7, 14, and 21 of lactation. $T_4$ and $T_3$ were measured by enzyme-linked immunosorbent assay. Values are means ± standard error of the means for groups of eight dams or eight litters. Asterisk (*) indicates $P < 0.05$ compared with the respective control groups using one-way analysis of variance and the Tukey test.

*Incorporation of $^3H_2O$ into liver of HT and Co lactating rats.* The incorporation of [$^3$H] from $^3H_2O$ into liver TG was significantly increased on day 14 of lactation compared to Co. On the other hand, incorporation into FC was significantly decreased on day 7, while incorporation into both FC and EC was increased on day 14. The incorporation in the EC was lower on day 21 compared with the Co group (Table 2).

*TG, cholesterol concentrations, and activities of FAS and ACC in livers of the pups of HT and Co lactating rats*. The TG concentrations in the HT group were increased significantly on day 7 and decreased on day 14 of lactation when compared with the Co group, but no differences were observed on day 21. FC concentrations in the pups of both HT lactating and Co dams were lower on day 14 compared with the other days of lactation. On this day the HT group had slightly higher values compared with the Co group, while there were no differences on days 7 and 21. On the other hand, there were no differences in the EC concentration between HT and Co groups on all the studied days, although an increase was observed in both groups on day 21 compared with the previous days (Table 2).

FAS liver activities decreased on day 7; however, there were no differences between HT and Co pups on days 14 and 21. The ACC liver activities decreased on day 14 but no differences were observed on days 7 and 21 of lactation (Table 2).

*Incorporation of $^3H_2O$ into lipids in liver of the pups of HT and Co lactating rats.* As shown in Table 2, no significant differences between HT and Co groups were observed in the incorporation of [$^3$H] from $^3H_2O$ into liver TG, FC or EC fractions. On the other hand, $^3H_2O$ incorporation into both fractions of cholesterol was increased on day 14 compared with day 7 and thereafter decreased to very low values on day 21 of lactation.

*Mammary gland TG and cholesterol concentrations and the incorporation of $^3H$ from $^3H_2O$ into the lipids of dams rats.* The mammary TG concentrations of the HT group showed lower values on day 14 compared with the Co group, while no changes were observed on days 7 and 21 of lactation. The concentration of TG was elevated on day 14 in both groups compared with the other days. FC concentrations were also decreased only on day 14 in the HT group when compared to Co, while no changes in EC concentrations were observed in the 3 d of lactation studied (Table 3).

In the mammary gland, there was a decrease in the incorporation of [$^3$H] into TG in the HT groups on days 7 and 21 of lactation compared with the Co, with no differences on day 14 of lactation. There was an increase in incorporation into FC in the HT group only on day 14 of lactation compared with the Co, while no differences were observed in the incorporation into EC fractions in the three studied days (Table 3).

## DISCUSSION

The present paper describes the changes in lipid metabolism caused by chronic $T_4$ treatment during the days previous to pregnancy, during pregnancy, and during lactation in the mammary gland and liver in the dams on days 7, 14, and 21 of lactation and the effects on the pups.

**TABLE 1**
**Effects of Hyperthyroidism on Body and Liver Weight and Liver Total Protein Concentration in Lactating Rats and Their Pups[a]**

| | Day 7 of lactation | | Day 14 of lactation | | Day 21 of lactation | |
|---|---|---|---|---|---|---|
| | Co | HT | Co | HT | Co | HT |
| Mothers | | | | | | |
| Liver weight (g) | 9.2 ± 0.5 | 11.2 ± 0.2[b] | 10.7 ± 1.1 | 12.0 ± 0.3 | 11.5 ± 0.4 | 10.8 ± 0.9 |
| Total liver protein (mg/g) | 104.2 ± 15.1 | 109.3 ± 16.4 | 187.4 ± 0.4 | 186.2 ± 2.9 | 181.9 ± 28.1 | 137.9 ± 16.9 |
| Total mammary protein (mg/g) | 121.6 ± 11.1 | 103.4 ± 6.8 | 128.0 ± 8.1 | 119.8 ± 8.8 | 122.5 ± 4.3 | 111.7 ± 3.5 |
| Body weight (g) | 250.7 ± 5.8 | 251.1 ± 11.1 | 253.0 ± 7.2 | 257.8 ± 5.2 | 260.2 ± 12.5 | 258.7 ± 2.3 |
| Pups | | | | | | |
| Liver weight (g) | 0.49 ± 0.03 | 0.40 ± 0.01[b] | 0.88 ± 0.04 | 0.84 ± 0.04 | 1.46 ± 0.17 | 1.65 ± 0.11 |

[a]Values are means ± standard error of the means for groups of eight dams. MG, mammary gland; for other abbreviations see Table 1.
[b]$P < 0.05$ compared with the respective control groups using one-way analysis of variance and the Tukey test. For abbreviations see Table 2.

*Effects of hyperthyroidism in lactating dams.* The dose of 10 μg of $T_4$ per 100 g body wt induced an increase in the circulating concentration of $T_3$ and $T_4$ in the dams at the three times of lactation studied, thus confirming the state of HT.

Long-chain fatty acids are structural components of all cells; they also serve as energy reserves and are involved in a variety of regulatory functions including their own synthesis and degradation (22). ACC is the enzyme that catalyzes the rate-limiting step in the biogenesis of long-chain fatty acids. It is well known that thyroid hormones increase FAS and ACC activities at a pretranslational step (23). In our experimental model the activities of FAS and ACC in the livers of HT rats increased on day 14 of lactation, corresponding to the increased synthesis of TG as observed by the $^3H_2O$ incorporation experiments, and accompanied by a paradoxical decrease in the mass of liver TG. Similar results were observed in HT virgin females (11), but no changes were found in enzyme activities on days 7 and 21 of lactation in spite of the decreased content of TG on day 21.

Increased malonyl-CoA, which is only generated by ACC, suppresses mitochondrial carnitine palmitoyltransferase I activity (CPT-I) (24); this may increase the level of cytosolic long-chain fatty acyl-CoA esters, which are known signals for insulin secretion (25). But, in the hyperthyroid state, fatty acid oxidation and ketogenesis are stimulated simultaneously along with a paradoxical stimulation of fatty acid synthesis (26). These processes may be linked, because thyroid hormones accelerate fatty acyl-CoA entry into the mitochondrial matrix by increasing mitochondrial CPT-I activity (27) and decreasing sensitivity of CPT-I to inhibition by malonyl-CoA (26). The liver plays a central role in the maintenance of whole-body cholesterol by integrating the regulation of a group of hepatic enzymes, receptors, and other proteins important for cholesterol homeostasis. During lactation the synthesis of cholesterol is increased, in part to provide *de novo* synthesized cholesterol for new membrane synthesis in the liver hypertrophy that occurs during lactation and also for lipoprotein secretion to provide cholesterol and triglycerides for milk production (28). Sixty percent of the total content of cholesterol in milk is of hepatic origin (29).

The lower content of FC in the livers of the HT mothers on day 14 of lactation compared to the control group, associated with the increased synthesis, may indicate that export from the liver to the mammary glands is also increased. On the other hand, in thyroxine-treated rats, an increase in the activity of hepatic acyl coenzyme A:cholesterol acyl transferase (ACAT) has been reported (30).

Consistent with this, we also observed an increase in the synthesis of EC on day 14 of lactation in the HT rat compared with the Co. The higher activities of hepatic lipogenic enzymes in the hyperthyroid rats suggest that there are sufficient fatty acids available for cholesterol esterification. However, the EC mass decreased in the HT rats, suggesting that export of EC from liver to mammary gland was also augmented.

In mammary tissue, acidic cholesterol ester hydrolase activities increase during lactation and fall 2 d after weaning, increasing the FC concentration destined to be secreted into milk (31). In our experimental model, we observed no differences in EC content and rate of synthesis in the HT rat compared with Co on day 7 or 21; however, on day 14 both groups showed the lowest EC content. On the other hand, in the HT group, FC concentration on day 14 of lactation was diminished, in spite of an increase in its synthesis, suggesting that there is an increased mobilization of cholesterol from the gland to milk on this day.

Milk TG and cholesterol are known to be derived from lipoproteins as well as originated from mammary *de novo* synthesis (28). On day 7 we observed a decrease in the synthesis of TG in the HT groups, without changes in TG tissue content. However, on day 14 there was a decrease in the mass of TG compared with the high values observed in the Co, while no changes were observed in the synthesis, which decreased on day 21. It is well known that milk stasis induces involution of the tissue (32). The decrease in TG synthesis and content observed on day 21, along with the reduced growth rate of the litter and histological changes (not shown), are suggestive of a premature mammary involution in the HT mothers.

Our results show that the most pronounced effects of HT in liver and mammary gland lipid metabolism were on day 14 of lactation, with effects that were similar to those observed previously in the virgin females. Day 14 may be considered the peak of lactation, when the growth rate of the litter is maximal, and, thus, the demand on maternal metabolism, especially mammary metabolism, may be at its greatest and the effects of HT most marked. In contrast, on day 7 no changes were observed, and on day 21 of lactation there was an amelioration of the effects observed on day 14. Moreover, the changes observed on day 21 could be associated with premature weaning and involution of the mammary glands.

*Effects of maternal HT on the metabolism of the pups.* We observed an increase in $T_4$ concentration in the HT pups at 7 and 14 d but not at 21 d old, suggesting that there is an important contribution of thyroid hormone from the milk. However, the $T_3$ concentration only increased in the pups at 14 d of life. Our results agree with previous data showing that the conversion rates of $T_4$ to $T_3$ in livers of pups before day 10 are very low and then rise to reach the maximal value at around day 23 of life (33). The $T_3$ and $T_4$ concentrations in pups at 21 d of life were not modified, probably because on this day the pups were already eating solid food and drinking water.

Chronic administration of $T_4$ to lactating rats negatively affected the growth rate of the litters in the 3 d studied, as is shown by the decrease in their body weights. These results agree with Rosato *et al.* (11), who showed that the administration of $T_4$ (100 μg/100 g body wt) produced an advance in lactogenesis in the mammary gland associated with a 100% mortality in the pups, suggesting deficient milk release, as the pups were unable to draw milk from the mothers in spite of vigorous suckling. Additionally we observed that the birth weights of the pups of hyperthyroid rats were smaller than the control group (HT: 6.11 ± 0.008 g and Co: 6.67 ± 0.11 g; $P < 0.001$). Moreover, we found that the liver weight in 7-d-old pups was also diminished. This decrease may be related to a loss in liver glycogen (HT: 47.15 ± 5.35 and Co: 110.86 ± 37.26 μM glucose/g of liver; $P < 0.05$) associated with a reduction in protein content.

Although thyroid hormones have been reported to stimulate the expression of ACC and FAS mRNA in the liver of the adult

rat, some evidence suggests that they do not play a primary role in the increase of lipogenic enzyme mRNA concentration after weaning to a high-carbohydrate, low-fat diet (34). Additionally, studies performed in suckling rats injected with $T_3$, during 2 d, reported no changes in the activity of the liver FAS (35). We observed in the liver of the pups a decrease in FAS activity at day 7 and of ACC activity at day 14 of lactation. On day 7 of lactation the liver TG of the pups are medium-chain TG and long-chain TG proceeding from the milk. The increased TG content at day 7 may be linked to the fact that thyroid hormone accelerates the absorption of lipids into the mucosal cells of the intestinal tract (36).

Maternal hyperthyroidism produces complex changes in liver and mammary lipid metabolism, which may be partially responsible for the diminished growth of the litter in combination with the hyperthyroid state of the pups themselves.

# Evidence for Specific Ceramidase Present in the Intestinal Contents of Rats and Humans

**Rui-Dong Duan*, Yajun Cheng, Liping Yang, Lena Ohlsson, and Åke Nilsson**

Department of Cell Biology B, Biomedical Center, B11, University of Lund, S-22184, Lund, Sweden

**ABSTRACT:** A neutral ceramidase activity stimulated by bile salt was previously identified in the intestinal content. Recently, bile salt stimulated lipase (BSSL) was found to have ceramidase activity. It is unknown whether the ceramidase activity previously found is attributable to BSSL. To address this question, we compared the behaviors of high quaternary aminoethyl (HQ) anion exchange chromatography, the distributions, the stability, and the responses to lipase inhibitor between ceramidase and pancreatic BSSL. The proteins from whole small intestinal contents of humans and rats were precipitated by acetone and dissolved in 20 mM Tris buffer pH 8.2. These proteins had neutral ceramidase activity but not BSSL activity against *p*-nitrophenyl acetate. When the proteins were subject to HQ chromatography, two peaks of ceramidase activity were identified, which had acid and neutral pH optima, respectively. Neither of them had BSSL activity against *p*-nitrophenyl acetate. Western blot using BSSL antiserum failed to identify BSSL protein in the fractions with high neutral ceramidase activity. In rat intestinal tract, pancreatic BSSL activity was high in the duodenum and declined rapidly in the small intestine, whereas neutral ceramidase activity was low in the duodenum and maintained a high level until the distal part of the small intestine. In addition, orlistat, the inhibitor of lipase, abolished human BSSL activity against *p*-nitrophenyl acetate and slightly reduced its activity against ceramide but had no inhibitory effect on ceramidase activity isolated by HQ chromatography. In conclusion, we provide the evidence for a specific ceramidase other than pancreatic BSSL present in the intestinal content. The enzyme may play important roles in digestion of dietary sphingolipids.

Paper no. L8758 in *Lipids 36*, 807–812 (August 2001).

In the gastrointestinal tract, there are several lipolytic enzymes, including gastric lipase, pancreatic lipase, pancreatic bile salt stimulated lipase (BSSL) and pancreatic phospholipase A2, that hydrolyze dietary lipids (1). While the enzymes responsible for digestion of fat and glycerophospholipids have been intensively studied, those for digestion of dietary sphingolipids have received less attention.

Sphingomyelin (SM) is the major form of sphingolipids. It is present not only in eukaryotic cell membranes but also in Western food such as milk, meat, fish, and egg in a considerable amount (2,3). SM is hydrolyzed by sphingomyelinase (SMase) that cleaves the phosphocholine head group and converts SM to ceramide. Ceramide is further hydrolyzed by ceramidase to sphingosine and fatty acids. In the intestinal tract, an SMase with an optimal alkaline pH was previously reported and characterized (4,5). The alkaline SMase may have important roles in triggering the digestion of dietary SM (4,6). A ceramidase activity was also previously identified in the intestinal mucosa of pig and duodenal content of human beings (7). The optimal pH of the activity is 7.4 to 7.6 in the presence of 2 mM taurodeoxycholate. Recently, Hui *et al.* (8) found that recombinant BSSL had lipoamidase activity. This result was confirmed and extended by Nyberg *et al.* (9), who showed that BSSL in human milk was able to hydrolyze ceramide at pH values ranging from 7 to 10 in the presence of 4 mM bile salt mixture. Pancreatic BSSL is the product of the gene of BSSL in milk and is present in pancreatic juice and released in the intestine (10). A question is thus naturally raised: Is the ceramidase activity found previously in the intestinal content actually contributed by pancreatic BSSL or is a specific ceramidase present in the intestinal content? In the present investigation, we address this question by comparing the chromatographic behaviors, the distributions, the stability, and the sensitivities to lipase inhibitor between the two enzymes.

## MATERIALS AND METHODS

*Materials.* Palmitoyl ceramide, taurocholate, and *p*-nitrophenyl acetate (*p*-NPA) were purchased from Sigma Co. (St. Louis, MO). 1-[$^{14}$C]Palmitoyl-labeled ceramide ([$^{14}$C]Cer) was provided by Astra Draco (Lund, Sweden), and was prepared by converting 1-[$^{14}$C]palmitic acid to the corresponding anhydride with palmitoyl chloride, followed by reacting the anhydride with sphingosine. The labeled ceramide was purified by flash-column chromatography, and the purified ceramide had a specific activity of 15.7 mCi/mmol with radiochemical purity more than 97% (9). Orlistat (capsule Xenical®) was obtained from University Hospital of Lund, Sweden. For *in vitro* use, the contents of one capsule were dissolved in ethanol (95%), followed by centrifugation for 10 min at 2,000 rpm to remove insoluble material (11). Antiserum against human BSSL was a gift from Dr. Berit Sternby, Lund University Hospital. The IgG purified from the antiserum has been previously shown to be able to inhibit BSSL activity against ceramide (9).

