**ABSTRACT:** The aim of the present study was to compare the effects of a low-fat diet enriched with oleic acid to those of a low-fat diet enriched with linoleic acid on fasting lipids, postprandial lipemia, and oxidative susceptibility of low-density lipoprotein (LDL) in patients with type 2 diabetes mellitus (DM). In a 3-wk randomized crossover study, eight patients with type 2 DM were given an experimental low-fat diet enriched with either oleic acid or linoleic acid. The oleic-acid-enriched diet contained 5, 15, and 5% energy from saturated, monounsaturated, and polyunsaturated fatty acids, and the linoleic-acid-enriched diet contained 5, 5, and 15% energy from saturated, monounsaturated, and polyunsaturated fatty acids, respectively. In addition to evaluating the fasting lipids and oxidative susceptibility of LDL, we evaluated postprandial lipemia using an oral fat load at the end of each 3-wk dietary phase. There were no significant differences in fasting lipid profile or lag time of LDL oxidation between the two experimental dietary phases. The average and maximal increments of remnant-like particle (RLP) cholesterol levels during oral fat load were significantly higher after the oleic-acid-enriched dietary phase than after the linoleic-acid-enriched dietary phase. The area under the curve of RLP cholesterol was also significantly larger after the oleic-acid-enriched dietary phase than after the linoleic-acid-enriched dietary phase. These results suggest that the oleic-acid-enriched diet was associated with increased formation of postprandial chylomicron remnants compared with the linoleic-acid-enriched diet.

Paper no. L8612 in *Lipids 36*, 1–6 (January 2001).

Postprandial lipemia is a potential risk factor for atherosclerosis that has been reported to be enhanced in patients with coronary heart disease (CHD) or diabetes mellitus (DM) (1–4). In particular, intestinal chylomicron remnants, which increase in circulating blood after fat intake, are thought to be atherogenic lipoproteins (5–9). Recently, these remnants have been reevaluated as remnant-like particles (RLP) that are not bound to immunoaffinity-mixed gels containing apolipoprotein (apo) A-I and apo B-100 monoclonal antibodies (10). Clinical studies using RLP have reported that RLP cholesterol in the fasting state is associated with atherosclerosis (11–13). RLP cholesterol has been known to increase in the postprandial state, so it is a useful and suitable marker of remnant lipoproteins after an oral fat-loading test (14). Nakamura *et al.* (15) reported that responses of RLP cholesterol after an oral fat load in CHD patients were higher than those in control patients with similar fasting lipid profiles. It is possible that optimizing diet reduces RLP cholesterol after a fat load could have beneficial effects in vascular disease.

The importance of dietary therapy in patients with type 2 DM is well known. Recent studies have suggested that oleic acid has several beneficial effects, such as decreasing low density lipoprotein (LDL) cholesterol without decreasing high density lipoprotein (HDL) cholesterol and providing protection from oxidation of the LDL particles (16–18). However, we previously reported that postprandial chylomicron remnants increase after an olive oil load compared to milk fat or safflower oil loads among healthy men using the measurement of RLP as intestinal chylomicron remnants (19). A high monounsaturated fatty acid-enriched diet is reportedly not preferable to a high-carbohydrate diet in patients with type 1 DM with regard to the occurrence of postprandial lipemia (20); however, it has been unclear whether this is also true for patients with type 2 DM.

In the Japanese population, the percentage of total daily calories from fat is lower than 30%, a lower percentage than most Western diets. To date, how various compositions of fatty acids in relatively low-fat diets might affect fasting and postprandial lipoproteins has been unclear. In the present study, we investigated the effects of oleic-acid-enriched and the linoleic-acid-enriched low-fat diets on fasting, postprandial lipemia, and susceptibility to LDL oxidation in patients with type 2 DM.

## MATERIALS AND METHODS

*Subjects*. We studied eight patients (two men and six postmenopausal women; mean age: 62.0 ± 6.9 yr; mean body mass index: 24.7 ± 2.5 kg/m$^2$) who were admitted to our hospital for control of hyperglycemia. The mean ± SD of fasting glucose, glycosylated hemoglobin, total cholesterol, triglyceride (TG), and HDL cholesterol levels were 170 ± 58 mg/dL, 8.8 ± 0.9%, 5.28 ± 0.78 mmol/L, 1.52 ± 0.40 mmol/L, and

Abbreviations: apo, apolipoprotein; AUC, area under the curve; CHD, coronary heart disease; DM, diabetes mellitus; FFA, free fatty acid; HDL, high density lipoprotein; HPLC, high-performance liquid chromatography; LDL, low density lipoprotein; LPL, lipoprotein lipase; LPO, lipid peroxidation; PBS, phosphate-buffered saline; RLP, remnant-like particles; TG, triglyceride.

1.14 ± 0.18 mmol/L, respectively. Four of the subjects were taking sulfonylureas, but none of the subjects was taking other medications that affect lipoprotein metabolism before or throughout the present study. All subjects gave written informed consent for participation in the present study. The experimental protocol was approved by the Ethical Committee of the National Defense Medical College of Japan.

*Experimental protocol.* A randomized crossover design was used with patients following each of the two experimental diets for 3 wk following admission to our hospital. The experimental diets consisted of 25, 58, and 17% energy from fat, carbohydrate, and protein, respectively. The oleic-acid-enriched diet contained 5, 15, and 5% energy from saturated, monounsaturated, and polyunsaturated fatty acid, and the linoleic-acid-enriched diet contained 5, 5, and 15% energy from saturated, monounsaturated, and polyunsaturated fatty acid, respectively. All food was prepared in the nutritional department of the National Defense Medical College Hospital. The number of calories and the amounts of cholesterol and fiber were about the same in both diets. All participants remained in the hospital during the experiment, and they consumed only food that was supplied. The total calories consumed and the amount of exercise each patient performed were continued and were not changed during the experiment.

To evaluate postprandial lipemia, all subjects underwent an oral fat-loading test after a 12-h fast at the end of each 3-wk dietary phase. The test drink was 25 g/$m^2$ body surface area of bovine milk fat emulsion (Fresh Cream; Meiji Milk Co., Tokyo, Japan) and 20 g/$m^2$ body surface area of sucrose. Blood samples were drawn before and at 2, 3, 4, 5, and 7 h after ingestion of the test drink. TG and RLP cholesterol levels of all samples were measured as markers of postprandial lipemia. Intake of food or drink was prohibited throughout the postprandial study. On another day, subjects received an intravenous injection of heparin (30 IU/kg body wt) after an overnight fast. A blood sample was collected 15 min later for determination of post-heparin lipoprotein lipase (LPL) mass.

*Biochemical analysis.* Blood was collected in tubes containing a final concentration of 0.1% EDTA. Plasma was immediately separated by centrifugation (2,000 rpm) for 20 min at 4°C. The analysis of TG, total cholesterol, and HDL cholesterol was performed using an enzymatic method (Determiner L; Kyowa, Tokyo, Japan). RLP particles were isolated from other lipoproteins as the unbound fraction in immunoaffinity mixed gels containing monoclonal apoA-I and apoB-100 antibodies within 48 h, following the method of Nakajima *et al.* (10). In brief, 5 μL of plasma was added to the mixture of 50 μL of CNBr Sepharose 4B (Amersham Pharmacia Biotec, Tokyo, Japan), which contained 125 μg of anti-apoA-I monoclonal antibody, 125 μg anti-apoB-100 antibody (JI-H), and 300 μL of reaction suspension. The mixture was shaken gently for 60 min to mix and then allowed to sit for 10 min. Thirty microliters of clear supernatant was taken, and the cholesterol level of RLP was determined enzymatically. Lipid peroxidation (LPO) in plasma was determined by using a commercially available kit (Determiner LPO; Kyowa) of a leukomethylene blue derivative with lipid peroxides in the presence of heme compounds. The oxidative susceptibility of LDL was evaluated by the modified method of Esterbauer *et al.* (21). LDL, adjusted to 50 μg protein/mL with phosphate-buffered saline (PBS), was incubated with 2 mmol/L $CuSO_4$ in PBS (final volume, 2 mL) at 37°C. Conjugated diene formation during LDL oxidation was monitored by changes in absorbance at 234 nm in a spectrophotometer (Shimadzu 160A; Shimadzu, Tokyo, Japan) equipped with a six-position automatic changer. The lag time of LDL oxidation was defined as the intercept of the tangent of the slope in the absorbance curve during the propagation phase. The LPL mass of post-heparin plasma was determined by sandwich enzyme-linked immunosorbant assay (Markit F LPL; Dainippon, Osaka, Japan). Plasma fatty acid composition was determined by gas chromatography (22). Plasma glucose and free fatty acid (FFA) levels were measured enzymatically, and insulin level was determined by radioimmunoassay (23). Vitamin E in LDL was determined by high-performance liquid chromatography (HPLC). In brief, LDL was precipitated with ethanol, and vitamin E was subsequently extracted with hexane. The hexane phase was evaporated under $N_2$ gas and the residue dissolved in ethanol. Vitamin E was separated by reversed-phase HPLC on C18 columns (TSK gel ODS-80Ts; Tohso, Tokyo, Japan) that were eluted with ethanol/distilled water (92:8, vol/vol) at 1.0 mL/min as the mobile phase and monitored at 295 nm in an ultraviolet detector (UV-8000; Tohso).

*Statistical analysis.* Statistical analyses were carried out using the Macintosh for Expert StatView 5.0 software. The fasting values between the pre-experiment levels and those detected at the end of each 3-wk dietary phase were compared by paired *t*-test. The fasting and postprandial values at the end of each 3-wk dietary phase were compared by repeated measures analysis of variance. The average level, maximal increment, and area under the curve (AUC) of TG and RLP cholesterol between groups during a fat load were compared by paired *t*-test. Values of $P < 0.05$ were considered significant.

## RESULTS

*Fasting parameters*. The total calories, amount of exercise, and medication dose(s) for each patient did not change throughout the study, and all subjects completed this experiment with good compliance. The change of fatty acid composition after each dietary phase is shown in Table 1. The percentage of 18:1n-9 in total fatty acids after the oleic-acid-enriched dietary phase and that of 18:2n-6 after the linoleic-acid-enriched dietary phase were significantly higher than the counterpart diets, respectively. The fasting parameters in blood at the end of each 3-wk dietary phase are shown in Table 2. Fasting blood glucose after both the oleic-acid-enriched dietary phase and the linoleic-acid-enriched dietary phase was significantly decreased compared to the pre-experiment value ($P < 0.05$, $P < 0.05$, respectively). The levels of TG and HDL cholesterol after each dietary phase did not change significantly compared to the pre-experiment value.

**TABLE 1**
**Change of Plasma Fatty Acid Composition at the End of Each Dietary Phase[a]**

| | Linoleic-acid-enriched diet | Oleic-acid-enriched diet |
|---|---|---|
| 16:0 | 23.3 ± 0.9 | 23.4 ± 2.2 |
| 18:0 | 6.3 ± 0.5 | 6.3 ± 0.6 |
| 18:1n-9 | 18.3 ± 0.9 | 20.4 ± 2.4* |
| 18:2n-6 | 30.5 ± 1.5 | 27.1 ± 3.2* |
| 18:3n-3 | 0.2 ± 0.1 | 0.2 ± 0.2 |
| 18:3n-6 | 0.7 ± 0.3 | 0.7 ± 0.1 |

[a]Values are mean ± SD. *, $P < 0.05$ difference from linoleic-acid-enriched diet.

**TABLE 2**
**Fasting Various Parameters at the End of Each Dietary Phase[a]**

| | Linoleic-acid-enriched diet | Oleic-acid-enriched diet |
|---|---|---|
| Blood glucose (mg/dL) | 121 ± 16 | 107 ± 12 |
| Insulin (μU/mL) | 5.9 ± 3.7 | 7.3 ± 5.9 |
| NEFA (meq/L) | 0.6 ± 0.2 | 0.7 ± 0.2 |
| Total cholesterol (mmol/L) | 4.68 ± 0.50 | 4.69 ± 0.66 |
| Triglyceride (mmol/L) | 1.22 ± 0.31 | 1.32 ± 0.71 |
| HDL cholesterol (mmol/L) | 1.19 ± 0.25 | 1.21 ± 0.25 |
| LDL cholesterol (mmol/L) | 2.96 ± 0.39 | 2.89 ± 0.46 |
| RLP cholesterol (mmol/L) | 7.3 ± 2.0 | 9.8 ± 6.3 |
| Lipoprotein lipase (ng/mL) | 216 ± 45 | 201 ± 52 |
| Lipid peroxide (nmol/L) | 0.9 ± 0.1 | 0.8 ± 0.4 |
| Vitamin E in LDL (μmol/g) | 8.3 ± 1.4 | 8.6 ± 2.3 |
| Lag time (min) | 61.9 ± 8.5 | 61.0 ± 9.2 |

[a]Values are presented as mean ± SD. There was no significant difference between the two dietary phases. NEFA, nonesterified free fatty acid; HDL, high density lipoprotein; LDL, low density lipoprotein; RLP, remnant-like particles.

The levels of total cholesterol and LDL cholesterol after the oleic-acid-enriched dietary phase were insignificantly decreased ($P = 0.06$, $P = 0.08$, respectively); however, those after the linoleic-acid-enriched dietary phase were significantly decreased ($P < 0.01$, $P < 0.05$, respectively). Fasting blood glucose was slightly lower after the oleic-acid-enriched dietary phase than after the linoleic-acid-enriched dietary phase, but the difference was not statistically significant ($P = 0.09$). There were no differences between the two diets in fasting insulin or FFA. The levels of total cholesterol, TG, HDL cholesterol, LDL cholesterol, RLP cholesterol and LPL mass, lipid peroxide, lag time of LDL oxidation, and vitamin E concentration in LDL were not significantly different between the two dietary phases.

*Postprandial parameters.* The increment in TG and RLP cholesterol levels after an oral fat load is shown in Figure 1.

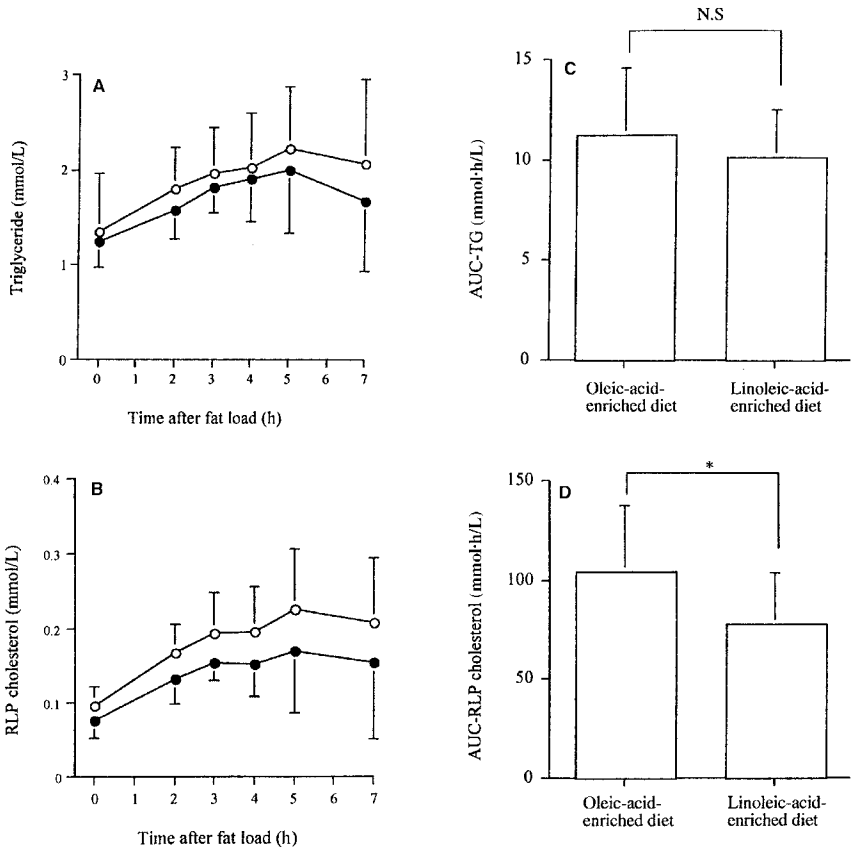

**FIG. 1.** The increment of triglyceride (TG) (A) and remnant-like particle (RLP) cholesterol (B) levels in plasma, and the area under the curve (AUC) of TG (C) and RLP cholesterol (D) during an oral fat load at the end of each 3-wk dietary phase ($n = 8$). Open circles indicate the oleic-acid-enriched dietary phase; closed circles, the linoleic-acid-enriched dietary phase.

**TABLE 3**
**Postprandial Parameters During Oral Fat Load at the End of Each Dietary Phase**

| | Linoleic-acid-enriched diet | Oleic-acid-enriched diet |
|---|---|---|
| Average of triglyceride | 150 ± 37 | 167 ± 51 |
| Maximal increment of triglyceride | 63 ± 40 | 76 ± 19 |
| AUC of triglyceride | 893 ± 202 | 992 ± 289 |
| Average of RLP cholesterol | 5.3 ± 1.9 | 6.9 ± 2.0* |
| Maximal increment of RLP cholesterol | 3.5 ± 2.6 | 4.9 ± 2.2* |
| AUC of RLP cholesterol | 31.5 ± 10.0 | 40.7 ± 11.3* |

*Values are presented as mean ± SD (mmol/L or mmol·h/L). AUC indicates area under the curve; see Table 2 for other abbreviation. *$P < 0.05$ difference from linoleic-acid-enriched diet.

The increment in plasma TG concentration was maximal 5 h after an oral fat load. The increment in TG during a fat load was not significantly different between the oleic-acid-enriched dietary phase and the linoleic-acid-enriched dietary phase. The increment in RLP cholesterol was also maximal 5 h after a fat load. RLP cholesterol levels during an oral fat load were not significantly higher after the oleic-acid-enriched dietary phase than after the linoleic-acid-enriched dietary phase. The average level, maximal increment, and the AUC of TG and RLP cholesterol during an oral fat load at the end of each dietary phase are shown in Table 3. The average level, maximal increment, and AUC of TG were similar between the two dietary phases. However, the average level, maximal increment, and AUC of RLP cholesterol during an oral fat load were significantly higher ($P < 0.05$) after the oleic-acid-enriched dietary phase than after the linoleic-acid-enriched dietary phase.

## DISCUSSION

We could confirm that all subjects completed the dietary study with good compliance, because all subjects consumed the experimental diets while staying in the hospital. Moreover, the expected change of plasma fatty acid after each dietary phase showed good compliance. In the present study, the oleic-acid-enriched diet increased the maximal increment of postprandial chylomicron remnants represented by RLP cholesterol after an oral fat load more than did the linoleic-acid-enriched diet. Although both diets improved fasting glucose levels, there was no statistically significant difference in fasting glucose, lipid profile, or susceptibility to LDL oxidation between the two experimental dietary phases.

It has been reported that linoleic acid decreases LDL cholesterol and HDL cholesterol in healthy subjects but that oleic acid decreases LDL cholesterol without decreasing HDL cholesterol (16). On the other hand, it was reported that lipid-lowering diets enriched with monounsaturated or polyunsaturated fatty acids have similar effects on serum lipid concentrations in hyperlipidemic patients (24). The latter findings might be in agreement with our present study, because the improvement in fasting lipid parameters was similar after the oleic-acid-enriched dietary phase and the linoleic-acid-enriched dietary phase. In the present study, the HDL cholesterol level did not decrease in the linoleic-acid-enriched diet. The initial HDL cholesterol level might be low and the initial LDL cholesterol level might be high in the present subjects without well-controlled DM, or the effect of fatty acid composition in the low-fat diets in the present study might not be enough to affect these lipoproteins. At the least, these lipoprotein levels might slightly improve if the patient follows a strict diet plan, although the effect of the different fatty acid composition in a low-fat diet on fasting glucose level was not clear in this study. Therefore, glucose metabolism might need to be controlled to gain an improved lipid profile.

Remnant lipoproteins, which appear in the postprandial state, have been thought to be one of the atherogenic lipoproteins because they are easily absorbed and increase the esterified cholesterol of cells (5–9). Therefore, a reduction of the usual increase in RLP in the postprandial state could be beneficial and might counter the development of atherosclerosis or its complications. In the present study, dietary intervention for 3 wk in the form of a diet enriched with oleic acid increased the appearance of postprandial remnants compared to a diet enriched with linoleic acid. The present result is similar to the findings of Georgopoulos *et al.* (20) in patients with type 1 DM. They reported that a high monounsaturated fatty acid-enriched diet might not be preferable to a high-carbohydrate diet in patients with type 1 DM with regard to the effect on postprandial lipemia. Moreover, two other recent studies reported increase postprandial lipemia by dietary oleic acid, despite the beneficial effects on hemostatic factors in healthy subjects (25,26). We consider these findings to be in agreement with our present study.

The mechanism of increased postprandial lipemia with the oleic-acid-enriched diet was not investigated in the present study. However, this finding could be due to increased influx or to delayed clearance of chylomicron remnants. We previously reported that the level of RLP cholesterol after an acute fat load enriched with olive oil increased more than that with milk fat and safflower oil (19). As chylomicron remnants increase in the postprandial state during consumption of the oleic-acid-enriched diet, they might remain steady during a fasting state. Several reports have described the effects of various fatty acids on the secretion of apoB-containing lipoproteins by Caco-2 cells and HepG2 cells, which have been used as experimental models of intestinal and hepatic lipoprotein synthesis. Both Caco-2 cells and HepG2 cells incubated with oleic acid secrete more particles than do cells incubated with palmitic or linoleic acid (27,28). Thus, oleic acid has been thought to have a strong affinity to substrates of acylcoenzyme A:cholesterol acyltransferase. In that case, oleic acid increases synthesis and secretion of TG-rich lipoproteins derived from the intestine and liver in patients and leads to an increase in chylomicron remnants in the blood by competition as a receptor to the TG-rich lipoproteins.

On the other hand, it has been suggested that linoleic acid activates the LDL receptor in the liver (29,30), which requires apo B100 or apo E in LDL for binding. Some researchers believe that chylomicron remnants, which are enriched with apo E, are taken up by the LDL receptor (31). Therefore, a linoleic-acid-enriched diet might activate the LDL receptor and accelerate the clearance of chylomicron remnants by this receptor. This process may be one reason that less RLP appears after a fat load when following a linoleic-acid-enriched diet than when following an oleic-acid-enriched diet.

It has been shown that oleic acid protects against LDL oxidation, which has been suggested to play an important role in atherogenesis (17,18). In contrast, Schwab *et al.* (32) reported that the dietary fatty-acid composition in reduced-fat diets has no significant differences in LDL lag time among olive oil, canola oil, corn oil, and rice bran oil. Our present study is in agreement with the latter study. The difference in fatty acid composition of low-fat diets (25 energy %) in the latter study, which is similar to the present study, might be too weak to affect susceptibility to LDL oxidation. Moreover, the similar level of vitamin E in LDL might be due to a similar susceptibility to LDL oxidation.

In conclusion, both the oleic-acid-enriched and the linoleic-acid-enriched diets we studied are low-fat diets with adequate calories to improve fasting glucose among patients with poorly controlled type 2 DM. However, the former diet might increase the appearance of postprandial chylomicron remnants more than the latter diet.

## ACKNOWLEDGMENTS

This work was supported in part by a grant from the Triglyceride Research Fund from Kissei Co. We wish to express our thanks to the members of the nutritional department of the National Defense Medical College for cooking the two types of test diets. We also thank Emiko Miyajima for technical assistance.

**ABSTRACT:** In this long-term study, we wanted to explore the effect of dietary supplementation of seal oil (SO) as compared cod-liver oil (CLO) on subjects with moderate hypercholesterolemia. The test parameters included fatty acid composition in serum, blood lipids, platelet aggregation, and the activity of blood monocytes. After a run-in period of 6 mon, 120 clinically healthy hypercholesterolemic (7.0–9.5 mmol/L; 270–366 mg/dL) subjects were randomly selected to consume either 15 mL of SO or CLO daily for 14 mon followed by a 4-mon wash-out period. A third group was not given any dietary supplement (control). Consumption of marine oils (SO and CLO) changed the fatty acid composition of serum significantly. Maximal levels were achieved after 10 mon. No further changes were seen after 14 mon. A wash-out period of 4 mon hardly altered the level of n-3 fatty acids in serum. Addition of SO gave 30% higher level of eicosapentaenoic acid, as compared to CLO. Subjects taking SO or CLO had lower whole-blood platelet aggregation than the control group. Neither SO nor CLO had any effects on the levels of serum total cholesterol, high-density lipoprotein cholesterol, postprandial triacylglycerol, apolipoproteins A1 and B100, lipoprotein (a), monocyte function expressed as monocyte-derived tissue factor expression, and tumor necrosis factor.

Paper no. L8549 in *Lipids 36*, 7–13 (January 2001).

During the last two decades it has been established that Greenland Eskimos living on their traditional diet have a lower incidence of coronary heart disease than Danes living on a Western diet (1,2).

The Eskimos have significantly prolonged primary bleeding time, a mild clinical bleeding tendency, increased level of n-3 fatty acids in blood plasma and cell membranes, lower serum total cholesterol, high density lipoprotein (HDL)-cholesterol, lower apolipoprotein (Apo) B100 and higher Apo A1 levels as compared to those regarding the Danes (3–6). These findings have been attributed to their diet, particularly the marine fatty acids.

Dietary intake of fish, fish oil, and n-3 fatty acid-containing capsules does not give similar findings of blood n-3/n-6 ratio, total cholesterol, HDL-cholesterol, Apo A1, and Apo B100 as in Greenland Eskimos.

The Eskimo diet consists mainly of meat and blubber of seal and whale, containing high amounts of monounsaturated acids (MUFA) and n-3 polyunsaturated fatty acids (PUFA) and relatively small amounts of saturated fatty acids (SFA) and fish (7,8).

Eskimos consume the bulk of their food raw or dried, seldom boiled or exposed to excessive heat. The fatty acid composition in seal and whale blubber also deviates from fish oil in the positioning of the n-3 fatty acids in the glycerol (9–11). It has also been shown that PUFA in marine mammals are quite well-protected from oxidation (12).

Seal oil (SO) contains slightly more MUFA as compared to cod-liver oil (CLO); the eicosapentaenoic acid (EPA; 20:5n-3) molecule is mainly in the 1,3-position of the glycerol, and SO also contains a strong natural antioxidant, not yet fully identified. If the positioning of the fatty acids in the glycerol molecule or the antioxidative abilities of seal fat are significant in the prevention of arteriosclerosis, it might be possible to detect effects on parameters related to the development of this condition, by ingesting SO or blubber.

The oils served in the present study were subjected to a traditional CLO refining process. The main objectives of such processes are to remove pesticides and to make an edible and stable product. Removal of molecules that cause off-flavors or taste by "steam stripping" (exposure to excessive heat) to improve sensory attributes may destroy potent antioxidants. Other steps in the process designed to remove impurities (protein, water, and polar lipids) may as well remove components with potential beneficial effects (13,14).

Reduced tendency of developing arteriosclerosis has been related to the lower reactivity of platelets and less production of proinflammatory products, e.g., cytokines, prostaglandins,

Abbreviations: ALAT, alanine amino transferase; ALP, alkaline phosphatase; Apo, apolipoprotein; AST, aspartate aminotransferase; CLO, cod-liver oil; CRP, C reactive protein; CV, coefficient of variation; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; HDL, high density lipoprotein; Lp(a), lipoprotein (a); MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids; SO, seal oil; TF, tissue factor; TNF, tumor necrosis factor.

and leukotrienes (15,16), and the maintenance of prostacyclin production in the endothelial cells (17). Various studies have verified that dietary intake of n-3 fatty acids (fish, fish oil, or fish oil capsules) increases the level of these fatty acids in blood plasma and cellular compartments and prolongs the bleeding time.

The objective of the present work is, by mimicking an aspect of the traditional Eskimo diet, to explore therapeutic and prophylactic possibilities of SO on parameters related to development of cardiovascular disease [n-3 fatty acids in serum, blood cholesterol, platelet activity, blood monocyte activity (tissue factor: TF), inflammatory activity (tumor necrosis factor: TNF)], as compared to CLO.

## MATERIALS AND METHODS

*Subjects.* The study was carried out at Hammerfest General Hospital (situated at 70° N latitude) in northern Norway. It included 120 clinically healthy volunteers from 43 to 66 yr of age (median age 55), 60 males (median age 54) and 60 females (median age 56); 102 subjects finished the study. The inclusion criteria were serum cholesterol 7.0–9.5 mmol/L (270–366 mg/dL), clinically healthy, and no lipid-lowering drugs. They were given general dietary advice (consume more vegetables, fruit and fish, and less saturated fat). All participants were asked to continue their daily habits. The study was approved by the Regional Board of Research Ethics.

*Study design.* The subjects were randomly divided into three groups. One group received 15 mL/d SO (about 1.1 g EPA, 20:5n-3 and 1.5 g DHA, 22:6n-3); another group received 15 mL CLO (about 1.5 g EPA and 1.8 g DHA); and a third group received no oil (control). The fatty acid composition of the oils is given in Table 1. The study was double-blinded for the groups given the dietary oils. No placebo was given in the control group, and the study of this group could thus not be blinded to test subjects or investigators. The groups were in parallel for a period of 2 yr.

Before the intake of the oils, there was a run-in period of 6 mon where the serum cholesterol level was monitored. The period of oil supplementation lasted 14 mon, followed by a 4 mon wash-out period.

*Oil supplements.* The oils were processed by a standard procedure. This included heating to minimum 150°C, removal of pesticides and dioxins, vitamins A and D, molecules that cause off-flavor or taste, and addition of vitamin E (tocopherol, 1 mg/mL). The oils were kept frozen until used by the participants. Each test subject was delivered one 250-mL bottle of oil at regular intervals from the start of the study.

Both SO and CLO are relatively rich in n-3 fatty acids (Table 1). SO contains higher amounts of MUFA (16:1, 18:1, 20:1, 22:1). The fatty acid content of both oils, kept in control bottles in a refrigerator at the test laboratory, were controlled several times during the study and did not change (Table 1).

*Diet.* The test subjects consumed an ordinary Norwegian diet throughout the study (in general about 40% fat with P/S ratio of 0.5, 15% proteins, and 45% carbohydrates). The dietary content was evaluated by a clinical dietician by means of a questionnaire at the entry of the study and repeated twice during the study to discover possible dietary changes. The test subjects were asked to report their weekly physical activity in the same questionnaire.

[a]The oils were kept at 4°C.

*Body weight.* Each of the participants was asked to report their body weight three times during the study (6 wk before oil intake, and after 2 and 6 mon of dietary oil supplementation).

*Blood sampling.* Blood samples were collected at 6 and 3 mon before the start of the oil supplementation (run-in period), at the start after 4, 10, and 14 mon of supplementation, and after the wash-out period (4 mon). The test subjects were informed not to drink alcohol or perform any strenuous exercise for 48 h prior to each blood sampling, and the food intake prior to the sampling (breakfast) in general contained coffee and bread. Blood samples were collected between 9:00 and 11:00 A.M. from nonfasted subjects. This implies that the variation/imprecision in measured triacylglycerol is considerable, and results are difficult to interpret.

*Lipids in serum.* Serum was prepared by whole blood clotted in a glass tube for 2 h at room temperature, followed by centrifugation (2,500 × *g* for 15 min). Serum was tested for total cholesterol (enzymatic colorimetric test, cholesterol esterase and cholesterol oxidase), HDL-cholesterol [after precipitating chylomicron, very low density lipoprotein (VLDL), low density lipoprotein (LDL) with phosphotungstic acid, and $Mg^{2+}$], triacylglycerol (enzymatic colorimetric test, lipoprotein lipase/oxidation/-peroxidase). The analyses were done in Axon autoanalyzer, Technicon/Bayer. Apo A1 and Apo B100

were determined in a Beckman Nephelometer Immunonephelometric method, with reagents from Beckman. Lipoprotein (a) [Lp(a)] was measured by enzyme-linked immunosorbent assay-technique, TintElize (Biopool, Ventura, CA).

*Fatty acids.* Total fatty acids in serum were determined after extraction by modified Folch method (chloroform/methanol/KCl aq., 8:4:3) and methylation ($BF_3$ in methanol) as described earlier (18,19). The fatty acids were analyzed by capillary gas–liquid chromatography (Hewlett-Packard 5880, SP 2380 capillary column; Palo Alto, CA), at an injection temperature of 250°C, column temperature of 180–225°C, and hydrogen flame-ionization detector temperature of 270°C. The signal was analyzed by a disc integrator and compared with those of assays on mixtures of fatty acids supplied by Nu-Chek-Prep (Elysian, MN). The fatty acid compositions of CLO and SO were expressed as relative percentage (area), and the individual fatty acids in serum were calculated by use of 17:0 as internal standard. The identification was based on retention times. Results were expressed as mmol/L.

*Standard clinical chemistry analysis.* Creatinine (modified Jaffe method), bilirubin (total), total protein, aspartate aminotransferase (AST) and alanine aminotransferase (ALAT), measured as photometrically determined NADH decrease (international standardized procedure), alkaline phosphatase (ALP; colorimetric assay), and C reactive protein (CRP) in serum were analyzed by Axon Autoanalyser, Technicon, with reagents from Technicon/Bayer. The CRP method did not measure "ultrasensitive" CRP.

*Standard hematological parameters.* Hemoglobin (modified cyanmethemoglobin-method), white cells, red cells, platelets, and hematocrit were determined by use of Cobas Argos, Roche Diagnostics Systems (Nutley, NJ).

TF and TNF were analyzed as earlier described (13).

*Platelet aggregation.* Fifteen subjects from each group (control, SO, CLO) were randomly selected, and after a period of 14 mon of oil supplementation, the subjects were tested for platelet aggregation using collagen as platelet agonist. Two concentrations of collagen (Collagen-reagent Horm) were used: 1.0 μg/mL and 10 μg/mL. Platelet aggregation was measured in citrated whole blood using a dual channel Crono-Log aggregometer model 540, Coulter Electronic Ltd., which operates by impedance method (20).

*Statistical analyses.* To compare the various fatty acids and platelet aggregation in the three groups, paired and two-sample *t*-tests were used. Handling of data was done using Microsoft Excel (Redmond, WA) and SAS statistical system (Cary, NC).

## RESULTS

The participants maintained their diet throughout the study, which on average contained 1–2 fish meals per week. The subjects tolerated oil supplementation well, and no adverse effects were reported. There were no effects on liver and kidney function or hematological parameters. The level of CRP remained unchanged. The body weight did not change significantly in any of the groups during the study (Table 2).

**TABLE 2**
**Body Weight (kg) at 6 wk Before and 2 and 6 mon After Dietary Addition of 15 mL Cod-Liver Oil (CLO) and Seal Oil (S)[a]**

| | Before | 2 mon | 6 mon | *n* |
|---|---|---|---|---|
| CLO | 70.8 (13.6) | 71.3 (13.8) | 71.3 (14.0) | 38 |
| SO | 72.6 (13.8) | 72.6 (13.2) | 72.4 (13.1) | 37 |
| Control | 69.8 (10.2) | 69.6 (9.9) | 69.0 (8.5) | 37 |

[a]Mean and SD.

*Lipids in serum.* The levels of serum total-cholesterol were unaffected both by CLO [mean (SD); 8.3 (0.8) mmol/L (320 mg/dL) before and 7.8 (0.9) mmol/L (301 mg/dL) after 14 mon of oil supplementation], and by SO [8.2 (0.9) mmol/L (316 mg/dL) before and 8.0 (0.7) mmol/L (309 mg/dL) after] as were HDL-cholesterol [CLO; 1.3 (0.4) mmol/L (50 mg/dL) before and 1.3 (0.4) mmol/L (50 mg/dL) after, SO; 1.3 (0.3) mmol/L (50 mg/dL) before and 1.4 (0.3) mmol/l (54 mg/dL) after], A1 [CLO; 1.6 (0.2) g/L before and 1.7 (0.3) g/L after; SO, 1.6 (0.3) g/L before and 1.8 (0.4) g/L after], B100 [CLO; 2.0 (0.3) g/L before and 2.0 (0.3) g/L after, SO; 2.0 (0.3) before and 2.0 (0.3) g/L after] and Lp(a) [CLO; 185 (181) mg/L before and 185 (194) mg/L after 14 mon of oil supplementation, SO; 163 (170) before and 183 (168) mg/L after]. The great SD of Lp(a) measurements is due to considerable interindividual differences in the Lp(a) level (50–800 mg/L). The intraindividual variation was relatively small (<20%), and the coefficient of variation of the assay (CV) was 4%.

The triacylglycerol level (nonfasting) was analyzed during and after the period of oil supplementation (Table 3). There were no significant differences between the controls and the subjects given the oil supplementation, and the wash-out period had no effect. The intraindividual variation was relatively great (10–40%), and the CV of the assay was 5%.

*Fatty acids.* The three groups (CLO, SO, control) did not differ in the level of any fatty acid, at the entry of the study (Table 4). No significant changes in the serum fatty acid pattern in the control group during the study were observed. Both the SO and the CLO had a significant effect on the composition of fatty acids in serum. This was more pronounced during the course of the study. The maximum effect was achieved after 10 mon. Analysis after 14 mon of oil supplementation showed no further changes.

In both in the CLO and SO groups, the level of several fatty acids was raised significantly including MUFA and the PUFA (Table 4). There was no significant fall in the absolute levels

**TABLE 3**
**Nonfasting Triacylglycerol Levels (mg/dL) in Hypercholesterolemic Subjects During Dietary Addition of 15 mL of CLO and SO and After a 4-mon Wash-out Period[a]**

| | Oil supplementation period | | | Wash-out, | |
|---|---|---|---|---|---|
| | 4 mon | 10 mon | 14 mon | 4 mon | *n* |
| CLO | 177 (79) | 203 (115) | 195 (124) | 195 (97) | 38 |
| SO | 186 (97) | 195 (88) | 168 (79) | 212 (159) | 38 |

of any fatty acid. Although SO is almost 30% (relative) lower in EPA as compared to CLO, the serum level of EPA (20:5n-3), after 14 mon of oil supplementation, is about 30% higher in the SO group (0.96 vs. 0.73 mmol/L).

After the wash-out period of 4 mon, the fatty acid changes, compared to the entry values, of both the SO and CLO groups were not so prominent, but they were still significantly different from the start of the study. For example the level of DHA (22:6n-3) did not fall during the wash-out period.

*Platelet aggregation.* Collagen-induced platelet aggregation was compared between 15 subjects of each group after ingestion of oils for 14 mon. The CLO group showed the lowest platelet aggregation, statistically significant lower than the control group ($P$ = 0.03) (Fig. 1, collagen 1 μg/mL). The aggregation in the SO

group was also reduced as compared with the control group, but the change was not statistically significant ($P$ = 0.07).

No effect of SO or CLO was seen on either TF or TNF (Table 5) after 10 mon of oil supplementation, when compared to the control group. The wash-out period of 4 mon had no effect in any of the groups (control, CLO,SO).

## DISCUSSION

The present study focused on subjects with hypercholesterolemia and included a run-in period of 6 mon, and an oil supplementation period of 14 mon, which should be sufficient to observe effect on the parameters studied, and a 4-mon wash-out period.

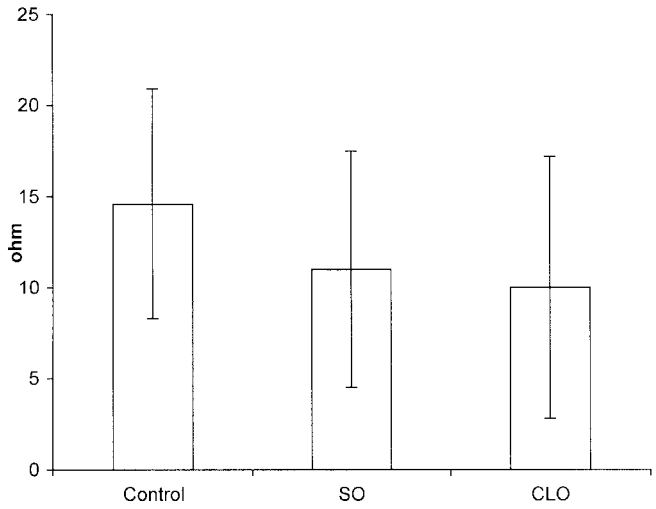

**FIG. 1.** Collagen (1 μg/mL)-induced platelet aggregation (ohm) in whole blood in subjects taking daily supplementation of 15 mL seal oil (SO; $P = 0.07$) and cod-liver oil (CLO; $P = 0.03$) for 14 mon, vs. control (no dietary addition) (mean and SD).

The n-3 fatty acid content of both CLO and SO represented a considerable daily addition, although well below the intake through original Eskimo diet. The serum level of EPA after intake of SO was about 30% higher as compared to CLO (Table 4), in spite of the fact that the EPA content of SO is 30% lower than in CLO (Table 1). It is an open question whether this implies that SO may be more efficient than CLO in preventing cardiovascular events. The mechanism behind the present observation is not clear, but may be related to the fact that EPA is located in position 1,3 in glycerol in SO, and in position 2 in CLO.

The n-3/n-6 ratio was moderately increased after the intake of both oils (Table 4). Still, this is far from the ratio in plasma of Greenland Inuit ($R = 0.7–1.2$) (4) and implies a different biological setting. During the study, the level of n-3 fatty acids in serum increased with *ca.* 100% in the CLO group and with about 140% in the SO group (Table 4). Also the level of n-6 fatty acids was elevated, although not to a similar degree. Intake of n-3 fatty acids may increase the enteral absorption of n-6 fatty acids (21).

The wash-out period of 4 mon hardly affected the serum levels of n-3 fatty acids. The level of DHA was quite similar at the end of the oil supplementation period and after 4 mon washout. Similar findings were reported in normal individuals (22). This probably reflects that the fatty acids were incorporated into the fat tissues (depot fat) and only slowly released.

One implication of this observation is that all crossover studies on PUFA should be interpreted carefully. This would also have significance for studies in subjects with traditionally high and low fish intake, and the finding also indicates that once the body depot fat is saturated with fatty acids, the need of supplementation is reduced, probably to one or two times a week.

Daily dietary addition of 15 mL of oil (about 180 kcal) might be expected to give a slight increase in the body weight. This did not occur (Table 2). The test subjects did not report increased physical activity, nor any significant change in their dietary habits. The n-3 fatty acids may increase β-oxidation of fatty acids and thereby counteract weight increase (23).

Neither SO nor CLO affected the levels of serum total cholesterol, HDL-cholesterol, and apo [Apo A1, Apo B100, Lp(a)]. This is in accordance with findings in normocholesterolemic subjects (13,24,25). By dietary addition of CLO and SO, SFA as well as PUFA are ingested. The level of SFA in serum is also raised after 14 mon of oil supplementation (Table 4). It might be that the intake of SFA is masking a possible lipid-lowering effect of PUFA. The more beneficial levels of total cholesterol in the Eskimos may be due to lower intake of SFA and possibly the fact that they consume a larger amount of unprocessed foods (higher amounts of biologically active compound, i.e., antioxidants) in their diet compared to a Western diet.

Intake of n-3 fatty acids is known to reduce the level of triacylglycerols in the blood (6). This was not confirmed in the present study, in which nonfasting serum was analyzed. This implies that triaclylglycerol in chylomicrons is included, which results in great intra- and interindividual variation in the level of serum triacylglycerol.

CLO supplementation is known to reduce platelet aggregation (18,26,27). In the present study aggregation was done in whole blood, rather than in platelet-rich plasma, which is a more common method. We found that platelet aggregation was statistically significantly reduced in the CLO group, as compared to the controls. Aggregation in the SO group was also lower than in the controls, although this was not statistically significant. The difference between the oil groups was small. Intra- and interindividual variation is substantial with respect to platelet aggregation, which influences the statistical calculations.

The mechanism of reduction in platelet aggregation is probably the same in both of the oil groups. EPA (20:5n-3) substitutes arachidonic acid (20:4n-6) in the platelet membrane phospholipids, and less potent prostanoids (tromboxane) are synthesized. We did not observe any effect of the oil supplementation on monocyte TF activity or TNF in blood. The level of both variables decreased during the study, in all groups. This may be related to biological and seasonal variations.

**TABLE 5**
**The Monocyte-derived Tissue Factor (TF) Activity in Whole Blood and Tumor Necrosis Factor (TNF, ng/mL) Before, During and After Dietary Addition of 15 mL of CLO and SO[a]**

| | | 6 wk before | 10 mon of oil supplementation | Wash out, 4 mon | *n* |
|---|---|---|---|---|---|
| TF | CLO | 16.8 (12.3) | 12.2 (7.8) | 9.9 (9.4) | 38 |
| | SO | 16.5 (8.9) | 16.2 (11.9) | 9.1 (5.8) | 38 |
| | Control | 18.9 (14.6) | 13.3 (10.9) | 9.7 (7.8) | 37 |
| TNF | CLO | 4.4 (1.9) | 1.0 (0.7) | 1.0 (0.6) | 38 |
| | SO | 4.5 (1.3) | 1.3 (1.1) | 1.5 (1.0) | 38 |
| | Control | 4.9 (1.8) | 1.2 (0.9) | 1.5 (1.2) | 37 |

[a]The TF activity is expressed as mU/$10^6$ cells of a standard. Values given as mean and SD. For other abbreviations see Table 2.

The present study mainly focused on certain parameters relevant to the development of cardiovascular disease (n-3 fatty acids in serum, other blood lipids, apo, blood platelets, monocyte activity, inflammation), leaving out aspects of oxidation, although the intake of vitamine E was increased. The oils utilized had been heated to 150°C, which may destroy natural antioxidants. It may well be that the positive influence of the Eskimo diet, and possibly also SO, is acting through such biological systems. This aspect of the Eskimo diet remains to be further explored, as unprocessed food items contain biological active components (antioxidants other than tocopherol), and the relationship between the natural fat and natural antioxidants of Eskimo diet is probably important.

In conclusion we found that dietary addition of SO increased the EPA level considerably more than CLO; after 10 mon of oil supplementation there was no further rise in serum fatty acid levels, and a wash-out period of 4 mon had only a modest effect on these levels.

# The Composition of Saturated Fatty Acids in Plasma Phospholipids Changes in a Way to Counteract Changes in the Mean Melting Point During Pregnancy

**S.R. De Vriese[a,*], A.C. v. Houwelingen[c], G. Hornstra[d], M. Dhont[b], and A.B. Christophe[a]**

[a]Department of Internal Medicine, Division of Nutrition, and [b]Department of Gynecology, Ghent University Hospital, Belgium, and [c]Department of Human Biology and [d]Nutrition and Toxicology Research Institute, Maastricht University, The Netherlands

**ABSTRACT:** It has been demonstrated that in pathological conditions with an increase in the calculated mean melting point (MMP) of phospholipid (PL) fatty acids (FA) there are changes in the composition of the saturated FA (SFA), which partially counteract this effect: shorter-chain SFA with lower melting points are increased, while longer-chain less fluid SFA are suppressed. The aim of this study was to determine whether there are differences in MMP during pregnancy and in the newborn and, if so, whether similar adaptive changes occur in the composition of the SFA. The FA composition of plasma PL was determined in healthy women ($n$ = 16) twice during pregnancy (15–24 wk and 29–36 wk) and at delivery and in umbilical venous blood obtained at birth. The MMP of maternal PL was significantly higher at delivery compared to mid-gestation, due to a loss of highly unsaturated FA (HUFA) which were replaced by SFA. In addition, changes in the SFA occurred: 16:0 with lower melting point was higher while 18:0 with higher melting point was lower at delivery. MMP of PL FA in umbilical plasma was lower than in maternal plasma at delivery, which was due to higher HUFA content. In contrast to maternal plasma, 16:0 was lower while 18:0, 20:0, and 24:0 were higher in umbilical plasma resulting in a higher MMP of SFA, tending to raise the overall MMP. It can be concluded that, during pregnancy and in the newborn, the FA composition of SFA changes in a way to counteract changes in MMP induced by reduced and increased HUFA, respectively.

Paper no. L8541 in *Lipids 36*, 15–20 (January 2001).

Holman *et al.* (1–4) introduced the concept of the calculated mean melting point (MMP) and calculated mean chain length (MCL) of fatty acids (FA) from plasma phospholipids (PL) as surrogate parameters of membrane fluidity. PL are the major structural components of membranes, and the FA pattern of plasma PL reflects that of tissue PL. Membrane fluidity depends among others on the amounts of PL, the FA composition of the PL, and the amount of cholesterol. Membrane fluidity plays an important role in the efficiency of ligand binding, the activity of membrane enzymes, membrane transport, and cell deformability (5). Changes in membrane lipid composition and, consequently, changes in membrane fluidity may result in differences in the function of membrane receptors. In preeclamptic women (6), membrane fluidity of platelets was significantly higher compared to that of normotensive women and was accompanied by higher levels of unsaturated FA in the membrane of platelets. When long-chain polyunsaturated FA (PUFA) are replaced by saturated (SFA) or monounsaturated FA (MUFA), the MMP increases and membrane fluidity decreases (1–4). It has been demonstrated that the MMP of FA of plasma PL of pregnant (36 wk of gestation), lactating, and nonlactating women (6 wk postpartum) is higher compared to that from nonpregnant women (3). Furthermore, it has been demonstrated that the MMP of plasma PL is significantly increased in patients with multiple sclerosis. The latter patients have reduced concentrations of PUFA due to impaired chain elongation, and PUFA are replaced with SFA (1). This overall increase in MMP is accompanied by changes in the composition of the SFA, which partially counteract this effect: shorter-chain SFA with lower melting points are increased while longer-chain, less fluid SFA are suppressed.

The objective of the present study was to determine whether similar adaptive changes in MMP occur during the course of pregnancy and in the newborn. Therefore, we determined the FA composition of PL, isolated from maternal venous plasma during the course of pregnancy and from umbilical venous plasma.

## MATERIALS AND METHODS

*Study population.* Healthy pregnant women at the Department of Gynecology of Ghent University Hospital, Belgium, were asked to participate in this study. All pregnant women signed a written informed consent form, approved by the ethics committee of Ghent University Hospital. Only singleton pregnancies were included. Inclusion criteria were: normotensive (DBP <90 mm Hg), not diabetic, no proteinuria, and not suffering from renal or cardiovascular disease. Twenty pregnant women entered the study. Two pregnant women delivered preterm and were excluded from the study. From one pregnancy the umbili-

Abbreviations: CI, confidence interval; FA, fatty acid; HUFA, highly unsaturated fatty acid; MCL, mean chain length; MMP, mean melting point; MUFA, monounsaturated fatty acid; OPI, oxidative potential index; PL, phospholipid; PUFA, polyunsaturated fatty acid; SFA, saturated fatty acid.

cal blood sample was lost and from another pregnancy we only obtained one antenatal sample. These pregnancies were also excluded. The study population thus consisted of 16 healthy pregnant women and their neonates (seven girls and nine boys).

Maternal venous blood was collected in EDTA-tubes twice during the course of pregnancy, between 15 and 24 wk of gestation (median 20 wk) and between 29 and 36 wk (median 32 wk) and at delivery (median 39.7 wk; range 38.0–41.4 wk). After delivery, a sample of umbilical venous blood was collected. Blood samples were temporarily stored at 6°C. Within 24 h of collection, plasma was isolated by centrifugation (600 × *g* during 5 min at 4°C) and stored in plastic tubes under nitrogen at −80°C until transportation in dry ice to Maastricht for analysis.

*FA analysis*. All samples of a given mother-infant pair were analyzed simultaneously. The FA analysis was performed as described previously (7). Previous to the FA analysis an internal standard [dinonadecanoyl lecithin, phosphatidylcholine 19:0] was added to every sample. Total lipid extracts of plasma were prepared using a modified Folch extraction (8). The PL fraction was isolated by solid-phase extraction on an aminopropyl silica column (9). The PL were saponified and the FA converted to the corresponding methyl esters by reaction with $BF_3$ in methanol (140 g/L) at 100°C during 1 h. The methyl esters were analyzed using a capillary gas–liquid chromatograph equipped with a 50 m BP1 nonpolar column, 0.22 mm i.d. × 0.10 μm film thickness, and a 50 m BP × 70 mm polar column, 0.22 mm i.d. × 0.25 μm film thickness (SGE, Bester BV, Amstelveen, The Netherlands). The injection temperature was set at 250°C and the detector temperature at 300°C. The starting temperature of the columns was 160°C, which after 4 min was increased to 200°C with a rate of 6°C/min. Subsequently, after a stabilization period of 3 min, the temperature was further increased to 270°C at a rate of 7°C/min. The carrier gas was helium, head pressure 370 kPa.

The results are expressed as mole percentage of total FA, and the absolute FA amount in the PL fraction is also reported (mg/L plasma). Thirty-one different FA with chain lengths between 14 and 24 carbon atoms were identified. The sum of all the SFA, the MUFA, the PUFA, the highly unsaturated fatty acids (HUFA: fatty acids with 20 or more carbon atoms and with at least three double bonds), Σn-7, Σn-9, Σn-3, and Σn-6 were calculated and are reported together with the individual FA.

The fluidity of lipids was assessed through the MMP, °C (sum of the mole fraction multiplied by the melting point for each fatty acid) and the MCL (number of carbon atoms, sum of the mole fraction multiplied by the number of carbon atoms in the FA). The oxidative potential index (OPI) of FA in plasma PL was estimated by summing the mole fraction of FA with 1, 2, 3, 4, 5, and 6 double bonds, multiplied by 1, 30, 70, 120, 180, and 240, respectively (10).

*Statistical analysis.* Normality of distribution was ascertained with the Kolmogorov-Smirnov test. The calculated parameters such as MMP, MCL, and OPI had a normal distribution. FA fractions were arcsin transformed to reach normality of distribution. Values are reported as mean [95% confidence interval of the mean (CI)]. Paired Student *t*-test was performed for FA comparisons between maternal samples of the first and second antenatal visit with maternal samples obtained at delivery and for maternal-umbilical FA comparisons at delivery and birth. In order to avoid type 2 errors, due to multiple comparisons, a value of $P < 0.005$ was taken as the criterion of significance. For maternal plasma, the correlations between the fraction of the PUFA and HUFA in the PL on the one hand and the MMP of SFA and the MMP of MUFA on the other hand, were calculated. For these calculations the results of the two antenatal visits and of delivery were used. The degree of association was calculated using Pearson correlation. The data were analyzed using the MedCalc statistical program, version 6 (MedCalc Software, Mariakerke, Belgium) (11).

## RESULTS

*Clinical characteristics.* The mean age of the mothers ($n = 16$) at delivery was 30 yr (range 20–38 yr). The mean body mass index of the women before pregnancy was 21.2 (range 16.5–24.2). All mothers were nullipara, all pregnancies were uncomplicated, and the infants were born healthy with a mean birth weight of 3169.4 g (range 2570–3860 g) and a mean birth length of 50.3 cm (range 47–53 cm). The median Apgar Score 1 min after birth was 9 (range 4–9) and 5 min after birth 9 (range 9–10).

The FA patterns of plasma PL (mol%) from maternal plasma during the course of pregnancy and at delivery and from umbilical plasma shortly after birth are given in Table 1. Calculated values derived from this FA composition are summarized in Table 2.

*Maternal FA composition*. In maternal plasma PL, a few significant differences between gestation and delivery occurred. The total amount of maternal plasma PL-associated FA did not differ significantly between gestation and delivery.

Neither PUFA nor MUFA changed significantly between mid-gestation and delivery. HUFA were lower, while SFA were higher at delivery compared to mid-gestation ($P < 0.005$).

Palmitic acid (16:0) and stearic acid (18:0), the two major SFA, changed significantly, but in opposite directions: 16:0 increased while 18:0 dropped during the last 20 wk of pregnancy ($P < 0.001$).

Few of the individual n-6 or n-3 FA differed significantly between mid-pregnancy and delivery; arachidonic acid (20:4n-6) and its elongation product 22:4n-6 declined ($P < 0.005$), but linoleic acid remained stable. In the series of n-3 FA, only 22:5n-3 was lower at delivery ($P < 0.005$).

The sum of the Δ5 desaturation products (20:5n-3, 20:4n-6, and 20:3n-9) was calculated as a parameter for the essential FA status of the mother because in some disorders in which Δ5 desaturation is affected, the conversion of 20:4n-3 to 20:5n-3, of 20:3n-6 to 20:4n-6, and of 20:2n-9 to 20:3n-9 may be equally altered. This would result in an unchanged triene/tetraene ratio. The sum of the Δ5 desaturase products was lower at delivery as compared to mid-pregnancy: 8.2 (7.6 to 8.8%) vs. 9.3 (8.5 to 10.0%); $P < 0.0005$.

*Umbilical plasma FA composition.* The amount of umbilical

[a]SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; HUFA, highly unsaturated fatty acids; ND, not detectable.
[b]Paired $t$ test performed after arcsin transformation of all the fatty acid fractions. a, significant difference ($P < 0.005$) between maternal values of second antenatal visit and delivery; b, significant difference ($P < 0.005$) between maternal values of first antenatal visit and delivery; c, significant difference ($P < 0.005$) between maternal values at delivery and umbilical venous plasma at birth.

plasma PL-associated FA was only 34% [95% confidence interval (CI) 30.2 to 38.7] of maternal plasma PL-associated FA at delivery. The FA composition of umbilical venous plasma PL was very different from that of maternal plasma PL at delivery.

Both SFA and HUFA were significantly higher in umbilical plasma PL compared to maternal values. No significant differences were observed in MUFA and PUFA between mother and neonate.

The SFA in umbilical plasma PL showed significant differences from the SFA content of maternal plasma PL; 16:0, the major SFA, was lower in umbilical plasma compared to maternal values. In contrast, the 18:0 content was significantly higher in umbilical plasma. The other long-chain SFA were also higher in the neonate compared to the mother, 20:0 ($P < 0.0001$) and 24:0 ($P < 0.001$). The odd-chain FA 15:0 ($P < 0.001$) and 23:0 ($P < 0.0001$) were lower in the neonate.

Umbilical plasma PL were significantly enriched in all the individual n-6 HUFA compared to maternal plasma. In contrast, maternal plasma contained more 18:2n-6. α-Linolenic acid (18:3n-3) was not detected in umbilical plasma. Eicosapentaenoic acid (20:5n-3) was significantly lower in umbilical plasma, while its elongation and desaturation product docosahexaenoic acid (22:6n-3) was significantly higher in umbilical plasma PL compared to maternal plasma PL.

*Calculated parameters. (i) Maternal plasma.* The MMP of the FA in plasma PL at delivery is significantly elevated compared to mid-pregnancy (increase of 1.13°C, 95% CI, 0.64 to 1.61, $P < 0.001$). The MCL was significantly lower at delivery compared to gestation. These parameters have an effect on

[a]OPI, oxidative potential index; MCL, mean chain length, expressed as number of carbon atoms; MMP, mean melting point, expressed as degrees Celsius. For other abbreviations see Table 1.
[b]a, significant difference ($P < 0.005$) between maternal values of second antenatal visit and delivery; b, significant difference ($P < 0.005$) between maternal values of first antenatal visit and delivery; c, significant difference ($P < 0.005$) between maternal values at delivery and umbilical venous plasma at birth.

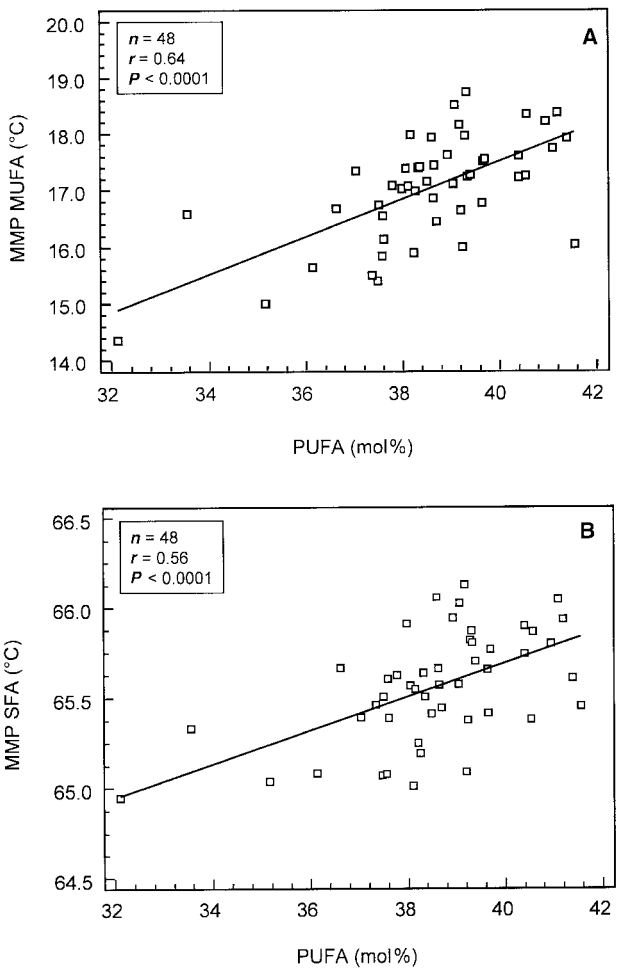

**FIG. 1.** Correlation between the mean melting point (MMP) of the monounsaturated fatty acids (MUFA) and of the saturated fatty acids (SFA) in plasma phospholipids and the fraction of polyunsaturated fatty acids (PUFA) in maternal plasma phospholipids (mol%).

membrane fluidity. The OPI of plasma PL, an index for susceptibility toward peroxidation, was significantly lower at delivery compared to gestation. The change in composition of the SFA results in a shorter MCL and consequently a lower MMP (decrease of 0.24°C, 95% CI, 0.13 to 0.34, $P < 0.001$) of the SFA. The same phenomenon was observed in MUFA, but it was less pronounced, the MCL of the MUFA is shorter at delivery compared to mid-pregnancy ($P < 0.005$) and their MMP is lower (0.60°C, 95% CI, 0.25 to 0.95, $P < 0.005$).

The mole fraction of the PUFA, but not of HUFA, in the PL correlated positively with both the MMP of SFA ($r = 0.56$, $n = 48$, $P < 0.0001$) and with the MMP of MUFA ($r = 0.64$, $n = 48$, $P < 0.0001$) (Fig. 1). Even without the two values with a low PUFA fraction (<34 mol%), the same association still exists.

*(ii) Umbilical plasma*. The high concentration of HUFA in umbilical plasma caused a significantly higher OPI, a longer MCL, and a lower MMP compared to maternal values. The lower global MMP in umbilical plasma PL compared to maternal plasma PL is associated with a higher MMP of the SFA (0.86°C, 95% CI, 0.61 to 1.11, $P < 0.001$) and of the MUFA (1.03°C, 95% CI, 0.46 to 1.60, $P = 0.002$).

Higher concentrations of HUFA in the newborn than in the mother are associated with higher concentrations of SFA, and a shift in the composition of SFA toward longer chain lengths. The MCL of the SFA is significantly higher in umbilical plasma compared to maternal plasma at delivery. These changes partially counteract the reduction in MMP induced by higher levels of HUFA.

## DISCUSSION

The loss of HUFA (mean 1.30% pts, 95% CI, 0.61–1.99) at delivery compared to mid-pregnancy was about equal to the increase in SFA and MUFA (mean 1.44% pts, 95% CI, 0.48–2.41). The lower content of HUFA in maternal plasma PL resulted in a higher MMP of the FA mixture in plasma PL.

HUFA were preferentially replaced by shorter-chain SFA, especially palmitic acid as was also demonstrated in anorexia nervosa (4). These shorter-chain FA are more fluid than their longer-chain homologs because they have lower melting points. The MMP of SFA was significantly lower at delivery compared to pregnancy. Although the shorter chain length of the SFA compensates only partially for the higher overall MMP, it is possible that FA metabolism in pregnancy attempts to maintain MMP homeostasis as was shown previously in multiple sclerosis (1). An additional indication for this hypothesis is the positive correlation between the fraction of PUFA in PL with the MMP of SFA and of MUFA. This indicates that a loss in PUFA, which would result in an increased MMP, is accompanied by an increase in shorter-chain SFA and MUFA, which have an opposing effect on the MMP. A difference as large as 10.8°C was observed by Holman *et al.* (3) between the MMP of plasma PL FA of nonpregnant healthy controls (15.3°C) and the MMP of plasma PL FA of women at parturition (26.1°C). Taking into account the differences in MMP found in different populations , the latter value compares favorably with ours at delivery (27.3°C). In our study population, the MMP increases only 1.13°C from mid-pregnancy until delivery. The MMP of the FA mixture of PL in umbilical plasma (24.49°C) is comparable with a previously calculated value of 20.07°C of PL in normal cord serum (2), but is much lower than maternal values due to higher HUFA status. A higher HUFA fraction in umbilical plasma PL is accompanied with more longer-chain, less fluid SFA. The observed changes in the FA composition of maternal plasma PL during the course of pregnancy are probably not due to changes in dietary intake. Indeed, analysis of food frequency questionnaires (surveyed at the beginning of pregnancy and in the third trimester) of Belgian pregnant women attended by the same obstetrician revealed no significant differences in the FA composition of the diet nor in fat intake during the course of pregnancy (DeVriese, S.R., Matthys, C., De Henauw, S., Christophe, A.B., and Dhont, M., unpublished results). Others confirm these findings: the maternal dietary fat composition of pregnant Dutch women was consistent during pregnancy (12).

Holman *et al.* (3) found that pregnant women in their 36th wk of gestation have significantly suppressed concentrations of all the products of Δ5 desaturation compared to nonpregnant women. Our data reveal a similar pattern; the concentration of Δ5 products in mid-pregnancy is significantly higher than at delivery.

The essential fatty acid composition of maternal PL slightly changed from mid-pregnancy to delivery; 20:4n-6 and its elongation product 22:4n-6 declined, but 18:2n-6 remained stable. No changes were observed in 18:3n-3, 20:5n-3, or 22:6n-3, while 22:5n-3 decreased. The sum of the Δ5 desaturation products was lower at delivery indicating a lower essential FA status of the mother; however, the differences were small. Similar deviations in maternal essential FA status, but of greater magnitude, were reported by Al *et al.* (10th wk of gestation vs. delivery) (13) and by Otto *et al.* (14th wk of gestation vs. delivery) (14). The FA pattern of umbilical plasma presented here is very different from maternal values as was noted in previous studies (2,11–13,15–17). HUFA, especially 20:4n-6 and 22:6n-3, are higher in umbilical than in maternal plasma and both FA are lower in maternal plasma PL after delivery compared to mid-pregnancy. As FA desaturation and elongation by fetal tissues cannot meet neonatal needs (18–20), this could indicate a preferential placental transfer of these long-chain FA to the fetus (21). The total amount of FA in PL (mg/L plasma), and of each individual FA, is much lower in umbilical plasma compared to maternal values (Table 1). This is in concurrence with literature findings (13).

In summary, small but significant deviations were found in maternal plasma PL essential FA between mid-gestation and delivery. This is in concurrence with previous reports on the essential FA status of the mother during pregnancy.

This study extends the concept that changes in overall MMP are counteracted by changes in the MMP of individual FA classes. We demonstrated that in maternal plasma, the loss of HUFA during gestation is accompanied by a shorter MCL and a decrease in the MMP of the SFA. The high content of HUFA in umbilical plasma is associated with a significantly longer MCL and a higher MMP of the SFA. Thus, the FA composition of the SFA changes in a way to counteract changes in the MMP induced by changed HUFA composition. Similar adaptations in the FA composition of SFA, to maintain homeostasis in the overall MMP, were found in multiple sclerosis (2), cystic fibrosis, and anorexia nervosa (4).

**ABSTRACT**: We investigated the influence of various substrates on the uptake of long-chain fatty acid into IEC-6, rat intestinal epithelial cell line. The uptake of [$^3$H]oleic acid into IEC-6 cells was a saturable function of the oleic acid concentration. Long-chain fatty acids significantly inhibited the oleic acid uptake into IEC-6 cells and shorter-chain fatty acids had little or no effect. Various fatty acid esters suppressed the oleic acid uptake into IEC-6. Fatty alcohols also inhibited oleic acid uptake into IEC-6 and the length of the carbon chain played an important role. These results suggest that long-chain fatty acid uptake was inhibited by the substrates which had a structure similar to long-chain fatty acids, especially those with a long carbon chain. At least two molecules, fatty acid translocase and fatty acid transport protein type 4, which are considered to be involved in the long-chain fatty acid transport into the cell, were expressed on IEC-6 cells, supporting the existence of the carrier-mediated system of long-chain fatty acid transport on IEC-6 cells.

Paper no. L8556 in *Lipids 36*, 21–26 (January 2001).

Fatty acids are important nutrients, liberated from dietary lipids, mainly in the form of triacylglycerol. Today, many people avoid a high-fat diet because excessive intake of dietary fats causes obesity, the most common nutritional disorder in humans. Intestinal absorptive cells can easily absorb free fatty acids. Recently, the mechanism of fatty acid absorption has become an important topic.

Cellular uptake of fatty acids was formerly believed to occur by a purely passive process. However, kinetic properties of facilitated transport of long-chain fatty acids in the small intestine (1,2) and other tissues (3–5) have been exhibited. Now, many molecules that help the absorption of long-chain fatty acids are known to exist in the intestine (6–9). Plasma membrane fatty acid-binding protein (FABPpm) is expressed in several tissues including the small intestine (6), and antibodies against FABPpm decrease oleate uptake (6). However, FABPpm was subsequently identified as the mitochondrial aspartate aminotransferase (10), and the transport mechanism of this protein remains unclear. Fatty acid translocase (FAT), a homolog of human CD36, is localized in the adipocytes and other tissues, and is also expressed in the small intestine (7). The expression of mRNA of FAT, and cytosolic fatty acid-binding protein, was increased in the small intestine of rats fed a high-fat diet (8). Fatty acid transport protein (FATP) has been identified from adipocytes (11). FATP type 4 molecule (FATP4) is expressed in the small intestine and has been suggested to be a novel fatty acid carrier (9).

In this study, we investigated the effects of various components on oleic acid uptake into IEC-6, rat normal intestinal cell line, and the expression of two fatty acid-carrier membrane proteins, FAT and FATP4. The results show that long-chain alcohol and other fatty acid derivatives, especially those that have a long carbon chain, lead to the inhibition of oleic acid uptake by IEC-6 cells and that long-chain fatty acid uptake is possibly mediated by some carrier proteins.

## EXPERIMENTAL PROCEDURES

*Materials*. Bovine serum albumin (BSA) essentially fatty acid free and sodium taurocholate (TC) were obtained from Sigma Chemical Co. (St. Louis, MO). Oleic acid, oleyl alcohol, methyl oleate, linoleic acid, glutamine, glutamic acid, and D-glucose were purchased from Nacalai Tesque, Inc. (Kyoto, Japan). Oleyl oleate, oleamide and fatty alcohols were from Tokyo Chemical Industry Co. (Tokyo, Japan). [$^3$H]Oleic acid (1.85 TBq/mmol) was purchased from Moravek Biochemicals, Inc. (Brea, CA).

*Cell culture conditions*. The intestinal epithelial cell line IEC-6 (from American Type Cell Culture Collection, Rockville, MD), which was established from rat small intestine (12), was maintained in Dulbecco's modified Eagle's medium (GIBCO-BRL, Grand Island, NY) supplemented with 50 mL/L of fetal bovine serum (Bio Whittaker, Walkersville, MD), insulin (4 mg/L), and antibiotics (50,000 units/L of penicillin G sodium and 50,000 μg/L of streptomycin sulfate; GIBCO-BRL) at 37°C in 5% $CO_2$/95% atmosphere. The medium was changed every second or third day. Cells were subcultured when they were 70–80% confluent. For experiments, cells were seeded at a density of $5 \times 10^4$

Abbreviations: BSA, bovine serum albumin; FABPpm, plasma membrane fatty acid-binding protein; FAT, fatty acid translocase; FATP4, fatty acid transport protein type 4; HBSS, Hanks' balanced salt solution; PCR, polymerase chain reaction; RT, reverse transcription; TC, sodium taurocholate.

cells/well in a 24-well multi-plate (tissue culture-treated) and grown during 3–4 d.

*Preparation of test solutions.* Radioactive oleic acid solution was prepared as follows: [$^3$H]oleic acid and nonradiolabeled oleic acid were solubilized and mixed in ethanol and equilibrated overnight at 4°C (final specific activity was 1.48 GBq/mmol). On the day of experiment, the radioactive oleic acid solution was suspended in Hanks' balanced salt solution (HBSS) containing 10 mM TC to the final concentration 50 μM (radioactivity 74 MBq/L), or various concentrations for determination of dose-response, and incubated at 37°C. Nonradiolabeled oleic acid and other fatty acids and fatty acid derivatives were dissolved in ethanol and the aliquots were suspended in TC-HBSS to the desired concentrations (<1% at ethanol) and incubated at 37°C. The radioactive solution was mixed with the same volume of nonradiolabeled lipid solution or HBSS (as control) just before the incubation with the IEC-6 cells.

*Determination of oleic acid uptake.* Oleic acid uptake into IEC-6 cells was determined based on a procedure previously reported (13), after some modifications. The monolayers of IEC-6 cells were incubated at 37 or 4°C and washed with cold HBSS three times. The test solution (preincubated at 37 or 4°C) was added to an IEC-6 monolayer. After a specified incubation time, the test solution was aspirated off, and the monolayer was washed three times with cold HBSS containing 0.1% BSA (fatty acid free) and 0.05% sodium azide. Then the monolayer was washed once more with cold HBSS and lysed with 1% Triton X-100. The radioactivity of lysate was measured as cellular uptake of oleic acid with Aquasol-2 (Packard Bioscience B.V., Groningen, The Netherlands) using a liquid scintillation counter. The protein concentration of the cell lysate was also determined using a commercial protein assay kit (Bio-Rad Laboratories, Hercules, CA) based on Bradford's method (14).

*RNA isolation and reverse transcription-polymerase chain reaction (RT-PCR).* Total cellular RNA was isolated from IEC-6 and rat intestinal epithelial cells by QuickPrep® Total RNA Extraction Kit (Amersham Pharmacia Biotech, Uppsala, Sweden). Rat intestinal epithelial cells were isolated as previously reported (15) from 10-wk-old male Wistar rats (Japan SLC Co., Hamamatsu, Japan). Five micrograms of total RNA was reverse-transcribed to obtain cDNA with an Oligo dT primer (TaKaRa, Kyoto, Japan). RT reaction conditions were 70°C for 10 min, 42°C for 50 min, 70°C for 15 min for 1 cycle. PCR was performed with 1 out of 10 μL of cDNA as a template with Ex Taq DNA polymerase (TaKaRa) in a PCR Thermal Cycler SP (TaKaRa).

The oligonucleotide primers used to amplify respective cDNA sequences were 5′-GAGGTCCTTACACATACAG-3′ and 5′-GTGCCATTAATCATGTCGCA-3′ for FAT [corresponding to nucleotide number from 336 to 819 of the published rat sequence (GeneBank accession number L19658)]; 5′-TGGTGTACTATGGATTCCGCATG-3′ and 5′-TATCCTCATTGACACGTACCAA-3′ for FATP4 [corresponding to nucleotide number from 395 to 862 of the published mouse sequence (GeneBank accession number AF072759)]; and 5′-AACACCCCAGCCATGTACGTAG-3′ and 5′-TGTCAAAGAAAGGGTGTAAAACGC-3′ for β-actin [corresponding to nucleotide number from 462 to 1,250 of the published mouse sequence (GeneBank accession number X03672)]. Samples were heated to 94°C for 1 min. Subsequent cycles were incubated in three temperature steps: 0.5 min at 94°C, 1 min at 55°C, and 1 min at 72°C for 30 cycles. The PCR products were separated on a 2% agarose gel (NuSieve3:1 agarose, TaKaRa).

*Statistics*. Data are presented as means ± SEM. Statistical analyses were carried out with InStat Version 2.00 for Macintosh (GraphPad Software, San Diego, CA). The significance of differences in results among more than three groups was analyzed using a nonparametric test for independent variables (16); for comparisons between two groups at a particular time, a nonparametric test (17) for independent variables was used.

Differences with $P < 0.05$ were considered to be significant in all experiments.

## RESULTS

*Intracellular uptake of oleic acid into IEC-6 cells*. Figure 1 shows the uptake of oleic acid as a function of time (Fig. 1A) and oleic acid concentration (Fig. 1B). When 50 μM of [$^3$H]oleic acid in 10 mM TC-HBSS was incubated with IEC-6 cells, cellular oleic acid uptake was a saturable function of the incubation time (Fig. 1A) and the oleic acid concentration of test solutions (Fig. 1B). When the monolayer was incubated at 4°C, the radioactivity detected in the lysate was significantly lower than that of 37°C at 30 s of incubation and thereafter (Fig. 1A) as reported previously (2,18). Radioactivity detected at 15 s was considered to contain a large amount of oleic acid that bound to cellular membrane nonspecifically because detected radioactivities at 37 and 4°C were almost the same. Since the uptake was linear for 30 s (Fig. 1A) at 37°C, the following experiments were done using 30-s time points. The initial rate of uptake was determined with various oleic acid concentrations in the range of 5 to 600 μM. The uptake was a saturable function of total oleic acid concentration (Fig. 1B). The concentration of oleic acid monomer, which can pass through the cell membrane, was not determined, but the monomer concentration was considered to be proportional to the concentration of the test solution, as previously reported on α-linolenic acid (18).

*Effects of various substrates on oleic acid uptake into IEC-6 cells*. In order to determine whether the uptake of oleic acid by IEC-6 cells was modified by the presence of other substrates in the incubation medium, we examined the effects of several fatty acids, various derivatives of oleic acid, amino acids, and D-glucose, each at 500 μM, added to 50 μM of [$^3$H]oleic acid test solution. The addition of nonradiolabeled long-chain fatty acids, oleic acid, or linoleic acid, reduced the uptake of oleic acid significantly (Fig. 2). In the case of octanoic acid with a shorter carbon chain, the inhibition of oleic acid uptake was weaker and butyric acid, C4, had no effect

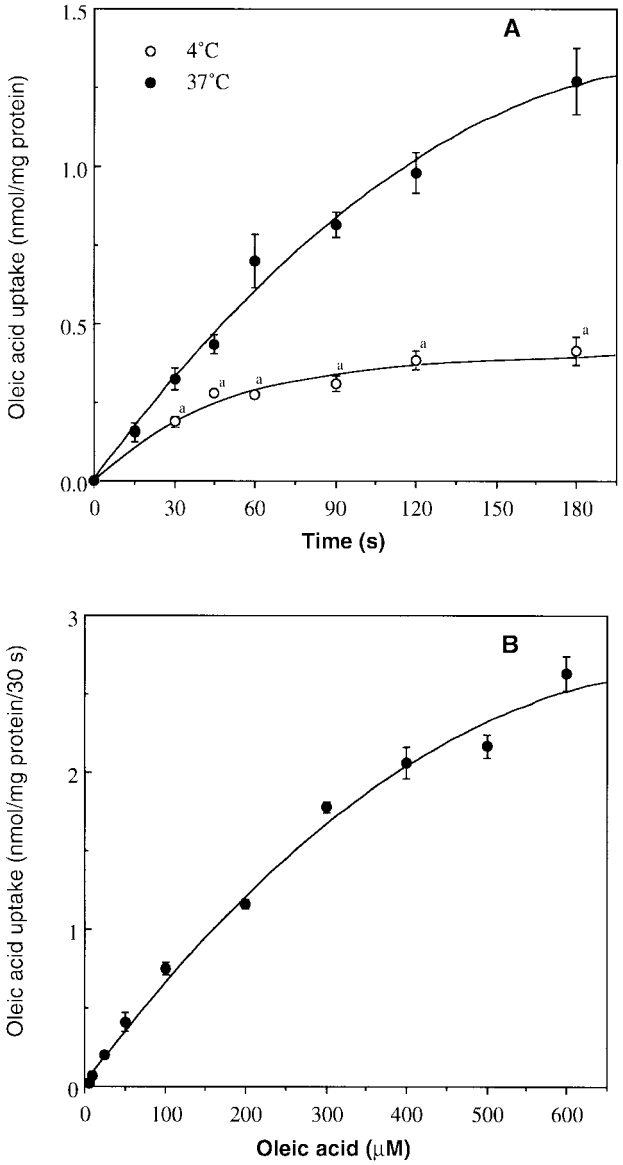

**FIG. 1.** Uptake of oleic acid by IEC-6 cells as a function of time (A) and oleic acid concentration (B). (A) The time course of oleic acid uptake at 37 and 4°C. IEC-6 monolayers (final concentration *ca.* 2.5 g protein/L) were incubated with [$^3$H]oleic acid (50 μM) in 10 mM sodium taurocholate-Hanks' balanced salt solution (TC-HBSS). Results are expressed as means ± SEM of two experiments. Values assigned a letter are significantly different at indicated time points at $P < 0.05$. (B) The uptake of oleic acid for 30 s at 37°C. IEC-6 monolayers (final concentration *ca.* 2.5 g protein/L) were incubated with various concentrations of [$^3$H]oleic acid in 10 mM TC-HBSS. Results are expressed as means ± SEM of two experiments.

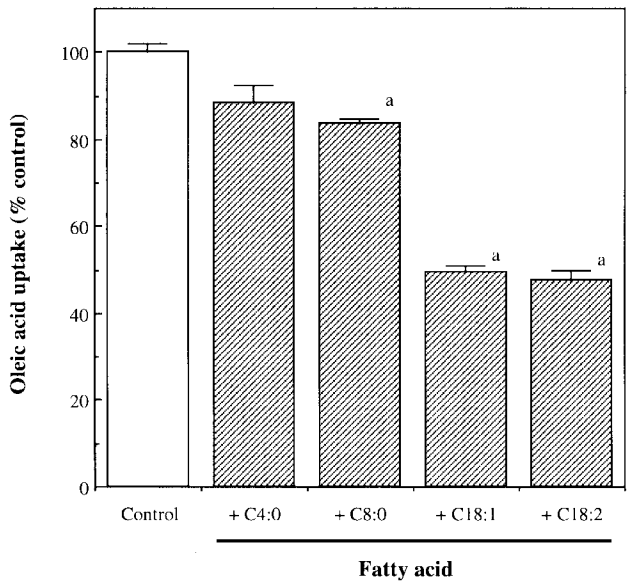

**FIG. 2.** Inhibition of oleic acid uptake with nonradiolabeled fatty acids in IEC-6 cells. IEC-6 monolayers were incubated with the test solutions containing [$^3$H]oleic acid (50 μM) and various fatty acids (500 μM), and mixed as described in the Experimental Procedures section for 30 s. Results are expressed as means ± SEM of four experiments, as % control (no nonradiolabeled fatty acid was contained). Values assigned a letter are significantly different from control at $P < 0.01$.

(Fig. 2). Changes in the cellular uptake of oleic acid induced by oleic acid analogs are shown in Table 1. When the oleic acid derivatives, in which the terminal carboxyl group was blocked (methyl ester, ethyl ester, and oleyl ester), were incubated simultaneously, oleic acid uptake was inhibited significantly. Oleamide and oleyl alcohol also inhibited the cellular uptake of oleic acid significantly. When the incubation medium was supplemented with glutamine or D-glucose that are actively transported by intestinal cells, but are not related to a fatty acid, there was no change in oleic acid uptake. Oleic acid uptake was slightly inhibited by glutamic acid, which has two carboxyl groups, although the differences were not significant. We also measured the uptake of Trypan blue at the same conditions to investigate cell viability. The viability of IEC-6 cells was not influenced by the incubation with these solutions (data not shown).

*Effects of various fatty alcohols on oleic acid uptake into IEC-6 cells*. Long-chain fatty acids inhibited oleic acid uptake into IEC-6 cells, while shorter-chain fatty acids did not.

**TABLE 1**
**Influence of the Various Unlabeled Substrates (500 μM) on Cellular Uptake of 50 μM [$^3$H]Oleic Acid into IEC-6 cells[a]**

| Additives | [$^3$H]Oleic acid uptake |
|---|---|
| | % Control |
| None (control) | 100.0 ± 1.6 |
| Oleic acid methyl ester | 75.1 ± 1.9* |
| Oleic acid ethyl ester | 61.1 ± 3.2* |
| Oleic acid oleyl ester | 56.2 ± 4.6* |
| Oleamide | 55.1 ± 3.6* |
| Oleyl alcohol | 63.2 ± 1.6* |
| Glutamic acid | 79.8 ± 7.8 |
| Glutamine | 94.0 ± 6.2 |
| D-Glucose | 96.0 ± 5.8 |

[a]Values are means ± SEM of four experiments. Oleic acid and additive substrates solutions were prepared separately in the presence of 10 mM of sodium taurocholate and mixed just before the incubation with IEC-6 cells. Uptake of radiolabeled oleic acid into cells was measured for 30 s. *Signficantly different from control, $P < 0.05$.

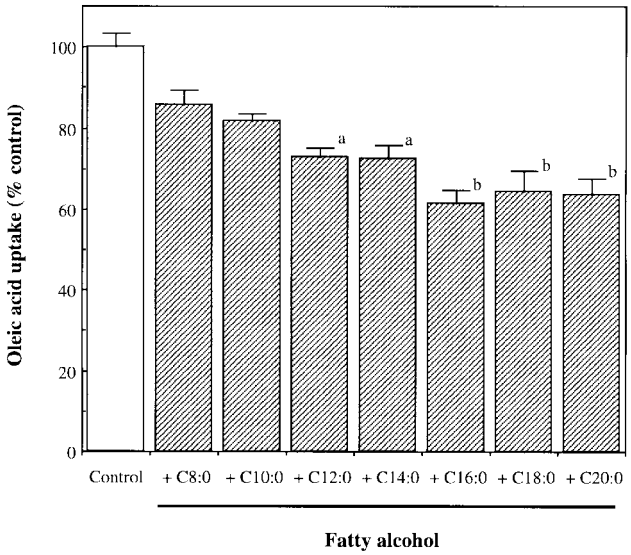

**FIG. 3.** Inhibition of oleic acid uptake with various fatty alcohols in IEC-6 cells. IEC-6 monolayers were incubated with the test solutions containing [$^3$H]oleic acid (50 μM) and saturated fatty alcohols with various carbon chain lengths (500 μM), and mixed as described in the Experimental Procedures section, for 30 s. Results are expressed as means ± SEM of four experiments, as % control (no fatty alcohol was contained). Values assigned letters are significantly different from control, $^aP < 0.01$, $^bP < 0.001$.

The effect of carbon chain lengths on the uptake of oleic acid was tested using various alcohols that had different carbon chain lengths. Oleic acid uptake into IEC-6 was inhibited by

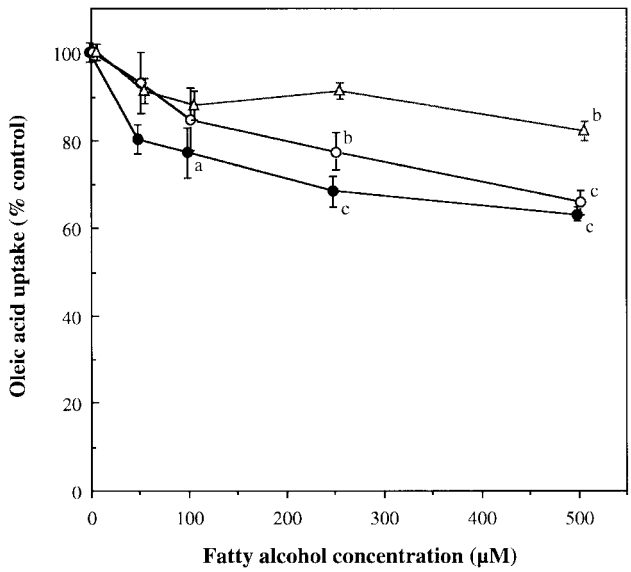

**FIG. 4.** Inhibition of oleic acid uptake with oleyl alcohol (●), stearyl alcohol (○), or octanol (△) in IEC-6 cells. IEC-6 monolayers were incubated with the test solutions containing [$^3$H]oleic acid (50 μM) and various amounts of fatty alcohols (25–500 μM), and mixed as described in the Experimental Procedures section, for 30 s. Results are expressed as means ± SEM of at least two experiments, as % control (no fatty alcohol was contained). Values assigned letters are significantly different from control, $^aP < 0.05$, $^bP < 0.01$, $^cP < 0.001$.

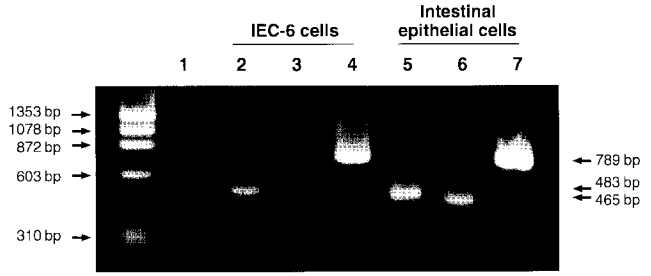

**FIG. 5.** Typical expression of fatty acid translocase (FAT), fatty acid transport protein type 4 (FATP4), and β-actin mRNA in IEC-6 cells and rat small intestinal epithelial cells by reverse transcription polymerase chain reaction (RT-PCR) experiments. Total RNA (5 μg) isolated from IEC-6 cells and intestinal epithelial cells were subjected to PCR (30 cycles), separated on a 2% agarose gel. Lane 1, without reverse transcriptase; lanes 2 and 5, FAT; lanes 3 and 6, FATP4; lanes 4 and 7, β-actin. IEC-6, lanes 2–4; intestinal epithelial cells, lanes 5–7. The size of the mRNA was determined by using a size marker (ϕX174/*Hae* III digest).

simultaneous incubation with fatty alcohol (Fig. 3). Octanol and decanol did not inhibit the uptake significantly, but dodecanol and other longer-chain alcohols inhibited the uptake significantly. Hexadecanol, octadecanol, and eicosanol were much more effective. Octanol also inhibited the oleic acid uptake in a dose-dependent manner, but not as much as oleyl alcohol and stearyl alcohol (octadecanol) (Fig. 4).

*Expression of the candidates of fatty acid transporter on IEC-6 cells.* Various plasma membrane proteins have been suggested to be involved in fatty acid uptake into cells. FAT and FATP4 are candidates of the carriers on intestinal fatty acid uptake. We investigated whether the carrier protein expressed on IEC-6 cells or not. RT-PCR analysis of the total RNA from IEC-6 cells was performed in comparison with rat small intestinal epithelial cells. Figure 5 shows the specific expression of RT-PCR products for FAT (483 bp) and FATP4 (465 bp) in IEC-6 cells and intestinal epithelial cells. FAT and FATP4 mRNA in IEC-6 cells were expressed substantially as in rat small intestine.

## DISCUSSION

Long-chain fatty acids have been believed to be taken into cells by simple diffusion for a long time. However, there are now many reports that various tissue cells express, at least in part, a saturable transport system of long-chain fatty acids (1–5). Here, we investigated whether the cellular uptake of oleic acid into IEC-6 cells was mediated by a kind of transporter or not.

IEC-6 is a normal rat small intestinal epithelial cell line (12). We have utilized IEC-6 cells as an adequate *in vitro* system of intestinal epithelial cells. Previously, we found that fatty acids activate the mobilization of $^{45}Ca^{2+}$, which might be concerned with signaling pathway by dietary fat in IEC-6 cells (19) as well as dispersed rat intestinal cells (15). This effect was inhibited by the presence of a fatty acid methyl ester and glutamic acid. These responses were similar to the effect of these substrates on the secretion of pancreatic juice in rats

(15). Thus, IEC-6 cells had a normal response to dietary components, especially to dietary fat. In this study, we investigated the cellular uptake mechanism of fatty acids using IEC-6 cells as a model and compared the results with the fatty acid recognition on IEC-6 cells.

We showed that oleic acid uptake into IEC-6 cells was saturable. This suggests a saturable transport mechanism and supports the carrier-mediated transport of long-chain fatty acids. Decrease of oleic acid uptake was observed at 4°C. This may be in part due to the change of the state of the cellular membrane and fatty acid micelles. On the other hand, the possibility of the energy-dependent active transport of fatty acids has been reported (18). It is possible that the radioactivity detected at 4°C reflected nonspecific binding and/or uptake into cells because this was almost constant at 30 s (*ca.* 50% of controls) and thereafter. Our results showed that nonradiolabeled long-chain fatty acids inhibited the oleic acid uptake into IEC-6 cells to 50%. In the case of the initial rate of uptake, half of the fatty acid uptake was probably caused by passive diffusion.

Our results showed that nonradiolabeled oleic acid and linoleic acid inhibited the oleic acid uptake into IEC-6 cells, but butyric acid and octanoic acid had little or no inhibitory effect. Similar results were reported previously. Gore *et al.* (18) reported that α-linolenic acid inhibited the linoleic acid uptake by isolated rat enterocytes. On the other hand, short-chain octanoic acid could not inhibit oleic and palmitic acid uptake into Caco-2 cells, a human colon adenocarcinoma cell line, which was generally used as an intestinal cell model (13). These results suggested that the absorption mechanism of long-chain fatty acids was different from that of short-chain fatty acids in the intestine.

Our results also showed that various fatty acid derivatives inhibited the oleic acid uptake into IEC-6 cells. The inhibitory effects varied from 25 to 45%, and the differences were caused by the differences in the structures of these molecules. A fatty acid methyl ester has been reported to inhibit the cellular uptake of linoleic acid and α-linolenic acid (18,20). In this study, we investigated the oleic acid uptake and focused the effect of fatty alcohols. Fatty alcohols exist in the form of wax esters in marine organisms (21) and plants (22) and are indeed contained in human foodstuff. Methyl esters can easily be hydrolyzed in the small intestine and absorbed in a manner similar to fatty acids in rats (unpublished data, Murota, K., Kawada, T., and Fushiki, T.), but fatty alcohols may remain in an intact form in the intestinal lumen and are hardly absorbed. It may be possible that small amounts of fatty alcohols free from wax esters are taken into the gastrointestinal tract and interact with dietary fatty acids. Our results showed that especially the substitutes that had a long carbon chain had a stronger effect. Glutamic acid also inhibited slightly the oleic acid uptake, but glutamine, which does not have a terminal carboxyl group, had no effect. Fatty acid esters and amide had a weaker effect than nonlabeled fatty acids. These results suggest that the carboxyl group also plays a role in fatty acid uptake. However, compared to our previous study on calcium mobilization by lipids (15,19), carboxyl group had a weak effect on fatty acid uptake. The fatty acid recognition mechanism by signal transduction pathways and absorption may not be the same. The test solution used in the calcium mobilization study contained serum albumin, different from taurocholate used in this study. Taurocholate has many hydroxyl groups and may have some interaction similar to fatty alcohol with a fatty acid carrier. Another possible factor is the influence of the condition of the test solution. Previously, we investigated the effect of oleyl alcohol on fatty acid absorpion of rats *in vivo* (23). Dietary fatty acids are solubilized as bile acid micelles in the small intestine. In the *in vivo* study, we used test solutions with a high concentration of oleic acid and oleyl alcohol (100–200 mM) as the emulsion with taurocholate, resulting in oleyl alcohol inhibiting the fatty acid absorption. The emulsions were very turbid, and the micellar condition was not negligible. It is possible that fatty alcohol and other derivatives exert an influence on the micellar condition and inhibit the oleic acid from being free monomers, especially in the high concentration solutions. Although oleic acid was also assembled into micelles with taurocholate to be solubilized in the aqueous phase in this study, the concentrations of oleic acid and other substrates in the test solutions in this study were significantly low (50–500 μM) and the solutions were absolutely clear. In either case, taurocholate has some influence on cellular fatty acid uptake, and fatty acid absorption into enterocytes may be controlled by bile acids *in vivo*.

Tranchant *et al.* (20) reported the inhibition effect of various lipids on the linolenic acid uptake into Caco-2 cells. They showed that the inhibition of initial rate of uptake was not due to a decrease of the monomer concentration of linolenic acid in the incubation medium but due to the inhibition of carrier-mediated transport. Gore *et al.* (18) also reported that the linoleic acid methyl ester inhibited linoleic acid uptake into isolated enterocytes of rats. However, Stahl *et al.* (9) reported that long-chain fatty acid methyl esters and ethyl esters hardly inhibited the incorporation of fluorescently labeled fatty acids into FATP4-expressing cells. It is possible that the characteristics of various molecules, for example fatty acid esters, caused a change in the micellar state and inhibited uptake. However, if fatty acid ester influenced the micelles, the existence of esters should certainly cause the inhibition of uptake in all cases. These reports suggest the existence of several carriers in enterocyte that recognize fatty acid in different way. Previously, both FAT and FATP4 have been considered as possible candidates concerning intestinal fatty acid transport. We showed that FAT and FATP4 were expressed on IEC-6 cells. The expression level of these molecules on IEC-6 cells was substantially same as in rat small intestinal epithelial cells.

In conclusion, oleic acid uptake was inhibited by fatty acid derivatives and the length of the carbon chain played an important role. Thus, our results suggest that long-chain fatty acids are probably taken into IEC-6 cells *via* a kind of transporter, with FAT and FATP4 as possible candidates, and the transporters recognize both the length of carbon chain and carboxyl group of the molecule.

**ABSTRACT:** Cholesteryl ester, along with triglyceride (TG), is the major core component of plasma lipoproteins. We investigated the effect of core composition on the physical state and metabolic behavior of lipid emulsions, as model particles of lipoproteins. Fluorescence studies using 1,6-diphenylhexatriene analogs showed that although cholesteryl oleate (CO) significantly decreased core mobility, the surface rigidity of phosphatidylcholine (PC) monolayers was independent of core composition. When intravenously injected into rats, the increased amount of core CO tended to retard TG emulsion removal from plasma, and the initial clearance rate was correlated with the amount of apolipoprotein E (apoE) bound from plasma. In addition, PC liposomes with a similar emulsion particle size showed negligible binding of apoE and were cleared at a slower rate compared to all emulsions. Furthermore, the effect of CO on the binding behavior of apoE to the emulsion surface and the emulsion uptake by hepatocytes was assessed *in vitro*. Replacing core TG with CO was found to decrease the apoE binding capacity to emulsions markedly without changing the binding affinity and thereby to reduce the cell uptake of emulsion particles by HepG2 cells. These results indicate that the physical state of core lipids, which can be modulated by CO content, plays a role in emulsion metabolism through the alteration in apoE binding.

Paper no. L8489 in *Lipids 36*, 27–33 (January 2001).

Apolipoprotein E (apoE) is a 299-residue plasma apolipoprotein that plays a key role in the hepatic metabolism of triglyceride (TG)-rich lipoproteins, such as chylomicrons, very low density lipoproteins (1–3), and lipid emulsions (4,5). In these particles, the hydrolysis of core TG by lipoprotein lipase leads to the production of relatively apoE-enriched remnant particles, which are rapidly taken up by the liver due to a specific interaction between apoE and cell receptors (6,7). In contrast, apolipoproteins C (C-I, C-II, and C-III-apoCs) inhibit this apoE-mediated hepatic uptake (8–11) probably through the displacement of apoE on these particles (12) or through a direct interaction with apoE (13). These findings indicate that the hepatic uptake of remnant particles is governed by the balance of apoE and apoCs on the particle surface. Although lysophosphatidylcholine (14,15) or cholesterol (16–19) is a key component influencing the balance of both apolipoproteins and consequent remnant metabolism, which factor(s) determine the binding behavior of apolipoproteins in lipoproteins remains obscure.

In addition to surface lipids, several lines of study have shown that the core composition of lipoproteins and lipid emulsions influences their metabolic fates. The increase in core content of cholesteryl ester in low density lipoproteins (LDL) (20) and lipid emulsions (21) facilitates the cellular uptake of these particles, probably through the alteration of apoB or apoE conformation. In fact, physical states of core lipids have been shown to affect the conformations of apoB in LDL (22). We previously demonstrated that cholesteryl oleate (CO) reduces the amount of apolipoprotein A-I (apoA-I) (23) and apoE (18) bound to emulsions and causes an alteration of emulsion metabolism in rats (24). However, the precise mechanism by which core composition affects apolipoprotein binding and metabolism of lipid emulsions is still unclear.

In this study, we investigated the relation of the binding behavior of apoE to plasma clearance in rats and cell uptake by human hepatoma cells (HepG2) of emulsion particles prepared by varying the core content of CO. The data presented here show that the decrease in core mobility caused by CO significantly reduces hepatic uptake of emulsions because of the inhibition of apoE binding.

## EXPERIMENTAL PROCEDURES

*Materials.* Recombinant human apoE (isoform E3) was provided by Pepro Tech EC Ltd. (London, United Kingdom). This apoE was previously shown to have similar physical and biological properties to native human plasma apoE (25). Sodium dodecylsulfate-gel electrophoresis of the current sample showed one major band (34 kDa) and two minor bands at 30–32 kDa (about 10% each). No bands indicating

Abbreviations: apoA-I, apolipoprotein A-I; apoE, apolipoprotein E; CO, cholesteryl oleate; DPH, 1,6-diphenylhexatriene; FBS, fetal bovine serum; FCR, fractional clearance rate; LDL, low density lipoprotein; PC, egg yolk phosphatidylcholine; py-CE, cholesteryl 1-pyrenedecanoate; TG, triglyceride; TMA-DPH, 1-[4-(trimethylamino)phenyl]phenylhexatriene; TO, triolein.

protein aggregation were observed. Egg yolk phosphatidylcholine (PC) was generously provided by Asahi Kasei Co. (Tokyo, Japan). Triolein (TO) and CO were purchased from Sigma Chemical Co. (St. Louis, MO) and used without further purification. Cholesteryl 1-pyrenedecanoate (py-CE), 1,6-diphenylhexatriene (DPH), and 1-[4-(trimethylamino)-phenyl]phenylhexatriene (TMA-DPH) were purchased from Molecular Probes Inc. (Eugene, OR). All other chemicals were of special grade from Wako Pure Chemicals (Osaka, Japan).

*Preparation of emulsions and vesicles.* Emulsion particles were prepared using a high-pressure emulsifier as previously described (18,26). Briefly, mixtures of TO, CO, and egg PC were suspended in 10 mM Tris-HCl buffer (pH 7.4), containing 150 mM NaCl, 1 mM EDTA, and 0.01% $NaN_3$, and successively emulsified at 60–70°C. After removing contaminating vesicles by ultracentrifugation, homogeneous emulsion particles were obtained. Quasi-elastic light scattering measurements (Photal LPA-3000/3100; Otsuka Electronic Co., Osaka, Japan) demonstrated weight-averaged diameters of 107 ± 26, 113 ± 27, and 119 ± 22 nm for TO-PC, TO/CO (1:1)-PC, and CO-PC emulsions, respectively. Egg PC vesicles with a diameter of 108 ± 12 nm were prepared by an extrusion technique (26).

*Cell cultures.* HepG2 cells were grown in a humidified incubator (5% $CO_2$) at 37°C in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum (FBS), L-glutamine, penicillin, and streptomycin (27). The FBS was changed to 10% human lipoprotein-deficient serum 24 h before each experiment.

*Fluorescence anisotropy measurements.* Emulsion samples were labeled with DPH or TMA-DPH by adding stock solutions of the probes to yield a probe/core lipids molar ratio of 1:200 for DPH and probe/PC ratio of 1:100 for TMA-DPH. Steady-state fluorescence anisotropy was measured with a Hitachi F-4500 spectrofluorometer (Tokyo, Japan) (26).

*Serum incubation studies.* Binding of apolipoproteins from human serum to emulsions and vesicles was examined as reported previously (18). Emulsions or vesicles were incubated with chylomicron-free serum for 20 min at 37°C, and then the mixtures were centrifuged to separate bound from free apolipoproteins. We did not observe transformation of large unilamellar vesicles into small disks in the present work. In vesicles, 3% sucrose was added to adjust serum density in which vesicles can be separated from lipoproteins by ultracentrifugation. ApoE concentration in the resulting emulsion-free serum was determined in single radial immunodiffusion assay plates, purchased from Daiichi Pure Chemicals (Tokyo, Japan). Intense scattering from lipid particles and ultraviolet absorption of PC and TO interfered with exact spectroscopic determination of the bound protein content. It was also difficult to provide appropriate references for the bound protein in the immunodiffusion assay. Accordingly, the amount of bound apolipoproteins was calculated as the difference between apolipoprotein concentrations in serum before and after incubation. Since the amount of apolipoprotein binding obtained per particle of phospholipid was almost constant, ranging in total lipid concentration of emulsions or vesicles from 1 to 5 mM, saturation of apolipoprotein binding to the particle surface appeared to be achieved in this condition.

*Injection studies in rats.* Fasted male Wistar rats weighing 200 ± 20 g were anesthetized with sodium pentobarbital (Nembutal). py-CE-labeled emulsion or vesicle fractions, containing 4–5 μmol of surface PC that corresponded to 30 μmol of total lipids for emulsions and 10 μmol of total PC for vesicles, were injected into the exposed femoral vein. At the indicated times, blood samples of 250 μL were taken from the carotid vein using a heparinized syringe and immediately centrifuged to separate plasma. To 100 μL of each plasma sample, 600 μL of chloroform/methanol (1:1, vol/vol) was added and then centrifuged to remove proteins from plasma. Fluorescence intensity (excitation 342 nm, emission 377 nm) in each sample was measured with a Hitachi F-4500 spectrofluorometer. Initial plasma clearance rates were calculated as fractional clearance rates from exponential curves fitted by least-squares statistical analysis. Animal work has been reviewed by the Faculty Board.

*ApoE binding assays.* ApoE binding assays were performed in Tris-HCl buffer (pH 7.4) in the presence of 0.25 M sucrose according to the method previously described (23). Briefly, after the incubation of emulsions with recombinant apoE for 30 min at 37°C, the mixtures were subjected to ultracentrifugation to separate both emulsions and lipid-bound apoE from free apoE. The free apoE concentration was determined by measuring the tryptophan fluorescence at 335 nm (excited at 280 nm). The lipid-bound apoE amount was calculated by subtracting the background of free apoE concentration in the top fraction obtained from the results of centrifugation of lipid-free apoE solution (28). Binding data were analyzed using Equation 1 (29),

$$P_f = [\mathrm{PL}]\,(P_f/P_b)\,N - K_d \qquad [1]$$

where $P_f$ and $P_b$ are free and bound protein concentrations, respectively, [PL] is the concentration of phospholipid, $N$ is the binding maximum, and $K_d$ is the dissociation constant.

*Cellular uptake assays.* py-CE-labeled emulsions or vesicles were preincubated with recombinant apoE (16 μg of apoE/μmol of neutral lipid for emulsions and 40 μg of apoE/μmol of PC for vesicles) at 37°C for 30 min to allow apoE equilibrium binding. This apoE-particle complex was diluted and added to the cells. After incubation at 37°C for 2 h, the cells were chilled on ice and washed three times in Hepes buffer, and then dissolved in 0.2% Triton X-100. Fluorescence intensity of py-CE and protein concentration of each sample were determined to calculate particle uptake.

*Lipid and protein analysis.* Phospholipid concentration was determined by phosphorus assay according to the method of Bartlett (30). The concentrations of other lipids were determined using enzymatic assay kits purchased from Wako Pure Chemicals. The protein concentration was determined by the method of Lowry (31), using bovine serum albumin (Bio-Rad, Richmond, CA) as a standard.

## RESULTS

*Fluorescence anisotropy in emulsions.* Figure 1A shows fluorescence anisotropy of DPH incorporated into TO-PC and CO-PC emulsions as a function of temperature. TO-PC emulsions showed a monotonical decrease in DPH anisotropy with increasing temperature, whereas CO-PC emulsions exhibited a temperature break at 41°C, which corresponds to an order–disorder transition of the core CO in emulsions (32). Over the temperature range studied, the anisotropy value of DPH in CO-PC emulsions was much higher than that of TO-PC emulsions, indicating that CO in the emulsion core has a more ordered structure than TO below and above the transition temperature.

As shown in Figure 1B, incorporation of CO into TO core caused an increase in DPH anisotropy with increasing CO. However, change in core mobility had no effect on TMA-DPH anisotropy, indicating that the physical states of lipids on the emulsion surface and in the core seem to be independent (18,33).

*Plasma clearance of emulsions in rats.* Previous work in our laboratory showed that replacing core TG with CO significantly reduces plasma clearance and liver uptake of emulsions in rats (24). To assess the effect of composition and physical states of core lipids on plasma clearance of emulsions more precisely, we evaluated the clearance rates of emulsions varying the core content of CO and of PC vesicles, which have no core lipids and are thought to be extreme particles, showing no effect of core lipids. Since these particles have a similar particle size (about 100 nm in diameter) and the same surface composition, i.e., only PC, the difference in plasma clearance is considered to be due to the core effect.

As shown in Figure 2, *in vivo* clearances of these particles (traced by py-CE label) depended strongly on core compositions. At 1 h after the injection, about 60% of the injected TO-PC emulsions was cleared from plasma. In contrast, increasing CO content in the emulsion core tended to retard the plasma clearance of emulsions. PC vesicles injected at similar numbers particle to emulsions were cleared from plasma at a slower rate compared to all emulsions studied. Table 1 lists the initial fractional clearance rates (FCR) of emulsions and vesicles *in vivo*. The table also summarizes DPH anisotropy values, representing the core mobility in emulsions except PC vesicles, and the binding amount of apoE in human serum, indicating the binding capacity for apoE of each particle. As seen in Table 1, the initial clearance rate of emulsions from plasma appeared to be correlated with apoE binding and inversely correlated with DPH anisotropy, suggesting that the core composition of emulsions regulates the initial plasma clearance *in vivo* through the decrease in apoE bound. In addition, PC vesicles exhibited a negligible binding capacity for apoE and a smaller clearance rate from plasma than all emulsions, providing further evidence for the importance of core lipids for apoE binding and therefore plasma clearance.

*ApoE binding to emulsions.* To further examine the effect of core CO on the binding behavior of apoE to the emulsion surface, we performed binding analysis of recombinant apoE using a centrifugation assay. Figure 3 shows the binding isotherms of apoE to emulsions and vesicles. Although apoE appeared to bind to all particles in a saturable manner, replacing core TO with CO markedly decreased the binding amount of apoE. According to the linearized plot of binding data (23,28), binding parameters, the dissociation constant $K_d$, and the binding maximum $N$ were obtained (Table 2). Increasing CO content in the TO core gradually reduced the binding capacity of apoE without changing the affinity. This was consistent with the results partly showing the effect of CO on apolipoprotein binding in cholesterol-containing emulsions. The binding capacity of apoE to PC vesicles was negligibly small compared to emulsions, as observed for apoA-I (23).

*Cell uptake of emulsion particles.* To determine the contribution of apoE to the cellular uptake of these particles, we compared the particle uptake by HepG2 cells. As shown in Figure 4, apoE enhanced the cellular uptake of all particles

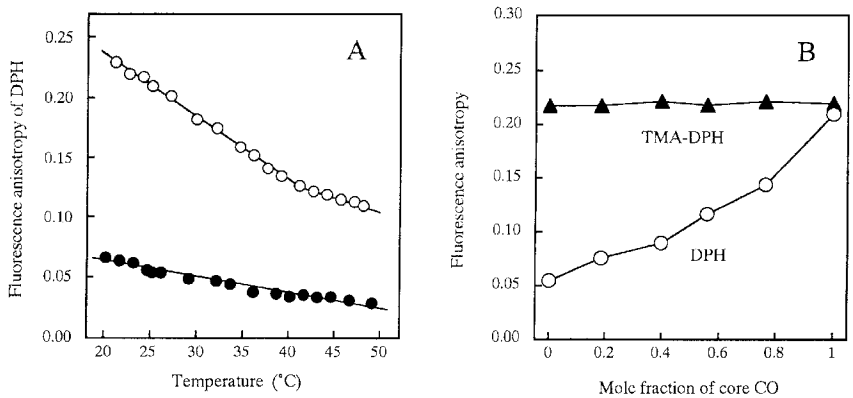

**FIG. 1.** (A) Fluorescence anisotropy of 1,6-diphenylhexatriene (DPH) in triolein-phosphatidylcholine (TO-PC) (●) and cholesteryloleate-phosphatidylcholine (CO-PC) (○) emulsions as a function of temperature. (35,36). Uptake of TO-PC emulsions increased up to 7–8-fold by the addition of apoE, but the effect of apoE decreased with increasing CO content and was almost negligible on the uptake of PC vesicles. From $K_d$ and $N$ values in Table 2, we estimated the number of apoE molecules bound to each particle at the cell experiment condition: approximately 36, 30, 19, and 5 apoE molecules per particle for TO-PC, TO/CO (1:1)-PC, CO-PC emulsions, and PC vesicles, respectively. The apoE molecules available on particle surface were comparable to the magnitude of particle uptake in the presence of apoE, suggesting that the cell uptake of these particles was modulated by the amount of bound apoE. In addition, the close correlation between the percentage cell association of each particle and the amount of apoE bound per particle, including results of TO-PC emulsions with varying added apoE content in which over 90% of the added apoE bound to the emulsion surface (Fig. 4, inset), clearly indicated that the reduced uptake of CO-containing emulsions in the presence of apoE was due to a decrease in apoE bound on the particle surface, not to the effect of unbound apoE.

## DISCUSSION

During the metabolism of plasma TG-rich lipoproteins, lipoprotein particles become smaller in size and vary in lipid composition, specifically, in their CO content in the core. Particle size is shown to be an important factor in regulating the distribution of plasma apolipoproteins (29) and the hepatic uptake of lipoproteins (37,38). Our previous studies partially indicated the importance of lipid compositions in apolipoprotein binding and plasma clearance of lipid emulsions (18,24). In this study, we systematically compared physical states of core lipids, binding of apoE, and metabolic behavior of emulsions with various core compositions.

As shown in Figure 1, although the increase in core CO content significantly reduced the mobility of core lipids of emulsions, there was no change in surface rigidity as determined from fluorescence anisotropy of TMA-DPH, indicating that the physical state of core lipids had a negligible influence on the acyl chain mobility of the emulsion surface. However, we showed previously (23) and in the present study that the replacement of core TG with CO reduced the binding capacity of apoE and to a lesser extent, binding of apoA-I. This clearly indicates that apolipoprotein binding to the emulsion surface can be regulated by the physical states of not only surface but also core lipids, despite the fact that binding of apolipoproteins appears to occur at the emulsion surface.

Both apoA-I and E have several amphipathic helical segments that are thought to be responsible for lipid binding (39). Based on the binding model of apolipoproteins proposed by Segrest *et al.* (40,41), the apolipoprotein helices are predicted to insert deeply into the surface layers such that the amphipathic helices are buried within the hydrophobic interior of phospholipid monolayers. Taken together with the finding that a significantly small amount of apolipoproteins can bind to the PC vesicle surface compared to TO-PC emulsions, we suggested that the penetration of core lipids into the emulsion surface layers could release the packing stress created by the binding of apolipoproteins, allowing more apolipoproteins to bind to the emulsion surface (18,23). The reduced core mobility in CO-PC emulsions would therefore result in the decrease in the apolipoprotein binding observed in this study. In addition, recent studies have shown that lipid binding of apoE induces the conformational opening in the N-terminal domain, which exposes the hydrophobic faces of four helices, permitting their direct contact with the lipid surface (42,43). Such a conformation of apoE would need large packing defects on the lipid surface layers, which may be unfavorable for particles having a lesser ability to reduce the packing stress.

The decreased binding of apoE caused by increasing CO content in the core is predicted to alter emulsion metabolism significantly. In plasma clearance studies in rats, the increase in core CO content was shown to retard emulsion clearance from plasma, and the calculated initial clearance rate, FCR, was positively correlated with the amount of apoE bound from plasma, including the case of PC vesicles. This suggested that the amount of apoE associated with the particle is crucial for removal of these lipid particles from plasma. Cell experiments, which can exclude the influence of various reactions occurring in plasma such as transfer of apolipoproteins and TG hydrolysis by lipases, further confirmed that core CO significantly affected the liver uptake of emulsion particles. As shown in Figure 4, the enhancement by apoE on cell association of particles diminished with decreasing apoE availability on the particle surface, indicating that the amount of apoE per particle affected directly the liver uptake, namely the uptake by low density lipoprotein (LDL) receptor or heparan sulfate proteoglycans-LDL receptor-related protein pathway (3). These results are consistent with the notion that the absolute number of apoE molecules bound on the particle surface determines the binding affinity of the particle to the receptor (44). Although Quarfordt *et al.* (21) reported that CO enhanced hepatocyte uptake of TO emulsions in the presence of apoE, they did not show the clear relation of the particle content of apoE with the increment in particle uptake by the cells. In addition to the importance of the amount of apoE on the particle, a conformational change of apoE has been suggested to be involved in the emulsion size-dependent receptor affinity (36) or the surface transition-induced change in $K_d$ (45). Since all emulsions used in this study have similar particle sizes and the same surface composition, the conformational change of apoE was unlikely to occur among emulsions, as reflected by the similar values of $K_d$ for all emulsions (Table 2).

When entering plasma, it is known that emulsion particles acquire plasma apolipoproteins, especially apoE and apoCs, and are consequently removed from plasma by the liver (5,46). Several lines of study have indicated that apoE plays a critical role in directing the clearance of emulsions from plasma and that the hepatic uptake of emulsions is modulated by the amount of apoE available (35,36). The present data demonstrate that the increase in core CO exerts its effect on emulsion metabolism by decreasing the binding capacity of apoE. We previously showed that replacing core TG with CO causes the relocation of cholesterol in the surface layers of emulsions, resulting in the alteration in emulsion surface properties (18). In this study, despite a lack of change in the surface rigidity of cholesterol-deleted emulsions, reduced mobility of core lipids caused by increasing CO content was shown to gradually reduce apoE binding and thereby retard cellular uptake of emulsion particles. Enrichment of CO in the metabolism of very low density lipoproteins to LDL is also accompanied by dissociation of apoE in animal plasma (18). Physiologically, the apoE-mediated hepatic uptake of plasma lipoproteins by cell receptors has been argued to be governed by the ratio of apoE to apoCs rather than the absolute apoE content (8,37,47). Further studies of the effects of cholesterol, in addition to those of CO, on the activation of apoE, apoE/apoCs balance and cell uptake of emulsion and lipoprotein particles are in progress.

# *In Vitro* Behavior of Marine Lipid-Based Liposomes. Influence of pH, Temperature, Bile Salts, and Phospholipase $A_2$

**Fabienne Nacka, Maud Cansell*, and Bernard Entressangles**

ISTAB, Laboratoire de Lipochimie Alimentaire, Université Bordeaux 1, F-33405 Talence cedex, France

**ABSTRACT:** To deliver polyunsaturated fatty acids (PUFA) by the oral route, liposomes based on a natural mixture of marine lipids were prepared by filtration and characterized in media that mimic gastrointestinal fluids. First the influence of large pH variations from 1.5–2.5 (stomach) to 7.4 (intestine) at the physiological temperature (37°C) was investigated. Acidification of liposome suspensions induced instantaneous vesicle aggregation, which was partially reversible when the external medium was further neutralized. Simultaneously, complex morphological bilayer rearrangements occurred, leading to the formation of small aggregates. These pH- and temperature-dependent structural changes were interpreted in terms of osmotic shock and lipid chemical alterations, i.e., oxidation and hydrolysis, especially in the first hours of storage. Besides, oxidative stability was closely related to the state of liposome aggregation and the supramolecular organization (vesicles or mixed micelles). The effects of bile salts and phospholipase $A_2$ ($PLA_2$) on the liposome structures were also studied. Membrane solubilization by bile salts was favored by preliminary liposome incubation in acid conditions. $PLA_2$ showed a better activity on liposome structures than on the corresponding mixed lipid–bile salt micelles. As a whole, in spite of slight morphological modifications, vesicle structures were preserved after an acid stress and no lipid oxidation products were detected during the first 5 h of incubation. Thus, marine lipids constituted an attractive material for the development of liposomes as potential oral PUFA supplements.

Paper no. L8566 in *Lipids 36,* 35–42 (January 2001).

Numerous liposome drug administration modes have been envisaged including parenteral, oral, topical, and pulmonary routes (1). Among them, oral intake appears versatile and safe. However, liposome physical stability in digestive tract conditions (low pH in the stomach, degradative enzymes and bile salts in the intestine) and absorption of the encapsulated material through the intestinal barrier remain two major problems to be solved. Whereas hydrosoluble drug delivery with oral liposome formulations may be controversial, lipophile molecule delivery led to more promising results (2). In this context, intake of n-3 polyunsaturated fatty acids (PUFA), mainly eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3), using liposomes can be envisaged. Indeed, these PUFA are associated with a variety of health benefits such as a reduced risk of coronary heart disease (3) or alleviated symptoms of rheumatoid arthritis (4). However, the benefit of n-3 PUFA intake is likely correlated with the bioavailability of these fatty acids. In humans, the PUFA acylglycerol form showed a better absorption rate than the corresponding ethyl ester form (5). More recently, DHA was shown to be assimilated better by preterm infants when administered in the phospholipid form than in the triglyceride form (6). On this basis, we have focused our attention on liposomes based on a natural mixture of lipids extracted from a marine organism and containing high contents of phospholipids with long-chain n-3 PUFA (7). The resulting liposomes were prepared by a simple method using one filtration step. Indeed, we deliberately chose not to reduce liposome size by sonication or extrusion so taking advantage of the multilamellar character to increase bilayer resistance to digestive fluids and, possibly, to improve PUFA absorption. These liposomes have already shown a good stability upon large pH changes regarding both their physical and chemical bilayer integrities (8). However, in the case of liposome administration by the oral route, the vesicle behavior has to be investigated when the temperature is elevated to a physiological value. Thus, chemical hydrolysis and oxidation as well as phospholipase $A_2$ ($PLA_2$) and bile salt actions were studied. As a whole, for incubation times compatible with the digestion process, we show that the marine lipid-based liposomes used in this study were quite stable as far as oxidation was concerned. Vesicles exhibited a complex morphological behavior as a function of large pH variations between 1.5–2.5 (for the stomach) and 7.4 (for the intestine). Nevertheless, the bilayer structures were mainly preserved so that $PLA_2$ could find the adequate interface for hydrolysis to proceed even in the absence of bile salts.

## EXPERIMENTAL PROCEDURES

*Material.* The natural lipid mixture supplied by IFREMER (Nantes, France) was extracted from a marine organism as previously described (7). The average lipid content was 69

wt% phospholipids (PL), 27 wt% cholesterol, and 4 wt% triglycerides (TG) (8). More precisely, PL were composed of 68 wt% phosphatidylcholine (PC), 23 wt% phosphatidylethanolamine (PE), 2 wt% phosphatidylserine, 2 wt% phosphatidylinositol, and 1 wt% sphingomyelin. In PL, 56% of total fatty acids were PUFA, among which EPA and DHA represented 30 and 59%, respectively. HEPES, bovine bile, and $PLA_2$ extracted from porcine pancreas were obtained from Sigma (St. Louis, MO). Sephacryl S-1000 was purchased from Pharmacia Fine Products (Uppsala, Sweden). All solvents were of analytical grade.

*Bovine bile purification.* Bovine bile was purified from colored pigments on activated charcoal. Dried bile (500 mg) in 10 mL water was added to 4 g of activated charcoal and the mixture was evaporated at 80°C. The powder was dissolved in absolute ethanol and distilled during 2 h. Charcoal was removed by filtration, and the decolorized bile was precipitated using diethyl ether. Precipitate was dried under a stream of nitrogen, and the total mass of purified bile was determined by weight. The different components of initial or decolorized bile were separated by silica gel thin-layer chromatography (TLC) using chloroform/methanol/acid acetic/water (65:25:15:9, by vol) as solvent and visualized by exposing the plates to iodine vapor (9). The same bile salt species were qualitatively identified, in initial and decolorized bile. Total PL amount was assayed by phosphorus analysis (10). Cholesterol and TG contents were analyzed using enzymatic kits (Boehringer Mannheim, Mannheim, Germany). Decolorized bile contained 11 wt% PL, 1 wt% cholesterol, and 1 wt% TG. Accordingly, bile salts represented 87 wt% of decolorized bile.

*Liposome preparation*. Liposomes were prepared by filtration of a lipid suspension according to a method based on Reference 11. Briefly, HEPES buffer (10 mM HEPES, 145 mM NaCl, pH 7.4) was used for hydrating a lyophilized lipid film. The lipid dispersion was successively filtered through polycarbonate membranes of variable pore diameters (Millipore Corp., Bedford, MA), i.e., 5, 1.2, and 0.4 µm. This preparation method led to a mixture of vesicles with a variable number of lamellae (8). Lipid losses by filtration through the membranes were quantified using phosphorus analysis for PL and enzymatic kits for cholesterol and TG. Total lipid concentrations ([lip]tot = [PL] + [cholesterol] + [TG]) given in this work took into account these lipid variations. Liposomes were exposed to acid conditions by dilution in solutions adjusted to pH 1.5 or 2.5 using HCl (10 N). Neutralization was carried out by addition of small volumes of NaOH (10 N) solution.

*Liposome characterization.* Liposome stability as a function of time was followed by turbidity measurements [optical density (OD) at 400 nm] in a 1-mm thick cuvette using a PerkinElmer Lambda Bio 20 spectrophotometer. The samples were maintained at 25 or 37°C in a thermostatted cell support during OD reading.

Gel exclusion chromatography (GEC) was performed using a Sephacryl S-1000 column (30 × 1 cm; Pharmacia) equilibrated at a flow rate of 0.4 mL $min^{-1}$ with HEPES buffer as elution buffer. The column was saturated with lipids by 1-mL repeated injections of a 0.4-µm liposome suspension (15.0 mM) until a constant elution profile was obtained. The liposomes conditioned in acid media (pH 1.5 or 2.5) were diluted in HEPES buffer before injection. Fractions (0.5 mL) were collected, and lipid presence was revealed by absorbance measurements at 280 nm. Fractions of interest were pooled and analyzed for PL content.

Size distribution, i.e., mean diameter and polydispersity index, was determined by quasi-elastic light scattering (QELS) and granulometry measurements. The apparatus used for QELS measurements consisted of a goniometer (BI-200SM; Brookhaven Instrument, Holtsville, NY), a photomultiplier tube (EMI PM-28B), a digital correlator (BI-9000AT; Brookhaven Instrument) and a krypton ion laser (Innova 90; Coherent, Santa Clara, CA) operated at a wavelength of 647.1 nm. The scattering cell was immersed in a refractive index matching fluid whose temperature was controlled at 25 ± 0.1°C. For each sample, data were acquired, typically for a duration of 10 min, for three runs at angles ranging from 30 to 150°C. Size measurements were also performed using a photon correlator spectrophotometer (Malvern Mastersize Ver. 214).

*Liposome micellization by bile salts.* Vesicle bilayer dissolution by bile salts was followed measuring the turbidity at 400 nm. Lipid–bile salt mixtures were prepared by adding defined volumes of a concentrated bile salt solution (650 mM calculated with an average molecular weight of 481 g $mol^{-1}$) to a liposome suspension with [lip]tot ranging from 0.3 to 0.8 mM. After stirring, the mixture was allowed to equilibrate until stable turbidity measurements were obtained. Solubilization was performed at 37°C, (i) on liposomes prepared in HEPES buffer and (ii) on liposomes that were first incubated 3 h in acid medium (pH 1.5) and then neutralized to get a final pH suspension at 7.4.

For each [lip]tot, a solubilization curve was obtained by plotting OD as a function of total bile salt concentration ([BS]tot). The solubilization point, corresponding to the bile salt amount required to completely transform the lipid bilayers into mixed micelles, was determined by the point at which additional detergent only slightly affected the suspension turbidity value, i.e., where OD was quasi-null (12,13). At this solubilization point, the concentration of bile salt molecules that are not associated with the lipids ([BS]bulk) and the bile salt to lipid molecular ratio in the mixed micelles ([BS/lip]mic) are given by the following equation (14):

$$[BS]tot = [BS]bulk + [BS/lip]mic \cdot [lip]tot \quad [1]$$

Using a linear regression analysis, [BS]bulk was found as the extrapolation to zero of the total lipid concentration, and [BS/lip]mic from the slope of the lines.

*Liposome PL hydrolysis by $PLA_2$.* PL hydrolysis in different lipid aggregates, i.e., bilayers and mixed lipid–bile salt micelles, was followed by titration with 0.01 N NaOH solution of the fatty acids liberated at 37°C using a pH-stat (Radiometer). Total lipid concentrations varied from 15.0 to 150.0 mM, which in terms of PL represented concentrations

([PL]tot) ranging from 10.0 to 103.0 mM. Initial liposome preparations were diluted in buffer (10 mM HEPES, 145 mM NaCl, 5 mM $CaCl_2$, pH 8) prior to enzyme addition. Then, liposomes were solubilized by addition of the required amount of bile salts in order to obtain mixed micelles. The hydrolysis reaction was initiated under stirring by $PLA_2$ addition (10 IU) to 2.5 mL of liposome or mixed micelle preparations. The initial velocity ($V_i$), defined as the micromoles of fatty acids liberated per minute, was determined from the initial slope of the titration curves of the hydrolysis experiment.

*Liposome chemical hydrolysis.* The different diacylphospholipid and lysophospholipid classes were assayed after lipid extraction (15) and two-dimensional TLC (8) on liposome dispersions incubated at 25 and 37°C, in HEPES buffer and acid medium (pH 1.5) for 0, 3, and 24 h. The different spots were scraped and analyzed for total phosphorus (10).

*Liposome oxidation.* Aldehydes were analyzed by static headspace gas chromatography (GC) (16). One-milliliter liposome samples ([lip]tot ranging from 0.2 to 7.5 mM) at different pH values (7.4, 2.5, and 1.5) were measured into special headspace 10-mL bottles, sealed under ambient air with Teflon caps, and incubated at two temperatures (25, 37°C) for 24 h. Liposomes and the corresponding mixed lipid–bile salt micelles ([lip]tot = 1.5 mM) were also compared in terms of peroxidation after storage at 37°C up to 30 h in acid medium (pH 1.5 and 2.5). Two-milliliter samples of the headspace were automatically taken and analyzed using a column coated with 1-µm thickness DB1701 (30 m × 32 mm; J&W Scientific, Folsom, CA) in conditions described in Reference 8. Quantification of the different aldehydes formed upon lipid peroxidation was carried out with calibration curves using pure standard solutions (hexanal, pentanal, propanal).

*Statistical analysis.* Differences between two groups were tested for significance using the Student's *t*-test. Data were expressed as mean values ± SD.

## RESULTS

*Liposome behavior under acid conditions.* Initial liposome suspensions were first characterized by granulometry. Vesicle mean diameter was found equal to 6.3 µm. In fact, liposomes prepared by filtration consisted of a polydisperse mixture of vesicles with diameters ranging from 0.5 to 30 µm. In order to mimic the gastrointestinal tract conditions, we examined the influence of medium acidification, as well as temperature increase up to a physiological value, on the vesicle behavior. Figure 1 shows the turbidity evolution, as a function of time, for liposome suspensions diluted in HEPES buffer and acid medium (pH 1.5) and stored at two temperatures (25 or 37°C). At pH 7.4, whatever the temperature, the turbidity remained stable for about 1 d, suggesting that liposome suspension was quite stable over this period of time. When liposomes were placed in an acid medium, turbidity drastically increased, indicating vesicle aggregation as confirmed by optical microscopy observation (8). Granulometry measurements indicated mean diameter of 14 µm for the aggregated

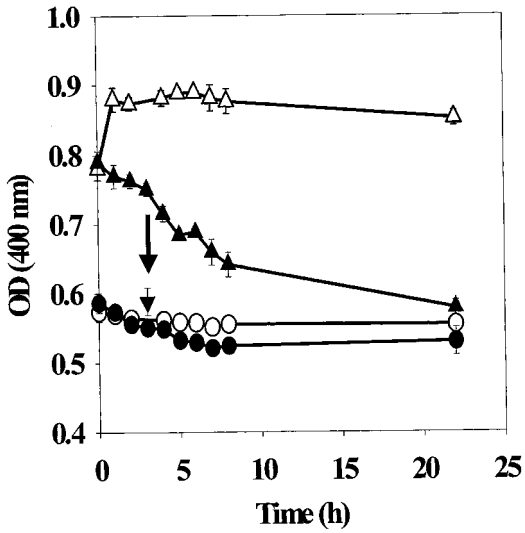

**FIG. 1.** Variations of optical density (OD) at 400 nm as a function of time for liposome suspensions incubated at different pH and 37°C: pH 7.4 (●); pH 1.5 (▲). Liposomes were prepared by the filtration technique using 5-µm pore diameter filters ([lip]tot = 0.3 mM). Acidification was performed using 10 N HCl solution. Sample corresponding to liposomes stored 3 h in acid medium (pH 1.5) was neutralized with 10 N NaOH solution (▼). Data at 25°C, pH 7.4 (○) and pH 1.5 (△), are reproduced from Reference 8. All experiments were performed at least three times with a SD of ±3%.

liposomes. While OD remained at a constant value when liposomes were stored at 25°C, over 24 h (8), a drastic turbidity decrease was observed at 37°C. In the physiological digestion process, liposomes would stay about 2–3 h in acid medium (stomach) before moving to a neutral environment (intestine). To mimic this gap in pH, a liposome sample previously stored under acid conditions during 3 h at 37°C was further neutralized. Medium neutralization induced a decrease in suspension turbidity, the resulting OD being close to that of an untreated sample.

Vesicle elution profile was studied for different incubation times, pH, and temperatures by GEC. The elution pattern of liposomes exposed to pH 7.4 at 25°C during 24 h showed a single peak, the maximum of which corresponded to an elution volume of about 11 mL (Fig. 2). Similar GEC profiles were obtained for liposomes stored, during 0 to 24 h, in the same pH (7.4) and temperature (25°C) conditions (results not shown), confirming the vesicle stability already suggested by the turbidity measurements (Fig. 1). For vesicles stored in an acid medium and/or at 37°C, the chromatograms displayed a second "peak" in the region of small lipid structures, this peak being broader when temperature and pH were combined. QELS measurements were performed on samples corresponding to the second peak. QELS mean diameters ranging from 350 to 500 nm were obtained for the different samples analyzed but their polydispersity in size did not allow discriminating the respective influence of pH and temperature. The relative proportion of the two GEC "peaks" was quantified by total PL analysis. Results are presented in Table 1. Storage of the liposome suspension at room temperature for 24 h led to

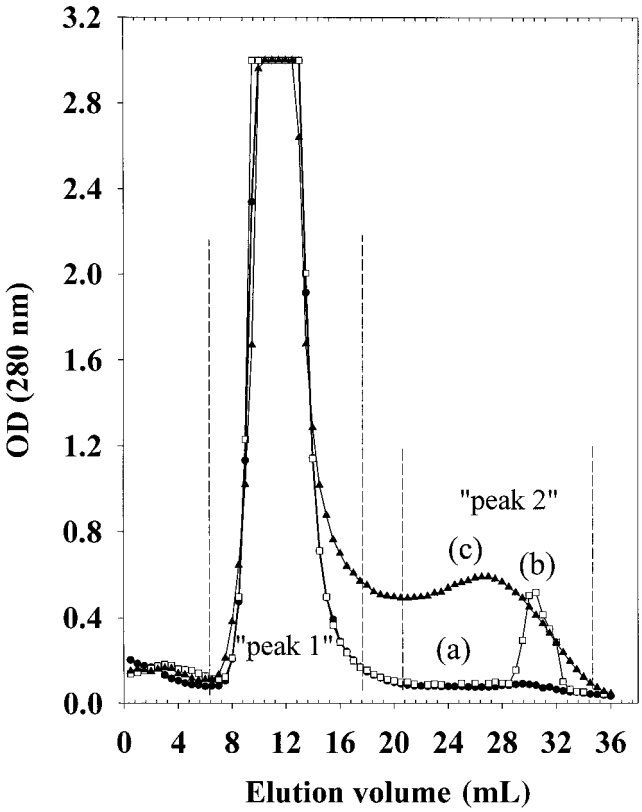

**FIG. 2.** Gel exclusion chromatograms of liposome suspensions after 24-h incubation time (a) in HEPES buffer (pH 7.4) at 25°C (●), (b) in HEPES buffer (pH 7.4) at 37°C (□), (c) after incubation for 3 h in acid solution (pH 1.5) at 37°C before neutralization and then 21 h of storage in buffer (pH 7.4) at 37°C (▲). Liposomes were prepared by the filtration technique using 0.4-μm pore diameter filters ([lip]tot = 15.0 mM, injected volume = 1 mL, flow rate = 0.4 mL $min^{-1}$). The chromatograms represented typical patterns out of four independent experiments.

a slight peak 2 increase (1%), which confirmed, once again, the liposome suspension stability under these storage conditions. When liposomes were incubated at 37°C, the amount of small structures associated with peak 2 slightly increased. However, the combination of pH (1.5 or 2.5) and temperature (37°C) drastically modified the liposome population profile since more than 20% of the initial liposome structures were turned into smaller structures.

*Liposome micellization by bile salts.* The solubilization process was visualized by the turbidity variations measured as a function of bile salt addition. Since detergent was externally added to preformed liposomes, it was essential to work with bile salts completely equilibrated within the lipid structures. Twenty-four hours were required to obtain constant, quasi-null turbidity values for the mixed micelle systems (result not shown), indicating that equilibrium was slowly reached compared to large unilamellar vesicles (14). To mimic the liposome route from the stomach to the intestine, liposomes were incubated 3 h at pH 1.5 then neutralized prior to bile salt addition. Medium acidification combined with temperature favored membrane solubilization by bile salts, and equilibration time was minimized so that 15 min were enough to get the

mixed micelles at equilibrium (result not shown). Varying the lipid concentration allowed the calculation of two parameters that describe the complete solubilization of the liposome membranes, i.e., [BS]bulk and [BS/lip]mic. The results are reported in Table 2 for mixed micelles at equilibrium. At neutral pH, increasing the temperature up to 37°C lowered both [BS/lip]mic and [BS]bulk values. However, at pH 7.4, the slight variation of [BS/lip]mic ratio with temperature may be related to the fact that, at 25°C, PL were already in the liquid-crystalline phase. Suspension acidification prior to bile salt action mainly affected the mixed micelle composition since [BS/lip]mic decreased significantly compared to the standard solubilization conditions (pH 7.4, 25°C). Influence of acidification on the amount of detergent molecules in the continuous medium was not so clear. Nevertheless, [BS]bulk values remained above the critical micellar concentration (cmc) of all the detergents (17) suggesting that, at the micellization point and afterward, mixed lipid–bile salt micelles and pure bile salt micelles coexist.

*Chemical stability of liposomes.* When containing PUFA chains, PL may undergo an oxidation process *via* a free-radi-

cal chain mechanism (18). Table 3 presents the analysis of volatile compounds as secondary oxidation products measured by headspace GC for liposomes at different concentrations, stored for 24 h under various pH and temperature conditions. Among the three aldehydes examined, propanal was the more abundant since it resulted from the oxidation of n-3 fatty acids that constituted about 95% of the total PUFA. For a given lipid concentration of 1.5 mM, whatever the pH medium, the rise of temperature from 25 (8) to 37°C increased the oxidized product amounts by a factor 2. For a given temperature, acid storage conditions also doubled oxidation product formation. The influence of the initial liposome concentration was also examined: the more concentrated the suspension, the less oxidation process observed. While at acid pH and high lipid concentration, the lipid oxidative stability may be related to the state of aggregation (19); at neutral pH, the results obtained remained unexplained. The time course of propanal formation in the liposomes and in the corresponding mixed micelles was examined at pH 1.5 and 2.5 up to 24 h (Fig. 3). Liposome suspensions were more stable than mixed micelles as evidenced by (i) the significant formation of propanal that occurred only after a lag period of 5 h instead of 1.5 h for mixed micelles and (ii) the lipid oxidation levels as a function of time that were globally lower in liposomes than in the corresponding mixed micelles. This suggests that the lipid resistance to oxidation is correlated with the different molecular packing conformations of PUFA acyl chains in the two types of lipid structures. Moreover, whatever the structure type, oxidation process was favored by decreasing pH values.

The resistance to chemical hydrolysis upon pH variations and temperature increase of liposomes based on marine lipids was investigated by the relative composition in PC, PE, and the corresponding lysophospholipids, i.e., lysophophatidylcholine (LPC) and lysophosphatidylethanolamine (LPE) (Table 4). At neutral pH and room temperature, 1-d storage slightly affected phospholipid hydrolysis (8). For a given pH, increasing the temperature from 25 to 37°C favored the degradation process as evidenced by significant increases of lysophospholipids. Moreover, hydrolysis was more pronounced in acid medium than in neutral medium, in agreement with ester cleavage being catalyzed in presence of acid (18). Finally, the hydrolysis process was significantly amplified when pH and temperature were combined.

$PLA_2$ catalyzes the hydrolysis of the *sn*-2 fatty acyl ester bonds of PL to produce 2-lysophospholipids and fatty acids. The catalytic behavior was studied on marine lipid-based vesicles exposed beforehand or not to acid conditions. Typical reaction process curves for the hydrolysis by $PLA_2$ of

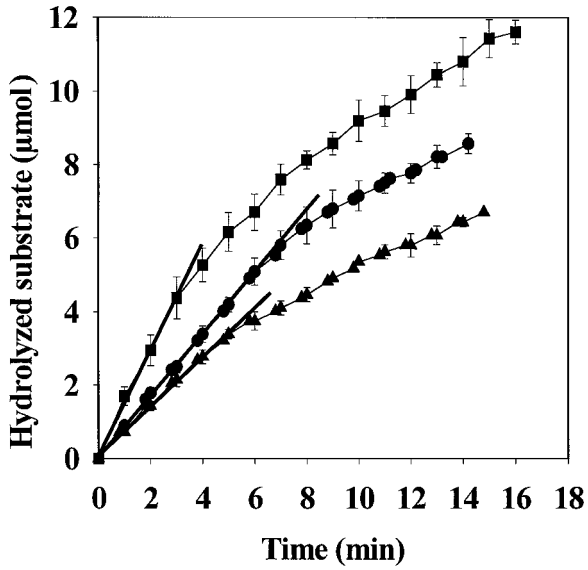

**FIG. 4.** Hydrolysis time course of liposomes (■), liposomes previously incubated 3 h at pH 1.5 and neutralized (●) and mixed lipid-bile salt micelles (▲) by phospholipase $A_2$ ([PL]tot = 27 mM, [$PLA_2$] = 13 µg $mL^{-1}$, [BS]tot = 0.5 M when used). The maximal velocity ($V_{max}$) was determined as the extrapolation of the linear line to 0 abscissa. All the experiments were performed at least four times with a SD of ±8%.

vesicles stored in neutral and acid pH media are shown in Figure 4. In these experiments, the lipid to enzyme ratio was above $10^5$ and ensured a saturating concentration of substrate (result not shown). The shape of the process curve was similar to that obtained by others (21,21), so that it may be assumed that $PLA_2$ hydrolysis obeys Michaelis-Menten kinetics. A similar profile was obtained for $PLA_2$ acting on mixed lipid-bile salt micelles (Fig. 4). The initial velocity per mg of enzyme protein under saturating conditions ($V_{max}$) was calculated from these three curves. Maximum activity value was obtained for the untreated liposome preparation (110 ± 15 µmol $min^{-1}$ $mg^{-1}$ of protein). $V_{max}$ value decreased when enzyme catalysis occurred on mixed micelles containing bile salts (56 ± 2 µmol $min^{-1}$ $mg^{-1}$ of protein). The 40% lower activity on detergent-dispersed micelles may result from a surface dilution of the substrate by the detergent (20). $PLA_2$ activity on vesicles previously incubated under acid conditions led to $V_{max}$ values (74 ± 4 µmol $min^{-1}$ $mg^{-1}$ of protein) intermediate to that obtained for mixed micelles and untreated liposomes. This may be correlated with acid storage conditions that initiated structural and chemical liposome modifications.

## DISCUSSION

Liposomes have been advocated in many applications since the demonstration of the existence of an internal aqueous volume promoted them to carriers of therapeutics and cosmetics agents. However, by virtue of their lipid composition, liposomes could also be effective for lipophilic drug delivery. Marine lipid-based liposomes were prepared with the aim to increase PUFA bioavailability. Nevertheless, liposome characterization with respect to vesicle composition and membrane integrity under various gastrointestinal constraints is needed before considering liposomes as a useful oral dosage form.

Liposome suspension acidification led to an instantaneous vesicle aggregation and to complex morphological bilayer rearrangements (8). Different mechanisms have been advocated to explain the liposome size decrease, including the osmotic shock occurring at acid pH and/or membrane vesiculation attributable to chemical lipid modifications. Increasing the temperature to 37°C seemed to speed these processes as shown by the decrease in turbidity (Fig. 1) and the formation of small lipid particles (Fig. 2 and Table 1). Simultaneously, chemical modifications, in particular oxidation and hydrolysis, occurred which may also proceed to structural changes. First, the greater amount of lysophospholipids formed upon temperature and pH could induce the beginning of a solubilization process or at least alter the membrane permeability. The effect of lysophospholipids and free fatty acids on liposome physical stability has been studied through membrane permeability and particle size measurements. For PC-based liposomes, 10% of lipid hydrolysis was required to promote calcein leakage (18). However, only hydrolysis levels higher than 40% modify liposome stability when monitored by turbidity and size measurements (22). Secondly, oxidation products are also known to increase membrane permeability toward encapsulated products (18). On the whole, the turbidity decrease of marine lipid-based liposome suspensions occurring in the first hours of storage at 37°C suggested that liposome destabilization proceeded by several simultaneous physical and chemical mechanisms. Among them, a simple slow dispersion of the aggregated liposomes as a function of time may not be excluded. With the view of using liposomes by the oral route, 3-h incubation in acid medium corresponds to a long residence time in the stomach for the physiological digestion process. At that time, the lysophospholipid production was not negligible (Table 4), but the oxidative stability was ensured (Fig. 3). Although after 3-h incubation under

acid conditions at 37°C, liposome turbidity had begun to decrease, the liposome membrane organization was globally preserved in simulated gastric conditions as suggested by restored turbidity values following suspension neutralization (Fig. 1). Moreover, optical microscopy observations indicated that part of the liposome aggregates were disrupted so that the suspension mainly contained isolated vesicles (not shown).

In physiological conditions, when in the intestinal tract, dietary lipids are first mixed with bile compounds, i.e., bile salts and phospholipids, so that an adequate lipid-water interface is created allowing pancreatic lipase and phospholipase adsorption and catalysis. Moreover, bile salt solubilization plays an important role in the intestinal absorption of lipids (23). By knowing that bile salt concentration in the intestine of a fasting patient is about 10 mM (24), our results suggested that the solubilization of marine lipid-based liposomes should not be complete in the intestine even after their passage in the stomach. Indeed, [BS]tot required to obtain the bilayer micellization exceeded a critical value of 17 mM for liposomes placed in conditions mimicking the physiological events (3 h at pH 1.5, 37°C, Table 2). The solubilization process is influenced by numerous parameters arising from both experimental conditions and liposome characteristics. Total transformation of PC bilayers into mixed micelles was achieved for a ratio of cholate per PC molecule equal to 8 (25). It is well established that the interactions of detergent with lipid bilayers depend on the lipid composition and especially the amount of cholesterol that stabilizes the membrane against cholate insertion (26). The presence of 27% cholesterol in the natural lipid mixture could explain the higher [BS/lip]mic values obtained in this work (Table 2). Only an acid treatment (pH 1.5) at 37°C prior to liposome solubilization decreased [BS/lip]mic values to that found in the literature for PC membranes. The temperature dependence for solubilization of various lipid–detergent systems has been pointed out for both ionic (27) and nonionic (28) detergents. In the case of ionic detergents, like bile salts, the temperature effect depended, at least partly, on the bile salt species and the lipid to bile salt ratio (27). For example, with taurodeoxycholate, at low lipid to bile salt ratio (corresponding to the presumed coexistence regime of simple and mixed micelles), temperature dependence was similar to the temperature dependence in pure bile salt solutions. The opposite phenomenon was observed at high lipid to bile salt ratio (where only mixed micelles were in presence), i.e., the micellar phase limit decreased with increasing temperature. On the whole, temperature may influence (i) the detergent solubility properties, i.e., the equilibrium between the surfactant dissolved in the aqueous medium and that associated with the lipid to form pure or mixed micelles; (ii) the meeting probability of detergent molecules and lipid membranes through increased Brownian motion. In our case, this temperature effect may explain the sample equilibration times required to obtain stable OD for the mixed micelle solutions: increasing the temperature from 25 to 37°C decreased the equilibration times from 24 h to 15 min (results not shown). Concerning pH influence, the higher [BS/lip]mic values observed at pH 7.4 compared to pH 1.5 may be related to increased amounts of degradation products (especially lysophospholipids) rather than to modifications of lipid packing. Indeed, if PC molecules in the liquid-crystalline phase experience a reduction in the disorder and motion after acidification (29), one must keep in mind that, in our experiments, a medium neutralization was performed prior to vesicle solubilization that should, at least partly, restore the original lipid organization. On the whole, liposome acid treatment seemed to favor bilayer solubilization by bile salts and incubation at 37°C may accelerate the kinetics of liposome micellization. Moreover, high amounts of bile salts required to completely solubilize the liposomes may not be prohibitory for liposome use and PUFA delivery. Indeed, in physiological conditions, $PLA_2$ acts simultaneously with bile salts and generates lysophospholipids that improve the solubilization process.

To mimic the entire lipid digestion process in the intestine, $PLA_2$ action toward liposomes was also addressed. Modulation of enzyme activity toward both physical and chemical membrane properties has frequently been invoked. Thus, phase separation (21,30), membrane curvature (21), or dynamic fluctuations of lipid packing (31) play a prominent role on the catalytic rate. In the same way, lipid composition (32,33), exogenous addition of lysophospholipids (34,35), and changing membrane composition during hydrolysis (36) also affect $PLA_2$ activity. In the present work, the size and lamellarity heterogeneities of the initial liposome dispersion and the membrane evolution as a function of time, pH, and temperature (i.e., small particle generation, lysophospholipid formation) prevented the accurate comparison of $PLA_2$ catalysis on liposomes (acidified or not) and micelles. However, it is clear that $PLA_2$ could act at the interface of liposomes previously incubated under acid conditions that mimic the gastric fluid. This result may be of particular importance for patients with bile secretion deficiency since the detergent would only be required for lipid intestinal absorption and not for the lipid-water interface creation.

In conclusion, we showed that marine lipid-based vesicles exhibited relative membrane physical and chemical stability in the gastric digestion conditions. Acidified liposomes were still an adequate binding surface for $PLA_2$ so that the enzyme was able to hydrolyze the PL present in such structures. On the whole, these results allowed envisaging these liposomes as an oral dosage form.

## ACKNOWLEDGEMENTS

The authors thank Drs. Jean Paul Gouygou and Philippe Roy (IFREMER, Nantes, France) and Dr. Gwenaël Baudimant (Phosphotec, France) for supplying the marine lipid extract. Maryse Maugey (Centre de Recherche Paul Pascal, CNRS, Pessac, France) is gratefully acknowledged for her technical assistance with the dynamic light scattering equipment.

**ABSTRACT:** Limited information is available regarding metabolism of vitamin E forms, especially the tocotrienols. Carboxyethyl-hydroxychromans (α- and γ-CEHC) are human urinary metabolites of α- and γ-tocopherols, respectively. To evaluate whether tocotrienols are also metabolized and excreted as urinary CEHC, urine was monitored following tocotrienol supplementation. Complete (24 h) urine collections were obtained for 2 d prior to (baseline), the day of, and 2 d after human subjects ($n = 6$) ingested tocotrienol supplements. The subjects consumed 125 mg γ-tocotrienyl acetate the first week, then the next week 500 mg; then 125 mg α-tocotrienyl acetate was administered the third week, followed by 500 mg the fourth week. Urinary α- and γ-CEHC were measured by high-performance liquid chromatography with electrochemical detection. Urinary γ-CEHC levels rose about four- to sixfold in response to the two doses of γ-tocotrienol and then returned to baseline the following day. Significant ($P < 0.0001$) increases in urinary α-CEHC were observed only following ingestion of 500 mg α-tocotrienyl acetate. Typically, 1–2% of α-tocotrienyl acetates or 4–6% of γ-tocotrienyl acetates were recovered as their respective urinary CEHC metabolites. A γ-CEHC excretion time course showed an increase in urinary γ-CEHC at 6 h and a peak at 9 h following ingestion of 125 mg γ-tocotrienyl acetate. In summary, tocotrienols, like tocopherols, are metabolized to CEHC; however, the quantities excreted in human urine are small in relation to dose size.

Paper no. L8424 in *Lipids 36,* 43–48 (January 2001).

Tocotrienols, members of the vitamin E family, have the same chromanol headgroup and are distinguished by an unsaturated phytyl chain. They are abundant in cereal grains, bran, some nuts, and in palm oil (1). *In vitro,* the tocotrienols are more potent antioxidants than the tocopherols (2,3). Their potent antioxidant activities have been suggested to be due to a combination of higher recycling efficiency from chromanoxyl radicals, more uniform distribution in membrane bilayers, and a stronger disordering effect on membrane lipids, which may make interaction of the chromanols with lipid radicals more efficient (2). Of further interest is the ability of tocotrienols, but not tocopherols, to suppress 3-hydroxy-3-methylglutaryl-CoA reductase activity in mammalian cells (4).

In humans, plasma tocotrienol concentrations remain low (less than 1 μM) after tocotrienol supplementation (5,6). Apparently, tocopherols and tocotrienols are absorbed and secreted in chylomicrons, but the tocotrienols disappear from plasma following chylomicron clearance, while α-tocopherol is preferentially secreted into the plasma. Maintenance of plasma α-tocopherol is under the control of the α-tocopherol transfer protein (α-TTP). This protein selects the naturally occurring *RRR*-α-tocopherol for secretion into the circulation. It has been shown, based on competition studies, that α-tocotrienol (α-T3) possesses only a 12% affinity for α-TTP compared with α-tocopherol (100%) (7), and in terms of biological activity based on the rat fetal resorption assay, the tocotrienols possess only between 10 and 30% activity compared to α-tocopherol (8).

Once tocotrienols and tocopherols are absorbed and delivered to the liver, their fates (other than that of *RRR*-α-tocopherol) are unknown; however, metabolism and/or excretion are likely. Relatively little is known regarding the metabolism of tocotrienols. Tocopherols can be metabolized to carboxyethyl-hydroxychroman (CEHC) derivatives and excreted in the urine (9–11). These metabolites are a result of chain shortening of the tocopherol molecule, presumably *via* a p450-mediated process and β-oxidation, although the exact pathways have not been described. Recent investigations revealed that *ca.* 1% of a dose of deuterium-labeled α-tocopherol is found in urine as the metabolite α-CEHC (11). Based on estimates of dietary intakes of γ-tocopherol, *ca.* 50% of γ-tocopherol may be converted to γ-CEHC (10).

Because of the structural similarity between the tocopherols and tocotrienols (Fig. 1), we hypothesized that α-T3 or γ-tocotrienols (γ-T3) would be metabolized to the same products as the corresponding tocopherols, that is, their CEHC derivatives. This hypothesis was tested in human subjects receiving varying doses of either α- or γ-tocotrienyl acetates as a source of tocotrienols; metabolism was monitored by following the urinary excretion of the CEHC derivatives.

## MATERIALS AND METHODS

*Supplements and reagents.* Capsules containing either α- or γ-tocotrienyl acetates (125 mg tocotrienol per capsule) were gifts from Drs. Peter Hoppe and Klaus Krämer of BASF Aktiengesellschaft (Ludwigshafen, Germany). The individual tocotrienols were isolated from food-grade palm oil by preparative high-performance liquid chromatography (HPLC), then acetylated with acetic anhydride, as described (6). The purity of the main component was determined by gas chromatography and verified by $^1$H nuclear magnetic resonance. The content of the other tocols was determined by gas chromatography and verified by HPLC. α-Tocotrienyl acetate contained ≥83% α-tocotrienyl acetate, with minor contamination from α-tocopherol (4.2%), α-tocomonoenol acetate (2.5%), other tocopherols (1.4%), and other tocotrienyls (0.9%). γ-Tocotrienyl acetate contained ≥94% γ-tocotrienyl acetate with minor contamination from β-tocotrienyl (3.4%), α-tocotrienyl (0.7%), and α-tocopherol (0.3%). Residual components were palm oil lipids, none of which exceeded 1%.

Standards of α-CEHC and γ-CEHC were kind gifts from Dr. W.J. Wechter, Loma Linda University (Loma Linda, CA). Trolox and β-glucuronidase were obtained from Sigma-Aldrich (St. Louis, MO). Solvents were all HPLC-grade; all other chemicals and reagents were of the highest purity available.

*Human subjects.* The study protocol was approved by the Institutional Review Board for the use of human subjects at Oregon State University. The subjects ($n$ = 5 males, 1 female) were healthy, nonantioxidant supplement takers and nonsmokers. (One subject dropped out after 2 wk because he found urine collections too time-consuming.) Complete urine collections (24 h) were obtained daily for 2 d before each subject consumed one gelatin capsule containing 125 mg γ-tocotrienyl acetate with breakfast. Urine collections were then obtained for the supplement day and the subsequent 2 d. This protocol was then repeated the following week, except the subjects consumed four capsules (500 mg) γ-tocotrienyl acetate with breakfast. This 2-wk protocol was then repeated with α-tocotrienyl acetate supplement. It should be noted that 250 mg of either of these supplements consumed daily for 8 wk minimally increased plasma tocotrienol concentrations (<1 μM) (6).

Subjects consumed their usual diets; no special restrictions were suggested because the supplements used were large in comparison to usual dietary vitamin E intakes.

*Analysis of vitamin E metabolites.* Urinary CEHC were extracted and analyzed, as described (12). Urine collected the 2 d prior to supplementation represented baseline levels. The total volume of the 24-h urine sample was recorded; then an aliquot was taken, frozen, and kept at −70°C. Prior to extraction, an internal standard was added (10 μg Trolox in ethanol) to 5 mL urine; then conjugated CEHC were hydrolyzed by addition of 400 μL enzyme solution (4 mg β-glucuronidase in 450 μL of 0.1 M sodium acetate buffer, pH 4.5) and incubation for 4 h at 37°C. After cooling on ice, the samples were acidified by addition of 50 μL 6 M HCl and extracted with 15 mL diethylether. An aliquot of the ether layer was dried under nitrogen, and the residue reconstituted in 200 μL ethanol and stored at −20°C until analysis. On the day of analysis (usually within 2 d of extraction), the samples were diluted 1:10 with ethanol to be in the range of the HPLC assay (see below). Unconjugated CEHC were extracted directly from urine, as described above except without hydrolysis.

CEHC were analyzed by HPLC (Shimadzu, Pleasanton, CA) with amperometric electrochemical detection (Bioanalytical systems, West Lafayette, IN), as described (12). Separa-

tion was performed using a 5 μm particle size column (Ultrasep ES100, RP 8 norm; Sepserv, Berlin, Germany) with a gradient system of acetonitrile (solvent A) and McIlvaine buffer (0.01 M citric acid, 0.02 M diammonium hydrogen phosphate, pH 4.15) (solvent B) both containing 1% lithium perchlorate. The gradient was established at a flow rate of 0.4 mL/min, as follows: 80% B for 6.5 min, decrease to 60% B in 1 min, 60% B for 12 min, then decrease to 5% B in 4 min, 5% B for 7 min, increase to 80% B in 1 min, and 80% B for 5 min. The electrochemical detector was operated at an applied voltage of 0.55 V. CEHC were identified by comparing their peak retention times to those of authentic compounds. Usual retention times were 19.5, 23.5, and 26 min for Trolox, γ-, and α-CEHC, respectively. To quantitate CEHC, peak areas of γ- and α-CEHC were compared to that of Trolox (internal standard).

Creatinine was measured using a kit (Sigma-Aldrich Company).

*Statistical analyses.* Data were analyzed using an analysis of variance model with repeated measures (StatView; SAS Institute Inc., Cary, NC). Differences were considered statistically significant if $P < 0.05$. If significant differences were found, then Fisher's least square mean *post-hoc* tests were used for making pairwise comparisons. Here differences between means were considered statistically significant if $P < 0.03$.

## RESULTS

*Daily α- and γ-CEHC excretion.* To test whether α- and γ-CEHC excretion increased in response to tocotrienyl acetate supplementation, urinary CEHC were monitored. The urinary excretion of γ- and α-CEHC during the 1 mon of supplementation with the various amounts and kinds of tocotrienols is shown in Figure 2. In response to the 125 mg γ-tocotrienyl acetate supplement administered during the first week, γ-CEHC excretion increased significantly in the 24-h urine sample collected on the day of supplementation compared with collections on each of the other days ($P < 0.0001$, except the day after supplementation $P = 0.0007$) (Fig. 2A). Supplementation with 500 mg γ-tocotrienyl acetate during the second week also resulted in a significant increase in γ-CEHC excretion on the day of supplementation compared with collections on each of the other days ($P < 0.0001$, except the day after supplementation $P = 0.03$). Urinary α-CEHC excretion was unaffected by either dose of the γ-tocotrienyl acetate supplement (Fig. 2B, weeks 1 and 2).

The smaller dose of the α-tocotrienyl acetate supplement (125 mg) did not appreciably increase α-CEHC excretion. However, supplementation with 500 mg α-tocotrienyl acetate resulted in significant increases in α-CEHC excretion on the day of supplementation compared with collections on each of the other days ($P < 0.0001$, except the day after supplementation $P = 0.0003$). γ-CEHC excretion did not change in response to supplementation with either dose of α-tocotrienyl acetate supplement.

Figure 2 also shows the individual values for each of the six subjects for the study month, except subject 5 who dropped out after 2 wk. The baseline α-CEHC excretion was relatively low and constant for all of the subjects, while γ-CEHC excretion was higher and more variable. Indeed subject 2 was quite responsive to dietary γ-tocopherol and excreted large amounts of γ-CEHC following a meal rich in soybean oil during week three of the study.

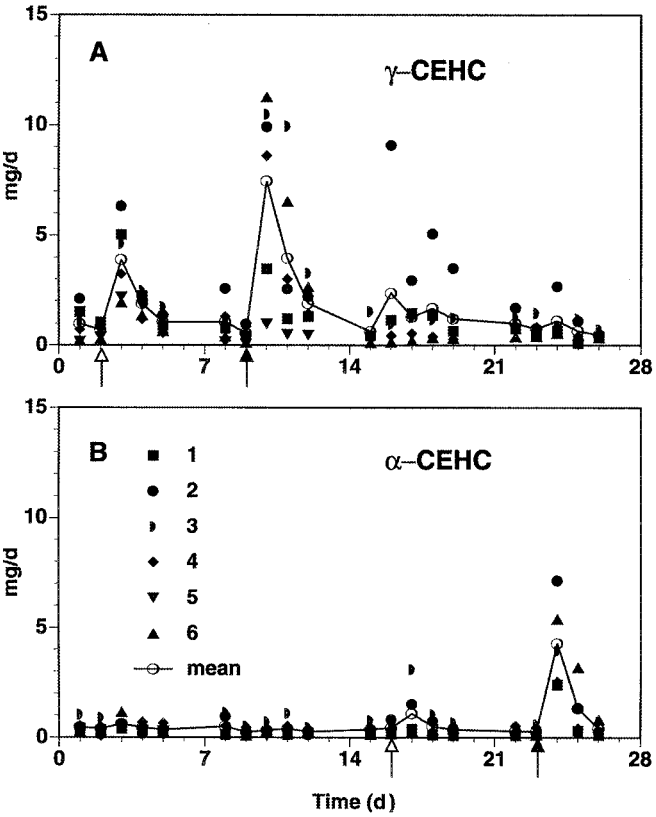

**FIG. 2.** Metabolism of tocotrienols to their CEHC derivatives following supplementation with tocotrienyl acetates. Excretion of γ-CEHC (A) and α-CEHC (B) in daily 24-h urine collections, 2 d prior to and following a 125-mg dose (open arrowhead) or a 500-mg dose (closed arrowhead) of either γ-tocotrienyl acetate (weeks 1 and 2) or α-tocotrienyl acetate (weeks 3 and 4). Shown are the individual responses for the six subjects (except #5 who dropped out after weeks 1 and 2); the open circle represents the mean. Urinary γ-CEHC on the day of 125 mg γ-tocotrienyl acetate supplementation was significantly different from the other days of week 1 ($P < 0.0001$, the day after supplementation $P = 0.0007$). Urinary γ-CEHC on the day of 500 mg γ-tocotrienyl acetate supplementation was significantly different from the other days of week 2 ($P < 0.0001$, except the day after supplementation $P = 0.03$). α-CEHC excretion in the 24-h urine sample following 500 mg α-tocotrienyl acetate supplementation was significantly different from collections the other days of week 4 ($P < 0.0001$, except the day after supplementation $P = 0.0003$). α-CEHC excretion was not affected by γ-tocotrienyl acetate supplementation nor was γ-CEHC excretion affected by α-tocotrienyl acetate supplementation. See Figure 1 for abbreviation.

*Total α- and γ-CEHC excretion in response to tocotrienol supplements.* The total amount of each respective CEHC excreted in urine on the 3 d following each tocotrienol supplement was calculated by summing the daily CEHC excreted minus the average CEHC excreted on days 1 and 2 of each week (Table 1). Overall, the increase in γ-CEHC excretion

**TABLE 1**
**Urinary Excretion of α- or γ-CEHC in Response to α- or γ-Tocotrienyl Acetate Supplementation**

| | γ-Tocotrienyl acetate | | α-Tocotrienyl acetate | |
|---|---|---|---|---|
| | γ-CEHC (mg above baseline)[a] | | α-CEHC (mg above baseline)[a] | |
| Subject | 125 mg | 500 mg | 125 mg | 500 mg |
| 1 | 4.70 | 4.18 | 0.23 | 2.51 |
| 2 | 5.58 | 9.38 | 0.69 | 8.35 |
| 3 | 5.87 | 20.70 | 2.74 | 4.50 |
| 4 | 2.95 | 9.80 | 0.21 | 2.04 |
| 5 | 4.32 | 1.59 | ND[b] | ND |
| 6 | 3.15 | 19.67 | 0.56 | 8.88 |
| Mean ± SD[c] | 4.4 ± 1.2 | 10.9 ± 7.8 | 0.9 ± 1.1 | 5.3 ± 3.2 |
| Percentage of dose excreted as metabolite[d] (mean ± SD) | 6.1 ± 1.7% | 3.7 ± 2.7% | 1.2 ± 1.4% | 1.8 ± 1.1% |

[a]The mg above baseline = average carboxyethyl-hydroxychroman (CEHC) excreted on days 1 and 2 was subtracted from values obtained on days 3, 4, and 5 of each week; the remainder was summed and is an estimate of the CEHC excreted in response to the tocotrienyl acetate supplement.
[b]ND, not determined; subject 5 did not complete this trial.
[c]γ-CEHC excretion was higher than α-CEHC (main effect, $P < 0.01$). The dose size of γ-tocotrienyl acetate did not affect the amount γ-CEHC excreted, while α-CEHC excretion increased with α-tocotrienyl acetate dose ($P < 0.02$).
[d]Percentage of dose excreted as metabolite was calculated using the molecular weights of the CEHC and their respective tocotrienyl acetates for each subject. The percentage of γ-tocotrienol dose excreted as γ-CEHC was higher than that of percentage of α-tocotrienol dose excreted as α-CEHC (main effect, $P < 0.0003$); there was no effect of dose size.

was higher than that of the α-CEHC increase in response to the respective supplements (main effect, $P < 0.01$). However, there was no effect of γ-tocotrienol dose on the amount of γ-CEHC excreted largely because of the intrasubject variability, while the increase from 125 to 500 mg α-tocotrienyl acetate administered resulted in a significant increase in α-CEHC excretion ($P < 0.02$).

The percentage of the dose administered, which was recovered as excreted CEHC, is also shown in Table 1. Typically the percentages of the doses recovered as the metabolites were low and never exceeded 8% for γ-CEHC or 3% for α-CEHC. The percentage γ-tocotrienol dose excreted as γ-CEHC was higher than that of percentage α-tocotrienol dose excreted as α-CEHC (main effect, $P < 0.0003$); the percentage of the dose excreted was not statistically significantly altered by dose size.

*γ-CEHC excretion time course*. Since the majority of γ-CEHC excretion appeared to occur on the day of the supplement ingestion, it was of interest to monitor the excretion of CEHC at intervals throughout the day following ingestion of 125 mg of γ-tocotrienyl acetate. A sample of urine was taken at each time of urination from two of the volunteers (subjects 4 and 6) and the time recorded. The excretion of CEHC was normalized to urinary creatinine, which was constant throughout the day. Figure 3 shows the result as a representative study. Increased γ-CEHC excretion was detected between 5 and 6 h following the supplement and reached a maximum observed at 9 h. In contrast, α-CEHC excretion remained relatively constant throughout the day. The excretion of the unconjugated form of γ-CEHC was also measured since this form has been discovered as a natriuretic factor in human urine (13). Excretion of unconjugated γ-CEHC also followed a similar pattern with a maximum after 9 h (Fig. 3B), and typically represented 10% of the total γ-CEHC, as previously shown (12).

## DISCUSSION

In response to tocotrienol supplements, an increase in urinary CEHC was observed, suggesting that humans metabolize tocotrienols to the same products as the corresponding tocopherols. Labeled tocotrienols were not used in this study, and therefore the conversion to CEHC cannot be claimed with certainty. However, the temporal relationship between the increase in urinary CEHC and the administration of tocotrienol supplements (which was observed with two different tocotrienols at two dif-

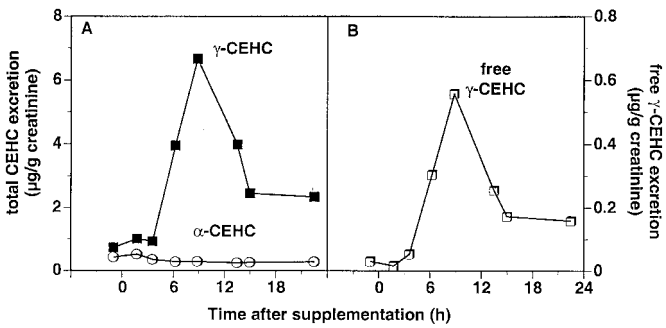

**FIG. 3.** Excretion of total and unconjugated γ-CEHC during a 24-h period. Urinary excretion of (A) total α- and γ-CEHC and (B) unconjugated γ-CEHC, throughout a 24-h period following a 125-mg dose of γ-tocotrienyl acetate in a representative subject of two. See Figure 1 for abbreviation. ■, Total γ-CEHC; ○, total α-CEHC; □, free γ-CEHC.

ferent doses, Fig. 2) provides strong evidence that tocotrienols are metabolized to their respective CEHC.

Only a small percentage of the ingested tocotrienol dose was recovered in the urine: about ~1–2% of α-T3 was recovered as α-CEHC, while ~4–6% of γ-T3 was recovered as γ-CEHC (Table 1). The fractional excretion as CEHC was not dose-dependent (at least between 125 and 500 mg). The fate of the remainder of the dose is unknown; however, there are a number of plausible explanations. The relatively low urinary excretion may be a consequence of either (i) poor absorption and bioavailability, (ii) poor selectivity of the metabolizing system for tocotrienols as compared to tocopherols, or (iii) an alternative pathway for metabolism and/or excretion.

Limited information is available regarding tocotrienol absorption and bioavailability; it is known that plasma tocotrienol levels increase only marginally after supplementation (5,6). Plasma concentrations could be low as a result of low absorption or poor re-incorporation of tocotrienols into plasma. With respect to intestinal absorption in humans, experiments with α-tocopherol have shown *ca.* 70% of the ingested dose is absorbed, as measured by fecal radioactivity (14); however, values as low as 21% have also been reported (15). Although there is apparently no intestinal discrimination of vitamin E in humans, it has been reported that α-T3 absorption in rats is significantly higher than that for α-tocopherol and the other tocotrienols (16). Thus, it is likely in humans that fractional absorption of tocotrienols and α-tocopherol is similar. Despite similar absorption, plasma tocotrienol concentrations are typically extremely low. Therefore, it is likely that the hepatic α-TTP discriminates against tocotrienols along with forms of tocopherol other than 2*R*-α-tocopherols. This is demonstrated in the relatively low biological activity of α-T3 (10–30%) compared to α-tocopherol (100%) (8), a value which correlates with the affinity of the vitamin E analogs for α-TTP (7).

With respect to excretion, studies in humans demonstrated that plasma α-tocopherol reached a maximum *ca.* 8 h after vitamin E administration (17–19), while biliary vitamin E was maximal 12 h after dosing (17). Urinary excretion of γ-CEHC following a dose of γ-tocotrienyl acetate was maximal *ca.* 9 h after ingestion (Fig. 3), thus it appears that vitamin E metabolism is rapid. Although relatively little of the tocotrienol doses were excreted as urinary CEHC, what percentage of the administered vitamin E is actually metabolized to CEHC is in fact unknown. Possibly CEHC are excreted in bile and then reabsorbed into the circulation for ultimate excretion in the urine. This enterohepatic circulation has been proposed to be important for the re-uptake of α-tocopherol; indeed α-tocopherol entering the bile does re-enter the circulation and is distributed to tissues (20).

γ-CEHC was discovered and named LLU-α by Wechter *et al.* (13) because it was found to be a potent natriuretic factor in human urine. Since the metabolite is biologically active, it is likely that specific pathways for the conversion of γ-tocopherol to γ-CEHC exist. Such a specific pathway would explain the relatively higher efficiency for conversion of γ-tocopherol to γ-CEHC. Based on dietary intakes of γ-tocopherol and baseline values of γ-CEHC (10), ≥50% of γ-tocopherol consumed may be converted to γ-CEHC. However, in the present study only ~4–6% of the large dose of γ-tocotrienol was recovered as γ-CEHC.

The fractional conversion of α-tocotrienol to α-CEHC observed in this study is similar to that reported previously for the conversion of α-tocopherol to α-CEHC (9,11), and the baseline amounts found in urine are similar to those of normal humans (12,21). In the present study, large interindividual differences were seen in the quantity of γ-CEHC excreted. These variations are presumably due to differences in absorption and metabolism within individuals. However, both α- and γ-CEHC baseline values fall into the same range as we reported previously (11,12) but are in some cases one-tenth of those reported for γ-CEHC by Swanson *et al.* (10).

Since forms of vitamin E other than naturally occurring *RRR*-α-tocopherol have been shown to be preferentially metabolized to CEHC (11), it was hypothesized that increased CEHC excretion would result from tocotrienol supplementation. However, relatively small amounts of the tocotrienol doses were recovered as urinary CEHC. Previously we observed that after 8 wk of tocotrienyl acetate supplementation, plasma concentrations remained less than 5% of plasma α-tocopherol concentrations (6). Taken together, these data suggest that alternative pathways for metabolism and/or excretion of the tocotrienols exist.

γ-T3 has received interest as a plasma cholesterol-lowering agent (22–24); however our rigorous controlled study in hypercholesterolemic subjects found no effect on plasma cholesterol levels (6). Nevertheless, it is interesting that its metabolite, γ-CEHC, may have an additional beneficial effect as a natriuretic factor, suggesting that specificity for γ-tocopherol exists, even though the actual metabolic pathways for vitamin E metabolism are unknown. For this reason the analysis of unconjugated forms of the metabolite is of importance. It will be of interest to investigate possible ways of increasing γ-CEHC excretion, especially as a possible treatment for hypertension, a risk factor for cardiovascular disease.

In summary, α-T3 and γ-T3 are metabolized to their CEHC derivatives and excreted in the urine. The percentage of dose recovered as the metabolites in the urine is low (only up to 8%). Further studies are required to investigate the biological fate of the remainder of the absorbed dose.

## ACKNOWLEDGMENTS

We would like to thank Kai Baldenius, Peter P. Hoppe, and Klaus Krämer at BASF Aktiengesellschaft (Ludwigshafen, Germany) for supplying the tocotrienyl acetate capsules and to BASF Aktiengesellschaft for providing support to J.K.L. Financial support was also provided in part by Tobacco-Related Disease Research Program (7RT-0160).

# Mechanisms of Dimer and Trimer Formation from Ultraviolet-Irradiated α-Tocopherol

**Ed S. Krol, Daniel D.J. Escalante, and Daniel C. Liebler***

Department of Pharmacology and Toxicology, College of Pharmacy, University of Arizona, Tucson, Arizona 87521

**ABSTRACT:** α-Tocopherol (α-TH) undergoes ultraviolet (UV)-induced photooxidation on the surface of mouse skin to produce a dihydroxydimer, a spirodimer, and trimers as the major products. To study the photochemistry involved, we UV-irradiated α-TH in a thin film on a glass petri dish. Photooxidation yielded a mixture of dihydroxydimer, spirodimer, and trimers. In the time-course studies, the dihydroxydimer accumulated and then was further oxidized, whereas the spirodimer and trimers accumulated more gradually. Reaction of two tocopheroxyl radicals forms the dihydroxydimer, whereas the spirodimer may be formed either by photooxidation of α-TH to an orthoquinone methide (*o*-QM) followed by a Diels-Alder reaction or by photooxidation of α-TH to the dihydroxydimer, followed by two-electron oxidation. Irradiation of a mixture of $d_{10}$-labeled and unlabeled ($d_0$) dihydroxydimer produced a mixture of labeled and unlabeled spirodimers as detected by positive atmospheric pressure chemical ionization–mass spectrometry. The absence of mixed label spirodimers among products indicated that direct oxidation of the dihydroxydimer is a facile route to the spirodimer and is probably the major spirodimer-forming reaction in α-TH photooxidations. Trimer formation from the dihydroxydimer and the spirodimer was observed, however, and requires an *o*-QM intermediate. Photooxidation of $d_{10}$-labeled and unlabeled ($d_0$) dihydroxydimers yielded mixed isotopomers of the trimer products, thus demonstrating that the dihydroxydimer and spirodimers underwent conversion to *o*-QM intermediates. Photochemical conversion of α-TH to UV-absorbing dimer and trimer products may contribute to photoprotection by topically applied α-TH.

Paper no. L8574 in *Lipids 36*, 49–55 (January 2001).

Increasing concern regarding ultraviolet (UV)-induced photodamage to skin has resulted in an increased effort to prevent the deleterious effects of UV radiation on humans. This has been accomplished mainly through the topical application of compounds capable of eliciting photoprotective effects. Several studies have shown that α-tocopherol (α-TH) provides protection from UV-induced photodamage. α-TH inhibits both UV-induced liposomal lipid peroxidation *in vitro* (1) and UV-induced pyrimidine dimer formation, a marker of direct UV-induced DNA damage *in vivo* (2) and *in vitro* (3). However, α-TH depletion occurs in a time-dependent manner when α-TH is exposed to UV-B radiation both in liposomes *in vitro* and in mouse skin *in vivo* (1,4).

The major photoproducts derived from topical application of α-TH to mouse skin followed by UV-irradiation have been identified as a mixture of α-TH dimers (4). Dimers previously have been observed as products in numerous oxidations of α-TH (5–13). In addition, trimers also have been described as α-TH oxidation products (9). The two most commonly observed dimers derived from α-TH oxidation are the 5a,5a′-dihydroxydimer **4** and the 5a,5a′-spirodimer **5** (5,13,14). The formation of the 5a,7a′-, 7a,5a′-, and 7a,7a′-dihydroxydimers seems to be less favorable. This preference for reactivity at the 5a position vs. the 7a position of α-TH has been observed in other α-TH oxidation products (15–17). This difference in reactivity may reflect steric and/or stereoelectronic factors at C7 vs. C5.

Several mechanisms have been postulated to explain the formation of α-TH dimers and trimers (5,10,18). The proposed mechanistic routes are summarized in Scheme 1. The initial step in tocopherol photooxidation is a one-electron oxidation of α-TH, which produces the tocopheroxyl radical **1** (Scheme 1). In pathway A, **1** undergoes a second oxidation (removal of one electron and a proton at the 5a-methyl position) to form an orthoquinone methide (*o*-QM), **2**. The spirodimer **5** is then formed as the result of a Diels-Alder cyclization of two *o*-QM (pathway D) (10,19). A second pathway to the spirodimer involves the initial formation of the dihydroxydimer **4**. Dihydroxydimer formation results from the combination of two carbon-centered, 6-hydroxy-7,8-dimethyltoc-5-ylmethyl radicals (orthomethyl tocopherol radicals) 3. Formation of **3** itself may occur through two possible pathways. The first (pathway C) involves a disproportionation between α-TH and an *o*-QM yielding a phenoxyl radical and an orthomethyl tocopherol radical **3** (18). Alternatively, it has been postulated that an intramolecular hydride transfer may occur between the oxygen and the 5-methyl group, producing the orthomethyl tocopherol radical (pathway B) (5). Finally, the spirodimer is formed by an overall two-electron

oxidation of the dihydroxydimer, followed by intramolecular cyclization, which likely occurs in a stepwise fashion (pathway F). The trimers (**6**) are believed to result from a Diels-Alder addition of **2** to **5** (6,19).

We have studied the photochemical formation of tocopherol dimers and trimers in an effort to elucidate their mechanisms of formation. We have compared the products generated by UVB (290–320 nm) photooxidation of α-TH with those generated by silver oxide oxidation. In these studies, we focused on the roles of quinone methide intermediates vs. the dihydroxydimer **4** as precursors to the spirodimer and trimers. Our data suggest that the dihydroxydimer **4** is a key intermediate in α-TH photooxidation and that *o*-QM intermediates are contributors to trimer formation.

## EXPERIMENTAL PROCEDURES

*Materials.* α-TH [(*R*,*R*,*R*)-α-tocopherol] was a gift from Henkel Fine Chemicals (La Grange, IL). The [5a,7a-$(C^2H_3)_2$]-α-tocopherol ($d_6$-α-TH) was synthesized from [5a,7a-$(C^2H_3)_2$]-α-tocopherol acetate ($d_6$-α-TAc) (15). Other reagents were obtained commercially from standard sources and were used without purification. Westinghouse FS-20 lamps were purchased from National Biological Corp. (Twinsburg, OH), and a UVX digital radiometer with a UVX-31 sensor was purchased from Ultraviolet Products, Inc. (San Gabriel, CA). Of the lamp output *ca.* 80% was in the UVB (290–320 nm), whereas the remainder was in the UVA (320–400 nm). UV-visible (vis) spectra were recorded on a Beckman DU-640B spectrophotometer (Beckman Instruments Inc., Fullerton, CA).

*Synthesis of α-TH dimers and trimers.* Tocopherol dimer standards were purified by reversed-phase, gradient high-performance liquid chromatography (HPLC) on a Spherisorb ODS-2, 5 μm, 250 × 4.6 mm column (Alltech, Deerfield, IL) with the UV detector set at 300 nm. A flow rate of 1.5 mL/min was used, with the initial mobile-phase composition consisting of methanol/ethyl acetate (75:25, vol/vol) for 18 min, increased to 30:70 over 10 min, and then back to 75:25 over 5 min. The identities of both the spirodimer and the dihydroxydimer were confirmed by atmospheric pressure chemical ionization–mass spectrometry (APCI-MS), tandem mass spectrometry (MS–MS), and by comparison of the UV-vis spectra with literature values (5). α-TH spirodimer **5** was prepared by $K_3FeCN_6$-catalyzed oxidation of α-TH using the method of Nelan and Robeson (13). Briefly, 50 mM α-TH in hexane was treated with 50 mM $K_3FeCN_6$ in NaOH (0.2 M) at 25°C for 5 min. The hexane layer was removed, washed with $H_2O$, dried over sodium sulfate, and the bright yellow liquid dried to leave a yellow residue. The spirodimer product eluted at 25 min under the above HPLC conditions. The dihydroxydimer **4** was prepared by the reduction of **5** with $LiAlH_4$/diethyl ether, using the method of Skinner and Alaupovic (5). Briefly, $LiAlH_4$ (600 mmol) was added slowly to spirodimer (10 μM) dissolved in diethyl ether. The reaction mixture was refluxed for 30 min, cooled to room temperature, and the reaction quenched by the addition of $H_2O$. The ether layer was removed, filtered, dried with sodium sulfate, and evaporated leaving a yellow residue. The residue was dissolved in mobile phase and purified by HPLC, with **4** eluting at 17 min.

The trimers could be further resolved into at least four separate species by an isocratic HPLC protocol, with a flow rate of 1.5 mL/min, utilizing a mobile phase consisting of methanol/ethyl acetate (65:35, vol/vol). The trimer peaks eluted at 27, 29, 38, and 40 min. Analysis by APCI-MS and MS–MS yielded values consistent with those expected for tocopherol trimers. The deuterium-labeled dimers and trimers were prepared in the same manner as the unlabeled compounds, except that $d_6$-α-TH was used in place of α-TH, and $LiAlD_4$ was used in the reduction of **2** to **1**.

*UV irradiation.* A solution of α-TH, dihydroxydimer, or spirodimer [100 nmol in ethyl acetate (200 μL)] was transferred to a 9.5-cm diameter glass petri dish. The solvent was allowed to evaporate at room temperature, leaving a thin film on the surface of the dish. The sample was irradiated from directly above for 60 or 240 min with a UV lamp at a dose rate of 10.0 J/m$^2$s (total dose 36,000 J/m$^2$). The sample was dissolved in ethyl acetate (2 × 1 mL), transferred to a test tube, and evaporated. The residue then was dissolved in mobile phase (ethyl acetate/methanol, 1:3 vol/vol). The photooxidation products were separated by reversed-phase HPLC on a Spherisorb ODS-2, 5 μm, 4.6 × 250 mm column. A flow rate of 1.5 mL/min was used, with the UV detector set at 300 nm. The initial conditions consisted of a mobile phase consisting of methanol/ethyl acetate (75:25, vol/vol) (0–18 min), ramped

to 30:70 (18–28 min), and then back to 75:25 (28–33 min).

*UV irradiation of* $d_0$ *and* $d_{10}$ *dihydroxydimer or spirodimer.* A solution of $d_0$- and $d_{10}$-dihydroxydimer ([5,5′-$(C^2H_2)_2$-7,7′-$(C^2H_3)_2$]-tocopherol dimer) or spirodimer [250 nmol, 1:1 (mol/mol)] in ethyl acetate (400 μL) was added by syringe to a 9.5-cm diameter glass petri dish. The sample was irradiated and isolated as above for APCI-MS analysis. The trimers from the initial HPLC collection were subjected to further purification as indicated above. The trimers from the spirodimer irradiation were analyzed by ESI–MS as Ag complexes (see below).

*MS analysis.* Product identities were confirmed by APCI-MS or ESI–MS with a Finnigan TSQ 7000 (Finnigan MAT, San Jose, CA) instrument in the Southwest Environmental Health Sciences Center Analytical Core laboratory at The University of Arizona. APCI-MS samples were analyzed by flow injection using acetonitrile as the mobile phase. Flow injection MS–MS analysis was also performed on α-TH dimer oxidation products and compared to MS–MS analyses of authentic standards prepared by $K_3FeCN_6$-catalyzed oxidation of $d_0$- or $d_6$-α-TH. The Ag-complexed species were prepared in methanol/ethyl acetate (65:35, vol/vol) containing 35 μM $AgNO_3$ and analyzed immediately by flow injection using methanol/ethyl acetate (65:35, vol/vol) containing 35 μM $AgNO_3$ in the mobile phase. Theoretical MS isotope distribution calculations were performed using the software package XMASS/TOF (Bruker, Billerica, MA).

## RESULTS AND DISCUSSION

The fate of UV-irradiated α-TH may involve several possible photooxidative pathways, which are summarized in Scheme 1. In accordance with Scheme 1, we first examined different ways in which the spirodimer **5** could be formed by nonphotooxidative reactions. $K_3FeCN_6$-catalyzed oxidation of α-TH is known to produce a mixture of both the dihydroxydimer **4** and the spirodimer **5** (13). In contrast, oxidation of α-TH with silver oxide in acetonitrile results in the formation of an *o*-QM, which forms the spirodimer exclusively as may be seen in the HPLC chromatogram shown in Figure 1A, suggesting that pathway A–D is a viable route to spirodimer formation. In addition, the spirodimer also may be prepared directly from the dihydroxydimer *via* silver oxide-catalyzed oxidation, as shown in Figure 1B,C.

A time-dependent depletion of α-TH with concomitant formation of dimers **4** and **5** is observed when α-TH undergoes UV irradiation *in vitro* in a thin film. The dimer levels appear to reach a maximum in 20–30 min, and then further

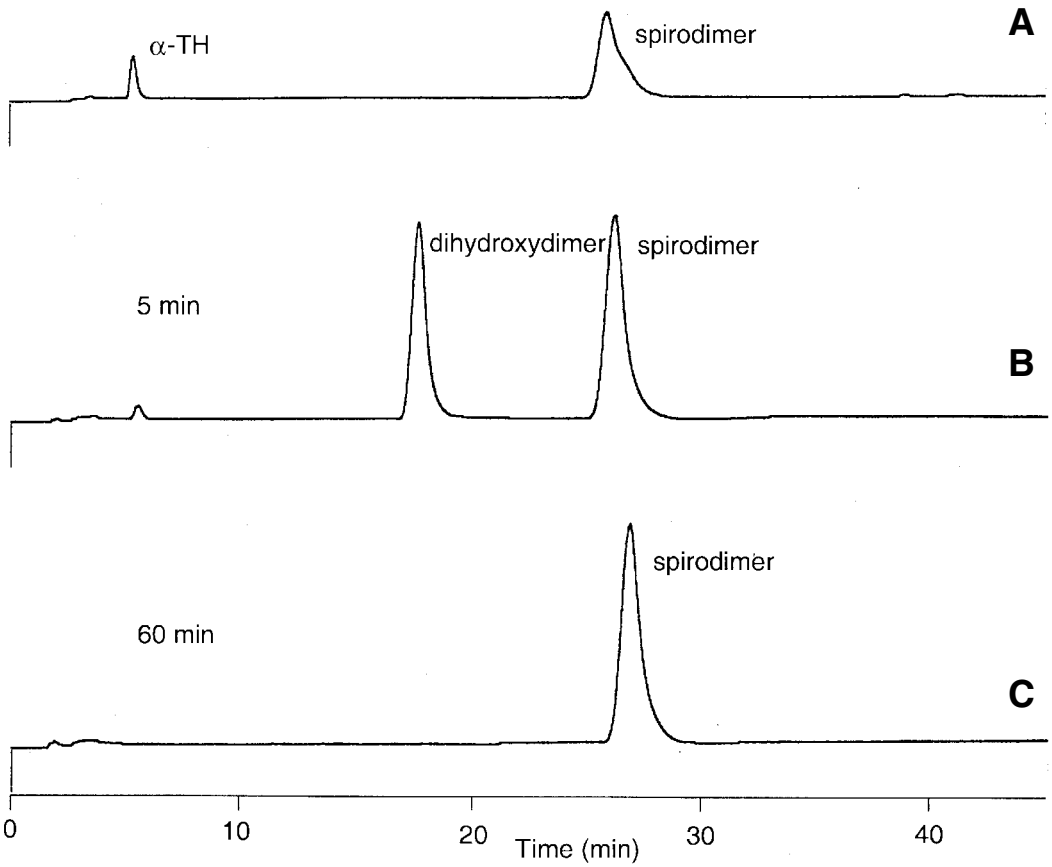

**FIG. 1.** High-performance liquid chromatography (HPLC) chromatogram of products for (A) silver oxide-catalyzed oxidation of α-TH to spirodimer, (B) silver oxide-catalyzed oxidation of dihydroxydimer **4** to spirodimer **5**, 5 min, and (C) silver oxide-catalyzed oxidation of dihydroxydimer to spirodimer, 60 min.

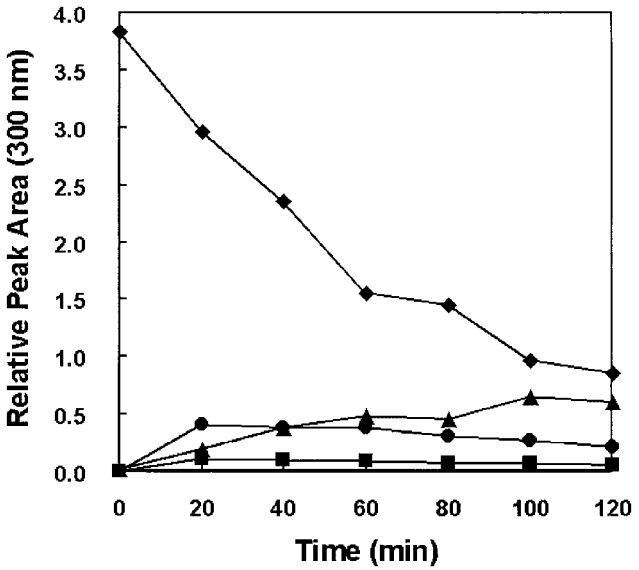

**FIG. 2.** Time course of ultraviolet (UV)-induced α-tocopherol (α-TH) depletion in a thin film. α-TH (◆), dihydroxydimer **4** (●), spirodimer **5** (■), and trimers (▲) were measured by HPLC as described in the Experimental Procedures section.

photooxidation yields trimers and other oxidation products (Fig. 2). Although we have not quantified yields of the dimer and trimer products, it appears that the levels observed probably do not account for α-TH consumption. This can be attributed to the photosensitivity of both dimer and trimer products, which most likely yields polymeric products that are not detected in our analyses. UV irradiation of dihydroxydimer **4** in the absence of α-TH also yields **5** and **6**, in addition to other oxidation products (Fig. 3). UV irradiation of **5** results in slow conversion to a mixture of trimers and unidentified

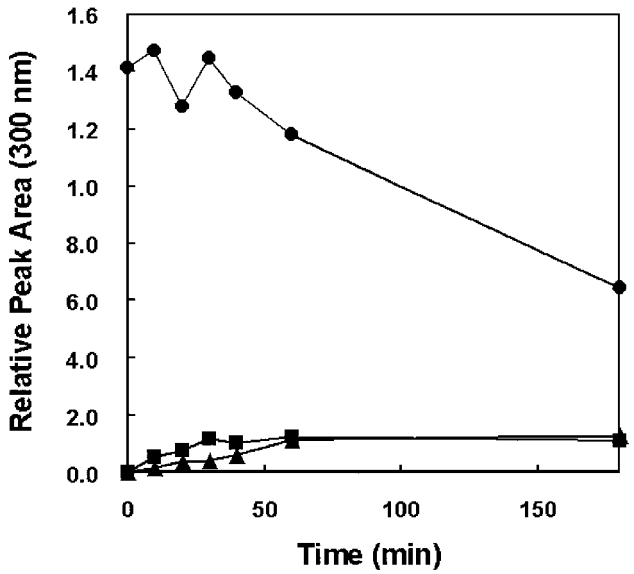

**FIG. 3.** Time course of UV-induced dihydroxydimer 4 depletion in a thin film. α-TH dihydroxydimer 4 (●), spirodimer 5 (■), trimers (▲) were measured by HPLC as described in the Experimental Procedures section. See Figures 1 and 2 for abbreviations.