Human small intestinal content was collected from stomas of three individuals who had been previously treated with ileostomy due to ulcerative colitis and were fully recovered from the operation. The contents were freeze-dried first and

Abbreviations: BSSL, bile salt stimulated lipase; [$^{14}$C]Cer, 1-[$^{14}$C]palmitoyl-labeled ceramide; *p*-NPA, *p*-nitrophenyl acetate; SM, sphingomyelin; SMase, sphingomyelinase; TBS, Tris-buffered saline.

then dissolved in ice-cold 0.15 M NaCl containing 1 mM benzamidine. The insoluble materials were removed by filtration through a nylon membrane. The proteins in the filtrate were precipitated by acetone to 50% at temperatures lower than −10°C. The precipitated proteins were dissolved in 20 mM Tris-HCl buffer, pH 8.2, containing 1 mM benzamidine. Insoluble materials were removed by centrifugation at 18,000 rpm at −10°C for 10 min. The supernatant obtained was used for the experiment.

Sprague-Dawley rats ranging from 200–250 g were obtained from Møllegård (Ry, Denmark). In one set of experiments, the intestinal content from whole small intestine was collected by rinsing the intestinal tract with 0.15 M NaCl containing 1 mM benzamidine. The proteins in the content were precipitated, and the precipitated proteins were dissolved as described above. In another set of experiments, the small intestine of rat was cut into five segments. The first one was 10 cm long and represented duodenum. The rest of the small intestine was cut into four segments of equal length. The contents of the five segments were collected, centrifuged at 3,000 rpm for 10 min, and the supernatants were used for studying enzyme activity distribution.

Human pancreatic juice was collected from a patient with pancreatic cyst *via* a drainage tube in the pancreatic duct. Human pancreatic BSSL was purified in the laboratory according to the method of Duan and Borgström (12).

*Ceramidase assay.* Ceramidase activity was determined by using [$^{14}$C]Cer as substrate (13). For each determination, 0.75 nmol [$^{14}$C]Cer (75,000 dpm) was dried under nitrogen. Tris-maleate buffer (90 μL of 50 mM) containing 10 mM taurocholate, pH 7.0, was added, and the mixture was sonicated for 2 min. The reaction was started by adding 10 μL of sample followed by incubation for 1 h at 37°C. The reaction was then terminated by addition of 0.6 mL methanol/chloroform/heptane (28:25:20, by vol) as described previously (14). The solution was alkalized by adding 0.2 mL of 0.05 M $K_2CO_3/K_2B_2O_4$, pH 10.0. The mixture was centrifuged at 10,000 rpm for 10 s and 200 μL of the supernatant was taken for liquid scintillation counting. The distribution of released fatty acids in the upper phase under this condition was about 80%, which was corrected for activity calculation (15). When the optimal pH for ceramidase was determined, 50 mM Tris-HCl buffer with pH 8–10 and 50 mM Tris-maleate buffer with pH 4–7 were used. All the buffers contained 10 mM taurocholate.

*BSSL assay.* The determination of BSSL activity was according to Shirai and Jackson (16), using *p*-NPA as substrate. The sample was added in 0.1 M Tris buffer, pH 7.2, containing 3 mM taurocholate and 0.5 mg *p*-NPA to a final volume of 200 μL. The incubation was performed at room temperature and the release of nitrophenyl was measured by the increase in absorbance at 405 nm, which was read at 0, 2, 5, and 10 min by a microplate reader (Bio-Rad). The activity was calculated as μmol/min/mg protein or per mL of the samples, with the adjustment of the blank values.

*Anion exchange chromatography.* The anion exchange high quaternary aminoethyl (HQ) cartridge (Bio-Rad, Hercules, CA) with total volume of 5 mL was equilibrated with 20 mM Tris-HCl buffer, pH 8.2, containing 1 mM benzamidine. About 30 mg of sample proteins in 5 mL equilibrate buffer were loaded on the cartridge at a rate of 2 mL/min. After washing the cartridge with 15 mL of the same buffer, the bound proteins were eluted with a gradient of NaCl from 0 to 0.25 M, and then the NaCl concentration rapidly increased to 0.5 M in a total volume of 50 mL of the equilibrate buffer. The fractions were collected every 1.5 min. The activities of ceramidase and BSSL in the fractions were determined as described above. The chromatography was performed at 4°C by a Bio-Logic HR chromatography system (Bio-Rad Co.) and the proteins in the fractions were monitored by an ultraviolet detector.

*Western blot.* Western blot against BSSL was performed using a kit purchased from Bio-Rad. Briefly, 10 μg of proteins from rat pancreatic homogenate and from the fractions with ceramidase activity were subject to 12% sodium dodecylsulfate (SDS) polyacrylamide gel electrophoresis. The proteins were transferred to a nitrocellulose membrane electrophoretically. The membrane was blocked with Tris-buffered saline (TBS) containing 3% gelatin. After washing with TBS buffer containing 0.3% Tween 20, the membrane was probed with antiserum against human BSSL at 1:1000 dilution in TBS buffer containing 1% gelatin for 2 h. After washing, the membrane was incubated with IgG antibody conjugated with alkaline phosphatase. The binding bands were visualized according to the instructions of the kit manufacturer.

*Response to orlistat.* Orlistat was dissolved in ethanol and was added in human pancreatic juice, ceramidase fraction from HQ chromatography, or purified human BSSL at various concentrations. After incubation for 5–10 min, the ceramidase and BSSL activities were determined as described. The ethanol without orlistat was also added in the samples to check whether ethanol had any effect on the enzyme activity. The maximal concentration of ethanol added was 10%, and at this concentration, ethanol had no significant effect on both enzyme activities.

## RESULTS

*Ceramidase activity in the acetone-precipitated proteins of whole small intestinal contents.* The ceramidase activity in the acetone-precipitated proteins from small intestinal contents of rats and human beings were determined, and the results are shown in Figure 1. In both cases, there were dose-dependent increases of ceramidase activity. The results confirmed the earlier findings of Nilsson (7) that ceramidase activity exists in the intestinal contents of several species. The specific activity was about 15 nmol/h/mg proteins of rat intestinal contents and 28 nmol/h/mg of human intestinal contents.

*Ceramidase activity of human pancreatic BSSL.* The ceramidase activity in the purified BSSL from human pancreatic juice is shown in Figure 2. Human pancreatic BSSL hydrolyzed ceramide in a dose-dependent manner. The specific

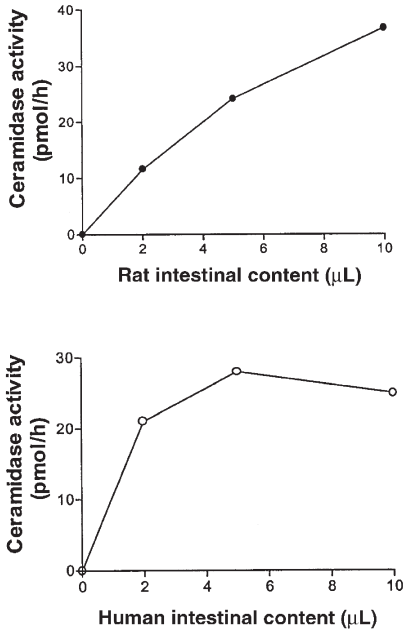

**FIG. 1.** Ceramidase activity in the proteins of intestinal contents of rats and human beings. The intestinal contents of the whole small intestine were collected from 10 rats. The proteins were precipitated by acetone at 50% and dissolved in 20 mM Tris-HCl buffer, pH 8.2. Human intestinal contents were collected from stomas of three patients after ileostomy and freeze-dried. The materials were resuspended in 0.15 M NaCl, and the proteins were precipitated and dissolved as above. Neutral ceramidase activity was determined using fatty acid-labeled [$^{14}$C]ceramide as substrate.

activity was about 155 nmol/h/mg. The results indicate that pancreatic BSSL, like BSSL in milk (9), has the ability to cleave the fatty acid from ceramide. Similar results were also obtained when the activity was determined in rat pancreatic homogenate (data not shown).

*Migration of intestinal ceramidase in HQ anion exchange chromatography.* To address whether the ceramidase activity shown in the intestinal content was contributed by pancreatic BSSL, the acetone-precipitated proteins from rat intestinal content were subject to HQ anion exchange chromatography. As shown in Figure 3, ceramidase activities were identified in two portions. The first one was in the proteins that were not retained in the HQ cartridge. The second one was in the proteins that were eluted by high concentrations of NaCl. The activity in the nonretained proteins was not caused by an overloading; we checked this by resubjecting these nonretained proteins to a new HQ cartridge. The result thus indicates the presence of at least two types of ceramidase activity in the intestinal contents.

*Optimal pH of the two ceramidases isolated after HQ chromatography.* The two portions with ceramidase activity were pooled and concentrated by ultrafiltration through a YM10 membrane (10 kDa cut-off; Millipore Co., Sundbyberg, Sweden). The ceramidase activities in both portions at various pH values were determined. As shown in the upper panel of Figure 4, the ceramidase that was not retained in the HQ cartridge preferred acid pH, whereas the retained one had high activity at neutral pH (lower panel).

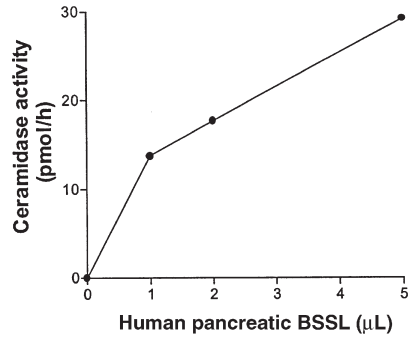

**FIG. 2.** Ceramidase activity of human pancreatic bile salt stimulated lipase (BSSL) at various doses. Human pancreatic BSSL was purified in the laboratory, and ceramidase activities were assayed using [$^{14}$C]ceramide as substrate.

*Determination of whether the fractions having ceramidase activity have BSSL activity.* We determined BSSL activities against *p*-NPA in both fractions having ceramidase activity after HQ chromatography with rat pancreatic homogenate and human pancreatic BSSL as positive controls. The results are shown in Table 1. Little activity in either nonretained or retained

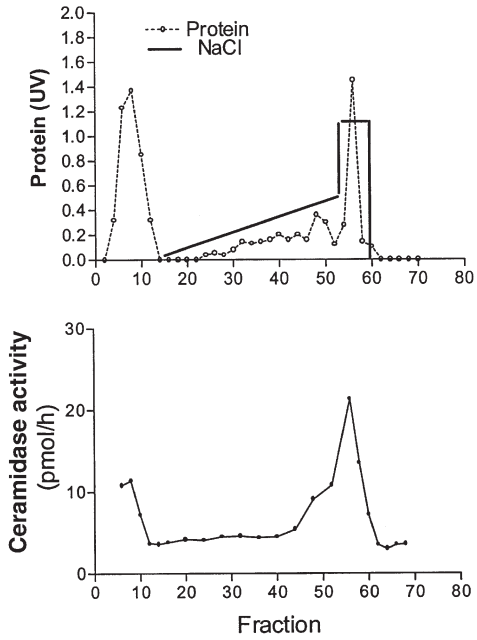

**FIG. 3.** Profile of high quaternary aminoethyl (HQ) anion chromatography of the proteins precipitated by acetone from rat intestinal tract. The precipitated proteins were dissolved in 10 mL of 20 mM Tris buffer pH 8.2 and loaded on an HQ cartridge that had been equilibrated with the same buffer. After washing the cartridge, the bound protein was eluted by a NaCl gradient from 0 to 0.25 M and the concentration of NaCl was then rapidly increased to 0.5 M. The flow rate was 2 mL/min, and the fractions were collected every 1.5 min. The proteins were monitored by an ultraviolet detector (upper panel). Chromatography was performed on a HR Bio-Logic system at 4°C. After chromatography, the ceramidase activity in the fractions was assayed (lower panel).

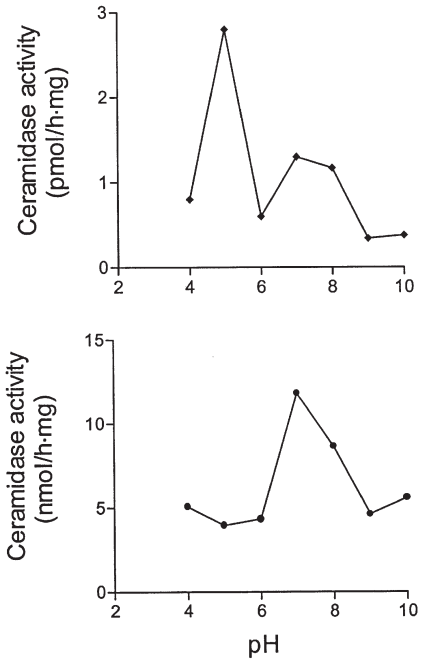

**FIG. 4.** The optimal pH of ceramidase activities isolated by HQ chromatography. The nonretained and retained portions with ceramidase activities were pooled, respectively, and the ceramidase activities of the two portions were determined in the buffers with various pH. Upper panel: ceramidase activity in the nonretained portions; lower panel: ceramidase activity in the retained portions. See Figure 3 for abbreviation.

fractions was detected. If the BSSL activities of nonretained and retained portions were expressed as μmol/min/mL, the activities were 2.31 and 2.24, respectively, which were lower than that of the blank value (Table 1). We further determined BSSL activities in all fractions of HQ chromatography as well as in the original sample loaded on the HQ cartridge. No BSSL activity could be identified (Table 1). The results show that in the proteins precipitated from whole small intestine by acetone, BSSL was denatured and ceramidase was preserved.

*Western blot of BSSL protein in fractions with high ceramidase activity.* To answer the question whether the negative esterolytic activity in the fractions with ceramidase is caused by the absence of BSSL or by the conformational changes under the sample preparation, western blot was performed. As shown in Figure 5, in rat pancreatic homogenate BSSL antiserum identified one protein band at 70 kDa, which corresponds to the molecular mass of rat BSSL (17). The antiserum also identified two smaller proteins in the pancreatic homogenate, which may represent degraded BSSL molecules. However, no band reacted with BSSL antiserum in the fractions with high ceramidase activity after HQ chromatography.

*Distribution of BSSL and ceramidase activities in the intestinal tract.* The distribution patterns of ceramidase and BSSL activity in rat intestinal tract were compared, and the results are shown in Figure 6. The pancreatic BSSL activity was high in the duodenum and sharply decreased in the small intestine, whereas ceramidase activity was low in the duodenum and high in the middle of the small intestine. The distribution patterns between BSSL and ceramidase are thus different.

**TABLE 1**
**Bile Salt Stimulated Lipase (BSSL) Activity in Various Samples**

| Sample | Activity (μmol/min/mg) |
|---|---|
| Blank control | 2.71[a] |
| Nonretained portion | 4.27 |
| Retained portion | 4.02 |
| Rat pancreatic homogenate | 23.82 |
| Human pancreatic BSSL | 208.13 |
| Acetone precipitated proteins of human intestinal content | 0.10 |
| Acetone precipitated proteins of rat intestinal content | 0.19 |

[a]0.15 M saline was used for blank. The unit of this value is μmol/min/ml.

*Response to lipase inhibitor, orlistat.* It is well known that orlistat is an inhibitor of several lipases, including pancreatic BSSL (18). Whether orlistat has similar inhibitory effects on pancreatic BSSL and ceramidase was studied. We found that orlistat dose-dependently inhibited the human BSSL activity against *p*-NPA and it also slightly reduced BSSL activity against ceramide by about 20%. However, orlistat had no inhibitory effect on the neutral ceramidase activity isolated from HQ chromatography (Fig. 7).

## DISCUSSION

Ceramidase activity in the intestinal content was first identified in 1969 (7). Recently an investigation showed that BSSL in milk had ceramide hydrolytic activity (9). Pancreatic BSSL is a product of the same gene of BSSL in milk (10) and is present in the intestinal tract. To investigate whether the ceramidase activity found previously in the intestinal content is contributed by pancreatic BSSL is important in understanding the events involved in the digestion of dietary sphingolipids. It also has clinical implications, because the ceramide levels in the gut are recently thought to have impact on mucosal cell proliferation and colon cancer development (19,20).

In the present study, we first confirmed the presence of enzymatic activities against ceramide in the intestinal content

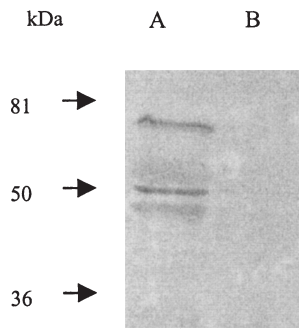

**FIG. 5.** Western blot of BSSL. Rat pancreatic homogenate (lane A) and the fraction with high ceramidase activity after HQ chromatography (lane B) were subjected to 12% sodium dodecylsulfate polyacrylamide gel electrophoresis. The proteins were transferred to nitrocellulose membrane electrophoretically. The membrane was probed with rabbit anti-BSSL antiserum first and then with IgG antibody conjugated with alkaline phosphatase. The bands were visualized by a kit from Bio-Rad Co. See Figures 2 and 3 for abbreviations.

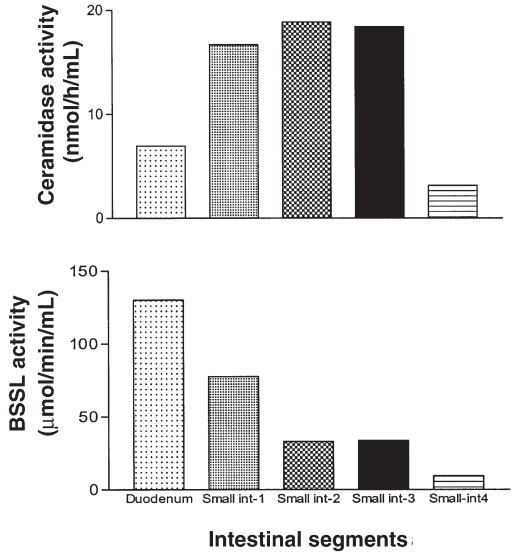

**FIG. 6.** Distribution of neutral ceramidase and BSSL activities in the rat small intestinal tract. The whole small intestine was cut into five parts. The first part was 10 cm long and represented duodenum. The rest of the small intestine was divided into four parts of equal length. The intestinal contents of each segment were suspended in 10 mL of saline containing 1 mM benzamidine. The activities of ceramidase and BSSL in each segment were assayed. For abbreviation see Figure 2.

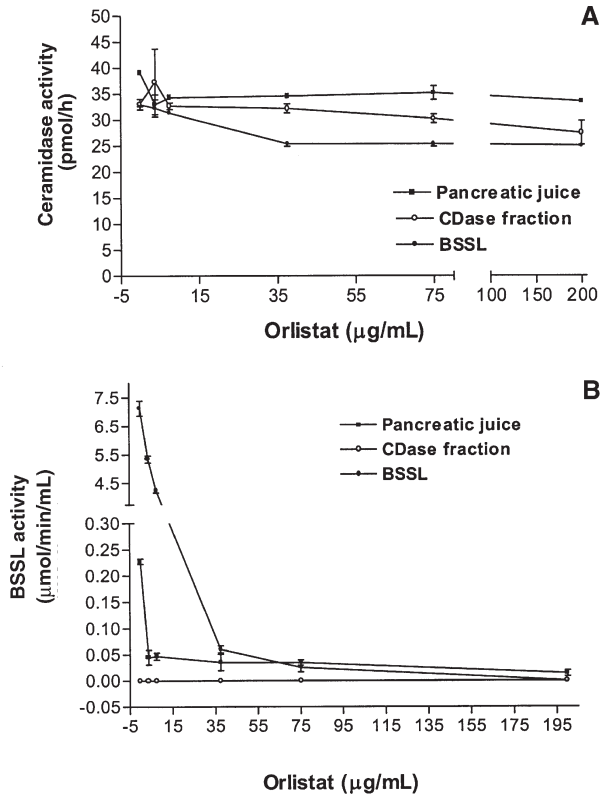

**FIG. 7.** Comparison of the effects of orlistat on ceramidase (CDase) and BSSL. Orlistat at various concentrations was incubated with pancreatic juice, neutral ceramidase fractions after HQ chromatography, and purified human BSSL for 10 min. The activities of ceramidase (upper panel) and BSSL (lower panel) after incubation were determined. For abbreviation see Figure 2.

and showed that pancreatic BSSL is able to hydrolyze ceramide in the same conditions. Then we provided several pieces of evidence supporting the presence of ceramidases in addition to BSSL in the intestinal content. First, when proteins from the intestinal contents of the whole small intestine were precipitated by acetone and subjected to HQ anion exchange chromatography, two portions of ceramidase activities were identified. Neither of them had esterolytic activity. Previous study suggested that the active sites of BSSL against ester and ceramide were different (8). However the negative esterolytic activity in HQ fractions is unlikely to be caused by a defect of a specific active site of BSSL, because Western blot failed to show BSSL band in the fractions with ceramidase activity. The two forms of ceramidase upon HQ chromatography preferred different pH values and were characterized as acid and neutral ceramidase, respectively. Based on this result, it seemed that BSSL has ceramidase activity, but not vice versa. Second, the distributions of neutral ceramidase and pancreatic BSSL in the intestinal tract differed significantly. The highest level of pancreatic BSSL was found in the duodenal content, and the activity sharply decreased in the jejunum and ileum. The activity of neutral ceramidase, in contrast, was low in the duodenal content but maintained a high level until the distal part of ileum. Since these results were obtained from the original intestinal content without acetone treatment, they also support the theory of the presence of two enzymes instead of one enzyme with two active sites for ester and ceramide in the intestine. The different distribution pattern is probably caused by the different stability of the enzyme in the presence of trypsin. It has been shown that intestinal ceramidase is resistant to trypsin digestion (15) whereas BSSL is not (21). This difference may also explain why BSSL activity is present in the duodenal content but is not detectable in the proteins precipitated by acetone from the contents of the whole small intestinal tract. Finally, we found that the responses of BSSL and ceramidase to orlistat, the inhibitor of pancreatic lipase and BSSL, are different. Orlistat strongly inhibited the BSSL activity against *p*-NPA but not ceramide hydrolytic activity in the fractions isolated from HQ chromatography. Orlistat also failed to strongly inhibit ceramide hydrolytic activity of BSSL at the doses that it completely inhibited esterolytic activity of BSSL. Because orlistat is an active-site directed inhibitor (22), the finding indicates that the structure of the active site of BSSL against *p*-NPA is different from that of ceramidase against ceramide. It also supports the previous findings that BSSL has different active sites for its esterolytic activity and ceramide hydrolytic activity (8).

In this study, we found at least three types of enzymes that can hydrolyze ceramide in the intestinal content: acid ceramidase, neutral ceramidase, and BSSL. These enzymes may contribute differently to the digestion of dietary ceramide. In the duodenum, acid ceramidase might be active due to the acid environment. Pancreatic BSSL might also be important in this part of the intestine due to the high levels of the enzyme. In the

rest of the small intestine, the hydrolysis of ceramide likely is dependent on the activity of neutral ceramidase, because the activity of neutral ceramidase, but not BSSL, is high in these parts of the small intestine. In addition, because dietary ceramide is mainly derived from the hydrolysis of SM, the digestion of ceramide is determined to some extent by the activity of SMase. The SMase in the intestinal tract responsible for digestion of SM is alkaline SMase (6). Its activity is high in the middle of the small intestine (5). The hydrolysis of SM and the formation of ceramide have been shown mainly in this part of the small intestine (6). It is reasonable to postulate that neutral ceramidase is more important than acid ceramidase and pancreatic BSSL in digestion of dietary ceramide.

Finally, it should be pointed out that orlistat had no effect on ceramide digestion by ceramidase and BSSL. We also determined previously that orlistat does not have a role in SM hydrolysis induced by purified alkaline SMase. The negative effects of orlistat on SM digestion might be interesting, because orlistat is used as a drug to reduce body weight by inhibition of hydrolysis of triglycerides (23). A high-fat diet is associated with an increasing risk of colorectal cancer, whereas SM hydrolysis in the gut may have protective effects on tumorigenesis in the colon (24–26).

Our work provides evidence for the presence of specific ceramidases other than pancreatic BSSL in the intestinal content. Different forms of ceramidase with different optimal pH in other organs such as skin (27) and liver (28) have been purified and characterized. Purifying and characterizing intestinal ceramidase will elucidate the physiological role of the enzyme in sphingolipid digestion.

**ABSTRACT:** Phosphorylation of extracellular signal-regulated kinases (ERK1/ERK2) has been implicated in cell proliferation of mammalian cells. In the present study, we investigated the role of docosahexaenoic acid (DHA) in the modulation of ERK1/ERK2 phosphorylation, stimulated either with phorbol 12-myristate 13-acetate (PMA) or transforming growth factor-alpha (TGFα) in NIH/3T3 cells. We observed that both PMA and TGFα induced ERK1/ERK2 phosphorylation within 5 min of stimulation. PMA acts upstream of MEK and *via* activation of protein kinase C (PKC), as GF109203X, a potent PKC inhibitor, and U0126, a MEK inhibitor, abolished its actions on ERK1/ERK2 phosphorylation. TGFα did not act *via* PKC because GF109203X failed to curtail the degree of ERK1/ERK2 phosphorylation in these cells. DHA alone failed to induce the phosphorylation of these mitogen-activated protein (MAP) kinases; however, this fatty acid significantly curtailed the PMA- but not TGFα-induced MAP kinase enzyme activity and phosphorylation in NIH/3T3 cells. Furthermore, we observed that DHA significantly inhibited PMA-induced translocation of two PKC isoforms, PKCα and PKCε, from cytosol to plasma membrane. Interestingly, DHA failed to inhibit the PMA-induced translocation PKCδ isoform in these cells. Furthermore, DHA decreased PMA-induced proliferation of NIH/3T3 cells. In this study, we show for the first time that DHA inhibits MAP kinase (ERK1/ERK2) activation and proliferation of NIH/3T3 cells *via* its inhibitory action on PKCα and ε isoforms.

Paper no. L8709 in *Lipids 36,* 813–818 (August 2001).

A number of receptors involved in growth and differentiation, such as those activated by epidermal growth factor (EGF) and platelet-derived growth factor, are themselves tyrosine-specific kinases (1). Transforming growth factor-alpha (TGFα), a mitogenic peptide, is an epidermal growth factor-ligand that is distinguished from EGF by its acid-labile structure and potent transforming structure. Lipeski *et al.* (2) showed that TGFα may activate EGF receptor (EGFr) coupled with Ras/MAP kinase pathway. EGF *via* EGFr is able to induce rapid activation of these kinases, which are thought to be key intermediate regulatory proteins functioning in signal transduction pathways (3). Binding of TGFα to its receptor induces intracellular receptor autophosphorylation on tyrosine residues and creates a recognition site for intracellular SH2-containing proteins, particularly the adaptator Grb2 implicated in $p21^{ras}$ dependent signaling pathway (4,5). Grb2 associated with SOS is translocated to the plasma membrane where $p21^{ras}$ is localized. Ras is active in the GTP-bound form, and the activation of Ras is mediated by the nucleotide exchange, as catalyzed by exchange factors such as SOS or Vav (6,7). The Ras-GTP binds directly to a serine/threonine kinase, Raf-1, which activates MAP kinase kinase (MAPKK or MEK1/2), which in turn activates MAPK isoforms (8). Raf-1 activates Raf/MEK/ERK cascade in a protein kinase C (PKC)-dependent manner. Hence, PKCα acts as a critical component of the MAPK signal transduction pathway as this enzyme phosphorylates Raf-1 (9). Moreover, EGF triggers MAPK activation *via* PLCγ-dependent pathway that converges with a Ras-dependent pathway on Raf-1 in NIH/3T3 cells (10). When EGFr is activated, a signal is transmitted to PLCγ, which leads to PKC activation, by the release of diacylglycerol cleaved from phosphatidylinositol and production of inositol 1,4,5-trisphosphate.

Numerous studies have been conducted on cell growth and differentiation to understand the consequences of MAPK cascade alteration and to determine the mechanisms implicated in downstream signaling (10,11). Reszka *et al.* (11) showed that MAPK activation is crucial for regulation of cell cycle progression. Hence, MAPK is associated with the cytoskeleton proteins such as microtubules in NIH/3T3 cells (11). In these cells, ERK2 is finally translocated into the nucleus where it regulates gene expression, involved in cell proliferation (12).

Several studies have demonstrated the involvement of polyunsaturated fatty acids, particularly of docosahexaenoic acid (DHA; 22:6n-3), in signal transduction and gene transcription (12,13). DHA has been shown to modify the segregation of membrane proteins, thus affecting fluidity of plasma membranes (14,15). Several authors have demonstrated that DHA modulates the production of diacylglycerol and

Abbreviations: ALA, α-linolenic acid (18:3n-3); DHA, docosahexaenoic acid (22:6n-3); ECL, equivalent chain length; EGF, epidermal growth factor; EGFr, EGF receptor; ERK, extracellular signal-regulated kinase; LA, linoleic acid (18:2n-6); MAPK, mitogen-activated protein kinase; MAPKK, MAPK kinase; MAPKK-ERKK (also known MEK1/2); PBS, phosphate-buffered saline; PKC, protein kinase C; PMA, phorbol 12-myristate 13-acetate; n-3 PUFA, polyunsaturated fatty acids of n-3 family; PVDF, polyvinylidine difluoride; SDS, sodium dodecyl sulfate; TGFα, transforming growth factor-alpha.

therefore inhibits DNA synthesis in different cell lines (15,16). In the present study, we investigated the role of this fatty acid in the regulation of MAP kinase signaling and in the proliferation of NIH/3T3 fibroblast cells.

## EXPERIMENTAL PROCEDURES

*Materials.* Antiphosphorylated MAP kinase (ERK1/ERK2) antibodies were obtained from New England Biolabs (Hitchen-Hertfordshire, United Kingdom). The MAP kinase assay kit, [$^3$H]thymidine (specific activity 20 Ci/mmol), and $\gamma^{32}$P-ATP were procured from Amersham (Orsay, France). GF109203X was obtained from Calbiochem (Meudon, France). PKC sampler kit for the detection of different isoforms was obtained from New England Biolabs. All other chemicals, including phorbol 12-myristate 13-acetate (PMA), TGFα and DHA, were purchased from Sigma (St. Quentin Fallavier, France). U0126 was a generous gift from Promega (Charbonniers, France).

*Cell culture and treatments.* NIH/3T3 fibroblasts, used in this study, were grown in 35-mm petri dishes in a humidified chamber with 5% $CO_2$ atmosphere at 37°C in RPMI 1640 medium supplemented with L-glutamine, penicillin (50 µg/mL), streptomycin (50 µg/mL), HEPES 20 mM, and 10% fetal calf serum.

Quiescent cells were obtained by serum-starvation for 18 h. Cells were incubated for 5 min with DHA (dissolved in ethanol, 0.01% wt/vol) and then stimulated with PMA (200 nM) or TGFα (50 ng/mL) for 5 min. Cells were lysed with 200 µL of Laemmli buffer (Tris, 62.5 mM; sodium dodecyl sulfate (SDS), 2%; glycerol, 25%; β-mercaptoethanol, 715 mM; bromophenol blue, 0.01%, pH 6.8) and used immediately or stored at −80°C for western blot detection of MAP kinase phosphorylation.

*Western blot analysis of MAP kinase phosphorylation.* Cell proteins were subjected to SDS-polyacrylamide gel electrophoresis (10%) and transferred to polyvinylidine difluoride (PVDF) membrane. The membrane was blocked by incubation with cream-free milk for 2 h and was then incubated with antiphosphorylated ERK1/ERK2 antibodies. MAP kinases were visualized using anti-rat peroxidase-conjugated antibody. These antibodies were used at 1:1000 dilution. Peroxidase activity was detected using the chemiluminescent equivalent chain (ECL) length system.