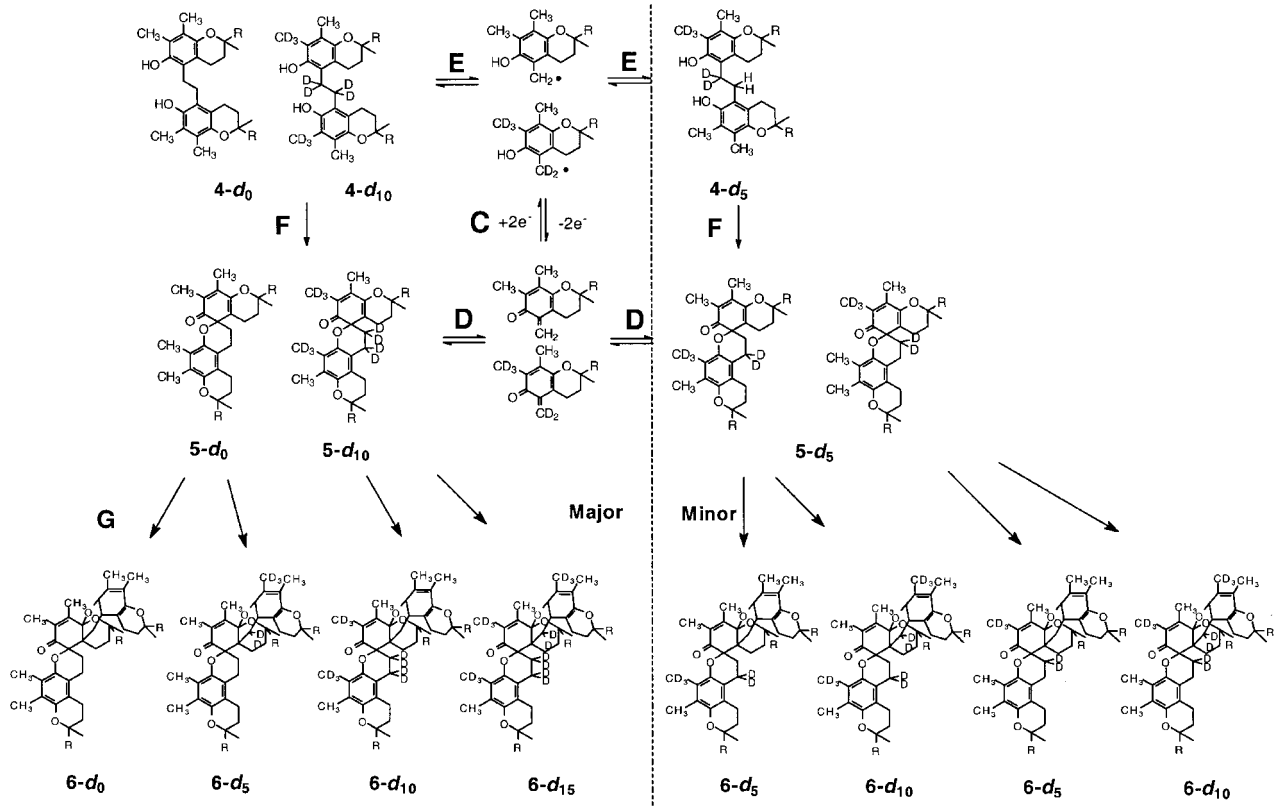
products (not shown). Thus, according to Scheme 1, either reactions D, E, or both must be reversible in order for trimer formation to occur from the dihydroxydimer.

α-TH trimer formation is believed to occur *via* a Diels-Alder reaction of a spirodimer with an *o*-QM (19). For this to occur, however, either the dihydroxydimer or the spirodimer must undergo photolytic cleavage to yield two monomeric units, at least one of which must be an *o*-QM. If a label could be incorporated into the dimers that would remain in each monomeric unit upon dissociation, then the fate of the label could be followed by MS. Accordingly, we prepared both the dihydroxydimer and the spirodimer from $d_6$-α-TH, in which the 5 and 7 methyl groups are fully deuterated. This results in $d_{10}$-dihydroxydimer and $d_{10}$-spirodimer that differ only in their mass from the unlabeled ($d_0$) dimers. Irradiation of a 1:1 mixture of **4-$d_0$** and **4-$d_{10}$** provides a method to follow the fate of the monomeric tocopherol units, which has been summarized in Scheme 2. If the spirodimer were formed *via* reversion and recombination (pathway E-C-D), then a mixed spirodimer, (**5-$d_5$**) in addition to **5-$d_0$** and **5-$d_{10}$**, would be formed. Under this scenario, it also follows that dissociation of **4** would form the mixed dihydroxydimer (**4-$d_5$**) *via* recombination of radicals derived from both **4-$d_0$** and **4-$d_{10}$**. Similarly, *o*-QM formation *via* dissociation of **5** (pathway D) should also produce some mixed spirodimer (**5-$d_5$**) in addition to **5-$d_0$** and **5-$d_{10}$**. Finally, direct oxidation of **4** to **5** without dissociation to monomeric units would produce no mixed (**$d_5$**) spirodimer products.

We irradiated a mixture of **4-$d_0$** and **4-$d_{10}$**, as a thin film, collected the products by HPLC, and then analyzed the products by APCI-MS. Figure 4A,B represents the mass spectra of standards of $d_0$-([M + H]$^+$ at *m/z* 860) and $d_{10}$-dihydroxydimer ([M + H]$^+$ at *m/z* 870), respectively. The mass spectrum of the dihydroxydimer HPLC peak (11 min) is shown in Figure 4C. A mixed dihydroxydimer ($d_5$) would have a mass between the two pure species ([M + H]$^+$ at *m/z* 865). No such mass is evident in the spectrum. Instead, a 1:1 mixture of **4-$d_0$** and **4-$d_{10}$** is observed.

The spirodimer was collected and analyzed in the same manner as for the dihydroxydimer. Figures 5A and 5B are representative spectra of standards of the $d_0$-([M + H]$^+$ at *m/z* 858) and $d_{10}$-spirodimers **5** ([M + H]$^+$ at *m/z* 868), respectively. Figure 5C shows the mass spectrum of the spirodimer product collected from the photooxidation (16 min peak), which does not demonstrate any evidence for the formation of a mixed dimer (**5-$d_5$**) ([M + H]$^+$ at *m/z* 863). Unfortunately, we were unable to obtain useful APCI-MS data for the trimer products of these photooxidations, since excessive fragmentation of the trimer [M + H]$^+$ ions occurred during analysis (figure not shown).

Because mixed isomers were not detected for either the dihydroxydimer or the spirodimer, dissociation of the dihydroxydimer to the tocopherol monomers (pathway E) and subsequent disproportionation to the *o*-QM (pathway C) appear to be a relatively minor pathway compared to direct oxidation of the dihydroxydimer to the spirodimer (pathway F). This may not be surprising since the acidity of excited singlet-state



**SCHEME 2**

phenols can be several orders of magnitude greater than in the ground state (20). This suggests that photodissociation of the phenolic hydroxyl group may be faster than other ground state reactions, so that a photodissociation of the dihydroxydimer followed by cyclization to the spirodimer would occur more rapidly than a Diels-Alder reaction. Although direct oxidation of α-TH to the spirodimer (pathway A–D) may occur, it appears to be a minor product-forming pathway.

Since UV photooxidation of the spirodimer also produces α-TH trimers, we performed an irradiation of a 1:1 mixture of **5-*d*$_0$** and **5-*d*$_{10}$** in a thin film. Once again, the spirodimer peak and the trimer peaks were collected by HPLC for MS analysis. APCI-MS resulted in extensive fragmentation of trimer $[M + H]^+$ ions, which precluded accurate measurements of isotopic distributions. Thus, we used a novel approach, in which compounds are ionized for electrospray by complexation with $Ag^+$ in the HPLC mobile phase (21,22). As was the case in the dihydroxydimer photooxidation, no mixing of label (**5-*d*$_5$**) was observed for the residual spirodimer (not shown). Standards of the $d_0$- and $d_{15}$-Ag-complexed trimers were detected by ESI–MS (Fig. 6A,B). We also were able to successfully detect Ag-complexed trimers from irradiation of a 1:1 mixture of the $d_0$- and $d_{10}$-spirodimers by this method (Fig. 6C). The spectrum indicates that some mixing of label, i.e., the formation of **6-*d*$_5$**, **6-*d*$_{10}$**, occurred.

Since spirodimer consumption was low in this experiment and we observed no mixed label spirodimer, this would seem to indicate that the majority of *o*-QM were trapped as trimers through reaction with the $d_0$- and $d_{10}$-spirodimers. This should result in a product ratio of 1:1:1:1 ($d_0/d_5/d_{10}/d_{15}$) being observed. However, the isotope distribution in Figure 6C does not reflect this ratio. We calculated isotope distributions for the $[M + Ag]^+$ ions for different ratios of the $d_0/d_5/d_{10}/d_{15}$ Ag-complexed trimers (not shown) to compare to our experimental results depicted in Figure 6C. The calculated isotope distribution closest to our experimental result in Figure 6C was a ratio of 1:4:1:4 ($d_0/d_5/d_{10}/d_{15}$).

This result suggests that trimer formation by the $d_5$-*o*-QM (to form $d_5$ and $d_{15}$ trimers) is favored over trimer formation by the $d_0$-*o*-QM. It may be that $d_{10}$ spirodimer dissociates more rapidly than the $d_0$-spirodimer, or that the $d_5$-*o*-QM reacts more rapidly to form trimers than does the $d_0$-*o*-QM. The rate of a Diels-Alder reaction is influenced by an inverse deuterium isotope effect (23), whereas a normal deuterium isotope effect is observed in the retro Diels-Alder (24). The former would favor trimer formation by $d_5$-*o*-QM, whereas the latter would reduce the availability of $d_5$-*o*-QM relative to $d_0$-*o*-QM for trimer formation. Our results are consistent with an inverse deuterium isotope effect, in which the Diels-Alder reaction of the $d_5$-*o*-QM with the spirodimer is more rapid than reaction of the $d_0$-*o*-QM with the spirodimer.

In summary, we have demonstrated that the major route of α-TH photooxidation is *via* tocopheroxyl radical dimerization to form dihydroxydimer **4**, which then undergoes further oxidation to spirodimer **5**. Although *o*-QM intermediates are not major contributors to spirodimer formation, they appar-

ently are formed in photooxidations, as indicated by the formation of trimer products. The UV-induced photooxidation of α-TH may play an important role in the photoprotective effects exerted by topically applied α-TH. DNA photodamage is markedly reduced by topically applied α-TH, although the photoprotective effect evidently occurs concomitantly with significant photochemical degradation of α-TH. The predominant products of α-TH photooxidation observed in this study are those detected on the surface of mouse skin after topical α-TH application and UV-irradiation *in vivo*. This suggests that α-TH dimers and trimers, which display UV spectra similar to α-TH, may contribute to photoprotective effects of topically applied vitamin E.

## ACKNOWLEDGMENTS

We wish to thank Sherry Daugherty and Dr. Tom McClure for help with the APCI– and ESI–MS, and Dr. Arpad Somogyi for help with the theoretical MS calculations. This work was supported by National Institutes of Health grants CA59585 and ES 06694.

# Effects of Ascorbate on Membrane Phospholipids and Tocopherols of Intact Erythrocytes During Peroxidation by *t*-Butylhydroperoxide: Comparison with Effects of Dithiothreitol

**Shiro Mawatari* and Kaori Murakami**

Department of Nutrition and Health Science, Faculty of Human Environmental Science, Fukuoka Women's University, Fukuoka, 813-8529, Japan

**ABSTRACT:** Peroxidation of intact human erythrocytes by *t*-butylhydroperoxide (tBHP)) was studied. By incubation of the erythrocytes with 1 mM tBHP, reduced glutathione (GSH) was exhausted within 1 min, and tocopherols (Toc) and phospholipids (PL) decreased to nearly their lowest levels (in this study) within 5 min. The rate of decrease of α-Toc was faster than that of γ-Toc, but α-Toc was never exhausted. The rates of decrease of Toc were faster than that of PL. Malondialdehyde increased slowly to reach a maximal value at 30 min. Methemoglobin (metHB) reached a maximum at 15 min. The maximal levels of these substances were maintained until 90 min incubation, which indicated that the peroxidation by tBHP had stopped spontaneously until at least 90 min. By the incubation with tBHP for 30 min, phosphatidylethanolamine (PE) and α-Toc decreased to about 70 and 30% of control levels, respectively, and γ-Toc and GSH were almost exhausted. Ascorbate (0.1 mM) afforded protection of 92% to PE, 50% to α-Toc, and 65% to γ-Toc against peroxidation, but ascorbate had no preventive effect at all on the formation of metHB and the decrease of GSH. These results may indicate that ascorbate-mediated protection of the membrane PL against the peroxidation depends primarily on Toc. On the other hand, dithiothreitol (DTT) (5 mM) almost completely prevented the formation of metHB, and DTT completely protected the PL and Toc against peroxidation, indicating the importance of sulfhydryl groups in erythrocytes.

Paper no. L8430 in *Lipids 36*, 57–65 (January 2001).

Peroxidation of cellular membrane lipids is implicated in the development of various diseases and in the process of aging (1,2). α-Tocopherol (α-Toc) may be the most important lipid-soluble antioxidant found in cellular membranes, whereas ascorbate (AsA) is the major water-soluble antioxidant in cells (3). Reportedly, AsA reduces tocopheroxyl radicals to α-Toc (3–8). However, whether AsA can regenerate α-Toc in living cells is still unsettled (9–15). Elucidation of the interaction between these two major vitamins in living cells seems to be important.

*tert*-Butylhydroperoxide (tBHP), an organic hydroperoxide, is known to induce oxidative damages to intact human erythrocytes (16–20). The susceptibility of erythrocytes to peroxidation is unique, because they have large amounts of hemoglobin. Hemoglobin may be oxidized to methemoglobin (metHB) by tBHP (16), and metHB itself may lead to peroxidative changes of the cell membranes (21–23). On the other hand, tBHP can cause peroxidative changes in the purified erythrocyte membranes (ghosts) without metHB (24,25). Therefore, molecular mechanisms of the peroxidation of erythrocyte membranes by tBHP may be complicated. Furthermore, it is unclear whether AsA can protect membrane Toc and phospholipids (PL) of intact erythrocytes against peroxidation by tBHP. One purpose of the current study was to investigate the time-dependent changes of tocopherols (Toc), PL, reduced glutathione (GSH), and hemoglobin during the peroxidation of intact human erythrocytes by tBHP. Another purpose was to investigate effects of AsA on membrane Toc and PL during peroxidation. GSH is implicated in antioxidative activities of erythrocytes (26) and is also related to reduction of dehydroascorbate to AsA in erythrocytes (8,27). Because dithiothreitol (DTT) is a protective agent for sulfhydryl groups in cells including GSH, effects of DTT on peroxidation were studied in parallel.

We recently reported a method employing high-performance liquid chromatography (HPLC) with ultraviolet (UV) detection that can detect all of the major PL classes of erythrocyte membranes including phosphatidylserine (PS) by means of a single chromatographic elution (28,29). We applied the HPLC method to investigate changes of membrane PL in intact human erythrocytes; these changes are expressed as the ratio of each PL to sphingomyelin (SM). Furthermore, α-Toc, γ-tocopherol (γ-Toc), and cholesterol of the erythrocytes in the total lipid extraction were simultaneously measured by an

Abbreviations: AsA, ascorbate; BHT, butylhydroxytoluene; DTNB, 5,5′-dithiobis(2-benzoic acid); DTT, dithiothreitol; ELSD, evaporative light-scattering detector; GSH, reduced glutathione; HPLC, high-performance liquid chromatography; MDA, malondialdehyde; metHB, methemoglobin; PBS, phosphate-buffered saline; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PL, phospholipids; PS, phosphatidylserine; SM, sphingomyelin; tBHP, *tert*-butylhydroperoxide; TEA, triethylamine; α- and γ-Toc, α- and γ-tocopherol; UV, ultraviolet.

HPLC method, and cholesterol was regarded as an internal standard for HPLC (29). Combination of the methods is relatively simple, and they are sensitive to the peroxidative changes of intact erythrocytes.

## MATERIALS AND METHODS

*Materials*. L-Ascorbic acid, tBHP, DTT, and 5,5′-dithiobis-(2-nitrobenzoic acid (DTNB) were obtained from Wako Pure Chemical Co. (Osaka, Japan). α-Toc and γ-Toc were obtained from Sigma Chemical Co. (Tokyo, Japan). Standard PL were purchased from Serdary Research Laboratory (Funakoshi Co., Tokyo, Japan). Other reagent-grade chemicals and HPLC-grade solvents were purchased from Wako Pure Chemical Co.

*Sample preparation.* Human venous blood from healthy adult volunteers who had fasted overnight was drawn into tubes containing EDTA-$Na_2$ and was processed immediately. Plasma and buffy coats were removed after centrifugation at 1000 × *g* for 10 min at 4°C, and erythrocytes were washed and centrifuged three times under the same conditions in cold phosphate-buffered saline (PBS), composed of 138 mM NaCl, 5 mM KCl, 6.1 mM $Na_2HPO_4$, 1.4 mM $NaH_2PO_4$, and 1 mM $MgCl_2$.

*Peroxidation of erythrocytes*. The washed erythrocytes were suspended in PBS to make a 10% hematocrit value. A cell counter (Sysmex F-800; Sysmex, Kobe, Japan) was used for the blood counts. The total volume of the reaction mixture was brought up to 4 mL by the addition of PBS. The final concentration of the erythrocytes was 5% hematocrit value. In some experiments, 1 mM tBHP, 0.1 mM AsA, 5 mM DTT, and 5 mM glucose were included. The incubations of different experimental conditions for the blood from each person were done in parallel. After pre-incubation for 5 min, the incubation at 37°C with shaking was started by addition of tBHP. Reactions were terminated by cooling in an ice bath, and then the erythrocytes were pelleted by centrifugation at 1000 × *g* for 6 min at 4°C.

*Extraction of total lipids from erythrocytes.* Extractions of total lipids including Toc from the packed erythrocytes were done immediately after the incubations. The extraction method was according to Burton *et al.* (30) with some modification. Briefly, the packed erythrocytes were hemolyzed by addition of 1 mL of 5 mM phosphate buffer (pH 7.4) containing 5 mM AsA, which was followed by addition of 1 mL of 80 mM sodium dodecyl sulfate. The solution was then sonicated for 30 s. Next, 2 mL of ethanol containing 1.2 mM butylhydroxytoluene (BHT) was added to the mixture, and the mixture was left at room temperature for 60 min. The 5 mM AsA was used to protect Toc during the extraction procedures (30,31). Next, 2 mL of *n*-hexane containing 1.2 mM BHT was added to the mixture, and it was vigorously mixed by a vortex mixer for 1 min (30 s × 2). After a brief centrifugation at 1000 × *g*, the *n*-hexane layer was transferred to another tube. The remaining aqueous layer was washed again with 2 mL of *n*-hexane. This hexane was combined with the first extract, and the combined hexane layer was dried under a stream of nitrogen gas.

*Determination of Toc and cholesterol*. Toc and cholesterol were measured simultaneously by an HPLC method (29) with minor modification. The dried hexane layer was dissolved in 300 μL of *n*-hexane/isopropanol (3:1, vol/vol), and after filtration through a 0.45 μm filter (Millipore Co., Tokyo, Japan) an aliquot of the solution (usually 5 μL) was injected into an HPLC system consisting of a Waters LC system (Waters Co., Tokyo, Japan) equipped with a four-solvent delivery system, a helium degassing unit, and an automatic injector. The system was connected in series to a fluorescence detector (FS-8020; Tosoh, Tokyo, Japan) and an evaporative light-scattering detector (ELSD) (SEDEX-55; Vitry sur Seine, France). The system was also connected to an interface (HP-35900E) and an HP-Vectra XM computer with HPLC ChemStation software (Hewlett-Packard, Tokyo, Japan). The column was a TSK-GEL ODS-80Ts, 250 × 4.6 mm (Tosoh) and the guard column was a Symmetry C18, 20 × 4 mm (Waters Co.). The mobile phase was methanol, and the flow rate was 1 mL/min at a 45°C column temperature. α-Toc and γ-Toc were detected with the fluorescence detector at 290 nm excitation and 330 nm emission (32), and cholesterol was detected with ELSD, which was set at 50°C for evaporation temperature and 2.4 bars for nebulization gas (compressed air).

*Separation of PL by HPLC*. The HPLC method for separation of the erythrocyte membrane PL was modified somewhat from our previous report (28,29). The column was a Wakosil 5 $NH_2$, 150 × 4.6 mm (Wako Pure Chemical Co.) and the guard column was a μ-Bondpak $NH_2$, 20 × 4 mm (Waters Co.). The mobile phase was composed of acetonitrile/methanol/0.25% triethylamine (TEA), pH 3.5 (68:21:11, by vol). The pH of the TEA solution was adjusted with phosphoric acid. HPLC was done by isocratic elution at 1 mL/min at a column temperature of 40°C. Each PL was detected with UV light at 205 nm. An aliquot (5 μL) of the lipid extract, which was used for the detection of Toc and cholesterol, was injected into the HPLC system.

*Determination of malondialdehyde (MDA) by HPLC*. The MDA concentration of the reaction mixtures was measured by the HPLC method reported previously (28). A fluorescence detector set at 515 nm for excitation and 553 nm for emission was used to detect MDA. 1,1,3,3-Tetramethoxypropane was used as standard for MDA.

*Determination of erythrocyte GSH concentration*. An aliquot of the reaction mixture (1.0 mL) was hemolyzed with 1 mL of water; and then 3 mL of metaphosphoric acid solution, which was composed of 1.67 g of metaphosphoric acid, 0.2 g of EDTA-$Na_2$, and 30 g of NaCl in 100 mL, was added. After filtration through a filter paper (No. 5B; Advantec, Tokyo, Japan), the filtrate (1 mL) was subjected to determination of GSH by using DTNB (33).

*Determination of metHB*. An aliquot (0.4 mL) of the reaction mixture was hemolyzed with 5 mL of a solution containing 100 mM phosphate buffer, pH 6.8, and 1% Triton X-100 (4:6, vol/vol) and then divided into two parts. Absorbances of the first part were read at 630 nm in the absence and then the presence of potassium cyanide. Absorbances of the second part were read at 630 nm in the presence of potassium ferricyanide and then at 630 nm after addition of potassium cyanide (34).

*Statistical analysis*. Statistical analyses of the differences of mean values compared to the control values using the *t*-test were performed with Microsoft Excel 2000 on Windows 98 (Microsoft, Tokyo, Japan). Differences with a $P$ value < 0.05 were considered statistically significant.

## RESULTS

*Changes of the membrane Toc*. α-Toc, γ-Toc, and cholesterol from the erythrocytes were clearly separated by the HPLC and were identified by the retention times for each standard substance (Fig. 1). Calibration curves of the Toc were linear up to at least 20 ng/30 μL, and that of cholesterol was linear up to at least 3 μg/30 μL (data not shown). The detection limit of α-Toc in the present system was less than 1 ng/30 μL, and that of cholesterol was less than 0.1 μg/30 μL. Because peroxidation of the erythrocyte membranes usually spares SM (28,35), the ratio of cholesterol to SM in each reaction mixture was calculated. No significant differences for the ratios were noted between the control incubations and the incubations with tBHP. The results of the present study indicated that no significant oxidation of cholesterol by tBHP occurred. Therefore, cholesterol was regarded as an internal standard for chromatography, and changes in Toc are expressed as the ratios of Toc to cholesterol (Figs. 2,3).

In the presence of 1 mM tBHP, α-Toc decreased rapidly to about 26% of the control levels at 3 min (Fig. 2A), and thereafter α-Toc remained at almost the same level for 90 min (Fig. 2B). γ-Toc decreased to about 10% of the control levels at 4 min (Fig. 2B) and then deceased gradually to almost exhaus-

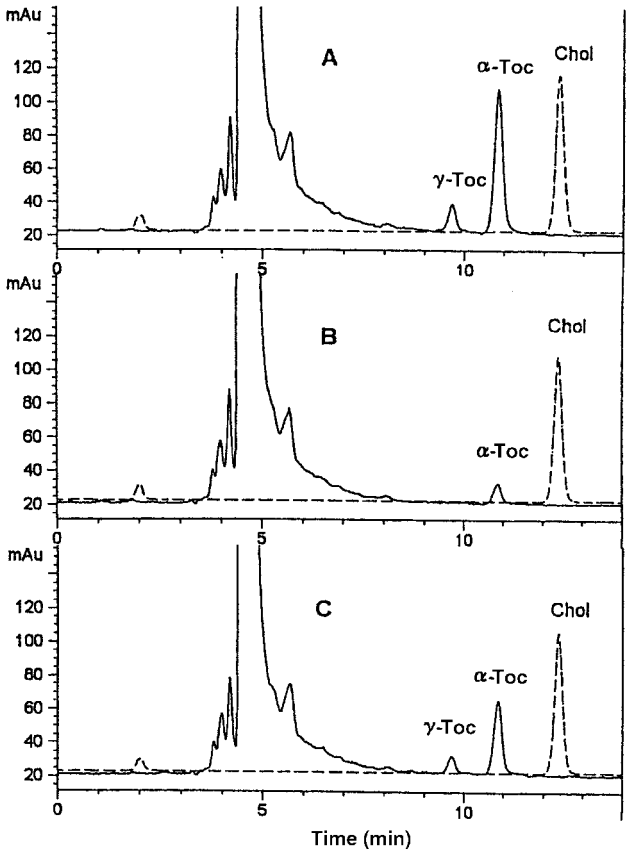

**FIG. 1.** Typical high-performance liquid chromatograms of tocopherols and cholesterol. Tocopherols were detected with a fluorescence detector (—), and cholesterol was detected with an evaporative light scattering detector (----). The column was TSK-GEL 80Ts, 250 × 4.6 mm (Tosoh, Tokyo, Japan). The mobile phase was methanol, and the flow rate was 1 mL/min at a column temperature of 45°C. In each chromatogram, the same amount of erythrocytes was incubated at 37°C for 30 min. (A) Control incubation; (B) incubation with 1 mM *tert*-butylhydroperoxide (tBHP); (C) incubation with both 1 mM tBHP and 0.1 mM ascorbate (AsA). Abbreviations: α-Toc,α-tocopherol; γ-Toc,γ-tocopherol; Chol, cholesterol; mAu, milli-absorbance units.

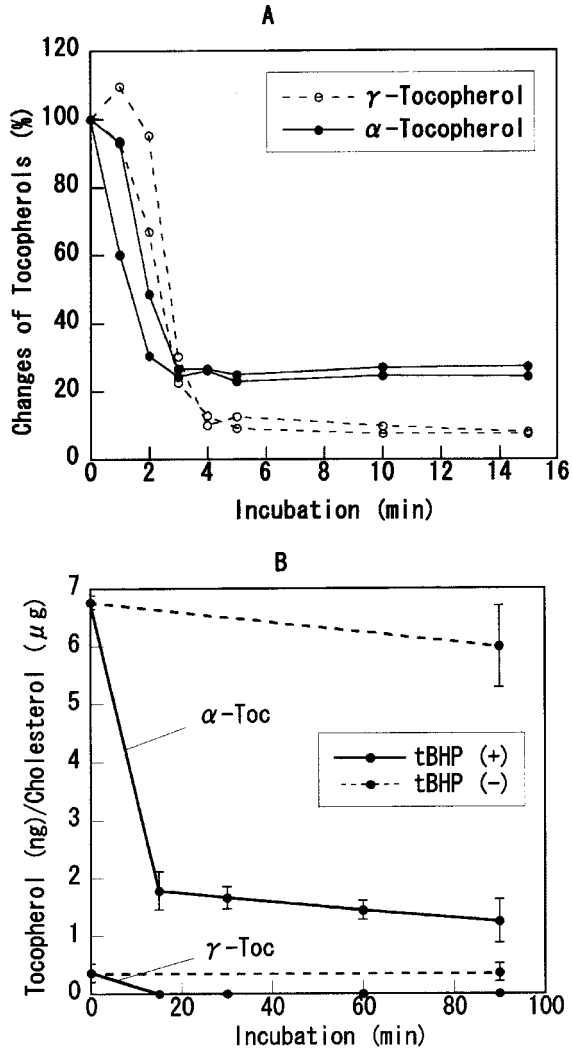

**FIG. 2.** Time courses for the changes of Toc after incubation with tBHP. (A) α-Toc and γ-Toc decreased to almost their lowest levels at 3 and 4 min, respectively, and (B) these minimal levels were maintained at least until 90 min. In (A) each data point represents the mean of two experiments using the same erythrocytes, the results from two different erythrocytes are shown. In (B), the mean ± SD of three experiments using same erythrocytes are shown. Abbreviations: tBHP (+), incubated with tBHP; tBHP (–), incubated without tBHP. For other abbreviations see Figure 1.

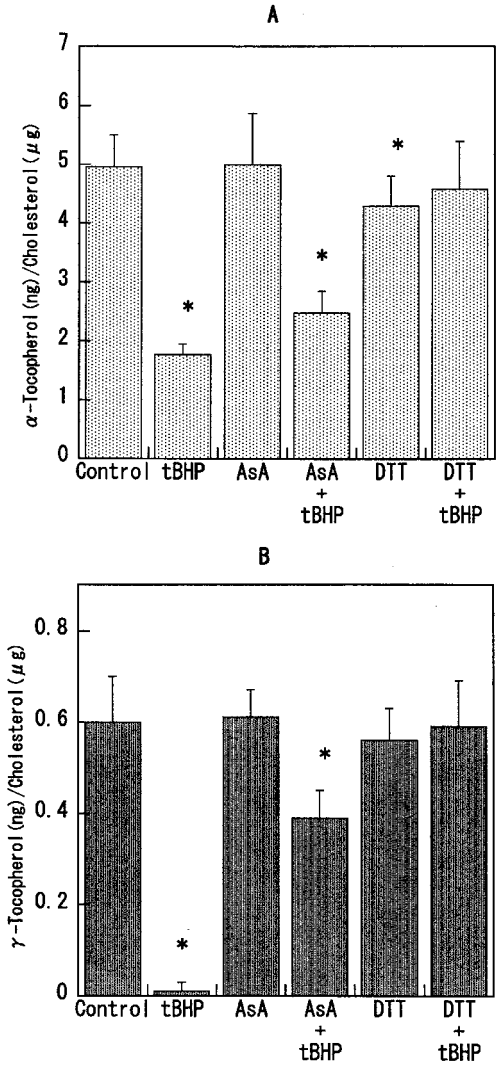

**FIG. 3.** Effects of tBHP, AsA (0.1 mM), and dithiothreitol (DTT) (5 mM) on the contents of α-Toc (A) and on γ-Toc (B) of the erythrocytes after incubation for 30 min with tBHP. The results are the mean ± SD of eight experiments of four different erythrocytes. Abbreviations: tBHP, incubation with 1 mM tBHP; AsA, incubation with 0.1 mM ascorbic acid; AsA + tBHP, incubation with both 0.1 mM AsA and 1 mM tBHP; DTT, incubation with DTT; DTT + tBHP, incubation with both tBHP and DTT; *, difference is statistically significant compared to control ($P < 0.05$).

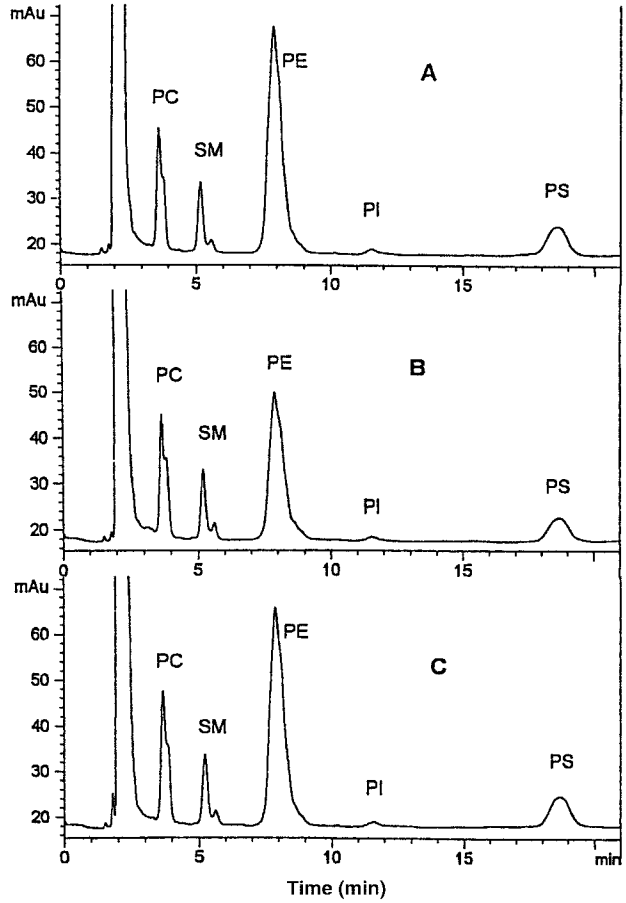

**FIG. 4.** High-performance liquid chromatograms of the erythrocyte membrane phospholipids. The column was a Wakosil 5 $NH_2$, 150 × 4.6 mm (Wako Pure Chemical Co., Osaka, Japan) at 40°C. The mobile phase was acetonitrile/methanol/0.25% triethylamine, pH 3.5 (68:21:11, by vol) delivered isocratically at 1 mL/min. Phospholipids were detected with ultraviolet at 205 nm. An aliquot of the same extraction used in Figure 1 was injected into the high-performance liquid chromatography (HPLC) system. (A) Control incubation; (B) incubation with 1 mM tBHP; (C) incubation with both 1 mM tBHP and 0.1 mM AsA. Abbreviations: PC, phosphatidylcholine; SM, sphingomyelin; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; for other abbreviations see Figure 1.

tion (Fig. 2B). When 0.1 mM AsA was included together with tBHP in the reaction mixture, α-Toc and γ-Toc were preserved at about 50 and 65 of the control levels respectively, after 30 min incubation, (Fig. 3A,3B). Incubation with DTT alone for 30 min showed a significant decrease of α-Toc ($P < 0.02$), but incubation with both tBHP and DTT showed no significant differences in α-Toc or γ-Toc levels from the control levels (Fig. 3). The addition of 5 mM glucose in the reaction mixtures from the start of the incubation did not show any significant differences from those without the addition of glucose (data not shown).

*Changes of the membrane PL.* Major PL classes of human erythrocytes were separated within 20 min of the initiation of the experiment, and the PL classes were identified by the retention times of each standard PL (Fig. 4). The concentration of each PL is expressed as its ratio to SM (Figs. 5,6). After the incubation of the intact erythrocytes with tBHP, phosphatidylcholine (PC), phosphatidylethanolamine (PE), and PS decreased to almost their lowest levels within the first 5 min, and then decreased more slowly until 15 min (Fig. 5). Thereafter, the maximal change of each PL was maintained until 90 min (Fig. 5). The degrees of decrease of PC, PE, and PS at 30 min incubation were about 90, 68, and 76% of each control level, respectively (Fig. 6). The incubation with AsA or DTT for 30 min showed no difference in PL from the control incubation (Fig. 6). The incubation with both AsA and tBHP for 30 min resulted in about an 8% decrease in PE ($P < 0.04$) without decreases of PC and PS (Fig. 6). The incubations with both DTT

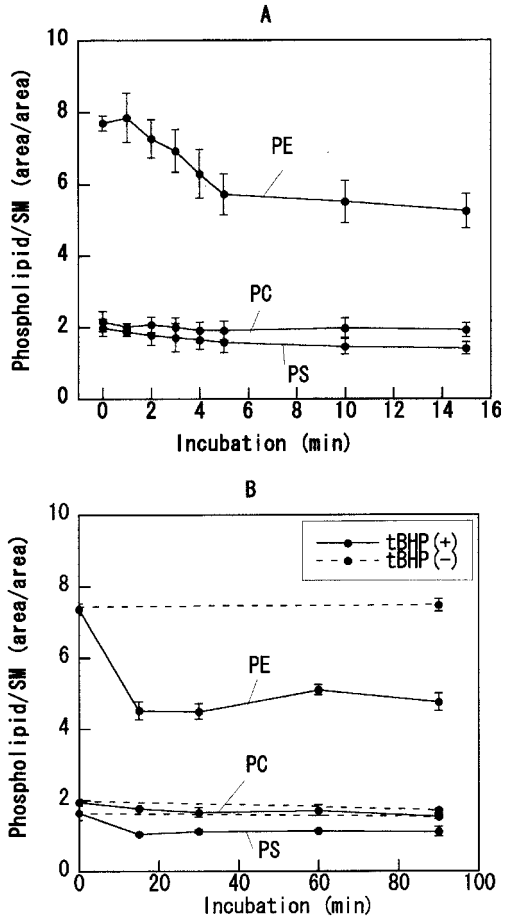

**FIG. 5.** Time courses of the changes in phospholipid levels after incubation with tBHP. (A) Phospholipids decreased rapidly to an almost minimal level at 5 min, and (B) the minimal levels were maintained until 90 min. Data points are the means ± SD of four experiments of two different erythrocytes (A) and of three experiments using the same erythrocytes (B). See Figures 1 and 4 for abbreviations.

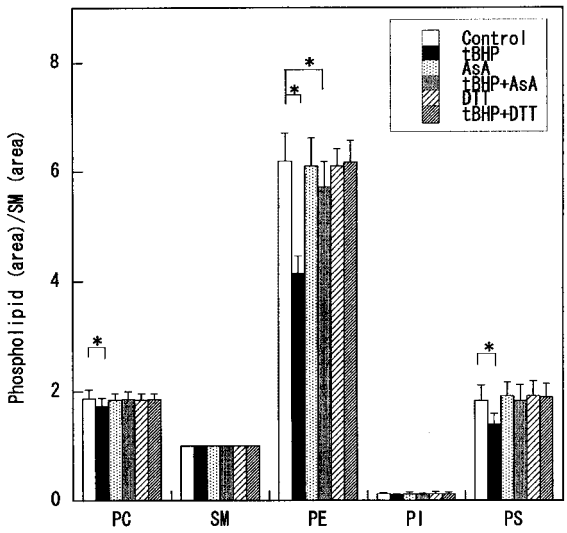

**FIG. 6.** Effects of tBHP, AsA (0.1 mM), and DTT (5 mM) on the phospholipid classes of erythrocyte membranes after incubation with tBHP for 30 min. Data points represent the means ± SD of eight experiments of four different erythrocytes. See Figures 1, 3, and 4 for abbreviations. *, difference is statistically significant compared to each control ($P < 0.05$).

and tBHP for 30 min showed no significant changes of PL (Fig. 6). The addition of 5 mM glucose to the reaction mixtures did not cause any significant differences from controls.

*Increase of MDA*. The MDA concentration in the supernatant from the control incubation was 30 ± 10 nM. Upon incubation with tBHP, MDA did not increase significantly until 3 min and then increased almost exponentially until 15 min (Fig. 7). MDA increased until 30 min upon incubation with tBHP (2,060 ± 330 nM) and thereafter MDA had almost the same value until 90 min (Fig. 7). The incubation with both AsA and tBHP for 30 min showed an increase of MDA (360 ± 80 nM), but the incubation with both DTT and tBHP showed no increase of MDA (40 ± 10 nM) (Fig. 8).

*Changes of GSH concentration*. The incubation of the erythrocytes with tBHP resulted in exhaustion of GSH within 1 min, and thereafter it was slightly recovered and maintained at the low levels until at least 60 min (Fig. 9). The incubation with both tBHP and AsA for 30 min did not show any differences from the incubation with tBHP only (Fig. 10). Because DTT

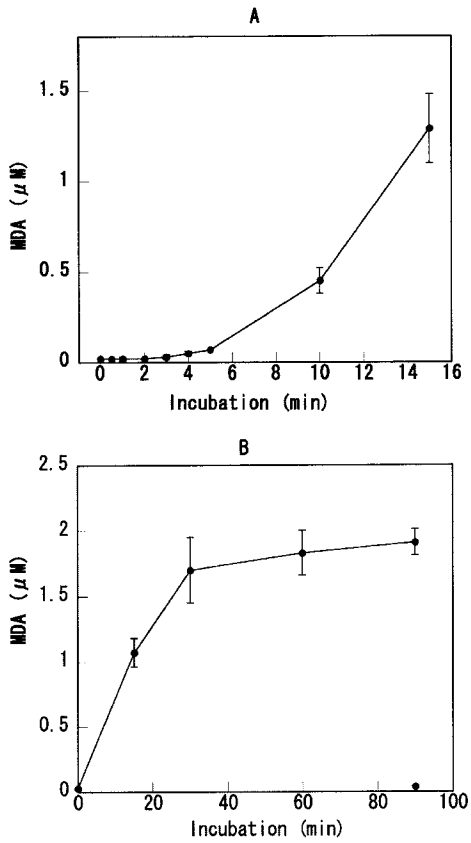

**FIG. 7.** Increase of malondialdehyde (MDA) in the supernatant of the reaction mixture after incubation with tBHP. Data are the means ± SD of four experiments (A) of two different erythrocytes and (B) of three experiments of same erythrocytes. In (B) the lower of the two MDA values at 90 min represents the value for the control incubation. For other abbreviation see Figure 1.

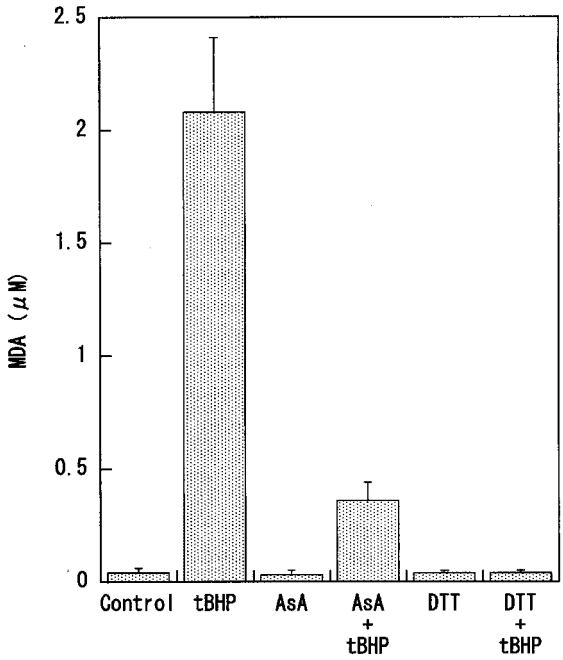

**FIG. 8.** Effects of tBHP, AsA (0.1 mM), and DTT (5 mM) on production of malondialdehyde (MDA) in the supernatant of the reaction mixture after the incubation with tBHP for 30 min. Data are the means ± SD of four experiments with two different erythrocytes. See Figures 1, 3, and 7 for abbreviations.

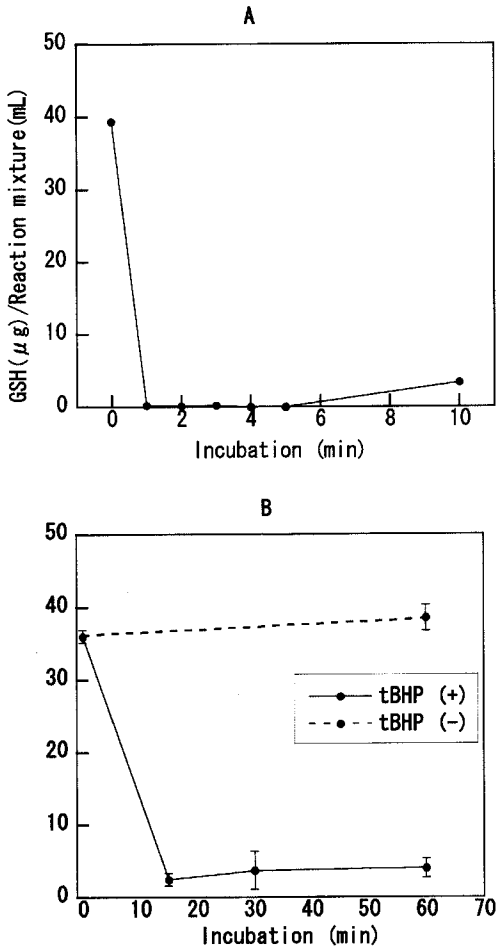

**FIG. 9.** Change of erythrocyte reduced glutathione (GSH) after the incubation with tBHP. Each value is the mean of the two experiments (A) and is the mean ± SD of three experiments (B). See Figure 1 for other abbreviation.

may react with DTNB, GSH level in the presence of DTT was not determined.

*MetHB*. After the incubations with 1 mM tBHP at 37°C, metHB increased almost linearly until 15 min, and then metHB stayed constant until at least 60 min (Fig. 11). AsA did not prevent at all the formation metHB by tBHP (Fig. 12), but the presence of 5 mM DTT together with tBHP prevented almost completely the formation of metHB at least until 30 min (Fig. 12). None of the supernatants of the reaction mixtures after the incubations of the erythrocytes showed coloration by monitoring at 540 nm, which indicated that no hemolysis was occurred in any conditions used in the present study.

## DISCUSSION

In this study, Toc and cholesterol in the total lipid extracts were measured simultaneously by an HPLC method, and the cholesterol was regarded as a kind of internal standard for the HPLC. Actually, the changes in the cholesterol levels on the chromatograms appeared to be negligible when compared to the changes of Toc (Fig. 1). Therefore, the changes of Toc are expressed on the basis of cholesterol (Figs. 2,3). Thus, variability of Toc values on the basis of blood counts after the long process of determination by the HPLC is diminished, and no blood counts of the samples are needed. We recently confirmed, by using human erythrocyte membranes, that the detection of membrane PL with UV depends primarily on unsaturated fatty acids (28,36) and that primary targets of peroxidation of the membrane PL are polyunsaturated fatty acids (28,35). Because SM of the human erythrocytes contains very small amounts of polyunsaturated fatty acids (28,37,38), peroxidation of the membrane PL usually spares SM (28). Therefore, the changes in the ratios of PC, PE, and PS to SM reflect changes in polyunsaturated fatty acid contents of these PL (Figs. 5,6).

After the incubation of the erythrocytes with 1 mM tBHP, GSH, Toc, and PL decreased almost maximally within a few minutes (Figs. 2,5,9). GSH was exhausted within 1 min, α-Toc decreased to about 30% of the control level at 3 min, and γ-Toc decreased to about 10% of the control level at 4 min. PE decreased to about 70% of the control at 5 min. However, MDA in the supernatant of the reaction mixture appeared slowly and increased until 30 min (Fig. 7). MetHB was formed linearly and reached a maximum at 15 min (Fig. 11). These results show that the peroxidative changes of the cell membranes of intact erythrocytes by 1 mM tBHP occur very rapidly and that the speeds and the degrees of decreases by tBHP are different among α-Toc, γ-Toc, and PE. The decrease of α-Toc is faster than that of γ-Toc, and the decreases of the Toc are faster than PE. The large discrepancy of time between the actual decreases

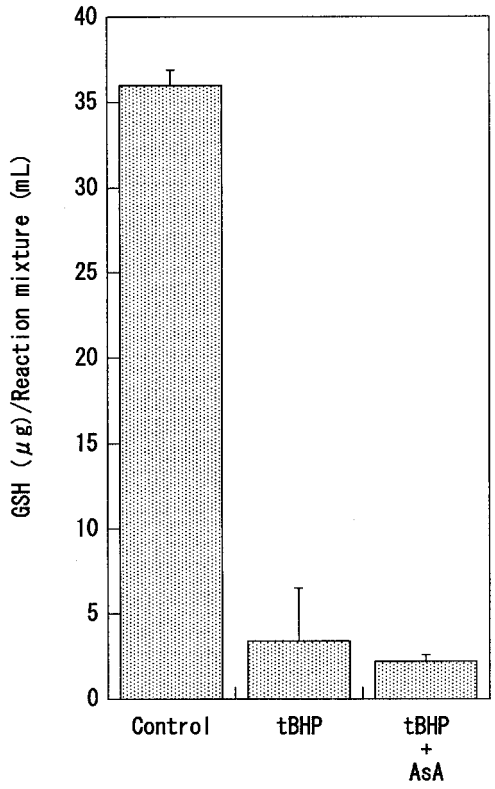

**FIG. 10.** Effects of tBHP and AsA (0.1 mM) on GSH of the intact erythrocytes after incubation for 30 min. GSH contents after the incubation with DTT were not determined because 5,5′-dithiobis(2-benzoic acid) may react with DTT. The data are the means ± SD of three experiments. See Figures 1, 3, and 9 for abbreviations.

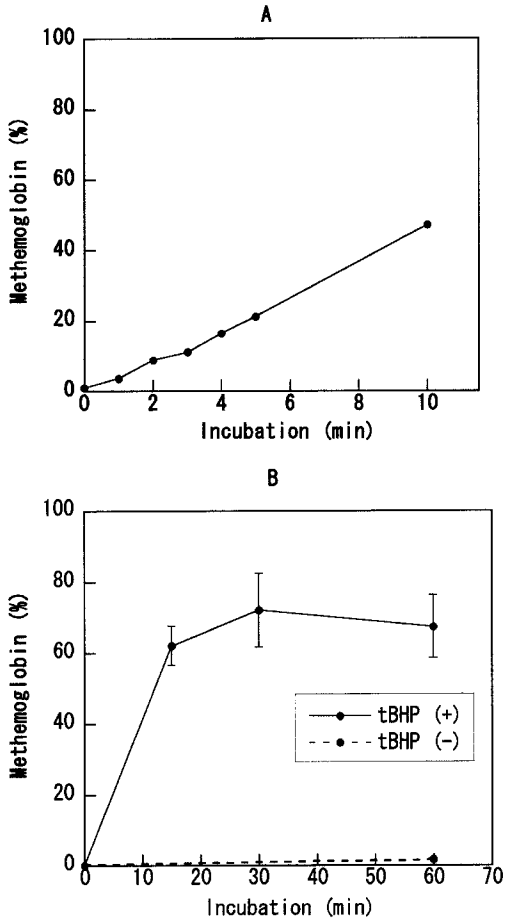

**FIG. 11.** Time course of the formation of methemoglobin (metHB) after the incubation with tBHP at 37°C. Values are mean of the two experiments (A) and are the means ± SD of three experiments (B). The erythrocytes for (A) and (B) were from different persons. See Figure 2 for abbreviation.

of PL and the increase of MDA may also be noteworthy. The results may indicate that the peroxidative changes of the cell membranes precede the formation of metHB.

After rapid initial changes, α-Toc, PL, and MDA showed almost the same levels until at least 90 min (Figs. 2,5,7). metHB was also at a nearly constant level until at least 60 min after reaching the maximal increase at 15 min (Fig. 11). The results indicated that propagation of the peroxidative changes was stopped spontaneously and was prevented spontaneously for a long period. These phenomena seem to be very important for understanding the molecular mechanisms of peroxidation of intact erythrocytes. GSH was exhausted within 1 min (Fig. 9), but α-Toc was never exhausted (Fig. 2). GSH recovered slightly after exhaustion (Fig. 9), but α-Toc had not significantly changed at 90 min (Fig. 2). However, exact mechanisms for the spontaneous cessation of the propagation of peroxidation over a long period remain to be elucidated.

When 0.1 mM AsA was included in the reaction mixture with tBHP, 92% of PE, 50% of α-Toc, and 65% of γ-Toc were preserved at the end of 30 min of incubation (Figs. 3,6). However, AsA did not prevent the formation of metHB and the decrease of GSH (Figs. 10,12). These results show that 0.1 mM AsA can protect the membrane PL and Toc of the intact erythrocytes against peroxidation by tBHP despite the formation of metHB and the decrease of GSH. In the presence of both AsA and tBHP, the decrease of PE was only 8% from the control level at 30 min of incubation, but the decrease of α-Toc was about 50% of the control. The results may support the notion that AsA-mediated protection of the membrane lipids depends primarily on α-Toc even in intact erythrocytes. Reportedly, the rate of entry of AsA into erythrocytes is more than 10 times slower than that of dehydroascorbate (39). The present study clearly shows that exogenously added AsA can protect and spare the membrane Toc of the cell, but it may not necessarily indicate that AsA regenerates tocopheroxyl radicals to Toc. Perhaps AsA merely spared the Toc by reacting directly with tBHP outside the cells.

γ-Toc showed more remarkable changes than α-Toc in both the decrease by peroxidation and the preservation by AsA; γ-Toc was almost exhausted by tBHP and was preserved at 65% of the control level by AsA, whereas α-Toc decreased to about 30% of the control and was preserved at 50% of the control (Fig. 3). In our previous study (29) γ-Toc of the purified membranes was exhausted by the incubation with lipoxygenase for 45 min. After this, further incubation of the mem-

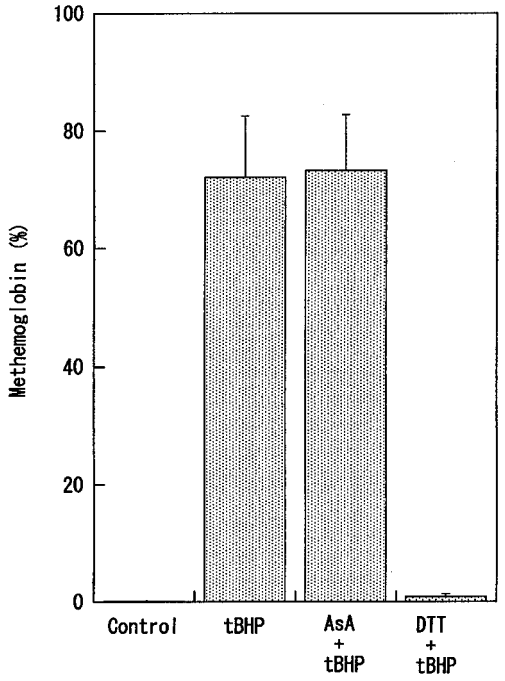

**FIG. 12.** Effects of tBHP, AsA (0.1 mM), and DTT (5 mM) on the formation of metHB after incubation for 30 min at 37°C. The results are the means ± SD of three experiments. See Figures 1, 3, and 11 for abbreviations.

branes with AsA resulted in partial recovery of γ-Toc. Therefore, it is probable that exogenously added AsA can regenerate the membrane Toc of intact erythrocytes within 30 min. The concentration of AsA in human plasma is reported to be 0.03–0.15 mM (3). Therefore, the 0.1 mM AsA used in the present study can be considered as physiological level.

The incubation of erythrocytes with 0.5 mM tBHP caused inhibition of Ca + Mg ATPase, and 20 mM AsA significantly decreased the inhibition of the ATPase (19). However, 20 mM ascorbic acid is far more than physiological concentration of human plasma (3). Dise and Goodman (17) reported that the incorporation of tritium-labeled oleic acid into PE of the erythrocyte membranes was enhanced, whereas incorporation of the oleic acid into PC decreased, in the presence of 1 mM tBHP and that the addition of 0.5 mM AsA in the reaction mixture with tBHP abolished the enhanced incorporation of the oleic acid into PE but not the decreased incorporation of the oleic acid into PC. Our results, in which PE decreased more than PC in the presence of 1 mM tBHP and membrane PL were preserved in the presence of AsA, may be related to the observation of Dise and Goodman (17).

DTT protected Toc and PL completely from peroxidation by tBHP (Figs. 3,6), and DTT also almost completely prevented the formation of metHB by tBHP (Fig. 12). The results show that DTT protects the membrane PL and Toc against peroxidation by tBHP in a different way from AsA. Because normal erythrocytes contain large amounts of GSH, the effects of DTT observed in the present study may largely reflect the effects of GSH (20,39–42). Reportedly, 1 mM DTT was completely effective in preventing tBHP-induced inhibition of the Ca-pump ATPase (20). Furthermore, the ability of DTT to protect the ATPase was abolished when glutathione peroxidase was inhibited by an inhibitor, which indicates that the protection of ATPase by DTT is due to protection and/or regeneration of GSH (20). The effects of DTT on the membrane PL and Toc presented in this study seem to be in agreement with these observations. On the other hand, reduction of metHB in normal erythrocytes depends primarily on NADH-cytochrome $b_5$ reductase, which is not directly related to GSH (43,44). Therefore, no single mechanism likely accounts for the complete prevention of metHB formation by DTT. The present results confirmed the importance of sulfhydryl groups of the erythrocytes on protection against the peroxidation.

After the incubation of the erythrocytes with DTT (without tBHP), a small but significant ($P < 0.02$) decrease of α-Toc and a tendency of γ-Toc to decrease were observed (Fig. 3). The results may indicate that DTT generated a superoxide in the erythrocytes *via* its reaction with GSH (45).

Finally, the procedure for combining the two HPLC methodologies for Toc and PL used in this study is relatively simple and is sensitive to the peroxidative changes of these substances in the cell membranes.

## ACKNOWLEDGMENT

The work presented in this paper was partly supported by a grant from the Institute of Rheological Function of Foods Co., Ltd., Fukuoka, Japan.

# Cacao Liquor Polyphenols Reduce Oxidative Stress Without Maintaining α-Tocopherol Levels in Rats Fed a Vitamin E-Deficient Diet

**Megumi Yamagishi[a], Naomi Osakabe[a,*], Toshio Takizawa[a], and Toshihiko Osawa[b]**

[a]Functional Foods R&D Laboratories, Meiji Seika Kaisha, Ltd., Sakado, Saitama 350-0289, Japan, and [b]Nagoya University Graduate School of Bioagricultural Science, Chikusa, Nagoya 464-8601, Japan

**ABSTRACT:** The effect of crude polyphenols (CLP) from cacao liquor on vitamin E-deficient rats was examined. The CLP fraction contained 49.8% antioxidative polyphenols such as catechins and their oligomers. Supplementation of the vitamin E-deficient diet with CLP for 7 wk did not prevent the decrease in α-tocopherol levels in the liver, kidney, heart, brain, and plasma. The lipid peroxide levels in these tissues increased in the group fed the vitamin E-deficient diet compared with the control group. However, these changes were inhibited in a dose-dependent manner as a result of supplementation of the vitamin E-deficient diet with 0.25, 0.5, or 1.0% CLP. The lipid peroxide levels in plasma increased in the group fed the vitamin E-deficient diet. This change tended to be suppressed as a result of supplementation of the diet with CLP, but the difference was not significant. There was no evidence of absorption and distribution of CLP to the tissues; however, CLP intake resulted in a decrease in oxidative stress without maintaining vitamin E levels in the plasma and the tissues.

Paper no. L8380 in *Lipids 36,* 67–71 (January 2001).

A protective role of plant polyphenols against atherosclerosis has been suggested by several studies. According to the results of epidemiological studies, plant polyphenol consumption is associated with a reduced risk of coronary heart disease (1–3). These studies suggested that such health benefits of polyphenols are dependent on their antioxidative activity. It has been reported that plant polyphenols reduce oxidative stress *in vivo*, as demonstrated using experimental animal models. Sesame seed (4)-, green tea (5)-, and grape (6)-derived polyphenols have been shown to decrease oxidative stress induced by vitamin E (VE) deficiency in rats.

Cacao beans, the seed of *Theobroma cacao*, are known to contain various polyphenolic substances (7–9). It has been reported that cacao liquor, one of the main ingredients of cocoa and chocolate, prepared by fermentation of raw beans, is rich in polyphenols in spite of the processes involved in its manufacture. Epicatechin (EC), catechin, and its oligomers as procyanidins are confirmed to be the major antioxidative components of cacao liquor (10–12).

Abbreviations: CLP, cacao liquor crude polyphenols; EC, epicatechin; PMC, 2,2,5,7,8-pentamethyl-6-chromarol; TBARS, thiobarbituric acid-reactive substances; VE, vitamin E.

In the present study, we examined the effect of polyphenolic antioxidants from cacao liquor on VE-deficient rats as an experimental model of oxidative stress.

## EXPERIMENTAL PROCEDURES

*Animals and diets.* Three-week-old male Sprague-Dawley rats were obtained from Clea Japan (Tokyo, Japan). The rats were housed individually and kept in a room maintained at 23–25°C and with controlled lighting in a 12-h light/dark cycle. The animals were fed a basal diet (MF, Oriental Yeast Co. Ltd., Tokyo, Japan) for 4 d. Forty rats were divided into five equal groups and assigned one of five diets shown in Table 1. The five experimental diets were a normal diet (control), a VE-deficient diet (VE-deficient), and VE-deficient diet containing 0.25, 0.5, or 1.0 % cacao liquor crude polyphenol (CLP; 0.25, 0.5, 1.0%). The rats were fed the assigned diet for 7 wk. The normal diet was the reformulated AIN-76 diet, containing 59.9 mg/kg α-tocopherol. The VE-deficient diet was prepared using VE-free corn oil and VE-free vitamin mixture. The VE-free corn oil was made from commercial oil using activated charcoal and silica gel. The VE-free vitamin mixture was the same as AIN-76 vitamin mixture except that it lacked VE acetate. The α-tocopherol concentrations in the corn oil and the VE-free corn oil were analyzed by high-performance liquid chromatography (HPLC) by the method of Ueda and Igarashi (13). The VE-deficient diet contained less than 6.0 μg/kg α-tocopherol. The present study was approved by the Animal Committee of Meiji Seika Functional Foods R&D Laboratories, and the animals received humane care under the guidelines laid down by this committee.

CLP was prepared from cacao liquor by the method described in a previous report (10). Briefly, cacao liquor was defatted with *n*-hexane and extracted with 80% ethanol. The extract was applied to a Diaion HP2MG column (Mitsubishikasei Co., Ltd., Tokyo, Japan), and the column was washed with 20% vol/vol ethanol to remove contaminants including xanthine derivatives. The fraction eluted with 80% vol/vol ethanol was collected as CLP and freeze-dried. The concentration of total polyphenols in the CLP fraction was about 50% as determined by the Prussian blue method using EC as the standard (14). The catechins and procyanidins in CLP measured by the HPLC method of Ricardo da Silva *et al*. (15)

**TABLE 1**
**Composition of the Experimental Diets**

| | Groups | | | | |
|---|---|---|---|---|---|
| (%) | Control | VE-deficient | CLP 0.25% | CLP 0.5% | CLP 1.0% |
| Corn starch | 41.5 | 41.5 | 41.5 | 41.5 | 41.5 |
| Casein | 25.0 | 25.0 | 25.0 | 25.0 | 25.0 |
| α-Potato starch | 10.0 | 10.0 | 10.0 | 10.0 | 10.0 |
| Cellulose powder | 8.0 | 8.0 | 7.75 | 7.5 | 7.0 |
| Corn oil | 6.0 | 0 | 0 | 0 | 0 |
| VE-free corn oil[a] | 0 | 6.0 | 6.0 | 6.0 | 6.0 |
| Mineral mixture[b] | 3.5 | 3.5 | 3.5 | 3.5 | 3.5 |

| VE-free vitamin mixture[d] | 0 | 1.0 | 1.0 | 1.0 | 1.0 |
| CLP | 0 | 0 | 0.25 | 0.5 | 1.0 |

[a]Vitamin E (VE)-free corn oil was prepared from corn oil treated with activated charcoal and silica gel.
[b]Mineral mixture was AIN-76 mixture obtained from Oriental Yeast Co., Ltd. (Tokyo, Japan).
[c]Vitamin mixture was AIN-76 mixture including choline bitartrate obtained from Oriental Yeast Co., Ltd.
[d]VE-free vitamin mixture was the same as the AIN-76 mixture except that it lacked VE. Abbreviation: CLP, cacao liquor crude polyphenols.

with slight modification were as follows: total polyphenol, 49.5%; catechin, 0.46%; EC, 1.83%; procyanidin B2, 1.69%; procyanidin C1, 2.37%; and cinnamtannin A2, 2.01%.

*Study design.* The animals were fed the assigned diet for 7 wk. Blood was taken from the tail vein before (0 time) and 2, 4, 6, and 7 wk after start of feeding, and the plasma α-tocopherol level was monitored. Lipid peroxides in plasma, assayed as thiobarbituric acid-reactive substances (TBARS), were measured 4 and 7 wk after the start of feeding. After 7 wk of feeding the assigned diet, the animals were anesthetized with ethyl ether, and blood samples were taken from the abdominal vein using heparinized needles and syringes. The tissues of the animals (liver, kidney, heart, and brain) were removed and homogenized in 1.15% KCl solution. An erythrocyte hemolysis test was conducted immediately after collection of the blood samples. Plasma and tissue homogenates were kept at −80°C until analysis.

*Analysis.* The oxidative hemolysis of erythrocytes was measured using dialuric acid (Tokyo Kasei Co., Ltd., Tokyo, Japan) (16). The α-tocopherol concentrations in the plasma and tissues were measured using a high-performance liquid chromatograph equipped with a fluorometric detector, with 2,2,5,7,8,-pentamethyl-6-chromarol (PMC; for biochemistry and analysis; Eisai Co., Ltd., Tokyo, Japan) as the internal standard (13). Lipid peroxides in plasma were measured as TBARS by a fluorometric method using LPO-test Wako (Wako Pure Chemical Industries, Ltd., Osaka, Japan). Liver, kidney, heart, and brain TBARS were measured by the method of Ohkawa *et al.* (17), using tetraethoxypropane (Wako Pure Chemical Industries, Ltd.) as the standard. Protein concentrations in tissue homogenates were determined by the method of Lowry *et al.* (18). Levels of EC and its metabolites in plasma were determined by HPLC (19). Glucuronide, sulfate and glucuronide-sulfate conjugates of EC in plasma were hydrolyzed to nonconjugated EC by treatment with sulfatase type H-5 (Sigma, St. Louis, MO). The sample pretreated with enzymes was analyzed by HPLC.

*Statistical analysis.* The data were expressed as the mean ± SD. Analyses were performed using SPSS statistical software (SPSS Inc., Chicago, IL). When analysis of variance revealed $P < 0.05$, the data were further analyzed using Scheffe's multiple range test. Differences were considered statistically significant at $P < 0.05$.

## RESULTS

In this study, food intake, body weight gain, and food efficiency were equal in all of the experimental groups, as shown in Table 2. The plasma α-tocopherol concentrations in the groups fed the VE-deficient diet or the 0.25, 0.5, and 1.0% CLP-containing VE-deficient diet decreased markedly in

comparison with the control (Table 3). The results of the test examining erythrocyte hemolysis, which is an index of VE deficiency, are shown as follows (mean ± SD): control, 0.42 ± 0.80%; VE-deficient, 97.07 ± 2.28%; CLP 0.25%, 97.89 ± 2.22%; CLP 0.5%, 92.34 ± 13.53%; CLP 1.0%, 96.46 ± 2.33%. In all of the groups fed a VE-deficient diet, a high degree of hemolysis was evident, and no significant difference was noted comparing these groups.

Lipid peroxide levels in the plasma are shown in Figure 1. After 4 wk, the plasma TBARS level was significantly increased in the group fed the VE-deficient diet without CLP, compared with the control. In the groups fed the CLP-containing VE-deficient diets, the plasma TBARS levels were slightly increased. After 7 wk, the plasma TBARS in the rats fed the VE-deficient diet were elevated to a level twice that in the control. The plasma TBARS levels showed a tendency to decrease in the groups fed the CLP-containing VE-deficient diets, but the changes were not significant.

The α-tocopherol concentrations in various tissues are shown in Table 4. In the liver, kidney, heart, and brain of the rats in the VE-deficient group, the α-tocopherol concentrations were decreased by 86, 81, 93, and 53% compared with the control. In the groups fed the CLP-containing VE-deficient diets, the α-tocopherol levels in the tissues were decreased to a similar extent.

The lipid peroxide levels in various tissues are shown in Figure 2. TBARS levels in various tissues of rats in the VE-deficient diet group were elevated fourfold in the liver,

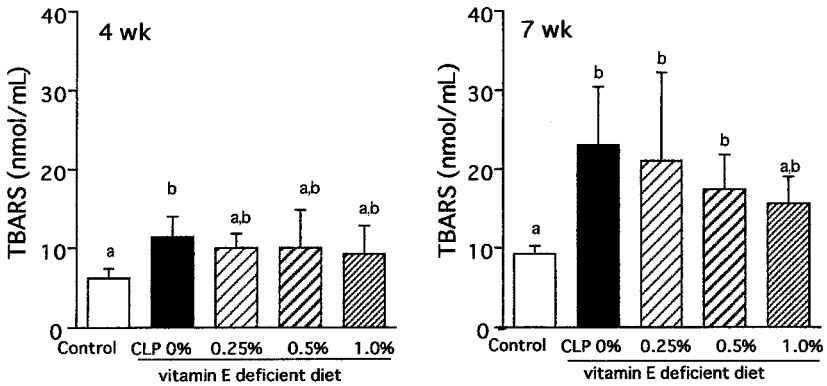

**FIG. 1.** Effect of cacao liquor crude polyphenols (CLP) on plasma lipid peroxide levels in rats fed the experimental diets, as determined after 4 wk and 7 wk. Values are means ± SD. Values not sharing the same letters are significantly different, $P < 0.05$. Abbreviation: TBARS, thiobarbituric acid-reactive substances.

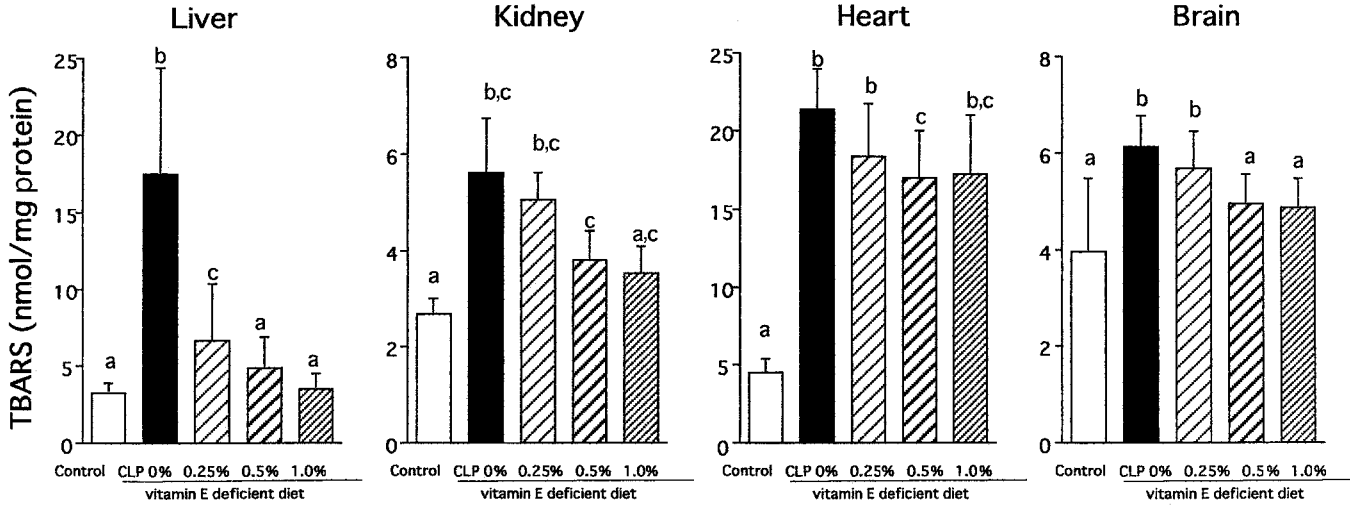

**FIG. 2.** Effect of CLP on lipid peroxide levels in various tissues of rats fed the experimental diets. Values are means ± SD. Values not sharing the same letters are significantly different, $P < 0.05$. For abbreviations see Figure 1.

twofold in the kidney, fourfold in the heart, and 1.5-fold in the brain compared with the control. In the case of rats fed the CLP-containing VE-deficient diets, the liver TBARS levels were decreased markedly in a dose-dependent manner compared with the rats fed the VE-deficient diet. A significant reduction of the kidney TBARS levels was observed in the groups fed the 0.5 and 1.0% CLP-containing VE-deficient diet, but such a decrease was not observed in the 0.25% CLP group. A significant suppression of the increase in heart TBARS levels was evident only in the group fed the 0.5% CLP-containing VE-deficient diet. The groups fed the 0.5 and 1.0% CLP-containing VE-deficient diets showed significant decreases in brain TBARS levels.

In plasma, neither free EC nor its metabolites produced through enzymatic treatment coud be detected by HPLC.

## DISCUSSION

The effect of antioxidants derived from cacao liquor on VE-deficient rats was evaluated. As a result, it was confirmed that the α-tocopherol concentrations in plasma and various tissues were markedly decreased, and lipid peroxide levels were markedly increased in rats fed the CLP-free VE-deficient diet (Tables 3 and 4; Figs. 1 and 2). VE is known to function as a strong antioxidant. Among the experimental oxidative stress models, VE -deficient animals have been well investigated. In these animals, there is a deficiency of VE in the cell membranes, the antioxidative status in the lipid bilayers is decreased, and severe membrane damage occurs (20). Yamashita *et al.* (21,22) evaluated the effects of antioxidative lignans in sesame seeds on VE-deficient rats. These reports indicated that sesame seed lignans reduced oxidative stress in VE-deficient rats. They speculated that the antioxidative mechanism of action of these lignans involved maintenance of VE levels in the organs. According to a previous report, supplementation of a low-selenium and VE-deficient diet with various flavonoids and phenols was not effective to maintain VE levels in plasma and tissues of animals (23,24). However, the increase in lipid peroxide levels in the organs of rats fed the low-selenium and VE deficient diet was suppressed by ingestion of these compounds.

In this study, CLP supplementation did not affect α-tocopherol metabolism in the case of VE deficiency (Tables 3 and 4). However, TBARS production as a consequence of VE deficiency was reduced by intake of CLP in a dose-dependent manner (Fig. 2). CLP inhibited the oxidative damage, especially in the liver. It was considered that the antioxidative component of CLP was absorbed and distributed to the liver more than to other tissues. The mechanisms of absorption and metabolism of polyphenols remain obscure, but recently many studies focusing on these aspects have been reported. Piskula and Terao (19) reported that epicatechin, which is one of the antioxidative components of CLP, was absorbed and could be detected in the blood of rats. In most cases, glucuronide and/or sulfate conjugates were formed. It has been reported also that epicatechin was detected in plasma after intake of black chocolate in man (25). In addtion, Hollman *et al.* (26) reported that orally administered epicatechin was absorbed and distributed in various tissues including liver and kidney. We have reported that cacao liquor polyphenols are absorbed and can be detected in plasma in rats (27). Thirty to 60 min after oral administration of cacao liquor to rats, the concentrations of epicatechin and its metabolites reached a maximum in plasma. At the same time, the level of plasma lipid peroxide production induced by a radical generator was reduced compared with the level before supplementation. In this study, the epicatechin concentration in plasma did not increase following oral administration because the rats were given CLP as a component of the diet. Under these conditions we could not detect epicatechin in plasma nor inhibition of lipid peroxide production induced by a radical generator (data not shown). However, our findings suggested that CLP in the

diet was absorbed and showed antioxidative activity similar to the case of oral administration.

In conclusion, when consumed orally CLP markedly reduce oxidative stress induced by VE deficiency without maintaining VE levels in the plasma and tissues.

# Removal of Fat from Cow's Milk Decreases the Vitamin E Contents of the Resulting Dairy Products

**Supriya Kaushik[a], Rosemary Wander[b], Scott Leonard[c], Bruce German[d], and Maret G. Traber[a,c,e,*]**

[a]Department of Nutrition and Food Management, and [b]Department of Nutrition and Food Service Systems, University of North Carolina, Greensboro, North Carolina, [c]Linus Pauling Institute, Oregon State University, Corvallis, Oregon, [d]Department of Food Science, University of California, Davis, California, and [e]Department of Internal Medicine, University of California School of Medicine, Davis, Sacramento, California

**ABSTRACT:** The present study was undertaken to determine whether decreases in fat contents result in lower vitamin E contents. Milk samples of varying fat contents (half and half, whole milk, reduced-fat milk, low-fat milk, and nonfat milk) were obtained from a local dairy on six different occasions. α-Tocopherol was the major form of vitamin E (>85%); γ-tocopherol and α-tocotrienol were present to a lesser extent. As the fat contents of milk products decreased from 11 to 0.3%, the vitamin E contents decreased. For example, raw milk as compared to nonfat milk had both higher α-tocopherol contents (45.5 ± 4.6 vs. 4.5 ± 0.5 μg/100 g; $P \leq 0.0001$) and higher total lipids (3.46 ± 0.49 vs. 0.30 ± 0.07 g/100 g; $P \leq 0.0001$). Vitamin E, cholesterol, and total lipids increased as cream was added back to nonfat milk during production. For every 1 mg cholesterol increase, there was an increase of approximately 4 μg of α-tocopherol; for every 1 g total lipids increase, the α-tocopherol content increased by 17 μg. These data demonstrate that removal of milk fat markedly decreases the vitamin E content of various milk products.

Paper no. L8538 in *Lipids 36,* 73–78 (January 2001).

In recent years, the term "antioxidant vitamins" has caught the attention of consumers. This is in part due to an increase in the research and understanding of the significant roles of antioxidant vitamins in disease processes. Vitamin E is one such essential lipid-soluble, chain-breaking antioxidant. Several prospective studies have suggested inverse associations between dietary intakes or plasma concentrations of antioxidants and cardiovascular disease (1,2). In some studies, this association has been observed for dietary vitamin E, but in other instances the relationship was seen only in persons taking high doses of vitamin E as supplements (3,4).

There have been three major intervention studies testing the effects of vitamin E on coronary heart disease risk. The Cambridge Heart Antioxidant Study, a double-blind placebo controlled study, looked at the effect of vitamin E (α-tocopherol) in the secondary prevention of coronary heart disease. The study demonstrated a 76% reduction in second nonfatal heart attacks in patients, who previously had had one heart attack (5). The GISSI-Prevenzione trial was a study of more than 11,000 individuals with a recent myocardial infarction (MI) who were randomly assigned to consume fish oil, vitamin E, or both, in a 2 × 2 factorial design study. The results were favorable for the fish oil supplement and neutral for vitamin E, but a *post-hoc* statistical analysis suggested a positive outcome for vitamin E supplementation (7). However, the Heart Outcomes Prevention Evaluation Trial of more than 9,000 subjects with vascular disease and diabetes also did not show a benefit for vitamin E, although the angiotension-converting enzyme inhibitor ramipril was shown to be beneficial in reducing cardiovascular risk (8). In contrast, in a trial with 196 patients with endstage renal disease, vitamin E (800 IU) compared to placebo showed a 46% reduction in the primary end point (cardiovascular disease including sudden death), and a reduction in MI by 70% (9). Thus, the role of vitamin E in decreasing coronary heart disease risk remains controversial.

Both vitamin E and fat are important in human health, but may have opposite effects. The American public has focused on decreasing dietary saturated fat to benefit health. However, modifying dairy product fat contents by either reducing total fat or altering the kind of fat may alter the vitamin E contents. Since vitamin E is a fat-soluble vitamin, it is likely to be removed by fat-modification of dairy foods. Is this detrimental because it reduces vitamin E intake? The present study was undertaken to analyze vitamin E, total lipid, and cholesterol in regular and fat-modified dairy products to assess whether decreases in fat result in lower vitamin E contents.

## MATERIALS AND METHODS

*Selection of analytical samples.* Milk samples were obtained from Loch Mead Dairy (Junction City, OR) on six different occasions. Briefly, raw milk was processed by the dairy to separate cream and nonfat milk. Depending on the type of milk being produced, a varying amount of fat in the form of

*To whom correspondence should be addressed at Linus Pauling Institute, 571 Weniger Hall, Oregon State University, Corvallis, OR 97331-6512. E-mail: maret.traber@orst.edu

Abbreviations: FDA, Food and Drug Administration; HPLC, high-performance liquid chromatography; MI, myocardial infarction.

cream was added back to the nonfat milk; homogenization and pasteurization followed immediately. The U.S. Food and Drug Administration (FDA) regulations define the names for various milk products based on the fat contents (half and half, 11%; whole milk, 3%; reduced-fat milk, 2%; low-fat milk, 1%; and nonfat milk, 0.5% fat).

Six aliquots of each milk sample were obtained for analysis from a single batch of raw milk being processed on the same day. All the samples were transferred from the dairy to the laboratory on ice and analyzed within 24 h from the time of collection. Six different batches were analyzed.

*Laboratory analyses. (i) Vitamin E.* The distribution of α- and γ-tocopherols and α- and γ-tocotrienols in half and half, raw, whole, reduced-fat, low-fat, and nonfat milk was determined as previously described (10). Briefly, the milk vitamin E was extracted with hexane [*n*-hexane high-performance liquid chromatography (HPLC) grade; EM Science, Cherry Hill, NJ] following saponification with ethanolic potassium hydroxide. An aliquot of the hexane layer was evaporated under nitrogen and the residue was resuspended in 1:1 ethanol/methanol. An appropriate aliquot was then injected onto the HPLC. The HPLC was configured with an SIL-10AD$_{VP}$ autoinjector with a sample cooler (Shimadzu, Kyoto, Japan) consisting of a SCL-10A system controller, a LC-10AD$_{VP}$ HPLC series isocratic pump, a Beckman Ultrasphere (ODS C-18 column, 4.6 mm i.d., 25 cm, 5 μm particle size) with a Waters® Spherisorb ODS guard column and detected using LC-4C amperometric detector with a glassy carbon electrode (Bioanalytical Systems Inc., Lafayette, IN). The mobile phase was a mixture of methanol/water (99:1, % vol/vol) and 0.1% (wt/vol) lithium perchlorate. The total run time for the assay was approximately 12 min. Peaks were integrated using Shimadzu Class-VP automated software program (Columbia, MD). Authentic α- and γ-tocopherols and α- and γ-tocotrienols were used as external standards for quantification of vitamin E (Cognis, La Grange, IL). No γ-tocotrienol was detected in the samples.

*(ii) Cholesterol.* The cholesterol content of the milk sample was measured using a cholesterol kit from Sigma Diagnostics (Procedure No. 352, St. Louis, MO) in an aliquot of hexane saved from the extract described for vitamin E analysis.

*(iii) Total lipids.* Total lipids were extracted from milk samples using methanol and chloroform (11). The total lipids were calculated from the weight of the dried aliquot and expressed as weight in grams per 100 g milk.

*Statistical analysis.* Data were analyzed using a one-way analysis of variance model using StatView (SAS Institute Inc., Cary, NC). Differences between means were considered statistically significant if $P < 0.05$. If significant differences were found, then Fisher's *post-hoc* tests were used for making pairwise comparisons. Here differences between means were considered statistically significant if $P < 0.01$.

## RESULTS

*Milk vitamin E, cholesterol, and total lipids.* Routine processing of milk involves separation of the cream from raw milk and later adding the cream back to nonfat milk in appropriate amounts depending on the dairy product. The total lipid, cholesterol, and vitamin E contents (α- and γ-tocopherols and α-tocotrienol) of half and half, raw, whole milk, reduced-fat milk, low-fat milk, and nonfat milk were analyzed and results are shown in Table 1. α-Tocopherol was the most abundant form of vitamin E in all types of milk—it represented from 84 to 92% of the vitamin E, while γ-tocopherol and α-tocotrienol were each roughly 5%.

The total lipids content of milk increased from 0.30 ± 0.07 g/100 g in nonfat to 11.6 ± 0.53 g/100 g in half and half with the addition of increasing amounts of cream to nonfat milk. The cholesterol contents of milk also varied with the amount of cream added, with the highest concentrations in the products with the highest fat contents. Similarly, the α- and γ-tocopherols and α-tocotrienol contents varied in the different products apparently depending on the fat content. Half and half contained the most fat and had the highest amount of α-tocopherol (193 ± 1.66 μg/100 g) among all the products tested. The other products had lower fat and α-tocopherol contents. For example, the α-tocopherol concentration of whole milk (43.9 ± 2.2 μg/100 g) was

**TABLE 1**
**Total Lipid, Cholesterol, and Vitamin E Concentrations in Milk**

| | Total lipids (g/100 g)[a] | Cholesterol (mg/100 g)[b] | α-Tocopherol (μg/100 g)[a] | γ-Tocopherol (μg/100 g)[a] | α-Tocotrienol (μg/100 g)[d] |
|---|---|---|---|---|---|
| Raw | 3.46 ± 0.49 | 16.0 ± 1.5 | 45.5 ± 4.6 | 1.92 ± 0.44[c] | 1.96 ± 0.51[c] |
| Whole | 3.40 ± 0.11 | 14.3 ± 1.4 | 43.9 ± 2.2 | 2.06 ± 0.38[d] | 1.76 ± 1.76[d] |
| Reduced-fat | 2.12 ± 0.15 | 7.06 ± 0.5 | 26.4 ± 3.9 | 1.34 ± 0.58[e] | 1.09 ± 0.31[e] |
| Low-fat | 1.16 ± 0.15 | 3.56 ± 0.4 | 14.2 ± 1.7 | 0.96 ± 0.31[f] | 0.59 ± 0.09[f] |
| Nonfat | 0.30 ± 0.07 | 1.74 ± 0.3 | 4.5 ± 0.5 | 0.62 ± 0.11[g] | 0.14 ± 0.03[g] |
| Half and half | 11.6 ± 0.53 | 47.7 ± 1 | 193 ± 1.7 | 12.1 ± 2.17[c,d,e,f,g] | 7.00 ± 2.74[c,d,e,f,g] |

[a]For both total lipid and α-tocopherol concentrations, pairwise comparisons between means for each of the products shown were significantly different ($P < 0.0001$) (except between raw and whole milk which was not significantly different).
[b]For cholesterol concentrations, pairwise comparisons between means were significantly different for all milk products ($P < 0.0001$); except $P < 0.009$ between raw and whole milk and $P < 0.004$ between reduced-fat and nonfat milk.
[c]For γ-tocopherol concentrations, pairwise comparisons between means were significantly different ($P < 0.0001$) only between [c,d,e,f,g]half and half and [c]raw, [d]whole, [e]reduced-fat, [f]low-fat, and [g]nonfat milks.
[d]For α-tocotrienol concentrations, pairwise comparisons between means were significantly different ($P < 0.0001$) only between [c,d,e,f,g]half and half and [c]raw, [d]whole, [e]reduced-fat, [f]low-fat, and [g]nonfat milks.

| Reduced-fat | 3.34 ± 0.18[c,d] | 12.4 ± 1.2 | 0.63 ± 0.26 | 0.51 ± 0.14 |
| Low-fat | 3.08 ± 0.25 | 12.3 ± 1.2[a] | 0.83 ± 0.25 | 0.51 ± 0.09 |
| Nonfat | 6.13 ± 1.86[a,b,c] | 15.7 ± 3.9 | 2.22 ± 0.80[a,b] | 0.50 ± 0.17 |
| Half and half | 4.11 ± 0.12 | 16.7 ± 0.6[a] | 1.04 ± 0.19 | 0.60 ± 0.24 |

[a]For cholesterol per total lipids, pairwise comparisons between means were significantly different between [a,b]nonfat and [a]whole or [b]raw milks ($P < 0.0001$), or between [c,d]reduced-fat and [c]nonfat or [d]raw milks ($P < 0.01$).
[b]For α-tocopherol per total lipids, pairwise comparisons between means were significantly different between [a]low-fat milk and [a]half and half ($P < 0.001$).
[c]For γ-tocopherol per total lipids, pairwise comparisons between means were significantly different between [a,b]nonfat milk and [a]whole or [b]raw milks ($P < 0.0001$).

higher than reduced-fat milk (26.4 ± 3.6 μg/100 g), low-fat milk (14.2 ± 1.7 μg/100 g), or nonfat milk (4.5 ± 0.5 μg/100 g).

*Vitamin E and cholesterol concentrations relative to total lipids.* Table 2 provides the vitamin E and cholesterol contents of milk relative to the total lipids for all the milk samples. The α-tocopherol per total lipids in nonfat milk was higher than in raw milk. Similarly, cholesterol per total lipids was higher in nonfat milk (6.13 ± 1.86 μg/g) as compared with raw milk (4.64 ± 0.39 μg/g, $P < 0.0003$). The α-tocopherol and the total lipids in different dairy products were correlated (Fig. 1); for every 1 g increase in total lipids, the α-tocopherol content increased by 17 μg.

*Vitamin E content relative to cholesterol content.* Table 3 provides the vitamin E content of milk relative to the cholesterol content for the milk samples analyzed. The α-tocopherol per cholesterol content was greatest in half and half (4.0 ± 0.1 μg/mg) and lowest in nonfat milk (2.6 ± 0.3 μg/mg, $P < 0.0001$). Interestingly, the γ-tocopherol per cholesterol content in nonfat milk was higher than that in raw milk ($P < 0.0001$). The α-tocopherol and the cholesterol contents in the different dairy products were also correlated (Fig. 2); for every 1 mg of cholesterol there was an increase of approximately 4 μg of α-tocopherol.

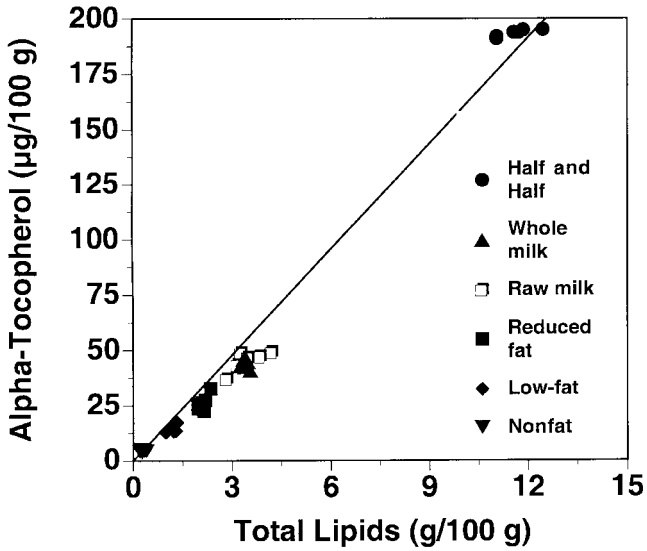

**FIG. 1.** Relationship between α-tocopherol and total lipids in milk samples of varying lipid contents. [$f(x) = 17.0x - 7.8$; $R^2 = 0.985$].

## DISCUSSION

α-Tocopherol was the major vitamin E form found in this study of cow's milk products of varying fat contents; γ-tocopherol and α-tocotrienol were found to lesser extent, while γ-tocotrienol was not detected. As the fat contents of the dairy products decreased from (11 to 0.3%), the vitamin E content also decreased. The α-tocopherol content of whole milk reported in this study was 44 μg/100 g. Previously, whole milk (3.3%) was reported to contain 30 μg α-tocopherol/100 g, while milk containing 2% fat (protein-fortified) contained 40 μg α-tocopherol/100 g (12). Most dietary vitamin E is found in fats and oils. α-Tocopherol is found predominantly in canola, olive, and sunflower oils (14). Indeed, the major food source of vitamin E in the diet of Americans, as a result of its high fat contents, is desserts (15). Importantly, decreasing fat intake also decreases vitamin E intake (16).

The milk products examined in this study contained typical lipid levels. The fat contents ranged from 11.6% total lipid for half and half to 0.3% for nonfat milk. These total lipid values meet the FDA food labeling requirements for the products described. The total lipids in the raw milk that we obtained were typical for raw milk (3 to 5% total lipids) as previously reported (17).

Cholesterol is the major form of sterol found in dairy products and it, like vitamin E, varied with the total lipid contents of the dairy products. In our study, the cholesterol contents of different dairy products were: half and half 47.7 mg/100 g, whole milk 14.3 mg/100 g, reduced-fat milk 7.06 mg/100 g, low-fat milk 3.56 mg/100 g, and nonfat milk 1.74 mg/100 g. These values are similar to the values reported in the nutrition analysis software "The Food Processor" by ESHA Research (Salem, OR) (18).

The unique finding in our study was that dairy products

**TABLE 3**
**Vitamin E Content of Milk Relative to Cholesterol Content**

| | α-Tocopherol per cholesterol (μg/mg)[a] | γ-Tocopherol per cholesterol (μg/mg)[b] | α-Tocotrienol per cholesterol (μg/mg)[c] |
|---|---|---|---|
| Raw | 2.8 ± 0.1[a] | 0.12 ± 0.03[a,e] | 0.12 ± 0.03 |
| Whole | 3.1 ± 0.2[b,d] | 0.15 ± 0.03[b] | 0.12 ± 0.02 |
| Reduced-fat | 3.7 ± 0.3[d] | 0.19 ± 0.09[c] | 0.15 ± 0.05[b] |
| Low-fat | 4.0 ± 0.2 | 0.27 ± 0.10[a,b] | 0.17 ± 0.03[a] |
| Nonfat | 2.6 ± 0.3[c,d] | 0.37 ± 0.10[c,d] | 0.08 ± 0.01[a,b,c] |
| Half and half | 4.0 ± 0.1[a,b,c,d,e] | 0.25 ± 0.05[d,e] | 0.15 ± 0.06[c] |

[a]Pairwise comparison for α-tocopherol per cholesterol were statistically significant ($P < 0.0001$) between [a,b,c]half and half and [a]raw or [b]whole and [c]nonfat milks; between [d]nonfat and [d]whole milk ($P < 0.0006$).
[b]Pairwise comparisons for γ-tocopherol per cholesterol were statistically significant between [a,b]low-fat and [a]raw ($P < 0.001$), and [b]whole milk ($P < 0.004$); between [c,d]nonfat and [c]reduced-fat ($P < 0.0015$) and [d]half and half (0.004); between [e]half and half and [e]raw milk ($P < 0.01$).
[c]For α-tocotrienol significant differences were observed between [a,b,c]nonfat and [a]low-fat ($P < 0.01$), [b]reduced-fat milk ($P < 0.01$); or [c]half and half ($P < 0.005$).

contain α-tocotrienol. This particularly piqued our interest because of the potent antioxidant properties of α-tocotrienol. Although α-tocotrienol has just one-third the biological activity of α-tocopherol in rats (19), it has equal (20) or higher antioxidant activity compared with α-tocopherol (21,22). The α-tocotrienol contents of dairy products ranged from 1.76 μg/100 g for whole milk to 0.14 μg/100 g for nonfat milk (Table 1). Other studies have not reported the presence of tocotrienols in dairy products. This may be because we used an extremely sensitive method for detection of tocopherols and tocotrienols (10). Nonetheless, γ-tocotrienol, a predominant vitamin E form in palm oil (14), was not found in milk. Alternatively, the presence of α-tocotrienol in milk may be attributed to the tocotrienol content of the feed, specifically grasses consumed by the cows. Grasses of green pastures in the early stage of growth have an increased α-tocotrienol content (23). Our milk samples were all obtained in late spring from the neighborhood dairy where cows were allowed to eat grass.

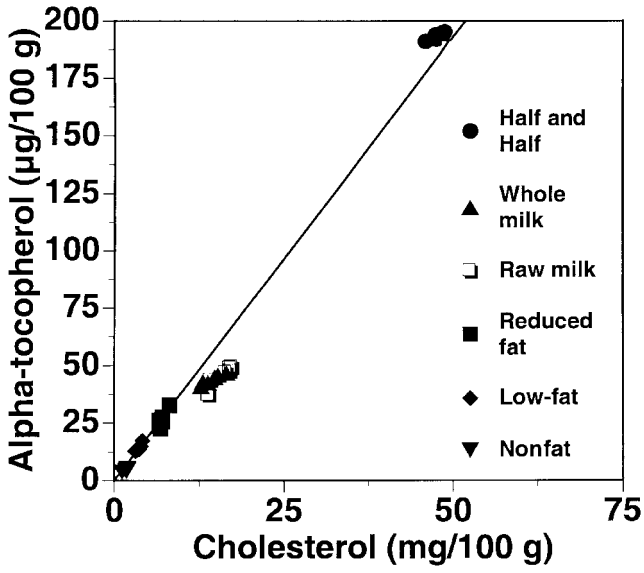

**FIG. 2.** Relationship between α-tocopherol and cholesterol in milk samples of varying lipid contents. [f($x$) = 4.1$x$ – 6.8; $R^2$ = 0.985].

It is clear that increased amounts of fat in the milk products result in increases in both cholesterol and vitamin E contents; therefore, the different forms of vitamin E were normalized to total lipid and cholesterol contents. The total lipids-adjusted cholesterol was highest in nonfat milk (Table 2). A possible explanation for this observation could be the disruption of milk fat globules during the centrifugation procedure, to isolate cream thereby contributing to residual fat globule membranes disproportionately rich in cholesterol, which accumulate in the nonfat milk (24). The cholesterol-adjusted α-tocopherol content was found to be lowest in nonfat milk (Table 3), suggesting association of α-tocopherol with the fat droplets rather than the membranes. Milk production typically involves separation of cream from raw milk and later adding the cream back to nonfat milk in varying amounts depending on the dairy product. Although statistically significant differences were found in the ratios between the vitamin E forms and lipids or cholesterol, in general, these differences were relatively minor and not likely to represent significant differences to the consumer.

Vitamin E was present in all the dairy products analyzed. Given in Table 4 is the vitamin E content of different milk products, when a quart is consumed, compared to rich sources of dietary vitamin E, almonds and frozen spinach (14). A single serving of almonds nearly provides the recommended daily allowance for vitamin E , while even a quart of whole milk does not provide an equivalent amount of α-tocopherol. For example, one serving of almonds provides 15 g fat and 12 mg α-tocopherol, while a cup of frozen spinach provides 1.5 g fat and 3.4 mg α-tocopherol. Even though spinach has one-tenth the fat content of almonds, it provides a significant amount of vitamin E as compared to quart of whole milk, which provides 33 g fat and 0.4 mg α-tocopherol. Although, milk cannot be considered a primary food source of vitamin E, it is the most commonly consumed dairy product and if large enough amounts of milk products are consumed they become a significant source of vi-

**TABLE 4**
**Comparison of Milk Products, Almonds and Frozen Spinachs as Vitamin E Sources**

| | Amount consumed | Calories (kcal) | Total fat (g) | α-Tocopherol (mg) | γ-Tocopherol (mg) | α-Tocotrienol (mg) |
|---|---|---|---|---|---|---|
| Whole milk | 1 quart | 599 | 33 | 0.42 | 0.019 | 0.017 |
| Reduced-fat milk | 1 quart | 485 | 19 | 0.25 | 0.013 | 0.010 |
| Low-fat milk | 1 quart | 409 | 10 | 0.13 | 0.009 | 0.006 |
| Nonfat milk | 1 quart | 342 | 2 | 0.04 | 0.006 | 0.001 |
| Spinach, frozen | 1 cup | 54 | 1.5 | 3.4 | — | — |
| Almonds | 2 Tbsp. | 166 | 15 | 12 | 0.51 | 0.56 |

tamin E. However, according to the 1994–1995 Continuing Survey of Food Intakes by Individuals data, nonfat milk consumption is increasing, while whole milk intake is decreasing (25). Because the vitamin E content of nonfat milk is one-tenth that of whole milk, we suggest that vitamin E fortification of milk might be a reasonable approach to restore α-tocopherol intakes to those seen with whole milk. This is especially important because children consuming relatively low-fat diets have decreased vitamin E intakes (26).

In conclusion, this study indicates that vitamin E, especially α-tocopherol, γ-tocopherol, and α-tocotrienol, is present in milk of various fat contents. Importantly, the α-tocopherol content of milk decreases along with cholesterol content as the fat content decreases.

## ACKNOWLEDGMENTS

This study was supported in part by a grant from the Diary Council of California. Milk samples were provided by Loch Mead Dairy (Junction City, OR).

# Biosynthesis of Eicosapentaenoic Acid in the Sea Urchin *Psammechinus miliaris*

**Michael V. Bell[a,*], James R. Dick[a], and Maeve S. Kelly[b]**

[a]Institute of Aquaculture, University of Stirling, Stirling, Scotland FK9 4LA, and [b]Scottish Association of Marine Sciences, Dunnstaffnage Marine Laboratory, Oban, Scotland PA34 4AD

**ABSTRACT:** The sea urchin *Psammechinus miliaris* (Gmelin) (Echinodermata: Echinoidea) was shown by using a deuterated tracer ($D_5$-18:3n-3) and quantitation by negative chemical ionization gas chromatography–mass spectrometry to convert 18:3n-3 to 20:5n-3. The rate of conversion was very slow, corresponding to 0.09 μg/g tissue/mg 18:3n-3 eaten over 14 d. Deuterated arachidonic acid ($D_8$-20:4n-6) was also included in the diet to give a measure of the relative amounts of diet eaten by the different animals. The recovery of this fatty acid in tissue lipids was 33.7% compared with only 0.95% recovery of $D_5$-18:3n-3 and its anabolites, indicating that the majority of the $D_5$-tracer was catabolized. Considerable elongation of $D_5$-18:3n-3 into 20:3n-3 and a trace of 22:3n-3 was found, and these were accompanied by minor amounts of the intermediates 18:4n-3 and 20:4n-3. No deuterated 22:6n-3 was found.

Paper no. L8587 in *Lipids 36,* 79–82 (January 2001).

The biosynthesis of polyunsaturated fatty acids (PUFA) in invertebrates is seldom studied, and no quantitative information is available on rates of formation. PUFA are abundant in the marine environment with 16-, 18-, 20-, and 22-carbon PUFA, all found in different classes of phytoplankton, while higher consumers, both invertebrate and vertebrate, retain and concentrate $C_{20}$ and $C_{22}$ PUFA (1). This abundance of dietary $C_{20}$ and $C_{22}$ PUFA may mask biosynthetic capability in consumers. Radiotracer studies have shown that some terrestrial invertebrates can synthesize PUFA *de novo* (2,3) and that *Artemia* can convert 18:2n-6 to 18:3n-3 and then to 20:5n-3 (4). These were formerly functions associated only with photosynthetic organisms.

Tracer experiments using [1-$^{14}$C]-18:2n-6 and [1-$^{14}$C]-18:3n-3 have been conducted in a number of invertebrates including the clam *Mesodesma mactroides* (5), the calanoid copepod *Paracalanus parvus* (6), and the prawn *Penaeus japonicus* (7) and have shown small percentage conversions to longer-chain more unsaturated products. However, a drawback of using [1-$^{14}$C]-labeled substrates is the possible loss of label by β-oxidation and reincorporation of labeled acetate. Thus results may be ambiguous beyond the first elongation step. None of the above studies using radiolabeled tracers quantitated the amounts of fatty acid moving through the pathway.

The sea urchin *Psammechinus miliaris* has recently been identified as a possible aquaculture species (8), as the roe (gonad of both males and females) is a valuable food product. As such there is a requirement for artificial diets which enhance gonad growth. In the wild, *P. miliaris* grazes on living and detached kelp (9), but it also feeds on a wide selection of other algae and encrusting invertebrates (10). Gonad growth in *P. miliaris* was enhanced by commercially prepared salmon feed (11), and gonad growth was also stimulated by diets containing lower levels of lipid (6–8%) of mainly vegetable origin (12). It was unclear whether *P. miliaris* is capable of producing $C_{20}$ and $C_{22}$ PUFA from shorter-chain precursor fatty acids, or indeed whether this species has a requirement for such fatty acids.

In this study we demonstrate, using a deuterated tracer and quantitation by gas chromatography–mass spectrometry (GC–MS), that *P. miliaris* can elongate and desaturate 18:3n-3 to produce 20:5n-3. This method is very sensitive and overcomes the problems of interpretation when using [1-$^{14}$C]-labeled fatty acids.

## MATERIALS AND METHODS

*Chemicals.* Chloroform, methanol, ethanol, isohexane, and diethyl ether were high-peformance liquid chromatrography-grade from Fisher (Loughborough, Leicestershire, United Kingdom). Butylated hydroxytoluene and standard fatty acids were obtained from Sigma (Poole, Dorset, United Kingdom) and diisopropylamine, anhydrous acetonitrile, and pentafluorobenzyl bromide from Aldrich (Gillingham, Dorset, United Kingdom). Deuterated tracer $D_5$ (17,17,18,18,18)-linolenic acid and $D_8$ (5,6,8,9,11,12,14,15)-arachidonic acid were purchased from Cambridge Isotope Laboratories (Andover, MA) as the fatty acid ethyl esters.

*Preparation of diet.* The experimental diet was based on a standard fish diet with vegetable meals and vegetable oils substituting for fish meal and fish oil to eliminate preformed $C_{20}$ and $C_{22}$ PUFA. The diet comprised (g/100 g): soy flour 39, wheat meal 31, corn gluten meal 11.4, lysine 0.3, methionine 0.3, mineral mix 4.0, vitamin mix 1.0, carboxymethylcellulose 2.0, and oil 11.0. The oil component consisted of, mg/g dry diet: $D_5$-18:3n-3 fatty acid ethyl ester 27, $D_8$-20:4n-6 fatty acid ethyl ester 5.9, and linseed oil 81. The diet was produced as a 1-mm diameter pellet.

Abbreviations: $D_n$, deuterated; GC–MS, gas chromatography–mass spectrometry; PUFA, polyunsaturated fatty acid; tri23:0, tritricosanoyl.

*Animals. Psammachinus miliaris* were collected by SCUBA divers from a depth of 5 m in Loch Creran, Scotland (56°32′20″ N; 5°17′00″ W) in early September. Six urchins (horizontal test diameter 2–3 cm, wet weight 9–12 g) were selected at random and placed in aquaria that had an independent supply of 250 L filtered seawater at ambient temperature (11.8–15.3°C) and salinity. The photoperiod was maintained at a constant 16-h light/8-h dark cycle throughout the experiments. The urchins were fed on the macroalga *Laminaria saccharina ad libitum* for 2 wk to equilibrate their nutritional status. The seawater supply was then exchanged for a 5-µm filtered supply, and the urchins were starved for 48 h prior to feeding the labeled diet. The urchins were fed 0.54 g of labeled diet over the course of 3 h. Urchins were individually presented with pellets that they readily accepted, trapping them with their tube feet and rapidly manipulating them to their jaws. All the diet was ingested. The urchins were returned to a diet of *L. saccharina* and sacrificed 14 d later. They were weighed, the gonad and gut dissected, and the tissues, including the test, weighed. Samples were stored at –70°C prior to analysis.

*Lipid extraction.* The gonads and guts were thawed on ice then homogenized in 10 mL chloroform/methanol (2:1, vol/vol). Tritricosanoylglycerol (tri23:0 glycerol) standard (30 µg) was added to the gonad homogenates and 10 µg to the gut homogenates. The homogenates were shaken and then stood on ice for 1 h with periodic shaking. The eviscerated tests were crushed in a pestle and mortar, and the slurry was homogenized in 20 mL chloroform/methanol (2:1, vol/vol) with 100 µg tri23:0. The homogenate was left on ice for 2½ h with periodic shaking. The homogenates were then filtered and a Folch extract prepared (13). The final total lipid fraction was weighed and stored under argon at –20°C.

*Quantitation of deuterated fatty acids.* One milligram of total lipid was saponified with 2 mL of 0.1 M KOH in 95% (vol/vol) ethanol under nitrogen for 1 h at 78°C. Nonsaponifiable material was removed by extracting with isohexane/diethyl ether (2:1, vol/vol), the aqueous phase was acidified then free fatty acids were extracted with diethyl ether. Pentafluorobenzyl esters were then prepared from 100 µg free fatty acid using acetonitrile/diisopropylamine/pentafluorobenzyl bromide (1000:10:1, by vol) at 60°C for 30 min under nitrogen as described by Pawlosky *et al.* (14). Excess reagent and solvent were then removed under nitrogen, samples dissolved in isohexane, and stored at –20°C under argon until analysis. Calibration standards of individual fatty acids with 23:0 were prepared by varying the amount of unknown fatty acid while keeping the 23:0 constant and plotting the peak area ratio against the mass ratio of the fatty acids. Sample volumes for analysis were adjusted such that the amount of 23:0 injected onto the GC–MS was constant. Pentafluorobenzyl esters were chromatographed and quantitated on a Fisons MD 800 GC–MS fitted with an on-column injector and a Chrompack CP wax 52CB column (30 m × 0.32 mm i.d., 0.25 micron film thickness) (Burke Analytical, Alva, Clackmannanshire, United Kingdom) using helium as carrier gas (column head-pressure 7 psi) and running in negative chemical ionization mode with methane as reagent gas (pressure 7 psi). The temperature program was 80–190°C at 40°C/min, 190–240°C at 1.5°C/min, then 240°C for 10 min. Peaks were identified by selective ion scanning for the required masses using a dwell time of 80 ms and cycle time of 20 ms and quantitated by reference to the appropriate standard fatty acid.

## RESULTS

After 14 d, all three tissues contained $D_5$-18:3n-3 and its anabolites together with $D_8$-20:4n-6 (Table 1). The distribution of labeled fatty acids within the tissues varied between the animals with gonad, gut and test each having the majority of $D_5$-labeled fatty acids in two animals. However, $D_8$-20:4n-6 was predominantly found in the test (Table 1) (five out of six animals). When expressed as mg lipid or fatty acid per g tissue, gut was the most lipid-rich tissue for total lipid and labeled fatty acids (Table 1). The total recoveries of labeled fatty acids were 139 µg for $D_5$-18:3n-3 and metabolites and 1.076 mg of $D_8$-20:4n-6, corresponding to 0.95 and 33.7% of ingested material, respectively, suggesting that most of the tracer was catabolized.

There was a good correlation between the total $D_5$-fatty acids and $D_8$-20:4n-6 recovered in the six animals ($r$ = 0.9917). This indicated that the fatty acids were being processed similarly in the animals. The proportion of $D_8$-20:4n-6 recovered in individual animals was used to calculate the amount of $D_5$-18:3n-3 eaten by individuals. The data for fatty acid incorporation were then expressed as µg fatty acid/g tissue/mg $D_5$-18:3n-3 ingested.

**TABLE 1**
**The Distribution of Lipid and Deuterated Fatty Acids in the Different Tissues (mean ± 1 SD, *n* = 6)**

| | Tissue | | | |
|---|---|---|---|---|
| | Gonad | Gut | Test | Total |
| Lipid (mg) | 12.9 ± 5.7 | 5.3 ± 0.8 | 30.5 ± 10.4 | 48.7 ± 12.9 |
| mg lipid/g tissue | 24.8 ± 8.3 | 28.3 ± 4.5 | 5.6 ± 1.1 | 4.7 ± 0.9 |
| Total $D_5$-fatty acids (µg) | 6.4 ± 5.7 | 9.3 ± 8.8 | 7.5 ± 2.6 | 23.2 ± 14.2 |
| µg $D_5$-fatty acid/g tissue | 11.5 ± 8.9 | 49.2 ± 44.6 | 1.4 ± 0.3 | 2.2 ± 1.2 |
| $D_8$-20:4n-6 (µg) | 31.6 ± 26.2 | 70.6 ± 68.4 | 77.2 ± 30.4 | 179.4 ± 89.6 |
| µg $D_8$-20:4n-6/g tissue | 57.0 ± 40.5 | 373.6 ± 345.6 | 14.4 ± 4.8 | 17.1 ± 7.4 |

**TABLE 2**
**Fatty Acids Derived from $D_5$-18:3n-3 Present 14 d After a Pulse of 14.6 mg $D_5$-18:3n-3 (mean ± 1 SD, *n* = 6)**

| | μg $D_5$-Fatty acid/g tissue/mg $D_5$-18:3n-3 eaten | % Recovered |
|---|---|---|
| $D_5$-18:3n-3 | 0.33 ± 0.07 | 38.0 |
| $D_5$-20:3n-3 | 0.35 ± 0.05 | 39.9 |
| $D_5$-22:3n-3 | 0.021 ± 0.005 | 2.3 |
| $D_5$-18:4n-3 | 0.011 ± 0.004 | 1.1 |
| $D_5$-20:4n-3 | 0.076 ± 0.018 | 8.4 |
| $D_5$-22:4n-3 | Trace | <0.1 |
| $D_5$-20:5n-3 | 0.090 ± 0.015 | 10.2 |
| $D_5$-22:5n-3 | Trace | <0.1 |

[a]Trace = <0.001 μg $D_5$-fatty acid/g tissue/mg $D_5$-18:3n-3 eaten. Percentage recovered is percentage of total $D_5$-fatty acid recovered.

The initial substrate $D_5$-18:3n-3 and its immediate elongation product 20:3n-3 were the predominant labeled fatty acids recovered (Table 2), together accounting for 77.9% of the recovered label. Further elongation to 22:3n-3 accounted for 2.3% of deuterated fatty acids. Octadecatetraenoic acid (18:4n-3), the Δ6-desaturation product of 18:3n-3, was a minor component (Table 2), accounting for 1.1% of label. The subsequent elongation product 20:4n-3 was some seven times more abundant, and its Δ5-desaturation product 20:5n-3 accounted for 10.2% of recovered label. This represented 0.009% of the 18:3n-3 ingested (0.09 μg/g tissue/mg $D_5$-18:3n-3 eaten). Only trace amounts of 22:4n-3 and 22:5n-3 were found, and we could not detect any $D_5$-22:6n-3. The samples were analyzed also for the elongation and desaturation products of $D_8$-20:4n-6. There was some elongation to 22:4n-6 (5.7% of substrate) but no further elongation to 24:4n-6 or desaturation to 22:5n-6.

## DISCUSSION

Deuterated arachidonic acid ($D_8$-isomer) was added to the diets to give an indication of the amount of diet eaten. The reasoning behind this was that a $C_{20}$ PUFA, which is an important structural fatty acid of cell membranes (a major PUFA in this species, *ca.*10% of total fatty acids) and also a precursor of the eicosanoids (15), is less likely to be heavily catabolized than a $C_{18}$ PUFA, or indeed a saturated or monounsaturated fatty acid. The data supported this hypothesis as $D_8$-20:4n-6 was retained much better than $D_5$-18:3n-3 and its metabolites, with recoveries of 33.7 and 0.95%, respectively. The great majority of the $D_5$-18:3n-3 therefore either was not assimilated or was catabolized. It is likely that "nonessential" fatty acids were being oxidized to provide energy for either somatic growth or gonad recovery. Therefore, we used the relative amounts of $D_8$-20:4n-6 recovered in the different animals to deduce the amount of diet, and hence $D_5$-18:3n-3, ingested. Using this correction reduced the variability in the data.

*Psammechinus miliaris* has an annual reproductive cycle, peak gonad indices being obtained during June and July in the area where these urchins were collected (16). The urchins used in this study were in the postspawning or recovery phase of the reproductive cycle (17), and their gonads were therefore relatively depleted in lipid (2.5% wet weight) compared to 7.1% for urchins of the same species in the premature phase (18). In the recovery phase of the gametogenic cycle, urchins replenish the nutrient stores in the nutritive phagocytes of the gonad (17). Therefore, the urchins used in this study were likely to have been sequestering lipid.

The results clearly showed that the urchins were capable of synthesizing 20:5n-3 from 18:3n-3, even when reared on a natural diet (*L. saccharina*), which contains 20:4n-6 and 20:5n-3 as the major PUFA. The rate of formation of 20:5n-3 was slow, equivalent to only 0.009% of the $D_5$-18:3n-3 ingested over a 14-d period. In a preliminary experiment, we found that the amounts of $D_5$-18:4n-3, $D_5$-20:4n-3, and $D_5$-20:5n-3 in gonad approximately doubled between day 7 and day 14 post-dose, whereas the amount of substrate $D_5$-18:3n-3 decreased (data not shown). Of the label recovered from $D_5$-18:3n-3, 42.2% was in elongation products and 19.7% in Δ6-desaturation products. This indicates an active $C_{18}$–$C_{20}$ elongase that effectively reduces the substrate availability for the desaturase. There was only limited elongation of $C_{20}$ PUFA to $C_{22}$ PUFA; $D_5$-22:3n-3 (6.0% of substrate $D_5$-20:3n-3) and $D_8$-22:4n-6 (5.7% of substrate $D_8$-20:4n-6) were measurable while $D_5$-22:4n-3 and $D_5$-22:5n-3 arising from $D_5$-20:4n-3 and $D_5$-20:5n-3, respectively, were barely detectable. The much larger amounts of $D_5$-20:3n-3 and $D_8$-20:4n-6 allowed their elongation products to be measured. Urchins reared on a natural diet of *Laminaria* contained 11.3% 20:4n-6, 10.0% 20:5n-3, 0.1% 22:5n-6, and 1.5% 22:6n-3 (18), supporting the finding that conversion of $C_{20}$ PUFA to $C_{22}$ PUFA is low in this species. The urchins clearly contain an active Δ5-desaturase. This was suggested by earlier fatty acid compositional data (19) which showed a number of unusual Δ5-monounsaturated fatty acids and Δ5-nonmethylene-interrupted dienes. In *P. miliaris* feeding on salmon diet or the detritus from salmon cages that contains $C_{20}$ and $C_{22}$ monounsaturated fatty acids, the corresponding Δ5-20:2 and Δ5-22:2 nonmethylene-interrupted dienes were found (18).

The data show conclusively that *P. miliaris* can synthesize 20:5n-3 from 18:3n-3 and that this species therefore has the genetic apparatus necessary to bring about this conversion, i.e., a Δ6-desaturase, $C_{18}$ to $C_{20}$ elongase, and a Δ5-desaturase. However, further desaturation reactions do not occur while further elongation to $C_{22}$ PUFA is limited. The rate of formation of 20:5n-3 was very slow, about one-twentieth of the rate of 22:6n-3 formation measured in rainbow trout using the same method (Bell, M.V., unpublished data), and was well below that necessary to account for the amount of 20:5n-3 present in the animals which must have been accumulated from the diet. The ability to synthesize $C_{20}$ PUFA when the diet usually contains these fatty acids is perhaps surprising and suggests an essential role for $C_{20}$ PUFA in echinoderms, probably as prostanoid precursors. Several B series prostaglandins were reported in 10 species of Japanese echinoderms (20).

# The First Naturally Occurring α-Methoxylated Branched-Chain Fatty Acids from the Phospholipids of *Amphimedon complanata*

**Néstor M. Carballeira* and Johanna Alicea**

Department of Chemistry, University of Puerto Rico, Río Piedras, Puerto Rico 00931

**ABSTRACT:** The phospholipid fatty acid composition of the sponge *Amphimedon complanata* was reinvestigated, and the 2-methoxy-13-methyltetradecanoic acid, 2-methoxy-14-methylpentadecanoic acid, and 2-methoxy-13-methylpentadecanoic acid were identified for the first time in nature. Structure characterization was accomplished by means of gas chromatographic retention times and gas chromatography–mass spectrometry. These acids could have originated from bacteria in symbiosis with the sponge.

Paper no. L8555 in *Lipids 36,* 83–87 (January 2001).

The only naturally occurring α-methoxy fatty acids known to date are those from the phospholipids of sponges (1–3). Earlier examples include normal-chain saturated 2-methoxy fatty acids between $C_{19}$–$C_{24}$ carbons and very long chain monounsaturated fatty acids such as (2*R*,21*Z*)-2-methoxy-21-octacosenoic acid, which was the first-reported α-methoxy fatty acid from a phospholipid (2). All of these acids were reported to have the *R* configuration at the chiral center. Recent efforts have concentrated on the $C_{16}$ family of α-methoxylated fatty acids, such as the 2-methoxy-5(*Z*)-hexadecenoic acid, 2-methoxy-6(*Z*)-hexadecenoic acid, and the 2-methoxyhexadecanoic acid, which were identified in the phospholipids of several Caribbean sponges such as *Amphimedon compressa* (4). Both 2-methoxy-5(*Z*)-hexadecenoic acid and 2-methoxyhexadecanoic acid occur more often in the phospholipids of sponges than their Δ6 analogs (5).

Despite these isolation efforts there are no reports in the literature as to any natural source for branched-chain α-methoxylated fatty acids although some mid-chain methoxylated fatty acids, such as (4*E*,8*E*)-7-methoxy-9-methylhexadeca-4,8-dienoic acid from *Lyngbya majuscula*, are known (6). We have now investigated the sponge *A. complanata* (7), collected at a different site, and found a novel series of iso and anteiso $C_{15}$–$C_{16}$ α-methoxylated phospholipid fatty acids that we describe herein. These novel compounds could have originated from the phospholipids of a novel bacterium in symbiosis with *A. complanata*.

## MATERIALS AND METHODS

*Instrumentation*. Gas chromatography–mass spectrometry (GC–MS) data were collected at 70 eV with a Hewlett-Packard 5972A MS ChemStation (Palo Alto, CA) equipped with a 30 m × 0.25 mm special performance capillary column (HP-5MS) cross-linked with 5% phenyl methylpolysiloxane. The temperature program for the analyses was as follows: 130°C for 2 min, then increased at 3°C/min to 270°C and maintained for 40 min.

*Sample collection*. *Amphimedon complanata* was collected on February 27, 2000, at El Natural, Aguadilla, Puerto Rico, at a depth of 25 ft (7.6 m). The sponge was washed in seawater, carefully cleaned of all nonsponge debris, and lyophilized. A voucher specimen is available at the Department of Chemistry of the University of Puerto Rico, Río Piedras campus.

*Extraction and isolation of phospholipids*. The freeze-dried sponge (48.2 g) was extracted with 2 × 250 mL of chloroform/methanol (1:1, vol/vol) yielding the total lipids (11.9 g). The neutral lipids, glycolipids, and phospholipids (1.2 g) were separated by column chromatography on silica gel (60–200 mesh) using the procedure of Privett *et al*. (8). The phospholipid classes were investigated by preparative thin-layer chromatography (TLC) using silica gel and $CHCl_3$/MeOH/$NH_4OH$ (65:35:5) as solvent and comparing with authentic samples. The principal phospholipids were phosphatidylethanolamine and phosphatidylserine, as previously described (7).

*Preparation and isolation of fatty acid derivatives*. The fatty acyl components of the phospholipids were obtained as either their methyl or ethyl esters by reaction of the phospholipids with methanolic or ethanolic HCl followed by column chromatography (9). The double-bond positions in the monounsaturated acids were determined by dimethyl disulfide (DMDS) derivatization following the standard procedure previously described (10). *N*-Acylpyrrolidide derivatives were prepared by direct treatment of the methyl esters with pyrrolidine-HOAc (10:1) in a capped vial (24 h at 100°C). The methyl esters were hydrogenated in 10 mL absolute methanol in the presence of catalytic amounts of platinum oxide ($PtO_2$). Mass spectral data for the novel methoxylated acids and some of their derivatives follow.

*Methyl 2-methoxy-13-methyltetradecanoate*. Equivalent chain length (ECL) = 15.86; GC–MS *m/z* (relative intensity) $M^+$ 286 (1), 270 (1), 236 (2), 228 (17), 227 (100), 213 (1),

## RESULTS

As previously reported, the main phospholipids from *A. complanata* were phosphatidylethanolamine and phosphatidylserine, with lesser amounts of phosphatidylcholine (7). Transesterification with either 1.0 N HCl/MeOH or HCl/EtOH permitted the characterization of the fatty acids as methyl or ethyl esters and the aldehydes as dimethyl or diethyl acetals using GC–MS. A total of 72 phospholipid fatty acids were identified. DMDS derivatives were used to locate the double bonds in the monounsaturated methyl esters, whereas pyrrolidides were mainly used to locate methyl branching. The total phospholipid fatty acid composition of *A. complanata* is presented in Table 1. Saturated normal-chain fatty acids between $C_{12}$ and $C_{29}$ predominated in these phospholipids (42%), in particular the acids 16:0 and 18:0, which were the most abundant in this family (12.3%). Monounsaturated fatty acids between $C_{16}$ and $C_{30}$ were the second-most abundant series of compounds (26.8%) and noteworthy among these was vaccenic acid. Branched-chain iso and anteiso fatty acids accounted for only 7% of the total composition, but most of these acids had chain lengths between $C_{15}$ and $C_{19}$, which are the typical chain-lengths of iso and anteiso bacterial fatty acids.

Attention was centered on six α-methoxylated fatty acids that constituted 1.7% of the total phospholipid fatty acid composition. Three of these acids, namely, 2-methoxy-5(*Z*)-hexadecenoic acid, 2-methoxy-6(*Z*)-hexadecenoic acid and 2-

[a]The following aldehydes were also identified in the sponge: 16:0, 17:0, 18:0, 19:0, 20:0, and 25:0.
[b]These acids are unprecedented in nature.

methoxyhexadecanoic acid, were previously reported by us from several Caribbean sponges (3,4). The finding in *A. complanata* that has never been observed before is that all three of these acids were present (at low levels) in the same sponge. Characterization of the remaining three saturated methoxylated acids (as either methyl or ethyl esters) was possible using GC–MS as well as gas chromatographic ECL values as compared to synthetic standards (4). For example, the mass spectrum of one of these methyl esters, **1a** (Scheme 1), displayed a molecular ion peak at *m/z* 286 and a strong $M^+ - 59$ peak at *m/z* 227 (100%), together with a small peak at *m/z* 104 (McLafferty rearrangement) typical of an α-methoxylated saturated methyl ester (4). On the other hand, both methyl esters **1b** and **2** yielded molecular ion peaks at *m/z* 300 and strong $M^+ - 59$ peaks at *m/z* 241, together with small peaks at *m/z* 104, confirming that both were α-methoxylated $C_{16}$ saturated methyl esters (4). The natural origin of the α-methoxy substitution was further confirmed when the corresponding ethyl esters were directly prepared from the phospholipids, since α-methoxylated ethyl esters were obtained. For example, in the mass spectrum of the ethyl ester of **1a**, the molecular ion peak shifted to *m/z* 300 and the McLafferty rearrangement peak to *m/z* 118, but the *m/z* 227 peak remained the same. In the mass spectrum of ethyl esters **1b** and **2**, the $M^+$ shifted to *m/z* 314 and the McLafferty rearrangement peak to *m/z* 118, but the *m/z* 241 peak remained the same. Therefore, this simple transesterification reaction (HCl/EtOH) proved that the methoxylated fatty acids are not artifacts arising from the HCl/MeOH reaction.

Although the α-methoxy substitution in these novel $C_{15}$–$C_{16}$ methyl esters was confirmed, the GC retention times suggested that all of these methoxylated methyl esters were branched. The position of the methyl branching was determined from ECL values and mass spectral data. For example, methyl esters **1a** and **1b** presented ECL values of 15.86 and 16.86, respectively, whereas **2** had an ECL value of 16.94 on the nonpolar capillary column. These values suggested methyl branching near the end of the chain, in particular when compared to a calculated ECL value of *ca.* 16.2 expected for a normal-chain methyl 2-methoxypentadecanoate and an ECL value of 17.2 reported for methyl 2-methoxyhexadecanoate (4). From the ECL values it was also clear that **1a** and **1b** had the same methyl substitution, while the methyl substitution in **2** was different. Additional data further favored an iso branching for **1a** and **1b**, and an anteiso branching for **2**. For example, the methyl branching in methyl 2-hydroxy-13-methyltetradecanoate was determined by actually synthesizing the methoxylated ester **1a** and further looking in its mass spectrum at the intensity of the *m/z* 43 fragment (11). Comparing the intensity of the *m/z* 43 fragment (loss of a propyl unit) with that of other fragments and further comparing their respective intensities to those observed in the mass spectrum of a normal-chain α-methoxy methyl ester are good ways to confirm the iso branching (11). In fact, the intensity of the *m/z* 43 fragments in **1a** and **1b** was increased compared to other mass peaks, such as the *m/z* 57 fragments. For this comparison the mass spectrum (measured under the same conditions as **1a** and **1b**) of methyl 2-methoxyhexadecanoate, previously synthesized and also present in this sponge, was used. In the case of **2,** a distinctive ion at $[M - 61]^+$ (*m/z* = 239) was observed, indicative of anteiso branching. Another piece of evidence favoring the iso branching for **1a** and **1b** and the anteiso branching for **2** was obtained from their GC retention times when gas chromatographic ECL values were calculated using only the α-methoxy methyl esters as standards. In such a calculation **1a** and **1b** present fractional chain-length (FCL) values of 0.67, while **2** has an FCL of 0.74, in reasonable agreement with those values reported for the traditional iso and anteiso fatty acid methyl esters (12). Therefore, it can be concluded that the α-methoxylated methyl esters in question are the iso methyl 2-methoxy-13-methyltetradecanoate (**1a**) and methyl 2-methoxy-14-methylpentadecanoate (**1b**), as well as the anteiso methyl 2-methoxy-13-methylpentadecanoate (**2**).

Pyrrolidide derivatives were also synthesized in an attempt to determine the methyl branching in the methoxylated acids by GC–MS, but fragmentations involving the polar methoxy group obscured the typical fragmentation pattern expected from a branched pyrrolidide (13). For example, in the mass spectrum of *N*-2-methoxy-13-methyltetradecanoylpyrrolidine a molecular ion peak ($M^+$) at *m/z* = 325 was observed together with strong fragmentations at *m/z* = 295 ($M^+ - 30$), *m/z* = 227 ($M^+ - 98$), and the typical McLafferty rearrangement at *m/z* = 143 confirming the α-methoxy functionality. However, a strong ($M^+ - 15$) peak at m/z = 310 was also identified, and the intensity of this ($M^+ - 15$) peak was higher than the corresponding peak in the mass spectrum of *N*-2-methoxyhexadecanoyl pyrrolidine, which we also synthesized. This observation also supported the iso-branching for **1a**. Therefore, pyrrolidide derivatization has limited usefulness in locating methyl branching in α-methoxylated fatty acids.

## DISCUSSION

This specimen of *A. complanata* contains a very complex phospholipid fatty acid profile typical of sponges belonging

to the genus *Amphimedon* (4,5,7). Noteworthy is its ability to extend the n-7 and n-9 families of even-numbered chain monounsaturated fatty acids from 9-18:1 and 11-18:1 to 21-30:1 and 23-30:1, respectively. In fact, this is the first report of both 21-triacontenoic acid and 23-triacontenoic acid from the phospholipids of an *Amphimedon* sponge. These $C_{30}$ fatty acids were reported before from sponges such as *Trikentrion loeve* (14). The n-6 and n-7 families predominated in the odd-numbered chain monounsaturated fatty acid series, but they mainly reached $C_{25}$–$C_{27}$ chain lengths.

The interesting feature of this *Amphimedon* is that it contains all of the $C_{16}$ short-chain α-methoxylated fatty acids reported to date plus a series of novel iso-anteiso α-methoxylated $C_{15}$–$C_{16}$ fatty acids. These are the first branched α-methoxylated phospholipid fatty acids from any natural source. An analogy to the corresponding iso-anteiso α-hydroxylated $C_{15}$–$C_{16}$ fatty acids is unavoidable, and in fact the methoxylated acids could have originated, although not necessarily, from the corresponding α-hydroxylated fatty acids. For example, the 2-hydroxy-13-methyltetradecanoic acid is known as a characteristic lipid constituent of gliding bacteria such as *Flexibacter elegans* (11); it has been identified in the phospholipids of Gram-positive Flavobacteria such as *Flavobacterium meningosepticum* and also, in addition to α-OH iso-$C_{16}$, in the Actinomycetales such as *Arthrobacter simplex* (15–17). The occurrence of α-OH anteiso-$C_{16}$ is rare, but it is known to be a constituent of the ceramide dihexosides from the spermatozoa of the starfish *Asterias amurensis* and a phospholipid constituent of *Arthrobacter simplex* (18,19). In addition, α-OH anteiso-$C_{16}$ has been identified in Antartic lake sediment (19).

The identification of small amounts of α-methoxylated iso-anteiso $C_{15}$–$C_{16}$ fatty acids in *A. complanata* suggests that these acids are probably constituents of a novel bacterium associated with the sponge. There are several pieces of information that point in this direction. One is their low abundance in the sponge, which indicates that they are not major sponge phospholipid constituents. The typical sponge fatty acids are the Δ5,9 acids, and several biosynthetic experiments tend to indicate that the shorter-chain $C_{15}$–$C_{19}$ fatty acids are actually of bacterial origin (21). A structural comparison of these α-methoxylated fatty acids with known α-hydroxylated fatty acids also suggests a bacterial origin, as most of the α-OH iso and anteiso $C_{15}$–$C_{17}$ acids are indeed bacterial in nature (22). In fact, some myxobacteria contain phosphatidylethanolamines as the major phospholipid with α-hydroxy iso-$C_{17:0}$ fatty acids in the 2-position and nonhydroxy fatty acids in the 1-position (22). Therefore, it is very likely that in *A. complanata* a novel symbiotic marine bacterium could actually contain novel phosphatidylethanolamines with iso and anteiso branched α-methoxylated fatty acids at the 2-position, similar to what is known for the α-hydroxy iso-$C_{17:0}$ fatty acids in myxobacteria (22).

**ABSTRACT:** Partition coefficients ($K_p$) between egg yolk phosphatidylcholine multilamellar vesicles and water were determined for two nonsteroidal anti-inflammatory drugs (indomethacin and acemetacin) using two independent methodologies: derivative spectrophotometry and variation of the experimental acidity constant in the presence of increasing vesicle concentration. Second-derivative spectrophotometry allowed for total elimination of background signal effects arising from lipid vesicles, without the need for separation techniques that may disturb equilibrium states. By using a model based on a simple partition, the values of $K_p^T$ can be obtained directly; furthermore, by performing determinations at two different pH values it is possible to calculate partition coefficients for the neutral and negatively charged forms of the drugs ($K_p^{AH}$ and $K_p^{A}$). In the other methodology, values of apparent acidity constants ($K_{app}$) were determined by spectrophotometry at different pH values and different lipid concentrations, and an increase in $K_{app}$ with decreasing lipid concentration was observed for both drugs, and from this dependence it was possible to calculate $K_p^{AH}$ and $K_p^{A^-}$ for each drug. These values were used as a check for those obtained by derivative spectroscopy, which has proven to be a reliable and more expeditious method to obtain $K_p^{AH}$ and $K_p^{A^-}$.

Paper L8484 in *Lipids 36,* 89–96 (January 2001).

The hydrophobicity of an organic compound is one of its physicochemical characteristics that extensively controls its absorption, biomembrane transport, bioaccumulation, and even environmental accumulation. Traditionally, the octanol–water partition coefficient has been used to measure compound hydrophobicity, which has then been correlated with drug activity, toxicity, and distribution processes (1). The octanol–water system is a good membrane model when polar group interactions between the solute and the phospholipid bilayer are minimal or absent, but better systems are needed for molecules that can establish this type of interactions (1–3), because octanol can only model nonpolar molecular interactions between solutes and membranes. Biomembranes and other lipid phases in organisms have a more complex structure than octanol; and hydrophobic, electronic, and steric forces contribute to the overall interaction with a molecule (1). Thus, the partitioning of solutes into bilayer membranes is argued to occur by a mechanism that is different from that into an oil phase (2,4). To overcome this problem, alternative systems have been developed to model the partitioning of a molecule into a lipid phase. Among these, polymer–water, micelle–water and cell–water, as well as systems using artificial membranes, such as immobilized artificial membranes or liposome suspensions, have been developed (2–9). Those with liposome suspensions not only present a good correlation with the behavior observed in membranes but also are easy to prepare and to handle.

Drug interactions with heterogeneous media typically induce changes in some physicochemical properties of the drug (spectroscopic properties, solubility, apparent acidity), and by monitoring these changes it is possible to quantify drug binding, which is normally expressed by two related quantities, drug/liposome association constants or partition coefficients between aqueous and lipid phases (5,7,10–13). Partition coefficients are important in defining the characteristics of absorption, distribution, metabolism, and excretion of a drug because they provide an indication of the extent of drug interaction with membranes and/or drug penetration in cells. If the drug's site of action is the membrane itself, then the determination of partition coefficient can help elucidate the drug's mechanism of action.

Partition coefficients are dependent on variables such as the nature of the membrane, temperature, and, when the drug and/or membrane carries ionizable groups, pH. Several methods have been devised to measure partition coefficients, namely, ultracentrifugation (4,9), hygroscopic desorption (14,15), microdialysis (6), chromatography (7,8), fluorimetry (10), and spectrophotometry (11–13,16). As most methods rely on phase separation, a process that can disturb the equilibrium state of the samples (12,13), it is of great interest to develop methods that may circumvent this time-consuming process. Direct application of spectrophotometric methods has been hampered by the intense background signals originating from light scattered by liposomes. Derivative spectrophotometry can eliminate background signals and improve the resolution of overlapping bands, and its application to liposome media, which avoids separation procedures, has been reported (11–13,16).

In this work we present two independent spectrophotometric methods to determine partition coefficients between aqueous and lipid pseudophases for two nonsteroidal anti-inflammatory drugs (indomethacin and acemetacin) in egg yolk phosphatidylcholine (EPC) multilamellar liposomes. The in-

Abbreviation: EPC, egg yolk phosphatidylcholine.

teraction of indomethacin with EPC has previously been studied by differential scanning calorimetry (17), but the extension of the interaction was not quantified. Of these two spectrophotometric methods, one is based on the shift in drug acidity constant caused by an increase in phospholipid concentration, whereas the other relies on direct application of derivative spectrophotometry. The latter method not only provides a fast and reliable path to obtain partition coefficients for both forms (neutal and negatively charged) of the drugs but also requires only two determinations at different pH values. Its reliability was confirmed by the similarity of the values so obtained with those of the former method.

## EXPERIMENTAL PROCEDURES

*Reagents.* The anti-inflammatory drugs indomethacin and acemetacin and EPC were from Sigma, and the other chemicals from Merck (analytical grade; Darmstadt, Germany); all were used as received. Solutions were prepared with double-deionized water (conductivity less than 0.1 μS $cm^{-1}$).

*Vesicle preparation*. Multilamellar liposomes were prepared by hydration of a lipid film (18). In this method a known amount of EPC was taken in chloroform/methanol (9:1), and the suspension was evaporated to dryness under a stream of nitrogen. The lipid film was then hydrated, either with the appropriate buffer [Hepes (10 mM, $I$ = 0.1 M NaCl), acetate buffer (29.6 mM acetic acid, 70.4 mM sodium acetate; $I$ = 0.1 M NaCl)] or aqueous solution ($I$ = 0.1 M NaCl), and the mixture was stirred in a vortex. The EPC concentration in vesicle suspensions was determined by phosphate analysis using the phosphomolybdate method (20).

*Potentiometric measurements*. All potentiometric measurements were carried out with a Crison 2002 pH meter and 2031 piston buret controlled by a personal computer, which was also used for data manipulation. The electrode assembly was made up of an Orion 900029/4 Ag/AgCl reference electrode and a Russel SWL glass electrode, and the titrations were made in a double-wall cell. System calibration was performed by the Gran method (19) in terms of hydrogen ion concentration, using strong acid-strong base titration [HCl (0.001 M)/NaOH (≈0.02 M)] with solutions whose ionic strength was adjusted to 0.1 M with NaCl. Titrations were always carried out under a nitrogen atmosphere, and the temperature was kept constant at 25.0 ± 0.1ºC by circulating thermostated water in the cell.

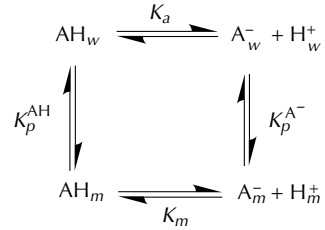
*Spectrophotometric determination of acidity constants*. All absorption spectra were recorded at 25.0 ± 0.1ºC with a Hitachi U-2000 dual-beam spectrophotometer, using quartz cells with a 1-cm path length. The temperature was kept constant by circulating thermostated water in the cell holder. Acidity constants of the anti-inflammatory drugs were obtained from ultraviolet/visible data in aqueous solution and in liposome media, and in all cases the ionic strength was adjusted to 0.1 M with NaCl. Drug/EPC suspensions were prepared by addition of drug to pre-formed EPC suspensions. Data were collected for at least six different drug concentrations in the range 20 to 80 μM, and for each drug concentration at least eight different suspensions of EPC were used (concentration between 0 and 360 μM). After an equilibration period of 2 h in the dark, aliquots of strong base or strong acid were added to these suspension to adjust –log [$H^+$] to the desired value (–log [$H^+$] range used: 3–9); –log [$H^+$] measurements and system calibration were performed by potentiometry as described above. Throughout this work the pH values referred are actually values of –log [$H^+$]. Acidity constants were calculated with the program SQUAD (21) by using data from at least two independent experiments, each with more than eight solutions, and in the wavelength range from 210 to 400 nm, at 2-nm intervals.

*Determination of partition coefficients by derivative spectrophotometry*. Partition coefficients were determined at pH 3.0, 5.0, and 7.4; at the extreme values the drugs are predominantly in the neutral and deprotonated form. At each pH, two sets of solutions containing different concentrations of EPC in the range 0–360 μM were prepared: solutions without drug, and solutions to which a fixed amount of drug was added (in each experimental run, as described above, drug concentration was kept constant and the different values used ranged from 20 to 80 μM). First-derivative spectra were calculated from the recorded spectra after blank subtraction, whereas second-derivative spectra were calculated directly from the recorded spectra. For each drug at least six independent experiments were performed at each pH.

In the experiments at pH 7.4, for which the pH was kept constant with Hepes buffer (10 mM, $I$ = 0.1 M NaCl), two methods were used to prepare drug/liposomes suspensions. In the incubation method, the lipid film was hydrated with Hepes and the drug dissolved in the same buffer was added after liposome formation; the suspensions were then incubated for 2 h. In the encapsulation method, the lipid film was hydrated with a buffer solution (Hepes) to which the drug had been previously added. At pH 3.0 and 5.0, only the incubation method was used: the drug was added to a suspension of liposome ($I$ = 0.1 M NaCl) in the appropriate buffer. The pH was adjusted to 3.0 by addition of a strong acid solution, and to 5.0 using an acetate buffer (29.6 mM acetic acid, 70.4 mM sodium acetate; $I$ = 0.1 M NaCl).

## RESULTS

In drug/EPC suspensions the acid-base equilibria in Scheme 1 must be considered (22) where $K_a$ and $K_m$ are drug acidity



**SCHEME 1**

constants in the aqueous and liposome pseudophases, $K_p^{AH}$ and $K_p^{A^-}$ are the partition coefficients of neutral (AH) and negatively charged ($A^-$) forms of the drug; the subscripts *w* and *m* stand for species in aqueous phase and in the liposome phase, respectively. The different equilibrium constants are defined next, where $V_L$ and $V_w$ stand for the lipid and aqueous solution volumes:

$$K_a = \left[H_w^+\right]\frac{\left[A_w^-\right]}{\left[AH_w\right]} \quad [1]$$

$$K_m = \left[H_w^+\right]\frac{\left[A_m^-\right]}{\left[AH_m\right]} \quad [2]$$

$$K_{app} = \left[H_w^+\right]\frac{\left[A_w^-\right]+\left[A_m^-\right]}{\left[AH_w\right]+\left[AH_m\right]} \quad [3]$$

$$K_p^{AH} = \frac{\left[AH_m\right]/V_L}{\left[AH_w\right]/V_w} \quad [4]$$

$$K_p^{A^-} = \frac{\left[A_m^-\right]/V_L}{\left[A_w^-\right]/V_L} \quad [5]$$

$$K_p^T = \frac{\left[AH_m\right]+\left[A_m^-\right]/V_L}{\left[AH_w\right]+\left[A_w^-\right]/V_w} \quad [6]$$

A few comments must be made regarding acidity constant definitions: $K_m$ corresponds to the value of $[H_w^+]$ of the bulk aqueous phase when $[A_m^-] = [AH_m]$, and the apparent acidity constant $K_{app}$ to the value of $[H_w^+]$ of the bulk aqueous phase when $[A_m^-] + [A_w^-] = [AH_m] + [AH_w]$. Finally, it must be stressed that $K_p^T$ is a global drug partition coefficient that accounts for the partition of both forms of the drug between the two pseudo-phases.

*Determination of partition coefficients using shifts in* $pK_{app}$. Any substance that ionizes in water exists normally in more than one form, and when in the presence of organized media (micelles or liposomes) these distinct forms have different binding constants (or partition coefficients; these two quantities are related). The concentrations of "free" (unbound) deprotonated and neutral forms are thus dependent on the extent of their interactions with the organized media, and consequently their apparent acidity constant, $K_{app}$, changes with lipid concentration (22). The values of $K_{app}$ are calculated directly from spectrophotometric data with the program SQUAD by assuming that all forms of the drug exist free in aqueous solution.

Shifts in $K_{app}$ arise from changes in the electrostatic potential and in the local dielectric constant of the liposome microenvironment, and can provide indirect information on the type of drug/liposome interactions (23). A number of different mathematical models have been developed to quantify micellar or membrane effects on equilibrium constants of different substances, and in these models the organized and aqueous media are assumed to form two separate pseudo-phases, with the drugs partitioned between them, eventually also exchanged with a counterion (23–27). In this work, the model proposed by Berezin (24) was used to provide a quantitative interpretation of changes in the apparent acidity constants of anti-inflammatory drugs in EPC liposomes (23–25). This model neglects ion exchange and it was chosen because it is the simplest model able to describe adequately the experimental results. Berezin and coworkers (24) proposed that the species formed upon dissociation of weak acids are partitioned differently between the liposomic and aqueous phases, and they expressed the apparent acidity constant, $K_{app}$, as

$$K_{app} = K_a \frac{1 + K_p^{A^-} C_L}{1 + K_p^{AH} C_L} \quad [7]$$

which, after linearization becomes:

$$\frac{\left(1 - \frac{K_{app}}{K_a}\right)}{C_L} = K_p^{AH}\frac{K_{app}}{K_a} - K_p^{A^-} \quad [8]$$

where $C_L$ represents EPC concentration. The values of $K_p$ obtained from these equations have dimensions of $M^{-1}$, and can be transformed to those in Equations 4–6 dividing by the lipid molar volume, $V_\Phi = 0.688\ M^{-1}$. The molar volume is obtained from the specific volume (0.983 mL/g) (28) and mean molecular weight (700) of EPC through equation $V_\Phi = V_L/(V_w \times C_L)$ (18).

The dependence with $C_L$ of the values of apparent acidity constants determined from spectrophotometric data, both in aqueous and in EPC media, calculated using the program SQUAD, are plotted in Figure 1. The values of $pK_{app}$ increase with increasing EPC concentration but level out to a constant value at high EPC concentrations. In aqueous solutions, the values of $pK_a$ determined for indomethacin and acemetacin were, respectively, 4.46 and 3.76. We note that the acidity constant obtained in aqueous solution for indomethacin is similar to that reported in the literature ($pK_a = 4.5$) (29,30).

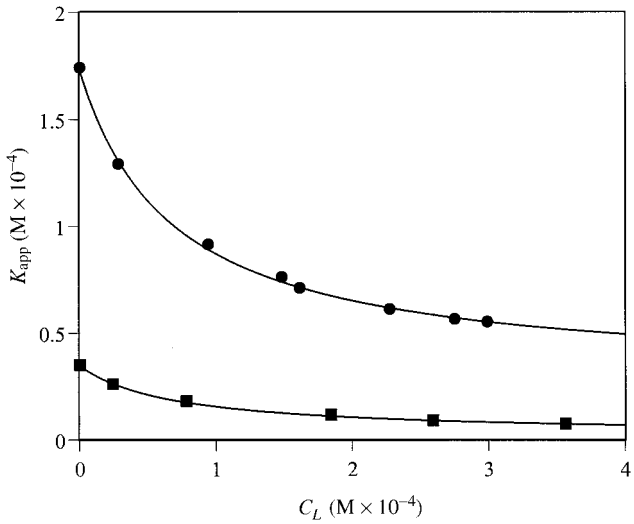


**FIG. 1.** The dependence of the apparent acidity constant, $K_{app}$, on egg yolk phosphatidylcholine (EPC) concentration for indomethacin (■) and acemetacin (●); the curve is the best fit by the Berezin model (Eq. 7).

Plots of $\left(1 - K_{app}/K_a\right)/C_L$ vs. $K_{app}/K_a$ for both drugs yielded straight lines and provided the corresponding partition coefficients. For indomethacin the slope is $1.40 \times 10^4$ and the intercept $7.28 \times 10^2$ ($R^2 = 0.98$), and for acemetacin the slope is $1.59 \times 10^4$ and the intercept $2.83 \times 10^3$ ($R^2 = 0.99$). The values of $K_p^{AH}$ and of $K_p^{A^-}$ are obtained by dividing the slope and the intercept, respectively, by $V_\Phi$. For indomethacin, $K_p^{AH} = 20{,}350$ and $K_p^{A^-} = 1{,}060$, and for acemetacin the values are 23,110 and 4,110, respectively. The data were then fitted by Equation 7 using nonlinear regression methods (DeltaGraph 4.0) ($R = 0.999$) and in Figure 1 the calculated curves are superimposed on the experimental points. The calculated values for the partition coefficients and the respective standard deviations are included in Table 1.

Alternatively, from the values of $K_p^{AH}$ and of $K_p^{A^-}$ determined by shifts in $K_{app}$ and from the $pK_a$ it is possible to calculate $K_p^T$ at any pH; the calculated values at pH 3.0, 5.0, and 7.4 are also included in Table 1.

*Determination of partition coefficients using derivative spectroscopy.* Normally, it is not possible to obtain partition coefficients using direct spectrophotometric methods, owing to the intense background signals that arise from light scattered by lipid vesicles. Thus, partition coefficients of lipid suspensions are typically determined in the aqueous phase after lipid separation. However, as the separation procedures are time-consuming and may disturb the equilibrium state of sample suspensions, an alternative procedure is to use derivative spectrophotometry, as it has been shown to eliminate the background signal and to improve the resolution of overlapping signals. This technique has been applied to the direct determination of drug partition coefficients in aqueous lipid suspensions without disturbing the equilibrium state (11–13).

Partition coefficients of indomethacin and acemetacin between lipid and aqueous phases were determined by derivative spectrophotometry in the presence of different concentrations of EPC (0–360 μM). Drug concentration was kept constant in each experimental run, and the partition coefficients obtained for experiments with different drug concentrations (between 20 and 80 μM) were found to be concentration-independent. Furthermore, as the drugs are carboxylic acids, experiments were performed at pH 3.0 and 7.4, values for which the drug exists predominantly in the neutral and deprotonated form, respectively, as well as at intermediate pH 5.0.

Light absorbance of both drugs decreases with an increase in EPC concentration. Figure 2 shows the second derivative spectra for acemetacin. The existence over a wide range of EPC concentration of three isosbestic points in second-derivative spectra provides an indication that (i) scattering due to the liposome is completely eliminated (12) and (ii) the system has only two states: drugs in polar bulk aqueous and in nonpolar EPC bilayer phases (11,12). Additional support for this latter assertion can be understood by noting the bathochromic (red) shift observed in $\lambda_{max}$ when the anti-inflammatory drugs are moved from aqueous solution to liposomic suspensions, as part of the drug molecules are transferred to nonpolar media (11,12).

The partition coefficient (Eqs. 4–6) can also be expressed in mole fractions:

$$K_p^T = \frac{\left(\left[F_m\right]/\left[F_t\right]\right)/C_L}{\left(\left[F_w\right]/F_t\right)/C_w} \quad [9]$$

where $[F_w]$ and $[F_m]$ stand for drug concentration in the aqueous solution and in the liposomes, respectively, $C_L$ is the concentration of EPC, and $C_w$ that of water. By representing total drug concentration by $[F_t]$, ($[F_t] = [F_w] + [F_m]$), and the mole fraction of drug bound to lipid by θ, it is possible to write Equation 9 as [the partition coefficient in this equation has dimension $M^{-1}$, see above]

$$K_p^T = \frac{\theta/C_L}{(1-\theta)/V_w} \quad [10]$$

Similarly with what is found for absorbance, the derivative intensity ($D_t$) at a specific wavelength is the sum of the derivative intensities in aqueous phase ($D_w$) and in the liposome phase ($D_m$), and is given by

$$D_t = E_w\left[F_w\right] + E_m\left[F_m\right] \quad [11]$$

in which $E_w$ and $E_m$ are the drug molar derivative intensities in water and in the lipid bilayer. The mole fraction of drug bound to the lipid, θ, is thus given by

$$\theta = \frac{\left[F_m\right]}{\left[F_t\right]} = \frac{D_w - D_t}{D_w - D_m} \quad [12]$$

From $[F_t] = [F_w] + [F_m]$, and by defining $E_t = E_m - E_w$ (12), Equation 11 becomes

$$D_t = E_w\left[F_t\right] + E_t\left[F_m\right] \quad [13]$$

From Equations 10, 12, and 13 it is possible to derive Equation 14, which allows the calculation of the partition coefficients of the protonated and neutral forms of indomethacin and acemetacin by nonlinear regression:

**TABLE 1**
**Partition Coefficients for Neutral and Negatively Charged Forms ($K_p^{AH}$ and $K_p^{A^-}$) of Indomethacin and Acemetacin in EPC Multilamellar Liposomes[a]**

| | Drug | |
|---|---|---|
| Partition coefficients | Indomethacin | Acemetacin |
| $K_p^{A^-}$ | 1,158 | 3,492 |
| $K_p^{AH}$ | 20,869 | 21,474 |
| $K_p^T$ (pH 3.0) | 20,208 | 18,811 |
| $K_p^T$ (pH 5.0) | 5,569 | 4,470 |
| $K_p^T$ (pH 7.4) | 1,181 | 3,496 |

[a]Obtained directly from apparent acidity constants experimental data. Global partition coefficients ($K_p^T$) calculated for different pH values assuming that $K_p^T$ is the weighted average of $K_p^{AH}$ and $K_p^{A^-}$. EPC, egg yolk phosphatidylcholine.

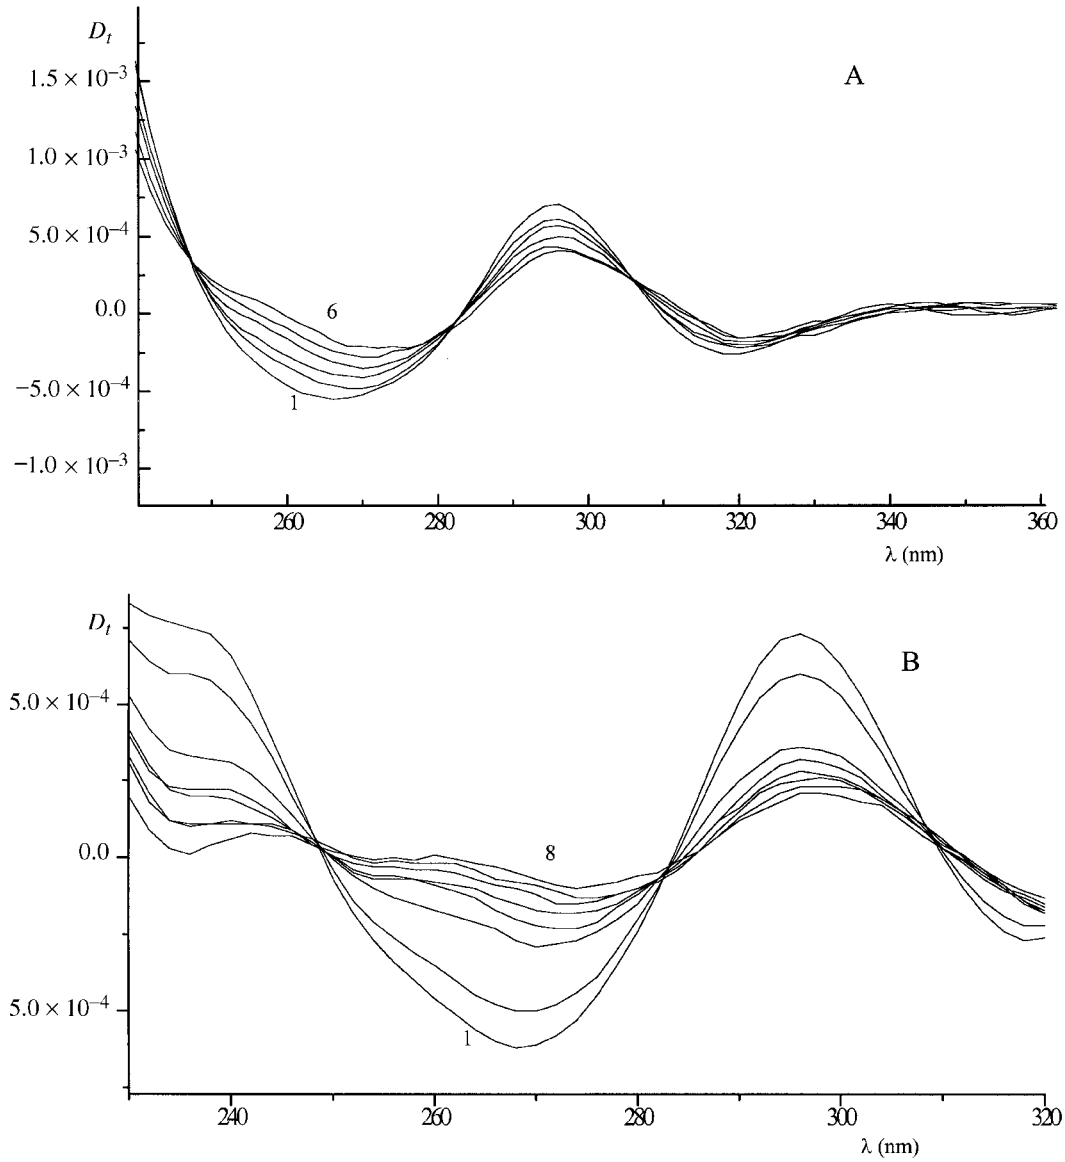

**FIG. 2.** Second-derivative spectra of acemetacin at different concentrations of EPC. At pH 3.0 (A); EPC concentration (μM): (1) 0; (2) 18; (3) 45; (4) 92; (5) 157; (6) 255. At pH 7.4 (B), EPC concentration (μM): (1) 0; (2) 19; (3) 77; (4) 121; (5) 147; (6) 171; (7) 229; (8) 276. For abbreviation see Figure 1.

$$D_t = D_w + \frac{E[F_t]K_p^T C_L}{1 + K_p^T C_L} \quad [14]$$

Equations 10 and 12 can be rearranged to yield a linear relation between $[1/(D_w - D_t)]$ and $(1/C_L)$:

$$\frac{1}{D_w - D_t} = \frac{1}{D_w - D_m} + \frac{1}{(D_w - D_m)K_p^T}\frac{1}{C_L} \quad [15]$$

and from a plot of $[1/(D_w - D_t)]$ vs. $1/C_L$, the intercept is $[1/(D_w - D_m)]$, and the slope allows for the determination of $K_p^T$.

Again, the linear form (Eq. 15) was used to test the applicability of the model and straight lines were obtained for both drugs. By using this approach, the following values were obtained for the total drug partition coefficients ($K_p^T$) (both forms): for indomethacin $1.84 \times 10^4$ at pH 3.0, $5.55 \times 10^3$ at pH 5.0, and $1.11 \times 10^3$ at pH 7.4; for acemetacin $1.95 \times 10^4$ at pH 3.0, $4.29 \times 10^3$ at pH 5.0, and $4.02 \times 10^3$ at pH 7.4. The experimental data were fitted to Equation 14 with correlation coefficients higher than 0.99, and the values for the partition coefficients, which are similar to those obtained from the double reciprocal plots, are included in Table 2. In Figure 3 the experimental values of $D_t$ of indomethacin and acemetacin at pH 3.0 are plotted as a function of $C_L$; superimposed is the curve that best describes the experimental data. The values of $K_p^T$ were found to be independent of drug concentration in the range studied (20 to 80 mM), and of the method used in liposome preparation.

It must be pointed out that by subtracting from the first-derivative spectra, those absorption spectra of the drug-free liposome solutions, it is possible to obtain spectra with much

**TABLE 2**
**Global Partition Coefficients ($K_p^T$) for Indomethacin and Acemetacin in EPC Multilamellar Liposomes[a]**

| Global partition coefficients | | Drug: Indomethacin | Drug: Acemetacin |
|---|---|---|---|
| $K_p^T$ (pH 3.0) | | 20,834 ± 1490 | 20,465 ± 1970 |
| $K_p^T$ (pH 5.0) | | 5,755 ± 390 | 4,500 ± 420 |
| $K_p^T$ (pH 7.4) | | 1,150 ± 80 | 3,583 ± 340 |
| Calculated partition coefficients | | | |
| pH 3.0 and 5.0 | $K_p^{A^-}$ | 1,211 | 3,411 |
| | $K_p^{AH}$ | 21,514 | 23,429 |

| | $K_p^{AH}$ | 21,517 | 23,400 |
| pH 5.0 and 7.4 | $K_p^{A^-}$ | 1,127 | 3,580 |
| | $K_p^{AH}$ | 21,806 | 20,495 |

[a]Obtained directly from derivative spectrophotometry experimental data at different pH values. Partition coefficients for neutral and negatively charged forms ($K_p^{AH}$ and $K_p^{A^-}$) calculated assuming that $K_p^T$ is the weighted average of $K_p^{AH}$ and $K_p^{A^-}$.

reduced scattering. These can be used to determine partition coefficients by the process described above and yield similar results. However, second-derivative spectroscopy is the preferred method, not only because the results exhibit a smaller dispersion but also because it is less time consuming, as there is no need to obtain spectra of drug-free solutions.

The values of $K_p^T$ obtained from derivative spectroscopic data are related to total drug, and not to the individual partition coefficients of neutral and anionic forms. However, from the values of $K_p^T$ determined at two different pH values it is possible to obtain individual partition coefficients, because any of the anti-inflammatory drugs studied exist as a conjugate pair in solution. As their acidity constants ($K_a$) are known, by solving the two equations resulting from applying the Henderson-Hasselbalch at each of the two different pH for which the values of $K_p^T$ are known, it is possible to obtain the mole ratios [AH]/([AH] + [$A^-$]) and [$A^-$]/([AH] + [$A^-$]). Furthermore, as $K_p^T$ is the weighted average of $K_p^{AH}$ and $K_p^{A^-}$, from the values of $K_p^T$ and the calculated mole ratios at two pH values, it is straightforward to calculate $K_p^{AH}$ and $K_p^{A^-}$. The values calculated from data obtained at three pH values are included in Table 2.

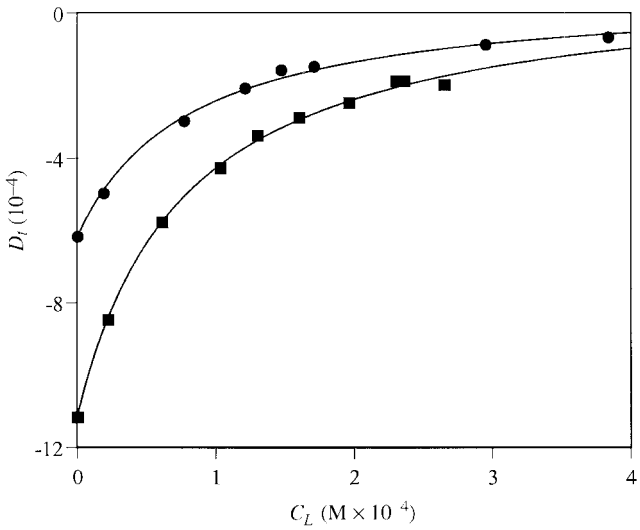

**FIG. 3.** Second-derivative spectrophotometric data at λ = 268 nm for indomethacin (■) and acemetacin (●) at pH 3.0 at different EPC concentrations; the curves represent the best fit by Equation 14. For abbreviation see Figure 1.

*Comparison of the results obtained by the two methodologies.* We start by pointing out that the values of $K_p^{AH}$ and $K_p^{A^-}$ calculated from derivative spectrophotometry using the Henderson-Hasselbalch equation are very similar to those obtained from shifts in $K_{app}$ (Tables 1 and 2).

By inserting the values of $K_a$ and of $K_p^{AH}$ and $K_p^{A^-}$ in the cycle of Scheme 1, it is possible to calculate the acidity constant of the drugs in the liposome pseudo-phase. Values of 5.72 for indomethacin and of 4.55 for acemetacin were obtained for p$K_m$ using values from shifts of p$K_{app}$; data from derivative spectrophotometry yielded values of 5.73 and 4.52. The fact that acidity constants are smaller in the liposome pseudo-phase is a consequence of preferentially binding by the neutral (protonated) form to the liposome. Furthermore, as the difference p$K_m$ – p$K_a$ is roughly 1.3 for indomethacin and only 0.8 for acemetacin the deprotonated form of the latter interacts more extensively with EPC than the deprotonated form of indomethacin.

To assess the quality of the data and the agreement of the results from the two methodologies, we note that by using the values of $K_p^T$ obtained from derivative spectrophotometry and the acidity constant it is possible to calculate values of $K_{app}$ for different concentrations of EPC by using Equation 3, which states that p$K_{app}$ = –log [$H^+$] when [$A_m^-$] + [$A_w^-$] = [$AH_m$] + [$AH_w$]. In Figures 4A and 4B such a plot is presented for acemetacin, and the values obtained are identical, within experimental error, to the measured values of p$K_{app}$.

Finally, to assess the invariability of $K_m$ with EPC content, the values of $K_p^{AH}$ and of $K_p^{A^-}$ can be used to calculate $K_m$ (Eq. 2) at several EPC concentrations, as $K_m$ = –log [$H^+$] when [$A]_m$ = [$AH_m$]. In Figure 4C the fraction of bound neutral and deprotonated forms of acemetacin are plotted vs. pH, and it is clear that the values of $K_m$ so calculated are independent of EPC concentration.

## DISCUSSION

First, it must be stressed that the values of $K_p^{AH}$ and $K_p^{A^-}$ obtained using the two methodologies are identical within experimental error (Tables 1 and 2), which supports the use of derivative spectroscopy in the determination of partition coefficients. With regard to drug interaction with EPC, our data show that the neutral form interacts more strongly with EPC than the charged form, an observation that supports the suggestion of Hwang and Shen (17) for indomethacin that the interaction of the drug takes place predominantly with the nonpolar matrix of the bilayer, and we propose that the anti-in-

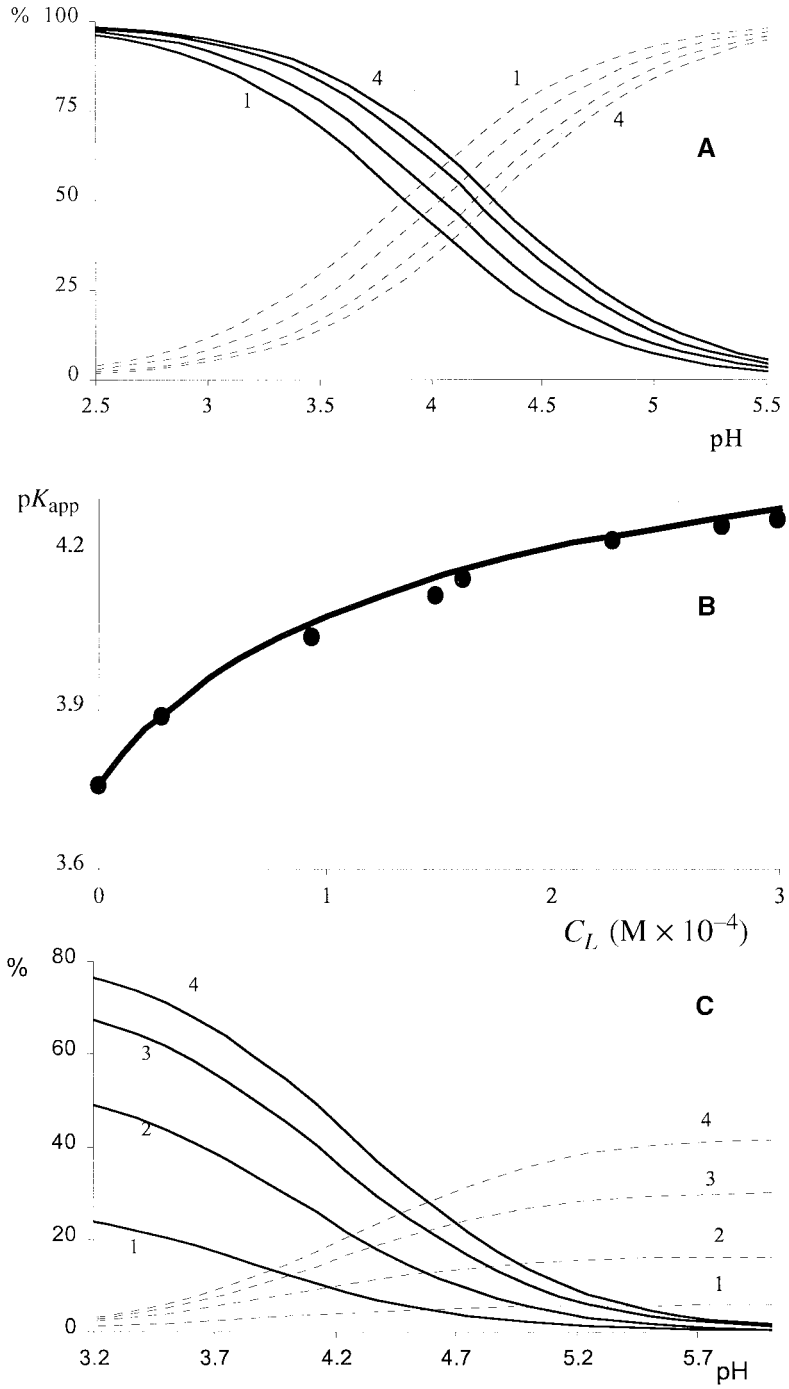

**FIG. 4.** (A) Distribution diagram for total (aqueous and lipid bound) neutral (solid) and deprotonated (dashed) forms of acemetacin at different EPC concentrations [(1) 25; (2) 80; (3) 180, and (4) 300 μM]. (B) Values of $pK_{app}$ calculated from the pH at which the curves in (A) intercept (solid curve) and experimental values obtained by direct spectrophotometry (●). (C) Distribution diagram for lipid bound forms of acemetacin (neutral: solid; deprotonated: dashed) calculated from derivative spectrophotometry values at several concentration of EPC [(1) 25; (2) 80; (3) 180, and (4) 300 μM]. The intercept of the curves yields $K_m$. For abbreviation see Figure 1.

flammatory molecules must be interdigitated between the hydrocarbon chains of the phospholipid. This model accounts for the smaller partition coefficients obtained for the charged drug forms, as the negatively charged carboxylic groups must be at the surface and facing the aqueous solution, which reduces the extent of interdigitation between the hydrophobic chains of the phospholipid and creates a repulsion between the charged groups of the drug and the negatively charged heads of the phospholipid, and thus renders drug incorporation less favorable.

The determination of partition coefficients from shifts in $pK_{app}$ is a well-established method, albeit somewhat tedious, as it requires extensive data sets and a very precise potentiometric system. It has been used to provide partition coefficients that have been used as a check for those obtained by derivative spectroscopy. This latter methodology, on the other hand, is a fast and easily implemented method to obtain values of $K_p^T$ for drugs in vesicles; and by using the approach outlined above, which assumes $K_p^T$ to be the weighted average of $K_p^{AH}$ and $K_p^A$, it is straightforward to calculate these latter partition coefficients from values of $K_p^T$ at two different pH values. As a final comment, we point out that the use of derivative spectroscopy has proved to be a fast and reliable method to obtain partition coefficients for drugs in vesicles, thus addressing the obvious limitations of the water–octanol method.

# A Novel Assay Method for Glycosphingolipid Deacylase by Enzyme-Linked Immunochemical Detection of Lysoglycosphingolipid

**Kazuo Izumi* and Michiko Takagi Sawada**

Hokkaido National Industrial Research Institute, AIST, MITI, Sapporo 062-8517, Japan

**ABSTRACT:** Lysoglycosphingolipids consist of a sphingoid long-chain base and monosaccharide or complex sugar, and they lack the fatty acyl group present in native glycosphingolipids. Less than 1 pmol of lyso-Forssman glycolipid and lysoganglioside GM1 were detected on a thin-layer chromatogram by an enzyme-linked immunochemical coloration method with anti-Forssman glycolipid antibody (FOM-1) and cholera toxin B subunit, respectively. Each spot between 1 and 100 pmol lyso-Forssman glycolipid was immunostained as densely as that of the same amount of native Forssman glycolipid. The density of the lyso-Forssman glycolipid spots increased proportionally with increment in the amount of lysoglycolipid. The density of spots of 0.2–100 pmol lysoganglioside GM1 was also proportional to the amount of each lyso-GM1 spot. These results indicated that less than 1 to 100 pmol of deacylated glycosphingolipid was quantifiable by the immunochemical coloration method with sugar chain-specific antibodies. Glycosphingolipid deacylase, which cleaved an amide bond between the sphingoid long-chain base and fatty acyl chain in ceramide of glycosphingolipid, was assayed by detecting the lyso-Forssman glycolipid produced. Lipophilic compounds, recovered from an aliquot of the reaction mixture of Forssman glycolipid and crude enzyme at appropriate times, were analyzed by thin-layer chromatography. It was found that lyso-Forssman glycolipid was produced in the first 1–2 h by the enzyme and production increased with incubation time. This coloration method is more sensitive and specific than the visualization method with a nonspecific reagent such as orcinol-sulfuric acid reagent.

Paper no. L8544 in *Lipids 36*, 97–101 (January 2001).

Glycosphingolipidoses are metabolic disorders that occur accompanying an abnormal storage of glycosphingolipids. Lysoglycosphingolipids, which consist of a sphingoid long-chain base and monosaccharide or complex sugar, have been reported to be present in the lipid storage. Svennerholm *et al.* (1) found galactosylsphingosine in brains taken from patients with Krabbe disease. They also found glucosylsphingosine in brains, spleens, and livers of patients with Gaucher disease (2,3). Accumulation of lysosulfatide has been found in the brain of a patient with metachromatic leukodystrophy (4,5) and in a normal brain (5). Lysoganglioside GM2 has been detected in the brain of a patient with Tay-Sachs disease (6), and lysogangliosides GM1 and GM2 have been detected in tissues of patients with Sandhoff disease, Tay-Sachs disease, and GM1 gangliosidoses (7).

Lysoglycosphingolipids lack the fatty acyl group present in native glycosphingolipids. Glycosphingolipid deacylase (8–10) and sphingosine ceramide deacylase (11) have been shown to hydrolyze the amide bond between the sphingosine base and fatty acid in the ceramide moiety of glycosphingolipid and to release lysoglycosphingolipid and fatty acid. The existence of these enzymes has been proven only in bacteria. Glycosphingolipid deacylase has been found on the bacterial membrane of *Rhodococcus* sp. (8), *Nocardia* sp. (9), and *Streptomyces* sp. (10), and sphingosine ceramide deacylase has been found in the culture broth of *Pseudomonas* sp. (11). Glycosphingolipid deacylase and sphingosine ceramide deacylase have different substrate specificities, although both enzymes have been shown to hydrolyze glycosphingolipid into lysoglycosphingolipid and fatty acid. Glycosphingolipid deacylase hydrolyzed only glycosphingolipid with a long sugar chain (more than three sugars), and sphingosine ceramide deacylase hydrolyzed glycosphingolipid with more than one sugar and sphingomyelin. The existence of the enzymes was demonstrated by proving the production of lysoglycosphingolipids on a thin-layer chromatogram (TLC) visualized with resorcinol-hydrochloric acid reagent or orcinol-sulfuric acid reagent (8–11). The release of fatty acid from radioisotope-labeled glycosphingolipid was also reported to assay the enzyme (8,9). The existence of deacylase in eucaryotes, such as mammals, however, has not yet been proven, probably because the products of the enzymes are minor among the abundant glycolipids of mammalian cells and are hydrolyzed by glycosidases.

Antiglycosphingolipid antibodies and lectins that recognize the sugar chains of glycosphingolipids have been developed. Higashi *et al.* (12) reported a highly sensitive method for detecting glycosphingolipids on TLC by an enzyme-immunochemical staining method. Rosengren *et al.* (5) quantified lysosul-

Abbreviations: FOM-1, anti-Forssman glycolipid antibody, manufactured by Biomedicals AG (August, Switzerland); $Gb_4Cer$, globoside; HPTLC: high-performance thin-layer chromatography; HRP, horseradish peroxidase; PBS, phosphate-buffered saline; PVP, polyvinylpyrrolidone; TLC, thin-layer chromatography.

fatide and *N*-acetyllysosulfatide by radioimmunoaffinity TLC. In the present study, we demonstrated that lysoglycosphingolipids with pentose as the hydrophilic moiety were detectable at the same detection limit as that of the native glycosphingolipid by an immunostaining method with glycosphingolipid-specific antibodies. In this paper, we describe a new method for detecting glycosphingolipid deacylase by visualization of lysoglycosphingolipid formed by the enzyme.

## EXPERIMENTAL PROCEDURES

*Materials and reagents.* Anti-Forssman glycolipid antibody (FOM-1) was a product of Biomedicals AG (August, Switzerland), and the biotin-labeled second antibody (biotin-rabbit anti-rat immunoglobulin M) and horseradish peroxidase (HRP)-labeled third antibody (HRP-mouse anti-biotin) were purchased from Zymed (San Francisco, CA). Cholera toxin B subunit-HRP conjugate (Research Biochemicals International, Natick, MA) was used to stain ganglioside GM1. A Polygram Sil G TLC plate (No. 805013; Macherey-Nagel, Düren, Germany) was used for coloration of glycosphingolipids with specific antibodies.

The bacterium, *Rhodococcus* sp. strain GL-26, isolated in our laboratory (8), was cultivated in a medium of 5 g/L of phytone peptone (BBL, Cockeysville, MO), 5 g/L of yeast extract (BBL), and 5 g/L of glucose (pH 7.0). The cells were harvested, washed twice with 50 mM tris-HCl buffer (pH 7.4), suspended in the same buffer, and incubated in the presence of globoside ($Gb_4Cer$) at 2 mg/mL to induce glycosphingolipid deacylase. Induced cells were harvested, washed, and frozen at −80°C until use. After the cells had been disrupted by sonication, the cell membranes were collected by ultracentrifugation at 100,000 × *g* for 1 h.

Ganglioside GM1 and lysoganglioside GM1 were purchased from Sigma (St. Louis, MO). $Gb_4Cer$, the inducer of glycosphingolipid deacylase, was extracted from porcine erythrocyte membrane and purified by Iatrobeads column chromatography (13). Forssman glycolipid ($IV^3GalNAc\alpha$-$Gb_4Cer$) was extracted from equine kidney, purified by Iatrobeads column chromatography, acetylated (14,15), purified by Iatrobeads column chromatography again, and deacetylated. The purity of Forssman glycolipid was checked with high-performance TLC (HPTLC; No. 5631, Merck, Darmstadt, Germany) by developing with the solvent system of chloroform/methanol/water/acetic acid (60:35:7:1, by vol) or chloroform/methanol/2.5 M ammonia (5:4:1, by vol) and visualizing with orcinol-sulfuric acid reagent. Forssman glycolipid gave a single band on the HPTLC with each solvent system.

Deacylation of Forssman glycolipid was performed by a procedure similar to that used for the induction of GL-26 cells using Forssman glycolipid as the inducer instead of $Gb_4Cer$. Whole lipophilic compounds, recovered from the deacylation mixture of Forssman glycolipid and the bacteria, were applied on a reversed-phase HPLC column (STR HPLC Column Pre-ODS, 250 × 20 mm, i.d.; Shimadzu, Kyoto, Japan). Lyso-Forssman glycolipid was eluted from the column with a linear gradient of methanol and chloroform/methanol/distilled water (60:30:4.5, by vol). The purity of lyso-Forssman glycolipid was checked by the same method as that used to check the purity of Forssman glycolipid. Lyso-Forssman glycolipid also gave a single band.

*Immunochemical coloration of glycosphingolipids on TLC.* Sensitive coloration of glycosphingolipids with a glycosphingolipid-specific antibody was performed according to the procedure reported by Higashi *et al.* (12) with a minor modification. Forssman glycolipid and lyso-Forssman glycolipid were separated on a Polygram Sil G TLC plate by developing with a solvent system of chloroform/methanol/distilled water/acetic acid (60:40:8:1, by vol). After complete removal of the solvent from the TLC by leaving the plate in air followed by blowing hot air, the plate was soaked in a solution of 1% ovalbumin (2× crystallization; Seikagaku Corp., Tokyo, Japan) and 1% polyvinylpyrrolidone (PVP) in phosphate-buffered saline (PBS) in an appropriate-sized plastic box. The plate was shaken gently (about 30 rpm) for 1 h at 37°C followed by washing five times with PBS. Forssman glycolipid and lyso-Forssman glycolipid on the plate were detected by subsequent immunochemical reactions with FOM-1, biotin-labeled second antibody, and HRP-labeled anti-biotin antibody. HRP-conjugates on the plate were stained blue by peroxidase-specific chromogenic reagents (HP-1000; Konica, Tokyo, Japan).

Ganglioside GM1 and lysoganglioside GM1, separated with the solvent system of chloroform/methanol/distilled water/acetic acid (50:40:9:1, by vol), were detected with cholera toxin B subunit-HRP conjugate and the chromogenic reagents.

The plate image was replicated with a scanner (Epson GT-9600), a computer (Macintosh G4), and the software program Adobe Photoshop 5.5 (Sanvosa, CA). The plate image data was saved in a PICT file, which was then opened using the software NIH Image 1.62. Each blue spot was enclosed with an ellipse, and the area and mean density of the ellipse were computed using the software. The total density of each spot was calculated by multiplying the area and mean density. The relative density was calculated from the total density by dividing by that of 10 pmol of native glycosphingolipid.

## RESULTS

*Immunochemical coloration of lyso-Forssman glycolipid.* Lyso-Forssman glycolipid ($R_f$, 0.18) was separated from Forssman glycolipid ($R_f$, 0.41) by developing on a Polygram Sil G TLC plate with a solvent system of chloroform/methanol/distilled water/acetic acid (60:40:8:1, by vol). Both the lyso-Forssman glycolipid and native Forssman glycolipid were visualized in blue spots by the immunochemical coloration method as described in the Experimental Procedures section. Although spots of 0.2 and 0.5 pmol lyso-Forssman glycolipid and a spot of 0.2 pmol Forssman glycolipid were not distinguishable from the background or control (0 pmol), more than 1 pmol of lyso-Forssman glycolipid and more than 0.5 pmol Forssman glycolipid were stained visibly by this method (Fig.

1A). Each spot of 1 to 100 pmol of lyso-Forssman glycolipid was shown to be as dense as that of the same amount of Forssman glycolipid. The density of each spot was computed, and the relative density was calculated with a spot of 10 pmol of Forssman glycolipid as the standard spot (Figs. 1B and 1C). The relative density of lyso-Forssman glycolipid was shown to increase proportionally with the increment in the amount of glycolipid applied to the TLC, although spots of 0.2 and 0.5 pmol lyso-Forssman glycolipid and 0.2 pmol Forssman glycolipid, which were not distinguishable from the background, did not appear on the calibration line. The amount of lyso-Forssman glycolipid between 1 and 100 pmol was demonstrated to be computable from the density.

*Immunochemical coloration of lysoganglioside GM1.* Lysoganglioside GM1 ($R_f$, 0.23) was clearly separated from ganglioside GM1 ($R_f$, 0.32) by Polygram Sil G TLC. Ganglioside GM1 and lysoganglioside GM1 were detected with cholera toxin B subunit-HRP conjugate and peroxidase-specific chromogenic reaction. Spots of 0.05 pmol of deacylated or native ganglioside GM1 were indistinguishable from the background, but faint spots of 0.1 pmol of both lysoganglioside GM1 and native ganglioside GM1 were observed (Fig. 2A).

From the calculation of relative density, each spot of between 0.2 and 100 pmol of lysoganglioside GM1 was immunostained as densely as that of the same amount of ganglioside GM1 (Figs. 2B and 2C). The relative density of lysoganglioside GM1 was shown to increase proportionally with increment in the amount of glycolipid.

*Quantitative analysis of glycosphingolipid deacylase by determining lyso-Forssman glycolipid production.* Glycosphingolipid deacylase hydrolyzes Forssman glycolipid, concluding production of lyso-Forssman glycolipid. The amount of lyso-Forssman glycolipid in the reaction mixture of the glycolipid and the enzyme was determined in high sensitivity by the enzyme-linked immunochemical detection method with the antibody FOM-1. As shown in Figure 3, it was observed that lyso-Forssman glycolipid was produced in the first 1–2 h of incubation with a GL-26 membrane. It was also demonstrated that the amount of lyso-Forssman glycolipid increased with incubation time and with the amount of enzyme source. Glycosphingolipid deacylase (120 μg membrane protein) was calculated to liberate 4.61 pmol of lyso-Forssman glycolipid per hour (38.5 pmol/h/mg membrane protein).

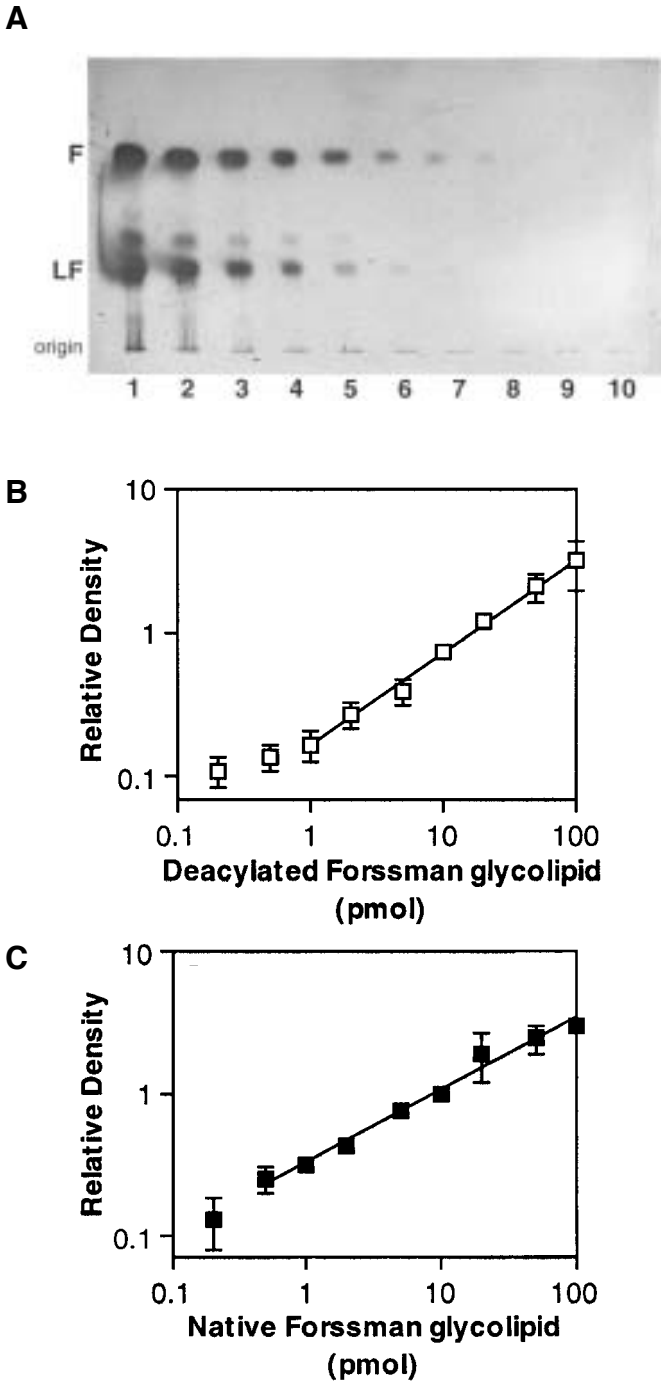

**FIG. 1.** Calibration curves of thin-layer chromatography (TLC)-immunostaining of lyso-Forssman glycolipid (LF). The amount of LF in the original mixture was determined by densitometric scanning of high-performance TLC visualized with orcinol-sulfuric acid reagent spray with Forssman glycolipid (F) as the standard. (A) One of four immunostained TLC plates of LF and F. Serially decreasing amounts of F and LF were applied on the same plate of Polygram Sil G. The plate was developed and stained by the enzyme-linked immunochemical method as described in the Experimental Procedures section. The amounts were as follows (pmol); lane 1, 100; lane 2, 50; lane 3, 20; lane 4, 10; lane 5, 5; lane 6, 2; lane 7, 1; lane 8, 0.5; lane 9, 0.2; lane 10, 0. (B) Standard curve for LF (□). (C) Standard curve for F (■). Symbols represent the average of the relative density (total density of each spot/total density of 10 pmol F) of four TLC plates; bars represent the standard deviation.

## DISCUSSION

It has been demonstrated that it is possible to determine the density of a spot using the combination of a computer, scanner, and software (PhotoShop and NIH Image), all commonly available these days.

It was also demonstrated that it is possible to calculate the amount of deacylated glycosphingolipid by computing the density of spots that had been stained by the enzyme-linked immunochemical coloration method. The detection limits of both native glycosphingolipid and its deacylated compound on immunostained plates were the same. These results con-

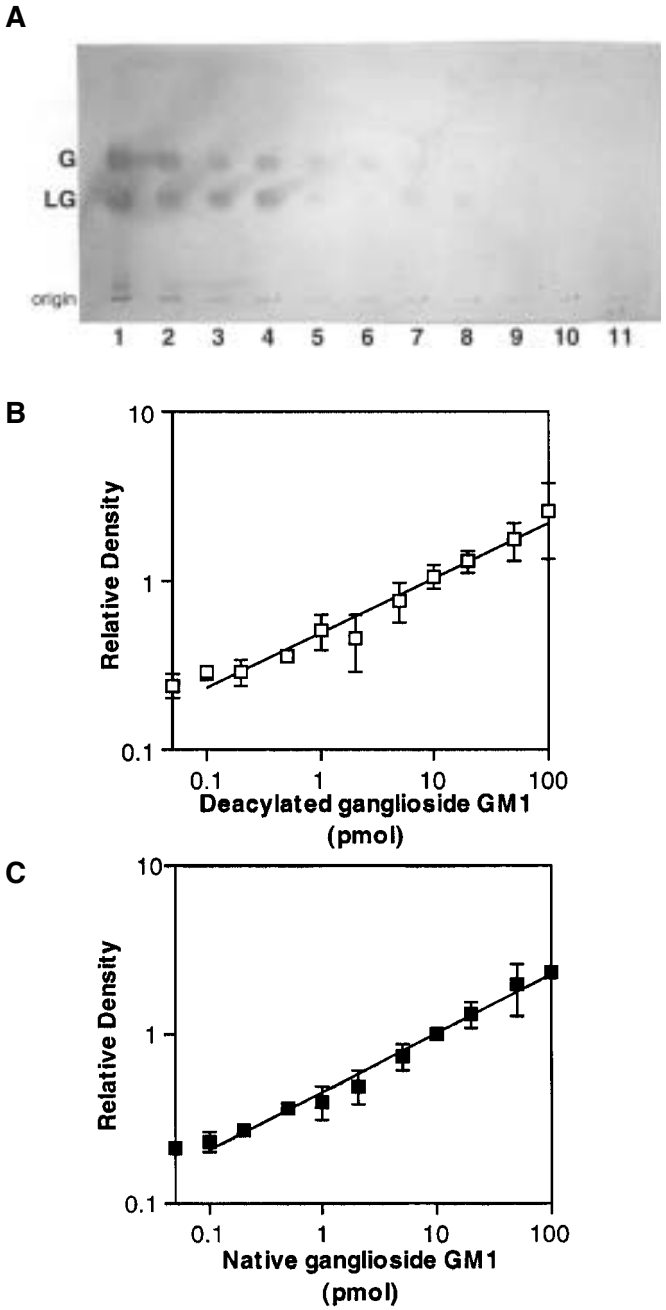

**FIG. 2.** Calibration curves of TLC-immunostaining of lysoganglioside GM1 with cholera toxin B. (A) One of three immunostained TLC plates of lysoganglioside GM1 (LG) and ganglioside GM1 (G). Serially decreasing amounts of G and LG were applied on the same TLC plate and immunostained as described in the Experimental Procedures section. The amounts were as follows (pmol); lane 1, 100; lane 2, 50; lane 3, 20; lane 4, 10; lane 5, 5; lane 6, 2; lane 7, 2; lane 8, 0.5; lane 9, 0.2; lane 10, 0.1; lane 11, 0.05. (B) Standard curve for LG (□). (C) Standard curve for G (■). Symbols represent the average of the relative density (total density of each spot/total density of 10 pmol G) of three TLC plates, and bars represent the standard deviation. For abbreviations see Figure 1.

firmed that sugar chains of Forssman glycolipid and ganglioside GM1 were recognized by FOM-1 and cholera toxin B subunit, respectively, and that modification of the ceramide part of the glycolipids had no effect on antibody recognition.

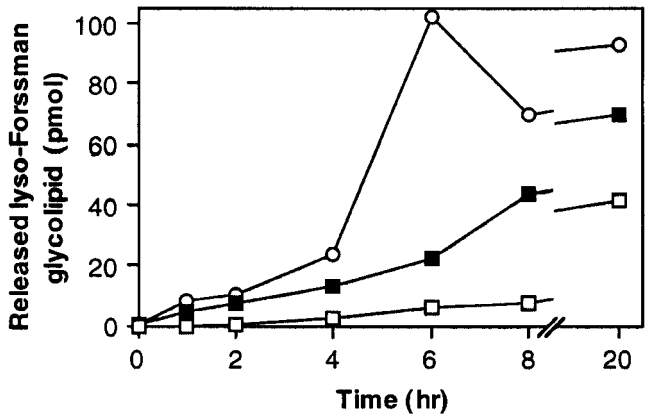

**FIG. 3.** Enzymatic production of LF by glycosphingolipid deacylase. F (1.6 μg, *ca.* 1.10 nmol) was incubated with the membrane of *Rhodococcus* sp. strain GL-26 in the presence of 3-(*N*-morpholino)propane sulfonic acid (40 μmol), cholate (0.4 μmol), and $CaCl_2$ (8 μmol) in 0.8 mL. An aliquot of 100 μL was withdrawn at each time and applied on a Sep Pak $C_{18}$ cartridge (1 μL; Waters, Milford, MA). After salts had been removed by washing the cartridge column with 1 mL of distilled water, lipophilic compounds were recovered by eluting 0.5 mL of methanol and 1 mL of chloroform/methanol (2:1, vol/vol). The combination of the eluted solution was dried *in vacuo* and applied on a Polygram Sil G plate. The plate was developed and immunostained as described in the Experimental Procedures section. F (10 pmol) was developed on the same plate as the standard material to calculate relative density. □, 60 μg of protein; ■, 120 μg of protein; ○, 180 μg of protein in the aliquot. See Figure 1 for abbreviation.

From less than 1 to 100 pmol of glycosphingolipid as well as the native glycosphingolipid were sustained on the Polygram Sil G plate during the procedure of blocking with ovalbumin; immunochemical reactions with the primary, second, and third antibodies, or lectin; and washing steps. Although deacylated glycosphingolipid, which possessed only a sphingoid long-chain base as the hydrophobic moiety and lacked a fatty acyl chain, was more hydrophilic than the native glycosphingolipid, no lysoglycosphingolipids seemed to be lost during the procedure.

Glycosphingolipid deacylase cleaved the amide bond between the sphingoid long-chain base and fatty acyl chain in ceramide of glycosphingolipid (8–10). These enzymes, which hydrolyzed only glycosphingolipids with more than three saccharides in the hydrophilic moiety, existed on the bacterial membrane and have never been solubilized with a variety of detergents. The membranes or bacteria themselves were the enzyme source for the assay. The enzymes were demonstrated to produce lysoglycosphingolipids, which were visualized on TLC with resorcinol-hydrochloric acid reagent or orcinol-sulfuric acid reagent. From the assay mixture of deacylase from strain GL-26, all lipophilic compounds, including Forssman glycolipid (substrate), lyso-Forssman glycolipid and fatty acid (products), and lipids of GL-26 cells were recovered by the SepPak $C_{18}$ (Waters, Milford, MA) cartridge technique. It is often difficult to analyze a small amount of released product by visualization on TLC with a nonspecific reagent of orcinol-sulfuric acid reagent or resorcinol-hydrochloric acid

reagent, because some bacterial lipids might be visualized by the reagent. Detection of the release of fatty acid from glycosphingolipid labeled with radioisotopic fatty acid is a more sensitive and specific assay method for deacylase. Labeled glycosphingolipid was obtained by the synthesis of lysoglycosphingolipid and radioisotopic fatty acid. The detection limit of this method might be improved by prolongation of exposure to radioisotopes. The immunochemical staining method described in this paper is also a highly sensitive and highly specific method. A few picomoles of lysoglycosphingolipid were detected, although most of the contaminating bacterial lipids were insensitive to the antibody and remained invisible. Therefore, a small amount of glycosphingolipid deacylase is detectable by this immunostaining method of lysoglycosphingolipid. It was difficult to clarify the substrate specificity in this immunostaining method as well as in the radioisotopic method. However, various antibodies against glycosphingolipids have recently been extensively investigated, and they should be applicable to the detection of lysoglycosphingolipids and the deacylase assay. The development and use of more sensitive primal antibodies, experimentation with various combinations of secondary (or third and more) antibodies, and the evolution of chromogenic reaction will enable detection of a smaller amount of glycosphingolipid on TLC.

COMMUNICATION

# Variation in Molecular Species of Polar Lipids from *Thermoplasma acidophilum* Depends on Growth Temperature

**Ikuko Uda[a,*], Akihiko Sugai[a], Yuko H. Itoh[b], and Toshihiro Itoh[a]**

[a]Division of Chemistry, Center for Natural Science, Kitasato University, Kanagawa 228-8555, Japan, and
[b]Department of Bioengineering, Faculty of Engineering, Soka University, Tokyo 192-8577, Japan

**ABSTRACT:** Five types of molecular species of $C_{40}$ isoprenoid chains, having different numbers of cyclopentane rings, were detected in the ether core lipid of *Thermoplasma acidophilum*. The average cyclization number of the hydrocarbon chains in the lipids increased with increasing growth temperatures.

Paper no. L8633 in *Lipids 36*, 103–105 (January 2001).

The membrane lipid structures of Archaea are composed of different lengths of isoprenoid chains with an ether linkage to glycerol in the *sn*-2,3 configuration (1,2). The hydrocarbon chain constituents of ether lipids are commonly the $C_{20}$, $C_{25}$, and $C_{40}$ isoprenoid chains. In the thermoacidophilic Archaea, caldarchaeol (2,2′,3,3′-tetra-*O*-dibiphytanyl-*sn*-diglycerol), which contains 2 mol of $C_{40}$ isoprenoid, is the major core lipid (3,4). Five types of molecular species, classified by the number of cyclopentane rings, have been detected in the core lipid of *Thermoplasma acidophilum* and other extreme thermophiles including *Sulfolobus solfataricus* (5–7); these are the acyclic-, monocyclic-, bicyclic-, tricyclic-, and tetracyclic-$C_{40}$ hydrocarbons. De Rosa *et al.* (8) reported that cyclization of the chain increased systematically with the growth temperature from 75 to 89°C in *S. solfataricus,* which is an extreme thermoacidophilic Crenarchaeon belonging to the order Sulfolobales. *Sulfolobus solfataricus* can grow from 50 to 87°C and optimally at 87°C. *Thermoplasma acidophilum* belongs to the Euryarchaeota, a subdomain of Archaea, and grows from 45 to 62°C (optimally at 59°C) (9). The cell is wall-less, and the major core lipid of the cell membrane is caldarchaeol (10).

In contrast to the report on *S. solfataricus* (8), Yang and Haug *et al.* (11) reported that the average cyclization number of the total lipids of *T. acidophilum* grown at 37°C was greater than that grown at 56°C. Recently, at least five types of neutral lipids and eight types of acidic lipids have been identified in *T. acidophilum,* and most of their structures have been characterized (12–14).

This report describes the effect of growth temperature on the degree of cyclization of the major lipids, five neutral lipids, and four acidic lipids in *T. acidophilum*, in all of which the core lipid is caldarchaeol.

## EXPERIMENTAL PROCEDURES

*Thermoplasma acidophilum* (ATCC 27658) was grown aerobically with low-speed stirring at 40, 50, and 60°C (±1°C) at pH 2.0. The medium (1.5 L, wt/vol) consisted of inorganic salts, 0.1% yeast extract, and 1% glucose in 2-L flasks, as previously described (13). Cells grown at 60°C were used as inoculum. Lipid extraction from the cells and the preparation of the neutral lipids and acidic lipids from the total lipids were carried out as previously described (13). As complete lipid extraction is necessary for reproducible results, the whole cells were treated with acidic methanolysis during the first step. Five neutral glycolipids (GL-1a, GL-1b, GL-2a, GL-2b, and GL-2c), and four acidic phosphoglycolipids (GPL-A, GPL-B, GPL-C, and GPL-D) were fractionated by the combination of column chromatography and preparative thin-layer chromatography (TLC). All of the core lipids from these intact lipids were co-chromatographed with caldarchaeol ($R_f$ = 0.55) by TLC analysis. Each lipid was purified by preparative TLC using boronic acid-impregnated high-performance TLC (HPTLC) plates of silica gel (Merck, Darmstdt, Germany). The HPTLC plates were developed with either chloroform/methanol/water (75:25:2, by vol) for purification of each neutral lipid, chloroform/methanol/0.2% $CaCl_2$ (55:45:7, by vol) or chloroform/methanol/1 M aqueous ammonia (65:35:5, by vol) for each acidic lipid.

The core lipids were obtained from whole cells or intact lipids by acid methanolysis. The core lipids bound to the intact polar lipids were completely cleaved and extracted by a chloroform/methanol mixture from the methanolyzate. TLC analysis of the core lipids was performed using an HPTLC plate of silica gel and developed with hexane/diethyl ether/acetic acid (60:40:2, by vol). Core lipids were detected by spraying with 18 M $H_2SO_4$ followed by heating at 150°C. Preparation of the hydrocarbon chains from the core lipids were obtained by HI degradation as described previously (13). The hydrocarbon chains were analyzed by gas–liquid chromatography (GLC) and gas chromatography–mass spectrometry (GC–MS). GLC was performed on a Hitachi 163 gas chromatograph (Hitachi, Tokyo, Japan) equipped with a flame-ionization detection system. Hydrocarbon chains were analyzed on 3% Dexsil 300 in a glass column (3 mm × 1 m)

## RESULTS AND DISCUSSION

Freeze-dried whole cells were directly methanolyzed, then prepared as hydrocarbon chains. The gas chromatogram of the hydrocarbon chain from the core lipid (caldarchaeol) showed five peaks corresponding to the $C_{40}$ hydrocarbon chains detected in *S. solfataricus* (8). The peaks for $[M]^+$ obtained from the GC–MS EI spectra at *m/z* 562, 560, 558, 556, and 554 were identified as $C_{40}H_{82}$ (acyclic), $C_{40}H_{80}$ (monocyclic), $C_{40}H_{78}$ (bicyclic), $C_{40}H_{76}$ (tricyclic), and $C_{40}H_{74}$ (tetracyclic), respectively. The distribution of molecular species of the $C_{40}$ isoprenoid and the average cyclization in the whole cells and fractionated lipids of *T. acidophilum* grown at 40, 50, and 60°C, are shown in Table 1. From these results, the average cyclization of the $C_{40}$ hydrocarbon chains increased with the increasing growth temperature. These results are similar to those from *S. solfataricus*, but opposite to that of a previous report on *T. acidophilum* (11).

Distribution of the molecular species of the $C_{40}$ isoprenoid and average cyclization from the neutral glycolipids and acidic phosphoglycolipids are shown in Table 2. An increasing degree of cyclization was seen in all the lipids examined. The existence of a lipopolysaccharide with 24 mannose residues in its polar head portion has been reported in *T. acidophilum* (15,16). In our experiments, the lipopolysaccharide was not detected on the TLC plate, probably because of its behavior based on high molecular weight and high polarity. The efficiency of extraction for the high molecular weight lipids depends on the extraction solvents, which should be affected by the cyclization number in the total lipids. The previous contradictory result (11) from *T. acidophilum* might have been related to the extraction conditions. The phosphoglycolipids are more cyclized than the glycolipids. The reason for this might be that the physical volume of the polar head groups of the phosphoglycolipids are larger than that of the glycolipids; the volume of the core lipid as a membrane anchor part needs to become larger for controlling the distance between the polar heads.

Changing the number of cyclopentane rings in the core lipids of thermoacidophilic Archaea could maintain stable fluidity of the membrane against environmental temperature changes, similar to the change in the unsaturation of the fatty acylester lipids of Eukarya and Bacteria (17,18).

The main molecular species of the $C_{40}$ hydrocarbon chain of the major cellular lipid GPL-A and total lipids from *T. acidophilum* grown at its optimum of 60°C in 5 L of medium without stirring contains one cyclopentane ring ($C_{40}$ monocyclic). In the case of the cultivation carried out in a 1.5-L medium with stirring at 60°C, the main molecular species of the hydrocarbon chain was the bicyclic $C_{40}$ hydrocarbon. Thus cyclization might be a response not only to temperature but also to physical stimulation. *Thermoplasma acidophilum* is wall-less and its cell membrane directly faces into the environment. The stability of the membrane structure also might be controlled by cyclization of hydrocarbon chains against the physical stress, like stirring cultivation.

ARTICLE

# Measurement of Human Chylomicron Triglyceride Clearance with a Labeled Commercial Lipid Emulsion

**Yongsoon Park*, Bart D. Damron, John M. Miles, and William S. Harris**

University of Missouri-Kansas City, Department of Medicine and Cardiovascular Research Department, Mid America Heart Institute, Saint Luke's Hospital, Kansas City, Missouri 64111

**ABSTRACT:** Human chylomicron triglyceride (TG) kinetics has been difficult to determine directly owing to technical limitations. This report describes a new method for studying chylomicron metabolism. Healthy volunteers ($n$ = 10) sipped a drink providing 175 mg fat·kg$^{-1}$·h$^{-1}$ for 7.5 h to produce a steady-state chylomicronemia. A commercial 10% intravenous lipid emulsion was labeled with [$^3$H]triolein, purified by high-performance liquid chromatography, and sterilized. A trace amount of labeled emulsion was injected intravenously 30 min before (i.e., in the fasting state) and 5, 6, and 7 h after sipping began (i.e., triplicate determinations in the fed state). Chylomicron half-lives were calculated from the monoexponential decay curves, and apparent distribution volumes were estimated by back-extrapolation to time zero. Plasma and estimated chylomicron TG concentrations increased from 89 ± 13 and 0.8 ± 0.3 to 263 ± 43 and 91 ± 39 mg/dL (mean ± SEM), respectively, with feeding. Tracer-determined chylomicron TG half-lives were 5.34 ± 0.58 and 6.51 ± 0.58 min during the fasting and fed states, respectively ($P < 0.01$). The apparent distribution volume during the fasting state was 24% greater than plasma volume (4515 ± 308 vs. 3630 ± 78 mL, $P < 0.02$), consistent with significant margination of lipid emulsion particles to endothelial binding sites. Margination was reduced during the fed state, suggesting that native chylomicrons competed with lipid emulsion particles for endothelial lipoprotein lipase. The results indicate that a radiolabeled commercial lipid emulsion is metabolized in a fashion similar to native chylomicron TG, and thus can be used to study chylomicron TG kinetics.

Paper no. L8611 in *Lipids 36,* 115–120 (February 2001).

Chylomicrons are lipoproteins secreted by the intestine after fat ingestion and are thus the primary vehicle for lipid absorption. These particles, and especially their remnants, are thought to be major contributors to atherosclerosis since excessive postprandial lipemia is characteristic of patients at increased risk for myocardial infarction and stroke (1–5). Thus there is a growing need to understand the details of chylomicron metabolism.

Previous methods for determining chylomicron kinetics *in vivo* have been fraught with technical difficulties or used approaches of dubious physiological relevance. The ideal technique would be to inject endogenously labeled chylomicrons harvested from thoracic duct lymph (6), but this method has obvious limitations related to its invasiveness. Although an improvement, a duodenal fat perfusion test causes discomfort and requires fluoroscopic tube replacement (7,8). Others have used the intravenous fat tolerance test (8,9). This method alters triglyceride (TG) pool size, influences kinetic parameters (10), and has the potential to produce transient reticuloendothelial uptake of lipid (11). A radiolabeled lipid emulsion allows for an essentially massless injection with negligible pool perturbation. The noncommercial emulsion has been used with success (12–14) and is a reasonable approach. However, if a commercially available lipid emulsion could be easily labeled with a radioactive TG and injected, it could theoretically simplify the study of chylomicron TG metabolism in humans. The purpose of this study was to evaluate such a method.

## EXPERIMENTAL PROCEDURES

*Subjects.* Volunteers (ages 21–70 yr) were recruited who had body mass index of 22–30 kg/m$^2$, fasting serum low density lipoprotein (LDL) cholesterol concentrations less than 160 mg/dL, high density lipoprotein (HDL) cholesterol concentrations greater than 35 mg/dL, and TG concentrations less than 200 mg/dL. Individuals with known hepatic, renal, or gastrointestinal diseases, lactose intolerance, or those taking medications known to affect lipid metabolism or fat absorption were excluded. The study was approved by Saint Luke's Hospital Institutional Review Board, and informed, written consent was obtained from all participants.

*Protocol*. Subjects were provided with a low-fat meal (<30% energy from fat) the night before and asked to refrain from alcohol and strenuous exercise for 48 h before the test. They reported to the Metabolic Research Unit on the morning after an overnight (12 h) fast. Intravenous sampling cannula was place in a forearm vein and an injection cannulae in a contralateral vein; both were kept patent with infusions of 0.9% NaCl. Subjects consumed a priming dose (350 mg fat/kg) of a test drink made up of 87 parts of a 50:50 blend of cream and milk (Half and Half®) and 13 parts of chocolate syrup. Two hours later, they began to take a small portion of the drink every 15 min for the next 5.5 h in order to produce an overall fat ingestion rate of 175 mg·kg$^{-1}$·h$^{-1}$. The drink provided 25 kcal/kg (~68% of average daily allowance): 47%

as fat, 16% as protein, and 37% as carbohydrate. A commercial lipid emulsion (see below) containing 4 μCi [$^3$H]triolein (140 mg TG in 2 mL) was injected 30 min before, and 5, 6, and 7 h after ingestion of the priming dose. Thus, the emulsion was injected four times: once in the fasting state and three times in the fed state. Blood samples (6 mL each) were drawn at 0, 1, 3, 5, 7, 9, 13, 17, 20, and 30 min after each bolus injection.

*Laboratory methods. (i) Purification of lipid emulsion.* The 9,10-$^3$H(N)-triolein (30 μCi/200 μL in ethanol; American Radiolabeled Chemicals, St. Louis, MO) was added to 1 mL of 10% Liposyn® (Abbott Laboratory, Chicago, IL) in a sterile vial, and the solution was incubated for 5 min in a 60°C water bath. Preliminary experiments indicated that maximal incorporation occurred within this time frame. We found that a substantial fraction (~40%) of the radioactivity was incorporated into TG-poor, phospholipid (PL)-rich vesicles present in the emulsion to enhance stability (15). In order to isolate only the large, chylomicron-sized particles for injection, the labeled emulsion was subjected to high-performance liquid chromatography (HPLC; Millipore Waters, Milford, MA) with a TSK Guard PW1 and three size-exclusion TSK G5000 PWx2 columns (TOSO Haas, Montgomeryville, PA) in series (16). Preliminary experiments showed that this procedure was able to isolate a fraction containing particles *ca.* 0.34 μm in diameter (the size of chylomicrons) as measured by both dynamic light-scattering (16) and ratio of TG/PL (17). A 4-mL fraction was collected into 4 mL of unlabeled 10% Liposyn® to stabilize the purified emulsion. The mixture was then autoclaved for 15 min prior to injection (a procedure routinely used to sterilize commercial lipid emulsions). In the preliminary *in vivo* experiments, $C^{14}$-labeled and autoclaved lipid emulsion was injected simultaneously with unautoclaved $H^3$-labeled emulsion in a subject, and their clearance rates were compared. The half-lives of $C^{14}$- and $H^3$-labeled emulsion were 5.1 and 5.5 min, respectively. We concluded that autoclaving did not materially alter the kinetic behavior of TG particles. We also verified that there was no exchange of radioactivity from the purified, labeled TG-rich particles to the smaller TG-poor vesicles of the unlabeled emulsion (16).

*(ii) Lipid profile*. Plasma was analyzed for total cholesterol, TG and HDL cholesterol concentrations using a Cobas Fara II with enzymatic reagents from Boehringer Mannheim (Indianapolis, IN) (18); very low density lipoprotein (VLDL) and LDL cholesterol concentrations were estimated by the Friedewald equation (19). Whole plasma, adjusted chylomicron (see below), HDL, and LDL TG concentrations were used to estimate VLDL TG concentrations. We assumed that HDL and LDL TG concentrations were the same during the fasting and fed states. Chylomicron TG concentration was determined by gas chromatography as described previously (16) in order to increase our ability to detect the very low chylomicron TG concentrations in the fasting samples. Our laboratory participates in the CDC NIH lipid standardization program and the Excel program from Pacific Biomed (Seattle, WA).

*(iii) Chylomicron isolation.* To isolate chylomicrons, 2 mL of plasma was underlayered below 8 mL of distilled water in an ultracentrifuge tube and spun in an SW41 rotor for 30 min at 25,000 rpm in a Beckman L7-65 ultracentrifuge (16). This procedure was repeated two more times to remove as much VLDL as possible from the chylomicron fraction. Preliminary experiments in which the labeled purified lipid emulsion was mixed with plasma and then subjected to this triple-spin technique indicated that the recovery of chylomicrons averaged 30% with a coefficient of variation of <0.5%. This factor was used to calculate adjusted chylomicron TG concentrations.

*(iv) Radioactivity of chylomicrons.* Chylomicron fractions were transferred to vials containing 10 mL Opti-fluor (Packard, Meriden, CT) and counted in a Wallac 1410 liquid scintillation counter (Pharmacia, Gaithersburg, MD) using appropriate quench curves established for dual label counting. Background counts at zero minutes were subtracted from each data point for each of the four injections.

*(v) Margination volume.* Margination volume is defined as the difference between the apparent distribution volume and the actual plasma volume (20). A comparison of these two volumes is a reflection of the extent of margination, or endothelial binding of the lipid emulsion particles. To measure distribution volume using the labeled emulsion as the tracer, lipids were extracted from postinjection plasma (500 μL) after adding [$^{14}$C]triolein in 5 μL of ethanol as an internal standard (21). The lipid extracts were dried under nitrogen, and the $^3$H and $^{14}$C radioactivity was determined as described above.

*Calculations.* Chylomicron TG half-lives ($t^{1/2} = 0.693/k$) were estimated from the monoexponential radiolabeled lipid disappearance curves ($y = \alpha e^{-kx}$; Microsoft Excel, version 4.0). Plasma $^3$H concentration at the moment of injection (from which apparent distribution volume was calculated) was estimated by back extrapolation of the monoexponential curve to time zero. The following formulae were used to calculate:

$$\text{apparent distribution volume (mL)} = \frac{\text{total dpm of lipid emulsion injected}}{\text{plasma radioactivity extrapolated to the moment of injection (dpm/mL)}} \quad [1]$$

where margination volume (mL) = apparent distribution volume – plasma volume, and plasma volume (mL) = 31.47 × body weight (kg) + 627 (7).

*Statistical analysis*. We used Repeated Measures analysis of variance with Student Newman Keuls test to compare tracer-determined half-lives, TG concentrations, and distribution volumes during the fasting and the fed states. The relationship between half-lives and plasma TG concentration was analyzed using linear regression. A two-tailed $P$ value of <0.05 was required for statistical significance.

## RESULTS

There were two female and eight male subjects in the study. Age and body mass index (kg/cm$^2$) of two women were 32 and 43, and 27 and 30, respectively. Average age and body mass index of men were 39 ± 5 and 27 ± 1, respectively. Con-

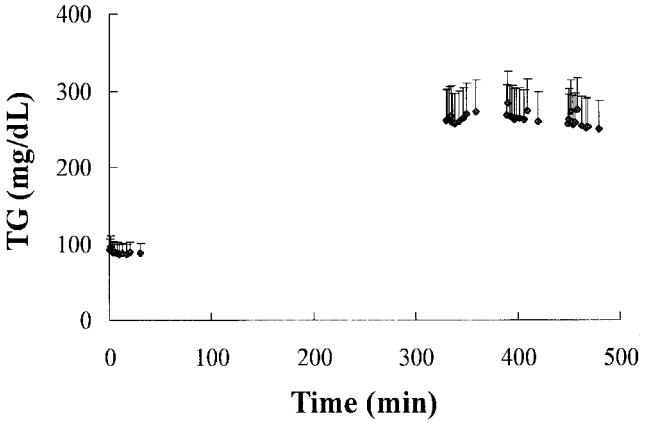

**FIG. 1.** Whole plasma triglyceride (TG) concentrations. Values are means ± SEM; $n = 10$.

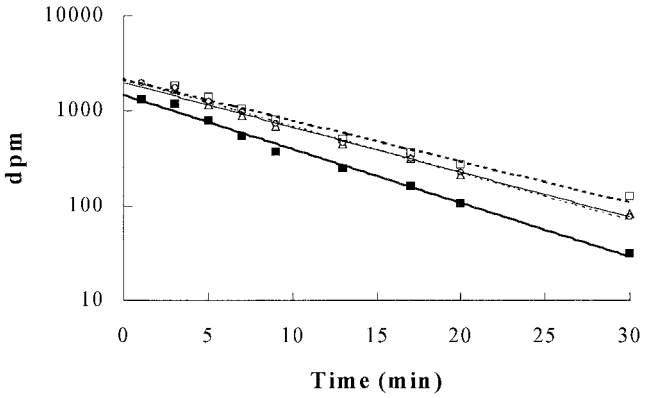

**FIG. 2.** Disappearance of lipid emulsion from chylomicron fraction during the fasting (—■—), and the fed states after injections one (---□---), two (—△—), and three (---○---). Monoexponential curves in logarithmic scale were $y = 1921.7e^{-0.1451x}$ ($R^2 = 0.9629$) during the fasting state, and $y = 2302.5e^{-0.1057x}$ ($R^2 = 0.9582$), $y = 2267.3e^{-0.1198x}$ ($R^2 = 0.9691$), and $y = 2345.1e^{-0.1235x}$ ($R^2 = 0.9781$) for the three injections during the fed state, respectively. $n = 10$.

centrations of fasting plasma LDL, HDL, and VLDL cholesterol were 103 ± 5, 39 ± 3, and 19 ± 3 mg/dL, respectively ($n = 10$). Fasting plasma TG concentrations at baseline were 89 ± 13 mg/dL and increased to 263 ± 43 mg/dL by the end of the study (Fig. 1). The unadjusted and adjusted chylomicron TG concentrations were 27.3 ± 11.7 and 91 ± 39 mg/dL during the fed state (Table 1). There were no significant differences on whole plasma, unadjusted and adjusted chylomicron, and VLDL TG concentrations between injections during the fed state, although there was a tendency for the 5-h chylomicron TG values to be higher than those at 6 and 7 h (Table 1).

Background counts before each injection were negligible (28 ± 8 dpm), consistent with the virtually complete removal of labeled TG after 30 min. Tracer-determined chylomicron TG half-lives were 22% longer when measured in the fed than in the fasting state ($P < 0.05$, Fig. 2 and Table 1). In addition, half-lives at the sixth and seventh hours were 13 and 19%, shorter, respectively, than those at the fifth hour ($P < 0.05$, Table 1). There was a positive correlation between estimated chylomicron TG half-lives and plasma TG concentrations during the fasting and the fed states (Fig. 3). Additionally, chylomicron TG half-lives were significantly correlated with VLDL TG concentration during the fasting state ($R^2 = 0.5452$, $P < 0.01$) and nearly during the fed states ($R^2 = 0.3482$, $P = 0.07$).

Apparent distribution volumes were calculated from the whole plasma (not chylomicron) clearance curves. Radiolabeled lipid emulsion disappeared more rapidly from whole plasma during the fasting than the fed states (Fig. 4). Apparent distribution volume was greater (24%, $P < 0.02$) than plasma volume in the fasting state, but was not different from plasma volume in the fed state (Fig. 5). There was also a significant (15%; $P < 0.02$) difference in apparent distribution volume between the fasting and the fed states. Margination volume was 2.4 times greater during the fasting than the fed states (885 ± 296 vs. 289 ± 217 mL; $P < 0.02$).

## DISCUSSION

We found that a labeled, commercial lipid emulsion produced estimates of chylomicron TG half-lives similar to those ob-

served using more complex methods (6–8). Consistent with this are the margination data, which suggest that lipid emulsion particles compete with endogenous chylomicrons for binding to endothelial lipoprotein lipase (LpL). These two findings support the hypothesis that this preparation can serve as a tracer for chylomicron TG catabolism.

Over 35 years ago, Nestel *et al.* (6) infused harvested human chylomicrons and estimated chylomicron half-lives to be 5 to 8 min. Grundy and Mok (7) and Cohen (8) confirmed this estimate using a duodenal fat perfusion test. Since duodenal intubation may alter normal gastrointestinal physiology and can be unpleasant for the subject, we chose to utilize a chronic "sipping" procedure. We found that this more physiologic approach did achieve its goal of producing a relative steady-state hypertriglyceridemia (16) and was much less stressful for the subjects.

Since our radioactively labeled, commercial intravenous lipid emulsion had earlier been shown to accurately estimate chylomicron TG rate of appearance (16), it followed that it would also trace chylomicron TG catabolism. Previous attempts to use a bolus of unlabeled lipid emulsion produced estimates of chylomicron TG half-life 100% (9) to 200% (8) longer than that of native chylomicron TG. Compared to an unlabeled emulsion, a bolus injection of a trace amount of radiolabeled emulsion allows the administration of much less mass with less perturbation of the system. Other studies using labeled noncommercial emulsions have been useful in tracing not only chylomicron TG but also chylomicron particle clearance rates by labeling with both TG and cholesteryl esters. Using such emulsions, Nakandakare *et al.* (12) estimated the chylomicron TG residence time to be 5.9 min and Maranhão *et al.* (22) reported a chylomicron TG half-life of 6.6 min in rats. These results are similar to data from harvested chylomicrons (6,23) and duodenal fat perfusion studies (7,8). A similar observation was made in the present study using a labeled commercial emulsion. Plasma TG concentrations were unaltered after each bolus injection (since only 140 mg of TG was injected each time), and thus multiple injections of the labeled lipid emulsion are possible. In this setting, half-lives during the fed and the fasting states were 6.5 and 5.3 min, respectively.

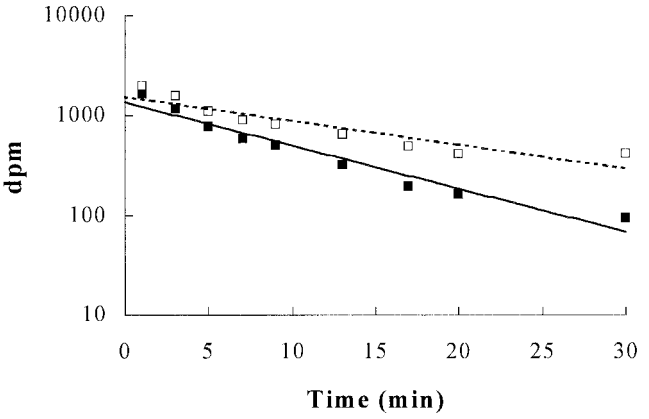

**FIG. 4.** Disappearance of lipid emulsion from whole plasma during the fasting (—■—) and the fed states (---□---); average of three tests. Monoexponential curves in logarithmic scale were $y = 1463.6e^{-0.1368x}$ ($R^2 = 0.9447$) during the fasting state and $y = 1574.6e^{-0.0766x}$ ($R^2 = 0.9189$) during the fed state. $n = 10$.

Hultin *et al.* (24) found that a labeled lipid emulsion was cleared 35–40% more slowly than native chylomicrons in rats. Slow clearance of emulsion particles in that study could also be explained by the presence of PL-rich vesicles which have been shown to inhibit lipolysis of TG-rich particles *in vivo* (25) and *vitro* (26). During emulsion production, PL is added in excess as a stabilizer. Preliminary studies with our emulsion confirmed that a substantial fraction of radiolabeled triolein (40%) added to the emulsion was associated with these vesicles (16). Since these particles can accumulate in the plasma after infusion (15), their kinetic behavior may differ from that of the large, TG-rich particles; thus they should be removed prior to injection if the kinetics of chylomicron TG is to be traced. It is also important that the particles in the infused emulsion be of similar size to chylomicrons because the affinity of LpL for TG-rich lipoproteins is influenced by particle size (27). Both of these goals were achieved using HPLC as described.

Preparation of a noncommercial emulsion requires special homogenization and multiple centrifugations to isolate the

proper-sized particles. Although the present method does not require these, it does require an HPLC system to obtain the proper particles for injection. Thus, both approaches have their own technical challenges.

Chylomicron TG half-lives are clearly influenced by background TG concentrations. Since LpL is saturable, one would expect a prolongation of half-life at higher TG concentration (28,29). Accordingly, we found that chylomicron TG half-lives were 22% longer during the fed than during the fasting state. In addition, there was a positive relationship between chylomicron TG half-lives and plasma TG concentrations (Fig. 3), and half-lives tended to plateau after TG levels of 300 mg/dL were reached. These observations suggest that the labeled particles in the commercial lipid emulsion used in our studies behave like nascent chylomicron particles.

We observed that chylomicron TG half-lives appeared to decrease during the latter portion of feeding protocol, between hours 5 and hours 6 and 7. Since we have no reason to believe that fat absorption was slower at 5 h than at 7 h, the decreasing chylomicron TG levels at the latter suggest that LpL activity may have been slowly increasing, possibly because more enzymes had been exposed on the endothelium, the affinity of existing LpL for its substrate had increased, or blood flow in LpL-rich tissues had increased. Karpe *et al*. (30) reported that preheparin (circulating) LpL activity was doubled 6 h after consuming an oral fat load and correlated as expected with an increase of serum free fatty acids (31). An alternative mechanism may involve the lipolysis-stimulated receptor which binds TG-rich lipoproteins when activated by free fatty acids generated locally by chylomicron TG hydrolysis (32). Further studies will be needed to explore this possible increase in lipolytic potential with prolonged feeding and the mechanisms behind it.

There is controversy as to whether the rise in plasma TG concentration following the ingestion of fat is due to chylomicrons or/and VLDL (33,34). Schneeman *et al*. (35) reported that 80% of the postprandial increase of TG-rich lipoprotein particle number is accounted for by VLDL, whereas 80% of the postprandial TG is carried by chylomicrons (36). In the present study, the postprandial TG increase was due to both chylomicrons and VLDL (90 and 81 mg/dL, respectively).

In an effort to explore other possible similarities between native chylomicrons and our emulsion, we determined margination volumes in the fasting and the fed states. We found that the apparent distribution volume in the fasting state was 24% greater than the plasma volume. Karpe *et al*. (20) reported that apparent distribution volume was 67% greater than plasma volume using plasmapheresis-derived, TG-rich lipoproteins ($S_f > 400$). They proposed that this was due to margination of TG-rich particles to endothelial LpL. The larger the difference between the apparent volume and the true plasma volume, the greater the vascular binding capacity (what we have called "margination volume"). The observation that there was no significant difference between the apparent distribution volume and plasma volume during the fed state is consistent with the presence of saturable endothelial binding sites. In other words, margination volume was small (i.e., LpL binding sites were few) when nascent chylomicrons were present. This suggests that when LpL binding sites are occupied by chylomicrons during steady-state absorption of a fat meal, intravenous lipid emulsion particles are unable to bind. This is consistent with the observation that an acute infusion of lipid emulsion after injection of retinyl palmitate-labeled chylomicrons induces a rapid release of chylomicrons from endothelial binding sites (20).

In summary, we found that a radiolabeled, commercial intravenous lipid emulsion was metabolized in a fashion similar to native chylomicrons. This conclusion is supported by three observations: (i) we found similar TG half-lives as have others using native chylomicrons; (ii) lipid emulsion TG half-lives were slower when chylomicrons were present; and (iii) margination volumes were reduced in the presence of chylomicrons. This technique could be useful in future studies investigating the effects of diets (high vs. low fat, different fatty acid compositions, fiber, etc.), drugs (pancreatic lipase inhibitors, bile acid reuptake receptor blockers, etc.), disease (obesity, diabetes, coronary heart disease, gastrointestinal disease, etc.), and physiological perturbations (exercise, pregnancy, lactation, aging, etc.) on chylomicron TG clearance.

# Major Clofibrate Effects on Liver and Plasma Lipids Are Independent of Changes in Polyunsaturated Fatty Acid Composition Induced by Dietary Fat

**Graciela L. Pennacchiotti*, Eduardo N. Maldonado, and Marta I. Aveldaño**

Instituto de Investigaciones Bioquímicas de Bahía Blanca, Consejo Nacional de Investigaciones Científicas y Técnicas y Universidad Nacional del Sur, 8000-Bahía Blanca, Argentina

**ABSTRACT:** The effects of clofibrate on the content and composition of liver and plasma lipids were studied in mice fed for 4 wk on diets enriched in n-6 or n-3 polyunsaturated fatty acids (PUFA) from sunflower oil (SO) or fish oil (FO), respectively; both oils were fed at 9% of the diet (dry weight basis). Only FO was hypolipidemic. Both oil regimes led to slightly increased concentrations of phospholipids (PL) and triacylglycerols (TG) in liver as compared with a standard chow diet containing 2% fat. Clofibrate promoted hypolipidemia only in animals fed SO. Its main effect was to enlarge the liver, such growth increasing the amounts of major glycerophospholipids while depleting the TG. SO and FO consumption changed the proportion of n-6 or n-3 PUFA in liver and plasma lipids in opposite ways. After clofibrate action, the PUFA of liver PL were preserved better than in the absence of oil supplementation. However, most of the drug-induced changes (e.g., increased 18:1n-9 and 20:3n-6, decreased 22:6/20:5 ratios) occurred irrespective of lipids being rich in n-6 or n-3 PUFA. The concentration of sphingomyelin (SM), a minor liver lipid that virtually lacks PUFA, increased with the dietary oils, decreased with clofibrate, and changed its fatty acid composition in both situations. Thus, oil-increased SM had more 22:0 and 24:0 than clofibrate-decreased SM, which was significantly richer in 22:1 and 24:1.

Paper no. L8485 in *Lipids 36,* 121–127 (February 2001).

In rodents, the administration of clofibrate and of a wide range of structurally diverse compounds causes liver peroxisomes, mitochondria, and endoplasmic reticulum to proliferate in hepatic parenchymal cells (1–3). Treatment with these xenobiotics also leads to alteration in the level of expression of many enzymes, including peroxisomal and mitochondrial β-oxidation proteins (4), some enzymes involved in the microsomal synthesis of lipids (5) and fatty acids (6), and hydrolases, such as the carboxylesterases, capable of hydrolyzing lipophilic substances with ester, thioester, and amide groups (7). Most of these changes may in fact play a role in successful detoxification. Peroxisomal proliferators are known to act by binding to a receptor protein, a ligand-activated transcription factor being responsible for intensifying the transcription of specific nuclear genes (8). Sustained treatment with these drugs in high doses promotes liver hypertrophy and hyperplasia and may eventually lead to the development of tumors (9). Our previous work, focusing specifically on the lipids (10), showed that the enlargement induced in mouse liver by clofibrate was accompanied by an increase in the amount, though not in the concentration, of liver glycerophospholipids and a decrease in both the amount and the concentration of triacylglycerols (TG). Although the fatty acid composition of the newly formed phospholipids (PL) was less affected than that of TG, both had reduced percentages of polyunsaturated fatty acids (PUFA), especially those of the n-3 series, with respect to controls. The PUFA of liver TG were apparently consumed in the process of supporting the stimulated PL synthesis, but still were insufficient to provide for the increased energetic and biosynthetic demands imposed by the drug-induced cell growth and proliferation. It was suggested that the chow diet (CD), although adequate for most purposes, in this case may have been short of n-3 PUFA. In the present work we investigate the effects of clofibrate in mice whose liver and plasma lipids were considerably enriched in n-3 or n-6 PUFA.

## EXPERIMENTAL PROCEDURES

Male albino mice of the Balb-C strain, weighing 32 ± 2 g, were kept under standard laboratory conditions for 4 wk, and divided into SO (sunflower oil) and FO (fish oil) groups. An additional group of animals receiving a standard rodent chow diet (CD), containing 2% fat, was used for comparison. Each group consisted of five animals, of which four were analyzed. The experimental diets consisted of 23.2% protein, 62.8% carbohydrates, 4.9% vitamin and mineral supplements, and 9.1% of the corresponding oil, on a dry weight basis. From day 15 onward, half the animals from the SO and FO groups continued with their regimes, and the other half were fed the same diet but with the addition of clofibric acid (Sigma Chemical Co., St. Louis, MO), 0.5 g per 100 g of food (10). The protocol for the study conformed to accepted standards of animal care and experimental procedures. The fatty acid

Abbreviations: CD, chow diet; CE, cholesterol esters; DPG, diphosphatidylglycerol; FO, fish oil; GC, gas chromatography; MFA, monounsaturated fatty acids; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PL, phospholipids; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids; SM, sphingomyelin; SO, sunflower oil; TG, triacylglycerols; TLC, thin-layer chromatography.

composition of CD, SO, and FO, in that order, was as follows: saturated fatty acids (SFA): 19.3, 14.1, and 25.8%; monounsaturated fatty acids (MFA): 22.4, 22.0, and 29.6%; n-6 PUFA: 57.9, 63.8, and 13.7%; and n-3 PUFA: 0.4, 0.1, and 30.9%, respectively. Taking into account the amount of fat in each diet, and the above fatty acid percentages, the content (w/w) of n-3 PUFA was similar in CD and SO (~0.8%), whereas the content of n-6 PUFA was similar in CD and FO (~1.2%). At day 30 the animals were killed after having been anesthetized with acepromazine and ketamine. Blood samples were obtained by cardiac puncture, collected using heparinized material, and centrifuged to separate plasma from blood cells. The livers were removed, rinsed in saline, weighed, cut into pieces, and homogenized in the solvents used for lipid extraction.

Plasma lipids were determined with commercial kits and the standard techniques used in clinical settings for human plasma. Lipid extracts were prepared from liver and plasma (11), and total lipid phosphorus was determined. Neutral lipids were separated by thin-layer chromatography (TLC) on silica using hexane/ether/acetic acid (80:20:2, by vol). The PL, TG, and cholesterol ester (CE) bands were scraped off after being located with dichlorofluorescein, and eluted (12). Liver PL were resolved into classes by TLC (13) and quantified by phosphorus measurement (14). For sphingomyelin (SM) fatty acid analysis, this lipid was isolated by TLC (15), eluted (12), dried under $N_2$, treated with 0.5 N NaOH in methanol at 50°C for 10 min, and subjected again to TLC. This ensured that SM was free of any possible contamination with traces of glycerophospholipids.

Fatty acids of all lipids were analyzed by standard gas chromatography (GC) of their fatty acid methyl esters on packed columns (10). Before GC, the methyl esters prepared from lipids were purified by TLC using hexane/ether (95:5, vol/vol) on silica plates that had been pre-washed with methanol/ether (75:25, vol/vol), and were recovered from the support by partition between water/methanol/hexane (1:1:2, by vol). Statistical analysis of the results was performed using the two-tailed Student's *t* test.

## RESULTS AND DISCUSSION

*Liver and plasma lipid concentrations.* Against our expectations, and despite the substantial amount of fat ingested on a long-term basis by our animals fed on both PUFA-rich diets, SO and FO, there was no proportional change in liver lipid content (Table 1). Both dietary oils resulted in unchanged body weight, and the small increase in liver weight was significant only when expressed in terms of the liver/body weight ratio. By contrast, the administration of clofibrate to animals receiving either SO or FO promoted a significant liver enlargement, similar in percentage to that previously reported in animals receiving CD, without affecting body weight (10).

[a]Plus and minus signs indicate the presence or absence of clofibrate. Results are presented as mean values ± SD ($n$ = 4 animals per group). CD, chow diet; SO, sunflower oil; FO, fish oil.
[b]Significant differences due to change in diet (SO or FO vs. CD; $P < 0.05$).
[c]Significant differences due to dietary oil type (SO vs FO; $P < 0.05$).
[d]Significant differences due to clofibrate (SO or FO without, vs. SO or FO with, clofibrate; $P < 0.05$).

The total amount of PL per liver was augmented slightly with the SO and FO diets, but increased considerably upon addition of clofibrate to the diets irrespective of oil type (Table 1). Since liver PL and liver weight increased simultaneously, the resultant PL concentration per gram of tissue was unchanged by the drug. In contrast, the amount and the concentration of TG increased after 1 mon on both PUFA-rich diets. The TG increase was modest, especially considering that irrespective of this enrichment, the TG were dramatically depleted by clofibrate treatment (Table 1). The diacylglycerols did not change in any of the experimental conditions. The CE, unaffected by dietary oils, were also reduced by clofibrate, whereas free cholesterol did not change.

In plasma, the concentrations of PL, TG, and total cholesterol, which were not affected by dietary SO, were decreased by FO supplementation (Table 1). Conversely, clofibrate did not much affect the lipids already reduced by FO, but it decreased plasma TG and cholesterol in animals receiving SO. In both diets clofibrate decreased high density lipoprotein-cholesterol.

The TG depletion induced by clofibrate may be ascribed to drug-induced changes that demand and consume fatty acids, such as peroxisomal and mitochondrial biogenesis to provide for drug substrate oxidation, or microsomal membrane formation to provide for conjugation; in turn, these processes cause hypertrophy. The latter, and the hyperplasia that ensues upon prolonged drug treatment, are processes that require PL and fatty acids. By having their fatty acids assist as substrates for oxidative and synthetic processes, liver TG may support PL formation and liver enlargement. A possible explanation for the failure of our high-fat diets to increase liver TG more than a few mg/g in the presence of unchanged body weight and unchanged or even decreased lipid plasma levels may be that the excess dietary fat may have modified the way the body metabolized fat. Even when tissue PL admit a given amount of n-6 or n-3 exogenous PUFA, the prolonged excess of these fatty acids may have resulted in the stimulated oxidation of the own fat provided. This possibility is supported by the fact that, in rats, the number of peroxisomes and mitochondria and the rates of β-oxidation increase under high-fat diets especially those containing a high n-3/n-6 PUFA ratio (16).

*Fatty acids of liver and plasma lipids.* The fatty acid profiles of principal lipids from liver and plasma (Table 2) were notably influenced by the type of oil given in the diet and by clofibrate. The effects of the two dietary oils tended to affect the n-6/n-3 PUFA ratios in opposite ways. The most marked qualitative changes were produced in the fatty acids of TG. In liver, SO or FO resulted in increased percentages of n-6 or n-3 PUFA, which partly replaced the major TG component, 18:1n-9. In turn, the most conspicuous outcome of clofibrate administration was that it decreased TG PUFA. Since TG levels were substantially reduced by the drug treatment (Table 1), it caused a greater decrease in the polyunsaturated than in the other acyl groups of TG. This was accompanied by a significant clofibrate-related increase in the percentage of 18:1n-9, to the point where this fatty acid again became the major TG acyl group.

The fatty acid composition of mouse liver and plasma CE (Table 2) and the changes induced by diet and clofibrate on such fatty acids are not extensively known. The content of liver CE was small, and low in PUFA; compared with the other lipids it was modified little in amount or fatty acid composition by the dietary manipulations. On the contrary, the abundant plasma CE changed from an n-6 to an n-3 fatty acid-rich lipid class as a consequence of dietary FO, the major circulating CE fatty acid becoming 20:5n-3 instead of 20:4n-6. Clofibrate tended to affect EC and its fatty acids in the same direction as those of TG.

In FO-consuming mice, while liver clofibrate-wasted TG were selectively depleted of PUFA, the major PUFA profiles of the enlarged PL fraction remained quite similar to those of their controls. This observation contrasts with previous results in which the mass of PL formed after clofibrate action was relatively impoverished in n-3 PUFA (10) and agrees with the interpretation that CD, even when not n-3 PUFA-deficient, was insufficient to provide for the stimulated PL biosynthesis imposed by the proliferator.

The increase in the percentage of 18:1n-9 in TG and in PL may be related to the fact that, like other peroxisomal proliferators, clofibrate induces hepatic stearoyl CoA desaturase (2, 16) among many other enzymes. Recent studies have shown that clofibrate increases, whereas PUFA decrease, the level of activity and the mRNA content of 9-desaturase (17). Another general change induced by clofibrate is a significant increase in the percentage of 20:3n-6 (Table 2), leading to a markedly increased 20:3n-6/20:4n-6 ratio in all lipids analyzed but especially in liver PL. With the present diets, the 22:4n-6/22:5n-6 and the 22:5n-3/22:6n-3 ratios in liver PL are increased by clofibrate just as in previous work (10), suggesting an action of the drug on PUFA desaturases. The administration of clofibrate thus resulted in qualitative changes in specific fatty acids that were independent of the type of PUFA predominating in the diet.

*Liver phospholipid classes and their fatty acids.* In plasma, dietary FO decreased total PL. Since this reduction mostly affected PC, the proportion of other circulating PL, including SM, increased with no apparent changes in concentration (data not shown). Clofibrate did not affect this situation, the plasma PL composition remaining similar to that in the corresponding SO or FO controls. In liver (Table 3), some small but significant differences in PL proportions were observed that indicated effects of dietary oils on specific lipid classes. Thus, SO and FO ingestion resulted in a different percentage of PC (48.0 ± 1.1 to 43.0 ± 1.7%, respectively) with an unchanged percentage of PE, and hence in slightly different phosphatidylcholine/phosphatidylethanolamine (PC/PE) ratios (1.8 ± 0.1 to 1.5 ± 0.2, respectively). An interesting effect of SO and FO was that both tended to increase liver diphosphatidylglycerol (DPG) and SM relatively more than other PL, the increase in DPG being similar with both oils and that of SM being larger for FO. In the presence of clofibrate

[a]Values are weight percent, as mean values ± SD ($n$ = 4 animals per group). SFA, saturated fatty acids; MFA, monoenoic fatty acids; PUFA, polyunsaturated fatty acids; for other abbreviations and for explanation of +/– signs see Table 1.
[b]Significant differences due to change in diet (SO or FO vs. CD; $P < 0.05$).
[c]Significant differences due to dietary oil type (SO vs. FO; $P < 0.05$).
[d]Significant differences due to clofibrate (SO or FO without, vs. SO or FO with, clofibrate; $P < 0.05$).

in both diets, the major hepatic glycerophospholipid classes (PC, PE, phosphatidylserine and phosphatidylinositol) increased to a similar extent in response to the growth imposed by the proliferator (Table 3), with respect to their corresponding controls. In contrast, the proportion of liver DPG, and even more markedly that of SM, tended to decrease with clofibrate, showing that the amount of these components increased less than that of other PL, or even decreased. SM was the only liver lipid whose concentration (Table 4) was significantly reduced in liver by clofibrate under both diets.

The increase in liver DPG may be correlated to the proliferation of mitochondria (16) that is induced by excessive

[d]Significant effects of clofibrate ($P < 0.05$).

PUFA consumption, since this glycerophospholipid is a well-known component of the inner mitochondrial membrane. Our DPG, which was exceedingly rich in 18:2n-6, admitted even more n-6 and a considerable amount of n-3 PUFA with the intake of SO or FO diets, respectively, while reducing the percentage of its monounsaturated fatty acids, mainly 18:1 and 16:1 (not shown). These diet-induced compositional changes could influence mitochondrial enzyme activity. Clofibrate affected the fatty acid composition of DPG as in other lipids, decreasing the percentage of PUFA and increasing that of 18:1n-9.

The fatty acid profile of liver SM (Table 4) was significantly affected by the consumption of both PUFA-rich diets, which resulted in an increase in SM very long chain SFA such as 22:0 and 24:0. By contrast, in clofibrate-treated mice there was a marked decrease in the percentage (and hence in the concentration) of the major SFA of SM; instead, very long chain MFA such as 22:1 and 24:1 became principal acyl chains.

The selective reduction of SM with clofibrate had also been observed in the absence of oil supplementation (10). More recently, several peroxisomal proliferators including clofibrate have been shown to increase liver PC and PE, while decreasing SM in rat liver (18) in agreement with our results. To our knowledge, the only previous report showing that the intake of PUFA can affect the fatty acids of liver SM is that by Bettger *et al.* (19). The mechanism(s) involved and the possible physiological effects of such diet-induced SM modification are still unknown. The fact that clofibrate affects the ratios between very long chain saturated and monoenoic very long chain fatty acids of SM had also been observed in animals fed the CD (10). Thus, this effect of clofibrate does not depend on the amount or type of fatty acids provided in the diet.

The diet-induced SM increase may arise from stimulated synthesis or inhibited degradation of this phospholipid, and conversely, the clofibrate-induced SM decrease may be the result of inhibited synthesis or activated degradation. The possibility that clofibrate affects enzymes involved in SM degradation is exciting, since ceramide and sphingosine are well-known regulators of protein kinase C and therefore mediators of important cell functions including proliferation, differentiation, and death (20). Clofibrate has been shown to inhibit apoptosis in liver (21). A potential consequence of the clofibrate-induced decrease in SM could be the generation of SM metabolites that could be responsible for the inordinate cell proliferation induced by the drug.

Since SM is a ubiquitous lipid, the cellular and subcellular locations of the contrasting effects of dietary oils and clofibrate need to be established. A possible relationship between SM changes and nuclear PL is worth investigating, since SM is an important lipid component of liver nuclear chromatin (22) and nuclear membrane (23). Neutral sphingomyelinase has also been characterized in liver hepatic chromatin fractions and nuclear membranes, and shown to be stimulated after the typical hepatocyte regeneration/proliferation induced by hepatectomy (24,25), a process that is comparable to the clofibrate-induced liver mass expansion seen in the present work.

## ACKNOWLEDGMENTS

We wish to express our appreciation to Dr. Héctor Corsetti, from Raffo Laboratories, S.A., Argentina, who kindly provided the salmon liver oil used in this study. This work was supported by grants from CONICET, SGCyT-UNS, and FONCYT, Argentina. E.N.M. is a research fellow from the Colegio de Veterinarios, Provincia de Buenos Aires, Argentina.

# Low Density Lipoprotein Receptor mRNA in Rat Liver Is Affected by Resistant Starch of Beans

**Michihiro Fukushima[a,*], Tetsu Ohashi[a], Michiyuki Kojima[a], Kiyoshi Ohba[b], Hideki Shimizu[b], Kei Sonoyama[c], and Masuo Nakano[a]**

[a]Department of Bioresource Science, Obihiro University of Agriculture and Veterinary Medicine, Obihiro, Hokkaido 080-8555, Japan, [b]Hokkaido Tokachi Area Regional Food Processing Technology Center, Obihiro, Hokkaido 080-2462, Japan, and [c]Laboratory of Food Biochemistry, Division of Applied Bioscience, Graduate School of Agriculture, Hokkaido University, Sapporo, Hokkaido 060-8589, Japan

**ABSTRACT:** The effects of resistant starches of beans on serum cholesterol and hepatic low density lipoprotein (LDL) receptor mRNA in rats were investigated. Rats were fed a cholesterol-free diet with 150 g/kg corn starch (CS), 150 g/kg adzuki (*Vigna angularis*) starch (AS), 150 g/kg kintoki (*Phaseolus vulgaris*, variety) starch (KS), or 150 g/kg tebou (*P. vulgaris*, variety) starch (TS) for 4 wk. There were no significant differences in body weight among groups through the experimental period. The liver weight in the CS group was 1.1–1.2 times higher than that in the AS, KS, and TS groups. The cecum weight in the TS was 1.4 times higher than that in the CS group, and the cecal pH in the CS group was significantly higher than in the other groups. The serum total cholesterol, very low density lipoprotein + intermediate density lipoprotein + LDL-cholesterol and high density lipoprotein (HDL)-cholesterol concentrations in the bean starch groups were significantly lower than those in the CS group through the feeding period. The total cholesterol/HDL-cholesterol ratio in the bean starch groups was also significantly lower than that in the CS group at the end of the 4-wk feeding period. The hepatic cholesterol concentration in the TS group was significantly higher than in the CS group at the end of the 4-wk feeding period. The relative quantity of hepatic apo B mRNA in the AS group was 1.2 times higher than that in the CS group, and the hepatic LDL receptor mRNA levels in the AS and TS groups were 1.8–2.0 times higher than that in the CS group. The results of this study demonstrate that AS, KS, and TS lowered the serum total cholesterol level by enhancing the hepatic LDL receptor mRNA level.

Paper no. L8531 in *Lipids 36*, 129–134 (February 2001).

The possibility of lowering plasma cholesterol concentration by interfering with the absorption of cholesterol or bile acids has been extensively investigated using either compounds of natural origin (e.g., gel-forming fibers, resistant starch, phytosterols, and saponins) or synthetic sequestrants such as cholestyramine (1). Fiber is known to be a nonnutritional substrate. On the other hand, starch is generally the major constituent of the human diet and has long been regarded to be almost entirely digested in the upper part of the digestive tract. Soluble fibers are generally broken down by large intestine microflora, and the resulting production of short-chain fatty acids (SCFA) may be involved in the metabolic effects of fibers (2). Resistant starch is also broken down by the colonic microflora, essentially to SCFA, which allows the recovery of a part of the chemical energy by the host. Rats fed resistant starch had significantly lower plasma cholesterol (–32%) and triglyceride (–29%) concentrations than control rats fed a wheat starch diet or rats fed a cholestyramine diet (3). SCFA may be involved in lowering serum cholesterol concentration (4).

Sonoyama *et al.* (5) reported that the plasma cholesterol concentration was significantly lower in rats fed sugar beet fiber than in those fed fiber-free or cholestyramine diets, and this difference was due mainly to a lower high density lipoprotein (HDL)-cholesterol concentration. Fukushima *et al.* (6) also reported that serum very low density lipoprotein (VLDL) + intermediate density lipoprotein (IDL) + low density lipoprotein (LDL)-cholesterol concentration was significantly lower in rats fed mushroom fiber and sugar beet fiber than in rats fed a cellulose fiber diet, and the hepatic LDL receptor mRNA level in the mushroom fiber and sugar beet fiber groups was significantly higher than that in the cellulose group. It was reported that resistant starch was more effective in lowering plasma HDL-cholesterol and LDL-cholesterol concentrations (3). However, the mechanism is not fully understood. In this study, we examined the effects of diets containing adzuki (*Vigna angularis*) starch, kintoki (*Phaseolus vulgaris*, variety) starch, and tebou (*P. vulgaris*, variety) starch on serum lipids, liver lipids, and hepatic mRNA.

## MATERIALS AND METHODS

*Animal and diets.* Male F344/DuCrj rats (8-wk old) were purchased from Charles River Japan Inc. (Yokohama, Japan). All animals were housed individually in cages on a 12-h light/dark cycle. Temperature and humidity were controlled at 23 ± 1°C and 60 ± 5%, respectively. The rats were divided into four groups of six animals each by randomization. There were no significant differences in body weights and serum total cholesterol concentrations between groups at the start of

the experimental period. The composition of each diet is shown in Table 1. Each starch was retrograded after each type of bean was boiled. The experimental groups were fed for 4 wk one of the following diets that contained 150 g/kg of adzuki starch (AS), kintoki starch (KS), and tebou starch (TS). The compositions of AS, KS, and TS (g/100 g) were as follows: moisture, 2.7, 1.4, and 2.7; total dietary fiber, 7.7 (insoluble fiber, 7.6; water-soluble fiber, 0.1), 16.6 (insoluble fiber, 15.9; water-soluble fiber, 0.7) and 23.5 (insoluble fiber, 23.1; water-soluble fiber, 0.4); protein (N × 6.25), 4.9, 4.3, and 4.2; lipid, 0.1, 0.2 and 0.2; carbohydrate, 81.5, 74.4, and 65.6; ash, 3.1, 3.1, and 3.8, respectively. Total dietary fiber, insoluble fiber, water-soluble fiber, protein, lipid, carbohydrate, moisture, and ash were determined by AOAC procedures (7). The control group consisted of rats fed 150 g/kg of corn starch (CS). The adzuki, kintoki, and tebou beans were kindly provided by the Hokkaido Tokachi Area Regional Food Processing Technology Center, Obihiro, Hokkaido, Japan. The rats were allowed free access to experimental diets and water for 4 wk. Body weight and feed consumption were recorded weekly and every day, respectively. All animal procedures described conformed to standard principles in *Guide for the Care and Use of Laboratory Animals* (8).

*Analytical procedures.* Blood samples (1 mL) were collected between 0800 and 1000 h from the jugular veins of fasting rats. The samples were taken into tubes without an anticoagulant. After the samples stood at room temperature for 2 h, serum was prepared by centrifugation at 1500 × *g* for 20 min. At the end of the experimental period of 4 wk, all fecal excretion during 2 d was collected. Fecal dry weights did not significantly differ among groups. The rats were killed by ether inhalation, and the livers and cecum quickly removed, washed with cold saline (9 g NaCl/L), blotted dry on filter paper, and weighed before freezing for storage.

*Chemical analysis.* Total cholesterol, HDL-cholesterol, and triglyceride (TG) concentrations in the serum were determined enzymatically using commercially available reagent kits (assay kits for the TDX system; Abbott Laboratory Co., Irving, TX). The VLDL + IDL + LDL-cholesterol concentration was calculated as follows: VLDL + IDL + LDL-cholesterol = total cholesterol – HDL-cholesterol.

Total lipids were extracted from liver and feces by a mixture of chloroform/methanol (2:1, vol/vol) (9). The neutral sterol in each total lipid obtained by saponification was acetylated (10) and analyzed by gas–liquid chromatography (GLC) using a Shimadzu 14A chromatograph (Kyoto, Japan) with a DB17 capillary column (0.25 mm × 30 m; J&W Scientific, Folsom, CA) with nitrogen as the carrier gas. Acidic sterols in feces were measured by GLC following the method of Grundy *et al.* (11). A part of the cecum was taken out into desalting water in a vial without exposure to air, and suspended. The suspension of cecum was deproteinized with perchloric acid (final concentration 50 g/L) cooled in ice, and the supernatant was added to a NaOH solution to precipitate perchloric acid and to form sodium salts of the SCFA. Individual SCFA was measured by GLC with a glass column (2000 × 3 mm) packed with 80–100 mesh Chromosorb W-AW DMCS with $H_3PO_4$ (100 mL/L) as the liquid phase after adding $H_3PO_4$ by the procedure of Hara *et al.* (12).

*RNA isolation, reverse transcription-polymerase chain reaction (RT-PCR), and Southern blot analysis.* Total RNA was isolated by the acid guanidium/phenol/chloroform method, using Isogen (Nippon Gene, Tokyo, Japan) from liver (13). mRNA encoding apolipoprotein (apo) B, LDL receptor, and glyceraldehyde-3-phosphate dehydrogenase (GAPDH, used as an invariant control) was analyzed by semiquantitative RT-PCR and subsequent Southern hybridization of the PCR products with each inner oligonucleotide probe. Total RNA samples were treated with DNase RQ1 (Promega, Madison, WI) to remove genomic DNA and subjected to RT-PCR by using Moloney murine leukemia virus reverse transcriptase (GIBCO, Gaithersburg, MD) and EX-Taq polymerase (Takara, Tokyo, Japan) with apo B primers of oligonucleotides (upstream primer, 5′-GAAAGCATGCTGAAAACAACC-3′; downstream primer, 5′-AGGCCTGACTCGTGGAAGAA-3′), LDL receptor primers of oligonucleotides (upstream primer, 5′-ATTTTGGAGGATGAGAAGCAG-3′; downstream primer, 5′-CAGGGCGGGGAGGTGTGAGAA-3′), and GAPDH primers of oligonucleotides (upstream primer, 5′-GCCATCAACGACCCCTTCATT-3′, downstream primer, 5′-CGCCTGCTTCACCACCTTCTT-3′). The reaction mixtures for the PCR contained 25 pmol of each primer, 1.25 U EX-Taq polymerase, 1 × PCR buffer (Takara), and 200 mM deoxynucleoside 5′-triphosphates in a 50 μL reaction volume. The expected sizes of DNA fragments amplified with these primers were 725 bp for apo B, 931 bp for the LDL receptor, and 702 bp for GAPDH. Temperature cycling was as follows: first cycle, denaturation at 94°C for 3 min, annealing at 60°C for 1 min, and extension at 72°C for 2 min. Subsequent cycles were denaturation at 94°C for 1 min, annealing at 60°C for 1 min, and extension at 72°C for 2 min. The thermal cycling was completed by terminal extension at 72°C for 10 min. In total, 25 cycles were performed for the apo B and the LDL receptor, and 20 cycles for GAPDH. Amplification products were electrophoresed on 2% agarose gel, and transferred to a nylon membrane (Biodyne B; Pall Bio-

Support, East Hills, NY). Blots were hybridized with an apo B probe of a 54-base oligonucleotide (5′-TCCTTGCTTAC-CAAAAAGAGCTTC CAGTGTTGGCTCAAAGCCCTTT-CCTTCTAA-3′), LDL receptor probe of a 54-base oligonucleotide (5′-GTGAAC-TTGGGTGAGTGGGCACTGATCT-GAGGGGCAGGCAG-GCACATGTACTGG-3′), and GAPDH probe of a 54-base oligonucleotide (5′-TGATGACCAGCTTC-CCATTCTCAGCCTTGACTGTGCCGTTGAACTTGC-CGTGGG-3′). The probe was 3′-tailing labeled with digoxigenin (DIG), using a DIG oligonucleotide tailing kit (Boehringer Mannheim, Mannheim, Germany). Prehybridization, hybridization, and detection were carried out with a DIG luminescent detection kit (Boehringer Mannheim) as recommended by the manufacturer. The relative quantity of mRNA was estimated by densitometry scanning with X-ray film.

*Statistical analysis.* Data are presented as means and standard deviations. The mean and standard deviation for serum total cholesterol, HDL-cholesterol, and VLDL + IDL + LDL-cholesterol for each time point were calculated. The significance of differences among treatment groups was determined by analysis of variance with Duncan's multiple-range test (SAS Institute, Cary, NC). Results were considered significant at $P < 0.05$.

## RESULTS

*Feed intake, rat growth, and liver weight.* The results are summarized in Table 2. There were no significant differences in body weight among groups through the experimental period. The liver weight in the CS group was 1.1–1.2 times lower than that in the AS, KS, and TS groups. The cecum weight in the TS group was 1.4 times higher than that in the CS group, and the cecal pH in the CS group was significantly higher than in the other groups.

*Tissue lipid concentration.* Table 3 shows the serum total cholesterol, VLDL + IDL + LDL-cholesterol, HDL-choles-

[a]Values are expressed as means ± standard deviations for six rats. Means within the same columns bearing different superscript roman letters are significantly different ($P < 0.05$). HDL, high density lipoprotein; VLDL, very low density lipoprotein; IDL, intermediate density lipoprotein; LDL, low density lipoprotein; see Table 1 for other abbreviations.

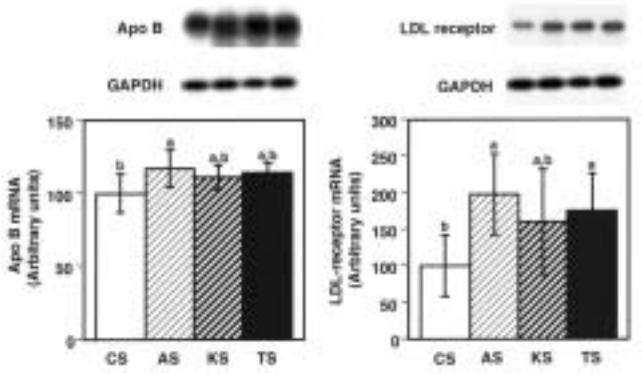

**FIG. 1.** Hepatic apolipoprotein (apo) B mRNA and low density lipoprotein (LDL) receptor mRNA concentrations in rats fed bean starches for 4 wk. Each value represents the mean ± standard deviations for data obtained from six animals. Means values were significantly different ($P < 0.05$), as determined by analysis of variance with Duncan's multiple-range test. The values of apo B mRNA and LDL receptor mRNA were normalized to the value of glyceraldehyde-3-phosphate dehydrogenase (GAPDH), and values for the rats fed the adzuki starch (AS), kintoki starch (KS), and tebou starch (TS) diets are expressed relative to the average values for rats fed the corn starch (CS) diet, which was set to 100. Inset illustrates the representative Southern hybridization of polymerase chain reaction-amplified apo B cDNA and LDL receptor cDNA of hepatic RNA.

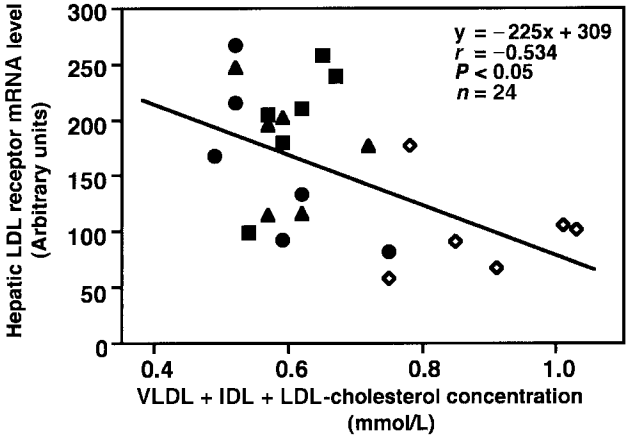

**FIG. 2.** Relationships between the hepatic LDL receptor mRNA level and serum very low density lipoprotein (VLDL) + intermediate density lipoprotein (IDL) + LDL-cholesterol concentration in rats fed CS (◇), AS (■), KS (●), or TS (▲) for 4 wk. The values were significantly different ($P < 0.05$), as determined by simple correlation. For abbreviations see Figure 1.

terol and triglyceride concentrations, and total cholesterol/HDL-cholesterol ratio in rats. The serum total cholesterol, VLDL + IDL + LDL-cholesterol, and HDL-cholesterol concentrations in the bean starch groups were significantly lower than those in the CS group throughout the feeding period. The serum triglyceride concentrations in the KS and TS groups were significantly lower than those in the CS group at the end of the 4-wk feeding period. The total cholesterol/HDL-cholesterol ratio in the bean starch groups was also significantly lower than that in the CS group at the end of the 4-wk feeding period.

The effects of the bean starches on the liver cholesterol concentration in rats at the end of the experimental period were as follows (μmol/g wet liver): CS, 2.7 ± 1.1; AS, 4.0 ± 0.9; KS, 4.0 ± 1.0; and TS, 5.0 ± 2.0. (Values are expressed as means ± standard deviations for six rats.) The cholesterol concentration in the TS group was significantly higher than in the CS group.

*Hepatic apo B and LDL receptor mRNA.* The relative quantities of mRNA were determined by the Southern hybridization of PCR-amplified apo B cDNA and LDL receptor cDNA (Fig. 1) in the rat liver. The values of apo B and LDL receptor mRNA were normalized to the value of GAPDH. The values of the bean starch-fed rats were expressed relative to the average values of the CS-diet group, which were normalized to 100. The relative quantity of hepatic apo B mRNA in the AS group was significantly higher than that in the CS group ($P < 0.05$). Hepatic LDL receptor mRNA levels in the AS and TS groups were significantly higher than in the CS group ($P < 0.05$). Hepatic LDL receptor mRNA levels in the KS groups also tended to be elevated compared to the CS group. The hepatic LDL receptor mRNA level in relation to the serum VLDL + IDL + LDL-cholesterol concentration is shown in Figure 2. The hepatic LDL receptor mRNA level correlated negatively with the serum VLDL + IDL + LDL-cholesterol concentration, the correlation coefficient ($r$) being –0.534 ($P < 0.05$).

*Cecal and fecal lipid concentrations.* Table 4 shows the SCFA concentrations in the cecum in rats. The cecal propionic acid and *n*-butyric acid pool sizes were significantly higher in the resistant starch groups than those in the CS group. The cecal total SCFA pool size in the TS group was higher than in the CS, AS, and KS groups. The neutral and

acidic steroid concentrations in feces at the end of the experimental period are shown in Table 5. The fecal total bile acid extraction in the KS group was higher than in the AS group, and there were no significant differences in fecal cholesterol concentrations among groups.

## DISCUSSION

In the present study we examined the effects of bean starches on serum cholesterol and hepatic LDL receptor mRNA levels in rats. The serum total cholesterol concentrations in the bean starch groups were significantly lower than in the CS group. The factor lowering the cholesterol concentrations in all resistant starch groups was the lowering of HDL- and VLDL + IDL + LDL-cholesterol. It has been suggested that sugar beet fiber reduces ileal concentrations of apo A-I and apo A-IV mRNA in rats (5). In the present experiment, the total cholesterol/HDL-cholesterol ratio in the bean starch groups was significantly lower than that in the CS group at the end of the 4-wk feeding period. It is suggested that lowering the LDL-cholesterol concentration may be also important factor in lowering serum total cholesterol concentration. In fact, the VLDL + IDL + LDL-cholesterol concentrations in the AS, KS, and TS groups were significantly lower than in the CS group. The LDL-receptor mRNA levels in the AS and TS groups were also significantly higher than in the CS group. One of the reasons for the lower serum VLDL + IDL + LDL-cholesterol concentrations in the AS and TS groups may have been elevation of the LDL receptor level, because the hepatic LDL receptor mRNA level correlated negatively with the serum VLDL + IDL + LDL-cholesterol concentration. It has been reported that dietary fish oil and dietary fiber elevate hepatic LDL receptor activity and hepatic LDL receptor mRNA level, respectively (6,14) and dietary high cholesterol and saturated fat suppress hepatic LDL receptor mRNA in African green monkeys (15). However, there are almost no reports of a relationship between dietary resistant starch and hepatic LDL receptor mRNA. In this experiment, we used the cholesterol-free diet to eliminate possible related diet effect on the cholesterol metabolism in rats. The elevation of the hepatic LDL receptor mRNA level observed in both the AS and TS fed rats appears interesting.

There was no significant difference in the liver cholesterol concentration among the groups, except for the TS group. It has been reported that dietary fiber and resistant starch decreased or had no effect on liver cholesterol concentration (3,6,16). However, the liver cholesterol concentration in the TS group was significantly higher than in the CS group in the present experiment. Although the reason for this result was unclear, it is possible that an increase of liver cholesterol concentration was due to an increase of hepatic LDL receptor mRNA level, and there were no significant differences in fecal cholesterol and total bile acid concentrations between the CS and TS groups. Hara *et al.* (17) reported that products of fermentation of sugar beet fiber by cecal bacteria lower the plasma cholesterol concentration in rats and that SCFA, as fermentation products, suppress cholesterol synthesis in the rat liver and intestine (18). The propionic acid and *n*-butyric acid pool sizes were elevated in the cecum in rats fed retrograded starch as compared with the control group in this experiment. Younes *et al.* (3) reported that amylase-resistant starch led to a marked rise in the cecal pool of SCFA and the activity of hydroxymethylglutaryl-CoA reductase was increased twofold by resistant starch compared with wheat starch. Furthermore, Evans *et al.* (19) reported that the chemical composition and structure of dietary galactomannans lowered plasma cholesterol and hepatic cholesterol synthesis. This may result from differences in the chemical composition and structure of the AS, KS, and TS, although these data were not considered here.

Trautwein *et al.* (20) reported that antihyperlipemia activities of resistant starch were due to the acceleration of bile acid excretion and that there was no effect on excretion of neutral steroids. Buhman *et al.* (21) also reported that feeding psyllium to rats enhanced fecal bile acid and total steroid excretion as well as cholesterol 7α-hydroxylase activity. However, there was no correlation between the fecal bile acid excretions and serum total cholesterol concentration, respectively ($r = -0.278$, $P > 0.05$). The bile acid may be reabsorbed abundantly in enterophepatic circulation.

In conclusion, the effects of the bean starches were most clearly seen when compared with rats fed CS. The resistant starch elevated hepatic LDL receptor mRNA level in the AS and TS groups, reduced the HDL-cholesterol concentration in the AS, TS, and KS groups, and lowered serum total and IDL + LDL-cholesterol concentrations in the resistant starch groups.

# Dietary Supplementation with Conjugated Linoleic Acid Does Not Alter the Resistance of Mice to *Listeria monocytogenes* Infection

**Lori Turnock[a], Mark Cook[b], Howard Steinberg[a], and Charles Czuprynski[a,]***

[a]Departments of [a]Pathobiological Sciences and [b]Animal Sciences, University of Wisconsin-Madison, Madison, Wisconsin 53706

**ABSTRACT:** Conjugated linoleic acid (CLA) has been used experimentally as a dietary supplement to increase lean body weight and to modulate inflammation in a variety of animal species. In addition, human use of dietary CLA as a supplement to regulate body fat has received both scientific and public attention. No reports have been published regarding the effects of dietary CLA on antimicrobial resistance. In this study, we provide evidence that feeding CLA for up to 4 wk does not alter host defense against *Listeria monocytogenes* in mice. These findings suggest that the anti-inflammatory effects of CLA do not impair cellular immunity to this intracellular pathogen.

Paper no. L8599 in *Lipids 36,* 135–138 (February 2001).

Conjugated linoleic acid (CLA) has been studied as a dietary supplement. There is evidence that it increases resistance to tumor initiation and growth, increases lean body mass, and has other beneficial effects (1–5). At least some of these biological activities are thought to be mediated in part through the capacity of CLA to modulate immune and inflammatory responses. For example, there is evidence that CLA can decrease the biological activity of tumor necrosis factor (TNF) *in vivo* (5–7) and the release of IL-2 by lymphocytes (8) and IL-6 and TNF by macrophages *ex vivo* (9). Although these studies suggest that dietary CLA is a potent immunomodulator, there has been little or no investigation of the direct effects of dietary supplementation with CLA on resistance to bacterial infection.

Murine listeriosis is a valuable model for studying cellular immunity to an intracellular facultative bacterial pathogen. *Listeria monocytogenes* can invade and multiply in macrophages, hepatocytes, and various other cell types (10). Anti-*Listeria* resistance requires coordination of an effective cellular immune response. This involves both innate immune mechanisms (i.e., granulocytes) and an antigen-specific adaptive immune response (i.e., $CD4^+$ and $CD8^+$ T-cells) (10–12). In particular, rapid mobilization of an innate immune response, consisting of neutrophils and inflammatory cytokines, is essential for restricting the early growth of *L. monocytogenes* in the spleens and liver of experimentally infected mice (10–15). Because CLA is reported to dampen the inflammatory response to bacterial products (5,6), we hypothesized that it might impair anti-*Listeria* resistance. Therefore, in this study we used murine listeriosis as a model system to assess the possible effects of dietary supplementation with CLA on antibacterial resistance.

Abbreviations: CLA, conjugated liinoleic acid; IL, interleukin; PPAR, peroxisome proliferator-activated receptor; TNF, tumor necrosis factor.

## MATERIALS AND METHODS

*Mice.* Female CD1 mice were obtained at six wk of age from Charles Rivers Laboratories (Indianapolis, IN) and housed in the AAALAC certified animal care facility of the UW-Madison School of Veterinary Medicine. Mice were used at either 2 or 6 mon of age. Individual mice were identified by ear punches. We received approval for these experiments from the University of Wisconsin School of Veterinary Medicine Animal Use and Care Committee.

*Diet.* Mice were fed *ad libitum* a semipurified diet (TD94060, 99% basal mix; Harlan-Teklad, Madison, WI) that contained 5% corn oil. To the diet was added 0.5% sucrose (w/w) and either 0.5% CLA or 0.5% corn oil. The CLA contained 95% conjugated dienes, primarily consisting of *cis*9,*trans*11- (43%), and *trans*10,*cis*12-isomers (44%) as described previously (1). Mice were individually weighed before they were put on their respective diets, immediately before inoculation with *L. monocytogenes*, and at the time they were euthanized.

*Listeria monocytogenes. Listeria monocytogenes* strain EGD was grown and prepared for inoculation in our laboratory as described previously (12). Briefly, the organism had been passaged through a mouse by intravenous infection. The mouse was euthanized and its spleen removed and homogenized in sterile saline. The spleen homogenate was diluted in saline and plated on blood agar. A single colony was picked from those that grew on blood agar, inoculated into brain heart infusion broth, and grown to log-phase at 37°C. Glycerol was then added (20% by volume), and the bacteria were stored as aliquots at −70°C. Immediately before an experiment, an aliquot was thawed and diluted to the indicated concentrations in sterile saline.

*Experimental infection.* In two separate experiments, we examined the effects of dietary supplementation with CLA on the subsequent resistance of mice to intraperitoneal (i.p.) infection with *L. monocytogenes*. Two- or six-month-old female CD1 mice were fed the diet mentioned above that contained

either 0.5% CLA, or corn oil as a control, *ad libitum*. Mice were given the diet for 14 d (Expt. 1) or 32 d (Expt. 2) before they were challenged i.p. with *L. monocytogenes* strain EGD ($2.5 \times 10^5$ and $1.5 \times 10^5$ in 0.2 mL sterile saline, respectively, in the two experiments). These challenge doses were chosen because they would result in a sublethal infection. At 4 and 8 d after bacterial inoculation, groups of 4 or 5 mice were euthanized by asphyxiation with $CO_2$, followed by cervical dislocation. These time points were chosen because they represent the peak of the bacterial burden during experimental infection (day 4), and a time point when the listeriae should be in the process of being cleared from these tissues (day 8). After weighing the mice, their abdomens were aseptically opened and one-half of the spleen and the front lobe of the liver were removed. These tissues were weighed and then placed in sterile tissue grinders that contained cold sterile saline. The tissues were homogenized with a pestle, and the homogenates serially diluted in sterile saline. Samples (0.1 mL) of appropriate dilutions were plated in duplicate on blood agar. The plates were incubated for 48 h at 37°C and the colonies enumerated. The results are expressed as the $\log_{10}$ CFU *L. monocytogenes* per g tissue (wet wt).

*Histopathology.* Portions of the spleen and liver were removed to buffered formalin at necropsy. Following fixation, these sections were cut, mounted on glass slides, and stained with hematoxylin and eosin, or with periodic acid Schiff stain to detect lipid deposits. These slides were then examined microscopically by an American College of Veterinary Pathologists board certified pathologist (H.S.), and representative slides photographed.

*Data analysis.* Data were analyzed by a two-way analysis of variance. If a significant $F$ value ($P < .05$) was obtained, then relevant comparisons were made using paired $t$ tests as performed by the Prism software package (GraphPad Software, San Diego, CA).

## RESULTS

Our results indicated that dietary supplementation with CLA had little ($P > .05$) effect on the body weight of mice in the experiment. The CLA-treated mice exhibited slightly decreased body weight before challenge, whereas the control mice exhibited a slight weight gain (Table 1). However, both CLA-treated and control mice lost weight during *L. monocytogenes* infection. Thus, CLA supplementation was unable to spare mice from the cachexia that occurs during experimental listeriosis.

In two separate experiments, CLA feeding had no significant effect ($P > .05$) on the numbers of *L. monocytogenes* recovered from the spleens and livers of experimentally infected mice (Table 2). Although we observed some variability between the two experiments, this was likely due to the differences in age and weight of the mice used in the two experiments (Table 2).

Although we did not perform a quantitative histopathologic analysis, the severity of damage to the spleen and liver did not differ substantially between the two groups of mice. In the control animals, scattered necrotic foci were observed in the liver. Most of these were small to moderate in size and contained inflammatory neutrophils and mononuclear cells. Scattered aggregates of inflammatory neutrophils and mononuclear cells were observed in CLA-treated mice, some of which were associated with necrotic hepatocytes. In Experiment 2, we observed a tendency for hepatic lipidosis in the livers of CLA-treated animals. As illustrated in Figure 1, histopathological examination revealed random hepatocytes with macrovesicular lipid vacuoles in the CLA-treated mice. Periodic acid Schiff staining confirmed that the vacuoles contained lipid (not shown). In contrast, control mice exhibited slightly swollen hepatocytes with lacy cytoplasm (Fig. 1). However, the presence or absence of lipidosis had no apparent relationship with the severity of histopathologic lesions caused by *L. monocytogenes* infection, or the numbers of viable *L. monocytogenes* recovered from the spleen and liver.

## DISCUSSION

The results of this study were somewhat surprising. Our prediction had been that treatment with CLA, which is known to diminish the catabolic response to endotoxin and the inflammatory cytokine TNFα (5,6,9), would dampen host defense against *L. monocytogenes*. This supposition was based on pre-

**TABLE 1**
**Effects of Conjugated Linoleic Acid (CLA) Supplementation on Body Weight Before and After *Listeria monocytogenes* Infection**

| | | Body weight (g), mean ± SEM | | | |

[a]In Experiment 1, 2-mon-old female CD1 mice were fed CLA-supplemented or control diet for 14 d before i.p. inoculation with $2.5 \times 10^5$ *L. monocytogenes*. Mice were continued on their respective diets after infection. Groups of four mice per treatment group were euthanized 4 and 8 d later, and the number of viable *L. monocytogenes* per g wet weight spleen and liver, was determined.
[b]In Experiment 2, 6-mon-old female CD1 mice were fed CLA-supplemented or control diet for 32 d before i.p inoculation with $1.5 \times 10^5$ *L. monocytogenes*. Mice were continued on their respective diets until they were euthanized 4 d after bacterial inoculation. The numbers of viable *L. monocytogenes* per g (wet weight) in the spleen and liver were then determined as discussed earlier. For abbreviations see Table 1.
[c]Not done.

vious studies which demonstrated that early release of TNFα and other inflammatory cytokines (ie., IL-12 and interferon-γ), was essential for restricting the multiplication of *L. monocytogenes* and reducing the severity of listeriosis in mice (10,13,15). Unfortunately, we did not verify the effects of CLA treatment on TNFα expression in our experiments. However, previous studies conducted using diet-fed mice under similar circumstances to those reported here indicated a decreased response to TNFα (7). Likewise, work performed in one of our laboratories (M.E.C.) demonstrated that autoimmune disease-prone NZB/W mice fed the same diet, with a similar concentration of CLA, exhibited less severe endstage lupus-like disease (16).

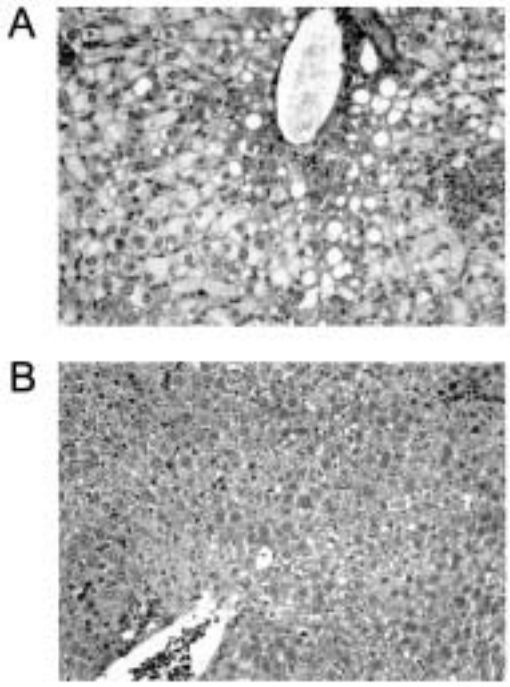

**FIG. 1.** Mice that received the conjugated linoleic acid (CLA)-supplemented diet for 32 d exhibited hepatic lipidosis during *Listeria monocytogenes* infection. (A), Mice on the CLA-supplemented diet exhibited midzonal swollen hepatocytes with lacy cytoplasm, and the presence of macrovesicular lipid vacuoles. (B), In contrast, mice on the control diet (0.5% corn oil) exhibited scattered random clusters of slightly swollen hepatocytes with lacy cytoplasm. Liver sections were stained with hematoxylin and eosin and photographed at 200× magnification.

One possible explanation for the absence of an adverse effect of CLA is that CLA treatment dampens the release of both protective inflammatory cytokines like TNFα and anti-inflammatory mediators (i.e., prostaglandin $E_2$, IL-4, and IL-10) that have been demonstrated to reduce resistance to listeriosis in mice (10,15,17,18). A different biological role of CLA also deserves consideration. It has been reported that CLA is potent high-affinity ligand and activator of peroxisome proliferator-activated receptor alpha (PPARα) in hepatocytes (4,19). Since *L. monocytogenes* multiplies to a large extent in hepatocytes (11–13), one can envision that an alteration in hepatocyte physiology might alter its ability to multiply. Although modulation of immune reactivity by PPAR receptors has been reported (20,21), their ability to alter antibacterial resistance *in vivo* has not been established. The absence of an effect of CLA on anti-*Listeria* resistance in the present study suggests that neither cytokines nor PPAR, were modulated in a manner that was adverse to host defense.

There have been other investigations of the effects of dietary lipid on anti-*Listeria* resistance. Mice fed a high-fat diet (20% corn oil) at 3 wk of age exhibited enhanced resistance to listeriosis (22). However, mice fed the same diet at 6 or 12 wk of age had impaired resistance (22). Mice fed a diet high in cholesterol, lard, and sucrose also exhibited improved anti-*Listeria* resistance (23). Mice fed a diet containing 17% fish oil and 3% corn oil exhibited less resistance to *L. monocytogenes* than mice fed lard or soybean oil (24). These same investigators later showed that mice fed n-3 polyunsaturated fatty acids from fish oil produced less IL 12, and more interferon gamma during *L. monocytogenes* infection than control mice (25). Recently, it was reported that mice fed a hydrogenated coconut oil diet exhibited increased resistance to *L. monocytogenes* infection (26).

In summary, these results suggest that dietary supplemen-

tation with CLA does not alter antibacterial resistance, as evaluated using murine listeriosis as a model. Although our results are limited to this one animal model, murine listeriosis is widely used to assess antibacterial resistance following modulation of the immune system, or exposure to toxicologic insults. Our findings are also consistent with the absence of any reported relationship between dietary CLA supplementation in humans and altered resistance to bacterial infection.

## ACKNOWLEDGMENTS

**ABSTRACT:** Conjugated linoleic acid (CLA; 18:2), a group of positional and geometric isomers of linoleic acid (LA; 18:2n-6), has been shown to modulate immune function through its effect on eicosanoid synthesis. This effect has been attributed to a reduced production of n-6 polyunsaturated fatty acid (PUFA), the precursor of eicosanoids. Since Δ6-desaturase is the rate-limiting enzyme of the n-6 PUFA production, it is our hypothesis that CLA, which has similar chemical structure to LA, interacts directly with Δ6-desaturase. A unique and simple model, i.e., baker's yeast *(Saccharomyces cerevisiae)* transformed with fungal Δ6-desaturase gene, previously established, was used to investigate the direct effect of CLA on Δ6-desaturase. This model allows LA to be converted to γ-linolenic acid (GLA; 18:3n-6) but not GLA to its metabolite(s). No metabolites of CLA were found in the lipids of the yeast transformed with Δ6-desaturase. The inability to convert CLA to conjugated GLA was not due to the failure of yeast cells to take up the CLA isomers. CLA mixture and individual isomers significantly inhibited the activity of Δ6-desaturase of the transformed yeast *in vivo*. Even though its uptake by the yeast was low, CLA *c*9,*t*11 isomer was found to be the most potent inhibitor of the four isomers tested, owing to its high inhibitory effect on Δ6-desaturase. Since CLA did not cause significant changes in the level of Δ6-desaturase mRNA, the inhibition of GLA production could not be attributed to suppression of Δ6-desaturase gene expression at the transcriptional level.

Paper no. L8554 in *Lipids 36,* 139–143 (February 2001).

Conjugated linoleic acid (CLA) refers to a group of geometric and positional dienoic isomers derived from linoleic acid (LA). CLA exhibits many beneficial biological effects in cell cultures and animal models. For example, CLA decreases breast cancer cell proliferation and inhibits tumorigenesis in mammary gland, skin, and stomach in experimental animals (1–5). CLA can also reduce the development of atherosclerosis in hamsters and rabbits, and it modulates immune function in rats (6–8).

The mechanism by which CLA exerts its biological function is still not clear. It has been shown that CLA modulates immune function through its effect on eicosanoid synthesis (9–11). This effect has been attributed to a reduced production of n-6 polyunsaturated fatty acid (PUFA), the precursor of eicosanoids. Since Δ6-desaturase is the rate-limiting enzyme of n-6 PUFA production, it is our hypothesis that CLA, which has similar chemical structure to LA, interacts directly with Δ6-desaturase. However, owing to the complexity of mammalian cell systems and to the unavailability of purified Δ6-desaturase, there is no evidence which demonstrates that CLA interacts directly with Δ6-desaturase.

We have previously established a transformed yeast (*Saccharomyces cerevisiae*) culture in which a fungal (*Mortierella alpina*) Δ6-desaturase gene has been introduced, and is expressed (12). This model provides a unique and simple system to investigate whether CLA interacts directly with Δ6-desaturase. The objectives of this study were (i) to determine if CLA can be metabolized by Δ6-desaturase and (ii) to examine whether CLA affects the activity of Δ6-desaturase.

## MATERIALS AND METHODS

*Chemicals.* LA and a mixture of CLA isomers (free fatty acid form, containing 41% *c*9,*t*11/*t*9,*c*11 isomers, 44% *t*10,*c*12 isomer, and others) were purchased from Nu-Chek-Prep, Inc. (Elysian, MN). Four major isomers of CLA (*c*9,*t*11; *t*9,*t*11; *c*9,*c*11, and *t*10,*c*12) were obtained as individual free fatty acids from Matreya Inc. (Pleasant Gap, PA). Yeast minimal medium (YMM) composed of dropout base medium with 2% galactose plus a complete supplement mixture lacking uracil were from Bio 101, Inc. (Vista, CA). YPD medium containing yeast extract, peptone, and dextrose was from Difco Laboratories (Detroit, MI). Hexane was ultraviolet (UV) grade and other solvents were distilled-in-glass quality.

*Plasmids and yeast strain.* Two plasmids, pYES2 (vector only) and pCGR5 (with fungal Δ6-desaturase gene), were constructed and transformed into a host strain of baker's yeast (*S. cerevisiae*), SC334 (12). The transformation protocol and growth conditions followed the procedure described previously (13).

*Incubation conditions and experimental design.* Colonies of transformants were grown overnight in YPD media at 30°C. Cultures ($1 \times 10^8$ cells) were then used to inoculate 100 mL of YMM. Cell numbers were maintained at the same level in all studies. The culture was grown for 48 h at 15°C. This

Abbreviations: CLA, conjugated linoleic acid; GC, gas chromatography; GLA, γ-linolenic acid; LA, linoleic acid; PUFA, polyunsaturated fatty acid; YMM, yeast minimal medium; YPD, yeast extract, peptone, and dextrose medium.

temperature (15°C) has previously been shown to be optimal for expression of the Δ6-desaturase activity (12). After harvest by centrifugation, cell pellets were washed once with sterile distilled/deionized $H_2O$ to remove the media. The host strain transformed with vector (pYES2) alone was used as a negative control as indicated.

To confirm the activity of Δ6-desaturase (conversion of LA to γ-linolenic acid, GLA) in the transformed yeast used in this study, LA (25 μM) was provided as the exogenous substrate in the minimal media. To examine whether CLA could be converted to conjugated GLA by Δ6-desaturase, 25 μM CLA was added to the medium. To study if addition of CLA could affect the conversion of LA to GLA by Δ6-desaturase, both LA and CLA were supplemented at a fixed concentration of 25 μM. To determine if CLA isomers could be taken up by transformed yeast, four CLA isomers were supplemented in media at different levels (10, 25, and 50 μM). To determine if CLA affects the expression of Δ6-desaturase, the levels of Δ6-desaturase mRNA in cultures incubated with 50 μM LA (control) and a mixture containing 50 μM CLA and 50 μM LA were compared.

*Lipid extraction and fatty acid analysis.* The extraction of yeast lipids followed the procedures described previously (13). Briefly, rinsed cell pellets were extracted with 6.5 mL of methanol and 13 mL of chloroform containing 16 μg of tritridecanoin (a synthetic triacylglycerol containing three molecules of tridecanoic acid, 13:0, used as the internal standard). After extraction, the yeast lipids were saponified and methylated. Fatty acid methyl esters were then analyzed by gas chromatography (GC) by using a Hewlett-Packard 5890 II Plus gas chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a flame-ionization detector and a fused-silica capillary column (Omegawax; 30 m × 0.32 mm i.d.; Supelco, Bellefonte, PA). In the present study, the Δ6-desaturase activity was determined from the ratio of the product and substrate concentrations. The amount of CLA isomers taken up by the yeast was calculated from the percentage of CLA isomers in total yeast lipids.

*Isolation and analysis of RNA.* Total RNA amounts were isolated by hot phenol/chloroform extraction as described previously (14). Equal amounts of total RNA from various experimental cultures were separated by 1% formaldehyde/agarose gel electrophoresis, transferred to a nylon membrane (Roche, Indianapolis, IN), and auto cross-linked to the membrane with an UV Stratalinker 1800 (Stratagene, La Jolla, CA). The DNA probes used for hybridization overnight at 50°C were synthesized using the DIG High Prime Random Labeling kit (Roche, Indianapolis, IN). The *M. alpina* Δ6-desaturase gene from pCGR5 (12) was used for desaturase mRNA detection, and the 2.2 kb *Hind*III fragment of *CryI* (15) was used to show that equal amounts of RNA had been loaded. Following hybridization, detection of the signal was performed with reagents from Roche following the manufacturer's instructions. Finally, the hybridization signals were quantitated by densitometry (IS-1000 system; Alpha Innoteck, San Leandro, CA).

*Statistical analyses*. Data were analyzed by analysis of variance and Fisher's protected least significant difference to determine differences between means of the uptake rate of CLA isomers and between means of the decrease in Δ6-desaturase activity. Means differences were considered significant at the $P \leq 0.05$ level.

## RESULTS

Significant levels of GLA (18:3 $\Delta^{6,9,12}$ converted from 18:2 $\Delta^{9,12}$) were formed in yeast strain 334(pCGR5) when incubated for 48 h with 25 μmM LA (Fig. 1B). A small level of 16:2 $\Delta^{6,9}$ (converted from 16:1 $\Delta^{9}$) was also observed. Neither 16:2 nor GLA was formed in the 334(pYES2) yeast, which lacks the Δ6-desaturase gene (Fig. 1A). This confirms that Δ6-desaturase was synthesized and active in the transformed 334(pCGR5) yeast used in this study.

When the transformed yeast cells, with or without Δ6-desaturase, were incubated with 25 μM CLA for 48 h, CLA was incorporated mostly into the phospholipid fraction (53.4% of total CLA in yeast lipid extract), followed by the free fatty acid fraction (26.6%). However, there were no metabolites of CLA in total lipid extract (Fig. 2) (data not shown). Thus, CLA under the current condition described in this study could not be metabolized by the Δ6-desaturase.

Figure 3 shows that conversion of LA to GLA was significantly inhibited (33%) by the addition of mixed CLA into the growth medium. When four CLA isomers were examined individually, the extent of inhibition of Δ6-desaturase activity was greatest (40%) when *c*9,*t*11 was added to the medium. Although *t*10,*c*12, *c*9,*c*11, and *t*9,*t*11 isomers significantly inhibited the conversion of LA to GLA, there was no signifi-

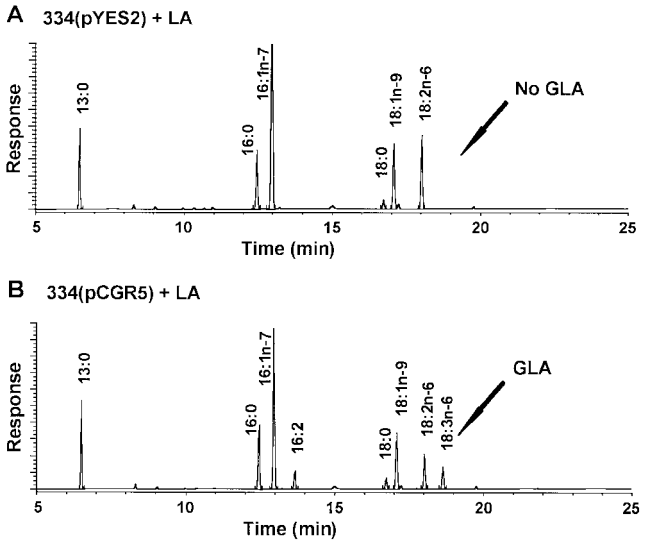

**FIG. 1.** Gas chromatographic analysis of fatty acid methyl esters of total lipids in *Saccharomyces cerevisiae* 334 harboring (A) the vector pYES2, and (B) the Δ6-desaturase gene-bearing plasmid pCGR5. All yeast cells were incubated in the medium containing linoleic acid (LA). Solid arrows indicate the appearance of γ-linolenic acid (GLA).

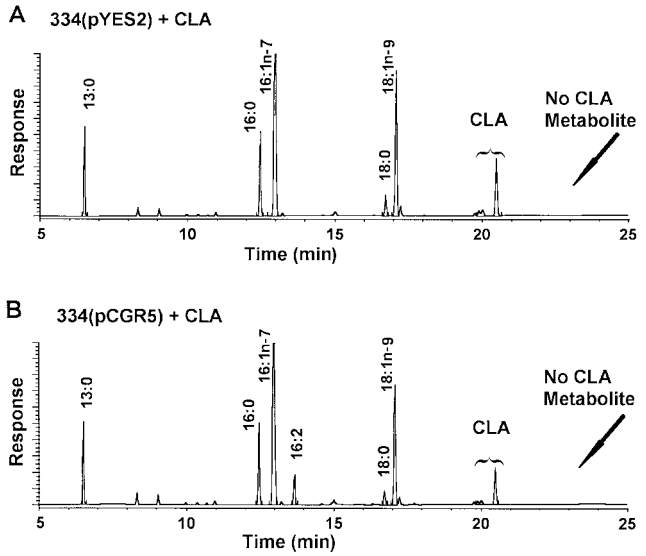

**FIG. 2.** Gas chromatographic analysis of fatty acid methyl esters of total lipids in the transformed yeast with vector only [334(pYES2)] (A) and those with the Δ6-desaturase gene [334(pCGR5)] (B). Cells had been incubated in medium containing conjugated linoleic acid (CLA). Solid arrows indicate the appearance of CLA metabolites.

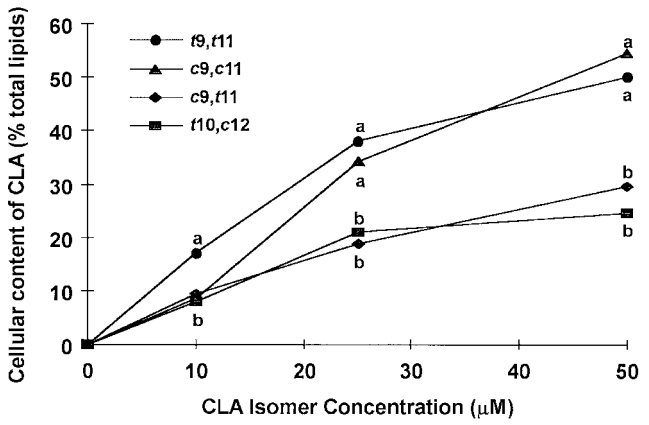

**FIG. 4.** Uptake of different CLA isomers by transformed yeast with Δ6-desaturase gene. The uptake of CLA isomers is indicated by the presence of CLA isomers (% total lipids) in yeast lipids. Each value point represents the mean of four incubations. Different letters indicate a significant difference ($P < 0.05$) within the same concentration point. CLA *c*9,*t*11 isomer (◆), CLA *t*10,*c*12 isomer (■), CLA *c*9,*c*11 isomer (▲), and CLA *t*9,*t*11 isomer (●).

cant difference among them. The inhibitory effects of individual isomers were dose-dependent (data not shown).

The uptake rate of CLA isomers by the transformed yeasts is shown in Figure 4. The level of uptake was directly proportional to the concentration of CLA isomers in the medium. However, the rate of uptake varied significantly among the four CLA isomers. The uptakes of *t*9,*t*11 and *c*9,*c*11 isomers were greater than those of *c*9,*t*11 and *t*10,*c*12.

To determine whether the inhibitory effect of CLA on Δ6-desaturase activity was regulated through the Δ6-desaturase gene expression, the transformed yeast were cultured in YMM containing 50 μM of LA with or without the addition of 50 μM of CLA. Figure 5 shows that there were no significant differences in the relative abundance of Δ6-desaturase mRNA between the transformed yeasts treated or not treated with CLA.

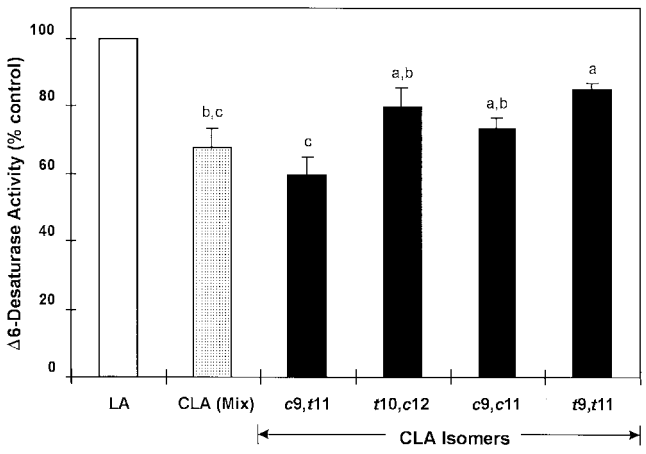

**FIG. 3.** Effect of CLA isomers on the Δ6-desaturase activity in transformed yeast cultures. All results are mean ± SE of four incubations. Values with different letters are significantly different from each other at $P < 0.05$. For abbreviations see Figures 1 and 2.

## DISCUSSION

In the present study, a unique model, in which baker's yeast was transformed with fungal Δ6-desaturase gene, was used to provide a direct assay for studying the first regulating step of n-6 PUFA production. Since no PUFA is found in baker's yeast cells owing to the lack of enzymes for PUFA synthesis, the insertion of Δ6-desaturase gene enables these yeast cells to convert exogenous LA to GLA. Based on our unpublished observation (Chuang, L.-T., J.M. Thurmond, J.-W. Liu, and Y.-S. Huang), the newly formed GLA was not further metabolized. Therefore, the ratio of GLA to LA could serve an index of Δ6-desaturase activity.

In using this model, we clearly demonstrated that none of the CLA isomers could be metabolized by the recombinant Δ6-desaturase to conjugated GLA, despite the similarity in chemical structure between LA and CLA. In addition, the inability to convert CLA to conjugated GLA was not due to the failure of yeast cell to take up the CLA isomers. The competitive inhibition of Δ6-desaturase between CLA and LA was also demonstrated. The simplicity of our model allows us to define the interaction between CLA and Δ6-desaturase. Our finding differs from previous studies which found CLA metabolites in animals fed CLA (10,16). Multiple steps or alternative metabolic pathways could have been involved in these studies.

Our results showed that all CLA isomers inhibited significantly the activity of Δ6-desaturase. The *c*9,*t*11 isomer was found to be the most potent inhibitor (40% inhibition) (Fig. 3), despite its lower uptake by the yeast cells when compared with other isomers (Fig. 4). The CLA mixture also exhibited a significant inhibition (33%) on the activity of Δ6-

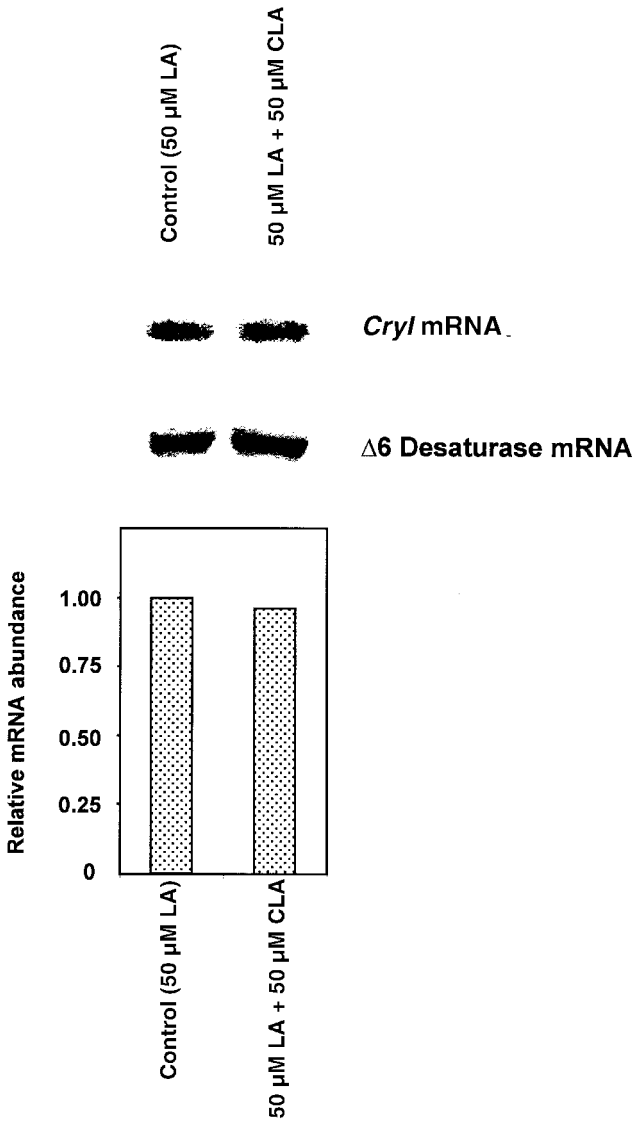

**FIG. 5.** Effect of CLA on Δ6-desaturase mRNA expression in transformed yeast 334(PCGR5). Data are expressed as the ratio of Δ6-desaturase/*Cryl* mRNA. Similar results were observed in three separate experiments. For abbreviations see Figure 1.

desaturase. This could be due to the presence of a high percentage (41%) of *c*9,*t*11/*t*9,*c*11 isomers in the mixture. This finding indicates that *c*9,*t*11 may be the most active CLA isomer. Based on their studies in mice supplemented with CLA, Ha *et al*. (5) and Ip *et al*. (2) have also suggested that *c*9,*t*11 is the active form of CLA. This conclusion was supported by an early observation reported by Bretillon *et al*. (17) in which hepatic microsomes were used as the source of Δ6-desaturase.

Inhibition of CLA on Δ6-desaturase activity could be due to its ability to modulate cellular signal transduction by upregulating gene expression and protein production as suggested by Lee *et al*. (18). The suggestion was based on the finding that CLA reduced stearoyl-CoA desaturase activity by decreasing the stearoyl-CoA desaturase gene mRNA in mouse liver and H2.35 cells. Results in the present study showed that there were no changes in the level of Δ6-desaturase mRNA in the transformed yeast cells treated with CLA. This suggests that the inhibitory effect of CLA on Δ6-desaturase activity was not exerted through the suppression of Δ6-desaturase gene transcription. Alternatively, CLA may inhibit the binding of LA to the catalytic sites of Δ6-desaturase by simply occupying the same sites due to the similarity in their chemical structures. Further study is needed to verify this hypothesis.

In summary, results in the present study clearly demonstrated the interaction between CLA and Δ6-desaturase using a simple but unique transformed yeast model. We have shown that CLA could not be metabolized by Δ6-desaturase directly. Nevertheless, CLA, particularly the *c*9,*t*11 isomer, could inhibit Δ6-desaturase activity. The *c*9,*t*11 isomer may be the most potent isomer of CLA owing to its high inhibitory effect on Δ6-desaturase activity even though its uptake by yeast was low. Since CLA did not result in significant changes in the level of Δ6-desaturase mRNA, their inhibition on GLA production could not be attributed to the suppression of CLA on gene expression at the transcription level.

**ABSTRACT:** Octadecapentaenoic acid (all-*cis* Δ3,6,9,12,15-18:5; 18:5n-3) is an unusual fatty acid found in marine dinophytes, haptophytes, and prasinophytes. It is not present at higher trophic levels in the marine food web, but its metabolism by animals ingesting algae is unknown. Here we studied the metabolism of 18:5n-3 in cell lines derived from turbot *(Scophthalmus maximus),* gilthead sea bream *(Sparus aurata),* and Atlantic salmon *(Salmo salar)*. Cells were incubated in the presence of approximately 1 μM [U-$^{14}$C]18:5n-3 methyl ester or [U-$^{14}$C]18:4n-3 (octadecatetraenoic acid; all-*cis* Δ6,9,12,15-18:4) methyl ester, both derived from the alga *Isochrysis galbana* grown in $H^{14}CO_3^-$, and also with 25 μM unlabeled 18:5n-3 or 18:4n-3. Cells were also incubated with 25 μM *trans* Δ2, all-*cis* Δ6,9,12,15-18:5 (2-*trans* 18:5n-3) produced by alkaline isomerization of 18:5n-3 chemically synthesized from docosahexaenoic acid (all-*cis* Δ4,7,10,13,16,19-22:6). Radioisotope and mass analyses of total fatty acids extracted from cells incubated with 18:5n-3 were consistent with this fatty acid being rapidly metabolized to 18:4n-3 which was then elongated and further desaturated to eicosatetraenoic acid (all-*cis* Δ8,11,14,17,19-20:4) and eicosapentaenoic acid (all-*cis* Δ5,8,11,14,17-20:5). Similar mass increases of 18:4n-3 and its elongation and further desaturation products occurred in cells incubated with 18:5n-3 or 2-*trans* 18:5n-3. We conclude that 18:5n-3 is readily converted biochemically to 18:4n-3 *via* a 2-*trans* 18:5n-3 intermediate generated by a $\Delta^3$,$\Delta^2$-enoyl-CoA-isomerase acting on 18:5n-3. Thus, 2-*trans* 18:5n-3 is implicated as a common intermediate in the β-oxidation of both 18:5n-3 and 18:4n-3.

Abbreviations: 18:4n-3, octadecatetraenoic acid (all-*cis* Δ6,9,12,15-18:4); 18:5n-3, octadecapentaenoic acid (all-*cis* Δ3,6,9,12,15-18:5); 2-*trans* 18:5n-3, 2-*trans* octadecapentaenoic acid (*trans* Δ2, *cis* Δ6,9,12,15-18:5); 20:4n-3, eicosatetraenoic acid; 20:5n-3, eicosapentaenoic acid; 22:6n-3, docosahexaenoic acid; AS, Atlantic salmon cell line; FBS, fetal bovine serum; GC, gas chromatography; HPLC, high-performance liquid chromatography; NMR, nuclear magnetic resonance; PUFA, polyunsaturated fatty acid; SAF-1, gilthead sea bream cell line; TF, turbot fin cell line; TLC, thin-layer chromatography.

Octadecapentaenoic acid (all-*cis* 18:5n-3) is a fatty acid characteristically present in certain algal groups in marine phytoplankton (1), including dinoflagellates (2), haptophytes (3,4), and prasinophytes (5), all of which have important roles in the marine ecosystem. The acid 18:5n-3 is usually co-associated in these organisms with docosahexaenoic acid (22:6n-3). Given that biosynthesis of 22:6n-3 involves peroxisomal chain shortening of its precursor 24:6n-3, it is possible that 18:5n-3 is biosynthesized by chain shortening of eicosapentaenoic acid (20:5n-3) (see Ref. 6). Marine zooplankton and fish ingesting phytoplankton contain little or no 18:5n-3, demonstrating that this fatty acid is readily metabolized by marine animals. Clearly it could be completely catabolized by marine animals by β-oxidation, but it may also be directly chain-elongated to 20:5n-3. We decided to test the latter possibility in fish cell cultures because marine fish in general have a very limited ability to convert 18:3n-3 to 20:5n-3 and thence to 22:6n-3 (7,8). In some species of marine fish, e.g., turbot, this appears to be due to a deficiency of $C_{18}$ to $C_{20}$ fatty acid elongase (9), whereas in others, e.g., sea bream, it appears to be due to a deficiency of Δ5 fatty acid desaturase (10). The availability of 18:5n-3 can help distinguish between these two possibilities and, in the event of it being a substrate for $C_{18}$ to $C_{20}$ fatty acid elongase, algae containing this fatty acid could be useful dietary supplements in marine fish larval culture.

In this study we prepared 18:5n-3 from the haptophycean alga *Isochrysis galbana* and also by chemical synthesis from 22:6n-3, and studied its metabolism in cultured cells from turbot, seabream, and Atlantic salmon that differ in their abilities to perform $C_{18}$ to $C_{20}$ elongation and Δ5 fatty acid desaturation reactions. The results show that 18:5n-3 is very readily converted by cells from all three species to octadecatetraenoic acid (18:4n-3) *via* a 2-*trans* 18:5n-3 intermediate.

## MATERIALS AND METHODS

*Fatty acid substrates.* The methyl esters of [U-$^{14}$C]18:4n-3 and [U-$^{14}$C]18:5n-3 were prepared from cultures of *I. galbana* (Parke) (S.M.B.A. strain No. 58 C.C.A.P. strain 927/1) grown in $H^{14}CO_3^-$ as described by Ghioni *et al.* (9). In brief, total lipid was extracted from the radioactive algal cells and transmethylated by incubation with 1% sulfuric acid

in methanol at 50°C for 16 h to generate fatty acid methyl esters; the methyl esters of 18:4n-3 and 18:5n-3 were then isolated by silver nitrate thin-layer chromatography ($AgNO_3$-TLC) (11). A total of 5 μCi of methyl esters of both [U-$^{14}$C]18:4n-3 and [U-$^{14}$C]18:5n-3 were obtained, with a specific activity of approximately 12 and 19 mCi/mmol, respectively. The identity of the 18:4n-3 and 18:5n-3 methyl esters was confirmed, and their purity (>99%) and specific activity were determined by radio-gas chromatography (GC) as described by Buzzi *et al*. (12).

Unlabeled methyl esters of 18:5n-3 and 18:4n-3 were prepared by extracting total lipid from *I. galbana* cultures that were not incubated with labeled bicarbonate, transmethylating as described above, and recovering the fatty acid methyl ester fraction enriched in polyunsaturated fatty acids (PUFA) by TLC in hexane/diethyl ether/acetic acid (90:10:1, by vol). Methyl esters of 18:5n-3 and 18:4n-3 were then separated from the fatty acid methyl ester fraction on an ODS C18 high-performance liquid chromatography (HPLC) column (diameter 5 mm) by eluting with acetonitrile at 1.5 mL/min, using ultraviolet (UV) detection at 215 nm. Under these conditions, 18:5n-3 was the first fatty acid eluted. The purity of the methyl esters of both 18:5n-3 and 18:4n-3 was >99% as determined by GC and by GC–mass spectrometry as detailed previously (9,13).

Unlabeled 18:5n-3 was also prepared in greater quantities as the free acid by chemical synthesis according to the method of Kuklev *et al*. (14), which involved a γ-iodo-lactonization of 22:6n-3. The 22:6n-3 used in the synthesis was a concentrate (>95%) kindly supplied by Croda Universal Ltd. (Hull, United Kingdom).

The methyl ester of unlabeled 2-*trans* 18:5n-3 was prepared by first saponifying up to 10 mg of all-*cis* 18:5n-3 methyl ester in 1 M KOH in ethanol/water (95:5, vol/vol) at 78°C for 1 h. The solution was then acidified with HCl, extracted with isohexane/diethyl ether (1:1, vol/vol), evaporated to dryness, and transmethylated and extracted as for the other fatty acid samples. The procedure yielded four compounds in constant relative proportions, all of which were confirmed as methyl esters of 18:5n-3 by electron impact GC–mass spectrometry (13). The four isomers of 18:5n-3 methyl ester were separated by isocratic HPLC on an ODS column using acetonitrile as eluting solvent as described above. Isomer 1 (25% of the total) had a retention time on HPLC corresponding to the original all-*cis* Δ3,6,9,12,15-18:5 (18:5n-3) prepared from *I. galbana* or by chemical synthesis, and its chemical structure was confirmed by $^1$H nuclear magnetic resonance (NMR) spectroscopy at 600 MHz: δ 0.97 (*t*, 3H, *J* = 7.5 Hz, H-18), 2.07 (quintet, 2H, *J* = 7.5 Hz, H-17), 2.60–2.83 (four overlapping *t*, 8H, H-5, H-8, H-11, H-14), 3.13 (*d*, 2H, *J* = 5.8 Hz, H-2), 3.68 (*s*, 3H, –$OCH_3$), 5.34–5.44 (8H, overlapping *m*, alkene-H), 5.53–5.62 (2H, overlapping *m*, alkene-H). Isomer 3 (62% of the total) was obtained as a pure compound by the ODS-HPLC and identified as *trans* Δ2, all-*cis* Δ6,9,12,15-18:5 (2-*trans* 18:5n-3) by $^1$H NMR spectroscopy at 600 MHz: δ 0.96 (*t*, 3H, *J* = 7.5 Hz, H-18), 2.07 (quintet, 2H, *J* = 7.5 Hz, H-17), 2.20–2.29 (*m*, 4H, H-4, H-5), 2.78–2.84 (*m*, 6H, H-8, H-11, H-14), 3.72 (*s*, 3H, –$OCH_3$), 5.27–5.43 (8H, overlapping *m*, *cis*-alkene-H), 5.85 (*dt*, 1H, *J* = 15.6, 1.6 Hz, H-2), 6.96 (*dt*, 1H, *J* = 15.6, 6.6 Hz, H-3). The remaining two isomers, 2 (4% of the total) and 4 (9% of the total), could not be obtained in sufficient amounts for $^1$H NMR identification. Complete epoxidation of the isomeric methyl ester mixture with peracetic acid (15) yielded two distinct epoxide species: (i), 89.4% of the total, which accounts for the sum of isomers 1 and 3; (ii), 10.6% of the total, which accounts for the sum of isomers 2 and 4.

*Cell cultures.* The Atlantic salmon (*Salmo salar*) cell line (AS) (16) was originally obtained from Dr. N. Frerichs (Virology Unit, Institute of Aquaculture, University of Stirling, United Kingdom). The turbot (*Scophthalmus maximus*) cell line (TF) was supplied by Dr. B. Hill (Ministry of Agriculture, Food and Fisheries, Fish Diseases Laboratory, Weymouth, United Kingdom). The gilthead seabream (*Sparus aurata* L.) cell line, SAF-1, developed from fin tissue without immortalization, was provided by Dr. M.C. Alvarez (Department of Cell Biology and Genetics, University of Malaga, Spain) (17).

Cell cultures were grown in 75 cm$^2$ flasks at 22°C in Leibovitz L-15 medium containing 10 mM HEPES and supplemented with 2mM glutamine, 50 IU/mL penicillin, 50 mg/mL streptomycin, and 10% fetal bovine serum (FBS). Approximately 24 h prior to experimentation the cells were subcultured into fresh medium as above except containing only 2% FBS. The cells were then incubated with fatty acid substrates for 6 d as follows. Labeled substrates were added in 50 μL of ethanol at a radioactive concentration of 0.25 μCi per flask containing 15 mL of medium, equivalent to a total mass of 0.021 μmol (1.4 μM) and 0.013 μmol (0.87 μM) for the methyl esters of [U-$^{14}$C]18:4n-3 and [U-$^{14}$C]18:5n-3, respectively. Unlabeled fatty acid methyl esters were added as above at a level of approximately 0.375 μmol/flask providing a concentration of 25 μM. All incubations/experiments were conducted in triplicate.

Preliminary experiments incubating AS cells with 25 μM unlabeled 18:4n-3, added as the fatty acid salt complexed to bovine serum albumin, as the methyl ester complexed to bovine serum albumin, or as the methyl ester in ethanol, showed no differences in the metabolism of these substrates *via* desaturation and elongation to 20:4n-3 and 20:5n-3 (see Ref. 9). No methyl esters were detectable in total lipid extracted from cells incubated with methyl esters. Therefore, the methyl esters of both 18:4n-3 and 18:5n-3 (and 2-*trans* 18:5n-3) were used in order to avoid having to saponify the methyl ester of 18:5n-3 to its free fatty acid (see the Results section).

*Lipid extraction and analysis.* Methods for the extraction of total lipids from cells, preparing fatty acid methyl esters from total lipid, determining radioactivity in fatty acid methyl esters separated on $AgNO_3$, and analyzing fatty acids by GC and radio-GC were as described in detail previously (9,10, 12). The identities of individual radioactive fatty acid methyl esters separated by $AgNO_3$ for radioassay were confirmed by direct radio-GC analyses (12).

[a]The [U-$^{14}$C]18:4n-3 and [U-$^{14}$C]18:5n-3 had specific activities of approximately 12 and 19 mCi/mmol, respectively, and were added to cell cultures as methyl esters in 50 μL ethanol at an isotopic concentration of 0.25 μCi per flask containing 15 mL of medium, equivalent to 0.021 μmol (1.4 μM) and 0.013 μmol (0.87 μM) for [U-$^{14}$C]18:4n-3 and [U-$^{14}$C]18:5n-3, respectively. Data for incorporation into fatty acid fractions are percentages of total radioactivity recovered in fatty acids. All results are presented as means ±SD of triplicate experiments. The statistical significance of differences between mean values obtained for each cell line was analyzed by the Student's *t*-test with differences reported as significant as indicated by an asterisk if $P < 0.05$. ND, not detected; AS, Atlantic salmon cell line; SAF-1, gilthead sea bream cell line; TF, turbot fin cell line.

*Materials.* Sodium [$^{14}$C]bicarbonate (~50 mCi/mmol) was purchased from ICN Biomedicals Ltd. (Thame, United Kingdom). TLC (20 cm × 20 cm × 0.25 mm) and high-performance TLC (10 cm × 10 cm × 0.15 mm) plates, precoated with silica gel 60, were obtained from Merck (Darmstadt, Germany). All solvents were of HPLC grade (Rathburn Chemicals, Walkerburn, Peebleshire, Scotland). Ecoscint A was purchased from National Diagnostic (Atlanta, GA). Leibovitz L-15 medium, Hanks' balanced salt solution, FBS, glutamine/penicillin/streptomycin (200 mM L-glutamate, 10,000 U penicillin, and 10 mg streptomycin per mL of 0.9% NaCl), HEPES buffer, fatty acid-free bovine serum albumin, trypsin/EDTA, and standard octadecatetraenoic acid (all-*cis* 18:4n-3) were obtained from Sigma Chemical Co. Ltd. (Poole, United Kingdom).

*Statistical analysis.* All results are presented as means ± SD of three experiments. The statistical significance of differences between mean values in Table 1 obtained for each cell line were analyzed by the Student's *t*-test with differences reported as significant if $P < 0.05$ (18).

## RESULTS

The initial experiments in this study were performed with radiolabeled 18:4n-3 and 18:5n-3 isolated from the alga *I. galbana* grown in the presence of radioactive bicarbonate. The fatty acids were prepared as methyl esters following transmethylation of total lipid extracted from the alga. In preparing the free acid by saponifying the methyl ester of 18:5n-3, we noted by TLC analyses of the reaction products that all-*cis* 18:5n-3 was present in low yield and accompanied by other unknown compounds. We compared the incorporation of 18:5n-3 free acid and its methyl ester into lipids of the three cultured cell lines chosen for study, adding the substrates to the cells in ethanol. No differences were found in the incorporation patterns for the free acid and its methyl ester. Therefore, to maximize the use of the limited amounts of 18:5n-3 methyl ester prepared from *I. galbana*, we routinely used the methyl ester of 18:5n-3 in subsequent experiments.

The results of the incorporation of the methyl esters of [U-$^{14}$C]18:4n-3 and [U-$^{14}$C]18:5n-3 into the three cell lines are shown in Table 1. In these experiments fatty acid methyl esters were prepared from total lipid isolated from the cell cultures and then separated by $AgNO_3$-TLC for radioassay, with the results being confirmed by radio-GC. In no case was radioactive 18:5n-3 recovered from the cells. Rather, 18:4n-3, 20:4n-3, and 20:5n-3 were the major fatty acids labeled after incubation with either [U-$^{14}$C]18:4n-3 or [U-$^{14}$C]18:5n-3 in all three cell lines. The percentage distribution of radioactivity between 18:4n-3, 20:4n-3, and 20:5n-3 differed in the different cell lines depending upon the relative activities of $C_{18}$–$C_{20}$ elongase and Δ5 desaturase. In TF, the percentages of radioactivity recovered in 18:4n-3, 20:4n-3, and 20:5n-3 were the same in cells incubated with [U-$^{14}$C]18:4n-3 and [U-$^{14}$C]18:5n-3, with 18:4n-3 containing a high percentage of radioactivity, 20:5n-3 a modest percentage, and 20:4n-3 a minor percentage. A similar result was obtained for SAF-1 except that the percentages of radioactivity in 20:4n-3 and 20:5n-3 were essentially reversed compared to the turbot cell line. AS gave a different result in that the highest percentage of radioactivity was recovered in 20:5n-3, with both 18:4n-3 and 20:4n-3 having moderate percentages of radioactivity. The species (cell line) differences were emphasized by presenting the data as the summed products for each enzymic step in the pathway, with the marine fish cells clearly show-

[a]All results (percentage of total radioactivity recovered) are presented as means ± SD of triplicate experiments. The statistical significance of differences between mean values obtained for each cell line was analyzed by the Student's *t*-test with differences reported as significant if $P < 0.05$ (denoted by an asterisk). Δ-6′ desaturase, formerly termed Δ-4 desaturase; for other abbreviations see Table 1.

ing considerably lower $C_{18}$–$C_{20}$ elongase activity and, in the case of sea bream cells, lower Δ5 desaturase activity compared to the salmon cells (Table 2). However, as with the marine fish cell lines, the percentage distribution patterns in AS were the same for cells incubated with [U-$^{14}$C]18:4n-3 and cells incubated with [U-$^{14}$C]18:5n-3. Thus, the two radioactive substrates yielded the same result in a given cell line irrespective of the pattern of desaturation/elongation expressed by the cell line. Table 1 also shows that of the 0.25 μCi of radioactive fatty acid substrate added, averaged values of 32 and 23% of radioactivity were recovered as fatty acids from cells incubated with [U-$^{14}$C]18:4n-3 and [U-$^{14}$C]18:5n-3, respectively, from the three cell lines. However, the difference between the two substrates was significant only for AS.

An obvious explanation for the findings in Table 1 is that 18:5n-3 is rapidly converted to 18:4n-3 in the cells. This possibility, together with the apparent lability of 18:5n-3 during alkaline saponification of its methyl ester, prompted us to examine the stability of 18:5n-3 in more detail. Therefore, we synthesized 18:5n-3 as the free acid from 22:6n-3 using the γ-iodo-lactonization of 22:6n-3 method as described by Kuklev *et al*. (14). Treating the 18:5n-3 product with aqueous alkali generated four compounds, two major and two minor, as shown by HPLC analysis (see the Materials and Methods section). The two major products were identified by $^1$H NMR and GC as all-*cis* 18:5n-3 (25% of the total products) and 2-*trans* 18:5n-3 (62% of the total products). We then studied the metabolism of the methyl esters of the two isomers of 18:5n-3 (and 18:4n-3) in AS. As there was insufficient isotopically labeled 18:5n-3 available to produce labeled 2-*trans* 18:5n-3 using the method above, the experiment was performed with unlabeled fatty acid substrates at higher concentrations (25 μM) to enable analysis by conventional GC methods. The results showed that cells incubated with 25 μM of all three fatty acid substrates showed increased proportions of 18:4n-3, 20:4n-3 and, to a lesser extent, 22:4n-3 and 20:5n-3 in their lipids over time up to 24 h after supplementation (Table 3). There was no change in the proportions of 22:6n-3 or 22:5n-3 in cell cultures incubated with any of the three fatty acid substrates. The increased concentration of 18:4n-3 in cellular lipids was somewhat less with 2-*trans* 18:5n-3 than all-*cis* 18:5n-3, but the patterns were similar for all three substrates and broadly the same as those observed with the methyl esters of [U-$^{14}$C]18:4n-3 and [U-$^{14}$C]18:5n-3 in Table 1. The results in Table 3 also show that no 18:5n-3 was detected in lipids recovered from the cells incubated with any of the fatty acid substrates.

## DISCUSSION

Octadecapentaenoic acid (all-*cis* 18:5n-3; Fig. 1) is present in classes of algae that have major roles in the marine environ-

[a]All supplemented fatty acids were unlabeled and added as methyl esters in 50 μL ethanol at a fatty acid concentration of 25 μM as described in detail in the Materials and Methods section. Results are expressed as percentage of weight of total fatty acids and are mean values ±SD of three determinations. For abbreviations see Table 1.

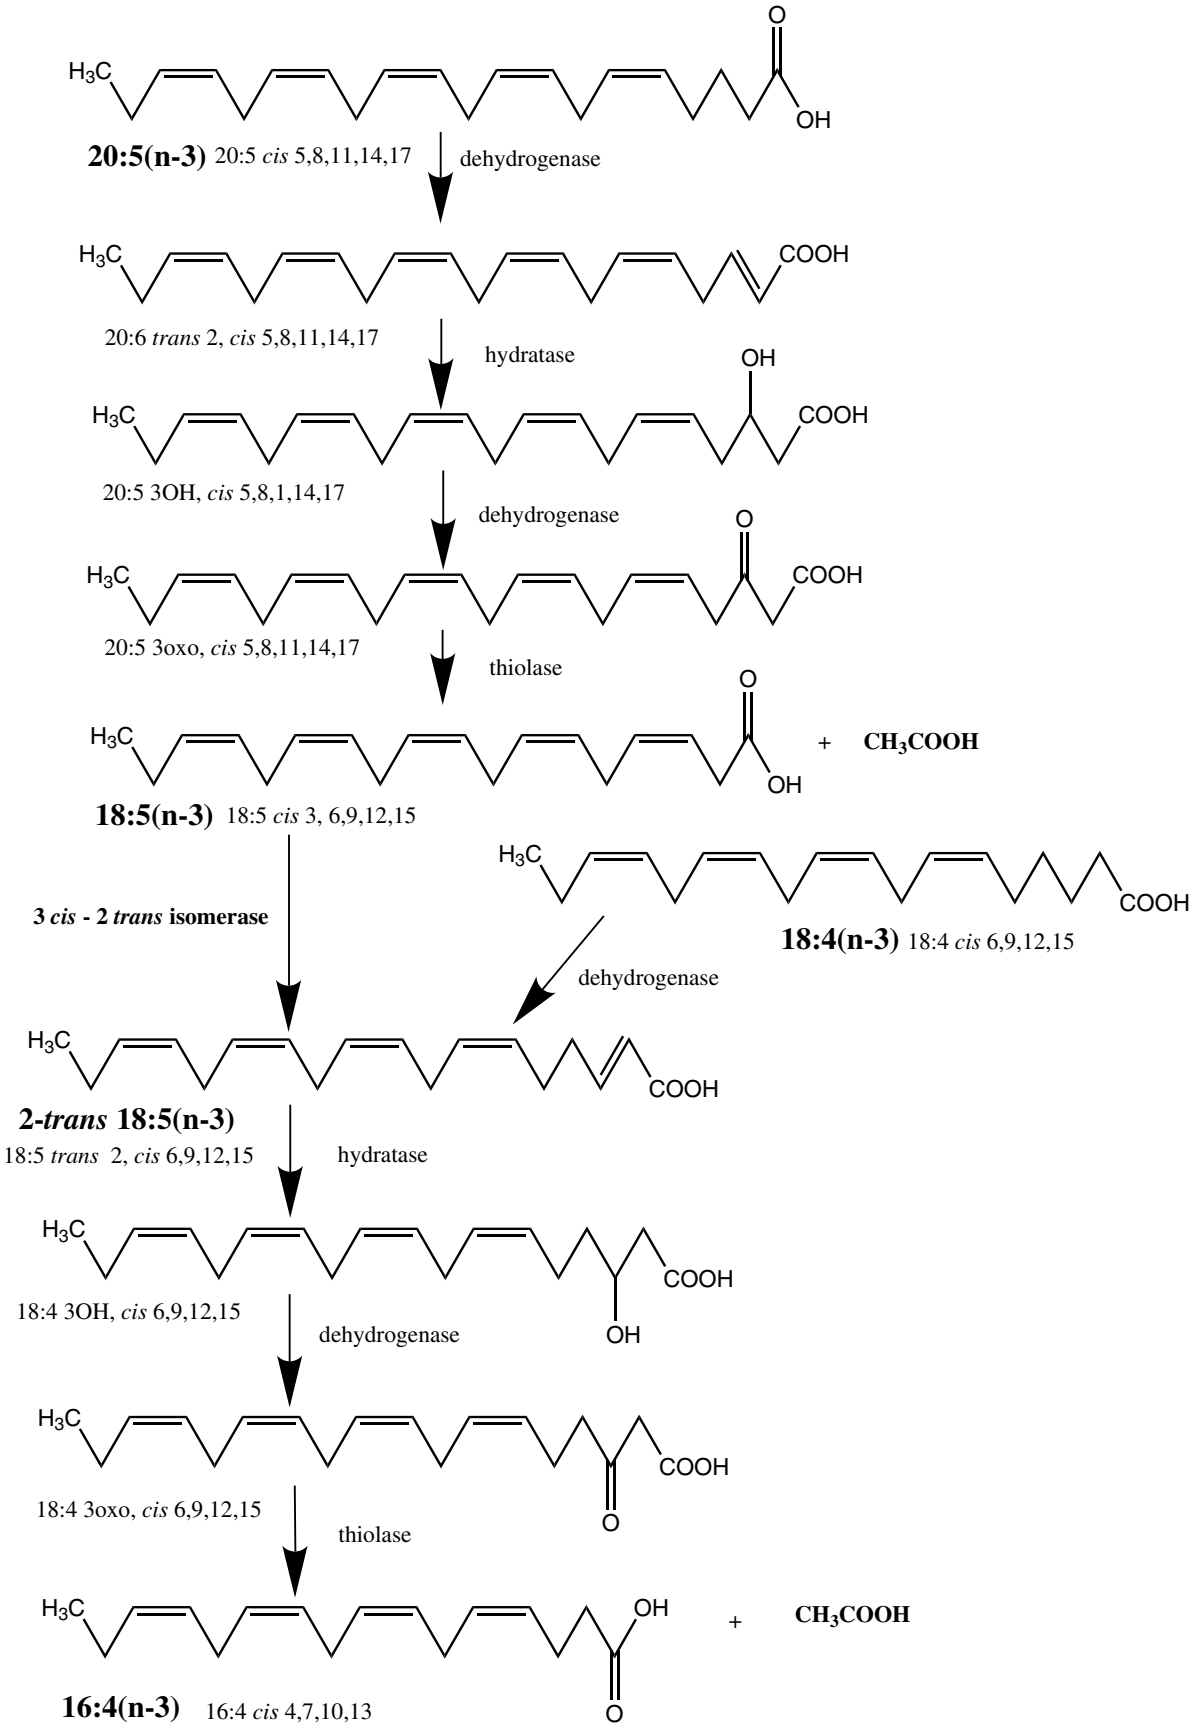

**FIG. 1.** Section of the β-oxidation pathway for n-3 polyunsaturated fatty acids showing the position of 2-*trans* 18:5n-3 as a common intermediate in the β-oxidation of 18:5n-3 and 18:4n-3.

ment (6). Thus, dinoflagellates can form large toxic blooms; the haptophycean *Phaeocystis pouchetti* is a major source of scum polluting beaches and inshore waters of mainland European coasts; the haptophycean coccolithophore *Emiliania huxleyi* is a major source of marine $CaCO_3$ deposits; the latter two organisms are major sources of dimethyl sulfide implicated as a source of "acid rain." The acid 18:5n-3 can account for more than 15% of the total fatty acids in these organisms, being present in glycolipids where it can account for 66% of the total fatty acids (6). However, it is seldom if ever detected in significant amounts in phytoplankton-consuming animals (1), i.e., in zooplankton and some fish, consistent with its being rapidly metabolized by marine animals.

The acid 18:5n-3 coexists in the aforementioned organisms with 22:6n-3, and it is unusual in sharing with 22:6n-3 the property of having the maximum number of double bonds possible in a carbon chain. However, unlike 22:6n-3 whose terminal double bond is four carbons from the carboxyl terminus, the terminal double bond in 18:5n-3 is three carbons from the carboxyl terminus. The insertion of the last (Δ4) double bond in 22:6n-3 occurs by a mechanism whereby 24:5n-3 is Δ6-desaturated to 24:6n-3, which is then chain-shortened in peroxisomes to 22:6n-3 (19). Similarly, the biosynthesis of 18:5n-3 is not thought to be possible solely through the action of desaturases and elongases with the conventional pathway from 18:3n-3 to 20:5n-3 proceeding *via* 18:4n-3 then 20:4n-3. However, by analogy with the biosynthesis of 22:6n-3, the formation of 18:5n-3 is probably straightforward, at least in principle, in that it can be formed directly from 20:5n-3 by chain-shortening as postulated previously (6). The precise subcellular location(s) of these putative chain shortening steps in the biosynthesis of 22:6n-3 and 18:5n-3 in these marine phytoplankton are not known (20).

As its biosynthesis requires a special mechanism, so the catabolism of 22:6n-3 requires a special mechanism in that the 2-*trans*,4-*cis* intermediate formed by the initial direct dehydrogenation of 22:6n-3 is converted by a 2,4-dienoyl reductase to a 3-*trans* intermediate, which is then converted by a $\Delta^3$,$\Delta^2$-enoyl isomerase to a 2-*trans* intermediate (21,22). The latter two enzymes are auxiliary enzymes to the multifunctional enzymes of β-oxidation required for the β-oxidation of PUFA in both mitochondria and peroxisomes (23,24). The 2-*trans* 22:6n-3 intermediate can then continue in the conventional β-oxidation pathway through hydration across the 2,3-*trans* double bond to yield the 3-hydroxy and then the 3-keto intermediate. Similarly, catabolism of 18:5n-3 requires, in principle, the operation of a $\Delta^3$,$\Delta^2$-enoyl isomerase to generate the 2-*trans* intermediate required for entry into the β-oxidation pathway though, to our knowledge, this reaction has never been studied with 18:5n-3 (Fig. 1).

The results here establish the ease with which all-*cis* 18:5n-3 can be converted to its 2-*trans* isomer. Thus, all-*cis* 18:5n-3, chemically synthesized from 22:6n-3, was readily converted in high yield to its 2-*trans* isomer by treatment with alkali in aqueous ethanol. The protons at C-2 of all-*cis* 18:5n-3 are both allylic to the *cis*-3,4-double bond and α to the terminal carboxyl group, and hence should experience a reduction in $pK_a$ (relative to, for example, the corresponding protons in 18:4n-3). These combined effects would be expected to result in an increased tendency of the 18:5n-3 to undergo enolization, particularly in protic solvents. Enolization results in the conjugation of the 3,4-double bond with the enol and hence the configurational stability of the 3,4-double bond may be compromised. Furthermore, when reprotonation of the intermediate enol occurs, it can do so either at C-2 (regenerating 18:5n-3 with either *cis*- or *trans*-stereochemistry at C-3), or at C-4, which would result in the conjugation of the double bond with the carboxylic acid. The latter process is expected to be thermodynamically preferred and would be expected to result in the preferential formation of the *trans* Δ2, all-*cis* Δ6,9,12,15-18:5n-3 acid. The chemical isomerization of all-*cis* 18:5n-3 to *trans* Δ2, all-*cis* Δ6,9,12,15-18:5n-3 has not, to our knowledge, been reported before. However, it may have been observed but misinterpreted in that, in reducing all-*cis* 18:5n-3 with hydrazine to determine double bonds, Napolitano *et al.* (25) noted a loss of 18:5n-3 and mentioned the occurrence of an extra peak of 18:4n-3 in gas chromatograms of the reaction products. It is possible that the extra peak was a 2-*trans* 18:5n-3 isomer whose formation was prompted by availability of protons in the reaction.

In contrast to 18:5n-3, which is an intermediate in the conventional β-oxidation pathway of 22:6n-3 and 20:5n-3, 18:4n-3 is not, as one cycle of β-oxidation of 18:5n-3 results in the formation of 16:4n-3 *via* 2-*trans* 18:5n-3, 3-hydroxy 18:4n-3 and 3-oxo 18:4n-3 (26) (Fig.1). However, the first step in the β-oxidation of 18:4n-3 is the action of dehydrogenase to yield 2-*trans* 18:5n-3. Therefore, 2-*trans* 18:5n-3 is a common intermediate in the β-oxidation of both 18:5n-3 and 18:4n-3 (Fig. 1).

When the various cell lines were incubated with [U-$^{14}$C]-18:5n-3 methyl ester, no radioactive 18:5n-3 was detected in total lipid extracted from the cells. However, radioactivity was readily detected in 18:4n-3 and its elongated and further desaturated products, 20:4n-3 and 20:5n-3. Moreover, for a given cell line, the distributions of radioactivity in 18:4n-3, 20:4n-3, and 20:5n-3 from cells incubated with [U-$^{14}$C]-18:5n-3 were essentially the same as those generated from the same cells incubated with [U-$^{14}$C]18:4n-3. Similarly, the increases in the mass percentage of 18:4n-3, 20:4n-3, and 20:5n-3 in Atlantic salmon cells incubated with 25 μM 18:4n-3 were similar in cells incubated with 25 μM all-*cis* 18:5n-3 and also with 25 μM 2-*trans* 18:5n-3. The observed patterns are in accord with our previous findings and conclusions that Atlantic salmon cells convert 18:4n-3 to 20:5n-3 more readily than either turbot or sea bream cells, owing to a relative deficiency in the $C_{18}$–$C_{20}$ fatty acid elongase in turbot cells and a relative deficiency in the Δ5 fatty acid desaturase in the sea bream cells (9,10). Consequently, production of radiolabeled 22:5n-3 was higher in the salmon cells incubated with labeled 18:4n-3 and 18:5n-3 than in turbot and sea bream cells, but although 22:5n-3 is a poor substrate for retroconversion to 20:5n-3 and serves as a substrate for 22:6n-3

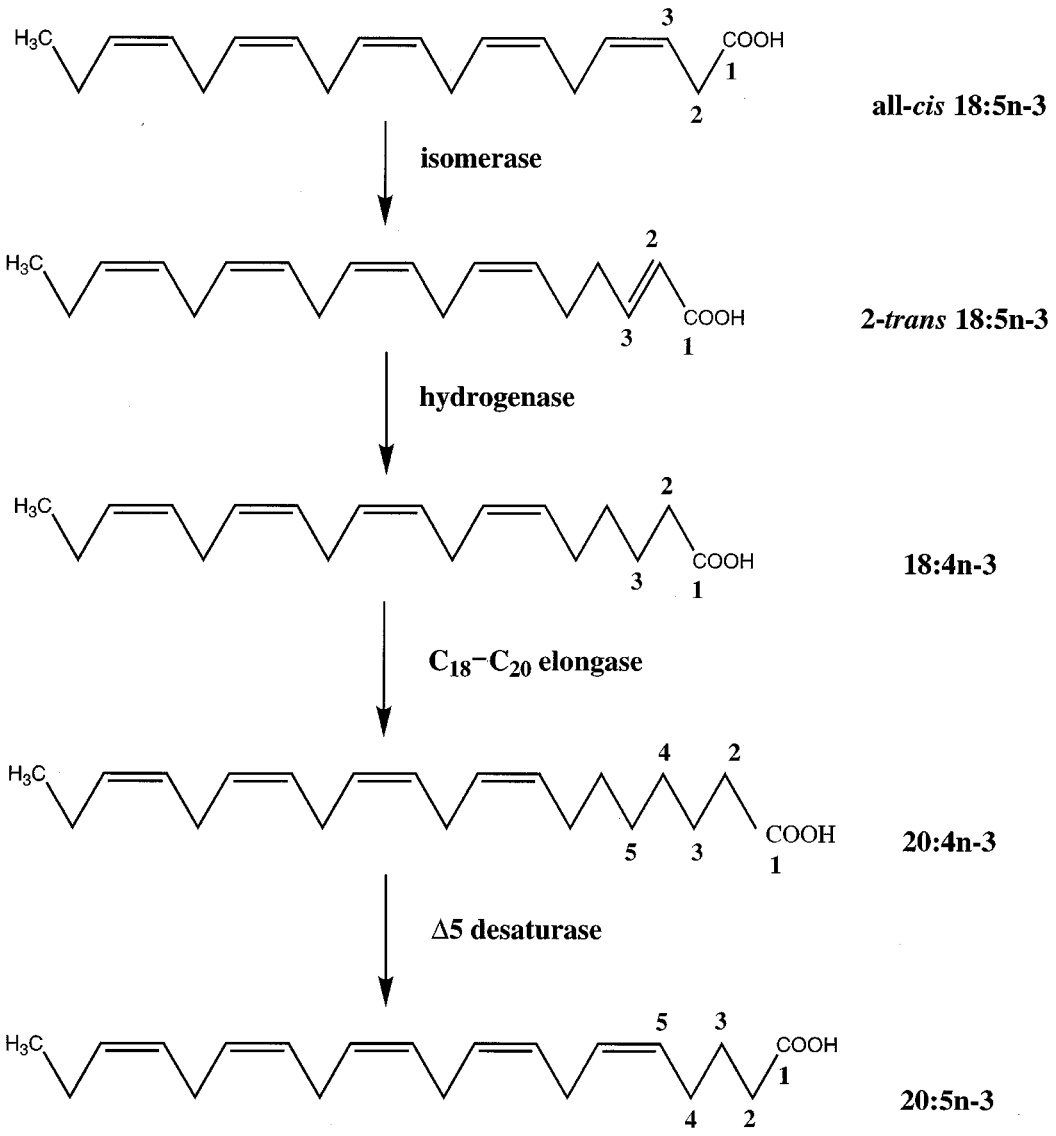

**FIG. 2.** Reaction scheme whereby 18:5n-3 is converted to 18:4n-3 and thence to 20:5n-3 in cultured fish cells.

formation (27), there was virtually no production of 22:6n-3 in salmon cells similar to the marine fish cell lines. This is not unexpected as most established cells in culture lack the ability to produce substantial amounts of 22:6n-3 although the precise reason in enzymic terms is unknown (20). The results are also consistent with all-*cis* 18:5n-3 being readily converted to 18:4n-3 in all the cell lines, *via* a $\Delta^3$,$\Delta^2$-enoyl isomerase generating a 2-*trans* 18:5n-3 intermediate followed by a hydrogenase (reversed dehydrogenase activity) operating on the 2-*trans* 18:5n-3 intermediate to generate 18:4n-3 (Fig. 2). The 18:4n-3 so produced is then available for elongation and desaturation reactions to generate 20:4n-3 and 20:5n-3 (Fig. 2).

As noted earlier, some 32 and 23% of the radioactivity added as [U-$^{14}$C]18:4n-3 and [U-$^{14}$C]18:5n-3, respectively, was recovered from cellular total lipid as 18:4n-3, 20:4n-3, and 20:5n-3, the remainder presumably being converted to β-oxidation products (Fig. 1). That 18:5n-3 is more readily β-oxidized than 18:4n-3 by the cells implies that the isomerization of added all-*cis* 18:5n-3 to 2-*trans* 18:5n-3 proceeds more readily in the cells than the 2,3-dehydrogenation of added 18:4n-3 to 2-*trans* 18:5n-3. This may reflect the fact that the cells studied here were actively growing and dividing and therefore as much concerned with directing exogenous PUFA into biosynthetic pathways directed toward membrane lipid formation as into β-oxidation.

Irrespective of how the relevant anabolic and catabolic pathways are controlled, the ease of conversion of all-*cis* 18:5n-3 to 2-*trans* 18:5n-3 and thence to 18:4n-3, demonstrated here in fish cells, readily accounts for the absence of 18:5n-3 from marine trophic levels higher than the algae.

## ACKNOWLEDGMENTS

We thank Dr. D.V. Kuklev for his advice in the chemical synthesis of 18:5n-3 from 22:6n-3 and Dr. M.V. Bell for his help in purifying fatty acids by HPLC. The research was funded by the European Union under the FAIR initiative (GT97-0641).

# Characterization of *N*-Acylphosphatidylethanolamine and Acylphosphatidylglycerol in Oats

**Jan Holmb ck[a,*], Anders . Karlsson[b], and Kristina C. Arnoldsson[c]**

[a]Department of Chemistry, Organic Chemistry, Royal Institute of Technology, SE-100 44 Stockholm, Sweden , [b]Nycomed Innovation AB, Medeon, SE-205 12 Malmö, Sweden, and [c]Lipocore AB, SE-113 84 Stockholm, Sweden

**ABSTRACT:** Two polar lipid classes, both with three acyl groups, were isolated from an extract of oats and characterized by nuclear magnetic resonance spectroscopy, electrospray mass spectrometry (MS), and electron ionization MS (EIMS). Distortionless enhancement by polarization transfer (DEPT) and the two-dimensional correlation experiments $^1$H-detected heteronuclear multiple quantum coherence spectroscopy, heteronuclear multiple bond correlation spectroscopy, double quantum filtered correlation spectroscopy, and total correlation spectroscopy provided sufficient information for determination of the structure of the two lipid classes. The polar lipid classes were found to be *N*-acylphosphatidylethanolamine [1,2-diacyl-*sn*-glycero-3-phospho-(*N*-acyl)-1′-ethanolamine; *N*-acyl-PE] and acylphosphatidylglycerol [1,2-diacyl-*sn*-glycero-3-phospho-(3′-acyl)-1′-*sn*-glycerol]. High-performance liquid chromatography with electrospray ionization MS (HPLC-ESMS) and with electrospray ionization tandem MS (HPLC-MS/MS) were utilized for the separation and subsequent determination of molecular species. With HPLC-ESMS, ions of deprotonated molecules were obtained and with HPLC-MS/MS carboxylate ions (representing acyl groups) were obtained as well as other structurally significant ions. Fifty molecular species of *N*-acylphosphatidylethanolamine and 24 molecular species of acylphosphatidylglycerol were found, with a molecular mass range of 924–1032 Da and 959–1035 Da, respectively. Identification of the fatty acid isomers, as picolinyl ester derivatives, was done with gas chromatography with EIMS. Three isomers of 16:1 fatty acids were found in *N*-acyl-PE, and their double bond positions were determined to 6, 9, and 11 with a relative abundance of 4:10:1.

Paper no. L8392 in *Lipids 36,* 153–165 (February 2001).

Cereals such as oats, wheat, and rye have traditionally not been considered as potential sources for lipids due to their low lipid content. However, oats (*Avena sativa* L.) has been reported to have higher lipid content, with a higher nutritional value, than other cereals (1–3). Oat oil and fractions thereof have interesting physical, nutritional, and dermatological properties, and can find many uses in the food, cosmetics, and pharmaceutical industries (4–6).

Polar lipid fractions from cereals show a high content of galactolipids as well as wide variety of different phospholipid classes, such as phosphatidylcholine, phosphatidylethanolamine (PE; 1,2-diacyl-*sn*-glycero-3-phospho-1′-ethanolamine) and phosphatidylglycerol (PG; 1,2-diacyl-*sn*-glycero-3-phospho-1′-*sn*-glycerol) (1). However, several of the minor components have not yet been identified.

Among the minor components in cereals that have been described, N-acylated glycerophospholipids are perhaps the most interesting, since they have been reported in only a handful of biological systems. The properties of N-acylated glycerophospholipids have been thoroughly reviewed (7), and their presence in microorganisms, plants, fish, and mammalian tissues are reported. It has been suggested that the occurrence of these compounds is an artifact owing to conditions of extensive cellular degeneration (8) or to incorrect identification (9), but later evidence showed that they play a metabolic role in the tissues where they appear (7,10,11). Recent reports indicate the importance of *N*-acylphosphatidylethanolamines (*N*-acyl-PE) as precursors for *N*-acylethanolamines, which in turn play a physiological role during germination of seeds and in defense systems in plants (12,13). The levels and decrease of *N*-acyl-PE during early germination of various seeds have been reported (14). The content of *N*-acyl-PE in oats was found to be significantly higher (up to 13% of total seed phospholipids) than in the other species studied.

Several aspects motivate the characterization of these components in cereals. Firstly, since the lipid class composition differs from other plant tissues, it is of interest to study the significance of the components for the membrane structure of the seed tissues. Secondly, it is important to investigate the chemical composition in order to understand the physical behavior of cereal lipid extracts (15,16). Lastly, as already indicated, some of them may have biological functions apart from being constituents of the biological membranes, and it is therefore important to be able to detect them.

Nuclear magnetic resonance (NMR) spectroscopy is an ideal technique for the study of polar lipids and especially

glycerophospholipids (17,18). $^{1}H$, $^{13}C$, and $^{31}P$ spectra and correlation experiments of the combinations of these nuclei can be achieved. The diversity of functional groups within the molecules yields a good spread of signals in the $^{1}H$ and $^{13}C$ spectra, thus providing significant structural information.

Another powerful technique used today in the analysis of intact polar lipids is high-performance liquid chromatography (HPLC) on-line with mass spectrometry (MS) and/or tandem mass spectrometry (MS/MS). The process of first separating the polar lipid extract by HPLC into either different lipid classes or molecular species within a class and then detecting them with MS makes simultaneous determination of molecular ions and identification of several structural elements possible. Several papers have recently reported the use of electrospray ionization mass spectrometry (ESMS), with or without HPLC separation, in the structural determination of many different intact polar lipids (19–24).

Important features of lipid molecules are the chain length and position of double bonds and other structural elements in the fatty acid. A convenient analytical technique for obtaining this information is gas chromatography–mass spectrometry (GC–MS) of certain fatty acid derivatives (25). The derivative should be able to retain the charge when the molecule is ionized in the mass spectrometer, to minimize double-bond migration and to give diagnostic ions for structural elements. Nitrogen-containing derivatives meet these requirements, and the picolinyl ester is commonly used for the determination of double-bond positions and other structural features (26,27).

In this paper we have characterized two components in oats, *N*-acyl-PE (Fig. 1) and 3′-*O*-acylphosphatidylglycerol (acyl-PG, Fig. 2) by one- and two-dimensional $^{1}H$- and $^{13}C$-NMR, HPLC–ESMS, HPLC–MS/MS and GC–electron ionization mass spectrometry (EIMS) of fatty acid picolinyl esters. *N*-Acyl-PE has previously been reported as a component in oats and other plant seeds (1,14,28). To our knowledge, acyl-PG has been found in microorganisms such as mold (29), bacteria (30–32), trichomonads (33), and in mammalian tissues (34–37), but not in plants.

## EXPERIMENTAL PROCEDURES

*Polar lipids from oat*. Fractionated oat oil extracts (Galactolec™; Ref. 38), obtained from Scotia LipidTeknik AB (Stockholm, Sweden), were used as a starting material for most experiments. For quantitative determinations fresh oat flakes, obtained by rolling oat grains (*A. sativa* L., cv. Freia) under mild conditions, were extracted by ethanol.

*Chemicals*. Solvents used for liquid chromatography (LC) were of HPLC quality. All other solvents and chemicals were of analytical grade. Glacial acetic acid, aqueous ammonia 25%, potassium hydroxide, isohexane, diethyl ether, methanol, chloroform, and dichloromethane were purchased from

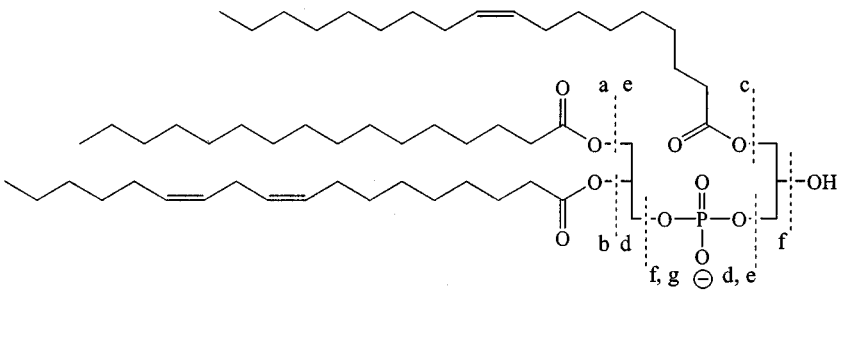

**FIG. 2.** Structure of acylphosphatidylglycerol [1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phospho-(3′-lineoloyl)-1′-glycerol; acyl-PG]. Suggested cleavage sites using negative ion electrospray with collision-induced dissociation are indicated by dashed lines.

Merck (Darmstadt, Germany), absolute ethanol from Kemetyl (Haninge, Sweden), and oxalyl chloride and 3-(hydroxymethyl)pyridine from Sigma-Aldrich (Steinheim, Germany). Hexane and isooctane were purchased from CertiFi (Fisher Scientific, London, United Kingdom), tetrahydrofuran and water from LabScan (Dublin, Ireland), isopropanol from Fisons (Loughborough, United Kingdom), and ammonium acetate from BDH Chemicals Ltd. (Poole, United Kingdom). Chloroform-$d_1$ and methanol-$d_4$ were purchased from Aldrich (Milwaukee, WI).

Nano-Platten® SIL-20 $UV_{254}$ (Macherey-Nagel, Düren, Germany) were used for analytical thin-layer chromatography (TLC) and PSC-Fertigplatten Kieselgel 60, 2 mm (Merck) for preparative TLC.

*Isolation*. Galactolec™ (100 mg) was dissolved in 0.5 mL of hexane and applied to two Sep-Pac Plus Silica cartridges (Waters, Milford, MA) coupled in series. The cartridges were subsequently washed with 10 mL of hexane, 10 mL of hexane/2-propanol (9:1, vol/vol), 40 mL of hexane/2-propanol (8:2), and 60 mL of acetone. A fraction was then eluted by 10 mL of chloroform/methanol (2:1) yielding 11 mg. TLC analysis on silica, with chloroform/methanol/concentrated ammonia (40:10:2, by vol) as eluant, indicated two major components in this fraction, **1** ($R_F$, 0.62) and **2** ($R_F$, 0.42). The procedure was repeated several times, and the obtained fractions were pooled. Components **1** and **2** were then separated by running preparative TLC with chloroform/methanol/aqueous ammonia 25% (40:10:2, by vol). The contents of **1** and **2** in the different fractions were roughly quantified by the use of a previously described HPLC method (39).

*NMR analysis*. Sample (10–20 mg) was dissolved in a mixture of 0.6 mL chloroform-$d_1$ and 0.3 mL methanol-$d_4$ and transferred to an NMR tube (5 mm o.d.).

The $^1$H NMR spectra were acquired at 500 MHz and the $^{13}$C spectra at 125.8 MHz.

To facilitate structural elucidation, distortionless enhancement by polarization transfer (DEPT) and the two-dimensional (2D) correlation experiments $^1$H-detected heteronuclear multiple quantum coherence spectroscopy (HMQC), heteronuclear multiple-bond correlation spectroscopy (HMBC), double quantum filtered correlation spectroscopy (DQF-COSY), and total correlation spectroscopy (TOCSY) were performed.

*HPLC–MS and HPLC–MS/MS analysis*. A Varian model 9012 gradient pump (Varian Chromatography Systems, Walnut Creek, CA) with a Rheodyne injector (Rohnert Park, CA) fitted with a 10-µL loop was used for the sample introduction. The LC separations were performed on a PVA-Sil column, 250 × 3.0 mm i.d. (5 µm; YMC, Inc., Wilmington, NC). Solvent mixture A consisted of hexane/isopropanol/tetrahydrofuran/isooctane/ammonium acetate (2.3 mM)/water (64:26:4.5:4.5:0.4:1, by vol) and solvent mixture B of isopropanol/tetrahydrofuran/isooctane/ammonium acetate (2.3 mM)/water (81:4.5:4.5:0.4:10, by vol). The flow rate was 0.4 mL/min and the column temperature 80°C. The solvent composition followed a linear gradient profile: at 0 min, 100% A; at 25 min, 0% A; at 26 min, 0% A; at 26.5 min, 100% A; and at 40 min, 100% A. Prior to use of the column, a blank gradient was run.

MS was performed on a Micromass QUATTRO II mass spectrometer (Micromass Instruments, Altrincham, United Kingdom) equipped with a pneumatically assisted electrospray ion source. Data handling was performed on a VG Masslynx NT32 data handling system (Manchester, United Kingdom). Full scan spectra, between *m/z* 150 and 2,000, were obtained at a scan speed of 250 Da/s with a mass resolution of 1 Da at half peak height. The LC effluent entered the mass spectrometer through an electrospray (ES) capillary set at 2.4 kV at a source temperature of 160°C and a cone voltage of 60 V. Nitrogen was used as the drying gas as well as the nebulizing gas at a flow rate of 250–300 and 20 L/h, respectively. The collision-induced dissociation (CID) spectra, at a cone voltage of 60 V, were recorded at a collision energy of 25 eV, with a mixture of xenon + argon (1:3, vol/vol) as collision gas at a pressure of $1 \times 10^{-3}$ mbar. Approximately 5–10 µg of sample was injected in all of the analyses.

*Preparation of picolinyl esters for GC–MS analysis*. Alkaline hydrolysis of the sample was performed on 5 mg of lipid dissolved in 1 mL of absolute ethanol using 0.1 mL of 1 M potassium hydroxide solution. The reaction was carried out in a stoppered tube at 50°C during 3 h. After cooling, 2 mL of water was added and the sample was acidified with glacial acetic acid. The free fatty acids were extracted twice with 6 mL of hexane/diethyl ether (1:1, vol/vol). The combined extracts were dried with sodium sulfate before being taken to dryness in a gentle stream of nitrogen.

Derivatization of the free fatty acids to picolinyl esters was accomplished *via* the acid chloride (40). Oxalyl chloride (0.5 mL) was added to the free fatty acids and kept in a stoppered tube at room temperature overnight. The excess oxalyl chloride was evaporated, and the acid chloride was taken immediately to derivatization. A volume of 0.5 mL of a solution of 3-(hydroxymethyl)pyridine, dissolved in dichloromethane (20 mg/mL) was added to the acid chloride. The sample was cooled in an ice bath for 5 min and then held at room temperature for an hour, after which the solvent was evaporated. Water (5 mL) was added, and the picolinyl esters were recovered by extraction with 2 mL hexane. The extract was dried with sodium sulfate, evaporated, and the picolinyl esters were redissolved in hexane to an appropriate concentration for GC–MS analysis.

*GC–MS analysis*. GC–MS analysis was performed using a Varian GC 3400 connected to a Varian Saturn GC MS (Varian, Walnut Creek, CA). The GC separations were done using a Supelcowax 10 fused-silica column, 30 m × 0.25 mm, 0.25 µm film thickness (Supelco Inc., Bellefonte, PA). The oven was programmed as follows: 130°C for 2 min, thereafter the temperature was raised first to 180°C at a rate of 20°C/min and next to 280°C at 2°C/min and held there for 60 min. The injector was programmed from 180 to 260°C in 0.6 min and held there for 2 min. The ion trap was held at 220°C and the transfer line at 240°C. The scan rate was 1 scan/s from 50 to 500 amu.

## RESULTS AND DISCUSSION

*Isolation*. Two fractions, containing **1** and **2**, respectively, were obtained from the preparative TLC run as described above. These two preparations were used for NMR analysis. For the HPLC–ESMS and GC–EIMS investigations, the mixture was used. HPLC analysis of fractions from fresh oat flakes indicates a content in dry oats of 0.8–1.1 mg/g for **1** and *ca.* 0.3 mg/g for **2**. This corresponds to 3–4% (by weight) and 1.0–1.3% (by weight) of total polar lipids, or 10–12% (by weight) and 3–4% (by weight) of the total phospholipids in oats for **1** and **2**, respectively.

*NMR results*. One-dimensional (1D) and 2D experiments were utilized to determine the structures of **1** and **2** as outlined below. The reasoning was partly based on comparison with spectral data from PE and PG.

The $^{1}$H NMR spectra of **1** and **2** (summarized in Tables 1 and 2) display a pattern of signals in the regions typical for polar glycerolipids, e.g., signals from the acyl groups at δ 0.8–2.8, from olefinic protons at δ 5.3, and from protons next to nitrogen or oxygen at δ 3.4–5.2 ppm.

In the $^{13}$C NMR spectrum signals from the acyl moiety appear in the δ 14–36 ppm region, with olefinic carbons at δ 128–131 and carbonyls at δ 173–175 ppm. Three distinct carbonyl signals are visible for both **1** and **2**, showing that three acyl groups are present in both compounds. This is also confirmed by the integral ratio between the methyl group (9H) and the signal at δ 5.18–5.19 ppm (1H) in the proton spectrum.

Signals from carbons attached to hydroxyl or carboxylate groups appear at δ 60–75 ppm in the $^{13}$C spectrum. By running DEPT experiments these carbons can be classified as methylene ($CH_2$) groups (δ 64.6, 63.9, and 63.0 ppm in **1** and δ 67.1, 65.2, 63.9, and 62.9 ppm in **2**) or methine (CH) groups (δ 70.9 ppm in **1** and δ 70.8 and 69.2 ppm in **2**).

The TOCSY experiment of **1** shows the different $^{1}$H spin systems in the molecule. It is possible to identify one spin system (1A) consisting of the signals at δ 5.18, 4.37, 4.13, and 3.93 ppm and another one (1B) with signals at δ 3.89 and 3.40 ppm.

In the 2D spectrum obtained from the HMQC experiment, each one-bond $^{1}$H-$^{13}$C coupling is represented by a cross peak (see Fig. 3). Thus, all the proton signals in the 1A spin system and the signal at δ 3.89 ppm can be paired with $^{13}$C signals of methylene and methine groups in the δ 60–75 ppm range.

The chemical shifts and geminal and vicinal coupling patterns of protons in the 1A spin system, as seen in DQF-COSY (Fig. 4), as well as the chemical shifts of the corresponding $^{13}$C signals, are almost identical to the data for the diacylglycerol moiety in PE and PG. This implies that **1** contains a phosphatidyl (diacylglycerophosphate) moiety.

The HMQC experiment shows that the $^{1}$H signal at δ 3.40 ppm has a cross peak at δ 40.6 ppm, a chemical shift typical for carbons attached to an amine or amide group, e.g., C-2 in PE at δ 40.9 ppm. The chemical shift for the protons at C-2 in PE is δ 3.09 ppm. With an acyl group attached to the nitrogen by an amide bond, the signal is shifted downfield, which ex-

[a]The signal at δ 3.30 ppm from residual $CD_2HOD$ was used as shift reference.
[b]The signal at δ 49.0 ppm from $CD_3OD$ was used as shift reference.
[c]In chloroform-$d_1$/methanol-$d_4$ (1:1, vol/vol). Acyl-PG, 1,2-diacyl-*sn*-glycero-3-phospho-(3′-acyl)-1′-*sn*-glycerol; PG, 1,2-diacyl-*sn*-glycero-3-phospho-1′-*sn*-glycerol. For other abbreviation see Table 1.

plains the observed difference (approximately 0.3 ppm) in the proton shifts.

The effect on the proton shift at C-1 in the ethanolamine moiety is less pronounced (*ca*. 0.1 ppm upfield) whereas the $^{13}$C signal at C-1 is shifted *ca*. 2.6 ppm downfield, which is in accordance with empirical calculations.

Protons at the C-2 position in acyl groups are generally slightly more shielded in amides as compared to esters, which

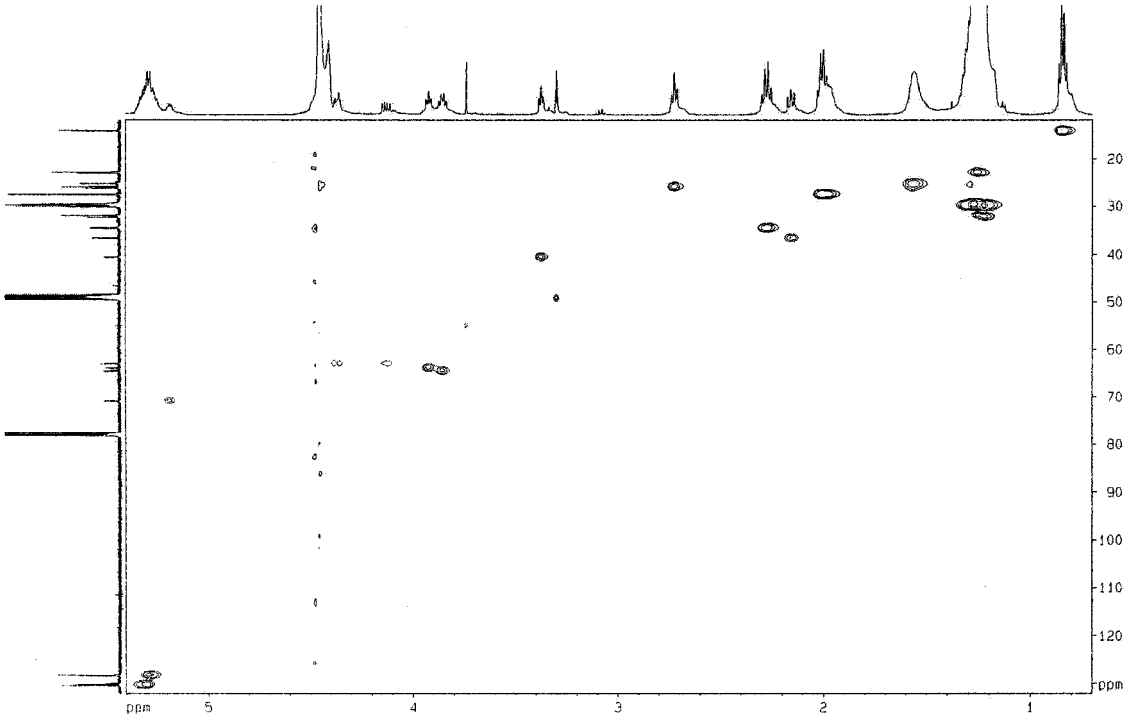

**FIG. 3.** $^1$H-Detected heteronuclear multiple quantum coherence spectroscopy spectrum of *N*-acyl-PE, showing cross peaks due to $^1J_{CH}$-couplings. For abbreviation see Figure 1.

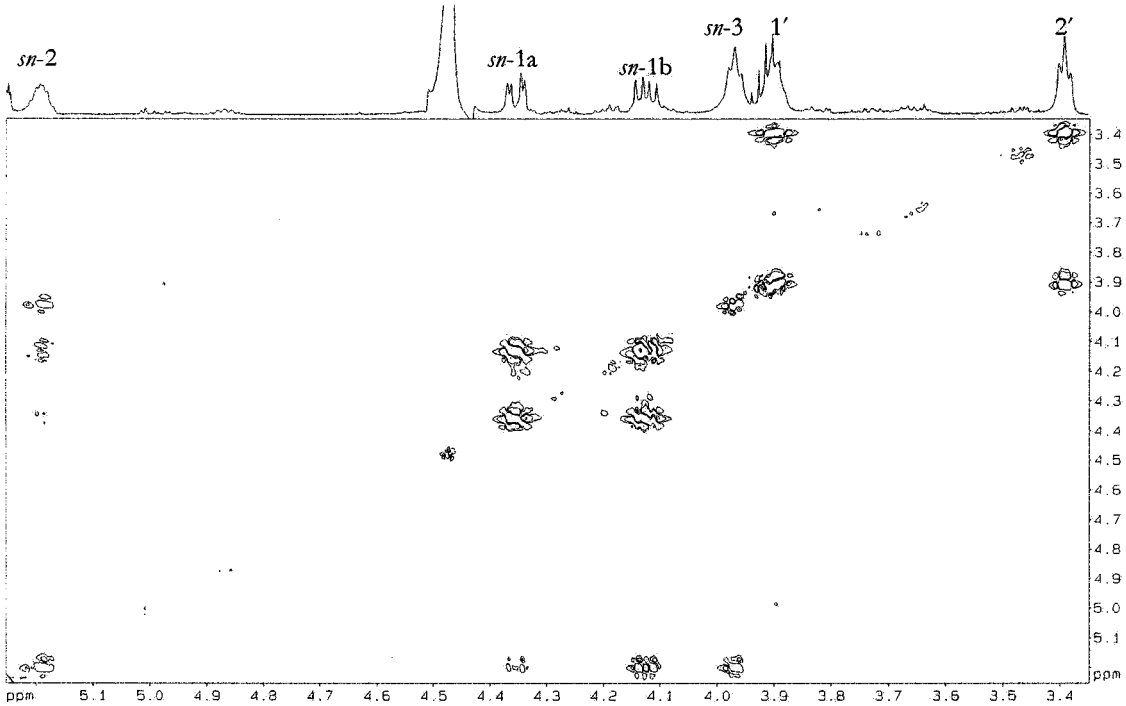

**FIG. 4.** Detail of the double quantum filtered correlation spectroscopy spectrum of *N*-acyl-PE, showing cross peaks due to $^{2}J_{HH}$ and $^{3}J_{HH}$ couplings in the glycerol moiety (*sn*-1a, *sn*-1b, *sn*-2, and *sn*-3) and the ethanolamine moiety (1′ and 2′). For abbreviation see Figure 1.

explains the signal at δ 2.17 ppm in the spectrum of **1** that does not appear in the spectrum of PE. The integral ratio between this signal and the C-2 signal from ester-bound acyl groups (δ 2.27 ppm) is also, as expected, approximately 1:2.

This evidence allows us to conclude that compound **1** is 1,2-diacyl-*sn*-glycero-3-phospho-(*N*-acyl)-1′-ethanolamine (*N*-acylphosphatidylethanolamine; *N*-acyl-PE).

For compound **2**, the TOCSY experiment allows the identification of one spin system for the proton signals at δ 5.19, 4.37, 4.13, and 3.94 ppm (2A) and another one at δ 4.09, 3.92, 3.87, and 3.81 ppm (2B). For the 2A spin system, similar reasoning as above implies that we have a diacylglycerophosphate moiety present.

The 2B spin system also resembles the glycerol moieties in the reference compounds with the exception of the signal at the *sn*-2 position, which has been shifted upfield. This effect could be explained by the substitution of a carboxylate for a hydroxyl group in this position, which leads to the conclusion that **2** is an acylphosphatidylglycerol (acyl-PG).

From these experiments it is not possible to determine the absolute stereochemistry of acyl-PG. However, it can be assumed that this compound is derived from the form of PG that is frequently found in nature, and has the phosphate ester bond at the *sn*-1′ position of the second glycerol. The extra acyl group is attached to the other primary hydroxyl group, which with the mentioned assumption implies the *sn*-3′ position. This leads to the conclusion that the compound is 1,2-diacyl-*sn*-glycero-3-phospho-(3′-acyl)-1′-*sn*-glycerol.

The conclusions regarding the structures of **1** and **2**, outlined above, can be confirmed by studying $^{13}C$-$^{31}P$ coupling constants and long-range $^{13}C$-$^{1}H$ couplings.

The signals from carbons situated close to the phosphate in the molecule appear as doublets due to the $^{13}C$-$^{31}P$ spin-spin coupling. For glycerophospholipids $^{3}J_{CP}$ is generally larger than $^{2}J_{CP}$, owing to the preferred *trans* conformation of the *sn*-3 C–O bond which gives a torsion angle of approximately 180° (41,42). In *N*-acyl-PE this is demonstrated by comparing the coupling constants for the *sn*-2 carbon in the glycerol (8 Hz) and C-2 in the ethanolamine moiety (7 Hz) with the coupling constants for the *sn*-3 carbon (5 Hz) and C-1 in the ethanolamine moiety (5 Hz).

For acyl-PG, doublets due to the $^{3}J_{CP}$ coupling can be seen in the signals for the *sn*-2 carbons in both glycerol moieties (8 and 7 Hz, respectively). These can be compared to the $^{2}J_{CP}$ coupling constants for the *sn*-3 carbon in the diacylglycerol moiety (5 Hz) and the *sn*-1′ carbon in the monoacylglycerol moiety (5 Hz).

Carbons without directly bonded protons can be assigned by utilizing an HMBC experiment in which $^{2}J_{CH}$ and $^{3}J_{CH}$ couplings give rise to cross peaks, provided that the experimental settings match the long-range coupling constants. This also holds true for couplings through ester bonds. In Figure 5, for instance, $^{3}J_{COCH}$ cross peaks can be observed for the three carbonyl carbons.

*HPLC–MS results*. The sample was first analyzed with both positive and negative electrospray (ES, ES–) MS. The total ion current (TIC) at the retention time of both acyl-PG and *N*-acyl-PE was one order of magnitude higher in ES– than in ES. In ES–, deprotonated molecules were obtained

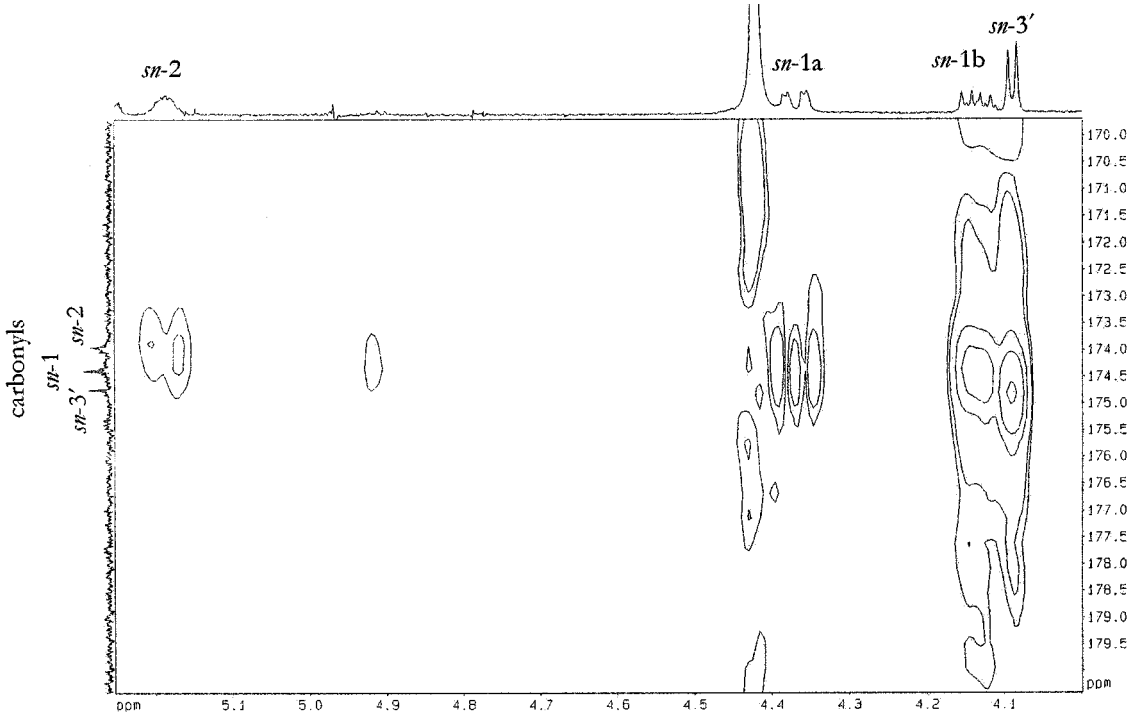

**FIG. 5.** Detail of the heteronuclear multiple-bond correlation spectroscopy spectrum of acyl-PG, showing cross peaks due to $^{3}J_{COCH}$ couplings between $^{13}C$ in carbonyls, over the ester bonds, to $^{1}H$ in the glycerol moieties. For abbreviation see Figure 2.

whereas in ES both sodium adducts ions and protonated molecules were obtained. Thus, since the TIC was higher in ES– and distinct deprotonated molecules (without adduct ions) were obtained, ES– was chosen for the MS-analysis of acyl-PG and *N*-acyl-PE in this work.

The detected ions of deprotonated *N*-acyl-PE (even-numbered integers) and acyl-PG (odd-numbered integers) in Figures 6 and 7 are summarized in Table 3 and 4. Some chromatographical overlapping is observed in the mass spectra in Figures 6 and 7, in that relatively polar molecular species of

acyl-PG (e.g., ions with *m/z* 1001.7) elute with *N*-acyl-PE. Also, relatively nonpolar molecular species of *N*-acyl-PE (e.g., ions with *m/z* 980.6) elute with acyl-PG. Other deprotonated molecules and/or fatty acids than those described in Tables 3 and 4 may exist but were then present in amounts below the detection limit.

*HPLC–MS/MS results*. The deprotonated molecules in Table 3 and 4 were first detected by negative ion electrospray. Then, in product ion analysis (ES–, CID) with the deprotonated molecules as precursor ions, product ions representative of the fatty acids (i.e., carboxylate ions) of the deprotonated molecules were obtained (20) (Figs. 8,9). Also, as a second confirmation as to the origin of the product ions obtained, precursor ion analysis of the selected product ions was performed (Fig. 10). In this way, the fatty acid compositions of the chosen precursor ions (deprotonated molecular ions) were determined. For acyl-PG, the two major peaks in the product ion spectrum of precursor ions with *m/z* 1009.5 are carboxylate ions with *m/z* 255, 279, and 281 representing 16:0, 18:2, and 18:1 fatty acids, respectively (Fig. 9). This is in accor-

dance with an acyl-PG molecular species containing 16:0/18:2/18:1 fatty acids.

Other fragments appear following two tentative cleavage routes (see Fig. 2). One route involves the loss of the monoacylglycerol part together with loss of an acyl part in either the *sn*-1 or *sn*-2 position of the diacylglycerol part, i.e., $(M - H–R^3COOCH_2CHOHCH_2–R^1COOH)^-$ or $(M - H–R^3COOCH_2CHOHCH_2–R^2COOH)^-$, (19). $R^1$, $R^2$, and $R^3$ refer to the hydrocarbon chains of the acyl groups at *sn*-1, *sn*-2, and *sn*-3′, respectively. For $R^1COO–$ = 16:0, $R^2COO–$ = 18:2, and $R^3COO–$ = 18:1, this gives product ions with *m/z* 391 and 415. With 16:0 at the *sn*-3′ position, ions with *m/z*

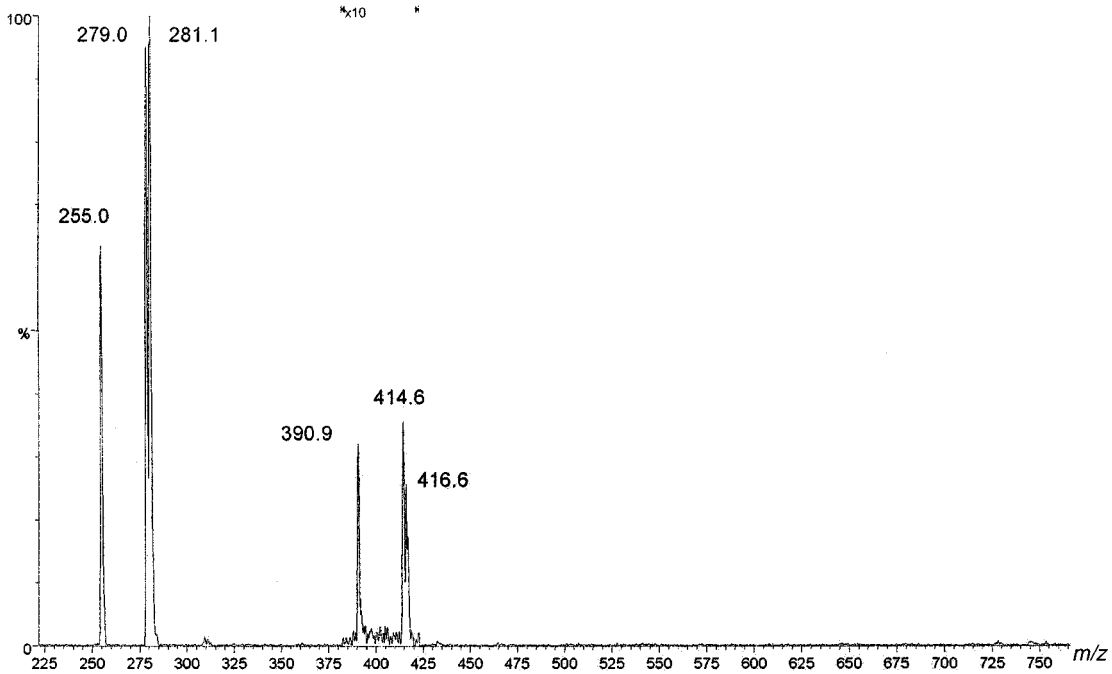

**FIG. 9.** Product ion mass spectra (ES–, CID) of deprotonated acyl-PG with *m/z* 1009.5. *Note:* The interval 380–425 is amplified ×10. For abbreviations see Figures 2 and 8.

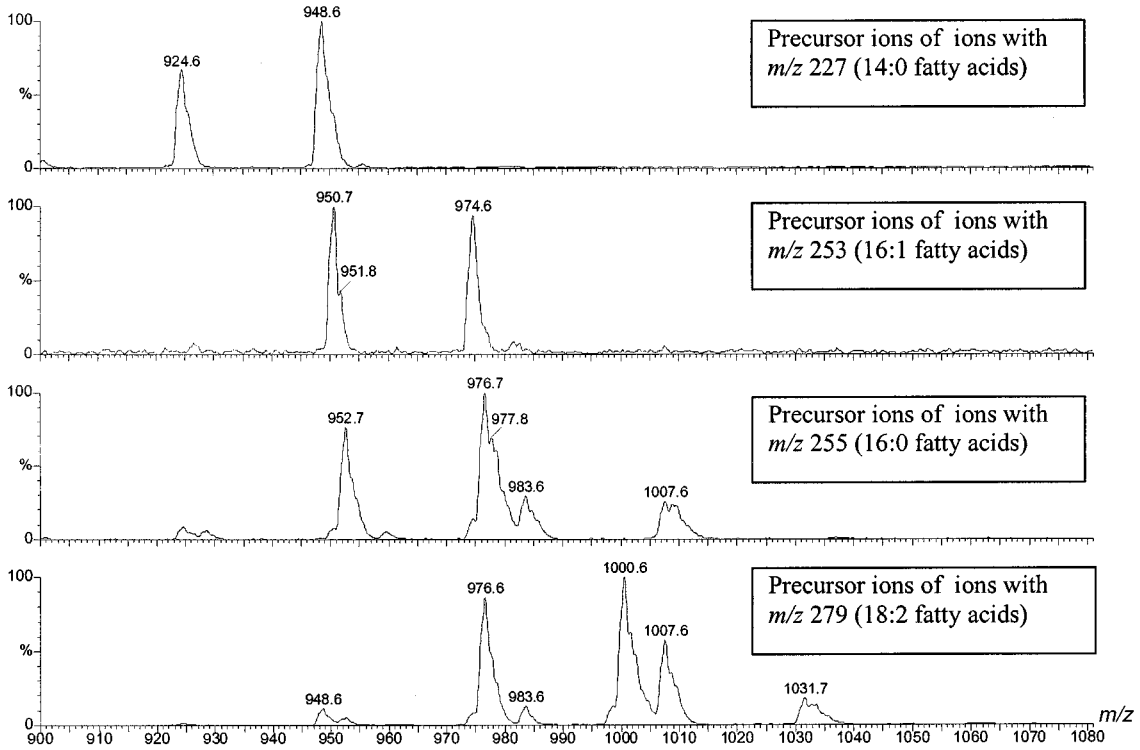

**FIG. 10.** Precursor ion mass spectra (ES–, CID) of ions with *m/z* 227, 253, 255, and 279, representing the fatty acids 14:0, 16:1, 16:0, and 18:2, respectively. For abbreviations see Figure 8.

415 and 417 are observed. Rearrangement of the fatty acids at different positions also give the above-mentioned ions. Another cleavage route involves the loss of the diacylglycerol part and, together with the loss of one molecule of water, the product ions $R^3COOCH_2CHOHCH_2O_3POH–H_2O^-$ are formed that, for $R^3COO–$ = 18:1, 18:2, or 16:0, give product ions with *m/z* 417, 415, or 391, respectively. In some spectra, ions with *m/z* 433 were observed, indicating the presence of *m/z* 415 without loss of water. It may thus be noted that ions with a certain *m/z* value may then be composed of either one or several of the fragment ions described above.

For *N*-acyl-PE, the base peaks in the product ion mass spectrum of precursor ions with *m/z* 976.6 are the carboxylate ions with *m/z* 255 and 279 (Fig. 8). This gives a theoretical fatty acid composition of 16:0/18:2/18:2-*N*-acyl-PE. The fragmentation pattern of *N*-acyl-PE follows similar routes (Fig. 1) as compared to acyl-PG. The cleavage involving loss of the $R^3CONHCH_2CH_2$ (in this case $R^3$ represents the hydrocarbon chain of the N-acyl group) part and one acyl group leads to analogous product ions as for acyl-PG, i.e., ions with *m/z* 415 and 391.

Similar fragments as for acyl-PG are also obtained *via* another route, i.e., involving loss of the diacylglycerol part giving fragment ions with *m/z* 402, $(R^3CONHCH_2CH_2O_3POH)^-$ with $R^3CONH–$ = 18:2. With $R^3CONH–$ = 16:0 ions with *m/z* 378 would be produced. However, these were not observed in the product ion spectrum, indicating the absence of 16:0 fatty acids in the amide group. Ions with *m/z* 458 corresponding to deprotonated molecules with neutral loss of one carboxylic acid and one alkyl ketene from the *sn*-1 and *sn*-2 positions, respectively $[M - H–R^1COOH)^-$ and $(M - H–R^2C=O)^-$, where $R^1COO–$ = 16:0 and $R^2COO–$ = 18:2 were also observed (19). No ions of this type corresponding to $R^1COO–$ = $R^2COO–$ = 18:2 were observed. In addition to these ions, high-mass ions with *m/z* 714 are observed, corresponding to deprotonated molecules with neutral loss of one 18:2-ketene from the *sn*-2 position. Saturated fatty acids are generally observed at the *sn*-1 position whereas unsaturated fatty acids are found at the *sn*-2 position (43). Also, several authors have described that *sn*-2 carboxylate ions appear at higher intensities than the *sn*-1 carboxylate ions following CID of deprotonated molecules (19). Thus, for the *N*-acyl-PE molecular species in Figure 8, 16:0 may assumed to be found at the *sn*-1 position with 18:2 fatty acids at *sn*-2 and at the ethanolamine part. For acyl-PG the same reasoning indicates that 16:0 fatty acids are generally found at the *sn*-1 position since the corresponding ions appear with lower intensity than those of 18:2 and 18:1 fatty acids. The fact that the 18:2/16:0 ratio is higher in the *N*-acyl-PE spectrum than in a spectrum of 16:0/18:2/18:2-acyl-PG (mass spectrum not shown) may be explained by the fact that, for acyl-PG, 18:2 fatty acids from the monoacylglycerol part also contribute to the intensity of the 18:2 peak. For *N*-acyl-PE, the 18:2 fatty acid in the ethanolamine part is amide-bound and does not form carboxylate ions. Thus, for the ions described above, in case of several different carboxylate ions in a product ion mass spectrum, the base peak may be assumed to represent the fatty acid at the *sn*-2 position.