*MAP kinase enzyme activity.* MAP kinase enzyme activity was determined according to the instructions furnished with the kit. The enzyme activity was assessed by monitoring the incorporation of $^{32}P_i$ into a peptidic fraction of EGFr, containing a proline-leucine-serine/threonine-proline sequence that is a more specific substrate for MAP kinases than the myelin basic protein.

*Cell lysis and western blot detection of different isoforms of PKC.* After incubation of NIH/3T3 cells ($8 \times 10^6$ cells/dish) with DHA and/or PMA, cells were washed twice with phosphate-buffered saline (PBS), pH 7.4, and the reaction was stopped by addition of a buffer that contained the following: Tris-HCl, 25 mM; EDTA, 0.5 mM; EGTA, 0.5 mM; β-mercaptoethanol, 10 mM; phenylmethyl sulfonyl fluoride, 50 µM; and leupeptin, 10 µg/mL, pH 7.5. Cells were scraped off, sonicated twice for 2 s at 4°C and then centrifuged ($500 \times g \times 10$ min at 4°C) to isolate the nuclear fractions. The supernatant was used to isolate plasma membrane and cytosolic fractions by centrifuging ($100{,}000 \times g \times 60$ min), essentially according to Szallasi *et al.* (17). The particulate and cytosolic fractions were used to detect PKC translocation after electrophoresis and transfer onto the PVDF membrane. The anti-PKC antibodies and secondary anti-rat antibody were employed at 1:1000 dilution. The different isoforms of PKC were visualized by detecting peroxidase activity using the chemiluminescent ECL system.

*Proliferation assay*. NIH/3T3 cells were seeded into 24-well plates at a density of $50 \times 10^3$ cells/well and cultured in complete RPMI 1640 medium. At subconfluence, cells were serum-starved for 24 h and incubated with DHA at increasing concentrations in the presence of PMA (1 µM) for another 24 h. Cell proliferation was determined by addition of [$^3$H]-thymidine (20 Ci/mmol; 1 µCi/well) for the last 6 h. The incubation was stopped by removing the medium and adding cold methanol. The cells were washed with PBS, fixed with 10% perchloric acid, and dissolved in NaOH (0.5 N) for scintillation counting.

*Statistical analysis.* Results are shown as mean ± standard deviation of quadruplicate assay samples. Statistical analysis of data was carried out using Statistica (version 4.1, Statsoft, Paris, France). The significance of the differences between mean values was determined by analysis of one-way variance, followed by a least significant difference (LSD) test.

## RESULTS

*Rapid activation of ERK1/ERK2 by PMA and TGFα.* In order to determine the time required to induce phosphorylation of ERK1/ERK2 by two mitogenic agents, cells were exposed to PMA or TGFα for different times (5, 10, or 30 min). Figure 1 shows that both PMA and TGFα phosphorylated MAP kinases within 5 min of incubation. Interestingly, PMA-induced ERK1 and ERK2 phosphorylation completely disappeared

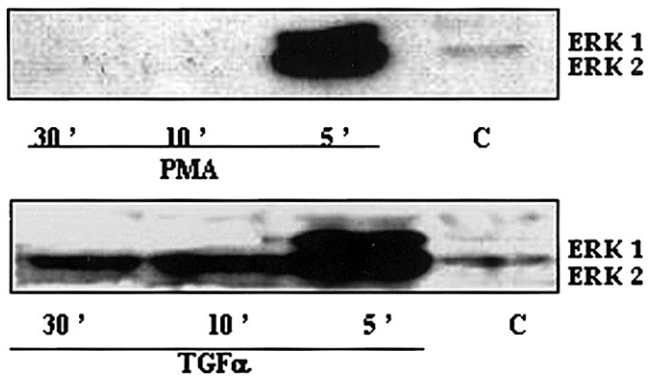

**FIG. 1.** Time course phosphorylation of extracellular signal-regulated kinases (ERK1/ERK2) by phorbol 12-myristate 13-acetate (PMA) and transforming growth factor-alpha (TGFα). NIH/3T3 cells ($3 \times 10^6$ cells/dish) plated in 60-mm petri dishes were growth-arrested at confluence by overnight serum starvation. Cells were treated or not (Control, C) with PMA (200 nM) and TGFα (50 ng/mL) at 37°C for different times. Phosphorylated mitogen-activated protein (MAP) kinases were detected by immunoblotting as described in the Experimental Procedures section.

after 10 min; although TGFα-induced ERK2, but not ERK1, phosphorylation was apparent until 30 min of incubation (Fig. 1).

*MAPK activation* via *MEK is partially PKC-dependent*. Pretreatment of cells with GF109203X, a specific inhibitor of PKC, curtailed PMA-induced ERK1/ERK2 phosphorylation; however, this inhibitor was inefficient when cells were activated by TGFα (Fig. 2). We also employed U0126, a specific inhibitor of MEK, and observed that this agent completely abolished the TGFα- and PMA-stimulated MAPK phosphorylation (Fig. 2).

*DHA inhibits PMA- but not TGFα-induced MAP kinase activation*. To determine the molecular mechanism of action of DHA on ERK1/ERK2 activation, we assessed two aspects; determination of the degree of phosphorylation, and the enzyme activity of MAP kinases. For the latter, we used a specific substrate that is a part of EGFr (see Experimental Procedures section). It is interesting to note that DHA alone did not induce any activation of MAPK under basal conditions (Figs. 3 and 4) whereas Figure 3D shows that linoleic acid and α-linolenic acid alone are capable to induce MAPK phosphorylation. DHA inhibited, from 5 to 40 μM, MAPK phosphorylation, stimulated by PMA (Fig. 3B). On the contrary, DHA failed to reduce MAPK phosphorylation significantly (Fig. 3C) and enzyme activity (Fig. 4) stimulated by TGFα. In parallel control assays, Figure 3A shows the presence of nonphosphorylated MAPK in NIH/3T3 cells.

*DHA seems to act* via *PKC-dependent pathway.* Because DHA curtailed PMA-induced MAPK activation, we assessed the effect of DHA in the presence or absence of PMA on translocation of different isoforms of PKC from cytosol to plasma membrane. We observed that DHA alone did not induce translocation of any isoform of PKC (Fig. 5). However, DHA completely inhibited the PMA-induced translocation of PKCα and PKCε isoforms in these cells. It is interesting to note that DHA failed to inhibit the PMA-induced translocation of PKCδ isoform (Fig. 5). On the other hand, PMA did not induce the translocation of PKCζ in these cells (Fig. 5). PKCβ and PKCγ were not significantly detectable in these cells (results not shown).

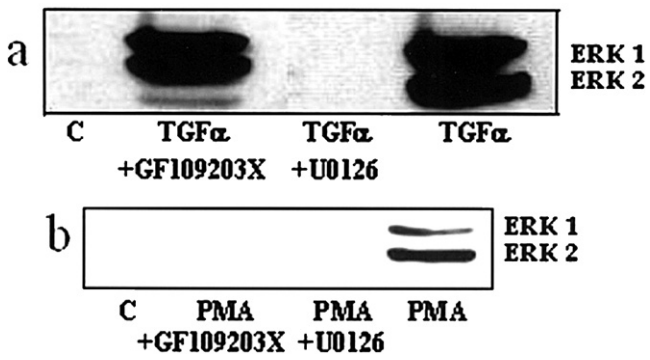

**FIG. 2.** Effect of U0126 and GF109203X on MAP kinase phosphorylation. NIH/3T3 cells (3 ×$10^6$ cells/dishes) plated in 60-mm petri dishes were growth-arrested at confluence by overnight serum starvation. Cells were pretreated or not (control, C) with GF109203X (500 nM) or U0126 (10 μM) and then incubated with TGFα (50 ng/mL) or PMA (200 nM) at 37°C for 5 min. MAP kinases were detected by immunoblotting as described in the Experimental Procedures section. See Figure 1 for abbreviations.

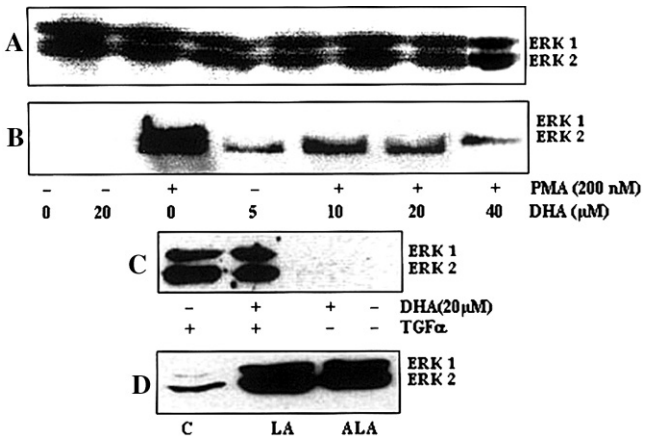

**FIG. 3.** Effects of docosahexaenoic acid (DHA) on PMA- and TGFα-induced MAPK phosphorylation. NIH/3T3 cells (3 × $10^6$ cells/dish) plated in 60-mm petri dishes were growth-arrested at confluence by overnight serum starvation. Panel A shows unphosphorylated MAPK present in unstimulated cells. In panel B, cells were pretreated or not (control) with DHA at increasing concentrations (5, 10, 20, 40 μM) in the presence of PMA (200 nM) for 5 min at 37°C. In panel C, cells were treated with DHA (20 μM) and stimulated with TGFα (50 ng/mL) for 5 min at 37°C. In panel D, cells were pretreated or not (control, C) with linoleic acid (LA; 20 μM) and α-linolenic acid (ALA; 20 μM). Cell lysates were prepared as described in the Experimental Procedures section. Similar amounts of proteins of each sample were loaded into sodium dodecyl sulfate polyacrylamide gel electrophoresis and MAPK were detected by immunoblotting as described in the Experimental Procedures section. See Figures 1 and 2 for other abbreviations.

*DHA diminishes cell proliferation stimulated by PMA*. To investigate the effects of DHA on proliferation of NIH/3T3 fibroblasts, we stimulated cells by PMA and treated or not by DHA at increasing concentrations. We observed that DHA inhibited PMA-induced cell proliferation dose-dependently (Fig. 6). It is noteworthy that DHA does not influence cell viability as assessed by trypan blue exclusion test.

## DISCUSSION

In NIH/3T3 cells, MAPK plays an important role in cell cycle progression (18). Several studies have demonstrated that inhibition of MAPK cascade inhibits cell growth (10,18). In these studies, authors have used ERK2 antisense constructs that were derived from epitope-tagged $p44^{mapk}$ cloned into pc DNA-neo vector (18). Hence, the transfection of rat fibroblasts with $p44^{mapk}$ cDNA constructs arrested these cells in G0 phase of the cell cycle. These experiments, which result in destruction of *de novo* synthesized MAP kinase RNA, clearly indicate that MAPK isoforms are necessary to cell growth and, particularly, to pass the restriction point of the cell cycle (18). In another recent study, Abbott and Holt (19) employed PD98059, a MEK inhibitor, in order to probe whether this kinase is specifically required during the progression of G2/M phase of the cell cycle in NIH/3T3 cells.

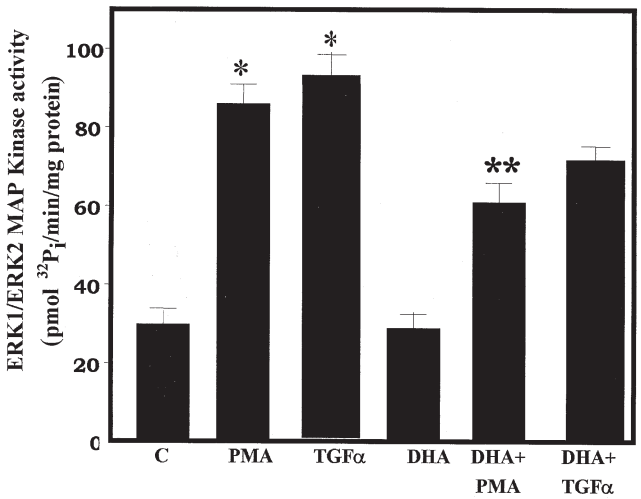

**FIG. 4.** Effects of DHA on PMA- and TGFα-induced MAPK enzyme activity. NIH/3T3 cells ($3 \times 10^6$ cells/dish) plated in 60-mm petri dishes were growth-arrested at confluence by overnight serum starvation. Cells were pretreated or not (control, C) with DHA (20 μM) and then exposed to PMA (200 nM) or TGFα (50 ng/mL). The enzymatic activity was determined as described in the Experimental Procedures section. Each value represents the mean ± standard deviation of quadruplicate assay samples, reproduced at least two times independently. Data are significant as compared to control (*$P < 0.001$) and PMA-activated cells (**$P < 0.001$), following the least significant difference test of significance. See Figures 1–3 for abbreviations.

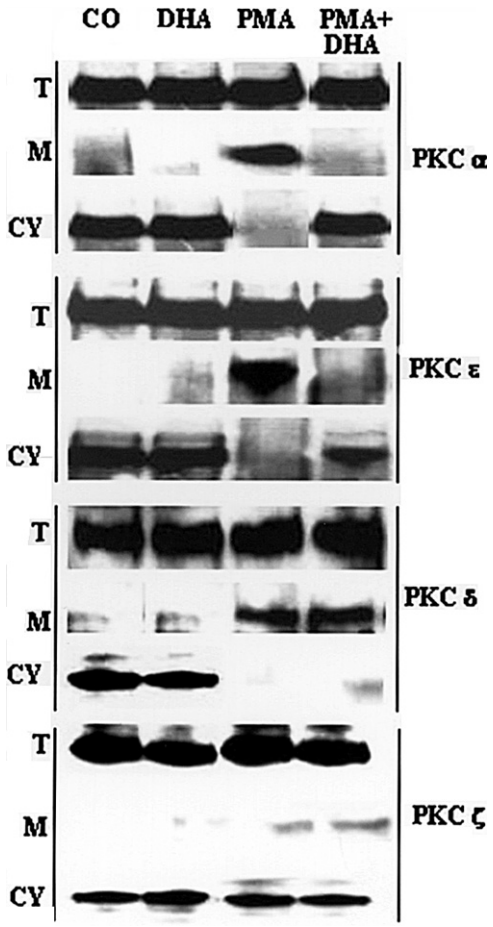

**FIG. 5.** Effects of DHA on PMA-induced translocation of protein kinase C (PKC) isoforms. NIH/3T3 cells ($3 \times 10^6$ cells/dishes) plated in 60-mm petri dishes were growth arrested at confluence by overnight serum starvation. Cells were pretreated or not (control) with DHA for 5 min. Cells were stimulated or not (control, CO) with PMA (200 nM). Upper panel (total, T) shows PKC in unphosphorylated/unstimulated cells. Different isoforms of PKC were detected in plasma membrane (M) and cytosolic (CY) fractions by immunoblotting as described in the Experimental Procedures section. See Figures 1 and 3 for abbreviations.

These investigators added this inhibitor to cells in late S phase of the cell cycle and observed that the phosphorylation of MEK was indispensable for progression through G2/M checkpoint arrest in NIH/3T3 cells exposed to ionizing radiation (19). These observations indicate that cell cycle progression is a MAP kinase-dependent phenomenon.