**TABLE 5**
**Fragments for Identification of Double-Bond Positions in Gas Chromatography—Mass Spectrometry Spectra of Picolinyl Esters of *N*-Acyl-PE**

| | Double-bond position between carbon $k$ and $k + 1$ | |
|---|---|---|
| $k$-16:1 $[M^+] = 345$ | Double bond fragments $k - 1$ and $k + 1$ ($m/z$) | Allylic fragments $k + 2$ and $k + 3$ ($m/z$) |
| $k = 6$ | 206[a], 218 | —[b], 246 |
| $k = 9$ | 234, 260 | 274, 288 |
| $k = 11$ | 262, 288 | 302, 316 |

[a]This fragment represents cleavage of the double bond.
[b]No $k + 2$ fragment was found in this spectrum. For abbreviation see Table 1.

*GC–MS results*. GC–MS analysis of fatty acids as picolinyl ester derivatives showed several fatty acids containing double bonds in one or more positions. Of special interest were three isomers of 16:1 which previously had been found in fractions of total polar lipids from oats and identified as 11-16:1, 9-16:1, and 7-16:1 (Arnoldsson, K.C., unpublished data). LC–MS analysis of *N*-acyl-PE showed several molecular species containing 16:1 fatty acids, whereas acyl-PG had practically no 16:1-containing species.

Three 16:1 fatty acid isomers were identified from the mass spectrum of their picolinyl ester derivatives and shown to be 11-16:1, 9-16:1, and 6-16:1 (data in Table 5, sample spectrum in Fig. 11). As a result of the charge-retaining properties of the picolinyl ester derivative, the fragmentation occurs along the carbon chain from the methyl end giving fragments 14 Da apart. The position of the double bond was determined by the specific gap of 26 Da ($C_2H_2$) between carbon chain fragments, which represents cleavage on each side of the double bond. In the spectrum of 9-16:1 this gap occurs between $m/z$ 234 and 260 (Fig. 11). Often, there are also prominent losses due to abstraction of allylic hydrogens, resulting in formation of conjugated species (44), which gives fragments containing the double bond plus one or two carbons, represented by $m/z$ 274 and 288 in Figure 11. Deviations from this occur mostly when the double bond is near the terminal end of the carbon chain or near the carboxyl group as in 6-16:1 where the $k + 2$ fragment, $m/z$ 232, could not be found (see Table 5).

Two 16:1 isomers (11-16:1 and 9-16:1) found in total polar lipid fractions from oats were thus also found in the *N*-acyl-PE/acyl-PG fraction together with 6-16:1, which could not be seen in the total polar lipid fraction. The relative abundance of 16:1 isomers in the *N*-acyl-PE/acyl-PG fraction was estimated to 4:10:1 for the 6-, 9-, and 11-double bond position respectively.

In conclusion, the following types of experiments were run: (i) 1D and 2D NMR experiments, which provided the general structure features of the compounds, (ii) HPLC–ESMS, which gives the molecular weight of the species present, (iii) the subsequent HPLC–MS/MS analysis which, by giving fragmentation information on both product ions and their precursors, revealed the molecular species composition, and (iv) GC–EIMS of picolinyl esters, which was used to determine the double-bond positions in the acyl groups.

The combination of these techniques proved to be a versatile tool for structural elucidation. Thus, the structures of *N*-acyl-PE and acyl-PG were confirmed, and assignments of all $^1H$ and $^{13}C$ NMR signals could be done. From HPLC–MS/MS, 50 different molecular species of *N*-acyl-PE were determined with a molecular mass range from 924 to 1032 Da. For acyl-

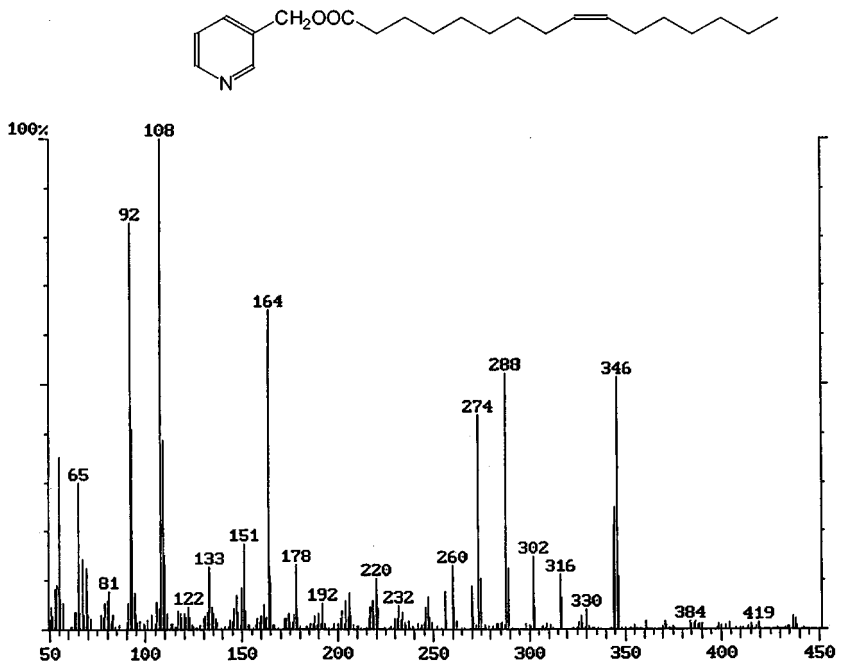

**FIG. 11.** Electron ionization mass spectrum of 9-16:1 picolinyl ester from N-acyl-PE. For abbreviation see Figure 1.

PG, 24 different molecular species were determined with a molecular mass range from 959 to 1035 Da. Three isomers of 16:1 fatty acids were found in *N*-acyl-PE, and the double-bond positions were determined by GC–EIMS to be 6, 9, and 11.

It was found that *N*-acyl-PE and acyl-PG together constitute as much as *ca.* 15% of the total phospholipids in oats. This is in agreement with early studies of the content of *N*-acyl-PE in oats (14).

# Fatty Acid Composition of Lipids Present in Selected Lichenized Fungi: A Chemotyping Study

**Guilherme L. Sassaki, Leonardo M. Cruz, Philip A.J. Gorin, and Marcello Iacomini***

Departamento de Bioquímica, Universidade Federal do Paraná, Curitiba-PR, Brazil

**ABSTRACT:** The total-lipid composition of 21 lichens of the ascomycetous genera *Cladonia* (11) and *Cladina* (1) of the family Cladoniacea, *Cladia* (1), *Parmotrema* (3), *Ramalina* (2), *Leptogium* (1), *Cetraria* (1), and the basidiomycetous genus *Dictyonema* (1) was determined. Analyses of those of *Dictyonema glabratum* were carried out with a total extract and those obtained after successive extractions with various solvents. Each extract was partitioned between *n*-heptane/isopropanol and 1 M sulfuric acid, giving triglycerides (TG) in the upper phase. Extracts were methanolyzed and the resulting methyl esters were analyzed by gas chromatography–mass spectrometry. Methanolyzates of TG unexpectedly contained esters of 9-oxo-decanoic, 9-methyl-tetradecanoic, 6-methyl-tetradecanoic, 3-hydroxy-decanoic, nonanedioic, and decanedioic acids, as well as common fatty acids. Fatty acid methyl ester profiles from the lichens were submitted to cluster analysis, and the resulting dendogram showed a cluster consistent with *Cladonia* spp., suggesting an efficient aid to lichen taxonomy. The total carbohydrate content of each lipid extract was determined by a modified phenol-sulfuric acid method, which compensated for the presence of pigments.

Paper no. L8518 in *Lipids 36,* 167–174 (February 2001).

Many different types of lipids occur in lichens, including fatty acids, phospholipids, and glycolipids (1–6). A β-galactosyl ceramide and digalactosylglyceride were found in *Ramalina celastri* (5,6), the latter being isolated from a *Sticta* sp. after deacylation (7). Each component was analyzed in terms of carbohydrates and lipids. More recently, a family of galactolipids was obtained from the basidiomycetous lichen *Dictyonema glabratum* and completely characterized (8). The presence of fatty acids in fungi has long been observed (9–11) and summarized in a review by Wassef (12), who described the composition of lipids in many fungal species and their utilization for taxonomic purposes. This review proposed a separation into phycomycetes (>$C_{18:3}$, $C_{20:0}$, and $C_{22:0}$), ascomycetes, and deuteromycetes (fungi imperfecti), which contained little or no polyenoic acids and >$C_{16:1}$, and basidiomycetes with α- rather than γ-linoleic acid: all groups contained $C_{16:0}$, $C_{18:1}$, and $C_{18:2}$ as major fatty acids.

Investigations that involve cladistic analysis of fatty acids as an aid in the taxonomy of fungi gave rise to positive results for correlation of fungal species (13–15). The most important class of fungal lipids is the triglycerides (TG), which represent the major component found in the lipid extracts of fungi. These are mainly esterified by unsaturated fatty acids such as oleic and linoleic at the HO-2 position of the glycerol moiety and at HO-1 and HO-3 by saturated fatty acids. The presence of TG in terms of fatty acid composition in lichens has not been described to date.

There is a complex relationship between lichen phytobionts and mycobionts, but as the latter comprise ~90% of the total biomass (16), the fatty acids of total lipid might be expected to be those of the mycobiont. We now study the composition of the lipid extracts of 21 selected lichens from various genera, having ascomycetes and a basidiomycete as mycobionts, in terms of carbohydrates, fatty acids that arose from TG, and total fatty acid, which could serve as taxonomic aid, including a modification of the phenol-sulfuric acid method (17), modified to compensate for the presence of pigments.

## EXPERIMENTAL PROCEDURES

*Lichens.* Lichens of the genus *Cladonia (C. clathrata*, *C. imperialis, C. signata, C. furcata*) and *Cladia aggregata* were collected during May 1993 in the Serra da Mantiqueira, Itamonte, State of Minas Gerais, Brazil, and *C. connexa, C. crispatula*, *C. ibitipocae*, *C. miniata*, *C. penicillata*, *C. salmonea*, and *C. substellata* in the Serra da Ibitipoca, Lima Duarte, State of Minas Gerais, 1994. *Cladina rangiferina* was collected in Uusimaa, Finland, August 1998. *Dictyonema glabratum* was harvested September 1998 from an embankment close to the 47-km sign of the National Highway (BR) 277, at an altitude of 900 m, in the proximity of Curitiba, State of Paraná, Brazil. *Ramalina usnea, R. celastri,* and *Leptogium phyllocarpum* were collected in 1998, in the Serra da Graciosa, PR, Brazil. *Cetraria islandica* (Iceland moss) was obtained from S.S. Penick and Co. (New York, NY; material obtained in 1984). *Parmotrema delicatum, P. mantiqueirense,* and *P. shindler* were collected in 1998, Lapa, State of Paraná, Brazil. Brazilian lichens were identified by Prof. Marcelo Marcelli and the Finnish one by Dr. Teuvo

Ahti. All lichens were each cleaned, dried, and powdered prior to the lipid extraction procedures.

*General experimental procedures.* Lipid extracts obtained from each sample were obtained by three successive extractions with 10 vol/wt of refluxing $CHCl_3$/MeOH (2:1, vol/vol) and (1:1, vol/vol), for 2 h. *Dictyonema glabratum* (15 g) was similarly extracted in order to compare yields with: $Me_2CO$, $CHCl_3$/MeOH (2:1, vol/vol), $CHCl_3$/MeOH (1:1, vol/vol), EtOH/$H_2O$ (9:1, vol/vol), and $CHCl_3$/MeOH/$H_2O$ (7:10:3, by vol), except that the $Me_2CO$ extraction was carried out at room temperature. All extracts were evaporated at <40°C under reduced pressure, dried, and stored in sealed tubes maintained below −10°C. Thin-layer chromatography (TLC) was performed on silica gel G plates from Merck (Darmstadt, Germany); solvent: $CHCl_3$/MeOH/$H_2O$ (65:25:4, by vol) and isopropyl ether/HOAc (96:4, vol/vol).

In order to obtain TG, each total lipid extract was partitioned between *n*-heptane/isopropanol/1 M $H_2SO_4$ (33.6:59.1:7.3, by vol) following vortex homogenization for 1 min. The upper organic phase, which contained TG, was evaporated at <40°C under reduced pressure and stored in a sealed tube below −10°C: the lower one was discarded. TG were developed with one-dimensional, two-step TLC using (i) isopropyl ether/HOAc, 96:4, vol/vol) and (ii) *n*-heptane/$Et_2O$/HOAc, 90:10:1, by vol) and detected with a 40% aqueous $H_2SO_4$ spray with heating at 120°C (18). The TG samples were estimated by colorimetric determination of the glycerol component. They were dissolved in $CHCl_3$ (5 mL), and an aliquot (0.1 mL) was mixed with of 0.1 mL of 7 M KOH in EtOH/$H_2O$ (3:1, vol/vol). The mixture was maintained at 56°C for 15 min, after which was added 0.5 mL of water, followed by periodic acid/0.35 M $H_2SO_4$ (0.35 mL), which resulted in the formation of formaldehyde. For estimation of liberated formaldehyde, the solution was treated with 3.0 mL of the acetylacetone/$NH_4OAc$/sodium arsenate/water reagent (4 mL), and the mixture was maintained at 56°C for 5 min, resulting in an yellow complex that absorbed at 410 nm.

In order to analyze the fatty acid composition of the lichens, each total lipid extract and TG (5 mg) was methanolyzed by refluxing in 3% HCl in MeOH for 2 h (19). The resulting fatty acid methyl esters (FAME) were extracted from water with $CHCl_3$, and these were analyzed by their gas chromatography–mass spectrometry (GC–MS), $R_t$ values, and electron ionization–mass spectrometry (EI–MS) profiles and compared with those of standards (Sigma products for lipids) on a DB-23 capillary column (30 m × 0.25 mm i.d. and 60 m × 0.25 mm i.d.), programmed from 50 to 180°C and 200°C (40°C·min$^{-1}$), then held. The sugar components were examined by GC–MS as alditol acetates, on a DB-225 capillary column (30 m × 0.25 mm i.d), programmed from 50 to 220°C (40°C·min$^{-1}$), then held.

*Colorimetric estimation of sugars in the pigment-containing lipid extracts using a modified phenol-sulfuric acid method.* Lipid extracts were added to a tube (1 to 3 mg) containing M trifluoroacetic acid (TFA) (1 mL) and hydrolyzed at 100°C for 8 h, and to these mixtures were added $CHCl_3$ (1 mL) and the extracted lipids discarded. An aliquot (0.5 mL) of components soluble in the acid solution was added to a tube containing 0.5 mL of 5% aqueous PhOH-$H_2SO_4$ (2.5 mL). The optical density (OD) at 490 nm was determined against a blank (B) containing 0.5 m; of M TFA, plus reagent. Another tube (S) containing 24 µg of galactose and 2 mg of lipid extract (from *C. islandica*) was submitted to the above procedure as a control and gave an OD of 0.702. For calibration, standards used were of 10, 30, 50, and 70 µg of galactose; 35 µg of galactose gave an OD of 0.608.

*Aqueous acid hydrolysis of lipid extracts.* Hydrolyses were performed with 1 M TFA at 100°C for 8 h (8), followed by evaporation to dryness, and the residue was partitioned between $CHCl_3$ and water. The aqueous phase was reduced with $NaBH_4$ and the product acetylated with $Ac_2O$/NaOAc at 120°C for 1 h. The $Ac_2O$ was destroyed with ice water, and the resulting alditol acetates were extracted with $CHCl_3$ (20) and analyzed by GC–MS, as described above.

*Numerical analysis of FAME data.* Total lipids were extracted, and the FAME data from 21 lichen species (GC–MS) were submitted to cluster analysis. Dendograms were constructed using the unweighted pair group with mean average from the pairwise Euclidean distance units. The analysis was performed using an NTSys program (Exeter Software, Setauket, NY).

## RESULTS

*Relationship between organic solvent extracts with yields and fatty acid composition of the lichen species after successive extractions*. *Dictyonema glabratum* was extracted separately with the following solvents in order to compare the yields of extracts and the fatty acid composition of each one: $Me_2CO$ (ext. A), $CHCl_3$/MeOH (2:1, vol/vol, ext. B), $CHCl_3$/MeOH (1:1, vol/vol, ext. C), EtOH/$H_2O$ (9:1, vol/vol, ext. D), and $CHCl_3$/MeOH/$H_2O$ (7:10:3, by vol, ext. E), as shown in Table 1. The principal methyl esters obtained after methanolysis of the total extracts were from the saturated fatty acids, 14:0, 16:0, and 18:0, but the longer-chain 20:0, 22:0, and 24:0 derivatives were also observed. Odd-number esters were observed in smaller proportions, 17:0 being found in 13 lichens. Unsaturated fatty acids were present, the most abundant and common being 18:1 (Table 2).

Eleven species of the genus *Cladonia* showed similarities in their fatty acid composition in terms of the chain length, but with some percentage variation. Observed were 16:0, 18:0, 17:0, 23:0, and 24:0 in six lichens, 22:0 in eight, 14:0 and 18:1 in nine, and 20:0 in ten. The presence of other fatty acids is shown in Table 2. *Cladina rangiferina* components were compared with those of *Cladonia* spp., since it also belongs to the family Cladoniaceae. The fatty acid composition was quite similar, showing 14:0, 16:0, 17:0, 18:0, 18:1, 20:0, 22:0, and 23:0, the only difference being the proportion of each one. The fatty acid composition agrees with the data obtained by Dembitsky *et al*. (3). *Parmotrema delicatum, P. mantiqueirense,* and *P. shindler* did not give rise to long-chain

**TABLE 1**
**Fatty Acid Composition Arising from Different Types of Extraction (Ext) of *Dictyonema glabratum***

| Fatty acid | $R_t$[a] | Ext (A) | Ext (B) | Ext (C) | Ext (D) | Ext (E) |
|---|---|---|---|---|---|---|
| | | Percentage yields of the different types of extraction | | | | |
| | | 0.6 | 2.7 | 4.9 | 4.3 | 6.3 |
| 10:0 (caproic) | 5.49 | 5.3 | 1.6 | — | — | — |
| 12:0 (lauric) | 7.00 | 9.4 | 3.0 | 6.3 | 5.0 | 5.1 |
| 14:0 (myristic) | 8.32 | 8.45 | 3.75 | 6.3 | 4.7 | 5.8 |

| 24:0 (lignoceric) | 28.27 | — | — | — | 0.3 | — |

[a]Retention time ($R_t$) in minutes. Ext (A) $Me_2CO$, Ext (B) $CHCl_3$/MeOH (2:1), Ext (C) $CHCl_3$/MeOH (1:1, vol/vol), Ext (D) EtOH/$H_2O$ (9:1, vol/vol), and Ext (E) $CHCl_3$/MeOH/$H_2O$ (7:10:3, by vol).

or odd-numbered fatty acid esters. The acids 16:0 and 18:0 were observed in all of the lichens examined as were unsaturated fatty acids 18:1 and 18:3. The fatty acid composition of the basidiolichen, *D. glabratum* (21), showed the presence of short-chain fatty acids such as 10:0, 12:0, and 16:2.

*Fatty acid composition of TAG extracts.* TG were extracted with a solution of *n*-heptane/isopropanol/1 M sulfuric acid (33.6:59.1:7.3, by vol) as described above, and the resulting upper phase contained TG, whose yields ranged from 11.4 to 37.3%: its respective fatty acid composition is shown in Table 3. The fatty acids were obtained *via* methanolysis and analyzed by GC–MS. The main saturated FAME were: 14:0, 16:0, and 18:0, along with smaller proportions of 20:0, 22:0, 22:1, 22:2, 23:0, and 24:0. Detected in lower quantities were the odd-number fatty acids, 15:0 and 17:0, which were found in 13 of 15 lichens. The unsaturated fatty acids 16:1, 18:1, 18:2, 18:3, and 22:2 were also observed (Table 3).

Unusual lipids such as dicarboxylic fatty acids, a long-chain alcohol, branched- and hydroxy-fatty acids, and keto-fatty acids were unexpectedly detected (Table 4). The resulting GC–MS profile of each sample was analyzed on the basis of a EI–MS library, incorporating the NIST/NBS Library of Masslinks Library Service, to determine chemical structures. The main mass fragments are shown in Table 4. The most frequently encountered unusual FAME was nonanedioic acid methyl ester, this compound being present in 15 species. Its main fragments (*m/z*) and intensities (%) were, respectively, 185 (27), 152 (70), 143 (30), 111 (45), 83 (63), 74 (100), 69 (47), 55 (81), 43 and 41 (40), and 40 (2), although its ion peak did not appear. Also present were esters of 9-oxo-decanoic and 9-oxo-nonanoic. The latter showed fragments with *m/z*: 155 (16), 143 (35), 115 (7), 111 (33), 87 (53), 74 (100), 55 (47), 43 and 41 (35), and 40 (2).

*Dendograms of fatty acid profiles: evaluation of lichen relationships.* The FAME profiles of the 21 lichen species were submitted to cluster analysis. Twenty different FAME, varying in chain length from 10 to 24 carbons (saturated or unsaturated), were identified (Table 2). The resulting dendogram resolved species most consistent with their taxonomic position. Ten *Cladonia* species are grouped in two related subclusters (I and II, Fig. 1). However, one *Cladonia* sp., *C. miniata*, was distantly related, clustering with *P. mantiqueirense. Cladina rangiferina* clustered within subcluster II and, surprisingly *P. delicatum* was clustered in this same group. The dendrogram was reinforced by a cophenetic coefficient of 0.89. This value gives an idea of the consistency of the dendrogram, when related to the distance matrix.

*Modification of the PhOH-$H_2SO_4$ method to estimate carbohydrates in the presence of pigments and monosaccharide composition.* The total carbohydrate content of the lipid extracts, obtained from 21 lichen species, was initially determined using a conventional PhOH-$H_2SO_4$ procedure (17), using 1000 µg to 50 µg of each extract. All the values obtained for the samples obeyed the Lambert-Beer's law over a range of 0–80 µg hexose. Good results were obtained with total hydrolysis using 1 M TFA at 100°C. This procedure produced free sugars, the lipids being removed by partition between chloroform and an aqueous solution. Another control of the method (S) was carried out using 24 µg of galactose (OD of 0.417) and 2 mg of the lipid extract from *C. islandica*; this control containing 40.4 µg of total sugar, giving an OD of 0.702. The total carbohydrate content of 2 mg for *C. islandica* was 16.92 µg corresponding to an OD of 0.294, such controls confirming the validity of the modified method. The standard curve and the total sugar yields are represented in Figure 2 and Table 5, respectively.

The yields in terms of total carbohydrates varied from 0.2 to 3.3% for all lichens of the genus *Cladonia*, whereas those of the genus *Parmotrema* varied from 0.9 to 1.9% and those of *Ramalina* from 0.8 to 1.3%. Values for other species are presented in Table 5.

The sugar compositions were determined as derived alditol

**TABLE 2**

[b]Retention time ($T_M$) relative to palmitic acid methyl ester.
[c]All the lichens were studied (21), but only 19 species contained these types of lipid. See Table 2 for lichen abbreviations.

acetates, which were analyzed by GC–MS. The monosaccharides obtained after total hydrolysis (Table 5) show the presence of glucose, mannose, galactose, and xylose in all cases. Fucose was observed only in extracts of *C. islandica*, *P. mantiqueirense*, and *P. shindler*. Rhamnose was found in most lichens, but not in those of *C. aggregata*, *P. shindler, P. mantiqueirense*, and *R. celastri*.

## DISCUSSION

Extractions with various solvents gave rise to different yields and fatty acids; the best yields were obtained with extracts D, C, and E, although all of them contained different fatty acids. The procedure of Extract A was the most efficient for extracting short-chain fatty acids. The advantages of using EtOH/$H_2O$ (9:1, vol/vol) under reflux were apparent since it gave a high yield, was cheaper and less toxic. It is capable of extracting polar glycolipids, according to Leeden and Yu (22). However, for a more reliable examination of total fatty acids in tissues, a battery of different solvents is necessary. *Dictyonema glabratum* was chosen as the best candidate, as its fresh tissues were more readily obtainable in greater amounts.

Total lipids were examined, and palmitic and stearic acids were present in all studied lichens. This observation was supported by the natural biosynthetic route of lipids in fungi and by the fact that most organisms produce fatty acids with various chain lengths ($C_{12}$–$C_{20}$), as described by Wassef (12). Since lichens contain ~90% mycobiont (16), similar results would be expected. The presence of odd-number fatty acids was shown by Lynen (cited in Ref. 12), and these arose using propionate as primer in the substitution of acetate and the use of isobutyrate, leucine, valine or isoleucine, which gave rise to iso- and anteiso-branched fatty acids (Baraud, cited in Ref. 12). In our upper organic phases, other unusual lipids were detected, namely they were aldehyde, keto, hydroxy, and dicarboxylic fatty acids. These have not been previously described in lichens. We also showed the presence of dicarboxylic acids, and the main one found was nonanedioic (azelaic) acid (Table 4); these are probably formed by ω-oxidation (23). Nonanedioic and hexanedioic acids have a cytotoxic effect against squamous carcinoma affecting cell proliferation (24). However, why are these compounds present in lichens? Other types of unusual lipids were the aldehyde and keto-derivatives, 9-oxo-nonanoic and 9-oxo-decanoic acids, which can be associated with cold-acclimation (25). Another reason to justify this hypothesis is the presence of large amounts of unsaturated fatty acids in lichens when they are submitted to cold conditions (4).

The family Cladoniaceae includes 11 genera with polyphyletic assemblage (26). We have now investigated lichens of the *Cladonia* and *Cladina* genera for their carbohydrate and FAME compositions, both of total fatty acids and isolated TG. Although the relationship of these genera is not totally clear (27), the dendogram derived from FAME data shows that they have similar profiles on fatty acid analysis. The cluster analysis evaluated for *Cladonia*, *Cladina*, and other

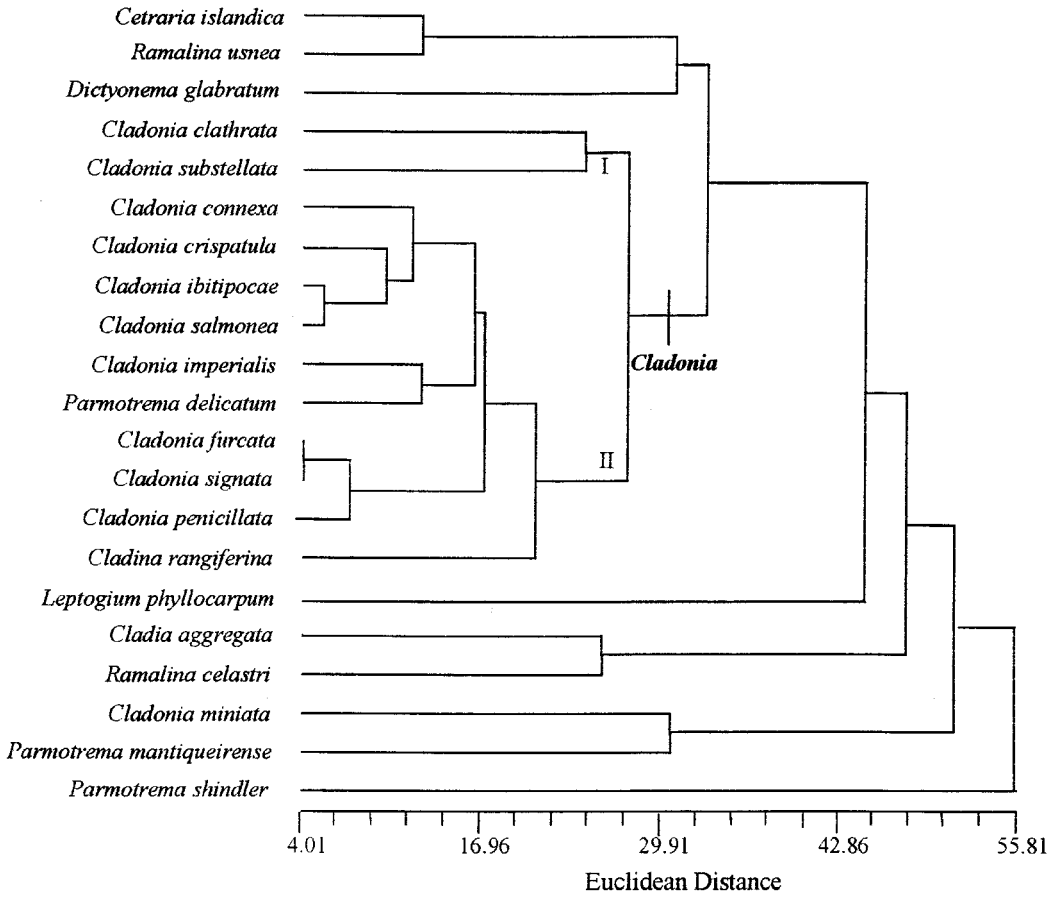

**FIG. 1.** Unweighted pair group with mean average from pairwise calculated distances obtained comparing fatty acid methyl ester profiles from 21 lichen species performed using the NTSys program. (I and II) *Cladonia* subclusters.

lichens from these data enabled the consistent conjunction of *Cladonia* species. Although these lichens were subjected to different growth conditions, this criterion is important: the option of laboratory culture in synthetic media of so many lichens is very laborious. The data suggest a similar profile of fatty acids for the *Cladonia* genus. *Cladia miniata* showed a different fatty acid composition and was positioned outside the group. This agrees with morphological, chemical, and ecological characteristics evaluated by Stenroos *et al.* (27), who carried out cluster analysis of *Cladonia* and *Cladina* genera. On the other hand, *C. rangiferina* clustered with *Cladonia* species, emphasizing a pronounced relationship between these genera. It should be observed that the genus *Cladina* is not well established. In the Americas, Asia, Australasia, and Russia, it is now usually recognized, while in Europe most lichenologists consider it a subgenus of *Cladonia* (27). *Cladia aggregata* did not show the same pattern of fatty acids as obtained for the lichens of the genera *Cladonia* and *Cladina*. This observation could have taxonomic value (12), since *C. rangiferina* belongs to the same family as those of the genus *Cladonia*. The basidiolichen *D. glabratum* appeared to be interesting for comparison of its fatty acid profile, which was quite different from that of lichenized ascomycetes (28), with the presence of the short-chain fatty acids, 10:0, 12:0, and 16:2. The lichen *L. phyllocarpum* is ascomycetous and with a cyanobacterium symbiosis, and its fatty acids were similar to those of other ascolichens. These observations (ascomycetous and basidiomycetous) showed that the fatty acids might be derived from the mycobionts, since they are different and phycobionts are cyanobacteria.

It is possible that some lichen fatty acids could be formed directly by the phytobiont and modified by the mycobiont. An

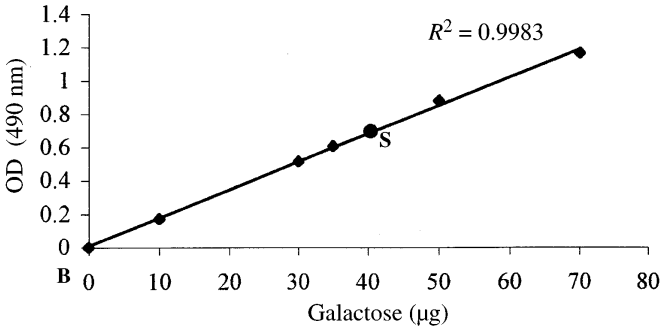

**FIG. 2.** Blank tube (B) containing 0.5 mL of M trifluoroacetic acid and the phenol-sulfuric acid mixture. Standard (S) containing 24 µg of galactose and 2 mg of lipid extract *(Cetraria islandica)*. Calibration was carried out with standards of 10, 30, 50, and 70 µg of galactose. OD, optical density.

[a]SD (standard deviation), triplicates of total sugar concentration varied from ± 0.009 to ± 0.021. See Table 2 for lichen abbreviations.

example of this process occurs in the transformation of free aldoses to polyalcahols as suggested by Ahmadjian (29), although evidence has not yet been observed in lichens that fatty acids, or any other metabolite, can be synthesized in the mycobiont and later modified or transferred to the phycobiont (16,29). It appears likely that lichen fatty acids should arise from the mycobiont, which comprises ~90% of the mycelial biomass and which is formed in large amounts in fungi (16). Many of the fatty acids are similar to those in lichenized fungi (16,29); these observations may show the lichen fatty acids as markers for taxonomical study just like those observed in fungi (13). For better results, more cladistic analyses should be carried out on FAME profiles in other well-classified genera, although the value of the FAME profiles appears to be an important additional parameter that can be used in lichen taxonomy.

The colorimetric estimation of the total sugar in pigmented material is a common problem. The use of direct TFA-hydrolyzed material instead of water in the conventional method did not interfere with the optical densities, enabling accurate determinations with the phenol-sulfuric acid method.

Monosaccharide analysis of the 21 lichens showed high levels of total galactose, expected since the major phycobiont glycolipids are galactolipids, but the presence of high levels of arabinose, mannose, and glucose was not. It may be significant that the presence of their corresponding polyalcohols in lichens has been observed (29). The presence of arabinitol and mannitol could be explained by the carbohydrate movement (29), the glucose produced by the phycobiont being rapidly converted to mannitol and arabinitol by the mycobiont. Although *C. aggregata* showed high levels of arabinose (91.3%), when compared to total monosaccharide, this suggests a difference in taxonomical position, in relationship to the genus *Cladonia* (Table 5). The presence of high levels of polyalcohols and saccharide derivatives would be expected, since they are more soluble in hot organic solvents. Another possible explanation is that aldoses were liberated by hydrolysis from lipopolysaccharides, since this polymer is produced by some algae and fungi (30,31), and is soluble in organic solvents.

## ACKNOWLEDGMENTS

The authors wish to thank the Brazilian agencies, CNPq (Conselho Nacional de Pesquisas) and FINEP (Financiadora Nacional de Ensino e Projetos), for financial assistance, the latter *via* PRONEX-CARBOIDRATOS. Thanks are also due to Douglas Olsen and Steven Ambrose, Plant Biotechnology Institute, National Research Council of Canada, Saskatoon, Saskatchewan, for carrying out GC–MS–FAME analysis and quantifying and identifying the lipid products using the Masslynx Library Service, which incorporates the NIST/NBS Library.

# A New Ceramide from the Basidiomycete *Russula cyanoxantha*

**Jin-Ming Gao[a,b], Ze-Jun Dong[a], and Ji-Kai Liu*[,a]**

[a]Laboratory of Phytochemisty, Kunming Institute of Botany, the Chinese Academy of Sciences, Kunming 650204, People's Republic of China, and [b]College of Life Science, Northwest Science & Technology University of Agriculture and Forestry, Yangling, Shaanxi 712100, People's Republic of China

**ABSTRACT:** A new phytosphingosine-type ceramide (**1**) was isolated along with nine other compounds—5α,8α-epidioxy-(22*E*,24*R*)-ergosta-6,22-dien-3β-ol, 5α,8α-epidioxy-(24*S*)-ergosta-6-en-3β-ol, (24*S*)-ergosta-7-ene-3β,5α,6β-triol, (22*E*,24*R*)-ergosta-7,22-dien-3β,5α,6β-triol, inosine, adenine, L-pyroglutamic acid, fumaric acid, and D-allitol from the ethanol and chloroform/methanol extract of the fruiting bodies of the basidiomycete *Russula cyanoxanotha* (Schaeff.) Fr. The structure of (**1**) was established as (2*S*,3*S*,4*R*,2′*R*)-2-(2′-hydroxytetracosanoylamino) octadecane-1,3,4-triol by means of spectroscopic and chemical methods.

Paper no. L8628 in *Lipids 36*, 175–180 (February 2001).

The family Russulaceae is one of the largest in the subdivision Basidiomycotina in Whitthaker's Kingdom of Fungi and comprises hundreds of species (1). Although secondary metabolites occurring in the fruiting bodies of European *Lactarius* species have well been investigated, the *Russula* mushrooms have received less attention, notwithstanding the larger number of existing species (2). Recently some new terpenoids from *Russula* species have been reported (2,3).

The fruiting bodies of *Russula cyanoxantha* have long been used as foods and medicinal agents in China; an extract of its fruiting bodies has been shown to be active against tumors (4). In a preceding paper, we reported on two sphingadienine-type glucocerebrosides isolated from *R. ochroleuca* (5). In a continuation of our study on the bioactive metabolites of the higher fungi in Yunnan Province, the chemical constituents of *R. cyanoxantha* collected at Ailao Mountains in Yunnan Province of the People's Republic of China were investigated. Ten compounds were isolated from the fruiting bodies of *R. cyanoxantha*, and the structure of **1** was established as (2*S*,3*S*,4*R*,2′*R*)-2-(2′-hydroxytetracosanoylamino) octadecane-1,3,4-triol. The present report deals with the isolation and structure elucidation of the new ceramide (**1**) from the $CHCl_3$-soluble fraction of the EtOH and $CHCl_3$/MeOH extract of the fruiting bodies of this fungus by repeated column chromatography (CC).

## EXPERIMENTAL PROCEDURES

*Chromatographic and instrumental methods.* Melting points were obtained on an XRC-1 apparatus (Sichuan, People's Republic of China) and uncorrected. Optical rotations were measured on a Horiba SEPA-300 polarimeter (Horiba, Tokyo, Japan). The nuclear magnetic resonance (NMR) spectra ($^1H$, $^{13}C$ NMR and two-dimensional NMR) were recorded on Bruker AM-400 and DRX-500 NMR instrument (Karlsruhe, Germany) at 500 MHz for $^1H$ and 100 MHz for $^{13}C$ NMR; tetramethylsilane was used as an internal standard and coupling constants were represented in Hertz. Mass spectra were carried out with a VG Autospec3000 mass spectrometer (VG, Manchester, England). Infrared (IR) spectra were obtained in KBr pellets on a Bio-Rad FTS-135 infrared spectrophotometer (Bio-Rad, Richmond, CA). Gas chromatography–mass spectrometry (GC–MS) was performed on a Finnigan 4510 GC–MS spectrometer (San Jose, CA) employing the electron impact (EI) mode (ionizing potential 70eV) and a capillary column (30 m × 0.25 mm) packed with 5% phenyl-dimethylsilicone on HP-5 (Hewlett-Packard, Palo Alto, CA). Helium was used as carrier gas; column temperature 160–240°C (rate of temperature increase: 5°C/min).

*Materials.* CC was conducted over silica gel (200–300 mesh; Qingdao Marine Chemical Ltd., Qingdao, People's Republic of China). Thin-layer chromatography (TLC) analysis was carried out on plates precoated with silical gel $F_{254}$ (Qingdao Marine Chemical Ltd.). Reversed-phase chromatography was carried out on LiChroprep® RP-8 (40–63 μm) (Merck, Darmstad, Germany).

Fresh fruiting bodies of *R. cyanoxantha* were collected from Ailao Mountains of Yunnan Province in August 1998 and identified by Prof. P.G. Liu and X.H. Wang (Kunming Institute of Botany, the Chinese Academy of Sciences, Kunming, Yunnan, People's Republic of China). A voucher specimen is deposited at the Herbarium of Kunming Institute of Botany, the Chinese Academy of Sciences, People's Republic of China.

*Extraction and isolation.* Dried fruiting bodies (300 g) of *R. cyanoxantha* were extracted with 95% EtOH (1.2 L × 3), followed by extraction with $CHCl_3$/MeOH (1:1, vol/vol) at

Abbreviations: CC, column chromatography; DMSO, dimethyl sulfoxide; EI–MS, electron impact–mass spectrometry; FAB–MS, fast atom bombardment–mass spectrometry; GC–MS, gas chromatography–mass spectrometry; HMBC, heteronuclear multiple bond connectivity; HR–EI–MS, high resolution–electron impact–mass spectrometry; IR, infrared spectrometry; NMR, nuclear magnetic resonance; TLC, thin-layer chromatography.

room temperature. The combined extracts were concentrated *in vacuo* to give a crude extract, which was partitioned between $H_2O$ and $CHCl_3$ to provide a $CHCl_3$ extract (17 g) and a water-soluble fraction. The $CHCl_3$-soluble fraction was subjected to CC elution with a solvent mixture of petroleum ether/acetone (50:1–1:1, vol/vol) to give 18 fractions. Fraction 4 after crystallization from *n*-hexane furnished 5α,8α-epidioxy-(22*E*,24*R*)-ergosta-6,22-dien-3β-ol (73 mg). Fraction 6 subjected to CC (petroleum ether/EtOAc 7:3, vol/vol) afforded 5α,8α-epidioxy-(24*S*)-ergosta-6-en-3β-ol (38 mg) and (24*S*)-ergosta-7-ene-3β,5α,6β-triol (15 mg), respectively. Recrystallization of Fraction 9 from petroleum ether/acetone produced (22*E*,24*R*)-ergosta-7,22-dien-3β,5α,6β-triol (5 mg). Fraction 16 was submitted to repeated CC ($CHCl_3$/MeOH 8:2, vol/vol), and then recrystallized from petroleum ether/acetone (6:4) to give **1** (50 mg). The concentrated $H_2O$ fraction was dissolved in warm MeOH, and the resulting MeOH-soluble fraction (24.2 g) was subjected to CC ($CHCl_3$/MeOH 9:1–4:6, vol/vol) to give 13 fractions. Preparative TLC ($CHCl_3$/MeOH/$H_2O$ 8.5:1.5:0.02, by vol) purification of Fraction 5 afforded inosine (11.2 mg). Fractions 3–4 were further purified by LiChroprep RP-8 CC (using a gradient of 5%–10% MeOH/$H_2O$, vol/vol, 20 min, ultraviolet detector) afforded adenine (7.6 mg). Fraction 8 was chromatographed over silica gel ($CHCl_3$/MeOH/ $H_2O$ 9:1:0.05, by vol) to yield L-pyroglutamic acid (20 mg). Further CC purification of Fraction 10 gave fumaric acid (21 mg). Fraction 14 afforded D-allitol (6.2 g) after crystallization from MeOH/$H_2O$.

*(2*S*,3*S*,4*R*,2′*R*)-2-(2′-hydroxytetracosanoylamino) octadecane-1,3,4-triol (**1**).* White amorphous powder. mp 140–142°C (petroleum ether/acetone); $[\alpha]_D$ = +9.4° (*c* = 0.21, pyridine). IR (KBr) ν 3340, 3220 (OH), 2919, 2850, 2487, 2395,
1619 (N–C=O), 1544 (NH), 1468, 1353, 1068, 1027, 723 $cm^{-1}$; $^1H$ and $^{13}C$ NMR (500 and 100 MHz, pyridine-$d_5$) see Table 1; high resolution–electron impact–mass spectrometry (HR–EI–MS) *m/z* 683.6407 $[M]^+$ ($C_{42}H_{85}NO_5$ calcd. 683.6427); EI–MS (70 eV) *m/z* (relative intensity %) 683 $[M]^+$ (2), 665 $[M - H_2O]^+$ (11), 651 $[M - CH_2OH - 1]^+$ (5), 456 $[M - CH_3(CH_2)_{13}CHOH]^+$ (13), 439 $[456 - OH]^+$ (18), 409 $[439 - CHOH]^+$ (22), 384 $[CH_3(CH)_{21}CH(OH)CONH_2 + H]^+$ (24), 357 $[M - CH_3(CH_2)_{21} - OH]^+$ (27), 339 (4), 320 (7), 227 (13).

*(2*S*,3*S*,4*R*,2′*R*)-2-(2′-acetoxytetracosanoylamino) octadecane-1,3,4-triacetoxyl (**1a**).* Compound **1** (6.9 mg) was dissolved in pyridine (1.1 mL); the mixture was treated with $Ac_2O$ (1.1 mL) and was left standing overnight at room temperature. The reaction solution was then diluted with 3 mL of water and extracted with EtOAc (3 × 10 mL). The EtOAc extract was washed with brine and dried over $Na_2SO_4$, then evaporated to dryness under reduced pressure. The residue obtained was subjected to silica gel CC (petroleum ether/ethyl acetate 8:2, vol/vol) to give 5.5 mg of the peracetate (**1a**) as white powder solids. EI–MS (70 eV) *m/z* (relative intensity, %) 851 $[M]^+$ (9), 611 $[M - 4 \times CH_3COOH]^+$ (2), 543 $[M - CH_3(CH_2)_{21} - H]^+$ (85). Positive fast atom bombardment–mass spectroscopy (FAB–MS) *m/z* 853 $[M + 1]^+$ (29); $^1H$ NMR (400 MHz, $CDCl_3$, in ppm) δ 4.01 (1H, *dd*, *J* = 11.6, 3.1 Hz, 1-Ha), 4.34 (1H, *dd*, *J* = 11.6, 5.4, 1-Hb), 4.44 (*m*, 2-H), 5.10 (*m*, 3-H), 4.95 (*m*, 4-H), 1.82 (*m*, 2H, 5-$H_2$), 1.63 (*m*, 2H, 6-$H_2$), 1.25 (28 × $CH_2$ *brs*), 0.88 (6H, *t*, *J* = 6.5 Hz, 2 × $CH_3$), 5.10 (*m*, 2′-H), 1.63 (*m*, 3′-$H_2$), 2.18 (*s*, OAc), 2.09 (*s*, OAc), 2.06 (*s*, OAc), 2.03 (*s*, OAc), 6.61 (1H, *d*, *J* = 9.2 Hz, NH).

*Methyl 2-(*R*)-hydroxytetracosanoate (**1b**).* Compound **1** (28 mg) was refluxed with 2.2 mL of 0.9 mol/L HCl in 82% aqueous methanol at 80°C for 16 h. The reaction mixture was extracted with petroleum ether, and the petroleum ether layer was concentrated and chromatographed using silica gel (petroleum ether/ethyl acetate 9:1–7:3, vol/vol; ratios changed as 9:1, 8:2, 7:3) to give a methyl ester of fatty acid (**1b**) as

The above data are in agreement with those reported.

*Adenine (= 2-aminopurine).* White amorphous powder, mp > 338°C (dec.); EI–MS (70 eV) *m/z* (relative intensity %): 135 $[M]^+$ (100), 108 (35), 81 (14), 54 (12); $^{13}C$ NMR (DMSO-$d_6$, 100MHz) δ 151.5 (*d*, C-2), 151.9 (*s*, C-4), 116.6 (*s*, C-5), 154.4 (*s*, C-6), 139.8 (*d*, C-8); $^1H$ NMR (DMSO-$d_6$, 400 MHz, in ppm) δ 7.62 (*s*, 1H, H-8), 7.59 (*s*, 1H, H-2), 6.59 (*brs*, 1H, $NH_2$). These data are in agreement with those

reported.

*L-Pyroglutamic acid [= (S)-2-pyrrolidone-5-carboxylic acid].* Colorless crystals, mp 156–158°(C (MeOH), $[\alpha]_D$ = –11° ($H_2O$); EI–MS (70 eV) *m/z* (relative intensity %): 129 $[M]^+$ (34), 101 (18), 84 (82), 56 (100); negative FAB–MS *m/z* 128 $[M - H]^-$; $^{13}C$ NMR ($CD_3OD$ 100 MHz, in ppm ) δ 181.5 (*s*, COOH), 176.1 (*s*, CO), 57.0 (*d*, CH), 30.4 (*t*, C-3), 26.0 (*t*, C-4); $^1H$ NMR ($CD_3OD$, 400 MHz, in ppm) δ 6.75 (1H, *s*), 4.24 (1H, *dd, J* = 4.6, 8.6 Hz, 2-H), 2.49 (1H, *m*, 3-$H_a$), 2.14 (1H, *m*, 3-$H_b$), 2.31 (2H, *m*, 4-$H_2$). The above data are in accord with those reported.

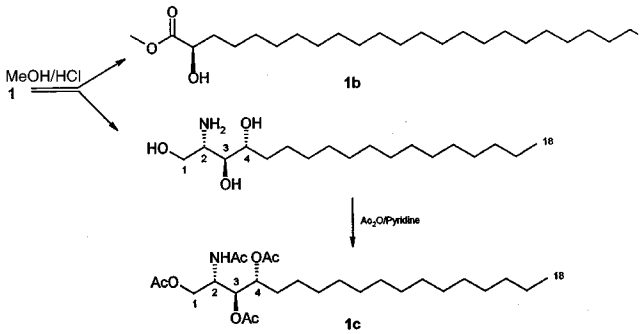
*Fumaric acid (= E-butenedioic acid).* Leaf-like crystals, mp 210°C (MeOH/$CHCl_3$, sublimation). EI–MS (70 eV) *m/z* (relative intensity %): 116 $[M]^+$ (43), 98 $[M - H_2O]^+$ (100), 88 $[M - CO]^+$ (27), 81 $[M - HO - H_2O]^+$ (20), 72 $[M - CO_2]^+$ (37), 71 $[M - COOH]^+$ (34), 55 (29), 53 (87); $^{13}C$ NMR (100 MHz, acetone-$d_6$, in ppm) δ 166.06 (*s*), 134.65 (*d*); $^1H$ NMR (400 MHz acetone-$d_6$, in ppm) δ 8.03. The above data are consistent with those reported.

*D-Allitol.* Colorless needles, $[\alpha]_D$ = 0° (c = 0.36, $H_2O$); mp 154.5–156°C (MeOH/$H_2O$). IR $\nu_{max}^{KBr}$ $cm^{-1}$: 3271, 2959, 2936, 1461, 1377, 1351, 1332, 1304, 1092, 1025; $^1H$ NMR (400 MHz, DMSO-$d_6$, in ppm) δ 4.42 (2H, *d, J* = 5.4 Hz, H-1, 6), 4.36 (2H, *t, J* = 5.4 Hz, H-3, 4), 3.46 (2H, *d, J* = 1.8 Hz, H-1, 6), 3.36 (2H, *q, J* = 5.4 Hz, H-2, 5); $^{13}C$ NMR (100 MHz, pyridine-$d_5$, in ppm) δ 73.45 (*d*, C-3, 4), 72.33 (*d*, C-2, 5), 65.54 (*t*, C-1, 6); EI–MS (70 eV) *m/z* (relative intensity %): 183 $[M + H]^+$ (36), 146 (15), 133 (70), 115 (26), 103 (73), 93 (53), 85 (46), 74 (84), 73 (100), 61 (89). The above data are consistent with literature values.

## RESULTS AND DISCUSSION

The $CHCl_3$-soluble fraction of the EtOH and $CHCl_3$/MeOH extract from the fruiting bodies of *R. cyanoxantha* was subjected to repeated column chromatography to yield (2*S*,3*S*, 4*R*,2′*R*)-2-(2′-hydroxytetracosanoylamino) octadecane-1,3,4-triol (**1**).

Compound **1** was obtained as a white amorphous powder, $[\alpha]_D$ +9.4° (*c* = 0.21, pyridine). The HR–EI–MS spectrum of **1** indicated a molecular formula of $C_{42}H_{85}NO_5$ ($M^+$ 683.6407, calcd. 683.6427). The IR spectrum of **1** revealed the absorption bands of hydroxyls at 3340 and 3220 $cm^{-1}$, a secondary amide at 1544 and 1619 $cm^{-1}$, and the long aliphatic chains at 723 $cm^{-1}$. The $^1H$ NMR spectrum of **1** showed the presence of two terminal methyls at δ 0.86 ppm (6H, *brt, J* = 6.7 Hz) and methylenes at δ 1.25–1.41 ppm (*ca.* 56H, *brs*), an amide proton signal at δ 8.57 ppm (1H, *d, J* = 8.8 Hz). In the $^{13}C$ NMR (distortion enhancement by polarization transfer) spectrum of **1** the signals for carbons (1 × C, 4 × CH, 35 × $CH_2$, 2 × $CH_3$) were recognized in which the presence of one quaternary carbon at δ 175.37 ppm (CONH, C-1′), four methines at δ 53.10 (CHNH, C-2), 72.56 (CHOH, C-2′), 73.12 (CHOH, C-4), and 76.89 ppm (CHOH, C-3) and a methylene at 62.14 ppm ($CH_2OH$, C-1) were followed from NMR data. Compound **1** possesses five characteristic signals of protons geminal to hydroxyls at δ 4.28 (1H, *m*), 4.35 (1H, *dd, J* = 6.5, 4.0 Hz), 4.62 (1H, *dd, J* = 7.6, 4.0 Hz), 4.43 (1H, *dd, J* = 10.6, 5.2 Hz), and 4.52 ppm (1H, *dd, J* = 10.6, 4.5 Hz). A sixth signal at low field appeared as a multiplet at δ 5.12 ppm and was assigned as a methine proton vicinal to the nitrogen atom. Therefore, all of the above spectral data revealed that **1** should be a phytosphingosine-type ceramide containing a 2-hydroxy fatty acid (6,7). Furthermore, compound **1** was considered to possess normal- type side chains since the carbon atom signals due to terminal methyl groups were observed at δ = 14.28 (*normal* form) (8) in the $^{13}C$ NMR spectrum of **1** (Table 1).



To determine the numbers of hydroxyl groups, compound **1** was acetylated with $Ac_2O$-pyridine at room temperature to yield the corresponding tetra-acetylated product **1a** which gave prominent peaks at *m/z* 851 $[M]^+$, 611 $[M - 4 \times CH_3COOH]^+$ in the EI–MS. The peracetate **1a** showed four ester methyl proton signals at δ 2.18, 2.09, 2.06, and 2.03 ppm in the $^1H$ NMR spectrum; thereby the presence of four hydroxyl groups in the original structure of **1** was confirmed.

Acidic methanolysis (6) of **1** with 0.9 N HCl solution in 82% aqueous MeOH yielded a fatty acid methyl ester and a long-chain base (Scheme 1). The fatty acid methyl ester was identified as methyl 2′-hydroxytetracosanoate (**1b**) by the help of GC–MS analysis. The existence of this fatty acyl moiety in **1** was also confirmed by the significant fragment ion peaks at *m/z* 384 $[CH_3(CH_2)_{21}CH(OH)CONH_2 + H]^+$ and 357 $[M - CH_3(CH_2)_{21}(OH]^+$ in the EI–MS. In addition, the $^1H$ NMR spectrum and optical rotation ($[\alpha]_D$ = –4.5°) of **1b** are in good accord with the data reported in the literature (6),

therefore the absolute configuration at C-2′ in **1b** is also supposed to be *R*. The long-chain base, namely phytosphingosine, is a $C_{18}$ aliphatic amino alcohol unit containing three hydroxyls and an amino group. It was confirmed by treatment of methanolysis product of **1** with $Ac_2O$/pyridine at 70°C to afford a tetraacetylphytosphingosine, i.e., 2-acetoamino-1,3,4-triacetoxyoctadecane (**1c**). The $^1H$ NMR spectrum and optical rotation ($[\alpha]_D = +10.9^\circ$) for **1c** was found to be identical to that of the known counterpart (7).

The relative stereochemistry at C-2, C-3, C-4, and C-2′ was proposed as 2*S*,3*S*,4*R*,2′*R*, since the chemical shifts and coupling constants of 1-H, 2-H, 3-H, 4-H, and 2′-H in **1** were in good agreement with those of the natural ceramide, (2*S*, 3*S*,4*R*,2′*R*)-2-(2′-hydroxytetracosanoylamino) hexadecane-1,3,4-triol (**2**) isolated from the starfish *Acanthaster planci* (Table 2) (8) and which was confirmed by synthesis (9). The above fact and the comparison of the optical rotations of **1** with compound **2** (natural, $[\alpha]_D = +11.5°$; synthetic, $[\alpha]_D = +9.1°$) (8,9) suggested that **1** has the same absolute configuration as that of the natural one for the core structure like positions 2, 3, 4, 2′ chiral centers. Accordingly, the above evidence led to the establishment of the structure of **1** as (2*S*,3*S*, 4*R*,2′*R*)-2-(2′-hydroxytetracosanoylamino) octadecane-1,3,4-triol, whose structure as shown in Scheme 2 was verified by further two-dimensional NMR experiments: $^1H$-$^1H$ correlation spectroscopy heteronuclear multiple bond connectivity, and heteronuclear multiple quantum coherence.

Based upon comparison of spectroscopic (MS, IR, $^1H$ and $^{13}C$ NMR) and physical data with the literature, the structures of the other nine known compounds were characterized as 5α, 8α-epidioxy-(22*E*,24*R*)-ergosta-6,22-dien-3β-ol (10,11), 5α, 8α-epidioxy-(24*S*)-ergosta-6-en-3β-ol (10), (24*S*)-ergosta-7-ene-3β,5α,6β-triol (12,13), (22*E*,24*R*)-ergosta-7,22-dien-3β,5α,6β-triol (12,14), inosine (15), adenine (5), L-pyroglutamic acid (16), fumaric acid (17), and D-allitol (5), respectively.

The ceramides, cleavage products of various sphingolipids including gangliosides and cerebrosides, are involved in various signal transduction pathways (18). Many extracellular stresses, such as tumor necrosis factors-α and human immunodeficiency virus, have been shown to activate sphingomyelinases that release ceramides which inhibit cell growth and induce apoptosis (19,20). Because of the importance of ceramides, the chemistry and biology of ceramides have been a vital subject of research in recent years (9,21,22).

The occurrence of the ceramide-containing $C_{18}$-phytosphingosine and an α-hydroxy fatty acid is rather common in the bonding form in mushrooms. More recently, Jennemann *et al.* (23) reported on a series of glycoinositolphosphoceramides possessing this type of ceramide from higher mushrooms (*Agaricus*). However, except for the fact that this type of ceramide (phytosphingosine/α-fatty acid) itself is a normal constituent of the glycosylphosphoinositolcermides of fungi in general, it has been reported previously to occur in the free state only in the fungus *Phellinus pini* (7). This probably represents a precursor of these glycolipids. One functional aspect of the hydroxyl group cluster of this ceramide, especially in the neighborhood of a phosphoinositol, may indeed be to strengthen the structures where it occurs.

These ergostane-type compounds were previously obtained from marine organisms (11–13) and mushroom (10,14). Biogenetically, $\Delta^6$-ergosterol peroxides and $\Delta^7$-polyhydroxysterols seem quite obviously to originate from ergosterol distributed widely in both fungi and marine organisms (12,13). The occurrence of closely related ergostane derivatives and ceramides in taxonomically remote species is interesting and may indicate the connection with a common producer, probably symbiotic microorganisms. The above fact suggests that a close correlation between terrestrial fungi and marine organisms appears to exist, which is of evolutionary value.

**ABSTRACT:** *Ab initio* and density functional theory molecular orbital calculations were carried out at both the HF/6–31+G(d) and B3LYP/6–31+G(d) levels for the four antioxidants, *p*-hydroxycinnamic acid derivatives, namely, the *p*-coumaric, caffeic, ferulic, and sinapinic acid and the corresponding radicals, in an attempt to explain the structural dependency of the antioxidant activity of these compounds. Optimized resulting geometries, vibrational frequencies, absolute infrared intensities, and electron-donating ability are discussed. Both the high degree of conjugation and the extended spin delocalization in the phenoxyl radicals offer explanation for the scavenging activity of the four acids. In structurally related compounds, the calculated heat of formation value in radical formation appears as a meaningful molecular descriptor of antioxidant activity in accordance with experimental data. This becomes more clear at the B3LYP level.

Paper no. L8594 in *Lipids 36,* 181–190 (February 2001).

Structure-activity relationship studies using theoretical methods are gaining interest among scientists for prediction or elucidation of differences in the activity of series of molecules (1–6). Phenolic antioxidants such as tocopherols, flavonoids, and phenolic acids are the most intensively examined categories because of their broadly accepted biological function (7–10). Difficulties in theoretical approach are related to the various factors that determine the performance of a molecule as an antioxidant; scavenging of free radicals, metal chelation, and lipophilicity are the most important ones (11,12). Although a considerable number of molecular descriptors have been examined, only a few of them prioritize the molecules in accordance to conclusions derived by experimental data. Various factors have been considered so far for the characterization of free radical scavenging activity of antioxidants, for instance, (i) the difference in the heat of formation (ΔHOF) between the antioxidant and the free radical (1–4), (ii) the spin distribution in the radical (4), (iii) the dissociation energy of the phenolic O–H bond (5,6,13) and (iv) the energy-eigenvalue of the highest-occupied molecular orbital (HOMO) (2,13–16). Owing to the large size of the antioxidant molecules, semiempirical quantum-chemical methods have been employed in most cases and *ab initio* calculations are quite rare (4–6,13,17–19).

Korzekwa *et al.* (20) proposed that a linear relationship exists between stability of radicals and activation energies of hydrogen abstraction in the reaction of a flavonoid with a radical in a series of analogous substrates. Consequently, the calculated enthalpy difference (ΔHOF) between the parent antioxidant molecule and its potential radical indicates the relative order of hydrogen atom abstraction, and the difficult task of determining transition states could be avoided for the moment. Based on these, the above hydrogen abstraction scheme is generally accepted (1,21) for the phenolic acid antioxidants, the parent molecule phenoxyl radical couple exhibiting the lowest theoretical ΔHOF value will be considered the one that most easily allows hydrogen atom abstraction by any free radical. The derived radical could then scavenge another one. Hydrogen atom abstraction depends mostly on enthalpy differences (as reflected by calculated ΔHOF values), whereas radical scavenging depends on the spin distribution. The calculated ΔHOF values of the parent molecule phenoxyl radical couples correlate well with the experimental antioxidant activity trend of the same molecules. This was also found by both Zhang (1,2) for certain phenolic antioxidants and van Acker *et al.* (4) for certain flavonoids. Zhang derived ΔHOF values from semiempirical calculations, whereas van Acker *et al.,* from *ab initio* ones; still the antioxidants studied by both exhibited profound structural differences. Moreover, van Acker *et al.* effectively used the radical spin distribution to

account for the ease of a second radical scavenging. Hence, the molecular descriptors considered to be worth examining are the ΔHOF values and the radical spin distribution.

In the present study, high level *ab initio* and density functional theory (DFT) molecular orbital calculations, at both the HF/6-31+G(d) and B3LYP/6-31+G(d) levels, are carried out to optimize the geometries of four structurally related antioxidants, *p*-hydroxycinnamic acid derivatives, namely caffeic, sinapinic, ferulic and *p*-coumaric acids (parent molecules) and the corresponding phenoxyl radicals (Scheme 1). The geometries of the parent molecules and their phenoxyl radicals, the vibrational frequencies and the electron-donating ability of the parent molecules are examined and discussed.

The ΔHOF values, giving information about the ease with which the radical is formed, are compared, too. The radical spin distributions, which are measures of the radical stability since they provide information about the degree of delocalization as well as the electron-donating ability, are also calculated and considered. Calculations for the molecular descriptors considered in this study are CPU-intensive and physical memory-demanding. To our knowledge, no *ab initio* and/or DFT results are available regarding energetics and structural parameters for the molecules under examination. The only relative paper is that of Hueso-Urea *et al.* (22), in which, some molecular descriptors have been calculated, using semiempirical approaches, to establish structure-liquid chromatographic retention time relationships for certain phenolic compounds. Neither structural nor detailed frequency data were given in that paper. The only experimental data available for the four acids under study are solid-state X-ray crystallographic studies for caffeic and ferulic acids (23,24) and solid-state infrared spectroscopic data for all of them (25).

The *p*-hydroxycinnamic acids under study are widely examined experimentally, and the order of their activity is well established in practice. Additional experiments are also carried out to support theoretical results.

## MATERIALS AND METHODS

*Quantum-chemical calculations*. The geometries of all minimum energy structures for all four hydroxycinnamic acid derivatives and the corresponding radicals were fully optimized, employing the Hartree-Fock (HF) (26) theory (namely, the restricted HF for the parent molecules and unrestricted HF for the radicals) and the Becke's Three Parameter Hybrid Functional using the Lee-Yang-Parr correlation functional theory (B3LYP) (27) of available DFT ones, both with the 6–31+G(d) basis set (28–33). To form the radical, an H· was removed from the phenolic hydroxyl group in each acid. Diffuse functions (32) were added to heavy atoms, e.g., C and O, and inclusion of *d* polarization functions (33) on heavy atoms was considered necessary for the calculation of molecular properties. Pure *d* functions were used in the *d* shells, i.e., the *d* functions have five components. $C_1$ point group symmetry for each species was assumed as the initial geometry of the optimization procedure, and all redundant internal coordinates (34) were fully optimized (35). All calculations investigating the structural parameters of the molecules addressed here are based on final frequency calculations that provide energy minima with certainty. For each molecule full optimization calculations were performed in an attempt to determine the closest structure to the global minimum. The nonappearance of negative frequencies was assumed to be evidence for a global potential energy minimum of each calculated structure. The GAUSSIAN-94 software package (36), installed on a Hewlett-Packard 9000 series workstation (model J210 with 128 MB of memory; Hewlett-Packard, Palo Alto, CA), was used throughout this study.

The 298 K theoretical difference of heat of formation, ΔHOF, between the parent phenolic antioxidant, HOF*m*, and its free radical, HOF*f*, produced after the H-abstraction equals

$$\Delta\text{HOF} = \text{HOF}f - \text{HOF}m + \text{E}h + RT \quad [1]$$

where HOF*f*, HOF*m*, and E*h* are the sum of electronic, zero-point and thermal energies of the radical, the parent molecule, and the H atom, respectively; *R* is the gas constant, and *T* is the absolute temperature.

*Samples and standards.* Commercial refined olive oil was from Elais S.A. (Piraeus, Greece). Sinapinic acid and *p*-coumaric acid were from Sigma Chemical Co. (St. Louis, MO), whereas ferulic and caffeic acids were from Fluka (Buchs, Switzerland). Silicic acid (100–200 mesh size, Sigma Chemical Co.), celite (Riedel de Häen, Seelze, Germany), commercial sucrose, activated carbon (100 mesh size, Aldrich, Dorset, England), and *n*-hexane (Riedel de Häen) were used for column chromatography. 2,2-Diphenyl-l-picrylhydrazyl radical (DPPH) (approximately 90%) was from Sigma Chemical Co., and 2-propanol for spectroscopy was from Merck (Darmstadt, Germany). All solvents used were of appropriate grade.

*Estimation of antiradical activity of the four* p*-hydroxycinnamic acids by DPPH and antioxidant activity on olive oil triacylglycerol fraction*. The antiradical activity of the molecules under study was determined using the free radical DPPH ($6 \times 10^{-5}$ M) in ethanol (37). The reduction of DPPH was followed by monitoring the decrease in its absorbance at 515 nm, automatically recorded every 60 s. The exact initial DPPH concentration ($C_{\text{DPPH}}$) in the reaction medium was calculated from a calibration curve using the equation

$$\text{Abs}_{515\,\text{nm}} = 11{,}589 \times (C_{\text{DPPH}}) + 0.0027$$

(correlation coefficient, $r = 0.999$) [2]

where Abs = absorbance.

Different concentrations (expressed as the number of antioxidant moles per mole of DPPH) were used, and for each antioxidant, the reaction kinetics were plotted. From these graphs, the percentage of DPPH remaining at the steady state was determined. These values were transferred onto another graph showing the percentage of residual stable radical at the steady state as a function of the molar ratio of antioxidant to DPPH. The latter was used to determine the efficient concentration ($EC_{50}$), which is the amount of antioxidant necessary to decrease the initial DPPH concentration by 50%. The lower the $EC_{50}$, the higher the antioxidant activity is. Then, the antiradical power (ARP) was calculated as $ARP = 1/EC_{50}$.

Commercial refined olive oil was purified in our laboratory using column chromatography (38) and stored at −18°C till use. The quality characteristics of the substrate were evaluated as reported elsewhere (39). Samples (2.5 g) of purified olive oil containing phenolic antioxidants dissolved in ethanol at a concentration of $2.8 \times 10^{-3}$ M and control samples were prepared, and induction periods (IP) at 120°C were estimated using a Rancimat apparatus (679 Rancimat; Metrohm Ltd., Herisau, Switzerland.). IP is considered to be the time period over which the oil is resistant to oxidation with or without the presence of antioxidants. Protection factors (PF) were calculated as the ratio of IP in the presence of the antioxidant/IP of control, i.e., PF = IP (time units)/$IP_{control}$ (time units).

## RESULTS AND DISCUSSION

*Equilibrium geometries.* All tables with the structural data for all acids and phenoxyl radicals under examination are given as Supplementary Material (Tables S1–S5), available upon request from the author. Owing to the lack of structural experimental studies in the gas phase for the same acids, the X-ray solid-state ones for caffeic (23) and ferulic (24) acids are also given in Table S1. Although comparison between results in the gas and the solid state is not allowed, it is simply mentioned that the corresponding values do not deviate more than 1%. The resulting structures for the parent molecules (**I**, *p*-coumaric acid; **II**, caffeic acid; **III**, ferulic acid; **IV**, sinapinic acid), together with the adopted numbering scheme, are given in Figure 1; those of their radical species (**V**, *p*-coumaric acid radical; **VI**, caffeic-H acid radical; **VII**, caffeic-open radical; **VIII**, caffeic acid radical; **IX**, ferulic acid radical; **X**, sinapinic acid radical) in Figure 2. This was easily accomplished, since in all structures, with only a few exceptions, the dihedral angle values were either ±180° or 0°; planar structures were derived for the substituents OH and OMe, in excellent agreement with assumptions made by Wu and Lai (40). Moreover, owing to the very low deviations derived between the corresponding structural values of the parent molecules and the phenoxyl radicals, calculated at a particular level, mean structural values are given in both Figures 1 and 2. In the case of caffeic acid, possessing two neighboring hydroxyl groups in the phenyl ring, three different radical structures were considered. The first two correspond to the radical structures deriving from the OH group at C(3), in which the intramolecular hydrogen bond is retained (**VI**), or eliminated (**VII**), the third to the structure in which an $H^{\cdot}$ was eliminated from the OH group at C(4) (**VIII**), leading also to a nonhydrogen bonding structure. The reason for this separate consideration stems from the fact that an intramolecular hydrogen bond further stabilizes any molecule.

An unexpected discrepancy, found between the HF and B3LYP levels of theory geometrical parameters, lies in the dihedral angle between the phenyl ring and the carboxyl group of the caffeic acid, being 8.5° in the former and zero in the latter. This discrepancy leads to a symmetry point group of $C_1$ for the caffeic acid at the HF level and a corresponding one of $C_s$ at the B3LYP level. The planar calculated structures for all acids and radicals at the latter imply that the molecules are completely conjugated, hence a $C_s$ symmetry point group is also assumed for them.

As shown in both Figures 1 and 2, the phenyl ring and the carboxyl groups are *trans* to each other around the connecting carbon-carbon double bond. This is the case at both levels of theory. A *trans* configuration around the connecting carbon-carbon double bond accounts well for the correctness of our results concerning both series of compounds studied, since a *trans* configuration leads, in general, to a more energetically stable structure than a *cis* one.

An inspection of the numbers appearing in Figures 1 and 2 clearly shows that the computed bond distances at the B3LYP level are constantly slightly higher than those calculated at the HF level. With only a few exceptions, the computed bond lengths obtained from both levels of theory are in agreement within 1.5 %.

It is also observed that, when a substituent hydroxyl or methoxy group is added to the *p*-coumaric acid at position *ortho* to the aroxyl group (leading to any of the three other acids under study), particular distortions at bond lengths and angles appear. It is noteworthy that the existing C(4)–O bond distance becomes longer when a hydroxyl group is added, e.g., caffeic acid by *ca*. 0.01 Å at both levels of theory, and shorter when a methoxy is added, e.g., ferulic and sinapinic acids. Furthermore, the existing phenolic O–H bond distance is slightly shorter in caffeic acid and slightly longer in ferulic and sinapinic acids, as compared to the *p*-coumaric one, at both levels of theory. This molecular descriptor may be useful in the explanation of the antioxidant activity in a series of homologs, considering that for larger bond length the hydrogen can be removed more easily, thus forming the phenolic hydroxyl. Phenolic OH bond lengths along with the inhibition of lipid oxidation values of all parent molecules studied are given in Table 1.

An inspection of the figures presented in the table clearly shows that the B3LYP O-H bond-length values are consistently higher than the HF ones. It is clear that caffeic acid, the experimentally most active molecule, is the one having the shortest OH bond length, whereas *p*-coumaric acid, the weakest antioxidant experimentally among the four studied, ex-

hibits the second-shortest OH bond length. This could mean that phenolic OH bond length is not a fruitful molecular descriptor by itself, at this level of theory, to compare antioxidant activity of phenolic antioxidants. Zhang also reached an analogous conclusion by performing Austin Model 1 (AM1) semiempirical calculations on flavonoid antioxidants (1).

Formation of a hydrogen bond in both caffeic and ferulic acids is substantiated by the increase of the C(2)-C(3)-O angle by approximately 6.0° when a methoxy group is added to *p*-coumaric acid, compared to a 6.6° decrease of the C(3)-C(4)-O angle when a hydroxyl group is added instead. Sinapinic acid exhibits the same hydrogen bond structural effects with ferulic acid, as expected.

There is considerable C–C bond length alteration in the benzene ring on going from the parent molecules to the phenoxyl radicals. As a matter of fact, contrary to the equality of all C–C bonds in the acids [*ca.* 1.390 (1.400) Å], the two pairs of C–C bonds, C(1)-C(2), C(1)-C(6) and C(4)-C(3), C(4)-C(5) in the benzene ring in the radicals are longer than the C(2)-C(3) and C(5)-C(6) ones by *ca.* 0.04–0.06 Å, indicating quinoid structure. These deviations however, were larger for the former pair of C–C bonds corresponding to the C(4)-O˙ edge, than the latter corresponding to the C(1)-chain edge. Wu and Lai (40) also found very similar geometries for the B3LYP/6-31G(d) level radical structures of both phenol and anisole. Moreover, the C–O bond of the phenoxyl radical has considerable double-bond character, as indicated by the short bond length of *ca.* 1.238 (1.250) Å. The increase of the C(3)-C(4)-O(13) angle, on going from **VI** to **VII**, is probably

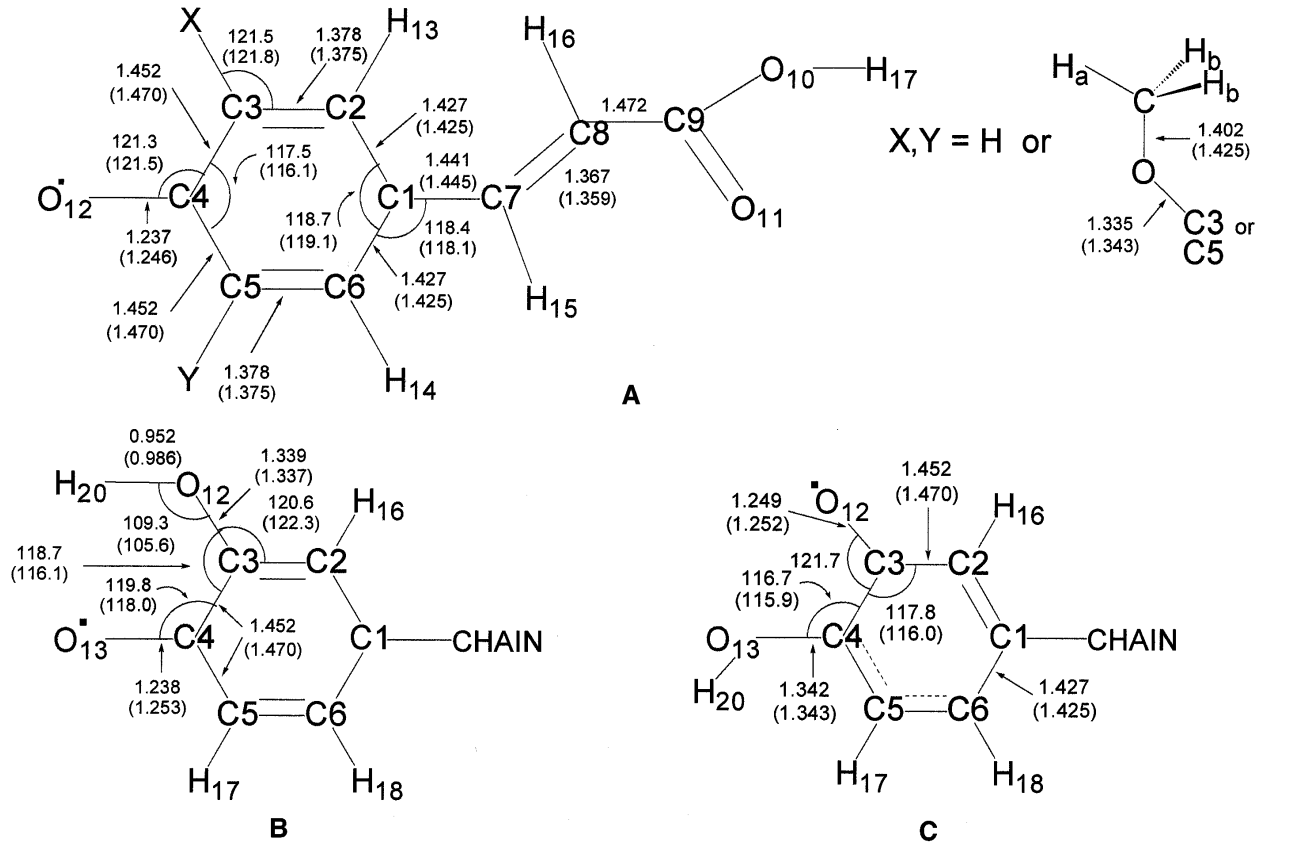

**FIG. 2.** Equilibrium structural parameters for the **V**, **IX** and **X** (A), **VI** (B) and **VII** (C) radicals. DFT values are given in parentheses. Where a particular structural parameter had identical values at both levels of theory, this is given once. Absence of a particular structural parameter value denotes identity to the corresponding one of the other acids. The C2-C3-X angle shown is the one for X = H; the one for X = O is 125.3° (125.5°). The C2-C3-O12, O13-C4-C3, C3-O12-H20, and C4-C3-O12 angle values for the **VIII** radical are 123.6° (123.9°), 121.7°, 111.3° (110.4°), and 116.2° (115.2°), respectively. For abbreviation see Figure 1.

due to the elimination of the O(13)…(H(20) hydrogen bonding. Moreover, the reduction of the C(4)-C(3)-O(12) angle and the concomitant increase of the C(2)-C(3)-O(12) one could be attributed to the H(20)…(H(16) repulsion.

Agreement between the computed values for the bond angles, obtained at both levels of theory, is within 1% or better. Dihedral angles calculated at both levels of theory are identical. However, this is mainly observed between *p*-coumaric and ferulic molecules and less for the sinapinic and caffeic ones (within 1%). The C–C and C–C–C phenyl-ring bonds and angles, and the phenolic C–O and O–H bonds are in excellent agreement with others derived theoretically (41) for the 2,6-dimethylphenol at the UHF/6–31G(d) level of theory; still, this is also the case with the carboxylic C–O, C=O and O–H bonds (42).

*Vibrational frequencies.* Frequency values calculated at the HF level contain known systematic errors (electron correlation is not taken into account, whereas B3LYP calculations include it) that produce an overestimate of about 10% compared to the experimental values. Therefore, it is usual to scale frequencies predicted at the HF level by an empirical factor of 0.8929 (43–45) along with one of 0.9613 (43–45) for the B3LYP model of DFT theory. The harmonic oscillator approach, which is used for calculated frequencies, usually produces higher values than the fundamental ones. Owing to the large size of the frequency tables for all acids under study, their unscaled calculated harmonic frequencies and infrared intensities are given as Supplementary Material (Tables S6–S9), available upon request from the author. An inspection of the figures presented in those tables clearly shows that the B3LYP frequency values are, contrary to those of the bond lengths, consistently lower than the HF ones with a minor exception for those between 200 and 450 $cm^{-1}$.

From all frequency values in Tables S6–S9 (available from the author upon request), only a few have been properly scaled and their values are given in Table 2. Those were chosen based upon the importance of the bond and the intensity of the corresponding absorption. Carboxylic acids, for instance, are mostly characterized by the O–H and C=O stretching bands (46). Table 2 includes the scaled calculated frequency values for these latter bands, as well as those for the phenolic O–H ones, along with their intensities, vibrating atoms, corresponding experimental frequencies in the vapor phase (47,48), and percentage differences between scaled calculated and experimental ones. The above frequencies are well characterized as stretch bands, since both their atom's

[a]The % $\nu_{sc.}/\nu_{exp.}$ discrepancy percentage (DP) is also shown.
[b]The corresponding experimental values are from References 46–48.
[c]Intensity of absorption at the HF level (arbitrary units).

orientation and eigenvector orientation lie on a single plane.

The first band examined corresponds to the phenyl O–H stretching frequencies. Those appear in the region of 3665–3630 $cm^{-1}$, where caffeic and ferulic acids define its two far ends, respectively. The corresponding absorption of *p*-coumaric acid is found at 3656 $cm^{-1}$, since there are no neighboring groups that would lead to a variation of the expected value. The formation of an intramolecular hydrogen bond between the two properly oriented neighboring hydroxy groups in caffeic acid leads to both a strengthening of the free O–H bond and a concomitant weakening of the one participating in the hydrogen bond, as compared to that of *p*-coumaric acid. In effect, this leads to both a shift toward higher frequency values (3665 $cm^{-1}$) for the former bond and a shift toward lower frequency values (3638 $cm^{-1}$) for the latter, followed by a simultaneous narrowing of both bands. This narrowing is further substantiated by its frequency intensity, since a high frequency intensity results in a narrow absorption bandwidth. This band narrowing will be discussed in the following section with respect to the corresponding absolute infrared intensities. Owing to the intramolecular hydrogen bond formation, the existing O–H covalent bond in the newly formed five-membered ring becomes weaker in all acids except *p*-coumaric. The corresponding absorption appears at a lower value (3633 $cm^{-1}$) in sinapinic acid rather than in *p*-coumaric one (3656 $cm^{-1}$). The O–H phenyl group frequency value for ferulic acid (3630 $cm^{-1}$) is very close to that of sinapinic acid because of the formation of an analogous five-membered intramolecular hydrogen-bonded ring. The lower frequency values derived for these latter two acids, as compared to that of caffeic (3665 $cm^{-1}$), is in excellent agreement with the known fact that the hydroxy group is a better electron donor than the methoxy one (49).

In a similar manner, the scaled calculated carboxylic O–H stretching frequency values range between 3606–3614 $cm^{-1}$ and are always lower than the scaled phenolic ones (see also Table 2). Moreover, it is easily seen that there are no large discrepancies between the carboxylic carbonyl C=O group stretching bands for all acids.

So far, each particular theoretical frequency value shown in Table 2 has been both assigned and explained regarding its relative shift in the infrared spectrum region. Frequency information from infrared and Raman spectra in the gas phase was not available for any of the molecules under study. Vapor phase frequency values (46–48) of the most characteristic groups closely match the calculated ones of the four acids under study. In particular, the OH stretching frequency of *m*- and *p*-substituted alkylated phenols, in vapor phase, appears as a single band in the region of 3360–3642 $cm^{-1}$ (48), and its mean value, 3651 $cm^{-1}$, is representative for comparison with *p*-coumaric acid. A frequency value lower than 3651 $cm^{-1}$ should be considered for the vapor phase of caffeic acid owing to formation of an intramolecular hydrogen bond (46). The OH stretching frequency is found at 3595–3569 $cm^{-1}$, when phenol exhibits an –OR group as an *o*-substituent (48). Hence, the mean value, 3582 $cm^{-1}$, of this latter frequency range was considered as the corresponding one for the vapor phase phenolic OH frequency values for both ferulic and sinapinic acids. The OH stretching frequency is found at 3585–3580 $cm^{-1}$, in the α,β-unsaturated monomeric carboxylic acids (47); its mean value, 3582 $cm^{-1}$, was considered as the corresponding one for the vapor-phase carboxylic OH frequency values for all acids. Finally, the vapor phase C=O band is near 1764–1760 $cm^{-1}$ in α,β-unsaturated carboxylic and its mean value, 1762 $cm^{-1}$, was considered as the vapor phase carboxylic C=O frequency for all acids.

An inspection of the values given in Table 2 clearly indicates that: (i) the calculated results coming from either level of theory are in excellent agreement with those in the vapor phase to within 1.5 %; (ii) most of the calculated frequency values are larger than the available vapor phase ones; (iii) the scaled calculated frequencies at the HF level better approximate vapor phase ones; (iv) scaled calculated HF frequencies are always larger than the DFT ones.

*Absolute infrared intensities.* The *ab initio* unscaled absolute infrared intensities for the four acids under study are also given in Table 2. An inspection of those values clearly shows that the intense infrared modes occur within the 1500–1800 and 3500–3700 $cm^{-1}$ regions. Unfortunately, there are no available experimental intensities in the gas phase for any of the four acids under study to compare with. Usually, individual band intensities cannot be accurately measured experimentally due to overlap with neighboring frequencies. However, calculated intensities of nonoverlapping bands occasionally deviate more than 50% from experimental ones (50).

As it was discussed before, formation of a five-membered intramolecular hydrogen-bond ring results in both a shift and a narrowing of the band corresponding to the covalent participating OH bond. The narrowing of the band is also substan-

tiated by its frequency intensity, since a high frequency intensity leads to a narrow absorption bandwidth. Based upon the calculated frequency intensities, it was shown that sinapinic acid exhibits the largest intensity value for the O–H stretching frequency, whereas *p*-coumaric acid the smallest. As a matter of fact, the effect of hydrogen bond formation is to increase the IR intensity and decrease the O–H stretching frequency (46). Sinapinic and ferulic acids, and to a minor extend caffeic acid, do exhibit stronger intensities of absorption as compared to those of *p*-coumaric acid due to intramolecular hydrogen-bond ring formation. It is well known that the stronger the hydrogen bond, the larger the OH stretching frequency shift toward a lower value (46), which predicts that hydrogen bonds formed in ferulic and sinapinic acids will be stronger than those in caffeic acid.

*Heat of formation, ΔHOF values.* Both Figures 1 and 2 clearly show that planar structures were derived. Structure planarity strongly supports complete conjugation within parent and radical molecular species. Intramolecular H-bond interactions found between the two neighboring phenolic hydroxyl groups in caffeic acid and between the phenolic hydroxyl group and the methoxy one in ferulic and sinapinic acids, as well as in caffeic-H acid radical, further strengthen stabilization of these molecules. The calculated ΔHOF values of the parent molecule-radical couples are shown in Table 3, which clearly states that the latter exhibits the lowest ΔHOF value among all radicals studied at both levels of theory. Caffeic acid has been reported to be more active than its counterparts (51–57). Sinapinic and ferulic acids present some antioxidant activity, whereas *p*-coumaric is almost inactive. These findings also are in agreement with experimental data given in Table 3.

ΔHOF numbers in Table 3 also indicate that there are significant energy differences between most phenoxyl radicals studied; the corresponding energy differences are in the range of 2–19 kJ/mol (DFT) and 3–23 kJ/mol (HF). The significant energy differences between the ΔHOF values at both levels of theory provide a secure and ready way to put the structurally related compounds under study in an order according to their antioxidant activity. Such differences have not been found by using semiempirical levels of theory (1). The inconsistency observed at the HF level, between the calculated ΔHOF value-trend and the experimental scavenging activity trend for some of the radicals studied, could be due to the fact that at this theoretical level electron correlation is not taken into account, whereas DFT calculations include it. The energy differences between ferulic and *p*-coumaric (DFT) and sinapinic and ferulic (HF) acids are small (2–3.3 kJ/mol). This is also the case with the experimental PF and ARP values of the former pair of compounds. The hydrogen-bonding interaction has a large stabilizing effect of *ca.* 23 kJ/mol (HF) or 34 kJ/mol (DFT) on the **VI** as compared to that of **VII**. Analogous stabilization effects have been observed in the case of the catechol radical where the corresponding energy gain was in the range of 15–25 kJ/mol (4). The higher value derived for the stabilization effect of the H-bond at the DFT level could be attributed to the functional model used. Actually, the precise choice of nonlocal functionals remains a matter of some uncertainty for the H-bonding interaction calculation. According to Gresh *et al.* (58) the Local Density Approximation seriously overestimates at 37 kJ/mol, whereas various nonlocal functionals provide lower energy results.

The spin density values of the atoms constituting the radicals studied are shown in Figure 3. An inspection of the numbers presenting in Figure 3 shows that the computed spin density values at the HF level are consistently higher than those calculated at the B3LYP level. If oxidation takes place in the phenolic OH, the spin delocalization spreads over all atoms participating in the extended conjugation system of the molecule. At each particular theoretical level, the spin density values on similar atoms are almost identical, so that the delocalization is large in all radicals studied. The planarity of the rad-

icals leads to their full conjugation, and this, in turn, to an extended spin delocalization. Van Acker *et al.* (4) reached an analogous conclusion. The excellent delocalization possibilities of the radicals under study could account for their potential radical scavenging activity. Absence of a high amount of localized spin in these compounds may diminish the possibility to initiate a radical chain reaction (4). It is worth mentioning that, contrary to the HF spin density values for the **VIII**, the DFT ones clearly show that almost all spin remains in the benzene ring and its substituents, and the delocalization possibilities are limited. This fact could account for a lower antioxidant activity. The inferior antioxidant activity of **VIII**, as compared to that of **VII**, could be due to its higher calculated ΔHOF value, hence to its relatively harder tendency for hydrogen atom abstraction.

*Molecular electron-donating ability.* In an attempt to investigate whether the antioxidant activity correlates with the redox potentials, the HOMO energy-eigenvalues were calculated at both levels of theory. HOMO is a parameter representing molecular electron-donating ability. Calculated HOMO values are also listed in Table 1. Numbers in the table clearly show that *p*-coumaric acid, exhibiting the lowest experimental antioxidant activity, is the one with the lowest HOMO energy-eigenvalue at both levels of theory. This could account for its low experimental antiradical activity. However, caffeic acid, despite having the highest experimental antioxidant activity, exhibits the second-lowest HOMO energy-eigenvalue. Considering that an electron-donating group, for instance, the second hydroxyl of caffeic acid, should increase the HOMO energy-eigenvalue and reduce the O–H bond strength at the same time (16), the relative HOMO-energy order of the two acids appears correct. Nevertheless, the ferulic acid HOMO energy-eigenvalue, which involves a less electron donating group (methoxy) than the hydroxyl one of caffeic acid, should lie in between those of *p*-coumaric and caffeic acids. Consequently, HOMO energy-eigenvalue differences among those three acids are not suitable to predict antioxidant activity, although redox potential is expected to be directly related to their antioxidant activity. Zhang reached an analogous conclusion (16) by performing semiempirical calculations on phenolic antioxidants.

With the exception of the ΔHOF value, none of the remaining molecular descriptors by themselves could be safely used for the explanation of the antioxidant activity of the four molecules under examination. All parent-molecule phenoxyl-radical couples under study exhibit a high degree of conjugation, owing to their planarity. All radicals have almost equal, although large, spin delocalization. Both findings could account for their potential radical-scavenging activity. The higher antioxidant activity of caffeic acid, among the rest, should be attributed to its lower ΔHOF value, which arises from the less-energy-demanding hydrogen atom abstraction. It is also observed that relatively large ΔHOF value differences could lead to important changes in reactivity of a molecule *in vitro* and possibly *in vivo*. However, **VII** exhibits less antioxidant activity than **VI**, due to both its higher ΔHOF value and its limited spin delocalization. Considering that the structures of the four antioxidants studied exhibit slight differences and only one parameter is considered, the data obtained from experimental procedures and theoretical calculations are in good agreement. DFT calculations afford a good descriptor, ΔHOF, to correlate well with the antioxidant activity in molecules exhibiting similar structural parameters.

**ABSTRACT:** The cleavage products formed by autoxidation of lycopene were evaluated in order to elucidate possible oxidation products of lycopene in biological tissues. Lycopene solubilized at 50 μM in toluene, aqueous Tween 40, or liposomal suspension was oxidized by incubating at 37°C for 72 h. Among a number of oxidation products formed, eight products in the carbonyl compound fraction were identified as 3,7,11-trimethyl-2,4,6,10-dodecatetraen-1-al, 6,10,14-trimethyl-3,5,7,9,13-pentadecapentaen-2-one, acycloretinal, apo-14′-lycopenal, apo-12′-lycopenal, apo-10′-lycopenal, apo-8′-lycopenal, and apo-6′-lycopenal. These correspond to a series of products formed by cleavage in the respective 11 conjugated double bonds of lycopene. The maximal formation of acycloretinal was 135 nM in toluene, 49 nM in aqueous Tween 40, and 64 nM in liposomal suspension. Acycloretinoic acid was also formed by autoxidation of lycopene, although its formation was lower in the aqueous media than in toluene. The pig liver homogenate had the ability to convert acycloretinal to acycloretinoic acid, comparable to the conversion of all-*trans*-retinal to all-*trans*-retinoic acid. These results suggest that lycopene might be cleaved to a series of apolycopenals and short-chain carbonyl compounds under the oxidative conditions in biological tissues and that acycloretinal is further enzymatically converted to acycloretinoic acid.

Paper no. L8600 in *Lipids 36,* 191–199 (February 2001).

Provitamin A carotenoids are metabolized to vitamin A through enzymatic cleavage at central double bond to retinal in intestinal cells of vertebrates (1,2). Eccentric cleavage, by which double bonds of provitamin A were cleaved at random position, was also proposed as an additional pathway for retinoid synthesis (3). Thus, the enzymatic oxidations of provitamin A carotenoids have an essential role to provide vertebrates with vitamin A. However, the cleavage products such as retinal and β-apocarotenals with different carbon chain length also have been known to be produced from β-carotene by nonenzymatic oxidation under various conditions: autoxidation in solvents; oxidation with peroxy radical initiators, singlet oxygen, and cigarette smoke; and cooxidation by lipoxygenase (4–10). Canthaxanthin was also reported to give a series of cleavage products by oxidation with nickel peroxide (11). Moreover, 4-oxo-retinoic acid was identified as an oxidation product of canthaxanthin that had been incubated in a cell-culture medium and was found to activate retinoic acid receptor (RAR-β) gene promoter and to enhance gap junctional communication (12,13). The oxidation product of β-carotene, 5,8-endoperoxy-2,3-dihydro-β-apocarotene-13-one, has been shown to inhibit growth and cholesterol synthesis of breast cancer cells (14). A urinary metabolite of canthaxanthin in rats was identified as 3-hydro-4-oxo-7,8-dihydro-β-ionone (15), and one of the astaxanthin metabolites in primary culture of rat liver was found to be a glucuronide of 3-hydroxy-4-oxo-β-ionone (16). These two products were cleavage products at the 9-10 double bond of the respective carotenoid. Therefore, these reports suggest that oxidation of carotenoids including non-provitamin A carotenoids gives eccentric cleavage products in biological tissues and that some of the cleavage products are biologically active compounds as retinoids. In other words, some of the biological effects of carotenoids, whether provitamin A or not, are potentially dependent on their oxidation products formed in tissues. Thus, it is worth evaluating oxidation products of carotenoids formed under oxidative conditions in tissues and their biological effects.

Lycopene, one of non-provitamin A carotenoids, has attracted much attention for its beneficial effect on human health. The epidemiological studies showed that the high consumption of tomato and tomato-based foods rich in lycopene and the high level of plasma lycopene have been associated with a reduction of the risk of prostate cancer (17,18). Lycopene was also suggested to have a protective role in the development of arteriosclerosis (19,20). In animal experiments, dietary lycopene was demonstrated to repress the formation, induced by carcinogens, of aberrant crypto foci in the intestine (21–23). Induction of differentiation, inhibition of proliferation, and enhancement of gap junctional communication in several cancer cell lines were also observed as biological effects of lycopene (24–28). However, mechanisms underlying these biological effects still remain to be elucidated, although the chemical nature of lycopene such as radical scavenging and singlet oxygen quenching activities would be responsible for some of biological effects (29–31). Oxidation products of lycopene might be involved in biological effects

as mentioned above. Several oxidation products of lycopene have been reported, but little is known about their biological effects. Photosensitized oxidation of lycopene produced 2-methyl-2-hepten-6-one and apo-6′-lycopenal (32), and oxidation with hydrogen peroxide and *m*-chloroperbenzoic acid produced lycopene-1,2-epoxide and lycopene-5,6-epoxide (33,34). Khachik *et al.* (35) found 5,6-dihydroxy-5,6-dihydrolycopene in human serum as an oxidation product of lycopene. However, the formation of cleavage products of lycopene has not been documented and has received little attention. In the present study, the formation of cleavage products from lycopene under several oxidative conditions was evaluated *in vitro,* in order to investigate possible oxidation products formed in biological tissues and their relationship to the biological effects of lycopene.

## MATERIALS AND METHODS

*Materials.* Tomato oleoresin (Lyc-O-Mato™ 6%) was obtained from Ajinomoto Takara Co. (Tokyo, Japan). All-*trans*-retinal, all-*trans*-retinoic acid, Tween 40, and 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine were purchased from Sigma Chemical Co. (St. Louis, MO). High-performance liquid chromatography (HPLC)-grade acetonitrile was purchased from Nacalai Tesque, Inc. (Kyoto, Japan). *d*-α-Tocopherol was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Other chemicals and solvents were of reagent grade.

*Preparation of acycloretinal, apolycopenals, and acycloretinoic acid.* Lycopene, which was purified from tomato oleoresin by crystallization, was subjected to ozonolysis in ice-cold dichloromethane. Ozone gas, which was generated with a Matsui MO-5A ozone generator (Matsui Co., Tokyo, Japan) equipped with an ultraviolet (UV) lamp (8W), was bubbled into 2 mM lycopene dissolved in dichloromethane at a flow rate of 260 mL/min. The bubbling was stopped when lycopene was decreased to 10% of the initial concentration. The reaction mixture was evaporated *in vacuo* to dryness. The residue was dissolved in hexane/ethyl acetate (99:1, vol/vol), applied to a silica gel column (kiesel gel, 30–70 mesh; Merck, Darmstadt, Germany) which was preconditioned with the same solvent as above. The column was washed with an adequate amount of hexane/ethyl acetate (99:1, vol/vol), and carbonyl compounds were eluted with hexane/ethyl acetate (95:5, vol/vol).

The eluate (carbonyl compound fraction) was analyzed by HPLC with an MCPD-3600 photodiode array detector (Otsuka Electronics Co. Ltd., Osaka, Japan) and liquid chromatography–mass spectrometry (LC–MS) analyses on a TSK-Gel ODS 120T column (Tosoh Co., Tokyo, Japan) 4.6 × 250 mm. The solvent system consisted of acetonitrile/water (90:10, vol/vol) containing 0.1% ammonium acetate (solvent A) and methanol/ethyl acetate (70:30, vol/vol) containing 0.1% ammonium acetate (solvent B). A linear gradient from solvent A (100%) to solvent B (100%) was applied for 10 min at a flow rate of 1 mL/min, followed by isocratic elution with solvent B (100%) for an additional 10 min. Eight major peaks were detected at 6–12 min. They were assigned as 3,7,11-trimethyl-2,4,6,10-dodecatetraen-1-al, 6,10,14-trimethyl-3,5,7,9,13-pentadecapentaen-2-one, acycloretinal (3,7,11,15-tetramethyl-2,4,6,8,10,14-hexadecahexaen-1-al), apo-14′-lycopenal, apo-12′-lycopenal, apo-10′-lycopenal, apo-8′-lycopenal, and apo-6′-lycopenal, based upon its UV–visible (VIS) spectra and $[M + H]^+$ ion. The $\lambda_{max}$ values in their UV–VIS absorption spectra were 340, 365, 400, 420, 445, 460, 470, and 490 nm, respectively.

Acycloretinal was separated from the carbonyl compound fraction on a LiChroprep RP-18 column (40–63 μm, 11 × 200 mm; Merck) with a linear gradient from acetonitrile/water (90:10, vol/vol) to methanol/ethyl acetate (70:30, vol/vol) for 20 min at flow rate of 2 mL/min. The acycloretinal fraction was further purified on a TSK-Gel Silica 60 column (Tosoh Co.), 4.6 × 250 mm with hexane/ethyl acetate (92:8, vol/vol) as a mobile phase. $^1$H nuclear magnetic resonance (NMR) data of the purified acycloretinal were consistent with the values reported (36,37). Acycloretinoic acid (3,7,11,15-tetramethyl-2,4,6,8,10,14-hexadecahexaenoic acid) was prepared from the purified acycloretinal with Tollens reagent by the method of Barua and Barua (38). It was further purified on a TSK-Gel Silica 60 column, 4.6 × 250 mm with hexane/ethyl acetate (92:8, vol/vol) containing 0.1% acetic acid as a mobile phase. The purified acycloretinoic acid had the following spectral data: UV–VIS ($\lambda_{max}$, ethanol) 365 nm, E (1%, 1 cm) 1960; $^1$H NMR (600 MHz, $CDCl_3$) δ ppm, 1.62 (3H, *s*, C15-C$H_3$), 1.69 (3H, *s*, C16-*H*), 1.84 (3H, *s*, C11-C$H_3$), 2.01 (3H, *bs*, C7-C$H_3$), 2.13 (4H, *bs*, C12-*H,* and C13-*H*), 2.36 (3H, *s*, C3-C$H_3$), 5.10 (1H, *m*, C14-*H*), 5.80 (1H, *s*, C2-*H*), 5.98 (1H, *d*, *J* = 10.3 Hz, C10-*H*), 6.19 (1H, *d*, *J* = 12.3 Hz, C6-*H*), 6.24 (1H, *d*, *J* = 15.3 Hz, C8-*H*), 6.32 (1H, *d*, *J* = 15.2 Hz, C4-*H*), 6.60 (1H, *dd*, *J* = 15.3, 10.3 Hz, C9-*H*), 7.04 (1H, *dd*, *J* = 15.2, 12.3 Hz, C5-*H*); $^{13}$C NMR (150 MHz, $CDCl_3$) δ ppm, 13.0 (C7-*C*$H_3$), 14.2 (C3-*C*$H_3$), 17.3 (C11-*C*$H_3$), 17.8 (C15-*C*$H_3$), 25.4 (C16), 26.2 (C13), 41.0 (C12), 117.8 (C2), 124.1 (C14), 125.6 (C10), 127.4 (C9), 130.2 (C6), 131.6 (C5), 134.3 (C15), 134.6 (C8), 135.4 (C4), 138.0 (C11), 140.5 (C7), 155.0 (C3), 172.0 (C1). The carbonyl compound fraction, the purified acycloretinal and acycloretinoic acid were used as references to analyze cleavage products of lycopene by HPLC.

*HPLC analyses.* Lycopene was analyzed by HPLC on a TSK-Gel ODS 80Ts column (Tosoh Co.) 4.6 × 250 mm, attached to a precolumn (2 × 20 mm) of Pelliguard LC-18 (Supelco, Inc., Bellefonte, PA). Methanol/ethyl acetate (70:30, vol/vol) containing 0.1% ammonium acetate was used as a mobile phase at a flow rate of 1 mL/min with the photodiode array detector. The retention time of lycopene was 14.6 min. Lycopene was monitored at 470 nm and was quantified from the peak area by use of standard curve with lycopene. Acycloretinal and apolycopenals were analyzed by HPLC on the same column as above. The solvent system consisted of acetonitrile/methanol/water (75:15:10, by vol) containing 0.1% ammonium acetate (solvent A) and methanol/ethyl acetate (70:30, vol/vol) containing 0.1% ammonium acetate (solvent B). A linear gradient from solvent A (100%) to sol-

vent B (100%) was applied for 10 min at a flow rate of 1 mL/min, followed by isocratic elution with solvent B (100%) for an additional 10 min. They were monitored at each $\lambda_{max}$ with the photodiode array detector as described in section *"Preparation of acycloretinal, apolycopenals and acycloretinoic acid."* Acycloretinal was quantified from the peak area by use of standard curves of purified acycloretinal. Apolycopenals were quantified from the peak area by use of a standard curve of acycloretinal and the ratio of their extinction coefficients to that of acycloretinal. Extinction coefficient (ε) values used were as follows: acycloretinal, 56,888 (39); apo-12′-lycopenal, 84,700; apo-10′-lycopenal, 101,000; apo-8′-lycopenal, 118,300 (40); apo-6′-lycopenal, 108,290 (41). Apo-14′-lycopenal was not determined because of lack of published data on its extinction coefficient.

Acycloretinoic acid was analyzed by HPLC on the same column as above with acetonitrile/methanol/water (70:20:10, by vol) containing 0.1% acetic acid used as a mobile at a flow rate of 1 mL/min. It was monitored at 365 nm with a photodiode array detector and was quantified from its peak area of HPLC by use of a standard curve of purified acycloretinoic acid.

*Autoxidation of lycopene.* Autoxidation of lycopene, solubilized at 50 μM in toluene, aqueous Tween 40 or liposomal suspension, was carried out by incubating under atmospheric oxygen at 37°C for 72 h. Lycopene dissolved in 1 mL of toluene was placed in a long test tube (1.3 × 16 cm) and incubated at 37°C. After incubation, 0.2 mL of 0.1% α-tocopherol/ethanol was added, and the mixture was stored at −80°C until extractions. Lycopene solubilized in an aqueous 5% Tween 40 was prepared as follows. One milliliter of 5% Tween 40/acetone and 50 nmol of lycopene dissolved in dichloromethane were mixed in a test tube (1.3 × 10 cm), and solvents were removed with a stream of argon gas. The residue was dissolved in 1 mL of deionized water. Lycopene solubilized in a liposomal suspension was prepared as follows. Five micromoles of 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine and 50 nmol of lycopene dissolved in dichloromethane were mixed in a test tube (1.3 × 10 cm), and the solvent was removed under a stream of argon and then *in vacuo* for 30 min. The residue was dispersed in 1 mL of 0.01 M Tris-HCl buffer, pH 7.4, containing 0.5 mM of diethylenetriamine pentaacetic acid by mixing with a vortex mixer for 1 min and sonicating with a Branson 1210J ultrasonicate (Branson, Danbury, CT) for 30 s at ambient temperature. Lycopene solubilized in an aqueous Tween 40 and liposome was incubated at 37°C with continuous shaking at 120 rpm. After incubation, 1 mL of 0.02% α-tocopherol/ethanol was added, and the mixture was stored at −80°C until extractions. For evaluation of acycloretinoic acid formation in the aqueous media, the incubation mixture was scaled up from 1 to 20 mL because of the limited formation.

*Extraction of oxidation products*. Residual lycopene and its oxidative products formed in toluene were extracted as follows. The stored mixture was evaporated to dryness under argon gas, and the residue was redissolved in 2 mL of acetone. A 20-μL aliquot was subjected to an HPLC analysis under conditions used for the analysis of lycopene. For extraction of acycloretinal and apolycopenals, the stored mixture was evaporated to dryness under argon gas and the residue was redissolved in 300 μL of hexane/ethyl acetate (99:1, vol/vol). The residue was applied to a Bond Elut solid-phase cartridge (SI 100 mg; Varian, Harbor, CA), preconditioned with the same solvent as above. The cartridge was washed with 1 mL of hexane/ethyl acetate (99:1, vol/vol). The eluate with 3 mL of hexane/ethyl acetate (95:5, vol/vol) was dried and the residue was dissolved in 200 μL of acetonitrile. A 100-μL aliquot of the eluate was subjected to an HPLC analysis under conditions used for the analysis of acycloretinal and apolycopenals. For extraction of acycloretinoic acid, the stored mixture was evaporated to dryness under argon gas. The residue was dissolved in 1 mL of ethanol, and then 1 mL of 0.1 N NaOH was added. After washing three times with 2 mL of hexane, the aqueous phase was acidified with 30 μL of 6 N HCl, and acycloretinoic acid was extracted three times with 2 mL of hexane. The combined extract was dried and the residue was dissolved in 200 μL of acetonitrile/methanol/water (70:20:10, by vol) containing 0.1% acetic acid. A 100-μL aliquot of the extract was subjected to HPLC analysis.

Residual lycopene and its oxidation products formed in an aqueous Tween 40 and liposomal suspension were extracted as follows. Lycopene was extracted three times with 2 mL of hexane from the stored mixture. The combined extract was evaporated to dryness under argon gas, and the residue was dissolved in 2 mL of acetone. A 20-μL aliquot of the final extract was subjected to an HPLC analysis under conditions used for analysis of lycopene. Acycloretinal and apolycopenals were extracted as in the case of lycopene, and the extract was dissolved in 300 μL of hexane/ethyl acetate (99:1, vol/vol). The extract was fractionated with a Bond Elut solid-phase cartridge and subjected to HPLC analysis as described above. For the extraction of acycloretinoic acid, 2 mL of 1 N NaOH was added to the stored mixture (40 mL). The mixtures were washed three times with 40 mL of hexane. The aqueous phase was acidified with 600 μL of 6 N HCl, and then acycloretinoic acid was extracted three times with 40 mL of hexane. The combined extracts were evaporated to dryness under argon gas and dissolved in 200 μL of hexane/ethyl acetate (92:8, vol/vol). A 50 μL aliquot of the extract was subjected to fractionation by HPLC on a TSK-Gel Silica 60 column, 4.6 × 250 mm, attached to a precolumn (2 × 20 mm) of Pelliguard LC-SI (Supelco, Inc.) with hexane/ethyl acetate (92:8, vol/vol) containing 0.1% acetic acid as a mobile phase at flow rate of 1 mL/min. The combined fraction of acycloretinoic acid from three-time fractionations was evaporated to dryness under argon gas, and the residue was redissolved in 200 μL of acetonitrile/methanol/water (70:20:10, by vol) containing 0.1% acetic acid. A 100-μL aliquot of the acycloretinoic acid fraction was subjected to HPLC analysis.

*Conversion of acycloretinal to acycloretinoic acid by liver homogenate.* The pig liver was homogenized with a Potter-Elvehjem homogenizer in 5 vol of 0.1 M $KH_2PO_4$–$K_2HPO_4$ buffer, pH 7.4, and 0.15 M KCl. A supernatant solution of homogenate, after centrifugation at 9,000 × *g* for 30 min, was

used to evaluate metabolic activity of liver homogenate for conversion of acycloretinal to acycloretinoic acid under the modified conditions reported previously (42). The final reaction mixture contained 10 μM acycloretinal or all-*trans*-retinal, 0.5 M Tricine-KOH buffer, pH 8.0, 150 mM KCl, 2 mM NAD, 2 mM dithiothreitol, and homogenate (9.1 mg protein) in a total volume of 1 mL. The mixture of all the components except for acycloretinal or retinal was first preincubated at 37°C for 10 min. The reaction was then initiated by adding 5 μL of 2 mM acycloretinal or all-*trans*-retinal in dimethyl sulfoxide, and the mixture was incubated at 37°C for 60 min. The reaction was stopped by adding 3 mL of 0.025 N KOH in ethanol. The mixture was washed two times with 6 mL hexane. The aqueous phase was then acidified with 0.12 mL of 6 N HCl, and acycloretinoic acid was extracted three times with 6 mL of hexane containing 0.001% butylated hydroxytoluene. The combined extract was dried under a stream of argon gas, dissolved in 200 μL of acetonitrile/methanol/water (70:20:10, by vol) containing 0.1% acetic acid and subjected to HPLC analysis. Protein concentration in the homogenate was determined by Bradford's method (43) with the bovine serum albumin as standard.

*Spectral analyses.* To identify the cleavage products obtained from ozonolysis of lycopene, the carbonyl compound fraction was subjected to an LC–MS analysis. Positive-ion mass spectra were obtained using a model M-1200AP mass spectrometer equipped with an atmospheric pressure chemical ionization–MS interface, and a model L-7100 gradient HPLC system (Hitachi Co., Tokyo, Japan).

For GC–MS analysis, the acycloretinoic acid formed by autoxidation of lycopene in toluene was purified by HPLC both on a silica column and on an ODS column under the condition described in section *"Preparation of acycloretinal, apolycopenals, and acycloretinoic acid."* The purified acycloretinoic acid and the standard acycloretinoic acid synthesized from acycloretinal were converted to methyl ester with diazomethane. The methyl ester of acycloretinoic acid was analyzed by GC–MS. The separation of acycloretinoic acid methyl ester was carried out on an MP65HT fused-silica column with 65% phenyldimethylsiloxane as a bonded phase, 10 m × 0.25 mm (Quadrex Co., Woodbridge, CT), using helium gas at a flow rate of 1.8 mL/min. The splitless injector and interface were both at 250°C. The column temperature was raised from 60 to 250°C at the rate of 40°C/min and then held at 250°C for 10 min. The GC column was coupled to a Shimadzu QP-5000 MS system (Shimadzu Co., Kyoto, Japan) with electron impact ionization at 70 eV.

The $^{1}H$ and $^{13}C$ NMR spectra of acycloretinal and acycloretinoic acid were obtained in a solution of $CDCl_3$ with a Bruker (Karlsruhe, Germany) DRX 600 spectrometer.

## RESULTS

Autoxidation of lycopene under the three different conditions, where lycopene was solubilized in toluene, aqueous Tween 40, or liposomal suspension, produced a number of compounds with absorption in the UV–VIS region. The crude extract from the autoxidation mixture was fractionated on a silica column (Bond Elut SI), and the eluate with hexane/ethyl acetate (95:5, vol/vol) showed clearly the presence of a series of carbonyl compounds that were formed by cleavage of conjugated double bonds of lycopene. Figure 1 shows an HPLC chromatogram of the carbonyl compound fraction obtained from the oxidized lycopene in liposomal suspension. The peaks from 1 to 8 were assigned by comparing retention time and UV–VIS spectra with those of the reference cleavage products prepared by ozonolysis of lycopene. They had a characteristic bell-shaped UV–VIS absorption spectrum similar to that of all-*trans*-retinal, but different with $\lambda_{max}$ (Fig. 2). Peak 3 (acycloretinal) was the cleavage product at the central double bond of lycopene. Peak 1 (3,7,11-trimethyl-2,4,6,10-dodecatetraen-1-al) and peak 5 (apo-12′-lycopenal) were the cleavage products at the C11–C12 double bond. Peak 2 (6,10,14-trimethyl-3,5,7,9,13-pentadecapentaen-2-one) and peak 4 (apo-14′-lycopenal) were the cleavage products at the C13–C14 double bond. Long-chain apolycopenals such as apo-10′-lycopenal (peak 6), apo-8′-lycopenal (peak 7) and apo-6′-lycopenal (peak 8) were also detected. Their structures are shown in Figure 3.

The extract under acidic conditions from the oxidized lycopene in toluene contained the oxidation product with the same retention time (9.8 min) and UV–VIS spectra as standard acycloretinoic acid in HPLC analysis (Fig. 4, A and D). The oxidation product was also detected when lycopene solubilized in an aqueous Tween 40, or a liposomal suspension

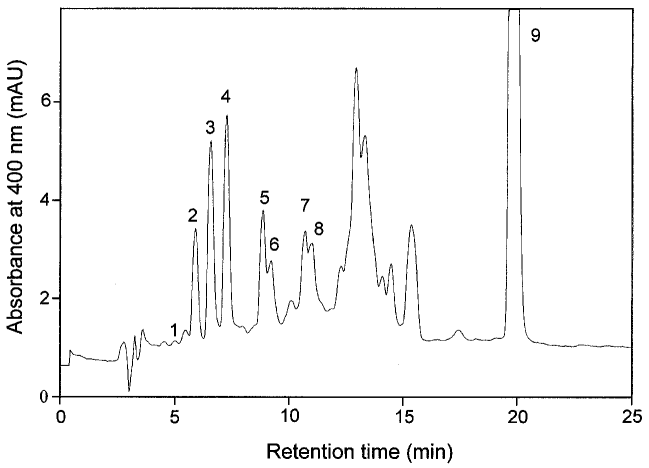

**FIG. 1.** High-performance liquid chromatography (HPLC) chromatogram of cleavage products by autoxidation of lycopene. Lycopene was solubilized at 50 μM in the liposomal suspension of 5 mM dimyristoylphosphatidylcholine and incubated at 37°C for 24 h. The cleavage products extracted from the incubation mixture were separated by HPLC on a TSK-Gel ODS 80Ts column, 4.6 × 250 mm, and were monitored at 400 nm with the photodiode array detector as described in the Materials and Methods section. Peak 1, 3,7,11-trimethyl-2,4,6,10-dodecatetraen-1-al (5.1 min); peak 2, 6,10,14-trimethyl-3,5,7,9,13-pentadecapentaen-2-one (5.9 min); peak 3, acycloretinal (6.6 min); peak 4, apo-14′-lycopenal (7.3 min); peak 5, apo-12′-lycopenal (8.9 min); peak 6, apo-10′-lycopenal (9.2 min); peak 7, apo-8′-lycopenal (10.7 min); peak 8, apo-6′-lycopenal (11.0 min); peak 9, lycopene (19.9 min).

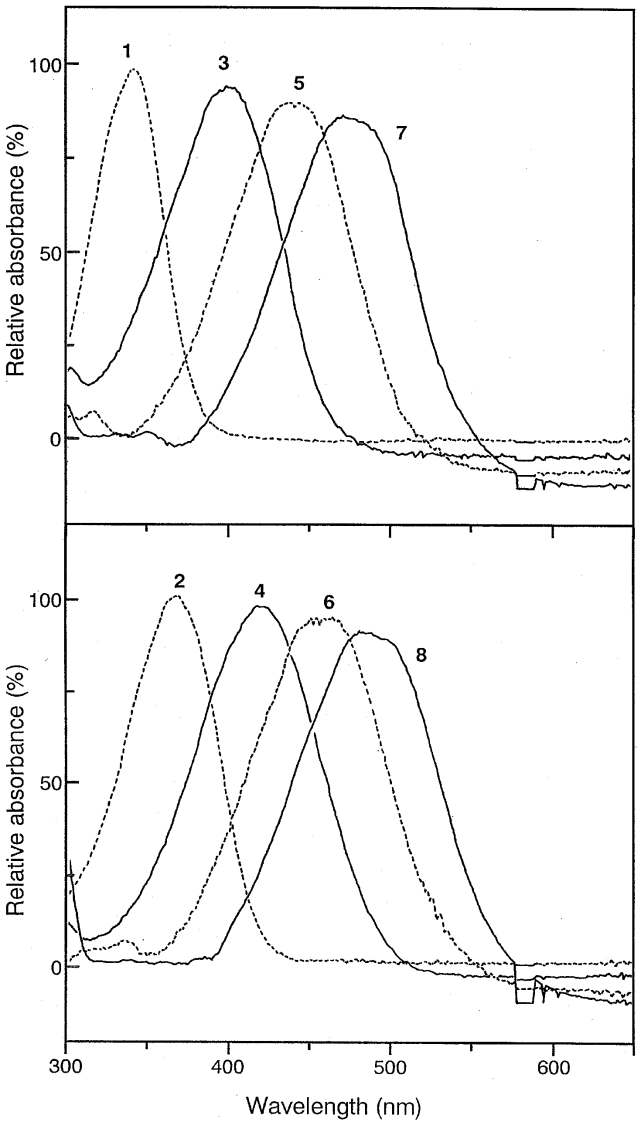

**FIG. 2.** Ultraviolet–visible (UV–VIS) spectra of the cleavage products formed from lycopene. The spectra of the cleavage products detected in Figure 1 were measured with the photodiode array detector. The number indicates the peak number in Figure 1.

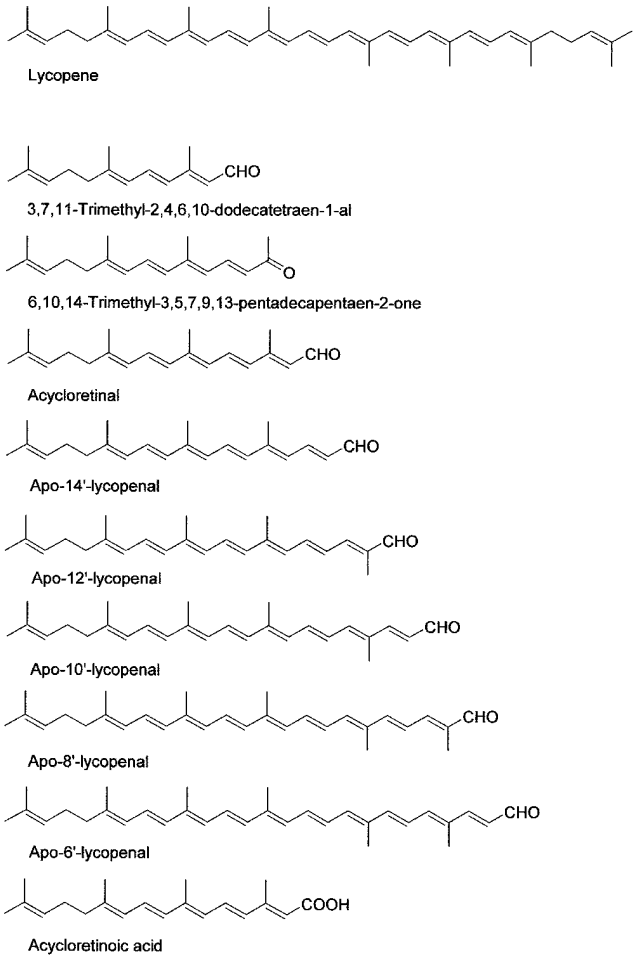

**FIG. 3.** Structure of cleavage products formed by autoxidation of lycopene.

was incubated (Figs. 4B and 4C). The acidic extract from the oxidized lycopene in the aqueous media had to be fractionated by HPLC on a silica column prior to detection of the oxidation product by HPLC on ODS column, because the amount of the oxidation product formed in these aqueous conditions was very low in comparison with those of the interfering substances. The oxidation product formed in toluene was isolated and purified by HPLC with both silica and ODS columns and then was methylated with diazomethane. The oxidation product at 9.8 min disappeared in the HPLC profile, while a new peak appeared with the same retention time (21.3 min) and UV–VIS spectrum as standard acycloretinoic acid methyl ester. The methylated oxidation product gave the same mass fragmentation as standard acycloretinoic acid methyl ester by GC–MS analyses (Fig. 5). A molecular ion at *m/z* 314 and $[M - 69]^+$, which lost a terminal dimethylallyl moiety, was observed. Thus, the oxidation product found in acidic extract from the oxidized lycopene under the three different conditions was assigned as acycloretinoic acid.

The decrease of lycopene and the formation of its oxidation products were quantitatively evaluated during the course of autoxidation at 37°C for 72 h under the three different conditions (Fig. 6). Among the eight cleavage products, 3,7,11-trimethyl-2,4,6,10-dodecatetraen-1-al, 6,10,14-trimethyl-3,5,7,9,13-pentadecapentaen-2-one, and apo-14′-lycopenal were not quantified because of the lack of their extinction coefficient in the literatures, although they showed remarkably large peaks in the HPLC profiles monitored at their wavelength of maximum UV–VIS absorption. Lycopene was more susceptible to autoxidation in toluene than in aqueous Tween 40 and in liposomal suspension. Lycopene in toluene was decreased from 50 to 0.9 μM after 48-h incubation. On the other hand, the lycopene solubilized in an aqueous Tween 40 or a liposomal suspension decreased to 9.3 and 26.9 μM, respectively. The amounts of total apolycopenals, including acycloretinal, apo-12′-lycopenal, apo-10′-lycopenal, apo-8′-lycopenal, and apo-6′-lycopenal, reached maxima of 819.3 and 387.0 nM after 24-h incubation in toluene and aqueous Tween 40, respectively, while in liposome, total apolycope-

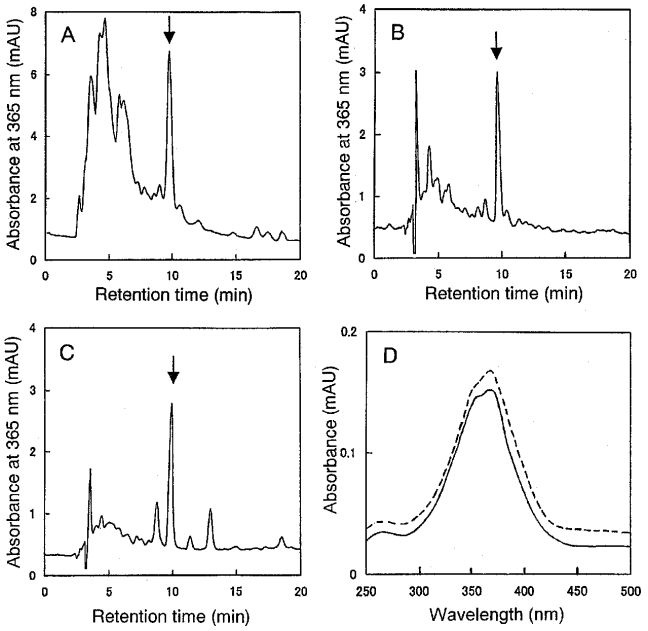

**FIG. 4.** HPLC analysis of acycloretinoic acid formed by autoxidation of lycopene. Lycopene was solubilized at 50 μM in toluene (A), in aqueous 5% Tween 40 (B), and in the liposomal suspension of 5 mM dimyristoylphosphatidylcholine (C). After incubation at 37°C for 24 h (A, B) or 72 h (C), the extracts of the incubation mixture were analyzed by HPLC as described in the Materials and Methods section. UV–VIS spectra (D) of the HPLC peaks of standard acycloretinoic acid (broken line) and of acycloretinoic acid formed (solid line) in toluene were measured with the photodiode array detector. The arrow indicated the retention time (9.8 min) of standard acycloretinoic acid. See Figures 1 and 2 for abbreviations.

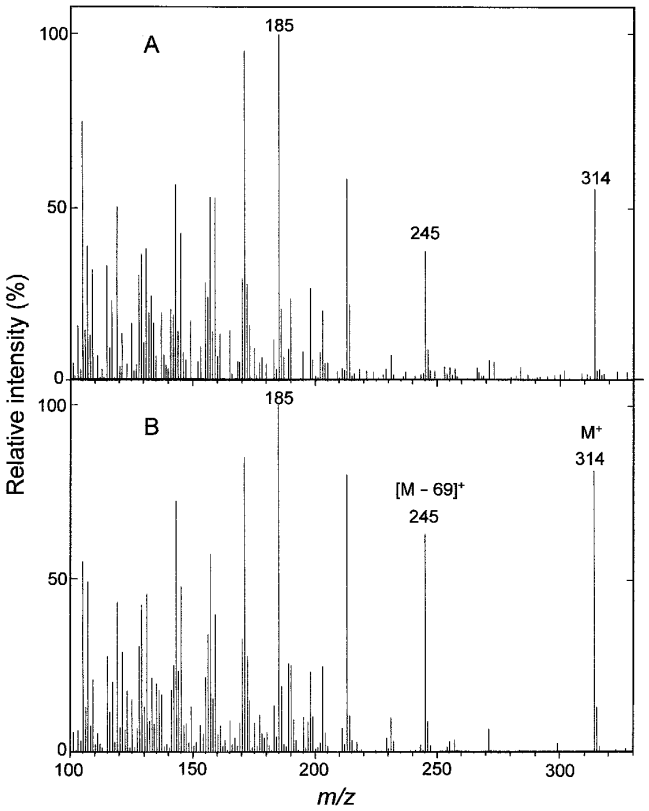

**FIG. 5.** Mass spectra of acycloretinoic acid methyl ester. (A) Methyl ester of the cleavage product formed by autoxidation of lycopene in toluene; (B) standard acycloretinoic acid methyl ester.

nals increased continuously to 238 nM at 72-h incubation. The ratio of maximal formation of acycloretinal to the initial level of lycopene (50 μM) was 0.3% (135 nM) in toluene, 0.1% (49 nM) in aqueous Tween 40, and 0.13% (64 nM) in liposomal suspension. Acycloretinoic acid reached 52.5 nM at 48 h in toluene with about 0.1% molar ratio to initial lycopene level. In an aqueous Tween 40 and liposome, acycloretinoic acid formation was also detected although its formation was at the lower level (1–2 nM) than in toluene. Formation of apo-6′-lycopenal was not observed in toluene and in an aqueous Tween 40, but a significant amount of apo-6′-lycopenal was detected in liposomal suspension (Table 1). The level of apo-10′-lycopenal in toluene was the highest among the aldehydes evaluated at any time point, while apo-8′-lycopenal was the highest in an aqueous Tween 40, and apo-6′-lyocpenal level was the second highest to acycloretinal in a liposomal suspension. Thus, acycloretinal and a series of apolycopenals were produced by autoxidation of lycopene in the three different conditions. However, acycloretinoic acid formation was significantly suppressed under the aqueous conditions.

To evaluate the metabolic conversion of acycloretinal into acycloretinoic acid in tissue homogenate, pig liver homogenate was incubated with 10 μM acycloretinal. Acycloretinal and all-*trans*-retinal were efficiently converted to the corresponding carboxylic acids by incubating with pig liver homogenate as shown in Table 2. No conversion in the control incubations of minus homogenate and heat-inactivated homogenate indicated the enzymatic catalysis. The conversion ratios of the incubated acycloretinal and retinal to the

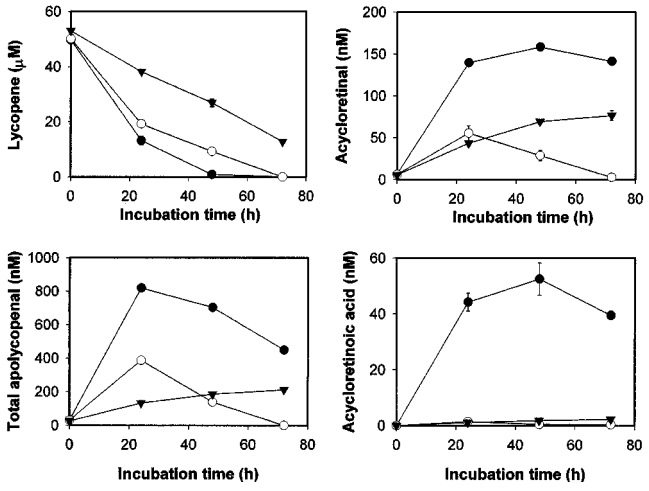

**FIG. 6.** Formation of cleavage products during autoxidation of lycopene under three different conditions. Lycopene was solubilized in toluene (●), 5% aqueous Tween 40 (○), and liposomal suspension of 5 mM dimyristoylphosphatidylcholine (▼) and incubated at 37°C for 72 h. Total apolycopenal was expressed as the combined amount of acycloretinal, apo-12′-lycopenal, apo-10′-lycopenal, apo-8′-lycopenal, and apo-6′-lycopenal. Values represent means ± SD ($n$ = 3).

acids were 96.3 and 79.1%, respectively, after incubation for 60 min.

## DISCUSSION

Carotenoids are highly susceptible to oxidation under certain oxidative conditions to produce a number of compounds. Recently several studies reported that oxidation products of carotenoids showed biological effects *in vitro*. Thus, some of the oxidation products might participate in biological effects of carotenoids reported in animal models and cell culture system. We have evaluated the *in vitro* oxidation products of lycopene, a typical non-provitamin A carotenoid, and have identified a homologous series of carbonyl compounds formed by cleavage at the conjugated double bonds and an analog of retinoic acid.

Numerous oxidation products appeared by autoxidation of lycopene under the three different conditions. In toluene, lycopene was homogeneously dissolved in nonaqueous media. Lycopene was solubilized as a micelle in an aqueous Tween 40 and was incorporated in a phospholipid membrane of liposome as a model of biological tissues. The carbonyl compounds were clearly separated in HPLC analysis after fractionation on a small silica column. The eight products identified were 3,7,11-trimethyl-2,4,6,10-dodecatetraen-1-al, 6,10,14-trimethyl-3,5,7,9,13-pentadecapentaen-2-one, acycloretinal, apo-14′-lycopenal, apo-12′-lycopenal, apo-10′-lycopenal, apo-8′-lycopenal, and apo-6′-lycopenal. Lycopene was oxidized rapidly in toluene, and considerable amounts of acycloretinal and apolycopenals were produced, compared with autoxidation in an aqueous Tween 40 and in liposomal suspension. The chain reaction in autoxidation of lycopene might be disturbed in the latter conditions, because of difficult interaction between lycopene molecules separated by Tween 40 and phosphatidylcholine bilayers. That formation of long-chain 6′-lycopenal was not detected in toluene, while it was a major apolycopenal in liposomal, suggests that 6′-lycopenal is further oxidized to a short-chain apolycopenal under the accelerated autoxidation in toluene.

These results were consistent with the autoxidation of β-carotene in organic solvent. Mordi *et al*. (5) proposed a cleavage reaction at the double bond through a dioxetane from peroxy radical of β-carotene. McClure and Liebler (6) identified apocarotenals as well as oxygenated apocarotenal as oxidation products of β-carotene initiated by azobis(2,4-dimethylvaleronitrile). They also identified β-apo-14′-carotenal, β-apo-10′-carotenal, and β-apo-8′-carotenal as products of β-carotene oxidized by singlet oxygen, suggesting 1,2-addition of singlet oxygen at each double bond to form dioxetane (7). Thus, taken together, the results in our study and in the previous reports suggest that the cleavage reaction to carbonyl compounds at the conjugated double bond by autoxidation, radical-mediated oxidation, and singlet oxygen occurs in any carotenoid with a long-chain of conjugated double bonds. These cleavage products may be produced *in vivo* if the tissues are exposed to an oxidative stress.

In terms of biological effects of oxidation products, it is important to know whether a compound analogous to retinoic acid is produced by oxidation of carotenoids, because retinoic acid is involved in regulation of gene expression through the nuclear receptors of RAR and RXR. Mordi *et al.* (5) suggested the formation of retinoic acid by autoxidation of β-carotene. In the present study, we clearly demonstrate the formation of acycloretinoic acid from lycopene by autoxidation in toluene at a significant amount comparable to each apolycopenal. Nikawa *et al.* (12) found 4-oxo-retinoic acid as oxidation product of canthaxanthin when incubated in a cell culture medium. We also found formation of acycloretinoic acid from lycopene in aqueous media, although the amount was much lower than that formed in toluene. The presence of water was suggested to suppress the formation of acycloretinoic acid from lycopene by autoxidation. Therefore, acycloretinoic acid formation would be very low if lycopene is oxidized in biological tissues. However, a conversion of acycloretinal to acycloretinoic acid might occur in biological tissues, because the biosynthesis of retinoic acid from retinol is mediated by microsomal retinol dehydrogenase and cytosolic retinal dehydrogenase (44). We found that the liver ho-

**TABLE 2**
**Conversion of Acycloretinal to Acycloretinoic Acid by Pig Liver Homogenate[a]**

| | Acycloretinoic acid | Retinoic acid |
|---|---|---|
| | (pmol/mg protein/h incubation) | |
| Complete incubation | 1,071 ± 24.2 | 902 ± 3.4 |
| Zero-time control | 6.6 ± 1.1 | 28.3 ± 1.3 |
| Minus homogenate control | 6.2 ± 1.3 | 22.0 ± 1.1 |
| Minus substrate control | ND[b] | 23.2 ± 1.1 |
| Heat-inactivated homogenate control[c] | 1.1 ± 0.0 | 18.2 ± 2.4 |

[a]Note: Acycloretinal and retinal were incubated at 10 μM with pig liver homogenate (9.1 mg protein/mL) at 37°C for 60 min, and the amounts of acycloretinoic and retinoic acids in the extracts were measured by high-performance liquid chromatography. Values are expressed as means ± standard deviations of triplicate incubations.
[b]ND, less than 0.1.
[c]Treatment of heat-inactivated homogenate was 100°C for 10 min.

mogenate had metabolic activity for conversion of acycloretinal to acycloretinoic acid, comparable to that for conversion of retinal to retinoic acid, although we did not evaluate whether apolycopenals were converted to the corresponding acids. Thus, acycloretinoic acid is potentially formed from acycloretinal, when lycopene is oxidized in biological tissues.

The results in the present study suggest that carotenoids including non-provitamin A carotenoids are nonenzymatically cleaved to a series of carbonyl compounds at conjugated C–C double bonds when the tissue is exposed to oxidative stress. Furthermore, central cleavage products among them may be enzymatically converted to the corresponding acids analogous to retinoic acid. This hypothesis is in part similar to the eccentric cleavage pathway (3) proposed for vitamin A formation in addition to the central cleavage (1). However, the eccentric cleavage was thought to occur by enzyme ubiquitously distributed in various tissues, while it was not evaluated whether non-provitamin A carotenoids were also cleaved by the same enzyme system.

In the present study, we demonstrated *in vitro* formation of acycloretinoic acid from lycopene by autoxidation. However, biological activities of acycloretinoic acid as an agonist of retinoic acid were not so marked as retinoic acid. Araki *et al.* (45) found that acycloretinoic acid could not activate a retinoic acid receptor element (RARE) of RAR-β gene and a retinoid X receptor element (RXRE) of human cellular retinol-binding protein Type II gene, but could bind to cellular retinoic acid binding protein. On the other hand, Stahl *et al.* (24) showed that acycloretinoic acid induced gap junctional communication and transactivated RAR-β2 promoter, although it was less active than retinoic acid. Several oxidation products of carotenoids other than lycopene are already known to have biological effects. 4-Oxo-retinoic acid, an oxidation product of canthaxanthin, was found to work as a ligand for RAR and to induce differentiation of cancer cells (12). 5,8-Endoperoxy-2,3-dihydro-β-apocarotene-13-one, an oxidation product of β-carotene, showed a growth inhibition of breast cancer cells (14). 5,6-Epoxy-β-carotene was reported to have significantly greater differentiation-inducing activity than β-carotene toward NB4 human leukemia cells (46). These results strongly suggest that oxidation products as well as intact carotenoids potentially have biological effects on human health. The formation of cleavage products of non-provitamin A carotenoids has never been demonstrated in the human body. However, 3-hydro-4-oxo-7,8-dihydro-β-ionone and 3-hydroxy-4-oxo-β-ionone were identified as the metabolites of canthaxanthin in rats and astaxanthin in rat hepatocytes, respectively (15,16). The results suggest the *in vivo* formation of the cleavage products of carotenoids. The detection and identification of oxidation products of carotenoids formed *in vivo* are needed to clarify their possible involvement in biological effects of carotenoids.

# Cyclodehydration Reactions of Methyl 9,10-; 10,12-; and 9,12-Dioxostearates with 1,2-Diaminoethane Under Ultrasonic Irradiation

**Marcel S.F. Lie Ken Jie*, Maureen M.L. Lau, and Prabhavathi Kalluri**

Department of Chemistry, The University of Hong Kong, Hong Kong, SAR, China

**ABSTRACT:** Reaction of methyl 9,10-dioxostearate (**1**) and 9,12-dioxostearate (**2**) with 1,2-diaminoethane under concomitant ultrasonic irradiation (10–15 min, 60°C) in water furnished the corresponding 2,3-dihydropyrazine (**4**, 79%) and 1,2,3,4-tetrahydro-1,4-diazocine (**5**, 70%) derivatives, respectively. Reaction of methyl 10,12-dioxostearate (**3**) with 1,2-diaminoethane was successful only when glacial acetic acid was used instead of water under ultrasonic irradiation (4 × 10 min, 70°C) to give a 2,3-dihydro-1*H*-1,4-diazepine (**6**, 95%) derivative. The structures of these novel six-membered (**4**), seven-membered (**6**), and eight-membered (**5**) *N*-heterocyclic fatty ester derivatives were confirmed by a combination of infrared, nuclear magnetic resonance spectroscopic and mass spectral analyses.

Paper no. L8529 in *Lipids 36*, 201–204 (February 2001).

Many organic reactions under concomitant ultrasonic irradiation show significant increases in their rates of reaction (1). We have reported the successful preparation of numerous novel derivatives of fatty acid esters under such "extreme" conditions. Some of the products cannot be obtained when the same reactions are conducted under thermal conditions (2–4).

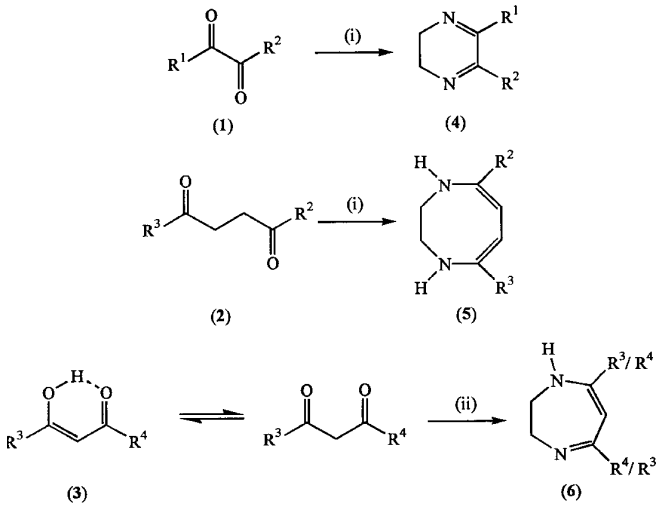
Fatty esters containing an *N*-heterocyclic nucleus (forming a part of the alkyl system of the fatty acid chain) were prepared by reaction of oxygenated $C_{18}$ fatty ester derivatives under concomitant ultrasonic irradiation. For example: methyl 12-azido-9-oxostearate reacted with triphenylphosphine in tetrahydrofuran to give a 1-pyrroline fatty ester derivative (2); ultrasound-assisted reaction of methyl 10,12-dioxostearate with hydrazines in water gave $C_{18}$ pyrazole derivatives (3); and methyl 9,12-dioxostearate reacted with hydrazines in water under ultrasound to yield a pyridazine derivative (4). It was interesting to realize that in the last two cases, the reactions were conducted entirely in water without any organic solvents despite the fact that the substrates were insoluble in water. Reactions carried out under ultrasonic irradiation appeared to overcome the problem of solubility of fatty ester substrates in the reaction medium, and at times such reactions furnished products that could not be achieved under thermal condition (5).

In this paper we report the successful cyclodehydration reactions of methyl 9,10-dioxostearate (**1**), methyl 9,12-dioxostearate (**2**), and methyl 10,12-dioxostearate (**3**) with 1,2-diaminoethane under concomitant ultrasonic irradiation (Scheme 1).

## MATERIALS AND METHODS

Methyl 9,10-dioxostearate (**1**) was prepared by oxidation of oleic acid with potassium permanganate in acetic anhydride (6) and followed by methylation. Methyl 9,12-dioxostearate (**2**) was obtained by hydration of methyl 12-oxo-9-octadecynoate (3), and methyl 10,12-dioxostearate (**3**) was derived from methyl ricinoleate by hydration of the double bond followed by chromic acid oxidation (4). 1,2-Diaminoethane was purchased from Merck KGaA (Darmstadt, Germany).

Ultrasonication was carried out using a 20 kHz (54 W/cm$^2$) ultrasound horn (Sonoreactor; Undatim Ultrasonic,



$R^1 = CH_3(CH_2)_7$; $R^2 = (CH_2)_7COOCH_3$; $R^3 = CH_3(CH_2)_5$; $R^4 = (CH_2)_8COOCH_3$

Reaction conditions: (i) $H_2NCH_2CH_2NH_2$, water, ))))), 60°C, 10–15 min

(ii) $H_2NCH_2CH_2NH_2$, AcOH, ))))), 70°C, 4 × 10 min

Louvain la Neuve, Belgium) with the reaction mixture contained in a water-jacketed cell (40 mm i.d., 80 mm length). Column chromatographic separation was performed on silica gel (Merck; Art. 7730, type 60, 70–230 mesh) as the adsorbent using gradient elution with a mixture of *n*-hexane/diethyl ether as the mobile phase. Infrared (IR) spectra were recorded on a Bio-Rad FTS-165 Fourier transform (FT)-IR spectrometer (Bio-Rad Inc., Hercules, CA). Samples were run as neat films on NaCl plates. Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker Avance $DPX_{300}$ (300 MHz) FT NMR spectrometer (Bruker, Fallanden, Switzerland) from solutions in deuteriochloroform ($CDCl_3$) (0.2–0.3 mM) with tetramethylsilane (TMS) as the internal reference standard. Chemical shifts are given in δ-values in ppm downfield from TMS ($\delta_{TMS}$ = 0 ppm). High-resolution mass spectroscopy (HRMS) and electron-ionization mass spectroscopy (EIMS) spectra were recorded on a Finnigan Mat 95 mass spectrometer (Finnigan Mat Corp., San Jose, CA).

*General procedure for the synthesis of* N*-heterocyclic fatty esters (**4,5**) from methyl dioxostearates (**1,2**) as exemplified by the reaction of methyl 9,10-dioxostearate with 1,2-diaminoethane*. A mixture of methyl 9,10-dioxostearate (**1**, 0.3 g, 0.92 mmol) or methyl 9,12-dioxostearate (**2**, 0.3 g 0.92 mmol), 1,2-diaminoethane (0.110 g, 1.84 mmol), and water (25 mL) was irradiated under ultrasound for 10–15 min at 60°C. The reaction mixture was extracted with diethyl ether (3 × 30 mL), and the organic extract was successively washed with brine (10 mL), water (10 mL), and then dried ($Na_2SO_4$). The filtrate was evaporated, and the residue was chromatographed on a silica (15 g) column using a mixture of *n*-hexane/diethyl ether (5–20%, vol/vol, gradient elution) to give the corresponding 2,3-dihydropyrazine derivative (**4**, 0.26 g, 79%) as a pale yellow oil.

*Methyl 8-(5-octyl-2,3-dihydro-pyrazin-6-yl)-octanoate* (**4**, 79% yield). Thin-layer chromatography (TLC), $R_f$ = 0.3 (*n*-hexane/diethyl ether, 1:1 vol/vol, as developer); IR (neat) 2928, 2855, 1741, 1593, 1459, 1437, 1200, and 1160 $cm^{-1}$; $^1H$ NMR ($CDCl_3$, $\delta_H$): 0.88 (*t, J* = 6.7 Hz, 3H, C*H*$_3$), 1.2–1.7 (*m*, 18H, C*H*$_2$), 2.31 (*t, J* = 6.4 Hz, 2H, 2-*H*), 2.42 (*t, J* = 7.7 Hz, 4H, 8-*H* and 11-*H*), 3.32 (*s*, 4H, C*H*$_2$ of ring), and 3.66 (*s*, 3H, COOC*H*$_3$); $^{13}C$ NMR ($CDCl_3$, $\delta_C$): 14.03 (C-18), 22.59 (C-17), 24.79 (C-3), 25.89, 26.03, 28.92, 29.00, 29.06, 29.11, 29.29, 29.33, 29.55, 31.76 (C-16), 33.93 (C-2), 35.29 and 35.38 (C-8/C-11), 44.83 (*C*H$_2$ of ring), 51.32 (COO*C*H$_3$), 162.66 and 162.75 (C-9/C-10) and 174.05 (*C*OOCH$_3$); HRMS, found: $M^+$, 350.2936, $C_{21}H_{38}N_2O_2$ requires 350.2933; EIMS, *m/z* (peak intensity relative to base peak = 100%): 207 (32), 208 (100), 251 (26), 252 (89), 319 (21), 350 (33).

*Methyl 8-(9-hexyl-1,2,3,4-tetrahydro-[1,4]diazocin-5-yl)-octanoate* (**5**, 70% yield, pale yellow oil). TLC, $R_f$ = 0.6 (*n*-hexane/diethyl ether, 1:1 vol/vol, as developer); IR (neat): 3383, 3318, 2929, 2856, 1740, 1459, 1437, 1425, 1295, 1198, 1172, and 749 $cm^{-1}$; $^1H$ NMR ($CDCl_3$, $\delta_H$): 0.89 (*t, J* = 6.7 Hz, 3H, C*H*$_3$), 1.2–1.75 (*m*, 18H, C*H*$_2$), 2.31 (*t, J* = 7.5 Hz, 2H, 2-*H*), 2.52 (*t, J* = 7.8 Hz, 4H, 8-*H* and 13-*H*), 2.91 (*t, J* = 7.1 Hz, 2H, C*H*$_2$ of ring), 3.67 (*s*, 3H, COOC*H*$_3$), 3.82 (*t, J* = 7.1 Hz, 2H, C*H*$_2$ of ring), and 5.82 (*s*, 2H, 10-*H* and 11-*H*); $^{13}C$ NMR ($CDCl_3$, $\delta_C$): 14.25 (C-18), 22.77 (C-17), 25.06 (C-3), 26.85 and 26.91 (C-8/C-13), 28.78, 28.83, 29.21, 29.29, 29.51, 29.58, 31.90 (C-16), 34.21 (C-2), 42.88 and 46.28 (*C*H$_2$ of ring), 51.60 (COO*C*H$_3$), 104.11 (C-10 and C-11), 132.57 and 132.77 (C-9/C-12) and 174.44 (*C*OOCH$_3$); HRMS, found: $M^+$, 350.2930, $C_{21}H_{38}N_2O_2$ requires 350.2933; EIMS, *m/z* (peak intensity relative to base peak = 100%): 207 (100), 279 (89), 308 (67), 320 (98), 319 (22), 350 (73).

*Methyl 9-(7-hexyl-2,3-dihydro-1H-[1,4]diazepin-5-yl)-nonanoate* (**6**, 95% yield). A mixture of methyl 10,12-dioxostearate (**3**, 0.3 g, 0.92 mmol), 1,2-diaminoethane (0.110 g, 1.84 mmol), and glacial acetic acid (25 mL) was irradiated under ultrasound for four periods of 10 min at 70°C. A break of about 10 min between irradiation period was necessary to prevent the transducer of the ultrasonic horn from overheating. The reaction mixture was extracted with diethyl ether (3 × 30 mL), and the organic extract was successively washed with brine (10 mL), water (10 mL), and then dried ($Na_2SO_4$). Removal of the solvent under reduced pressure gave the 2,3-dihydro-1*H*-1,4-diazepine derivative as a viscous yellow oil (**6**, 0.31 g, 95%). TLC, $R_f$ = 0.1 (*n*-hexane/diethyl ether, 2:3 vol/vol, as developer); IR (neat): 3340, 2920, 2850, 1740, 1575, 1440, 1260, 920, and 730 $cm^{-1}$; $^1H$ NMR ($CDCl_3$, $\delta_H$): 0.86 (*t, J* = 6.4 Hz, 3H, C*H*$_3$), 1.2–1.7 (*m*, 20H, C*H*$_2$), 2.29 (*t, J* = 7.5 Hz, 2H, 2-*H*), 2.38 (*m*, 4H, 9-*H*, 13-*H*), 3.66 (*s*, 3H, COOC*H*$_3$), 3.70 (*brs*, 4H, C*H*$_2$ of ring), 4.59 (*s*, 1H, 11-*H*), and 10.6 (*brs*, 1H, N-*H*); $^{13}C$ NMR ($CDCl_3$, $\delta_C$): 14.12 (C-18), 22.60 (C-17), 24.96 (C-3), 28.87, 29.24, 29.35, 29.48, 31.67 (C-16), 34.08 (C-2), 37.49 (C-9/C-13), 48.62 (*C*H$_2$ of ring), 51.43 (COO*C*H$_3$), 88.70 (C-11), 170.28/170.39 (C-10/C-12), and 174.20 (*C*OOCH$_3$); HRMS, found: $M^+$, 350.2921, $C_{21}H_{38}N_2O_2$ requires 350.2933; EIMS, *m/z* (peak intensity relative to base peak = 100%): 124 (74), 137 (100), 194 (57), 207 (41), 280 (19), 293 (26), 319 (15), 350 (10).

## RESULTS AND DISCUSSION

Cyclodehydration was readily achieved when methyl 9,10-dioxostearate (**1**, a 1,2-diketo ester), and methyl 9,12-dioxostearate (**2**, a 1,4-diketo ester) were reacted with 1,2-diaminoethane in water under concomitant ultrasonic irradiation. However, no reaction occurred when methyl 10,12-dioxostearate (**3**, a 1,3-diketo ester) was treated under similar conditions unless the water medium was replaced by glacial acetic acid. The strong acidic condition required for the last reaction reflects the stability of methyl 10,12-dioxostearate (a 1,3-diketo), which prefers the enolic form when under neutral condition (7). Protonation of methyl 10,12-dioxostearate therefore permits the enol form to tautomerize to the less stable keto form. The amino groups of 1,2-diaminoethane are then able to attack the carbonyl groups of the 1,3-diketo tautomer to yield the requisite 2,3-dihydro-1*H*-1,4-diazepine derivative (**6**, 95% yield).

Reaction of methyl 9,10-dioxostearate (**1**) with 1,2-di-

aminoethane gave the 2,3-dihydropyrazine ester (**4**, 79% yield). The proton NMR spectrum showed the characteristic proton shifts of the two methylene groups of the dihydropyrazine ring system at $\delta_H$ 3.32 (*s*, 4H) (8). The 2,3-dihydropyrazine ring system was confirmed from the carbon shifts of the ring methylene groups [$\delta_C$ 44.83, and correlated with the signal at $\delta_H$ 3.32 in the $^{13}C$-$^{1}H$ correlation spectroscopy (COSY) spectrum] and from the shifts of the quaternary carbon atoms six-membered *N*-heterocyclic ring (at $\delta_C$ 162.66/162.75). The position of the 2,3-dihydropyrazine system in the alkyl moiety of the fatty ester was evident from the mass spectral analysis: *m/z* (peak intensity in parentheses) 207 (32), 208 (100, base peak), 251(26), 252 (89), 319 (M – 31, 21), 350 ($M^+$, 33).

Reaction of methyl 9,12-dioxostearate (**2**) with 1,2-diaminoethane gave the 1,2,3,4-tetrahydro-1,4-diazocine derivative (**5**, 70% yield). The IR spectrum showed two distinct vibrational bands at 3318 and 3383 $cm^{-1}$, which hinted to the presence of N-H bonds. The shift of the N-H protons appeared at an upfield region at $\delta_H$ 1.43 (very broad singlet), which was confirmed by deuterium NMR technique (by running the $^{1}H$-decoupled spectrum at 76.77 MHz of the sample after $D_2O$ exchange).The protons of the two methylene groups in the 1,2,3,4-tetrahydro-1,4-diazocine ring gave rise to two distinct triplets at $\delta_H$ 2.91 and 3.82, which were correlated to the carbon shifts at $\delta_C$ 42.88 and 46.28, respectively. Using a space-filled model of compound **5**, the geometric arrangement of the various atoms of the eight-membered *N*-heterocyclic ring system showed that one of the two methylene groups of the ring was located much closer to the conjugated diene system than the other methylene group. This stable configuration appeared to have affected the chemical environment of the nuclei of these methylene groups. And as a result, the two methylene groups in the ring were fully resolved. To ensure that the signals at $\delta_H$ 2.91 and 3.82 did arise from the shifts of the protons from two adjacent methylene groups, the $^{1}H$-$^{1}H$ COSY spectral analysis was performed. The result showed that the triplets at $\delta_H$ 2.91 and 3.82 were indeed correlated. From the $^{1}H$-$^{13}C$ COSY spectrum, the triplet at $\delta_H$ 2.91 was correlated to the carbon nucleus at $\delta_C$ 42.88, while the triplet at $\delta_H$ 3.82 was correlated to the signal at $\delta_C$ 46.82. The shift of the olefinic protons (10-*H* and 11-*H*) gave a singlet at $\delta_H$ 5.82, which was correlated to the carbon shift at $\delta_C$ 104.11. The quaternary olefinic carbon nuclei appeared $\delta_C$ 132.57/132.77 (C-9/C-12) and could not be further differentiated. The position of the 1,2,3,4-tetrahydro-1,4-diazocine system in the alkyl chain of the fatty ester was determined from the mass spectral analysis, *m/z*, intensity in brackets: 207 (100, base peak), 279 (89), 308 (67), 320 (98), 319 (M – 31), 350 ($M^+$).

A 2,3-dihydro-1*H*-1,4-diazepine derivative (**6**) was obtained from methyl 10,12-dioxostearate (**3**) with 1,2-diaminoethane in glacial acetic acid. The product showed a distinct band at 3340 $cm^{-1}$ for the N-H vibration in the IR spectrum. The proton shift of the N-H appeared at $\delta_H$ 10.6 (a very broad singlet and $D_2O$ exchangeable). Compound **6** exists as tautomers with the proton of N-H interchanging between the two nitrogen atoms of the ring. The rapid inversion of the half-chair-shaped seven-membered 2,3-dihydro-1*H*-1,4-diazepine ring was evident from the broad singlet obtained for the shifts of the ring methylene protons at $\delta_H$ 3.70. The corresponding signals of the ring methylene groups at $\delta_C$ 48.62 appeared also as broad signals in the $^{13}C$ NMR spectrum. Similar NMR observations were reported by Potter *et al.* (9) and Lloyd *et al.* (10–12) on 2,3-dihydro-1*H*-1,4-diazepinium salts. When the $^{1}H$-$^{13}C$ COSY experiment was performed on compound **6**, the correlation of the ring methylene protons and the corresponding ring methylene carbon nuclei did not show up in the spectrum. The nonobservance of such correlation was evidence of the high rate of inversion of the ring system at 27°C (operating temperature of the NMR instrument).

To slow down the inversion rate, compound **6** in $CDCl_3$ was shaken with $D_2O$. The proton–carbon correlation of the methylene groups in the ring system was then clearly shown when the hydrogen of the N-H group of compound **6** was deuterium-exchanged with $D_2O$ (Fig. 1, $^{1}H$-$^{13}C$ COSY). The deuterated form of compound **6** (containing N-D bonds) also allowed the broad signals arising from the shifts of the ring methylene protons and carbon nuclei to be "sharpened" up as compared to the corresponding signals observed for the nondeuterated form of compound **6**. With the hydrogen atom of N-H replaced by a deuterium, the isotopic effect caused the shifts of the ring methylene protons and carbon nuclei in the deuterated form of **6** to appear at $\delta_H$ 3.59 and $\delta_C$ 49.01, respectively. The replacement of the hydrogen of the N-H group by deuterium in compound **6** had apparently slowed down the rate of inversion of the half-chair-shaped seven-membered ring. The methylene groups of the ring system have become fixed in their orientation, hence the improved shape of the NMR signals. The position of the 2,3-dihydro-1*H*-1,4-diazepine system in the alkyl moiety of compound **6** was evident from the mass spectral analysis: *m/z* (intensity in brackets) 124 (74), 137 (100 = base peak), 194 (57), 207 (41), 280 (19), 293 (26), 319 (M – 31, 15), 350 (10).

Ultrasound-assisted experiments involving diketo fatty esters and diaminoethane allowed cyclodehydration reactions to be readily achieved in aqueous or acidic media. When these reactions were repeated under thermal (silent) condition, only compound **6** could be obtained in high yield from methyl 10,12-dioxostearate with 1,2-diaminoethane after refluxing the mixture for at least 1 h in glacial acetic acid. The role of ultrasound (at 60–70°C) in these reactions was therefore to enable the reacting groups to be brought sufficiently close for chemical reactions without the need for the substrates to be soluble in the reaction medium.

METHOD

# Dialysis and Gel Filtration of Isolated Low Density Lipoproteins Do Not Cause a Significant Loss of Low Density Lipoprotein Tocopherol and Carotenoid Concentration

**Mridula Chopra*, Patricia Fitzsimons, Marie Hopkins, and David I. Thurnham**

NICHE, School of Biomedical Sciences, University of Ulster, Coleraine BT52 1SA, Northern Ireland, United Kingdom

**ABSTRACT:** The resistance of isolated low density lipoprotein (LDL) to copper-initiated oxidation is often used as a measure of effectiveness of an antioxidant intervention. Prior to oxidation, excess salt and EDTA are removed *via* dialysis or gel filtration of the LDL sample. However, there is concern over whether the antioxidant content of dialyzed or gel-filtered LDL is truly representative of native LDL extracted from a blood sample. Previously, the experiments done after the storage of native and dialyzed LDL at –80°C showed that the dialysis step can cause a loss of up to 60% in the tocopherol and carotenoid content of LDL. In the present study, a comparison of the micronutrient concentration in freshly prepared dialyzed and native LDL from 35 subjects showed that after the correction for cholesterol, only lycopene (13%, $P < 0.001$) and to a lesser extent α-carotene (8%, $P < 0.02$) were significantly decreased, and the absolute fall in concentration was far smaller than previously reported. Other experiments done with smaller numbers of samples suggested that there were minimal micronutrient losses following gel filtration and that it was important to include 10 μmol/L EDTA in the dialysis and elution buffer; otherwise micronutrient losses did occur. In summary, immediate dialysis of freshly isolated LDL in the presence of 10 μmol/L EDTA does not cause any major loss in the concentration of tocopherol and most carotenoids.

Paper no. L8558 in *Lipids 36*, 205–209 (February 2001).

Antioxidant components in low density lipoprotein (LDL) are believed to play a significant role in protecting LDL against oxidation both *in vivo* and *in vitro* (1,2). Several *in vivo* and *in vitro* supplementation studies have used antioxidant micronutrients such as vitamin E (3), carotenoids (4), flavonoids (5), and ubiquinols (6) in an attempt to increase the inherent antioxidant capacity of the LDL particle (7). The effectiveness of antioxidant intervention is mostly assessed by *ex vivo* measurement of the resistance of LDL to oxidation. Blood for such studies is mostly collected in preservatives such as EDTA. Likewise, during the isolation of LDL, salt solutions containing EDTA are used to prevent premature oxidation during isolation and storage. However, prior to the *in vitro* Cu-initiated oxidation of LDL (the most widely used method for measuring the oxidative resistance), excess EDTA has to be removed by gel filtration (8) or dialysis (9).

Scheek *et al.* (10) reported that the dialysis step leads to the loss of antioxidant micronutrients, and thus the postdialysis results may not be truly representative of freshly isolated or native LDL. Examination of literature showed that several groups have avoided dialysis and expressed their concerns in using the dialysis step (11–14) because of the results reported by Scheek *et al.* (10). In the present study we report the effect of dialysis and gel filtration on the freshly prepared LDL samples.

## METHODS

*Subjects.* The subjects were recruited from the University staff. Ethical approval was obtained from The University of Ulster Ethical Committee. Subjects were asked to fast for 8 h prior to giving blood.

*Blood collection and plasma preparation.* The blood was collected in plain tubes containing 1 mg/mL EDTA (sodium salt; Sigma Chemical Co., St. Louis, MO) and was centrifuged at $1000 \times g$ for 10 min to separate the plasma. Plasma was further centrifuged for 45 min at $1000 \times g$ to remove any remaining cell debris.

*LDL isolation.* The density of plasma was adjusted by the addition of 0.32 g of potassium bromide (KBr) per mL of plasma. The density-corrected plasma (4 mL) was layered underneath 7 mL of KBr solution (density 1.007 g/mL, pH 7.4, containing 1 mg/mL EDTA) in an Optiseal Polyallomer centrifuge tube (Beckman Instruments, London, United Kingdom). LDL was isolated at 7°C after ultracentrifugation for 2-1/2 h at 60 K in XL-70 Beckman ultracentrifuge using NVT65 rotor (Beckman Instruments). This procedure creates a density gradient such that LDL forms a discrete orange band *ca.* one-third of the way from the top of the tube. The LDL fraction was removed by puncturing the side wall of the tube with a hypodermic needle attached to a syringe. LDL samples

Abbreviations: BHT, butylated hydroxytoluene; DLDL, dialyzed low density lipoprotein; GLDL; gel-filtered low density lipoprotein; HPLC, high-performance liquid chromatography; LDL, low density lipoprotein; PBS, phosphate-buffered saline.

were immediately purged with nitrogen, and the lid additionally was sealed with Parafilm® to reduce the infiltration of oxygen; samples were then stored at 4°C. Electrophoresis of LDL using Paragon lipoprotein gels (Beckman, Fullerton, CA) showed that LDL was free of contamination from plasma proteins and high density lipoprotein.

*Dialysis of LDL.* LDL were dialyzed within 6 h of collection of blood. Samples (0.5 mL) were transferred to Visking dialysis tubing (Size 1, diameter 8/32″-6.3 mm; 30 m, Medicell International Ltd., Liverpool, United Kingdom) and dialyzed in buffer pH 7.4 containing 0.01 mol disodium hydrogen phosphate, 0.16 mol sodium chloride, 0.01 mmol EDTA (sodium salt), and 0.3 mmol of chloramphenicol per liter. Dissolved gases in the buffer were reduced by vacuum degassing for 20 min, followed by purging with nitrogen for 15 min. Samples were dialyzed for 24 h at 4°C, stored under nitrogen, and micronutrient analysis on native and dialyzed LDL was done on the day of preparation of the dialyzed sample.

*Gel filtration.* LDL was filtered using desalting columns (Econo-Pac 10 DG; BioRad, Hercules, CA) filled with Bio-Gel® P-6DG gel (bed volume of 10 mL and void volume of 3.3 mL). Desalting columns were stored in 0.01 mol/L phosphate buffer containing 0.01 mol/L sodium chloride and 0.02 % sodium azide; therefore, prior to the application of sample to the column, columns were washed with phosphate-buffered saline (PBS; Poole, Dorset, United Kingdom) containing 10 μmol/L EDTA.

For gel filtration, 1.0 mL of an LDL sample was run onto the column followed by 2.3 mL of 0.01 mmol $Na_2EDTA$ per liter PBS buffer pH 7.4 under gravity. Finally an additional 1 mL of PBS was added to the column, and the LDL was collected in 1 mL eluate. Nitrogen was purged through the samples for *ca.* 15 s, and they were stored at 4°C until ready for analysis. Micronutrient analysis was carried out on the same day as the preparation of the sample. Cu-initiated oxidation of gel-filtered and dialyzed LDL was carried out on the day of preparation of samples by the method described previously (15). Briefly, the final reaction mixture consisted of 0.25 mg LDL mass/mL (equivalent to 0.1 μmol LDL/L) and 11.7 μmol/L copper chloride. The diene conjugate formation was monitored at 234 nm, and the lag phase (resistance of LDL to oxidation) was calculated by drawing a tangent to the propagation phase to determine the intercept with the x-axis. The oxidation experiment was repeated on gel-filtered (GLDL) and dialyzed LDL (DLDL) prepared from plasma stored at –70°C for 4 wk (plasma samples were stored in 0.6% sucrose). The results are means of triplicate measurements.

*Cholesterol determination.* The cholesterol content of lipoproteins (native, dialyzed, and gel-filtered) was determined using CHOD-PAP kit from Boehringer (Mannheim, Germany). Intra-assay precision on freshly isolated LDL sample (10 measurements) was 2.5%.

*High-performance liquid chromatography (HPLC) analysis of micronutrients in lipoproteins.* The micronutrient content of the native, dialyzed, and gel-filtered LDL was determined using reversed-phase HPLC as described previously (16). Briefly, 0.1 mL of sample was mixed with 0.1 mL of sodium dodecyl sulfate and 0.2 mL of ethanolic tocopherol acetate (40 mg/mL). To the mixture, 1 mL of heptane was added and samples were vortexed vigorously for 3 min. Samples were centrifuged at $800 \times g$ for 10 min at 10°C. Heptane layer (0.7 mL) was removed, evaporated to dryness, and reconstituted in 0.1 mL of reconstitution mobile phase [i.e., mobile phase plus 90 mg butylated hydroxytoluene (BHT)/L]. Of the sample, 50 μL was injected onto a 3-μm Spherisorb ODS2 column (10 cm × 4 mm) and eluted with mobile phase pumped at 1 mL/min, and micronutrients were measured using a multichannel ultraviolet/visible detector set at the wavelengths 295 (for the detection of tocopherols) and 450 (for carotenoid detection) nm. Mobile phase consisted of acetonitrile/methanol/dichloromethane (500:500:128, by vol) and 0.01 g BHT/L. Data were collected and integrated using Maxima software (Waters, Millipore, Watford, United Kingdom). Within-assay precision of micronutrients analyzed in freshly prepared native and dialyzed LDL samples was less than 8%.

*Statistical analysis.* Data were examined for normality and found to be skewed both before and after transformation to logarithms. Therefore, nonparametric tests were used, particularly the Wilcoxon Paired Rank Sum to calculate the significance of changes observed following the dialysis.

## RESULTS

Table 1 shows results for cholesterol and micronutrient analyses of freshly prepared native and DLDL before and after correction for cholesterol. Both cholesterol and micronutrient concentration were significantly lower in DLDL. However after correction of the data using cholesterol, the differences in micronutrient concentration between native and DLDL disappeared except for α-carotene and lycopene.

The micronutrient concentration of DLDL prepared in the presence and absence of EDTA in dialysis buffer is shown in Table 2. Values shown have been corrected for cholesterol. Results show that the loss in both vitamin E and carotenoids is greater when EDTA is not included in the dialysis buffer.

The results of experiments to compare dialysis with gel filtration are shown in Table 3. The data shown are corrected for cholesterol, and very similar changes in micronutrient content were obtained both following dialysis and gel filtration. The data suggest that the changes in carotenoids and tocopherol following dialysis or gel filtration in the presence of 10 μmol/L EDTA are more likely to be due to experimental error, since both positive and negative changes were obtained by both methods. Due to a smaller number of samples (LDL done in duplicate and results for GLDL and DLDL are an average of four measurements), it was not possible to do the statistical analysis of the data. Nevertheless, the results for dialyzed samples were similar to those obtained with other experiments. No difference was observed in the LDL lagphase between DLDL and GLDL samples. Freezing of plasma prior to isolating DLDL or GLDL did not affect the lagphase measurements.

[a]Low density lipoprotein (LDL) (0.5 mL) from 35 healthy females (24–52 yr) were dialyzed in *ca.* 700 vol of degassed phosphate-buffered saline buffer pH 7.4 for 24 h at 4°C under nitrogen. Significance of difference was calculated using Wilcoxon paired rank sum test. * denotes $P < 0.05$, and *** $P < 0.001$.

## DISCUSSION

The effect of dialysis on LDL micronutrient concentration in freshly prepared LDL and DLDL samples was determined in samples obtained from 35 subjects. The results suggested that there was an apparent loss of micronutrients on dialysis. However, this effect was due to dilution since most of the differences were accounted for if the micronutrients were corrected using cholesterol. The exceptions were α-carotene and lycopene, but in both cases the difference between the mean values was only 0.01 μmol/mmol cholesterol. These small losses may be real, particularly for lycopene since in-house experience with lycopene standards has shown it to be far less stable than the other commonly measured carotenoids. However, the small (~1%) but statistically significant increase in α-tocopherol content of DLDL, which was observed, is probably within the precision of analysis of α-tocopherol.

The experiment in which dialysis was done with and without EDTA clearly shows the protective effect of EDTA during dialysis. When EDTA was not included in the buffer, concentration of all nutrients except γ-tocopherol was significantly lower than those in the native LDL in spite of correcting the data for cholesterol. However, both lutein and lycopene were significantly lower in the dialyzed samples even in the presence of EDTA in the dialysis buffer.

The results from our study are in disagreement with the reports of Scheek *et al.* (10), who found a 66% reduction of α-tocopherol, 56% in β-carotene, and 65% in lycopene following a 22-h dialysis in the presence of EDTA. However, our results are in agreement with reports by Esterbauer *et al.* (17)

**TABLE 2**
**Effect of the Presence of EDTA in the Dialysis Buffer on the Micronutrient Concentrations of LDL**

| | Micronutrient concentration in LDL (μmol/mmol cholesterol) | | |
|---|---|---|---|
| | Native Median (range) | Dialyzed with EDTA Median (range) | Dialyzed without EDTA Median (range) |
| α-Carotene | 0.026 (0.022–.027) | 0.023 (0.022–0.026) | 0.019* (0.015–0.021) |
| β-Carotene | 0.079 (0.066–0.082) | 0.081 (0.076–0.091) | 0.062* (0.054–0.066) |

| γ-Tocopherol | 0.204 (0.186–0.212) | 0.197 (0.179–0.209) | 0.175 (0.164–0.203) |
| β-Cryptoxanthin | 0.028 (0.028–0.029) | 0.026 (0.025–0.029) | 0.020* (0.019–0.025) |

[a]Plasma from five male volunteers was pooled, LDL prepared and separated into three fractions. Two fractions were dialyzed each in five separate aliquots with and without EDTA. Significance of decrease in micronutrient concentration in dialyzed compared to native LDL samples was calculated using a Wilcoxon paired rank test. *$P < 0.05$. See Table 1 for abbreviation.

**TABLE 3**
**Comparison of Effect of Dialysis and Gel Filtration on LDL Micronutrients[a]**

| | Native LDL $n = 2$ | Dialyzed (DLDL) $n = 4$ | Gel-filtered (GLDL) $n = 4$ | Change (%) After dialysis | Change (%) After filtration |
|---|---|---|---|---|---|
| LDL micronutrients (μmol/mmol cholesterol) | | | | | |
| α-Carotene | 0.030 ± 0.035 | 0.036 ± 0.003 | 0.035 ± 0.004 | +12 | +9 |
| β-Carotene | 0.078 ± 0.084 | 0.078 ± 0.006 | 0.085 ± 0.005 | +4 | +5 |
| Lutein | 0.022 ± 0.025 | 0.020 ± 0.002 | 0.025 ± 0.003 | –13 | +10 |
| Lycopene | 0.178 ± 0.190 | 0.166 ± 0.011 | 0.168 ± 0.011 | –10 | –9 |
| α-Tocopherol | 3.51 ± 3.90 | 3.27 ± 0.33 | 3.88 ± 0.22 | –11 | +5 |
| Lagphase (min) | | | | | |
| A | — | 41 ± 5 | 42 ± 1 | | |
| B | — | 46 ± 1 | 38 ± 6 | | |

[a]Native LDL was prepared from pooled plasma and split into three fractions. One fraction was dialyzed in duplicate and one treated using gel filtration in duplicate. All samples were then analyzed for micronutrients in duplicate. Lag phase measurements were done in triplicate on dialyzed and gel-filtered samples prepared from fresh (A) and stored plasma (B). See Table 1 for abbreviation.

and Carbonneau *et al.* (18). Esterbauer *et al.* (17) showed that when EDTA or BHT is present in the dialysis buffer, there is no loss in the antioxidant micronutrient or the polyunsaturated fatty acid content of LDL. Carbonneau *et al.* (18) did report a small loss in α-tocopherol (*ca.* 11%) following the dialysis step, but this change was much smaller than reported by Scheek *et al.* (10) Carbonneau and co-workers (18) suggested that such changes are unlikely to have an effect on the LDL oxidation as very large increases in the LDL antioxidant content are required to increase the resistance of LDL to oxidation. In the experiments done by Scheek *et al.* (10), the analysis of micronutrients in LDL and DLDL was done after the storage of samples (both native and DLDL) at –80°C. In the present study, we show that when the analysis is done on the freshly prepared native and dialyzed DLDL, only small changes in micronutrients are observed. However, in our preliminary experiments (data not shown), we found that the changes in micronutrient concentrations were greater when LDL samples (both native and dialyzed) were stored at –70°C, but the losses in carotenoids were smaller (20–40%) than that reported by Scheek *et al.* (10). We suggest that freezing of LDL and DLDL samples can cause greater losses of micronutrients, and in our experience freezing also leads to a greater inaccuracy in micronutrient determination due to the tendency for LDL to aggregate in thawed samples.

Gel filtration is another frequently used method for the removal of EDTA from LDL samples prior to *in vitro* oxidation (8). A comparison of gel filtration and dialysis was done using duplicate samples prepared from the same LDL preparation. In both cases the changes in micronutrient concentration observed were of a similar magnitude but slightly higher than the assay precision of micronutrients. The carotenoids α-carotene and lutein may be subject to a greater experimental error due to their lower concentrations in LDL. The β-carotene and lycopene are sensitive to degradation by light and oxidation (19,20); therefore, some variation in micronutrient concentrations can be expected between different experiments. Although precautions were taken for a minimal exposure of samples to the light and EDTA was included in most preparations, some losses are unavoidable during the experiment. LDL oxidizability as measured by the lag phase was not different between dialyzed and gel-filtered samples when either fresh or frozen plasma samples were used. The results shown in Table 3 from frozen plasma are in agreement with our previously published report in which between-assay variation of lag phase in LDL prepared from frozen plasma was found to be less than 5% (15).

In summary, dialysis or gel filtration of freshly isolated LDL does not cause a significant loss of micronutrients if the dilution occurring during dialysis or gel filtration is taken into account. Small differences in micronutrient concentration can, however, be attributed to losses occurring during the removal of EDTA as well as experimental errors in the HPLC procedure.

# α-Linolenic Acid and Its Δ5-Desaturation Product, Coniferonic Acid, in the Seed Lipids of *Tsuga* and *Hesperopeuce* as a Taxonomic Means to Differentiate the Two Genera

Sir:

In our systematic study of Pinaceae seed fatty acid (SFA) compositions, we have analyzed *ca.* 150 species, subspecies, and varieties, which represent approximately one-half of total recognized taxa of this family (1). We additionally screened many geographical variants. Pinaceae seeds analyzed so far include: *Pinus*, 76 taxa; *Abies*, 36 taxa; *Picea*, 17 taxa; *Larix*, 8 taxa; *Cedrus*, 5 taxa; *Tsuga*, 4 taxa; *Keteleeria*, 2 taxa; *Pseudotsuga*, 1 taxon (2–5; Wolff, R.L., unpublished data). Recently, we had the opportunity to analyze the monospecific genus *Pseudolarix* (*P. amabilis*, golden larch; central and northeastern China) and *Tsuga mertensiana* (mountain hemlock; western North America, from southern Alaska to central California), with uncertain taxonomic position (1,6,7). With the exception of the monospecific genera *Cathaya* and *Nothotsuga*, all Pinaceae genera have now been screened for their SFA compositions. Unexpectedly, the two species studied here appear exceptional regarding their α-linolenic acid content as compared to all other Pinaceae analyzed so far, being placed at the extreme positions (lowest and highest contents in *T. mertensiana* and *P. amabilis*, respectively).

In all species from all Pinaceae genera analyzed so far, α-linolenic acid has always been present in the narrow range of 0.2–1.4% of total fatty acids, with one exception, *Pinus merkusii* (the only *Pinus* species that extends into the Southern Hemisphere), at 2.7% (5). The Δ5-desaturation product of α-linolenic acid, coniferonic (5,9,12,15-18:4) acid, reaches a maximum of 0.2% in Pinaceae seed lipids, being most often present at the limit of detection. However, in some Cupressaceae species, i.e., *Chamaecyparis lawsoniana* and *Fokienia hodginsii,* coniferonic acid can reach much higher levels [2.0 and 2.8%, respectively (8)], and these species are considerably richer in α-linolenic acid than any Pinaceae species.

Analyses of the species described here were made according to our standardized procedures (5), and their SFA compositions are given in Table 1. As can be seen from that table, the level of α-linolenic acid in *P. amabilis* is 5.2%, and this acid is accompanied by a fairly high level of coniferonic acid (1.8%), which is quite exceptional among Pinaceae species. On the other hand, *T. mertensiana* is devoid of these two fatty acids. Among Pinaceae species analyzed so far, *P. amabilis* and *T. mertensiana* thus appear as representing the two extreme species when considering their seed lipid α-linolenic acid content.

[a]Ethylenic bonds are in the *cis* configuration; aiso-17:0, anteiso-17:0 or 14-methylhexadecanoic acid.
[b]Minimum and maximum values determined in the seed lipids of *T. canadensis, T. caroliniana, T. chinensis,* and *T. heterophylla*.
[c]Sum of two isomers, 7- and 9-16:1 acids.
[d]Not detected.
[e]Sum of Δ5-olefinic acids and 7,11,14-20:3 acid.
[f]Include minor and unknown fatty acids.

The taxonomic ranking of *P. amabilis* has been recognized for a long time, but that of *T. mertensiana* has been and is still a matter of debate. It has been considered a hybrid, or even a monospecific genus, *Hesperopeuce* (1,6,7). Regarding the latter species, we also give in Table 1 the range of values encountered in the genus *Tsuga*, based on data established for *T. canadensis*, *T. heterophylla* (3), *T. caroliniana*, and *T. chinensis* (Wolff, R.L., unpublished data). This is intended to show the similarities and dissimilarities between *T. mertensiana*

Paper no. L8616 in *Lipids 36,* 211–212 (February 2001).

and other representatives of the same genus. The narrow ranges in which *Tsuga* spp. SFA compositions lie are noteworthy (see, e.g., 9,12-18:2 acid). Differences between *T. mertensiana* and *Tsuga* spp. appear for oleic, linoleic, and particularly α-linolenic acids. Oleic acid is considerably higher in *T. mertensiana* than in *Tsuga* spp., whereas linoleic acid is slightly lower. Δ5-Olefinic $C_{18}$ acid levels do not differ significantly, whereas it would appear that the elongation product of linoleic acid, 11,14-20:2 acid, and its desaturation product, sciadonic (5,11,14-20:3) acid, are definitely lower in *T. mertensiana* than in other *Tsuga* species. The most conspicuous feature, however, is the absence of α-linolenic acid and consequently of coniferonic acid in *T. mertensiana* seed lipids as compared to other *Tsuga* species.

Interestingly, *P. amabilis* and *T. mertensiana* SFA include the anteiso-17:0 acid found in all other Pinaceae genera and species (9). In the latter species, preliminary results obtained by mass spectrometry coupled to gas–liquid chromatography indicate that some fatty acids in *T. mertensiana* seeds, included here in the category "others" (Table 1), would be unsaturated branched $C_{19}$ acids, possibly similar to those characterized in *Picea abies* (Norway spruce) wood extracts by Ekman (10). However, this deserves further investigations.

In conclusion, as regards its SFA composition, *T. mertensiana* differs from all other *Tsuga* spp., which otherwise appear as a very homogeneous genus; and this observation, along with other botanical criteria, would support its ranking at the genus level (i.e., *Hesperopeuce mertensiana*) rather than at a *Tsuga* species level. On the other hand, *P. amabilis* is a genus quite distinct from all other genera of the Pinaceae family. Moreover, if one compares *P. amabilis* (Pinaceae) on the one hand, with *C. lawsoniana* and *F. hodginsii* (Cupressaceae) on the other hand, the Δ5-desaturation of α-linolenic acid appears more efficient in the former species. The two Cupressaceae species contain *ca.* 8–10 times more α-linolenic acid [40 and 50%, respectively (8)] than *P. amabilis*, although the levels of coniferonic acid are rather similar in the three species.

# Overestimates of Oleic and Linoleic Acid Contents in Materials Containing *Trans* Fatty Acids and Analyzed with Short Packed Gas Chromatographic Columns

Sir:

*Trans* fatty acids (FA), mainly comprising *trans* 18:1 isomers, are found in milk and other dairy foods produced by ruminal biohydrogenation and in partially hydrogenated edible oils. Some *cis* isomers other than oleic acid (9*c*-18:1) are also found. These *cis* and *trans* isomers are not completely separable by a gas–liquid chromatography (GLC) analysis even with a 100-m polar column. Only thin-layer chromatography (TLC) separation of the methyl esters into bands of *trans* and *cis* isomers followed by further analyses of the separated esters with the column above allows an almost complete resolution of all isomers. This procedure is called the argentation TLC/GLC (Ag-TLC/GLC) method (1). Partial resolution can be attained by GLC alone, with polar capillary columns (1). However, as shown in Figure 1, the isomers cannot be resolved from, for example, 9*c*-18:1, by using the short packed GLC columns universally employed before the long, small-diameter capillary columns became available in the early 1980s. The single peak on the GLC chart designated as 18:1 could contain about 21 *cis* and *trans* isomers. The high-resolution Ag-TLC/GLC procedure was first employed by Wolff and Bayard (2) and Precht and Molkentin (3) in 1995. They used 100-m capillary columns to separate almost all individual *trans* and *cis* isomers in ruminant fats or partially hydrogenated oils. However, the overlaps with oleic acid cannot be quantified because, although they had high achievable resolution, they presented only the contents of the *trans* isomers (3). In the same year, Chen *et al.* (4) published results obtained by another method involving preseparation by Ag-TLC and further cleavage by oxidative ozonolysis and GLC of the resulting products. Also here, the overlaps cannot be quantified precisely because these authors presented the contents of the isomers only in bar graphs.

While preparing a review on *trans* unsaturated FA in human milk, one of us (RGJ) belatedly realized that the amounts of some unsaturated *cis* FA in materials which could

contain *trans* FA, obtained with the packed columns and reported in older papers, e.g., (5–7), were all overestimated. The quantities in peaks identified as 18:1 and 18:2 reported in these papers are too high because the *trans* and some of the *cis* isomers coeluted with those of the major FA, oleic and linoleic acids. In this paper, we describe the calculation of factors needed to correct the overestimates of 9*c*-18:1 (oleic acid) and 9*c*,12*c*-18:2 (linoleic acid) obtained with short packed columns and present examples. On the other hand, *trans*-18:1 acid contents, even when determined by capillary column GLC, are mostly underestimated, and appropriate correction factors to obtain more precise data have been published (1,8).

As shown in Figure 1 and described below, the old GLC peaks identified as 18:1 and 18:2 contained numerous *cis* and *trans* isomers that were not 9*c*-18:1 or 9*c*,12*c*-18:2. From the chromatograms in Figure 1 obtained from the same sample of bovine milk fat and published identifications (1–3,9), we find that the 4–15 *cis* and *trans* isomers coelute with 9*c*-18:1 on the short packed GLC columns. These were identified and quantified as oleic acid (18:1) in the older publications. The old 18:2 peak contained 9*c*,12*c*-18:2, all of the *trans* 18:2 isomers with at least one *trans* double bond (except conjugated linoleic acids, and 16*t*-18:1. We have calculated correction factors by dividing the correct by the old or overestimated contents. The latter were obtained by adding the quantities of other *cis* and *trans* isomers from Ag-TLC/GLC analyses of German bovine and human milk lipids, and margarine FA to the exact contents of 9*c*-18:1 and 9*c*,12*c*-18:2 from these analyses. All of this information and references are given in Table 1.

In Table 1, we have provided seasonal (feed) correction factors for bovine milk. These should be generally applicable to most data since the FA contents of bovine milk lipids have stayed relatively stable for years. Further, Table 1 gives correction factors for margarines and human milk. Application of these factors to old U.S. data and the old German data on human milks from Harzer *et al.* (7) yields the corrected amounts of 18:1 and 18:2 in Table 2. Harzer *et al.* employed columns (4 m × 1/8″) that contained Silar 10C, a polar material. However, they did not detect *trans* 18:1. Thus, depending on the material, the contents of oleic and linoleic acids have been overestimated by 19-100% and 3–108%, respectively.

Our correction factors for human milk may not be so widely applicable since the consumption of foods containing partially hydrogenated oils varies considerably worldwide (13). The contents of fatty acids in human milk respond overnight to the quantities in the diet. The amounts of 18:1, 18:2, and *trans* isomers in margarines also vary depending upon the oils and processing methods used. Some manufacturers have reduced the *trans* FA content of their products. To summarize, the quantities of 18:1 and 18:2 in old data on FA contents of materials, which may have contained *trans* FA and which were analyzed with short packed GLC columns, are overestimated by up to more than 100%. The universally employed phases for packed columns were of medium polarity, e.g., diethylene glycol succinate (DEGS), with column lengths of 2 to 4 m. The major source of data on FA composition in the United States is available from the website of the U.S. Department of Agriculture (USDA): (http://www.nal.usda.gov/fnic/foodcomp). Many recommendations for changes in FA consumption are based on these data. However, these tables do not contain data on positional *cis* or *trans* FA isomers. Oleic and linoleic acids are assumed to be the 9*c*-18:1 and 9*c*,12*c*-18:2 FA, but are overlapped by the numerous other *cis/trans* isomers mentioned (9). However, in future

releases, the USDA will be publishing such values as these data become available from contract analyses and the literature. It is clear that all future analyses of materials containing positional and geometric isomers of unsaturated FA must be done with the Ag-TLC/GLC or a comparable method. Omission of the TLC step will result in an underestimate of *trans*-18:1 and total *trans* FA contents (1) and overestimates of 9*c*-18:1 and occasionally 9*c*,12*c*-18:2 even with capillary columns. However, linoleic acid (18:2) is not changed when columns 100 m in length are employed, with or without the TLC step. The contents of the essential linoleic acid and oleic acid in old 18:2 or 18:1 data are reduced by the correction factors. Are the old levels of 18:2 that were recommended to prevent deficiency symptoms incorrect? Possibly. This suggestion may also apply to the amounts of relevant FA in recent findings concerning premature atherosclerosis (3). This should be checked. Special effects of individual isomers on metabolism have already been found (e.g., Ref. 14), and more may exist but will not be detected until the contents of these isomers are determined. More relevant information is given in Reference 15.

## ACKNOWLEDGMENT

# The Effect of Conjugated Linoleic Acid on Platelet Function, Platelet Fatty Acid Composition, and Blood Coagulation in Humans

**P. Benito, G.J. Nelson*, D.S. Kelley, G. Bartolini, P.C. Schmidt, and V. Simon**

Western Human Nutrition Research Center, ARS, USDA, Davis, Californa 95616

**ABSTRACT:** Despite extensive research on conjugated linoleic acid (CLA) showing multiple beneficial effects in animal models, little is known about the role of dietary CLA in human health. To investigate if the beneficial effects of CLA seen in animal models are relevant to humans, we conducted a study with 17 healthy female volunteers who lived in the Metabolic Research Unit of the Western Human Nutrition Research Center for 93 d. This paper reports only the results from this study that are related to the effects of CLA supplementation on blood coagulation, platelet function, and platelet fatty acid composition. Throughout the study, the subjects were fed a low-fat diet (30 en% fat, 19 en% protein, and 51 en% carbohydrate) consisting of natural foods with the recommended dietary allowances for all known nutrients. After a 30-d stabilization period, subjects were randomly assigned to either an intervention group ($n$ = 10) whose diet was supplemented with 3.9 g/d of CLA or a control group ($n$ = 7) who received an equivalent amount of sunflower oil consisting of 72.6% linoleic acid with no detectable CLA. Platelet aggregation was measured in platelet-rich plasma using adenosine diphosphate, collagen, and arachidonic acid agonists. No statistical difference was detected between the amount of agonist required to produce 50% aggregation of platelet-rich plasma before and after the subjects consumed the CLA, with the exception of a decrease in response to collagen. This decrease was found in both control and intervention groups with no significant difference between the groups, suggesting that both linoleic acid (sunflower oil) and CLA might have similar effects on platelet function. The prothrombin time, activated partial thromboplastin time, and the antithrombin III levels in the subjects were determined. Again, there was no statistically significant difference in these three parameters when pre- and post-CLA consumption values were compared. The *in vivo* bleeding times were also unaffected by CLA supplementation (10.4 + 2.8 min pre- and 10.2 + 1.6 min postconsumption). Platelet fatty acid composition was not markedly influenced by the consumption of dietary CLA, although there was a small increase in the amount of the 9 *cis*,11 *trans*-18:2 isomer normally present in platelets after feeding CLA for 63 days. In addition, small amounts of the 8 *trans*,10 *cis*-18:2 and the 10 *trans*,12 *cis*-18:2 isomers were detected in the platelets along with traces of some of the other isomers. Thus, when compared to sunflower oil, the blood-clotting parameters and *in vitro* platelet aggregation showed that adding 3.9 g/d of dietary CLA to a typical Western diet for 63 d produces no observable physiological change in blood coagulation and platelet function in healthy adult females. Short-term consumption of CLA does not seem to exhibit antithrombotic properties in humans.

Paper no. L8620 in *Lipids 36*, 221–227 (March 2001).

Atherosclerosis causes heart attack, gangrene, and stroke and is the cause of half of all mortalities in the United States (1). Platelets adhere to the wall of the blood vessel and contribute to atherogenesis by releasing growth factors (1). There are many studies on how dietary fatty acids could reduce platelet activation, thus minimizing the risk of cardiovascular disease. However, most of those studies have focused on the long-chain n-3 fatty acids and have consistently found a decrease in platelet activation after consuming fish oil diets or supplementation (2). In contrast, human studies on the effects of n-6 polyunsaturated fatty acids (PUFA) on platelet function are far less frequent, and the results are more controversial. On the one hand, linoleic acid, an n-6 PUFA, has been found to be antithrombotic in various *ex vivo* filtragometer human studies (3–5). On the other hand, there are intervention studies that have shown increased *in vitro* platelet aggregation in response to various agonists after consuming high-linoleic acid diets (6,7). However, the effect of dietary conjugated linoleic acid (CLA; a collective term for a mixture of positional and geometric isomers of linoleic acid) on platelet function in humans has not been studied.

CLA is a PUFA found naturally in the food supply. It is especially abundant in food lipids derived from ruminant animals such as beef and lamb and dairy products (8,9) due to increased conversion of linoleic acid to CLA by rumen microorganisms. Ever since Pariza and Hargraves (10) reported in 1985 that CLA exhibited anticarcinogenic activity in mouse skin and whose findings were later confirmed by other studies involving other types of tumors (stomach, mammary gland, and colon) (11–15), there has been great interest in these fatty acids. This interest intensified even more after numerous studies reported that CLA also exhibited other beneficial physiological effects such as protection against atherosclerosis (16–19), enhancement of immunological function (20–23), and reduction of body fat while increasing lean mass (24–28) and bone mass (29).

Abbreviations: AA, arachidonic acid; APTT, activated partial thromboplastin times; CLA, conjugated linoleic acid; FAME, fatty acid methyl esters; GLC, gas–liquid chromatography; PRP, platelet-rich plasma; PT, prothrombin time; PUFA, polyunsaturated fatty acids; TX, thromboxane; WHNRC, Western Human Nutrition Research Center.

Since all of these effects have been observed in experiments with only human cell culture and animal models, we conducted a strictly controlled human feeding study to better understand the physiological and metabolic effects of dietary CLA in humans. Relevant to this paper is whether consumption of CLA may have thrombotic properties by affecting platelet function and blood coagulation. Here we report the effects of supplementing a natural food diet with 3.9 g/d of CLA in the form of a commercially available preparation, Tonalin® (Pharmanutrients, Inc., Lake Bluff, IL), on platelet function *in vitro*, bleeding times, coagulation factors, and platelet fatty acid composition. The study was conducted in a metabolic ward with healthy female subjects under the constant supervision of our dietary and nursing staffs.

*Study design.* The design was a randomized, placebo-controlled, single-blind feeding study in which healthy female volunteers ($n$ = 17) lived in the Metabolic Research Unit of the Western Human Nutrition Research Center (WHNRC) for 93 d. It was conducted with two cohorts since the Metabolic Research Unit can only accommodate 12 subjects.

From day 1 and throughout the study, subjects consumed a low-fat diet equivalent to the American Heart Association's Step II Diet with the RDA for all known nutrients and 30% of the calories from fat. During the stabilization period, the caloric intake of each subject was estimated, and the caloric value of the individual's menu adjusted accordingly to ensure that no significant gain or loss in body weight would occur. During the first 30 d (stabilization period), subjects received two placebo capsules (sunflower oil) with each meal every day to become accustomed to taking daily capsules. On day 31, subjects were randomly assigned to either the intervention group receiving supplemental CLA (3.9 g administered in six capsules daily, two with each meal) to the end of the study or the control group which continued taking the placebo capsules for all 93 d. Blood draws were taken at the start of the study (day 1), the end of the baseline period (day 30), midpoint of the supplementation period (day 63), and the end of the study (day 93).

## MATERIALS AND METHODS

*Subjects.* The protocol of this study was approved by the Institutional Review Boards of the University of California at Davis (Davis, CA) and the United States Department of Agriculture (Washington, DC). The recruitment and screening processes have been described previously in other papers from our Center (30–33).

The physical parameters of the 17 volunteers who completed the study were: age, 27.9 ± 6.0 yr; weight, 63.1 ± 8.5 kg; body mass index, 22.9 ± 2.4 kg/m$^2$; systolic blood pressure, 109.5 + 5.8 mm Hg; diastolic blood pressure, 67.4 + 7.8 mm Hg; menstrual cycle length, 28.6 + 1.9 d.

*Diet.* The nutrient composition of the diet was calculated from a computerized nutrient databank using the data from USDA Handbook No. 8 (34), the USDA Nutrient Database for Standard Reference (35), and the Food Processor for Windows (36). Diets were adjusted to provide at least the recommended daily intake for known essential nutrients (37). According to these databases, the nutrient composition of the diet was 30 en% fat, 19 en% protein, and 51 en% carbohydrate. The cholesterol content was 258 mg. All food was prepared in the WHNRC kitchen, and a 5-d menu cycle was used throughout the study. Specific menus were designed so that the fat would consist of saturated, monounsaturated, and polyunsaturated varieties at 10% each for both the placebo and intervention groups.

Sample menus were prepared before the study began to analyze the fatty acid composition of the diet so that the actual values would correspond to the theoretical values computed from the nutrient databank tables.

The fatty acid composition and a more detailed description of the diet are given in a companion paper from this study (38). A complete description of the diet, listing all major and minor nutrients, is available upon request.

*CLA supplements.* Subjects consumed a total of 3.9 g pure CLA daily (six Tonalin® capsules of 0.65 g of CLA each). This amount of CLA represents *ca.* 1.5% of the volunteers' total caloric intake. The placebo had the same daily amount of high-linoleic sunflower oil. All Tonalin® and placebo capsules were donated by Pharmanutrients, Inc.

The fatty acid compositions of the Tonalin® and placebo capsules are reported in a companion paper from this study (38). The CLA content of the Tonalin® capsules used for this study was *ca.* 65% of the total fatty acids. We identified 10 CLA isomers: the four major *cis/trans* (*c/t*) isomers (11.4% 9*c*,11*t*-18:2; 10.8% 8*t*,10*c*-18:2; 15.3% 11*c*,13*t*-18:2; 14.7% 10*t*,12*c*-18:2); their corresponding *c,c* varieties (1.38% 8*c*,10*c*-18:2; 1.59% 9*c*,11*c*-18:2; 2.45% 10*c*,12*c*-18:2; and 1.32% 11*c*,13*c*-18:2); and two *t,t* varieties (0.97% 11*t*,13*t*-plus 8*t*,10*t*-18:2 and 5.02% 9*t*,11*t*-plus 10*t*,12*t*-18:2).

*Materials.* Three individual CLA isomers, *c*-9,*t*-11 (catalog # 1248), *t*-9,*t*-11 (catalog # 1181), and *t*-10,*c*-12 (catalog # 1249) were obtained as free fatty acids from Matreya Inc. (Pleasant Gap, PA). A CLA reference standard containing a mixture of fatty acid methyl ester (FAME) isomers was used (catalog # UC-59-M; 99% pure; Nu-Chek-Prep, Inc., Elysian, MN), and the approximate isomeric composition of CLA according to the manufacturer's assay was: 41% *c,t/t,c*-9,11-18:2; 44% *c,t/t,c*-10,12-18:2; 10% *c,c*-10,12-18:2; others ~5% (*t,t*-9,11-18:2, *t,t*-10,12-18:2, *c,c*-9,11-18:2). Analyses in our laboratory indicated similar composition except that we also found the *c,t/t,c*-11,13 isomer (44% *c,t/t,c*-9,11-18:2; 35.5% *c,t/t,c*-10,12-18:2; 18% *c,t/t,c*-11,13-18:2; 2% others).

*Measurements.* Blood was drawn between 7:00 and 8:00 A.M. after an overnight fast or at least 12 h without food. Blood was drawn into either anticoagulant-coated vacutainers using Teflon catheters (Angiocath; Deseret Medical, Sandy, UT) for fatty acid analysis, or syringes containing 1 mL of citrate solution for platelet studies.

Platelet-rich plasma (PRP) was prepared by low-speed centrifugation for 15 min at 100 × *g*. Platelet-poor plasma was prepared by respinning the blood after the removal of PRP for

15 min at 400 × *g*. Red cells for fatty acid analysis (data not shown here) were prepared from the residue by resuspending the cells in 10 mL of phosphate-buffered saline and recentrifuging at 400 × *g* for 15 min three times. The supernatant was discarded. Platelets were isolated by centrifuging the PRP at 400 × *g* for 15 min, resuspending them in 7 mL of phosphate-buffered saline and recentrifuging at 400 × *g* for 15 min two more times. The supernatant was discarded. Samples were frozen at –70°C until extraction of the lipids.

*Platelet aggregation.* Platelet aggregation tests were performed as described previously (39,40). Aggregating agents were prepared as recommended by Chrono-log (Havertown, PA): ADP, 1 mM/mL; collagen, 0.5 mg/mL; arachidonic acid (AA), 0.05 mM. The *in vitro* aggregation characteristics of the subjects' platelets were measured in a dual channel aggregometer (model 560; Chrono-log Corp.). Briefly, 235 μL of PRP was added to an aggregation tube containing a Teflon-coated stirring bar. The blank was 250 μL of the individual platelet-poor plasma, unstirred. The instrument was zeroed to 10% transmission of the sample vs. the blank. An appropriate amount of aggregating reagent was added to the PRP, and aggregation was measured as the increase in transmission of light through the PRP. The threshold for aggregation was determined when the amount of a particular reagent produced at least 50% of maximum aggregation within 15 min of its addition to the PRP. Preparations of PRP were all adjusted to 300,000 platelets/mm$^3$. All aggregation tests were performed within 4 h of the initial blood draw.

*Platelet counts.* Platelet counts were determined with an electronic particle counter (model 9300, Differential Cell Counter; Baker-Serono Diagnostics, Inc., Allentown, PA) and a cytometer using the manufacturer's recommended procedures (Operations Manual No. DS-014A, 1988, Baker-Serono Diagnostics, Inc.).

*Bleeding times.* Bleeding times were measured on the left or right proximal forearm of each subject using a 1-mm deep by 1-cm long incision and a Simplate II bleeding time device (Organon Teknika, Durham, NC). A wipe of the incision was made every 30 s. Time was measured with a hand-held stopwatch (39).

*Clotting factors.* Prothrombin time (PT) and the activated partial thromboplastin times (APTT) were measured by the methods described by Houghie (41). Briefly, platelet-poor plasma was prepared as described elsewhere (37), and the PT and APTT were measured (MCA 110; Bio Data Corporation, Hatboro, PA) with coagulation reagents (Organon Teknika). Antithrombin III was measured by an automated centrifugal analyzer method (42). All tests for the clotting factors were performed within 1 h of separation of the plasma from the whole blood. Plasma samples were kept on ice until warmed to 37°C for the test.

*Lipid extraction and preparation of FAME.* The lipids were extracted as described by Nelson (43,44) using chloroform/methanol (2:1, vol/vol). The total lipid extracts and the free fatty acid CLA standards were transmethylated with sodium methylate for 10 min at 55°C followed by reaction with 1 N hydrochloric acid in methanol for 10 min at 80°C, as described by Carreau and Dubacq (45), in order to avoid isomerization of CLA isomers (46,47). The FAME were extracted with hexane and purified by thin-layer chromatography as described elsewhere (42) before dilution and injection into the gas chromatograph.

*Gas–liquid chromatography (GLC).* The FAME were analyzed by GLC (model 6893; Hewlett-Packard, Palo Alto, CA) with the Hewlett-Packard ChemStation III software running on an IBM-compatible desktop computer.

A SP-2380 column (100 m × 0.25mm i.d. × 0.2 mm film thickness; Supelco Inc., Bellefonte, PA) was used. The column was operated at 75°C for 4 min, then temperature-programmed at 13°C/min to 175°C, and held there for 27 min, followed by a second temperature program at 4°C/min to 215°C, then held there for 31 min. The total run time was 79.69 min.

Fatty acids were identified by comparison of their retention time with authentic standards. If a GLC peak was not clearly identified by its retention time, ion trap mass spectra were compared to mass spectra from NIST or mass spectra prepared in our laboratory.

*Statistical analysis.* Data from the start of the intervention diet (day 30) and the end of the study (day 93) were compared. The clotting data and aggregation data were analyzed using the paired *t*-test. A *P*-value of less than 0.05 was considered significant. The fatty acid data were using two-way analysis of variance (ANOVA) and Fisher post-ANOVA test. All statistical analyses were performed with the PC SAS Data System (Version 6.11) obtained under license from the SAS Institute (SAS PC Manual; SAS Institute, Chapel Hill, NC, 1993).

## RESULTS

No change in blood clotting and platelet function was detected in subjects who consumed CLA at 3.9 g/d for 63 d. The average bleeding time for the 10 subjects after consuming CLA for 63 d was 10.22 ± 1.64 min as compared to the baseline value of 10.40 ± 2.80 min after consuming a low-fat diet without supplement for 30 d. The difference between these values was not statistically significant. Similarly, blood pressure, measured daily in all subjects, did not change significantly from the corresponding baseline values in either the intervention or control groups throughout the study.

Table 1 shows the platelet aggregation *in vitro* and the platelet counts for both intervention and control groups after 63 d on either CLA or sunflower oil supplements, respectively. The platelet counts are the actual platelet numbers in the whole blood of the subjects, not the adjusted values used for the aggregation tests. Again, there was no statistically significant change in either the aggregation values or the platelet counts when the results from the two groups (intervention and control) were compared. Although there was a decrease in platelet aggregation in response to collagen for both groups after consuming CLA for 63 d, the difference between the

intervention and control groups was not statistically significant.

Table 2 lists values for the soluble blood coagulation parameters for these subjects before and after they consumed the CLA. Neither the PT nor the APTT value changed after CLA consumption. Antithrombin III values before and after CLA feeding were not significantly different either.

Table 3 compares the total fatty acid composition of the whole platelets after the subjects consumed CLA for 63 d. No major difference was detected in the normal fatty acids present in human platelets although the main CLA isomers present in the diet during the intervention phase of the study did show a slight increase after 63 d of CLA feeding. The CLA isomers present in significant amounts were the 9*c*,11*t* (perhaps some 8*t*,10*c*), and the 10*t*,12*c* varieties. Other minor CLA isomers were also detected but in amounts too small to quantify with the available samples. It should be noted that the quantities of these isomers present in platelets were minute, i.e., never more than 0.30 wt% of the total fatty acids in the platelets.

## DISCUSSION

While very little has been reported about the effects of CLA on platelet aggregation, the results of one *in vitro* study (48) suggest that CLA isomers may possess antithrombotic properties. Truitt *et al.* (48) found that 9*c*,11*t*-18:2 and 10*t*,12*c*-18:2 inhibited AA- and collagen-induced platelet aggregation more than their nonconjugated 9*c*,12*c* isomer (linoleic acid).

Among the different aggregating agents used by Truitt *et al.* (48), the most pronounced inhibitory effect was found with collagen. In our study, we also found a decrease in platelet aggregation in response to collagen for both placebo and intervention groups. However, the difference between the groups was not significant, suggesting that both linoleic acid (the sunflower oil used as placebo contained 72.6% linoleic acid with no detectable CLA) and CLA have similar effects on platelet aggregation. This finding contradicts those from Truitt's study in which they found CLA to be more effective than linoleic acid in reducing platelet aggregation. We did not find any effect on platelet aggregation in response to either ADP or AA.

The CLA used by Truitt *et al.* (48) consisted of two individual isomers (9*c*,11*t* and 10*t*,12*c*) and a mixture consisting mainly of these two isomers (44% 9*c*,11*t*, 46% 10*t*,12*c*) plus a small amount of other CLA isomers (4%) and other fatty acids (4% linoleic acid; 2% oleic acid). The antithrombotic effect was found with both the individual isomers and CLA mixture. In our study, these two isomers made up about 40% of all isomers while in Truitt's CLA mix these two isomers were 90% of all the CLA isomers. Perhaps the discrepancy between our and Truitt's results is related to the difference in CLA composition since it is becoming apparent that different isomers appear to produce different effects (49). We used Tonalin® since purified isomers of CLA for human feeding trials were not available at the time we conducted this study. However, despite the fact that Tonalin® contains isomers other than the 9*c*,11*t* and the 10*t*,12*c* varieties, it should be noted that in the platelets of those volunteers who consumed the CLA we found mainly these two isomers.

It should also be noted that the study by Truitt *et al.* (48) consisted of a series of *in vitro* experiments where platelets obtained from human donors were isolated and platelet suspensions were preincubated with various concentrations of fatty acid followed by the addition of aggregating agents. However, in our study, platelet aggregation was measured in PRP from volunteers who had consumed a controlled diet supplemented with CLA for 63 d. To the best of our knowledge, our study is the first to examine the effects of CLA supplementation on platelet function and aggregation in humans. Further research is necessary to better understand the role of CLA on platelet function.

Linoleic acid can be converted to AA by humans and other animal species. Platelet aggregation involves the release of endogenous AA which is converted to the proaggregatory thromboxane $A_2$ ($TXA_2$). Our data on eicosanoids are not available yet, but the study by Truitt *et al.* (48) suggests that CLA may act as a competitive inhibitor of the AA substrate for the cyclooxygenase enzyme. When they compared the effects of CLA on the platelet cyclooxygenase and lipoxygenase activities (measured by $TXB_2$ and 12-hydroxyeicosatetraenoic acid formation, respectively) to linoleic acid, they found that the 9*c*,11*t*- and 10*t*,12*c*-isomers, as well as the CLA isomer mix, inhibited the formation of the proaggregatory cyclooxygenase-catalyzed product, $TXA_2$, as measured

[a]ND, not detected. Values with different superscripts are significantly different at $P < 0.05$ using two-way analysis of variance (ANOVA) and Fisher post-ANOVA test. DMA stands for dimethyl acetal; *c* for *cis*; and *t* for *trans*. CLA1 is the 9*c*,11*t*-18:2 isomer; CLA2 is the 8*t*,10*c*-18:2 isomer; CLA3 is the 10*t*,12*c*-18:2 isomer; and CLA4 is the 11*c*,13*t*-18:2 isomer.

by decreased production of its inactive metabolite $TXB_2$ from exogenously added AA. However, none of the CLA isomers tested inhibited the production of the platelet lipoxygenase metabolite 12-HETE.

We did not find, after 63 d of CLA consumption at 3.9 g/d, any significant effect on *in vivo* bleeding times and soluble clotting factors as measured by PT, APTT, and antithrombin III (considered a measure of *in vivo* thrombotic tendency). We did find that CLA isomers, mainly the 9*c*,11*t*- and 10*t*,12*c*-isomers, were present in the platelets of those volunteers who consumed the CLA supplement for 63 d. However, the amount present in the platelet was at a much reduced level compared to the amount fed in the diet. It would appear that all *cis*, polyunsaturated, nonconjugated fatty acids are more readily incorporated into platelets than their conjugated analogs. While our supplement contained more than 20% of the 11*c*,13*t*-isomer of CLA, we did not find any trace of this compound in the volunteers' platelets. It is believed that the 11*c*,13*t*-isomer is an artifact of the synthetic process, thus not found in natural CLA present in food sources or produced by bacteria in the lumen of ruminants. The finding here suggests that this CLA isomer is not incorporated in tissues as readily as the CLA isomers normally found in the human food chain. We have reported the effects of dietary CLA on the fatty acid composition of plasma and adipose tissue, as well as on blood lipid concentrations, lipoproteins, and apolipoproteins, in a companion paper (38) using other data from this study.

The amount of CLA that subjects consumed in this study was three to four times that found in the Western diet. Daily consumption of CLA by the U.S. population is estimated to be from several hundred mg/person/d (11,50) to 1 g/person/d (13,51,52). We chose to provide *ca.* 1.5% of calories from CLA (3.9 g/d) because that concentration had been shown to affect mammary tumorigenesis and immune response in experimental animals, and no additional beneficial effect was observed when the dose exceeded that threshold (13,53,54). In our study, no short-term adverse health effect or discomfort was observed or reported when CLA was consumed continuously for 63 d at such dosage.

The absence of measurable effects of dietary CLA supplement in humans, as we have reported in other papers containing other results from this study (32,33,38,55), is in marked contrast to the effects of CLA in animal studies (16,20–23,56–59). Of course, one of the major differences between many of the animal studies and our study is that most of the animal studies were conducted in young animals undergoing rapid growth. Here we studied mature women with stable body weight. It could be that for CLA to exert its effects, the animal

must be in a growth phase. Another possible explanation for the differences between our study and most of the animal studies reported to date is that we fed our volunteers for only 63 d while many of the animal studies extended the feeding period to the equivalent of human years. In addition, ours was a metabolic ward study; thus the number of subjects was relatively small: 10 in the intervention group and 7 in the control group. With only 17 volunteers in this study, the statistical power was not necessarily sufficient to rule out the possibility of false negative results. The platelet function tests using ADP and AA were subject to a large standard deviation and hence cannot be considered definitive. The test with collagen was borderline at a power of 80% to detect a 25% change at the 0.05 significance level. The sample size was adequate for the fatty acid composition data and the bleeding parameters.

In summary, the results of this study suggest that dietary CLA consumed at the level used in this study has little, if any, effect on blood clotting and platelet function, despite the fact that CLA isomers are incorporated into platelets during the course of this study. CLA has no detectable adverse effect in human females at the level fed in this study for 63 d.

## ACKNOWLEDGMENTS

We would like to express our appreciation for the dietary and nursing staffs of the Metabolic Research Unit as well as the staff of the Bio-Analytical Lab at the WHNRC. We are also indebted to the subjects for their participation in this study and to Pharmanutrient, Inc., Lake Bluff, IL 60044, for their donation of the Tonalin® capsules.

# The Effect of Conjugated Linoleic Acid on Plasma Lipoproteins and Tissue Fatty Acid Composition in Humans

**P. Benito, G.J. Nelson*, D.S. Kelley, G. Bartolini, P.C. Schmidt, and V. Simon**

Western Human Nutrition Research Center, ARS, USDA, Davis, California 95616

**ABSTRACT:** Conjugated linoleic acid (CLA) has been suggested by some animal studies to possess antiatherogenic properties. To determine, in humans, the effect of dietary CLA on blood lipids, lipoproteins, and tissue fatty acid composition, we conducted a 93-d study with 17 healthy female volunteers at the Metabolic Research Unit of the Western Human Nutrition Research Center. Throughout the study, subjects were fed a low-fat diet [30 energy percent (en%) fat, 19 en% protein, and 51 en% carbohydrate] that consisted of natural foods with the recommended dietary allowances for all known nutrients. After a 30-d stabilization period, subjects were randomly assigned to either an intervention group ($n$ = 10) supplemented daily with capsules containing 3.9 g of CLA or a control group ($n$ = 7) that received an equivalent amount of sunflower oil. The CLA capsules (CLA 65%) contained four major *cis/trans* geometric isomers (11.4% 9 *cis*-,11 *trans*-18:2; 10.8% 8 *trans*-,10 *cis*-18:2; 15.3% 11 *cis*-,13 *trans*-18:2; and 14.7% 10 *trans*-,12 *cis*-18:2) and their corresponding *cis/cis* (6.74% total) and *trans/trans* (5.99% total) varieties in smaller amounts. Fasting blood was drawn on study days 30 (end of the stabilization period), 60 (midpoint of the intervention period), and 93 (end of the intervention period). Adipose tissue samples were taken on days 30 and 93. CLA supplementation for 63 d did not change the levels of plasma cholesterol, low density lipoprotein cholesterol, high density lipoprotein cholesterol, and triglycerides. The weight percentage of CLA in plasma increased from 0.28 ± 0.06 to 1.09 ± 0.31 ($n$ = 10, $P < 0.05$) after the supplementation. The 9 *cis*-,11 *trans*-isomer was the most prominent variety followed by the 11 *cis*-,13 *trans*- and 10 *trans*-,12 *cis*-isomers in lesser amounts. CLA in adipose tissue was not influenced by the supplementation (0.79 ± 0.18 to 0.83 ± 0.19 wt%) ($n$ = 10) and the 9 *cis*-,11 *trans*-variety was the only isomer present. Thus, contrary to findings from some animal studies, CLA does not seem to offer health benefits, in the short term, regarding the prevention of atherosclerosis in humans. CLA supplementation for 2 mon did not alter the blood cholesterol or lipoprotein levels of healthy, normolipidemic subjects. The supplementation did increase CLA in the plasma but only 4.23% of the ingested CLA was present in the plasma at any given time. No adverse effect of CLA supplementation was detected in this study.

Paper no. L8619 in *Lipids 36,* 229–236 (March 2001).

Abbreviations: apo, apolipoprotein; CLA, conjugated linoleic acid; DMA, dimethyl acetal; FAME, fatty acid methyl ester; HDL, high density lipoprotein; LDL, low density lipoprotein; PRP, platelet-rich plasma; RDA, recommended daily allowance; TG, triglyceride; USDA, U.S. Department of Agriculture; WHNRC, Western Human Nutrition Research Center.

Conjugated linoleic acid (CLA) is a polyunsaturated fatty acid found naturally in the food supply. It is especially abundant in food lipids derived from ruminant animals such as beef, lamb, and dairy products (1,2) due to increased conversion of linoleic acid to CLA by rumen microorganisms.

Ever since Pariza and Hargraves reported in 1987 that CLA exhibited anticarcinogenic activity in mouse skin (3), which was subsequently confirmed by studies involving other types of tumors (stomach, mammary gland, and colon) (4–8), there has been great interest in these fatty acids. This interest intensified even more after numerous studies reported that CLA also exhibited other beneficial physiological effects such as protection against atherosclerosis (9,10), enhancement of immunological function (11,12), and reduction of body fat while increasing lean mass (13–16) and bone mass (17).

However, all of these effects have been observed in experiments with only human cell culture and animal models; little is known of the physiological effects of dietary CLA in humans. Therefore, we conducted a strictly controlled human feeding study in which healthy female subjects consumed 3.9 g CLA/d for 63 d while living in our metabolic ward under the constant supervision of our dietary and nursing staffs. Although the overall objective of the study was to evaluate, in humans, the potentially beneficial physiological effects attributed to dietary CLA in animal studies, relevant to the findings reported in this paper is whether consumption of CLA may have health benefits in the prevention of arteriosclerosis and other cardiovascular diseases by improving the blood lipid levels and lipoprotein profile. Here we report the effects of supplementing a natural food diet for 63 d with 3.9 g/d of CLA in the form of a commercially available triglyceride (TG), Tonalin®, on several lipid parameters. Specifically, we examined the blood lipid levels, fatty acid composition of the plasma and adipose tissue, and lipoprotein cholesterol levels.

## STUDY DESIGN

The design was a randomized, placebo-controlled, single-blind feeding study in which healthy female volunteers ($n$ = 17) lived in the Metabolic Research Unit of the Western Human Nutrition Research Center (WHNRC) for 93 d.

From day 1 and throughout the study, subjects consumed a low-fat diet equivalent to the American Heart Association's Step II Diet with the recommended dietary allowance (RDA) for all known nutrients and 30% of the calories from fat. Dur-

ing the first 30 d (baseline/stabilization period), subjects received two placebo capsules (sunflower oil) with each meal every day to become accustomed to taking daily capsules. On day 31, subjects were randomly assigned to either the intervention group receiving supplemental CLA (3.9 g administered in six capsules daily, two with each meal) to the end of the study or the control group that continued taking the placebo capsules for all 93 d. Blood samples were drawn at the start of the study (day 1), the end of the baseline period (day 30), in the middle of the supplementation period (day 60), and the end of the study (day 93). Details of the study design have also been reported in other papers (18–21).

## MATERIALS AND METHODS

*Subjects.* The protocol of this study was approved by the Institutional Review Boards of the University of California at Davis (Davis, CA) and the United States Department of Agriculture (USDA, Washington, DC). The recruitment and screening processes have been described in other papers (18–21). The physical characteristics of the subjects at entry into the study (day 0) are given in Table 1.

*CLA supplements.* All Tonalin® and placebo capsules were donated by Pharmanutrients, Inc. (Lake Bluff, IL). The Tonalin® oil produced by Pharmanutrients met all the requirements for human consumption. The fatty acid compositions of the Tonalin® and placebo capsules are shown in Table 2. The CLA content of Tonalin® used for this study was approximately 65% of all fatty acids in the capsule. We identified 10 CLA isomers consisting of the four major *cis/trans* isomers (11.4% 9 *cis*-,11 *trans*-18:2; 10.8% 8 *trans*-,10 *cis*-18:2; 15.3% 11 *cis*-,13-*trans* 18:2; 14.7% 10 *trans*-,12 *cis*-18:2), their corresponding *cis/cis* varieties (1.38% 8 *cis*-,10 *cis*-18:2; 1.59% 9 *cis*-,11 *cis*-18:2; 2.45% 10 *cis*-,12 *cis*-18:2; 1.32% 11 *cis*-,13 *cis*-18:2), and two *trans/trans* varieties (0.97% 11 *trans*-,13 *trans*- plus 8 *trans*-,10 *trans*-18:2 and 5.02% 9 *trans*-,11 *trans*- plus 10 *trans*-,12 *trans*-18:2).

The subjects consumed a total of 3.9 g CLA daily (six Tonalin® capsules containing 0.65 g of CLA each). We chose this amount of CLA to represent approximately 1.5% of the volunteers' total caloric intake. This CLA concentration was comparable to that used in many of the animal studies.

**TABLE 1**
**Characteristics of Subjects[a]**

| Parameter | Values | |
|---|---|---|
| | Intervention group | Control group |
| Number of subjects completing study | 10 | 7 |
| Age (yr, mean ± SD) | 27.0 ± 5.6 | 29.3 ± 6.8 |
| Weight (kg, mean ± SD) | 63.1 ± 6.5 | 63.2 ± 11.4 |
| Body mass index (kg/m$^2$, mean ± SD) | 23.6 ± 1.5 | 21.9 ± 3.1 |
| Menstrual cycle length (d, mean ± SD) | 27.4 ± 0.5 | 29.7 ± 2.0 |
| Blood pressure (systolic, mean ± SD) | 109.7 ± 4.3 | 109.1 ± 7.8 |
| Blood pressure (diastolic, mean ± SD) | 66.9 ± 7.1 | 68.0 ± 9.3 |

[a]All female; no smokers.

[a]FAME: fatty acid methyl ester.
[b]Values given as means ± SD ($n$ = 5); Tonalin® and placebo supplied by Pharmanutrients, Inc. (Lake Bluff, IL).

The placebo contained high-linoleic sunflower oil of equal quantity.

*Diet.* The diet was equivalent to the American Heart Association's Step II Diet containing the RDA for all known nutrients and 30% of the calories from fat. It consisted of natural foods except for the CLA supplement in the form of Tonalin® and sunflower oil capsules. In addition, a supplement of D-α-tocopherol (vitamin E, 100-mg capsules given every 5 d; Bronson Pharmaceutical, St. Louis, MO) was included in the diet to ensure adequate antioxidant levels in the volunteers during the study.

All food was prepared in the WHNRC kitchen and a 5-d menu cycle was used throughout the study. Specific menus were designed so that the fat would consist of saturated, monounsaturated, and polyunsaturated varieties at 10% each for both the placebo and intervention groups. No alcohol was included in these diets. Either two Tonalin® or placebo (sunflower oil) capsules were administered to the subjects before each meal (breakfast, lunch, and dinner) under the supervision of the kitchen staff. Consequently, compliance was 100%.

The nutrient composition of the diet was calculated from a computerized nutrient databank using the data from USDA Handbook No. 8 (22), the USDA Nutrient Database for Standard Reference (23), and the Food Processor for Windows (24). The diet was adjusted to provide at least the RDA for known essential nutrients (25). A complete description of the diet, including all major and minor nutrients, is available upon request. Based on these databases, the nutrient compo-

sition of the diet was 30 en% fat, 19 en% protein, and 51 en% carbohydrate. The cholesterol content was 258 mg.

Sample menus were prepared before the study began to analyze the fatty acid composition of the diet so that the actual values would correspond to the theoretical values computed from the nutrient databank tables. For these analyses, five individual diet composite samples were taken from each menu and the results for the five composite samples were averaged. Table 3 shows the measured fatty acid composition of the diet supplemented either with two CLA capsules (diet + CLA) or with two sunflower oil capsules (diet + placebo).

The caloric intake of each subject was estimated during the stabilization period and the caloric value of each individual's menu was adjusted accordingly to ensure that no significant gain or loss in body weight due to caloric intake would occur during the study. The intakes for each volunteer were averaged during the entire study and the mean energy intake was approximately 2,100 Kcal/d (2,116.51 ± 191).

*Materials*. A CLA reference standard containing a mixture of fatty acid methyl ester (FAME) isomers (99% pure) was obtained from Nu-Chek-Prep, Inc. (catalog # UC-59-M; Elysian, MN), and the approximate isomeric composition of CLA according to the manufacturer's assay was: 41% *c,t/t,c*-9,11-18:2; 44% *c,t/t,c*-10,12-18:2; 10% *c,c*-10,12-18:2; others approximately 5% (*t,t*-9,11-18;2, *t,t*-10,12-18:2, *c,c*-9,11-18:2). Analyses in our laboratory indicated similar compositions except that we found it also contained the *c,t/t,c*-11,13 isomer (44% *c,t/t,c*-9,11-18:2; 18% *c,t/t,c*-11,13-18:2; 35.5% *c,t/t,c*-10,12-18:2; 2% others). Three individual CLA isomers (*c*-9,*c*-11, catalog # 1248; *t*-9, *t*-11, catalog # 1181; and *t*-10,*c*-12, catalog # 1249) were obtained from Matreya Inc. (Pleasant Gap, PA) as free fatty acids.

[a]Values given as means ± SD ($n$ = 5). Diet w/o suppl., diet without supplementation; DMA, dimethyl acetal; for other abbreviations see Table 2.

*Measurements*. Blood was drawn between 7:00 and 8:00 A.M. after an overnight fast or at least 12 h without food. Blood was drawn into anticoagulant-coated vacutainers using Teflon catheters (Angiocath; Deseret Medical, Sandy, UT) for fatty acid analysis. The blood was spun at 100 × *g* for 15 min, and the platelet-rich plasma (PRP) was removed. The PRP was spun again at 400 × *g* to remove the platelets and platelet-poor plasma. Samples were frozen at −70°C until extraction of the lipids.

Adipose tissue biopsy samples were taken from the buttocks using a hypodermic syringe equipped with a 13-gauge, stainless steel needle (26,27). The samples (10 to 50 mg) were immediately transferred to cold (0°C) isotonic saline, then placed in a −70°C freezer within an hour and stored until further processing.

*Lipid extraction and preparation of FAME.* The lipids were extracted as described by Nelson (28,29) using chloroform/methanol (2:1, vol/vol). The total lipid extracts and the free fatty acid CLA standards were transmethylated with sodium methylate (methoxide) for 10 min at 55°C followed by reaction with 1 N hydrochloric acid in methanol for 10 min at 80°C as described by Carreau and Dubacq (30) in order to avoid isomerization of CLA isomers (31,32). The FAME were extracted with hexane and purified by thin-layer chromatography as described elsewhere (29) before dilution and injection into the gas chromatograph.

*Gas–liquid chromatography (GLC).* The FAME were analyzed by GLC (model 6890; Hewlett-Packard, Palo Alto, CA) with the Hewlett-Packard ChemStation III software running on an IBM-compatible desktop computer. A SP-2380 column (100 m × 0.25 mm i.d. × 0.2 mm film thickness; Supelco Inc., Bellefonte, PA) was used. The column was operated at 75°C for 4 min, then temperature-programmed at 13°C/min to 175°C, and held there for 27 min, followed by a second temperature program at 4°C/min to 215°C, and finally held there for 31 min. The total run time was 79.69 min. Fatty acids were identified by comparison of their retention times with authentic standards. If a gas chromatograph peak was not clearly identified by its retention time, ion trap mass spectra were compared to mass spectra from NIST or mass spectra prepared in our laboratory.

*Plasma lipid analyses*. Plasma cholesterol, TG, low density lipoprotein (LDL) cholesterol, and high density lipoprotein (HDL) cholesterol were analyzed in a Cobas-Faras centrifugal analyzer (Hoffman-La Roche, Nutley, NJ) using automated enzymatic methods as described by McGowan *et al*. (33) and Allain *et al*. (34).

**TABLE 4**
**Plasma Cholesterol, Lipoprotein Cholesterol, and Triglyceride Concentrations[a]**

| | Intervention group[b] | | | Control group[c] | | |
|---|---|---|---|---|---|---|
| | Day 30 (mg/dL) | Day 93 (mg/dL) | *P*-value[d] | Day 30 (mg/dL) | Day 93 (mg/dL) | *P*-value[d] |
| Triglycerides | 75.0 ± 21.7 | 52.5 ± 18.0 | 0.01 | 68.6 ± 18.2 | 51.1 ± 11.5 | 0.10 |

| HDL-cholesterol | 52.1 ± 7.9 | 51.8 ± 5.7 | 0.93 | 57.9 ± 13.0 | 55.5 ± 12.0 | 0.22 |

[a]Mean values ± SD.
[b]$n = 10$.
[c]$n = 7$.
[d]Paired *t*-test (SD at day 30 vs. SD at day 93). LDL, low density lipoprotein; HDL, high density lipoprotein.

*Statistical analysis*. Data from the end of the stabilization period (day 30) and the end of the intervention period (day 93) were compared and analyzed using the paired *t*-test. The subjects acted as their own controls. A *P*-value of less than 0.05 was considered significant. The fatty acid data were analyzed with a single tailed *t*-test. All statistical analyses were performed with the PC SAS Data System, Version 6.11, obtained under license from the SAS Institute, PC-SAS (SAS PC Manual, SAS Institute, Chapel Hill, NC, 1993).

## RESULTS

*Blood lipids*. Table 4 shows the blood lipid values for both intervention and control groups on days 30 (end of baseline) and 93 (end of intervention). Consuming CLA for 63 d did not alter the plasma LDL cholesterol and HDL cholesterol levels of the volunteers in the intervention group. In fact, their levels did not differ significantly from the values of their counterparts in the control group. Although the total cholesterol values of both groups decreased somewhat, neither group's value reached statistical significance. Although plasma TG levels did decrease in both groups, most likely due to the consumption of a 30% fat diet, the difference between the intervention and control groups was not significant.

*Apolipoproteins (apo)*. Table 5 lists the values for apo A-1 and B before and after the subjects consumed the CLA supplement for 63 d. Whereas the intervention group did not exhibit any significant change in the apo A-1, the control group did show a significant change after 63 d on the placebo containing linoleic acid. This may be due to the added linoleic acid in the diet of the control group or an artifact of the paired *t*-test as the difference was small and the standard deviation large. However, all seven subjects showed a decrease in their level of apo-A-1—an effect that would have large impact on a paired *t*-test. Apo-B values differed significantly between the baseline and the end of intervention at the $P < 0.05$ level, but for the control group did not. The absolute change in apo-B was 2.7 mg/dL in the intervention group and 4.7 mg/dL in the control group. The difference in the intervention group, while statistically significant, is unlikely to have any major physiological impact. This apparent statistical anomaly is probably due to the use of a paired *t*-test. A paired *t*-test gives more significance to a group in which a particular change occurs in the same direction for each menber of the group than for a group which has both positive and negative changes as was true here for the intervention and control group, respectively.

*Plasma fatty acids*. After a 63-d intervention, the supplementation did increase CLA in plasma but we found only 4.23% of the ingested CLA in plasma on any given day. While the major increase in the CLA isomer was the 9 *cis*-,11 *trans*-variety, there were noticeable increases in several of the other CLA isomers as well. The weight percentage of CLA in plasma increased from 0.28 ± 0.06 to 1.09 ± 0.31 ($n = 10$, $P < 0.05$) after the supplementation. The 9 *cis*-,11 *trans*-isomer was the most prominent variety followed by the

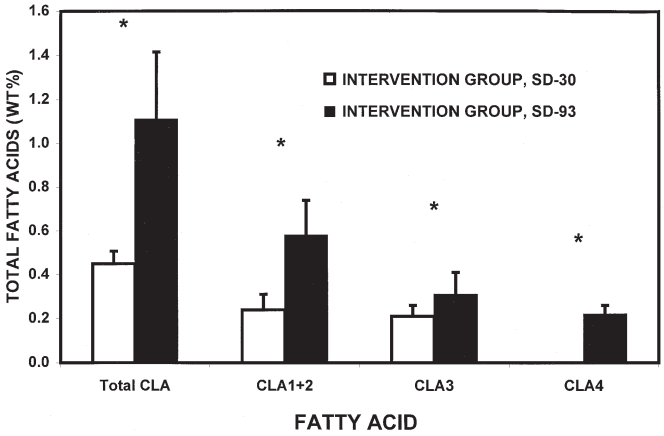

**FIG. 1.** The major conjugated linoleic acid (CLA) isomers found in plasma after supplementation with 3.9 g/d of CLA for 63 d. An asterisk indicates that the baseline and intervention values differed significantly at a $P < 0.05$ level using a paired *t*-test. CLA1 is the 9*c*,11*t*-18:2 isomer; CLA2 is the 8*t*,10*c*-18:2 isomer; CLA3 is the 11*c*,13*t*-18:2 isomer; and CLA4 is the 10*t*,12*c*-18:2 isomer. SD, study day.

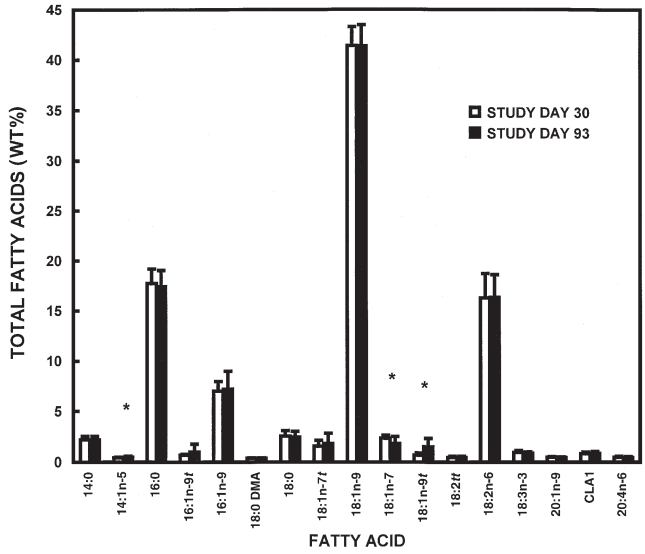

**FIG. 2.** The fatty acid composition of total lipid extract of adipose tissue before and after supplementation with 3.9 g/d of CLA for 63 d. An asterisk indicates that the baseline and intervention values differed significantly at a $P < 0.05$ level using a paired *t*-test. Fatty acids are designated with a shorthand where the number of carbon atoms in the chain is followed by the number of double bonds and the position of the first double bond from the methyl end of the molecule. DMA stands for dimethyl acetal; *c* for *cis*; and *t* for *trans*. CLA1 is the 9*c*,11*t*-18:2 isomer.

11 *cis*-,13 *trans*- and 10 *trans*-,12 *cis*-isomers in lesser amounts (see Fig. 1). Still, the total amount of CLA (all isomers) found in the plasma was rather small and well below the total amount consumed on a daily basis. Despite the presence of many CLA isomers in the diet, there was a bioconcentration of the 9 *cis*-,11 *trans*-18:2 variety followed by the 11 *cis*-,13 *trans*- and 10 *trans*-,12 *cis*-isomers. Also, the consumption of CLA appeared to have little or no effect on the major fatty acid composition of plasma, i.e., none of the major fatty acids such as linoleic, oleic, or palmitic acid showed significant changes in its percentage in plasma (data not shown). There was a slight rise in the plasma *trans*-18:1n-9 content in the intervention group, but we have no explanation for this change. It is also worth noting that the control group's plasma (data not shown) did not exhibit an increase in *trans*-18:1n-9 which did occur in the intervention group's plasma.

*Adipose tissue*. CLA in adipose tissue was not influenced by the supplementation (0.79 ± 0.18 to 0.83 ± 0.19 wt%) ($n$ = 10), and the 9 *cis*-,11 *trans*-variety was the only isomer present. This isomer is present in normal humans who are not taking CLA supplements and presumably is slowly incorporated into adipose tissue over many years. Short-term supplementation does not seem to have a detectable effect in 63 d. The adipose tissue fatty acid composition of the intervention group is shown in Figure 2.

## DISCUSSION

Antiatherogenic properties have been attributed to CLA (9,10) and are believed to be due, at least in part, to the changes in lipoprotein metabolism (9). Contrary to those hypocholesterolemic observations in animal studies, we did not observe any change in the levels of plasma cholesterol, LDL cholesterol, or HDL cholesterol in our study when the diet was supplemented with 3.9 g of CLA in an isocaloric substitution for linoleic acid for 63 d. Although at the end of the supplementation period we observed a decrease in the plasma TG levels in the intervention group, a similar reduction was also detected in the control group, indicating that this reduction was due to the consumption of the 30% fat diet by our normolipidemic subjects and not the CLA intervention. The fact that statistical difference was not achieved in the control group might have been due to the small sample size ($n$ = 7) or slightly higher TG values at baseline in the intervention group.

Lee *et al*. (9) reported that when rabbits were fed an atherogenic diet with or without CLA (0.5 g/d) for 22 wk, the CLA group showed markedly lower LDL cholesterol and TG levels in the blood by week 12 than did the control rabbits. The ratios of LDL to HDL cholesterol and total cholesterol to HDL cholesterol were significantly reduced by CLA feeding. The CLA-fed rabbits showed less atherosclerosis as estimated by examining the aorta of each animal at the end of the study. Similar effects in hamsters were reported by Nicolosi *et al*. (10). Those hamsters fed an atherogenic diet supplemented with CLA for 11 wk had lower plasma lipoprotein cholesterol and lipid levels and a significant reduction in aortic fatty streak formation when compared to controls fed an atherogenic diet alone or supplemented with linoleic acid.

Our intervention period lasted approximately 9 wk but the effects in the animal studies were detected after 11 or 12 wk. Whether a longer intervention period would have shown changes in the cholesterol and lipoprotein levels is not known. However, animals in those studies were fed a diet high in cholesterol and saturated fat while our human volunteers were all

healthy, normolipidemic subjects who consumed a low-fat diet. It is more difficult to achieve lipid reductions in normolipidemic individuals than in hyperlipidemic subjects (26,35,36). In our study, we fed the subjects a low-fat diet, instead of a hypercholesterolemic diet, to more accurately reflect the current eating habits of the U.S. population. Thus, our data indicate that, under the conditions of this study, consumption of dietary CLA at levels three to four times higher than those found in the normal diet does not have any effect on cholesterol and lipoproteins levels. Furthermore, there is no reason to expect a similar decrease in LDL cholesterol as total plasma cholesterol decreases between the control and intervention group. The placebo for the control group was high in linoleic acid, which is well known to selectively lower LDL cholesterol (LDL-C); thus, it is likely that we would observe different LDL-C values in the control and intervention group after 60 d on the two diets. Based on what is known about mono-*trans* fatty acids effects on LDL-C, there is no reason to believe that CLA would suppress LDL-C like linoleic acid. However, the decreases found here in the total cholesterol values of both groups did not reach statistical significance (see Table 4); thus, this issue does not seem to be a point worth discussing in any detail.

It is believed that humans do not have the inherent ability to synthesize CLA (37) and that most of the CLA in human tissues comes from dietary sources. Two studies of free-living persons showed that increased dietary intake of CLA increases plasma concentrations of CLA in men (38,39). Britton *et al*. (38) directed 14 subjects to consume self-selected diets, either high or low in CLA content, for 3 wk. Diet histories recorded by the subjects were used to estimate CLA intake. The serum phospholipid esterified CLA concentration and the molar ratio of CLA to linoleic acid increased significantly in the group consuming the high-CLA diet and decreased significantly in the group consuming the low-CLA diet. Huang *et al.* (39) reported that the amount of plasma phospholipid esterified CLA increased significantly (19–27%) after a dietary intervention in nine subjects who consumed approximately 100 g of Cheddar cheese (approximately 180 mg CLA) with their regular diets for 4 wk. As in Britton's study, the molar ratio of CLA to linoleic acid in the study of Huang *et al.* (39) also increased significantly after the dietary intervention.

In our controlled study, we found that plasma CLA isomers tended to reflect the CLA isomers in the supplement but were present in a smaller amount than would have been predicted from the amount fed to the volunteers. The weight percentage of plasma total CLA increased almost fourfold (from 0.28 to 1.09%) after the subjects consumed CLA for 63 d. In a typical, fasting, normolipidemic individual, there is a pool of 15 g of plasma fatty acid in the circulation based on a typical plasma total lipid level of 5 mg/dL and a 6-L blood volume. Normally, the plasma fatty acid profile reflects the fatty acid composition of dietary fat (40–43), but our calculation of the percentage of CLA in plasma (1.09%) after CLA supplementation indicated that only 4.23% of the ingested CLA was present on any given day. We observed that the 9 *cis*-,11 *trans*- and, perhaps, the 8 *trans*-,10 *cis*-isomers (since the chromatogram peaks were not separated at such low levels) were most abundant and that the 11 *cis*-,13 *trans*- and 10 *trans*-,12 *cis*-isomers existed in lesser quantities. It appears that, in humans, CLA is rapidly metabolized and eliminated from tissues. In fact, metabolites of CLA isomers were shown to occur in animal tissues (31,44). Data from Sébédio *et al*. (31) indicated that the 10 *trans*-,12 *cis*-18:2 isomer was metabolized to 8,12,14-20:3 and 5,8,12,14-20:4 in rats deficient in essential fatty acids.

It is interesting that we have found no increase in the level of CLA in the adipose tissue after feeding CLA for 63 d, yet the data on rats from Sugano *et al*. (45) indicate that adipose tissue and the lungs contained the highest proportion of the incorporated CLA. In humans, it appears that in the short term the increased dietary CLA metabolizes rapidly to other products and thus is not available for incorporation into adipose tissue. Despite the fact that Tonalin® contains isomers other than the 9 *cis*-,11 *trans*-variety, it is also interesting that this isomer was the only one present in the adipose tissue of the test subjects. As reported previously (21) in the platelets of those subjects who consumed CLA, we found mainly the 9 *cis*-,11 *trans*- and the 10 *trans*-,12 *cis*-isomers. Our supplement contained more than 20% of the 11 *cis*-,13 *trans*-isomer. It is believed that the 11 *cis*-,13 *trans*-isomer is an artifact of the synthetic process, and thus is not found in natural CLA present in food sources or produced by bacteria in the lumen of ruminants. The finding here suggests that this CLA isomer is not incorporated in tissues as readily as the CLA isomers normally found in the human food chain. We used the mixture of CLA isomers (Tonalin®) because purified isomers of CLA for human feeding trials were not available at the time we conducted this study. It should be noted that there was no obvious adverse effect on the health of the volunteers in this study.

Although no mechanism for CLA's beneficial effects in animal studies has been established, it is speculated that CLA may alter fatty acid composition and subsequent eicosanoid metabolism, perhaps by removing eicosanoid precursors such as arachidonic acid (46). In fact, arachidonic acid levels have been found to be reduced in the muscle and fat pad of CLA-fed rats (47). However, in our study the levels of arachidonate in adipose tissue did not change after the CLA feeding. Furthermore, we have not found any obvious beneficial effect of CLA supplementation. In other papers from this study (18–21), we have reported that CLA supplementation had little effect on platelet function and blood coagulation, indices of immune response, body composition, and appetite.

In summary, our study shows that, in normolipidemic subjects, CLA supplementation for 2 mon at a level three to four times that found in a typical Western diet offers no obvious benefit in terms of blood lipid and lipoprotein profile. Dietary CLA at this level caused a fourfold increase in the plasma CLA levels of the volunteers but only 4.23% of the ingested dietary CLA on any given day was found in the plasma.

Among all the isomers in the plasma, there was a bioconcentration of the 9 *cis-*,11 *trans*-18:2 isomer followed by the 11 *cis*-,13 *trans*- and 10 *trans*-,12 *cis*- varieties. Dietary CLA was not incorporated into adipose tissue at significant levels. In humans, CLA appears to metabolize rapidly to other products.

## ACKNOWLEDGMENTS

We would like to express our appreciation for the dietary and nursing staffs of the Metabolic Research Unit as well as the staff of the Bio-Analytical Lab at the WHNRC. We are also indebted to the subjects for their participation in this study and to Pharmanutrient, Inc. (Lake Bluff, IL) for their donation of the Tonalin® capsules.

# Peripheral Differential Leukocyte Counts in Humans Vary with Hyperlipidemia, Smoking, and Body Mass Index

**Zei-Shung Huang[a,*], Kuo-Liong Chien[a], Chi-Yu Yang[a], Keh-Sung Tsai[b], and Chiu-Hwa Wang[b]**

Departments of [a]Internal Medicine and [b]Laboratory Medicine, College of Medicine, National Taiwan University, 10016, Taipei, Taiwan, Republic of China

**ABSTRACT:** Reports of diverse relationships between blood concentrations of different lipids and peripheral total leukocyte count, and a unique lower peripheral monocyte count in hypercholesterolemia, have driven us to think that in humans, peripheral differential leukocyte counts may be influenced differently by different types of hyperlipidemia. Our subjects were Taipei residents who attended a regular health check program in our hospital in 1998. A total of 3,282 subjects was enrolled, including 1,677 normolipidemic, 960 untreated borderline hyperlipidemic, and 645 untreated hyperlipidemic subjects. By one-way analysis of variance (ANOVA), we found that different types of hyperlipidemia were associated with significant differences in differential leukocyte counts. In hypertriglyceridemia, the total leukocyte count and counts of all leukocyte subtypes were significantly higher than those in normolipidemia. Pure hypercholesterolemia, by contrast, was associated with a significantly lower monocyte count and no significant difference in other leukocyte counts. By two-way ANOVA adjusted for presence and degree of hyperlipidemia, we found significantly higher counts of total leukocytes and of all leukocyte subtypes in smokers, and significantly positive trends in relationships between body mass index (BMI) and counts of all leukocytes, neutrophils, lymphocytes, and monocytes. By multivariate regression analysis including all subjects, the serum triglyceride (TG) level was positively correlated with total leukocyte count and counts of all subtypes except eosinophils. On the contrary, serum high density lipoprotein-cholesterol had a negative correlation with total leukocyte count and with counts of neutrophils, monocytes, and basophils. In these multivariate regression analyses, there was no significant correlation between lipid levels and eosinophil count, whereas smoking was consistently associated with significantly higher counts of all leukocyte subtypes, including eosinophils. BMI had a significantly positive correlation with counts of all leukocytes, neutrophils, lymphocytes, and monocytes.

Paper no. L8472 in *Lipids 36,* 237–245 (March 2001).

Reports of a positive association between human peripheral total leukocyte counts and serum triglyceride (TG) levels (1,2), a negative association between peripheral total leukocyte count and serum high density lipoprotein (HDL)-cholesterol level (1–3), and a lower peripheral monocyte count in hypercholesterolemia (4) suggest that different types of hyperlipidemia may influence peripheral differential leukocyte counts differently. There is little information concerning this issue so far in the literature. An in-depth study on this point may help in understanding the pathophysiology of hyperlipidemia-induced atherosclerosis, since accumulating evidence from human studies has shown that hyperlipidemia is a major cause of atherosclerosis and cardiovascular disease (CVD) (5–7), that different types of leukocytes are likely to play important but different roles in atherosclerosis (8–10), and that a higher peripheral total leukocyte count is associated with an increased incidence of CVD (3,11–13). In addition, because cigarette smoking and obesity are frequently found in association with both lipid disorders (14–16) and a higher peripheral leukocyte count (1,3,13,17–19), we included the factors of smoking and body mass index (BMI) in the study.

## MATERIALS AND METHODS

*Study subjects.* Our subjects were selected from participants of a regular health check program in our hospital in 1998. The first condition for enrollment was to be a resident of the Taipei area including Taipei City and neighboring Taipei County. This condition was to ensure the feasibility of telephone interviews of hyperlipidemic and borderline hyperlipidemic subjects to see if they had received medication for hyperlipidemia before undergoing their health check in 1998. Among Taipei residents in 1998 who attended our health check program, 4,461 subjects were selected initially because they fit the following two conditions: (i) they had received serum lipid analysis with the same biochemical analyzer (Automatic Multichannel Biochemical Analyzer, Hitachi-7450; Hitachi, Tokyo, Japan); and (ii) they had received peripheral leukocyte analysis with the same blood cell counter (Sysmex Cell Counter NE-8000; TOA Medical Electronics, Kobe, Japan). Among the 4,461 subjects, 67 cases with serum TG level ≥ 450 mg/dL were separated as a special group because of the profound influence of their very high TG levels on the laboratory measurements of serum low density lipoprotein (LDL)-cholesterol levels. In the remaining 4,394 subjects, diagnoses of normolipidemia, untreated hyperlipidemia, untreated bor-

Abbreviations: ANOVA, analysis of variance; BMI, body mass index; CVD, cardiovascular diseases; HDL, high density lipoprotein; LDL, low density lipoprotein; SE, standard error; TC, total cholesterol; TG, triglyceride.

derline hyperlipidemia, and others were made according to the criteria listed in the following *Diagnostic criteria for hyperlipidemia* subsection, based on health records and results of telephone interviews for the history of and treatment for hyperlipidemia. Telephone interviews were conducted as follows. For each subject, at least seven calls were made, each call on a separate day, with the aim of having verbal communication with the enrolled subject personally over the telephone. Information from the family was considered unreliable and was not taken. Only information taken from the enrolled subjects themselves was used to conclude whether they had received medication for hyperlipidemia before undergoing the health check in 1998. Ultimately, 3,282 subjects were enrolled in the study, including 1,677 normolipidemic subjects, 645 untreated hyperlipidemic subjects, and 960 untreated borderline hyperlipidemic subjects. The 645 untreated hyperlipidemic subjects were subclassified into 102 cases of pure hypercholesterolemia, 187 cases of pure hypertriglyceridemia, 111 cases of combined hyperlipidemia, and 245 cases of probable combined hyperlipidemia.

*Laboratory data.* The following data were collected from the health records: (i) age, gender, weight, height, existence of a smoking habit, and history of and treatment for hyperlipidemia; and (ii) results of serum lipid study and leukocyte analysis. BMI was calculated as body weight/body height$^2$ (in kg/m$^2$). The items of the lipid study included serum levels of total cholesterol (TC), HDL-cholesterol, LDL-cholesterol, and TG (all in mg/dL). The leukocyte analyses included total leukocyte count (in $10^9$/L) and differential percentages (%) of neutrophils, lymphocytes, monocytes, eosinophils, and basophils, as analyzed by the same Sysmex Cell Counter NE-8000 as mentioned above. Any specimen with abnormal or atypical leukocytes that had been re-analyzed by using another blood cell counter was excluded from the study. The differential percentages of the above five kinds of leukocytes add up to 100%. The absolute count of a leukocyte subtype (in $10^9$/L) was calculated as the product of its respective differential percentage and total leukocyte count.

*Diagnostic criteria for hyperlipidemia.* (i) Hypercholesterolemia: The diagnosis of normocholesterolemia was made when serum TC level was <200 mg/dL and there was no history of treatment for hyperlipidemia. Untreated hypercholesterolemia was diagnosed in a subject with serum TC level ≥240 mg/dL and no previous treatment for hyperlipidemia. Untreated borderline hypercholesterolemia was diagnosed in a subject with serum TC level between 199 and 240 mg/dL and no previous treatment for hyperlipidemia. Those subjects with unknown or uncertain history of and/or treatment for hypercholesterolemia or who did not fit any of the above criteria for normocholesterolemia, untreated hypercholesterolemia, and untreated borderline hypercholesterolemia were classified as "others." (ii) Hypertriglyceridemia: The diagnosis of normotriglyceridemia was made when serum TG level was <130 mg/dL and there was no history of treatment for hyperlipidemia. Untreated hypertriglyceridemia was diagnosed in a subject with serum TG level ≥200 mg/dL and no previous treatment for hyperlipidemia. Untreated borderline hypertriglyceridemia was diagnosed in a subject with serum TG level between 129 and 200 mg/dL and no previous treatment for hyperlipidemia. Those subjects with unknown or uncertain history of and/or treatment for hypertriglyceridemia or who did not fit any of above criteria for normotriglyceridemia, untreated hypertriglyceridemia, and untreated borderline hypertriglyceridemia were classified as "others." (iii) Pure or combined hyperlipidemia: In untreated hyperlipidemic subjects, the presence of hypercholesterolemia with normotriglyceridemia was diagnosed to have "pure hypercholesterolemia," and the presence of hypertriglyceridemia with normocholesterolemia was diagnosed to have "pure hypertriglyceridemia." Subjects with both hypercholesterolemia and hypertriglyceridemia were diagnosed as having "combined hyperlipidemia." Those who had hypercholesterolemia with borderline hypertriglyceridemia or had hypertriglyceridemia with borderline hypercholesterolemia were diagnosed as having "probable combined hyperlipidemia."

*Statistical methods.* The data in the study were analyzed by using the SAS statistical program (SAS, Cary, NC) as follows: (i) The following comparisons were analyzed by one-way analysis of variance (ANOVA) using Bonferroni method to compare pairs of means: various laboratory measurements in normolipidemic and different hyperlipidemic groups (Tables 1 and 2), and differential leukocyte counts in negative, borderline, and positive groups for different types of hyperlipidemia separately (Table 3); (ii) the following comparisons were analyzed by two-way ANOVA: differential leukocyte counts between nonsmokers and smokers adjusted for the presence and degree of hyperlipidemia (Table 4) and differential leukocyte counts by three levels of BMI adjusted for the presence and degree of hyperlipidemia (Table 5); and (iii) multivariate regression analyses of differential leukocyte counts on age, gender, BMI, smoking, and serum lipid levels in all study subjects ($n$ = 3,282) were estimated by the ordinary least squares method (Tables 6 and 7).

## RESULTS

Table 1 shows the results of comparisons of age, various serum lipid levels, and differential leukocyte counts in normolipidemic, untreated borderline hyperlipidemic, and untreated hyperlipidemic groups by one-way ANOVA. The serum levels of TC, LDL-cholesterol, and TG and the counts of all leukocytes, neutrophils, lymphocytes, and basophils all had a significantly positive association with the presence and degree of hyperlipidemia ($P < 0.0001$). The serum HDL-cholesterol level, on the contrary, had a significantly negative correlation with the presence and degree of hyperlipidemia ($P < 0.0001$). The monocyte count in the hyperlipidemic group, but not in the borderline hyperlipidemic group, was significantly higher than that in the normolipidemic group ($P < 0.05$). There was no significant difference in eosinophil count in these three groups.

The results of comparisons of various laboratory measure-

**TABLE 1**
**Comparisons of Age, Serum Lipid Levels, and Peripheral Differential Leukocyte Counts in Normolipidemic, Untreated Borderline Hyperlipidemic, and Untreated Hyperlipidemic Groups by One-way ANOVA[a]**

| | | Serum lipid levels (mg/dL) | | | |
|---|---|---|---|---|---|
| | Age (yr) | TC | HDL-cholesterol | LDL-cholesterol | TG |
| Normolipidemic group ($n$ = 1,677) | 51.77 ± 0.32 | 169.1 ± 0.507 | 53.50 ± 0.331 | 99.31 ± 0.476 | 81.54 ± 0.606 |
| Borderline hyperlipidemic group ($n$ = 960) | 55.23 ± 0.37 | 201.9 ± 0.773 | 50.84 ± 0.478 | 124.4 ± 0.744 | 133.2 ± 1.271 |
| Hyperlipidemic group ($n$ = 645) | 54.67 ± 0.42 | 224.7 ± 1.526 | 46.08 ± 0.577 | 134.1 ± 1.553 | 223.6 ± 3.242 |
| $P$ value | <0.0001[b] | <0.0001[c] | <0.0001[c] | <0.0001[c] | <0.0001[c] |

| | Leukocyte count ($10^9$/L) | | | | | |
|---|---|---|---|---|---|---|
| | All leukocytes | Neutrophils | Lymphocytes | Monocytes | Eosinophils | Basophils |
| Normolipidemic group ($n$ = 1,677) | 6.055 ± 0.038 | 3.309 ± 0.029 | 2.126 ± 0.015 | 0.386 ± 0.003 | 0.197 ± 0.004 | 0.037 ± 0.001 |
| Borderline hyperlipidemic group ($n$ = 960) | 6.398 ± 0.050 | 3.500 ± 0.039 | 2.262 ± 0.020 | 0.392 ± 0.004 | 0.204 ± 0.004 | 0.039 ± 0.001 |
| Hyperlipidemic group ($n$ = 645) | 6.727 ± 0.063 | 3.657 ± 0.045 | 2.418 ± 0.027 | 0.403 ± 0.006 | 0.206 ± 0.006 | 0.043 ± 0.001 |
| $P$ value | <0.0001[c] | <0.0001[c] | <0.0001[c] | <0.05[d] | NS | <0.0001[c] |

[a]Values are means ± SE. NS, no significant difference.
[b]The mean age in the normolipidemic group was significantly lower than those in other two groups.
[c]For the specified lipid level or leukocyte count, there was a significant trend of relationship, either positively or negatively, in the normolipidemic, borderline hyperlipidemic, and hyperlipidemic groups.
[d]For the monocyte count, a significant difference exists only between the normolipidemic group and the hyperlipidemic group. ANOVA, analysis of variance; TC, total cholesterol; HDL, high density lipoprotein; LDL, low density lipoprotein; TG, triglyceride.

ments in normolipidemic, pure hypercholesterolemic, pure hypertriglyceridemic, combined hyperlipidemic, and probable combined hyperlipidemic groups by one-way ANOVA are shown in Table 2. Major findings include the following: (i) In the pure hypertriglyceridemic group, the total leukocyte count and counts of all leukocyte subtypes were significantly higher than those in the normolipidemic group. (ii) In contrast, in the pure hypercholesterolemic group, the total leukocyte count and counts of all leukocyte subtypes were not significantly different from those in the normolipidemic group. The monocyte count in the pure hypercholesterolemic group was significantly lower than that in normolipidemic group when compared by Student's $t$ test [$(0.350 \pm 0.015) \times 10^9$/L, $n$ = 102, and $(0.386 \pm 0.003) \times 10^9$/L, $n$ = 1,677, respectively, $P < 0.05$]. (iii) In the combined and the probable combined hyperlipidemic groups, the total leukocyte count and counts of neutrophils, lymphocytes, and basophils were significantly higher than those in the normolipidemic group. The obviously lower monocyte count in the patients with pure hypercholesterolemia was not seen in these combined hyperlipidemic groups.

The results of comparisons of differential leukocyte counts in negative, borderline, and positive groups for hypercholesterolemia, pure hypercholesterolemia, hypertriglyceridemia, and pure hypertriglyceridemia, made separately by one-way ANOVA, are listed in Table 3. The results confirmed several interesting findings in Tables 1 and 2. (i) In both the hypertriglyceridemic and the pure hypertriglyceridemic groups, the total leukocyte count and counts of all leukocyte subtypes were significantly higher than those in the normolipidemic group and showed significantly positive trends of relationships with the presence and degree of hypertriglyceridemia. (ii) In contrast, in the pure hypercholesterolemic group, only the monocyte count was significantly different from that in the normolipidemic group. It showed a negative relationship with the presence and degree of hypercholesterolemia. The significantly lower monocyte count in the pure hypercholesterolemic group, as compared with the normolipidemic group, did not exist in the hypercholesterolemic group that contained subjects with hypertriglyceridemia.

Because of well-documented positive associations between smoking and lipid disorders (14,15) and higher peripheral total leukocyte counts (1,3,13,17,18), we compared differential leukocyte counts between smokers and nonsmokers in normolipidemic, borderline hyperlipidemic, and hyperlipidemic groups by two-way ANOVA, as shown in Table 4. This analysis confirmed a higher total leukocyte count ($P < 0.0001$), resulting from higher counts of all leukocyte subtypes ($P$ values all <0.0001), in smokers after adjustments for presence and degree of hyperlipidemia. Obesity has been also associated with both lipid disorders (16) and higher peripheral total leukocyte counts (18,19). Comparisons of differential leukocyte counts by three levels of BMI in normolipidemic, borderline hyperlipidemic, and hyperlipidemic groups by two-way ANOVA showed a significantly positive relationship between BMI and counts of all leukocytes, neutrophils,

[a]Values are means ± SE.
[b]For age, significant difference exists only between the normolipidemic and the combined hyperlipidemic groups.
[c]For TC and LDL-cholesterol levels, there was no significant difference between the pure hypercholesterolemic and the combined hyperlipidemic groups.
[d]For HDL-cholesterol level, there was no significant difference between the combined hyperlipidemic and the probable combined hyperlipidemic groups.
[e]For TG level, significant difference exists between any two study groups.
[f]For all leukocytes, neutrophils, lymphocytes, and basophils, the counts from the normolipidemic group were significantly lower than those in other study groups except for the pure hypercholesterolemic group.
[g]For monocytes, the count for the normolipidemic group was only significantly lower than that in the pure hypertriglyceridemic group, and the pure hypercholesterolemic group was significantly lower than those in other three hyperlipidemic groups.
[h]For eosinophils, the count for the normolipidemic group was only significantly lower than that in the pure hypertriglyceridemic group, and the pure hypercholesterolemic group was significantly lower than those in pure hypertriglyceridemic and probable combined hyperlipidemic groups. For abbreviations see Table 1.

lymphocytes, and monocytes after adjustments for presence and degree of hyperlipidemia (Table 5).

In all subjects taken together ($n$ = 3,282), there were universal significant linear correlations between any two levels of serum TC, HDL-cholesterol, LDL-cholesterol, and TG. The correlation coefficients and probability values estimated by Pearson's analysis were as follows (data not shown in tables): TC and HDL-cholesterol, $R = 0.1904$, $P < 0.0001$; TC and LDL-cholesterol, $R = 0.9041$, $P < 0.0001$; TC and TG, $R = 0.3473$, $P < 0.0001$; HDL-cholesterol and LDL-cholesterol, $R = -0.0474$, $P < 0.01$; HDL-cholesterol and TG, $R = -0.4596$, $P < 0.0001$; and LDL-cholesterol and TG, $R = 0.1570$, $P < 0.0001$. These significantly linear correlations are likely to have a great influence on the demonstration of true correlations between each lipid level and the differential leukocyte counts in a multivariate regression analysis including all lipid levels. Therefore, we performed the multivariate regression analysis repeatedly using one kind of lipid level each time, adjusted for age, gender, BMI, and smoking. The results, as listed in Table 6, revealed the following: (i) Smoking was associated independently with higher total leukocyte count and counts of all leukocyte subtypes; (ii) age had independently negative correlations with total leukocyte count and counts of all leukocyte subtypes except neutrophils; (iii) BMI had independently positive correlations with total leukocyte count and counts of neutrophils, lymphocytes, and monocytes; (iv) men had significantly higher counts of monocytes and eosinophils; (v) serum levels of TC, LDL-cholesterol, and TG all had independently positive correlations with total leukocyte count ($P$ values all <0.0001), neutrophil count ($P < 0.01$, <0.01, and <0.0001, respectively), and lymphocyte count ($P$ values all <0.0001); (vi) serum TC and TG levels also had independently positive correlations with basophil count ($P < 0.01$ and <0.0001, respectively). Serum TC level

[a]Values are means ± SE.
[b]The diagnosis of hypercholesterolemia did not exclude coexisting hypertriglyceridemia or borderline hypertriglyceridemia, whereas a diagnosis of pure hypercholesterolemia was made only when serum TG level was normal. The difference between hypertriglyceridemia and pure hypertriglyceridemia is similarly defined.
[c]For the specified leukocyte count, there was a significant positive trend of relationship in the negative, borderline, and positive groups.
[d]Significant difference exists only between the group with the largest mean value and the group with the smallest mean value. For abbreviations see Table 1.

had an independently negative correlation with monocyte count ($P < 0.05$); (vii) serum HDL-cholesterol level had independently negative correlations with total leukocyte count ($P < 0.0001$), neutrophil count ($P < 0.0001$), monocyte count ($P < 0.0001$), and basophil count ($P < 0.05$); and (viii) interestingly, there was no significant correlation between the studied lipid levels and eosinophil count in these multivariate regression analyses.

To see which lipid levels were most closely associated with each type of leukocyte, we performed the multivariate regression analyses (Table 6) a second time including the serum levels of HDL-cholesterol, LDL-cholesterol, and TG simultaneously. The serum TC level was excluded because of its extremely strong positive linear correlation with serum LDL-cholesterol level ($R = 0.9041$). The major findings, as shown in Table 7, are as follows: (i) Serum TG level was an independently positive determinant for total leukocyte count and for counts of all leukocyte subtypes except eosinophils.

[a]Values are means ± SE. In the statistical analysis, the normolipidemic, borderline hyperlipidemic, and hyperlipidemic groups were represented digitally by 0, 1, and 2, respectively, and the groups of BMI < 22, BMI = 22–25, and BMI > 25 were represented by 0, 1, and 2, respectively.
[b]Probability values were tested for different lipid groups and adjusted for BMI levels.
[c]Probability values tested for BMI levels and adjusted for different lipid groups. BMI, weight (kg)/height$^2$ (m$^2$); for other abbreviations see Table 1.

It was the only independent determinant for basophil count among the studied lipid levels; (ii) serum HDL-cholesterol level was an independently negative determinant for total leukocyte count and for counts of neutrophils and monocytes, and it was an independently positive determinant for lymphocyte count; and (iii) serum LDL-cholesterol level had independently positive correlations with total leukocyte count and counts of neutrophils and lymphocytes. The same multivariate regression analyses in Table 7 were performed once again after replacing the serum LDL-cholesterol level with serum TC level. The results were very similar to those in Table 7, probably because of the strong positive linear correlation between LDL-cholesterol level and TC level.

Among the 67 subjects not included in the above analyses owing to a very high TG level (≥450 mg/dL) that interfered with the laboratory calculation of serum LDL-cholesterol level, 33 patients had never received medication for hyperlipidemia before their health check in 1998. The mean ± SE of age, serum lipid levels, and differential leukocyte counts in these 33 untreated extremely hypertriglyceridemic subjects were as follows: age, 49.73 ± 2.06 yr; TC level, 220.1 ± 6.598 mg/dL; HDL-cholesterol level, 35.15 ± 1.346 mg/dL; TG level, 561.8 ± 19.32 mg/dL; total leukocyte count, (7.391 ± 0.330) × $10^9$/L; neutrophil count, (4.134 ± 0.269) × $10^9$/L; lymphocyte count, (2.501 ± 0.099) × $10^9$/L; monocyte count, (0.458 ± 0.031) × $10^9$/L; eosinophil count, (0.247 ± 0.027) × $10^9$/L; and basophil count, (0.051 ± 0.005) × $10^9$/L. The means of these leukocyte counts were all obviously higher than those in the normolipidemic group, the untreated borderline hyperlipidemic group, and the untreated hyperlipidemic group (see data in Table 1), but probably because of a small sample size with a large SE in the extreme hypertriglyceridemic group, only the differences in total leukocyte count and counts of neutrophils and monocytes reach statistical significances estimated by using Student's $t$ test. When compared with the pure hypertriglyceridemic group (with serum TG level between 199 and 450 mg/dL, see data in Table 2), the means of all leukocyte counts in the extreme hypertriglyceridemic group were also all higher, but only the differences in total leukocyte count and neutrophil count reach statistical significances by Student's $t$ test [(6.713 ± 0.107 vs. 7.391 ± 0.330) × $10^9$/L and (3.671 ± 0.082 vs. 4.134 ± 0.269) × $10^9$/L, respectively, both $P < 0.05$].

## DISCUSSION

Although several human studies have found different associations between peripheral total leukocyte count and different serum lipid levels (1–3), the actual relationships between counts of different leukocyte types and different patterns of hyperlipidemia in humans have been unclear. Our study has shown that different types of hyperlipidemia are associated with very different peripheral differential leukocyte counts (Tables 2 and 3). A higher peripheral total leukocyte count in human hyperlipidemia (Table 1) was associated with pure hypertriglyceridemia but not pure hypercholesterolemia (Table 2), and the higher total leukocyte count in hypertriglyceridemia seemed secondary to higher counts of all leukocyte subtypes (Tables 2 and 3). In multivariate regression analyses, we demonstrated that serum TG level had independent and positive correlations with total leukocyte count and counts of all leukocyte subtypes except eosinophils (Tables 6 and 7) and serum TG was the only lipid level having an independent correlation with basophil count (Table 7). The means of total leukocyte count and counts of all leukocyte subtypes in the extreme hypertriglyceridemic group were all higher than those in the pure hypertriglyceridemic group, although only the differences in total leukocyte count and neu-

[a]Regression coefficients were estimated by ordinary least squares method, and probability values were calculated by $t$-test.
[b]In the statistical analysis, female, male, nonsmoker, and smoker were represented digitally by 0, 1, 0, and 1, respectively. For abbreviations see Tables 1 and 5.

trophil count reached statistical significances (see data in the last paragraph of the Results section). There is accumulating evidence from human studies that hypertriglyceridemia is a risk factor for atherosclerosis and CVD (6,7), and it seems likely that different leukocytes play different roles in atherogenesis (8–10,20). A higher peripheral total leukocyte count is associated with a higher risk of CVD (3,11–13) and the association of hypertriglyceridemia with a higher CVD risk

[a]Regression coefficients were estimated by ordinary least squares method, and probability values were calculated by *t*-test.
[b]In the statistical analysis, female, male, nonsmoker, and smoker were represented digitally by 0, 1, 0, and 1, respectively. For abbreviations see Tables 1 and 5.

may relate in part to its coexistence with higher peripheral counts of all leukocyte subtypes (Tables 2 and 3), probably except eosinophils (Tables 6 and 7).

For pure hypercholesterolemia, the results were quite different from those in pure hypertriglyceridemia. Compared with the normolipidemic group, pure hypercholesterolemia was associated with a significantly lower monocyte count and no significant difference in other leukocyte counts (Tables 2 and 3). Such a result may be partly related to the following complex relationships: (i) Both serum HDL-cholesterol and LDL-cholesterol levels were significantly higher in the pure hypercholesterolemic group (Table 2); (ii) there were independent and negative correlations between serum HDL-cholesterol level and total leukocyte count and counts of neutrophils and monocytes (Tables 6 and 7); and (iii) there were independent and positive correlations between serum LDL-cholesterol level and total leukocyte count and counts of neutrophils and lymphocytes (Tables 6 and 7). A finding in Table 3 worth mentioning here is that the significantly lower monocyte count in the pure hypercholesterolemic group, as compared with the normolipidemic group, did not exist in the hypercholesterolemic group. The reason may be simply that the hypercholesterolemic group contained subjects with hypertriglyceridemia that was associated with a significantly higher monocyte count which had masked the presence of a significantly lower monocyte count associated with hypercholesterolemia.

The significantly lower monocyte count in pure hypercholesterolemia (Tables 2 and 3) and the independent and negative correlations between serum HDL-cholesterol level and counts of both monocytes and neutrophils (Tables 6 and 7) may be related to an anti-inflammatory effect of HDL particles. Several studies of humans have shown the abilities of HDL to bind inflammatory mediators, neutralize their leukocyte chemotactic activities, and thus attenuate the inflammation- or infection-induced increase in the count or recruitment of leukocytes, especially the monocytes and neutrophils (21, 22). In this way, HDL may ultimately reduce the peripheral monocyte and neutrophil counts. This may be one of the reasons that a high circulating HDL-cholesterol level is antiatherogenic (23,24) in view of the possible underlying immunoinflammatory nature of atherosclerosis (8,10).

Smoking has been well documented to have a positive effect on peripheral total leukocyte count (17,18). Our study not only confirms such an independent and positive link between smoking and total leukocyte count but also reveals that such a link is related to independent and positive links between smoking and counts of all leukocyte subtypes (Tables 4, 6, and 7). These results strongly indicate that whenever peripheral leukocyte counts are the subjects of study, the factor of smoking should always be considered and included. Obesity has also been found to be associated with a higher peripheral total leukocyte count (18,19). Our study confirms the existence of an independent and positive correlation between BMI and total leukocyte count and, furthermore, demonstrates independent and positive correlations between BMI and counts of neutrophils, lymphocytes, and monocytes (Tables 5, 6, and 7). These findings, together with other related results in the study and a positive association between obesity and lipid disorders (16), imply a close and complex inter-

relationship among obesity, hyperlipidemia, and counts of neutrophils and monocytes.

In summary, our study revealed that an increase in peripheral total leukocyte count in hyperlipidemia is mainly associated with a higher serum TG level and the presence of hypertriglyceridemia. The higher total leukocyte count in hypertriglyceridemia is apparently due to increases in counts of all leukocyte subtypes except eosinophils. In contrast, pure hypercholesterolemia is associated with a lower monocyte count, possibly related to both a higher serum HDL-cholesterol level in pure hypercholesterolemia and a negative link between serum HDL-cholesterol level and monocyte count. Our study also reveals that smoking is independently associated with higher total leukocyte count and counts of all leukocyte subtypes, and BMI has independent and positive correlations with total leukocyte count and counts of neutrophils, monocytes, and lymphocytes.

**ABSTRACT:** Diet and fatty acid metabolism interact in yet unknown ways to modulate membrane fatty acid composition and certain cellular functions. For example, dietary precursors or metabolic products of n-3 fatty acid metabolism differ in their ability to modify specific membrane components. In the present study, the effect of dietary 22:6n-3 or its metabolic precursor, 18:3n-3, on the selective accumulation of 22:6n-3 by heart was investigated. The mass and fatty acid compositions of individual phospholipids (PL) in heart and liver were quantified in mice fed either 22:6n-3 (from crocodile oil) or 18:3n-3 (from soybean oil) for 13 wk. This study was conducted to determine if the selective accumulation of 22:6n-3 in heart was due to the incorporation of 22:6n-3 into cardiolipin (CL), a PL most prevalent in heart and known to accumulate 22:6n-3. Although heart was significantly enriched with 22:6n-3 relative to liver, the accumulation of 22:6n-3 by CL in heart could not quantitatively account for this difference. CL from heart did accumulate 22:6n-3, but only in mice fed preformed 22:6n-3. Diets rich in non-22:6n-3 fatty acids result in a fatty acid composition of phosphatidylcholine (PC) in heart that is unusually enriched with 22:6n-3. In this study, the mass of PC in heart was positively correlated with the enrichment of 22:6n-3 into PC. The increased mass of PC was coincident with a decrease in the mass of phosphatidylethanolamine, suggesting that 22:6n-3 induced PC synthesis by increasing phosphatidylethanolamine-*N*-methyltransferase activity in the heart.

Paper no. L8504 in *Lipids 36,* 247–254 (March 2001).

Dietary oils rich in n-3 fatty acids have cardioprotective effects including the inhibition of ischemia-reperfusion induced cardiac dysfunction in rats (1–3), reduced arrhythmia in normal or ischemic marmoset monkeys (4) and rats (5), and the prevention of ischemia-induced ventricular fibrillation in dogs (6). Dietary 22:6n-3 is at least in part responsible for these effects. Docosahexaenoic acid given as a dietary supplement in the absence of other n-3 fatty acids increased the survival of isolated rat cardiomyocytes subjected to hypoxia/reoxygenation (7), altered cardiomyocyte beta-adrenergic function (8), inhibited ischemia-induced arrhythmias in rats (9), and lowered the heart rate of humans (10,11). The mechanisms underlying these cardioprotective actions are not yet understood, nor is it known how 22:6n-3 accumulates in specific cells and membrane components.

Heart phospholipids (PL) rapidly accumulate 22:6n-3 in response to dietary 22:6n-3 (12–14). Although 22:6n-3 is usually consumed in the form of marine oils that also contain 20:5n-3, the accumulation of 22:6n-3 in heart PL occurs without a similar increase in heart 20:5n-3 content (12,14–16), suggesting a specific mechanism for the uptake and/or retention of 22:6n-3. One possible mechanism for the accumulation of 22:6n-3 in heart would be a highly selective incorporation into PL classes that are notably rich in heart. Heart tissue is mitochondria-dense and as a result, the mitochondrial PL cardiolipin (CL) comprises as much as 15% of the PL mass of rat heart (17,18). Since dietary 22:6n-3 is known to enrich CL with 22:6n-3 to as much as 50 mol% of its fatty acid composition (12,19), the high concentration of CL in heart tissue may explain the selective incorporation of 22:6n-3 in heart.

Considerable information can be obtained from the relative fatty acid compositions of individual lipid classes. The present study was designed to couple highly quantitative data on fatty acid and lipid class mass with precise compositional data. Combined, accurate mass and compositional data provide a powerful tool for making metabolic inference. To determine the effect of dietary n-3 fatty acids on the mass of individual lipid classes in heart, dietary 22:6n-3 [from crocodile oil (CRO), which contained 1.1 and 2.9 mol% 20:5n-3 and 22:6n-3, respectively] was compared with 18:3n-3 [from soybean oil (SO), which contained 7.4 mol% 18:3n-3 as the only source of n-3 fatty acid] for its influence on the mass and fatty acid composition of liver and heart PL classes.

## MATERIALS AND METHODS

*Reagents.* All chromatography solvents were obtained from Fisher Scientific (Pittsburgh, PA). Silica Gel 60 thin-layer chromatography (TLC) plates (10 × 20 cm) were obtained

Abbreviations: CE, cholesterol ester; CL, cardiolipin; CRO, crocodile oil; FFA, free fatty acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PEMT, phosphatidylethanolamine-*N*-methyltransferase; PL, phospholipids; SO, soybean oil; TG, triacylglyceride; TLC, thin-layer chromatography.

from E. Merck (Darmstadt, Germany). EDTA and butylated hydroxytoluene were obtained from Sigma Chemical Co. (St. Louis, MO). Fatty acid methyl ester standards were obtained from Nu-Chek-Prep (Elysian, MN), and internal standard PL were obtained from Avanti Polar Lipids (Alabaster, AL).

*Animals*. Litters of mice were obtained from a breeding colony of HTLV-1 mice derived from an original founder line (20) maintained at the University of California, Davis. Weanling, 21-d-old mice were housed either individually or as same-sex pairs from identical liters in stainless steel wire-bottomed cages in a room with a 12-h light and 12-h dark cycle at 20–23°C and 50% relative humidity. Mice were assigned to each diet group and fed until 112 d of age. At that time, the mice were killed and the tissues harvested for fatty acid analyses.

*Diets*. Mice were fed a nutritionally adequate, amino acid-based diet (21) (Dyets, Bethlehem, PA), without added succinyl sulfathiazole, in which essential fatty acid requirements were met by addition of 0.5% SO by weight. Dietary CRO or SO were added at 6.5% by weight; thus the total dietary fat content was 7% by weight. CRO was chosen because it is a novel food oil with a low concentration of 20:5n-3 and 22:6n-3. Seven mice fed SO and four mice fed CRO were used in these analyses. The CRO was a gift (Madagascar CrocFarm, Ivato, Madagascar). Diets were fed to the mice for 13 wk before necropsy and tissue harvest following $CO_2$ anesthesia. Animal care and use protocols were approved by the University of California, Davis, Animal Welfare committee. The fatty acid composition of each dietary oil (Table 1) was determined by gas chromatographic analysis. Preparation of fatty acid methyl esters and chromatographic conditions are described below. Mice had unrestricted access to food and water and were provided fresh food daily.

*Extraction and TLC*. TLC plates were impregnated with 1 mM EDTA, pH 5.5, and washed by ascending development using the method of Ruiz and Ochoa (22). Just before use, each plate was activated by heating at 110°C for 10 min and allowed to cool to room temperature. Lipids were extracted from *ca.* 100 mg of tissue by homogenization in 6 mL chloroform/methanol, (2:1, vol/vol) (23). Phosphatidylcholine (PC) and CL internal standards (Avanti Polar Lipids) were added to facilitate quantification. Sample extracts were dried under nitrogen and spotted onto EDTA-impregnated TLC plates. Two TLC standard lanes consisting of authentic PC, phosphatidylethanolamine (PE), CL, and free fatty acid (FFA) were spotted on the outside lanes of the TLC plate as reference samples. The mobile phase employed for the separation of PL classes was a modification of the solvent system described by Holub and Skeaf (24) that consisted of chloroform/methanol/acetic acid/water (100:67:7:4, by vol). For the separation of lipid classes [total PL, FFA, triacylglycerides (TG), and cholesterol esters (CE)], a solvent system consisting of petroleum ether/diethyl ether/acetic acid (80:20:1, by vol) (25) was employed.

*Isolation and methylation of lipid classes*. Lipid classes and individual PL classes were identified by comparison with the authentic standards chromatographed in the reference lanes. Reference samples were visualized by cutting the reference lanes from the plate, dipping the reference lanes in 10% cupric sulfate/8% phosphoric acid, and charring them at 200°C. The reference lanes were then compared to the uncharred plate to determine the location of individual lipid classes in the sample. Each lipid fraction was scraped from the plate and methylated by incubating the silica in 3 N methanolic-HCl in sealed vials under a nitrogen atmosphere at 100°C for 45 min. Fatty acid methyl esters were extracted with hexane containing 0.05% butylated hydroxytoluene and prepared for gas chromatography by sealing the hexane extracts under nitrogen.

*Fatty acid analysis.* Fatty acid methyl esters were separated and quantified by capillary gas chromatography using a Hewlett-Packard (Wilmington, DE) gas chromatograph (model 6890) equipped with a 60 m DB-23 capillary column (J&W Scientific, Folsom, CA), a flame-ionization detector, and Hewlett-Packard ChemStation software.

*Data analysis*. The mass of total fatty acids, PL fatty acids, PC fatty acids, and CL fatty acids were quantified per gram of tissue using the internal standards described above. TG, FFA, and CE were quantified by adding 5 μg of tritridecanoin as an internal standard to each fraction after TLC separation. The ratio of the sum of areas from fatty acids to the area of tridecanoic acid in each chromatogram was used to calculate the mass fraction of each lipid class. PE was calculated as the difference between the mass of total PL and the sum of the masses of PC and CL. Therefore, mass data for PE include the masses of other minor PL including phosphatidylserine and sphingomyelin. However, PC, PE, and CL represent 90 wt% of the PL mass of heart tissue (26,27), and thus the majority of this fraction is composed of PE. The statistics were performed in the Statistical Support Laboratory at the University of California at Davis. Differences between tissues,

lipid classes, and diets were determined by a multivariate GLM/ANOVA using SAS/STAT (Cary, NC). Correlation analyses were performed in Excel '97 (Microsoft Co., Redmond, WA), and significance was assigned to a correlation if the absolute value of the Pearson's sample correlation coefficient ($r$) was greater than the critical value for significance. Linear regressions were also performed in Excel '97.

## RESULTS

*Fatty acid composition*. SO contained 18:3n-3 as the only source of n-3 fatty acid, whereas CRO contained 22:6n-3, 20:5n-3, and 18:3n-3 (Table 1). The fatty acid compositions of total PL, PC, PE, and CL in heart from mice fed SO or CRO are shown in Table 2. The fatty acid compositions of total PL, PC, PE, and CL from liver in mice fed SO or CRO are shown in Table 3. Only trace amounts of dietary 18:3n-3 accumulated as 18:3n-3 in liver or heart PL, indicating that the fatty acid was rapidly catabolized, exported, or converted to 20:5n-3, 22:5n-3, or 22:6n-3. Eicosapentaenoic acid was also poorly accumulated by heart PL. However, PC and PE from liver of mice fed CRO each contained 1.7 mol% 20:5n-3. In stark contrast to the low concentrations of 18:3n-3 and 20:5n-3 found in tissues, PL from the hearts of mice fed SO or CRO contained 23.4 and 32.3 mol% 22:6n-3, respectively. Heart PL, therefore, were rich in 22:6n-3, regardless of whether 22:6n-3 was fed intact (as a component of CRO) or as its precursor 18:3n-3 (as a component of SO). With respect to 22:6n-3, tissue-specific incorporation of the fatty acid was clearly more important than the dietary source of n-3 fatty acid. Table 4 shows the differential enrichment of heart and liver with 22:6n-3. The percentage difference in the 22:6n-3 of heart relative to liver was consistent in both PC and PE, regardless of the type of dietary n-3 fatty acid. Surprisingly, the 22:6n-3 content of CL was similar for heart and liver from mice fed SO. However, the CL in heart from mice fed CRO contained 104% more 22:6n-3 than did the CL in liver. Table 5 shows the percentage difference in the amount of 22:6n-3 in PL classes between mice fed CRO and mice fed SO. The total PL, PC, and PE from heart and liver incorporated more 22:6n-3 when mice were fed CRO than when the mice were fed SO. The percentage increase in the amount of 22:6n-3 in total PL, PC, and PE of mice fed CRO relative to mice fed SO was consistent between heart and liver. However, the CL in heart from mice fed CRO contained 318% more 22:6n-3 than the CL in heart of mice fed SO. The magnitude of this difference was not mirrored in liver, where mice fed CRO had only 82% more 22:6n-3 than mice fed SO. Therefore, unlike PC and PE, the 22:6n-3 content of CL was dependent on the form of dietary n-3 fatty acid.

*Lipid mass analysis.* The mass of total lipids, total PL, FFA, TG, CE, PC, PE, and CL from heart or liver were measured by quantifying the mass of individual fatty acids present in each fraction. Diet did not significantly affect the mass of total lipid per gram of heart or liver. Heart tissue from mice fed SO or CRO contained 33.9 or 36.1 mg of fatty acid per

gram of tissue, respectively (data not shown). Liver tissue from mice fed SO or CRO contained 45.5 or 48.1 mg of fatty acid per gram of tissue, respectively (data not shown). Mass fractions for each lipid class were calculated by dividing the mass of PL, FFA, TG, or CE by the mass of total lipid (measured per gram of tissue). Mass fractions for PC and CL were calculated by dividing the mass of PC or CL by the mass of total PL. The mass fraction of PE was calculated by difference as described in the Materials and Methods section. Mass fraction data are shown in Table 6. The mass fractions of PL, FFA, TG, CE, PC, PE, and CL in liver were not different between mice fed SO or CRO. The mass fractions of PL, FFA, TG, CE, and CL in heart were not different between mice fed SO and mice fed CRO. However, the mass fraction of PC in heart from mice fed CRO was significantly greater than the mass fraction of PC in heart from mice fed SO. Therefore, although the amount of total PL per gram of heart was constant, there was a significant shift in the composition of total PL toward a greater amount of PC and a lesser amount of PE in mice fed CRO relative to mice fed SO. Heart contained similar amounts of total PL, but significantly more CL per gram than liver.

*Interaction between PL mass and fatty acid composition.* Because the mass fraction of PC was greater in mice fed CRO than in mice fed SO, regressions were performed to determine if specific fatty acids were associated with the increased mass of PC. All mice, regardless of dietary group, were included in the regressions. The mass fraction of PC in heart was significantly and positively correlated with the mol% of 22:6n-3 found in PC. Figure 1A shows a positive relationship between the amount of 22:6n-3 in the PC of heart and the mass frac-

tion of PC in heart. Ten other fatty acids (14:0, 16:0, 18:2n-6, 18:3n-3, 20:0, 20:2n-6, 20:3n-6, 20:4n-6, 22:0, and 24:1n-9) were significantly but negatively correlated with the mass fraction of PC in heart. Because these fatty acids were negatively correlated with heart PC content, they were likely co-variables of the incorporation of 22:6n-3 into PC. Indeed, the increase in 22:6n-3 mass observed in all mice accounted for 96% of the combined mass decrements in the other responsive fatty acids. A linear regression of the sum of the fatty acids negatively correlated with the PC content of heart, in mol%, plotted against the mol% of 22:6n-3 in the PC of heart produced a line with a slope of −1.04 and an $r^2$ of 0.96 (data not shown). This strongly indicated co-variation and that 22:6n-3, not the negatively correlated fatty acids, was linked to the greater PC content of heart. No fatty acid was significantly related to the mass fraction of any other lipid in heart. No fatty acid was significantly related to the mass fraction of any lipid in liver tissue. Figure 1B shows the absence of a relationship between the mol% of 22:6n-3 in the PC of liver and the mass fraction of PC in liver.

*Distribution of fatty acids among lipid classes*. Hearts from SO-fed mice contained 7.24 µg of 22:6n-3 per gram, whereas CRO-fed mice had 9.77 µg 22:6n-3 per gram of heart. The distribution of the mass of 22:6n-3 among lipid classes in heart and liver is shown in Table 7. Heart from mice fed SO contained only 0.19 µg of 18:3n-3 and less than 0.01 µg of 20:5n-3 per gram despite the fact that the mice consumed a diet containing 7.4 mol% 18:3n-3. Mice fed CRO had 0.03 µg of 18:3n-3 and 0.08 µg of 20:5n-3 per gram of heart, demonstrating a clear selection against uptake and/or

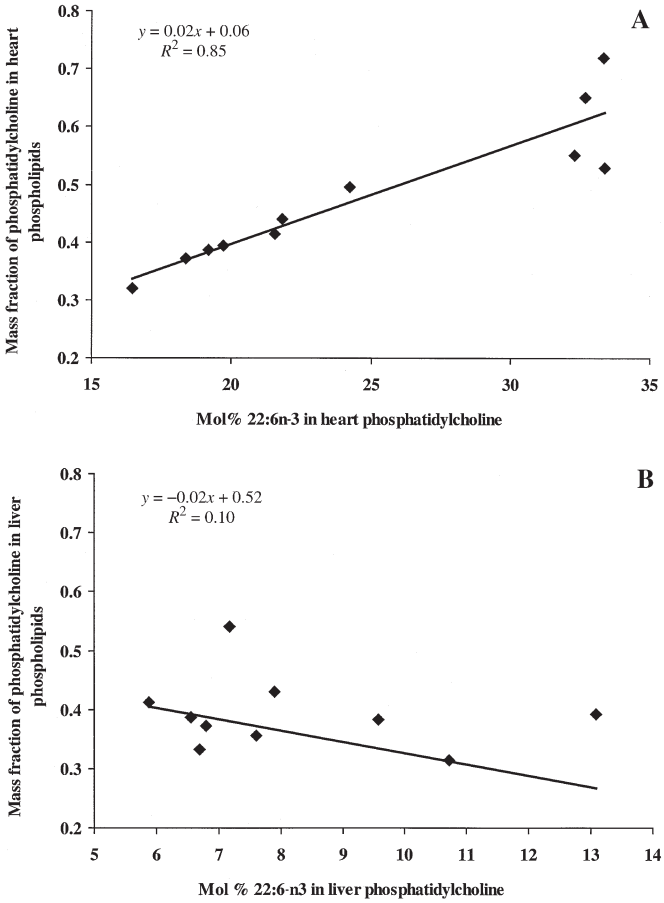

**FIG. 1.** (A) Relationship between 22:6n-3 and the mass of phosphatidylcholine in heart. The mass of phosphatidylcholine is expressed as a mass fraction of total phospholipids. Mass fractions were calculated for each mouse by dividing the mass of phosphatidylcholine per gram of heart by the mass of total phospholipids per gram of heart. The mass fraction of phosphatidylcholine was significantly and positively correlated with the 22:6n-3 content of phosphatidylcholine. (B) Relationship between 22:6n-3 and the mass of phosphatidylcholine in liver. The mass of phosphatidylcholine is expressed as a mass fraction of total phospholipids. Mass fractions were calculated for each mouse by dividing the mass of phosphatidylcholine per gram of liver by the mass of total phospholipids per gram of liver. Liver phosphatidylcholine content did not correlate with 22:6n-3 content.

retention of these fatty acids by the heart. The increased contribution of 22:6n-3 in the PC of mice fed CRO to the total 22:6n-3 in heart was directly proportional to an increase in the mass of PC (Tables 6 and 7). Likewise, the contribution of 22:6n-3 in PE to the total 22:6n-3 in heart was decreased proportionally with the decreased mass of PE in heart from mice fed CRO. However, 22:6n-3 from CL, which accumulated 22:6n-3 only when 22:6n-3 was fed intact, contributed a larger fraction of the total 22:6n-3 in heart from mice fed CRO without a proportional increase in the mass of CL.

## DISCUSSION

We applied a comprehensive lipid analysis technique encompassing both mass and compositional analyses to elucidate metabolic processes occurring in heart from mice fed 18:3n-3 or 22:6n-3. Whereas the retention of 22:6n-3 by all tissues may be due to the fact that 22:6n-3 is an extremely poor substrate for β-oxidation (28), the preferential accumulation of 22:6n-3 by heart remains unexplained. The basis for the preferential incorporation of 22:6n-3 into heart may be its accumulation in PL that are especially prevalent in heart. Several investigators have reported the rapid incorporation of 22:6n-3 into the CL of heart upon feeding 22:6n-3 or dietary oils containing 22:6n-3 (12,19,29). In the present study, heart from mice fed SO or CRO accumulated significantly more 22:6n-3 than did liver. However, CL did not accumulate more 22:6n-3 than other PL classes, and the mass of CL per gram of heart did not change in response to diet. Heart from mice fed SO and CRO contained 3.1 and 4.3 μg more 22:6n-3 per gram, respectively, than liver. Mass analysis demonstrated that 22:6n-3 in the CL of heart accounted for only 4 or 17 wt% of this difference in mice fed SO or CRO, respectively. Therefore, incorporation of 22:6n-3 into CL cannot quantitatively account for the preference of heart for 22:6n-3. Rather, 22:6n-3 accumulated preferentially in each of the PL classes of heart relative to liver. Thus, an explanation for the selective accumulation of 22:6n-3 in the heart cannot be based on the argument that heart is a CL-rich tissue.

With the notable exception of CL, the PL in heart were enriched with metabolic products of 18:3n-3 in mice fed SO. The abundance of 22:6n-3 in the hearts of animals fed SO suggested that either 18:3n-3 was converted to 22:6n-3 within the heart itself or that the heart preferentially accumulated fatty acids from a plasma lipid pool rich in 22:6n-3. It is not clear whether heart is capable of desaturating/elongating 18:3n-3 to 22:6n-3. However, production of 22:6n-3 from 18:3n-3 in heart could explain both why 22:6n-3 accumulates preferentially in heart and why 22:6n-3 accumulates in CL only when the dietary source of n-3 fatty acid is 22:6n-3.

When 22:6n-3 enters a cell intact, it is available for acylation into phosphatidic acid, a precursor to all PL, or for acylation into lyso-PL. Therefore, it is available for the biosynthesis or remodeling of all PL classes. However, when the n-3 fatty acid entering a cell is a precursor to 22:6n-3, there are two possible metabolic fates for the fatty acid apart from catabolism. The fatty acid is either acylated into glycerolipids or metabolized *via* elongation/desaturation to 22:6n-3. The data demonstrate that 18:3n-3 and 20:5n-3 are not accumulated by any glycerolipid in heart, but that mice fed 18:3n-3 had a substantial quantity of 22:6n-3 in the total PL of heart. The final step in the conversion of 18:3n-3 or any other n-3 fatty acid to 22:6n-3 requires a two-carbon chain-shortening reaction that takes place in the peroxisome (30–32). When the product of peroxisomal chain shortening contains a delta-four unsaturated bond, the fatty acid is preferentially moved to the endoplasmic reticulum for acylation into lyso-PL (32–34). Therefore, any 22:6n-3 produced from n-3 precursor by a cell is preferentially incorporated into PL that have synthesis or remodeling pathways present at the endoplasmic reticulum. If this metabolic pathway is active in heart, it would explain

the absence of an accumulation of 22:6n-3 in CL from mice fed 18:3n-3 because CL and the enzymes required for its synthesis and remodeling are present only in the inner-mitochondrial membrane (35–37). The conversion of 18:3n-3 to 22:6n-3 within the heart would also explain the preferential accumulation of 22:6n-3 by the heart.

In investigating the accumulation of 22:6n-3 by PL classes in heart, it was observed that the mass of 22:6n-3 in PC accounted for 26% more of the total mass of 22:6n-3 in heart in mice fed CRO than in mice fed SO (Table 7). The increased contribution of 22:6n-3 from PC to the total amount of 22:6n-3 in heart resulted from an increased mass of PC per gram of total PL. Regression and correlation analyses demonstrated that the mass of PC in heart was significantly and positively associated with the amount of 22:6n-3 in PC (Fig. 1A). This relationship remained significant even when mice fed CRO were removed from the regression, suggesting that dietary 18:3n-3 was also capable of increasing heart PC content. No relationship was found for liver PC content and 22:6n-3 (Fig. 1B). The data suggest that 22:6n-3 induced an increase in the PC content of heart. Because the increased mass of PC was not accompanied by an increase in the mass of total PL (Table 6), the mechanism for increasing PC was likely to be increased conversion from PE *via* phosphatidylethanolamine-methyl transferase (PEMT) activity (38), rather than *de novo* synthesis *via* the Kennedy pathway (39). Quantitative measurements of lipid and PL support this hypothesis (Table 6). Previously, PEMT activity was thought to contribute significantly to PL metabolism only in the liver, with nonliver organs expressing less than 2% of liver PEMT activity (38). However, the present study suggested that heart PEMT activity was induced by dietary n-3 fatty acids and that 22:6n-3 was responsible for this induction in heart. There is some precedent for an increase in PEMT activity in response to dietary lipid, as brain synapses and liver microsomes (40) contained increased PEMT activity in rats fed polyunsaturated fatty acids and coconut oil, respectively. There is also evidence for increased di-saturated PC synthesis in lung in response to 22:6n-3 (41,42). However, an increase in the activity of CTP:phosphocholine cytidylyltransferase, and therefore an increase in CDP-choline mediated PC synthesis, was responsible for these observations.

Insignificance of extrahepatic PEMT activity was based on a view toward evaluating the ability of PEMT to maintain whole-body PC content during choline deficiency. However, PEMT may serve a different and specific function in the heart. In light of the current findings, it is interesting to note that data from isolated hepatocytes indicated that only newly synthesized PE was a substrate for PC synthesis *via* PEMT (43) and that 16:0-22:6 PE was PEMT's preferred substrate (44).

The present study was designed to couple mass and compositional data to make metabolic inference about heart tissue n-3 fatty acid metabolism. Fatty acid composition and quantitative PL mass measurements suggested that 22:6n-3 induced PEMT activity in the heart. Further, the data suggested that dietary 18:3n-3 was capable of inducing this activity, presumably because heart rapidly accumulated 22:6n-3 in response to dietary 18:3n-3. The induction of PEMT in heart by 22:6n-3 or 18:3n-3 may be partially responsible for the beneficial effects of n-3 fatty acids on heart function. In contrast to the induction of PEMT activity, dietary 22:6n-3 was required for the enrichment of CL with 22:6n-3. The difference between the metabolic fates of various n-3 fatty acids in heart is important to nutrition and health and should be investigated. CL containing 22:6n-3 has been shown to induce a decrease in mitochondrial oxygen consumption (29) and an increase in cellular oxidant production (19). Based on the findings of this study, the selective accumulation of 22:6n-3 by heart may be linked to the conversion of n-3 precursors to 22:6n-3 within the heart itself. An increased mass of 22:6n-3-rich PC also partially accounts for this phenomenon.

# 1-$^{14}$C-Linoleic Acid Distribution in Various Tissue Lipids of Guinea Pigs Following an Oral Dose

**Zhong Fu, Nadia M. Attar-Bashi, and Andrew J. Sinclair***

Department of Food Science, RMIT University, Melbourne, Victoria, 3001, Australia

**ABSTRACT:** A recent study on the metabolism of 1-$^{14}$C-α-linolenic acid in the guinea pig revealed that the fur had the highest specific activity of all tissues examined, 48 h after dosing. The present study investigated the pattern of tissue lipid labeling following an oral dose of 1-$^{14}$C-linoleic acid after the animals had been dosed for the same time as above. Guinea pigs were fed one of two diets with a constant linoleic acid content (18% total fatty acids) and a different content of α-linolenic acid (0.3 or 17.3%) from weaning for 3 wk and 1-$^{14}$C-linoleic acid was given orally to each animal for 48 h prior to sacrifice. The most highly labeled tissues (dpm/mg of linoleic acid) were liver, followed by brain, lung and spleen, heart, kidney and adrenal and intestines, in both diet groups. The liver had almost a threefold higher specific activity than skin and fur which was more extensively labeled than the adipose and carcass. Approximately two-thirds of the label in skin plus fur was found in the fur which, because of a low lipid mass, would indicate that the fur was highly labeled. All tissues derived from animals on the diet with the low α-linolenic acid level were significantly more labeled than the tissues from the animals on the high α-linolenic acid diet, by a factor of 1.5 to 3. The phospholipid fraction was the most highly labeled fraction in the liver, free fatty acids were the most labeled fraction in skin & fur, while triacyglycerols were the most labeled in the carcass and adipose tissue. In these tissues, more than 90% of the radioactivity was found in fatty acids with 2-double bonds in the tissue lipids. These data indicate that the majority of label found in guinea pig tissues 48 h after dosing was still associated with a fatty acid fraction with 2-double bonds, which suggests there was little metabolism of linoleic acid to more highly unsaturated fatty acids in this time frame. In this study, the labeling of guinea pig tissues with linoleic acid, 48 h after dosing, was quite different from the labeling with α-linolenic acid reported previously. The retention of the administered radioactivity from $^{14}$C-linoleic acid in the whole body lipids was 1.6 times higher in the group fed the low α-linolenic acid diet (diet contained a total of 1.8 g PUFA/100 g diet) compared with the group fed the high α-linolenic acid diet (diet contained 3.6 g PUFA /100 g diet). The lack of retention of $^{14}$C-labeled lipids in the whole body would be consistent with an increased rate of β-oxidation of the labeled fatty acid on the diet rich in PUFA, a result supported by other studies using direct measurement of labeled carbon dioxide.

Paper no. L8607 in *Lipids 36*, 255–260 (March 2001).

The essential fatty acids (EFA) linoleic and α-linolenic acid (18:3n-3) were discovered in 1930 (1). It is now known that each EFA is the parent member of a family of fatty acids (n-6 family and n-3 family) that have different biological functions. For the n-6 family, linoleic acid prevents water loss through the skin (2), while arachidonic acid is the precursor of all the main eicosanoids. In the case of the n-3 family, eicosapentaenoic acid and docosahexaenoic acid (DHA) are effective in reducing plasma triacylglycerol levels (3) while DHA plays an important role in membranes in excitable tissues such as the brain, retina and heart (4–6).

The classical symptoms of EFA deficiency in mammals are alterations in skin and fur integrity, including scaly skin, dandruff, and hair loss in rats (7). Other studies have shown that linoleic acid plays an important role in skin in preventing water loss and in maintaining epidermal integrity (2,8). Linoleic acid is included in commercial dog foods to maintain "shiny coats" (9). The effects of EFA deficiency on the skin and fur of other species, including man, have been widely reported as reviewed by Holman (7).

The effect of α-linolenic acid deficiency on mammals is less obvious than combined EFA deficiency, with generally subtle effects being reported in various species on the electroretinogram (5) and other membrane-related events in tissues such as the brain and heart (4,10,11). Some studies have indicated that α-linolenic acid might also play a role in skin and fur (12–14).

We have recently reported that guinea pig skin contains a substantial quantity of α-linolenic acid (15), an observation that supports data also reported recently in rats (16,17). Furthermore, we showed that skin & fur of guinea pigs were extensively labeled following oral dosing with 1-$^{14}$C-linolenic acid. It was speculated that in the guinea pig α-linolenic acid may have a function in relation to fur, perhaps as a secreted lipid from sebaceous glands to protect the fur from damage by water, light or other agents.

Because the extensive labeling of fur with 1-$^{14}$C-α-linolenic acid was unexpected, the present study investigated the distribution of radioactivity in all tissue lipids following an oral dose of 1-$^{14}$C-linoleic acid in guinea pigs using the same single time point (48 h).

## MATERIALS AND METHODS

The experimental protocol was approved by the Animal Ethics Committee of RMIT University, Melbourne, Australia. Male pigmented guinea pigs, 4 wk old, were purchased from Monash University in Melbourne, Australia. After having been fed on a guinea pig chow diet for 10 d, they were randomly divided into two groups ($n$ = 4/group), fed with one of two semisynthetic diets mixed with normal chow for 1 wk, and then fed with the semisynthetic diet only for the next 3 wk. The major ingredients, including the vitamin and mineral composition, have been reported previously (18). The fat, pro-

tein, and carbohydrate content of the diets were 10, 30, and 47% (by weight), respectively, with the remainder being made up of vitamins, minerals, and fiber. The oils used in the diet consisted of mixtures of coconut, linseed, palm stearin, safflower, sunola, and canola oils in order to provide two diets, each with a constant proportion of linoleic acid and variable α-linolenic acid content. The fatty acid compositions of these two different diets are shown below. For the high α-linolenic acid diet, the percentages of the following fatty acids were determined (in duplicate, as described below): caprylic + myristic 10.9%, palmitic 13.7%, stearic 4.3%, oleic 35.3%, linoleic 18.2%, and α-linolenic 17.3%. For the low α-linolenic acid diet, the percentages of the following fatty acids were determined: caprylic + myristic 11.4%, palmitic 31.7%, stearic 4.1%, oleic 34.5%, linoleic 17.5%, and α-linolenic 0.3%. The ratio of 18:2n-6/18:3n-3 was 1.05 and 58 in the high and low α-linolenic acid diets, respectively. After 19 days on the diet, each guinea pig was given an oral dose of 1.95 μCi of 9,12-[1-$^{14}$C-]linoleic acid (NEN Life Sciences Product Inc., Boston, MA; specific activity 1.961 gbq/mmol) mixed in 0.4 mL of olive oil; the dose was given using a 1-mL syringe fitted with a blunt, wide-gauge needle and while the oil was dripped into their mouths, the guinea pigs were tightly held in a vertical position. The guinea pigs were then returned to their cages for 48 h, where they had normal access to food and water.

At the conclusion of the study, the guinea pigs were asphyxiated in $CO_2$ gas, the head was severed from the body, and then the skin and fur were removed from the skull and carcass of the body, respectively. About 2–5 g of skin was cut into slices for lipid analysis. Part of the fur from the carcass was shaved for lipid analysis. The other tissues were collected, washed free from blood in ice-cold normal saline, and dried with blotting paper; the total weight of the organs was recorded, and then the tissues were stored at −20°C. The stomach and intestines were opened and washed free of digesta/feces and stored as above. Lipids were extracted from approximately 2 g of each tissue using chloroform/methanol as described previously (18). One aliquot of each tissue lipid was counted in a scintillation counter, another aliquot was converted to fatty acid methyl esters for determination of the tissue fatty acid content by capillary gas–liquid chromatography using 23:0 as an internal standard on a BPX-70 column (SGE, Melbourne, Australia) (15), and a third aliquot was subjected to thin-layer chromatography (TLC) on silica gel G to separate the neutral lipids into fractions, which were then scraped into vials and counted in a scintillation counter. Fatty acid methyl esters from some tissues were examined by silver nitrate TLC to separate trienoic from dienoic and tetraenoic fractions with petroleum ether/diethyl ether (40:60, vol/vol). Part of the fur was shaved from the carcass for further radioactivity counting. The lipids on the surface of the fur were extracted separately from the lipids contained within the hairs based on a procedure devised for wool fiber (19). Briefly the surface lipids were extracted by refluxing with *t*-butanol for 1 h and then with *n*-heptane for another hour. The extracts were combined and considered to be the surface lipids (19). For the internal fur lipids, the lipids were extracted overnight at 4°C from the residue of the above treatment with chloroform/methanol (1:1, vol/vol).

## RESULTS

The weights of the animals after the 3-wk feeding study were 587 ± 55 and 570 ± 55 g (mean ± SD) in the high and low α-linolenic acid diet groups, respectively. The animals appeared healthy in each group.

The tissue n-6 and n-3 fatty acid contents (mg/total weight of tissue) and the fatty acid composition (%) in tissue data have been published previously (18). The proportional distribution of individual fatty acids in each tissue as a percentage of whole body fatty acid content (sum of fatty acids in all tissues) is shown in Table 1. In both diet groups, the major sites for linoleic acid, α-linolenic acid, and arachidonic acid accumulation were adipose, carcass (muscle plus bone), and skin & fur, with approximately 90% of these PUFA in the whole body being found in these tissue sites. In the case of DHA, the brain and carcass were the major sites of deposition in both groups, and adipose was also a site of DHA accumulation in the high α-linolenate group.

Table 2 shows the $^{14}$C-label per total tissue (dpm/total weight of tissue) in each diet group. All tissue lipids derived from animals on the diet with low α-linolenic acid level contained more $^{14}$C-label than the tissues from animals on the high α-linolenic acid. The total of $^{14}$C-label found in the whole body was $1.7 \times 10^6$ dpm on the high α-linolenic acid diet and $2.7 \times 10^6$ dpm on the low α-linolenic acid diet. For both diet groups, the most highly labeled tissues were carcass, followed by adipose, skin & fur, liver, stomach and intestine, and kidney plus adrenal. When the data were expressed as a specific activity (dpm/mg linoleic acid), the most highly labeled tissues in the high and low α-linolenic acid diets were (in descending order): liver, brain, lung and spleen, hearts, guts, and skin & fur (head). For both diet groups the liver had a higher specific activity than the skin & fur by approximately four- to sevenfold. There was a significantly higher specific activity for all tissues on the low α-linolenic acid diet compared with the high α-linolenic acid diet group.

The mean recovery of the oral dose in the body as carbon $^{14}$C-labeled lipids for the high-α-linolenic acid diet group was 39%, which was significantly lower than the recovery for the animals in the low α-linolenic acid diet group of 62% ($P < 0.05$). In both diet groups, the phospholipids were the most labeled fraction in the liver (approximately 90%), while the label was mostly in the triacylglycerol fraction in adipose tissue and carcass (>95%), and free fatty acids were the most labeled fraction in skin & fur of the carcass and the head (>66%) (Table 3). For both diet groups, more than 92% of the label in the fatty acids separated by silver nitrate TLC was found in the 2-double bond fraction in the liver, adipose, carcass, and skin & fur of the head & carcass (data not shown).

Of the combined counts in the skin and fur, more than 65% of the counts were in the fur compared with the skin lipids.

| | Low | <0.1 | 3 ± 1 | ND | 3 ± 1 | 23 ± 2 |

[a]High 18:3n-3 diet contained 1.73 g 18:3n-3 per 100 g diet, whereas the low 18:3n-3 diet had 0.03 g/100 g of 18:3n-3.
[b]Represents the mass of linoleic acid in the carcass relative to the mass of linoleic acid in the whole body, expressed as a percentage. The whole body value was obtained by summing the values for each tissue.
[c]Results are shown as mean ± SD, $n = 4$ per diet group. ND, not detected (<0.05% fatty acids).

About 80% of the counts was recovered in the surface lipids of the fur. The $^{14}C$ distribution in the surface and internal fur was not different between the two diet groups. In both diet groups, more than 95% of the counts was in the free fatty acid fraction for the surface fur lipids, and more than 92% of all the counts was in the 2-double bond fraction.

## DISCUSSION

A previous study in guinea pigs reported that more than 47% of the administered dose of $^{14}C$-α-linolenic acid was found in the skin and fur 48 h after an oral dose (15). The aim of the present study was to examine the distribution of $^{14}C$-labeled-

[b]Results are shown as mean ± SD, $n$ = 4 per diet group.

linoleic acid throughout the body with a view to compare the results with the previous study using the same strain of guinea pigs maintained on semisynthetic diets for the same length of time and orally dosed with the $^{14}$C-label for the same time (48 h). As shown in Figure 1, the pattern of tissue lipid labeling with each of the EFA at this single time point was quite different. In the present linoleic acid study, the majority of the label was found in carcass and adipose lipids, with skin & fur, liver, and the intestinal lipids also being substantially labeled. The pattern of labeling of tissue lipids with linoleic acid was quite different from the former study using α-linolenic acid (15) (Fig.1), where skin and fur were the most labeled, followed by carcass, adipose, liver and intestines.

In the present experiment, the most highly labeled tissues in both the high and low α-linolenic acid diet groups (dpm/mg linoleic acid) were liver, brain, lung and spleen, stomach and intestine, and skin & fur (head). These data are quite different from our previous findings using $^{14}$C-labeled-α-linolenic acid, where the most highly labeled tissue (dpm/mg α-linolenic acid) was the skin & fur (head) by a factor of about four times over the next most highly labeled tissues (15). In the α-linolenic acid study, the order of labeling of the tissue in terms of specific activity was skin & fur of the head, liver, stomach and intestines, brain, and skin & fur of the carcass. In a study of guinea pigs given $^{14}$C-labeled linoleic acid intravenously for up to 60 min, the liver and lung were the most highly labeled tissues of 12 tissues examined (dpm/g tissue) (20). Skin and fur were not examined in that study.

Although the skin & fur were not the most highly labeled at 48 h after dosing with $^{14}$C-linoleic acid, the fur was still substantially labeled. The mass of lipid in the surface fur was insignificant, thus the specific activity of the surface fur would be much higher than the value for the combined skin & fur shown in Table 2 and perhaps the fur was one of the most highly labeled tissues.

While these comparative data suggest a substantial difference between the $^{14}$C-labeling of tissues following the oral dosing with linoleic acid (this study) and α-linolenic acid (15), it does not reveal the time course of tissue labeling since only one time point was examined. Zhou *et al.* (20) found there was a rapid loss of label from serum over 200 min, with the liver retaining up to 20% of the injected dose in the first 10 min. This report did not investigate whether skin & fur were labeled in this time nor did it provide a clue to the tissues likely to be labeled by 48 h.

Of the tissues examined (liver, carcass, adipose, and skin & fur), most of the radioactivity was found in the tissue fatty acids containing two double bonds (determined as methyl esters). This was surprising since it might be expected that in the time frame of the experiment some label would be detected in the four double bond fraction (as arachidonic acid), especially in the liver where most of the label was in the phospholipid fraction. A possible explanation is the reported low activity of the Δ-5 desaturase level in guinea pig liver compared with rat (21) and the fact that diets rich in linoleic acid inhibit the expression of the Δ-6 desaturase in liver (22). Others have noted the relatively low proportion of long-chain PUFA in guinea pig plasma, erythrocytes, liver, and heart by comparison with rat tissues (23,24) which is consistent with a low rate of desaturase activity. In contrast, in weanling rats fed an oral dose of $^{14}$C-linoleic acid, the proportion of the label associated with liver phospholipid arachidonic acid was 23% and that with linoleic acid 65%, 48 h after the dose (25). Zhou *et al.* (20) reported that at 60 min postlabeling most tissues showed less than 5% of the label as arachidonic acid, although with spleen and bone marrow the proportion was higher at 12–16% (the present study did not examine either of these two tissues separately). In most tissues, Zhou *et al.* (20) found more label in 20:3n-6 than in arachidonic acid in the short time frame of their experiment. It is unlikely that the techniques used in the two experiments could account for the different patterns of labeling of fatty acids. In the study of Zhou *et al.* (20), the fatty acids were separated by high-performance liquid chromatography, whereas in the present work the fatty acids (as methyl esters) were separated by silver nitrate TLC which clearly separated 3- and 4-double bond fatty acids from dienoic fatty acids.

It has been widely reported that EFA deficiency increases water loss through the skin and leads to the development of scaly skin, loss of hair, and a roughened hair coat in a number of different species (2,7). Although these effects are attributed to a lack of linoleic acid, some studies have indicated that α-linolenic acid might also play a role in skin and fur function

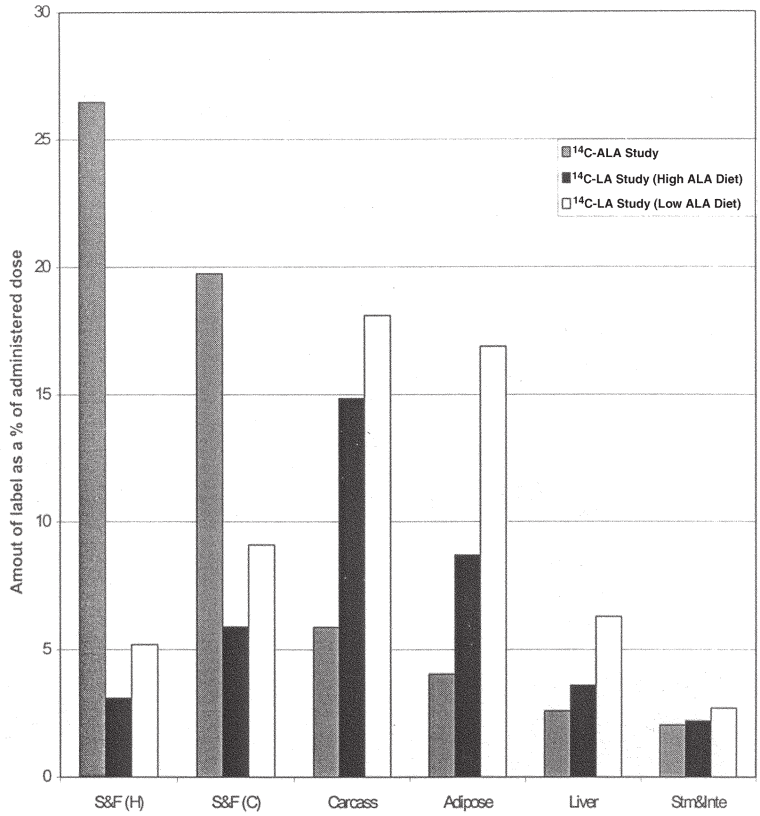

**FIG. 1.** The amount of label in tissue lipids as a percentage of administered dose. Comparison between the 1-$^{14}$C-α-linolenic acid (ALA) experiment (15) and the 1-$^{14}$C-linoleic acid experiment (high and low ALA diets). S&F (H) = skin & fur (head), S&F (C) = Skin & fur (carcass), and Stm& Inte = Stomach & Intestine.

(12–14). For example, an early study in rats showed that linseed oil contained a factor that promoted fur growth compared with a fat-deficient control group, and that α-linolenic acid was more effective than linoleic acid in restoring fur growth (12). A later study in capuchin monkeys reported skin lesions, fur loss, and abnormal behavior on a high linoleic acid, low α-linolenic acid diet, and a restoration of normal skin and fur appearance following the inclusion of linseed oil into the diet (13).

Based on the results in this experiment, it is possible to speculate that in the guinea pig, linoleic acid and α-linolenic acid may have a function in relation to fur, perhaps as a secreted lipid from sebaceous glands to protect the fur from damage by water, light, or other agents. This speculation is perhaps consistent with the use of linoleic acid in dogs to maintain their coats in good condition (9).

There was a substantially lower recovery of the $^{14}$C-label in the whole body tissue lipids in the high α-linolenic acid diet group compared with the low α-linolenic acid diet group by a factor of 0.7. In other words, approximately 40% of the label was lost as $CO_2$ or in feces in the low α-linolenic acid group compared with 60% lost in the high α-linolenic acid diet group. Pan and Storlien (26) reported that β-oxidation of α-linolenic acid increases with increasing levels of PUFA in rats. Assuming that this scenario applies in the guinea pig, could account for the increased loss (presumably by β-oxidation) in the high α-linolenic acid diet group since this group had nearly twice as much dietary PUFA compared with the low α-linolenic acid diet group (35 vs. 18% PUFA). It has been reported that in EFA-deficient rats fed 0.3% of energy as linoleic acid, less linoleic acid was oxidized to $CO_2$ compared with rats fed 10% of the energy as linoleic acid, and the retention of linoleic acid in the tissue of rats fed low EFA was greater than those fed high levels of linoleic acid (27,28).

In both diet groups, the major sites for linoleic acid, α-linolenic acid, and arachidonic acid accumulation were adipose, carcass, and skin & fur with approximately 90% of these PUFA in the whole body being found in these tissue sites. In this study, skin would include epidermis, dermis, and perhaps some subcutaneous fat. The carcass, as sampled in this study, includes muscle and bone; however, it is assumed that the majority of the lipids originated from muscle. Few other studies have examined all tissues as sites of deposition of PUFA. Cunnane and Anderson (16) examined all major tissues in young rats fed equal amounts of linoleic acid and α-linolenic acid and found that adipose, carcass, and skin were the main sites for linoleic acid and α-linolenic acid accumulation. Bowen and Clandinin (17) also report that skin is a major site of deposition of α-linolenic acid in young rats.

There were two main limitations to this study. The first was that we only took one time point (48 h) after the administration

of the oral dose of radioactively labeled fatty acid, which restricts the information regarding the turnover of the label in tissues. The aim of the study was to compare the labeling with that of the previous study using α-linolenic acid, under identical conditions. The second limitation of the study was that oral dosing of the animals may have led to some contamination of the fur from the oral dose. If contamination did occur, it would be necessary to speculate that more contamination occurred in the α-linolenic acid study than in the present study with linoleic acid, if indeed contamination was the source of the label on the fur. It should be noted that in both this and the previous study, we reported that skin contained high levels of the EFA, which may explain why this tissue becomes labeled. In order to establish if oral contamination contributes to the labeling of skin and fur, future studies will examine whether there is a similar labeling of skin and fur following either intravenous or intraperitoneal dosing of the animals.

In conclusion we report that following an oral dose of $^{14}$C-labeled-linoleic acid in guinea pigs, the skin and fur (combined) had a lower specific activity relative to other tissues, compared with previous data in guinea pigs fed with an oral dose of $^{14}$C-labeled-α-linolenic acid. Despite this, in the present experiment the fur was likely to have had a high specific activity. We also found that there was a higher recovery of the $^{14}$C-label in tissue lipids on the diet with the lowest PUFA level, suggesting a reduced β-oxidation of linoleic acid on this diet.

# Effects of Diets Enriched in n-6 or n-3 Fatty Acids on Cholesterol Metabolism in Older Rats Chronically Fed a Cholesterol-Enriched Diet

**Michihiro Fukushima[a], Tetsu Ohhashi[a], Syugo Ohno[a], Hidetoshi Saitoh[a], Kei Sonoyama[b], Ken-ichiro Shimada[a], Mitsuo Sekikawa[a], and Masuo Nakano[a,*]**

[a]Department of Bioresource Science, Obihiro University of Agriculture and Veterinary Medicine, Obihiro, Hokkaido 080-8555, Japan, and [b]Department of Bioscience and Chemistry, Faculty of Agriculture, Hokkaido University, Sapporo, Hokkaido 060-8589, Japan

**ABSTRACT:** Hypocholesterolemic effects in older animals after long-term feeding are unknown. Therefore, aged rats (24 wk of age) fed a conventional diet were shifted to diets containing 10% perilla oil [PEO; oleic acid + linoleic acid + α-linolenic acid; n-6/n-3, 0.3; polyunsaturated fatty acid/saturated fatty acid (P/S), 9.6], borage oil [oleic acid + linoleic acid + α-linolenic acid; n-6/n-3, 15.1; P/S, 5.3], evening primrose oil (EPO; linoleic acid + γ-linolenic acid; P/S, 10.5), mixed oil (MIO; oleic acid + linoleic acid + γ-linolenic acid + α-linolenic acid; n-6/n-3, 1.7; P/S, 6.7), or palm oil (PLO; palmitic acid + oleic acid + linoleic acid; n-6/n-3, 25.3; P/S, 0.2) with 0.5% cholesterol for 15 wk in this experiment. There were no significant differences in the food intake and body weight gain among the groups. The liver weight in the PEO (n-6/n-3, 0.3) group was significantly higher than those of other groups in aged rats. The serum total cholesterol and very low density lipoprotein (VLDL) + intermediate density lipoprotein (IDL) + low density lipoprotein (LDL)-cholesterol concentrations of the PLO (25.3) group were consistently higher than those in the other groups. The serum high density lipoprotein cholesterol concentrations of the PEO (0.3) and EPO groups were significantly lower than in the other groups at the end of the 15-wk feeding period. The liver cholesterol concentration of the PLO (25.3) group was significantly higher than those of other groups. There were no significant differences in the hepatic LDL receptor mRNA level among the groups. Hepatic apolipoprotein (apo) B mRNA levels were not affected by the experimental conditions. The fecal neutral steroid excretion of the PLO (25.3) group tended to be low compared to the other groups. The results of this study demonstrate that both n-6 fatty acid and n-3 fatty acids such as γ-linolenic acid and α-linolenic acid inhibit the increase of serum total cholesterol and VLDL + IDL + LDL-cholesterol concentrations of aged rats in the presence of excess cholesterol in the diet compared with dietary saturated fatty acid.

Abbreviations: ALA 18:3n-3, α-linolenic acid; apo, apolipoprotein; BRO, borage oil; DG, diacylglycerol; DIG, digoxigenin; EPO, evening primrose oil; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; GLA, γ-linolenic acid; GLC, gas–liquid chromatography; HDL, high density lipoprotein; IDL, intermediate density lipoprotein; LA 18:2n-6, linoleic acid; LDL, low density lipoprotein; MIO, mixed oil; PEO, perilla oil; PLO, palm oil; P/S, polyunsaturated fatty acid/saturated fatty acid; RT–PCR, reverse transcriptase–polymerase chain reaction; TAG, triacylglycerol; VLDL, very low density lipoprotein.

It has been reported that dietary high-linoleate safflower oil is not hypocholesterolemic in aged mice compared with perilla oil (PEO) and fish oil (n-3 fatty acids) after long-term feeding (1). However, Fukushima *et al.* (2) reported that evening primrose oil (EPO) containing about 71% linoleic acid (LA) and 9% γ-linolenic acid (GLA) has a hypocholesterolemic function compared with soybean oil containing about 53% LA and 8% α-linolenic acid (ALA) in cholesterol-fed rats after 13-wk of feeding, and that the effect of the diet could be due to the lesser amount of LA. Responses to marine lipids vary remarkably among different animal species. In the rat, dietary fish oil consistently lowers plasma cholesterol and triacylglycerol (TAG) concentrations. Although the cholesterol content of all lipoprotein fractions declines, the greatest reductions occur in lipoproteins that contain apolipoprotein (apo) B-100 or apo E (3). The fall in plasma low density lipoprotein (LDL) concentrations in rats fed fish oil is due primarily to an increase in receptor-dependent LDL uptake by the liver (3). However, there are almost no reports that ALA reduces lipoproteins containing apo B and apo E.

Numerous studies have shown that dietary polyunsaturated (P) and saturated (S) fatty acids can regulate plasma lipid and apo concentrations at the mRNA level in nonhuman primates (4–7). However, most such studies have been performed using relatively young animals. For aged rats, the data concerning the comparison between n-6 and n-3 fatty acids in this process are extremely limited, and the effects in the older animals after long-term feeding are unknown. The purpose of the present study was to investigate the effect of dietary n-6 and n-3 fatty acids in plant oils on cholesterol metabolism and the hepatic apo B and LDL receptor mRNA levels in aged rats (24 wk old) fed a cholesterol-enriched diet after long-term (15-wk) feeding.

## MATERIALS AND METHODS

*Animals and diets.* Male F344/DuCrj rats (24 wk old) were purchased from Charles River Japan Inc. (Yokohama, Japan). Twenty-five animals were housed individually in cages in a room with controlled temperature (23 ± 1°C), humidity (60 ± 5%), and light (12-h light/dark cycle). The composition of the

experimental diet was as follows (wt%): casein, 20; fat 10; cornstarch, 15; cellulose powder, 5; DL-methionine, 0.3; mineral mixture, 3.5 (AIN-76) (8); vitamin mixture, 1 (AIN-76) (8); choline bitartrate, 0.2; cholesterol, 0.5; sodium cholate, 0.125; and sucrose to 100. PEO (0.3), EPO, borage oil (BRO) (15.1), and palm oil (PLO) (25.3) were purchased from Sugiyama Yakuhin Co. (Nagoya, Japan), Summit Oil Co. (Chiba, Japan, licensed by Efamol Ltd.), Nippon Gohsei Chemical Industry Co. (Osaka, Japan), and Asahi Electric Industry Co. (Tokyo, Japan), respectively. Mixed oil (MIO) (1.7) was a mixture of PEO (0.3) and BRO (15.1) (1:2, vol/vol). The negative control group consisted of rats fed 100 g/kg PLO (25.3) containing large amounts of S.

Table 1 shows the lipid class and fatty acid compositions of the dietary fats. The rats (24 wk old) were divided into 5 groups of five animals each. They were allowed free access to experimental diets and water for 15 wk. To avoid autooxidation, each diet was stored at −20°C and freshly prepared each day. All animal procedures described conformed to recognized principles (9).

*Analytical procedures.* Blood samples (1 mL) were collected between 0800 and 1000 h from the jugular veins of fasting rats. The samples were taken into tubes without an anticoagulant. After the samples stood at room temperature for 2 h, serum was prepared by centrifugation at 1500 × *g* for 20 min. At the end of the experimental period of 15 wk, all fecal excretion during 2 d was collected. Fecal dry weights did not differ among the groups. The rats were killed by ether inhalation, and the livers quickly removed, washed with cold saline (9 g NaCl/L), blotted dry on filter paper, and weighed before freezing for storage.

*Chemical analysis.* Total cholesterol and high density lipoprotein (HDL)-cholesterol concentrations in the serum were determined enzymatically using commercially available reagent kits (assay kits for the TDX system; Abbott Laboratory Co., Irving, TX). The very low density lipoprotein (VLDL) + intermediate density lipoprotein (IDL) + LDL-cholesterol concentration was calculated as follows: VLDL + IDL + LDL-cholesterol = total cholesterol − HDL-cholesterol.

Total lipids were extracted from liver, and feces by a mixture of chloroform/methanol (2:1, vol/vol) (10). Neutral steroids in feces and liver obtained by saponification were acetylated (11) and analyzed by gas–liquid chromatography (GLC) with a DB 17 capillary column (0.25 mm × 30 m; J&W Scientific, Folsom, CA). Acidic steroids in feces were measured by GLC following the method of Grundy *et al.* (12).

*Reverse transcriptase–polymerase chain reaction (RT–PCR) and Southern blot analysis.* Total RNA was isolated by the acid guanidium–phenol–chloroform method, using Isogen (Nippon Gene, Tokyo, Japan) from liver (13). mRNA encoding apo B, LDL receptor, and glyceraldehyde-3-phosphate dehydrogenase (GAPDH, used as an invariant control; 14,15) were analyzed by semiquantitative RT–PCR and subsequent Southern hybridization of the PCR products with each inner oligonucleotide probe. Total RNA samples were treated with DNase RQ1 (Promega, Madison, WI) to remove genomic DNA and subjected to RT-PCR by using Moloney murine leukemia virus RT (Gibco, Gaithersburg, MD) and EX-Taq polymerase (Takara, Otsu, Japan) with apo B primers of oligonucleotides (upstream primer, 5′-GAAAGCATGCTGAAAACAACC-3′; downstream primer, 5′-AGGCCTGACTCGTGGAAGAA-3′), LDL receptor primers of oligonucleotides (upstream primer, 5′-ATTTTGGAGGATGAGAAGCAG-3′; downstream primer, 5′-CAGGGCGGGGAGGTGTGAGAA-3′), and GAPDH primers of oligonucleotides (upstream primer, 5′-GCCATCAACGACCCCTTCATT-3′; downstream primer, 5′-CGCCTGCTTCACCACCTTCTT-3′). The reaction mixtures for the PCR contained 25 pmol of each primer, 1.25 U EX-Taq polymerase, 1 × PCR buffer (Takara), and 200 μM dNTP in a 50-μL reaction volume. The expected sizes of DNA fragments amplified with these primers were 725 bp for apo B, 931 bp for the LDL receptor, and 702 bp for GAPDH. Temperature cycling was as follows: first cycle, denaturation at 95°C for 3 min, annealing at 55°C for 1 min, and extension at 72°C for 2 min. Subsequent cycles were denaturation at 95°C for 1 min, annealing at 55°C for 1 min, and extension at 72°C for 2 min. The thermal cycling was completed by terminal extension at 72°C for 10 min. In total, 25 cycles were performed for the apo B amplification, 35 cycles for the LDL receptor, and 20 cycles for GAPDH. Amplification products were electrophoresed on a 2% agarose gel and transferred to a nylon membrane (Biodyne B; Pall Bio-Support, East Hills, NY). Blots were hybridized with an apo B probe of a 54-base oligonucleotide (5′-TCCTTGCTTACCAAAAAGAGCTTCCAGTGTTGGCTCAAAGCCCTTTCCTTCTAA-3′), LDL receptor probe of a 54-base oligonucleotide (5′-GTGAACTTGGGTGAGTGGGCACTGATCTGAGGGGCAGGCAGGCACATGTACTGG-3′), and GAPDH probe of a 54-base oligonucleotide (5′-TGATGACCAGCTTCCCATTCTCAGCCTTGACTGTGCCGTTGAACTTGCCGTGGG-3′).

[c]P/S = (18:2n-6 + 18:3n-6 + 18:3n-3)/(14:0 + 16:0). PEO, perilla oil; BRO, borage oil; EPO, evening primrose oil; MIO, mixed oil; PLO, palm oil.

**TABLE 2**
**Body Weight Gain, Food Intake, and Liver Weight in Rats Fed Dietary Fats for 15 wk[a]**

| | Diet | | | | |
|---|---|---|---|---|---|
| | PEO | BRO | EPO | MIO | PLO |
| Body initial wt (g) | 340 ± 18 | 345 ± 9 | 344 ± 31 | 350 ± 14 | 344 ± 42 |
| Body wt gain (g/15 wk) | 67 ± 9 | 58 ± 8 | 74 ± 11 | 58 ± 19 | 74 ± 31 |
| Body final wt (g) | 407 ± 19 | 403 ± 16 | 418 ± 31 | 409 ± 27 | 419 ± 28 |
| Food intake (g/15 wk) | 1543 ± 65 | 1547 ± 75 | 1608 ± 121 | 1533 ± 118 | 1624 ± 14 |
| Liver wt (wet g/100 g body weight) | 4.1 ± 0.1[a] | 3.1 ± 0.2[d] | 3.4 ± 0.2[c] | 3.3 ± 0.2[c,d] | 3.8 ± 0.1[b] |

[a]Values are means ± standard deviations for five rats. Means within the same rows bearing different roman superscripts are significantly different ($P < 0.05$). See Table 1 for abbreviations.

The probe was 3′-tailing labeled with digoxigenin (DIG), using a DIG oligonucleotide tailing kit (Boehringer Mannheim, Mannheim, Germany). Prehybridization, hybridization, and detection were carried out with a DIG luminescent detection kit (Boehringer Mannheim) as recommended by the manufacturer. The relative quantity of mRNA was estimated by densitometric scanning with X-ray film.

*Statistical analysis.* Data are presented as means and standard deviations. The mean and standard deviations for serum total cholesterol, HDL-cholesterol, and VLDL + IDL + LDL-cholesterol for each time point were calculated. The significance of differences among treatment groups was determined by analysis of variance with Duncan's multiple-range test (SAS Institute, Cary, NC). Results were considered significant at $P < 0.05$.

## RESULTS

*Feed intake, rat growth, and liver weight.* The results are summarized in Table 2. There were no significant differences in the food intake and body weight gain among the groups. The liver weight in the PEO (0.3) group was significantly higher than those of the other groups.

*Tissue lipid concentration.* The serum total, VLDL + IDL + LDL-cholesterol, and HDL-cholesterol concentrations are shown in Table 3. The serum total cholesterol and VLDL + IDL + LDL-cholesterol concentrations of the PLO (25.3) group were consistently higher than those in the other groups. The serum total cholesterol and VLDL + IDL + LDL-cholesterol concentrations of all groups except for the MIO (1.7) group decreased between 8 and 15 wk. The serum HDL-cholesterol concentrations of the PEO (0.3) and EPO groups were significantly low compared with the PLO (25.3) group, at the end of the 15-wk feeding period.

Figure 1 illustrates the cholesterol concentrations in the livers of rats at the end of the 15-wk feeding period. The liver cholesterol concentration in the PLO (25.3) group was significantly higher than in the other groups, and that in the BRO (15.1) group was significantly lower than in the PEO (0.3), EPO, and PLO (25.3) groups.

[a]Values are means ± standard deviations for five rats. Means within the same columns bearing different roman superscripts are significantly different ($P < 0.05$). VLDL, very low density lipoprotein; LDL, low density lipoprotein; IDL, intermediate density lipoprotein; HDL, high density lipoprotein. See Table 1 for other abbreviations.

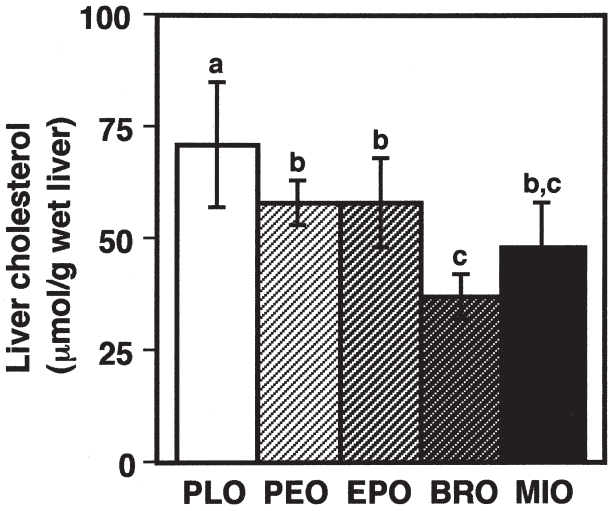

**FIG. 1.** Liver cholesterol concentration in rats fed dietary fats for 15 wk. Rats were fed a semisynthetic diet enriched with cholesterol and saturated triacylglycerol (TAG) or the same diet in which n-3 or n-6 polyunsaturated TAG replaced saturated TAG. Each value represents the means ± standard deviations for data obtained from five animals. Means values (a, b, c) were significantly different ($P < 0.05$), as determined by analysis of variance with Duncan's multiple-range test. PLO, palm oil; PEO, perilla oil; EPO, evening primrose oil; BRO, borage oil; MIO, mixed oil.

*mRNA levels of hepatic apo B and LDL receptor.* Figures 2 and 3 show representative results of Southern hybridization of PCR-amplified apo B cDNA and LDL receptor cDNA in the rat liver. Values for apo B mRNA and LDL receptor mRNA in liver are expressed relative to the average value for the PLO (25.3)-fed rat normalized to 100. There were no significant differences in the hepatic LDL receptor mRNA and apo B mRNA levels among the groups.

*Fecal lipid concentration.* Table 4 shows the effects of the dietary oils on fecal neutral steroid and bile acid concentrations in aged rats at the end of the experimental period. The excretion of cholesterol in the MIO (1.7) group was significantly higher than in the PLO (25.3) group. The excretion of coprostanol in the MIO (1.7) group was significantly higher than in the BRO (15.1) and EPO groups.

The excretion of chenodeoxycholic acid in the EPO group was highest among the groups, and the excretion of deoxycholic acid in the BRO (15.1) group was significantly higher than in the EPO, MIO (1.7), and PLO (25.3) groups. However, there were no significant differences in the excretion of cholic acid, lithocholic acid, and total bile acid among the groups.

## DISCUSSION

Ishihara *et al.* (1) suggested that n-6 fatty acid LA had no hypocholesterolemic effect in long-term feeding (120 d). In this long-term feeding (105 d) in aged rats, PEO (0.3) containing about 57% ALA was compared with EPO containing about 71% LA and 9% GLA, BRO (15.1) containing about 38% ALA and 24% GLA, MIO (1.7) containing about 26% ALA and 15% GLA, and PLO (25.3) containing about 46% palmitic acid.

This study indicated that dietary PEO (oleic acid + LA + ALA; n-6/n-3, 0.3; P/S, 9.6), BRO (oleic acid + LA + ALA; n-6/n-3, 15.1; P/S, 5.3), and MIO (oleic acid + LA + GLA + ALA; n-6/n-3, 1.7; P/S, 6.7), in the same manner as EPO (LA + GLA; P/S, 10.5), were more efficient in inhibiting increases of serum total cholesterol in long-term feeding than PLO (25.3), which contained abundant S. These results agreed with those for young rats (Fukushima, M., unpublished data). Ishihara *et al.* (1) reported that increased intake of high-linoleate vegetable oil was not useful for the prevention of hypercholesterolemia-associated diseases; however, dietary oils rich in n-3 fatty acids might be useful. However, dietary GLA is hypocholesterolemic in the same manner as PEO, which contains abundant ALA, in aged rats. Thus, our results might not agree with the results of Ishihara *et al.* (1) because our conditions were different from theirs using mice (1).

The cholesterol content in the livers of rats fed the PLO (25.3) diet was the highest among the five groups in the aged rats. On the other hand, the cholesterol content in the livers of aged rats fed abundant GLA tended to decrease more than in the EPO group. Our results using aged rats agreed with a previous report (2) that the liver cholesterol concentration in the PLO group tended to increase compared with the group

**TABLE 4**
**Fecal Steroid Concentrations in Rats Fed Dietary Fats for 15 wk[a]**

| | Diet | | | | |
|---|---|---|---|---|---|
| | PEO | BRO | EPO | MIO | PLO |
| Cholesterol | $4.39 \pm 1.11^{a,b}$ | $5.26 \pm 1.05^{a,b}$ | $6.18 \pm 1.76^{a,b}$ | $6.64 \pm 1.36^{a}$ | $3.99 \pm 2.45^{b}$ |
| Coprostanol | $0.43 \pm 0.13^{a,b}$ | $0.25 \pm 0.27^{b}$ | $0.31 \pm 0.13^{b}$ | $0.71 \pm 0.21^{a}$ | $0.55 \pm 0.28^{a,b}$ |
| CA | $0.28 \pm 0.37$ | $0.48 \pm 0.11$ | $0.37 \pm 0.18$ | $0.25 \pm 0.21$ | $0.34 \pm 0.12$ |

[a]Values are means ± standard deviations of diets (μmol/g 100 g body weight/d) for five rats. Means within the same rows bearing different roman superscripts are significantly different ($P < 0.05$). CA, cholic acid; CDCA, chenodeoxycholic acid; DCA, deoxycholic acid; LCA, lithocholic acid; TBA, total bile acid. See Table 1 for other abbreviations.

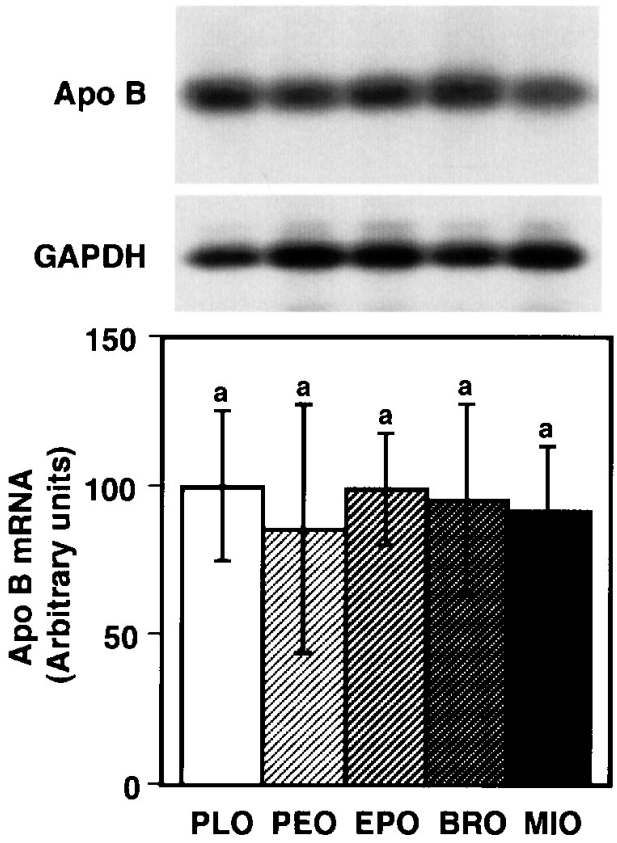

**FIG. 2.** Effect of dietary n-6 and n-3 polyunsaturated fatty acids (PUFA) on hepatic apolipoprotein (apo) B mRNA in rats fed dietary fats for 15 wk. Rats were fed a semisynthetic diet enriched with cholesterol and saturated TAG or the same diet in which n-3 or n-6 polyunsaturated TAG replaced saturated TAG. Each value represents the means ± standard deviations for data obtained from five animals. Means values were significantly different ($P < 0.05$), as determined by analysis of variance with Duncan's multiple-range test. The value of apo B mRNA was normalized to the value of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA, and values for the rats fed the PEO, EPO, BRO, and MIO diets are expressed relative to the average values for rats fed the PLO diet, which was set to 100. Inset illustrates the representative Southern hybridization of polymerase chain reaction (PCR)-amplified apo B cDNA of hepatic RNA. See Figure 1 for other abbreviations.

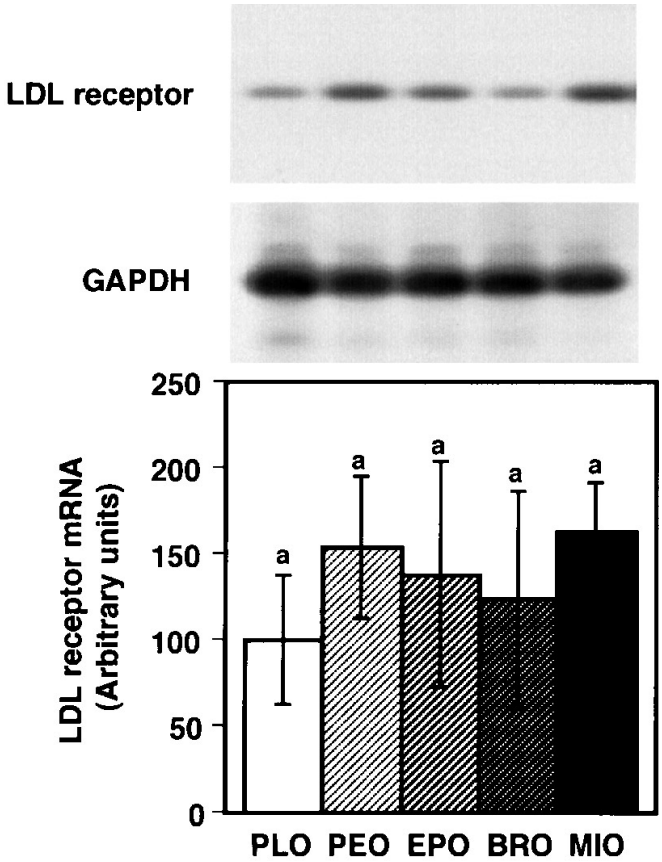

**FIG. 3.** Effect of dietary n-6 and n-3 PUFA on hepatic low density lipoprotein (LDL) receptor mRNA in aged rats fed dietary fats for 15 wk. Rats were fed a semisynthetic diet enriched with cholesterol and saturated TAG or the same diet in which n-3 or n-6 polyunsaturated TAG replaced saturated TAG. Each value represents the means ± standard deviations for data obtained from five animals. Means values were significantly different ($P < 0.05$), as determined by analysis of variance with Duncan's multiple-range test. The value of LDL receptor mRNA was normalized to the value of GAPDH mRNA, and the rats fed the PEO, EPO, BRO and MIO diets are expressed relative to the average values for rats fed the PLO diet, which was set to 100. Inset illustrates the representative Southern hybridization of PCR-amplified LDL receptor cDNA of hepatic RNA. See Figures 1 and 2 for other abbreviations.

containing GLA in young rats. Ventura *et al.* (3) reported that dietary n-6 or n-3 fatty acid increased hepatic LDL receptor activity compared with dietary S in the rat. However, there were no significant differences in the hepatic LDL receptor mRNA levels among the groups. Dietary cholesterol presumably suppresses hepatic LDL receptor activity *via* this mechanism (16) and, indeed, dietary cholesterol has been shown to reduce hepatic LDL receptor mRNA levels in nonhuman primates (17). In this study, it is possible that dietary cholesterol suppressed hepatic LDL receptor mRNA levels in all groups. Ihara-Watanabe *et al.* (18) have reported that the activity and mRNA expression of HMG-CoA reductase were lower in rats on an ALA-diet than in those on a GLA-diet without cholesterol, though there were no significant differences in the activity and mRNA expression of HMG-CoA reductase between the ALA-diet and GLA-diet during cholesterol feeding. There were no significant differences in the excretion of neutral and acidic sterol concentrations between n-6 and n-3 fatty acid groups in this experiment. In this respect, the rat is highly resistant to the effects of dietary cholesterol. The major factors appear to be a much higher basal rate of hepatic bile acid synthesis in the rat, allowing a much greater inflow of dietary cholesterol to be balanced by suppression of hepatic sterol synthesis (19). It may be that the excretion of neutral and acidic steroid concentrations did not affect the response of serum LDL cholesterol and liver cholesterol in n-6 and n-3 fatty acid groups in this experiment.

In conclusion, the results of this study demonstrate that both n-6 and n-3 fatty acids inhibit increases of serum total cholesterol and VLDL + IDL + LDL-cholesterol concentrations as compared with S in the presence of excess cholesterol in the diet after long-term feeding.

## ACKNOWLEDGMENT

This work was partly supported by a grant-in-aid for encouragement of young scientists from the Ministry of Education, Science, and Culture of Japan.

# Acute Effect of Ethanol on 7-Hydroperoxycholesterol in Muscle and Liver

**Junko Adachi[a,*], Migiwa Asano[a], Yasuhiro Ueno[a], Jaspaul S. Marway[b], Peter M. Camilleri[b], Timothy J. Peters[b], and Victor R. Preedy[c]**

[a]Department of Legal Medicine, Kobe University School of Medicine, Kobe 650-0017, Japan, [b]Departments of Clinical Biochemistry, Guy's, King's and St. Thomas' School of Medicine, King's College, London, and [c]Department of Nutrition and Dietetics, King's College, London, United Kingdom

**ABSTRACT:** We tested the hypotheses that ethanol sensitivities of muscle and liver can be discerned in the initial periods of ethanol exposure, especially when acetaldehyde levels are markedly raised with cyanamide, an aldehyde dehydrogenase inhibitor. To test this, we measured cholesterol hydroperoxides in soleus (Type I) and plantaris (Type II) muscle in four groups of rats acutely (i.e., 2.5 h) exposed to: [S] saline (control), [Cy] cyanamide, [EtOH] ethanol, or [Cy + EtOH] cyanamide + ethanol. Comparative reference was also made to the response of the liver. After 2.5 h, ethanol alone significantly increased 7α-hydroperoxycholest-5-en-3β-ol (7α-OOH) and 7β-hydroperoxycholest-5-en-3β-ol (7β-OOH) levels in plantaris muscle. Identical qualitative effects were seen in rats treated with cyanamide + ethanol, but there was no discernible difference between groups [EtOH] and [Cy + EtOH]. In both the soleus muscle and liver, none of the treatments with either ethanol or cyanamide + ethanol had any effect on any of the measured parameters. This is the first report of a differential response of 7α-OOH and 7β-OOH in Type II, compared to Type I predominant muscles, and the first time that muscle has been shown to be more sensitive than the liver in terms of its lipid marker response to oxidative stress. Perturbations in the muscle membrane lipid domain may contribute to impairment of muscle in alcoholism.

Paper no. L8663 in *Lipids 36,* 267–271 (March 2001).

Skeletal muscle abnormalities affect up to 60% of alcohol abusers compared with an estimated 15–20% prevalence for cirrhosis (1). Type II (anaerobic, fast-twitch) fibers are particularly affected, whereas Type I (aerobic, slow-twitch) are relatively resistant to alcohol-induced muscle disease, although they are both affected in extreme circumstances (1). Despite the frequent occurrence of alcohol-induced muscle disease, the pathogenic mechanisms are unknown, although both perturbed membrane function and increased generation of reactive oxygen species have been proposed (2–4). Previous studies have identified 7α- (7α-OOH) and 7β-hydroperoxycholest-5-en-3β-ol (7β-OOH) in skeletal muscles formed *via* reactive oxygen species. They are therefore putative markers of oxidative stress, and are increased in both Types I (represented by the soleus) and II (represented by the plantaris) fiber-predominant skeletal muscles of rats 1 d after an acute ethanol load (5). These changes are attributable to perturbations in the membrane lipid domain by reactive oxygen species, a hypothesis supported by the observation that the membrane phospholipid profiles are also altered. Altered membrane function may initiate the deleterious processes that precipitate the ethanol-induced reductions in protein synthesis (6–10).

We have shown that an acute bolus of ethanol reduces the synthesis of muscle proteins (6,8,11). When acetaldehyde levels are raised with the aldehyde dehydrogenase inhibitor cyanamide, greater reductions in protein synthesis are obtained, implicating acetaldehyde as a potent protein synthetic perturbant (7).

Paradoxically, the changes in cholesterol hydroperoxides and fatty acid profile in 24-h dosed rats are equally observed in both Types I and II fibers. This is at variance with the known fiber sensitivities to alcohol (reviewed in Refs. 2–4). Certainly, Type I muscles have a higher antioxidant status (such as catalase, glutathione peroxidase, and superoxide dismutase activities and α-tocopherol concentrations) than the susceptible Type II muscles (12). It is quite possible that marked differential effects of ethanol-induced changes in membrane lipids will be observed at earlier time points such as at 2.5 h, as originally demonstrated for protein synthesis alterations (8,11). Furthermore, there is no information on how these metabolites change when endogenous acetaldehyde levels are raised in the presence of ethanol. Finally, previous data for muscle cholesterol hydroperoxides have been taken in isolation (5), without reference to the effects on the liver which is a major target organ for alcohol's deleterious effects, particularly with respect to oxidative stress (2).

To resolve the issues raised above we measured cholesterol hydroperoxides in Types I and II muscles and in liver in alcohol-dosed rats with or without cyanamide pretreatment.

## MATERIALS AND METHODS

*Materials.* 3,5-Di-*tert*-butyl-4-hydroxytoluene, luminol (3-aminophthaloylhydrazine), and cytochrome c (from horse heart, type VI) were purchased from Wako Pure Chemical Co.

*To whom correspondence should be addressed at Department of Legal Medicine, Kobe University School of Medicine, Kusunoki-cho 7 Chuo-ku Kobe 650-0017, Japan. E-mail: adachi@med.kobe-u.ac.jp

Abbreviations: 5α-OOH, 5α-hydroperoxycholest-6-en-3β-ol; 7α-OOH, 7α-hydroperoxycholest-5-en-3β-ol; 7β-OOH, 7β-hydroperoxycholest-5-en-3β-ol; CL, chemiluminescence; DIH, 2,4-dinitrophenyl hydrazine-1,3-indandione-1-azine; HPLC, high-performance liquid chromatography.

(Osaka, Japan). Acetaldehyde, cyanamide, ethanol, and 2,4-dinitrophenyl hydrazine-1,3-indandione-1-azine (DIH) were purchased from Sigma-Aldrich Chemical Co. (Poole, Dorset, United Kingdom). Acetonitrile, methanol, and hydrochloric acid for the high-performance liquid chromatography (HPLC) determination of acetaldehyde were obtained from BDH Chemicals (Poole, Dorset, United Kingdom). Cholesterol hydroperoxides, 5α-hydroperoxycholest-6-en-3β-ol (5α-OOH), 7α-OOH, and 7β-OOH were synthesized as described previously (13,14). β-Sitosterol-5α-hydroperoxide (as internal standard) was prepared by irradiating a solution of β-sitosterol and hematoporphyrin in pyridine (13).

*Animal treatments.* Animals were housed in a Home Office-approved Comparative Biology Unit. All experimental animal work was conducted at King's College under approval from the appropriate local and national authorities. Male Wistar rats were obtained from accredited commercial suppliers at about 60 g body weight. They were maintained in a temperature- and humidity-controlled animal house for 1 wk until they weighed approximately 100–150 g. They were then ranked and divided into four groups of equal mean body weight. All rats had access to food throughout the study period up to and including the postinjection period. The experimental treatment of the rats involved two steps, i.e., pretreatment (30 min) followed by treatment (150 min) stages as follows: [S], saline + saline; [Cy], cyanamide + saline; [EtOH], saline + ethanol; [Cy + EtOH], cyanamide + ethanol. Rats were pretreated with an intraperitoneal injection (5 mL/kg body weight) of solution containing either saline (0.15 mol NaCl/L) or cyanamide (0.5 mmol/kg body weight). At 30 min after the pretreatment injection, rats were treated with an intraperitoneal injection (10 mL/kg body weight) of solution containing either saline (0.15 mol NaCl/L) or ethanol (75 mmol/kg body weight). At 150 min after commencement of the treatment step, rats were killed by decapitation. A separate group of identically treated rats was used for acetaldehyde (to facilitate rapid trapping of this volatile agent) and lipid determinations. For cholesterol hydroperoxides, soleus (Type I fiber-predominant) muscle, plantaris (Type II fiber-predominant) muscle, and liver were dissected.

*HPLC-chemiluminescence (CL) analysis of cholesterol hydroperoxides.* Cholesterol hydroperoxides were determined by reversed-phase HPLC-CL, comprising two LC-10AD vp pumps (Shimadzu, Kyoto, Japan), a SPD-6A spectrophotometric detector (Shimadzu), a CLD-10A CL detector (Shimadzu), and a Chromatopac C-R4A integrator (Shimadzu). A TSK gel Octyl-80Ts column (Tosoh, Tokyo, Japan) was used. One pump delivered the mobile phase of methanol/water/acetonitrile (89:9:2, by vol). The second pump delivered the chemiluminescent reagent, which consisted of cytochrome c and luminol in alkaline borate buffer as described previously (15). After the column eluant had passed through an ultraviolet detector set at 210 nm, it was mixed with the luminescent reagent in the postcolumn mixing joint of the CL detector. Standard curves were prepared from the analyses of 1–20 ng of 5α-OOH and 7β-OOH and from 0.5–10 ng of 7α-OOH using 5 ng of the internal standard. Regression lines of the ratios of hydroperoxides to the internal standard vs. the standard concentrations were linear.

*Tissue extraction procedures for lipids.* For peroxidation products, total lipid was extracted by adding 5 mL of ice-cold chloroform/methanol (2:1, vol/vol), containing 0.005% (vol/vol) butylated hydroxytoluene (as antioxidant) and 500 pmol β-sitosterol 5α-hydroperoxide as the internal standard, to approximately 0.1 g of muscle or liver, and homogenizing under ice-cold conditions. The homogenate was mixed with 5 mL of chloroform/methanol (2:1, vol/vol) and 1 mL of distilled water, vortexed vigorously, and centrifuged ($800 \times g$). The chloroform layer was aspirated, concentrated in a rotary evaporator, and dried under nitrogen. A cholesterol-rich fraction was isolated from the total lipid by solid phase extraction. A silica column (Sep-Pak; Waters Co., Milford, MA) packed with aminopropyl-derivatized silica ($-NH_2$) was initially conditioned by washing with 5 mL of acetone and 10 mL of *n*-hexane. The total lipid sample, dissolved in a small amount of chloroform, was added to the column, then flushed with a mixture of 2 mL chloroform and 1 mL isopropanol, giving an eluate that mainly consisted of cholesterol. This was concentrated in a rotary evaporator and dried under a nitrogen stream. The cholesterol-rich fraction was dissolved in methanol and stored until analysis.

*Acetaldehyde determinations.* The conditions for the acetaldehyde determinations were essentially those described in detail previously (16). Briefly, the trapping agent was prepared by dissolving 30 mg DIH in 100 mL of methanol and acetonitrile (80:20, vol/vol), and then storing at 4°C. The blood was immediately collected *via* heparinized funnels into tubes containing the aldehyde trapping agent DIH (16). All tubes used for blood collection were pre-cooled on ice and all samples were maintained at 0–4°C during the experiments. For determination of muscle acetaldehyde, the combined gastrocnemius and plantaris muscles were rapidly dissected and immediately homogenized in DIH trapping agent. The combined analysis of both the gastrocnemius and plantaris was necessary to minimize the period between death and suspension of tissue homogenate in DIH. In addition, the amount of plantaris and soleus muscle was too small (less than 0.1 g for each leg) to analyze acetaldehyde levels in each muscle. Samples of liver tissue were similarly treated. The blood (1 g) or tissue (about 1 g) was added to 4 mL of ice-cold DIH reagent in a glass vial, capped, and the contents were either immediately mixed thoroughly (i.e., blood) or homogenized (i.e., muscle or liver) with a Polytron Highspeed Homogenizer (Philip Harris, United Kingdom). After centrifugation, the supernatants were mixed with hydrochloric acid and incubated in a water bath at 37°C for 10 min. The samples were then stored at −70°C until analysis. Samples were then subjected to quantitative analysis by HPLC with a Shimadzu system controller with a LC-6A pressure pump and SIL-6A autoinjector (Dysons Instruments Ltd., Tyne and Wear, United Kingdom) and Hypersil MOS 2 column (Phenomonex, Macclesfield, United Kingdom), as described previously (16,17). The azine derivatives of acetaldehyde were detected

by fluorescence spectroscopy (excitation 430 nm, emission 525 nm; Merck Hitachi, Luterworth, United Kingdom). Assays employed standard solutions of acetaldehyde (0.1–10 mmol/L).

*Statistics.* All data are expressed as mean ± SD of 5 or 6 observations in each group. Differences between groups were assessed by nonparametric Kruskal-Wallis test.

## RESULTS

*Cholesterol hydroperoxides.* There was clear separation of cholesterol hydroperoxides (5α-OOH, 7α-OOH, and 7β-OOH) together with the internal standard β-sitosterol-5α-hydroperoxide in standard solutions as well as in muscle samples. Lipid extracts from muscle contained 7α-OOH and 7β-OOH, but not 5α-OOH, as previously described (5).

The mean concentrations of 7α-OOH and 7β-OOH in muscle of control rat are shown in Table 1. In plantaris muscle from Group [S], 7α-OOH (0.81 nmol/g) was significantly lower than 7β-OOH (1.98 nmol/g). In the soleus muscle from Group [S], 7α-OOH (0.43 nmol/g) was lower than 7β-OOH (0.58 nmol/g), but it did not reach statistical significance. In both muscles, values of 7α-OOH were lower compared to 7β-OOH which may reflect the fact that 7α-OOH is easily epimerized to 7β-OOH (5). Compared to soleus muscle, significantly higher values of 7α-OOH and 7β-OOH were found in plantaris muscles confirming previous observations (5). High levels of 7α-OOH and 7β-OOH in plantaris compared to the soleus muscle may reflect the lower antioxidant capacity of Type II fiber-rich muscles (12,18–21). Moreover, in liver the concentrations of 7α-OOH and 7β-OOH were approximately 10-fold higher than muscle (Table 1).

Following acute treatment with cyanamide, concentrations of 7α-OOH and 7β-OOH were unaffected in all three tissues.

In response to ethanol, there were no significant changes in 7α-OOH and 7β-OOH in soleus muscle (Table 1). However, there were significant increases in 7α-OOH and 7β-OOH in plantaris muscle at 2.5 h following acute ethanol administration (Table 1). Evidence for the greater relative sensitivity of the Type II fibers compared to the Type I fibers was obtained by examining the soleus/plantaris ratio of individual analytes in each rat. Thus, the soleus/plantaris ratio for 7α-OOH decreased from 0.56 to 0.26 ($P < 0.01$), and a similar change was observed for 7β-OOH (from 0.37 to 0.16, $P < 0.025$). There was no change in the liver hydroperoxides in response to ethanol (Table 1).

The effects of raising acetaldehyde with cyanamide (i.e., Group [S] vs. [Cy + EtOH]) were similar to treatments with ethanol alone (i.e., Groups [S] vs. [EtOH]). Thus, compared to Group [S], significant elevations in 7α-OOH and 7β-OOH were observed in plantaris muscle following treatment with cyanamide + ethanol (in both instances, increases were approximately 70%, $P < 0.01$). Neither 7α-OOH nor 7β-OOH in soleus muscle or liver, respectively, were affected following treatment with cyanamide + ethanol, i.e., Groups [S] vs. [Cy + EtOH], $P > 0.05$ not significant (Table 1). Furthermore, compared to Group [Cy], significant elevation in 7β-OOH and elevation in 7α-OOH (not significant) were observed in plantaris muscle following treatment with cyanamide + ethanol (increase of 7β-OOH was 64%, $P < 0.01$).

*Ethanol levels.* Blood ethanol levels were not measured in the present experiment, but under identical experimental conditions using rats of the same size and age, plasma values of ethanol were as follows (all data as mean; mmol/L) [S], <1; [Cy] <1; [EtOH], 33; [Cy + EtOH] 46 (7) . The statistics are as follows; [S] vs. [EtOH], $P < 0.001$; [S] vs. [Cy + EtOH], $P < 0.001$; [EtOH] vs. [Cy + EtOH], $P < 0.01$ (7).

*Acetaldehyde levels*. Table 2 shows the acetaldehyde levels in the blood of rats in the four groups. There were no differences in blood acetaldehyde levels between the Groups [S] and [Cy]. Blood acetaldehyde levels increased sixfold in rats treated with ethanol (Group [EtOH]

compared to Group [S]). In Group [Cy + EtOH], blood acetaldehyde was 500-fold higher compared to either Group [S] or Group [Cy] and significantly higher than levels in Group [EtOH].

Acetaldehyde concentrations in muscle of cyanamide + ethanol rats (Group [Cy+EtOH]) increased 16-fold compared to Group [S] (Table 2). Acetaldehyde concentrations in liver of cyanamide + ethanol rats increased 38-fold compared to Group [S] (Table 2).

## DISCUSSION

We examined hydroperoxide as an index of free radical activity (5,22,23). 7α-OOH and 7β-OOH are formed as a consequence of oxidative stress *per se* rather than other routes of metabolism (22). The HPLC-CL quantification of 7α-OOH and 7β-OOH have been utilized as a marker of lipid peroxidation in human erythrocyte membranes (22). More direct assessment of conjugated diene levels, or reaction of lipid peroxidation products with thiobarbituric acid or protein carbonyl, are limited as they are nonspecific and possibly insensitive (5). In the present investigation, we report increased levels of 7α-OOH and 7β-OOH cholesterol hydroperoxides in the plantaris muscle of acutely ethanol-dosed rats, an effect not seen in the soleus muscle or liver. We therefore describe for the first time evidence for the differential effects of ethanol-induced increases in 7α-OOH and 7β-OOH cholesterol hydroperoxides in accordance with the known antioxidant properties of the different muscle types.

In these studies we analyzed the soleus and plantaris, which are Type I and II fiber-predominant muscles, respectively. We showed that there were significant biochemical differences between these two muscles in control rats in accordance with previous observations. This included a higher concentration in plantaris muscle of 7α-OOH and 7β-OOH. There were some differences between cholesterol hydroperoxides in control rats of the present experiments (Table 1) and previously published studies (5). These differences possibly reflect the markedly divergent nutritional states of rats in the two studies, which were fed (having access to food throughout the study period up to and including the postinjection period) in the present study (see the Materials and Methods section), compared to starved in the previous analysis (5).

There are particular difficulties in examining biochemical mechanisms in individual Type I and II fibers, mainly because insufficient material can be analyzed. To resolve this, the soleus and plantaris muscle (the latter being equivalent to the extensor digitorum longus muscle used by some groups) muscles were taken to represent Type I and Type II fibers, respectively. Previous comparisons of these two muscles have included diverse subject areas such as signal transduction, the examination of muscle with respect to the fasting-feeding transition, the metabolism of muscle triacylglycerol and glycogen in response to dietary modification, and the effect of exercise (see for example Ref. 24). Their suitability is further supported by the observation that in response to alcohol (albeit with chronic alcohol feeding models) individual Type II fibers within both the soleus and plantaris display atrophy and that the individual Type I fibers in the soleus and plantaris muscles are resistant (25). Furthermore, the suppression of protein synthesis in acutely dosed rats is much less in Type I muscles (8). We believe that the resilience of the Type I fiber is related to the antioxidant status of these muscles compared to the Type II fibers.

Previous studies have also shown that muscle and liver respond differently to alcohol. For example, after 2.5 h, acute ethanol reduces the synthesis rates of skeletal muscle but not liver (11,26). Further evidence for the differential responses of tissues are obtained from studies showing that ethanol administration reduces the antioxidants catalase and glutathione in liver, but not in muscle (27). The reduction of hepatic catalase and glutathione may reflect the utilization of these protective agents (27).

Moreover, in the present studies we used cyanamide, a potent inhibitor of aldehyde dehydrogenase. The increase in acetaldehyde in response to cyanamide + ethanol was 500-fold in blood, 16-fold in muscle, and 38-fold in liver compared to Group [S]. Although levels of ethanol and acetaldehyde were extremely high, we failed to observe changes of cholesterol hydroperoxides in liver due to the high antioxidant capacity of this tissue. For example, α-tocopherol concentrations are considerably higher in the liver than in skeletal muscle (26). Previous studies have shown that ethanol reduces skeletal muscle protein synthesis by approximately 30%, and cyanamide + ethanol treatment reduces protein synthesis in skeletal muscle by approximately 65% (7). As far as we are aware, the magnitude of this reduction in protein synthesis in such acute conditions is the highest ever reported. Cyanamide pre-dosing therefore offers the opportunity of measuring metabolic perturbations when there is a marked suppression of protein synthesis. Acetaldehyde-mediated muscle damage probably results from inhibition of protein synthesis rates, but free radical-mediated muscle damage may not result from high acetaldehyde levels, because acetaldehyde can react with protein to form protein adduct but cannot react with lipids themselves. Alternatively, it is possible that only trace amounts of acetaldehyde can cause increases in cholesterol hydroperoxides as was observed in plantaris muscle of rats only dosed with ethanol. Nevertheless, we can conclude that the failure to observe changes in soleus muscle and liver is not due to limitations in the dosing regimen but rather

a reflection of the antioxidant defences or other cytoprotective mechanisms within these tissues.

In conclusion, this is the first report of a differential response of 7α-OOH and 7β-OOH in Type II, compared to Type I predominant muscles and the first time that muscle has been shown to be more sensitive than the liver in terms of its response with respect to lipid markers of oxidative stress. These results signify perturbations in the membrane, which may have important consequences for the pathogenesis of alcohol-induced muscle disorders.

## ACKNOWLEDGMENTS

We are grateful to The Royal Society for funding the travel between the United Kingdom and Japan. This work was supported in part by a Grant-in-Aid for Scientific Research from Japan Society for Promotion of Science. The analysis of acetaldehyde was carried out by PC at the Roehampton Institute, University of Surrey.

# Incorporation and Distribution of Saturated and Unsaturated Fatty Acids into Nuclear Lipids of Hepatic Cells

**Ana Ves-Losada[a,b,*], Sabina M. Maté[a], and Rodolfo R. Brenner[a]**

[a]Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), Facultad de Ciencias Médicas, UNLP-CONICET, and [b]Departamento de Ciencias Biológicas, Facultad de Ciencias Exactas, UNLP, 1900-La Plata, Argentina

**ABSTRACT:** Liver nuclear incorporation of stearic (18:0), linoleic (18:2n-6), and arachidonic (20:4n-6) acids was studied by incubation *in vitro* of the [1-$^{14}$C] fatty acids with nuclei, with or without the cytosol fraction at different times. The [1-$^{14}$C] fatty acids were incorporated into the nuclei as free fatty acids in the following order: 18:0 > 20:4n-6 ≫ 18:2n-6, and esterified into nuclear lipids by an acyl-CoA pathway. All [1-$^{14}$C] fatty acids were esterified mainly to phospholipids and triacylglycerols and in a minor proportion to diacylglycerols. Only [1-$^{14}$C]18:2n-6-CoA was incorporated into cholesterol esters. The incorporation was not modified by cytosol addition. The incorporation of 20:4n-6 into nuclear phosphatidylcholine (PC) pools was also studied by incubation of liver nuclei *in vitro* with [1-$^{14}$C]20:4n-6-CoA, and nuclear labeled PC molecular species were determined. From the 15 PC nuclear molecular species determined, five were labeled with [1-$^{14}$C]20:4n-6-CoA: 18:0-20:4, 16:0-20:4, 18:1-20:4, 18:2-20:4, and 20:4-20:4. The highest specific radioactivity was found in 20:4-20:4 PC, which is a minor species. In conclusion, liver cell nuclei possess the necessary enzymes to incorporate exogenous saturated and unsaturated fatty acids into lipids by an acyl-CoA pathway, showing specificity for each fatty acid. Liver cell nuclei also utilize exogenous 20:4n-6-CoA to synthesize the major molecular species of PC with 20:4n-6 at the *sn*-2 position. However, the most actively synthesized is 20:4-20:4 PC, which is a quantitatively minor component. The labeling pattern of 20:4-20:4 PC would indicate that this molecular species is synthesized mainly by the *de novo* pathway.

Paper no. L8605 in *Lipids 36,* 273–282 (March 2001).

Saturated and unsaturated fatty acids are important cellular components involved in different biological processes. In cells, fatty acids are essential structural and functional components of all membranes, and they are principally esterified to glycerolipids. Besides the traditional roles of fatty acids as nutrients and as a source of metabolic energy and structural components of complex lipids, fatty acids *per se* have physiological and pathological effects. Fatty acids are the source of signaling molecules involved in cellular transduction (1). A correlation between fatty acid alteration in phospholipid (PL) composition and initiation of apoptotic cell death has also been described (2,3). In particular, arachidonic and linoleic acid metabolites were reported to have both metastatic and mitotic potential (4,5).

However, in addition to the biological functions described above, fatty acids are also important determinants and mediators in gene expression (6–9). Dietary polyunsaturated fatty acids (PUFA) have been shown to decrease mRNA levels and transcription of several rat hepatic lipogenic genes such as S14 protein, glucose-6-phosphate dehydrogenase, fatty acid synthase (10–12), and stearoyl-CoA desaturase in different tissues and species (7–9,13). It has been proposed that the genes of stearoyl-CoA desaturase are co-regulated by fatty acids and cholesterol through a common class of transcription factor, the sterol regulatory element binding proteins (9). Also, arachidonic acid has been found to have a rapid inhibitory effect on gene transcription of stearoyl-CoA desaturase, and this repression is probably due to a noneicosanoid role of 20:4n-6 (8,14,15). If this is the case, it is very important to know how nuclear lipid metabolism operates in the cell.

Nuclear lipid metabolism is very active. However, its precise topology and the relationship between nuclear lipids and cell functions have not been fully elucidated. The most abundant PUFA from total lipids in hepatic cell nuclei are those of the n-6 series which represent 46% of the total fatty acid composition, arachidonic acid being the main one (23%) (16). Moreover, recent studies have proposed that the nucleus is a key subcellular site for enzymes involved in the release and metabolism of arachidonic acid (17). Thus, arachidonic acid is not only an important nuclear structural membrane component (16) but also the primary substrate for the synthesis of eicosanoids. In nuclei, arachidonic acid may come from: (i) cell cytoplasm where it can be synthesized in the endoplasmic reticulum from 18:2n-6 acid which is desaturated by Δ6 desaturase to 18:3n-6 acid, elongated to 20:3n-6, and finally desaturated by Δ5 desaturase to 20:4n-6 (18); (ii) hydrolyzed from other lipids; (iii) synthesized in nuclei by Δ5 desaturase from 20:3n-6 previously activated as 20:3n-6-CoA by means of nuclear long-chain fatty acyl-CoA synthetase (16,19). We have also investigated the distribution of 20:3n-6 and its desaturation product, 20:4n-6, into nuclear lipids during *in vitro* Δ5 desaturation (20). As previously demonstrated by others

Abbreviations: CE, cholesterol ester; DG, diacylglycerol; ELSD, evaporative light scattering detector; FABP, fatty acid binding protein; FFA, free fatty acid; GC, gas chromatography; GLC, gas–liquid chromatography; HPLC, high-performance liquid chromatography; IM, incubation mixture; N, nuclear pellet; PC, phosphatidylcholine; PL, phospholipid; PPAR, peroxisome proliferator activated receptor; PUFA, polyunsaturated fatty acid; RHPLC, reversed-phase HPLC; TG, triacylglycerol; TLC, thin-layer chromatography.

in fibroblasts, the nuclear membrane is an important compartment for the uptake and release of arachidonate from PL, which in this way, become available for eicosanoid production (21). It is very interesting to note that another desaturase has recently been described in rat liver nuclei, the Δ9 desaturase (22).

Taking into acount that fatty acids regulate gene expression (9) and that information on nuclear fatty acid metabolism is scarce, the aim of the present study has been to investigate the incorporation and distribution of saturated and unsaturated fatty acids into nuclear lipids and to determine nuclear phosphatidylcholine (PC) pools. For this reason, cell liver nuclei were incubated *in vitro* with [1-$^{14}$C] stearic (18:0), linoleic (18:2n-6), or arachidonic (20:4n-6) acids with and without a cytosol fraction. To study nuclear PC pools, molecular species of PC were determined and the incorporation of [1-$^{14}$C]20:4n-6-CoA into them was also studied.

## MATERIAL AND METHODS.

*Materials.* [1-$^{14}$C]Stearic acid (18:0) (56.0 mCi/mmol, 99% radiochemically pure), [1-$^{14}$C]linoleic acid (18:2n-6) (54.7 mCi/mmol, 98.5% radiochemically pure, 1% *trans* isomer), [1-$^{14}$C]arachidonic acid (20:4n-6) (54.9 mCi/mmol, 99% radiochemically pure), and [1-$^{14}$C]arachidonyl-CoA (20:4n-6-CoA) (51.6 mCi/mmol, 97% radiochemically pure) were purchased from New England Nuclear Corp. (Boston, MA). Cofactors used were provided by Sigma Chemical Co. (St. Louis, MO), thin-layer chromatography (TLC) precoated silica gel G 20 × 20 cm plates were from Merck (Buenos Aires, Argentina) and all unlabeled fatty acids were from Nu-Chek-Prep Inc. (Elysian, MN). 1,2-Diarachidonoyl-*sn*-glycero-3-phosphocholine was purchased from Avanti Polar Lipids, Inc. (Alabaster, AL). All chemicals and solvents were of analytical and high-performance liquid chromatography (HPLC) grade.

*Animals*. In this study, international regulations for animal care were observed. Male Wistar rats of 60–70 d of age, weighing 180–200 g were maintained on a commercial standard pellet diet (Nutrimento rat chow 3; Escobar, Argentina) and tap water *ad libitum*. The diet contained 4.0% of total lipid; its fatty acid composition was as follows 16.7% 16:0 (palmitic acid), 0.8% 16:1 (palmitoleic acid), 4.9% 18:0 (stearic acid), 21.8% 18:1 (oleic acid), 52.4% 18:2n-6 (linoleic acid), and 4.3% 18:3n-3 (linolenic acid). All animals were subjected to a daily photoperiod of 12-h light and 12-h darkness (midnight being the midpoint of the dark period).

*Preparation of homogenate and subcellular fractions*. Rats were killed by decapitation at 8 A.M. to equalize circadian effect (23). Livers from 3–5 animals were pooled and homogenized in sucrose 0.25 M in TKM buffer (0.05 M Tris-HCl, pH 7.5, 0.0025 M KCl, 0.005 M $MgCl_2$) 1:2 (wt/vol). All steps were carried out at 4°C. Highly purified nuclei were isolated from liver homogenate by sucrose-density ultracentrifugation using the method of Blobel and Potter (24), modified by Kasper (25) as described in a previous work (16). Concentration of nuclei in terms of protein was determined by the method of Lowry *et al.* (26) using crystalline bovine serum albumin as standard. The postmicrosomal supernatant, prepared as described previously (16), was centrifuged three times at 100,000 × *g* for 60 min to obtain the cytosolic fraction, then stored at −80°C (18 mg cytosol protein/mL of homogenizing solution). Cytosol fraction was checked for purity by enzymatic analysis as described previously (16). The nuclear fraction was resuspended in 25% glycerol (10 mM Tris-HCl, pH 7.9) and stored at −80°C until used.

*Criteria for nuclear purity.* Nuclear preparations were checked for purity by electron microscopy and enzymatic analysis as described previously (16). To assess the levels of possible contamination produced by endoplasmic reticulum, cytosol, lysosomes, and mitochondria, the nuclear fraction was assayed for the respective marker enzymes, arylesterase (27), lactate dehydrogenase (28), acid phosphatase (29), and succinate dehydrogenase (30). Each assay was performed in duplicate. Negligible amounts of microsomal, cytosolic, lysosomal, and mitochondrial marker enzymes were found in the isolated nuclei as described previously (16). Based upon the above morphological and biochemical assays, the isolated nuclei were judged highly homogeneous and pure.

*Incorporation of radioactive fatty acids.* The incorporation reactions were initiated by the addition of the nuclei (6 mg of nuclear protein) to flasks containing, unless otherwise indicated, 68 µg cytosolic protein, 2.0 µM of [1-$^{14}$C]-labeled fatty acid (18:0, 18:2n-6, or 20:4n-6), 41.7 mM NaF, 41.7 mM $K^+$ phosphate buffer (pH 7.4), 0.15 M KCl, 0.25 M sucrose, 5.0 mM $MgCl_2$, and 1.6 mM *N*-acetylcysteine, final pH 7.4, 60 µM CoA (sodium salt), 1.3 mM ATP, in a final volume of 1.6 mL according to the procedure described previously (16). Samples that were 2, 4, and 8 µM in [1-$^{14}$C]20:4n-6-CoA were incubated with nuclei with the same incubation mixture but CoA and ATP were omitted. Reaction mixtures were incubated in open tubes under constant shaking at 36°C. Blank incubations without the protein source were done concurrently. After 2.5, 5, 10, and 20 min, nuclei, as a nuclear pellet (N), were separated from the incubation mixture (IM) by centrifugation at 5,000 × *g* at 4ºC for 10 min.

*Lipid analysis.* Lipids from each fraction (N and IM) were extracted by the procedure of Folch *et al.* (31), and the radioactivity of the chloroform (*c*) and water/methanol (*w*) phases was assessed by liquid scintillation counting. Lipids were recovered from the original chloroform extract (IM*c* and N*c*) and separated into different classes by TLC on precoated silica gel G plates, using hexane/diethylether/acetic acid (80:20:1, by vol) as mobile phase. The plates were then subjected to radiochromatographic scanning on a Berthold Ld-2723, Dunnschicht Scanner (Wildbad, Germany) and peaks corresponding to lipid location were compared to those of known lipid standards that were visualized by exposure to iodine vapor. Individual lipids were scraped off from the plate into glass centrifuge tubes, and neutral lipids (DG: diacylglycerols, TG: triacylglycerols, CE: cholesterol esters, and FFA: free fatty acids) and polar lipids were extracted from the silica gel with chloroform/methanol/hexane (2:1:3, by vol)

and assayed for $^{14}C$ by liquid scintillation counting. Fatty acids from individual lipids were analyzed by gas–liquid chromatography (GLC).

*Fatty acid analysis.* Fatty acid methyl esters from nuclear lipids were prepared with $BF_3$/MeOH according to the method of Morrison and Smith (32) and analyzed by gas chromatography (GC), using a Shimadzu 9A GC (Tokyo, Japan) fitted with an Omegawax 250 fused-silica column, 30 m × 0.25 mm, with 0.25 µm phase (Supelco, Bellefonte, PA). Peaks were identified by comparing the retention times with those from a mixture of standard methyl esters.

*Molecular species.* PC fractions for molecular species separation were isolated from the lipid extracts by HPLC using a Merck-Hitachi L-6200 pump (Darmstadt, Germany). Detection was performed using an Evaporative Light-Scattering Detector (5000 ELSD) purchased from Alltech Associates (Deerfield, IL). To separate the PL classes, we used as stationary phase an Econosil Silica normal-phase, 250 × 4.6 mm analytical column purchased from Alltech, packed with 10 µm spherical particles. A guard column packed with the same material was also used. Elution was performed at a flow of 1 mL/min at ambient temperature throughout the separation by a gradient of hexane/isopropanol/dichloromethane 40:48:12 to hexane/isopropanol/dichloromethane/water 40:42:8:8 for 15 min followed by additional elution with the latter solvent for 15 min (33). PC and other components were collected manually from the column effluent using a flow splitter (Alltech) located between the column and the detector. The column effluent was monitored by an ELSD operating at a $N_2$ gas flow rate of 2.2 mL/min and a drift tube temperature of 90°C. The eluate was evaporated to dryness under a stream of nitrogen and redissolved in chloroform/methanol 1:1.

Resolution of molecular species was performed on two 5 µm end-capped Lichrosphere 100, 250 × 4 mm, RP18 columns in series, obtained from Merck (Darmstadt, Germany). Isocratic elution was applied with a mobile phase composed of acetonitrile/methanol/triethylamine 40:58:2 at a rate of 1 mL/min at 10°C. The column effluent was monitored by an ELSD operating at a gas flow rate of 1.8 mL/min and a drift tube temperature at 100°C (34).

The individual PC molecular species were identified by determining the fatty acid composition of each peak as follows and by comparison with the literature (34). Ninety percent of the column eluate was collected using the flow splitter with a fraction collector LKB 2212 Helirac (Bromma, Sweden) every 30 s; the other 10% of eluate from the splitter was analyzed in the ELSD. According to the HPLC–ELSD mass chromatograms, tubes with eluates from the same peak were gathered manually and interesterified for capillary GLC.

PC-radiolabeled samples were injected onto the RP18 column with unlabeled PC of liver homogenate used as internal standard in order to reach the appropriate amount of mass for the ELSD detection. Column eluate (90%) was collected every 30 s by using a flow splitter with a fraction collector LKB 2212 Helirac for subsequent determination of radioactivity by liquid scintillation counting of each tube collected. The remaining 10% eluate from the splitter was quantified in the ELSD, and the HPLC mass chromatograms of each sample were used to identify the radiolabeled peaks of PC molecular species. Radioactivity in each peak was calculated by the addition of the disintegrations per minute from the corresponding eluates, and then as a percentage of the counts recovered in all peaks for that run.

*Data presentation*. Biochemical analyses were run in duplicate. All experiments were carried out five times on nuclear fractions isolated from pooled livers from 3–5 animals.

## RESULTS

*Time course of [1-$^{14}$C]18:0, [1-$^{14}$C]18:2n-6, and [1-$^{14}$C]-20:4n-6 fatty acid incorporation into nuclear lipids*. In order to study the incorporation of the most abundant saturated and unsaturated nuclear fatty acids into nuclear lipids, liver cell nuclei were incubated *in vitro* with [1-$^{14}$C]18:0, [1-$^{14}$C]-18:2n-6, or [1-$^{14}$C]20:4n-6 with or without cytosol. After incubation, the mixture was centrifuged and N was separated from the IM. Lipids from each fraction were extracted by the procedure of Folch *et al.* (31), and the incorporation of radioactivity was measured by liquid-scintillation counting (Fig. 1). The incorporation patterns are expressed as a percentage of the amounts of starting radioactivity (time zero) that contained 100% of the respective [1-$^{14}$C]fatty acid (as analyzed by HPLC).

By using this procedure, on average, 95% of the total radioactivity was recovered in N and IM. In N, for the three fatty acids tested, more than 95% of the radioactivity was incorporated into lipids (fraction N*c*) and less than 5% into nuclear water-soluble components (fraction N*w*) (Fig. 1A). The incorporation profiles of fatty acids into N and IM at all times tested were not affected by the presence of cytosol in the incubation mixture (data not shown).

The incorporation of the three labeled fatty acids into total nuclear lipids (N*c*) showed an early and rapid uptake followed by a later saturation;18:0 was almost fully incorporated (90%) into nuclei, whereas, 18:2n-6 and 20:4n-6 were incorporated 67 and 50%, respectively, at the latest time tested (Fig. 1A, N*c*).

The time-dependent profiles of the fatty acids that had not been incorporated into nuclear lipids and that had remained in the IM are shown in Figure 1B. When nuclei were incubated with 20:4n-6, 90% remained as FFA, whereas with 18:2n-6, 50% remained as FFA and the rest were found to be water-soluble components. In the incubation of nuclei with 18:0, the amount of radioactivity found in the IM was small (less than 10%) and as FFA, since the rest was incorporated in the nuclear lipids (Fig. 1B).