In the present study, we first investigated whether PKC was coupled to the activation of MAPK in NIH/3T3 cells. PKC represents a family of enzymes involved in signal transduction and cell proliferation (20,21). Down-regulation or overexpression of PKCα in NIH/3T3 has been shown to modulate growth rate and morphology of fibroblast cells (20). High levels of PKC in response to PMA reflected increased phosphorylation of critical cellular proteins involved in the control of cellular growth and morphology (20,21). As far as the activation of MAP kinases is concerned, our study shows that PMA and TGFα induced phosphorylation of ERK1/ERK2 after 5 min of incubation. To investigate whether PMA-induced MAPK phosphorylation is specifically PKC-mediated, we used GF109203X, a potent PKC inhibitor. GF109203X completely abolished the PMA-induced MAPK phosphorylation but exerted no effect on TGFα-induced MAPK phosphorylation. These results corroborate the observations of Ueda *et al.* (22), who reported that two activation pathways, a PKC-dependent and a PKC-independent, exist in NIH/3T3 fibroblasts. In fact, the Raf-independent pathway is stimulated by phorbol esters where PKC activates Raf-1 in a $p21^{ras}$-dependent manner in these cells (23). In NIH/3T3 cells, Raf-1 has been shown to be activated in response to EGF *via* PKC (24,25). It seems that PKC and Raf-1 are the key proteins in the MAP kinase cascade regulation. Furthermore, we have observed that U0126, a MEK inhibitor, completely abolished PMA and TGFα-induced MAPK activation in the NIH/3T3 fibroblasts (26), suggesting that MEK is an upstream regulator of MAPK whether the cells are stimulated by PMA or TGFα.

Most of the studies conducted hitherto have dealt with the role of arachidonic acid on MAP kinase activation (27–29). No study is available on the role of DHA in the modulation of MAPK activation and cell growth. In our study, eicosapentaenoic acid and arachidonic acid alone did not induce MAPK activation in these cells (results not shown). On the contrary, LA (18:2n-6) and ALA (18:3n-3) alone induced MAPK phosphorylation in NIH/3T3 cells. The fact that arachidonic acid stimulated MAPK activation in other studies (27–29) and failed to induce the same in our study may be due to the difference in cell type used. We used NIH/3T3 cells, whereas

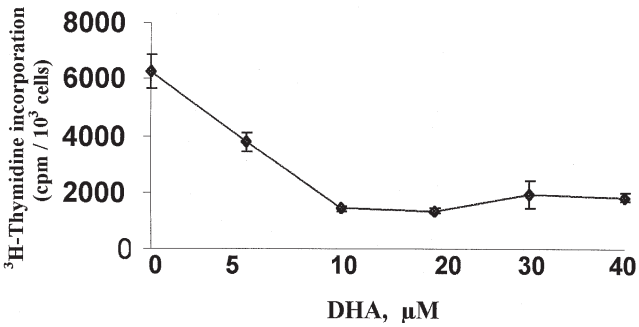

**FIG. 6.** Effects of DHA on PMA-stimulated proliferation of NIH/3T3 fibroblasts. NIH/3T3 cells were seeded in 24-well plates at a density of $50 \times 10^3$ cells/well and cultured in complete RPMI 1640 medium. At subconfluence, cells were serum-starved for 24 h and incubated with DHA at increasing concentrations in the presence of PMA (1 µM) for another 24 h. Cell proliferation was determined by addition of [$^3$H]-thymidine (20 Ci/mmol; 1 µCi/well) for the last 6 h. Data are mean ± standard deviation of quadruplicate assays, reproduced at least two times independently. See Figures 1 and 3 for abbreviations.

other investigators used rat epithelial cells (27), vascular smooth muscle cells (28), and rabbit renal proximal cells (29).

In our study, we observed that DHA alone did not induce MAPK activation under basal conditions in NIH/3T3 cells; rather, this fatty acid diminished PMA-induced, without affecting TGFα-induced, MAPK phosphorylation, suggesting that DHA may regulate MAPK pathway *via* PKC activation. Furthermore, we stimulated PKC activity by PMA in the presence or absence of DHA and observed that PKC enzyme activity was significantly curtailed when cells were pretreated with this fatty acid (results not shown). In order to trace out which isoform of PKC was implicated in the inhibition by DHA, we performed further experiments on translocation of cytosolic PKC toward plasma membrane. We observed that DHA alone did not induce the PKC translocation, but pretreatment by this fatty acid inhibited the PMA-induced translocation of PKCα and PKCε isoforms. It is noteworthy that DHA failed to inhibit the translocation of PKCδ isoform in these cells. Furthermore, we failed to detect PKCβ and PKCγ isoforms in these cells (results not shown). We also observed that PMA failed to induce translocation of PKCζ isoform. These observations are substantiated by the findings of Szallasi *et al.* (17), who reported that PKCβ and PKCγ are not expressed and PKCζ is not translocated by PMA in NIH/3T3 cells.

Several studies have shown that PKC activation is regulated by free fatty acids (30,31). In our study, whether DHA inhibits PKC activity directly or *via* the production of diacylglycerol containing DHA is not well understood. However, Vernhet *et al.* (31) showed that the replacement of arachidonic acid by an n-3 fatty acid into membrane phospholipid alters the DAG composition and, subsequently, inhibits PKC activity. In our study, DHA does not seem to act *via* lipoxygenase or cyclooxygenase pathways since this fatty acid is never metabolized into eicosanoids (32); rather, it is either degraded *via* its β-oxidation or reincorporated into plasma membrane phospholipids *via* acylation (32,33). However, our study shows that DHA modulates MAPK activation *via* its inhibitory action on two isoforms of PKC, PKCα and PKCε. These two isoforms of PKC were previously shown to regulate MAPK activation, upstream of MEK, in NIH/3T3 cells (9,17,24).

In order to assess the role of DHA in cell proliferation, we stimulated cell growth by addition of PMA, followed by treatment with DHA. Hence, we noticed that DHA inhibited PMA-stimulated cell proliferation. Our results show, for the first time, that DHA may modulate MAPK activation *via* MEK/PKC pathway and that DHA inhibits NIH/3T3 cell growth. Since activation of MAPK is known to be involved in expression of several genes essential for cell proliferation, DHA may modulate cell growth by inhibiting PKCα and PKCε upstream of MEK. Further studies are in progress in our laboratory to assess the implication of DHA in the expression of such genes.

## ACKNOWLEDGMENTS

Authors are thankful to the Fondation Pour la Recherche Médicale, Paris (France), for a contingent grant to help create the "Jeune Equipe" at the University of Burgundy, Dijon. The work was also supported by a contingent grant from Bourgogne Region, Dijon and Group Lipids & Nutrition, Paris (France).

**ABSTRACT:** Lipid emulsions (LE) contain triglyceride (TG)-rich particles (TGRP) and phospholipid-rich particles (PLRP). Various lipid and protein exchanges take place during *in vitro* incubations of LE with lipoproteins. These composition changes affect physical properties of particles. The aim of this study was to determine the role of different LE particles and the effect of TG composition on physical modifications. Low density lipoproteins (LDL: $1.025 < d < 1.040$ g/mL) or high density lipoproteins (HDL: $1.085 < d < 1.150$ g/mL) were incubated with the following four LE or their TGRP or PLRP, which were manufactured with the same phospholipid emulsifier: long-chain triglycerides (LCT): 100% soybean oil; medium-chain triglycerides (MCT)/LCT (MCT/LCT, 5:5, w/w); FO (100% fish oil); and MLF541 (MCT/LCT/FO, 5:4:1, by wt). After incubation, modified LE particles and lipoproteins were analyzed by fluorescence polarization. Observed physical modifications were significant in emulsion particles (ordering effect) but not in lipoproteins and also were significant for TG composition effect. Since intact emulsion contained a large excess of TGRP over PLRP, it is not surprising that intact emulsion had the same behavior as TGRP alone, and that PLRP had the same physical characteristics as lipoproteins. TG loss and cholesterol and protein acquisitions by emulsion particles rigidify their envelope. The two emulsions containing FO were less ordered after incubation. In conclusion, incubation of LE with lipoproteins changes physical properties of each kind of particle, and TG composition of the emulsion affects emulsion particle changes but has no effect on LDL and HDL. These order modifications induce more effective exchanges between LE particles and lipoproteins and modify their metabolism; HDL changes may increase the reverse cholesterol transport.

Paper no. L8688 in *Lipids 36,* 819–825 (August 2001).

Lipid emulsions (LE) used in parenteral nutrition mainly contain triglyceride (TG)-rich particles (TGRP), which resemble endogenous chylomicrons with respect to size and structural assembly. They only differ by the absence of structural apolipoproteins (apo) such as apo $B_{48}$ or apo A-I. These particles are suspended in a mesophase containing glycerol and some excess of emulsifier, which may be separated and recovered as liposomes that are also called phospholipid (PL)-rich particles (PLRP) (1).

Triglyceride-rich lipoproteins (TGRL), such as chylomicrons and very low density lipoproteins (VLDL), are known to undergo a series of interactions with high density lipoproteins (HDL) such as the transfer of several exchangeable apo and surface lipids, mainly during lipolysis (2). Similar to TGRL, emulsion particles interact with endogenous lipoproteins and acquire apo (namely, apo C and apo E) by transfer from plasma lipoproteins, mainly from HDL (3,4). In addition, exchanges of cholesteryl esters (CE) and TG, regulated by the cholesteryl ester transfer protein (CETP), take place between CE-rich lipoproteins [low density lipoprotein (LDL) and $HDL_2$] and TGRL. These exchanges affect lipid transport and lipoprotein remodeling in humans (5,6). TGRP are also involved in CETP-mediated lipid transfers (7). Furthermore, Kuksis *et al.* (8) suggested a rapid and extensive replacement of endogenous PL of plasma lipoproteins by exogenous PL during the infusion of LE. Lipoprotein composition changes induce modifications of the order of the particle (9,10).

Some lipid, apo, and other protein exchanges take place during *in vitro* incubations of LE in the presence of LDL or HDL (3,4). It appears that changes of LE and lipoprotein particle composition could affect the physical properties, notably lipid dynamics, of the respective components of the incubation mixture.

We recently demonstrated that modified LE fractions (M-LE), after incubation with LDL, were unexpectedly enriched in apo B as well as in CE (11). Apo B cannot freely exchange due to its very large structure, which is deeply anchored in the LDL particle. Each LDL particle possesses only one apo B molecule (12,13). The presence of apo B in the M-LE fraction strongly suggests an LDL binding to TGRP, which is corroborated by the CE enrichment of the M-LE fraction, independent of CETP activity. This LDL binding is a fast process and results in a strong interaction. In addition, LDL binding appears to involve both TGRP and PLRP and is markedly affected by the TG fatty acid (FA) composition of the emulsion (14), suggesting an important influence of the TG core on the physical properties of the PL surface layer.

[1]Deceased.

Abbreviations: apo, apolipoprotein; CE, cholesteryl ester; CETP, cholesteryl ester transfer protein; DPH, 1,6-diphenyl-1,3,5-hexatriene; FA, fatty acid; FO, fish oil; HDL, high density lipoprotein; LCT, long-chain triglycerides; LDL, low density lipoprotein; LE, lipid emulsion; MCT, medium-chain triglycerides; M-HDL, modified HDL; M-LDL, modified LDL; M-LE, modified lipid emulsion; MLF, MCT/LCT/FO emulsion; PBS, phosphate buffered saline; PL, phospholipid; PLRP, phospholipid-rich particle; *r*, fluorescence anisotropy; TG, triacylglycerol or triglyceride; TGRL, triglyceride-rich lipoprotein; TGRP, triglyceride-rich particle; VLDL, very low density lipoprotein.

Modifications of the chemical and physical properties of both LE particles and lipoproteins may induce more efficient exchanges between these particles, with eventual consequences on their metabolism.

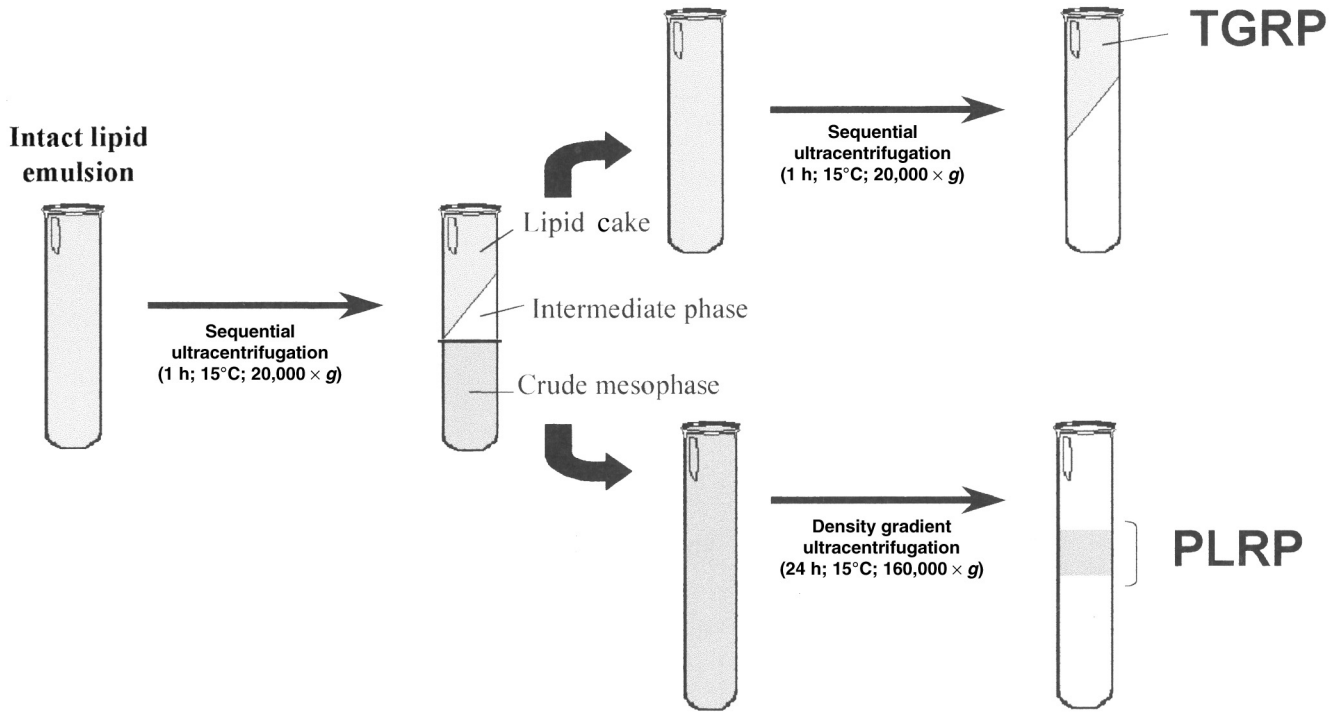
The aim of the present study was to elucidate the role *in vitro* of different components of LE (TGRP and PLRP) on physical property modifications of both LE and LDL or HDL and to explore if the TG core composition of LE plays a role in these modifications.

## EXPERIMENTAL PROCEDURES

*Plasma pool.* All 16 healthy overnight-fasted human subjects (2 males and 14 females, 25–50 yr old) were volunteers for the study, and informed consent was obtained from each volunteer. The blood was collected in tubes containing EDTA (1 mg/mL) and $NaN_3$ (0.2 mg/mL) and immediately placed in iced water. The plasma was separated at 4°C in a Beckman J2.21 (Beckman Instruments Inc., Fullerton, CA) at 3,000 rpm for 10 min. A pool of plasma was constituted, and the lipoprotein classes were immediately separated.

*Preparation of LDL and HDL fractions.* Individual lipoprotein classes were separated by sequential ultracentrifugation (227,000 × *g*; 20 h; 5°C) in a Beckman L8-55 ultracentrifuge using an angular Beckman 50.2Ti rotor (15). The LDL (density range: $1.025 < d < 1.040$ g/mL) and HDL (density range: $1.085 < d < 1.150$ g/mL) subfractions were selected to ensure a relatively homogeneous population of LDL or HDL particles (16,17). Isolated LDL and HDL were washed in KBr solutions of appropriate density. After isolation, the LDL and the HDL fractions were dialyzed in the dark against 40 vol of saline (0.19 M NaCl with 0.02% EDTA, $NaN_3$ 0.02%, pH 7.4). The dialysis solution was changed three times over a 24-h period (18).