*Incorporation and distribution of [1-$^{14}$C]18:0, [1-$^{14}$C]-18:2n-6, and [1-$^{14}$C]20:4n-6 into nuclear lipid classes.* Figure 2 shows the time course of the incorporation of [1-$^{14}$C]18:0, [1-$^{14}$C]18:2n-6, and [1-$^{14}$C]20:4n-6 into nuclear lipid classes. The radioactivity was found in PL, TG, DG, CE, and FFA. First, [1-$^{14}$C]18:0 was highly incorporated into

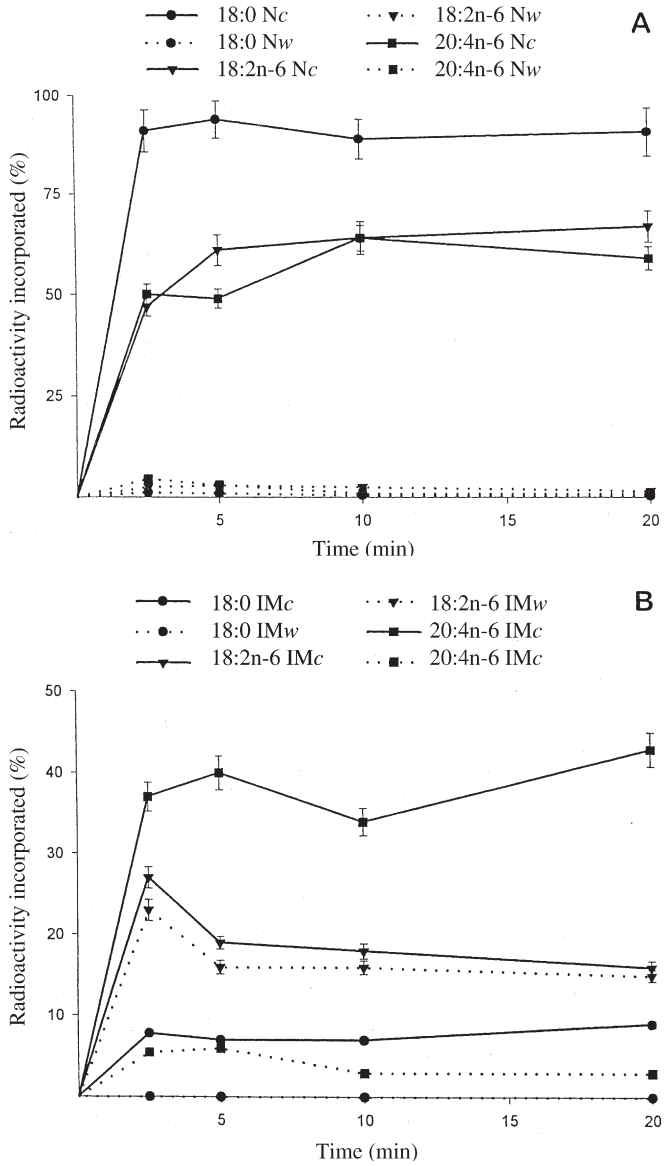

**FIG. 1.** Time-course incorporation of radioactivity into lipids. (A) Nuclear fraction (N) and (B) incubation mixture (IM). Liver nuclei were incubated with [1-$^{14}$C]18:0, [1-$^{14}$C]18:2n-6, or [1-$^{14}$C]20:4n-6 fatty acids. At different time points the incubation mixture was centrifuged to separate the nuclei from the incubation mixture. Lipids from each fraction were extracted by the method of Folch *et al.* (31), and the radioactivity at the chloroform (*c*) and water/methanol (*w*) phases was assessed by liquid scintillation counting. Results are the mean of five experiments ± SE.

nuclear lipids as FFA (78%) whereas [1-$^{14}$C]20:4n-6 was initially incorporated as FFA and esterified to PL (37 and 46%, respectively). Then the incorporated 18:0 and 20:4n-6 FFA decreased after esterification into nuclear lipids. On the other hand, the early incorporation of [1-$^{14}$C]18:2n-6 into cell nuclei as FFA was less and almost saturated from the beginning.

The three fatty acids studied were rapidly esterified mainly into nuclear PL, and this incorporation increased from [1-$^{14}$C]18:2n-6 to [1-$^{14}$C]18:0 and [1-$^{14}$C]20:4n-6 after 20 min of incubation. The incorporation of [1-$^{14}$C]18:2n-6 and [1-$^{14}$C]20:4n-6 into nuclear TG was not as rapid as into PL, increasing throughout the time tested. The incorporation of [1-$^{14}$C]18:0 into nuclear TG reached a low plateau very early, 5 min after incubation, indicating a low selectivity for this acid. The esterification of 18:0 into TG was saturated. This saturation cannot be due to a lack of substrate in the system since the amounts of 18:2 and 20:4 incorporated into TG were higher and increased throughout the test period. The incorporation of fatty acids into nuclear DG was only quantitatively important for [1-$^{14}$C]18:0. From the three fatty acids tested, [1-$^{14}$C]18:2n-6 was the only one esterified to CE under the experimental conditions used. This incorporation, after an initial delay of 2.5 min, increased in the next incubation times tested.

Three controls were done to determine if the esterification of 18:0, 18:2n-6, and 20:4n-6 acid into nuclear lipids followed an acyl-CoA-dependent pathway. Regarding these controls, [1-$^{14}$C]18:0, [1-$^{14}$C]18:2n-6, and [1-$^{14}$C]20:4n-6 acids were incubated, omitting the necessary cofactors for long-chain acyl-CoA synthetase (CoA and ATP) in the IM (Table 1). In these controls, [1-$^{14}$C]18:0, [1-$^{14}$C]18:2n-6, and [1-$^{14}$C]20:4n-6 acids were either incorporated into the nuclei or remained in the IM, exclusively as FFA. These results indicate that the esterification of 18:0, 18:2n-6, and 20:4n-6 into liver nuclear TG, DG, CE (only for 18:2n-6), and PL follows an acyl-CoA-dependent pathway. The incorporation profiles of fatty acids into N were not affected by the presence of cytosol in the incubation mixture as shown in Figure 2.

*PC molecular species of liver cell nuclei.* Typical reversed-phase HPLC (RHPLC) with an ELSD separation of PC molecular species of liver nuclei is illustrated in Figure 3A. In using this procedure, 15 molecular species of PC were identified and quantitated. They are shown in Table 2. The most abundant molecular species are 18:0-20:4 (36.7%), 16:0-20:4 (19.6%), 16:0-18:2n-6 (13.4%), and 18:0-18:2n-6 (11.1%). Arachidonic acid is mainly esterified in four molecular species at the *sn*-2 position of PC: 18:0-20:4, 16:0-20:4, 18:1-20:4, and 18:2-20:4, and in a minor species (0.25%) at both positions *sn*-1 and *sn*-2 in a 20:4-20:4 molecular species. Diarachidonyl PC molecular species coeluted with 18:2-22:6 species in approximately equal amounts, as revealed by the fatty acid analysis of peak 1 (Fig. 3A) which was identified

**TABLE 1**
**Effect of ATP and CoA on [1-$^{14}$C]Fatty Acid Incorporation[a]**

| Incubation conditions | Incorporation of radioactivity as FFA (%) | | | | | |
|---|---|---|---|---|---|---|
| | [1-$^{14}$C]18:0 | | [1-$^{14}$C]18:2n-6 | | [1-$^{14}$C]20:4n-6 | |
| | N*c* | IM*c* | N*c* | IM*c* | N*c* | IM*c* |
| With ATP and CoA | 40 | 100 | 12 | 53 | 10 | 93 |
| Without ATP and CoA | 100 | 100 | 100 | 100 | 100 | 100 |

[a]Liver nuclei were incubated with [1-$^{14}$C]18:0, [1-$^{14}$C]18:2n-6, or [1-$^{14}$C]20:4n-6 fatty acids with or without ATP and CoA for 20 min. After the incubation the samples were assayed as described in Figure 2. Results are presented as a percentage of the total $^{14}$C radioactivity incorporated as free fatty acids into nuclear lipids (N*c*: chloroform phase) and into the incubation mixture (IM*c*: chloroform phase).

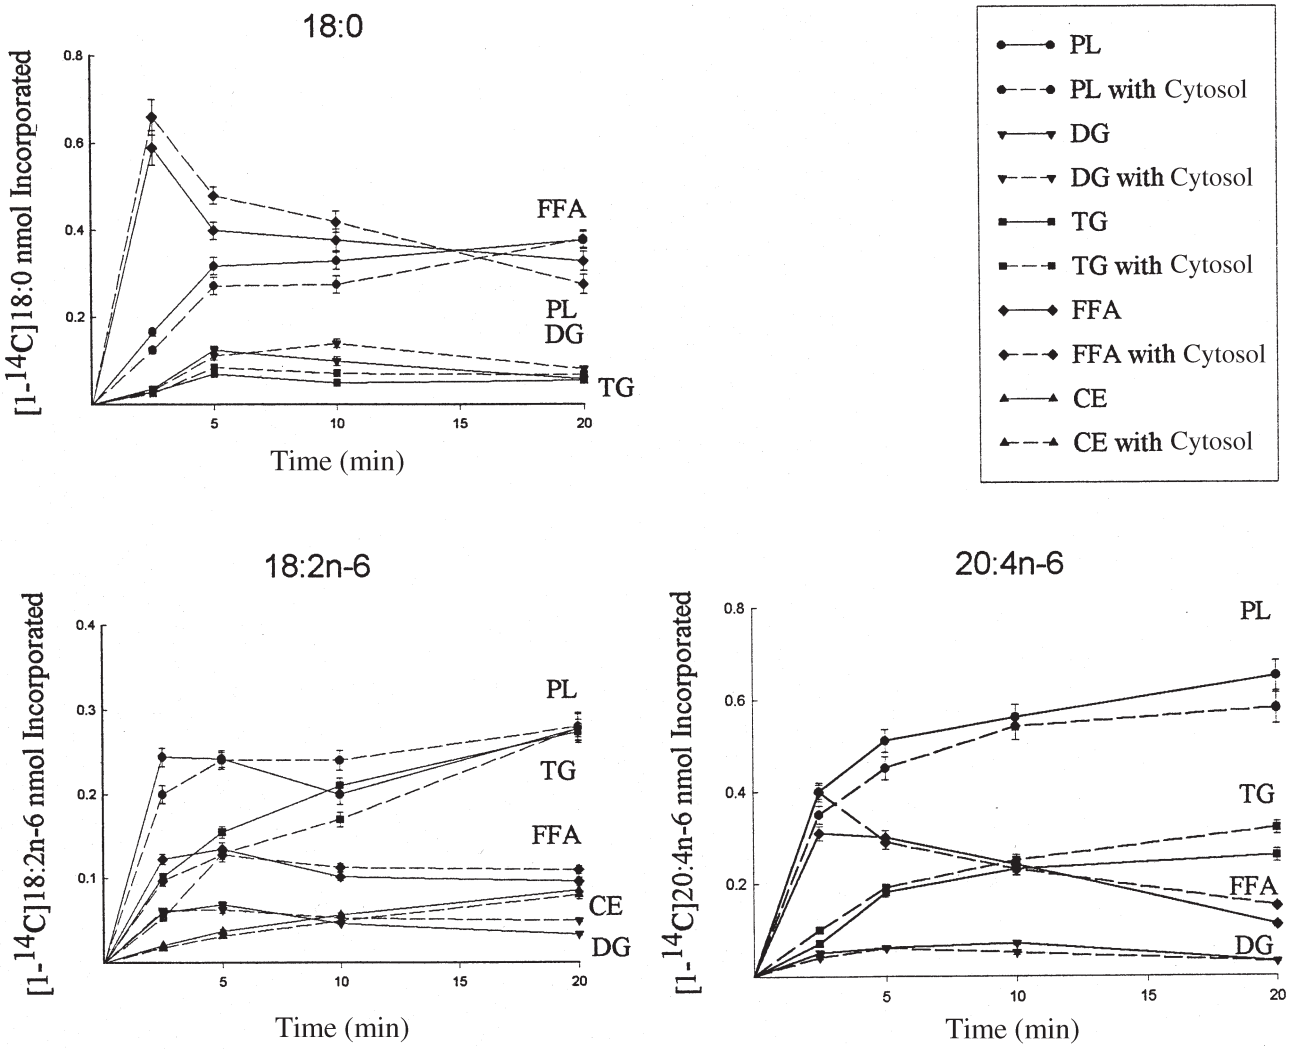

**FIG. 2.** Time-course incorporation of [1-$^{14}$C]18:0, [1-$^{14}$C]18:2n-6, or [1-$^{14}$C]20:4n-6 fatty acids into nuclear lipid classes. Liver nuclei were incubated with [1-$^{14}$C]18:0, [1-$^{14}$C]18:2n-6, or [1-$^{14}$C]20:4n-6 fatty acids with or without cytosol. After the incubation the fraction containing nuclei was separated as described in Figure 1; lipids were extracted and separated by thin-layer chromatography. Scanning of the thin-layer plates was performed as described in the Materials and Methods section. The $^{14}$C was recovered in phospholipids (PL) and in neutral lipids as triacylglycerols (TG), diacylglycerols (DG), cholesterol esters (CE), and free fatty acids (FFA). Results are the mean of five experiments ± SE.

by comparison with a commercial standard of 20:4-20:4 PC and by comparison with literature data (35).

*Incorporation of [1-$^{14}$C]20:4n-6-CoA into PC molecular species.* Liver cell nuclei were incubated *in vitro* with 2, 4, and 8 µM [1-$^{14}$C]20:4n-6-CoA, and the typical RHPLC-ELSD separation of labeled PC molecular species is shown in Figure 3B. From the 15 molecular species of liver nuclear PC, five peaks were labeled and identified by means of HPLC–mass chromatogram of each sample as described in the Materials and Methods section. Labeled peak 1 was identified with a commercial standard of 20:4-20:4 PC as described above.

Specific radioactivity of the molecular species of liver nuclear PC is presented in Table 2. The distribution of radioactivity among the five peaks was the same for the three concentrations of [1-$^{14}$C]20:4n-6-CoA tested. Therefore, data from these samples are presented together. These results could be due to the fact that [1-$^{14}$C]20:4n-6-CoA esterified into PL was saturated at all concentrations analyzed and that the excess of acyl-CoA added to the incubation and not esterified into PL, TG, and CE was hydrolyzed to FFA by nuclear acyl-CoA hydrolase (36) as shown in Figure 4.

The molecular species of PC showing the highest specific radioactivity after the incubation of liver nuclei with [1-$^{14}$C]-20:4n-6-CoA were 20:4-20:4 and, in a minor proportion, 18:2-20:4. In liver nuclei, 20:4-20:4 PC is quantitatively the minor molecular species, since it only represents 0.25 µmol% of total PC. On the other hand, the most abundant molecular species of liver nuclei PC, 18:0-20:4 and 16:0-20:4, showed the lowest specific radioactivity (Table 2).

These results demonstrated that liver cell nuclei can utilize exogenous 20:4n-6-CoA for the synthesis of molecular species with 20:4n-6 at the *sn*-2 position, although the most actively and newly synthesized PC contained 20:4n-6 at both

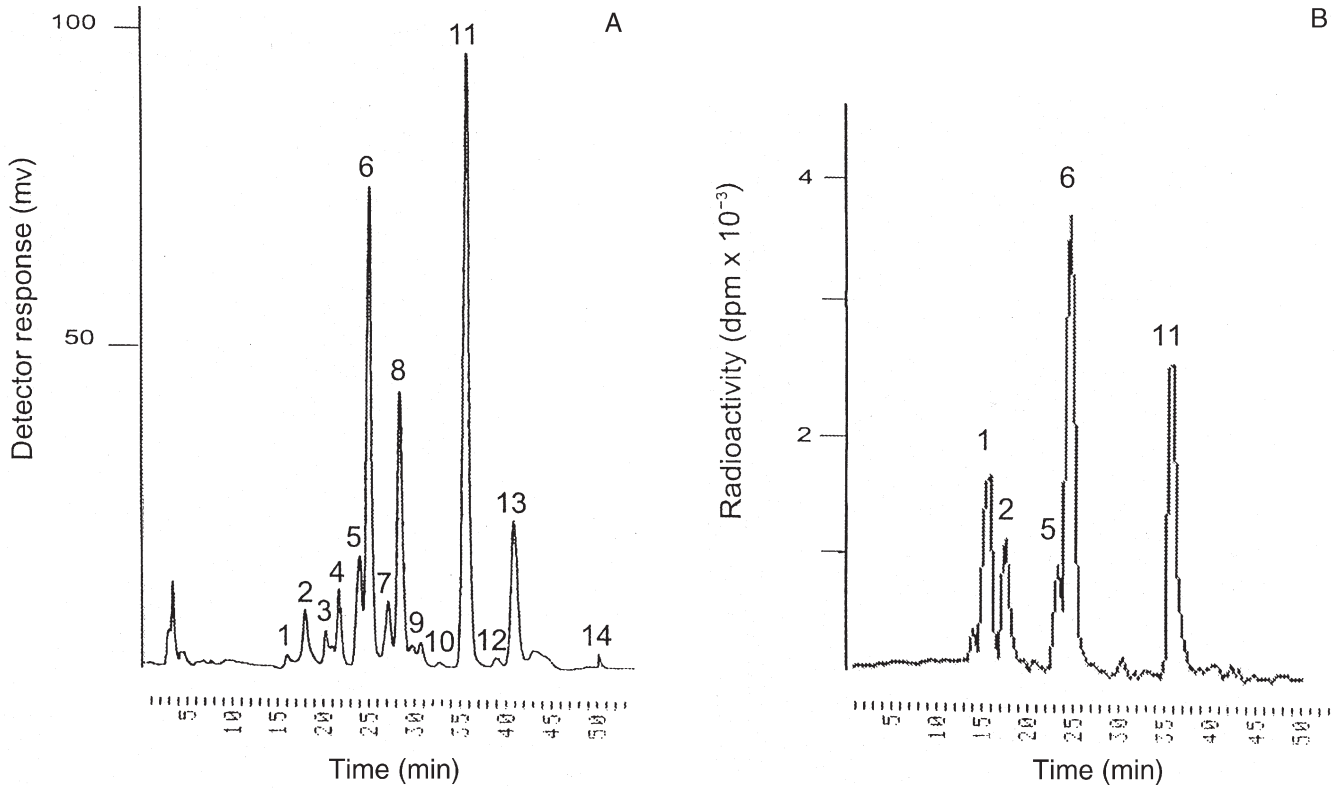

**FIG. 3.** Molecular species of phosphatidylcholine (PC) from liver cell nuclei. Molecular species of PC were analyzed by reversed-phase high-performance liquid chromatography as described in the Materials and Methods section. The identification and quantitation of each peak is presented in Table 2. (A) Typical chromatogram of mass distribution using evaporative light-scattering detector. (B) Labeled molecular species of PC after incubation of liver nuclei *in vitro* with [1-$^{14}$C]20:4n-6-CoA.

[a]Peak numbers correspond to those shown on the HPLC chromatogram in Figure 3. In peak 1, two different molecular species coeluted from the HPLC (18:2-22:6 and 20:4-20:4).
[b]Data were recalculated from peak areas (µmol%), dpm collected per peak (dpm %), and specific radioactivities calculated from total dpm and total µmol (dpm·µmol$^{-1}$). Values are means of $n$ incubations analyzed in duplicate. Boldface corresponds to molecular species with arachidonic acid. Disintegrations per minute, dpm.

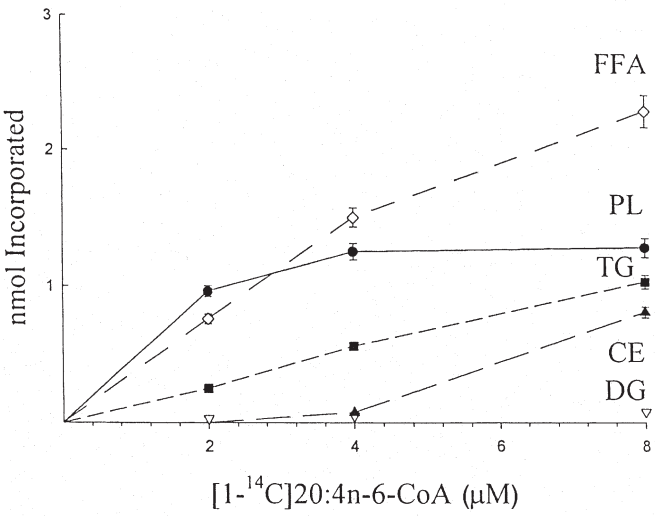

**FIG. 4.** Incorporation of [1-$^{14}$C]20:4n-6-CoA into nuclear lipid classes. Liver nuclei were incubated with different concentrations of [1-$^{14}$C]20:4n-6-CoA for 10 min. Nuclear lipids were extracted and separated as described for Figure 2. Results are the mean of five experiments ± SE. ●, PL; ▽, DG; ■, TG; ◇, FFA; ▲, CE. For abbreviations see Figure 2.

the *sn*-1 and *sn*-2 positions of the molecule. As Schmid *et al.* reported (35), the high specific radioactivity in this minor species would indicate that 20:4-20:4 PC was synthesized *de novo via* phosphatidic acid.

## DISCUSSION

In addition to the traditional roles of fatty acids as nutrients and sources of metabolic energy and structural components of complex lipids, fatty acids *per se* have physiological and pathological effects; they also regulate gene expression.

Regulation of gene expression by fatty acids is an event that takes place inside the nuclei of eukaryotic cells. It may be produced by a direct effect of fatty acids or fatty acyl-CoA (9,37) over gene expression, or through the activation of factors translocated into the nucleus (37). For instance, peroxisome proliferator-activated receptor-α can be activated by fatty acids (37), and PUFA-receptor element may regulate gene expression of stearoyl-CoA desaturase (9). On the other hand, hepatocyte nuclear factor-4α (HNF-4α) may bind acyl-CoA and be activated (38). Fatty acids in the nuclei may come from cytosol, be hydrolyzed from other nuclear lipids, or be synthesized in the same nuclei. Since information is scarce on nuclear fatty acid metabolism, on the precise topology of nuclear lipid metabolism, and on the relationship between nuclear lipids and cell functions, the aim of the present study was to investigate the incorporation and distribution of stearic (18:0), linoleic (18:2n-6), and arachidonic (20:4n-6) acids with or without the presence of the cytosol fraction in the presence of ATP and CoA.

The results showed that fatty acids tested were taken up by the nuclei and esterified into nuclear lipids by an acyl-CoA pathway. Fatty acids would be activated to the corresponding fatty acyl-CoA esters by the nuclear fatty acyl-CoA synthetase (19). We found different patterns of incorporation and esterification for 18:0, 18:2n-6, and 20:4n-6 fatty acids, showing a nuclear selectivity for them (Figs. 1 and 2). From all fatty acids tested, 20:4n-6 was the most esterified into nuclear lipids with respect to 18:2n-6 and 18:0.

In this study, the profiles of fatty acid incorporation and distribution into nuclear lipids were not affected by the presence of cytosol in the incubation mixture (Fig. 2). In consequence cytosolic proteins are apparently not necessary in this process. One of the reasons for which a cytosol fraction was added to the incubation mixture was to test the effect of some cytoplasmic proteins, since under physiological conditions, and as a result of their low solubility in water, fatty acids are transported through extracellular and intracellular aqueous spaces bound to albumin (39) and cytoplasmic fatty acid-binding proteins (FABP) (40), respectively. Recently, a nuclear FABP (41) and an acyl-CoA binding protein (37) have also been described.

In agreement with our results, Baker and Chang (42,43) found that neuronal nuclei isolated from cerebral cortices of rabbits esterified *in vitro* [$^{14}$C]oleate and [$^{3}$H]arachidonate into complex lipids. The incorporation was dependent upon ATP, CoA and acyl-CoA synthetase. A nuclear acyl-CoA synthetase was also observed by Stadler and Franke in chicken erythrocytes (44). In contrast, Surette and Chilton (45) found that isolated nuclei of human monocyte-like THP-1 were unable initially to incorporate arachidonic acid into their PL in the absence of cellular cytosol. These authors reported that this inability was due to the lack of fatty acyl-CoA synthetase and/or acyltransferase activity in their nuclear preparation of these cells, and that these enzymes would be present in their cytosol preparation. These results would indicate a different mechanism for the lipid nuclear metabolism between liver and cerebral cortex and inflammatory cells. Nuclei from liver (19) and cerebral cortex (42,43) have enzymatic activity of acyl-CoA synthetase whereas inflammatory cell nuclei would lack this enzymatic activity (45).

In our experiments, the 18:0 fatty acid was directly incorporated from the IM into the nuclei as FFA, whereas 20:4n-6 was initially incorporated as FFA and esterified to PL. The acids 18:0 and 20:4n-6 were mainly esterified into PL, and in a minor proportion into TG and DG by an acyl-CoA pathway. This incorporation increased throughout the incubation time (Fig. 2).Therefore, these results are in agreement with a previous report (20), showing that 20:4n-6 synthesized *in vitro* from 20:3n-6 by liver nuclear Δ5 desaturase is also esterified mainly into PL, and in a lesser proportion into TG and DG. On the other hand, unlike liver nuclei, neuronic nuclei from the cerebral cortex esterify 18:1 and 20:4n-6 into TG in a greater proportion than into PL, whereas in these cell microsomes, 20:4n-6 is incorporated mainly into PL with respect to TG (43).

The main difference found between 18:2n-6 and 18:0 and 20:4n-6 incorporation into nuclear lipids was that 18:2n-6 was largely esterified into both PL and TG (Fig. 2). Besides, 18:2n-6 was also esterified to CE. These results indicate a specific selectivity in nuclear fatty acid esterification.

It is known that all cells readily take up FFA from the culture medium and incorporate them into cellular PL and TG (46). In particular, when arachidonic acid is taken up by mammalian cells, it is initially esterified into nuclear glycerolipids, then it will regulate gene expression (47) and/or move into other cellular compartments as suggested by Schievella *et al.* (17).

In nuclei, most lipids are PL and structural components of nuclear membranes, although there are also PL in a minor proportion that are associated with chromatin and nuclear matrix (48–50). The main nuclear PL is PC, which constitutes over 56% of liver nuclear glycerophospholipids (data not shown). Taking into account that arachidonic acid was mainly esterified into PL (Fig. 2), we studied arachidonic acid nuclear pools analyzing PC molecular species. In using RHPLC-ELSD, 15 molecular species of PC were identified and quantified as shown in Table 2. The most abundant nuclear molecular species of PC contained arachidonic acid at the *sn*-2 position, and they were: 18:0-20:4 (36.7%) and 16:0-20:4 (19.6%). They were followed by less abundant molecular species containing linoleic acid also at the *sn-2* position:

16:0-18:2n-6 (13.4%) and 18:0-18:2n-6 (11.1%). The main PC nuclear pools of arachidonic acid are the following molecular species: 18:0-20:4, 16:0-20:4, 18:1-20:4, 18:2-20:4, these being arachidonic acid esterified at the *sn*-2 position of glycerol. A PC molecular species was also found, though in a minor proportion (0.25 %), in which both *sn*-1 and *sn*-2 positions were esterified to arachidonic acid. The pattern of molecular species of nuclear PC is the same as that in the whole organ (data not shown).

These results led us to consider that an active transesterification of 20:4n-6 exists in liver nuclei. Therefore, to get further information about the incorporation of arachidonic acid into nuclear cell pools, we incubated liver nuclei *in vitro* with [1-$^{14}$ C]20:4n-6-CoA and determined the labeled PC molecular species (Fig. 3B). From the 15 molecular species of liver nuclear PC, five peaks were labeled and identified. The specific radioactivity of these are presented in Table 2.

As expected, the most abundant molecular species containing arachondic acid:18:0-20:4 and 16:0-20:4 PC incorporated the highest label, but by far the highest specific radioactivity was found in the double 20:4-20:4 PC molecular species, which is a minor molecular species. Schmid *et al*. (35) reported that when the percentage of radioactivity exceeds the mol percentage, it is assumed that the species are primarily formed through *de novo* synthesis. In this regard, the same mechanism would be active in liver nuclei.

Generally, double 20:4-20:4 PC molecular species are present in very low levels in different animal tissues (51–53). However, Schmidt *et al*. (35,54) have shown that when arachidonic acid is offered to cells, the first step is the *de novo* synthesis of a molecular species of PC and phosphatidylethanolamine having arachidonic acid bound to both the *sn*-1 and *sn*-2 positions. But once 20:4-20:4 PC is formed, a remodeling occurs at the *sn*-1 position, with the result that the predominant species are 18:0-20:4n-6 and 16:0-20:4 PC. An analogy can be made with cell nuclei; then we can infer that a remodeling process is also active in the nuclei. That is, the 20:4-20:4 PC molecular species in liver cell nuclei is a minor component because it is synthesized and apparently remodeled by translocation. The *sn*-1 position would be mainly replaced by 16:0 and 18:0, the fatty acids that are generally found at this position.

It is not yet clear whether these diunsaturated PC molecular species that are in minor proportion in the cell and nuclei have physiological functions *per se*, or if they are only metabolic intermediates in *de novo* synthesis and lipid remodeling. By the way, PL containing arachidonic acid at the *sn*-1 position of glycerol are particularly important since these PL are precursors of anandamide (*N*-arachidonylethanolamine), which is a ligand of the cannabinoid receptor in mammalian tissues (55).

It is also important to remark that the enzymes responsible for metabolizing arachidonic acid to prostaglandins and leukotrienes have also been localized in the nuclear envelope (56–58); and phospholipase $A_2$, which hydrolyzes 20:4n-6 from PL and provides this substrate for these processes, translocates to the nuclear membrane (17). This fact implies that the nucleus is an important site for the control of some arachidonic acid cellular effects.

In conclusion, these findings indicate that liver cell nuclei possess the necessary enzymes to incorporate exogenous saturated and unsaturated fatty acids into nuclear lipids by an acyl-CoA-dependent pathway, showing a nuclear specificity for each fatty acid in these processes. Liver cell nuclei can also utilize exogenous 20:4n-6-CoA for the synthesis of the main molecular species of PC, the main species with 20:4n-6 at the *sn*-2 position, and the minor species with 20:4n-6 at both the *sn*-1 and *sn-2* positions of the molecule. The labeling pattern of 20:4-20:4 PC would indicate that this molecular species is synthesized mainly by the *de novo* pathway.

## ACKNOWLEDGMENTS

CONICET and the Agencia Nacional de Promoción Científica y Tecnológica supported this study financially. The authors wish to thank Norma Tedesco for her secretarial assistance and Ana Bernasconi for her technical assistance.

# Purification and Characterization of an Extracellular Lipase from *Penicillium candidum*

**Beatriz Ruiz[a], Amelia Farrés[b], Elizabeth Langley[a], Felipe Masso[c], and Sergio Sánchez[a,*]**

Departamentos de [a]Biotecnología del Instituto de Investigaciones Biomédicas y [b]Alimentos y Biotecnología de la Facultad de Química, Universidad Nacional Autónoma de México (UNAM), Ciudad Universitaria, México DF 04510, y [c]Instituto Nacional de Cardiología, S.S.A., México DF

**ABSTRACT:** *Penicillium candidum* produces and secretes a single extracellular lipase with a monomer molecular weight of 29 kDa. However, this enzyme forms dimers and higher molecular weight aggregates under nondenaturing conditions. The lipase from *P. candidum* was purified 37-fold using Octyl-Sepharose CL-4B and DEAE-Sephadex columns. The optimal assay conditions for lipase activity were 35°C and pH 9. The lipase was stable in the pH range of 5–6 with a pI of 5.5, but rapid loss of the enzyme activity was observed above 25°C. Tributyrin was found to be the best substrate for the *P. candidum* lipase, among those tested. Metal ions such as $Fe^{2+}$ and $Cu^{2+}$ inhibited enzymatic activity and only $Ca^{2+}$ was able to slightly enhance lipase activity. Ionic detergents inhibited the activity of the enzyme, whereas nonionic detergents stimulated lipase activity.

Paper no. L8609 in *Lipids 36,* 283–289 (March 2001).

Lipases [EC 3.1.1.3] are enzymes that hydrolyze ester bonds at oil–water interfaces producing mono- and diacylglycerols, glycerol, and free fatty acids (1). These enzymes have received much attention during the last 10 yr because of their potential industrial applications. Examples of their uses are resolution of racemic mixtures, production of optically active compounds, and ester synthesis. Currently they are mainly used in the dairy industry. In this field lipases have applications in flavor development of certain types of cheese, flavor enhancement, cheese ripening acceleration, and production of cheese-like products (2). Filamentous fungi are the preferred sources for industrial uses of lipases because their enzymes are extracellular. The most utilized species belong to the genera *Rhizopus*, *Rhizomucor*, *Geotrichum*, *Penicillium,* and *Aspergillus* (3).

*Penicillium candidum* is a deuteromycete that produces an extracellular, inducible lipase suitable for dairy flavor development. Previously, we reported some studies on enzyme formation in this fungus (3). In this paper we describe the purification of the lipase from *P. candidum* and the general characteristics of the purified enzyme.

## EXPERIMENTAL PROCEDURES

*Strain. Penicillium candidum* was acquired from the Instituto de Investigaciones Biomédicas Culture Collection, U.N.A.M., Mexico. This strain was preserved as reported by Celerin and Fergus (4).

*Culture conditions.* All fermentations were performed at 27°C and 160 rpm in 500-mL Erlenmeyer flasks with 100 mL of "D" medium (1% glucose, 1% casamino acids, 0.2% $KNO_3$, 0.1% $KH_2PO_4$, 0.05% $MgSO_4$), using 0.2% olive oil as inducer.

*Enzyme assays. (i) Spectrophotometric assay*. The method previously described by Isobe *et al.* (5) was used to determine lipolytic activity using the spectrophotometric measurement of *p*-nitrophenol release. The assay was performed using 2.5 mM *p*-nitrophenyl laurate as substrate in 20 mM Tris-HCl, pH 7.2, and 2% Triton X-100. One milliliter of the reaction mixture was incubated for 10 min at 37°C. Optical density at 410 nm was read before and immediately after incubation. Activity against different *p*-nitrophenyl derivatives was analyzed using this same method with 2.5 mM of each substrate. One unit of lipase activity is defined as the amount of enzyme which liberates 1 μmol *p*-nitrophenol/min under these assay conditions.

*(ii) Emulsion method*. Lipase activity was measured by determination of butyric acid released during hydrolysis as determined by measuring change in pH (6). Tributyrin (80 μmol) was emulsified in 3 mL of Tris-HCl 20 mM, pH 8. This mixture was incubated for 30 min at 37°C under constant agitation. Lipase-catalyzed hydrolysis of tributyrin was followed potentiometrically with a Beckman (Fullerton, CA) pH-meter model 3500. Activity against mono-, di-, and triglycerides was tested using the same reaction mixture and incubation conditions but changing the substrate (80 μmol each). One unit is defined as the amount of enzyme which liberates 1 μmol free fatty acid/min under the assay conditions.

*Protein measurement.* Protein in the enzyme preparation was determined by the method of Lowry *et al*. (7) using bovine serum albumin as standard.

*Electrophoresis*. Polyacrylamide gel electrophoresis (PAGE) under denaturing conditions was performed as described by Laemmli (8), in 12% running and 4% stacking gels. Protein was stained using the silver stain method reported by Rosenberg (9). Low molecular weight markers were used with the following reference proteins: phosphorylase B (97.4 kDa),

bovine serum albumin (66.2 kDa), ovalbumin (45 kDa), carbonic anhydrase (31 kDa), soybean trypsin inhibitor (21.5 kDa), and lysozyme (14.4 kDa) (Bio-Rad, Richmond, CA).

*Zymography. In situ* lipase activity was detected by zymography following sodium dodecyl sulfate (SDS)-PAGE. The gel was placed onto a solid lipase detection medium containing tributyrin and incubated at 37°C for 60 min (10).

*Enzyme purification. Penicillium candidum* was grown for 72 h, and culture medium was filtered through Whatman #1 paper (Whatman, Maidstone, England). The solution was concentrated by inverse dialysis against powdered sugar overnight at 4°C. Ammonium sulfate was added until the solution reached 20% saturation at 0°C overnight with agitation. The saturated solution was centrifuged for 20 min at 20,000 × *g* and 4°C. Ammonium sulfate was then gradually added to the supernatant until it reached 75% saturation under the same conditions. The solution was centrifuged for 20 min and the activity-containing precipitate was resuspended in 20 mM citrate buffer, pH 6.5.

The fraction containing enzymatic activity was adjusted to 1 M $(NH_4)_2SO_4$ and was applied to an Octyl Sepharose CL-4B column (Pharmacia, Uppsala, Sweden) (11 × 215 mm) previously equilibrated with 20 mM citrate buffer pH 6.5 containing 1 M $(NH_4)_2SO_4$. The column was washed with the same buffer and the enzyme was eluted by a decreasing step gradient of $(NH_4)_2SO_4$ in the same buffer, from 1 to 0 M, at a flow rate of 0.75 mL/min. Activity in each fraction was measured by the spectrophotometric method as described previously. The active fractions were combined and concentrated to 2 mL using an Amicon centriflo membrane cone (Amicon, Beverly, MA). The concentrated enzyme solution was loaded onto a DEAE-Sephadex A-50 column (Sigma, St. Louis, MO) pre-equilibrated with 50 mM citrate buffer, pH 6.5 containing 1% Nonidet P-40 (USB, Cleveland, OH). The column was washed with the same buffer to remove the unadsorbed material. The enzyme was eluted by an increasing step gradient of NaCl (0–500 mM) in the same buffer at a flow rate of 0.5 mL/min. Lipase fractions were pooled and concentrated by ultrafiltration with an Amicon centriflo membrane cone. As recovery of enzyme activity after the DEAE-column was low, lipase characterization was performed using the enzyme obtained after the octyl-sepharose column.

*Isoelectric focusing*. Electrofocusing was performed on a Phast System according to the manufacturer's instructions using IEF 3-9 Phast Gels (Pharmacia). Standards used were trypsinogen (pH 9.3), basic lentin lectin (pH 8.65), lentin lectin middle (pH 8.45), lentin lectin acidic (pH 8.15), basic myoglobin (pH 7.35), acidic myoglobin (pH 6.85), human carbonic anhydrase B (pH 6.55), bovine carbonic anhydrase B (pH 5.85), β-lactoglobulin A (pH 5.2), and amylglucosidase (pH 3.5) (Bio-Rad). Proteins were detected by Coomassie staining and zymography.

*Effect of pH and temperature on lipase activity*. Enzyme aliquots obtained after the octyl-sepharose column were incubated without substrate for 10 min at different temperatures from 4 to 75°C. Remaining activity was measured by the spectrophotometric assay. The optimal temperature for activity was determined by increasing the temperature in steps of 5°C, from 20 to 65°C.

The effect of pH on enzyme stability was tested using buffered solutions adjusted to different pH values (acetate buffer pH 4–6 and phosphate buffer pH 6–9) and incubating without substrate for 24 h at 37°C. After incubation the pH values remained constant. The remaining activity was determined by the spectrophotometric method.

Optimal pH was analyzed by the emulsion method using different pH values from 5 to 11 (citrate buffer from 5 to 6, 3-[*N*-morpholino]propanesulfonic acid (MOPS) buffer from 7 to 9 and bicarbonate buffer from 9 to 11). In order to avoid buffer effects on the enzyme assays, the pH optimum was determined using several sets of buffers obtaining similar results: Tris-HCl pH 7–8, glycine pH 9–10, MOPS, 7–9, bicarbonate pH 9–11 and borate pH 9–10.

*Effect of metal ions.* The effect of metal ions on lipase activity was measured using the spectrophotometric assay. The reaction mixture was supplemented with various salts at a final concentration of 1 or 10 mM. The salts tested were monovalent, such as KCl and NaCl, and divalent, such as $CaCl_2$, $MgCl_2$, $MnCl_2$, $SrCl_2$, $CoCl_2$, $CuCl_2$, and $FeCl_2$.

*Effect of detergents.* The enzyme solution was incubated for 1.5 h at 37°C in 20 mM citrate buffer, pH 5.5 containing 0.1 or 1% (wt/vol) of each detergent. Lipase activity was tested at 0 and 1.5 h by the spectrophotometric method. The detergents assayed were Nonidet P-40 (USB), Triton X-100, Tween 20, Tween 80 (Sigma), sodium cholate, sodium deoxycholate (Research Organics, Cleveland, OH), and Zwittergent (Fluka, Buchs, Switzerland).

*N-terminal sequence analysis*. The N-terminal sequence of *P. candidum* lipase was analyzed using an automated Protein Sequencer 491, Procise (Applied Biosystems, Foster City, CA), consisting of a gas-phase sequencer and liquid sequencer.

## RESULTS

*Lipase purification*. In order to obtain lipase from *P. candidum,* the fungus was grown for 72 h until late log phase. The extracellular medium was concentrated and then precipitated with ammonium sulfate. The sample obtained after precipitation with ammonium sulfate was applied to an octyl-sepharose chromatography column. The elution pattern showed a single peak with lipase activity (data not shown). This peak was eluted only after using 1% detergent, which indicates the hydrophobic character of this enzyme. The active samples were pooled and applied to a DEAE-Sephadex column. The enzyme was purified to homogeneity (about 36.7-fold) with a low recovery of activity (0.8%). A summary of the purification is shown in Table 1. Purified preparations had specific activities of approximately 14,000 units of lipase activity (U/mg).

*Enzyme characterization*. In order to determine the size of the lipase, we analyzed the protein using denaturing and non-

**TABLE 1**

[c]Sigma Chemical, St. Louis, MO.

denaturing PAGE. The enzyme was detected by silver staining and the activity by zymography after electrophoresis. The molecular weight of the enzyme was 29 kDa as determined by SDS-PAGE (Fig. 1). However, under nondenaturing conditions, the purified lipase migrated as a dimer and tetramer with molecular weights of approximately 64 and 130 kDa, respectively (Fig. 2). This behavior has been observed in other lipases from the genus *Penicillium* (11–14). Attempts to disaggregate the lipase using organic solvents such as ethanol and isopropanol failed due to denaturation of the enzyme causing loss of activity. Di- and tetra-aggregates showed lower lipase activity than the monomer on zymography assays (data not shown). Electrofocusing assays followed by zymography showed the isoelectric point to be 5.5.

*Effect of pH and temperature on lipase activity and stability.* The pH optimum for *P. candidum* lipase was studied in a range from pH 5 to 11 using the emulsion method. The enzyme was found to be most active at pH 9.0 and was most stable in the pH range from 4 to 6 when incubated at 37°C for 30 min (Fig. 3).

The effects of temperature on enzyme activity were examined through a range of 4 to 75°C using the spectrophotometric method. The optimal temperature was about 35°C, as shown in Figure 4. This temperature optimum is similar to that of other fungal lipases such as those from *Fusarium* sp. YM-30 (15), *P. caseicolum* (16), and *P. simplicissimum* (13).

Stability was tested after incubation at different temperatures for 10 min. The enzyme was stable at temperatures below 25°C. At 35°C the lipase retained 70% of its full activity while at 75°C, the enzyme completely lost activity. Remaining activity was determined using spectrophotometric assay.

*Effect of metal ions*. Table 2 indicates the effects of various metal ions on enzyme activity as determined by the spectrophotometric method. Calcium chloride at 1 mM was the only salt with a significant positive effect on lipase activity, although at 10 mM the effect became slightly negative. When $FeCl_2$ and $CuCl_2$ were added, the effect on enzyme activity was strongly negative at both concentrations tested. A negative effect on the lipase was observed upon adding $CoCl_2$, $MnCl_2$, and KCl only at a concentration of 10 mM. With NaCl, $MgCl_2$, and $SrCl_2$ the lipolytic activity was not affected.

*Substrate specificity*. To study the substrate specificity of *P. candidum* lipase, we tested esterase and lipase activities by using *p*-nitrophenyl derivatives and triglycerides, respectively. Hydrolysis of mono-, di-, and triglycerides with different fatty acid chain lengths was tested by the emulsion method. The *P. candidum* lipase preferred triglycerides to

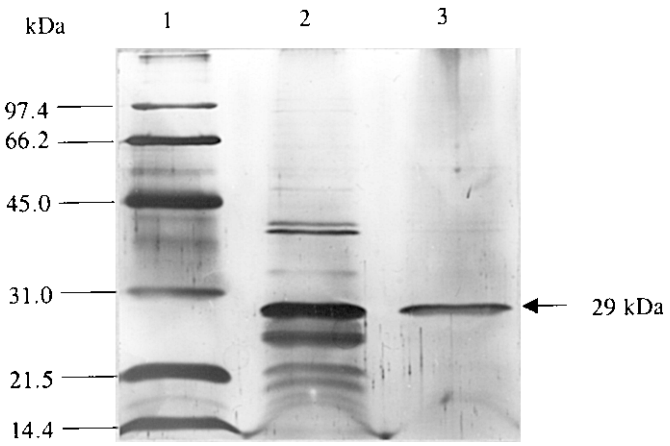

**FIG. 1.** Sodium dodecylsulfate-polyacrylamide gel electrophoresis (12%) of *Penicillium candidum* lipase. Lane 1: low molecular weight marker proteins; lane 2: octyl-sepharose eluate fraction; lane 3: DEAE-Sephadex eluate fraction. The arrow indicates the lipase.

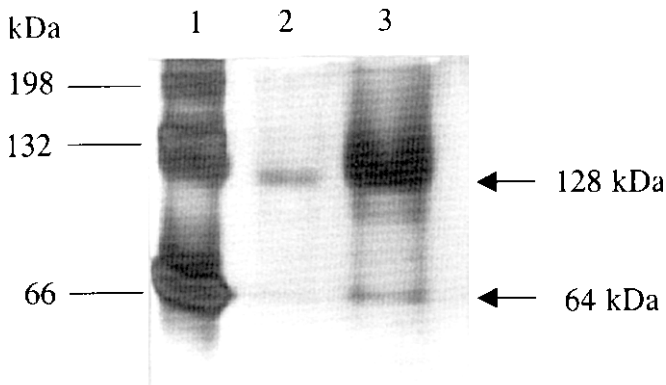

**FIG. 2.** Nondenaturing gel electrophoresis (12% acrylamide) conditions of the purified lipase from *Penicillium candidum* detected by silver staining. Lane 1: molecular weight marker for native electrophoresis (bovine serum albumin); lanes 2 and 3: purified lipase (0.18 and 2.9 μg of protein, respectively). Arrows indicate bands of di- and tetramers of the purified lipase.

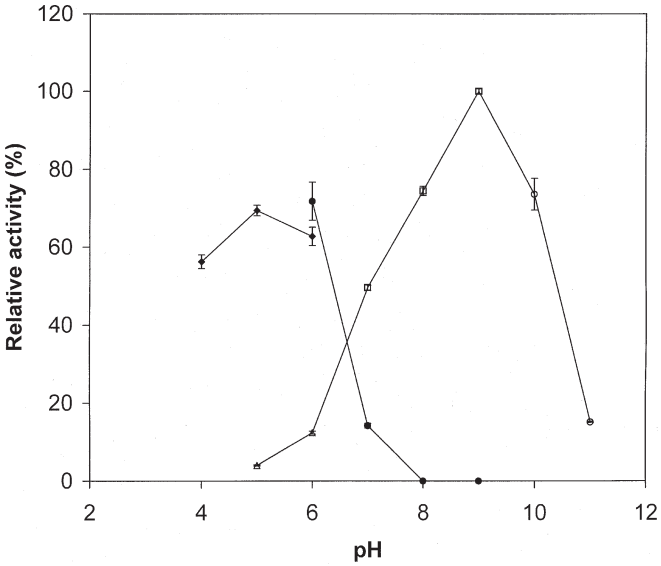

**FIG. 3.** pH effect on *Penicillium candidum* lipase activity. Optimal pH was determined using 20 mM citrate buffer pH 5–6 (△), 20 mM 3-[*N*-morpholino]propanesulfonic acid pH 7–9 (□), and 20 mM bicarbonate buffer pH 9–11 (○). Stability at different pH values: (◆) at pH 4–6 in acetate buffer, (●) at pH 6–9 in phosphate buffer. Optimal pH was determined by the emulsion method and pH stability by the spectrophotometric method. In both cases the reaction mixture was incubated at 35°C.

mono- or diglycerides such as monocaprin, monolaurin, monoolein, dicaprin and diolein. These substrates were hydrolyzed at 2–18% compared to tributyrin, its best substrate. For example, tricaprin was 41.5% hydrolyzed and its mono- and diglyceride were 11 and 13.5% hydrolyzed, respectively. Among various triglycerides, *P. candidum* enzyme showed preference for tributyrin and to a lesser degree for tricaprin, trilaurin, and triolein (Table 3).

When measuring its activity on *p*-nitrophenyl derivatives, we found the enzyme showed higher activity against *p*-nitrophenyl palmitate compared to the other substrates. Although palmitate and stearate are insoluble, the enzyme displayed higher activity on a suspension of these monoesters (Table 3).

*Effect of detergents.* Because the purified *P. candidum* lipase aggregates, causing a decrease in enzyme activity, we decided to test the effect of several detergents on its activity. *Penicillium candidum* lipase activity was assayed at concentrations of 0.1 and 1% (wt/vol) of several detergents

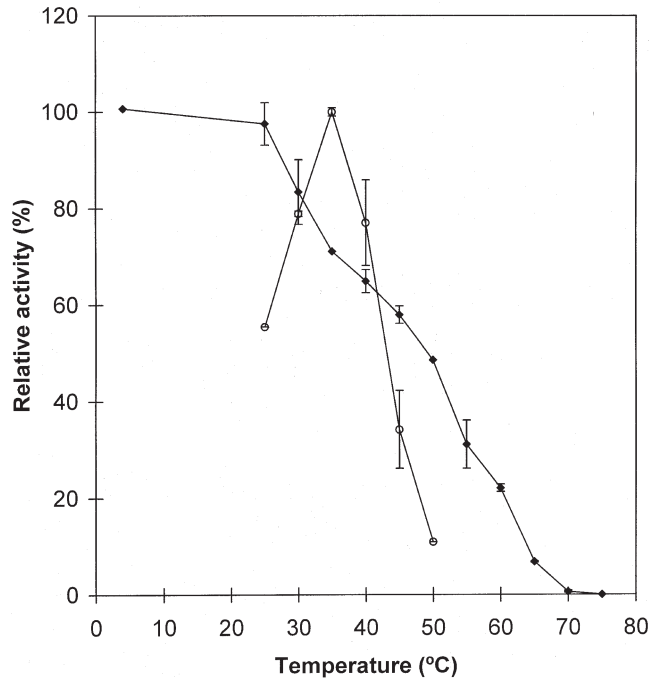

**FIG. 4.** Temperature effect on *Penicillium candidum* lipase activity. Optimal temperature (○), temperature stability (◆). Effects were determined by the spectrophotometric method using 20 mM citrate buffer pH 5.5.

| Tween 20[c] | 117.5 ± 14 | 117.8 ± 6 | 104.3 ± 7 | 69.3 ± 9 |
| Tween 80[c] | 97.3 ± 12 | 71.4 ± 19 | 120.6 ± 5 | 65.9 ± 13 |
| Nonidet P-40[c] | 108.1 ± 14 | 127.3 ± 16 | 130.1 ± 7 | 106.2 ± 2 |
| Zwittergent[c] | 150.6 ± 10 | 162.9 ± 17 | 467.5 ± 19 | 17.5 ± 2 |
| Sodium deoxycholate | 110.8 ± 16 | 42.4 ± 26 | 554.8 ± 18 | 105.6 ± 24 |
| Sodium cholate | 87.1 ± 12 | 99.6 ± 7 | 168.7 ± 1 | 125.3 ± 9 |

[a]Effect of detergents was analyzed by incubation of lipase for 1.5 h at 37°C, in 20 mM citrate buffer (pH 5.5) with each detergent, and remaining activity was determined using the spectrophotometric method with *p*-nitrophenyl laurate as substrate.
[b]Activities are expressed relative to the activity obtained without detergent and represent the arithmetic mean ± SD of at least three determinations.
[c]Nonidet P-40 (USB, Cleveland, OH; Triton X-100, Tween 20, and Tween 80 (Sigma, St. Louis, MO); sodium cholate and sodium deoxycholate (Research Organics, Cleveland, OH); and Zwittergent (Fluka, Buchs, Switzerland).

(Table 4). At 0 h and concentrations of 0.1%, all detergents had a positive effect except Tween 80 and sodium cholate, which showed a negative influence on lipase activity. The highest activity was obtained with Zwittergent at this concentration. At 1%, the initial activity (0 h) was high with all detergents, with sodium deoxycholate having the highest positive effect. However, after 1.5 h all activities decreased compared to the activity at the beginning of incubation. The most drastic reduction was caused by Zwittergent; it decreased lipase activity by approximately 83% compared to the control.

*N-terminal sequence analysis*. The N-terminal amino acid sequence of the lipase from *P. candidum* was found to be: STAAGAAFPDLHHAAALS. This sequence has been compared to the sequences of N-terminal fungal lipases as deposited in the TrEMBL and Swissprot databases: (http://www.ebi.ac.uk/). The 18 N-terminal amino acids of the *P. candidum* lipase showed high identity to the sequence reported for the *P. expansum* lipase (11). However, *P. candidum* lipase showed low identities to the N-terminal amino acid sequences of other fungal lipases (*Fusarium, Humicola, Rhizopus, Rhizomucor,* and *P. camembertii*). *Penicillium candidum* lipase shared only the Phe and Ala residues in positions 8 and 16, respectively, with other filamentous fungi sequences (Table 5).

## DISCUSSION

The fungus *P. candidum* produced a single extracellular lipase with a molecular weight of 29 kDa as determined by SDS-PAGE. However, when the sample was electrophoresed under native conditions, the enzyme showed dimeric and tetrameric forms. This behavior was also observed during the purification of enzymes from *P. expansum* (11), *P. simplicissimum* (13), *P. citrinum* (12), and *P. chrysogenum* (14). As with these lipases, the use of detergents with the *P. candidum* lipase is necessary to avoid aggregation which causes loss of activity. Lipases from some species of *Bacillus*, *Pseudomonas,* and *Staphylococcus* (17,18), as well as many from the genus *Penicillium,* are susceptible to this problem (11,13, 14,19,20). In our case, *P. candidum* lipase formed di-, tetra-, and higher aggregates, which requires the addition of detergents for optimal activity. This suggests that disaggregation of the enzyme would allow the lipase to have more contact with its substrate. This could also be the reason for the low purification factor after anionic chromatography. Studies using other lipases reported that aggregation caused difficulties in the estimation of enzymatic specific activity (13).

The finding that the enzyme has a pH optimum of 9 for activity is uncommon. Most lipases, both intracellular and extracellular, appear to be optimally active between pH 6 and 7 (21). However, an alkaline pH optimum has been reported for some fungal lipases such as those from *P. caseicolum,* pH 9 (15); *Fusarium* sp. YM-30, pH 7–8 (14); *P. expansum,* pH 9 (11); and *A. flavipes,* pH 8.8 (21). This suggest that *P. candidum* lipase could be useful as an ingredient in household detergents. Although it is unstable at alkaline pH values (optimal stability pH 4–6), this could be avoided using microen-

capsulation techniques. There are many reports of fungal lipases with a pH stability between 5 and 8. However, incubation times were shorter than those tested in this work (24 h).

The lipase from *P. candidum* preferred *p*-nitrophenyl derivatives with acyl lengths of 16:0 and 18:0 as substrates, whereas *p*-nitrophenyl esters with short chains (10:0 or less) were poorly hydrolyzed. A similar specificity has been reported only for the *P. simplicissimum* lipase (13). However, when the *P. candidum* enzyme was tested in emulsified substrates, it showed a preference for triglycerides with fatty acid chains of different lengths such as tributyrin, tricaprin, trilaurin, and triolein. More importantly, of triolein, stearate, palmitate, and butyrate, only triolein was capable of inducing lipase formation (3). Therefore, we consider this enzyme is a true lipase. Furthermore, when this fungus was grown on solid medium containing triolein as sole carbon source, it produced clear zones of hydrolysis. However, the rate of hydrolysis was slower compared to that using tributyrin on the same solid medium. For this reason, although tributyrin is now considered a questionable substrate for lipase activity, it was important to include it in the activity determination by the emulsion method. Helistö and Korpela (22) analyzed the activity of lipases from different sources on *p*-nitrophenyl substrates and triolein. They also observed low correlation between hydrolysis of different *p*-nitrophenyl derivatives and triolein. These authors suggested that the differences in specificity between *p*-nitrophenyl substrates and triolein might be due to the fact that these kinds of enzymes often have both lipase and esterase activities (22). The *P. candidum* lipase specificity is very similar to that of lipases used for food applications such as *P. caseicolum* (15). In the food industry, it is important to generate delicate flavors in dairy products. These are obtained with the release of short fatty acids during hydrolysis. Therefore, the enzyme from *P. candidum* could be used for the production of cheese-like flavors and related dairy products.

The positive effect of $CaCl_2$ has been observed in other fungal enzymes like *P. expansum* (11). In contrast, calcium had a strong negative effect on the lipase from *P. citrinum* (12). In fungi, it has been suggested that calcium ion is necessary for enzyme folding but is not essential to its catalytic activity (19).

EDTA had a negative effect on *P. candidum* lipase activity, confirming that this enzyme could be a metalloenzyme. Both $Fe^{2+}$ and $Cu^{2+}$ strongly inhibit lipolytic activity. Their effects on the lipase were similar to those found for several microbial lipases such as the *Fusarium* sp. YM-30 (14), *A. oryzae* (23), *H. lanuginosa* (24), *P. citrinum* (17), and *Beauveria bassiana* (25) lipases. For *B. bassiana*, it was demonstrated that iron ions inhibit the lipase by direct binding, and this effect can be reverted by the use of chelating agents such as EDTA.

Many lipase genes have been cloned from mammalian tissues, fungi, and bacteria, and their primary structures have been deduced from the nucleotide sequences. These lipases are classified into several families on the basis of their homologies. Most fungal lipases can be classified into *R. miehei* and *G. candidum* families (26). However, *P. expansum* lipase cannot be classified into either of these two families, as was previously reported (11). The N-terminal amino acid sequence similarity of *P. candidum* lipase to *P. expansum* lipase reveals that they can be defined within a separate family of *Penicillium* lipases with similar biochemical characteristics and substrate specificity. The most interesting behavior of these two enzymes is their tendency for aggregation, a characteristic that differentiates them from other fungal triacylglycerol lipases and from the *P. camembertii* mono- and diacylglycerol lipase.

## ACKNOWLEDGMENTS

This work was partially supported by a research grant from CONACyT (400313 1500N), Mexico. Beatriz Ruiz was financed by postgraduate fellowships from CONACyT, Mexico. We thank Laura Escalante and Jose Luis Roque for their technical assistance, and Dr. Jesus Aguirre for useful discussion. We are indebted to Marco A. Ortiz for strain preservation studies.

# Bovine Milk Gangliosides: Changes in Ceramide Moiety with Stage of Lactation

**María-Jesús Martín, Samuel Martín-Sosa, and Pablo Hueso***

Departamento de Bioquímica y Biología Molecular, Facultad de Biología, Universidad de Salamanca, 37007 Salamanca, Spain

**ABSTRACT:** The stage of lactation is one of the most important factors that influence milk composition. Changes in fatty acids from triacylglycerols and phospholipids have already been reported. In this study, we looked for a lactational change in the ganglioside lipid moiety since ganglioside contents and patterns vary strongly with stage of lactation. Individual gangliosides from four stages were isolated, methanolyzed to cleave the bonds between individual constituents, and derivatized for gas–liquid chromatography and gas chromatography/mass spectrometry analyses. Ceramide components, both fatty acids (as methyl esters derivatives) and long-chain bases, were identified and quantified. The results pointed to a marked change in ceramide from colostrum to milk that was characterized by a dramatic decrease in saturated and the longest-chain fatty acids as well as an increase in 18:1 and 18:2. The major long-chain base along lactation was a recently described structure, 3-ethoxy-15:0 sphinganine. Other new long-chain base structures appeared in these gangliosides. All these changes suggest differences in the fluidity of the fat globule membrane, reflecting physiological variations in cows with respect to milk production.

Paper no. L8699 in *Lipids 36,* 291–298 (March 2001).

Gangliosides are important constituents of neural membranes, and they also appear in extraneural tissues and body fluids. In milk, they are localized in the milk fat globule membrane (MFGM), where they are assumed to play a role in the defense of the newborn against infection (1). Ganglioside GM1 (GM ganglioside species have one sialic acid, GD have two sialic acids; see Ref. 2) binds cholera toxin although the ability to bind other ligands such as viruses, bacteria and hormones has also been reported (2). These would act as false ligands in the gut, blocking the pathogenic agents and their enterotoxins and preventing newborns from contracting possible infections.

The composition of milk fat is strongly influenced by physiological, seasonal, and nutritional factors (3). The ganglioside content varies with stage of lactation, being very high in colostrum and decreasing in ensuing stages. Nevertheless, the main gangliosides in bovine milk are always GD3 (>60%) and GM3. Several changes in their concentrations with stage of lactation have been reported (4), but until now no reports about changes in the ceramide moiety have been made.

The stage of lactation mainly affects the content of short-chain fatty acids (SCFA) of milk, since their proportions are very low early in lactation and increase over the following weeks. At the same time, the uptake of long-chain fatty acids (LCFA) from adipose stores decreases. A negative correlation between the proportions of several SCFA ($C_6$–$C_{14}$) and unsaturated $C_{18}$ compounds has been reported (5).

A theoretical dual origin for milk fatty acids (FA) has been proposed (3): SCFA would be synthesized in the mammary gland from plasma acetate or β-hydroxybutyrate while LCFA would derive directly from circulating lipoproteins. $C_{16}$ FA could have both origins.

Plasma FA have two sources: dietary lipids and those stored in adipose tissue. In nonruminant animals, circulating FA reflect the composition of the food ingested, but in the rumen of cattle, metabolism must be considered. Rumen microorganisms degrade food polysaccharides to produce some volatile FA and metabolic intermediates, such as propionate, butyrate or isobutyrate, which are used to synthesize their own odd-numbered or branched-chain FA. Moreover, rumen bacteria carry out extensive hydrogenation of $C_{18}$ polyunsaturated fatty acids (PUFA), yielding high amounts of 18:0 (6,7). Thus, the true uptake by cows consists mainly of saturated LCFA and small amounts of PUFA, although in general ruminants do not seem to suffer from any lack of essential FA (8). An extensive study of changes in triacylglycerol FA from bovine milk throughout the course of lactation (40 wk) has been carried out (9).

In the present work we determined the possible influence of lactation stage on the ceramide composition of gangliosides. Four different and particularly important stages in lactation were chosen: the two-day colostrum, milk from the midlactation stage (mature milk), and an earlier stage with intermediate features between colostrum and mature milk, known as transitional milk. Finally, we considered late lacta-

tion milk, just before the dry period, when the cow is pregnant again. We obtained gangliosides from all these samples and studied the ceramide components following a recently proposed method (10).

## EXPERIMENTAL PROCEDURES

*Samples.* Four Spanish-Brown cows were used in this study. Calving took place in December–January. A 300-mL milk sample from each animal was obtained on postpartum day 2 (colostrum), day 15 (transitional milk), day 90 (mature milk), and in the tenth month (late lactation milk). Samples were always obtained from the morning milking, frozen at −20ºC, lyophilized, and homogenized to ensure accurate distribution of the components.

*Chemicals*. Heptafluorobutyric anhydride (HFBAA) was from Fluka (Buchs, Switzerland) and high-performance liquid chromatography (HPLC)-grade acetonitrile from SDS (Peypin, France). Anhydrous acetonitrile was obtained by addition of calcinated calcium chloride (Prolabo, Paris, France), followed by storage in a closed vessel. The methanolysis reagent was obtained by dissolving anhydrous gaseous HCl (up to 0.5 M) at −50ºC in anhydrous methanol (M) previously redistilled on magnesium turnings. The 25QC3/BP1 column was from SGE trance SARL (Villeneuve St. Georges, France) and the CP-Sil5 CB capillary column was from Chrompak France (Les Ullis, France).

Monoclonal antibodies P3, 14F7, R24, and G1 were a kind gift from Dr. Ana María Vázquez (Centro de Inmunología Molecular, Havana, Cuba). Anti-A2B5 [mouse immunoglobulin M (IgM)] was provided by Roche Molecular Biochemicals (Mannheim, Germany). Anti-9-*O*-acetyl-GD3 (clone JONES, mouse IgG), mouse polyvalent Ig G-, Ig M-, Ig A-biotin conjugated, ExtrAvidin®-alkaline phosphatase, and FAST BCIP/NBT (5-bromo-4-chloro-3-indolyl phosphate/nitro blue tetrazolium) were from Sigma (St. Louis, MO). Poly(isobutyl methacrylate) (PIBM) was from Aldrich Chemical Company (Milwaukee, WI), and *n*-hexane was from Merck (Darmstadt, Germany). Albumin from bovine serum (BSA) was provided by Fluka.

*Extraction of gangliosides.* Gangliosides were isolated as previously described (4). Briefly, lyophilized milk was homogenized twice with 10 vol of cold acetone (−20ºC) to remove neutral lipids and filtered. The solid residue was successively extracted with 10 vol of chloroform/methanol (C/M) (2:1, 1:2, and 1:1, vol/vol). The combined extracts were evaporated to dryness, taken up in 10 vol of C/M (2:1), and subjected to a Folch partition (4). The upper phases, containing crude gangliosides, were combined and dialyzed against distilled water (volume ratio of sample to dialysate, 1:1000) at 4ºC for 2 d. Water was changed every 6–8 h. After dialysis, the material was lyophilized and dissolved in C/M (2:1).

The ganglioside content was quantified as lipid-bound sialic acids by the resorcinol assay (11). Gangliosides were separated by high-performance thin-layer chromatography (HPTLC) using solvent system A: C/M/0.2% $CaCl_2$ (5:4.5:1, by vol). Individual gangliosides (ganglioside pattern) were analyzed with a dual-wavelength thin-layer chromatography (TLC) densitometer (Shimadzu CS 9000; Kyoto, Japan) after separation by HPTLC. Gangliosides were visualized by spraying the plates with the resorcinol and orcinol reagents.

For the gas chromatography (GC) and GC–mass spectrometry (GC–MS) assays, individual gangliosides were purified by preparative TLC using solvent system B: methyl acetate/C/M/*n*-propanol/0.25% KCl, (25:20:20:20:17, by vol) (12).

*Methanolysis and acylation.* Ganglioside samples were dried under a nitrogen stream. Methanolysis reagent (300 µL) was added, and closed tubes were incubated for 20 h at 80ºC. Samples were evaporated to dryness under a nitrogen stream and derivatized with 25 µL of HFBAA and 200 µL of acetonitrile for 30 min at 100ºC. After cooling to room temperature, samples were dried and dissolved in an appropriate volume of anhydrous acetonitrile.

*GC*. Each HFBAA derivative was injected into a Shimadzu GC-14A gas chromatograph equipped with a Ross injector and a 25-m capillary column (25QC3/BP1, 0.5-mm film phase). The injector and flame-ionization detector temperatures were 260ºC. The temperature program was 1.2ºC/min from 100 to 140ºC, and then 4ºC/min up to 240ºC. This temperature was maintained for 10 min. The carrier gas (helium) pressure was 0.8 bar. This program allowed a good separation of monosaccharides into their different isomers; it has been used to identify each ganglioside before the GC–MS analyses (10).

*GC–MS analyses.*The GC separation was performed on a Carlo Erba GC 8000 gas chromatograph (Milan, Italy) equipped with a 60 m × 0.32 mm CP-Sil5 CB low-bleed/MS capillary column, 0.25 mm film phase. The temperature of the Ross injector was 280ºC, and the temperature program was as follows: 90ºC for 3 min, then 5ºC/min up to 260ºC. The temperature was held at 260ºC for purposes of cleaning. This column was coupled to a Finnigan Automass II mass spectrometer (mass limit 1000). Analyses were performed in the electron impact mode (ionization energy 70eV; source temperature 150ºC) (10).

*Immunostaining assay.* Immunostaining on HPTLC plates was performed as previously reported (13). Gangliosides from each stage of lactation were chromatographed with solvent system A. Once dried, the plates were soaked with 0.1% PIBM in *n*-hexane for 75 s and kept overnight at room temperature for drying. The plates were blocked with 1% BSA in Tris-0.1 N HCl for 30 min. They were then incubated with each monoclonal antibody (mAb) at room temperature for 2 h. After washing with phosphate-buffered saline (PBS), plates were incubated with conjugated biotin (1:2000 in 1% BSA in PBS) for 1 h 30 min, and then with streptavidin-alkaline phosphatase (1:1000 in the same buffer) for 1 h 30 min before developing with the substrate.

*Statistical assays.* In order to find statistically significant differences among the four stages of lactation, an analysis of variance test was applied in each case.

## RESULTS

*Ganglioside content.* The ganglioside contents at each stage of lactation, expressed as lipid-bounded sialic acids [mg/kg of milk, expressed as means ± SD ($n$ = 4 cows); three replicates were made per cow and sample time], were as follows: colostrum, 3.5 ± 1.7; transitional milk, 1.2 ± 0.5*; mature milk, 0.9 ± 0.4*; and late lactation milk, 1.8 ± 1.4. The asterisks indicate statistically significant differences ($P$ < 0.05) that were found between colostrum and transitional and mature milk but not between colostrum and late lactation milk nor among the other stages. No statistically significant differences among cows were found. The ganglioside content was high in colostrum but then slowly decreased until day 90, after which it increased again in late lactation milk.

Several gangliosides were separated on HPTLC (solvent system A) as resorcinol- and orcinol-positive spots and named G1 to G6 according to their mobility (increasing polarity). They were identified by co-migration with authentic standards and the ganglioside pattern previously found in cow's milk (4). Gangliosides were also analyzed by the HPTLC-overlay method, using specific mAb.

Ganglioside G1 co-migrated with standard GM3. G1 reacts with mAb 14F7 [specific for *N*-glycolylneuraminic acid (NeuGc)-containing GM3]. After mild hydrolysis (formic acid, pH 2) of the ganglioside, both *N*-acetylneuraminic acid (NeuAc) and NeuGc were found as sialic acid moieties by TLC. These data suggest that G1 is a mixture of NeuGc- and NeuAc-containing GM3. With TLC, G2 was found in the monosialoganglioside region, and it reacted with the JONES anti-*O*-acetyl GD3 mAb. This mAb only detected one band in colostrum and transitional milk but two bands in mature and late lactation milk. G2 was identified as *O*-acetyl GD3. Only traces of G2 were found in the first stages of lactation, but a clear increase was detected as lactation progressed.

G3 showed a mobility pattern identical to that of GD3. R24, a mAb with a high degree of specificity against GD3, reacted strongly with G3. The structure of G3 was therefore assumed to be GD3. Additionally, NeuAc and NeuGc were detected in the TLC analyses after hydrolysis, suggesting the presence of NeuGc- and NeuAc-containing GD3. G1 and G3 also showed a positive reaction with mAb P3, which is specific for NeuGc-containing gangliosides. The staining was very prominent in colostrum and weaker in the other stages, suggesting that the content of NeuGc in gangliosides decreases during the course of lactation.

G5 was located in the trisialoganglioside region of the chromatogram. G5 also reacted with the anti-A2B5 mAb (specific for GT3 as well as for *O*-acetyl GT3). According to this, G5 was identified as GT3. G4 and G6 were tentatively designated on the basis of their mobility on TLC plates and previous data (14). G4 could be a monosialoganglioside with a branched oligosaccharide chain, and G6 might be a trisialoganglioside with the same branched oligosaccharide chain. A specific mAb against GM1, called G1, was also used. No reaction was found in any stage of lactation, pointing to the notion that cow's milk does not contain GM1.

*Ceramide content.* Individual gangliosides were separated by TLC (solvent system B) and analyzed by GC–MS. FA and long-chain bases (LCB) of the different individual gangliosides were determined (data not shown). Table 1 shows the FA average content of gangliosides from the different stages. Values are means of the FA content of the different individual

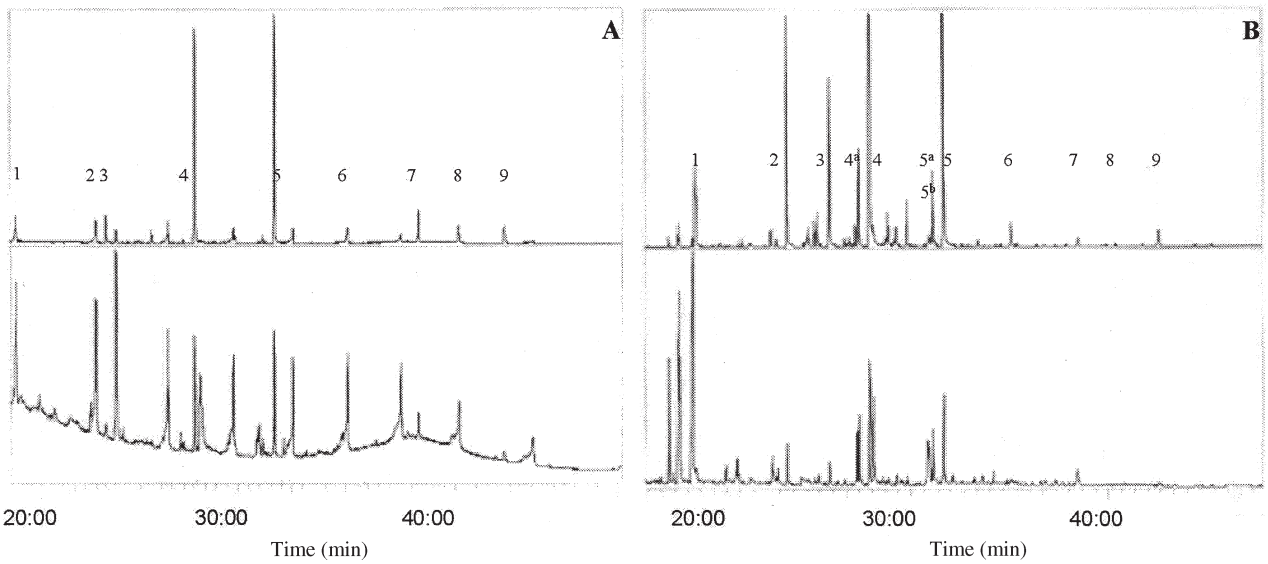

**FIG. 1.** Gas chromatogram of fatty acid methyl ester content of colostral (A) and transitional (B) gangliosides. Samples were methanolyzed (20 h at 80°C) and derivitized with heptafluorobutyric anhydride (30 min at 100°C). A Carlo Erba GC 8000 gas chromatograph coupled to a Finnigan Automass II mass spectrometer was used. The gas chromatograph was equipped with a 60 m × 0.32 mm CP-Sil5CB low-bleed/MS capillary column. gangliosides from each stage of lactation. FA were identified as fatty acid methyl esters (FAME) by the typical ions at *m/z* 74 and *m/z* 87 (Fig. 1). Each FAME could be identified by its retention time (RT) as well as by its molecular ion.

Several FA ($C_{12}$–$C_{26}$) were identified by MS analysis, including odd-numbered chains. No FA below $C_{12}$ was detected, although these are very common in milk fat (triacylglycerols). The most abundant were $C_{16}$ and $C_{18}$, whose proportions were over 65% of total saturated FA in gangliosides. The FA 22:0 was well represented in colostrum, but its percentage was below 4% in the other stages.

Monounsaturated FA—from 13:1 to 24:1—were also detected. Palmitoleic (16:1) and oleic (18:1) acids represented 69.9, 64.47, 81.32, and 63.7% of the total unsaturated FA from colostral, transitional, mature, and late lactation gangliosides, respectively. The only PUFA found was 18:2.

The saturated FA content in gangliosides changed over the course of lactation. Significant differences were found between colostrum and transitional ($P < 0.01$), mature ($P < 0.01$), and late lactation ($P < 0.05$) milk. Statistical assays revealed no differences among the last three stages, although a tendency to increase was observed, as seen in Figure 2. $C_{16}$

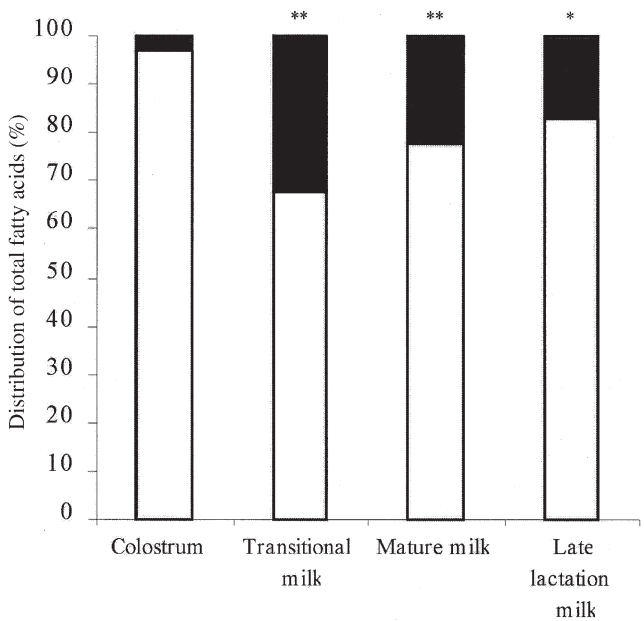

**FIG. 2.** Distribution of saturated (□) and unsaturated (■) fatty acids. Statistically significant differences from colostrum are shown: *$P < 0.05$, **$P < 0.01$.

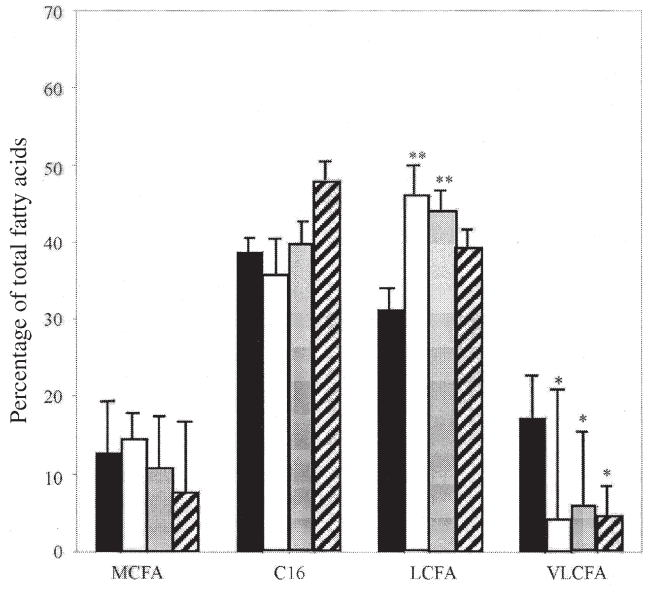

**FIG. 3.** Lactational variation of fatty acids: medium-chain fatty acids (MCFA, $C_{12}$–$C_{15}$), $C_{16}$ (includes 16:0 and 16:1), long-chain fatty acids (LCFA, $C_{17}$–$C_{21}$), and very long chain fatty acids (VLCFA, $C_{22}$–$C_{26}$). Statistically significant differences from colostrum are shown: $^*P < 0.05$, $^{**}P < 0.01$). Closed bar, colostrum; open bar, transitional milk; shaded bar, mature milk; striped bar, late lactational milk.

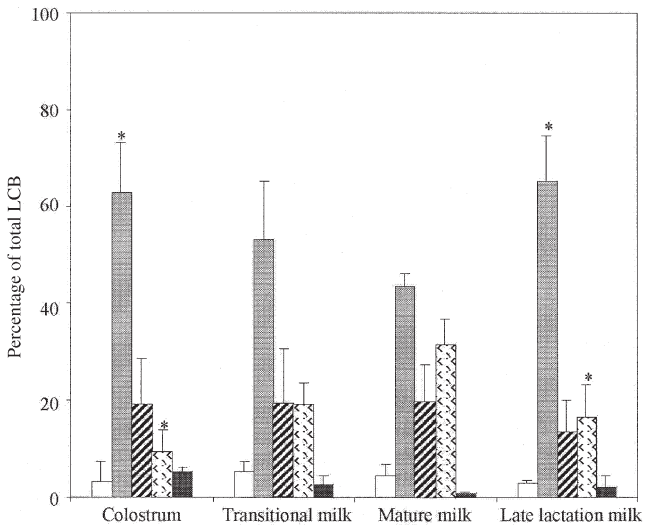

**FIG. 4.** Lactational variation of long-chain bases (LCB). Statistically significant differences from mature milk ($^*P < 0.01$) are shown. Open bar, 9-Me-3-*O*-ethoxy-$C_{14}$ sphinganine; shaded bar, 3-ethoxy-$C_{15}$ sphinganine; striped bar, 3-ethoxy-$C_{17}$ sphinganine; patterned bar, 18:1 sphingosine; closed bar, 20:0 phytosphingosine.

was the most abundant FA in all gangliosides for each stage, followed by 18:0.

Very long chain fatty acids (longer than $C_{20}$, VLCFA) decreased over the course of lactation, since in colostrum the proportion of $C_{18}$ FA was twice that of VLCFA but 10-fold higher in the rest of the stages (Fig. 3). A similar trend was found for $C_{16}$. In fact, the sum of $C_{16}$ and $C_{18}$ increased during the course of lactation from 67.9% in colostrum to 84.2% in the tenth month postpartum. The most radical changes occurred in the first 2 wk after calving: 22:0 decreased dramatically from 15% (on day 2) to 2.6% (on day 15) while unsaturated $C_{16}$ and $C_{18}$ increased to the same extent (palmitoleic, 0.73 to 9.01%; oleic, 1.32 to 11.56%).

The acids 15:0 and 17:0 were the only branched-chain FA detected in our analyses. They never represented more than 1.5% of the total, and they did not appear in all gangliosides. The branched $C_{15}$ was characterized by the molecular ion at *m/z* 256 (corresponding to the $C_{15}$ FAME) and by an ion at M – 29, indicating that it belonged to the anteiso series. The branched 17:0, whose molecular ion appeared at *m/z* 284, was also an anteiso branched FA.

Taking into consideration the three most abundant gangliosides (GM3, GD3, and GT3), we observed a within-group variability of certain FA: in colostrum, 18:0 varied from 38.1 (in GM3) to 18.8% (in GD3), and 22:0 represented 8.6% of the total in GT3 but represented 27.9% of FA in GD3. Transitional gangliosides were more homogeneous, like those of mature milk, although linoleic acid represented 4.68 and 16.13% of FA from transitional GD3 and GT3, respectively, and palmitic acid varied from 29.9 (in GD3) to 42.2% (in GT3) in mature milk. The most extreme values were found in 16:0 from late lactation gangliosides: from 25.2% in GD3 to 69.4% in GT3, and oleic acid represented 21.6% of total FA from GD3 although it was not detected in the most polar gangliosides.

By GC–MS, LCB were separated as heptafluorobutyric derivatives. In the electron impact mode, sphingosines (monounsaturated and dihydroxylated bases) gave a typical fragment ion at *m/z* 290, allowing unambiguous identification of two isomers at RT of 1.001 and 1.010 (relative to 18:0). $C_{20}$ phytosphingosine was found at RT 1.100. Three new LCB, recently reported (15), were predominant in milk gangliosides (Fig. 4). They gave a typical ion at *m/z* 510 corresponding to the substituted first three carbons. The most abundant one is 3-ethoxy-$C_{15}$ sphinganine, whose spectrum is shown in Fig-

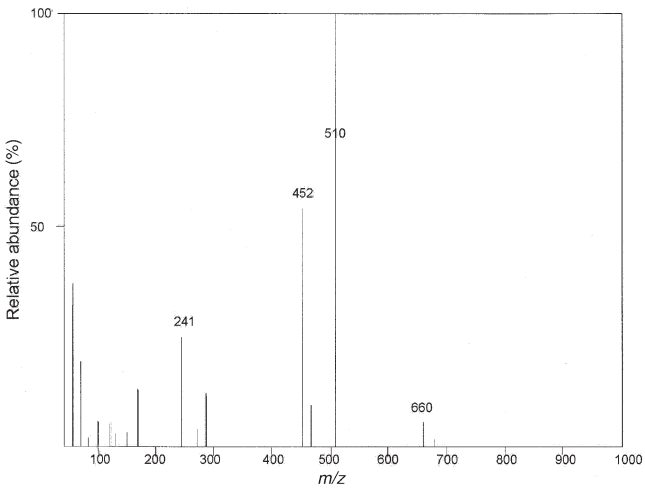

**FIG. 5.** Electron impact spectrum showing the characteristic ion sequence of 3-ethoxy-$C_{15}$ sphinganine.

ure 5. Table 1 also shows the LCB average content of gangliosides from the different stages of lactation. Values are means of the LCB content of the different individual gangliosides from each stage of lactation.

## DISCUSSION

Lipids are the most variable component in milk. The most abundant lipids are triacylglycerols, representing 97–98% of the total, followed by phospholipids and cholesterol. Glycosphingolipids (GSL) represent only 0.6% and are localized in the MFGM, although a small fraction of them is dispersed in the aqueous phase. Glucosyl- and lactosyl-ceramide are the main GSL in bovine milk (16), and GD3 is the most abundant ganglioside.

Our results are in agreement with a previous report demonstrating a decrease in the ganglioside content of the milk as lactation progresses (4). Nonstatistically significant variations among individual cows were observed. The individual ganglioside content (ganglioside pattern) revealed six different gangliosides. G1, G3 and G5 were identified as GM3, GD3, and GT3, respectively, and they account for 63–83% of total gangliosides depending on the stage of lactation. Several authors have also reported that about 80–90% of the gangliosides in bovine milk (expressed as lipid-bound sialic acid) consist of hemato-series gangliosides, such as GM3, GD3, and GT3. G4 and G6 were designated as a monosialo- and a trisialoganglioside, respectively, with a branched oligosaccharide chain, as previously reported (14). Since no specific monoclonal antibodies are available against these two gangliosides and since the amount of the latter was insufficient to determine their structure, their identification remains unclear. G2 was identified as *O*-acetyl GD3. We detected one band in colostrum and transitional milk but two bands in mature and late lactation milk. By using TLC, two bands in the region between GM3 and GM1 corresponding to alkali-labile gangliosides and reacting with JONES were observed in buttermilk (17). These were identified as 7,9-*O*-diacetyl GD3 (higher mobility) and a mixture of 7- and 9-*O*-acetyl GD3 (lower mobility). These data suggest that our G2 ganglioside could be a mixture of *O*-acetylated derivatives of ganglioside GD3.

We also detected several NeuGc-containing gangliosides (G1 and G3) by the HPTLC-overlay method. The staining was very strong in colostrum but weaker in the other stages, suggesting that the content of NeuGc in milk gangliosides decreases as lactation progresses. These data are consistent with other observations previously reported by our group (18). We did not detected ganglioside GM1 in bovine milk. This result is in contrast with a previous study reporting the presence of GM1 in bovine milk (19). However, our results are in agreement with the individual ganglioside content of milk and the biosynthetic pathways of these gangliosides. Milk gangliosides mainly consist of hemato-series gangliosides (GM3, GD3, and GT3). Other minor gangliosides, such as *O*-acetyl GD3 and *O*-acetyl GT3, share the same biosynthetic pathway, and there are also monosialo- and trisialogangliosides with a branched chain. Most researchers have failed to detect any ganglioside of the classical a-pathway of ganglioside synthesis in milk. Thus, the presence of GM1 in cow's milk would be unlikely. If it were present, this would in trace amounts, below the limit of detection by TLC immunostaining.

Regarding the ceramide content, it was found that MFGM gangliosides were richer in VLCFA (47.4%) than in 16:0 (25.6%) (20). Nevertheless, Palmquist and Schanbacher (21) found lower amounts of VLCFA (3.7%) than 16:0 (22.6%) in MFGM lipids. Except for the colostrum, our results are in agreement with the latter authors. According to several investigators (3), the proportion of the longest FA ($>C_{16}$) decreases as the mammary gland assumes responsibility for the major part of FA synthesis and as uptake from plasma ceases. Since MFGM comes from mammary gland cells, changes in the FA content of MFGM should reflect changes in mammary gland metabolism. Although we found no differences in the global content of LCFA, which persisted at around 45–50% throughout lactation, a marked decrease in the amounts of VLCFA was detected in the postcolostrum stages. Studying lactational changes in several phospholipids, some authors (22) have reported that 40–50% of sphingomyelin moieties have FA chains longer than $C_{20}$ (VLCFA) whereas other workers (23) have described the same characteristic in MFGM cerebrosides. However, these latter authors also showed that skim milk cerebrosides are richer in $C_{16}$ than in VLCFA. All these differences could be due to the influence of dietary fat intake (21).

The presence of branched-chain FA in milk lipids has been reported (24). These branched-chain FA would be of ruminal origin, since this kind of FA constitutes more than 20% of the total in rumen bacteria and plays an important role in membrane fluidity (25). The same source has been reported for odd-numbered FA.

Although there was an increase in the $C_{18}$ sphingosine percentage in mature milk, the 3-ethoxy-$C_{15}$ sphinganine predominated throughout lactation. This LCB has never been reported in milk gangliosides, nor has 3-ethoxy-$C_{17}$ sphinganine and 9-methyl-3-ethoxy-$C_{14}$ sphinganine. Nevertheless, $C_{18}$ sphingosine had been reported as the most abundant LCB in previous studies (14,26). Since those results had been obtained by GC, differences are probably due to the methodology employed.

To determine the biological significance of these changes in ceramide, membrane fluidity must be addressed. Changing both FA and LCB could control the fluidity of the membrane. In colostrum, the presence of high amounts of VLCFA and saturated FA would suggest a thick structure. In other stages of lactation the increase of unsaturated FA content points to a more fluid membrane. The increase of the length of LCB leads to a larger hydrophobic volume and affects the membrane organization (27). Gangliosides with longer LCB contribute to membrane thickening. Thus, the physiological changes in FA synthesis would be balanced by the proportions of the longest LCB.

The role of milk gangliosides in the protection of newborns against infection has been discussed for a long time (2). Milk

gangliosides could act as alternative receptor analogs for bacteria and/or toxins in the gut, preventing bacterial infection. The orientation of the carbohydrate moiety of membrane gangliosides may be influenced by the composition of ceramide. Furthermore, the ceramide moiety is essential in the lateral phase separation of gangliosides leading to the formation of ganglioside-enriched microdomains. This feature could be important in the presentation and/or accessibility of the ganglioside binding site (epitope) (28). Specific ceramide moieties involved in *Escherichia coli* binding have been reported. NeuGc-GM3 with highly hydroxylated ceramide was found to bind *E. coli* K99 more strongly than nonhydroxylated forms (29). Adhesion is mediated by electrostatic interactions between the bacterial adhesin and the carboxyl group of sialic acid (30). Changes in the position of this group could lead to variations in the adhesion properties, modulating the inhibitory activity of gangliosides.

A detailed knowledge of the ceramide composition of milk gangliosides and their interactions with bacteria could be useful to develop synthetic analogs, possibly easier to obtain than natural compounds.

## ACKNOWLEDGMENTS

Dedicated to the memory of our friend Professor André Verbert (Lille, France).

We would like to thank Dr. Ana María Vázquez and her group for kindly providing some of the antibodies used. We are very grateful to Dr. Jean-Pierre Zanetta from Laboratoire de Chimie Biologique (Université des Sciences et Technologies-Lille1 (France) for the FA and LCB analysis. We also acknowledge the invaluable technical support of Yves Leroy and Philippe Timmermann as well as the help of Alexandre Pons (Lille, France) in the GC–MS analyses. The authors also thank Nicholas Skinner (from the Servicio de Idiomas, Universidad de Salamanca) for revising the English version of the manuscript.

This work was partly supported by grants from the Programa de Apoyo a Proyectos de Investigación de la Junta de Castilla y León, España (SA68/98) and the Ministerio de Educación y Cultura de España (CICYT; ALI 95-05332).

# Comparative Investigation of Human Stratum Corneum Ceramides

**Jens-Peter Vietzke[a,*], Oliver Brandt[b], Dietrich Abeck[b], Claudius Rapp[a], Manfred Strassner[a], Volker Schreiner[a], and Ulrich Hintze[a]**

[a]Beiersdorf AG, 20245 Hamburg, Germany, and [b]Department of Dermatology and Allergy, Technical University of Munich, 80802 München, Germany

**ABSTRACT:** The stratum corneum (SC) requires ceramides, cholesterol, and fatty acids to provide the cutaneous permeability barrier. SC lipids can be analyzed by normal-phase high-performance thin-layer chromatography (HPTLC). However, without further analysis, some uncertainty remains about the molecular composition of lipids represented by every TLC band of an unknown sample. We therefore analyzed each ceramide band further by subjecting the isolated lipids to a direct coupling of reversed-phase high-performance liquid chromatography and electrospray ionization–mass spectrometry (HPLC/ESI-MS, or LC/MS). LC/MS analysis and ESI-MS/MS negative ion and collision-induced dissociation experiments revealed that ceramide band 4 contained not only *N*-(ω-OH-acyl)acyl-6-OH-sphingosine, Cer(EOH), but also *N*-(α-OH-acyl)-sphingosine. Band 5 exclusively contained *N*-acyl-6-OH-sphingosine. Our results demonstrate the benefit of LC/MS analysis for selective identification of human SC ceramides. Moreover, the combination of HPTLC for pre-separation and LC/MS for identification of lipids is an even more powerful tool for detailed ceramide analysis.

Paper no. L8553 in *Lipids 36*, 299–304 (March 2001).

The skin barrier protects the skin against excessive loss of water (1,2) as well as environmental influences (3,4). This feature is attributed mainly to the amount and composition of the intercellular lipid matrix in the stratum corneum (SC), which consists mainly of ceramides, free fatty acids, and sterols (5–7). Since alterations of barrier lipid composition are known to result in a functional impairment of the skin barrier or to delay barrier repair (8–10), different types of healthy human skin and skin diseases have been previously investigated for possible changes in overall barrier lipid composition (10–13).

Analysis of ceramides is usually performed by thin-layer chromatography (TLC) (13–15). Further analysis of ceramide fractions separated by TLC has previously been carried out by Wertz *et al.* (14). After hydrolysis and separation by gas chromatography Wertz *et al.* demonstrated that every ceramide species comprises a range of subspecies with different chain lengths in the sphingoid base as well as in the amide-linked fatty acid. More information about the molecular structure of the different ceramide species can be obtained by nuclear magnetic resonance (NMR) spectroscopy (15,16). Ceramides can also be separated by high-performance liquid chromatography (HPLC) on silica gel as well as on diol- and reversed phases with evaporative light-scattering detection (ELSD) (17–20). The separation of benzoyl derivatives of ceramides on reversed-phase (RP) material, as detected by ultraviolet (UV) absorbance or by atmospheric pressure chemical ionization mass spectrometry (MS), has also been described (21,22). Furthermore, direct coupling of high-performance liquid chromatography (HPLC) with an electrospray ionization (ESI) mass spectrometer has been reported (23).

In this study we compared two methods for the analysis of human SC ceramides; high-performance thin-layer chromatography (HPTLC) and direct coupling of nonaqueous RP HPLC/ESI ion trap mass spectrometry (LC-MS). To verify the HPTLC assignment of ceramide bands and to ensure the comparability of both methods, isolated SC lipids were first analyzed by HPTLC. The ceramide bands were investigated further by means of LC/MS and mass spectrometric fragmentation of specific ions (MS/MS) and collision-induced dissociation (CID) fragmentation experiments.

## MATERIALS AND METHODS

*Chemicals and reagents.* Ceramide reference standards [*N*-(α-OH-acyl]-sphingosine, Cer(AS); *N*-acyl-sphingosine, Cer(NS)] were obtained from Sigma (Deisenhofen, Germany). *N*-Acyl-4-OH-sphinganine [Cer(NP)] and *N*-(α-OH-acyl)-4-OH-sphinganine [Cer(AP)] were from Cosmoferm (Delft, The Netherlands). Ammonium acetate (analytical grade), cholesterol, palmitoleic acid, and all solvents (HPLC or analytical grade) were purchased from Merck (Darmstadt, Germany). Primulin was obtained from Sigma (Deisenhofen).

*SC lipid sampling.* SC lipids were collected from healthy Caucasian males and females in March 1999. Informed consent

E-mail: Vietzkj@Hamburg.Beiersdorf.com

Abbreviations: Cer(AP), *N*-(α-OH-acyl)-4-OH-sphinganine; Cer(AS), *N*-(α-OH-acyl)-sphingosine; Cer(EOH), *N*-(ω-OH-acyl)acyl-6-OH-sphingosine; Cer(EOP), an ω-esterified ceramide containing phytosphingosine as a sphingosine backbone and an ω-esterified linoleic acid; Cer(EOS), *N*-(ω-OH-acyl)acyl-sphingosine; Cer(NH), *N*-acyl-6-OH-sphingosine; Cer(NP), *N*-acyl-4-OH-sphinganine; Cer(NS), *N*-acyl-sphingosine; CID, collision-induced dissociation; ELSD, evaporative light-scattering detection; ESI–MS, electrospray ionization—mass spectrometry; HPLC, high-performance liquid chromatography; HPTLC, high-performance thin-layer chromatography; LC–MS: liquid chromatography–mass spectrometry; MS, mass spectrometry; MS/MS, mass spectrometric fragmentation of specific ions; NMR, nuclear magnetic resonance; RP, reversed-phase; SC, stratum corneum; TLC, thin-layer chromatography; UV, ultraviolet.

was obtained from all volunteers participating in the study. Lipids were collected from skin sites located on the volar aspect of the forearms by a single stripping with cyanoacrylate resin. The stripped SC sheets were extracted twice with hexane/ethanol (95:5, vol/vol) according to Imokawa *et al.* (12). The combined solvents were evaporated to dryness (SpeedVac, Jouan Unterhaching, Germany) and the lipid-residue was stored at –20°C until chromatographic separation.

*HPLC.* RP-HPLC analyses were performed with an HPLC system (1100 series; Agilent, Palo Alto, CA). The ceramides were separated on a Grom Sil 120 ODS 3-CP, 125 × 2 mm, 3 µm column (Grom Analytik + HPLC GmbH, Herrenberg-Kayh, Germany) at ambient temperature. Methanol containing 0.2 mM ammonium acetate (A) and *t*-butyl methyl ether (B) were used as the mobile phase in a binary gradient (200 µL $min^{-1}$). The program steps were: 0 min, 95% A, 5% B; 0.5 min, 95% A, 5%, B; 11 min, 70% A, 30% B; 13 min, 60% A, 40% B; 20 min, 60% A, 40% B; 20.5 min, 95% A, 5% B; and 30.0 min, 95% A, 5% B.

*MS.* MS was carried out with an Esquire ion trap mass spectrometer (Bruker Daltonics, Bremen, Germany) equipped with an atmospheric pressure ion-source and an ESI interface (Agilent). The HPLC effluent was delivered in total into the ion source. Nitrogen was used as nebulizing (18 psi) and drying gas (7 L $min^{-1}$, 300°C). Negative ions were acquired from 200–1200 *m/z*. The capillary voltage was +3800 V, and the capillary exit was –180 V. The ion trap was set to a sampling value of 3000, with a maximum accumulation time of 300 ms. CID fragmentation spectra were performed with a capillary exit voltage of –195 V. ESI MS/ MS-experiments were performed by isolating single ions in the ion trap (width: 3 *m/z*) and fragmentating them with an amplitude of 1.8 V.

All pseudomolecular and fragment ion masses shown in the figures are nominal masses with the mass defect omitted.

*HP TLC of SC lipids.* Lipid samples were dissolved in 200 µL chloroform/methanol (2:1, vol/vol) and applied to HPTLC Silica Gel 60 plates (Merck, Darmstadt, Germany) after cleaning the plates with chloroform/methanol (2:1, vol/vol) (14). The lipid samples and a reference lipid mixture containing Cer(NS), Cer(NP), Cer(AS), palmitoleic acid, and cholesterol dissolved in chloroform/methanol (2:1, vol/vol) were applied in neighboring lanes by using a Camag Linomat IV (Camag, Muttenz, Switzerland) (24). The applied lipids were separated in developing chambers (Desaga, Heidelberg, Germany) by using a solvent system of Wertz *et al.* (14) (chloroform/methanol/glacial acetic acid, 190:9:1) and a modified solvent system of Lampe *et al.* (25) (hexane/diethylether/glacial acetic acid, 80:20:1.5). Migration distance was 6.8 cm.

*Isolation of separated ceramides for LC–MS analysis.* The separated ceramide classes were visualized under UV light after spraying the plates with 5% primulin in acetone/water (80:20, vol/vol) as described by Guey *et al.* (22). The separated ceramide bands were scraped off the plates using a spatula. The silica gel was extracted once with 1.5 mL hexane/ethanol (95:5, vol/vol), sonicated for 5 min, and centrifuged for 5 min at 8000 rpm. The supernatant was collected, and the extraction procedure was repeated with 1.5 mL hexane/diethylether (95:5, vol/vol). The combined solvent was filtered through a 0.2-µm syringe-filter (Gelman Sciences, Ann Arbor, MI) and evaporated under nitrogen. The residue was dissolved in 150 µL methanol containing 0.2 mM ammonium acetate, and 5 µL were applied for LC–MS-analysis.

## RESULTS AND DISCUSSION

*Investigation of ceramides by HPTLC and LC/MS.* HPTLC separations of ceramides on normal-phase plates are based on hydrophilic interactions between the hydroxyl groups of the silica gel and polar groups of the ceramides. As a result, different ceramide species migrate with different speeds and are separated according to their polarity. The method has frequently been used in the past to demonstrate alterations in the overall barrier lipid pattern or even of the ceramide pattern in aging, dryness or disease of human skin, and produced valuable results. However, although several samples can be separated on the same plate, the whole evaluation process including development, staining, and densitometric quantification can be automated to only a limited extent and therefore is time consuming.

RP separation of ceramides is based on hydrophobic interactions between the alkylated silica gel of the stationary phase and the hydrophobic chains (amide bond, fatty acid, and sphingoid base) of the ceramide. The use of direct coupling of RP-HPLC and MS enables a sensitive and selective separation of molecular subfractions of each ceramide species (26). The structure of every ceramide subfraction can be investigated by means of MS/MS fragmentation experiments (26,27).

Figure 1 shows the MS/MS fragment spectra and proposed fragment structures (negative ion mode) of a sphingosine-derived ceramide with nonhydroxylated amide-linked fatty acid, Cer(NS), (A) and α-hydroxylated amide-linked fatty acid, Cer(AS), (B).

Figure 2 shows the MS/MS fragment spectra and proposed fragment structures (negative ion mode) of a phytosphingosine (4-OH-sphinganine)-derived ceramide with nonhydroxylated amide-linked fatty acid, Cer(NP) (A) and α-hydroxylated amide-linked fatty acid, Cer(AP) (B).

Comparison of the fragment pattern of different ceramides with nonhydroxylated and α-hydroxylated amide bond fatty acids resulted in general fragmentation schemes of ceramides. The mass differences between the fragment ions arising from cleavage between the amide-linked acyl chain and the $C_{18}$ backbone chain resulted in a series of fragment ion masses with differences of 18, 25, and 16 Da. This was referred to as the 18-25-16 series of fragments. The 18-25-16 series of fragments was characteristic for sphingosine-derived ceramides, e.g., Cer(NS) and Cer(AS). The fragment ion located between the mass differences of 18 Da and 25 Da was always the fragment of the amide bond fatty acid.

The series 16-43-12 was characteristic for phytosphingosine (4-OH-sphinganine)-ceramides, e.g., Cer(NP) and Cer(AP);

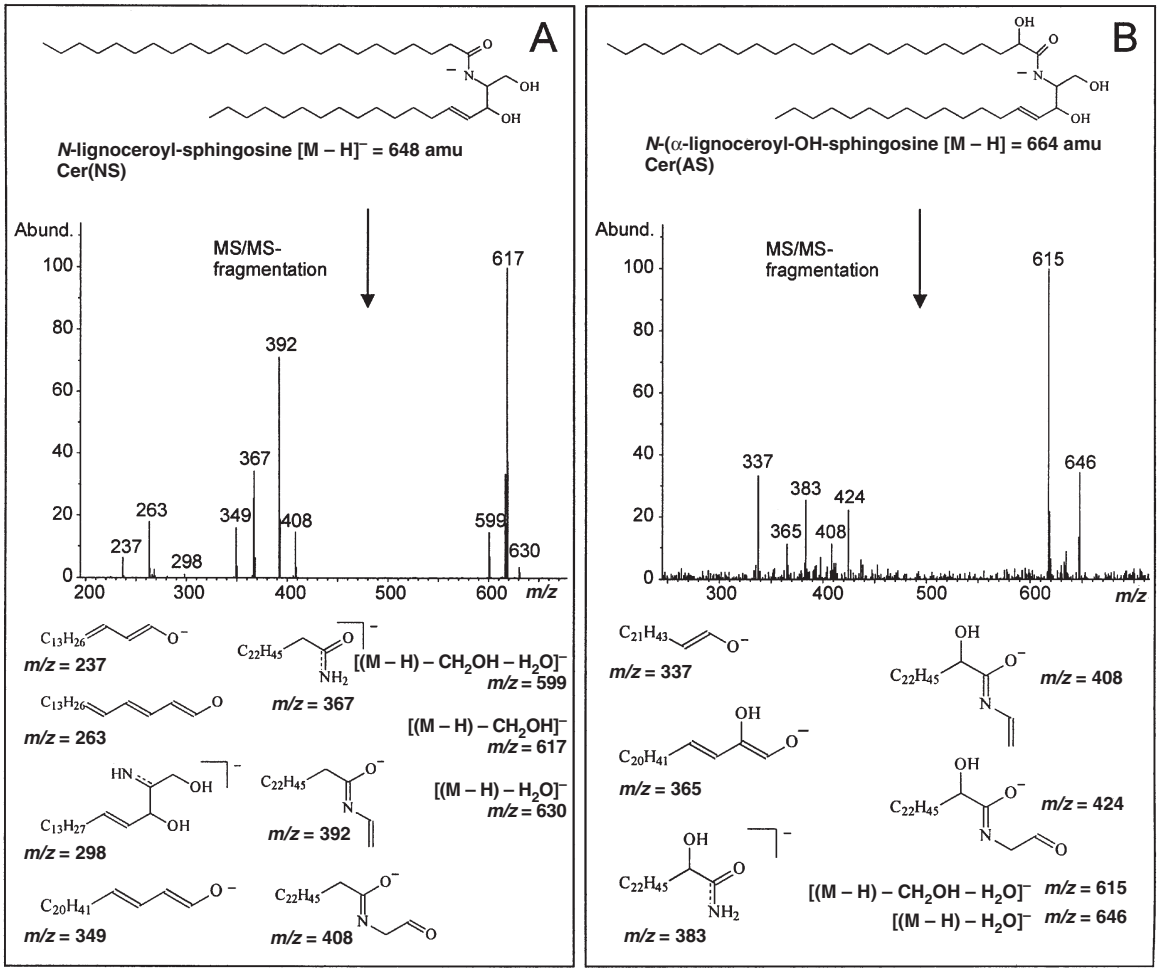

**FIG. 1.** Electrospray ionization–tandem mass spectrometry (ESI–MS/MS) negative ion mode fragment spectra of Cer(NS), (A), and Cer(AS), (B).

the amide bond fatty acid was always the fragment ion between the mass differences of 16 and 43 Da (Fig. 3).

This fragmentation scheme can be used as a tool to distinguish (i) ceramides containing sphingosine bases from phytosphingosine bases and (ii) ceramides containing α-OH-fatty acids from nonhydroxylated fatty acids. ω-Esterified ceramides *N*-(ω-OH-acyl)acyl-sphingosine [Cer(EOS)] and *N*-(ω-OH-acyl)acyl-6-OH-sphingosine [Cer(EOH)] did not show these kinds of fragmentation patterns. Nevertheless, structural information about these ceramides can be obtained by CID fragmentation spectra in the negative ion mode where the ω-esterified fatty acid splits off as an [(ω-fatty acid) – H]⁻- ion.

The use of LC/MS enables the selective analysis of many lipid samples overnight in an automated process using an autosampler. The resulting chromatograms can be processed using software-assisted evaluation procedures. The improved reproducibility of LC/MS compared to HPTLC is important if slight differences in the ceramide-pattern of different skintypes are to be evaluated and effects due to medical treatment of skin diseases and topical application of cosmetic formulations are to be demonstrated.

*Reinvestigation of isolated ceramide HPTLC bands by LC–MS.* Barrier lipids extracted from cyanoacrylate strippings of the human SC were first separated by HPTLC. A typical pattern of lipid bands on a HPTLC plate after charring is shown in Figure 4. LC–MS chromatograms of each ceramide band scraped off from the HPTLC plate showed a series of homologous subspecies. Identification of the ceramides was carried out by means of LC–MS and MS/MS and CID fragmentation experiments.

Although it is not possible to distinguish between variations of the chain length of either the amide-linked fatty acid or the sphingoid base from masses of intact molecular ions in the LC–MS chromatogram, we tried to describe the whole distribution of varying chain length by designation of the amide-linked fatty acids assuming a sphingoid chain length of $C_{18}$. The results are summarized in Table 1. The designation of the ceramides is in accordance with the nomenclature of Motta *et al.* (10) which was further modified by Robson *et al.* (15).

Our comparative analysis demonstrated that most of the ceramide bands on the HPTLC plate represented the molecular species corresponding to the assignment of Robson *et al.* (15) who described band 1 as Cer(EOS), band 2 as Cer(NS), band 3 as Cer(NP), band 4 as Cer(EOH), band 5 as Cer(AS), band 6 as Cer(AP) and band 7 as *N*-(α-OH-acyl)-6-OH-sphingosine. However, we discovered a few exceptions. First, cer-

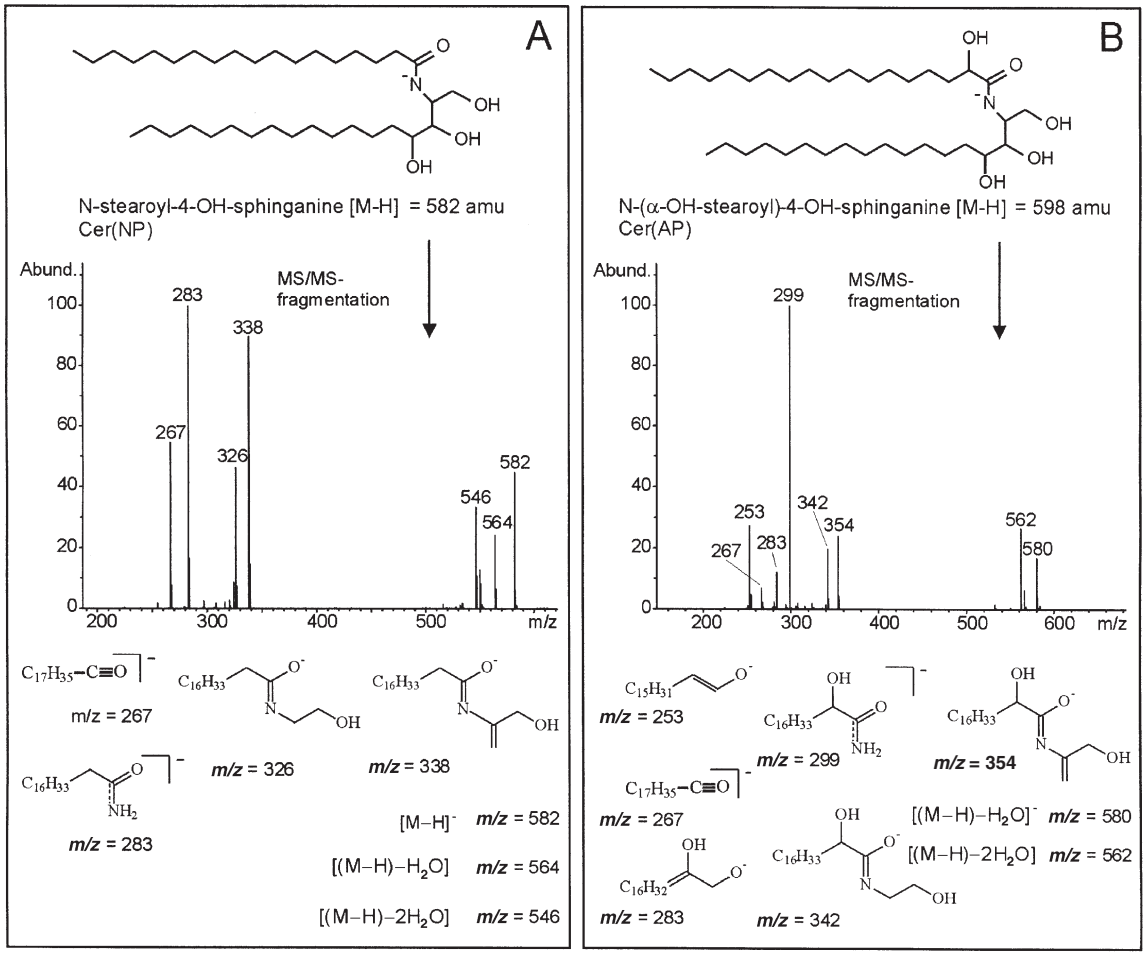

**FIG. 2.** ESI MS/MS negative ion mode fragment spectra of Cer(NP), (A), and Cer(AP), (B). For abbreviations see Figure 1.

amide band 2 comprises *N*-acyl-sphingosines, Cer(NS), as well as *N*-acyl-sphinganines. This is in agreement with the results of Wertz *et al.* (27). Second, apart from Cer(EOH), ceramide band 4 contained Cer(AS). Previous reports have ascribed band 5 to Cer(AS), which comigrates with the Cer(AS) standard (14,15). Moreover, in HPTLC-band 5 we detected *N*-acyl-6-OH-sphingosines, a relatively new class of ceramides described by Stewart *et al.* (16), Guey *et al.* (22), Vietzke *et al.* (26), and Bleck *et al.* (29).

**TABLE 1**
**Investigation by Means of Liquid Chromatography/Mass Spectroscopy (LC/MS) of Scraped-Off Ceramide Bands, Separated by High-Performance Thin-Layer Chromatography (HPTLC)**

| Scraped off HPTLC-based | Result of LC/MS-investigation | Ceramide-designation according to References 10,15 | Chain length of amidebond fatty acids (assumed chain length of sphingoid base: $C_{18}$) |
|---|---|---|---|
| Cer 1 | *N*-(ω-OH-acyl)acyl-sphingosine | Cer(EOS) | $C_{28}$–$C_{36}$ |
| Cer 2 | *N*-acyl-sphingosine | Cer(NS) | $C_{20}$–$C_{32}$ |
| | *N*-acyl-sphinganine | | $C_{22}$–$C_{36}$ |
| Cer 3 | *N*-acyl-4-OH-sphinganine | Cer(NP) | $C_{20}$–$C_{36}$ |
| Cer 4 | *N*-(ω-4-OH-acyl)acyl-6-OH-sphingosine | Cer(EOH) | $C_{28}$–$C_{36}$ |
| | *N*-(α-OH-acyl)-sphingosine | Cer(AS) | $C_{22}$–$C_{36}$ |
| Cer 5 | *N*-acyl-6-OH-sphingosine | Cer(NH) | $C_{22}$–$C_{34}$ |
| Cer 6 | *N*-(α-OH-acyl)-4-OH-sphinganine | Cer(AP) | $C_{20}$–$C_{32}$ |
| Cer 7 | *N*-(α-OH-acyl)-6-OH-sphingosine | Cer(AH) | $C_{22}$–$C_{32}$ |

Interestingly, LC–MS investigation of the scraped-off areas a, c, and d as well as the band of cholesterol (see Fig. 4) also shows ceramide-like lipids in small amounts. The molecular mass, the chromatographic behavior on RP-phases, and the CID fragmentation patterns in the spectra suggested the presence of further ω-esterified ceramides in the chromatogram containing ω-esterified saturated fatty acids and linoleic acid, respectively. One of these molecular species might even represent Cer(EOP), an ω-esterified ceramide that contains phytosphingosine as a sphingosine backbone and an ω-esterified linoleic acid. Remarkably, the glucosylated derivative of Cer(EOP) has already been identified by Hamanaka *et al.* (30). However, the assumptions made on the basis of the LC–MS data require further investigation to prove and verify the identification, e.g., analysis by NMR spectrometry.

However, the data presented here demonstrate that a combination of HPTLC and LC/MS enables a detailed analysis of the complex ceramide composition in human skin.

**ABSTRACT:** Antiproliferative properties of molecular regulators of lipid metabolism have been increasingly studied during recent years. Discussion is ongoing concerning optimal treatment conditions and assays used for monitoring proliferation and cytotoxicity. The objective of the present work was to optimize methods and treatment conditions used for studying antiproliferative effects of fatty acids and analogs, represented by palmitic acid (PA) and the β-oxidation-restricted fatty acid analog tetradecylthioacetic acid (TTA), in rat (BT4Cn) and human (D54Mg and GaMg) glioma cell lines. Changes in [$^3$H]thymidine incorporation preceded changes in cell number in TTA-treated glioma cell cultures, and the growth inhibition was more significantly expressed by [$^3$H]thymidine incorporation than cell number. Addition of bovine serum albumin decreased cellular fatty acid uptake and reduced the effects of TTA and PA on [$^3$H]thymidine incorporation. Determination of the antiproliferative effect of TTA in BT4Cn cells by MTT conversion and [$^3$H]thymidine incorporation yielded concordant results. TTA-mediated reduction in cell number corresponded to reduction in cellular protein and total DNA content in BT4Cn cells. Reduced growth potential in TTA-treated multicellular D54Mg and GaMg spheroids supported the findings from monolayer cultures. In conclusion, cell density, treatment period, fatty acid administration, and methods for growth determination may profoundly influence the outcome of cell growth experiments. Thus, experimental conditions should be carefully controlled when performing cell growth experiments, and effects on cell growth should preferably be confirmed by different methods.

Paper no. L8682 in *Lipids 36,* 305–313 (March 2001).

Anticancer properties of compounds modulating cellular lipid metabolism have been extensively studied during recent years. This category of compounds includes fatty acids such as essential fatty acids (EFA) (1–8) as well as more complex compounds such as fibrates and aromatic fatty acids (9,10). We have for several years investigated metabolic effects of a novel sulfur-substituted fatty acid analog tetradecylthioacetic acid (TTA; $CH_3$–$(CH_2)_{13}$–S–$CH_2$–COOH) that has major impacts on cellular metabolism (11,12). TTA itself cannot be β-oxidized but is, in other aspects, metabolized like ordinary fatty acids. The exact mechanism behind the antiproliferative effect of TTA is not fully elucidated, but it is thought to involve alterations in lipid metabolism (4,13) and changes in oxidative status (4,13,14). Increased cytosolic cytochrome c, indicating initiation of apoptotic cascades, was observed in glioma cells.

*In vitro* models have been useful experimental tools for studying the cytotoxic effects of fatty acids in cancer cells. However, the results from such studies have exhibited a certain degree of inconsistency concerning both type and magnitude of response. Differences in growth conditions, drug administration, treatment period, and the methods used for monitoring cancer cell growth may be reasons for such variations (15,16).

Commonly used methods for monitoring cell proliferation and cytotoxicity can be divided into two classes: (i) mass-based methods and (ii) metabolic-based methods. Mass-based methods are employed to quantify the amount of cellular material such as cell number, protein, or DNA. On the other hand, metabolic-based assays are used to measure metabolic activities that are closely related to the number of viable cells or proliferation rate, such as conversion of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) and incorporation of [$^3$H]thymidine. It has previously been concluded that different methods should be directly compared in the same settings when performing cytotoxicity assay (15). Care should be taken when designing these kinds of experiments since the reliability of some methods has been questioned (16,17).

The mode of fatty acid administration is likely to influence the cellular uptake of the fatty acids. The exact mechanisms behind cellular fatty acid uptake are not clearly understood, but the concept of fatty acid uptake consisting of two coexisting pathways, one passive and one carrier-mediated, is today generally accepted (see review in Ref. 18). In both pathways the concentration of unbound fatty acids seems to be of crucial importance, and the two pathways contribute differentially to net uptake depending on fatty acid/albumin ratios and cell types. Tissue-specific expression of putative fatty acid carriers further substantiates the notion that transport mechanisms may vary between tissues. Fatty acid transfer to the membrane is limited by tight fatty acid binding to high affin-

Abbreviations: BSA, bovine serum albumin; DMSO, dimethylsulfoxide; EFA, essential fatty acids; $IC_{50}$, 50% inhibitory concentration; MTT, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide; NBCS, new-born calf serum; PA, palmitic acid; PBS, phosphate-buffered saline; PPAR, peroxisome proliferator activated receptor; TTA, tetradecylthioacetic acid.

ity sites on albumin. In blood, fatty acids are present in millimolar concentrations (0.1–1), and the fatty acid/albumin ratio varies between 0.1 and 1.0 in circulating plasma. The concentration of nonprotein bound fatty acids in human plasma is on the order of 5–10 nM (19). The poor solubility of fatty acids in water impedes their administration in cell culture medium. Supplementation of albumin in the culture medium may overcome this problem; however, albumin may artificially perturb the effects of fatty acids (6,20,21). Another interfering factor is that supplemented albumin may alter the availability of fatty acids to normal and tumor cells (22,23). In serum-containing cell culture medium, supplementation of albumin can be avoided since the sera contain proteins capable of binding and transporting fatty acids.

Cell density may affect cellular metabolism, differentiation, and proliferation (16). Along this line, expression of peroxisome proliferator-activated receptors (PPAR), which are intimately involved in the regulation of lipid metabolism, may be controlled in response to cell density as has been observed in BT4Cn rat glioma cells (Berge, K., Tronstad, K.J., Flindt, E.N., Rasmussen, T.H., Madsen, L., Kristiansen, K., and Berge, R., unpublished data). Thus, because of the differences between confluent and subconfluent cells, the initial cell density and growth period should be carefully controlled.

To optimize the methodology and treatment conditions in our research on anticancer effects of fatty acids and analogs we used one rat (BT4Cn) and two human (D54Mg and GaMg) glioma cell lines as models. It was of interest to determine the importance of treatment period, methods for growth determination, and fatty acid administration.

## EXPERIMENTAL PROCEDURES

*Chemicals.* TTA and [1-$^{14}$C]TTA were prepared at the Department of Chemistry, University of Bergen, as previously described (24). [$^{3}$H]Thymidine (TRA 310) was purchased from Amersham International (Amersham, United Kingdom). [1-$^{14}$C]Palmitic acid (PA; 50 mCi/mmol) was obtained from New England Nuclear (Boston, MA). All other chemicals and solvents were of reagent grade from common commercial sources.

*Cells.* The rat glioma cell line BT4Cn (25) and the human glioma cell lines D54Mg and GaMg (26) were routinely kept in a standard culture incubator (37°C, 5% $CO_2$ and 95% air). The cells were grown as monolayer cultures in Dulbecco's modified Eagle medium supplemented with 10% new-born calf serum (NBCS), L-glutamine (0.58 mg/mL), streptomycin (100 μg/mL), penicillin (100 IU/mL), and three times the prescribed concentration of nonessential amino acids (all from Sigma, St. Louis, MO). For cell counting analysis, cells were seeded in 25 cm$^2$ tissue culture flasks ($10^5$ cells/flask) or 24-well tissue culture plates ($8 \times 10^3$ cells/well). For [$^{3}$H]thymidine incorporation, $10^3$ cells/well were seeded in 96-well tissue culture plates. The cells were allowed to settle overnight before the fatty acid treatments were started.

*Cell growth.* Cell number was determined in trypsinized cell suspensions using a Coulter Z1 Counter (Coulter Electronics, Luton, United Kingdom). [$^{3}$H]Thymidine incorporation was measured after 4 h of incubation with 1.0 μCi/well of [$^{3}$H]thymidine. Following incubation, the cellular DNA was transferred to UniFilter™-96 GF/C™ using a Filtermate Harvester (Packard Instruments, Meriden, CT), before the nuclear radioactivity was measured using a TopCount NXT™ microplate scintillation counter (Packard Instruments). The MTT assay was performed essentially as described in Reference 27. Bio-Rad protein assay (Bio-Rad Laboratories, Richmond, CA) was used for protein measurement. Bovine serum albumin (BSA), dissolved in distilled water, was used as standard. DNA amounts were determined by fluorometry. Cell samples were harvested by trypsination and dissolved in 1 mL high salt harvest buffer (10 mM Tris, 2 mM EDTA, 2 M NaCl; pH 7.4). Samples were then sonicated and properly diluted in high salt buffer (2 mM Tris, 2 mM EDTA, 2 M NaCl; pH 7.4), and the DNA amount was measured on a Hoefer DyNA Quant 200 (Hoefer Scientific Instruments, San Francisco, CA) in high salt buffer containing 0.1 μg/mL 2′-[4-hydroxyphenyl]-5-[4-methyl-1-piperazinyl]-2,5′-bi-1H-benzimidazole (Hoechst No. 33258).

*Multicellular tumor spheroids.* Multicellular tumor spheroids were produced by the agar overlay culture method described by Yuhas *et al.* (28). In the beginning of each experiment spheroids were individually transferred into agar-coated 24-well tissue culture plates before the treatments were started. The diameters of the spheroids were microscopically measured. The spheroid volume was calculated, and fold volume increase was calculated by dividing the spheroid volume by the initial volume.

*Preparation of TTA and PA.* (i) TTA or PA was dissolved in 0.1 M NaOH at 80°C to a final concentration of 25 mM. The 25 mM TTA stock solution was diluted in NBCS (40°C) to a concentration of 2 mM. This fatty acid-supplemented NBCS was used in the preparation of growth medium. The control medium was prepared in the same way, replacing 25 mM TTA or PA with 0.1 M NaOH. (ii) TTA or PA (25 mM, prepared as described above) was added to a 21.17% (wt/vol) solution of EFA-free BSA in phosphate-buffered saline (PBS) (40°C), to give a final concentration of 6 mM TTA or PA, and 2.4 mM BSA. This resulted in a solution with a molar fatty acid/BSA ratio of 2.5:1, which was diluted in culture growth medium.

For studying the cellular uptake of TTA or PA with different vehicles, the following preparations were made: 25 mM [1-$^{14}$C]TTA (12.5 μCi/mL) in (i) 0.1 M NaOH, (ii) 0.1 M KOH, (iii) dimethylsulfoxide (DMSO)/ethanol (1:10, vol/vol), and (iv) 0.1 M KOH/ethanol (1:3, vol/vol). These solutions were diluted to the final concentrations in culture growth medium.

*Cellular uptake of [1-$^{14}$C]TTA and [1-$^{14}$C]PA.* Cells were seeded in 24-well tissue culture plates (70,000/well) and incubated overnight. The cells were then incubated for 9 h with 50, 100, 200, or 500 μM [1-$^{14}$C]TTA or [1-$^{14}$C]PA (prepared as described above). Following incubation, the medium was

removed, and the cells were washed with 1.5 mL PBS before they were harvested by scraping. After centrifugation (2,000 rpm, 5 min), the cells were suspended in cold distilled water. Radioactivity in the cell suspension was measured by liquid scintillation counting.

*Statistical analysis.* The data are presented as mean ± standard deviation (SD) of triplicates or quadruplicates. The results were evaluated by a two-sample variance Student's *t* test (two-tailed distribution). The level of significance was set at $P < 0.05$. The data presented are representative of the results collected in at least two experiments.

## RESULTS

*Treatment period.* Cell counting and [$^3$H]thymidine incorporation measure population size and DNA synthesis, respectively, and thus the two methods represent different approaches for monitoring cell growth. It was of interest to see how these two methods agreed as a measure of the antiproliferative properties of TTA. The cell number and [$^3$H]thymidine incorporation in BT4Cn cultures were determined after 2, 4, and 6 d of incubation (Figs. 1A,1B). In control cultures the cell number increased exponentially, and the cultures reached confluence after 6 d. The amount of cellular protein closely corresponded to cell number (Fig. 1C). The [$^3$H]-thymidine incorporation was increased on day 4 compared to day 2; however, it was reduced at confluence on day 6. As can be seen from Figure 1A, there was only a modest increase in cell number during the incubation period in presence of 200 μM TTA. The cell number was reduced to 33 and 11% in TTA-treated cultures compared to the control after 4 and 6 d, respectively. [$^3$H]Thymidine incorporation was nearly abolished after 2 d with TTA, and it remained low during the 6-d incubation period. Thus, the antiproliferative effect of TTA was evident from cell number determination after 4 d, whereas [$^3$H]thymidine incorporation was reduced after only 2 d with TTA.

Optimal experimental conditions may differ from cell line to cell line; thus we measured the effect of TTA on cell number and [$^3$H]thymidine incorporation in the two human glioma cell lines D54Mg and GaMg (Fig. 2). A time-dependent decrease in cell number was found in TTA-treated D54Mg and GaMg cultures, compared to control cultures. In common with BT4Cn cells, the inhibitory effect of TTA was evident in D54Mg and GaMg cells after 4 d. Also in these two human cell lines the antiproliferative effect of TTA was more significantly expressed by [$^3$H]thymidine incorporation than by cell number. After 2 d, the [$^3$H]thymidine incorporation was reduced to 4% of the control in both D54Mg and GaMg. A drastic decrease in [$^3$H]thymidine incorporation after 6 d, as seen in untreated BT4Cn cells (Fig. 1B), was not seen in untreated D54Mg and GaMg cells, since these cells were still subconfluent at this stage.

**TABLE 1**
**$IC_{50}$ Concentrations of TTA (μM)[a]**

| | Day 2 | Day 4 | Day 6 |
|---|---|---|---|
| D54Mg | 150 | 125 | 100 |
| BT4Cn | 175 | 125 | — |
| GaMg | 75 | 40 | 30 |

[a][$^3$H]Thymidine incorporation was measured in three glioma cell lines after tetradecylthioacetic acid (TTA) treatment. The values given are the approximate TTA concentrations extrapolated to give 50% ($IC_{50}$) decrease in [$^3$H]thymidine incorporation. BTCn, rat glioma cells; D54Mg and GaMg, human glioma cells.

It can be seen from Table 1 that the TTA concentration ($IC_{50}$) giving 50% reduction in [$^3$H]thymidine incorporation decreased as the treatment period was prolonged in all three cell lines.

*Fatty acid administration.* It is likely that the mode of fatty acid administration influences the cellular fatty acid uptake, which consequently affects the observed effects on cellular growth and metabolism. To study how the mode of administration affected cellular fatty acid uptake in glioma cells, we compared the cellular uptake of TTA (1 sulfur + 16 carbon atoms) and the natural β-oxidizable PA (16 carbon atoms) when they were bound or not to BSA (Figs. 3A,3B). BSA-binding reduced the cellular uptake of TTA, especially at higher concentrations (Fig. 3A). The cellular uptake of BSA-bound TTA only marginally responded to increasing TTA concentrations, compared to the uptake of unbound TTA, which

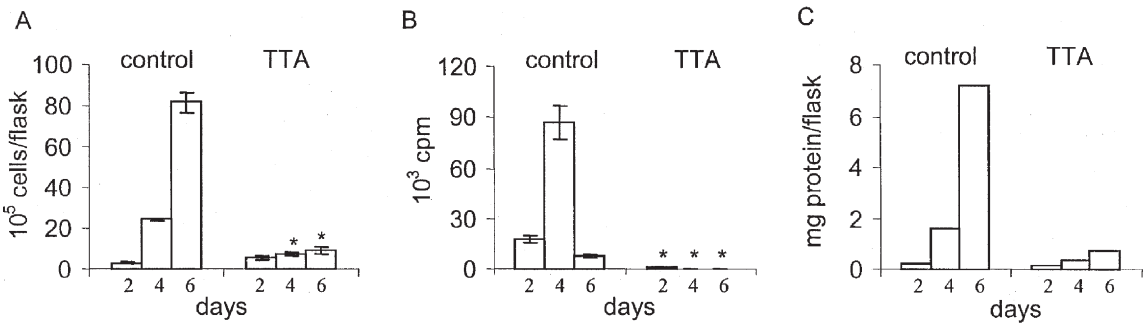

**FIG. 1.** Comparison of the effect of tetradecylthioacetic acid (TTA) on cell number (A), [$^3$H]thymidine incorporation (B), and protein content (C). BT4Cn rat glioma cells were treated, in triplicate or quadruplicate, for 2, 4, or 6 d with or without 200 μM TTA in the absence of bovine serum albumin (BSA). Cells (3500–4000/cm$^2$) were seeded in 25-cm$^2$ tissue culture flasks (cell number, protein content) or 96-well tissue culture plates ([$^3$H]thymidine incorporation). Samples within each group were pooled before cellular protein was measured. Vertical bars indicate standard deviation. *$P < 0.05$ compared to control.

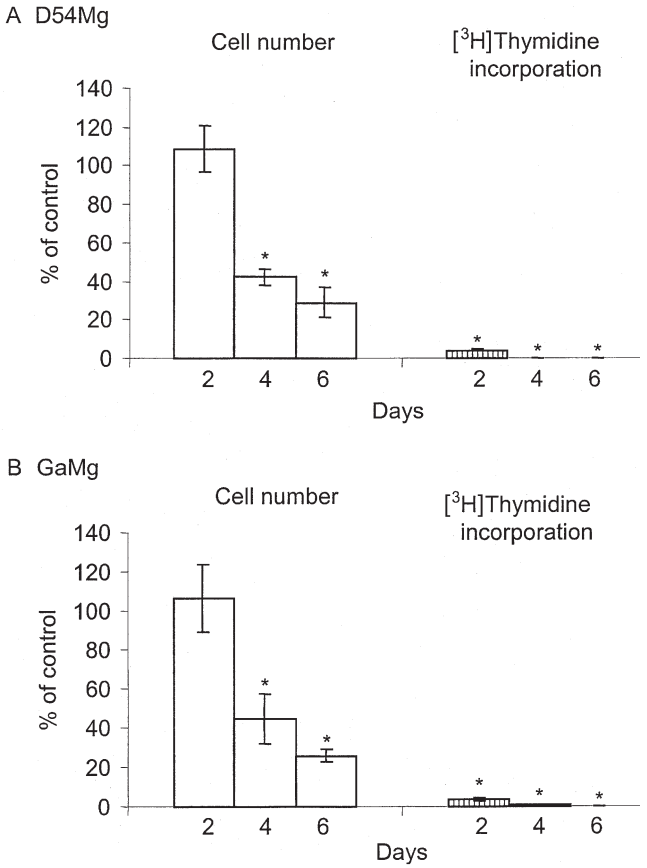

**FIG. 2.** Effects of TTA on cell number (open bar) and [$^3$H]thymidine incorporation (striped bar) in human glioma cell lines D54Mg (A) and GaMg (B) cell cultures. Cells (3500–4000/cm$^2$) were seeded in 24-well (cell number) or 96-well tissue culture plates ([$^3$H]thymidine incorporation). Three or four cultures in each group were treated for 2, 4, or 6 d with 200 μM TTA. Vertical bars indicate standard deviation. *$P < 0.05$ compared to control. For abbreviation see Figure 1.

strongly responded to increasing TTA doses. BSA binding also reduced the uptake of PA, but compared to TTA, the inhibitory effect was less pronounced (Fig. 3B). At concentrations of 200 and 500 μM, respectively, the uptake was reduced to 27 and 20% for BSA-bound TTA, and 54 and 36% for BSA-bound PA, compared to the unbound forms. Noncomplexed TTA and PA, at a concentration of 200 μM, gave a significantly higher cellular uptake than 500 μM of the BSA-bound forms. These data suggest that binding to BSA makes the fatty acids less available for cellular uptake. It is also worth noting that the uptake of BSA-complexed TTA was significantly lower than the uptake of BSA-complexed PA.

We also investigated the cellular uptake of noncomplexed TTA and PA using 0.1 M NaOH, 0.1 M KOH, KOH (0.1 M)/ethanol (1:3), or DMSO/ethanol (1:10) as solvents before addition to culture medium, as described in the Experimental Procedures section. Figures 3C and 3D show that there were only marginal differences between the preparations, and the cellular uptake of TTA and PA in BT4Cn cells increased with all four preparations in a dose-dependent manner. The use of 0.1 M NaOH as a vehicle seemed to give slightly higher uptake than observed with the other preparations. Interestingly, the cellular uptake of PA was significantly higher than the uptake of TTA in all preparations.

*Influence of BSA binding on antiproliferative properties of fatty acids.* Since BSA binding influenced the cellular uptake of TTA and PA, it is also likely to affect antiproliferative properties of these fatty acids. Although growth reduction was observed, BSA binding clearly attenuated the TTA-mediated reduction in [$^3$H]thymidine incorporation in BT4Cn, D54Mg, and GaMg cells compared to unbound TTA (Fig. 4). The [$^3$H]thymidine incorporation results from BT4Cn, D54Mg, and GaMg cells treated with unbound TTA have been presented previously (14), but are included here for comparison. The antiproliferative effect of TTA in BT4Cn cells was efficiently neutralized in BSA-supplemented cultures (Fig. 4A). Although PA retained antiproliferative properties in the presence of BSA, the PA concentration had to be increased significantly to get the same inhibition as with unbound PA (Fig. 4A). D54Mg cells were more sensitive to TTA than to PA in the absence of BSA, but the opposite was found in the presence of BSA as the antiproliferative effect of TTA was more affected than the antiproliferative effect of PA (Fig. 4B). Although unbound PA and TTA equally affected [$^3$H]thymidine incorporation in GaMg cells, the 50% inhibitory ($IC_{50}$) value of BSA-bound PA (approximately 150 μM) was lower than the $IC_{50}$ value of BSA-bound TTA (approximately 450 μM) (Fig. 4C). BSA alone significantly stimulated [$^3$H]thymidine incorporation in GaMg cells, whereas it had no effect on [$^3$H]thymidine incorporation in BT4Cn and D54Mg cells.

*[$^3$H]Thymidine incorporation and the MTT assay.* The MTT colorimetric assay measures the conversion of the orange-colored soluble MTT into purple insoluble formazan crystals by mitochondrial dehydrogenases, and it is used as a simple and inexpensive assay for monitoring survival and proliferation (27). To compare the MTT assay with [$^3$H]thymidine incorporation and to verify that these two assays reflect the number of BT4Cn cells, we compared the measurements that were obtained when the two assays were applied to BT4Cn cell cultures of different densities (0–100,000 cells per well) in 96-well tissue culture plates (Figs. 5A,5B). We found a linear correlation between cell number and MTT conversion in wells with up to 20,000 cells per well. In contrast, [$^3$H]thymidine incorporation correlated linearly with cell number up to at least 100,000 cells per well, which was the highest cell number tested. We also performed an experiment to compare the MTT assay with [$^3$H]thymidine incorporation in experiments with TTA. Figure 5C shows that both MTT conversion and [$^3$H]thymidine incorporation were similarly reduced in BT4Cn cells treated with 200 or 250 μM TTA for 40 h.

*Cell number, cellular protein, and total DNA content.* In conformity with cell number, cellular protein and total DNA content represent measures for the amount of cellular mass, and thus they can be used for monitoring cell growth. These three parameters were measured and compared in BT4Cn cell cultures grown for 4 or 8 d in 100 μM TTA. As expected, cell number, cellular protein and total DNA content were simi-

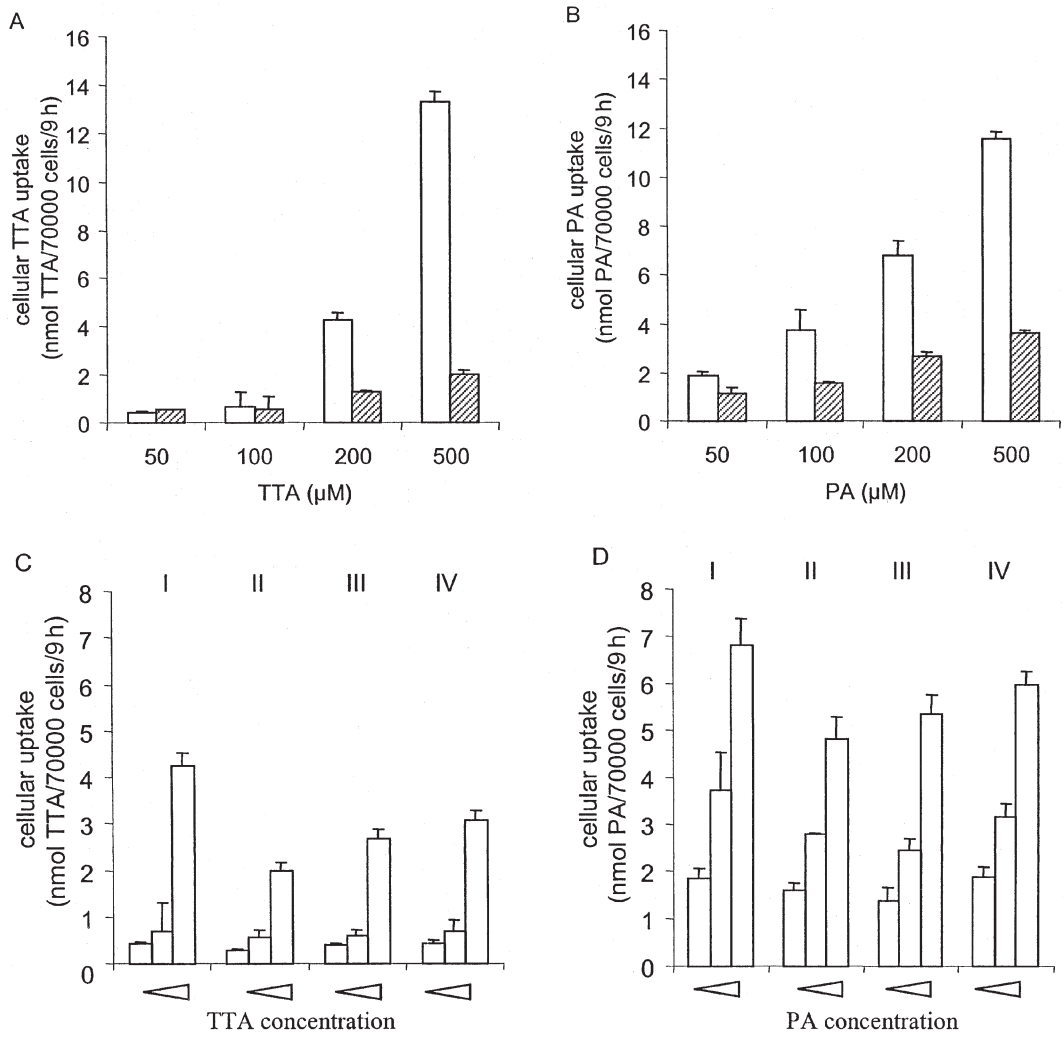

**FIG. 3.** Cellular uptake of TTA and palmitic acid (PA) in the presence of different vehicles. BT4Cn (70,000 cells per well) were seeded in 24-well tissue culture plates and incubated overnight before [1-$^{14}$C]-labeled TTA or PA was added in triplicate cultures. After 9 h of incubation the cells were washed, and the cellular radioactivity was measured. The cellular uptake of [1-$^{14}$C]TTA (A) and [1-$^{14}$C]PA (B) was measured in cells grown in culture medium with different concentrations of unbound (open bar) or BSA-bound (ruled bar) TTA or PA (vehicle: 0.1 M NaOH). The molar fatty acid/BSA ratio was 2.5:1. The cellular uptake of unbound [1-$^{14}$C] TTA (C) and [1-$^{14}$C] PA (D) was compared when they were dissolved in (I) 0.1 M NaOH, (II) 0.1 M KOH, (III) 0.1 M KOH/ethanol (1:3, vol/vol), or (IV) dimethylsulfoxide/ethanol (1:10, vol/vol) before addition to the growth medium (final concentration of TTA or PA: 50, 100, and 200 μM). Wedges indicate increasing concentrations. The data are given as mean ± SD. For abbreviations see Figure 1.

larly affected by the TTA treatment (Fig. 6). However, after 8 d of treatment, DNA content was more reduced than cell number and cellular protein.

*Multicellular tumor spheroids.* In contrast to two-dimensional monolayer models, multicellular spheroid models offer opportunities to investigate the behavior of three-dimensional tumor cell masses (28). Not all cell lines have the properties needed to develop spheroids, and consequently, this methodology has some limitations. In contrast to D54Mg and GaMg cells, BT4Cn cells were not able to form proper spheroids. The growth of D54Mg and GaMg spheroids decreased in the presence of 500 μM BSA-bound TTA compared to BSA alone (Figs. 7A,7B). A dose-dependent growth-inhibiting effect of TTA was observed in both cell lines (Figs. 7C,7D).

## DISCUSSION

We have evaluated and compared different protocols commonly used for the analysis of the effects of fatty acids on cellular proliferation. As expected, experimental design may profoundly influence the outcome of such experiments. Obviously, cell density has a major impact on the rate of [$^{3}$H]-thymidine incorporation, and hence this type of analysis is of limited value when analyzing the effects of fatty acid on post-confluent growth of transformed cells. Another problem associated with differences in degree of confluency is the fact that the expression of important regulators of lipid metabolism often changes according to growth phase. Thus, PPAR expression in rat BT4Cn glioma cells changes dramatically in

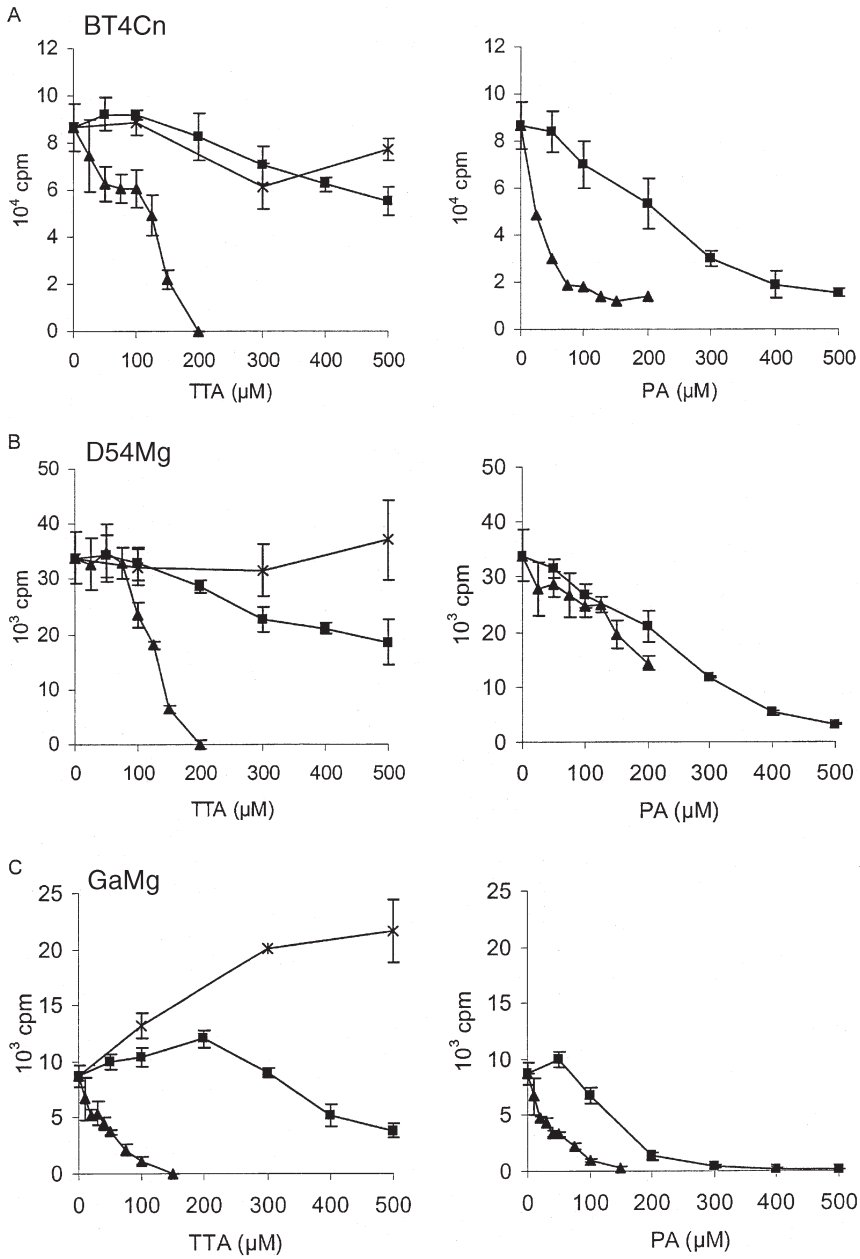

**FIG. 4.** Influence of BSA on antiproliferative effects of TTA and PA. BT4Cn (A), D54Mg (B), and GaMg (C) cells were grown in triplicate cultures for 4 d in different concentrations of TTA (left panel) or PA (right panel) in the absence or presence of BSA. Proliferation was measured by [$^3$H]thymidine incorporation in cultures treated with BSA alone (×) in concentrations corresponding to BSA concentrations in the fatty acid preparations, BSA-bound TTA or PA (■), and unbound TTA or PA (▲). The data (cpm) are presented as mean ± SD. For abbreviations see Figures 1 and 3.

response to cell density (Berge, K., Tronstad, K.J., Flindt, E.N., Rasmussen, T.H., Madsen, L., Kristiansen, K., and Berge, R., unpublished data). To get reliable and reproducible results, the degree of confluency should be carefully controlled, and measurements of postconfluent growth should be performed by mass-based methods since these are insensitive to metabolic changes caused by confluency.

Another parameter of importance is the duration of the treatment with fatty acids. Here, the $IC_{50}$ value, determined by [$^3$H]thymidine incorporation, decreased in conformity with prolonged periods of treatment in all three cell lines (Table 1). [$^3$H]Thymidine incorporation clearly was a more sensitive measure of the antiproliferative effect of TTA at the earlier stages than cell number in BT4Cn (Fig. 1), D54Mg (Fig. 2A), and GaMg (Fig. 2B) cells, possibly reflecting the ability of cells in M-, $G_2$- and late S-phase to undergo mito-

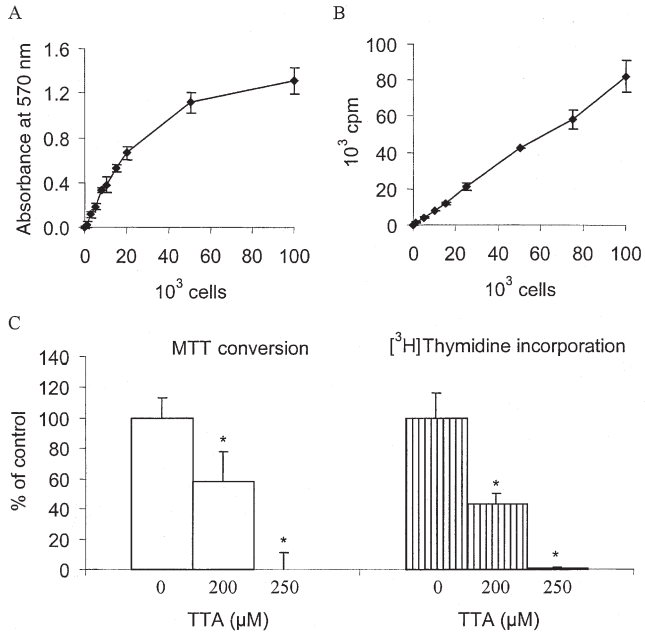

**FIG. 5.** 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) conversion and [$^3$H]thymidine incorporation. Different numbers of BT4Cn cells were seeded in 96-well tissue culture plates. MTT reduction (A) and [$^3$H]thymidine incorporation (B) were measured as described in the Experimental Procedures section. (C) BT4Cn cells (1,000 per well) in 96-well tissue culture plates were treated for 40 h with TTA, followed by detection of MTT conversion (open bar) or [$^3$H]thymidine incorporation (striped bar). The measurements were performed in triplicate cultures. The results are presented as mean ± SD. *$P < 0.05$ compared to control. For abbreviation see Figure 1.

sis, although TTA leads to DNA-synthesis arrest. In this case the cell number will increase at first, but the TTA-mediated arrest in DNA-synthesis will inhibit further mitosis.

Both [$^3$H]thymidine incorporation and MTT assays should be performed under standardized conditions, as variation in labeling/incubation conditions and, in the case of MTT assays, formazan solubilization may lead to experimental variation. When studying anticancer effects of compounds that cause metabolic changes unrelated to growth, metabolic assays, such as the MTT assay, may give erroneous results in terms of cellular proliferation. Furthermore, it was reported that cells induced to differentiate and exhibit morphological changes indicative of preapoptosis, take up [$^3$H]thymidine nonspecifically (16). In spite of these sources of variation, there was no discrepancy between MTT conversion and [$^3$H]thymidine incorporation in BT4Cn cells treated for 40 h with TTA (Fig. 5C).

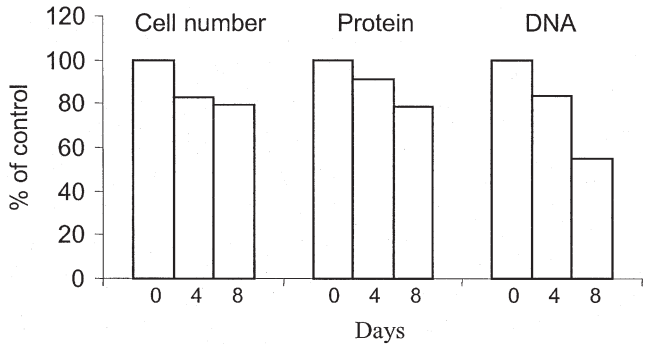

**FIG. 6.** Effects of TTA on cell number, cellular protein, and total DNA content. Cell number, cellular protein, and DNA content were determined in triplicate or quadruplicate BT4Cn cultures as described in the Experimental Procedures section after 2, 4, and 8 d of incubation in 100 μM TTA. The columns represent percentages of the respective controls. Standard deviations were less than 15%. Samples within each group were pooled before cellular protein was measured. For abbreviation see Figure 1.

Altered cellular metabolism mediated by TTA may change the amount of cellular protein. Furthermore, the production of apoptotic cellular fragments may lead to overestimation of cell number determined by an automatic particle counter. These factors may explain the small discrepancy between the measurements of cell number, cellular protein, and DNA content after 8 d of TTA treatment (Fig. 6).

Albumin has a very high affinity for fatty acids, which keeps the concentration of nonprotein bound fatty acids in human serum in the order of 5–10 nM (19). Dissociation of fatty acids from the albumin–fatty acid complex is thought to be facilitated by specific albumin-binding proteins, and both passive and active mechanisms are thought to be involved in cellular fatty acid uptake (18,29). In our experiments, the uptake of TTA and PA in BT4Cn glioma cells was significantly reduced when the fatty acids were bound to BSA, compared to nonbound TTA and PA (Figs. 3A,3B). In the fatty acid preparations without BSA supplementation, the serum still contained an abundance of fatty acid-binding proteins, including albumin, preventing the formation of micelles due to excessive concentration of the free fatty acid. Our results suggest that this provides more favorable conditions for fatty acid uptake.

Albumin supplementation has been reported to reduce the antiproliferative properties of polyunsaturated fatty acids in human and rat hepatoma (6,30). In the colon adenocarcinoma cell line HT29-D4, albumin addition induced cell growth accompanied with a low level of differentiation (20). However, in human MCF-7 breast cancer cells, proliferation was inhibited by albumin supplementation (21,31). In our experiments BSA significantly induced proliferation of GaMg, but not of BT4Cn and D54Mg cells. The differences in TTA and PA sensitivity in experiments with and without addition of BSA (Fig. 4) can be explained by fatty acid-specific changes in cellular uptake, since BSA seemed to affect the uptake of TTA more than the uptake of PA (Fig. 3). These data show that BSA is not a "silent factor," and it may mask fatty acid properties in these kinds of experiments. In preparations without BSA supplementation, there were only minor changes in cellular TTA and PA uptake between the tested fatty acid vehicles (Fig. 3).

The use of multicellular tumor spheroid cultures makes it possible to study three-dimensional growth *in vitro*. Furthermore, the treatment period can be extended compared to monolayer cell cultures since the multicellular tumor spheroids grow for a longer period and confluence effects are avoided. The spheroids have to be compact, since spheroid

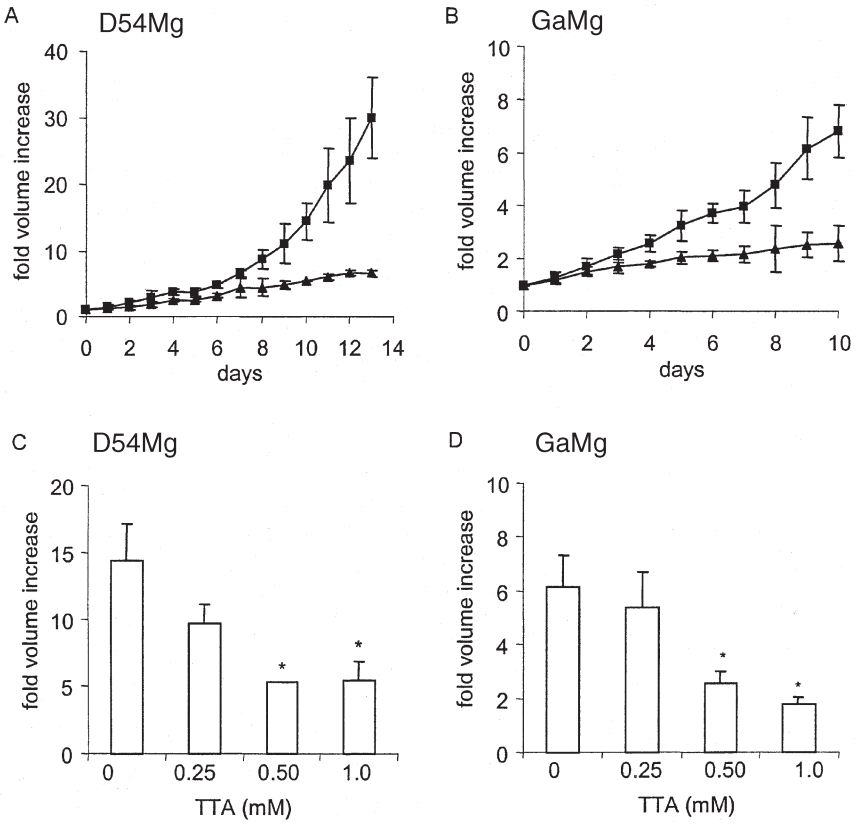

**FIG. 7.** Effects of TTA on the growth of multicellular tumor spheroids. D54Mg (A) and GaMg (B) multicellular tumor spheroids were treated in quadruplicate with BSA (control) (■) or 500 μM of BSA-bound TTA (▲). The diameters of the spheroids were microscopically measured. Fold volume increase was calculated by dividing the spheroid volume on initial spheroid volume. The effect of different doses of BSA-bound TTA on the growth of D54Mg (C) and GaMg (D) multicellular spheroids was measured after 10 and 9 d of incubation, respectively. The data are presented as mean ± SD. $^*P < 0.05$. For abbreviations see Figure 1.

splitting will complicate the microscopic growth determination. Thus, this methodology is restricted to those cell lines capable of making proper multicellular spheroids, and consequently, it has some limitations. In our experiments GaMg and D54Mg cells, but not BT4Cn cells, were capable of making proper multicellular spheroids. TTA was found to reduce the growth of both D54Mg and GaMg multicellular spheroids in a time- and dose-dependent manner (Fig. 7), which was in line with results from the monolayer experiments.

Enhanced radical generation and lipid peroxidation are commonly suggested mechanisms for the cytotoxic action of fatty acids on tumor cells. Consequently, since the redox situation in the cell cultures may be influenced, the levels of prooxidants and antioxidants in culture supplements are of importance in these kinds of experiments. Since the serum may vary from batch to batch with regard not only to levels of metals and antioxidants but also to growth factors, it is recommended to use serum from the same batch in a series of experiments and to test if the cellular response is altered when a new serum batch is employed. This advice should also be considered concerning BSA since it may contain substances, such as metals, that may influence the results.

In conclusion, during exponential growth of glioma cells, [$^3$H]thymidine incorporation was a more sensitive measure of the effects of TTA than measurements of cell number, whereas the reverse was found when the effect on postconfluent growth was determined. MTT conversion and [$^3$H]thymidine incorporation yielded concordant results in determination of the antiproliferative effects of TTA on BT4Cn cells. TTA-mediated reduction in cell number corresponded to the reduction in cellular protein and total DNA content in BT4Cn cells. Addition of BSA may significantly affect the effects of fatty acids on proliferation, as it both reduced the cellular fatty acid uptake and, in certain settings, exerted a growth-regulating function. The multicellular tumor spheroid technique is a valuable supplement providing additional opportunities in the studies of the antiproliferative properties of drugs.

## ACKNOWLEDGMENTS

The authors are grateful to Professor Rolf Bjerkvig for his helpfulness and for providing the cell lines. We will also thank Kari H. Mortensen for technical assistance. The Research Council of Norway supported this work.

# Changes in Conjugated Linoleic Acid Composition Within Samples Obtained from a Single Source

**R.O. Adlof*, L.C. Copes, and E.L. Walter**

Oil Chemical Research, National Center for Agricultural Utilization Research, USDA, ARS, Peoria, Illinois 61604

**ABSTRACT:** Conjugated linoleic acid (CLA; 9*c*,11*t*-18:2) and CLA isomers have been reported, in animals, to exhibit a variety of health-related benefits. Silver ion high-performance liquid chromatography (Ag-HPLC) was found to provide better resolution of the isomers than gas chromatography. Most commercially available samples of CLA, prepared by base-catalyzed isomerization of linoleic acid (9*c*,12*c*-18:2), are composed of mixtures of four major isomers. While these isomers have been characterized, we found significant changes in CLA isomer ratios within samples obtained from the same producer/commercial supplier over a period of 1.5 yr. In the first sample, the four *cis/trans* isomers (8*t*,10*c*-18:2, 9*c*,11*t*-18:2, 10*t*,12*c*-18:2 and 11*c*,13*t*-18:2) were present in a ratio of approximately 1:2:2:1, while in the second sample they were present in almost equal proportions. If indeed certain daily levels of CLA intake are required to produce suggested health benefits in humans, changes in concentrations of specific CLA isomers could significantly impact these effects. Care must be taken to analyze the CLA used in human and animal studies.

Paper no. L8684 in *Lipids 36*, 315–317 (March 2001).

**KEY WORDS:** Conjugated, linoleic, CLA, composition, isomers, HPLC, GC

Conjugated linoleic acid (CLA; 9*c*,11*t*-18:2), present in dairy products and beef, and its isomers have been reported in animals to have anticarcinogenic, growth-promoting, antiatherogenic, antidiabetic, and lean body mass-enhancing properties (1–8). Most commercially available samples of CLA, prepared by base-catalyzed isomerization (9) of linoleic acid (9*c*,12*c*-18:2), are composed of mixtures of CLA isomers. While 9*c*,11*t*-18:2 is the primary CLA isomer found in nature (10), the "CLA" available in diet supplements is composed (11) primarily (>80% by weight) of four isomers (8*t*,10*c*-18:2, 9*c*,11*t*-18:2, 10*t*,12*c*-18:2, and 11*c*,13*t*-18:2).

Data from animal models have been used to suggest the 9*c*,11*t*-isomer is responsible for CLA's anticarcinogenic properties, whereas the 10*t*,12*c*-isomer is considered responsible for the observed weight loss/muscle-mass enhancement effects (12,13). The different CLA isomers present in commercially available diet supplements may thus have different health-related benefits, and other isomers (11*c*,13*t*-18:2, for example) may potentially be harmful (14). To determine the effects of specific CLA isomers, pure samples of each isomer are required. Yet CLA mixtures continue to be used (15).

We wish to report a second problem: significant batch-to-batch variations over time in CLA isomer ratios within samples obtained from the same source. Although researchers have noted significant variations in CLA composition (Ref. 16; from 0 to 75% CLA) in samples obtained from different suppliers, the existence of differences in composition of samples obtained from the same producer/commercial supplier has not been adequately addressed.

## MATERIALS AND METHODS

Composition data from CLA samples obtained *ca.* 1.5 yr apart (June 1998 and December 1999) from the same commercial supplier were compared. The samples were obtained, in fatty acid form, in gel capsules. In each instance, 3 × 1 g capsules were opened, the contents combined, and one 30-mg sample was removed. The fatty acids were converted to fatty acid methyl esters with diazomethane (17) and analyzed in duplicate utilizing silver ion high-performance liquid chromatography (Ag-HPLC) [two Varian ChromSpher Lipids (C) columns (Varian Chrompack B.V., Middelburg, The Netherlands) linked in series; flow rate of 1.0 mL/min of 0.1% acetonitrile in hexane; ultraviolet detection at 233 nm] and gas–liquid chromatography [GC; Varian 3400; 100 m SP2380 (C) capillary column (Supelco, Inc., Bellefonte, PA); flame-ionization detector].

## RESULTS AND DISCUSSION

The results are summarized in Table 1. Analysis by Ag-HPLC yielded much improved separation of the CLA isomers than we observed utilizing GC. With Ag-HPLC, the *cis/trans* isomers were separated into four peaks (six peaks in the year 1999 sample), the *trans/trans* isomers into six peaks, and the *cis/cis* isomers into four peaks, all resolved at >90%. When GC was utilized, the *trans/trans* isomers were resolved into only two peaks (the 11,13-/12,14-isomers; then the 7,9-, 8,10-, 9,11-, and 10,12-isomers), the *cis/trans* isomers into three peaks (9*c*,11*t*- and 8*t*,10*c*-18:2 eluted as one peak), and the *cis/trans* and *cis/cis* peak patterns tended to overlap. (Elution order was: *cis/trans*, *cis/cis*, then *trans/trans*.)

[a]CLA isomers listed as eluted from silver-high-performance liquid chromatography (Ag-HPLC) as fatty acid methyl esters.
[b]Run number.
[c]Sum 11*t*,13*t*- and 12*t*,14*t*-18:2.
[d]Sum 7*t*,9*t*-, 8*t*,10*t*-, and 9*t*,11*t*-18:2.
[e]9*c*,11*t*- and 8*t*,10*c*-18:2 unresolved.
[f]Total CLA isomers (wt%) in sample. GC, gas–liquid chromatography.

Our "Total CLA" results (Table 1) determined by GC were in agreement with the "Total CLA" listed in the Material Safety Data Sheet (MSDS) included with the samples. We found the total percentage of conjugated isomers had increased *ca.* 10% by weight (GC data) from the year 1998 to the end of 1999 sample (16:0, 18:0, 9*c*-18:1, and 9*c*,12*c*-18:2 were also present at 35–40% by weight of total sample, with 9*c*-18:1 predominating at 23–25%). Between June 1998 and December 1999, the total percentage of *cis/cis* and *trans/trans* isomers increased slightly, and the % *cis/trans* totals decreased. The greatest change, however, was noted in the relative percentages of the four predominant *cis/trans* isomers (8*t*,10*c*-18:2, 9*c*,11*t*-18:2, 10*t*,12*c*-18:2, and 11*c*,13*t*-18:2). In the 1998 sample, the four *cis/trans* isomers were present in a ratio of approximately 1:2:2:1, but in the 1999 sample they were present in almost equal proportions. The presence of two other isomers (12*t*,14*c*- and 13*c*,15*t*-18:2?) in the 1999 sample is another indication that more "extreme" isomerization conditions were employed.

A quotation from a recent (18) paper, "CLA typically used in animal studies is prepared by alkali isomerization from pure linoleic acid, and contains more than 95% CLA, mainly *cis*-9, *trans*-11 and *trans*-10, *cis*-12 isomers (85–90%) along with other minor isomers (*trans,trans* or *cis,cis*)" might thus not be applicable to CLA obtained from other producers/suppliers. And if, indeed, certain daily levels of CLA intake are required to produce the suggested health benefits in humans, changes in concentrations of specific CLA isomers could significantly influence these effects. Care must be taken to analyze the CLA used. "Total % CLA" should not be considered a sufficient label for these materials.

# A New Δ7-Polyunsaturated Fatty Acid in *Taxus* spp. Seed Lipids, Dihomotaxoleic (7,11-20:2) Acid

**Frédéric Destaillats[a,b], Robert L. Wolff[b,*], and Paul Angers[a]**

[a]Department of Food Science and Nutrition, Dairy Research Center (STELA), Université Laval, Sainte Foy, Québec, Canada G1K 7P4, and [b]ISTAB, Université Bordeaux 1, 33405 Talence Cedex, France

**ABSTRACT:** A previously undescribed fatty acid, all-*cis* 7,11-20:2 (dihomotaxoleic acid, DHT), has been characterized by gas chromatography–mass spectrometry as being present (approximately 0.1%) in seed oils of two Taxaceae containing high levels (11–16%) of taxoleic acid (all-*cis* 5,9-18:2). This compound was absent from oils of 10 other conifer genera, as well as from one member of Taxaceae containing very low amounts of taxoleic acid, suggesting that DHT is a taxoleic acid elongation product.

Paper no. L8615 in *Lipids 36,* 319–321 (March 2001).

In a recent reinvestigation of the seed oils from some species of the Taxaceae family, we have characterized a new Δ7-polyunsaturated fatty acid, dihomotaxoleic (DHT; *cis*-7,*cis*-11 20:2) acid, not reported previously (1–3). We wish here to comment on our gas chromatography–mass spectrometry (GC–MS) investigation and the possible origin of DHT acid in *Taxus chinensis* and *T. baccata* (Chinese and English yew, respectively) seed lipids.

A few Δ7-methylene-interrupted unsaturated fatty acids naturally occur in lipids in significant amounts, i.e., 16:3n-3 and 16:1n-9 acids in plant lipids or 22:5n-3 and 22:4n-6 acids in animal tissues. Aitzetmüller *et al.* (4) have characterized phlomic (7,8-20:2) acid, an allenic fatty acid, in *Phlomis* seed oil, by GC–MS of its methyl esters. Two other docosadienoates, 7,13-22:2 and 7,15-22:2 acids, have been reported in mollusks (5,6) and one octadecadienoate, 7,11-18:2 acid, in the sponge *Haliclona cinerea* (7). The 7,13-20:2 and 7,10,13-22:3 acids have been characterized by GC–MS of the trimethyl silyloxy derivatives in the liver lipids of rats raised on a fat-free diet (8). It was also observed that 5,11,14,17-20:4 acid, derived from intracranially injected 11,14,17-20:3 acid in developing rat brain, was elongated to 7,13,16,19-22:4 acid (9). A conjugated linoleic acid, *trans*-7,*cis*-9 18:2 acid, was identified in cow milk, cheese, beef, and human adipose tissue by Yurawecz *et al*. (10). Establishment of its structure was performed by GC–MS of the 4,4-dimethyloxazoline (DMOX) derivative. In a recent publication, Precht and Molkentin (11) reported on *cis*-7 16:1 acid occurring in human milk fat, and Christie *et al.* (12) gave the mass spectra for DMOX as well as picolinyl ester derivatives of a synthetic *cis*-7 18:1 acid.

The Taxaceae seed oils were available from an earlier investigation, and details of their source, extraction, and fatty acid composition are given elsewhere (3). Conditions for GC–MS are those described by Bhaskara *et al*. (13), but with a 30-m BPX-70 capillary column (SGE, Melbourne, Australia). The DMOX derivatives of fatty acids from the seed oils of *T. chinensis* and *T. baccata* were prepared by heating the oils directly with 2-amino-2-methyl-1-propanol according to Garrido and Medina (14), and examined by GC–MS. The DMOX spectra (Fig. 1) gave prominent molecular ions for DHT acid and dihomopinolenic (DHP) acid (*cis*-7,*cis*-11,*cis*-14 20:3) that confirmed both chain length and number of double bonds. Analysis of DHP acid from conifer seed oils as DMOX and picolinyl ester derivatives was previously performed by Wolff *et al*. (15). DHP acid had been characterized earlier in the seeds of a few pine species by Medvedev *et al*. (16), and in *Picea abies* wood extracts by Ekman (17). The mass spectrum of this fatty acid as a DMOX derivative showed an especially prominent ion at $m/z$ = 208, representing cleavage between C8 and C9, i.e., at the center of the di-methylene-interrupted ethylenic bond system (3,18). The Δ7-double bond was indicated by a gap of 12 amu between $m/z$ = 262 and 274. The spectrum of the DMOX derivative of DHT acid showed a similar cleavage for the di-methylene-interrupted ethylenic bond system. As such, the ion at $m/z$ = 208, as well as the molecular ion at $m/z$ = 361, allowed determination of the 7,11-20:2 acid structure. The geometrical *cis* configuration of both double bonds was defined by calculation of the equivalent chain length (ECL) and comparison with the ECL of *cis*-5,*cis*-11 20:2 acid, widely found in small quantities in conifer seed oils (19), which eluted just before DHT acid. Additionally, 7,11-20:2, *cis*-5,*cis*-11 20:2, and *cis*-5,*cis*-9 18:2 (taxoleic) acids co-eluted in the same fraction after argentation thin-layer chromatography (results not shown), indicating similar configurations of the two ethylenic bonds.

This unusual all-*cis* Δ7 di-methylene-interrupted fatty acid occurred in *T. chinensis* and *T. baccata* seed lipids at 0.13 and 0.06% of total fatty acids, respectively. Both species contained a high amount of taxoleic acid with 16.4 and 10.6% of total fatty acids for *T. chinensis* and *T. baccata,* respectively.

Abbreviations: DHP, dihomopinolenic; DHT, dihomotaxoleic; DMOX, 4,4-dimethyloxazoline; ECL, equivalent chain length; GC–MS, gas chromatography–mass spectrometry.

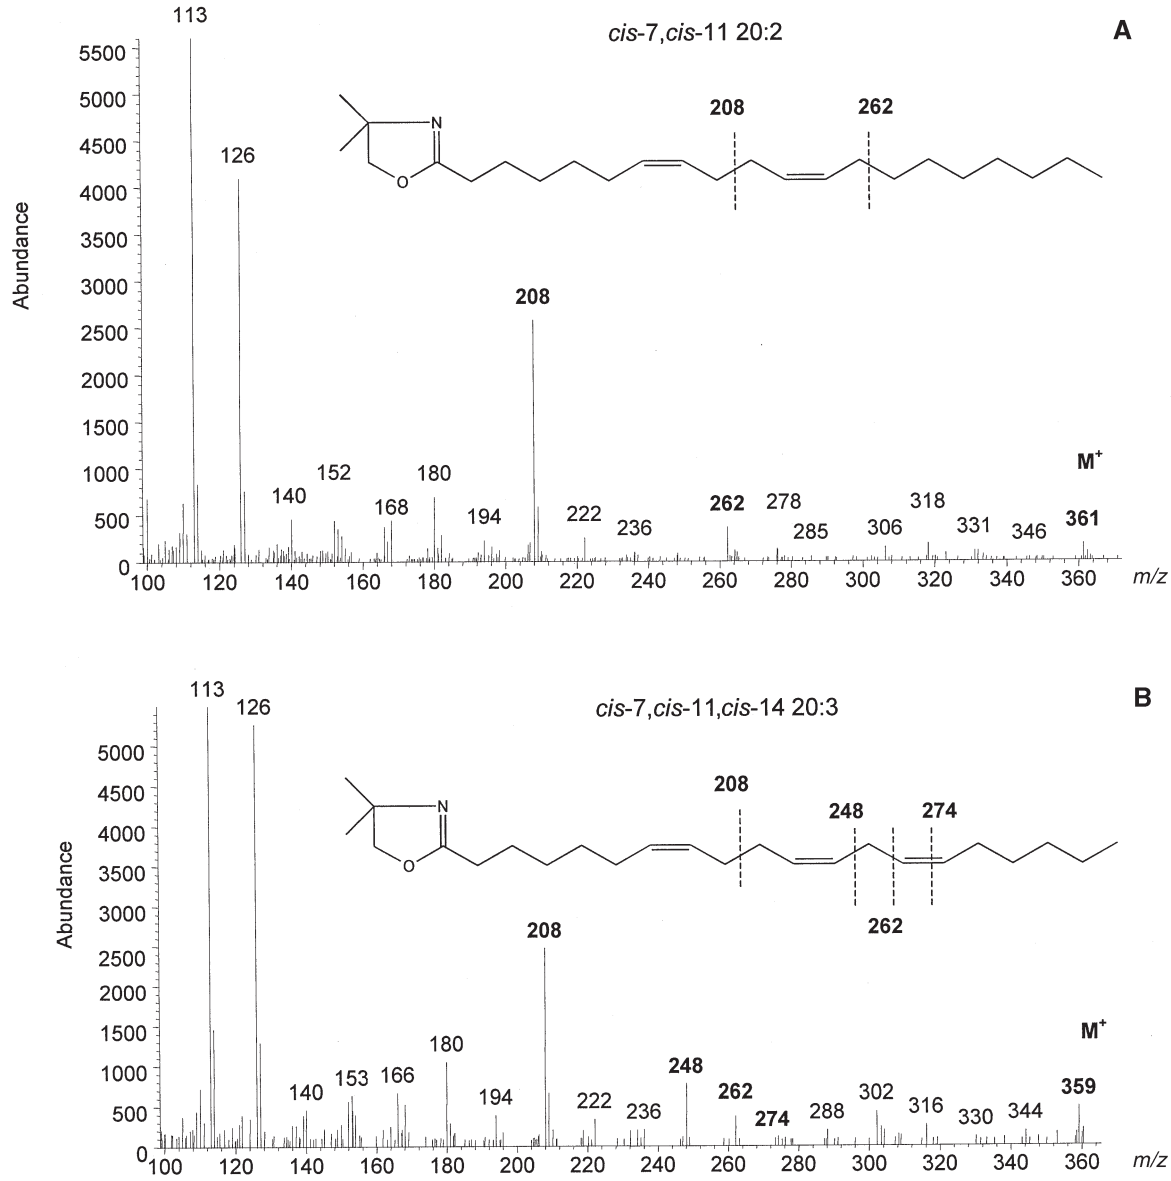

**FIG. 1.** Mass spectra of the 4,4-dimethyloxazoline derivatives of 7,11-eicosadienoate (A) and 7,11,14-eicosatrienoate (B) from *Taxus chinensis* seed lipids. Boldface numbers correspond to diagnostic ions.

These are the highest amounts found in conifers, and more generally, gymnosperm seed lipids. We did not find DHT acid in any other seed oil from several species of different conifer genera, i.e., *Pinus*, *Larix*, *Abies*, *Cedrus*, *Cephalotaxus*, *Nageia*, *Juniperus*, *Pseudolarix*, *Tsuga,* and *Hesperopeuce*, that contained at most 7.4% of taxoleic acid. *Torreya californica*, another member of the Taxaceae family, also is devoid of DHT acid, which can be explained by the fact that this species, in contrast to *Taxus* spp., contains only very minor amounts of taxoleic acid [0.03% (3)]. The coexistence of DHT acid and a high amount of taxoleic acid leads us to suggest that DHT acid could be the elongation product of taxoleic acid, in the same way as 7,11-18:2 acid could be the elongation product of 5,9-16:2 acid (7), and phlomic acid that of laballenic acid [(5,6-18:2) (4)].

REVIEW

# Atmospheric Pressure Chemical Ionization Mass Spectrometry for Analysis of Lipids

**William Craig Byrdwell**

Department of Chemistry & Biochemistry, Florida Atlantic University, Boca Raton, Florida 33431

**ABSTRACT:** Atmospheric pressure chemical ionization (APCI) mass spectrometry (MS) has proven to be a very valuable technique for analysis of lipids from a variety of classes. This instrumental method readily produces useful ions with gentle fragmentation from large neutral molecules such as triacylglycerols and carotenoids, which are often difficult to analyze using other techniques. Molecules that are easily ionized, such as phospholipids, produce molecular ions and diagnostically useful fragment ions that are complementary to those produced by methods such as electrospray ionization MS with collision-induced dissociation. The simplicity and versatility of APCI-MS make it an ideal tool for use in solving hitherto very difficult analytical problems.

Paper no. L8662 in *Lipids 36,* 327–346 (April 2001).

Mass spectrometry (MS) for analysis of liquid chromatographic effluent has long been a goal of chemists studying nonvolatile, often large molecules, which cannot be separated well, or at all, by gas chromatography. Many approaches have been developed to meet this objective, with particle beam, thermospray (TSP), continuous-flow fast atom bombardment (or the similar liquid secondary-ion MS, LSIMS), electrospray ionization (ESI), and atmospheric pressure chemical ionization (APCI) interfaces becoming most widely used (1). The recent book by Niessen (1) contains an excellent summary of the development and history of each, some of which is reflected here. Each approach has achieved varying degrees of success in allowing analysis of large molecules, and each has its own set of inherent drawbacks as well as benefits. Environmental and pharmaceutical samples have been the primary subjects of analysis, but lipids have also been analyzed extensively over the years by using each of these technologies as they were developed. TSP was the most popular commercially available liquid chromatography (LC)/MS interface for a period because of its relative simplicity, low background noise, and high flow rates allowed. But in recent years, TSP has been supplanted in popularity by two atmospheric pressure ionization (API) methods, ESI-MS and APCI-MS (1,2).

The first API source was developed in the 1970s by Horning *et al.* (3–6) at the Baylor College of Medicine (Houston, TX). The method described an ionization interface at atmospheric pressure, external to the high vacuum chamber of a modified Finnigan Model 1015 quadrupole mass spectrometer. Initially, a $^{63}$Ni foil was used as a source of electrons to perform ionization (3–5), but later a corona discharge electrode was used (5,6). This version with the corona discharge electrode became the model for modern commercially available APCI interfaces. Initially simply called API, this ionization method later become known as APCI to differentiate it from the other ionization source at atmospheric pressure, ESI. The full potential of APCI was not initially realized, and in the meantime the other emerging API source, ESI, was developed by Fenn and coworkers at Yale (New Haven, CT) (7). As ESI became recognized for its ability to identify the masses of large proteins (8), interest in API techniques increased. Improvements in commercial ESI sources, such as those made by Bruins *et al.* (9) to yield pneumatically assisted electrospray (called ionspray), allowed larger effluent flow rates than could previously be used. These improvements in ESI caused API methods to gain more widespread use. By the late 1980s and early 1990s, all major MS instrument manufacturers had introduced API sources, with most of them having both ESI and APCI interfaces. Although use of APCI is not yet as widespread as ESI, the number of reported applications of APCI-MS is burgeoning. A review of the applications of APCI-MS to analysis of lipids has appeared elsewhere (10). The number of recent applications reported in the literature warrants an updated chronicle of APCI-MS for lipid analysis.

APCI is a soft ionization technique, but unlike ESI, APCI usually does produce some degree of fragmentation that is useful for structural characterization. Very simple in its design, a typical APCI source has the following components, as shown in Figure 1: (i) a capillary out of which the LC effluent is sprayed through a nozzle by means of a concentric nebulizer gas surrounding the capillary, (ii) a heated vaporizer tube, concentric around the LC capillary outlet, which desolvates the analyte molecules, (iii) a corona discharge needle, which pro-

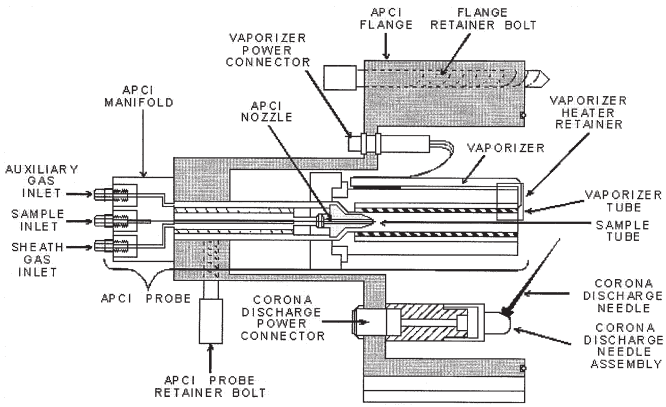

**FIG. 1.** Atmospheric pressure chemical ionization (APCI) source. (Reprinted with permission ThermoQuest Corp.)

duces ions from the molecular mist exiting the end of the heated vaporizer tube, and (iv) a pinhole entrance into an area of intermediate vacuum (~$10^{-3}$ Torr), followed by ion-focusing elements and skimmers that transport ions into the high-vacuum mass analyzer region. An auxiliary, or makeup, gas is often included concentric with the nebulizer gas to assist in desolvation. A countercurrent, or "curtain," gas is included in some designs to prevent clogging of the pinhole entrance by nonvolatile components, to assist in droplet evaporation, and to help break up solvent–ion clusters.

The primary reactions that lead to ion formation in a nitrogen atmosphere in the presence of water, at up to 4 Torr, were first studied by Good *et al.* (11). These reactions were recognized by Carroll *et al.* (4) to be the mechanism of hydronium ion formation in the APCI source. At atmospheric pressure, sufficient water is present that the principal ions present in the carrier gas without LC effluent or analyte are cluster ions of the type $H^+(H_2O)_n$. Figure 2 is a diagram of the ionization process for APCI. Spectra obtained using the $^{63}Ni$ β source were virtually identical to spectra obtained using a corona discharge needle, so the mechanism of ionization is assumed to be the same (6). At 200°C, with nitrogen as the carrier gas, and with only atmospheric water, the most abundant cluster is $(H_2O)_2H^+$, with $(H_2O)_3H^+$ and $H_3O^+$ also present. The $NO^+$ ion, $(H_2O)NO^+$, and $(H_2O)_2NO^+$ are also present. The following set of reactions result in the ionized water clusters responsible for ionization (3):

$$N_2 + e \rightarrow N_2^+ + 2e \quad [1]$$

$$N_2^+ + 2N_2 \rightarrow N_4^+ + N_2 \quad [2]$$

$$N_4^+ + H_2O \rightarrow H_2O^+ + 2N_2 \quad [3]$$

$$H_2O^+ + H_2O \rightarrow H_3O^+ + OH\cdot \quad [4]$$

$$H_3O^+ + H_2O + N_2 \rightarrow H^+(H_2O)_2 + N_2 \quad [5]$$

$$H^+(H_2O)_{n-1} + H_2O + N_2 \rightarrow H^+(H_2O)_n + N_2 \quad [6]$$

At atmospheric pressure in the presence of trace amounts of water and nitrogen gas, protonated molecular ions are formed by gas-phase ion–molecule reactions with water cluster ions. Thus, protonated molecular ions are the most common pseudomolecular ions observed using APCI-MS. However, the presence of chemicals in the LC effluent stream, or chemicals that are added as sheath liquid, can also participate in the chemical ionization reactions, as shown by applications below. The reactions and mechanisms observed under APCI conditions are nearly the same as those observed using TSP MS, direct insertion probe MS, desorption chemical ionization, and other soft ionization techniques. In positive ionization mode, the mechanisms are protonation, adduct formation, and charge transfer. In the negative ion mode, electron capture and anion attachment are the primary mechanisms of

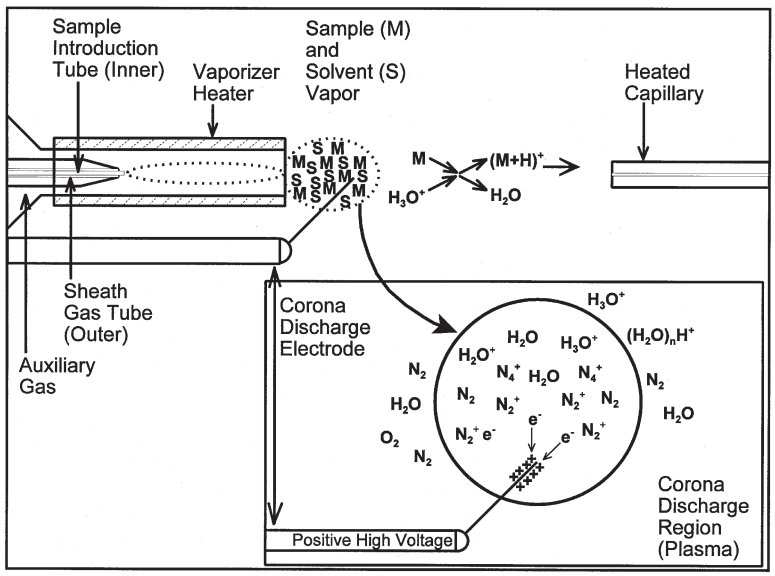

**FIG. 2.** Ionization process occurring in Atmospheric Pressure Chemical Ionization source. (Figure adapted from ThermoQuest Corp. operator's manual.)

ion formation (1) Most work on the APCI-MS analysis of lipids has been in positive ion mode, with ionization occurring according to the mechanisms above.

## FATTY ACID (FA) ANALYSIS

As mentioned, APCI was developed before ESI, but it took the popularity of ESI and the commercial availability of API interfaces to spur the use of APCI-MS. PE Sciex and Hitachi each introduced early API inlets to their machines in the mid-1980s. Through analysis of environmental and pharmaceutical chemicals, APCI became known as being suitable for analysis of neutral molecules of small to moderately large size. ESI was especially suited to charged or readily charged molecules, with quite large molecules such as proteins being characterized by their multiply charged ions. The Hitachi API interface with APCI source became commercially available in Japan and was used by Kusaka *et al.* (12) in 1988 for the first reversed-phase high-performance liquid chromatography (RP-HPLC)/APCI-MS analysis of a mixture of FA standards as their anilide derivatives. Anilide derivatives were formed because the API source did not provide sufficient sensitivity for methyl esters or the free acids. APCI was seen to yield virtually only molecular ions from the FA anilides. Ions at low mass arising from solvent clusters became relatively more abundant as the signal of the anilides decreased (i) with increasing fatty chain length, (ii) as a result of chromatographic peak broadening, and (iii) owing to the changing mobile phase composition. The potential use of LC/APCI-MS for qualitative and quantitative analysis of FA was demonstrated. Samples from 55 to 385 pg were injected to illustrate the potential for quantitative applications. Still, it was several more years until APCI-MS was further applied to analysis of lipids.

Ikeda and Kusaka (13) expanded their original work on FA anilides to a comparison of six amide-containing FA derivatives. In 1992, they reported a comparison of six amide derivatives useful for APCI-MS analysis of both hydroxy and non-hydroxy FA. Based on the slopes of calibration curves obtained for palmitamide derivatives, the sensitivities of the amides were found to increase in the following order: *N-n*-propyl amide (2.1) > anilide (1.0) > *N,N*-diethylamide (0.66) ≈ amide (0.62) > *N,N*-diphenylamide (0.44) > *N*-1-naphthylamide (0.06), where the numbers in parentheses represent the sensitivity relative to the original anilide derivative. The propyl amide derivative provided the greatest sensitivity, so this was used for further experiments. *N*-Propyl amide derivatives of hydroxy-containing FA were separated by RP-HPLC and detected using APCI-MS; typical APCI mass spectra are shown in Figure 3. The locations of the hydroxy groups had a distinct effect on the fragmentation of the FA under APCI conditions. FA standards with the hydroxy group in the middle of the chain (Δ12) produced primary fragments by loss of water from the protonated molecular ion $[M - H_2O + H]^+$, whereas the hydroxy group in the Δ2 position produced mostly protonated molecular ion, $[M + H]^+$. Prostaglandins and hydroxy FA from rat brain extracts were also analyzed.

Kusaka and Ikeda (14) then extended their analysis of FA derivatives to RP-HPLC/APCI-MS analysis of hydroxy and hydroperoxy FA standards and of bovine lecithin FA that underwent photo-oxidation. In this report, they produced a

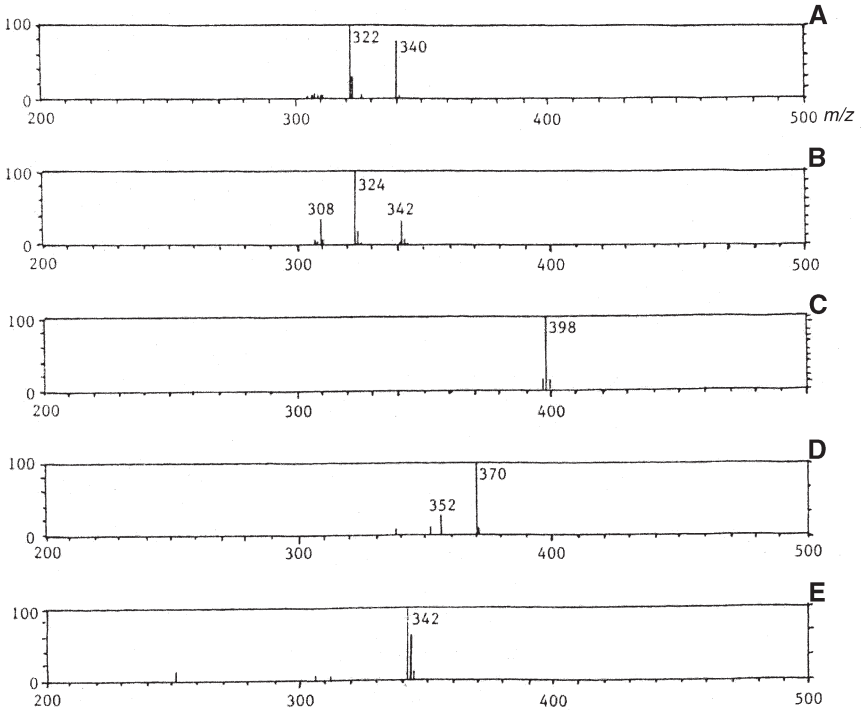

**FIG. 3.** Mass spectra of *N-n*-propylamide derivatives of hydroxy fatty acids. (A) 12-OH-$C_{18:1}$, (B) 12-OH-$C_{18:0}$, (C) 2-OH-$C_{22:0}$, (D) 2-OH-$C_{20:0}$, (E) 2-OH-$C_{18:0}$ (reprinted from Ref. 13 with permission from Elsevier Science).

fluorescent 3-bromomethyl-7-methoxy-1,4-benzoxazin-2-one (Br-MB) derivative that allowed the LC effluent to be monitored by absorption at 355 nm, as well as detection by APCI-MS. Hydroperoxy FA were seen to produce no molecular ion, but instead to produce fragments representing loss of water, $[M - H_2O + H]^+$ (base peak), or representing loss of the entire hydroperoxy group, $[M - H_2O - O + H]^+$. Hydroxy FA produced a primary fragment representing loss of water, $[M - H_2O + H]^+$ (base peak), and a protonated molecular ion, $[M + H]^+$.