*Emulsions.* The emulsions (supplied by B. Braun Melsungen AG, Melsungen, Germany) contained the same amounts of egg yolk PL emulsifier (12 g/L), TG (200 g/L), and glycerol (25 g/L). They differed only by their TG composition: 100% soybean oil [long-chain TG (LCT)]; 50% medium-chain TG (MCT)/50% soybean oil (MCT/LCT); 50% MCT/40% soybean oil/10% fish oil (FO) (MLF 541); 100% FO. Emulsion components (TGRP and PLRP) were fractionated as represented in Scheme 1 according to a method adapted from Férézou *et al.* (19). A 40-mL sample of each emulsion was ultracentrifuged (20,000 × *g*; 1 h; 15°C) in a heat-sealed polyallomer tube (Beckman) using an angular Beckman 50.2Ti rotor in a Beckman L8-55 ultracentrifuge. The tube was cut with a tube-slicer (Beckman) just under the limit of the lipid cake, which contained TGRP; and the crude mesophase (PLRP and glycerol) was discarded. Lipid cake was resuspended in a KBr solution of $d = 1.006$ g/mL. To isolate a pure fraction of TGRP, the lipid cake was washed by a second ultracentrifugation that was run under the same conditions (20,000 × *g*; 1 h; 15°C). TGRP were then resuspended to the initial volume with a solution of $d = 1.006$ g/mL at a TG concentration of 200 g/L. Moreover, PLRP of each emulsion were separated from a 2-mL sample of the crude mesophase by density gradient ultracentrifugation. The KBr gradient was carried out in Sorvall polyallomer tubes (ref. 03699) (Sorvall Instruments, E.I. du Pont de Nemours & Co. Inc., Wilmington, DE) by successively layering 2 mL of



**SCHEME 1**

crude mesophase, 1 mL of water, 1 mL of solution $d$ = 1.006 g/mL, 4 mL of $d$ = 1.019 g/mL, 2 mL of $d$ = 1.063 g/mL, and 1.9 mL of $d$ = 1.125 g/mL. After ultracentrifugation (24 h; 15°C; 160,000 × $g$) in a swinging-bucket rotor Beckman SW41Ti in a Beckman L8-55 ultracentrifuge, 24 fractions of 0.5 mL were successively needle-aspirated from the top of the tube and assayed for PL content. On the basis of the PL profile in the gradient, the PLRP fraction was isolated.

*Incubation protocol.* LDL (0.58 mg of apo B) or HDL (1 mg of apo A-I) fractions were incubated with various intact emulsions, with TGRP (7 mg of TG), or with PLRP (140 µg of PL) for 4 h in a shaking water bath at 37°C (Scheme 2) in sealed Beckman polyallomer Opti-Seal tubes (ref. 361621). After incubation, two fractions were separated by ultracentrifugation of the incubation mixture (163,000 × $g$; 20 h; 5°C) at the density $d$ = 1.006 g/mL in an angular Beckman 50.4Ti rotor using a Beckman L8-55 ultracentrifuge. The tubes were cut 1.5 cm from the bottom. The M-LE fraction containing TGRP or PLRP was in the supernatant, and modified LDL (M-LDL) or HDL (M-HDL) fraction was in the infranatant.

*Polarization fluorescence studies.* The fractions (intact emulsion, TGRP, PLRP, LDL, HDL, M-LDL, M-HDL, M-LE) were labeled with the classical lipophilic fluorescence probe: 1,6-diphenyl-1,3,5-hexatriene (DPH). In brief, 3 mL of a fresh dispersion of DPH in phosphate-buffered saline (PBS) (pH 7.4, 0.01 M) at a final concentration of $1 \cdot 10^{6}$ M were incubated with 100 µL of LDL, M-LDL, HDL, or M-HDL. Similarly, 10 µL of intact emulsion or TGRP or 40 µL of PLRP or M-LE were incubated, for 30 min at room temperature with constant and gentle agitation. The fluorescence anisotropy $r$ of each sample was obtained from fluorescence measurements with an Aminco SPF 500 spectrofluorometer equipped for fluorescence polarization as previously described (10). Each measurement was performed three times for each sample. Two independent samples were prepared for the intact emulsion, but anisotropy measurements were performed on a single sample for TGRP and PLRP. Our results are directly expressed as anisotropy $r$, which relates to the restriction of the probe movement when embedded in the sample (20). A high value of $r$ corresponds to a high structural order and vice versa (20,21). On the basis of our methodology, repeated $r$ values were within 0.002 of each other. Because analyses were performed on very small amounts of each fraction, we obtained values directly, which did not need correction for light scattering (10).

*Analytical procedures.* Lipid analyses were performed on each fraction. Total cholesterol concentration was determined by the cholesterol esterase–cholesterol oxidase method (CHOD-PAP, Roche Diagnostic, Mannheim, Germany). TG were measured enzymatically using a commercial test kit (triglycerides GPO-PAP, Roche Diagnostic). PL were determined by Bartlett method (22) and total protein was measured as described by Lowry *et al.* (23). Apo B and apo A-I were determined in each fraction using a specific enzyme-linked immunosorbent assay method as previously described (24). All reagents including KBr for density solutions were analytical grade products.

*Statistical analysis.* The results are expressed as mean values ± SEM. Student's unpaired test was used to assess the statistical significance between results obtained with different emulsion fractions and lipoproteins under different conditions. Differences were considered significant at $P \leq 0.05$ level.

## RESULTS

*Decrease of emulsion particle fluidity.* Table 1 shows anisotropy values at 24°C for emulsion particles after incubation with LDL or HDL.

Before incubation with lipoproteins, particles of intact emulsion and TGRP had anisotropy $r$ at 24°C that were less than 0.057; the comparable value for PLRP was 0.130. After

[a]After incubation (4 h; 37°C) of intact emulsions, triglyceride-rich particles (TGRP), or phospholipid-rich particles (PLRP) with low density lipoproteins (LDL) or high density lipoproteins (HDL), M-LE$_{LDL}$ and M-LE$_{HDL}$ fractions were separated by ultracentrifugation (20 h; 5°C; 163,000 × *g*) at *d* = 1.006 g/mL. Fluorescence anisotropy *r* was measured at 24°C in the M-LE fractions. Abbreviations: M-LE, modified lipid emulsion; LCT, long-chain triglycerides; MCT, medium-chain triglycerides; FO, fish oil; MLF, MCT/LCT/FO present in the ratio of 5:4:1, respectively; SEM, standard error of the mean.

incubation with LDL, the mean anisotropy *r* for all LE were increased, from 0.032 to 0.061 for the intact emulsion, from 0.022 to 0.069 for TGRP, and from 0.120 to 0.249 for PLRP. After incubation with HDL, *r* values of all LE also were increased, from 0.032 to 0.065 for intact emulsion, from 0.022 to 0.070 for TGRP, and from 0.120 to 0.234 for PLRP. An increased of *r* indicates a more ordered particle. This result was confirmed by other measurements made in parallel. The emulsion particles acquired proteins and cholesterol and lost TG (Table 2). These composition changes of LE were in the same order of magnitude, whether incubation was carried out with LDL or with HDL. No significant difference was observed between incubation with LDL and with HDL.

*Increase of lipoprotein fluidity.* In plasma, anisotropy values at 24°C of LDL and HDL were, respectively, 0.257 and 0.220. The lipoprotein anisotropy measurements at 24°C (Table 3) showed smaller values for HDL than for LDL, before and after incubation.

After incubation with intact emulsion, *r* values decreased from 0.258 to 0.243 for LDL and from 0.220 to 0.198 for HDL; after incubation with TGRP, *r* values also decreased from a mean of 0.258 to 0.236 for LDL and from 0.222 to 0.204 for HDL; and after incubation with PLRP, from 0.258 to 0.246 for LDL and from 0.220 to 0.212 for HDL. Thus, lipoprotein structural order was decreased. In parallel, lipoproteins had lost proteins and cholesterol and had acquired some TG. No differences were observed in the TG core composition of incubated LE.

Moreover, whichever the emulsion fraction under incubation, no effect was observed on lipoprotein fluorescence anisotropy. HDL were always less ordered than LDL.

*Behavior of various emulsion components.* Anisotropy values at 24°C before and after incubation are shown for emulsion particles and for lipoproteins LDL and HDL in Tables 1 and 3, respectively.

Initial intact emulsion and initial TGRP displayed low anisotropy *r* values (less than 0.060), whereas PLRP had an anisotropy around 0.120. After incubation with plasma lipoproteins, the structural order of emulsion particles was increased. The *r* values of intact emulsion particles were around 0.063; *r* for TGRP were approximately the same as the intact emulsion, and *r* values for PLRP were much higher, between 0.215 and 0.277. Modifications observed for intact emulsions were in the same range as for TGRP. But PLRP anisotropy after incubation had a value similar to lipoprotein ones (0.249 for LDL and 0.234 for HDL). That observation demonstrated that the intact emulsion had the same behavior as TGRP. In contrast, the thermal susceptibility of PLRP was in the same range as that observed for lipoproteins. As far as modifications of physical properties of lipoproteins were concerned, no differences were observed between incubation with intact emulsion, TGRP or PLRP, and each lipoprotein, LDL or HDL.

*Effect of TG core composition of LE.* The role of LE TG core composition was also addressed, as it has been shown that the nature of the acyl chains of TG influences the physical properties of the particle surface. A series of emulsions varying in the nature of their acyl chains were incubated with LDL or HDL fractions. Table 1 shows differences for TG composition of LE after incubation with both LDL and HDL. The structural order of LE containing only very long chain TG (FO) was increased. After incubation, M-LE particles from LCT emulsion were more rigid, with *r* values from 0.026 to 0.073.

**TABLE 2**
**Composition Modifications of Emulsion Particles During Co-incubation[a]**

| | Triglycerides (μg) | | | Total cholesterol (μg) | | | Total proteins (μg) | | |
|---|---|---|---|---|---|---|---|---|---|
| | Initial | M-LE$_{LDL}$ | M-LE$_{HDL}$ | Initial | M-LE$_{LDL}$ | M-LE$_{HDL}$ | Initial | M-LE$_{LDL}$ | M-LE$_{HDL}$ |
| LCT | 7000 | 4221 | 5615 | 68 | 99 | 85 | 8 | 121 | 125 |
| FO | 7000 | 5527 | 5728 | 31 | 185 | 71 | 16 | 179 | 133 |
| Mean ± SEM | 7000 ± 0 | 4874 ± 653 | 5671 ± 56 | 49 ± 19 | 142 ± 43 | 78 ± 7 | 12 ± 4 | 150 ± 29 | 129 ± 4 |

[a]After incubation (4 h; 37°C) of LCT or FO intact emulsions with LDL or HDL, M-LE$_{LDL}$ and M-LE$_{HDL}$ fractions were separated by ultracentrifugation (20 h; 5°C; 163,000 × *g*) at *d* = 1.006 g/mL. Triglycerides, total cholesterol, and total proteins were measured in the M-LE fractions. For abbreviations see Table 1.

**TABLE 3**
**Increase of Lipoprotein Structural Order[a]**

| | M-LDL (initial LDL = 0.258) | | | M-HDL (initial HDL = 0.220) | | |
|---|---|---|---|---|---|---|
| | Intact emulsion | TGRP | PLRP | Intact emulsion | TGRP | PLRP |
| LCT | 0.240 | 0.245 | 0.262 | 0.207 | 0.215 | 0.215 |
| MCT/LCT | 0.243 | 0.220 | 0.230 | 0.190 | 0.195 | 0.203 |
| MLF 541 | 0.243 | 0.230 | 0.247 | 0.200 | 0.195 | 0.217 |
| FO | 0.245 | 0.250 | 0.245 | 0.193 | 0.210 | 0.212 |
| Mean ± SEM | 0.243 ± 0.001 | 0.236 ± 0.007 | 0.246 ± 0.007 | 0.198 ± 0.004 | 0.204 ± 0.005 | 0.212 ± 0.003 |

[a]After incubation (4 h; 37°C) of intact emulsions, TGRP or PLRP with LDL or HDL, modified LDL (M-LDL) and modified HDL (M-HDL) fractions were separated by ultracentrifugation (20 h; 5°C; 163,000 × *g*) at *d* = 1.006 g/mL. Fluorescence anisotropy *r* was measured at 24°C in the M-LDL and M-HDL fractions. For abbreviations see Table 1.

However, the fluidity of lipoprotein fractions did not differ with the nature of the LE present in the incubation mixture (Table 3).

## DISCUSSION

Lipid emulsions used in parenteral nutrition interact with endogenous lipoproteins (4,6). Apart from their role as an energy source, some essential (ω-3 and ω-6) FA are largely incorporated in envelope PL and may markedly influence cell metabolism, with respect to lipid mediator production (25,26) and regulation of energy balance (27). *In vivo,* after their infusion into the blood stream, LE particles (devoid of apo) rapidly acquire several apo species (mainly C and E) by exchange from HDL (3,28). Such transfer, which also occurs spontaneously *in vitro*, is largely related to the physicochemical properties of emulsion particles and does not require any enzymatic mechanism. This transfer is, however, an absolute requirement for TGRP metabolism because it allows hydrolysis of an important part of TG by lipoprotein lipase and regulates the remnant particle uptake by cells in different tissues (4,29,30). To further characterize TGRP behavior in plasma from various kinds of lipid emulsions, an *in vitro* model was developed to address potential interactions of plasma LDL and HDL with artificial lipid particles.

LDL and HDL obtained from healthy human plasma were incubated with LE that differed only in TG composition and were prepared with an identical PL emulsifier. A fixed LE-TG/LDL-apo B or LE-TG/HDL-apo A-I ratio was used. The ratio was defined to ensure TG concentration similar to those currently in use in clinical practice; plasma apo B and apo A-I concentrations corresponded to the mean normal range.

These experiments allowed detection of an effect of the LE-TG core composition on structural order of LE particles after incubation with LDL and HDL. It was also possible to elucidate the role of different components of LE (TGRP and PLRP) in modifying physical properties of LE and LDL or HDL *in vitro*. During incubation of LE in the presence of LDL or HDL, modifications of physical properties and lipid dynamics took place both in emulsion particles and in lipoproteins.

With regard to LE particles, the structural order was increased after incubation in the presence of plasma lipoproteins. Yet, incubated emulsion particles remained less ordered. Moreover, the TG core composition of LE had an effect on the envelope modifications but these changes were of the same order of magnitude after incubation with LDL or with HDL. After incubation under almost physiological conditions, M-LE fractions were found unexpectedly enriched in apo B as well as in CE (11). Apo B cannot freely transfer due to its very large structure deeply anchored in the LDL particle. Each LDL particle possesses only one apo B molecule (12,13). The apo B presence in the M-LE fraction strongly suggests an LDL binding to TGRP. Thus, an association, aggregation, or fusion occurs between LE particles and LDL and accounts for apo B (and at least some CE) enrichment of the M-LE fraction. The LDL binding to LE was thus a specific property of lipid particles that was independent of the separation method and that was influenced by the particular chemical nature of TG in LE (14). An analogous event, i.e., a fusion of a TGRP (so-called nascent chylomicron) with a small apo B-containing particle, was recently described in the formation process of the endogenous chylomicron (31). A similar mechanism could account for apo B (and at least some CE) enrichment of the M-LE fraction. Besides the physical conditions, a number of factors related to the incubation mixture may modulate the formation of the complex. The most trivial ones are emulsion components other than TGRP, i.e., excess emulsifying PL present as liposomes (PLRP) and glycerol added as stabilizing agent. Preliminary observations have indicated that a number of proteins (mainly albumin present in large amounts in plasma) were able to bind to LE in our incubation conditions (32).

Major physical modifications were observed in intact LE and in two types of particles (TGRP and PLRP) that composed it. LE particles (intact, TGRP, and PLRP) were strongly ordered (Table 1) after incubation with lipoproteins. However, composition modifications owing to exchanges were different depending on the presence of LDL or HDL in the incubation mixture. LE envelope structural order changes were of the same order of magnitude in the two cases. Intact LE, which contains TGRP and PLRP, had almost the same behavior as TGRP. The presence of liposomal particles (PLRP) did not influence the intact emulsion behavior. After incubation, two LE containing FO (MLF 541 and FO) showed a higher envelope order, in spite of acquisition by FO of appreciable

amounts of ordering components (cholesterol and proteins). A more interesting issue in relation to the complex formation lies in the nature of FA contained in the TGRP. Striking differences in the modifications of physical properties of emulsions have been observed according to the TG core composition of LE particles. Isolated LDL, apo A-I, apo C, apo E, and other proteins bind far more to long-chain FA-containing emulsions (FO and LCT) than to MCT/LCT. Nevertheless, M-LE particles from FO emulsion remained the less ordered ones. M-LE from LCT emulsion, which also acquired ordering components (but less than FO), had a more decreased structural order. Along with liposoluble vitamins, TG are the main components of the LE particle core. Our results confirm that TG core composition largely affects surface layer properties (33), presumably by modulating the amount and the flexibility of TG dissolved in the PL surface (34). They also suggest that binding processes, whatever the resulting structure of the complex, regulate the physicochemical properties of the particle surface. On the other hand, PLRP, which are made of a PL bilayer, showed an envelope order similar to that of lipoproteins and did not play a significant role in modifications induced by incubations.