## TRIACYLGLYCEROLS (TAG)

Because TAG are large neutral molecules that are not amenable to gas chromatography (GC), better methods for detection of TAG separated by LC have long been sought. Whereas a host of derivatization methods is available for analysis of FA by GC and LC, there are relatively few methods for analysis of intact TAG. Thus, a technique like APCI-MS, which ionizes large neutral molecules in a broad range of mobile phases, is ideally suited for lipid analysis. In 1993, Tyrefors *et al.* (15) reported examples of APCI-MS spectra obtained from several classes of lipids after separation by a supercritical fluid chromatography (SFC) system using an open tubular column. The SFC system was attached to a Sciex API III tandem mass spectrometer *via* a lab-built column restrictor/interface system. Their results showed the separation of a FA methyl ester (FAME: either pentacosanoic acid methanoate or stearic acid methanoate), a TAG (trilaurin), cholesterol, and cholesterol palmitate. The data demonstrated the simple, uncluttered mass spectra that are characteristic of the ionization technique. Cholesterol yielded an $[M - 17]^+$ base peak (= $[M - H_2O + H]^+$), showing behavior similar to the alcohols reported by Kusaka *et al.* (12,13). Spectra of other molecules containing a hydroxy group [prostaglandin $F_{2\alpha}$ isopropanoate and bis(α-epoxyacrylate)] similarly exhibited loss of water from the protonated molecular mass. All of the spectra in the paper by Tyrefors *et al.* (15) exhibited a common characteristic. They each contained substantial water adducts in addition to, or instead of, protonated molecular ions. This was a result of the fact that the makeup gas used in the restrictor interface was synthetic air that was moistened by sparging through water before entering the oven where it was preheated to temperature. This demonstrated the effect of components in the nebulizer gas on the abundance of near-molecular ions produced during APCI. Similarly, components in the LC mobile phase can produce adduct ions with analyte molecules. Instrument manufacturer design differences may also lead to differences in proportions of near-molecular ions formed, but the published APCI spectra produced by most machines are remarkably similar, unless intended otherwise. Other authors have sparged carrier gas through solvents to improve the formation of high-mass ions, as discussed below.

Two years later, in 1995, Byrdwell and Emken (16) demonstrated the first RP-HPLC separation of a mixture of TAG with detection by APCI-MS. They used an RP-HPLC separation coupled to a Finnigan MAT SSQ 710C quadrupole mass spectrometer *via* an APCI interface for separation and identification of a mixture of synthetic TAG standards. The mass spectra produced by all of the TAG standards were simple and uncluttered, giving diacylglycerol (DAG) fragments and protonated molecular ions as primary peaks. It became apparent that the proportion of protonated molecular ion was dependent on the amount of unsaturation in the fatty acyl chains. TAG having the largest number of sites of unsaturation produced mostly a protonated molecular ion as a base peak, with a small abundance of DAG fragment ions. However, as the number of sites of unsaturation decreased, so did the amount of $[M + H]^+$. Fully saturated TAG gave virtually no protonated molecular ion, but instead gave only DAG fragment(s). Later results, such as the spectra in Figure 4, showed that spectra of TAG with more than four sites of unsaturation gave protonated molecular ions as base peaks, spectra of TAG with fewer than three sites of unsaturation had DAG fragment ions as base peaks, and TAG with three or four sites of unsaturation could have either of these ions as base peaks. The RP-HPLC/APCI-MS separation employed by Byrdwell and Emken (16) utilized propionitrile/hexane as the solvent gradient, and propionitrile adducts at $[M + 55]^+$ were reported. Water adducts were also reported, but spectra exhibited much lower abundances than the adducts observed by Tyrefors *et al.* (15) (because of the sparging through water).

Next, Neff and Byrdwell (17) reported the RP-HPLC/APCI-MS separation of natural mixtures of regular and genetically modified soybean oil TAG. These contained TAG with almost every combination of five FA, although only those present at > ~ 0.4% were reported. The chromatographic method used for the LC/MS in this report was later changed to an acetonitrile/methylene chloride separation to improve the separation quality, to eliminate propionitrile as solvent (due to adduct formation and the noxious nature of the solvent), and to match the method used with flame ionization-detection (FID) in their group. One, two, or three DAG fragment ions, and the protonated molecular ion, can result from a mixed-FA TAG. The tabulated APCI mass spectral results therein show the relative proportions (abundances) of the DAG fragment ions and protonated molecular ions. Some TAG with three sites of unsaturation have a $[M + H]^+$ ion as base peak [e.g., palmitic-linolenic-palmitic (PLnP)] while others with three sites have a DAG base peak (e.g., palmitic-oleic-linoleic (POL)]. Similarly, some TAG with four sites of unsaturation had $[M + H]^+$ ions as base peaks (e.g., LLP), while others had a DAG base peak (e.g., OLO). However, mass spectra of all TAG with less than three sites of unsaturation had DAG fragment ions as base peaks, while spectra of all TAG with more than four sites of unsaturation had $[M + H]^+$ ions as base peaks.

The next report by Neff and Byrdwell (18) of APCI-MS for analysis of TAG was on the TAG with naturally occurring functional groups contained in the specialty seed oils *Crepis alpina* and *Vernonia galamensis*. *Crepis alpina* contained crepenynic acid (*cis*-9-octadecen-12-ynoic acid), which had the alkyne functional group, and *V. galamensis* contained vernolic acid (*cis*-12,13-epoxy-*cis*-9-octadecenoic acid), which

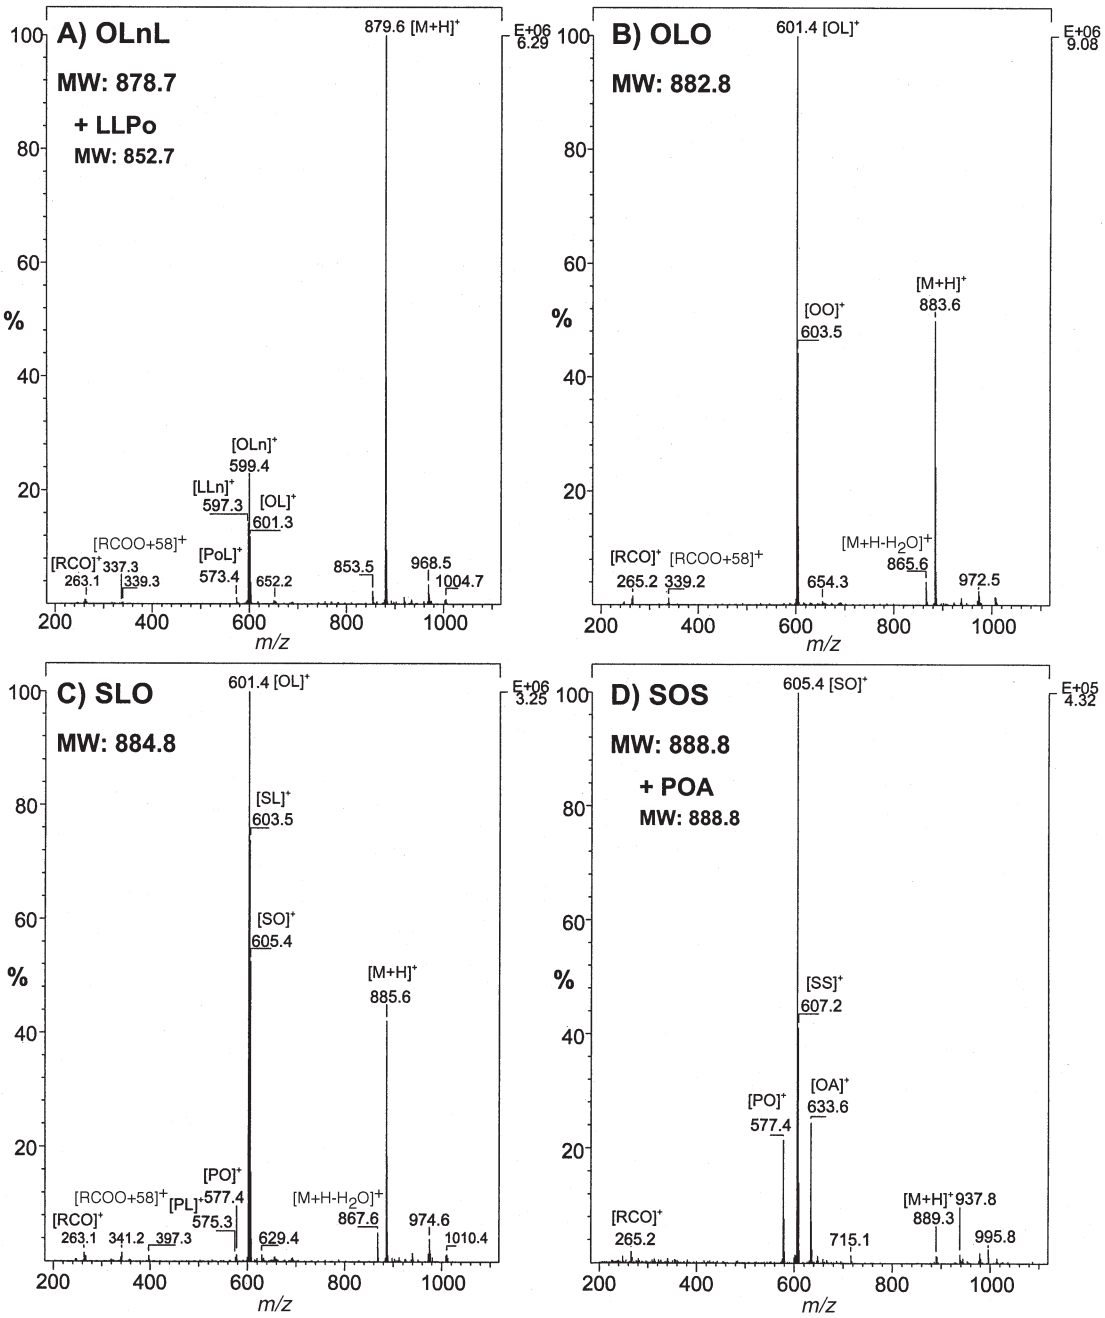

**FIG. 4.** Atmospheric pressure chemical ionization (APCI)-mass spectra of triacylglycerols in refined, bleached, deodorized soybean oil. (A) OLnL, (B) OLO, (C) SLO, (D) SOS. O, oleic acid; Ln, linolenic acid; S, stearic; L, linoleic; P, palmitic; A, arachidic; Po, palmitoleic.

contained an epoxide group methylene-interrupted from a double bond. These functional groups provided the opportunity to observe both complex fragmentation processes and adduct formation. The crepenynic acid-containing TAG behaved very much like any other unsaturated TAG. The spectra were simple, having a TAG protonated molecular ion as a base peak. Only small amounts of propionitrile and other adducts were observed from the crepenynic TAG. The vernolic acid-containing TAG, on the other hand, produced much more complicated spectra showing multiple fragmentation pathways, as well as adduct formation. The vernolic acid-containing TAG exhibited abundant protonated molecular ion peaks to allow molecular weight identification, and they also showed large peaks arising from loss of the epoxy groups through dehydration. The loss of 18 Da from the epoxides indicated that not only was the epoxy oxygen lost, which would leave a site of unsaturation, but also two other protons were removed, giving another site of unsaturation. This fragmentation occurred for the DAG fragments as well as the TAG molecular ions. In addition to dehydration, the epoxy-TAG underwent fragmentation by cleavage between the two carbons in the epoxide ring (intra-annular cleavage). Fragments appeared in which the epoxide oxygen left with the leaving fragment (hexanal), or in which the oxygen remained on the core TAG. The leaving

group containing the oxygen group then acted as a reactant to combine with another TAG molecule to produce adduct ions at $[M + 102]^+$. The epoxy groups appeared to have a stabilizing effect on the DAG fragments, because abundances of DAG fragments containing epoxy groups were larger than expected based on the number of sites of unsaturation.

## TAG POSITIONAL ISOMERS

Shortly after the initial reports of RP-HPLC/APCI-MS, Laakso and Voutilainen (19) demonstrated the application of silver ion (argentation) chromatography with APCI-MS detection using a Finnigan MAT TSQ 700 mass spectrometer. The silver ion chromatography method originally described by Christie (20) was combined with APCI-MS detection for analysis of seed oils containing both α- and γ-linolenic acids. Black currant, alpine currant, cloudberry, evening primrose, and borage oils were extracted and subjected to $Ag^+$-HPLC/APCI-MS analysis. The authors observed that the γ-linolenic acid isomer eluted prior to the α-isomer on the cation exchange column loaded with $Ag^+$ ions. Also, the position of the FA on the glycerol backbone was observed to affect the elution order on the column, with unsaturated FA in the 2-position causing the TAG to elute before the TAG having the same unsaturated FA in the 1- or 3-position. Because of the chromatographic resolution of positional isomers, differences in the mass spectra of the isomers could be observed. The authors found that the abundance of the 1,3-DAG (FA lost from the 2-position) was less than that of the 1,2- or 2,3-DAG, indicating that the ratio of DAG fragments could be used to deduce the positions of the acyl chains on regioisomers. In the mass spectrum of the TAG standard 1,3-dioleoyl-2-palmitoyl-*sn*-glycerol (OPO), the $[M - 16:0]^+$ ion was 8.5% of the abundance of the base peak, and for the 3-positional isomer, OOP, the abundance was 69.9% for the same fragment.

Around the same time, Mottram and Evershed (21) published results specifically to address the differences in mass spectra caused by different positions of FA on the glycerol backbone of TAG. They utilized loop injections made on a Finnigan MAT TSQ 700 with an APCI source to compare two types of TAG having the general form AAB vs. ABA. They showed that when B was in the 2-position, the ratio of the $[AA]^+$ to $[AB]^+$ DAG ions was much lower than when B was in the 1- or 3-position. For instance, POP would be expected to yield $[PO]^+$ and $[PP]^+$ ions in a two-to-one ratio, regardless of the positional placement of palmitic or oleic acid on the glycerol backbone. If the proportion of the $[PP]^+$ ion to $[PO]^+$ ion was substantially less than 1:2, or 50%, it meant that the $[PP]^+$ ion was energetically disfavored, by being the 1,3-isomer. The results by Mottram and Evershed showed that $[PP]^+/[PO]^+ = 0.20$, which is much less than the 0.50 which would occur if there were no discrimination between FA position. In the tabulated results reported by Neff and Byrdwell (17), the PPO in high-palmitic soybean oil exhibited a $[PP]^+$ fragment ion relative abundance of 16.8%, compared with the 50% relative abundance expected. Based on the results of Mottram and Evershed (21), this could be interpreted to mean that $[PP]^+$ was the 1,3-positional isomer, forming POP, since its fragment ion was energetically less favored. This low ratio is in agreement with the generally accepted trend that palmitic acid in vegetable oils is preferentially incorporated into the 1- and 3-positions. The very low relative abundance of the $[PP]^+$ fragment ion from PLP in the same results reported by Neff and Byrdwell, compared with the $[PL]^+$ fragment ion, also supports the general trend. Finally, the report by Mottram and Evershed showed that a TAG of the type ABC produced the smallest DAG abundance from the fragment produced by loss of the FA in the 2-position, or the AC fragment.

Mottram *et al.* (22) followed with a report showing the RP-HPLC/APCI-MS analysis of several seed, nut, and vegetable oils. They used the least-abundant DAG fragment ion to assign the most likely positional isomer identification. 2-Positional isomers were identified, without differentiation between the 1- and 3-positions. The most abundant isomers were identified for poppy seed, blackcurrant, evening primrose, hazelnut, rapeseed, olive, wheat germ, and soybean oils. A comparison with previous studies in which the soybean oil composition had been determined by evaporative light-scattering detector (ELSD) and by MS was given. Our own report, mentioned above, was included in the comparison. Our initial report (17), however, did not give a quantitative composition of soybean oils from APCI-MS, but instead stated that the semiquantitative results given there were from peaks in the ELSD chromatogram. As was stated therein, the ELSD detector is known to be nonlinear in its response to TAG. At the time the first report was published, a quantitative method was still being developed which could be used with confidence. The method for quantitation finally developed by Byrdwell *et al.* (23) was used by Mottram and Evershed (22), and the agreement with our results was good.

## QUANTITATIVE ANALYSIS

As mentioned in the initial reports on TAG, the relative abundances of DAG and protonated molecular ions were observed to vary dramatically with the number of sites of unsaturation in the TAG. And since protonated molecular ions have larger masses and are propagated through the mass spectrometer system less efficiently than DAG fragment ions, the TAG with more unsaturation (and strong $[M + H]^+$) yield less response per mole. This resulted in the observation that TAG with few or no sites of unsaturation were overrepresented during TAG quantification using APCI-MS, whereas those with a larger number of sites of unsaturation were underrepresented. A method for determining response factors was necessary. Byrdwell *et al.* (23) reported a comparison of several possible methods for response factor calculation. First it was shown that calibration curves with useful linear ranges could be constructed for individual TAG in a mixture of mono-FA synthetic TAG standards. The slopes of the calibration curves showed that the sensitivity was greater for TAG containing saturated FA (which yielded only DAG ions), followed by

monounsaturated FA, with the least sensitivity being exhibited by TAG having polyunsaturated FA (which gave abundant protonated molecular ions). However, because of the large number of TAG in a typical mixture (~30 to >100 TAG), a more practical means for determining TAG response factors was required. One approach shown was that response factors could be calculated from comparison of the raw APCI-MS data from a synthetic mixture of 35 TAG to its statistically known composition. The synthetic mixture was produced by random distribution of 5 FA. By setting the experimentally determined composition equal to the statistically known composition, a response factor for each TAG could be calculated. However, the response factors determined for the mixture were not generally applicable to samples with very different relative proportions of TAG. The next approach to quantitation used response factors calculated from a randomized sample, which were then applied to a normal, nonrandomized sample. This method worked quite well, because the response factors were calculated from a randomized oil sample (so its statistical composition could be known) that, ideally, had the exact same FA as the nonrandomized oil. This gave good results, but required the step of chemical randomization of the original oil sample to produce a calibration sample.

A fourth method for quantitation was also quite successful and was adopted as their standard method for quantitation of samples by APCI-MS (23). A method was developed that utilized response factors calculated for each FA, which were then multiplied together to produce response factors for each TAG. In APCI-MS extracted ion chromatograms (mass chromatograms extracted from the total, or reconstructed ion chromatogram), such as those shown in Figure 5, a peak appeared for each FA that was combined with a particular DAG fragment to form a TAG. The combination of the areas of all of the FA peaks in all of the DAG extracted ion chromatograms (EIC) plus the areas under the EIC of the protonated molecular ions allowed the calculation of a net FA composition from the mass data. The response of each FA in the EIC was similar to the behavior of mono-acid TAG: the smaller FA, and FA with fewer sites of unsaturation, gave more response than polyunsaturated FA. The FA composition calculated from the total areas from EIC was compared to the FA composition determined by calibrated GC-FID to determine a response factor for each FA. These FA response factors were then multiplied together to produce TAG response factors. This method had the benefit of reflecting the saturated/unsaturated dependence of FA and TAG, and also compensating for the isotope peak contribution of one FA to the peak area of another FA. Overstatement of the abundance of one FA could occur when its FA peak in a normal DAG EIC occurred at the same retention time as the isotope peak of a FA having one less site of unsaturation. For instance, the "L" peak in the EIC for $[PL]^+$ (*m/z* 575.5) gave an isotope peak in the $[PO]^+$ chromatogram (*m/z* 577.5) due to PLL molecules containing two $^{13}C$ isotopes or one $^{18}O$ isotope. The retention time of the "L" peak was similar to the "Ln" peak in the PO chromatogram, causing a contribution of the "L" LP isotope to the "Ln" PO abundance. Using the actual net FA composition from the mass data, which was normalized to the FA composition determined by GC-FID, effectively compensated for all saturation trends and isotope effects. Examples of normal and randomized soybean oil and normal and randomized lard demonstrated the efficacy of the last two approaches.

Byrdwell and Neff (24) followed up the initial report on quantitative analysis with a second report that described the same quantitation methods applied to the same samples mentioned above, but with the addition of normal and interesterified canola oil blends. Also described in this report was a mathematical model that attempted to compensate for the effect of saturation on the response factors of TAG, and the effect of chain length for 16- and 18-carbon chains, but which did not address the isotope contributions to peak areas. This report showed, more than the first, that the best methods for quantitative analysis of TAG were (i) use of response factors calculated using the FA composition obtained from the total areas from EIC normalized to the GC-FID FA composition, and (ii) use of a randomized oil to determine response factors for nonrandomized (or noninteresterified) oils. The combination of these reports showed that the final average relative error in the FA composition calculated from the TAG composition was very small compared to the FA composition determined by calibrated GC-FID when the GC-FID response factor normalization process was used. The average relative error was less than 5% for most normal seed oil samples, and was as low as 0.2% for randomized samples. For randomized or interesterified samples the error was lower than for nonrandomized samples, and was usually less than 2%. If the average relative error in the FA composition was larger than ~7%, then there was sufficient nonrandom distribution of FA to indicate that the TAG mixture was a blend, or had FA concentrated into a few TAG species present in higher proportions. Comparison of the TAG composition to the statistically expected composition allowed identification of which TAG were most responsible for the average relative error. A method for mathematically separating out the few TAG responsible for certain FA within a blend and applying separate response factors to the base oil vs. hardstock TAG was recently reported by Byrdwell, Neff, and List (25). This recent report also provided greater detail about the original quantitation method.

Mottram *et al.* (22) applied the method described above, with good agreement, to our results. Byrdwell and Neff (26) published another application of the method to normal, high-lauric, and high-stearic canola oils. Results were similar to those described above. TAG that contained FA present in small amounts were sometimes not reported in the quantitative results, although they could be unambiguously identified qualitatively.

Other groups have taken a simpler approach to quantitative analysis. Laakso (27) reported a study in which α- and γ-linolenic acid oils were separated using RP-HPLC/APCI-MS. Whereas the study focused primarily on qualitative identification of components, it did report unnormalized peak areas based on areas under peaks in the reconstructed (or total) ion chromatogram. No response factors were applied. However, since quantitation was dependent on the amount of unsatura-

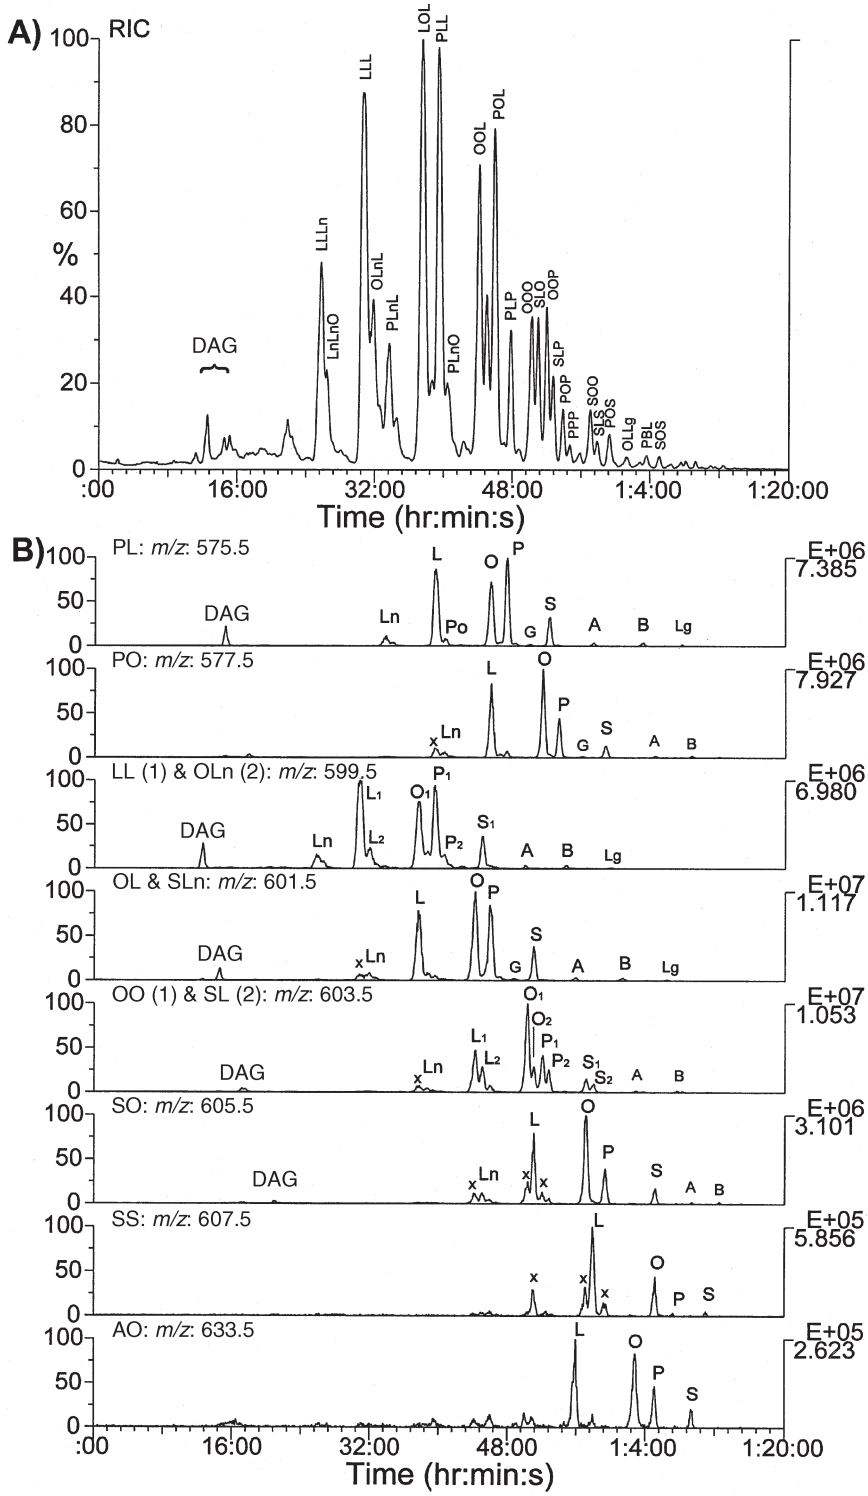

**FIG. 5.** (A) Reconstructed ion chromatogram (RIC) of refined, bleached, deodorized soybean oil. (B) Extracted ion chromatograms of diacylglycerol fragment ions. tion in the TAG, if the amount of unsaturation did not vary much between TAG species (all having a similar degree of unsaturation), then the response factors would not vary dramatically between the TAG. The main thrust of the work was to show that RP-HPLC/APCI-MS was capable of separating α- and γ-linolenic acid isomers, as had been reported earlier by these authors using $Ag^+$-ion HPLC/APCI-MS. On the RP column, however, the α-linolenic acid isomer eluted before

the γ-linolenic acid isomer, all else being equal. This was the opposite of the behavior observed for similar isomers separated by $Ag^+$-ion HPLC/APCI-MS.

## OXYGEN FUNCTIONAL GROUP-CONTAINING TAG

Ikeda and Kusaka (13) first reported the APCI mass spectra of FA amides containing hydroxy groups. Later, Kusaka and Ikeda (14) reported the APCI-mass spectra of hydroxy and hydroperoxy acids as Br-MB derivatives. The hydroxy-containing FA underwent dehydration, for a loss of 18 Da, to form a $[M - H_2O + H]^+$ fragment (13,14). These spectra displayed abundant molecular ion, $[M + H]^+$, but the fragment formed by dehydration was large, and was the base peak in some spectra. A hydroperoxy FA (hydroperoxy eicosatetraenoic acid) was seen to exhibit a different mass spectrum from that given by the hydroxy FA (14). The hydroperoxy FA formed a fragment representing loss of $H_2O$ to give a $[M - H_2O + H]^+$ fragment, and a fragment representing loss of the entire hydroperoxy group to yield $[M - H_2O - O + H]^+$ fragments. Kusaka *et al.* (28) then reported mass spectra for normal plant TAG and the mass spectrum of a sample of hydroperoxidized stearic-oleic-linoleic (SOL). However, these results exhibited a mass difference of 2 Da compared to other reports.

More recently, Neff and Byrdwell (29) reported the RP-HPLC/APCI-MS analysis of TAG oxidation products formed by autoxidation of synthetic TAG standards (triolein, trilinolein, and trilinolenin). This report showed the APCI-MS mass spectra of mono- and bis-hydroperoxides, which were the most abundant oxidation products, and mono- and bis-epoxides, which were also formed in substantial amounts. Comparison of APCI mass spectra of autoxidation products to spectra obtained from vernolic acid in *V. galamensis* (18) showed that some of the epoxides that were formed during autoxidation were identical to the epoxides from vernolic acid. It was further seen that the hydroperoxide-containing TAG gave ions identical to the epoxides as primary fragmentation products. By comparison of the epoxides formed from hydroperoxides with those such as vernolic acid, two distinct mechanisms of epoxide fragmentation were described. The first fragmentation pattern occurred when the epoxide group was not next to a double bond (such as in vernolic acid). In this case the epoxide was lost as $H_2O$, $[M - H_2O + H]^+$, meaning the epoxide oxygen was lost to give a site of unsaturation, and two more hydrogens were also lost, to yield another site of unsaturation. This was in contrast to the fragments formed when the epoxide was next to a double bond. In such a case, the epoxide was lost with the loss of only 16 Da, $[M - O + H]^+$, giving only one more site of unsaturation where the epoxide had been. Epoxides produced fragments that allowed the position of the epoxide on the fatty chain to be determined. Two major chain-shortened fragments resulted from epoxides, one in which the epoxide ring cleaved, leaving the oxygen behind on the remaining shortened TAG, and one in which the epoxide ring cleaved and the oxygen left with the leaving fragment. Hydroperoxides formed multiple isomers, which were detected by the fragment ions produced. Hydroperoxides formed epoxides as primary fragments, $[M - H_2O + H]^+$, which then fragmented further according to the two mechanisms identified for epoxides, to form $[M - H_2O_2 + H]^+$ fragments and/or $[M - 2H_2O + H]^+$.

Byrdwell and Neff (30) then reported the HPLC/APCI-MS analysis of triolein oxidation products produced at frying temperature. The low molecular weight oxidation products were similar to those produced by autoxidation, with mass spectra being virtually identical to those reported for autoxidation products (29). Hydroperoxides and epoxides were the primary products, although a keto-TAG and chain-shortened TAG were also reported. Higher molecular weight components were also reported. Dimers formed by addition of two oxidized triolein molecules were observed, as well as several large molecules formed by losses of acyl chains from the dimers. Larger molecules formed by addition of chain fragments to an intact dimer were also indicated. Direct detection of these large oxidation products allowed direct characterization of the intact nonvolatile decomposition products that remain after loss of small volatile fragments lost during oil decomposition.

Byrdwell and Neff (31) then extended the analysis of oxidation products to the autoxidation products of normal and genetically modified canola oil varieties. Normal, high-stearic acid, and high-lauric acid canola oils were allowed to undergo autoxidation, and the product mixture was analyzed using RP-HPLC/APCI-MS. The same fragmentation mechanisms described for TAG model standards were exhibited by the TAG in the autoxidized oils. Hydroperoxides and epoxides were the primary intact oxidation products. Highly saturated epoxy-TAG were observed in the high-stearic and high-lauric acid canola oil oxidation product mixtures. Chain-shortened species produced by cleavage of an acyl chain at the site of oxidation were reported. TAG containing multiple functional groups were also indicated.

TAG in hydroxy-containing seed oils were also analyzed by Byrdwell and Neff (32) using RP-HPLC/APCI-MS. Characterization of hydroxy-TAG in castor oil and two species of *Lesquerella* allowed the fragmentation patterns of these TAG to be elucidated. As had been observed for the hydroxy-containing FA (13,14), hydroxy-containing TAG readily underwent loss of the hydroxy groups by dehydration to produce abundant $[M - H_2O + H]^+$ ions. Less of the molecular ion was observed for hydroxy TAG than was observed for hydroxy FA. A series of three adducts was reliably and reproducibly formed from the hydroxy-TAG separated using the methylene chloride/acetonitrile solvent system. These adducts allowed facile identification of the molecular weights of the hydroxy-TAG even in the absence of a strong protonated molecular ion. The adducts were formed by a combination of acetonitrile in the mobile phase with nitrogen carrier gas.

## SFC

As mentioned above, the initial report of the application of APCI-MS to a TAG was based on separation of a mixture of

different lipid classes by SFC with detection by APCI-MS (15). The report described a lab-built open tubular column SFC/MS interface to a commercial APCI ionization source on a Sciex API III tandem quadrupole mass spectrometer. Several years later, Schmeer *et al.* (33) reported the analysis of lipids from the seed arils of *Commiphora guillaumini*, a tree species native to western Madagascar. TAG and DAG were separated using SFC and identified by APCI-MS. In-source fragmentation caused by orifice voltages greater than 80 V was used to provide structural information. Mass spectra exhibited an $[M + 18]^+$ ion, which was identified as an ammonium adduct, $NH_4^+$, but which was likely the water adduct, as no source of $NH_4^+$ was given in the procedure. 1,2-Dioleoylglycerol, previously identified as an ant attractant, was identified in the seed arils.

In 1997, Manninen and Laakso (34,35) described a capillary SFC (cSFC) system that was connected to a commercial APCI source on a Finnigan MAT TSQ 700 tandem mass spectrometer. This system was used for the cSFC analysis of TAG in berry oils. One paper reported the compositions of cloudberry seed oil and sea buckthorn pulp and seed oil, extracted with carbon dioxide by SFC (34). A second paper reported the compositions of black currant and alpine currant seed oils, extracted with carbon dioxide by SFC. Both studies used two 10 m × 50 μm i.d. SB-Cyanopropyl-25 (25% cyanopropyl/25% phenyl/50% methylpolysiloxane) columns in series [the first study also used a 10 m × 50 μm i.d. SB-octyl-50 (50% octyl/50% methylpolysiloxane)]. Following up on their previous work identifying the regioisomers by using DAG ion fragment abundances, Manninen and Laakso tabulated the ion abundances for DAG fragments and protonated molecular ions first from two mixtures of regiospecific isomer standards, then from the seed oils just mentioned. Regiospecific structures were estimated based on 2-position isomer DAG abundances. cSFC gave a separation in which some peaks contained up to seven TAG, some of which could have overlapping DAG fragments. However, if coeluting TAG did not have overlapping DAG fragments, then the regioisomer could be assigned. The mechanism by which TAG mixtures were separated by SFC/APCI-MS was different from that by RP-HPLC/APCI-MS. The retention time was dictated by the number of carbons in the acyl chains (ACN, acyl carbon number) plus two times the number of double bonds, ACN + 2*n*. This meant that a TAG containing an 18:1 chain plus two other FA coeluted with a TAG having two FA the same, and a 20:0 chain in place of the 18:1. A monounsaturate was retained similarly to the next-longer saturate, or similar to the next-shorter di-unsaturate. This is in contrast to the elution order given by RP-HPLC. RP-HPLC produces a separation by increasing equivalent carbon number (ECN), which is the number of carbons in the acyl chains minus two times the number of double bonds, ACN − 2*n*. By RP-HPLC, a TAG containing a monounsaturated FA eluted at a similar time to the TAG containing two FA the same and the next-shortest saturated FA in place of the monounsaturate. The peaks appear to be better resolved by RP-HPLC, with partial and sometimes complete separation between TAG with the same ECN.

In the first report by Manninen and Laakso (34), a comparison among four different reactants incorporated into the sheath gas was given. The reactant ions were introduced into the sheath gas by bubbling through 50 mL of a reactant liquid in a 200-mL bottle. Methanol, isopropanol, water, and 0.5% $NH_4OH$ aqueous solution were compared. Methanol as reactant ion produced the best combination of abundant $[M + H]^+$ and DAG, $[M - RCOO]^+$, ions. Isopropanol produced the lowest abundances of protonated molecular ions and DAG fragment ions. Water was found to be a good alternative to methanol, although ion formation was somewhat less stable. Ammonium hydroxide was reported to produce mostly $[M + 18]^+$ ions, even from relatively saturated TAG, which normally produce little to no $[M + H]^+$ ion.

Laakso and Manninen (36) next applied cSFC to the complex mixture of milk fat TAG. The mixture was sufficiently complex that very few specific TAG structures could be identified. The coeluted TAG in the chromatographic peaks produced up to 30 $[M - RCOO]^+$ DAG fragment ions, and small $[M + H]^+$ abundances. The most notable result from this study was that the abundances of near-molecular ions was increased by addition of ammonium hydroxide as reactant ion. The sheath gas was bubbled through a solution of 0.5% ammonium hydroxide in methanol before being preheated prior to introduction into the APCI source.

Sjoberg and Markides (37) reported a new SFC/APCI-MS interface that allowed an easy transition between APCI and ESI modes. The interface was fabricated in their laboratory, starting with the commercial source for the PE-Sciex API III mass spectrometer. The researchers used a capillary drawn to a small diameter to act as an integral SFC restrictor. A restrictor tip heating wire was used to minimize the adiabatic cooling caused by the expanding supercritical fluid carrier gas. The interface was designed to provide improved performance for the low flow rates associated with microscale analyses. In addition to polypropylene glycol, the authors used a mixture of FAME, trilaurin, cholesterol palmitate, cholesterol, and others to demonstrate the efficacy of their interface design. They later reported (38) optimization of the parameters used for the new interface design, with slight modifications, including optimal sheath liquid and mobile phase flow rates, capillary and restrictor dimensions and positions, corona needle position, and reagent solvent incorporated into the makeup liquid. The degree of fragmentation in mass spectra from APCI and ESI ionization was reported to be essentially the same, producing similar ratios of $[M + H]^+$ to $[M - RCOO]^+$ ions. Sodiated adducts under ESI conditions produced less fragmentation than protonated molecular ions under APCI conditions.

## OTHER FA AND TAG APPLICATIONS

The references cited above demonstrated the first applications and provided the precedent for analysis of FA and TAG using LC/APCI-MS. As the technique has gained recognition for its versatility and ease of use, the number of applications has increased.

Siegel *et al.* (39) reported a combination APCI/ESI source designed for low flow rates, which allowed operation in several modes. ESI only, APCI only, mixed ESI-APCI (in which both ESI and APCI operated simultaneously), and alternating ESI and APCI modes were available. The ESI and APCI modes had different optimal carrier gas temperatures, effluent compositions, and other parameters, but good results could be obtained from both ionization modes by employing intermediate ("compromised") parameters between the optimal values for each. Spectra of neutral molecules such as methyl stearate were shown to demonstrate the effects of varying different parameters.

Adas *et al.* (40) reported HPLC-APCI-MS for analysis of hydroxylated metabolites of elaidic and oleic acids in human and rat liver microsomes. The negative ion APCI-MS mass spectra exhibited strong $[M - H]^-$ ions as base peaks.

As already mentioned, formation of ammonium adducts increased the amount of near-molecular ions formed from saturated TAG in the APCI source. In 1998, Mochida *et al.* (41) reported the effect of ammonia addition to improve the amount of near-molecular ion formation from oleic acid hydroperoxides. An ammoniated molecular ion became the base peak when ammonia was incorporated into the LC mobile phase. The effects on the formation of the $[M + NH_4]^+$ ions of changing the nebulizer temperature, solvent flow rate, and drift voltages were investigated.

An interesting and thorough report of the application of LC/APCI-MS was reported by Shibayama *et al.* (42). They demonstrated the analysis of monoacylglycerols (MAG), DAG, TAG, and FA standards and components in the residue exuded from a painting in the National Gallery of Art, and in extracts of dried oil paint films. Their report demonstrated the utility of LC/APCI-MS for analysis of several lipid classes in artists' materials and its use in art conservation.

Holcapek *et al.* (43) compared three detectors: ultraviolet (UV) detection, ELSD, and APCI-MS, for analysis of rapeseed oil used for biodiesel production. As a first approximation, quantification was restricted to components containing the most abundant three FA, oleic acid (O), linoleic acid (L), and linolenic acid (Ln). As was previously demonstrated (23) under APCI-MS conditions individual TAG produced calibration curves with wide linear ranges, having sensitivities (slopes of the calibration curves) dependent on the degree of unsaturation. The ELSD was shown to produce distinctly nonlinear calibration curves. Quantitation was performed by producing correction factors obtained by averaging the slopes of the calibration curves for OOO, LLL, and LnLnLn.

Parcerisa *et al.* (44) recently reported analysis of olive and hazelnut oil mixtures by HPLC/APCI-MS. They used areas under peaks in the total ion chromatograms (TIC) of the oil mixtures to determine TAG compositions, which were then subjected to one-way analysis of variance. This statistical treatment allowed comparison of pure oils to oil mixtures. Statistically significant differences in the percentages of specific TAG could be identified, showing the potential use of HPLC-APCI-MS for detection of adulterated oils. Tocopherols and sterols were analyzed by gas–liquid chromatography of their *O*-trimethylsilyl derivatives. These nonsaponifiable components were identified using FID, after identification of retention times by conventional GC–MS with electron impact ionization.

Mu and Hoy (45) utilized RP-HPLC/APCI-MS on a Hewlett-Packard LC/MSD to separate and characterize TAG molecular species from rat lymph samples. Capillary-skimmer fragmentation and nebulizer heater temperature were optimized for maximal sensitivity. Ammonium acetate was added postcolumn to enhance the formation of pseudomolecular ions, especially of saturates. Animals were fed structured lipids or safflower oil, and the change in the composition of lymph TAG was monitored over time. Incorporation of caprylic acid into endogenous lipids was observed. In a related study, Mu, Sillen, and Høy (46) reported the characterization of DAG and TAG in a structured lipid sample. In this report, the authors emphasized the differences in the mass spectra obtained from DAG vs. TAG. They reported that DAG produced greater abundances of MAG-related fragment ions than TAG, which could aid in the identification of DAG.

Recently, Rezanka (47) demonstrated preparative $Ag^+$ ion chromatography followed by analytical-scale RP-HPLC/APCI-MS for analysis of the FAME of very long chain polyunsaturated FA in freshwater crustacean species. They used APCI-MS to identify 70 FA, 50 of which had chain lengths of 24 carbons or more, extending up to 40 carbons. It was reported that the ratio of the intensities of representative ions could be employed to localize the position of the double bonds in positional isomers. A second report by Rezanka (48) described the analysis of the FAME of polyunsaturated FA. Fragmentation of the FAME was enhanced by increasing the voltage between the nozzle and the skimmer cone. An increase in the number of sites of unsaturation in the FA led to larger correction factors used for quantitative analysis. The correction factors decreased with increasing carbon chain length.

Bylund *et al.* (49) reported analysis of oxygenated products produced by the enzymatic oxidation of arachidonic and linoleic acids. They reported negative ion tandem mass spectrometry (MS/MS) spectra of hydroxylated products, and identified diagnostically useful fragments produced in the Finnigan MAT LCQ ion trap mass spectrometer. APCI and ESI were reported to yield very similar results; and for most mass spectra presented, which ionization method was employed was not clear. Localization of the positions of oxygen functional groups was possible in many cases based on the fragmentation patterns observed for the various isomers.

## PHOSPHOLIPIDS

ESI-MS has arguably become the method of choice for phospholipid analysis. However, since ESI-MS normally produces no fragmentation, a mass spectrometer capable of MS/MS or $MS^n$ is sometimes considered necessary to produce fragmentation for complete structural elucidation. Alternatively, in-source or near-source fragmentation can be used to produce nonspecific fragment ions. The fragments produced by

ESI-MS with upfront fragmentation are not necessarily the same as those produced by APCI-MS. For example, ESI-MS produces only head group ions for some phospholipids in positive ion mode, whereas APCI-MS produces diagnostically useful fragments from the same phospholipids. APCI-MS typically produces some protonated or near-molecular ions with gentle fragmentation, which leads to structurally diagnostic fragment ions. However, some phospholipids produce such small abundances of molecular ions under APCI-MS conditions that identification of all molecular species can be problematic. In such cases the molecular weight information provided by ESI-MS can be invaluable. Thus, ESI-MS and APCI-MS techniques are both useful and complementary for analysis of phospholipids and other lipid molecules.

Karlsson *et al.* (50) showed positive and negative ion mass spectra of the pure standard distearoyl (di-18:0) phosphatidylcholine (PC) to demonstrate that near-molecular ions, DAG and FA fragments resulted from APCI-MS analysis of a phospholipid. They chose to utilize ESI-MS for the remainder of their study, however, because of its greater sensitivity.

Byrdwell and Borchman (51) reported HPLC/APCI-MS using an amine column for separation and characterization of the sphingolipids and other phospholipids of human eye lens membrane extracts. APCI-MS was shown to produce mostly fragments formed by loss of the phosphate-containing head group from the sphingolipids, with small abundances of protonated molecular ions. Because of the small amount of near-molecular ion formed from sphingolipids, the discrimination due to differences in acyl chain length was assumed to be less than the discrimination observed for TAG. Semiquantitative results for the sphingolipids were presented without the use of response factors. PC, on the other hand, produced little protonated molecular ion from a concentrated sample, but a protonated molecular ion as base peak from a human lens extract containing only a small amount of PC. A more thorough treatment of the quantitative analysis of phospholipids using APCI-MS is necessary. Discrimination between classes is expected, which will require the use of response factors. Within a class, discrimination is expected to be much less.

Byrdwell (52) extended the initial identification of phospholipids using HPLC/APCI-MS by employing two mass spectrometers and two other detectors for analysis of sphingolipid, glycerophospholipid, and plasmalogen molecular species. Byrdwell employed a single-quadrupole mass spectrometer with an APCI source connected in parallel to a triple-quadrupole mass spectrometer with an ESI source. An ELSD was attached as an auxiliary detector to the single quadrupole mass spectrometer, while a UV-visible (Vis) detector was attached to the triple quadrupole mass spectrometer. This "dual parallel mass spectrometer" arrangement produced data from four detectors simultaneously—two mass spectrometers, the ELSD, and the UV-Vis—from the same column effluent. Typical data for phospholipid standards from this arrangement are shown in Figure 6. The triple quadrupole mass spectrometer was programmed to automatically switch from full-scan mode to MS/MS [with the most abundant ion(s) as parents] when the signal passed a threshold. APCI-MS was shown to produce mostly protonated molecular ions from phosphatidylethanolamine and its plasmalogen. Protonated molecular ions were observed from PC and PC plasmalogen, but DAG fragment ions were the base peaks from PC. The sphingolipids produced smaller abundances of protonated molecular ions than PC, with fragments produced by loss of the head group appearing as base peaks. These results demonstrated the discrimination between phospholipid classes that occurred during APCI. Also shown in this report were strong ammonium adducts of TAG formed from the ammonium hydroxide electrolyte included in the mobile phase to produce a stable current during ESI-MS. The TAG ammonium adducts greatly increased the amount of near-molecular ion formation observed from TAG with few sites of unsaturation, similar to observations reported by others (34). Also, when insufficient aqueous component was included in the mobile phase, sodiated adducts were formed from both phospholipids and TAG under ESI-MS conditions. The ESI-MS mass spectra of TAG showed substantial sodiated adducts in the high-mass region and normal DAG fragments at lower masses.

Karlsson *et al.* (53) reported the analysis of sphingolipids from bovine milk, brain, erythrocytes, and chicken egg yolk using both APCI and ESI. APCI in-source fragmentation was followed by MS/MS analysis of the ceramide ion ($[M - PO_4(CH_2)_2N(CH_3)_3 + H]^+$) produced in the source. Both ESI and APCI produced only phosphorylcholine as product ions when the protonated molecular ion was chosen as the precursor ion. But when the ceramide fragment ion was selected as the precursor using APCI, fragments resulted that allowed characterization of both the long-chain base backbone and the amide-linked fatty acyl chain. Although the APCI method exhibited markedly lower sensitivity than the ESI method, the APCI spectra provided structural information that could not be obtained using ESI. Isobaric fragments were shown that potentially could lead to ambiguity in identification of the long-chain base, but the use of accompanying fragments could be used to make specific structural assignments.

Qiu *et al.* (54) reported the analysis of phospholipids in the archaebacterium *Natronobacterium magadii*. They demonstrated positive and negative ion mass spectra of distearoyl phosphatidylglycerol (PG) and diphytanoyl (3,7,11,15-tetramethyl 16:0) PC. In negative ion mode, PG gave a molecular anion (phosphate not protonated), but in positive mode, the distearoyl DAG fragment was the primary peak. In positive ion mode, PC gave a DAG fragment ion as base peak, with $[RCOO + 58]^+$, protonated molecular ion (phosphate protonated), and near-molecular ions also present. Diether PG methyl phosphate analogs extracted from *N. magadii* that contained 20:0 (phytanyl) and 25:0 (sesterphytanyl) FA were identified by these authors. Deprotonated molecular ions produced in negative ion mode allowed molecular weight confirmation. There was no fragmentation within the fatty chains, so the methyl-substituted molecular and DAG ions were isobaric with straight-chain FA.

Ceramides, which are nonphosphate-containing interme-

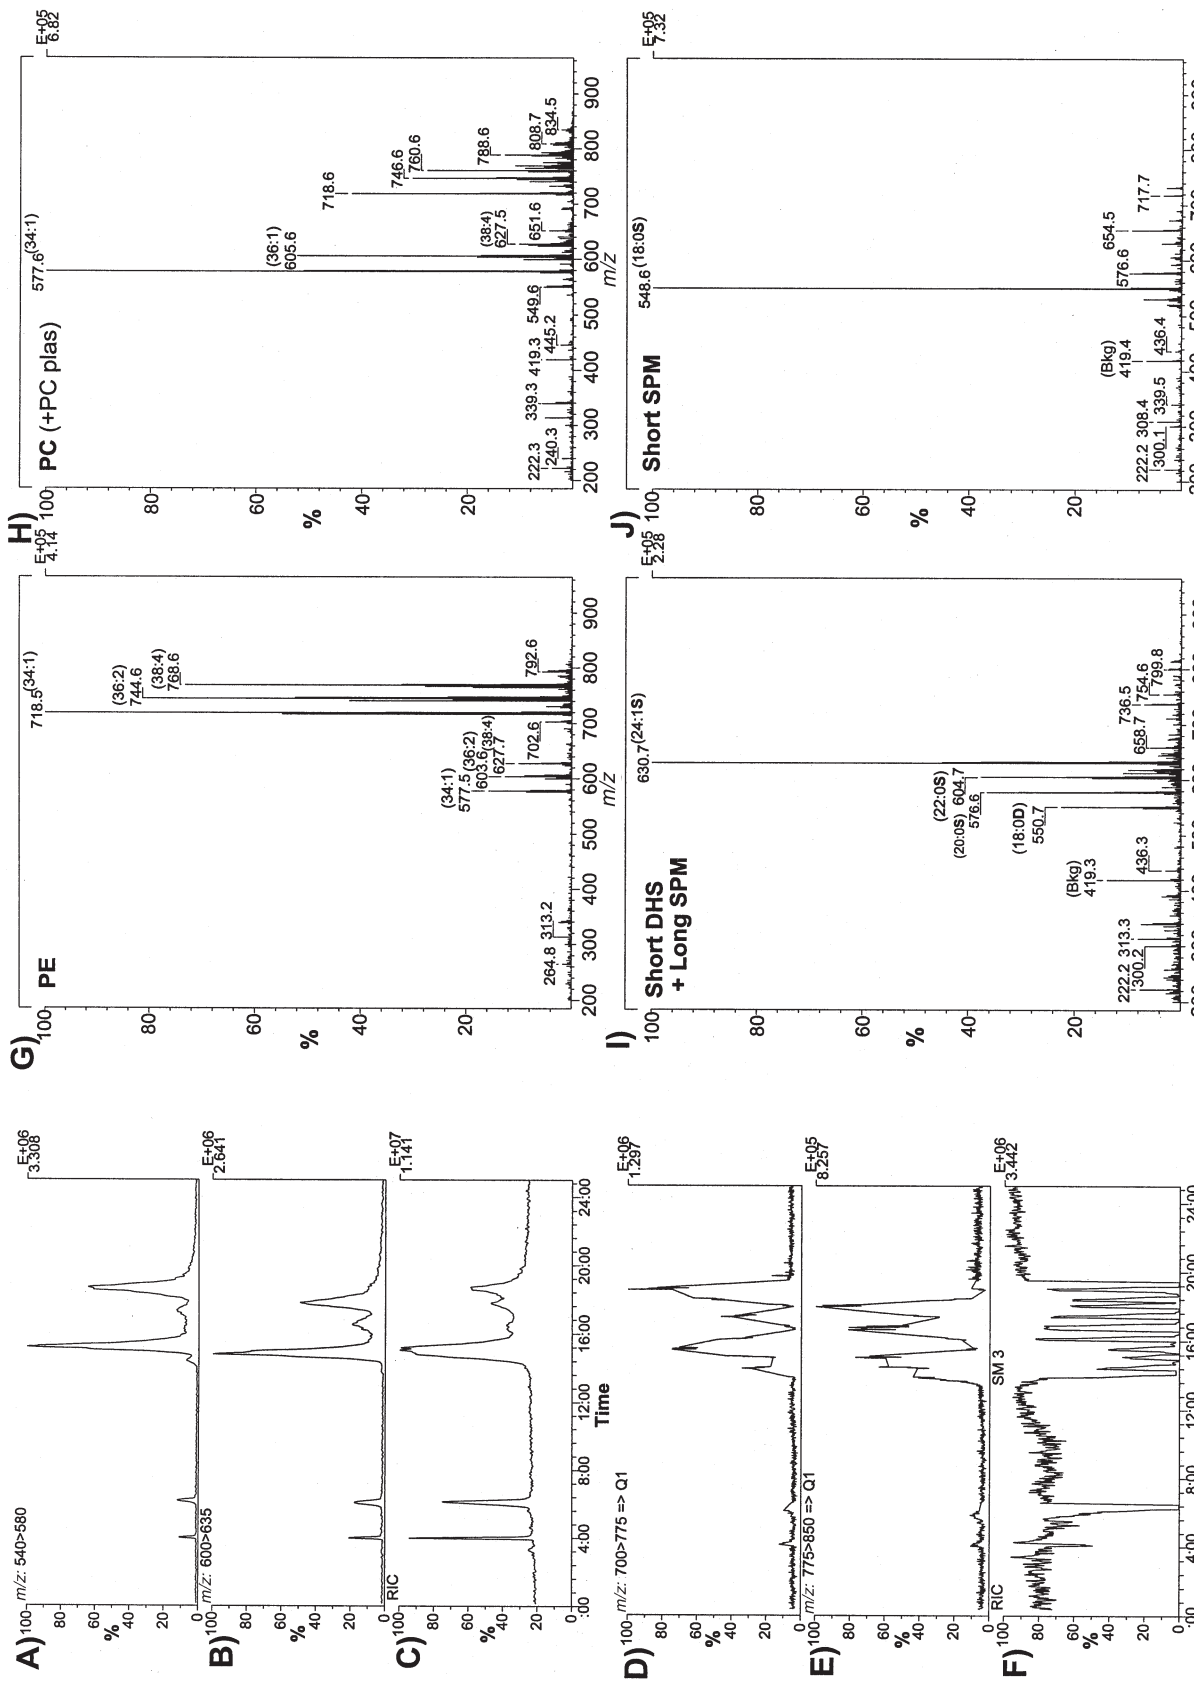

**FIG. 6.** (A) APCI-mass spectrometry (MS) extracted ion chromatograms (EIC) of short-chain phospholipids and (B) long-chain phospholipids; (C) APCI-MS RIC of phospholipids; (D) electrospray ionization (ESI)-MS EIC obtained in parallel with APCI-MS (filtered to show full scan mode); (E) ESI-MS EIC of short-chain phospholipids; (F) ESI-MS RIC of phospholipids (with cycling between full scan and MS/MS modes); (G) APCI-MS mass spectrum of phosphatidylethanolamine (PE) molecular species; (H) phosphatidylcholine (PC) + PC plasmalogen; (I) short-chain dihydrosphingomyelin (DHS) coeluted with long-chain sphingomyelin (SPM); (J) short-chain SPM molecular species. In (I) and (J), BKg is background, as in background contaminant. D (as in 18:00) refers to DHS, and S (as in 24:15) refers to SPM. These figures show that short-chain DHS species (e.g., 18:0) co-eluted with long-chain SPM (e.g., 24:1), but were easily differentiable by mass.See Figures 1 and 5 for other abbreviations.

diates in the biosynthesis of sphingolipids, were analyzed by Couch *et al.* (55) using HPLC with detection by APCI-MS. They reported the analysis of both underivatized and perbenzoylated ceramide standards and ceramides from human leukemic cells using detection by APCI-MS and UV-Vis. Selected ion monitoring was used on the VG (Manchester, United Kingdom) Platform II mass spectrometer to improve the sensitivity. Low skimmer cone voltages produced protonated molecular ions as base peaks, while higher cone voltages resulted in the fragment formed by loss of water (18 Da) as base peak. The highest cone voltage resulted in spectra in which a fragment representing loss of the fatty acyl chain was the base peak. The perbenzoylated derivatives produced spectra in which the primary fragment was formed by loss of a benzoic acid group.

## CAROTENOIDS AND RELATED MOLECULES

Carotenoids are large, nonvolatile, thermally labile tetraterpene molecules that have generally presented a number of difficulties for analysis. In 1996, Van Breeman *et al.* (56) reported the use of RP-HPLC/APCI-MS with a $C_{30}$ column for analysis of carotenoids in plant extracts. Their work demonstrated that APCI-MS produced both molecular ions and protonated molecular ions in positive ion mode, but in negative ion mode, molecular ions and deprotonated molecular ions were formed. The carrier gas (nebulizer gas) temperature could be adjusted to produce larger abundances of protonated molecular ions (below 400°C) or larger abundances of molecular ions (above 400°C). The hydroxy-containing xanthophyll lutein produced a base peak resulting from loss of water, similar to the behavior observed for other hydroxy-containing lipids, as already mentioned. Because only near-molecular ions were produced under APCI conditions, "in-source collision-induced dissociation (CID)" was used to increase the degree of fragmentation so as to provide structurally diagnostic fragment ions. This was accomplished by increasing the voltage between the capillary and the skimmer of the Hewlett-Packard HP 5989B MS Engine. Both positive and negative ion APCI-MS resulted in calibration curves with linear ranges spanning three orders of magnitude, with the lower limit of detection given in the negative ion mode. Thus, negative ion mode was used for quantification of β-carotene in extracts of fresh vs. heat-processed sweet potatoes.

Around the same time, Clarke *et al.* (57) reported the use of HPLC/APCI-MS for analysis of nine carotenoids from United Kingdom total-diet survey samples. The VG Platform single quadrupole mass spectrometer used for this study produced usable spectra only in positive ion mode. Seven of the compounds identified in this study produced protonated molecular ions as base peaks, while neoxanthin and lutein produced fragments resulting from the loss of water as base peaks. All of the hydroxy-containing carotenoids produced substantial $[M - H_2O + H]^+$ fragment ions, which, as mentioned, was the base peak for neoxanthin and lutein. These two compounds also showed substantial $[M - 2H_2O + H]^+$ fragments. In contrast to the work reported by van Breeman *et al.* (56), nonprotonated molecular ions were not observed under APCI conditions but were observed using ESI with high cone voltages. Hydroxy-containing carotenoids were detected with greater sensitivity than nonhydroxy components. Calibration curves exhibited sufficient linearity to allow quantitation of the carotenoids in total dietary study samples.

Liebler and McClure (58) described the analysis by APCI-MS of oxidation products from β-carotene with alkyl, alkoxyl, and alkylperoxyl free radicals formed by thermolysis with azobis(2,4-dimethylvaleronitrile) (AMVN). The primary oxidation products were epoxy and peroxy products, with the epoxy products representing the majority. Also formed were products formed from β-carotene with either AMVN radical fragments, AMVN-derived alkoxyl radical fragments, or AMVN-derived peroxyl radical fragments (collectively referred to by the authors as "substitution products"). Another group of ions was formed by combination of two of these radical fragments with a β-carotene molecule, referred to as "addition products." Daughter ion spectra and precursor ion spectra from CID of the oxidation products allowed structural elucidation of β-carotene-radical adducts and provided direct evidence for the reactions responsible for the antioxidant behavior of β-carotene.

Tang *et al.* (59) utilized flow injection (FI) APCI-MS for analysis of collected chromatographic fractions of β-carotene. They analyzed deuterium-labeled ($d_8$) β-carotene standard and in human serum extracts by FI/APCI-MS and then monitored its conversion to retinol using electron capture negative chemical ionization MS. Integration of the protonated molecular ion of labeled β-carotene produced a linear calibration curve (log-log plot), which was used to identify isotopic enrichment down to ~10% enrichment.

Hagiwara *et al.* (60) described the quantitative analysis of carotenoids in vegetable juice by RP-HPLC/APCI-MS on a $C_{18}$ column using selected ion monitoring (SIM) with cholesteroyl benzoate as internal standard. By using methanol as the mobile phase, mass spectra exhibited strong protonated molecular ions with little fragmentation, which were used for quantitative analysis. The reproducibility of the experiments was improved by using an iron corona discharge needle and by directing to waste the chromatographic effluent that came off the column prior to analyte elution (minimizing the effect of stains on the interface). After demonstrating low coefficients of variation and linear calibration curves, the concentrations of lycopene, α-carotene, and β-carotene were identified in eight commercially available vegetable juices.

Hagiwara *et al.* (61) later reported the application of RP-HPLC/APCI-MS to serum carotenoids. Unlike the vegetable juices, the hexane extracts of serum samples contained cholesterol-related components that co-eluted with the analytes, which fouled the interface. The mobile phase was changed to 70% methanol/30% acetonitrile to delay elution of the interferents. An automatic switching valve was used to admit only peaks containing the carotenoids into the mass spectrometer, while sending all other components to waste.

These changes, along with using squalene as the internal standard, resulted in a method useful for determination of the carotenoids in human serum. Sample mass spectra demonstrating the abundant protonated and nonprotonated molecular ions are shown in Figure 7.

Van Breeman *et al.* (62) reported a method for analysis of retinol (a diterpene that has a structure equal to one-half of a β-carotene molecule, plus the alcohol group) and retinyl palmitate in the hexane extracts of human serum samples. As with their method for carotenoid analysis (56), the method reported for the retinoids used a $C_{30}$ RP-HPLC system coupled to APCI-MS. Retinoids were analyzed intact, without derivatization, based on SIM of the mass of the retinyl moiety at *m/z* 269, the base peak which resulted from loss of water from

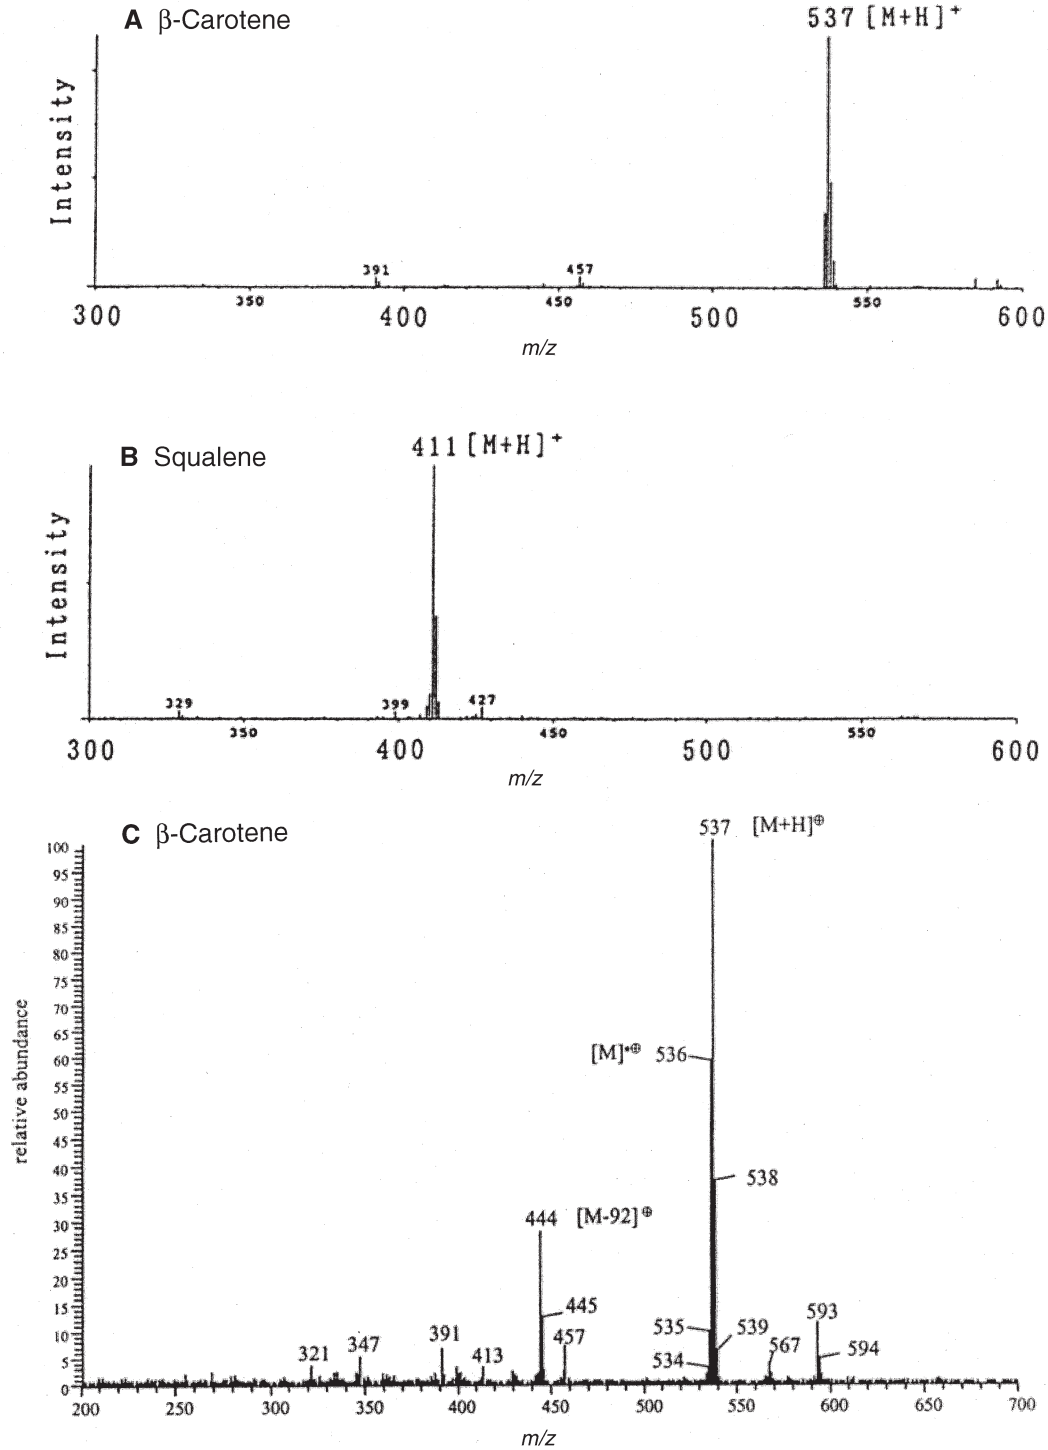

**FIG. 7.** APCI-MS mass spectra of carotenoids. (A) β-Carotene and (B) squalene from Reference 61; and (C) β-carotene from Reference 64. (Reprinted with permission from Elsevier Science.) See Figures 1 and 6 for abbreviations.

retinol, loss of the palmitic acid from retinyl palmitate, and loss of the acetate group from the internal standard, retinyl acetate. APCI-MS was shown to be superior to ESI-MS for retinoid analysis because APCI-MS exhibited linear response over several orders of magnitude.

More recently, Wang *et al.* (63) reported a method for the quantification of the bioavailability of $^{13}C_{10}$-labeled retinyl palmitate and β-carotene, and the bioconversion of β-carotene to retinol in Indonesian children. Building upon previous work (56,62), they showed that RP-HPLC/APCI-MS was a suitable analytical technique for monitoring physiologically relevant doses administered in a human intervention study. APCI-MS exhibited a wider linear dynamic range than ESI-MS. This wide dynamic range allowed determination of the amounts of low levels of isotope-labeled species in the presence of higher concentrations of endogenous compounds circulating in the serum, which coeluted chromatographically. SIM was used to produce detection limits below 1 pmol for both compounds.

A recent report by Lacker *et al.* (64) utilized a $C_{30}$ RP-HPLC/APCI-MS method for analysis of carotenoid standards and carotenoids in vegetable juice. Quantitation of β-carotene was based on the $[M + H]^+$ ion at *m/z* 537, whereas the $M^+$ ion was also present at an abundance more than half that of the $[M + H]^+$ base peak, as shown in Figure 7. Dioxygenated carotene was reported to elute at a short retention time, resulting in a base peak of *m/z* 565. *Cis* and *trans* isomers were differentiated by their UV-Vis spectra. Five carotenoids in a mixture and also carotenoids in a vegetable juice extract were separated and characterized by their $[M + H]^+$ ions.

Another class of lipids, which have structural similarities to carotenoids but which are not polyunsaturated and which contain the hydrocarbon chains ether-linked to a glycerol backbone, are tetraether lipids. A report of glycerol dialkyl glycerol tetraethers from the archaea *Sulfolobus solfataricus* and *Metallosphaera sedula* and two sediment samples was recently published (65). These large nonpolar molecules produced protonated molecular ions as base peaks and allowed characterization of previously unidentified tetraethers. Several of the tetraethers contained multiple cyclopentane rings and were analyzed intact, without derivatization (although acetylated derivatives were produced in small amounts as a by-product of the purification procedure). Protonated molecular ions in the range near 1300 Da highlighted the effectiveness of APCI-MS for ionization of large neutral molecules, which are difficult to ionize using other methods.

## CHOLESTEROL, STEROIDS, AND RELATED COMPOUNDS

The emphasis herein is primarily on lipids containing FA chains and acyl-like chains such as carotenoids. Cholesterol and structurally related steroids are also lipophilic molecules that are often associated with lipid systems, so these will be mentioned, but only briefly. A large number of articles have been published demonstrating the use of APCI-MS for analysis of steroid molecules. The number of such reports has grown such that a separate review of APCI-MS of these biomolecules is warranted. A review of LC/MS of steroids (66) and a review of the analysis of neurosteroids (67) recently appeared in Japanese journals. Therefore, this review will present only a few of these applications, to provide a starting point for researchers interested in pursuing this field.

Cholesterol has been mentioned in several of the reports just cited. It has either been part of a test mixture (15,37), been added as internal standard for analysis of other types of lipids (58), or been extracted with other lipid classes (49). Cholesterol produces a mass spectrum under APCI-MS conditions that consists of a base peak at 369, representing loss of the hydroxy group and giving a $[M - H_2O + H]^+$, or $[M - 17]^+$ peak. An APCI-MS analysis of cholesterol oxidation products has also been reported (68).

An early and quite extensive report of the use of LC/APCI-MS for steroid analysis was that of Kobayashi *et al.* (69). They reported the fragmentation characteristics of 60 steroids and the effects of nebulizer temperature and drift voltage on fragment abundances. They showed that protonated molecular ions were the base peaks formed by the majority of steroids, although a number of the steroids exhibited a near-molecular ion arising from loss of $H_2O$ from a protonated molecular ion. This fragmentation is now recognized as typical for hydroxy-containing compounds analyzed using APCI-MS. They also reported the formation of adducts with acetonitrile by some steroids.

Two other more recent reports also present extensive results for numerous steroids: Ma and Kim (70) reported results for 29 steroids, while Joos and van Ryckeghem (71) reported results for 36 steroids. Ma and Kim compared results obtained by APCI-MS with those obtained by ESI-MS. APCI was less sensitive for steroid analysis than ESI, but the slight fragmentation produced by APCI could assist in structural elucidation. The $[M + Na]^+$ near-molecular ions produced during ESI led to the best sensitivity in that ionization mode. Joos and van Ryckeghem reported results for fragmentation of steroids in multiple reaction monitoring mode. They reported optimized cone voltages and collision energies for each steroid.

Many other applications of APCI-MS analysis to steroids have been reported. Some of them are listed below. Analysis of brassinosteroids has been described by Gamoh *et al.* (72,73). Huopalahti and Henion (74) described LC/APCI-MS analysis of steroids after supercritical fluid extraction. Analyses of corticosteroids (75), ecdysteroids (76), and azasteroids (77) have been reported. Sjoberg and Markides (78) reported energy-resolved CID of geometric and positional isomers of steroids using both upfront (sometimes called "in source"—a misnomer) and conventional CID on a tandem mass spectrometer. Tuomola *et al.* (79) used SFC with APCI-MS for analysis of androstenone in pig fat, while Nakajima *et al.* (80) analyzed dehydroepiandrosterone in biological samples. Ikegawa *et al.* (81) used negative ion LC/APCI-MS to monitor dehydrogenation of 3α,7α,12α-trihydroxy-5β-cholestanoic acid (THCA) CoA thioester by THCA-CoA oxidases. Shimada and Muka (82) used LC/APCI isotope dilution MS

for analysis of derivatized pregnenolone and its 3-stearate in rat brains. Rule and Henion (83) used a semiautomated robotic 96-well solid-phase extraction sample preparation technique combined with APCI/MS/MS for analysis of equilenin and progesterone, using $d_4$-estrone as an internal standard.

## CONCLUSION

APCI-MS has become recognized for its ability to ionize large neutral molecules that are not amenable to ionization by most other techniques. Its versatility and ease of use is quickly making it a highly desirable method for lipid analysis. Naturally, the number of publications reporting its application is growing quickly as its popularity grows. Commercially available APCI sources are now readily available from most MS instrument manufacturers, usually in combination with the other API technique, ESI.

The spectra produced from APCI are simple, with a protonated molecular ion as the most common base peak, with minimal yet sufficient fragmentation to allow structural elucidation. For TAG and phospholipids, fragment ratios can often be used to determine the most likely positional isomers. Lower mass fragments ($[RCOO + 58]^+$ and acylium ions, $[RCO]^+$) can be used to identify individual fatty acyl chains to distinguish between isobaric DAG fragments. A wide variety of chemical ionization reagents are available to maximize near-molecule ion formation or sensitivity. Although the sensitivity of APCI-MS is usually less than that of ESI-MS, the structural information to be gleaned from the modest fragmentation is well worth the tradeoff in sensitivity. Some lipids containing oxygen functional groups (hydroperoxides and epoxides) yield information-rich fragmentation patterns that can allow not only the functional group but also sometimes their positions to be determined. However, some lipids containing oxygen functional groups yield such a paucity of pseudomolecular ions that identification of the molecular weight can be problematic. Examples include hydroxy-containing TAG, which readily lose $H_2O$, and oxoacylglycerols (aldehydes and ketones). In such cases, ESI can be an indispensable complement to APCI. A "dual parallel mass spectrometer" arrangement that combines these two ionization methods has already been demonstrated, and work is currently underway to apply this approach to highly complex mixtures of TAG oxidation products.

In the future, LC/APCI-MS should continue to gain more widespread usage and acceptance. Additional functional groups will be characterized, and their fragmentation patterns recognized. Also, the improvement of results by utilization and optimization of better chemical ionization reagents should continue. Although other ionization techniques have briefly flourished and then receded to give way to more advanced developments, it seems likely that API methods (both APCI and ESI) will endure well into the foreseeable future. They could likely endure long enough to participate in the never-ending push toward miniaturization, which continually produces smaller and more portable instrumentation. Handheld APCI and ESI mass spectrometers are not unfathomable. For now, those who already recognize the versatility and ease of use of API techniques will continue to solve difficult analytical problems that previously resisted facile instrumental solutions.

# Tolerance and Incorporation of a High-Dose Eicosapentaenoic Acid Diester Emulsion by Patients with Pancreatic Cancer Cachexia

**Matthew D. Barber and Kenneth C.H. Fearon***

University Department of Surgery, Royal Infirmary of Edinburgh, Edinburgh, Scotland, United Kingdom EH3 9YW

**ABSTRACT:** Chemotherapy and radiotherapy offer little benefit to patients with advanced pancreatic cancer. Eicosapentaenoic acid (EPA) has anticancer effects both *in vitro* and in animal models. The dose of EPA that can be administered to cancer patients has previously been limited by the low purity of available preparations and the tolerability of large capsules. A high-purity preparation of EPA as a 20% oil-in-water diester emulsion allowed a small study of the tolerance, incorporation, and effects of EPA in high doses in five patients with advanced pancreatic cancer. Patients underwent assessment at baseline and every 4 wk thereafter. All patients managed to tolerate a dose providing 18 g EPA per day, with doses between 9 and 27 g daily being taken for at least a month. Dosage was limited by a sensation of fullness, cramping abdominal pain, steatorrhea, and nausea. All such symptoms were controlled by dose reduction or pancreatic enzyme supplements. No other adverse effects attributable to the trial agent were observed. Plasma phospholipid EPA content increased from around 1% at baseline to 10% at 4 wk and 20% at 8 wk. Incorporation of EPA into red blood cell phospholipids reached levels of around 10%. The present study has shown that a novel, high-purity, EPA diester emulsion can be tolerated at a dose providing around 18 g EPA per day with side-effects being easily controlled. The acceptibility of large doses of oral EPA should allow larger controlled clinical studies into potential anticancer effects of EPA.

Paper no. L8299 in *Lipids 36*, 347–351 (April 2001).

There has been increasing interest in the properties of n-3 fatty acids in oncology in recent years. The n-3 polyunsaturated fatty acids in general and eicosapentaenoic acid (EPA) in particular have been shown to reduce the growth rates of malignant cell lines in culture (1–4). The administration of fish oil that is rich in EPA and of EPA itself to immunocompromised animals bearing human tumor xenografts derived from breast (5–9), lung (10,11), prostate (12), and colon (13,14) cancer cell lines has been shown to retard tumor growth. Fish oil (containing EPA) and higher-purity EPA preparations have been administered to human cancer patients and have been suggested to produce an attenuation of cachexia in pancreatic cancer patients (15–17) and a prolongation in survival in a mixed group of cancer patients (18). These effects in human disease have been attributed to the anti-inflammatory and immunomodulatory effects of EPA, to direct effects on novel mediators of cachexia (19), and to a possible influence on tumor growth.

Conventional cytotoxic chemotherapy in pancreatic cancer is of limited effectiveness. A modest prolongation in survival can be achieved in some cases, but side effects are substantial and objective response rates are seen in less than 25% (20,21). It is therefore clear that a new approach to the management of these patients is required. Until now trials using EPA have mainly focused on its anticachectic potential. Doses used in studies of EPA in cancer have ranged from 2 to 6 g daily in capsule form (15,16,18). In such studies with low-dose EPA, no objective tumor responses have been reported. Thus, to test the true potential of EPA as an anticancer drug, it would seem logical to develop new formulations that might allow dose escalation to see if there is a dose-response curve. The relatively low EPA content of mixed fish oil preparations and the poor appetite and early satiety of these patients has limited the dose of EPA that may be tolerated in capsules. The availability of a liquid emulsion containing a 95% EPA diester that can be swallowed by the patient allowed the present small study of the tolerability and incorporation of high-dose EPA.

## MATERIALS AND METHODS

*Patients.* After local ethical committee approval, five patients with a histological ($n$ = 4) or unequivocal operative ($n$ = 1) diagnosis of unresectable pancreatic adenocarcinoma were enrolled. Patients had a life expectancy of over 2 mon, a Karnofsky performance status of 70, and a history of weight loss at enrollment. Patients were excluded if they had received surgery or endoscopic stenting during the previous 4 wk, had other active medical conditions, or another malignancy. No patients had received radiotherapy or chemotherapy. On enrollment none of the patients was jaundiced, pyrexial, severely anemic, or had clinical or radiological evidence of infection; and none was taking steroid drugs. All patients had adequate pain control at the time of study. Four patients were taking pancreatic enzyme supplements at enrollment. Two patients had previously taken the mixed fish oil preparation MaxEpa® (Seven Seas Ltd., Hull, England) at a dose

Abbreviations: DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid.

**TABLE 1**
**Patient Characteristics Prior to Intervention[a]**

| Patient | MaxEpa® taken | Other relevant medications | Percentage weight loss | Lymphocyte count ($\times 10^9$/L) | Serum albumin (g/L) |
|---|---|---|---|---|---|
| 1 | Yes (7 mon) | Pancreatin, domperidone | 15 | 1.6 | 42 |
| 2 | Yes (6 wk) | Pancreatin | 17 | 1.5 | 38 |
| 3 | No | Pancreatin | 16 | 0.7 | 41 |
| 4 | No | Pancreatin | 9 | 2.4 | 34 |
| 5 | No | Diclofenac | 8 | 2.0 | 34 |

[a]MaxEpa, manufactured by Seven Seas Ltd., Hull, England.

providing around 1 g EPA daily. Further details of the enrolled patients are shown in Table 1.

*Trial preparation.* The preparation administered was a 20% w/w emulsion of 1,3-di-(*Z,Z,Z,Z,Z*-eicosa-5,8,11,14,17-pentaenoyloxy)-propane, a diester of 95% EPA with propane-1,3-diol, in water, flavored with peppermint (Scotia Pharmaceuticals, Stirling, United Kingdom). The preparation provided 18 g EPA per 100 mL of emulsion and was stored in 200-mL amber glass bottles under nitrogen at 4°C. The fatty acid composition of the trial preparation was as follows: 20:5n-3, 93.8%; 20:4n-6, 3.3%; other, 3.0%.

*Protocol.* The study was an open-label, dose-escalation study. At enrollment patients gave written informed consent and were weighed in light clothing on a beam scale (Avery, Birmingham, United Kingdom). Pre-illness stable weight and Karnofsky performance status were documented. Mid upper arm circumference and triceps skinfold thickness were measured, and a venous blood sample was taken for measurement of routine full blood count, clotting, urea, electrolytes, and liver function. Blood was also collected for characterization of plasma and red cell phospholipid fatty acids. Subjects were given a diary in which to record the dose of emulsion taken and the number of doses taken per day. They were also asked to record any symptoms experienced. Subjects were asked to consume 25 mL of the emulsion (equivalent to 4.5 g EPA) daily for 2 wk. Subjects were contacted by telephone at this point, and if tolerability was satisfactory they were asked to increase the dose to 50 mL per day (9 g EPA). After 4 wk subjects returned to the clinic for a repeat of the baseline assessments and were asked to increase the dose to 100 mL per day (18 g EPA). At 6 wk after further telephone contact the dose was increased to 200 mL daily (36 g EPA). After 8 wk subjects underwent assessment once more. The emulsion was continued thereafter at the choice of the patient, and assessments were repeated every 4 wk. Patients were permitted to lower the dose taken at their discretion throughout the study.

*Fatty acid analysis.* EDTA-anticoagulated venous blood samples were centrifuged at 2500 rpm for 15 min and the plasma was removed. The layer of platelets and white cells was removed from above the red cell layer and discarded. Red cells were washed twice in phosphate buffered saline. Plasma and red cells were stored at −70°C until subsequent analysis. Lipids were isolated and purified by the method of Folch *et al.* (22). Lipids were extracted from plasma and red blood cells by homogenizing in 20 vol of chloroform/methanol (2:1vol/vol). After separation by adding a saline solution, the chloroform layer containing the lipid extract was removed, and phospholipids were separated by thin-layer chromotography in hexane/diethyl ether/acetic acid (80:20:1 by vol). Samples were then saponified in 5% potassium hydroxide in methanol. The solution was acidified with hydrochloric acid, and the fatty acids were methylated with boron trifluoride in methanol (12% w/w) with heating to 90°C for 30 min; the solutions were then extracted with hexane. Samples were analyzed using a Hewlett-Packard 5880 gas chromatograph with a 2-m glass column of 2-mm internal diameter packed with gp 10% SP-2330 (Supelco, Bellefontaine, PA) on 100/120 Chromosorb WAW with a level 4 integrator. The column was operated under a temperature program with an initial temperature of 165°C, increasing to 195°C, maintained for 25 min, at a rate of 2°C/min with a gas flow of 30 mL/min of helium through the column. Injection port temperature was 200°C and flame-ionization detector temperature 220°C. The fatty acid methyl esters were identified by their retention times based on the use of authentic standards from Nu-Chek-Prep (Elysian, MN). Samples were analyzed in quadruplicate.

Red cell fatty acids are reported at baseline and 8 wk only.

## RESULTS

The five patients were able to take the study emulsion for the planned 8-wk study period, and all patients chose to continue it after the formal 8-wk study period had ended.

Two patients managed a maximum tolerated dose of 100 mL/d (18 g EPA), one 150 mL/d (27 g EPA), and two 200 mL/d (36 g EPA). This maximum dose was often only tolerated for around 1 wk when patients cut the dose to one with which they were comfortable and were able to tolerate for over a month. One patient settled on 50 mL/d (9 g EPA), two around 75 mL/d (13.5 g EPA), one on 100 mL/d (18 g EPA) and one on 150 mL/d (27 g EPA). Lower doses of 25 and 50 mL/d were taken once daily by the patients. Above 50 mL/d, two or three doses were generally taken daily although one patient took up to 150 mL daily in a single daily dose.

The dosage was limited by a sensation of fullness in three patients, steatorrhea in two patients, nausea in one patient, and cramping abdominal pain in two patients. All symptoms settled with dose reduction and pancreatic enzyme supplementation as appropriate. All patients required pancreatic enzyme supplementation by the end of the study period.

**TABLE 2**
**EPA Emulsion Consumption and Fatty Acid Incorporation in Five Evaluable Patients with Advanced Pancreatic Cancer**

| Period of EPA consumption (wk) | Total EPA consumed (g) | Plasma phospholipids | | | | | | Red blood cell phospholipids | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|

Patient survival from the time of study enrollment was 116, 160, 191, 203, and 232 d. The four longest-surviving subjects continued to take the EPA emulsion until the week of their demise. All patients died from progression of their disease. No consistent changes were noted in measured biochemical and hematological parameters. In particular, no patient had any change in clotting or platelet count outside the normal range. Prior to enrollment, patients had been losing weight at a median rate of 1.2 kg/mon (range 0.6–1.9). Two patients gained weight over the 8-wk study period (2 and 2.5 kg) and three patients continued to lose weight (0.9, 1.1 and 2.6 kg). Parallel changes in anthropometry were noted. Karnofsky performance status was stable or improved in all five patients over the study period.

Results of fatty acid analysis of plasma and red blood cell phospholipids are shown in Table 2. Large increases in the percentage of EPA in plasma phospholipids were achieved, from a median of 1.5 at baseline in those who had not previously received fish oil supplementation to 10.3% (range 8.4–17.6%) at 4 wk and 18.5% (range 13.6–22.6%) at 8 wk. Owing to the small number of patients included in this study, it was not possible to establish a clear relationship between the quantity of emulsion consumed and the EPA level achieved over this period. After 4 mon of consuming the supplement, three subjects underwent further measurement of plasma phospholipid fatty acids revealing EPA levels of 10.7, 15.3, and 20.3% at a long-term daily dose of emulsion of approximately 75 mL (13.5 g EPA), 100 mL (18 g EPA), and 150 mL (27 g EPA), respectively. Incorporation of EPA into red cell phospholipids was less marked, from an initial median of 0.8% in those who had not previously received fish oil to 7.3% (range 2.0–13.7%) at 8 wk. After 4 mon in the three sampled patients EPA levels were 10.5, 7.2, and 14.8%.

## DISCUSSION

The present study has demonstrated that large doses of EPA may be tolerated by advanced cancer patients in emulsion form. A dose of 100 mL (18 g EPA) was tolerated by most patients for a substantial period. Such a dose would require the consumption of twenty 1-g capsules of high-purity EPA or around 100 1-g capsules of fish oil daily. Eighteen fish oil capsules daily have been taken for several months by patients with advanced cancer and cardiovascular disease (15,18,23), and doses of around 6 g/d of high-purity EPA have been taken by those with cancer (16). A liquid fish oil preparation has been taken at a dose of 50 mL daily in cardiovascular disease without side effects (24,25). The dose tolerated in the present study thus represents a large increase in the dose that may be administered easily.

The side effects observed in the present study are perhaps predictable considering the intervention group and the product administered. Patients with pancreatic cancer frequently suffer from malabsorption, particularly of fat, due to a combination of organ destruction and duct blockage (26). The administration of substantial doses of EPA increased lipid consumption, resulting in symptoms of malabsorption in all patients. However, these were easily controlled by pancreatic enzyme supplements and dose reduction if necessary.

No adverse events related to bleeding were observed, and all clotting measurements remained within the normal range. It has been suggested that the formation of thromboxanes and

prostaglandins from EPA rather than arachidonic acid may result in a bleeding tendency due to their potential effect in prolonging bleeding time and inhibiting platelet function (27). However, only one study has found this to be a clinically significant problem with an increased rate of epistaxis in hyperlipidemic adolescents given fish oil (28).

Although EPA has been shown to affect human tumor growth in animal models, this could not be assessed from the present study without a control group. All patients in the present study died from progress of their cancer despite the consumption of a large quantity of EPA over several months. Clearly, EPA alone is not a cure for cancer, but further controlled studies may be worthwhile to assess an effect on tumor growth. It has been suggested that in cell culture EPA will increase the sensitivity of leukemia cells to the cytotoxic drug adriamycin (29); thus combination therapy may be of benefit.

Diol lipids similar to the trial preparation are found in the normal diet in small quantities (30). The results of fatty acid analysis of plasma and red cell phospholipids suggest that the trial preparation was well absorbed. Several previous studies in healthy volunteers and those with cardiovascular disease have suggested that, after 4 wk of supplementation with fish oil or EPA providing 2–10 g EPA daily, plasma phospholipid EPA will rise to around 6% (23–25). We have reported similar EPA incorporation after the provision of around 2 g EPA daily in a fish oil preparation to patients with pancreatic cancer (15,17). A plasma phospholipid EPA of around 10% was achieved in patients with pancreatic cancer after consumption of 6 g high-purity EPA daily for 4 wk (16). In Eskimos with a high intake of n-3 polyunsaturated fatty acids, EPA has been reported to make up around 7% of plasma phospholipids (31). A mixed group of 22 cancer patients was reported as tolerating a dose of around 21 1-g fish oil capsules (providing approximately 8 g EPA) daily for about 1 mon (32). We are not aware of previous reports of the level of incorporation of EPA achieved in the present study with EPA representing around 20% of plasma phospholipids after 8 wk of supplementation. Similar large increases in the proportion of EPA in red blood cell membrane phospholipids were observed in the present study although these took around 2 mon to be seen and did not reach the same levels as in plasma phospholipids. The reason for this was not clear. There was also an increase in the proportion of docosapentaenoic acid in phospholipids in the present study, however, levels of the other main n-3 fatty acid docosahexaenoic acid fell in keeping with the known lack of appreciable conversion of EPA to DHA in humans consuming high amounts of n-6 fatty acids (33).

In summary, the present study has demonstrated that doses of around 100 mL daily of a novel emulsion preparation of EPA (providing around 18 g EPA daily) can be tolerated by weight-losing patients with advanced pancreatic cancer. Such large doses appear to be absorbed and result in previously unreported levels of EPA incorporation into plasma phospholipids of around 20% after an 8-wk dose escalation period. Such tolerance and incorporation suggest that this preparation may be used in clinical studies to explore further the potential antitumor effects of EPA previously established in *in vitro* and in animal models.

# Effects of Carp and Tuna Oils on 5-Fluorouracil-Induced Antitumor Activity and Side Effects in Sarcoma 180-Bearing Mice

**Yoshiyuki Kimura[a,*], Takeshi Takaku[b], Shigeru Nakajima[c,1], and Hiromichi Okuda[a]**

[a]Second Department of Medical Biochemistry and [b]Central Research Laboratory, School of Medicine, Ehime University, Ehime 791-0295, Japan, and [c]St. Katarina Women's University, Ehime, 799-2431, Japan

**ABSTRACT:** In this study, we examined the effects of fish oils on 5-fluorouracil (5-FU)-induced antitumor activity in mice. First, we examined the antitumor activity of the oral administration of two fish oils (carp oil and tuna oil) in sarcoma 180-bearing mice. Carp oil (0.2 and 0.4 mL/mouse) and tuna oil (0.2 and 0.4 mL/mouse) had no effects on tumor growth. Next, we examined the combined effects of 5-FU plus two fish oils (carp oil and tuna oil) on the antitumor activity and side effects compared to the effects of 5-FU alone (12.5 mg/kg/d). We found that carp oil (0.4 mL/mouse) or tuna oil (0.2 or 0.4 mL/mouse) enhanced the ability of 5-FU (12.5 mg/kg/d) to prevent tumor growth, without increasing side effects such as myelotoxicity and immunocompetent organ toxicity. Tuna oil (0.2 mL/mouse) slightly reduced body weight as compared to the effects of 5-FU alone and water alone (control). The area under the curve (AUC) (0–120 min) of blood 5-FU levels was reduced by the oral co-administration of 5-FU with carp oil or tuna oil. Apparent $T_{max}$ was shortened by the oral co-administration of 5-FU with carp oil or tuna oil. On the other hand, AUC (0–4 h) of 5-FU incorporation into tumor RNA fraction was not affected by the oral co-administration of 5-FU with carp oil or tuna oil.

Paper no. L8256 in *Lipids 36,* 353–359 (April 2001).

Fish oils that contain high amounts of the n-3 polyunsaturated fatty acids eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) have been suggested to decrease the risk of development of cardiovascular disease (1). The freshwater carp has long been used in Korea, China, and Japan as a health food. In ancient Chinese medicine, carp was eaten as a diuretic and as a remedy for eye fatigue. In Japan, carp meat, oil, and blood have traditionally been consumed as tonics. The fatty acid composition of carp oil has not been reported. But freshwater fish usually are not rich in n-3 polyunsaturated fatty acids (PUFA). Tuna fish is also widely eaten, and it is rich in n-3 PUFA such as EPA and DHA (2). EPA and DHA reportedly have antitumor activities in tumor-bearing animals *in vivo* and inhibit tumor cell growth *in vitro* (3–6), and inhibit tumor metastasis and angiogenesis (7,8). Thus, there are suggestions that fatty acids found in fish have inhibitory effects on tumor growth. Therefore, to clarify whether fish oils have antitumor activity, we examined the effects of fish oils with high and low n-3 PUFA content on tumor growth in sarcoma 180-bearing mice, and compared their effects on the antitumor activity of 5-fluorouracil (5-FU). 5-FU was first synthesized by Duschinskey *et al*. (9) and has been used extensively in the treatment of certain types of cancer (10–13). It is well known that gastrointestinal toxicity (14), immunotoxicity (15–17), and myelotoxicity (18) are caused by the administration of high doses of 5-FU *via* its phosphorylation. In this study, we examined the antitumor activity and side effects of the combination of 5-FU and two fish oils (from freshwater carp and saltwater tuna) in sarcoma 180-bearing mice.

## MATERIALS AND METHODS

*Materials.* Carp oil, and oil prepared from the orbital adipose tissue of tuna, were supplied by Carp Food Co. (Tottori, Japan) and Maruho Co. (Tokyo, Japan), respectively. 5-FU was purchased from Wako Pure Chemical Inc. (Osaka, Japan). 5-[6-$^3$H]Fluorouracil (specific activity: 462.5 GBq/mmol) was purchased from NEN Life Science Products Inc. (Boston, MA). Other chemicals were of reagent grade. Dulbecco's modified Eagle's medium was purchased from Nissui Co. (Tokyo, Japan). Sarcoma 180 was maintained in the laboratory of the Second Department of Medical Biochemistry, School of Medicine, Ehime University. Sarcoma 180 was cultured for 7 or 10 d and used in Experiments 1 and 2, respectively.

*Analysis of fatty acids in carp oil and tuna oil.* Fatty acid composition was determined according to the method of Nelson *et al*. (19). Briefly, the total lipid extracts were transmethylated at 90°C for 2 h by adding 7% methanol/HCl (5 mL). The fatty acid methyl esters were then extracted with *n*-hexane and analyzed by gas–liquid chromatography (GC-14B, Shimadzu Co., Kyoto, Japan) under the following conditions: column: 0.25 mm i.d. × 25 m length (capillary column, Shinwa Chemical Industries Ltd., Tokyo, Japan); carrier gas flow rate: 1.5 mL/min (helium), column temperature: 250°C; injection and flame-ionization detector temperatures: 200°C.

Abbreviations: AUC, area under the curve; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; 5-FU, 5-fluorouracil; HPLC, high-performance liquid chromatography; PCA, perchloric acid; PUFA, polyunsaturated fatty acid; T/C, (mean tumor volume in drug-treated animals)/(mean tumor volume in sarcoma 180-bearing mice).

The compositions of fatty acids in the carp and tuna oils are shown in Table 1.

*Animals.* Male ICR strain mice (6 wk old) were obtained from Clea Japan Co. (Osaka, Japan). ICR mice were housed in a room maintained at 25 ± 1°C with 60% relative humidity and given free access to food and water. The room was illuminated for 12 h per day starting at 7:00 A.M. The treatment of animals was performed according to the ethical guideline of the Animal Center, School of Medicine, Ehime University.

*Measurement of antitumor activity of fish oil, 5-FU, and 5-FU plus fish oils in sarcoma 180-bearing mice.* The antitumor activity of two fish oils, 5-FU, or 5-FU plus fish oils, was studied in two separate experiments. *(i) Experiment 1.* Solid-type sarcoma 180 was prepared by subcutaneous transplantation of $1 \times 10^6$ cells into the right abdomen of mice on day 0. One of the two fish oils (0.2 or 0.4 mL/mouse) was orally administered daily for 14 consecutive days, starting 12 h after implantation of tumor cells. Control mice were given distilled water solution alone on the same schedule. The volume of tumor growth was determined by direct measurement with calipers and calculated by the formula (length × width$^2$/2) every 2 or 3 d. On day 15, blood was obtained by venous puncture under anesthesia with diethyl ether, and then tumor was removed and weighed for evaluation of antitumor activity. *(ii) Experiment 2.* 5-FU (12.5 mg/kg/d) or 5-FU (12.5 mg/kg) plus one of the fish oils (0.2 or 0.4 mL/mouse) was orally administered daily for 14 consecutive days, starting 12 h after implantation of tumor cells cultured for 10 d. The following procedures were performed by the same methods described above.

*Side effects such as myelotoxicity, immunotoxicity and gastrointestinal toxicity of fish oils (Experiment 1), 5-FU, and 5-FU plus fish oils (Experiment 2) in sarcoma 180-bearing mice.* On day 15, blood was obtained by venous puncture under anesthesia with diethylether, and then small intestine, liver, epididymal adipose tissue, spleen, and thymus were removed and weighed. Blood samples were collected into chilled test tubes containing heparin, and the numbers of leukocytes, red cells, and platelets were measured using a Coulter Counter (Japan Scientific Instruments Co. Ltd., Tokyo, Japan).

*Measurement of 5-FU in blood of sarcoma 180-bearing mice.* 5-FU (12.5 mg/kg), 5-FU plus carp oil (0.4 mL/mouse), or 5-FU plus tuna oil (0.2 mL/mouse) was administered orally to mice. Blood taken by venous puncture under anesthesia 5, 15, 30, 60, 90 and 120 min after the administration of 5-FU, 5-FU plus carp oil, or 5-FU plus tuna oil was centrifuged at 1500 × *g* for 10 min at 4°C to separate the plasma. The plasma sample (0.4 mL) was shaken with 3 mL of chloroform for 10 min. The mixture was centrifuged at 1500 × *g* for 10 min at 4°C, and the organic phase was removed. 5-FU in the remaining aqueous layer was extracted twice with 4 mL of ethyl acetate, and the ethyl acetate extract was concentrated at 40°C under a stream of nitrogen gas. Then the residues were dissolved in distilled water, and the 5-FU contents were determined by reversed-phase high-performance liquid chromatography (HPLC) under the following chromatographic conditions: monitoring wavelength, 280 nm; flow rate, 1 mL/min; the internal standard, uracil, was added to the blood sample prior to the extraction; mobile phase, 5 mM tetrabutylammonium hydroxide solution containing 2% methanol adjusted to about pH 5 with dilute formic acid. Recovery of added 5-FU from the blood was 95%.

*Measurement of 5-FU incorporation into RNA fractions of tumor tissues in sarcoma 180-bearing mice.* [6-$^3$H]5-FU (12.5 mg/kg; 18.5 MBq/kg), [6-$^3$H]5-FU (12.5 mg/kg; 18.5 MBq/kg) plus carp oil (0.4 mL/mouse), or [6-$^3$H]5-FU plus tuna oil (0.2 mL/mouse) was administered to sarcoma 180-bearing mice on day 8 after tumor implantation. The mice were killed 0.25, 0.5, 1.0, 1.5, 2.0 and 4 h after the oral administration of [6-$^3$H]5-FU, [6-$^3$H]5-FU plus carp oil, or [6-$^3$H]5-FU plus tuna oil, and then their tumor tissues were removed and promptly frozen and stored at −80°C until use. Tumor tissue (500 mg) was homogenized with 5 vol of cold 10% perchloric acid (PCA) and centrifuged at 1500 × *g* for 10 min at 4°C. The radioactivity incorporated into the RNA fraction present in the PCA-precipitable material was extracted using a slight modification of the method of Schneider (20) for determination of the amount of 5-FU incorporated into RNA. [6-$^3$H]5-FU incorporation into RNA was determined by liquid scintillation counting.

*Statistical analysis.* All values are expressed as mean ± standard error (SE). Statistical analysis was performed with Dunnet's test to determine significance using Super ANOVA Software. The areas under the curve (AUC) were calculated using PK for Mac version 2.0 Software (Meiji Seika Pharmaceutical Research Center, Tokyo, Japan).

**TABLE 1**
**Fatty Acid Components of Carp Oil and Tuna Oil**

| Fatty acid composition (%) | Carp oil | Tuna oil |
|---|---|---|
| Myristic acid (14:0) | 2.0 | — |
| Palmitic acid (16:0) | 23.8 | 17.9 |
| Palmitoleic acid (16:1n-7) | 7.8 | — |
| Stearic acid (18:0) | 3.3 | 3.8 |
| Oleic acid (18:1n-9) | 36.6 | 17.5 |
| Linoleic acid (18:2n-6) | 18.2 | 3.7 |
| Arachidonic acid (20:4n-6) | — | 1.9 |
| Eicosapentaenoic acid (EPA) (20:5n-3) | 0.9 | 7.7 |
| Docosahexaenoic acid (DHA) (22:6n-3) | 2.3 | 26.1 |
| Others | 5.1 | 21.4 |

## RESULTS

*Antitumor and side effects of two fish oils (carp oil and tuna oil) in sarcoma 180-bearing mice (Experiment 1).* As shown in Figure 1 and Table 2 (Experiment 1), carp oil and tuna oil had no effect on tumor growth and final tumor weight in sarcoma 180-bearing mice. The weight of spleen and thymus was not affected by the administration of carp oil (0.2 and 0.4 mL/mouse) or tuna oil (0.2 and 0.4 mL/mouse) in sarcoma 180-bearing mice (Table 3). The weight of liver, adipose tissue, and small intestine and the number of blood cells (leukocyte, red cell, and platelet) were not affected by the administration of two fish oils (data not shown).

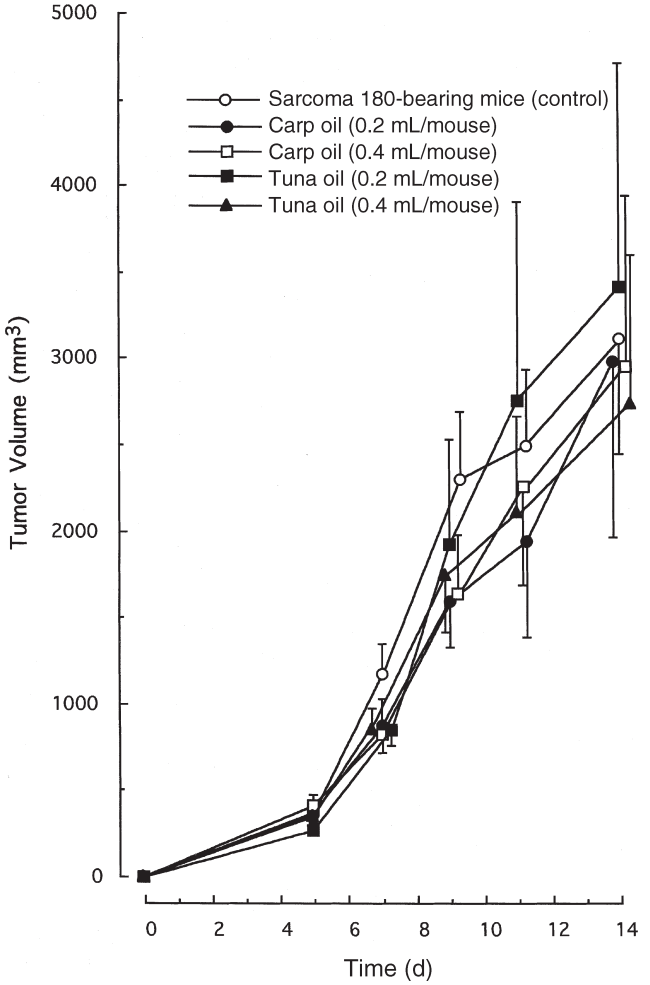

**FIG. 1.** Effects of carp oil and tuna oil on tumor growth in sarcoma 180-bearing mice (Experiment 1). Results are expressed as mean ± SE of 10 mice in each group.

*Antitumor and side effects of the combination of 5-FU (12.5 mg/kg/d) and carp oil or tuna oil (Experiment 2).* When 5-FU (12.5 mg/kg) was administered to sarcoma 180-bearing mice for 14 consecutive days, antitumor activities [T/C, (mean tumor volume in drug-treated animals/mean tumor volume in sarcoma 180-bearing mice (control)] were 40.9, 69.0, 61.4, 67.6, and 58.4 %, respectively, on days 5, 7, 10, 12 and 14 (Fig. 2). The T/C of final tumor weight was 64.5% (Fig. 3). In addition, the side effects such as myelotoxicity, immunocompetent organ toxicity and reduction of body weight did not occur. As shown in Figure 4, body weight was not affected by the combination of 5-FU (12.5 mg/kg/d) plus carp oil (0.2 or 0.4 mL/mouse). On the other hand, 5-FU plus tuna oil (0.2 mL/mouse) slightly reduced the body weight, as compared with sarcoma 180-bearing mice (control group) (Fig. 4). Tumor growth was inhibited by the combination of 5-FU plus carp oil (0.4 mL/mouse) (Figs. 2A and 3), and T/C of tumor volume for 5-FU plus carp oil (0.4 mL/mouse) were 41.6, 66.6, 54.8, 54.8, and 29.3%, respectively, on days 5, 7, 10, 12, and 14. The T/C of final tumor weight for 5-FU plus carp oil (0.4 mL) was 24.6%. Thus, the combination of carp oil plus 5-FU enhanced the antitumor activity induced by 5-FU alone. The T/C of tumor volume for the co-administration of 5-FU plus tuna oil (0.2 mL/mouse) were 25.9, 40.1, 39.6, 44.3, and 37.4%, respectively, on days 5, 7, 10, 12, and 14. Furthermore, the T/C of tumor volume for 5-FU plus tuna oil (0.4 mL/mouse) were 13.9, 26.4, 35.5, 34.5, and 27.4 %, respectively, on days 5, 7, 10, 12 and 14. The final T/C of tumor weight for the 5-FU plus tuna oil (0.2 mL) and 5-FU plus tuna oil (0.4 mL/mouse) were 24.5 and 17.6%, respectively. Thus, the dose of 0.2 and 0.4 mL/mouse of tuna oil plus 5-FU enhanced the antitumor activity induced by 5-FU alone. As shown in Table 3 (Experiment 2), the weight of spleen and thymus was not affected by the combination of 5-FU plus

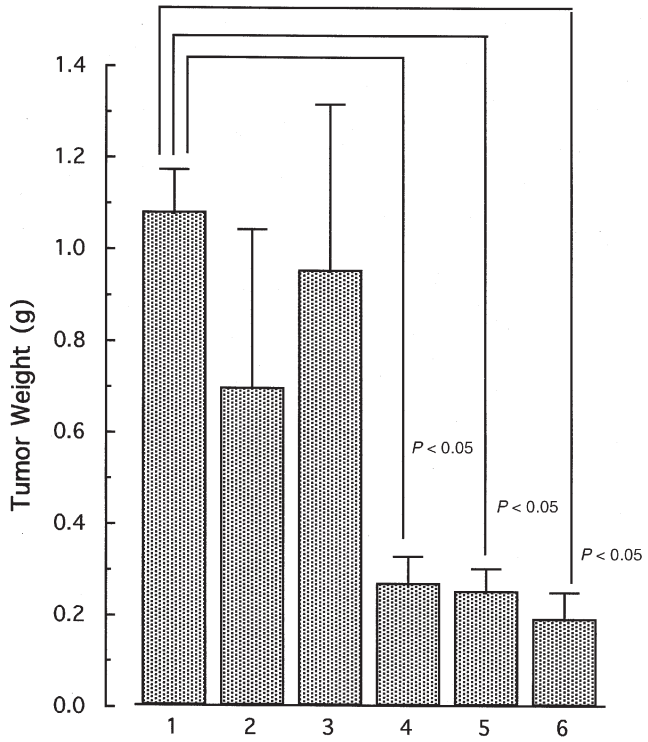

**FIG. 3.** Effects of the combination of 5-FU plus carp oil or tuna oil on tumor weight on day 15 in sarcoma 180-bearing mice (Experiment 2). Results are expressed as mean ± SE of 9 or 10 mice in each group. 1 = Sarcoma 180-bearing mice (control); 2 = 5-FU (12.5 mg/kg); 3 = 5-FU plus carp oil (0.2 mL/mouse); 4 = 5-FU plus carp oil (0.4 mL/mouse); 5 = 5-FU plus tuna oil (0.2 mL/mouse); 6 = 5-FU plus tuna oil (0.4 mL/mouse). See Figure 2 for abbreviation.

carp oil or 5-FU plus tuna oil (Table 3). The weight of liver, adipose tissue, and small intestine, and the number of leukocytes, red cells, and platelets were not affected by the combination of 5-FU plus two fish oils (data not shown).

*5-FU levels in the plasma of sarcoma 180-bearing mice after oral co-administration of 5-FU plus carp oil or 5-FU plus tuna oil.* As shown in Figure 5, the 5-FU levels in the blood of mice were about 133.8 ± 27.5 and 285.0 ± 19.3 ng/mL, respectively, at 5 and 15 min after the oral administration of 5-FU (12.5 mg/kg) and then decreased rapidly. Apparent $C_{max}$ and AUC (0–120 min) for the 5-FU administration were 285.0 ± 19.3 ng/mL and 138.16 ng·h/mL, respectively. On the other hand, the blood 5-FU levels after the co-administration of 5-FU plus carp oil (0.4 mL/mouse) were 99.7 ± 42.4, 48.9 ± 15.6, 39.9 ± 17.2, and 18.6 ± 9.75 ng/mL, respectively, at 5, 15, 30, and 60 min (Fig. 5). The apparent $C_{max}$ and AUC (0–120 min) for the 5-FU plus carp oil co-administration were 99.7 ± 42.4 ng/mL and 48.29 ng·h/mL, respectively. The blood 5-FU levels after the co-administration of 5-FU plus tuna oil (0.2 mL/mouse) were 376.4 ± 172.1, 182.6 ± 113.0, 33.9 ± 2.10, and 22.8 ± 5.73 ng/mL, respectively, at 5, 15, 30, and 60 min (Fig. 5). The apparent $C_{max}$ and AUC (0–120 min) for the 5-FU plus tuna oil were 376.4 ± 172.1 ng/mL and 97.83 ng·h/mL (Fig. 5). Thus, the apparent $T_{max}$ of the blood 5-FU was rapidly enhanced by the oral

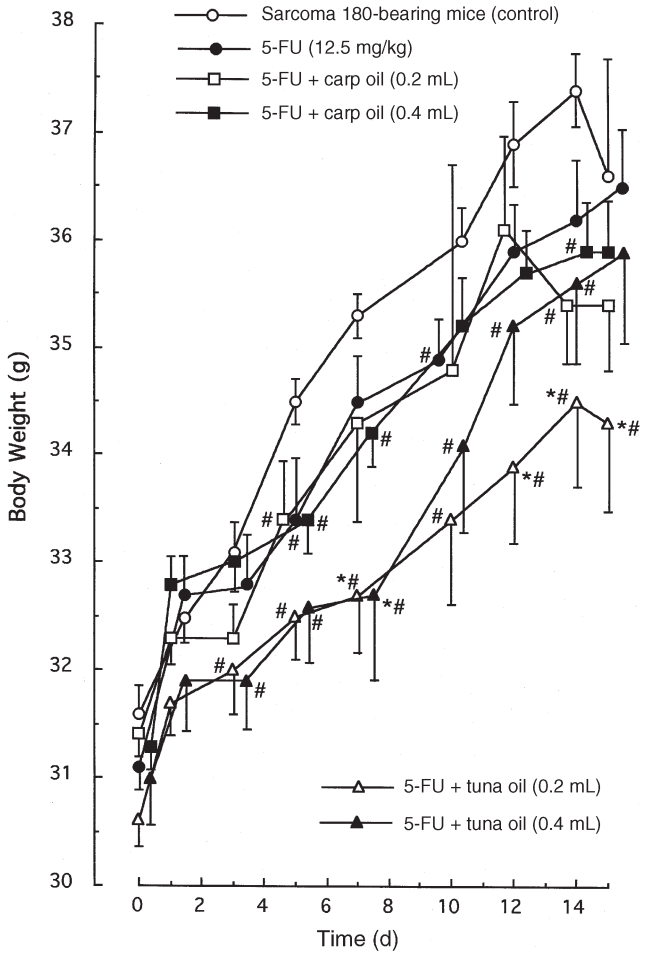

**FIG. 4.** Effects of the combination of 5-FU plus carp oil or 5-FU plus tuna oil on body weight of sarcoma 180-bearing mice (Experiment 2). Results are expressed as mean ± SE of 9 or 10 mice in each group. #Significantly different from sarcoma 180-bearing mice (control), $P < 0.05$. *Significantly different from 5-FU-treated group, $P < 0.05$. See Figure 2 for abbreviation.

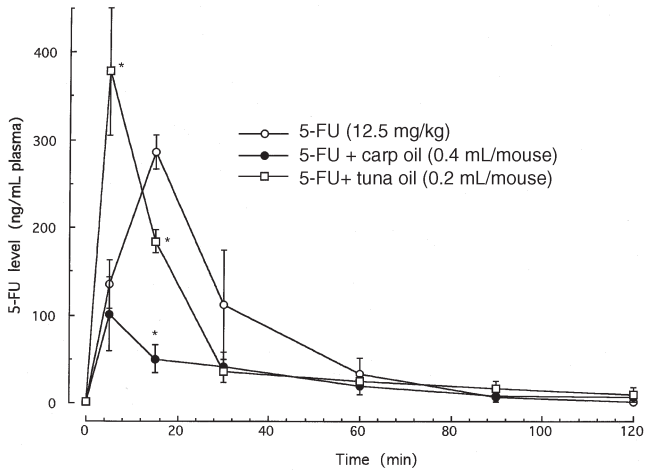

**FIG. 5.** 5-FU levels in the plasma of mice after oral co-administration of 5-FU plus carp oil or 5-FU plus tuna oil. Results are expressed as mean ± SE of five mice in each group. *Significantly different from the administration of 5-FU alone, $P < 0.05$. See Figure 2 for abbreviation.

co-administration of 5-FU with carp oil or tuna oil as compared with that of 5-FU alone. Apparent $C_{max}$ and AUC (0–120 min) of the blood 5-FU levels were significantly ($P < 0.05$) reduced by the oral co-administration of 5-FU with carp oil. In contrast, apparent $C_{max}$ of the 5-FU levels were significantly ($P < 0.05$) increased by the oral co-administration of 5-FU with tuna oil, while AUC (0–120 min) of the blood 5-FU levels after co-administration of 5-FU plus tuna oil slightly decreased as compared to that of 5-FU alone.

*Effects of fish oils on 5-FU incorporation into RNA fractions of tumor tissue in sarcoma 180-bearing mice.* As shown in Figure 6, 5-FU incorporation into RNA fractions of tumor tissue was about 2.35, 3.31, 5.34, 4.59, and 3.62 ($\times 10^3$) dpm/g tumor tissue, respectively, at 15 min, 30 min, 1 h, 2 h, and 4 h after the oral administration of [6-$^3$H]5-FU (12.5 mg/kg; 18.5 MBq/kg). The apparent $T_{max}$, $C_{max}$, and AUC (0–4 h) for the [6-$^3$H]5-FU administration were 1 h, 5.34 ± 1.84 ($\times 10^3$) dpm/g tumor tissue, and 16.70 ($\times 10^3$) dpm·h/g tumor tissue, respectively. The 5-FU incorporation into RNA fractions after the oral co-administration of [6-$^3$H]5-FU plus carp oil (0.4 mL) was 1.10, 1.12, 6.22, 4.73, and 4.07 ($\times 10^3$) dpm/g tumor tissue, respectively, at 15 min, 30 min, 1 h, 2 h, and 4 h (Fig. 6). The apparent $T_{max}$, $C_{max}$, and AUC (0–4 h) for the [6-$^3$H]5-FU plus carp oil were 1 h, 6.22 ± 1.39 ($\times 10^3$) dpm/g tumor tissue, and 17.25 ($\times 10^3$) dpm·h/g tumor tissue, respectively. The 5-FU incorporation into RNA fractions after the oral co-administration of [6-$^3$H]5-FU plus tuna oil (0.2 mL/mouse) was 3.60, 3.53, 3.96, 5.86, and 3.22 ($\times 10^3$) dpm/g tumor tissue at 15 min, 30 min, 1 h, 2 h, and 4 h (Fig. 6). The apparent $T_{max}$, $C_{max}$, and AUC (0–4 h) for the 5-FU plus tuna oil co-administration, were 2 h, 5.86 ± 1.50 ($\times 10^3$) dpm/g tumor tissue and 16.77 ($\times 10^3$) dpm·h/g tumor tissue, respectively. Thus, the apparent $T_{max}$ of 5-FU incorporation into RNA fractions was lengthened by the oral administration of

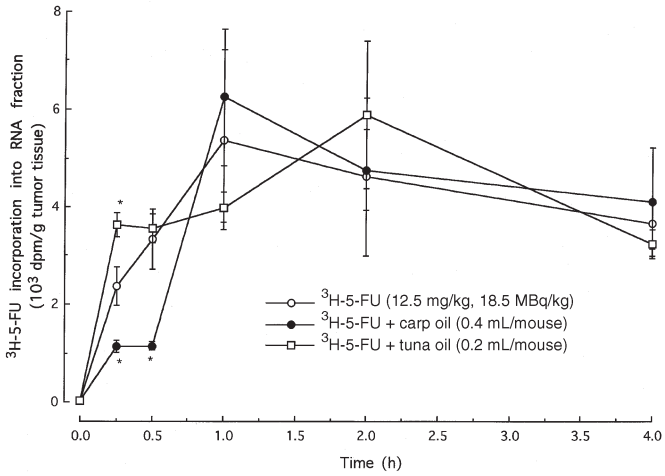

**FIG. 6.** [6-$^3$H]5-FU incorporation into RNA fractions of tumor after oral co-administration of [6-$^3$H]5-FU plus carp oil or [6-$^3$H]5-FU plus tuna oil. Results are expressed as mean ± SE of five mice in each group. *Significantly different from the administration of 5-FU alone, $P < 0.05$. See Figure 2 for abbreviation.

5-FU plus tuna oil, On the other hand, the apparent $T_{max}$ of 5-FU incorporation into RNA fractions was not affected by the oral administration of 5-FU plus carp oil. However, the apparent $C_{max}$ and AUC (0–4 h) were not shown to be different between the 5-FU-treated group and 5-FU plus carp oil group or 5-FU plus tuna oil group.

## DISCUSSION

In the present study, no antitumor activity was shown when carp oil (0.2 and 0.4 mL/mouse) or tuna oil (0.2 and 0.4 mL/mouse) was administered to sarcoma 180-bearing mice for 14 consecutive days. On the other hand, when 12.5 mg/kg/d of 5-FU was administered to sarcoma 180-bearing mice for 14 consecutive days, antitumor activities (T/C) were 40.9, 69.0, 61.4, 67.6, and 58.4%, respectively, on days 5, 7, 10, 12, and 14. The final T/C of tumor weight for 5-FU (12.5 mg/kg) was 64.5%. In addition, side effects such as myelotoxicity, immunocompetent organ toxicity, and the reduction of body weight did not occur. Therefore, to determine the enhancing effects of the two fish oils on the 5-FU-induced antitumor activity, we used the dose of 12.5 mg/kg/d of 5-FU, a dose which produced about 35–60% antitumor activity and did not cause side effects. The present study indicated that carp oil (0.4 mL/mouse) or tuna oil (0.2 or 0.4 mL/mouse) prevented tumor growth when combined with 5-FU (12.5 mg/kg/d) without side effects such as myelotoxicity (reduction of number of platelets, red cells, and leukocytes) or immunocompetent organ toxicity (reduction of spleen and thymus weights). Carp oil did not affect body weight, whereas tuna oil (0.2 mL/mouse) slightly reduced the body weight as compared to the effects of 5-FU alone. It was found that carp oil (0.4 mL/mouse) and tuna oil (0.2 and 0.4 mL/mouse) with 5-FU showed the 2.58-fold, 2.77-fold, and 3.61-fold antitumor activity, respectively, as compared with 5-FU alone. Thus, the present study showed that two fish oils containing unsaturated fatty acids enhanced the inhibition of tumor growth in combination with 5-FU *in vivo*. To study the mechanism of the antitumor activity of the combination of 5-FU plus the two fish oils, we designed an experiment in which the blood 5-FU level and 5-FU incorporation into tumor RNA fractions after the oral co-administration of 5-FU plus carp oil or 5-FU plus tuna oil to sarcoma 180-bearing mice were determined. From pharmacokinetic analysis after the oral co-administration of 5-FU plus carp oil or 5-FU plus tuna oil, apparent $C_{max}$ and AUC (0–120 min) in the blood 5-FU levels after oral co-administration of 5-FU plus carp oil were reduced more than that after 5-FU administration alone. However, AUC (0-4 h) of [6-$^3$H]5-FU incorporation into RNA fractions for the co-administration of [6-$^3$H]5-FU plus carp oil was similar to that of [6-$^3$H]5-FU administration. Thus, 5-FU incorporation into RNA fractions of tumor was similar to that of 5-FU alone, although the blood 5-FU level after co-administration of 5-FU plus carp oil (0.4 mL/mouse) was maintained at a low concentration. Therefore, these results suggest that the co-administration of 5-FU plus carp oil enhanced the 5-FU-induced antitumor activity without side effects. On the other hand, from the phamarcokinetic observation of 5-FU plus tuna oil (0.2 mL), 5-FU was rapidly absorbed following oral co-administration of 5-FU plus tuna oil. Furthermore, apparent $C_{max}$ of the blood 5-FU level was increased by the oral administration of 5-FU plus tuna oil, as compared with 5-FU alone. The AUC (0-4 h) of 5-FU incorporation into RNA fraction of tumor after the co-administration of 5-FU plus tuna oil was similar to that of 5-FU alone. These results suggest that the absorption of 5-FU is accelerated by the administration of tuna oil. Therefore, it seems likely that 5-FU-induced antitumor activity and side effects such as reduction in body weight may be caused by the decrease in $T_{max}$ and the increase in $C_{max}$ of the blood 5-FU levels after the co-administration of 5-FU plus tuna oil. Carp oil contained palmitic acid (22.8%), oleic acid (36.6%), linoleic acid (18.2%), and small amounts of EPA (0.9%) and DHA (2.3%). On the other hand, tuna oil contained palmitic acid (17.9%), oleic acid (17.5%), DHA (26.1%), and small amounts of linoleic acid (3.7%) and EPA (7.7%). Zhu *et al.* (21) reported that oleic acid and linoleic acid significantly prolonged the life spans of Ehrlich ascites carcinoma-bearing mice and inhibited the growth of Ehrlich solid carcinoma in mice compared with the findings in untreated control mice. And they suggested that the intraperitoneal administration of oleic acid and linoleic acid increased the contents of oleic acid and linoleic acid in phospholipids and triglycerides of tumor cells and consequently, that free fatty acids, especially unsaturated fatty acids, selectively inhibit the growth of tumor cells. There have been a number of reports that EPA and DHA have antitumor activity in tumor-bearing animals (3–6) and inhibit tumor growth (8). Yang *et al.* (8) reported that EPA inhibited vascular endothelial growth factor-induced angiogenesis in bovine carotid artery endothelial cells and suggested that the mechanism of the antitumor action of EPA may be related to its antiangiogenic action. It has been reported that DHA increases tumor permeability and uptake of cancer chemotherapy drugs such as adriamycin and mitoxanthrone and consequently enhances the sensitivity of tumor cells to the cytotoxicity of chemotherapy drugs (22–26). Ikushima *et al.* (27) reported that DHA enhanced the cytotoxic effect of vincristine twofold. Madhavi and Das (4) also reported that EPA augmented the cyototoxicity of vincristine in both vincristine-sensitive and -resistant human cervical carcinoma cells.

Therefore, it seems possible that the unsaturated fatty acids of the two fish oils might alter albumin-bindingof 5-FU or exert their effects *via* their incorporation into triglycerides or phospholipids. The unsaturated fatty acids in the fish oils, by altering the lipid composition of tumors or through some other mechanism, may enhance the susceptibility of 5-FU. Further studies are needed to identify which of the unsaturated fatty acids enhances of 5-FU-induced antitumor activity as well as the mechanisms involved. We conclude that carp oil and tuna oil enhanced the antitumor activity induced by 5-FU without increasing the side effects.

# Oxidative Stability of Low Density Lipoproteins and Vitamin E Levels Increase in Maternal Blood During Normal Pregnancy

**S.R. De Vriese[a,*], M. Dhont[b], and A.B. Christophe[a]**

Departments of [a]Internal Medicine, Division of Nutrition, and [b]Gynecology, Ghent University Hospital, Ghent, Belgium

**ABSTRACT:** In 24 healthy pregnant women, parameters related to the oxidative stability of low density lipoproteins (LDL) were determined at three times during pregnancy and shortly after delivery. The fatty acid composition of plasma phospholipids (PL) and the plasma concentrations of vitamin E, vitamin A, and β-carotene were assessed in the same samples. Total triglyceride (TG), total cholesterol, LDL-cholesterol, and high density lipoprotein (HDL)-cholesterol concentrations were also determined. The length of the lag phase of isolated LDL challenged with $Cu^{2+}$ ions significantly increased with the progression of pregnancy. The oxidation rate and the amount of conjugated dienes formed increased and reached a maximum at 29–37 wk of pregnancy. Total TG, cholesterol, and LDL-cholesterol reached a maximum in the third trimester of pregnancy. β-Carotene remained stable, vitamin A decreased, and vitamin E significantly increased throughout pregnancy. Vitamin E plasma concentration correlated positively with the length of the lag phase. The increased levels of vitamin E could contribute to the higher resistance of LDL toward oxidation with progressing gestation, measured by the prolonged lag phase. Furthermore, vitamin E plasma levels correlated positively with TG concentration but not with LDL-cholesterol. The level of polyunsaturated fatty acids in PL decreased with the progression of pregnancy. No correlation was found between the fatty acid composition of plasma PL, nor with the cholesterol concentration, and the parameters studied related to the oxidative stability of LDL. The major finding of this study is the increased oxidative resistance of LDL with progressing gestation.

Paper no. L8588 in *Lipids 36*, 361–366 (April 2001).

The third trimester of pregnancy is accompanied by hyperlipidemia. As pregnancy progressess, the maternal plasma triglyceride (TG) concentration, the low density lipoprotein (LDL) content, and total cholesterol concentration increase (1–6). Late pregnancy is also associated with the predominance of small and dense LDL-particles (3,7). These small and dense LDL-particles have been shown to be more susceptible to oxidation (8). Hyperlipidemia and the occurrence of small and dense LDL particles during late pregnancy might increase the oxidative damage and impair the outcome of pregnancy. Many studies have determined either the antioxidative defense systems or peroxidation products during pregnancy (9–12). Uncomplicated pregnancy, but especially preeclampsia and diabetic pregnancy, is associated with high serum levels of lipid peroxides (8–13). During normal pregnancy the higher levels of lipid peroxides are accompanied by higher maternal levels of vitamin E compared to nonpregnant women (9,10,12–14). However, the increase in vitamin E levels is more pronounced, i.e., the vitamin E/lipid peroxide ratio increases with progressing gestation .

The aim of this study was to determine whether the oxidative stability of LDL changes during the course of pregnancy and, if so, whether this change correlates with changes in vitamin E, vitamin A, and β-carotene levels or with changes in the fatty acid composition of plasma phospholipids (PL).

## SUBJECTS AND METHODS

Healthy pregnant women attending the Department of Gynecology were asked to cooperate in this study. All pregnant volunteers signed a written informed consent form, approved by the ethics committee of Ghent University Hospital. Only singleton pregnancies were included. Inclusion criteria were: first pregnancy, normotensive (diastolic blood pressure <90 mm Hg), not diabetic, no proteinuria, and not suffering from renal or cardiovascular disease. The study population consisted of 24 healthy pregnant women. None of the women used any medication. Maternal venous blood was collected in EDTA tubes thrice during the course of pregnancy: earlier than 18 wk of gestation (median 12 wk), between 20 and 26 wk (median 23 wk), between 29 and 37 wk (median 32 wk) and shortly after delivery (median 39 wk; range 36–41 wk). Blood samples were temporarily stored on ice, and plasma was isolated by centrifugation (600 × *g* during 5 min at 4°C) within 24 h of collection. Plasma was stored with sucrose (60%, 10 μL/mL) to prevent lipoprotein aggregation during deepfreezing (–80°C).

*Preparation and oxidation of LDL.* LDL were prepared by sequential ultracentrifugation at 4°C according to Esterbauer *et al.* (15) and isolated from the appropriate density fraction ($d$ = 1.019–1.063 g/mL). EDTA was present throughout all the steps of the isolation in a concentration of 1 mg/mL density solution. Immediately after isolation, the LDL samples

Abbreviations: HDL, high density lipoprotein; HUFA, highly unsaturated fatty acids (fatty acids with ≥20 carbon atoms and ≥3 double bonds); LDL, low density lipoproteins; PL, phospholipids; PUFA, polyunsaturated fatty acids; TG, triglyceride; *T*lag, length of the lag phase; *T*max, length of time required to obtain maximum levels of conjugated dienes.

were dialyzed at 4°C for 24 h against four changes of buffer (0.01 M $Na_2HPO_4$, 0.0022 M $NaH_2PO_4$, 0.16 M NaCl, 10 μM EDTA, and 0.1 μg/mL chloramphenicol; pH 7.4) which was made oxygen-free by vacuum degassing and subsequently was continuously purged with nitrogen. The protein content of the LDL fraction was determined according to Lowry *et al.* (16) with fatty acid-free serum albumin as standard. The concentration was initially adjusted to 500 mg/L with dialysis buffer. This solution was further diluted 10-fold in a quartz cuvette with EDTA and chloramphenicol-free phosphate buffer at a final protein concentration of 50 μg/mL.

Oxidation was initiated by addition of $CuCl_2$ (10 μM, in cuvette). The formation of conjugated dienes was determined by monitoring the change of absorbance at 234 nm at 30°C. The optical density was recorded every 3 min during a 3-h period. From the absorbance curve the following parameters were derived: length of the lag phase (*T*lag); length of the time required to obtain maximum levels of conjugated dienes (*T*max); length of the propagation phase, oxidation rate, and maximal amount of conjugated dienes formed. *T*lag (expressed in minutes) or the length of the lag phase is defined as the time interval between the addition of $CuCl_2$ to initiate oxidation and the onset of rapid oxidation. *T*max (expressed in minutes) is the time at which the absorbance reaches a maximum. After reaching the maximum value, the conjugated dienes slowly decreased by decomposition. The length of the propagation phase (during which the absorbance rapidly increases to a maximum) is the difference between *T*max and *T*lag. The oxidation rate was calculated from the slope of the tangent to the curve during the propagation phase and is expressed as moles of dienes formed per minute per gram of LDL protein. The maximal amount of conjugated dienes formed (expressed as mol dienes/g LDL-protein) was calculated by means of the molar extinction coefficient for conjugated dienes ($\varepsilon_{234}$ = 29,500 L/mol/cm). An actual experimental curve is given in Figure 1.

*Plasma lipid analyses.* Lipids were assayed using enzymatic-colorimetric methods based upon the technique of Allain *et al.* (17) for free and total cholesterol and that of Bucolo and David (18) for TG. LDL-cholesterol was calculated by difference between total cholesterol and cholesterol in the supernatant after precipitation of LDL with dextrane sulfate (QuantolipR, Immuno AG, Wien, Austria). HDL-cholesterol was determined in the supernatant after precipitation of the other lipoproteins with different concentrations of polyethylene glycol (QuantolipR, Immuno AG).

For the determination of the fatty acid composition of plasma PL, the following method was used. Lipids were extracted from 1 mL plasma according to Folch *et al* (19). The PL were prepared by thin-layer chromatography on rhodamine-impregnated silica gel plates using petroleum ether (bp 60–80°C; Merck Belgolab, Overijse, Belgium)/acetone 85:15 as mobile phase (20). The PL band was scraped off, and the fatty acids were converted into methyl esters by transesterifications with 2 mL of a mixture of methanol/benzene/HCl (80:20:5) (21). Fatty acid methyl esters were extracted with petroleum ether (bp 40–60°C), evaporated to dryness under a nitrogen flow at a temperature not exceeding 40°C, and analyzed by temperature-programmed capillary gas chromatography (Varian Model 3500) on a 25-m × 250 μm × 0.2 μm film thickness Silar 10C column (L. Restek, Interscience, Belgium) (21). The injection and detection temperatures were set at 285°C. The starting temperature of the column was 150°C, which was increased to 240°C after 3 min at a rate of 2°C/min. The carrier gas was nitrogen with a flow of 25 cm/s. Peak identification was performed by spiking with authentic standards (Sigma-Aldrich, Bornem, Belgium). Peak integration and calculation of the percentage composition were performed electronically with a Varian Model 4290 integrator.

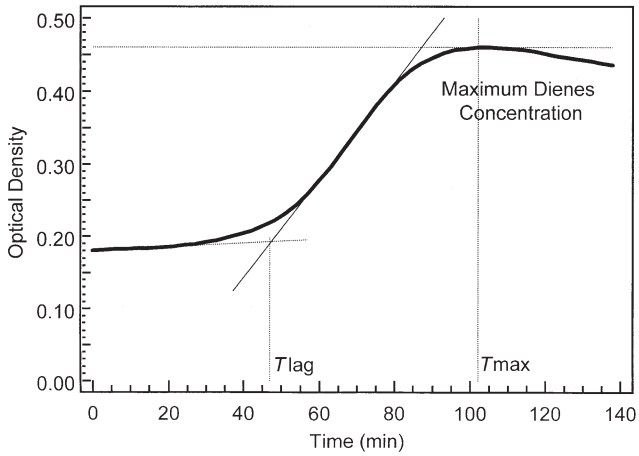

**FIG. 1.** Kinetics of density lipoprotein oxidation (actual experimental curve). *T*lag, length of the lag phase; *T*max, length of time required to obtain maximal levels of conjugated dienes.

*Plasma levels of lipid-soluble vitamins with antioxidant activity*. The concentrations of vitamin E, vitamin A, and β-carotene in plasma were measured by high-performance liquid chromatography as described by Catignani and Bieri (22). Peak identification was performed using the following standards: *d*-α-tocopherol, all-*trans*-retinol, and β-carotene (Sigma-Aldrich).

*Statistical analysis.* Normality of distribution was ascertained with the Kolmogorov-Smirnov test. Parameters related to LDL oxidative stability were log-transformed whereas the fatty acid fractions were arcsin transformed to reach normality of distribution. The vitamin levels (vitamin E, vitamin A, and β-carotene) had a normal distribution. Values are reported as mean (standard deviation). Differences in LDL oxidative stability-related parameters, in fatty acid composition of PL, and in vitamin levels between the first trimester and later stages in pregnancy or delivery were tested using the paired Student *t*-test. In order to avoid type 2 errors, due to multiple comparisons, a value of $P < 0.01$ was taken as the criterion of significance. Multiple regression and Spearman rank correlation coefficients were calculated to study the degree of association between LDL oxidative stability and antioxidant status-related parameters or plasma lipid concentrations. Trends during gestation were evaluated by computing Spearman's

rank correlation coefficients between gestational age and vitamin levels or plasma lipid concentrations. For the calculation of the correlation coefficients, samples from the same subject collected at different gestational ages were considered as independent samples. The data were analyzed using the MedCalc statistical program, version 6 (MedCalc Software, Mariakerke, Belgium) (23).

## RESULTS

*Clinical characteristics of the study population.* The mean age of the mothers at delivery was 30 yr (range 25–41 yr). The mean Body Mass Index of the women before pregnancy was 24.2 kg/m$^2$ (range 17.6–35.6 kg/m$^2$), and mean weight gain at delivery was 15 kg (range 7–23 kg). All pregnant women were nullipara, all pregnancies were uncomplicated, and the infants were born healthy with a mean birth weight of 3365 g (range 2590–4200 g) and a mean birth length of 51.2 cm (range 47–55 cm). The median Apgar score 1 min after birth was 8 (range 4–10) and 5 min after birth 9 (range 6–10). The sex ratio of the infants was 13 males and 11 females.

*Oxidative stability of LDL.* The oxidizability-related parameters of LDL throughout gestation are summarized in Table 1. *T*lag was significantly higher at later stages of pregnancy compared to the value earlier than 18 wk of gestation. *T*lag reached a maximum in the third trimester, namely 129% (SD 41.1%) of the value at the first antenatal visit. The length of the propagation phase did not change significantly during pregnancy. The oxidation rate increased to reach a maximum in the third trimester of pregnancy: 147% (SD 64.6%) of the oxidation rate at the first antenatal visit. A similar pattern was found for the maximal amount of conjugated dienes: the value in the third trimester was 142% (SD 52.4%) of the value at the first antenatal visit.

*Fatty acid composition of plasma PL.* Table 2 summarizes the fatty acid composition of the plasma PL. The sum of the highly unsaturated fatty acids (HUFA; fatty acids with 20 or more carbon atoms and with at least 3 double bonds) of the plasma PL steadily decreased with progressing gestation whereas the sum of the saturated fatty acids was slightly higher at delivery compared to the first trimester.

No correlation was found between the fatty acid fractions of plasma PL and any of the LDL oxidative stability-related parameters studied (data not shown).

*Plasma levels of cholesterol and TG (Table 3).* Cholesterol and TG concentrations could not be determined in all the plasma samples (aliquots were too small) obtained from this study population. Significance calculations were based on paired values. The values obtained for each women from the first trimester were compared with those obtained at later stages during pregnancy. The TG concentration reached a maximum in the third trimester of pregnancy. Both total cholesterol and LDL-cholesterol increased significantly during pregnancy and reached a maximum in the third trimester. HDL-cholesterol, on the other hand, reached a maximum in the second trimester and then leveled off again. To test whether the length of the lag phase depends on the plasma TG or LDL-cholesterol concentration, multiple regression analysis was performed. No significant correlations were found between any of the above-mentioned parameters.

*Plasma levels of lipid-soluble vitamins with antioxidant activity.* As was the case for the determination of the choles-

terol concentration, vitamin plasma levels (μmol/L) could not be determined in all the plasma samples (aliquots were too small) obtained from this study population. Calculations of significance were based on paired values. The values obtained for each woman from the first trimester were compared with those obtained at later stages during pregnancy. The results are summarized in Table 4. Plasma levels of vitamin E significantly increased from the first trimester and reached a maximum in the third trimester, whereas β-carotene remained stable throughout pregnancy. Vitamin A in maternal plasma was significantly lower at delivery compared to the beginning of pregnancy. When the vitamin status of all the women over all the visits was plotted vs. gestational age, the plasma vitamin E levels were found to increase and the vitamin A levels to decrease during gestation (Fig. 2). To test whether the oxidative stability-related parameters correlated with the vitamin plasma levels, multiple regression analysis was performed.

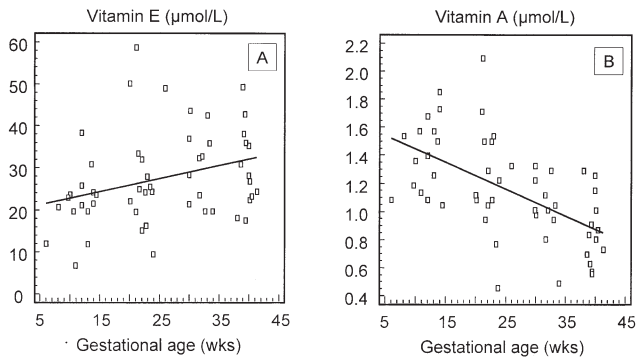

**FIG. 2.** Maternal plasma vitamin E (A) and vitamin A (B) levels (μmol/L) vs. gestational age. (Spearman's rank correlation coefficient, A: $r = 0.31$; $P = 0.025$; $n = 54$. B: $r = -0.62$; $P = 0.0001$; $n = 54$).

Only the vitamin E status correlated positively with *T*lag: $r = 0.54$; $P < 0.0001$ (Fig. 3) and with the amount of formed dienes: $r = 0.41$; $P < 0.01$. Neither vitamin A nor β-carotene correlated with the LDL oxidative stability-related parameters.

In our study population, no significant correlation was found between vitamin E plasma levels and total cholesterol or LDL-cholesterol concentration. On the contrary, vitamin E plasma levels correlated with the TG concentration during the course of pregnancy: $r = 0.41$; $P < 0.01$; $n = 49$.

## DISCUSSION

To our knowledge this is the first report on maternal plasma lipid-soluble antioxidant vitamin levels (vitamins E, A, and β-carotene) and *in vitro* formed peroxidation products (con-

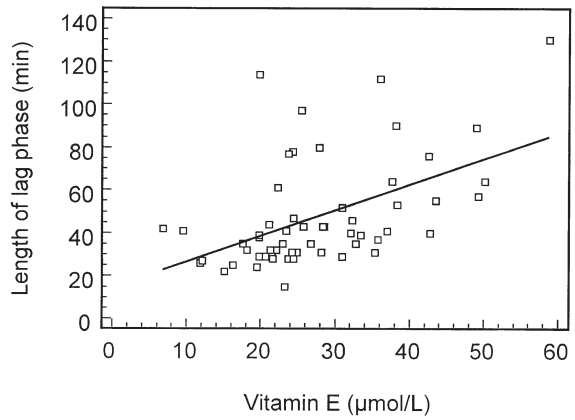

**FIG. 3.** Relation between the maternal plasma vitamin E concentration (μmol/L) and the length of the lag phase during *in vitro* oxidation of maternal low density lipoprotein (min). (Spearman's rank correlation coefficient, $r = 0.54$; $P = 0.0001$; $n = 57$).

jugated dienes of LDL), carried out in conjunction with determinations of the fatty acid compositions of maternal plasma PL at three times during normal uncomplicated pregnancy and at delivery.

Both the rate of formation and the amount of conjugated dienes formed reached a maximum in the third trimester. This could be due to a change in the composition of the LDL near the end of pregnancy. Indeed, structural changes in plasma lipoproteins during pregnancy have been described (1–7;24). An elevation of TG levels in all lipoprotein fractions during pregnancy compared to nonpregnant women was demonstrated previously (1,2,4,5). Longitudinal studies during various stages of pregnancy showed a steady rise of LDL-cholesterol and PL levels during pregnancy, which reached a maximum either at 36 wk of gestation (1) or at 2 wk postpartum (2). The observed increase in the concentration of plasma TG, cholesterol, and LDL-cholesterol in our study population is a well-known phenomenon during late pregnancy compared to early pregnancy or nonpregnant individuals (1,3–5). We observed an increase in HDL-cholesterol concentration that reached a maximum between 20 and 26 wk of gestation; others found a maximum of HDL-cholesterol at 28 wk of gestation (1).

The amount of conjugated dienes formed is a parameter for the concentration of substrate available for lipid peroxidation such as the amount of polyunsaturated fatty acids (PUFA) present in LDL. We did not determine the fatty acid composition of LDL, but it is conceivable that when the fatty acid composition of plasma PL changes there will be a related change in the LDL. In our study population the PUFA and HUFA status of plasma PL was significantly lower at delivery compared to the first trimester. No correlation was found between the fraction of PUFA or HUFA in PL and *T*lag or the amount of formed conjugated dienes.

It had been previously published that there is no correlation between the plasma α-tocopherol concentration and the α-tocopherol content of LDL (25). We found a positive correlation between *T*lag and plasma vitamin E concentrations during pregnancy. It is not clear how the higher plasma vitamin E concentrations can contribute to the higher resistance of LDL toward oxidation as measured by the prolonged lag phase. Vitamin E is tightly bound to LDL, and as LDL-cholesterol increases with progressing gestation it is expected that the vitamin E content will increase also. Our finding that vitamin E levels significantly rise during pregnancy is in line with reports by others (9,10,12–14). The observed increase in vitamin E levels during the course of pregnancy is probably not due to changes in dietary intake. Indeed, analysis of food frequency questionnaires surveyed at the beginning of pregnancy and in the third trimester of this study population revealed no significant differences in the vitamin E content of the diet, nor of the other vitamins, during the course of pregnancy (DeVriese, S.R., Matthys, C., De Henauw, S., Christophe, A.B., and Dhont, M., unpublished results). Our results suggest that when the amount of substrate available for lipid peroxidation in LDL increases (i.e., suggested by increased levels of conjugated dienes formed), the concentration of vitamin E increases also. Indeed, Esterbauer *et al*. (26) showed that the vitamin E content of LDL increases with the PUFA content of LDL. Vitamin A levels decreased with progressing gestation, as reported by others (14). We found no significant changes in maternal plasma β-carotene concentrations whereas others reported a decline in maternal β-carotene levels (14) or observed significantly higher β-carotene levels in pregnant women compared to nonpregnant women (27).

In conclusion, we report an increase in maternal plasma vitamin E levels, a decrease in vitamin A levels, and unchanged β-carotene levels during pregnancy. Furthermore, this study showed an increase in the oxidative stability of LDL with progressing gestation as measured by a prolonged lag phase after *in vitro* oxidation of isolated LDL with $Cu^{2+}$.

**ABSTRACT:** The goal of this study was to clarify the mechanism responsible for the catabolism of α-tocopherol. The vitamin, bound to albumin, was incubated with rat liver microsomes and appeared to be broken down. Optimal production of the metabolite was obtained when 1 mg of microsomal protein was incubated with 36 μM of α-tocopherol in the presence of 1.5 mM of NADPH. Chromatographic and mass spectrometric analyses of the metabolite led to the conclusion that it consists of an ω-acid with an opened chroman ring, although we could not perform nuclear magnetic resonance analysis to confirm this. Our data show that α-tocopherol is ω-oxidized to a carboxylic acid and that this process can occur in rat liver microsomes in the presence of NADPH and $O_2$. The oxidation to the quinone structure appears to be a subsequent event that may be artifactual and/or catalyzed by a microsomal enzyme(s).

Paper no. L8601 in *Lipids 36,* 367–372 (April 2001).

Owing to its antioxidant properties (1,2), α-tocopherol, the biologically most active form of vitamin E, may act to prevent the initiation or progression of spontaneous atherosclerosis (3) and to decrease the risk of certain types of cancer (4,5) and of cataracts (5). Since the idea arose of possible beneficial effects of α-tocopherol on these degenerative diseases, an increasing number of people supplement their diet with high amounts of vitamin E. Despite the absence of overt toxicity when these excessive doses are taken, the possibility of unexpected toxic effects after long-term treatment should not be overlooked. In this regard, it is important to obtain more information on the physiological breakdown and/or excretion of α-tocopherol.

Apparently, excess absorbed tocopherols are taken up in several tissues but mainly in liver, and are readily excreted in bile (6). Furthermore, metabolites of α-tocopherol were found in the urine of rats (6), rabbits (7,8), and humans (9–11) when high doses of the compound were given. Analysis of these metabolites suggested that α-tocopherol is degraded, possibly *via* ω-oxidation of the phytyl side chain followed presumably by peroxisomal β-oxidation. An alternative possibility would be a one- step scission of most of the hydrocarbon tail, but this does not seem to occur (12). To investigate whether the isoprenoid side chain of α-tocopherol is indeed first ω-oxidized to a carboxylic acid, we incubated rat liver microsomes with α-tocopherol in the presence of NADPH and $O_2$ and analyzed the oxidation products.

## MATERIALS AND METHODS

*Materials.* Ready Safe Cocktail was from Beckman Instruments (Fullerton, CA). [3,4-$^{14}$C]All-*rac* α-tocopherol (specific activity: 53.75 Ci/mol) was a generous gift from F. Hoffmann-La Roche Ltd. (Basel, Switzerland). The following products were obtained from Sigma (St Louis, MO): α-tocopherol, NADPH (tetrasodium salt), and butylated hydroxytoluene (BHT). Fatty acid-free bovine serum albumin (BSA) was from Boehringer Mannheim (Mannheim, Germany). Glutathione was obtained from Acros Organics (Pittsburgh, PA). α-Tocopheryl quinone was from ICN Biomedicals (Aurora, OH). The boron trifluoride/methanol reagent was obtained from Alltech (Deerfield, IL). Solvents were of analytical or high-performance liquid chromatography (HPLC) grade.

*Animals.* Male Wistar rats of approximately 150–200 g were used in all experiments; they were supplied and kept by the university facility for experimental animals. The rats were fed a standard laboratory diet, with unlimited access to water, and were fasted the night before the experiment. They were killed by cervical dislocation. After flushing with buffer A (see below) the liver was excised and homogenized as described below. The experimental protocol was approved by the university ethics committee.

*Tissue preparation.* Rat liver homogenates were prepared by adding three parts of cold buffer A (0.25 M sucrose/50 mM phosphate buffer pH 7.4/2.0 mM glutathione) to one part of liver (wet weight). The liver was homogenized in a Dounce hand homogenizer (8 up and down strokes with both pestle A and pestle B). After centrifugation of the homogenate at 400 × *g* for 5 min at 4°C, the resulting supernatant was centrifuged at 15,000 × *g* for 15 min at 4°C to remove most of the mitochondria, lysosomes, and peroxisomes. Microsomes were obtained by centrifuging the 15,000 × *g* supernatant at 105,000 × *g* for 60 min at 4°C (13). The resulting microsomal pellet was homogenized in buffer B [20% (vol/vol) glycerol/100 mM phosphate buffer pH 7.4/2.0 mM glutathione]. The microsomes were used on the day of preparation and were kept on ice before incubation. Protein determination was done

with the Bio-Rad protein assay (Richmond, CA) using BSA as standard (14). Although the purity of the microsomes was not routinely checked, the fractionation procedure has been in use in our laboratory for many years and yields a preparation that contains approximately 60, 20, 10, and 25% of, respectively, endoplasmic reticulum, peroxisomes/lysosomes, mitochondria, and protein of the liver (15).

*Preparation of solutions of α-tocopherol or α-tocopheryl quinone.* [3,4-$^{14}$C]α-Tocopherol, unlabeled α-tocopherol, or α-tocopheryl quinone was dissolved in an appropriate amount of dimethylformamide (DMF) and then mixed with a solution of BSA in a 66 mM Tris-HCl buffer pH 7.4 (molar ratio of α-tocopherol or α-tocopheryl quinone/BSA, 1:3). The suspension was vortexed immediately and diluted 1:2 with the same buffer. The final DMF concentration did not exceed 1.5% (vol/vol). Without inclusion of BSA we did not obtain a stable solution of α-tocopherol or α-tocopheryl quinone. Since α-tocopherol is sensitive to light and oxygen, solutions of α-tocopherol were always kept in the dark and sealed. The three compounds, dissolved in acetonitrile, were analyzed by HPLC (see below) to assess their purity. The cold and radiolabeleled α-tocopherol were both found to be approximately 97% pure, the remainder being mainly α-tocopheryl quinone; α-tocopheryl quinone appeared to be approximately 99% pure and contained virtually no α-tocopherol (data not shown).

*Incubation with microsomes.* Standard microsomal incubation medium consisted of 1.5 mM NADPH and radiolabeled α-tocopherol (specific activity 10 Ci/mol, at different concentrations; see further), or cold α-tocopherol (at a final concentration of 36 μM), or cold α-tocopheryl quinone (at a final concentration of 36 μM) in 66 mM Tris-HCl buffer pH 7.4. The incubations were performed under an atmosphere of 95% $O_2$ and 5% $CO_2$ in a gyratory shaker at 37°C for 15 to 120 min. The reaction was initiated by the addition of microsomes (0.1 mg to 5 mg of protein per vial), and the final volume was 1 mL. The following controls were included: incubation with buffer B instead of microsomes; and addition of HCl to stop the reaction (see below), before addition of microsomes.

*Analysis and purification of ω-oxidation products of α-tocopherol and [$^{14}$C]α-tocopherol.* The incubation of microsomes was stopped by the addition of 250 μL HCl 1 M. After vortexing, an aliquot (1 mL) was transferred to a screw-cap tube containing 3.75 mL of a chloroform/methanol (1:2, vol/vol) mixture, with 0.01% (wt/vol) BHT as antioxidant. After vigorous shaking, chloroform and water were added to a final ratio of chloroform/methanol/water of 2:2:1, resulting in a two-phase system. In the first experiments, which were done only with radiolabeled α-tocopherol, part of the chloroform layer was dried under nitrogen. The residue was then dissolved in methanol (70 μL) and subjected to HPLC using an Alltech (Deerfield, IL) Adsorbosphere C18 reversed phase column (4 μm; 150 × 3.9 mm). The eluant was methanol/water (96.25:3.75, vol/vol) at a flow rate of 1 mL/min, and the absorbance of the eluate was monitored at 280 nm. The radioactivity in the eluate was determined by collecting 0.5-mL fractions and counting in a Beckman LS-1701 liquid scintillation counter after addition of 5 mL Ready Safe cocktail.

In later experiments, the chloroform layer was evaporated to dryness under $N_2$. The lipid residue was dissolved in chloroform (500 μL) and applied to a Bond Elut $NH_2$ cartridge (Varian, Harbor City, CA). After washing with chloroform and chloroform/isopropanol (2:1, vol/vol), the ω-oxidation products were eluted with a solution of 3% acetic acid in diethyl ether. After evaporation of the diethyl ether, the residue was dissolved in a small volume (60 μL) of acetonitrile and analyzed by HPLC using an Alltech Adsorbosphere C8 reversed phase column (5 μm; 150 × 4.6 mm). Elution was performed isocratically with glycine-HCl buffer (30 mM, pH 2.6)/acetonitrile (60:40, vol/vol) for the first 5 min, followed by a linear gradient up to 100% acetonitrile over the next 10 min, and finally the column was eluted for 5 min with 100% acetonitrile. The eluate was monitored at 280 nm; and in some experiments with radiolabeled α-tocopherol, the radioactivity in the eluate was collected and counted as described above. The eluate of the other experiments, with labeled as well as with unlabeled α-tocopherol, was collected in 0.5-mL fractions, and those containing the ω-oxidation products were pooled and stored at –20°C until further analysis.

*Methylation of the ω-oxidation products.* The pooled fractions were evaporated to dryness under $N_2$, the residue was taken up in chloroform, and glycine was removed by washing with water. The chloroform layer was evaporated to dryness, and 200 μL of a boron trifluoride/methanol (14%, wt/vol) solution was added. The mixture was heated at 80°C for 4 min, cooled, and extracted with 1 mL of chloroform and 0.5 mL of water. The chloroform layer was removed and dried under $N_2$. The methylated products were purified on HPLC using an Alltech Adsorbosphere C8 reversed-phase column (5 μm; 150 × 4.6 mm). Elution was performed isocratically with water/acetonitrile (60:40, vol/vol) for the first 5 min, followed by a linear gradient up to 100% acetonitrile over the next 10 min; and finally the column was eluted for 5 min with 100% acetonitrile. The flow rate was maintained at 1 mL/min. In the experiments with radiolabeled α-tocopherol, the eluate was collected and counted for radioactivity as described above. In the experiments with unlabeled α-tocopherol the eluate was collected in 0.5-mL fractions. The fractions from different experiments, containing the methylated oxidation products, were pooled and used for analysis with HPLC coupled to a Finnigan Mat TSQ 70 triple stage quadrupole mass spectrometer, using atmospheric pressure chemical ionization (APCI) as ionization technique. HPLC was carried out with an Alltech Adsorbosphere C8 reversed phase column (5 μm; 150 × 2.1 mm). Elution was performed isocratically with water [containing 1% (vol/vol) acetic acid)/acetonitrile (60:40, vol/vol] for the first 5 min and then the same elution pattern was used as described above. The flow rate was maintained at 0.2 mL/min.

## RESULTS

*Optimization of incubation conditions.* The discovery of urinary metabolites of α-tocopherol in rabbits and humans given large doses of α-tocopherol suggests that the terminal methyl

group in the side chain may be ω-oxidized, followed by β-oxidation of the resulting carboxylic acid (7–10). With the aim of assessing whether this degradation mechanism is correct, we incubated microsomes with [3,4-$^{14}$C]α-tocopherol and investigated the breakdown products.

Since we had little radiolabeled α-tocopherol at our disposal, preliminary experiments related to the incubation conditions were not repeated or were done only twice. When the chloroform extracts, obtained after incubation of [3,4-$^{14}$C]α-tocopherol under standard conditions, were subjected to reversed-phase C18 HPLC analysis, using the isocratic system (see the Materials and Methods section), a radioactive peak was seen at the start of the chromatogram. The substance was not α-tocopherol (retention time of 12.5 min) or α-tocopheryl quinone (retention time of 7 min). Since it eluted at the solvent front, it could be a (mixture of) polar compound(s), which we refer to as "metabolite" in the following. No metabolite was formed in the absence of NADPH or at zero time of incubation; substituting buffer B for microsomes also abolished its formation. Studies on the concentration of α-tocopherol, on the amount of microsomal protein, and on the incubation time revealed that maximal production of metabolite was obtained when 1 mg of microsomal protein (Fig. 1A) was incubated with 36 μM of α-tocopherol (Fig. 1B) for 120 min (Fig. 1C) in the presence of 1.5 mM NADPH. There was a significant variability in the total amount of oxidation product formed between experiments. However, the effects of time, protein concentration, and substrate concentration were consistent. Over the 120-min incubation time, up to 2% of the added α-tocopherol was oxidized to the polar metabolite; of the remaining α-tocopherol, up to 5% was converted to α-tocopherylquinone (not shown). In order to exclude that the metabolite would have arisen from enzymatic degradation of α-tocopheryl quinone, present as a contaminant or generated *in situ*, microsomes were incubated for 120 min with α-tocopheryl quinone, as described in the Materials and Methods section. After purification, methylation, and mass spectrometry (MS; see below) we could not detect the presence of the metabolite in these incubation mixtures (results not shown), although it was present in mixtures incubated with α-tocopherol in parallel.

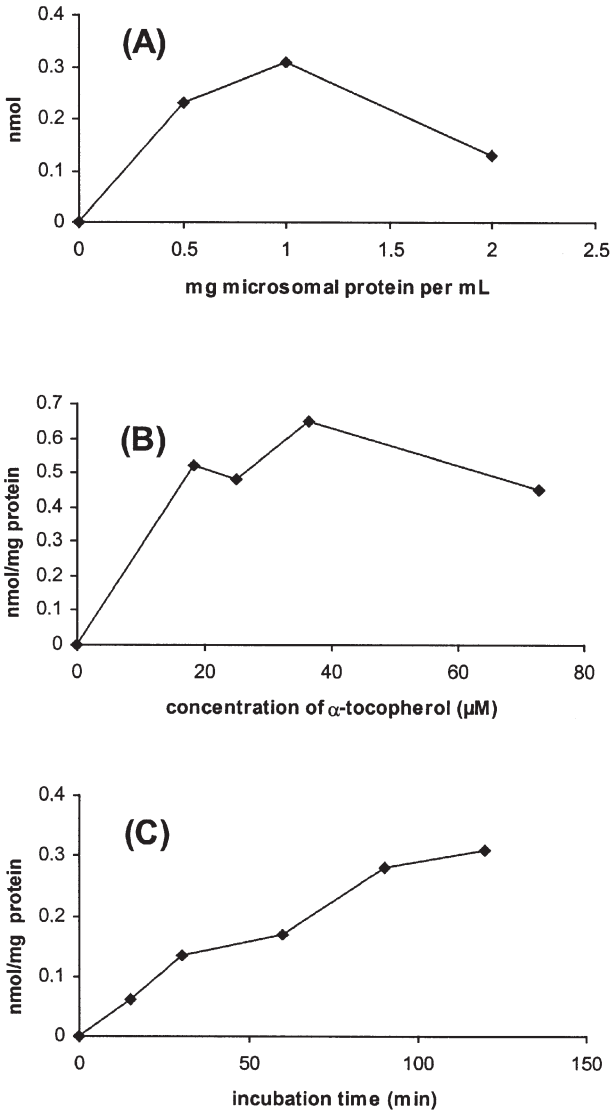

**FIG. 1.** α-Tocopherol catabolism as a function of (A) protein concentration, (B) concentration of α-tocopherol, (C) incubation time. The amount of metabolite formed was measured after incubation at 37°C in a reaction mixture containing 1.5 mM NADPH and, unless indicated otherwise in the abscissa, 36 μM of α-tocopherol and 1 mg of microsomal protein. Incubation time was 120 min except for condition (C) in which it was varied as indicated. The results are from one experiment.

Taken together, the data described above suggest that ω-oxidation did take part in the formation of the metabolite of α-tocopherol. The identification of this metabolite was the goal of the following experiments.

*Purification of the α-tocopherol metabolite.* To perform MS analysis, we needed at least 1 μg of pure unlabeled methylated product. A chloroform extract of liver microsomes contains a lot of organic material such as fatty acids, phospholipids and neutral lipids. In a first purification step, the extract was applied onto a weak anion exchange column. After elution, more than 90% of the radiolabeled metabolite was recovered in the acidic diethyl ether eluate. Analysis of this eluate on reversed-phase HPLC, using a C8 column and a glycine-HCl buffer pH 2.6/acetonitrile gradient (see the Materials and Methods section), revealed one major peak of radioactive material at 12.5 min with a shoulder of ultraviolet-absorbing material (Figs. 2A,B). When the glycine-HCl buffer was replaced by purified (grade I) water, the radiolabeled metabolite again eluted at the solvent front position. In the glycine-HCl buffer pH 2.6/acetonitrile mixture, the metabolite is probably fully converted to the acid form, whereas in the water/acetonitrile mixture the metabolite is probably mainly present in the ionic form. Thereafter, the radiolabeled metabolite was methylated and subjected again to HPLC using a C8 column and a water/acetonitrile gradient. In this system, we saw only one radioactive peak with a retention time of about 14 min, and hardly any signal at 280 nm

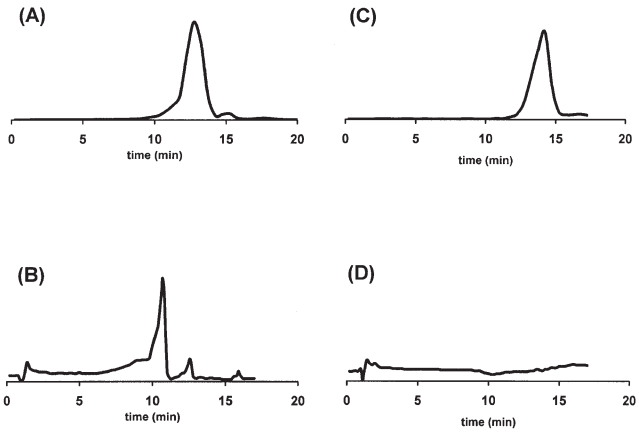

**FIG. 2.** Chromatograms of the α-tocopherol metabolite after purification on an $NH_2$ column (A and B) and of the methylated α-tocopherol metabolite (C and D). A and C show the radioactive signal and B and D show the absorbance at 280 nm. See the Materials and Methods section for experimental details. The results are from one representative experiment.

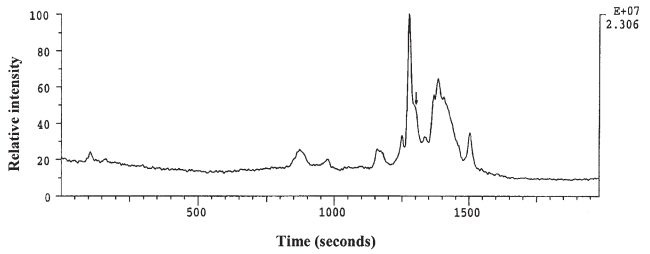

**FIG. 3.** Liquid chromatography/atmospheric pressure chemical ionization-mass spectrometry chromatogram of the methylated metabolite of α-tocopherol. The mass spectrometer was set to scan the *m/z* range 50 to 800. The arrow indicates the position of the peak at *m/z* 491.2 (retention time: 21.7 min; see text).

(Figs. 2C, 2D). After pooling the methylated metabolite from several experiments, performed with unlabeled α-tocopherol, we finally obtained about 5 µg of material. This quantity was sufficient for MS but did not allow nuclear magnetic resonance analysis.

*Characterization of unlabeled methyl ester by liquid chromatography (LC)–MS.* The following elements led us to conclude that the metabolite obtained (i) is an ω-acid derived from α-tocopherol, and (ii) has an opened chroman ring (quinone structure).

The purification by HPLC was done under a normal atmosphere. Different groups have demonstrated that α-tocopherol can autoxidize to α-tocopheryl quinone under aerobic conditions (16–18). The ω-oxidation product of α-tocopherol also appears to be even more sensitive to this conversion than the parent compound.

Reversed-phase LC–MS analysis of the methylated metabolite was done as described in the Materials and Methods section. The mass spectrometer was set to scan the *m/z* range 50 to 800. The total ion chromatogram showed several peaks (Fig. 3), indicating the presence of a number of impurities that had not been detected at 280 nm. The calculated molecular weight of the methylated acid with the quinone structure is 490, whereas the methylated acid with the intact chroman ring has a molecular weight of 474. Since APCI is a "soft" ionization technique, the initial ions produced are mainly of the type $(M + H)^+$ from which the molecular weight can be deduced easily. Therefore, the peaks with a retention time between 15 and 25 min were monitored for *m/z* 491 and *m/z* 475. No significant peak was seen at *m/z* 475, but the ion with *m/z* 491.2 was present in a peak with a retention time of 21.7 min, although it was not separated from a much larger peak (Fig. 3). The mass spectrum of the peak associated with *m/z* 491.2 contained ions with *m/z* 345.0, 319.0, 244.8 and 374.0 (Fig. 4). Selected ion monitoring (not shown) of the chromatogram, for each of these fragments, and MS–MS of *m/z* 491.2 (Fig. 5) clearly showed that these fragments could not be derived from *m/z* 491.2. The fragment ions with *m/z* 263.0 and 294.9 showed approximately the same chromatographic pattern as the ion with *m/z* 491.2, but they were not present in the MS–MS spectrum of *m/z* 491.2. The ions with *m/z* 473, 459.2, 431.1, and 413.1 (Fig. 4), on the other hand, are fragments of *m*/z 491.2. The one with *m/z* 473 $(M + H - 18)^+$ might be formed by the loss of water, which normally indicates the presence of a hydroxyl group. The fragment ion observed at *m/z* 459.2 $(MH - 32)^+$ probably resulted from the loss of $CH_3OH$. The ion peak at *m/z* 431.1 $(MH - 60)^+$ might be explained by the loss of $HCOOCH_3$, indicating the presence of a methylated carboxyl group. The ion peak at *m/z* 413.1 might originate from the combined loss of $HCOOCH_3$ and $H_2O$ from the $(M + H)^+$ ion. We concluded that the mass spectrum indicates the presence of a molecule with a molecular weight of 490 containing a hydroxyl function and a methylated carboxyl group. As mentioned before, the methylated carboxylic acid derived from α-tocopheryl quinone by ω-oxidation has a molecular weight of 490 and has a free hydroxyl group. Therefore, our structural proposal for the metabolite is the ω-acid of the α-tocopheryl quinone. We believe that α-tocopherol is indeed ω-oxidized by microsomes in the presence of NADPH and $O_2$, apparently followed by oxidation to the quinone structure. The latter may occur during the incubation

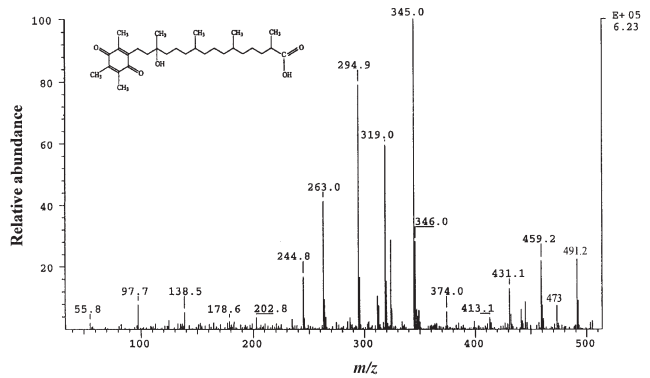

**FIG. 4.** Mass spectrum of the methylated metabolite, obtained at a retention time of 21.7 min (see text).

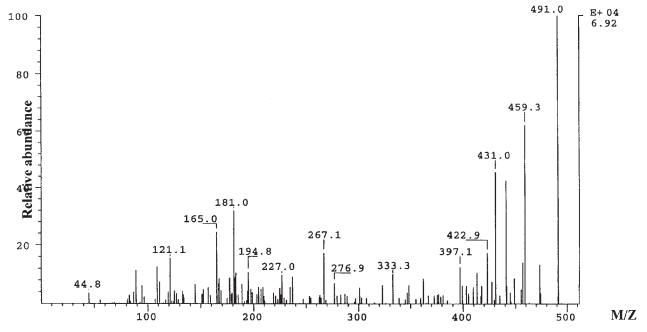

**FIG. 5.** Tandem mass spectroscopy spectrum of *m/z* 491.2, obtained at a retention time of 21.7 min (see text).

with the microsomes and/or during purification and analysis. Unfortunately the spectrum of the methylated metabolite contained ions that are not derived from this metabolite, but probably from impurities with more or less similar retention times. We have not identified these products.

## DISCUSSION

Both Simon *et al.* (8,10) and Schultz *et al.* (9) assumed that the metabolites of α-tocopherol found in the urine of rabbits and humans that had been given large doses of α-tocopherol were formed by ω-oxidation of the side chain followed by β-oxidation. According to Schultz *et al.* (9), the major urinary excretion product of vitamin E is the α-tocopherol-derived carboxylic acid 2,5,7,8-tetramethyl 2(2′-carboxyethyl)-6-hydroxychroman (α-CEHC). Other investigators (6,11) have confirmed this and found that α-CEHC is mainly derived from α-tocopherol stereoisomers that are present only in the synthetic vitamin. Wechter *et al.* (19) reported that γ-tocopherol is broken down in a similar fashion and that its metabolite is an endogenous natriuretic factor. The metabolites, tocopheronic acid [2-(3-hydroxy-3-methyl-5-carboxypentyl)-3,5,6-trimethyl benzoquinone] and its lactone (tocopheronolactone), found by Simon *et al.* (8,10), have a quinone structure, which means that the chroman ring was opened. Urinary metabolites of α-tocopherol are excreted as conjugates; before they can be analyzed chromatographically they must be hydrolyzed. Simon *et al.* used rather drastic procedures and did not avoid oxygenation during hydrolysis, whereas Schultz *et al.* (9) prepared their samples by enzymatic hydrolysis and excluded oxygen. The latter discovered that α-CECH was easily converted to α-tocopheronolactone by exposure to $O_2$, and they concluded that the Simon metabolites were in fact the result of oxidation of α-CEHC during sample preparation. On the basis of our results, we conclude that α-tocopherol can indeed be ω-oxidized to a carboxylic acid as hypothesized by Simon and Schultz, although we realize that the structural identification of the ω-acid of α-tocopherol is not definitive, since we could not obtain the product in pure form and in adequate quantities to perform further analysis (e.g., nuclear magnetic resonance). Furthermore, we have demonstrated that the conversion of α-tocopherol to the carboxylic acid can occur in liver microsomes. We did not obtain the ω-acid of α-tocopherol but of α-tocopheryl quinone, which seems to be formed by oxidation of the ω-acid of α-tocopherol, similar to the oxidation of α-CEHC to the Simon metabolites. Our control experiments, i.e., zero time incubations, incubations without microsomes, and incubations with α-tocopheryl quinone, strongly suggest that the proposed metabolite is not present as a contaminant in the substrate and is not formed by ω-oxidation of α-tocopheryl quinone. Thus, the microsomal ω-oxidation of α-tocopherol precedes the conversion to the quinone product that was finally obtained. Since we could only detect the latter, it appears that the conversion of the ω-acid of α-tocopherol to the corresponding quinone is rapid under our conditions, in contrast to the conversion of the parent compound (α-tocopherol) to α-tocopheryl quinone. This may be related to a differences in solubility, or the ω-acid may be a substrate for a microsomal enzyme catalyzing the opening of the chroman ring. The oxidation of α-tocopherol to a carboxylic acid presumably involves an ω-hydroxy intermediate, but we could not detect the latter in our system. When lauric acid is incubated with microsomes in the presence of NADPH and $O_2$, only hydroxylation occurs (20–22). However, literature data on the ω-oxidation of branched-chain fatty acids, incubated with washed microsomes in the presence of NADPH, indicate that the hydroxy compound is only a minor metabolite (23). Since α-tocopherol has a branched side chain, it is possible that the ω-hydroxy compound is not present or to such a low extent that we could not discern its presence. Microsomal alcohol and aldehyde dehydrogenases probably quickly converted the hydroxylated α-tocopherol to the ω-acid.

## ACKNOWLEDGMENTS

We thank Benny Das, Raoul Rozenberg, and Stan Asselberghs for expert technical assistance and Wendy Patteet for secretarial help. We are indebted to Dr. Jerun Bausch and Dr. George Wendt (F. Hoffmann-La Roche Ltd., Basel, Switzerland) for supplying the [3,4-$^{14}$C]α-tocopherol.

**ABSTRACT:** High-fat ketogenic diets are used to treat intractable seizures in children, but little is known of the mechanism by which these diets work or whether fats rich in n-3 polyunsaturates might be beneficial. Tissue lipid and fatty acid profiles were determined in rats consuming very high fat (80 weight%), low-carbohydrate ketogenic diets containing either medium-chain triglyceride, flaxseed oil, butter, or an equal combination of these three fat sources. Ketogenic diets containing butter markedly raised liver triglyceride but had no effect on plasma cholesterol. Unlike the other fats, flaxseed oil in the ketogenic diet did not raise brain cholesterol. Brain total and free fatty acid profiles remained similar in all groups, but there was an increase in the proportion of arachidonate in brain total lipids in the medium-chain triglyceride group, while the two groups consuming flaxseed oil had significantly lower arachidonate in brain, liver, and plasma. The very high dietary intake of α-linolenate in the flaxseed group did not change docosahexaenoate levels in the brain. Our previous report based on these diets showed that although ketosis is higher in rats consuming a ketogenic diet based on medium-chain triglyceride oil, seizure resistance in the pentylenetetrazol model is not clearly related to the degree of ketosis achieved. In combination with our present data from the same seizure study, it appears that ketogenic diets with widely differing effects on tissue lipids and fatty acid profiles can confer a similar amount of seizure protection.

Paper no. L8613 in *Lipids 36*, 373–378 (April 2001).

The high-fat ketogenic diet has regained popularity over the past 5 yr as a treatment of last resort for intractable epilepsy (1–3). Dairy fat is the predominant fat used in the classical ketogenic diet. This more common version of the diet is calculated to provide a fat to carbohydrate-plus-protein ratio of about 4:1. The diet has comparable anticonvulsant effects when prepared with other dietary oils such as medium-chain triglyceride (MCT) oil or corn oil (4,5), but MCT oil causes more gastrointestinal side effects (2) and corn oil is harder to incorporate into palatable foods. Animal studies modeling the protective effects of the ketogenic diet against seizures have used many different fat sources and have not shown consistent results between different seizure models (6–12). The mechanism by which the ketogenic diet suppresses or prevents seizures in humans is unknown, so we are attempting to reproduce its effects in animals in order to better understand how it works. We are not aware of any animal studies in which ketogenic diets containing different dietary fats have been compared.

The unusual amount and type of fat in the ketogenic diet is potentially problematic because this diet tends to be low in n-3 polyunsaturated fatty acids (PUFA), which are important for normal visual and neurological development (13,14). Interestingly, recent research implicates two of the n-3 PUFA, docosahexaenoate (DHA, 22:6n-3) and α-linolenate (ALA, 18:3n-3), as anticonvulsants (15,16). Owing to the potential role of n-3 PUFA as anticonvulsants and the substantial ketogenic potential of ALA (17), we recently evaluated the anticonvulsant efficacy of several high-fat ketogenic diets differing in fat composition. Ketogenic diets based on butter, ALA-rich flaxseed oil (FSO), or MCT all conferred moderate protection toward a low dose of pentylenetetrazol (PTZ) but not against electroshock-induced seizures (18). These beneficial effects were observed at blood ketone levels 30–80% lower than in humans on a diet of similar composition.

The present paper describes the changes in selected tissue lipids and fatty acid profiles from that study. We have emphasized the tissue levels of DHA and arachidonate (AA, 20:4n-6) because of the anticonvulsant effects of DHA (15) and the possible neuroexcitatory or proconvulsant effects of AA (19,20). A further aim was to determine whether the fatty acid profile of adipose tissue of rats on high-fat ketogenic diets tended to reflect the dietary fat profile as would be expected on diets containing 5–20 wt% fat.

## MATERIALS AND METHODS

*Animals.* All procedures involving animals received prior approval from the University of Toronto Animal Care Committee, the standards of which are set by the Canadian Council on Animal Care. Fourteen-day-old male Wistar rat pups arrived from the breeding facility (Charles River Canada, St. Constant, Québec) and were housed with their dams for 6 d before being weaned at 21 d of age and allocated to one of five dietary groups. To assist in adaptation to the ketogenic

[a]All ketogenic diets contained 7 wt% soybean oil (see CONTROL group for fatty acid profile) and 65.2 wt% of the fat shown. CONTROL, 7 wt% soybean oil; MCT, medium-chain triglyceride oil; FSO, flaxseed oil; MIXTURE, ketogenic diet based on a 1:1:1 mixture by weight of MCT, FSO, and BUTTER.

diet, the amount of fat was gradually increased over the first 8 d by providing ratios of fat/protein + carbohydrate of 1:1 for 4 d, 2:1 for 4 d, and finally 3.5:1 for a further 40 d.

*Diets.* Control animals received the American Institute of Nutrition-93G (AIN-93G) diet (18). The experimental animals received ketogenic diets prepared in our laboratory. The ketogenic diets were prepared by mixing specific fats/oils with a custom-formulated powdered diet mixture (Dyets, Bethlehem, PA) of the following composition (g/kg): 198.6 cellulose, 0.27 AIN-93G Vitamin Mix (without sugar), 22.0 AIN-93G Mineral Mix (without sugar), 153.9 casein, 12.0 dextrose, 54.7 soybean oil, 524.6 fat/oil, 2.0 choline bitartrate, and 32.0 sodium cyclamate (Sucaryl$^{R}$). Sodium cyclamate is commonly used as a sweetening agent in foods given to children on the ketogenic diet. It was used to improve the flavor and consistency of the diet. Butter, FSO, MCT, or a mixture of equal parts of butter, FSO, and MCT oils were used to formulate each diet (see Tables 1 and 2). MCT was a gift of Mead Johnson Nutritionals (Evansville, IN). The other oils/fats were obtained commercially. Butter and MCT were used to mimic the classical and MCT versions of the ketogenic diet. FSO was chosen for this study because it is 55% by weight ALA. Diets and drinking water were available *ad libitum.*

*Blood and tissue analysis.* After 48 d on the diets and completion of the seizure tests (reported elsewhere; Ref. 18), each rat was anesthetized with pentobarbital (40 mg/kg). Blood was drawn by cardiac puncture, and the brain, liver, and perirenal adipose tissue were excised. Each organ was weighed and stored at −20°C for subsequent lipid extraction. Total lipid extracts were prepared using the extraction method of Folch *et al.* (21). Approximately 1 g of tissue (1 mL of plasma) was weighed into vials. An internal standard solution comprising heptadecanoate, L-α-phosphatidylcholine diheptadecanoyl, and triheptadecanoin (Sigma Chemical Co, St. Louis, MO) in chloroform was then added to each sample for the quantification of free fatty acids, phospholipids, triglycerides, and free cholesterol, respectively.

The organs were homogenized, methanol was added to give a 2:1 ratio to chloroform, and the lipid phase was separated after centrifugation. Lipid classes of the total lipid extract were fractionated by neutral thin-layer chromatography (TLC) using silica gel plates (20 × 20 cm Whatman LK6D plates precoated with 250 μm of silica gel 60Å). The plates were transferred to a covered TLC tank containing the mobile phase solvent system (petroleum ether/diethyl ether/acetic acid, 80:20:1, by vol) and allowed to develop for 30 min. The spots were visualized with ultraviolet light after spraying the plates with 2′,7′-dichlorofluorescein. The resulting bands were scraped off each plate and the phospholipid, cholesterol, and total lipid fractions were saponified in KOH-methanol for 60 min at 90°C. Triglyceride and free fatty acid bands were not saponified and were immediately methylated. After adding hexane and then acidifying, the fatty acid phase was removed and methylated in boron trifluoride/methanol. The fatty acid methyl esters were analyzed by capillary gas chromatography (30-m DB column; J&W Scientific, Folsom, CA) with automated sample injection and comparison of retention times against several standards of known composition.

Plasma total cholesterol was measured using a commercially available kit (Sigma Chemical Co.). Brain cholesterol was measured by capillary gas chromatography after preparation of *t*-butyldimethylsilyl derivatives of brain total sterols, with quantification against 5-α-cholestane as an internal standard.

*Data analysis.* Statistical analyses were performed using

[a]Values are mean ± SD, $n$ = 6 rats/group. In each row, values with different roman superscripts are significantly different, $P < 0.05$. For abbreviations see Table 1.

SigmaStat 2.03 software package (Jandel Scientific Software, San Rafael, CA). Differences between diet groups were analyzed using one-way analysis of variance (ANOVA) with the Tukey test for multiple comparisons. For data sets that were not normally distributed, a Kruskal-Wallis ANOVA on ranks, with Dunn's method for multiple comparison, was used.

## RESULTS

Final body weights of rats were (mean ± SD) CONTROL group, 351 ± 15 g; MIXTURE group, 333 ± 15 g; BUTTER group, 309 ± 19 g; FSO group, 290 ± 21 g; and MCT group, 205 ± 14 g. Body weights of all the ketogenic diet groups differed from each other at $P < 0.05$. Liver weights varied with body weight but did not differ as a proportion of body weight (4.0–4.3% of final body weight in all the groups (not significantly different). Brain weights (1.7–1.8 g) did not differ between groups.

Both the degree of ketosis and the response to seizures of the rats in this study have previously been reported (18). In brief, three ranges of plasma β-hydroxybutyrate were observed; the lowest values (0.09 ± 0.03 mM/L) were in CONTROLS, a middle range (0.7–0.9 mM/L) was seen in the BUTTER, FSO, and MIXTURE groups, and the highest values (5.2 mM/L) were in the MCT group. Seizures induced by PTZ were most severe in the CONTROL and the MIXTURE groups and were reduced by 33–50% in the BUTTER, MCT, and FSO groups ($P < 0.05$) (18).

In general, the proportions of fatty acids in adipose tissue broadly reflected their proportions in the diet (Tables 1 and 2). However, the MCT group had much higher linoleic acid (LA, 18:2n-6), ALA, and AA compared with either the MCT diet itself or the adipose tissue fatty acid profiles of other ketogenic diet groups ($P < 0.05$). The FSO and MIXTURE groups had 6–23-fold higher percentage of ALA and 4–10- fold higher percentage of DHA in adipose tissue than the other groups ($P < 0.05$).

The concentration of plasma phospholipids in the BUTTER group was 20–60% higher than in the other groups (Table 3). The MCT group had the lowest plasma triglyceride level, but this was significant only in comparison to the BUTTER group ($P < 0.05$). Free fatty acid concentrations were significantly higher than CONTROL in the FSO and MIXTURE groups, while the other groups were similar. No significant differences were found in plasma cholesterol between any of the groups (Table 3).

The concentration of liver phospholipids in the FSO group was significantly higher than both the CONTROL and MCT groups ($P < 0.05$). Liver triglycerides in the BUTTER and MIXTURE groups were about 10 times higher than in the other groups. Liver free fatty acids in the FSO and MIXTURE groups were nearly twofold higher than those in the other groups. No differences across groups were found in the concentration of brain total or free fatty acids. Except in the FSO group, brain cholesterol was 11–18% higher in all the ketogenic diet groups than in the CONTROL group ($P < 0.05$, Table 3).

The percentage composition of palmitate (16:0), stearate (18:0), and DHA in brain free fatty acids was similar in all the groups (Table 4). The proportion of LA in brain free fatty acids was significantly higher in the FSO group compared with all other diet groups, while the proportion of AA in the FSO group was significantly lower. ALA and EPA were not detected in the brain of the CONTROL, MCT, and BUTTER groups, but they were present at 0.2–0.3% of total brain fatty acids in the FSO and MIXTURE groups.

Both the total concentration and proportion of AA in liver free fatty acids of the MCT group were up to twofold higher than in the other groups (Table 5). The groups consuming FSO had the lowest proportion of free AA in liver and plasma. There were no significant differences between groups in the amount of free AA in the brain. There was significantly more free DHA in the liver in the FSO and MIXTURE groups, but there were no differences between groups in the concentration or proportion of free DHA in the brain (Table 5).

## DISCUSSION

The higher ketosis in the MCT group (18) was probably due to the high proportion of medium-chain fatty acids (8:0, 10:0) in that diet. The higher level of plasma β-hydroxybutyrate in the MCT group was similar to that seen clinically but was no more protective against PTZ-induced seizures than the lower ketone levels seen in the FSO and BUTTER groups (18). Despite wide differences in the fatty acid profiles of the BUTTER, FSO, and MIXTURE diets, ketosis was similar in these groups, suggesting no clear role of individual dietary long-chain fatty acids in promoting ketosis. The lack of a clear relation between ketosis and seizure control in this model led us to seek other tissue lipid changes that might contribute to seizure protection.

We focused on possible changes in n-3 PUFA because of the anticonvulsant effects of both DHA and ALA in several different models (15,16,22). If levels of these n-3 PUFA in serum free fatty acids or in brain were elevated in the groups protected against the PTZ-induced seizures, we could conclude that at least part of the effect of ketosis could potentially be mediated by these fatty acid changes and not necessarily by ketosis itself. However, the present analysis does not clearly support a role for a specific fatty acid or dietary fat type in the mechanism by which ketogenic diets inhibit seizures because the MIXTURE and FSO groups consuming high amounts of ALA had higher n-3 PUFA in the tissues, but the MIXTURE group was not as well protected as the FSO group against the seizures induced by PTZ. Furthermore, the two most seizure-protected groups (BUTTER, FSO) had very few lipid or fatty acid changes in common that did not also occur in one or more other groups (Tables 2–5).

AA is an important fatty acid in membrane phospholipids, but excess free AA has a variety of excitatory and potentially neurotoxic effects (19,20) that could increase susceptibility to seizures. Our tissue fatty acid data do not support a proconvulsant effect of raised tissue levels of AA. This is because the MCT group, which had relatively high amounts of AA in adipose tissue, liver, and brain, had similar seizure incidence and scores to the rats on the other ketogenic diets. Hence, the proconvulsant effects of MCT-based ketogenic diets that are sometimes observed (9), especially when MCT oil is the predominant fat in the diet (23), do not appear to be directly related to increased tissue AA.

DHA protects against seizures (15), so we speculated that diets producing a high ratio of DHA to AA in blood or brain might be protective against seizures whereas a low DHA to AA ratio might promote seizures. Despite dramatic contrasts in ALA intake between the various groups in the present study, there was no significant difference in the percentage or concentration of DHA in brain total lipids or free fatty acids. At least in the free fatty acid fractions of plasma, liver, and brain, the DHA/AA ratio was not significantly correlated with seizure protection against PTZ (Table 5) (18). At the moment, therefore, any lipid- or fatty acid-related mechanism by which the ketogenic diet achieves seizure protection remains unclear. Our current lipid and fatty acid analyses of whole tissues are relatively crude and may need to become specific, focusing on particular brain regions or subcellular fractions.

The effect on adipose tissue composition of these ketogenic diets formulated with different fats was most interesting in the two groups given MCT oil (MCT and MIXTURE). In both these groups, the proportions of LA and ALA were much higher in adipose tissue than in the respective diets. This is unusual because proportions of LA and ALA in adipose tissue generally reflect dietary intake (24). However, on very high fat ketogenic diets containing MCT, it appears that the rat conserves LA and ALA or spares their release from adipose tissue more than usual. A possible explanation may be that the higher proportion of medium-chain fatty acids in the MCT diet effectively supports fat oxidation, thereby sparing PUFA such as LA and ALA that would normally be extensively β-oxidized (25). This apparent sparing of LA and ALA oxidation might help account for the higher adipose tissue AA and DHA in the MCT group.

Cholesterol levels in the rodent brain do not change even in the face of high saturated fat and cholesterol intake that would typically raise blood cholesterol by two- to threefold. Thus, as previously reported (26,27), exogenous cholesterol contributes little or nothing to brain cholesterol levels, probably because cholesterol crosses the blood-brain barrier poorly and because the brain can synthesize *de novo* all the cholesterol it requires (26). Interestingly, in the present study, the MCT, BUTTER, and MIXTURE groups had significantly higher brain cholesterol than that of the CONTROL and FSO groups ($P < 0.05$). These results illustrate that, although manipulation of dietary cholesterol itself does not affect brain cholesterol, a very high fat intake providing short- to medium-chain length fatty acids (6–14 carbons) can raise the level of cholesterol in the brain by 11–18%. This may be achieved by the long-term high level of blood ketones, which are important brain cholesterol precursors during early development (26).

One particular surprise in this study was the lack of significant change in plasma cholesterol, especially in the BUTTER group (Table 3). Weight gain was significantly reduced in all but one of the ketogenic diet groups, and this could potentially prevent an increase in plasma cholesterol. Our present data are consistent with the report that children with intractable epilepsy who are on the ketogenic diet have normal plasma cholesterol (28). However, adults on the ketogenic diet have the expected rise in plasma cholesterol associated with high saturated fat intake (3). The appropriateness of the rat as a model of human lipid metabolism while on a ketogenic diet therefore needs careful evaluation. We are aware of no reports involving humans on controlled experimental ketogenic diets, and there are few relevant reports describing lipid metabolism in animals on ketogenic diets. Rats are an important research tool for modeling seizure mechanisms and treatments, but it may be difficult to extrapolate between rats and humans. This caution applies not only to understanding the changes in cholesterol metabolism but also to the significant rise in liver triglycerides in the BUTTER and MIXTURE groups, changes that were not clearly obvious in plasma lipids (Table 3). If children on the ketogenic diet have such an elevation in liver triglycerides over 2–3 yr, compromised liver function would become a concern.

A ketogenic diet rich in n-3 PUFA may have indirect advantages for seizure control because, unlike dairy fat (29), n-3 PUFA do not raise serum lipids, even in a ketogenic diet (Table 3). In the present study, the FSO group had lower triglycerides in plasma and liver than those groups consuming butter (Table 3). The MCT group also had low plasma and liver triglycerides but, clinically, high intakes of MCT are commonly associated with gastrointestinal distress (2). FSO may therefore be an effective and acceptable alternative fat in the ketogenic diet. This has positive implications not only for children but also for adults who are looking to the ketogenic diet to control intractable seizures but who face serious dyslipidemia on the classical ketogenic diet (3).

## ACKNOWLEDGMENTS

Financial support for this study was received from the Natural Sciences and Engineering Research Council, the Dairy Farmers of Canada, the Stanley Thomas Johnson Foundation, the Bloorview Epilepsy Program, a Whipper-Watson studentship from the Bloorview Children's Hospital Foundation to KM, and a postdoctoral fellowship from Parke Davis-Epilepsy Canada to SSL.