With regard to plasma lipoproteins, the magnitude of physical modifications observed was less important than that detected for LE particles. M-LDL and M-HDL were only moderately less ordered. The structural order of lipoproteins was decreased after incubation with emulsion. HDL, after incubation, remained less ordered than LDL, as in the plasma. The TG composition of the emulsion had no effect on lipoprotein modifications. The high order at 24°C obtained for HDL and LDL reflects a strong lipid–protein interaction (35,36). These molecular order modifications, notably in HDL, are susceptible to increased reverse cholesterol transport to the liver. Moreover, the TG nature of emulsions influenced changes in physical properties of emulsion particles but had no significant effect on LDL and HDL. The HDL fluorescence anisotropy *r* value is positively correlated with free cholesterol percentage of HDL and negatively correlated with TG content and TG/PL ratio of HDL (9). No significant correlation was noted with total and free cholesterol, PL, and proteins of HDL. Consequently, a decreased order might be related to the effect of TG in HDL, as previously shown for LDL (37,38). Lipoprotein fluidity may not reflect only the degree of polyunsaturation of the ingested fat (9). Moreover, relations exist between lipoprotein order, diet, and atherogenicity. Tall *et al.* (39) showed that lipoproteins after consumption of an atherogenic diet were more ordered than the lipoproteins after a normal diet. Soutar (40) suggested that the atherogenicity of lipoproteins increased as they became less ordered. This physical property of lipoprotein could be an important factor in the reduced incidence of atherosclerosis observed in populations consuming a "Mediterranean diet," which is rich in olive oil. In the study by Sola *et al.* (9), a diet rich in monounsaturated FA, i.e., the olive oil diet, induced a reduced order of HDL. The order is an important determinant of the capacity of $HDL_3$ to accept cholesterol from the cells. Thus, a decreased order in lipoprotein is suitable for the acquisition of more cholesterol, a well-know rigidifying substance (41). However, a low molecular order may lead to perturbations in lipoprotein functions, for example, alterations of lipoprotein affinity for the receptor or disturbance of interactions with other lipoproteins. According to the optimal fluidity, which inversely relates to the molecular order hypothesis (42), a specific degree of HDL fluidity may exist that favors an optimal HDL capacity to remove cellular cholesterol and therefore to avoid its accumulation. These modifications could alter the HDL and LDL spatial configuration, induce changes in the apo configuration at the surface of these lipoproteins, and alter the interactions between different lipoproteins or between lipoproteins and cells.

Besides strictly physicochemical interactions, other plasma factors may play a role in the interplay between lipoproteins and emulsion components. Just like chylomicrons, TGRP can transfer TG and accept CE during exchange with LDL (7,43,44). These neutral lipid exchanges are influenced by CETP concentration (5,45). These physical modifications could induce more efficient exchanges between emulsion particles and lipoproteins and so influence metabolism of these different exogenous and endogenous particles.

## ACKNOWLEDGMENTS

We dedicate this paper to the memory of Jean-François Lontie, Ph.D. We would like to express our appreciation to Françoise Conan for her excellent technical assistance. The emulsions were kindly provided by B. Braun (Melsungen, Germany). Nathalie F. Chanson was supported by a CIFRE fellowship by B. Braun Medical.

# Comparative Studies on Individual Isomeric 18:1 Acids in Cow, Goat, and Ewe Milk Fats by Low-Temperature High-Resolution Capillary Gas–Liquid Chromatography

**Dietz Precht[a], Joachim Molkentin[a], Frédéric Destaillats[b], and Robert L. Wolff[b,*]**

[a]Bundesanstalt für Milchforschung, Kiel, Germany, and [b]Institut des Sciences et Techniques des Aliments de Bordeaux, Talence, France

**ABSTRACT:** The *trans*- as well as the *cis*-18:1 isomer profiles were established in cow, goat, and ewe cheese fats, with the assumption that these are representative of the corresponding milks. Argentation thin-layer chromatography was combined with low-temperature high-resolution gas–liquid chromatography on 100-m highly polar capillary columns, thus adding precision to earlier data for these species. Despite differences in the absolute content of *trans*-18:1 isomers between species, the relative profiles were essentially similar. Except for the minor *trans* Δ6–Δ8 group, all *trans*-18:1 isomers with their ethylenic bonds between positions Δ4 and Δ16 (including the resolved critical pair Δ13/Δ14) were separated and quantitated individually. As expected, vaccenic (*trans* Δ9-18:1) acid was the main isomer, accounting for as much as 37 to 50% of the total fraction. It was observed that the goat *trans*-18:1 isomer profile was usually rather close to that of cows in winter (barn feeding), whereas that of the ewe shows a seasonal dependence. The *trans*-18:1 profile of ewe milk fats from this study resembles that of cows in the transition period between winter and summer (pasture) feeding. Regarding the *cis*-18:1 acid fraction, two isomers (oleic and *cis*-vaccenic acids) accounted for *ca.* 97% of that fraction for the three species, with the *cis*-Δ12 isomer ranked third. The analytical procedure employed here appears a convenient alternative to oxidative-based procedures (generally ozonolysis), taking less time and alleviating some drawbacks of the latter procedure.

Paper no. L8750 in *Lipids 36,* 827–832 (August 2001).

As a result of earlier studies on the daily *trans*-18:1 acid consumption by European populations (1,2), it is well known that ruminant fats [mainly from dairy products (80–90%) and secondarily from meat fat and tallow (10–20%)] can constitute the main dietary source of *trans*-18:1 acids in many countries. A wealth of data has been published on the content and distribution of these isomers in cow milk fat, mostly by authors Precht and Molkentin (3–7) and Wolff (1,2,8), and these were recently reviewed in a book chapter (9) on natural edible sources of dietary *trans* fatty acids. On the other hand, ewe and goat milk fats are less well-documented, but useful data are available in the same chapter (9) and elsewhere (2). Also, important analytical data are to be found in an early paper by Bickerstaffe *et al*. (10) for goat milk fat.

To complete our knowledge on the distribution profile of *trans*-18:1 isomers in cow, goat, and ewe milk fats, we adopted for the present study a procedure that combines an argentation thin-layer chromatography (Ag-TLC) step with gas–liquid chromatography (GLC) on 100-m cyanopropyl-polysiloxane coated capillary columns operated under optimal temperature and carrier-gas pressure conditions. In France, cheeses are always manufactured with a single kind of milk. Cheeses were chosen because goat and ewe milks are almost exclusively employed for cheese processing. In all instances, total fatty acids starting with 4:0 acid were quantitated using a polyethylene-glycol coated 25-m capillary column, as well as polyunsaturated $C_{20}$ and $C_{22}$ acids (not reported here). *Trans*-18:1 acids were freed from overlapping *cis*-18:1 isomers, and from early-eluting isomeric 18:2 acids, thus ensuring reliable and accurate quantitative data. When the temperature of the columns is sufficiently low (e.g., 120°C is "low-temperature" GLC), base-line resolution is obtained for most individual *trans*-18:1 isomers, i.e., for the Δ4, Δ5, Δ9, Δ10, Δ11, Δ12, Δ15, and Δ16 isomers. The Δ6 to Δ8 isomers (minor), however, remain unresolved, whereas the Δ13 and Δ14 isomers are resolved with $R \approx 1$.

Data obtained under such conditions for the fat from French cow, ewe, and goat cheeses (12 samples each) were compared with earlier less well-detailed values for similar food categories (4,9). Differences among the three species are shown to be apparently species-dependent and are in fact most probably linked to the feed of the animals (abundance and nature of polyunsaturated acids in the feed). Data for ruminant fats may be compared with those for partially hydrogenated vegetable oils recently published for French processed foods (11). Also included in the present study are data for individual *cis*-18:1 positional isomers, not reported previously for goat and ewe milk fat.

## EXPERIMENTAL PROCEDURES

*Samples*. Three lots each of 12 different cheeses made with cow, goat, or ewe milks (produced in several regions of France) were purchased locally in supermarkets near Bordeaux (France) in May–June 1999. Genuineness of the samples was

Abbreviations: Ag-TLC, argentation thin-layer chromatography; FAME, fatty acid methyl ester; FFA, free fatty acid; GLC, gas–liquid chromatography; HPLC, high-performance liquid chromatography; TMSH, trimethyl sulfonium hydroxide.

ascertained by establishing the ratios of 12:0/10:0 acids (2). In this study, it was assumed that cheese fat fatty acids are representative of milk fat fatty acids, as milk fat globules are retained in the cheese matrix during cheese processing.

*Fat extraction*. Cheese fat was extracted according to Wolff *et al*. (8) using isopropanol and hexane. Representative portions of the cheeses (*ca*. 40 g) were homogenized in a mortar with a pestle, and 5 g of the homogenates were dispersed in 10 mL of isopropanol in a Teflon beaker with an Ultraturrax T25 (Janke & Kunkel GmbH & Co. KG, Staufen, Germany) before adding a sufficient amount of anhydrous $Na_2SO_4$ and 15 mL of hexane and performing a second dispersion with the Ultraturrax. The suspension was then filtered on a glass column containing a lower layer of anhydrous $Na_2SO_4$ and an upper layer of Celite 545 (*ca*. 2 cm in height each). The lipid solution was eluted three times successively with 25-mL portions of hexane/isopropanol (3:2, vol/vol) and collected in a 250-mL flask. After removal of the solvents in a rotary evaporator at 45°C, the fat was weighed and transferred into 5-mL vials and stored at 4°C until used.

*Fatty acid methyl ester (FAME) preparation*. To choose a suitable transesterification method, FAME were prepared from cheese fat samples with particularly high content of free fatty acids (FFA) using trimethyl sulfonium hydroxide (TMSH) as well as sodium methoxide. However, the results showed that the fatty acid composition was not significantly influenced by the present FFA contents. As compared to the TMSH method, the sodium methoxide method was found to be more accurate and reproducible. FAME were prepared by vigorously shaking for 3 min a mixture of 1.2 mL *n*-heptane, 0.3 mL of a 10% fat solution in *n*-heptane, and 30 µL of a 2 N sodium methoxide solution in methanol. After centrifugation, the supernatant was directly used for GLC analysis. For Ag-TLC, a 20% fat solution was used. The fat solutions used for FAME fractionation by Ag-TLC were obtained by blending equal amounts of fats from each of the 12 cheeses from a given species. Data reported here for individual isomeric 18:1 acids are thus for composite samples.

*Fractionation of FAME by Ag-TLC*. FAME were fractionated according to the number and geometry of double bonds by TLC on silica-gel plates impregnated with $AgNO_3$. The plates were prepared by immersion in a 20% aqueous solution of $AgNO_3$ as described by Precht and Molkentin (3). The developing solvent was the mixture *n*-heptane/diethyl ether (90:10, vol/vol). At the end of the chromatographic runs, the plates were briefly air-dried, lightly sprayed with a solution of 2′,7′-dichlorofluorescein, and viewed under ultraviolet light (234 nm). The *trans*- and *cis*-monoenoic acid bands were scraped off separately and eluted several times with diethyl ether. Complete evaporation of the combined eluates of each fraction was achieved with a light stream of $N_2$. The residues were dissolved in an appropriate volume of *n*-heptane for further GLC analysis.

*Analysis of FAME by GLC*. The total fatty acid composition covering *ca.* 70 fatty acids in the range 4:0 to 24:0, including all polyunsaturated fatty acids, was determined by GLC analysis of the methyl esters prepared from each individual cheese sample on a CP 9001 chromatograph (Chrompack, Middelburg, The Netherlands) equipped with a split injector (split ratio, 1:50) and a flame-ionization detector, using a 25-m capillary CP-Wax 58 CB column (0.25 mm i.d., 0.20 µm film thickness; Chrompack). The operating conditions were as follows: $H_2$ as the carrier gas at an inlet pressure of 40 kPa; injector and detector temperature, 265°C; and oven program of 50°C for 1 min, then 5°C/min to 225°C, 15 min isothermal, and finally 5°C/min to 260°C. Calibration of the individual fatty acids was achieved using the reference butterfat CRM 164.

Analyses of the *cis*- and *trans*-18:1 isomers in total FAME as well as in 18:1 isomer fractions isolated by Ag-TLC were performed using a gas chromatograph CP 9000 (Chrompack) with a split injector, a flame-ionization detector, and a fused-silica capillary column (100 m × 0.25 mm i.d.) coated with 0.20 µm CP-Sil 88 (Chrompack) under the following conditions: $H_2$ as the carrier gas; injector temperature 255°C; and detector temperature 280°C. The unfractionated FAME were analyzed isothermally at 172°C with a column head pressure of 160 kPa (split ratio, 1:50). Monoenoic TLC fractions were analyzed isothermally at a lower temperature, 120°C, with a column head pressure of 220 kPa (split ratio, 1:25) (5,12). Under these conditions, elution of *cis*- as well as *trans*-18:1 isomers was achieved in approximately 3.5 h.

The calibration of positional isomers of *trans*-18:1 acids present in the *trans*-monoenoate fraction was achieved with the isomer *trans* Δ11-18:1 that was quantitated by stearic acid in the isothermal chromatography of the unfractionated FAME on the CP-Sil 88 column. Before, stearic acid was determined by total FAME analysis on the CP-Wax 58 CB column. Further, *cis*-18:1 isomers found in the *cis*-monoenoate fraction were calibrated by *cis* Δ11-18:1 acid that could be determined in the isothermal chromatogram of unfractionated FAME. The high content of *cis* Δ9 was calculated from the unfractionated FAME subtracting the overlapping *trans* Δ13/Δ14 and *cis* Δ6-Δ8 isomers.

Identification of individual isomeric *cis* and *trans* octadecenoates was achieved by comparison of retention times with FAME standards of the 18:1 isomers Δ6, Δ7, Δ9, Δ11, Δ12, Δ13, and Δ15 (Sigma, St. Louis, MO,). *Trans*-18:1 acids isolated from butterfat were used as a secondary standard (2,3). Integration and quantitation were accomplished with an HP 3365 II ChemStation system (Hewlett-Packard, Palo Alto, CA). Calibration of GLC data included the conversion from FAME to FFA. Thus, results expressing absolute concentrations are given as g/100 g of total fatty acids.

## RESULTS AND DISCUSSION

In earlier studies on the distribution profile of *trans*- and *cis*-18:1 isomers in ruminant milk fats, except for data obtained by oxidative cleavage and further GLC analysis of the resulting fragments (10,13,14), GLC analyses of these isomers on 50-m columns allowed only partial insight into the pattern of individual isomers. The Δ6–Δ9 isomer group was largely

unresolved, as were the Δ10/Δ11 and the Δ13/Δ14 pairs. Shoulders could be observed in some instances, but their accurate quantitation was questionable (1–3,5,9,15). Since 1995 (16,17), the use of 100-m columns has permitted some improvements in their separation (i.e., the Δ6–Δ8 isomer group from the Δ9 isomer, and the Δ10 from the Δ11 isomer). A further improvement was obtained by greatly decreasing the oven temperature to 125 or 120°C, allowing resolution of the critical Δ13/Δ14 isomers pair (4,5). Improvements in the resolution *R* were due to an increase of both the column length *L* and the capacity factor *k′*, as well as the selectivity factor α that is known to vary with the temperature. Separation of the Δ13/Δ14 isomers pair is remarkable, as these two acids have equivalent chain lengths determined on both 50- and 100-m CPSil 88 capillary columns measured with authentic standards at 160°C that differ by no more than 0.01 carbon unit (Wolff, R.L., and Destaillats, F., unpublished results). An apparent drawback is a considerable increase in the time of analysis (*vide infra*). Despite this enhanced resolution, fractionation of *cis*- and *trans*-monoenoic acids is still a prerequisite to their accurate measurement because of unavoidable overlaps between some components of these two fractions, i.e., when direct GLC of FAME is used.

A typical chromatogram showing the resolution obtained with *trans*-18:1 isomers prepared from ewe cheese fat is shown in Figure 1, and Table 1 gives the relative proportions of all individual *trans*-18:1 isomers (except for the Δ6–Δ8 group) in cow, goat, and ewe cheese fats. As expected, genuineness of cheese samples was confirmed by the 12:0/10:0 acids ratios: cow, 1.11; goat, 0.45; and ewe, 0.57, which compare well with earlier data (2). The total contents of *trans*-18:1 acids were 4.5, 3.1, and 4.9% of total fatty acids, respectively. For the latter two species, data obtained in the present study are in fairly good agreement with previous data for the same species, 2.7 and 4.5% (2), respectively. Our data for goat milk fat, which are the lowest among the three species studied, are close to those reported for goat milk from Spain by Alonso *et al.* (18), 2.1%. As expected, the value for cow cheeses is close to the value for French spring butterfats (4.3%) (8). Considerably lower values are reached in winter (barn-feeding), *ca.* 2.4% (8) or 2.7% (4). This supports the well-known observation that grass, likely because of its high α-linolenic acid content, is the main factor that affects accumulation of *trans*-18:1 acids in milk fat. In France, goats are mostly barn-fed, whereas sheep are pasture-fed, as are cows in spring.

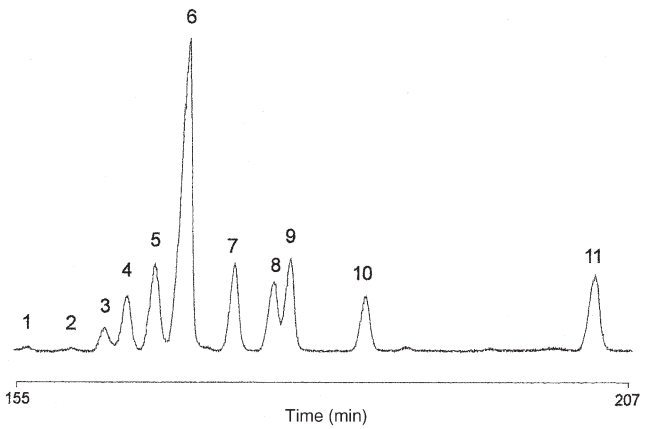

**FIG. 1.** Representative chromatogram of *trans*-isomeric octadecenoic acid methyl esters prepared from ewe cheese fat and fractionated by argentation thin-layer chromatography prior to analysis by low-temperature capillary gas–liquid chromatography on a 100-m CP-Sil 88 capillary column (Chrompack, Middelburg, The Netherlands; isothermal at 120°C, with $H_2$ as the carrier gas at an inlet pressure of 220 kPa). Peak numbering as in Table 1.

[c]Values established with composite samples (see Experimental Procedures section).

As a matter of comparison with most recent and extensive studies of cow milk fat in European countries, our data are between the values for the transition period in spring (3.8%; 236 samples) and the pasture-feeding period (5.08%; 593 samples) determined by Precht and Molkentin (4) for a large area of milk collection in Germany. The mean annual value for German butterfat (1756 samples) is 3.6% (3). However, our average *trans*-18:1 content for French cow cheese fats is similar to the annual mean content determined by the same authors (3) for milks collected in all other European countries (4.2%; 111 samples). These geographical variations are likely indicative of different climatic conditions and, thus, of different rearing habits in the countries considered (duration of pasture feeding vs. barn feeding). On the other hand, the present data and those quoted in the preceding references are significantly higher than those reported in the industry-sponsored TRANSFAIR study (19) covering 14 western European countries, for which a mean geographical content of 2.7% can be calculated. This discrepancy arises from differences in analytical procedures. In the TRANSFAIR study, *trans*-18:1 isomers were assessed by direct GLC runs, without Ag-TLC prefractionation. This procedure is known to give access only to the Δ4 to Δ11 isomers, with the Δ12 to Δ16 isomers masked by oleic and *cis*-vaccenic acid or even eluting after them (3). If we take as a reference the data from Precht and Molkentin (3) for European countries, established with the combined Ag-TLC/GLC procedure, a correction factor of 1.56 should be applied to data from the TRANSFAIR study, which consequently appear to

be underreporting by *ca*. 35%. This mean correction factor is exactly the same as that established for approximately 2,000 samples of milk or butterfat based on chromatographic considerations and taking into account seasonal as well as geographical variations (15). However, this correction factor can by no means be used to correct data for individual samples of ruminant fats, as it varies with the feed of the cattle (15).

It is common knowledge that vaccenic acid, the *trans*-Δ11 18:1 isomer, is the main constituent of *trans*-18:1 acids in ruminant fats. This acid was named from the Latin *vacca*, cow, by Bertram (20), who characterized it structurally for the first time in beef and sheep tallow as well as in butterfat as early as 1928. Here, it varies between 37 and 50% of the total fraction, depending on the species. The second main *trans*-18:1 isomer is either the Δ10 or the Δ16 isomer. The latter acid is frequently and unjustifiably ignored, though it is not negligible (between 8 and 9% of the *trans*-18:1 isomer group). In principle, this acid can be detected by single GLC analysis, as it is the only *trans*-18:1 isomer that elutes after *cis*-vaccenic acid, with the structure *cis* Δ11-18:1. This is due to a considerable retardation during GLC as compared to other isomers. However, quantitation of the Δ16 *trans* isomer by single GLC is impaired by an overlap with the *cis* Δ14-18:1 isomer. Some older papers already reported on this isomer (21) identified on chromatograms of total FAME. In partially hydrogenated vegetable oil, the *trans*-Δ16 18:1 isomer represents on average only 1% of total *trans*-18:1 acids (11,22). In fact, more than 90% of the *trans*-18:1 acid fraction in ruminant fats have their ethylenic bond between positions Δ9 and Δ16.

Within the *trans* Δ13/Δ14 pair, which can be resolved only under low-temperature conditions, the Δ14 isomer appears to be present in slightly higher amounts than the Δ13 isomer. This holds for the three species considered (Table 1). Unfortunately, even under such conditions, the group *trans* Δ6–Δ8 remains unresolved, but its total is rather low (5–7%). Parodi (14) found five times as much *trans*-Δ8 18:1 acid compared to *trans*-Δ6 or *trans*-Δ7 18:1 acids in butterfat using ozonolysis, and this may be the real reason for the lack in resolution. It is worth noting that elaidic (*trans*-Δ9 18:1) acid, the main *trans*-18:1 isomer in PHVO (11,22), is present in considerably lower amounts in ruminant milk fats, as it represents on average only 4 to 7% of total *trans*-18:1 acids.

In Table 2, data from the present study are compared with earlier data also obtained by the combination Ag-TLC/GLC, but employing a shorter (50-m) CP-Sil 88 capillary column. On this kind of column, the Δ6–Δ9 group and the Δ10/Δ11 and Δ13/Δ14 pairs of *trans*-18:1 isomers are not resolved. So, data from the present study are summed as a matter of comparison with earlier data from France (9). Two remarks can be made. The first one relates to the good reproducibility of data for goat and ewe milk fats, despite an interval of 5 yr between the two studies and some differences in the experimental procedures (e.g., 100- vs. 50-m columns, FAME instead of fatty acid isopropyl esters, different integration apparatuses). There is an obvious resemblance between milk fat from cows reared in winter and goat milk fats. This is attributable to the fact that goats in France are mostly kept in barn throughout the whole year. Second, the *trans*-18:1 acid isomeric profile of the ewe cheese fats from this study resembles that of cow milk fat from the transition period in Germany (1997) or from March in France (1995) as well as that of the present cow cheese samples. However, the ewe milk fats from 1995 are similar to cow milk fats from the pasture feeding period in France (1995) as well as in Germany (1997). In particular, the Δ10/Δ11 pair is within the narrow range 45–48% in cow milk in March and in goat milk, whereas it is about 10% more in cow milk in spring as well as in ewe milk (range 56–58%; Table 2). From this it can be inferred that the similar *trans*-18:1 isomer profile for cows and ewes likely results from similar feeding regimens and thus may vary throughout the year. The simultaneous course of *trans*-18:1 isomer profiles for cows and ewes results from a similar keeping of the species, different from goats. Similarities between ewes and cows can also be recognized from the absolute contents of *trans*-18:1 isomers shown in Figure 2. Among these fats originating all from the same season, ewe and cow milk fats exhibit almost the same content of *trans*-vaccenic acid (2.0%), while goat milk fat contains only one-half that quantity, 1.0%.

The *cis*-18:1 acid fraction is less complex than its *trans* counterpart, with only seven peaks (Fig. 3), of which those

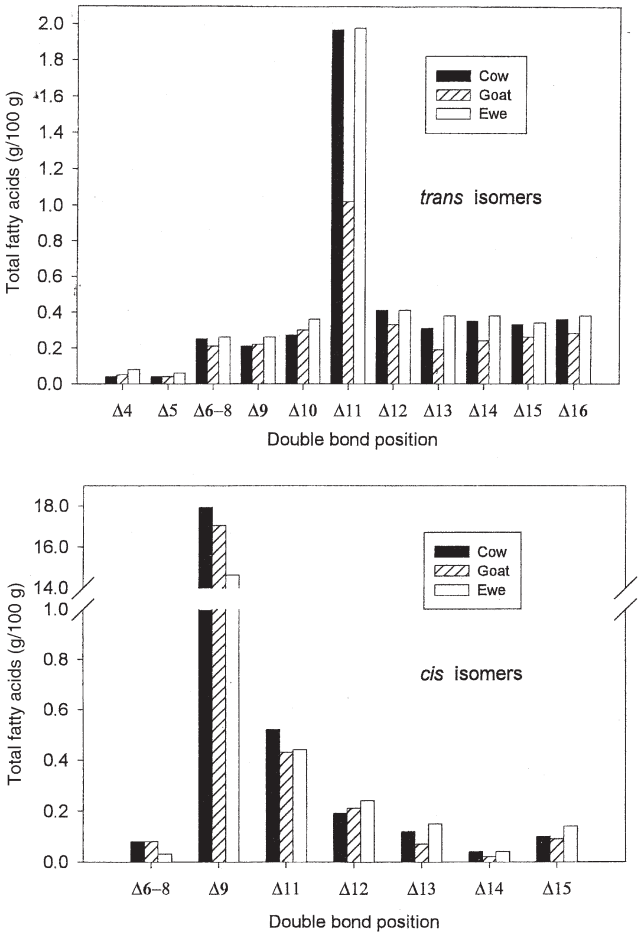

**FIG. 2.** Comparison of the absolute distributions of *trans*- and *cis*-octadecenoic acids (wt% relative to total fatty acids from 4:0 to 22:6n-3) in cow (black bars), goat (hatched bars), and ewe (open bars) cheese fats.

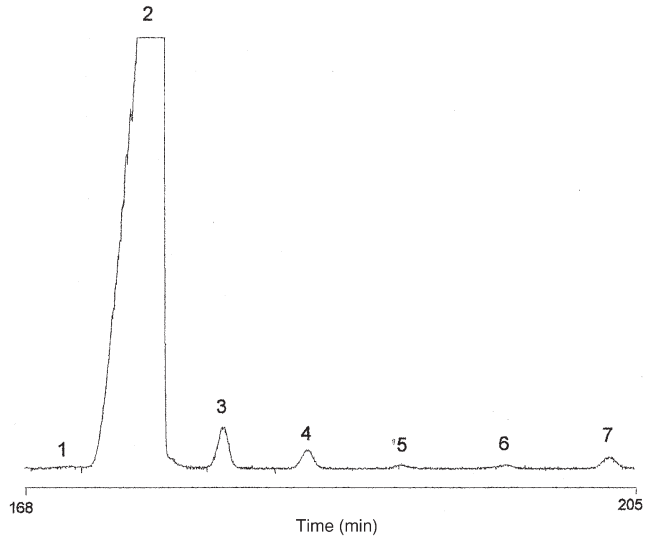

**FIG. 3.** Representative chromatogram of *cis*-isomeric octadecenoic acid methyl esters prepared from ewe cheese fat and fractionated by argentation thin-layer chromatography prior to analysis by low-temperature high-resolution gas–liquid chromatography on a 100-m CP-Sil 88 capillary column (same commercial source and operating conditions as in Fig. 1). Peak numbering as in Table 3.

corresponding to oleic and *cis*-vaccenic acids account for about 97% of the total fraction (Table 3). Other components are the Δ6–Δ8, and Δ12 to Δ15 isomers, most often each less than 1% of total *cis*-18:1 acids. The *cis* Δ6–Δ8 peak that elutes before oleic acid is of minor importance but slightly interferes with *trans* Δ13/Δ14-18:1 isomers during direct GLC analyses of FAME without prefractionation by Ag-TLC. Similarly, the *cis* Δ14-18:1 isomer interferes with the *trans* Δ16-18:1 isomer (results not shown). The *cis* Δ15-18:1 isomer is possibly derived from α-linolenic acid by biohydrogenation (23). Much more than for *trans*-18:1 acids, the relative *cis* isomer profiles do not seem to be species-dependent (Table 3).

In an earlier paper (2), it was noted that ewe and goat milk fats may not be negligible as a source of dietary *trans*-18:1 acids in those countries where cow rearing is not easily feasible, in particular in some Mediterranean countries (e.g., Greece) or regions. Whether data established in France can be extrapolated to such countries, however, remains to be established. We are aware of only one study on goat milk fat comparable to ours, that from Alonso *et al.* (18), who also employed the Ag-TLC/GLC procedure with a 100-m capillary CP-Sil 88 column. However, in that study, the operating conditions led to chromatograms similar to those obtained with 50-m columns, and integration might not have been perfect. Nevertheless, the total *trans*-18:1 isomer content was similar to, though slightly lower than, that reported in the present study.

Regarding the procedure for isomer profiling described here, it compares advantageously with ozonolysis-based procedures and requires less equipment. In the latter procedure, an argentation chromatography is also a prerequisite for further analysis. However, if the sample contains both *trans*-16:1 and -18:1 acids, as in ruminant fats (or other *trans*-monoenes, as in partially hydrogenated fish oils), a supplementary step is necessary to fractionate monoenoates as a function of their chain length: either by preparative GLC, or by reverse-phase high-performance liquid chromatography (HPLC). The purified fractions then have to be ozonolyzed, prior to GLC of the resulting fragments. Drawbacks of that procedure are: (i) dubious quantitative extraction of all fragments from the ozonolyzis medium, (ii) loss of the more volatile molecules

[c]Values established with composite samples (see Experimental Procedures section).

during any solvent evaporation step, and (iii) application of specific response factors for each fragment. With the Ag-TLC/GLC procedure, including low-temperature GLC, these drawbacks are avoided. The *trans*-16:1 as well as the *trans*-18:1 isomers can be determined during the same GLC run, evaporation will not lead to any loss, and no response factors are needed. Even if the time of analysis is about 3.5 h, there are no extra manipulations except for the Ag-TLC fractionation step. If the absolute contents are to be calculated, an additional analysis of the total FAME composition, common to both procedures, has to be performed. The equipment and supplies needed for the Ag-TLC/GLC are standard in most laboratories and there is no requirement for an HPLC and an ozonizer. The Ag-TLC/GLC procedure thus is a relatively fast and economical means of analysis of individual *trans*-monoenoates. Except for the minor Δ6–Δ8 group, data for individual isomers are thought to be more accurate and reliable than those obtained using ozonolysis.

Finally, it should be added that columns different from the CP-Sil 88 can be used, as well as derivatives of fatty acids other than FAME [isopropyl esters (8,16), or 4,4-dimethyloxazoline derivatives (24,25)].