# Energy Value and Digestibility of Dietary Oil Containing Mainly 1,3-Diacylglycerol Are Similar to Those of Triacylglycerol

**Hiroyuki Taguchi[a], Tomonori Nagao[a], Hiroyuki Watanabe[a], Kouji Onizawa[a], Noboru Matsuo[a,*], Ichiro Tokimitsu[a], and Hiroshige Itakura[b]**

**ABSTRACT:** Diacylglycerol (DAG) is a component of various vegetable oils. Approximately 70% of the DAG in edible oils are in the configuration of 1,3-DAG. We recently showed that long-term ingestion of dietary oil containing mainly 1,3-DAG reduces body fat accumulation in humans as compared to triacylglycerol (TAG) oil with a similar fatty acid composition. As the first step to elucidate the mechanism for this result, we examined the difference in the bioavailabilities of both oils by measuring food energy values and digestibilities in rats. Energy values of the DAG oil and the TAG oil, measured by bomb calorimeter, were 38.9 and 39.6 kJ/g, respectively. Apparent digestibility expressed according to the formula: (absorbed) × (ingested)$^{-1}$ × 100 = (ingested – excreted in feces) × (ingested)$^{-1}$ × 100 for the DAG oil and the TAG oil were 96.3 ± 0.4 and 96.3 ± 0.3% (mean ± SEM), respectively. The similarity in the bioavailabilities of both oils supports the hypothesis that the reduced fat accumulation by dietary DAG is caused by the different metabolic fates after the absorption into the gastrointestinal epithelial cells.

Paper no. L8669 in *Lipids 36,* 379–382 (April 2001).

Food energy values are calculated by application of Atwater conversion factors for carbohydrates, fats, and proteins or, alternatively, are determined by measurements using a bomb calorimeter (1). Fats and oils provide approximately 38 kJ/g of metabolizable energy compared to 17 kJ/g for proteins and carbohydrates (2,3). These energy availability coefficients have been approved and widely used to calculate the energy intake from various foodstuffs. Of course, these coefficients are generalized, and the precise energy of an individual food may vary depending on its composition and structure. These values are effective for most occasions except for specific experiments, therapeutics, and special diet programs where accurate caloric values are required. Research into the prevention of obesity would be a circumstances that would require precise determination of the food energy values.

Most edible oils contain diacylglycerol (DAG) as a minor constituent. Although the isoform of DAG that occurs in the process of triacylglycerol (TAG) digestion by lingual or pancreatic lipase is 1,2- or 2,3-DAG, a substantial fraction of DAG in edible oils has been converted to 1,3-DAG by acyl migration (4). We previously reported that the rate of lymphatic transport of TAG as chylomicron was significantly retarded in rats that had been intragastrically infused with DAG oil emulsion as compared to TAG oil emulsion (5). In the digestive tract, 1,3-DAG is hydrolyzed to glycerol and fatty acids (FA) through 1(3)-monoacylglycerol (MAG) (6) while TAG is hydrolyzed to 2-MAG and FA. Based on these results, we hypothesized that the limited availability of 2-MAG for re-esterification retards chylomicron-TAG transport in the rat infused with DAG oil emulsion. We recently reported that long-term ingestion of dietary DAG oil, in contrast to the TAG oil, reduces body fat accumulation in humans (7). We speculated that these effects are related to the different metabolic fates of the lipids caused by the structural differences of 1,3-DAG and TAG rather than a difference in food energy values between the oils. However, the difference in the energy value and digestibility between DAG and TAG has not been measured precisely.

Fats are digested in three different and coordinated processes: emulsification, hydrolysis of the substrate, and micellar solubilization of the hydrolysis products in the aqueous medium of the intestinal contents (8). Many determinants are therefore involved in these steps. It has been shown that intestinal fat absorption is influenced by TAG structures (9), FA chain length (10), the unsaturated/saturated FA ratio (10,11), the esterification form of FA (12), and the gastrointestinal flora (13–15).

The purpose of the present study was (i) to compare the energy values of the DAG and TAG oils by calculations and by bomb calorimetry, and (ii) to compare the absorption coefficients or digestibilities of the DAG and TAG oils to assess the contribution of the energy and digestibility differences to the functional differences observed in these dietary oils.

## EXPERIMENTAL PROCEDURES

*Fats.* The DAG oil was prepared by esterifying glycerol with FA from rapeseed oil by the method of Huge-Jensen *et al.* (16). The TAG oil was prepared by mixing rapeseed oil, soybean oil, and safflower oil so that the FA composition became similar to that of the DAG oil. All of these oils were obtained from Nissin Oil Mills Ltd. (Tokyo, Japan). Purified TAG and DAG were purchased from Sigma-Aldrich Japan (Tokyo, Japan). FA composition and acylglycerol composition were analyzed by gas chromatography. The measurements were performed by Japan Food Analysis Center (Tokyo, Japan).

*Calculation of available energy of dietary fats.* The FA composition and acylglycerol composition of each oil are shown in Table 1. The FA composition of the DAG oil was very similar to that of the blended TAG oil. The DAG concentration of the DAG oil was 87.0/100 g and the ratio of 1(3),2- to 1,3-DAG was 32:68. The amount of 1,3-isoform in equilibrium is intrinsic to the FA in the molecule (4). Using

[a]ND, not determined.

the approach outlined in the literature (17,18), we calculated the heat energy values of the DAG and the TAG oils.

The energy values for the FA were estimated by calculation using the equation

$$-\Delta H_c = 0.653n - 0.166d - 0.421 \quad [1]$$

where $-\Delta H_c$ is the heat of combustion in MJ/mol, $n$ is the number of carbon atoms/molecule of FA, and $d$ is the number of double bonds/FA, as described by Livesey (17). The energy value that was used for glycerol was 18.0 kJ/g (18). The heat of esterification was neglected because it amounts to only 3.8 kJ per mole of ester bond as determined with methyl stearate (19). In case of tristearin, this value corresponds to 13 J/g. A normalized percentage was used for the unknown components in the analysis of FA composition and acylglycerol composition.

*Energy measurements of the test oils.* The potential energies (combustion energies) of test oils of known acylglycerol and FA compositions were measured by a bomb calorimeter. Two measurements were carried out for each sample, and the averages were presented. The measurements were performed by Japan Food Analysis Center.

*Animals and experimental design.* Sixteen male Sprague-Dawley rats of 5 wk of age, obtained from CLEA Japan (Tokyo, Japan), were housed in metal cages and had free access to the TAG oil diet and drinking water. They were maintained in a temperature-controlled environment (22 ± 1°C) on a 12-h light/dark cycle. After an acclimatization period of 5 d, they were divided into two groups of eight, so that the body weight of each group became approximately equal, and transferred to the individual metabolic cages. Rats in one group were fed the DAG oil diet, and the others were fed the TAG oil diet (DAG group and TAG group). Food intake of all rats was recorded every day. Body weights of all rats were recorded every 3 or 4 d. Feces were collected and pooled from the last three study days, 13–15. All measurements and fecal collection were performed at the same time during the light cycle throughout the experiment. The digestibility coefficient is defined as the percentage of ingested fat that was not excreted in the feces (11,20,21). We calculated the value from the lipid analysis of the diet and 3-d fecal excretion. The study was approved by the Ethical Committee for the Experimental Animals of Kao Corporation.

*Diets.* The test diet contained 20 g/100 g of either DAG or TAG oil. The ingredients other than test oils were casein (20 g/100 g), cellulose (4 g/100 g), AIN-76 (22) mineral mixture (3.5 g/100 g), AIN-76 (22) vitamin mixture (1 g/100 g), and potato starch (51.5 g/100 g). Each diet was prepared in one batch for the entire experimental period and was stored at –22°C. The rats were provided with tap water *ad libitum*.

*Extraction of total fat from the diets and feces.* Collected feces were stored frozen and immediately freeze-dried as soon as the last specimen had been collected and frozen. The freeze-dried feces were ground with a mortar and pestle into a homogeneous mixture. Fecal lipids were extracted from the homogeneous mixture of freeze-dried feces using a modification of the method of Folch *et al*. (23). Dietary lipids were extracted by the same method as the feces extraction. The amount of extractable lipid was determined gravimetrically.

*Analysis of lipids by gas chromatography.* The lipid contents of the extracted total lipid were analyzed by gas chromatography. The lipid was silylated with trimethylsilylimidazole (GL Science, Tokyo, Japan) by the method of Sahasrabudhe and Legari (24). The trimethylsilyl ethers dissolved in chloroform were separated on a GC-18A gas chromatograph (Shimadzu, Kyoto, Japan) connected to a flame-ionization detector and fitted with a DB-1 capillary column (15 m × 0.25 mm × 0.1 μm; J&W Scientific, Folsom, CA). Operating conditions were: initial column temperature, 80°C; initial time, 3 min; rate of temperature increase, 10°C/min; final temperature, 335°C (held for 44.5 min); injector and detector temperature, 350°C; carrier gas, helium at 1.78 mL/min. Data interpretation was carried out by GC work station CLASS-GC 10 (Shimadzu, Kyoto, Japan) programmed for peak identification. The instrument was calibrated with a standard mixture of free FA, MAG, DAG, and TAG.

*Statistical analysis.* Data were expressed as means ± SEM. Statistical significance of the difference ($P < 0.05$) between the groups were determined by Student's *t*-test (two-tailed). The statistical calculations were performed with Stat View for Windows version 4.58 (Abacus Concepts. Inc., Berkley, CA).

## RESULTS AND DISCUSSION

*Heat energy values of test oils.* Since the FA compositions of the test oils were very similar (Table 1), the average molecular weights of the esterified FA in both oils were the same: 280.4 as free acids. The average molecular weights of TAG, DAG, and MAG in both oils were 879.2, 616.8, and 354.5, respectively. The theoretical energy values were calculated from the amount of FA and glycerol released from 1 g of test

oil and from the energy value for each FA (Table 2). The calculated energy values and those determined by bomb calorimeter for the DAG oil and the TAG oil are shown in Table 2. The energy values of distearin, tristearin, dicaprin, and tricaprin were also calculated and determined by bomb calorimeter as control fats. The energy values of distearin and tristearin determined by bomb calorimeter were 39.0 and 40.1 kJ/g, respectively, and the calculated values were 38.9 and 40.0 kJ/g, respectively. The energy values of dicaprin and tricaprin determined by bomb calorimeter were 34.7 and 35.8 kJ/g, respectively, and the calculated values were 34.7 and 36.0 kJ/g, respectively. The combustion energies measured by bomb calorimeter were in good agreement with the calculated values. The energy value of the DAG oil was approximately 98% of the TAG oil. Since the animal diet used in the present study contained 38.6 energy% fat, this caloric difference (2%) between the oils will produce a difference of only 0.8% in the energy value of the diet.

*Food consumption and body weight.* No significant difference between the rats fed different diets with respect to food consumption was seen. The body weight at the start of the experiment (day 1) did not differ statistically between the groups: 173.9 ± 2.1 and 174.5 ± 2.2 g (±SEM) for the TAG group and the DAG group, respectively. At the end of the experiment (day 15), the body weights did not differ significantly between the groups: 289.1 ± 4.4 and 283.8 ± 3.9 g (±SEM) for the TAG group and the DAG group, respectively.

The effect of different energy consumption on the growth or body weight has been studied quantitatively in the growth method for estimating the caloric availabilities of fats in the rat (25). This method compares the weight gain of rapidly growing rats receiving the test compound to the weight gain of animals receiving a substance of known caloric availability. The minimum energy added to create a standard curve was 209 kJ/100 g diet in this experiment. The 0.8% difference of the caloric value between the DAG diet and the TAG diet corresponds to 15 kJ/100 g. This difference is far less than the calories required to detect any differences in the growth of the rat at the maximum sensitivity. In the human trial (7), the contribution of the caloric difference to the results was much less (<0.1%) since the amount of the test oil substituted was only 10 g out of 42 g of total fat consumed daily. Our results in conjunction with the previous study suggest that the caloric difference between DAG and TAG is negligible.

Since the animal experiment in the present study was focused on the determination of the fat absorption coefficient, we adopted a typical experimental design in which rats were fed test foods for 2 wk. Although it was difficult to detect a difference in body fat accumulation or body weight gain between the treatment groups within 2 wk, the effect of substituting DAG for TAG on body fat accumulation in rats became significant by expanding the treatment period to 3 to 4 wk (6). Furthermore, Murase *et al*. (26) recently reported that substituting DAG for TAG prevented the increase in body fat associated with a high-fat and sucrose diet in obesity- and diabetes-prone C57BL/6J mice after 5 mon of *ad libitum* feeding. These results confirm a differential effect of DAG and TAG on body fat accumulation in rodents and thus replicate the data in humans.

*Fecal analysis.* The overall movements of fats in the rat during the last 3 d of the experiment are shown in Table 3. No significant differences between the diet groups were seen for all variables: food intake, fat intake, dried feces mass, fat excretion, fat content of dry feces, and fat absorption coefficients. We next examined the composition of the fecal lipids, which may be influenced by the composition of the diet, digestibility, and the intestinal microflora. To see the effect of

dietary DAG on the lipid composition in the feces, we analyzed the fecal lipid profile by gas chromatography. No significant differences between the diet groups were observed in the pattern of the fecal lipids (data not shown).

The rat is the animal model most frequently used to predict digestibility of various food components. Bach Knudsen *et al*. (27) demonstrated that the digestibility values for protein, energy, and fat were very similar in rats and humans. Wisker *et al*. (28) also reported that digestibility of energy, protein, fat, and nonstarch polysaccharides in a low-fiber diet and in diets containing coarse or fine whole-meal rye are comparable in rats and humans. It should therefore be reasonable to predict that the digestibility of the DAG oil is similar to that of the TAG oil in humans from the results obtained in the present study. In light of these findings, the physiological differences between DAG and TAG observed in rats and humans are caused by the different metabolic fates after the absorption into the gastrointestinal epithelial cells.

These results encourage further studies on the mechanism of the function of dietary DAG in the reduction of body fat accumulation in humans.

# Nonalcoholic Components in Wine Reduce Low Density Lipoprotein Cholesterol in Normocholesterolemic Rats

**Esther Cascón, Roser Roig, Anna Ardèvol, M. Josepa Salvadó, Lluis Arola, and Cinta Bladé***

Departament de Bioquímica i Biotecnologia, CeRTA, Universitat Rovira i Virgili, Tarragona, Spain

**ABSTRACT:** Using an experimental model that enables the effects of alcohol to be distinguished from the effects of the nonalcoholic components present in wine, we determined whether wine has effects other than those of alcohol on the metabolism of cholesterol. Male rats were fed a standard diet and had free access to water and either wine or an equivalent alcohol solution for 45 d or 6 mon. Alcohol intake was similar in the two groups of animals. Consumption of the alcohol solution or wine did not influence plasma cholesterol or high density lipoprotein-cholesterol. At 45 d, the consumption both of wine and of alcohol solution reduced low density lipoprotein (LDL)-cholesterol and very low density lipoprotein cholesterol. At 6 mon, only the rats that consumed wine had reduced LDL-cholesterol. After 45 d of consuming alcohol solution, total cholesterol in the aorta was significantly increased mainly as a result of the rise in free cholesterol. In the aorta, the effect of wine consumption was similar to the effect of alcohol solution consumption, although it was less intense. The only clear effect that could be ascribed to the nonalcoholic components in wine was that the LDL-cholesterol was reduced in the long term, although aortic cholesterol was not.

Paper no. L8636 in *Lipids 36*, 383–388 (April 2001).

Considerable evidence suggests that small amounts of alcoholic beverages reduce the risk of vascular disease by about a third and reduce total mortality in middle and old age (1,2). But whether all alcoholic beverages protect to the same degree is not so clear because, as well as alcohol, they contain other characteristic compounds. The French Paradox (3) suggests that wine is more protective than other alcoholic beverages, but there is no agreement as to why this is so. Some authors consider that the benefit is directly due to the alcohol content and the extra benefit attributed to wine is due to drinking and diet patterns (1,4,5); others consider that the phenolic compounds in wine play a crucial role in cardioprotection (6, 7).

Phenolic compounds, particularly flavonoids, have been described as having considerable biological activity (8,9). Red wine is particularly rich in flavonoids and contains more than 100 different phenols, of which anthocyanins (0.2–0.8 g/L) and catechins as monomer and oligomer (1–3 g/L) are the two major classes (10). Oligomeric catechins from grape seed have an antiatherosclerotic effect in cholesterol-fed rabbits (11), and red wine reduces the progression of atherosclerosis in apolipoprotein E-deficient mice (12). This beneficial effect may be associated with the better resistance of low density lipoprotein (LDL) to oxidation and the changes in cholesterol metabolism. Although many studies show the antioxidant capacity of wine (13) *in vivo* in both humans and animals, there are fewer about the effects of wine on cholesterol metabolism, particularly in normocholesterolemic conditions. In using rats fed on a high-cholesterol diet, grape seed catechins were shown to have a pronounced antihypercholesterolemic effect because they enhance reverse cholesterol transport, reduce intestinal cholesterol absorption, and increase bile acid secretion (14,15). It has been suggested that free radicals are atherogenic not only because they modify LDL but also because they act on the cellular cholesterol metabolism (16,17). Flavonoids may affect cholesterol homeostasis because of their direct action on cellular cholesterol metabolism or because of their antioxidant power.

To determine whether wine really does have properties that are in addition to or different from those of alcohol, we developed an experimental model (18) that discriminates the effects of alcohol from the effects of the nonalcoholic components present in wine in healthy rats. Using this model, we determined whether wine has effects on cholesterol metabolism in normocholesterolemic rats that alcohol does not.

## MATERIALS AND METHODS

All experiments involving animals were approved by the ethics committee of the Universitat Rovirai Virgili. Male Wistar rats were purchased from IFFA-CREDO (Barcelona, Spain). They were bred at the Animal Service of the University under controlled conditions of light (12 h on/12 h off), humidity (70–80%), and temperature (20–22°C). The animals (weighing about 125 g) were individually housed in metabolic cages and were then divided into three groups of 14 animals each. One group of animals (Control Group = C) had free access to a standard diet (A04, Panlab S.L., Barcelona, Spain) and water. The remaining two groups had free access to a standard diet, water, and wine or an equivalent ethanol solution. Of these two groups, one consumed red table wine (Appellation Contrôlée Priorat, Spain) with an ethanol concentration of 13.5% and 2.64 g/L of overall phenolic compounds (Red Wine group = RW). The second group con-

Abbreviations: HDL, high density lipoprotein; LDL, low density lipoprotein; VLDL, very low density lipoprotein.

sumed an aqueous ethanol solution (13.5% ethanol solution) equivalent to the red wine (Alcohol Solution group = AS). Both the wine and alcoholic solution were given to the rats in a glass feeding bottle (especially designed to avoid wine losses) that was separate from the water bottle, and they were allowed to consume as much as they desired (18). Spillage was also discounted as a possible source of wine loss because wine stains are easily observable and no such evidence was found when the cages were cleaned. Feces of 24 h were collected at day 1, day 44, and day 179 of treatment and stored at −80ºC until cholesterol and bile acids were determined. Seven nonfasted animals from each group were beheaded after 45 d and the other seven after 6 mon. Blood, with EDTA as anticoagulant, was centrifuged at 1500 × *g* for 5 min to obtain plasma. The liver, heart, and aorta were removed immediately, frozen with liquid $N_2$, and stored at −80ºC until they were used.

Lipoprotein was separated from fresh plasma using KBr (19,20) in a Beckman L8-70M centrifuge. Each fraction was dialyzed with phosphate-buffered saline for 24 h immediately after it had been obtained. Triglycerides (21) and cholesterol (22) in plasma and lipoproteins were measured by spectrophotometric-enzymatic methods. Total lipid content in the liver was determined by the method of Folch *et al.* (23).

The feces, liver, heart, and aorta were homogenized first with 9% NaCl and then with chloroform/methanol (2:1, vol/vol) to determine total cholesterol, free cholesterol, and cholesteryl esters. The homogenates were shaken for 24 h at 4°C. The organic fraction was separated and divided into two fractions: total cholesterol was determined in one and free cholesterol in the other. The fractions were evaporated under a stream of $N_2$ gas. For total cholesterol to be determined, the samples were hydrolyzed with 33% KOH, and cholesterol was extracted with hexane and evaporated with $N_2$ gas. All samples were dissolved in isopropanol, and cholesterol levels were measured using cholesterol oxidase. Cholesteryl ester values were calculated as total cholesterol minus free cholesterol from each animal. After they had been extracted with methanol from feces, bile acids were determined by the method described by de Wael *et al.* (24).

Analysis of variance was used to evaluate the effect of wine and alcohol. The statistical comparisons were made between the three groups (control, wine, and alcohol solution) of the same period (45 d or 6 mon). After a significant *F* test ($P < 0.05$), the Scheffé test was used to determine differences between group means. Although we studied consumption over two periods of time, each group was compared only with the other groups of the same period, because the aim of the analysis was to compare the effect of alcohol or wine consumption over short or long periods of time, not to compare the effect of age of the animals.

## RESULTS

Wine consumption was 1.9 ± 0.2 mL wine/d/rat. Alcoholic solution consumption was 1.7 ± 0.2 mL/d/rat, similar to that of the wine it was simulating. The daily alcohol consumption—as wine or alcohol solution—by rats was 0.2 mL alcohol/rat (0.6–0.4 mL alcohol/kg body weight). The percentage of daily energy supplied by alcohol was 1.5% in the two groups.

In the control animals, the values of the parameters studied were similar in the two periods studied, except for total cholesterol in the plasma and the aorta. The fact that total cholesterol increases in the plasma with age is in agreement with the results of other authors (25). The changes in total cholesterol in the aorta may be due to changes in the diameter of the artery and in the characteristics of the arterial wall during aging (26).

Figure 1 shows the levels of plasma cholesterol and lipoprotein cholesterol after 45 d and 6 mon of wine or alcohol consumption. There was no effect on plasma cholesterol and high density lipoprotein (HDL)-cholesterol. At 45 d, both wine and

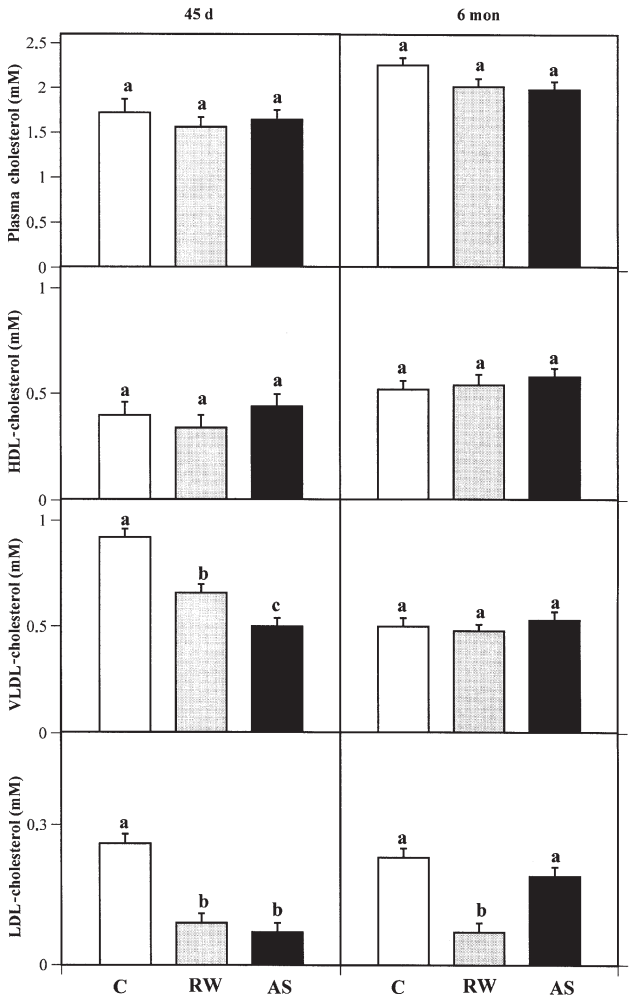

**FIG. 1.** Plasma cholesterol, HDL-cholesterol, VLDL-cholesterol and LDL-cholesterol in control rats (C) and in rats that consumed wine (RW) or an equivalent alcoholic solution (AS) for 45 d (left) or 6 mon (right). Each bar is the mean ± SEM of seven animals. Statistical analysis was performed by analysis of variance and the Scheffé test. The statistical comparisons were made between the three groups (control, wine, and alcohol solution) of the same period (45 d or 6 mon). Different superscripts indicate a significant difference between groups ($P < 0.05$). HDL, high density lipoprotein; VLDL, very low density lipoprotein; LDL, low density lipoprotein.

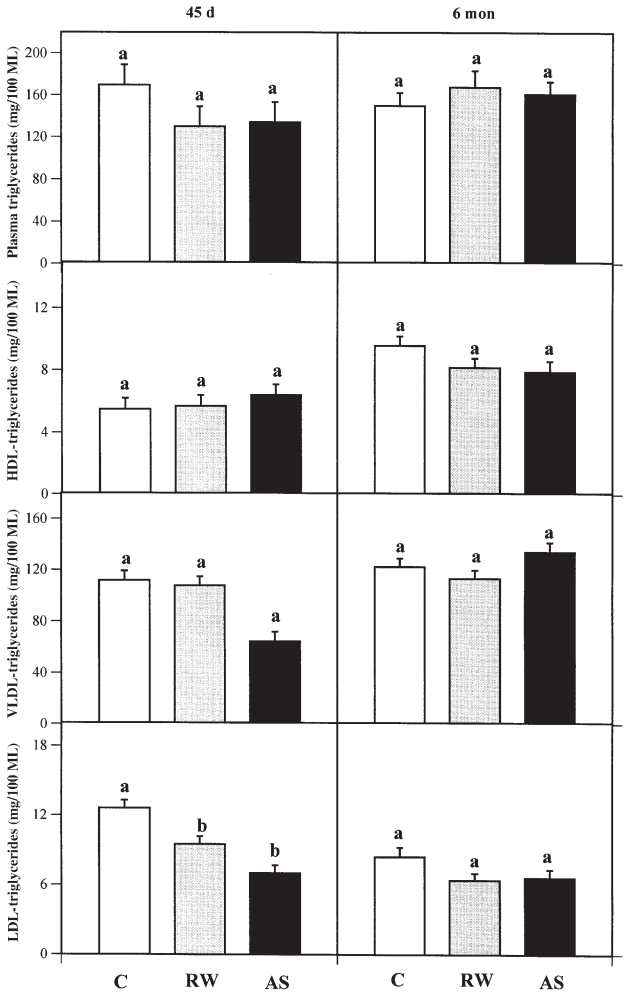

**FIG. 2.** Plasma triglycerides, HDL-triglycerides, VLDL-triglycerides and LDL-triglycerides in control rats (C) and in rats that consumed red wine (RW) or an equivalent alcoholic solution (AS) for 45 d (left) or 6 mon (right). Each bar is the mean ± SEM of 7 animals. Statistical analysis was performed by analysis of variance and the Scheffé test. The statistical comparisons were made between the three groups (control, wine, and alcohol solution) of the same period (45 d or 6 mon). Different superscripts indicate a significant difference between groups ($P < 0.05$). For abbreviations see Figure 1.

alcohol reduced LDL-cholesterol and very low density lipoprotein (VLDL)-cholesterol. At 6 mon, only the rats that consumed wine had reduced LDL-cholesterol.

Figure 2 shows the levels of plasma triglyceride and lipoprotein triglyceride of nonfasted animals. These levels were only slightly affected by wine and alcohol (Fig. 2) and only LDL-triglyceride was reduced in the rats that consumed wine or alcohol solution for 45 d.

The lipid content in the liver was similar in the controls and in the rats that consumed wine or alcohol (about 3 g lipids/100 g liver). Total cholesterol, free cholesterol, and cholesteryl esters in the liver (Table 1) were not affected by wine or alcohol consumption. In the control group, free cholesterol and cholesteryl esters were 70 and 30% of total liver cholesterol, respectively. This distribution was similar in the livers of the rats that consumed wine or alcohol (70–80% for free cholesterol and 20–30% for cholesteryl esters).

Table 2 shows the levels of total cholesterol, free cholesterol, and cholesteryl esters in the heart of control rats and rats that consumed wine or alcohol. Total cholesterol in the heart was not affected by wine or alcohol consumption, but cholesterol distribution—as free cholesterol and cholesteryl esters—was modified in rats that consumed wine. In the control group, free cholesterol and cholesteryl esters were 80 and 20% of the total cholesterol, respectively. At 45 d, however, free cholesterol was significantly reduced (60%) in the hearts of animals that consumed wine; at 6 mon, the distribution was similar to that of control animals. In the rats that consumed alcohol, free cholesterol and cholesteryl esters were 70 and 30% of total cholesterol, respectively, in the two periods studied.

Cholesterol content in the aorta was higher in rats that consumed alcohol (Table 3). After 45 d of alcohol consumption, total cholesterol in the aorta was significantly higher; alcohol also had this effect in the long term, but it was not significant. The effect of wine consumption was similar to the effect of alcohol consumption, although it was less intense.

Cholesterol excretion in the feces (Table 4) was not affected by alcohol or wine consumption. At 45 d, bile acid excretion in feces was lower in rats that consumed wine.

## DISCUSSION

Research has shown that the incidence of heart disease is lower in countries where wine is consumed on a moderate and regular basis than in countries where other types of alcohol are more commonly consumed (3). It has been suggested that moderate consumption of wine has positive effects because it

contains not only alcohol but also phenolic compounds, in particular, flavonoids. To determine whether the nonalcoholic component of wine can modify cholesterol homeostasis, we used a healthy animal model that distinguishes the effects of alcohol from the effects of other components (18). There are differences in the lipoprotein metabolism among species; rats lack the cholesteryl ester transfer protein (25) and, unlike humans, are resistant to developing atherosclerosis due to high-cholesterol feeding, but it is not unusual to use the rat to study compounds, particularly flavonoids, that affect cholesterol metabolism (26,27).

The wine used in this study is from the Appellation Contrôlée Priorat (Spain). It is a young, tannic red wine with a relatively high alcohol content, which is commonly consumed with meals in our country and which, therefore, is representative of what could be called the Mediterranean consumption. The rats consumed wine regularly and in moderate quantities (1.9 ± 0.2 mL wine/d/rat) consumed. The amounts of alcohol solution drunk were similar to the amounts of wine (1.7 ± 0.2 mL alcohol solution/d/rat). The concentration of alcohol in the blood was below the limits of detection by the usual methods, so the experiment is not a study of alcohol abuse.

Lipoprotein metabolism plays a significant role in the pathogenesis of atherosclerosis and the risk of vascular disease: high levels of LDL and low levels of HDL are linked to the risk of cardiovascular disease. Although one of the effects of moderate drinking includes increased plasma HDL-cholesterol (28), these levels were not modified in the rats that consumed wine or alcohol solution. On the other hand, LDL-cholesterol was dramatically decreased by wine consumption. In the short term, it seems that the LDL-cholesterol levels are affected by the alcohol content of wine because after 45 d, the rats that consumed wine and the rats that consumed alcohol solution had lower LDL-cholesterol levels. This reduction in

**TABLE 4**

| Alcohol | 27.4 ± 3.1[a] | 50.5 ± 3.7[a] | 35.2 ± 3.7[a] | 20.4 ± 2.1[a] | 26.2 ± 2.9[a] | 19.8 ± 4.11[a] |

[a]Each value is the mean ± SEM of six or seven animals. Statistical analysis was performed by analysis of variance and the Scheffé test. The statistical comparisons were made between the three groups (control, wine, and alcohol solution) of the same period (1 d, 45 d, or 6 mon after treatment). Different superscripts indicate a significant difference between groups ($P < 0.05$).

LDL-cholesterol coincided with a reduction in VLDL-cholesterol, so it might be caused by a minor hepatic VLDL-cholesterol secretion induced by alcohol consumption. After 6 mon, only the rats that consumed wine had lower LDL-cholesterol levels, suggesting that it is the nonalcoholic components of wine that have this effect in the long term. This reduction was not the result of decreased VLDL levels, so it seems that the nonalcoholic components of wine increase the removal of LDL from blood. Rajendran *et al.* (29) showed that tincture of Crataegus, of which flavonoids are one of the major components, enhances the LDL-receptor activity in the liver of rats on an atherogenic diet, so the rats that consumed wine may have a greater influx of plasma cholesterol into the liver.

Despite this decrease in the LDL-cholesterol of rats that consumed wine, there was no reduction in the total cholesterol in the heart, and there was even a tendency for cholesterol to increase in the aorta. Arterial cholesterol also increased in the animals that consumed alcohol solution (significant at 45 d), suggesting that this effect was the result of the alcohol content of wine. However, the animals that consumed wine did not accumulate as much cholesterol in the aorta as the rats that consumed alcohol solution. This indicated that nonalcoholic components in wine counteract the accumulation of cholesterol in the aorta induced by alcohol. The accumulation of cholesterol in arteries is related to LDL-cholesterol, so we find our results difficult to explain. We found that cholesterol accumulation in the aorta of rats that had consumed alcohol solution was more significant at 45 d, when LDL-cholesterol was substantially reduced. In recent years, attention has been drawn to the relation between the qualitative features of plasma LDL particles and cardiovascular risk. The atherogenic potential of LDL particles has been related to their size (30), degree of oxidation (31), aggregation (32), and cholesteryl ester content (33). Carr *et al.* (33) showed that, in hamsters on a cholesterol diet, there is no linear relationship between plasma LDL-cholesterol concentration and aorta cholesterol, whereas cholesteryl ester content of LDL is directly associated with increased total aorta cholesterol. We can discount LDL oxidation because the lipid oxidation index in the plasma of rats that drink wine or alcohol solution is lower than in control animals (34).

Total cholesterol and free cholesterol in the liver and heart were not modified by either alcohol or wine consumption. However, after 45 d, cholesteryl ester concentrations were lower in the liver and higher in the heart in the wine group than in controls, although these differences were not significant. The concentrations of cholesteryl esters were not obtained by direct measurement but by the difference between total and free cholesterol values; therefore, small differences in the value of these two parameters lead to large differences in the cholesteryl ester values.

The effects of flavonoids on bile acid excretion are controversial: some authors describe an increase (14,15) while others describe a reduction (35). We observed a reduction in bile acid excretion after 45 d in rats that consumed wine, but this excretion was similar to that in control rats at 6 mon. It is possible that the specific type or class of flavonoids used and the concentration and time for which they are administered affect the excretion of cholesterol and bile acids.

Previous studies have stated that flavonoids are hypocholesterolemic (11,14,15,35) in animals on a hypercholesterolemic diet, but we have not detected this effect. In healthy animals, then, the nonalcoholic components of wine reduced LDL-cholesterol in the long term but did not reduce the cholesterol content of the aorta or the heart. Our animals did not have hypercholesterolemia, so it seems that wine or alcohol protection is only effective in hypercholesterolemic situations. Although human and rat lipoprotein metabolism are not directly comparable, our results agree with authors who suggest that drinking is protective in middle and old age (1), a period in life when metabolic disturbances are more frequent.

## ACKNOWLEDGMENTS

We would like to thank Santiago Moreno for his assistance in handling the animals. This research project was supported by grant number ALI98-0452 from the Comisión Interministerial de Ciencia y Tecnologia (CICYT) from the Spanish government and by a personal grant from the Catalonian government (CIRIT).

# Wax Ester Biosynthesis in the Liver of Myctophid Fishes

**Hwan-Sook Seo[a], Yasushi Endo[a], Masatoshi Moku[b], Kouichi Kawaguchi[b], and Kenshiro Fujimoto[a,*]**

[a]Graduate School of Agricultural Science, Tohoku University, Sendai 981-8555, Japan, and
[b]Ocean Research Institute, University of Tokyo, Tokyo 164-0014, Japan

**ABSTRACT:** The biosynthetic properties of wax esters in the liver were compared between two types of myctophid fishes having different body lipid composition, i.e., three triglyceride-rich species (*Lampanyctus jordani*, *Diaphus theta,* and *Symbolophorus californiensis*) and three wax ester-rich species (*L. regalis, Stenobracius nannochir*, and *Stenobracius leucopsarus*). *n*-Heptadecanol (17:0-ALC) and/or 10-*cis*-heptadecenoic acid (17:1-ACID) was incubated with liver homogenate of the six myctophid fishes and with co-factors such as NADPH and ATP for 2 to 5 h. Considerable amounts of wax esters with odd-numbered fatty acids and/or alcohols were produced in the liver homogenate of the wax ester-rich species. *Stenobracius nannochir* and *L. regalis*, which exclusively contained wax esters as neutral lipids, showed the highest activity of wax ester synthesis, followed by *S. leucopsarus,* which contained triglyceride as the minor constituent. Only trace amounts at most of odd-numbered fatty acids and alcohols were incorporated into the wax esters after incubation with the liver homogenates of the triglyceride-rich fishes. Active interchange between the fatty acids and the alcohols occurred during wax ester biosynthesis in the wax ester-rich fishes. The chain elongation and shortening of acyl moieties were also observed during incubation. These results suggested that the deposition of lipids in myctophid fishes is mainly due to their biosynthetic activities.

Paper no. L8494 in *Lipids 36*, 389–393 (April 2001).

Myctophid fishes, which are abundant in the mesopelagic zone of the world's oceans, are regarded as one of the most promising unused marine biological resources (1–3).

We have examined nutritional components such as lipids (4,5) and amino acids (6) contained in the muscle of myctophid fishes caught in the subarctic and transitional waters of the Pacific ocean. We observed a fairly good correlation between the major tissue lipids and migration patterns of the myctophid fishes. Most myctophid fishes make diel vertical migrations to feed in the productive upper 100 m at night. Based on their migratory patterns, myctophid fishes in the subarctic Pacific are grouped into surface migrants, midwater migrants, semimigrants, and nonmigrants (7). Among the subarctic Pacific species, the nonmigratory or semimigratory species store large quantities of wax esters in their whole bodies (the wax ester-rich fishes), whereas the migratory ones contain triglycerides (the triglyceride-rich fishes) (4).

In this paper, we examined the capacity for wax ester biosynthesis in the liver of migratory, semimigratory, and nonmigratory myctophid fishes to elucidate the ecological role of wax esters in their lives.

## EXPERIMENTAL PROCEDURES

*Myctophid fishes.* The myctophid fishes were caught in the northwestern Pacific ocean by *Marusada-maru*, a commercial trawler, in August, 1996. Among the six species used in the experiments, three species (*Lampanyctus jordani, Diaphus theta,* and *Symbolophorus californiensis*) were rich in triglycerides (more than 90% of their total lipids) in whole body, whereas the others (*L. regalis, Stenobrachius nannochir,* and *Stenobrachius leucopsarus*) were rich in wax esters (more than 90% of their total lipids) in whole body (4). The fish were stored at 0°C for 10 h until the experiment.

*Incubation of liver homogenate with the marker fatty acid and alcohol to assess wax biosynthesis.* Crude enzyme was prepared by homogenizing 1.0 g of livers pooled from 5 to 10 individual myctophid fish in 10 mL of 0.05 M citrate phosphate buffer (pH 5.0) with a Teflon glass homogenizer. The enzymatic reaction was done principally according to the method of Mankura and Kayama (9). 10-*cis*-Heptadecenoic acid (17:1-ACID; Sigma, St. Louis, MO; 3.7 nmol), *n*-heptadecanol (17:0-ALC, Nu-Chek-Prep, Elysian, MN; 3.7 nmol), or a mixture of 17:1-ACID and 17:0-ALC [1:1 (mol/mol), total 3.7 nmol] was dissolved in 0.1 mL of 5% bovine albumin (inactivated by heating; Sigma) in 0.05 M citrate phosphate buffer (pH 5.0) with Triton X-100 (1.0 mg) and sodium deoxycholate (1.0 mg) by sonication for 5 min. The substrate solution was mixed with 0.9 mL of the crude enzyme solution (6.2 mg protein) added to CoA (0.15 μmol), ATP (5.0 μmol), $MgCl_2$ (4.0 μmol), NADPH (2.0 μmol), in the final volume of 1.0 mL. The reaction was allowed to proceed for 2 and 5 h at 30°C. Incubation was terminated by the addition of an equal volume of methanol. The amounts of the incorporated odd-numbered fatty acid and alcohol were calculated following Lepage and Roy (10). The wax ester content in liver was also measured before and after incubation.

The amount of incorporated odd-numbered fatty acids and/or alcohols equals the levels of odd-numbered fatty acids

and/or alcohols in liver homogenate with 17:1-ACID and/or 17:0-ALC) minus (the levels of odd-numbered fatty acids and/or alcohols in the liver homogenate without 17:1-ACID and/or 17:0-ALC).

Data for enzymatic reactions were averaged for three determinations per sample.

*Lipid analyses*. Lipids were extracted from the reaction mixture by the method of Bligh and Dyer (11) and analyzed qualitatively by thin-layer chromatography (TLC) using Kieselgel 60 plates (Merck, Darmstadt, Germany) with a mixture of *n*-hexane/diethyl ether (7:3, vol/vol) as a mobile phase. The lipids were detected by spraying the plates with 50% $H_2SO_4$ and heating. The lipid classes were, however, quantitatively determined by TLC with a hydrogen flame-ionization detector (FID) using an Iatroscan TH-10 (Iatron Laboratory, Tokyo) with silica gel rods (S-III) and *n*-hexane/diethyl ether/formic acid (80:20:1, by vol) as a mobile phase. All TLC data presented are from the averages of five measurements for each individual sample.

For the analyses of fatty acids and alcohols in the wax esters, the wax esters were isolated by TLC and saponified (4). The compositions of fatty acids and alcohols before incubation with odd-numbered alcohols and/or fatty acids were analyzed as described previously (4). After incubation, the fatty acids were isolated, hydrogenated (12), and then methylated (13) prior to gas chromatography (GC) analysis using a GC-380 gas chromatograph (GL Sciences, Tokyo, Japan) equipped with an FID. Hydrogenation was essential to simplify the chromatograms and to clearly identify the peaks of odd-numbered fatty acids on the chromatograms. The column was a CP-SIL 88 capillary column (0.25 mm × 50 m; Chrompack, Middelburg, the Netherlands). The FID and injection temperatures were 250°C and the column temperature was programmed from 170 to 225°C at 3°C/min. Fatty acids were identified by comparing retention times with those of authentic standards and by comparing chromatograms of standards subjected previously to GC–mass spectrometry.

Fatty alcohols obtained by the saponification of the wax esters were analyzed by GC after hydrogenation and acetylation. Acetylation improved the recovery and resolution of alcohols in GC analysis. Analytical conditions were the same as in the case of the wax ester except for the column temperature, which was programmed from 170 to 225°C at 4°C/min.

## RESULTS

*Lipid classes and wax ester compostition in the liver.* The lipid compositions in the liver of six species of myctophid fishes were examined (Table 1). They were somewhat different from the composition of the whole body reported previously (4), although the level of wax esters in the liver was higher in the wax ester-rich fish than in the triglyceride-rich fish. In the whole body of the wax ester-rich fish, such as *S. leucopsarus, S. nannochir* and *L. regalis*, the wax esters occupied more than 90% of the total lipids in the whole body. However, triglycerides (37.4–136 mg/g tissue) more than wax esters (30.3–78.5 mg/g tissue) were contained in the liver lipids of the wax ester-rich fish, as shown in Table 1. Small amounts of wax esters (0–7.4 mg/g tissue) were found in the liver lipids of three species among the triglyceride-rich fishes, although the major liver lipid classes were triglycerides.

The alcohol and fatty acid compositions in wax esters in liver of wax ester-rich species are shown in Table 2. The patterns of both alcohols and fatty acids were similar to wax esters extracted from the whole body reported previously (4), but the percentages of major alcohols and fatty acids were somewhat different.

*Synthesis of wax esters from 17:0-ALC and 17:1-ACID.* Figure 1 shows the increments of wax esters in the liver homogenate of four myctophid species during incubation with 17:1-ACID and/or 17:0-ALC. Large amounts of wax ester (372–865 μg/g tissue) were produced in the wax ester-rich fishes such as *S. nannochir* and *L. regalis* during incubation. The level of wax ester was lower (65–99 μg/g tissue) in *S. leucopsarus*. Only trace amounts (less than 2 μg/g tissue) of wax esters were detected in the triglyceride-rich fish. This result showed that the wax ester-rich myctophid fishes had a very high capability for biosynthesizing of wax ester. In the

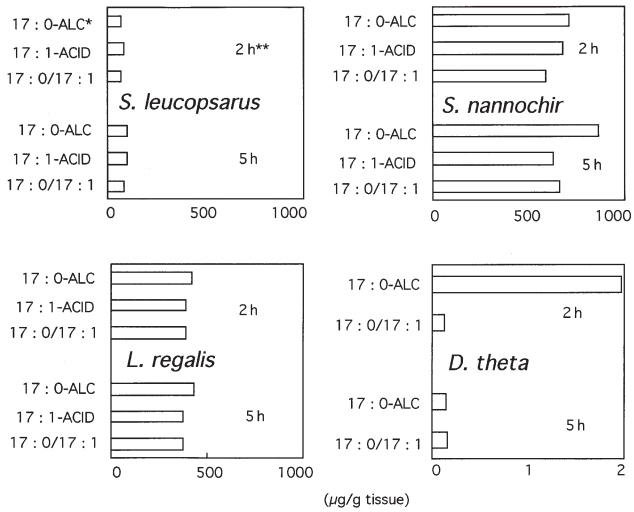

**FIG. 1.** Increment of wax esters in the liver of myctophid fishes during incubation with *n*-heptadecanol (17:0-ALC) and/or 10-*cis*-heptadecenoic acid (17:1-ACID). *17:0-ALC, incubated with 17:0-ALC; 17:1-ACID, incubated with 17:1-ACID; 17:0/17:1, incubated with 17:0-ALC and 17:1-ACID. ** Incubation time. Fish: *Stenobracius leucopsarus; S. nannochir; Lampanyctus regalis; Diaphus theta.*

wax-rich fish, the synthesis of wax ester reached a maximum at 2 h and no or very little increase was observed during 2 to 5 h (Fig. 1). The amounts of odd-numbered alcohols and fatty acids in wax esters after incubation of the liver homogenate of three wax-rich myctophid fishes with 17:0-ALC and/or 17:1-ACID are shown in Figure 2.

*Stenobracius leucopsarus*. When 17:0-ALC and a mixture of 17:0-ALC and 17:1-ACID were added to the liver homogenate, the total amount of odd-numbered alcohols was 32–95 nmol/g tissue. The level of odd-numbered alcohols was much higher (207–218 nmol/g tissue) when 17:1-ACID was added. In particular, greater amounts of odd-numbered alcohols with a carbon chain length other than 17 were observed. These observations showed that the added 17:1-ACID was reduced to alcohol after chain elongation and β-oxidation and then incorporated into wax ester in the liver.

When 17:1-ACID and a mixture of 17:0-ALC and 17:1-ACID were added to a liver homogenate of *S. leucopsarus*, the level of odd-numbered fatty acids was 25–68 nmol/g tissue. The level of odd-numbered fatty acids was higher (75–148 nmol/g tissue) when 17:0-ALC was added. Considerable amounts of odd-numbered fatty acids with a carbon chain length other than 17 were also found in the liver homogenate after incubation with 17:0-ALC. More than half of the added 17:0-ALC was transformed into fatty acids and then incorporated into wax ester in the liver.

From analyses of fatty acids and alcohols in wax esters of the liver of *S. leucopsarus*, one can see that most of the added fatty acids and alcohols were not directly incorporated into the wax esters of the liver but rather were transformed into the corresponding alcohols and fatty acids before incorporation into the wax esters.

*Stenobracius nannochir*. High levels of odd-numbered alcohols were observed in the wax esters after the incubation of liver homogenates with 17:0-ALC (533–974 nmol/g tissue) and 17:1-ACID (793–1123 nmol/g tissue). These levels were about five times higher than observed in *S. leucopsarus*.

The level of odd-numbered fatty acids in wax esters was higher in the liver homogenate with added 17:0-ALC (1600–2271 nmol/g tissue) and 17:1-ACID (977–1516 nmol/g tissue). This result was also different from that in *S. leucopsarus*. Added 17:1-ACID was incorporated into the wax esters as fatty acids, although the level of 17:1-ACID incorporated into the wax esters was less than that of 17:0-ALC. The level of 17:1-ACID incorporated into the wax esters as fatty acids in the liver of *S. nannochir* was 16 times higher than in *S. leucopsarus*. These observations suggested the occurrence of much higher wax ester biosynthetic activity in *S. nannochir* under the laboratory conditions used.

*Lampanyctus regalis.* Considerable amounts of odd-numbered alcohols were observed in the wax esters of liver homogenate incubated with 17:1-ACID (975–1049 nmol/g tis-

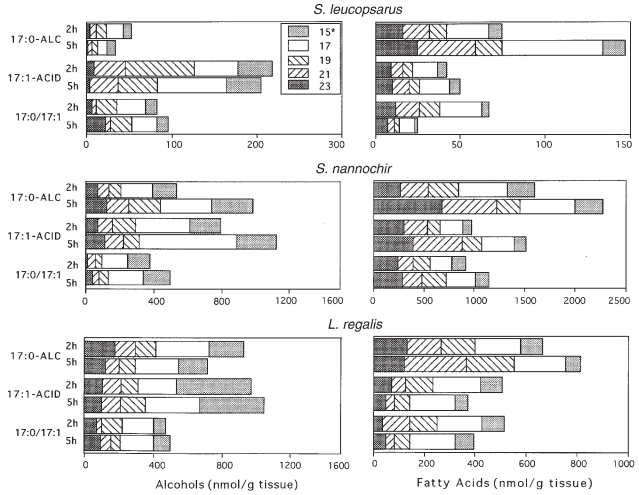

**FIG. 2.** Incorporated odd-numbered fatty alcohols (left panels) and fatty acids (right panels) in wax esters in the liver of wax ester-rich myctophid fishes after incubation with *n*-heptadecanol (17:0-ALC) and/or 10-*cis*-heptadecenoic acid (17:1-ACID). Upper: *S. leucopsarus;* middle: *S. nannochir;* lower: *L. regalis.* *Carbon chain length of odd-numbered alcohols and fatty acids in wax esters. See Figure 1 for abbreviations.

sue) and 17:0-ALC (721–930 nmol/g tissue). These results were similar to those observed in *S. nannochir*. However, the levels of incorporated fatty acids in *L. regalis* were lower than those in *S. nannochir*. The 17:0-ALC was incorporated into wax esters as fatty acids as well as alcohols, but 17:1-ACID was preferentially incorporated as alcohols rather than fatty acids.

*Triglyceride-rich species*. Among the three triglyceride-rich fishes, neither odd-numbered fatty acids nor alcohols were incorporated into the wax esters in *L. jordani* and *S. californiensis* after incubation with 17:0-ALC and/or 17:1-ACID. As no measurable amount of wax ester was synthesized after incubation of the liver homogenates of these two species with 17:0-ALC and 17:1-ACID, we suggested that wax ester is not biosynthesized in the liver of these species at all under these experimental conditions. In the case of *D. theta*, small amounts of odd-numbered fatty acids were detected in the wax esters after incubation with 17:0-ALC (Fig. 3) whereas no odd-numbered alcohols were detected at all in the wax esters. These results, if taken together, indicate that the activity of wax ester synthesis in the liver of triglyceride-rich myctophid fishes was very low and in some cases negligible.

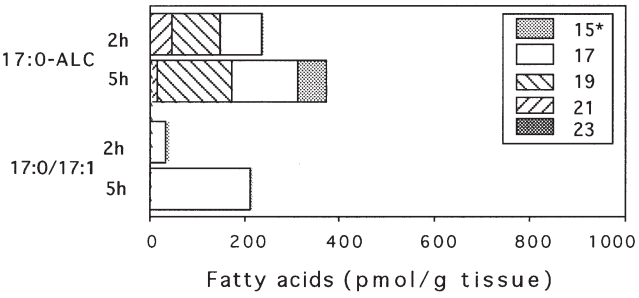

**FIG. 3.** Incorporation of odd-numbered alcohol (17:0-ALC) and fatty acid (17:1-ACID) in the fatty acids of wax esters in the liver of *D. theta* after incubation with 17:0-ALC or with 17:0-ALC plus 17:1-ACID. There was no incorporation detected of 17:0-ALC or 17:0-ALC/17:1-ACID into fatty alcohols of wax esters. For abbreviations see Figure 1.

## DISCUSSION

We have previously found that there were two types of myctophid fishes from the point of view of lipid properties (4). That is, one is a wax ester-rich fish, the other is a triglyceride-rich fish. We also analyzed the lipid composition of the stomach contents of myctophid fishes because body lipids might derive from prey organisms as reviewed by Benson and Lee (14). However, we found no significant differences in lipid composition in the stomach contents between the wax ester-rich and triglyceride-rich fishes. Thus, in this study we examined the capacity for biosynthesis of wax esters in the liver of the wax ester-rich and triglyceride-rich fishes to understand whether the wax ester synthesis in the liver may determine lipid compositions of the myctophid fishes.

The wax ester-rich fish had high contents of wax esters in the liver, which correlated with those in the whole body. We examined the synthesis of wax ester in their livers using 17:0-ALC and 17:1-ACID as substrates. In the liver, wax ester synthesis was much higher for the wax ester-rich fishes. In particular, activities in the nonmigrant species (*S. nannochir* and *L. regalis*) were greater than in the semimigrant species (*S. leucopsarus*). In the wax ester-rich fishes, most of the added 17:1-ACID and 17:0-ALC was transformed to alcohols and fatty acids, respectively, and then incorporated into the wax ester after chain elongation and β-oxidation. Both 17:1-ACID and 17:0-ALC were incorporated into the wax esters as fatty acids and alcohols without transformation. The 17:1-ACID, added to liver homogenates of the triglyceride-rich fishes, was incorporated in part into triglycerides, whereas most of it remained as free fatty acids (data not shown).

From these results, the wax content in the whole body of myctophid fishes (4) showed a good correlation with the wax ester biosynthetic activity in the liver rather than with foods consumed. The very active incorporation of $^{14}$C-labeled acetate into wax ester in the liver of orange roughy, which is known to accumulate wax ester in skin and swim bladder, was also reported (15). Moreover, we found that fatty acids and alcohols were mutually transformed during wax ester synthesis in the liver of the wax ester-rich myctophid fishes. Mankura and Kayama (9) reported the similar transformation from alcohols to fatty acids, but not from fatty acids to alcohols in the liver of carp.

Our results also showed that wax ester-rich myctophid species are restricted to nonmigratory and semimigratory species in the subarctic and transitional waters of the western Pacific. Nonmigrants (*S. nannochir* and *L. regalis*) especially showed high synthetic ability for wax ester. This supports the view that wax esters contribute to the static lift for neutral buoyancy.

## ACKNOWLEDGMENTS

This work was supported in part by a grant from the Ministry of Education, Science, Sports and Culture of Japan, No.06454096, and a grant from Marino Forum 21 Project "Technical Development of Utilization of Myctophid Fish Resources." We are indebted to Dr. Toshiyuki Tanabe of Tohoku National Fisheries Research Institute and Marino Forum 21 for providing the valuable myctophid samples analyzed.

# Water-Soluble Organosulfur Compounds of Garlic Inhibit Fatty Acid and Triglyceride Syntheses in Cultured Rat Hepatocytes

**Lijuan Liu and Yu-Yan Yeh***

Nutrition Department, The Pennsylvania State University, University Park, Pennsylvania 16802

**ABSTRACT:** The putative hypolipidemic effect of garlic remains controversial. To gain further insight into the effect of garlic on lipid metabolism, the present study determined the inhibitory effects of water-soluble organosulfur compounds present in garlic on triglyceride (TG) and fatty acid synthesis in cultured rat hepatocytes. When incubated at 0.05 to 4.0 mmol/L with cultured hepatocytes, *S*-allyl cysteine (SAC) and *S*-propyl cysteine (SPC) decreased [2-$^{14}$C]acetate incorporation into triglyceride in a concentration-dependent fashion achieving a maximal inhibition at 4.0 mmol/L of 43 and 51%, respectively. The rate of [2-$^{14}$C]acetate incorporation into phosphlipids was depressed to a similar extent by SAC and SPC. SPC, SAC, *S*-ethyl cysteine (SEC), and γ-glutamyl-*S*-methyl cysteine decreased [2-$^{14}$C]acetate incorporation into fatty acid synthesis by 81, 59, 35, and 40%, respectively, at 2.0–4.0 mmol/L concentrations. Alliin, γ-glutamyl-*S*-allyl cysteine, γ-glutamyl-*S*-propyl cysteine *S*-allyl-*N*-acetyl cysteine, *S*-allylsulfonyl alanine, and *S*-methyl cysteine had no effect on fatty acid synthesis. The activities of lipogenic enzymes, fatty acid synthase (FAS), and glucose-6-phosphate dehydrogenase (G6PDH) were measured in cultured hepatocytes treated with the inhibitors. The activity of FAS in cells treated with 4.0 mmol/L SAC and SPC, respectively, was 32 and 27% lower than that of nontreated cells. Neither SAC nor SPC affected G6PDH activity. The results indicate that SAC, SEC, and SPC inhibit lipid biosynthesis in cultured rat hepatocytes, and further suggest that these *S*-alk(en)yl cysteines of garlic impair triglyceride synthesis in part due to decreased *de novo* fatty acid synthesis resulting from inhibition on FAS. Whether tissue concentrations of active garlic components can achieve levels required to inhibit TG synthesis *in vivo* warrants further investigation.

Paper no. L8519 in *Lipids 36,* 395–400 (April 2001).

The cardiovascular protective effects of garlic have been extensively investigated in the past decades. It has been reported that garlic and various garlic preparations (e.g., aged garlic extract) reduce platelet aggregation in humans (1,2) and production of thromboxane $B_2$ in rats (3). Aged garlic extract has also been shown to decrease development of fatty streak and fibro fatty plaques in rabbits (4). Similarly, garlic powder supplementation in healthy adults attenuated age-related increase in aortic stiffness by increasing aortic elasticity (5). A recent study with human volunteers has further demonstrated that aged garlic extract lowered the susceptibility of low density lipoprotein (LDL) to oxidation (6). The potential reduction of risk for atherosclerosis and cardiovascular diseases by garlic has been attributed primarily to its hypolipidemic property. However, the lipid-lowering effects of garlic in humans remain controversial. Although a number of studies reported that garlic lowered plasma total cholesterol, LDL-cholesterol, and triglyceride (TG) in animals (7–10) and in humans (11–14), several recent human intervention studies were unable to confirm the hypocholesterolemic effects of different garlic preparations (15–17). One of the possible explanations for the discrepancy may stem from the different ingredients of garlic or garlic preparations used in various studies (18). Moreover, the active components of garlic responsible for the putative lipid-lowering effects are ill defined (18). Raw garlic and garlic powder contain lipid-soluble thiosulfinates, thiosulfinate transformation products, and sulfides (19). Among these compounds, allicin and vinyl dithiins have been suggested as potential lipid-lowering agents (19). In addition, garlic in general, and aged garlic extract in particular, contains a significant amount of water-soluble organosulfur compounds including *S*-alk(en)yl cysteines and γ-glutamyl-*S*-alk(en)yl cysteines (19–21). We recently demonstrated that *S*-alk(en)yl cysteines and γ-glutamyl-*S*-alk(en)yl cysteines inhibited cholesterol biosynthesis in cultured rat hepatocytes (22). Among the compounds tested in cultured hepatocytes, three water-soluble *S*-alk(en)yl cysteines, i.e., *S*-allyl-cysteine (SAC), *S*-ethyl cysteine (SEC), and *S*-propyl cysteine (SPC), were the most potent inhibitors of cholesterol biosynthesis, achieving 42 to 55% maximal inhibition, albeit at high concentrations (22).

Despite extensive studies on understanding the effects of garlic on human lipid metabolism, little is known about the mechanisms underlying possible hypotriglyceridemic action of garlic or garlic preparations. A previous study from our laboratory demonstrated that garlic extracts inhibited [$^3$H]glycerol incorporation into TG in rat cultured hepatocyte in the presence of acetate (10). When oleate was incubated with [$^3$H]glycerol, such an inhibitory effect of the garlic extracts was no longer apparent (10). Consistent with these *in vitro* experiments, dietary supplementation of garlic decreased incorporation of [$^{14}$C]acetate into fatty acids in various tissues of the rabbit (23). It is therefore reasonable to speculate that the inhibition of TG synthesis by garlic may in part be attributed to an impairment of fatty acid synthesis. The reduction of hepatic synthesis of TG could suppress very low density lipoprotein (VLDL)

Abbreviations: ANOVA, analysis of variance; DMEM, Dulbecco's modified Eagle medium; DTT, dithiothreitol; FAS, fatty acid synthase; FBS, fetal bovine serum; G-6-P, glucose-6-phosphate; G6PDH, glucose-6-phosphate dehydrogenase; GSAC, γ-glutamyl-*S*-allyl cysteine; GSMC, γ-glutamyl-*S*-methyl cysteine; GSPC, γ-glutamyl-*S*-propyl cysteine; $IC_{50}$, concentration required for 50% maximal inhibition; LDL, low density lipoprotein; PPB, potassium phosphate buffer; SAC, *S*-allyl cysteine; SAMC, *S*-allyl mercaptocysteine; SANC, *S*-allyl-*N*-acetyl cysteine; SASA, *S*-allylsulfonyl alanine; SEC, *S*-ethyl cysteine; SMC, *S*-methyl cysteine; SPC, *S*-propyl cysteine; TG, triglyceride; VLDL, very low density lipoprotein.

synthesis in the liver and hence decrease plasma TG level (24). Therefore, the present study was undertaken to determine the inhibitory potency of garlic-derived organosulfur compounds on TG and fatty acid synthesis *de novo* in cultured rat hepatocytes. The results indicated that SAC and SPC at high concentrations (2.0–4.0 mmol/L) were potent inhibitors of fatty acid and TG synthesis. In addition, SAC and SPC decreased the activity of fatty acid synthase (FAS) but had no effect on that of glucose-6-phosphate dehydrogenase (G6PDH).

## MATERIALS AND METHODS

*Animals*. Male Sprague-Dawley rats (200–300 g) were obtained from Harlan Sprague-Dawley Co. (Indianapolis, IN) and fed a nonpurified diet (Purina Rat Chow; Ralston Purina, St. Louis, MO). The animals were housed individually in stainless steel cages at approximately 24°C and 50% relative humidity on a 12-h light/dark cycle (0600–1800). The animal protocol was approved by The Pennsylvania State University Institutional Animal Care and Use Committee.

*Hepatocyte isolation and cell culture*. Hepatocytes were isolated from rats according to the method detailed previously (22). From each liver, 100–250 $\times$ $10^6$ cells were obtained with a viability of 92–94% judging by trypan blue exclusion. The cells were resuspended in Dulbecco's modified Eagle medium (DMEM) supplemented with 10% fetal bovine serum (FBS) and antibiotics (100 units penicillin/mL and 100 μg streptomycin/mL) to obtain 0.5–0.8 $\times$ $10^6$ cells/mL of suspension. Aliquots (2 mL) of the suspension were plated in each well of a six-well culture plate (Becton Dickinson Labware, Franklin Lakes, NJ) and incubated at 37°C under an atmosphere of 95% air and 5% $CO_2$. After 4 h of incubation, nonadhering cells were removed and discarded. Hepatocytes that adhered to the culture plate were re-fed with DMEM and incubated overnight for 16 h.

*Metabolic study*. At the end of the overnight incubation, cells were washed three times with 2 mL of FBS-free DMEM, followed by incubation with 2 mL of the same medium containing sodium salt of [2-$^{14}$C]acetate (specific activity, 37 MBq/mmol) and 0.5 mmol/L nonlabeled sodium acetate in the presence or absence of organosulfur compounds. Four hours after incubation, the medium was discarded and cells were harvested with 1.3 mL of ice-cold water by scraping with a cell scraper.

*Lipid analysis*. Cell suspension was mixed with 20 mL of chloroform/methanol (2:1, vol/vol) to extract lipids according to the method of Folch *et al*. (25) with minor modifications. For measurement of [2-$^{14}$C]acetate incorporation into fatty acid, the lipid extract was saponified with 6 mL of 3.75% methanolic KOH in a sealed ampule at 90°C for 4 h (26). After removal of the nonsaponifiable fraction, the extracts were acidified with concentrated HCl, and the fatty acids were extracted with petroleum ether (b.p. 35–60°C). For quantification of [2-$^{14}$C]acetate incorporation into TG and phospholipid, the lipid extracts were separated by thin-layer chromatography (TLC) on Silica Gel H coated plates (Analtech, Inc., Newark, DE) using hexane/diethyl ether/acetic acid (80:20:1, by vol) as developing solvent (27). The silica gel bands corresponding to TG and phospholipid were scraped into scintillation counting vials. The radioactivity of $^{14}$C-labeled products was measured by liquid scintillation counting (Beckman Model LS 3801; Beckman Instruments, Fullerton, CA). The specific activity of [2-$^{14}$C]acetate incorporation into fatty acid, TG, and phospholipid was expressed as pmol acetate incorporated/4 h/mg cellular protein. Cellular protein was determined by the procedure of Lowry *et al*. (28). The relative rate of [2-$^{14}$C]acetate incorporation into fatty acid, TG, and phospholipid by cells treated with organosulfur compounds was expressed as percentage of control by calculating specific activity of treatment group/specific activity of control nontreatment group $\times$ 100. $IC_{50}$ (concentration required for 50% maximal inhibition) was calculated by regression and correlation analysis between substrate concentration and percentage inhibition.

*Determination of enzyme activities*. For measurement of enzyme activities, the cells were cultured in 60 mm-diameter culture dishes (Becton Dickinson Labware) plated with 3 $\times$ $10^6$ cells/dish. Cells were treated and incubated under the same conditions described above for metabolic study. After 4 h of treatment, the medium was removed, and the cells were washed three times with ice-cold phosphate-buffered saline. The dishes were placed on ice and immediately the following were added: 0.5 mL of potassium phosphate buffer (PPB, 100 mmol/L, pH 7.4) containing sucrose, 250 mmol/L; EDTA, 1 mmol/L; and dithiothreitol (DTT), 1 mmol/L (29,30). The cells harvested by scraping were subjected to freezing and thawing three times and centrifuged at 20,000 $\times$ *g* for 30 min at 4°C (29). The supernatant obtained was used to determine the enzyme activities and protein concentration. FAS activity was determined spectrophotometrically by the method of Nepokroeff *et al*. (31) in PPB (500 mmol/L, pH 7.0) containing malonyl CoA, 0.1 mmol/L; acetyl CoA, 0.05 mmol/L; NADPH, 0.1 mmol/L; EDTA, 1 mmol/L; and DTT, 5 mmol/L. The reaction was initiated by the addition of 0.1 mL malonyl CoA to a final volume of 1 mL, and the rate of oxidation of NADPH was monitored at 340 nm and 30°C with a Beckman DU®-50 LS 5801 spectrophotometer (Beckman Instruments). G6PDH was measured by the method of Deutsch (32). The reaction mixture contained Tris buffer (100 mmol/L), pH 7.8, KCl (100 mmol/L), NADP (0.4 mmol/L), $MgCl_2$ (5 mmol/L), and glucose-6-phosphate (G-6-P) (5 mmol/L). The reaction was initiated by the addition of 0.1 mL of G-6-P to a final volume of 1 mL. The reduction of NADP was monitored spectrophotometrically at 340 nm. The specific activity of enzyme was defined as nmol NADPH oxidized/mg protein/min for FAS and nmol NADP reduced/mg protein/min for G6PDH.

*Materials*. Culture media, FBS, penicillin, and streptomycin were purchased from GIBCO (Gaithersburg, MD). Collagenase D was obtained from Boehringer Mannheim Corp. (Indianapolis, IN). All water-soluble organosulfur compounds of garlic: SAC, SEC, *S*-methyl cysteine (SMC), SPC, γ-glutamyl-*S*-allyl cysteine (GSAC), γ-glutamyl-*S*-methyl cysteine (GSMC), γ-glutamyl-*S*-propyl cysteine (GSPC), *S*-allyl cysteine sulfoxide (i.e., alliin), *S*-allyl-*N*-acetyl cysteine (SANC), *S*-allyl-mercaptocysteine (SAMC), and *S*-allylsulfonyl alanine (SASA) were pro-

vided by Wakunaga of America Co., Ltd. (Mission Viejo, CA). Sodium [2-$^{14}$C]acetate was obtained from Amersham Corp. (Arlington Heights, IL). All other chemicals of reagent grade were purchased from Sigma Chemical Co. (St. Louis, MO).

*Statistics*. Data are presented as means ± SEM (standard error of the mean). The comparisons of the test compounds were analyzed by analysis of variation (ANOVA) with the general linear model. When statistical significance was indicated by ANOVA, the Bunnett test was applied to identify the significant difference between the treatment and control at $P < 0.05$.

## RESULTS

Eleven water-soluble organosulfur compounds present in garlic or aged garlic preparations were tested for inhibition potency on fatty acid synthesis in cultured hepatocytes. The rate of [2-$^{14}$C]acetate incorporation into fatty acid in the untreated (control) group varied from 801 to 1127 pmol acetate/mg cellular protein/4 h among all experiments. The incorporation of [2-$^{14}$C]acetate into fatty acids was taken as a measure of fatty acid synthesis. The rate of fatty acid synthesis in the untreated cells for individual experiments was arbitrarily defined as 100%. Among *S*-alk(en)yl cysteines, SAC, SEC, and SPC, but not SMC, inhibited [2-$^{14}$C]acetate incorporation into fatty acid with maximal inhibition of 35–80% (Fig. 1). The inhibition was apparent at concentrations as low as 0.05 mmol/L for SAC and SEC, and 0.2 mmol/L for SPC (data not shown). The maximal inhibition was the highest by SPC, followed by SAC and SEC. Among γ-glutamyl *S*-alk(en)yl cysteines, GSMC inhibited the rate of [2-$^{14}$C]acetate incorporation into fatty acid to a maximum of 40%, while GSAC and GSPC did not alter the rate of the incorporation (Fig. 2). SAMC decreased the [2-$^{14}$C]acetate incorporation into fatty acid by 35% at 0.05 mmol/L (Fig. 2). Increasing concentration of SAMC to 2.0 and 4.0 mmol/L diminished fatty acid synthesis. Other water-soluble compounds (i.e., alliin, SANC, and SASA) had no effect on the rate of [2-$^{14}$C]acetate incorporation into fatty acid within the range of concentrations (0.05 to 4.0 mmol/L) tested (data not shown).

The concentration-dependent inhibition shown in Figures 1 and 2 permitted us to calculate maximal inhibition and $IC_{50}$ of water-soluble compounds on fatty acid synthesis. The maximal inhibition was the highest by SPC (81%) followed by SAC (59%), GSMC (40%), and SEC (35%), whereas the $IC_{50}$ (expressed as mmol/L) was the lowest with GSMC (0.72) followed by SEC (0.8), SPC (0.84), and SAC (0.91).

The effects of two potent inhibitors of fatty acid synthesis on the incorporation of [$^{14}$C]acetate into TG and phospholipid were determined. SPC and SAC inhibited the rate of [$^{14}$C]acetate incorporation into TG in a concentration-dependent fashion exhibiting 51 and 43% maximal inhibition, respectively, at 4.0 mmol/L (Fig. 3). A significant inhibition was observed at 0.05 mmol/L for SAC. In contrast, the inhibition by SPC was not apparent until the concentration was increased to 1.0 mmol/L. SAC and SPC inhibited [$^{14}$C]acetate incorporation into phospholipid as well, but the inhibitory potency was less than that on TG (Fig. 4). A significant inhibition of phospholipid production was not apparent until relatively high concentrations, i.e., 1.0 mmol/L for SAC and 2.0 mmol/L for SPC, were present in the incubation medium. The maximal inhibition was 43% for SAC, which was similar to that on TG (43%), and 30% for SPC, which was lower than that on TG (51%).

The marked inhibition on fatty acid biosynthesis led us to determine the effects of organosulfur compounds on the activities of lipogenic enzymes in cultured hepatocytes. The cells were incubated with SAC or SPC at the highest concentration (i.e., 4.0 mmol/L) that exhibited the maximal inhibition of fatty acid synthesis and at $IC_{50}$. The activity of FAS in

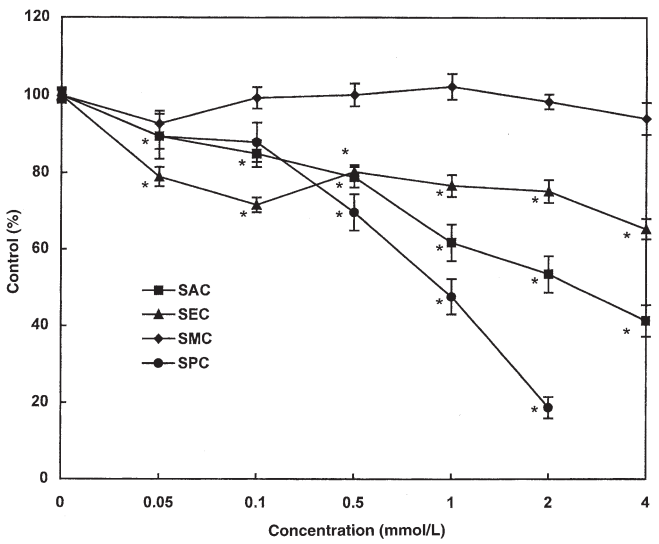

**FIG. 1.** Inhibition of [2-$^{14}$C]acetate incorporation into fatty acid by *S*-allyl cysteine (SAC), *S*-ethyl cysteine (SEC), *S*-methyl cysteine (SMC), and *S*-propyl cysteine (SPC) in primary rat hepatocyte culture. Data are expressed as a percentage of the control and represent means ± SEM of eight samples. *Statistically significant difference from controls at $P < 0.05$.

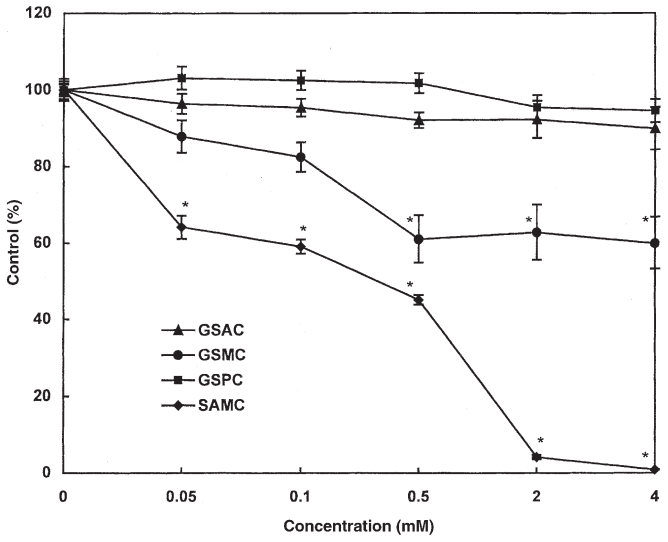

**FIG. 2.** Inhibition of [2-$^{14}$C]acetate incorporation into fatty acid by γ-glutamyl-*S*-allyl cysteine (GSAC), γ-glutamyl-*S*-methyl cysteine (GSMC), γ-glutamyl-*S*-propyl cysteine (GSPC), and *S*-allyl mercaptocysteine (SAMC) in primary rat hepatocyte culture. Data are expressed as a percentage of the control and represent means ± SEM of eight samples. *Statistically significant difference from controls at $P < 0.05$.

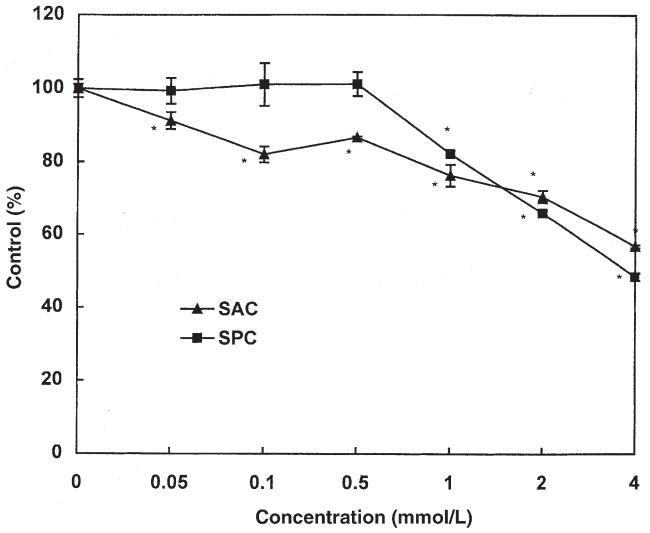

**FIG. 3.** Inhibition of [2-$^{14}$C]acetate incorporation into triglyceride by SAC and SPC in primary rat hepatocyte culture. Data are expressed as a percentage of the control and represent means ± SEM of eight samples. *Statistically significant difference from controls at $P < 0.05$. For abbreviations see Figure 1.

cells treated with 4.0 mmol/L SAC was 32% lower than that of nontreated cells (Table 1). SAC at $IC_{50}$ (i.e., 0.91 mmol/L) depressed the FAS activity by 19%. On the other hand, SPC depressed the activity of FAS only at 4.0 mmol/L but not at $IC_{50}$ (i.e., 0.84 mmol/L). Neither SAC nor SPC altered the activity of G6PDH at the concentrations tested (Table 1).

## DISCUSSION

Hypertriglyceridemia is a risk factor independent of plasma level of cholesterol for cardiovascular disease (33). Further, this risk factor is not necessarily associated with decreased plasma level of high density lipoprotein cholesterol, and hence a reduction of TG-rich lipoprotein (i.e., VLDL) may attenuate the progression of coronary artery disease (34).

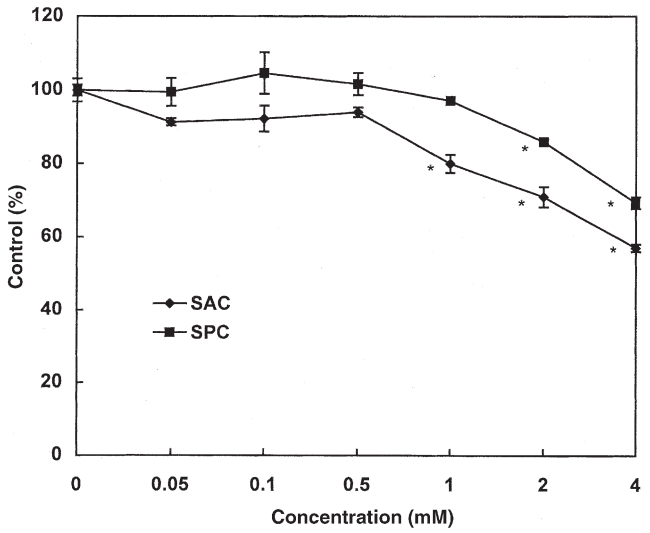

**FIG. 4.** Inhibition of [2-$^{14}$C]acetate incorporation into phospholipid by SAC and SPC in primary rat hepatocyte culture. Data are expressed as a percentage of the control and represent means ± SEM of eight samples. *Statistically significant difference from controls at $P < 0.05$. For abbreviations see Figure 1.

**TABLE 1**
**Activities of Fatty Acid Synthase (FAS) and Glucose-6-phosphate Dehydrogenase (G6PDH) in Hepatocytes Treated with or Without SAC and SPC[a]**

| Compounds | Concentration (mmol/L) | FAS[b] | G6PDH[b] |
|---|---|---|---|
| SAC | 0 | 3.71 ± 0.37 | 38.76 ± 3.43 |
| | 0.91 ($IC_{50}$) | 3.00 ± 0.19* | 37.12 ± 1.55 |
| | 4.0 | 2.53 ± 0.32* | 33.67 ± 1.81 |
| SPC | 0 | 4.06 ± 0.35 | 40.72 ± 1.96 |
| | 0.84 ($IC_{50}$) | 3.57 ± 0.18 | 40.29 ± 1.00 |
| | 4.0 | 2.94 ± 0.20* | 37.36 ± 2.65 |

[b]The specific activity of enzyme is defined as nmol NADPH oxidized/mg protein/min for FAS and nmol of NADP reduced/mg protein/min for G6PDH. Data represent means ± SEM of six samples. *Statistically significant difference from nontreated group, $P < 0.05$.

Evidence has suggested that garlic reduces the risk of cardiovascular disease by reducing the plasma level of cholesterol (4,12,13,23). Garlic may also decrease cardiovascular disease risk if it lowers plasma TG levels. In fact, some clinical studies have shown that garlic or garlic preparations did lower plasma TG levels (14,35). However, the mechanism underlying such a lowering action of garlic is unclear. Our previous study indicated that a TG-lowering effect of garlic extracts might stem in part from inhibition on hepatic TG synthesis (10). Furthermore, the reduction of TG synthesis was accompanied by depressed fatty acid synthesis in rat hepatocytes treated with various garlic extracts. Garlic is known to contain a large number of sulfur compounds (19). Although some of these compounds, such as SAC, have been shown to depress fatty acid synthesis (10), garlic constituents foremost responsible for inhibiting TG synthesis are yet to be determined. The present study revealed that sulfur-containing cysteine derivatives (i.e., SAC and SPC) were potent inhibitors of TG synthesis *in vitro*. Moreover, SAC and SPC were found to be the most potent inhibitors of fatty acid synthesis among *S*-alk(en)yl cysteines (e.g., SAC, SEC, SMC, and SPC) and γ-glutamyl-*S*-alk(en)yl cysteines (e.g., GSAC, GSMC, and GSPC) tested. These observations are consistent with our earlier study suggesting that garlic decreases hepatic TG production by inhibiting fatty acid synthesis (10). In addition, the current study further identified SAC and SPC as the most active garlic components for inhibition of fatty acid synthesis. The present data, however, do not exclude the possibility that garlic constituents affect the distal pathway of TG synthesis. For example, whether SAC, SPC, or other cysteine derivatives alter activities of glycerolipid-synthesizing enzymes such as glycerol-3-phosphate acyltransferase, monoacylglycerol acyltransferase, phosphatidate phosphohydrolase, and diacylglycerol acyltransferase is not known (36). It is worthwhile to note that the incorporation of [2-$^{14}$C]acetate into phospholipid was also inhibited in a similar manner as TG synthesis. Since phospholipid synthesis shares most acyl-

transferases and phosphatidate phosphohydrolase with TG synthesis, this finding tends to support the notion that the inhibition of TG synthesis by sulfur compounds may not involve esterification steps catalyzed by the acyltransferases.

Another important finding was that organosulfur compounds decreased fatty acid synthesis (Figs. 1 and 2), and the patterns of inhibition were similar to those on cholesterol synthesis as reported previously (22). Three *S*-alk(en)yl cysteines, SAC, SEC, and SPC, but not SMC, significantly decreased fatty acid synthesis with maximal inhibition of 59, 35, and 81%, respectively. Among γ-glutamyl *S*-alk(en)yl cysteines, GSMC reduced [2-$^{14}$C]acetate incorporation into fatty acid, while GSAC and GSPC did not affect fatty acid synthesis. Consistent with the unaltered rate of cholesterol synthesis, alliin, SANC, and SASA did not change [2-$^{14}$C]acetate incorporation into fatty acid, whereas SAMC containing two sulfur atoms markedly decreased fatty acid synthesis. However, unlike other water-soluble compounds, SAMC is highly cytotoxic, as reported earlier by this laboratory (22). Therefore, the reduction on [2-$^{14}$C]acetate incorporation into fatty acid by SAMC may result from cytotoxicity. The decrease of [2-$^{14}$C]acetate incorporation into fatty acid by other compounds, i.e., SAC, SEC, SPC, and GSMC, may result from impairment in the enzyme or enzymes regulating fatty acid synthetic pathways. In fact, the present study with cultured hepatocytes demonstrated that SAC and SPC incubated at the concentration (4.0 mmol/L) that caused maximal inhibition of fatty acid synthesis decreased the activity of FAS by 32 and 27%, respectively, when compared with nontreated cells. Neither SAC nor SPC exhibited an inhibitory effect on the activity of G6PDH. These data suggest that the sulfur-containing compounds depress fatty acid synthesis by inactivating FAS, the rate-limiting enzyme for fatty acid synthesis. Earlier animal studies by other investigators showed that garlic-supplemented diets decreased activities of not only lipogenic FAS but also G6PDH (7–9). The reason for the discrepancy in G6PDH activity observed between the present study and that of others (7–9) is not readily understood. However, it is important to point out that SAC and SPC isolated from garlic were used in the present *in vitro* experiment as compared with various garlic extracts fed to animals (7–9). Garlic extracts used in the studies contained not only SAC and SPC but also other water-soluble and fat-soluble sulfur compounds (37). Thus, animal studies are warranted to further delineate the differential effects of individually isolated compounds as compared with garlic extracts on lipogenic enzymes. Also, it should be stressed that whether SAC, SEC, SPC, and other sulfur-containing compounds interfere with fatty acid chain elongation by [2-$^{14}$C]acetate and hence play any role in the observed inhibition of TG synthesis remains to be ascertained.

Finally, the present study using cultured rat hepatocytes demonstrated that water-soluble organosulfur compounds of garlic, especially SAC and SPC, inhibited TG synthesis by depressing fatty acid synthesis *de novo*. The inhibition of fatty acid synthesis, on the other hand, was associated with decreased activity of FAS. Overproduction of TG-rich VLDL in liver is known to induce hypertriglyceridemia (38). It is therefore tempting to speculate that decreased hepatic TG synthesis by water-soluble organosulfur compounds may explain in part the hypotriglyceridemic effect of garlic reported previously (14,35). However, one must be cautious about the extrapolation of *in vitro* data to *in vivo* situations. It is important to stress that although maximal inhibition of fatty acid and TG synthesis was obtained at 4.0 mmol/L of alk(en)yl cysteines (i.e., SAC and SPC), significant inhibition of fatty acid synthesis was detected at a concentration as low as 0.05 mmol/L in the present *in vitro* study (Figs. 1,3). The inhibition of TG synthesis by SAC was also apparent in the same concentration range of 0.05 to 4.0 mmol/L (Fig. 3). It is essential to know whether these concentrations can be achieved under *in vivo* conditions. Unfortunately, there is no such information available for humans. Nonetheless, the present study *in vitro* clearly indicates that fatty acid and TG synthesis are inhibited by SAC and other alk(en)yl cysteines in a concentration-dependent manner. These findings further suggest that any effect of inhibition of the sulfur compounds on cholesterol synthesis and plasma cholesterol is likely dependent upon their tissue concentrations. Although garlic and garlic preparations have been shown to reduce (11–14, 39) or have no effect (15–17) on the plasma concentration of cholesterol and TG, the reported reduction of plasma concentration of cholesterol was mild with a mean of 9% according to the meta-analysis of Warshafsky *et al*. (39). Whether the low magnitude of the reduction in plasma cholesterol concentration is attributable to low tissue level of potential active components of garlic remains to be established. The reason for the contradictory observations of the effect of garlic on cholesterol is uncertain, but it may be explained in part by nonstandardized experimental designs. In addition, the present study further suggests the following parameters as important determinants of whether garlic affects plasma lipids: (i) the type of garlic preparations, e.g., garlic powder, garlic oil, or aged garlic extract, used in different studies; (ii) active components, e.g., lipid-soluble allicin and vinyl dithiin oils or water-soluble alk(en)yl cysteines, available in garlic preparations; and (iii) if the amount of active components is sufficient to achieve the plasma concentration required for inhibition of hepatic cholesterol and TG biosynthesis.

**ABSTRACT:** Cholesteryl ester transfer protein (CETP) is an important determinant of lipoprotein function, especially high density lipoprotein (HDL) metabolism, and contributes to the regulation of plasma HDL levels. Since saturated and polyunsaturated fatty acids (FA) appear to influence the CETP activity differently, we decided to investigate the effects of FA on the expression of CETP mRNA in HepG2 cells using an RNA blot hybridization analysis. Long-chain FA (>18 carbons) at a 0.5 mM concentration were added to the medium and incubated with cells for 48 h at 37°C under 5% $CO_2$. After treatment with 0.5 mM arachidonic (AA), eicosapentaenoic (EPA), and docosahexaenoic acid (DHA), the levels of CETP mRNA were less than 50% of the control levels (AA, $P = 0.0005$; EPA, $P < 0.01$; DHA, $P < 0.0001$), with a corresponding significant decrease in the CETP mass. These results suggest that FA regulate the gene expression of CETP in HepG2 and this effect is dependent upon the degree of unsaturation of the acyl carbon chain in FA.

Paper no. L8672 in *Lipids 36,* 401–406 (April 2001).

Cholesteryl ester transfer protein (CETP) is known to be a key protein in reverse cholesterol transport. By promoting the transfer and exchange of neutral lipids among plasma lipoproteins (1), it determines the plasma lipoprotein profile. A CETP deficiency markedly elevates plasma high density lipoprotein levels and decreases low density lipoprotein levels (2). The normal plasma CETP concentration of normolipidemic subjects ranges between 1.1 and 1.7 mg/L (3,4). CETP cDNA clones have been isolated from humans, cynomolgus monkeys, rabbits, and hamsters, with about an 80–95% sequence homology among the species (5–8). In humans, the organs with the most abundant expression of CETP mRNA are the liver, spleen, and adipose tissue, with lower expression levels in the small intestine, adrenal glands, kidney, and heart (5,6).

Abbreviations: AA, arachidonic acid; aLA, α-linolenic acid; BSA, bovine serum albumin; C/EBP, CCAAT/enhancer binding protein; CETP, cholesteryl ester transfer protein; DgLA, dihomo-γ-linolenic acid; DHA, docosahexaenoic acid; DMEM, Dulbecco's modified Eagle's medium; ELISA, enzyme-linked immunosorbent assay; EPA, eicosapentaenoic acid; FA, fatty acid; gLA, γ-linolenic acid; LA, linoleic acid; LCAT, lecithin-cholesterol acyltransferase; LPL, lipoprotein lipase; OA, oleic acid; PBS, phosphate-buffered saline; PUFA, polyunsaturated fatty acid; SA, stearic acid; SDS, sodium dodecyl sulfate; SREBP, sterol regulatory element-binding protein; SSPE, saline-sodium dihydrogenphosphate-ethylenediaminetetraacetate buffer.

The level of CETP mRNA is responsive to various environmental factors (9,10). High-fat and high-cholesterol diets (i.e., atherogenic diets) have been shown to raise both the mass and mRNA levels of CETP (6,8,11), whereas marine lipids, mainly n-3 polyunsaturated fatty acids (PUFA), have been shown to reduce plasma cholesterol and triglyceride levels (12) and to decrease the CETP mass level in hypercholesterolemic subjects (13). A recent study also reported that plasma CETP activity increased in a palmitic acid-rich diet in comparison to a stearic acid (SA)-rich diet (14) and that dietary *trans* fatty acids (FA) (e.g., elaidic acid) significantly increased CETP activity in comparison to diets rich in either SA, linoleic acid (LA) or palmitic acid (15,16).

*In vitro* studies with CaCo-2 cells (17) and HepG2 cells (18) have demonstrated that oleate or butyrate can up-regulate CETP secretion. Although the effects of various dietary FA on plasma CETP activity have been reported (19,20), whether various types of FA regulate the synthesis or expression of the CETP mass and/or the mRNA has yet to be explained.

To elucidate the action of dietary FA on CETP expression, we investigated the effects of long-chain FA on the mRNA and protein levels of CETP using HepG2 cells as an *in vitro* model.

## MATERIALS AND METHODS

*Cell culture*. The human hepatoma cell line HepG2 was purchased from the Riken gene bank (Wako, Japan), and the cells were maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 100 U/mL penicillin, 100 µg/mL streptomycin, 265 µg/mL thymidine (all from Life Technologies Ltd., Grand Island, NY) and 10% (vol/vol) fetal calf serum (Intergen Co., Purchase, NY) at 37°C under 5% $CO_2$. For the experiments described herein, the cells were seeded in 60-mm diameter collagen-coated culture dishes (Sumitomo Bakelite Co., Ltd., Tokyo, Japan) at a density of $2 \times 10^5$/dish and then were cultured to approximately 90% confluency.

*FA treatments*. HepG2 cells were grown to 90% confluency in the same medium and then were incubated with 10% (vol/vol) fetal calf lipoprotein-deficient serum-DMEM supplemented or not with 0.5 mM of FA: SA (18:0), oleic (18:1, OA), LA (18:2), alpha-linolenic (18:3, aLA), gamma-linolenic (18:3, gLA), arachidonic (20:4, AA), eicosapentaenoic (20:5, EPA) and docosahexaenoic (22:6, DHA) acids, which were dissolved in 10% essential FA-free bovine serum albumin (BSA) (all from the Sigma Chemical Co., St. Louis, MO).

Following a 48-h incubation at 37°C, cell-conditioned media were collected to determine the CETP mass, and the cells were dissolved in a denaturing solution for RNA extraction.

*Northern blot analysis*. Total RNA was isolated using an acid guanidinium thiocyanate-phenol-chloroform extraction method (21). The yield of purified RNA samples was determined by absorbance at 260 nm. RNA samples (15 µg per lane) were separated by electrophoresis in 1% agarose/5.5% formaldehyde gel containing 0.84 µM ethidium bromide, followed by capillary transfer to nylon membranes (Nytran-N, Schleicher & Schuell GmbH, Dassel, Germany) that were then cross-linked by exposure to ultraviolet light. The membranes were prehybridized (4 to 5 h) at 42°C, and then were probed overnight at 42°C with a CETP cDNA fragment (365–624 bp) which had been labeled with [alpha-$^{32}$P]dCTP (NEN Life Science Products, Inc., Boston, MA) using a commercial kit (Random Primer DNA Labeling Kit; Takara Co., Otsu, Japan) in 5 × saline-sodium phosphate-ethyltetraacetate buffer (SSPE), 5 × Denhardt's, 10% dextran sulfate, 50% deionized formamide, 1% sodium dodecylsulfate (SDS), 0.2 mg/mL of heat-denatured salmon sperm DNA, and 1 mg/mL of BSA. The blot was washed twice at 42°C and twice further at 50°C for 30 min with 2 × saline-sodium citrate buffer (SSC), 0.2% SDS and then was exposed to an imaging plate (Fuji Film, Tokyo, Japan). The mRNA levels were quantitated by estimating the photostimulated luminescence per area of the corresponding band with an imaging analyzer (BAS 2000; Fuji Film). The data obtained were normalized for a glyceraldehyde phosphate dehydrogenase level. Northern hybridization detected CETP mRNA in HepG2 dose-dependently ($r = 0.977$, $P < 0.0001$) when the total RNA per lane varied in mass from 0 to 20 µg.

*Measurement of the CETP mass*. The CETP mass secreted by HepG 2 cells into 4 mL of culture medium/60-mm i.d. dish was measured using an enzyme-linked immunosorbent assay (ELISA) (22). One milliliter of a cultured medium was concentrated to about 100 µL using Microcon-10 (Amicon, Inc., Beverly, MA), and then the CETP mass of the concentrated medium was determined using the CETP (Chugai) ELISA kit (Chugai Pharmaceutical Co., Ltd., Tokyo, Japan). The results obtained were then adjusted to the original volume.

*Analysis of the FA content in HepG 2 cells*. The cells were washed three times with PBS without $Ca^{2+}$/$Mg^{2+}$ before the cell lipids were extracted by the method of Folch *et al.* (23). The lipids were analyzed after methylation using HCl/methanol with margaric acid (17:0) as an internal standard as described in a previous paper (24). The FA content was then measured by gas–liquid chromatography (PerkinElmer Auto System GC, Palo Alto, CA) on an Rscot Sillier 5CP capillary column (0.25 mm i.d. × 50 m; Nihon Chromato Works Ltd., Tokyo, Japan). The protein concentration of the cells was determined with a Micro BCA Protein Assay Reagent kit (Pierce Laboratories Inc., Rockford, IL) using BSA as a standard.

*Statistical analysis*. The results are presented as the mean ± SE. Statistical comparisons of the experimental groups and a linear regression analysis were performed using one-way analysis of variance, and each group was compared with each other by Fisher's protected least significant difference test. The level of significance was set at $P < 0.05$. Analyses were performed using the StatView J4.51.1 software package (Abacus Concepts Inc., Berkeley, CA).

## RESULTS

*Expression of CETP by FA treatment.* To investigate the influence of FA on the CETP mRNA levels, HepG2 cells were treated with 0.5 mM of various kinds of FA. After 48 h of incubation, both the cell growth and morphology were normal in these treatments. Figures 1A and 1B show the effect of various FA on the levels of mRNA and protein of CETP in the HepG2 cells, respectively. After treatment with 0.5 mM of AA, EPA, and DHA, the expression of CETP mRNA was less than 50% of that of the control (Fig. 1A, $P < 0.0001$). De-

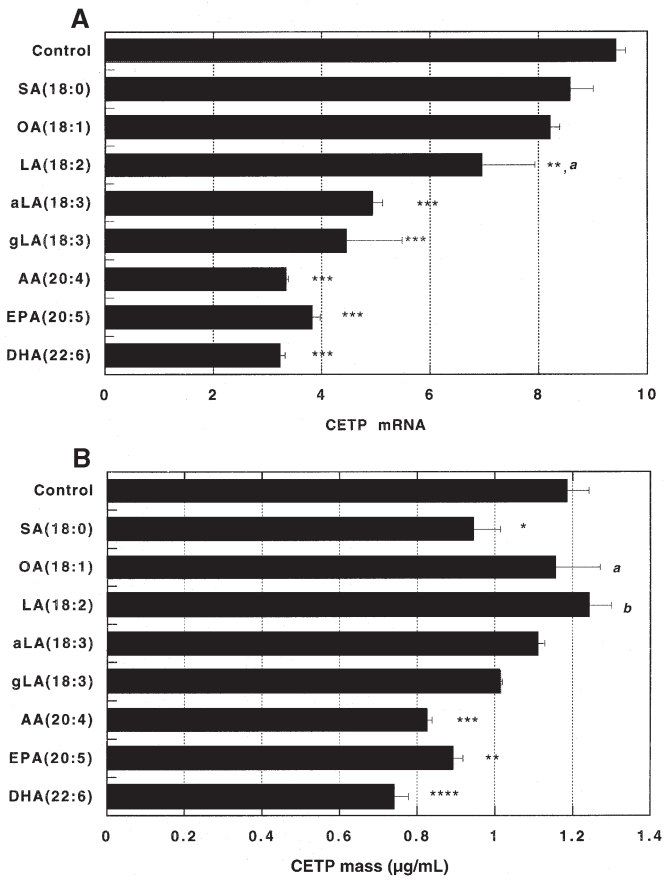

**FIG. 1.** Comparative effects of various saturated and unsaturated fatty acids (FA) on the expression of the cholesteryl ester transfer protein (CETP) mRNA (A) and mass (B). HepG2 cells were incubated with 0.5 mM of various FA or 1.25% bovine serum albumin (as a control) for 48 h in Dulbecco's modified Eagle's medium with 10% lipoprotein-deficient serum. The CETP mRNA and mass were measured as described in the text. Each data point represents the mean ± SE from three dishes. In A, statistical differences are shown as $^{**}P < 0.005$, $^{***}P < 0.0001$ relative to the control; and in B, $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P = 0.0005$, $^{****}P < 0.0001$; and in both, $^{a}P < 0.05$, $^{b}P < 0.005$ relative to stearic acid (SA). OA, oleic acid; LA, linoleic acid; aLA, alpha-linoleic acid; gLA, gamma-linoleic acid; AA, arachidonic acid; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

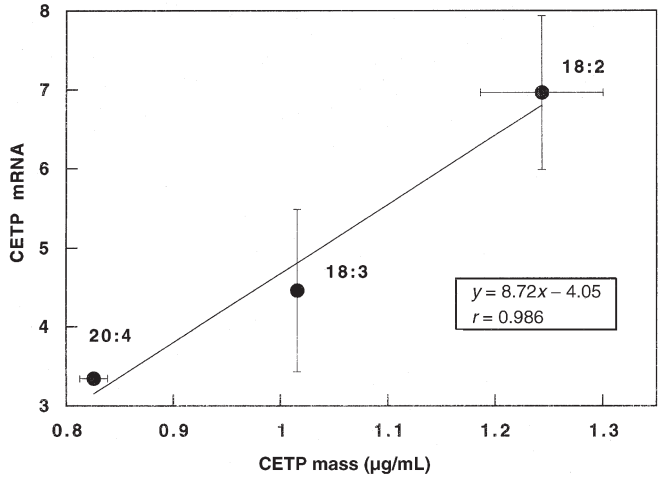

**FIG. 2.** Relationship between the CETP mRNA and mass secreted into the medium after the treatment of n-6 FA. A linear regression analysis demonstrates a positive correlation between CETP mRNA and mass ($r$ = 0.986). Each data point represents the mean ± SE from three dishes. For abbreviations see Figure 1.

creases in the CETP mRNA levels correlated with the increases in the degree of unsaturation of FA. As shown in Figure 1B, AA, EPA, and DHA also induced a significant decrease, relative to the control, in the CETP mass levels that correlated with the expression of CETP mRNA (AA, $P$ = 0.0005; EPA, $P < 0.01$; DHA, $P < 0.0001$). On the other hand, in the presence of 0.5 mM of SA, OA, and LA, each of which contains 18 acyl carbons, the induction of the CETP mass was facilitated as the degree of unsaturation increased (OA vs. SA, $P < 0.05$; LA vs. SA, $P < 0.005$), even though the mRNA level decreased in these cases.

*Correlation between the CETP protein mass and the mRNA level.* To analyze the correlation between the CETP mass and the mRNA level, we plotted the levels of the CETP mass and mRNA obtained after treatment with both the n-6 and n-3 series of FA, respectively (Figs. 2,3). These plots indicated that the n-6 and n-3 series each reduced both the CETP mass and mRNA level as the degree of unsaturation increased. The degree of unsaturation was strongly related to the expression of CETP if FA were classified into two groups consisting of the n-6 and n-3 series. Furthermore, the CETP mass and the mRNA levels both showed a positive correlation in this experiment (n-6, $r$ = 0.986; n-3, $r$ = 0.998).

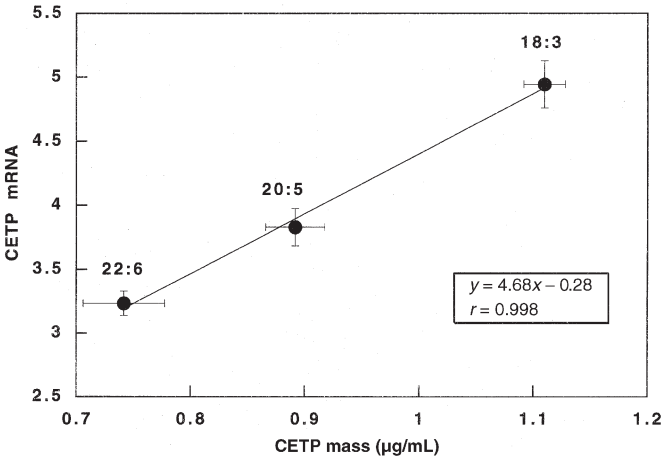

**FIG. 3.** Relationship between the CETP mRNA and mass secreted into the medium after the treatment of n-3 FA. A linear regression analysis demonstrates a positive correlation between CETP mRNA and mass ($r$ = 0.998). Each data point represents the mean ± SE from three dishes. For abbreviations see Figure 1.

*Incorporation and metabolism of FA.* As shown in Table 1, each FA added to the media increased the cellular FA concentration in comparison to the control, which was incubated without FA, thus indicating that FA were incorporated into HepG2 after 48 h of incubation. The metabolism of PUFA in humans and other animals proceeds by both chain elongation, such as biosynthesis of dihomo-γ-linolenic acid (DgLA, 20:3n-6) from gLA (18:3n-6), and desaturation, such as biosynthesis of gLA (18:3n-6) from LA (18:2n-6). For example, in the n-9 series, the concentration of OA (18:1n-9) and 20:3n-9, the metabolites of SA (18:0n-9), increased from 639.7 to 1424.9 nmol/mg protein and from undetectable levels to 78.2 nmol/mg protein after 48 h of incubation, respectively. In the n-6 series, DgLA and AA (20:4n-6), the metabolites of LA, were undetectable but rose to 172.1 nmol/mg protein and from 38.0 to 65.2 nmol/mg protein, respectively. Similarly in the n-3 series, 20:4n-3, the undetectable metabolite of aLA, increased to 203.8 nmol/mg protein. By the addition of LA, DgLA increased to 172.1 nmol/mg protein, while AA rose to a level that was 27.2 nmol/mg protein more than the control. Similarly, 20:4n-3 increased to 203.8 nmol/mg protein, while EPA (20:5n-3) was not detectable after treatment with aLA. These results supported the findings of previous reports in which the low activity of Δ5-desaturase in HepG2 resulted in the accumulation of DgLA or 20:4n-3 (24).

## DISCUSSION

These studies demonstrate that FA influence both the expression of CETP mRNA and protein in HepG2 cells. The human hepatoma-derived cell line HepG2 reveals many characteristic differences from normal differentiated hepatocytes, and very low levels of CETP gene expression and CETP activity in the medium have been reported (18,25,26). In the present study, using a northern blot analysis, we succeeded in detecting low amounts of radioactivity in bands corresponding to CETP mRNA.

FA of various chain lengths and degrees of unsaturation have been reported to affect the expression of enzymes and proteins involved in lipid metabolism (27–31). For example, previous studies reported that long-chain FA increase lipoprotein lipase (LPL) mRNA but reduce the degree of LPL activity, therefore presumably regulating the posttranslational processing of LPL (29). Skretting *et al.* (30) also found that lecithin-cholesterol acyltransferase (LCAT) activities and mRNA levels in HepG2 cells decreased due to a posttranscriptional mechanism following sodium butyrate treatment. Faust *et al.* (17) reported that CETP secretion measured by

[a]Data are expressed as nmol/mg cell protein and are the means ± SE from three dishes. ND, not detectable. [a]$P < 0.05$; [b]$P < 0.01$; [c]$P < 0.005$; [d]$P < 0.0005$; [e]$P < 0.0001$; significantly different from the control according to the analysis of variance and Fisher's protected least significant difference test.

the CETP activity was regulated in response to the OA concentration in CaCo-2 cells.

We therefore investigated whether various types of FA, particularly those with different degrees of unsaturation, influenced the expression of CETP. The results demonstrated that increasing degrees of unsaturation of FA reduced the CETP mRNA levels; for example, the expression of the CETP mRNA decreased to less than 50% of that of the control with 0.5 mM of AA, EPA, or DHA (Fig. 1A). The CETP mass levels also decreased significantly based on the levels of CETP mRNA expression. These results were also supported by the findings of previous studies, which suggested that the mRNA level is a major determinant of secreted CETP protein (11,26). The increasing FA concentration in HepG2 cells after FA treatments also indicated that the FA influenced the expression of CETP mRNA and protein (Table 1). Although the mechanism of regulation of CETP protein secretion by FA remains unknown, some interesting findings have appeared. Agellen *et al.* (26) indicated that CCAAT/enhancer binding protein (C/EBP)-α levels influence CETP mRNA expression, since C/EBP-α binds to the site of the CETP gene promoter and activates the CETP promoter activity. Raclot *et al*. (27) found that C/EBP-α mRNA level is influenced by PUFA in the following order: DHA-rich diets > EPA-rich diets > OA-rich diets. Our observations are in accord with this finding, which may, in part, suggest that the mechanisms for the modulation of the mRNA levels by PUFA occur indirectly through the expression levels of C/EBP because the transcriptional levels of CETP are partly dependent on C/EBP. Ritsch *et al.* (32), however, reported that C/EBP had no specific influence on the expression of CETP in HepG2. Another possible mechanism for the regulation of the CETP gene expression by FA may be the influence of apolipoprotein regulatory protein-1 (ARP-1) and/or v-erbA-related proteins-3 (Ear-3)/chicken ovalbumin upstream promoter transcription factor (COUP-TF) (33), which are orphan receptors, and sterol regulatory element-binding proteins (SREBP) (34,35). These transcriptional factors, especially SREBP-1 (34,35), play an important role in controlling CETP gene expression. Kim *et al.* (36) described how SREBP-1 expression in the liver nuclei of fish oil-fed mice decreased by 57% compared with safflower oil-fed mice. Yahagi *et al.* (37) reported that dietary PUFA drastically decreased the mature, cleaved form of SREBP-1 protein in the nucleus in the liver of wild-type mice, presumably due to the reduced cleavage of the SREBP-1 precursor protein. Therefore, the regulation of the CETP gene expression by FA may be mediated by the cooperative interaction with SREBP-1 and other transcriptional factors.

On the other hand, the concentration of FA in lipoprotein particles influences the CETP-mediated cholesteryl ester transfer activity *in vitro* (20,38,39); that is, a low concentration of FA stimulates and promotes CETP activity while increasing the FA concentrations above an optimal level, thus inhibiting the CETP activity in a dose-dependent manner. Both the length and degree of unsaturation of the FA acyl carbon chain also affect the CETP activity. The CETP activity is

thus likely to be influenced by double bonds in the *trans* instead of the natural *cis* configuration (15,16); however, we did not investigate the effects of *trans* fatty acids on the gene expression of CETP. Further studies are needed to reveal whether a different configuration (*cis*- or *trans*-) of FA possibly controls the expression of CETP mRNA.

Our present data indicate that FA regulate gene expression of CETP in HepG2, and this effect is dependent upon the degree of unsaturation of the acyl carbon chain in FA. FA may therefore be convenient modulators of both the CETP expression level and the cholesteryl ester transfer activity.

# Modulation of Prostaglandin H Synthase Activity by Conjugated Linoleic Acid (CLA) and Specific CLA Isomers

**Jennifer A. Bulgarella, David Patton, and Arthur W. Bull***

Department of Chemistry, Oakland University, Rochester, Michigan 48309-4477

**ABSTRACT:** Conjugated linoleic acid (CLA) has been shown to inhibit tumorigenesis in animal models and is cytostatic to numerous cell lines *in vitro*. However, the mechanism of action is unknown. In the current study, we determined the effects of CLA and specific isomers of CLA on the rate of oxygenation of arachidonic acid by prostaglandin H synthase (PGHS) in ram seminal vesicle microsomes. The enzyme was incubated with 0.1 to 100 μM CLA or specific isomers of CLA for 2 min prior to the addition of 44 to 176 μM arachidonate. The isomers tested were 9(*E*),11(*E*) CLA; 9(*Z*),11(*E*) CLA; 9(*Z*),11(*Z*) CLA, and 10(*E*),12(*Z*) CLA. For a positive inhibitor control, flurbiprofen was used at 0.75 to 2.50 μM. Enzyme activity was assessed by measuring the rate of oxygen consumption. Inclusion of CLA or specific isomers of CLA in the incubation mixtures inhibits PGHS. The efficacy differs for each isomer, with the 9(*Z*),11(*E*) CLA isomer being the most effective and the 9(*Z*),11(*Z*) CLA isomer being the least effective inhibitor among the four CLA isomers tested. The $K_i$ values obtained by Dixon replots range from 18.7 μM for the most effective isomer, 9(*Z*),11(*E*) CLA, to 105.3 μM for the least effective isomer, 9(*Z*),11(*Z*) CLA. The $K_i$ value for flurbiprofen with ram seminal vesicle microsomes was 0.33 μM. As the concentration of arachidonate was increased, the CLA-dependent inhibition of PGHS decreased, suggesting competitive inhibition. The results of this study demonstrate the potential of CLA and specific isomers of CLA to modulate prostaglandin biosynthesis.

Paper no. L8571 in *Lipids 36,* 407–412 (April 2001).

Conjugated linoleic acid (CLA) is a term used to describe a mixture of positional and geometric isomers of linoleic acid (1,2). Dietary CLA has been shown to inhibit tumorigenesis in a number of animal models, which is in distinct contrast to the effects of the parent compound linoleic acid (3–8). More recently, the suppression of mammary tumor growth by CLA was reported to be lost when the content of CLA in the neutral lipid fraction of mammary gland tissue is depleted (9). Although the nutritional requirements for observing the tumor-inhibitory effects of CLA have been fairly extensively investigated, very little is known about the mechanism by which the compounds act.

In addition to the whole animal studies reported above, *in vitro* studies on several cell lines have shown CLA to be cytostatic when present in the culture medium at concentrations in the micromolar range (10). As in the tumor studies just mentioned, the precise mechanism by which CLA modulates biological activity is unknown although some studies have suggested the compound may have antioxidant activity, inhibit peroxidases, alter the response to estrogen, interact with peroxisome proliferator-activated receptors (PPAR), or perturb eicosanoid biosynthesis (5,6,11–15). CLA has also been shown to reduce prostaglandin $E_2$ ($PGE_2$) production in phorbol ester-induced events in murine keratinocytes and mouse epidermis (16–18). This leads to the important question of whether the mixture of CLA isomers, a specific isomer of CLA, or a metabolite of CLA functions as the active agent.

Three families of enzymes are responsible for the initial generation of bioactive lipid oxidation products from linoleic acid (LA) and arachidonic acid (AA). Cyclooxygenases, lipoxygenases, and cytochromes P-450 all produce relatively short-lived, pluripotent products that play a role in a myriad of processes at both the cellular and higher levels of organization (19–21). Numerous studies have shown that modulation of the activity of these oxidative enzymes has significant consequences for biochemical processes in both normal and pathologic situations (22–24).

Given the structural similarities between many of the bioactive lipid oxidation products and CLA, in particular the presence of a conjugated diene moiety, it is conceivable that CLA itself may interact with either the enzymes involved in the generation of these bioactive lipids or the ultimate cellular receptors of these bioactive compounds. Therefore, to investigate the former possibility, the present investigations were undertaken to determine if CLA and specific isomers of CLA are capable of altering the activity of a representative cyclooxygenase, prostaglandin H synthase-1 (PGHS).

## EXPERIMENTAL PROCEDURES

Ram seminal vesicle (RSV) microsomes were used as the source of PGHS and were prepared in our laboratory. CLA, a mixture of isomers, was obtained from Nu-Chek-Prep Inc. (Elysian, MN). According to the manufacturer, the isomer composition was 41% 9(*Z*),11(*E*) and 9(*E*),11(*Z*) CLA; 44% 10(*E*),12(*Z*) CLA; 10% 10(*Z*),12(*Z*); 5% 9(*Z*),11(*Z*), 9(*E*),11(*E*), and 10(*E*),12(*E*) CLA; and less than 1% 9(*Z*),12(*Z*) linoleate. The following specific isomers of CLA were obtained from Matreya (Pleasant Gap, PA), and their structures are shown in Scheme 1: 9(*Z*),11(*E*) CLA,

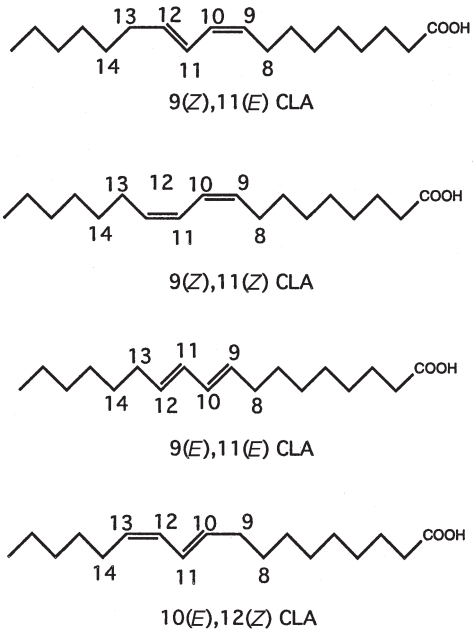
Abbreviations: AA, arachidonic acid; CLA, conjugated linoleic acid; DDC, diethyldithiocarbamate; LA, linoleic acid; $PGE_2$, prostaglandin $E_2$; PGHS, prostaglandin H synthase-1; PPAR, peroxisome proliferator-activated receptor; PUFA, polyunsaturated fatty acids; RSV, ram seminal vesicle.



**SCHEME 1**

9(*Z*),11(*Z*) CLA, 9(*E*),11(*E*) CLA, and 10(*E*),12(*Z*) CLA. All other reagents were obtained from routine laboratory suppliers and were of the highest grade available.

*PGHS.* RSV, a tissue source high in PGHS, were used to prepare RSV microsomes for enzyme assays. The RSV were homogenized in 100 mM potassium phosphate pH 7.8, containing 300 μM diethyldithiocarbamate (DDC), 250 mM mannitol, and 10 mM EDTA using a Polytron tissue homogenizer. The RSV microsomes were purified through a series of three centrifugations. After retaining the supernatant for the first two steps and the pellet for the last, the homogenate was centrifuged at 650 × *g* for 15 min, 8700 × *g* for 10 min, and then ultracentrifuged at 100,000 × *g* for 80 min. The pellet was resuspended in 10 mM Tris pH 8.0, containing 0.5 mM EDTA, 1% Tween 20, and 300 μM DDC for storage at −80°C until use. The protein concentration was determined by the method of Bradford (25).

*Enzyme assays*. Enzyme activity was determined by measuring the rate of oxygen consumption using a Clark electrode obtained from Yellow Springs Instruments Inc. (Yellow Springs, OH). The electrode was connected to a strip chart recorder to monitor changes in oxygen concentration. Reactions were maintained at a constant temperature of 37°C using a Neslab Endocal circulating bath. For all experiments, incubations were performed in duplicate with control incubations at the beginning and end of a series of incubations to assess possible loss of enzyme activity over the course of the experimental period.

The rate of oxygen consumption by PGHS, using AA as substrate, was determined in 1.0-mL incubations containing the following components: 100 mM Tris buffer pH 7.8, 150 μg RSV microsomal protein, 0.5 mM phenol, 44–176 μM AA, and various concentrations of inhibitor. The compounds tested for inhibition were CLA, specific isomers of CLA, flurbiprofen, LA, and oleic acid. The term CLA is used to describe the commercially available mixture of isomers described above. Fatty acids were delivered as solutions in ethanol. The final ethanol concentration did not exceed 2.0%. The CLA, or specific isomers of CLA, were added to the reaction 2 min prior to the substrate, AA. Reactions were monitored for 3 min after substrate addition, then terminated by the addition of sodium dithionite. The initial concentration of oxygen was assumed to be 190 μM based on $O_2$ solubility at 37°C, and the concentration of oxygen after the addition of sodium dithionite was taken to be 0 μM (26). The rate of oxygen consumption reported was measured at maximal velocity, which typically occurred 0.3–1 min after substrate addition. The rate of nonenzymatic oxygenation of AA was monitored and subtracted from all incubations.

## RESULTS

The activity of PGHS, using AA as substrate, is readily determined by monitoring the uptake of molecular oxygen by means of a Clark electrode. In the following experiments, the effect of CLA, and specific isomers of CLA, on PGHS activity was determined. A representative experiment is shown in Figure 1. As shown, the addition of 9(*Z*),11(*E*) CLA inhibited the rate, and extent, of oxygen consumption catalyzed by RSV microsomal PGHS. Additional incubations were performed to determine whether CLA is a substrate for PGHS and whether the observed inhibition of PGHS is CLA-specific. When CLA, at concentrations up to 100 μM, was incubated with PGHS in the absence of AA, no oxygen uptake was detected. Thus, CLA does not serve as a substrate for the enzyme (data not shown).

It is conceivable that the observed inhibition of PGHS by CLA is not specific for CLA but is due to an alteration in substrate availability as a result of altered partitioning in the presence of an increased fatty acid concentration. To examine this possibility, 100 μM oleic acid was substituted for CLA in the presence of 44 μM AA. The observed reaction rates were 105 ± 11.3 μM $O_2$/min in the controls and 103 ± 17.0 μM $O_2$/min in the presence of oleic acid. Therefore, the observed effects on PGHS are CLA-specific.

On the basis of the preceding results, a series of experiments was performed to evaluate the concentration dependence for the substrate, AA, and the inhibitors CLA and specific isomers of CLA. The concentration of AA was varied from 44 to 176 μM, and the concentration of CLA, or the specific isomers of CLA, was varied from 0.1 to 100 μM. Lineweaver-Burk and Dixon plots were used to determine $K_m$, $V_{max}$, and $K_i$ for each inhibitor. In the absence of inhibitors, the RSV microsomal protein with AA as substrate yielded a $V_{max}$ of 1177 μM $O_2$/mg·min and a $K_m$ of 84.5 μM. The reported $K_m$ value for homogeneous PGHS is 10 μM (27). The higher $K_m$ with RSV microsomes is most likely due to the fact that the preparation of microsomes does not yield pure PGHS.

In Dixon analysis, the manner in which the lines intersect allows one to determine the type of inhibition(28). From the transformation of the data to 1/*V* vs. [*I*], shown in Figure 2, the commercial CLA mixture and the specific isomers of CLA

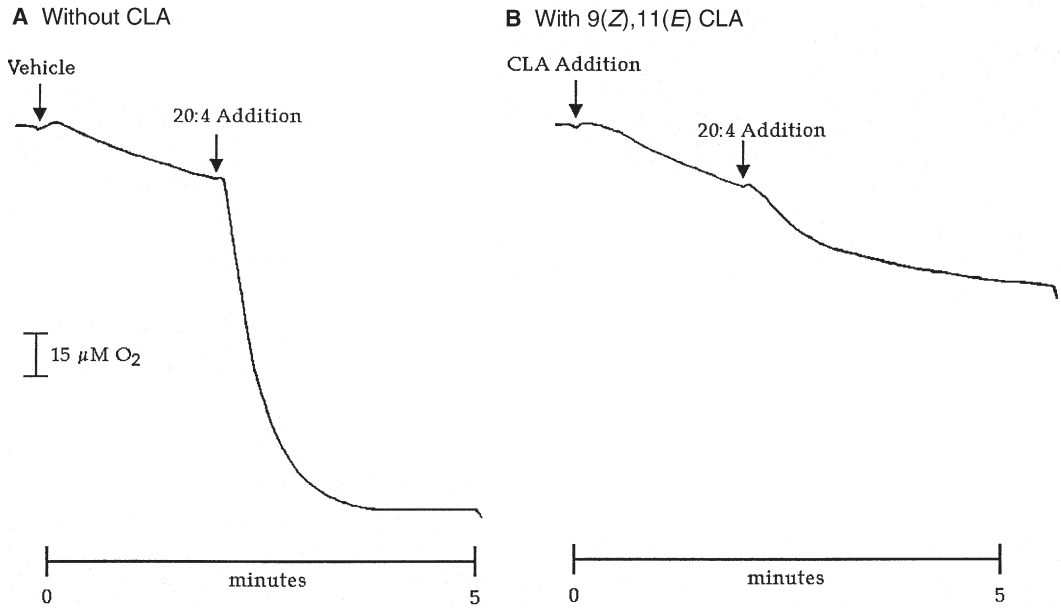


**FIG. 1.** Representative oxygraph recording of the effect of 9(*Z*),11(*E*) conjugated linoleic acid (CLA) on prostaglandin H synthase (PGHS). (A) PGHS in the absence of CLA. (B) PGHS in the presence of 100 μM 9(*Z*),11(*E*) CLA.

appear to exert competitive inhibition. The degree of inhibition of PGHS was concentration-dependent and isomer-specific. The 9(*Z*),11(*E*) CLA isomer was the most potent of the four isomers tested. The least effective was 9(*Z*),11(*Z*) CLA. Furthermore, whereas the degree of inhibition varied for each specific isomer, the extent of inhibition with the commercial mixture was not directly proportional to the isomer composition.

In a Dixon plot for the analysis of inhibition, the point where all lines intersect equals $-K_i$. Since this point is not always easy to identify, an additional method for determining $K_i$ values, the Dixon replot, was employed (28). This technique plots the slopes from the Dixon graph against 1/[*S*]. The resulting slope of the line in a Dixon plot is $K_m/V_{max}K_i$. Using this reciprocol replot and the previously determined $V_{max}$ and $K_m$ values, the $K_i$ values for CLA and the specific isomers of CLA are reported in Table 1. The $K_i$ values range from 18.7 to 105.3 μM with the 9(*Z*),11(*E*) CLA isomer having the lowest value and the 9(*Z*),11(*Z*) isomer having the highest.

To determine the potency of CLA as an inhibitor of PGHS, LA, a weak substrate of PGHS, and flurbiprofen, a known inhibitor of PGHS, were also tested. Addition of 100 μM LA reduced the rate of oxygen consumption in the presence of 44 μM AA. Unlike the results with CLA, the total extent of $O_2$ consumption by PGHS was not affected by LA. The observed reduction in reaction rate with 100 μM LA was equivalent to that of 100 μM 9(*Z*),11(*E*) CLA. The rate was reduced from 104.8 μM $O_2$/min to 22.9 ± 4.0 and 23.8 ± 1.6 μM $O_2$/min for LA and 9(*Z*),11(*E*) CLA, respectively. The effects of 0.75–2.50 μM flurbiprofen on RSV microsomes were also examined. The calculated $K_i$ for flurbiprofen in these experiments is 0.33 μM.

Finally, experiments were performed to investigate whether the inhibition of PGHS by CLA is time dependent. Either the commercial mixture or the 9(*Z*),11(*E*) isomer, 100 μM each, were incubated with PGHS for 2 and 30 min prior to the addition of AA. The results are shown in Table 2. The time of inhibitor preincubation did not affect the observed inhibition. For CLA, the percentage of control activity was 42.2 and 54.2% after 2- and 30-min preincubation, respectively. The more potent 9(*Z*),11(*E*) CLA gave 17.0% of control after 2 min and 16.3 % of control after 30 min of preincubation. A

**TABLE 1**
**$K_i$ Values for CLA, Specific CLA Isomers, and Flurbiprofen with RSV Prostaglandin H Synthase-1**

| Inhibitor | $K_i$ (μM)[a] | Normalized $K_i$[b] |
|---|---|---|
| CLA | 28.34 | 85.88 |
| 9(*Z*),11(*E*) CLA | 18.73 | 56.76 |
| 9(*Z*),11(*Z*) CLA | 105.32 | 319.15 |

[a]Rates are the average of duplicates. Errors are the standard deviation.
[b]Incubations were performed in 44 μM arachidonic acid in the presence of 100 μM inhibitor. Controls contained an equal volume of CLA solvent. For abbreviation see Table 1.

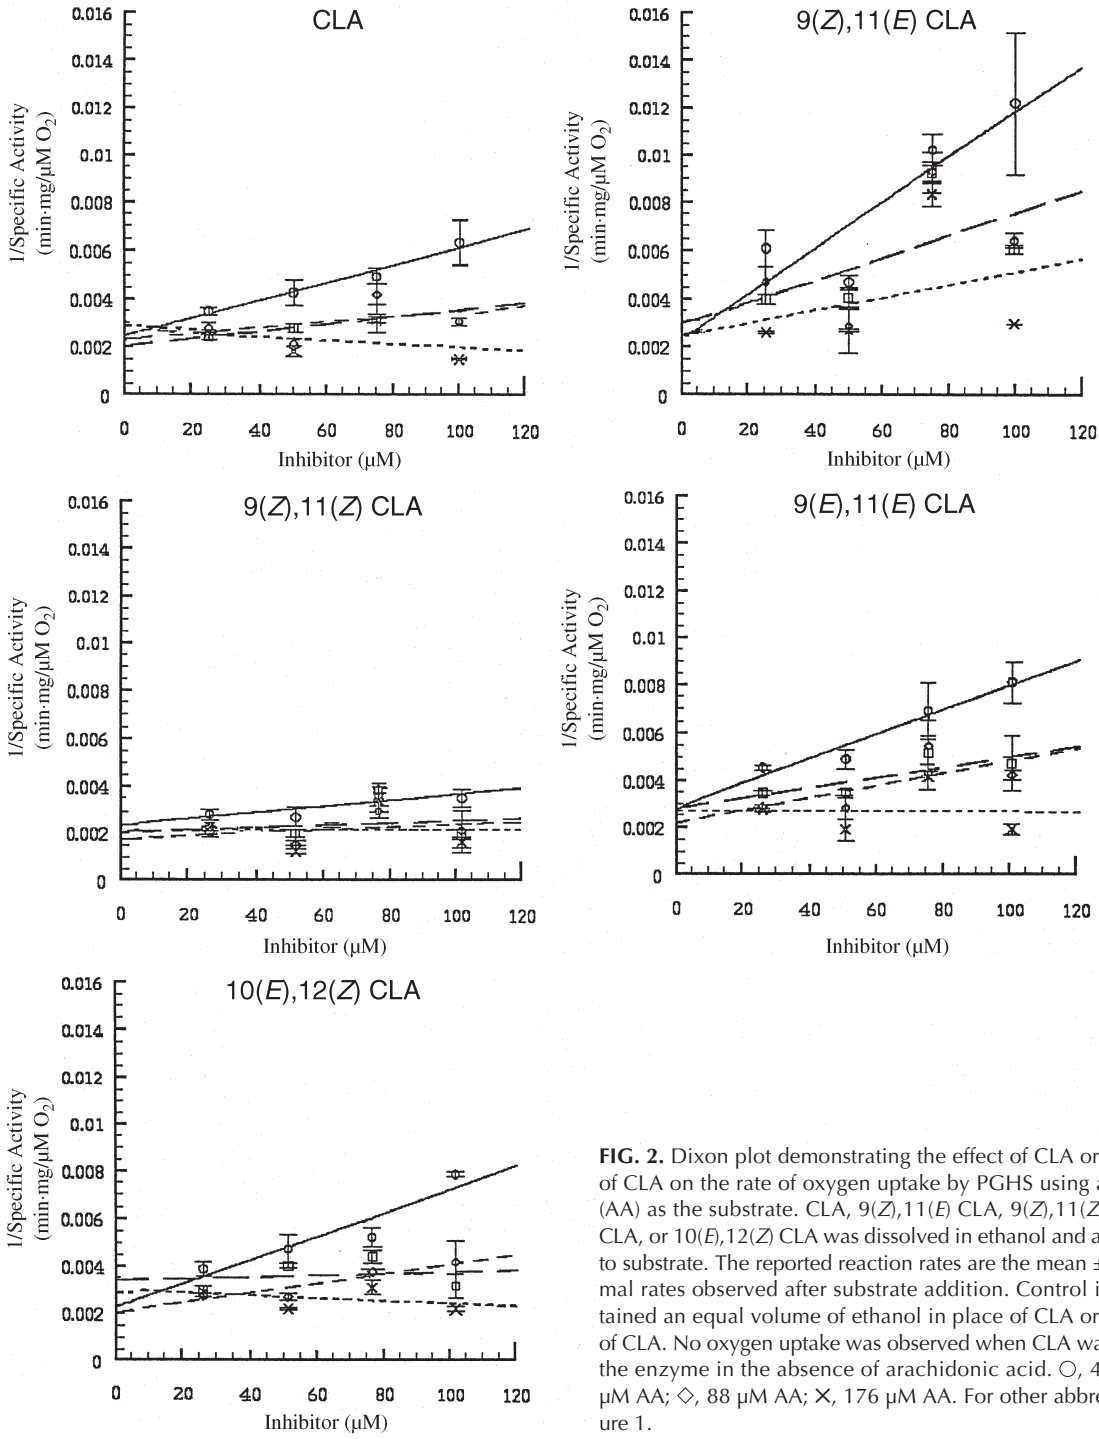

**FIG. 2.** Dixon plot demonstrating the effect of CLA or specific isomers of CLA on the rate of oxygen uptake by PGHS using arachidonic acid (AA) as the substrate. CLA, 9(*Z*),11(*E*) CLA, 9(*Z*),11(*Z*) CLA, 9(*E*),11(*E*) CLA, or 10(*E*),12(*Z*) CLA was dissolved in ethanol and added 2 min prior to substrate. The reported reaction rates are the mean ± SD of the maximal rates observed after substrate addition. Control incubations contained an equal volume of ethanol in place of CLA or specific isomers of CLA. No oxygen uptake was observed when CLA was incubated with the enzyme in the absence of arachidonic acid. ○, 44 μM AA; □, 66 μM AA; ◇, 88 μM AA; ×, 176 μM AA. For other abbreviations see Figure 1.

9.9% decrease in velocity was also observed in the controls between 2 and 30 min.

## DISCUSSION

The modulation of biological activities by CLA has not yet been fully characterized (7,11,12,29,30). A number of potential mechanisms have been suggested including antioxidant activity, inhibition of peroxidase activity, alteration of estrogen response, modulation of eicosanoid systems, and interaction with PPAR (5,6,11–15). Data in the present report provide support for one means by which CLA and specific isomers of CLA can modulate biological function. Specifically, these experiments demonstrate inhibition of PGHS by CLA and specific isomers of CLA. It is well known that prostaglandin biosynthesis is involved in tumor growth in numerous systems (22,31). For example, many colon tumors produce high levels of prostaglandins and other eicosanoids, and

inhibitors of prostaglandin biosynthesis inhibit colon tumorigenesis (22). Recently it was reported that in both cultured systems and whole animals, CLA treatment reduces $PGE_2$ production (16,18,32). The experiments in the present report are consistent with these observations; however, the concentrations of CLA required to inhibit PGHS activity may be beyond the physiologically significant range.

The mixture of fatty acids known as CLA contains compounds that have structural similarities to products derived from enzymatic polyunsaturated fatty acid (PUFA) oxygenation. In particular, the conjugated diene moiety of CLA is also present in hydroxyeicosatetraenoates and hydroxyoctadecadienoates. Owing to this conjugated diene moiety, CLA has the potential to function as a product analog, and such interactions could be one means by which CLA exerts biological activity. It is noteworthy that while CLA inhibits the oxygenation of AA by PGHS, CLA does not serve as a substrate for the enzyme.

From the data, we conclude that the efficacy with respect to the inhibition of PGHS differs for each isomer of CLA. The 9(*Z*),11(*E*) CLA isomer is the most effective inhibitor followed by the 9(*E*),11(*E*) CLA, 10(*E*),12(*Z*) CLA, the commercial mixture CLA, and finally the 9(*Z*),11(*Z*) CLA isomer. The fact the CLA mixture showed less inhibition than some of the individual isomers, and more than others, supports the evidence of differing isomer efficacy. Although the efficacy of the individual isomers is not consistent with the isomer composition of the commercial mixture, the most effective isomer is a major component in this mixture. It is interesting that the most potent isomer, 9(*Z*),11(*E*) CLA, is the primary isomer produced in the rumen by linoleate isomerase and is the isomer most preferentially incorporated into phospholipids (5,33).

To place the inhibition of PGHS by CLA in the proper context, we compared CLA and the specific isomers of CLA to LA, a weak substrate for PGHS, and flurbiprofen, a known inhibitor of PGHS. The rate of AA metabolism in the presence of 100 μM LA was equivalent to the rate observed in the presence of 100 μM 9(*Z*),11(*E*) CLA. As previously mentioned, CLA does not appear to be metabolized by PGHS, but it does compete for the active site as efficiently as the weak substrate LA. The known inhibitor of PGHS, flurbiprofen, was also compared to CLA. The $K_i$ obtained in the present experiments is 0.33 μM, which is somewhat smaller than the value of 1 μM reported by Rome and Lands (34), who also used crude PGHS. Thus, CLA is significantly less effective than flurbiprofen as an inhibitor. On the other hand, flurbiprofen is an especially potent PGHS inhibitor; therefore, comparisons to other inhibitors may be more enlightening. For example, if the $K_i$ value for flurbiprofen is adjusted to 1 μM and the values for CLA are normalized to this value, then CLA and the specific isomers of CLA appear to be as potent as indomethacin with respect to the inhibition of PGHS (34). Based on the Dixon analysis presented in Figure 2, the mode of inhibition of CLA and of the specific CLA isomers appears to be competitive. This would appear to be pure competitive inhibition as there was no evidence of time-dependent phenomena with CLA. The absence of time-dependent inhibition by CLA is in clear distinction to the effects of many PGHS inhibitors and may influence the *in vivo* efficacy of these fatty acids compared to xenobiotic inhibitors.

Of the four isomers tested, those containing *trans* geometry were the most potent inhibitors of PGHS, and the all-*cis* isomer, 9(*Z*),11(*Z*) CLA, was the weakest. Thus, the presence of a *trans* configuration, involving C-11 in conjugation with another double bond, may be important for inhibition of PGHS by CLA. Enzymatic oxidation of AA to $PGH_2$ involves an initial hydrogen abstraction at C-13 of AA. The C-11 of CLA is the same distance from the ω end of the molecule as the C-13 of AA. However, C-13 of AA is a doubly allylic carbon whereas C-11 of CLA is vinylic. This hydrogen abstraction of C-11 of CLA is relatively unfavorable, which may play an important role in the ability of CLA to block the active site of PGHS. Furthermore, it is unlikely the inhibition of PGHS by CLA involves covalent interactions as the inhibition is not time-dependent and CLA itself does not serve as a substrate for the enzyme.

In an effort to explain some of the biological activity of CLA, several recent reports have examined the possibility of antioxidant activity (5,6). However, other investigators have observed that CLA is a relatively weak antioxidant and produces oxidation products somewhat different from those usually observed with PUFA; thus this mechanism of inhibition is unlikely (35,36). The present report describes an alternative mechanism by which CLA can modulate biological activity, in particular the inhibition of fatty acid oxygenases. The inhibition of the cyclooxygenase activity of PGHS, reported in the present work, is in distinction to the previously reported inhibition of peroxidase-mediated activation of the food mutagen 2-amino-3-methylimidazo[4,5-f]quinoline by the peroxidase activity of PGHS (11). Therefore, modulation of both the cyclooxygenase and peroxidase activities of PGHS could contribute to the biological activity of CLA (37).

**ABSTRACT:** Hen egg yolk and white were found to contain high amounts of lysophosphatidic acid (acyl LPA) in addition to small amounts of lysoplasmanic acid (alkyl LPA). The levels of acyl LPA in hen egg yolk (44.23 nmol/g tissue) and white (8.81 nmol/g tissue) were on the same order as or higher than the levels of acyl LPA known to be required to elicit biological responses in various animal tissues. Noticeably, there is a marked difference between the fatty acid composition of egg yolk acyl LPA and of egg white acyl LPA; egg yolk acyl LPA predominantly contains saturated fatty acids as the acyl moiety, whereas egg white acyl LPA primarily contains polyunsaturated fatty acids. We found that the level of acyl LPA, especially polyunsaturated fatty acid-containing acyl LPA, in egg white was augmented markedly during the incubation at 37°C, while there was no change in egg yolk. We confirmed that egg white contains both the substrate, i.e., polyunsaturated fatty acid-containing lysophosphatidylcholine (LPC), and the enzyme activity catalyzing the hydrolysis of polyunsaturated fatty acid-containing LPC to the corresponding acyl LPA. Egg yolk LPA and egg white LPA may play separate physiological roles in the development, differentiation, and growth of embryos.

Paper no. L8687 in *Lipids 36,* 413–419 (April 2001).

Lysophosphatidic acid (1- or 2-acyl-*sn*-glycero-3-phosphate, acyl LPA) and lysoplasmanic acid (1-*O*-alkyl-*sn*-glycero-3-phosphate, alkyl LPA) are common precursor molecules of the *de novo* synthesis of a variety of glycerolipids in animal tissues. In addition to the role as a metabolic intermediate, it is becoming evident that LPA act as important intercellular mediators in various tissues and cells (1–6). LPA have been shown to exert diverse biological activities *in vitro* and *in vivo*. For example, LPA induce hypertension in rats (7), smooth muscle contraction (8), activation of human or feline platelets (9–11), cell proliferation (12), neurite retraction (13,14), neurotransmitter release (15), cell survival (16), apoptosis (17), tumor cell invasion (18), accelerated development of embryos (19), and stimulation of ovum transport in oviducts (20). It has long been assumed that these cellular responses are mediated through specific binding sites for LPA expressed on the cell surface (1–4), yet detailed characteristics of such binding sites remained obscure until recent cloning of the cDNA for LPA receptors (21–26). Although the exact physiological roles of LPA as messenger molecules are not yet fully elucidated, evidence is accumulating that LPA play some essential roles in embryonic development and differentiation (19,20,27,28) in addition to other pathophysiological processes such as wound healing (29).

What then are the actual tissue levels of LPA? Furthermore, what types of molecular species of LPA are present in animal tissues? Little information is available concerning these important issues except for a few cases such as rat brain (30,31), rat liver, heart, testis, kidney, and lung (31), rat plasma (32,33), human plasma (34–36), human serum (36), and human ascites fluids (37). The levels of LPA required to elicit biological responses differ considerably depending on the types of response as well as the tissues and cells involved (1–6), and the intrinsic biological activities differ markedly among various molecular species of LPA (7,8,11,13,38–45). Thus, detailed information concerning the tissue levels as well as the molecular species composition of LPA is essential for better understanding the physiological roles of LPA in animal tissues. Several years ago, Tigyi *et al.* (46) reported that an LPA-like molecule was present in human amniotic fluid, mouse ascites fluid, and human and rat cerebrospinal fluids, although neither the chemical structure nor the amounts of the LPA-like molecule were determined in their pioneering study. Also, even though information on levels as well as the molecular species composition of LPA in embryonic tissues is particularly important, little has appeared concerning LPA in embryonic tissues. Tokumura *et al.* (27,28) did demonstrate the occurrence and the production of LPA in human ovarian follicular fluids.

In the present study, we examined in detail whether LPA are present in hen eggs. Hen eggs were chosen for these reasons: (i) Hen eggs contain sufficient amounts of egg yolk and white for accurate lipid analyses. (ii) Hen eggs are often used in the field of developmental biology. We found that hen egg yolk and white contain high amounts of LPA. We also found that the molecular species composition of acyl LPA obtained

Abbreviations: Acyl LPA, lysophosphatidic acid (1- or 2-acyl-*sn*-glycero-3-phosphate; alkyl LPA, lysoplasmanic acid (1-*O*-alkyl-*sn*-glycero-3-phosphate); GC, gas chromatography; LPA, monoradyl-*sn*-glycero-3-phosphate (lysophosphatidic acid, lysoplasmanic acid, and lysoplasmenic acid); LPC, lysophosphatidylcholine; MS, mass spectrometry; PA, phosphatidic acid; PC, phosphatidylcholine; TLC, thin-layer chromatography; TMS, trimethylsilyl.

from egg white is strikingly different from that of acyl LPA obtained from egg yolk.

## MATERIALS AND METHODS

*Chemicals.* [$^3$H]Arachidonic acid (100 Ci/mmol) and 1-[$^{14}$C]-palmitoyl-*sn*-glycero-3-phosphocholine [LPC (1-[$^{14}$C]16:0)] (56 mCi/mmol) were obtained from NEN (Boston, MA). Arachidonic acid, heptadecanoic acid, LPC (1-16:0), *sn*-glycero-3-phosphocholine cadmium chloride complex, and phospholipase $A_2$ *(Naja naja)* were obtained from Sigma (St. Louis, MO). Phospholipase D *(Streptomyces chromofuscus)* was purchased from Boehringer Mannheim GmbH (Mannheim, Germany). Dicyclohexylcarbodiimide was obtained from Wako Pure Chem. Ind. (Osaka, Japan). Dimethylaminopyridine was from Aldrich Chemical Co. (Milwaukee, WI). 1(2)-Heptadecanoyl-*sn*-glycero-3-phosphate [acyl LPA (17:0)] was prepared according to the method described previously (30). All other chemicals were reagent grade.

*Preparation of 1-[$^3$H]arachidonoyl*-sn-*glycero-3-phosphocholine and 2-[$^3$H]arachidonoyl*-sn-*glycero-3-phosphocholine.* 1-[$^3$H]Arachidonoyl-*sn*-glycero-3-phosphocholine [LPC (1-[$^3$H]20:4n-6)] was prepared as follows. *sn*-Glycero-3-phosphocholine and [$^3$H]20:4n-6 (5 mCi/mmol) were mixed in chloroform (ethanol-free) containing dicyclohexylcarbodiimide and dimethylaminopyridine. The mixture was stirred at room temperature for 24 h under nitrogen gas (47). The resultant radiolabeled phosphatidylcholine [PC (1,2-di[$^3$H]20:4n-6)] was purified by thin-layer chromatography (TLC) using chloroform/methanol/water (65:25:4, by vol). LPC (1-[$^3$H]20:4n-6) was prepared from PC (1,2-di[$^3$H]20:4n-6) by treatment with phospholipase $A_2$ and purified by TLC using chloroform/methanol/water (55:25:4, by vol) as the solvent system. LPC (2-[$^3$H]20:4n-6) was prepared as follows. Total lipids were extracted from rabbit heart by the method of Bligh and Dyer (48) and fractionated by TLC using chloroform/methanol/water (65:25:4, by vol) as the solvent system. Choline glycerophospholipids were extracted from the silica gel and then treated with 0.5 M methanolic sodium methoxide solution at room temperature for 20 min. The resultant lysoplasmenylcholine (with a small amount of lysoplasmanylcholine) was extracted and purified by TLC using chloroform/methanol/water (55:25:4, by vol) as the solvent system. To obtain 1-*O*-alkenyl-2-[$^3$H]20:4n-6-*sn*-glycero-3-phosphocholine, lysoplasmenylcholine and [$^3$H]20:4n-6 (5 mCi/mmol) were mixed in chloroform (ethanol-free) containing dicyclohexylcarbodiimide and dimethylaminopyridine at room temperature for 24 h (47). Plasmenylcholine (1-*O*-alkenyl-2-[$^3$H]20:4n-6) was purified by TLC using chloroform/methanol/water (65:25:4, by vol) as the solvent system. LPC (2-[$^3$H]20:4n-6) was prepared immediately before use from plasmenylcholine (1-*O*-alkenyl-2-[$^3$H]20:4n-6) by treatment with 10 mM $HgCl_2$ at 37°C for 40 min to cleave an alkenyl ether bond. LPC (2-[$^3$H]20:4n-6) was purified by TLC using chloroform/methanol/water (55:25:4, by vol) as the solvent system.

*Purification of LPA from hen egg yolk and white.* Fresh unfertilized hen eggs were obtained from a local poultry farm. Egg yolks and whites were carefully separated and homogenized in a mixture of chloroform/methanol/water using a Waring blender (the final volume of the mixture, 760 mL for egg yolk and 380 mL for egg white; the final ratio of chloroform/methanol/water in the mixture, 1:2:0.8, by vol). Butylated hydroxytoluene (final content 0.05%) was added to prevent lipid peroxidation. In experiments where fatty acid composition of acyl LPA was determined by gas chromatography (GC), acyl LPA (17:0) was added as an internal standard (40 nmol for egg yolk and 20 nmol for egg white). To make two phases, chloroform and an aqueous ammonia solution (0.07%) were added, as described previously (final ratio of chloroform/methanol/water; 2:2:1.8, by vol) (30). After vigorous shaking, the mixture was left to stand at 4°C for 12 h. The mixture was then centrifuged to allow phase separation. We confirmed that LPA were recovered exclusively from the upper phase (30); the upper phase was carefully transferred to glass tubes and washed with chloroform. Four hundred (for egg yolk) or 200 mL (for egg white) of chloroform and a 3.2 (for egg yolk) or 1.6 mL (for egg white) of 12 M HCl were then added to the upper phases. After vigorous shaking and centrifugation, the lower phase was carefully aspirated. The upper phase was washed twice with chloroform, and the lower phases were taken and combined. LPA were purified by TLC using chloroform/acetone/methanol/acetic acid/water (4.5:2:1:1.3:0.5, by vol) as the solvent system in a developing tank sealed with nitrogen gas. The area corresponding to LPA were scraped off the TLC plates into a glass tube. LPA were extracted from the silica gel by the modified method of Bligh and Dyer (48) where HCl was added (final concentration of HCl in the upper phase; 0.07 M) prior to the phase separation. LPA were further purified by TLC using chloroform/methanol/25% ammonia (65:35:5, by vol) as the solvent system and then by TLC using chloroform/acetone/methanol/acetic acid/water (4.5:2:1:1.3:0.5, by vol) as the solvent system (30).

*Mild alkaline hydrolysis of LPA.* LPA obtained from egg yolk and white were treated with 0.2 M NaOH in 90% methanol or 90% methanol alone (control) for 20 min, as described previously (30). The LPA remaining were then extracted by a modified method of Bligh and Dyer (48) where HCl was added to the extraction mixture prior to the phase separation to acidify the upper phase. The lower phase was transferred to another tube, and the upper phase was washed twice with chloroform. The combined lower phases were evaporated to dryness. The amount of LPA (alkali-stable or total) was determined by measuring lipid phosphorus (30).

*Analysis of the fatty acyl moiety of acyl LPA by GC.* The fatty acyl moiety of acyl LPA was converted to fatty acid methyl esters by treating purified acyl LPA with 0.5 M methanolic sodium methoxide. The resultant fatty acid methyl esters were extracted and analyzed in a gas chromatograph (GC8A; Shimadzu, Kyoto, Japan) equipped with a fused-silica column (SP2330; Supelco, Bellefonte, PA).

*Fast atom bombardment mass spectrometry (MS) analysis of LPA.* The structures of LPA were confirmed by fast atom bombardment MS using a JEOL JMS-SX102A mass spectrometer (Tokyo, Japan). A 2:1 mixture of thioglycerol and dithiothreitol/dithioerythritol (3:1) was used as the matrix, as described previously (30).

*GC/MS analysis of the trimethylsilyl (TMS) derivative of LPA.* LPA were treated with 50 µL of *N,O*-bis(trimethylsilyl)trifluoroacetamide containing 1% trimethylchlorosilane and 50 µL of pyridine at 60°C for 30 min and converted to the triTMS derivative essentially according to the method of Tokumura *et al.* (49). The electron impact (70 eV) mass spectra of the triTMS derivatives of LPA were obtained using a JEOL JMS-SX102A mass spectrometer (accelerating voltage, 10 kV; ionizing current, 300 µA) coupled with a gas chromatograph equipped with a fused-silica column (DB-1, 30 m × 0.25 mm i.d., 0.25 µm thickness; J&W Scientific, Folsom, CA). The column temperature was increased from 270 to 320°C at the rate of 70°C/min, and the temperature of the injection port was 300°C (30).

*Generation of LPA in ovo during incubation.* Fresh unfertilized eggs were incubated at 37°C for 24 h in an automatic incubator (Showa, Urawa, Japan). LPA were extracted and purified from egg yolk and white. The fatty acyl moiety of acyl LPA was determined by GC.

*Enzymatic formation of acyl LPA from exogenously added LPC.* Radiolabeled LPC (5 nmol, 50,000 dpm), 0.1 mL of egg white, and 0.1 mL of 0.1 M Tris-HCl buffer (pH 7.4) were incubated at 37°C for 0–3 h. The reaction was stopped by the addition of chloroform and methanol (1:2, vol/vol). Lipids were extracted by a modified method of Bligh and Dyer (48) where HCl was added to acidify the mixture. LPC and LPA were purified by two-dimensional TLC developed first with chloroform/methanol/25% ammonia (65:35:5, by vol) and second with chloroform/acetone/methanol/acetic acid/water (4.5:2:1:1.3:0.5, by vol). The radioactivities were determined in a liquid scintillation counter.

*Analysis of fatty acid composition of LPC in egg white.* Total lipids were extracted from egg white by the method of Bligh and Dyer (48). LPC was purified by two-dimensional TLC developed first with chloroform/methanol/25% ammonia (65:35:5, by vol) and second with chloroform/acetone/methanol/acetic acid/water (4.5:2:1:1.3:0.5, by vol). LPC was extracted from the silica gel by the method of Bligh and Dyer (48). The fatty acyl moiety of LPC was analyzed as the fatty acid methyl esters by GC.

## RESULTS

First, we examined whether LPA, growth factor-like lipids, were present in fresh hen eggs. Table 1 summarizes the experimental results. We found that high amounts of acyl LPA were present in both egg yolk (44.23 nmol/g) and egg white (8.81 nmol/g). We also confirmed that both egg yolk and egg white contained small amounts of alkyl LPA in addition to acyl LPA.

**TABLE 1**
**Amounts of Acyl LPA and Alkyl LPA in Hen Egg Yolk and Egg White**

| Subclass | Egg yolk | Egg white |
|---|---|---|
| | nmol/g (%) | |
| Acyl LPA | 44.23 ± 9.48[a] (97.6 ± 0.6)[b] | 8.81 ± 2.24[a] (99.8 ± 0.1)[b] |
| Alkyl LPA | 1.09[c] (2.4 ± 0.6)[b] | 0.02[c] (0.2 ± 0.1)[b] |
| Total | 45.32 (100.0) | 8.83 (100.0) |

[a]The fatty acyl moieties of lysophosphatidic acid (LPA) obtained from egg yolk and egg white were converted to fatty acid methyl esters and analyzed by gas chromatography. Acyl LPA (17:0) was added as an internal standard before the extraction of total lipids as described in the Materials and Methods section. The values are the means ± SD of four (egg yolk) or nine (egg white) determinations.
[b]The ratio of alkyl LPA to acyl LPA was determined by mild alkaline hydrolysis of LPA obtained from egg yolk and white without the addition of acyl LPA (17:)), and is expressed as the mean percentage ± SD of three determinations.
[c]The amount (nmol/g) of alkyl LPA was calculated from the amount of acyl LPA and the ratio of alkyl LPA to acyl LPA.

Figure 1 illustrates the molecular species compositions of acyl LPA obtained from hen egg yolk and white. As shown in Figure 1A, the fatty acyl moiety of acyl LPA present in egg yolk consisted mainly of saturated fatty acids such as 16:0 and 18:0. The levels of polyunsaturated fatty acid-containing species were low. Noticeably, the molecular species composition of acyl LPA obtained from egg white was quite different from that of acyl LPA obtained from egg yolk. As shown in Figure 1B, the major fatty acyl constituents of acyl LPA in egg white were 18:2n-6 and 20:4n-6. The levels of saturated fatty acid-containing species were very low. Hen eggs contain 15.8 ± 1.9 g of yolk/egg (mean ± SD of eight determinations) and 34.5 ± 4.1 g of white/egg (mean ± SD of eight determinations); it was calculated that 90% of the saturated species of egg acyl LPA is localized in the egg yolk and that 93% of the polyenoic species of egg acyl LPA is localized in the egg white.

We then examined the structures of LPA obtained from egg yolk and white by fast atom bombardment MS. Figure 2 shows the negative ion mode mass spectrum of LPA obtained from

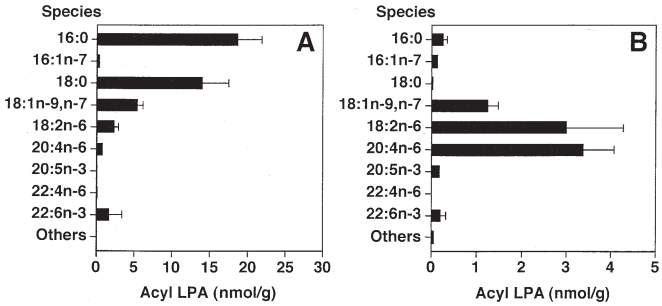

**FIG. 1.** Molecular species compositions of acyl lysophosphatidic acid (LPA) obtained from egg yolk (A) and egg white (B). The fatty acyl moiety of acyl LPA was analyzed as the fatty acid methyl esters by gas chromatography as described in the Materials and Methods section. The values are the means ± SD of four (egg yolk) or nine (egg white) determinations.

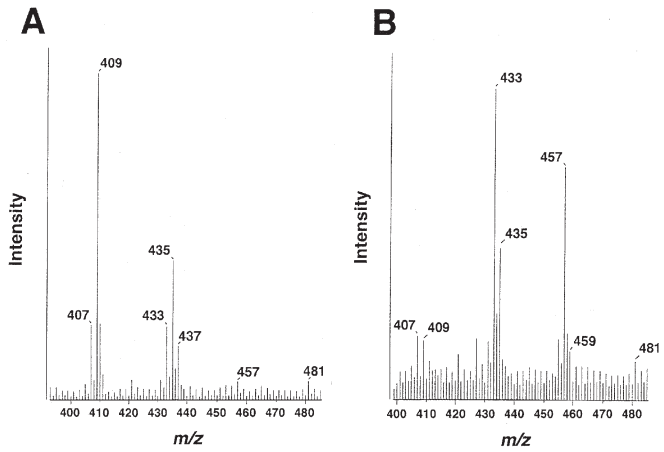

**FIG. 2.** Negative ion mode mass spectrum of LPA obtained from egg yolk (A) and egg white (B). LPA obtained from egg yolk and egg white were analyzed by fast atom bombardment mass spectrometry as described in the Materials and Methods section. For abbreviation see Figure 1.

egg yolk (Fig. 2A) and egg white (Fig. 2B): *m/z* 407 for acyl LPA (16:1n-7) ($[M - H]^-$), *m/z* 409 for acyl LPA (16:0) ($[M - H]^-$), *m/z* 433 for acyl LPA (18:2n-6) ($[M - H]^-$), *m/z* 435 for acyl LPA (18:1n-9,n-7) ($[M - H]^-$), *m/z* 437 for acyl LPA (18:0) ($[M - H]^-$), *m/z* 457 for acyl LPA (20:4n-6) ($[M - H]^-$), *m/z* 481 for acyl LPA (22:6n-3) ($[M - H]^-$).

We further confirmed the structures of LPA by GC/MS as triTMS derivatives without hydrolytic pretreatment. The GC/MS data provide further evidence that various molecular species of acyl LPA are actually present in egg yolk and white (data not shown). We also confirmed that small amounts of alkyl LPA (16:0) are present in egg yolk and white by GC/MS analysis (data not shown).

We next examined whether any changes in the levels of acyl LPA occur during the incubation of the eggs. Figure 3 shows the levels of acyl LPA in egg yolk and white before and after 24-h incubation at 37°C. Changes were not apparent in the levels of acyl LPA in egg yolk before and after incubation. In contrast, the level of acyl LPA in egg white was augmented 1.5-fold after 24-h incubation. We confirmed that the levels of two major species of acyl LPA, i.e., 18:2n-6- and 20:4n-6-containing species, were both markedly elevated after incubation [from 2.66 ± 0.65 to 4.20 ± 1.08 nmol/g and from 3.64 ± 0.80 to 5.00 ± 1.02 nmol/g, respectively (means ± SD of four determinations)], whereas the levels of saturated species such as the 16:0-containing species remained unchanged [from 0.28 ± 0.10 to 0.27 ± 0.06 nmol/g (the mean ± SD of four determinations)].

*In ovo* generation of polyunsaturated fatty acid-containing acyl LPA in egg white during the incubation strongly suggests the occurrence of both enzyme activity and the substrate involved in the synthesis of polyunsaturated fatty acid-containing acyl LPA. To investigate this issue, we examined the enzyme activity. Tokumura *et al.* (32,33) previously demonstrated that acyl LPA was produced from LPC through the action of a lysophospholipase D in rat blood plasma; therefore, we examined whether similar enzyme activity was present in hen egg white. As shown in Figure 4, egg white contained an enzyme activity catalyzing the formation of acyl LPA from corresponding LPC. The amounts of the newly formed acyl LPA increased with time at least up to 3 h. We confirmed that the enzyme activities, estimated using polyenoic LPC (1-20:4n-6 and 2-20:4n-6) as the substrates, were considerably higher than those estimated with saturated LPC (1-16:0).

Finally, we examined whether polyunsaturated fatty acid-containing LPC, a putative substrate for the synthesis of polyunsaturated fatty acid-containing acyl LPA, was present in egg white. As shown in Figure 5, substantial amounts of 20:4n-6-, 18:2n-6-, and 18:1n-9,n-7-containing species, besides a small amount of 16:0-containing species, occurred in egg white: the sum of the 20:4n-6-containing species and the 18:2n-6-containing species accounted for as high as 57.2% of the total. Thus, it is evident that both the enzyme activity and the substrate are present in egg white. Taken together, at least part of the polyunsaturated fatty acid-containing acyl LPA generated in egg white is derived from the corresponding polyunsaturated fatty acid-containing LPC through a phospholipase D-type reaction.

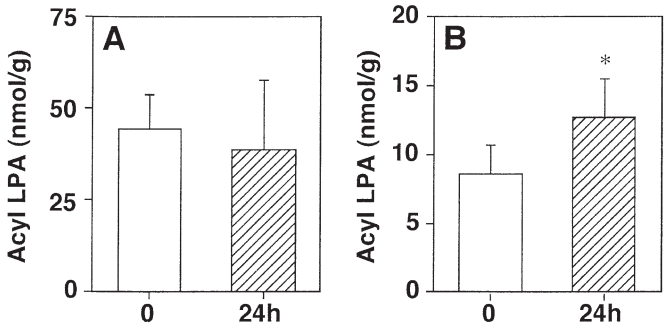

**FIG. 3.** The levels of acyl LPA in egg yolk (A) and egg white (B) before and after incubation at 37°C for 24 h. Fresh eggs were incubated at 37°C for 24 h. LPA were extracted and analyzed as described in the Materials and Methods section. The values are the means ± SD of four determinations. *$P < 0.02$ [compared with control (Student's *t* test)]. For abbreviation see Figure 1.

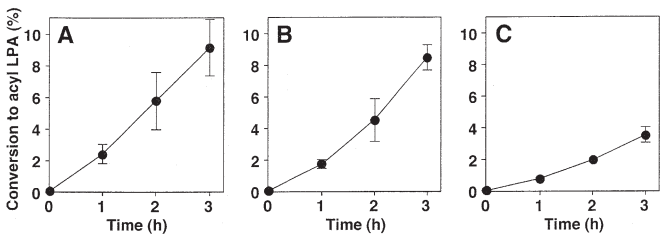

**FIG. 4.** Enzymatic formation of acyl LPA from exogenously added lysophosphatidylcholine (LPC). Radiolabeled LPC (50,000 dpm), 0.1 mL of egg white, and 0.1 mL of 0.1 M Tris-HCl buffer (pH 7.4) were incubated at 37°C for 0–3 h. Lipids were extracted and purified as described in the Materials and Methods section. The enzyme activity was calculated from the radioactivity of LPA and that of LPC. (A) LPC (1-[$^3$H]20:4n-6); (B) LPC (2-[$^3$H]20:4n-6); (C) LPC (1-[$^{14}$C]16:0). The values are the means ± SD of four determinations. For abbreviation see Figure 1.

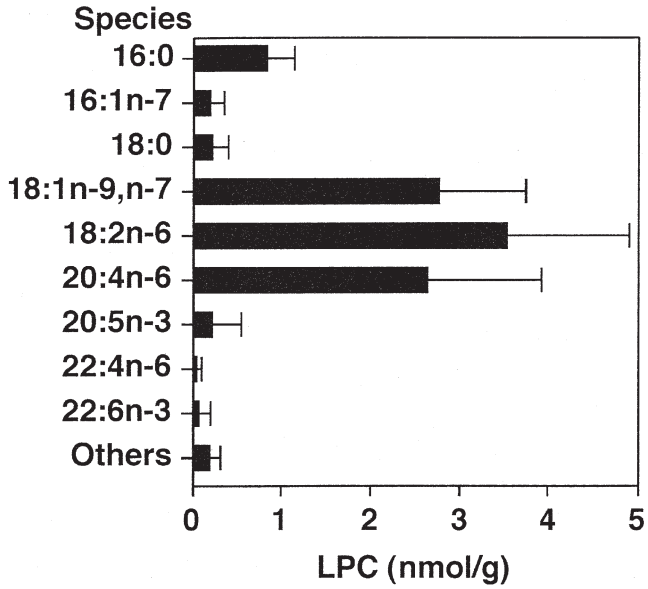

**FIG. 5.** Molecular species composition of LPC obtained from egg white. The fatty acyl moiety of LPC was analyzed as the fatty acid methyl esters by gas chromatography as described in the Materials and Methods section. The values are the means ± SD of six determinations. See Figure 4 for abbreviation.

## DISCUSSION

Naturally occurring LPA include a number of different molecules with different chemical structures in terms of (i) the structure of the aliphatic chain (number of carbon atoms, number and position of double bonds), (ii) the location of the aliphatic chain (*sn*-1, *sn*-2), (iii) the type of bond between glycerol and the aliphatic chain (*O*-acyl, *O*-alkyl, *O*-alkenyl), and (iv) the structure of the backbone (noncyclic, cyclic). Evidence is accumulating that these lipid phosphoric acid molecules compose a novel class of bioactive lipid family. Importantly, the biological activities or potencies of these LPA molecules are considerably different (7,8,11,13,38–45). Several lines of evidence strongly suggest that certain subclasses or analogs of LPA [e.g. lysoplasmenic acid (alkenyl LPA), alkyl LPA, and cyclic phosphatidic acid (cyclic PA)] interact with specific or preferential receptors in addition to other subtypes of LPA receptors, thereby eliciting biological responses (3,44,45). Thus, detailed studies on these subclasses as well as various molecular species of LPA are indispensable for a full understanding of the diverse physiological roles and functions of LPA in animal tissues.

In the present study, we examined in detail the levels as well as the molecular species compositions of LPA in hen egg yolk and white. We found that egg yolk and white contain high amounts of acyl LPA besides small amounts of alkyl LPA (Table 1). Apparently, the levels of acyl LPA found in egg yolk (44.23 nmol/g) and white (8.81 nmol/g) are on the same order as or higher than the levels of acyl LPA required for eliciting biological responses in various animal tissues (1–6). The occurrence of high levels of acyl LPA in hen egg yolk and white is quite noticeable in view of the fact that embryonic cells, such as *Xenopus* oocytes, have been shown to express the LPA receptor (13,22) and that the development of mouse embryos from the four-cell stage to the blastocyst was accelerated markedly in the presence of acyl LPA (19). LPA present in egg yolk may play some essential roles as signaling molecules in addition to the role as metabolic intermediates during the course of differentiation and development of embryos.

A striking observation in the present study was the marked difference between the molecular species composition of egg yolk acyl LPA and that of egg white acyl LPA. Egg yolk acyl LPA consisted mainly of saturated species, whereas egg white acyl LPA consisted mainly of polyenoic species (Fig. 1). Further detailed studies are needed to clarify whether there are specific *in ovo* physiological functions or roles for the saturated species of acyl LPA localized predominantly in the egg yolk and the polyenoic species of acyl LPA localized almost exclusively in the egg white.

The marked difference in the molecular species composition of egg yolk and white acyl LPA may be attributed to the difference in the mechanisms underlying the formation of acyl LPA in egg yolk and white. We found that significant amounts of unsaturated species of acyl LPA were formed in the egg white during the incubation at 37°C (Fig. 3). We obtained evidence that both the enzyme activity (lysophospholipase D) and the substrate (LPC) required for the generation of acyl LPA are present in the egg white (Figs. 4,5). In contrast, acyl LPA was not generated in the egg yolk during the incubation. It is conceivable that acyl LPA was synthesized *de novo* during the process of egg yolk formation in the hen and stored in the egg yolk with other phospholipids such as egg PC.

The lysophospholipase D, which catalyzes the formation of acyl LPA from corresponding LPC, was first identified in rat plasma by Tokumura *et al.* (32,33). This enzyme is specific to lysophospholipids and distinct from other types of phospholipase D, which hydrolyze diacyl phospholipids to generate PA (33). Similar enzyme activity was also detected in human follicular fluids (27). Several lines of evidence suggest that lysophospholipase D plays a crucial role in the generation of acyl LPA, a growth factor-like lipid, in blood plasma and ovarian follicular fluids (27,28,32,33).

Interestingly, this unique lysophospholipase D preferentially utilizes polyunsaturated fatty acid-containing LPC as the substrate (Fig. 4) (27,28,32,33), yet this enzyme is able to metabolize the saturated species of LPC as well at slower rates. In any case, the presence of a lysophospholipase D, which preferentially utilizes polyunsaturated fatty acid-containing LPC in blood plasma, follicular fluids and egg white, strongly suggests that polyunsaturated fatty acid-containing LPA such as acyl LPA (18:2n-6) and acyl LPA (20:4n-6) play some essential role(s) in wound healing, egg maturation, fertilization and development, and differentiation of embryos. Xu *et al.* (37) reported that polyunsaturated fatty acid-containing LPA such as acyl LPA (18:2n-6), acyl LPA (20:4n-6), and acyl LPA (22:6n-3) exhibit much more potent ovarian

cancer-activating activity than saturated or monoenoic fatty acid-containing LPA, although the details still remain to be elucidated. Presumably, the mechanism and/or the site of the action of polyunsaturated fatty acid-containing LPA is considerably different from that of saturated or monoenoic LPA. Bandoh *et al.* (25) recently reported that Edg7 is a specific receptor for unsaturated fatty acid-containing LPA. Further studies are required to clarify the mechanism of the action as well as the exact physiological role(s) of polyunsaturated fatty acid-containing LPA that are abundant in several animal tissues and fluids.

In conclusion, we found that hen egg yolk and white contained high amounts of acyl LPA in addition to small amounts of alkyl LPA. The molecular species composition of egg yolk acyl LPA and of egg white acyl LPA were quite different. Egg yolk acyl LPA, composed mainly of saturated species, and egg white acyl LPA, composed primarily of polyunsaturated species, may possess inherent separate physiological functions *in ovo* during the course of development, differentiation and growth of chick embryos.

# Fullerene Lipids: Synthesis of Novel Nitrogen-Bridged [60]Fullerene Fatty Ester Derivatives

**Marcel S.F. Lie Ken Jie*, Sunny W.H. Cheung, and Janette C.M. Ho**

Department of Chemistry, The University of Hong Kong, Hong Kong, SAR, China

**ABSTRACT:** Reactions of methyl 6-azido-hexanoate, 8-azido-octanoate, and 12-azido-dodecanoate with [60]fullerene (**1**) gave the corresponding aza-[60]fullerene ester derivatives (**2a-2c**, 22–35% based on the amount of [60]fullerene reacted). The nitrogen atom is bonded to the [60]fullerene cage to yield a "[5,6]-open" type aza substructure. This was confirmed by the appearance of 30–31 $sp^2$ signals at $\delta_C$ 133–147 in the carbon nuclear magnetic resonance spectra. Reaction of methyl 11-azido-7-undecynoate with [60]fullerene furnished a mixture of aza-[60]fullerene (**2d**, 53%) and aziridine-[60]fullerene (**2e**, 38%) ester derivatives. Compound **2e** was identified as the "[6,6]-closed" type aziridine-[60]fullerene derivative, which displayed 10 $sp^2$ signals in the region $\delta_C$ 140–145 and one signal at $\delta_C$ 85.05 for the $sp^3$ carbons of the cage. Refluxing a solution of compound **2d** in toluene for 50 h gave about 50% yield of compound **2e**, but not vice versa.

Paper no. L8689 in *Lipids 36*, 421–426 (April 2001).

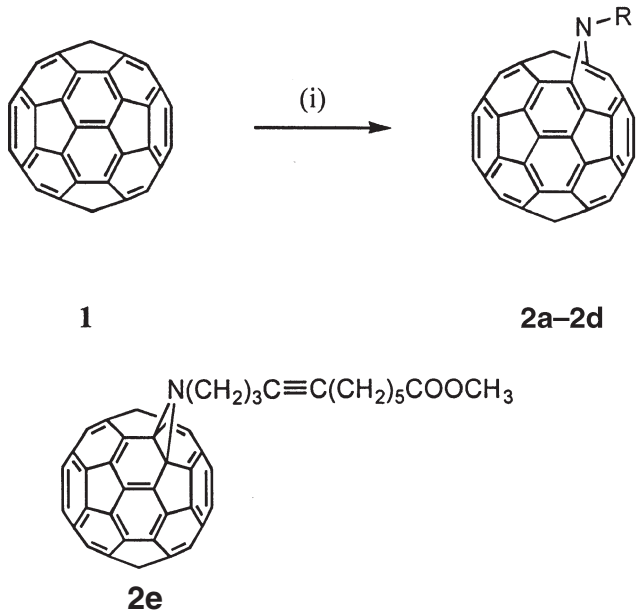

**FIG. 1.** Reagents and conditions for synthesis of nitrogen-bridged[60]-fullerene fatty ester derivatives. (i) $RN_3$, chlorobenzene, reflux for 16 h. 2a, R = $(CH_2)_5COOCH_3$; 2b, R = $(CH_2)_7COOCH_3$; 2c, R = $(CH_2)_{11}$-$COOCH_3$; 2d, R = $(CH_2)_3C{\equiv}C(CH_2)_5COOCH_3$; 2e, R = $(CH_2)_3C{\equiv}C$-$(CH_2)_5COOC_3$.

Studies of the chemical reactivity of [60]fullerene have drawn keen attention since the discovery of the novel $C_{60}$ carbon sphere in 1985 (1). Numerous books and review articles have been published, which describe the syntheses and properties of [60]fullerene derivatives and their potential applications (2–7). Of interest is the inhibition of human immunodeficiency virus-protease activities of water-soluble fullerene derivatives (8–10). We have reported the synthesis of two series of fullerenoid lipid molecules: *viz.*, saturated and unsaturated dialkyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylate derivatives (11) and [60]fullerene lipids bearing long-chain saturated or unsaturated esters (12). The incorporation of a [60]fullerene unit into lipid molecules has opened a new frontier to fatty acid chemistry.

Prato *et al.* (13) first reported the reactions of organic azides with [60]fullerene to yield aza-fullerene derivatives, which are potent precursors for the production of nitrogen heterofullerenes. Two comprehensive reviews concerning heterofullerenes have been published recently (14,15). In this paper we describe the reactions of saturated methyl ω-azido fatty esters of various chain lengths and that of a $C_{11}$ acetylenic ω-azido fatty ester with [60]fullerene (Fig. 1). The spectroscopic properties of such novel fatty ester derivatives are reported.

## MATERIALS AND METHODS

Melting points (m.p.) were determined on a heating stage TC92 (Linkam Scientific Instruments Ltd., Waterfield, Surrey, United Kingdom). Infrared (IR) spectra were recorded on a Bio-Rad FTS-165 Fourier transform IR (Bio-Rad Inc., Hercules, CA) spectrometer. Samples were run as neat films on KBr discs. Ultraviolet-visible (UV-vis) spectra of solutions in dichloromethane were recorded on a Hewlett Packard Diode Array Spectrophotometer, model 8452A (Hewlett-Packard, Palo Alto, CA). Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker Avance $DPX_{300}$ (300 MHz) Fourier Transform NMR spectrometer (Bruker, Fallanden, Switzerland) from solutions in deuteriochloroform ($CDCl_3$) with tetramethylsilane (TMS) as the internal reference standard. Chemical shifts are given in δ-values in ppm downfield from TMS ($\delta_{TMS}$ = 0 ppm) and *J* constants are given in Hz.

Abbreviations: APCI, atmospheric pressure chemical ionization; IR, infrared; m.p., melting point; MS, mass spectrometry; NMR, nuclear magnetic resonance; THF, tetrahydrofuran; TLC, thin-layer chromatography; TMS, tetramethylsilane; UV-vis, ultraviolet-visible spectroscopy.

Mass spectral analyses were carried out on a Finnigan MAT-LCQ [atmospheric pressure chemical ionization (APCI)] spectrometer (Finnigan Corp., San Jose, CA). Precoated thin-layer chromatography plates (silica gel 60 $F_{254}$, 20 × 20 cm on glass, E. Merck No. 1,05715) were purchased from Merck (Schuchardt, Germany) and were cut into 1.5 × 6.0 cm strips for general use.

[60]Fullerene was purchased from Materials and Electrochemical Research Corp. (Tucson, AZ). 6-Bromo-hexanoic acid, 8-bromo-octanoic acid, 12-bromo-dodecanoic acid, and 1-pentyn-4-ol were purchased from Aldrich Chemical Co. (Milwaukee, WI). Methyl 6-azido-hexanoate, methyl 8-azido-octanoate, and methyl 12-azido-dodecanoate were derived by methylation of the corresponding bromo-acids (with $BF_3$/methanol) followed by chemical substitution of the bromide group by an azide (*via* sodium azide) as described by Alvarez and Alvarez (16).

*Synthesis of methyl 11-hydroxy-7-undecynoate.* 4-Pentyn-1-ol (22 g, 0.26 mol) in tetrahydrofuran (THF: 20 mL) was added to lithium amide [prepared from lithium (5.2 g) in liquid ammonia (500 mL) with a catalytic amount of iron(III) nitrate]. The reaction mixture was stirred for 30 min. 6-Bromohexanoic acid (60 g, 0.30 mol) in anhydrous THF (50 mL) was added over a period of 30 min. The reaction mixture was stirred for a further 16 h, and the liquid ammonia was allowed to evaporate. Dilute HCl (6 M, 400 mL) was added, and the reaction mixture was extracted with diethyl ether (3 × 150 mL). The ethereal layer was washed with brine (100 mL), water (100 mL), and dried over anhydrous $Na_2SO_4$. The filtrate was evaporated, and the residue was refluxed in methanol (200 mL) and $BF_3$/MeOH complex (14% w/w, 15 mL) for 30 min. About 150 mL of the solvent of the reaction mixture was evaporated under reduced pressure distillation. Water (200 mL) was added, and the reaction mixture was extracted with diethyl ether (3 × 200 mL). The ethereal layer was washed with aqueous $NaHCO_3$ (5%, 100 mL), water (2 × 100 mL), dried ($Na_2SO_4$), and filtered. The filtrate was evaporated, and the residue was chromatographed on a silica gel (250 g) column using a mixture of *n*-hexane/diethyl ether, 5:1, vol/vol, to give methyl 11-hydroxy-7-undecynoate (36 g, 46%). TLC ($R_f$): 0.1 ($Et_2O$/*n*-hexane, vol/vol, 1:4); IR (KBr, neat): 3441 (br, O-H str.), 1738 (C=O, str.) $cm^{-1}$; $^1H$ NMR ($CDCl_3$, $\delta_H$): 3.70 (*t*, *J* = 6.6, 2H, 11-*H*), 3.67 (s, 3H, $COOCH_3$), 2.98 (s, 1H, $D_2O$ exchangeable, O-*H*), 2.33 (*t*, *J* = 7.5, 2H, 2-*H*), 2.28–2.22 (*m*, 2H, 9-*H*), 2.18–2.11 (*m*, 2H, 6-*H*), 1.72 (*qn*, *J* = 6.6, 2H, 10-*H*), 1.64 (*qn*, *J* = 7.5, 2H, 3-*H*), 1.22–1.54 (*m*, 4H, 4-*H*, 5-*H*); $^{13}C$ NMR ($CDCl_3$, $\delta_C$): 174.25 (C-1), 80.25 (C-7), 79.60 (C-8), 61.36 (C-11), 51.43 ($COOCH_3$), 33.85 (C-2), 31.64 (C-10), 28.54 (C-5), 28.18 (C-4), 24.37 (C-3), 18.45 (C-6), 15.19 (C-9); mass spectrometry (MS) (APCI): 213.2 ($C_{12}H_{20}O_3$, calc. $M^+$ *m/z* = 212.289).

*Methyl 11-bromo-7-undecynoate*. Methyl 11-hydroxy-7-undecynoate (2.7 g, 10.3 mmol) was added to a mixture of triphenylphosphine (3.4 g, 13.0 mmol) and bromine (1.64 g, 10.3 mmol) in $CH_2Cl_2$ (50 mL) at 0–5°C. The mixture was stirred for 20 min, and the solvent was evaporated under reduced pressure. The residue was chromatographed on a silica gel (50 g) column using *n*-hexane/diethyl ether, 95:5, vol/vol (200 mL) as eluant to give methyl 11-bromo-7-undecynoate as a colorless oil (2.39 g, 92%). TLC ($R_f$): 0.5 ($Et_2O$/*n*-hexane, vol/vol, 1:4); IR (KBr, neat): 1738 (C=O, str.) $cm^{-1}$; $^1H$ NMR ($CDCl_3$, $\delta_H$): 3.67 (*s*, 3H, $COOCH_3$), 3.52 (*t*, *J* = 6.6, 2H, 11-*H*), 2.36–2.31 (*m*, 4H, 9-*H*, 2-*H*), 2.15 (*tt*, *J* = 2.4, 6.8, 2H, 6-*H*), 2.00 (*qn*, *J* = 6.6, 2H, 10-*H*), 1.64 (*qn*, *J* = 7.5, 2H, 3-*H*), 1.56–1.36 (*m*, 4H, 4-*H*, 5-*H*); $^{13}C$ NMR ($CDCl_3$, $\delta_C$): 174.13 (C-1), 81.14 (C-7), 78.14 (C-8), 51.50 ($COOCH_3$), 33.98 (C-2), 32.61 (C-11), 31.85 (C-10), 28.62, 28.33 (C-5, C-4), 24.48 (C-3), 18.56 (C-6), 17.48 (C-9).

*Methyl 11-azido-7-undecynoate*. A mixture of methyl 11-bromo-7-undecynoate (1.7g, 6.5 mmol) and sodium azide (638 mg, 9.6 mmol) was stirred at 70°C in dimethylsulfoxide (20 mL) for 4 h. Water (60 mL) was added, and the reaction mixture was extracted with diethyl ether (3 × 50 mL). The organic extract was washed with water (20 mL), brine (20 mL), and dried over anhydrous sodium sulfate. The filtrate was evaporated under reduced pressure, and the residue was separated on a silica (30 g) column using a mixture of *n*-hexane/diethyl ether (5:1, vol/vol, 300 mL) to give a colorless oil (1.4 g, 92%). TLC ($R_f$): 0.5 ($Et_2O$/*n*-hexane, vol/vol, 1:4); IR (KBr, neat): 2126 ($N_3$, str.), 1739 (C=O, str.) $cm^{-1}$; $^1H$ NMR ($CDCl_3$, $\delta_H$): 3.67 (*s*, 3H, $COOCH_3$), 3.40 (*t*, *J* = 6.8, 2H, 11-*H*), 2.32 (*t*, *J* = 7.5, 2H, 2-*H*), 2.27 (*tt*, *J* = 2.4, 6.8, 2H, 9-*H*), 2.15 (*tt*, *J* = 2.4, 6.8, 2H, 6-*H*), 1.74 (*qn*, *J* = 6.8, 2H, 10-*H*), 1.64 (*qn*, *J* = 7.5, 2H, 3-*H*), 1.55–1.35 (*m*, 4H, 4-*H*, 5-*H*); $^{13}C$ NMR ($CDCl_3$, $\delta_C$): 174.12 (C-1), 81.16 (C-7), 78.42 (C-8), 51.48 ($COOCH_3$), 50.29 (C-11), 33.97 (C-2), 28.65, 28.36, 28.23 ($CH_2$), 24.50 (C-3), 18.57 (C-6), 16.08 (C-9); MS (APCI): 238.2 ($C_{12}H_{19}O_2N_3$, calc. $M^+$ *m/z* = 237.303).

*General procedure for the reaction of methyl ω-azido fatty esters with [60]fullerene as exemplified by the synthesis of 1-(5-carbonylmethoxy-pentyl)-aza-[2′,3′;5,6] [60]fullerene* (**2a**). A solution of methyl 6-azido-hexanoate (308.8 mg, 1.8 mmol) in chlorobenzene (250 mL) was added dropwise through a condenser to a refluxing solution of [60]fullerene (1.0 g, 1.39 mmol) in chlorobenzene (750 mL) under an atmosphere of argon. The reaction mixture was refluxed for a further 16 h. The color of the reaction mixture gradually changed from magenta to dark brown. The solvent was evaporated under reduced pressure to give a residue (1.47 g). A portion of the residue (200 mg) was dissolved in toluene (10 mL) and was loaded onto a silica gel (200 g) column. The column was eluted with a mixture of *n*-hexane/toluene (1:1, vol/vol, 400 mL) to remove unreacted [60]fullerene (66.1 mg). The column was then eluted with toluene (700 mL) to give 1-(5-carbonylmethoxy-pentyl)-aza-[2′,3′;5,6][60]fullerene (**2a**, 14.9 mg). Repeated column chromatographic separation on 200 mg of the residue furnished a total of 504 mg of unreacted [60]fullerene and 109.8 mg of the requisite product (**2a,** 9% yield based on the initial amount of [60]fullerene used or 22% based on the amount of [60]fullerene reacted). Note: 50-mL fractions of eluant were collected during the chromatographic run, and the composi-

tion of each fraction was closely monitored by TLC analysis (using toluene as the developer).

(i) *1-(5-Carbonylmethoxypentyl)-aza-[2',3';5,6][60]fullerene (**2a**).* Dark brown solid: m.p.: >350°C. Yield: 22% based on the amount of [60]fullerene reacted. TLC ($R_f$): 0.6 (toluene); IR (KBr, neat): 2924, 2857, 1736 (C=O, str.) and 526 ($C_{60}$) $cm^{-1}$; $^1H$ NMR ($CDCl_3$, $\delta_H$): 3.81 (*t*, *J* = 7.2, 2H, [60]NC$H_2$), 3.71 (*s*, 3H, COOC$H_3$), 2.44 (*t*, *J* = 7.3, 2H, 2-*H*), 2.05 (*qn*, *J* = 7.3, 2H, 5-*H*), 1.87–1.70 (*m*, 4H, C$H_2$). $^{13}C$ NMR ($CDCl_3$, $\delta_C$): 174.11 (C-1), [147.82, 146.84, 145.05, 144.75, 144.56, 144.47, 144.33, 144.30, 144.14 (2C: Intensity of this signal is about twice that of the others), 143.85, 143.66, 143.55, 143.40, 143.22, 143.11, 142.91, 142.81, 142.71, 142.65, 141.45, 140.82, 140.76, 139.23, 138.51, 138.04, 137.86, 137.29, 137.23, 136.22, 135.84, 133.75 ($C_{60}$-$sp^2$)], 51.62 (*C*$H_2$N[60]), 51.42 (COO*C*$H_3$), 34.04 (C-2), 29.26, 29.83, 24.82 (C-3); MS (APCI): 863.5 ($C_{67}H_{13}O_2N$, calc. $M^+$ *m/z* = 863.846).

(ii) *1-(7-Carbonylmethoxyheptyl)-aza-[2′,3′;5,6][60]fullerene (**2b**).* Dark brown solid: m.p.: >350°C. Yield: 27% based on the amount of [60]fullerene reacted. TLC ($R_f$): 0.6 (toluene); IR (KBr, neat): 2920, 2857, 1735 (C=O, str.), 525 ($C_{60}$) $cm^{-1}$; $^1H$ NMR ($CDCl_3$, $\delta_H$): 3.80 (*t*, *J* = 7.3, 2H, [60]NC$H_2$), 3.69 (*s*, 3H, COOC$H_3$), 2.36 (*t*, *J* = 7.5, 2H, 2-*H*), 2.02 (*qn*, *J* = 7.7, 2H, 7-*H*), 1.75–1.62 (*m*, 4H, 3-*H*, 6-*H*) 1.53–1.38 (*m*, 4H, C$H_2$); $^{13}C$ NMR ($CDCl_3$, $\delta_C$): 174.22 (C-1), [147.88, 147.07, 145.10, 144.79, 144.60, 144.50, 144.37, 144.33, 144.20 (2C: Intensity of this signal is about twice that of the others), 143.89, 143.70, 143.59, 143.44, 143.26, 143.15, 142.95, 142.85, 142.77, 142.68, 141.50, 140.90, 140.79, 139.26, 138.56, 138.09, 137.88, 137.35, 137.31, 136.28, 135.91, 133.81 ($C_{60}$-$sp^2$)], 51.76 (*C*$H_2$N[60]), 51.47 (COO*C*$H_3$), 34.13 (C-2), 29.71, 29.59, 29.15, 27.16, 24.96 (C-3); MS (APCI): 891.5 ($C_{69}H_{17}O_2N$, calc. $M^+$ *m/z* = 891.900).

*(iii) 1-(11-Carbonylmethoxyundecyl)-aza-[2′,3′;5,6][60]-fullerene (**2c**).* Dark brown solid: m.p.: >350°C. Yield: 35% based on the amount of [60]fullerene reacted. TLC ($R_f$): 0.6 (toluene); IR (KBr, neat): 1738 (C=O, str.), 1460, 1428, 1174, 525 ($C_{60}$) $cm^{-1}$; $^1H$ NMR ($CDCl_3$, $\delta_H$): 3.80 (*t*, *J* = 7.3, 2H, [60]NC$H_2$), 3.67 (*s*, 3H, COOC$H_3$), 2.31 (*t*, *J* = 7.5, 2H, 2-*H*), 2.02 (*qn*, *J* = 7.7, 2H, 7-*H*), 1.65–1.58 (*m*, 4H, 3-*H*, 10-*H*), 1.46–1.25 (*m*, 12H, C$H_2$); $^{13}C$ NMR ($CDCl_3$, $\delta_C$): 174.35 (C-1), [147.85, 147.11, 145.07, 144.75, 144.56, 144.46, 144.38, 144.28, 144.17 (2C: Intensity of this signal is about twice that of the others), 143.84, 143.65, 143.54, 143.40, 143.21, 143.10, 142.90, 142.81, 142.72, 142.62, 141.45, 140.88, 140.73, 139.19, 138.50, 138.00, 137.83, 137.31, 137.22, 136.20, 135.85, 133.74 ($C_{60}$-$sp^2$)], 51.73 (*C*$H_2$N[60]), 51.46 (COO*C*$H_3$), 34.14 (C-2), 29.63, 29.61, 29.59, 29.48, 29.29, 29.18, 27.32, 24.98 (C-3); MS (APCI): 949.1 ($C_{73}H_{25}O_2N$, calc. $M^+$ = 948.008).

*Reaction of methyl 11-azido-7-undecynoate with [60]fullerene.* A mixture of methyl 11-azido-7-undecynoate (100 mg, 0.42 mmol), [60]fullerene (400 mg, 0.56 mmol), and chlorobenzene (350 mL) was refluxed for 16 h under argon. The reaction mixture was evaporated under reduced pressure. The residue was dissolved in toluene (50 mL) and was loaded onto a silica gel (150 g) column. The unreacted [60]fullerene (360 mg) was eluted with a mixture of *n*-hexane/toluene (1:1, vol/vol, 400 mL). A second fraction (brown in color) was eluted with toluene (500 mL) to give compound **2d** (27.8 mg, $R_f$ = 0.5 (toluene), yield of 5.3% based on the amount of [60]fullerene used or 53% based on the amount of [60]fullerene reacted). A third fraction (red in color) was eluted with toluene (500 mL) to give compound **2e** (19.6 mg, $R_f$ = 0.4 (toluene), 3.8% yield based on the amount of [60]fullerene used or 38% based on amount of [60]fullerene reacted).

*(i) 1-(10-Carbonylmethoxy-4-decynyl)-aza-[2′,3′;5,6]-[60]fullerene (**2d**).* Dark brown solid: m.p.: >350°C. Yield: 53% based on the amount of [60]fullerene reacted. TLC ($R_f$): 0.5 (toluene); UV-vis ($CH_2Cl_2$, $\lambda_{max}$, nm): 430, 548; IR (KBr, neat): 1725 (C=O, str.), 1557, 1428, 1077, 525 ($C_{60}$) $cm^{-1}$; $^1H$ NMR ($CDCl_3$, $\delta_H$): 3.91 (*t*, *J* = 6.9, 2H, 11-*H*), 3.67 (*s*, 3H, COOC$H_3$), 2.60 (*tt*, *J* = 2.3, 6.9, 2H, 9-*H*), 2.33 (*t*, *J* = 7.5, 2H, 2-*H*), 2.21 (*qn*, *J* = 6.9, 2H, 10-*H*), 2.18 (*tt*, *J* = 2.3, 6.8, 2H, 6-*H*), 1.65 (*qn*, *J* = 7.5, 2H, 3-*H*), 1.55–1.42 (*m*, 4H, C$H_2$); $^{13}C$ NMR ($CDCl_3$, $\delta_C$): 174.15 (C-1), [147.79, 146.66, 145.04, 144.72, 144.55, 144.46, 144.32 (2C: Intensity of this signal is about twice that of the others), 144.15, 144.12, 143.83, 143.63 (2C: Intensity of this signal is about twice that of the others), 144.39, 143.20, 143.10, 142.90, 142.79, 142.70, 142.64, 141.40, 140.80, 140.73, 139.20, 138.50, 138.01, 137.84, 137.32, 137.23, 136.19, 135.84, 133.70 ($C_{60}$-$sp^2$)], 81.15 (C-7), 79.30 (C-8), 51.52 (COO*C*$H_3$), 50.49 (C-11), 34.01 (C-2), 28.96, 28.74, 28.44, 24.52 (C-3), 18.72 (C-6), 16.75 (C-9); MS (APCI): 930.2 ($C_{72}H_{19}O_2N$, calc. $M^+$ *m/z* = 929.949).

*1-(10-Carbonylmethoxy-4-decynyl)-aziridino-[2',3';6,6][60]fullerene (**2e**).* Dark brown solid: m.p.: >350°C. Yield: 38% based on the amount of [60]fullerene consumed; TLC ($R_f$): 0.4 (toluene); UV-vis ($CH_2Cl_2$, $\lambda_{max}$ nm): 424, 492; IR (KBr, neat): 1738 (C=O, str.), 1429, 1349, 1173, 1072, 526 ($C_{60}$) $cm^{-1}$; $^1H$ NMR ($CDCl_3$, $\delta_H$): 3.80 (*t*, *J* = 6.9, 2H, 11-*H*), 3.67 (*s*, 3H, COOC$H_3$), 2.67 (*tt*, *J* = 2.3, 6.9, 2H, 9-*H*), 2.34 (*qn*, *J* = 6.9, 2H, 10-*H*), 2.33 (*t*, *J* = 7.5, 2H, 2-*H*), 2.19 (*tt*, *J* = 2.3, 6.9, 2H, 6-*H*), 1.66 (*qn*, *J* = 7.5, 2H, 3-*H*), 1.55–1.32 (*m*, 4H, C$H_2$); $^{13}C$ NMR ($CDCl_3$, $\delta_C$): 174.15 (C-1), [145.19, 145.14, 144.65, 144.56, 143.81, 143.10, 142.90, 142.30, 142.15, 140.79 ($C_{60}$-$sp^2$)], 85.05 ($C_{60}$-$sp^3$), 81.35 (C-7), 79.46 (C-8), 51.54 (COO*C*$H_3$), 49.95 (C-11), 34.03 (C-2), 29.05, 28.71, 28.47, 24.56 (C-3), 18.73 (C-6), 16.82 (C-9); MS (APCI): 930.2 ($C_{72}H_{19}O_2N$, calc. *m/z* = 929.949).

## DISCUSSION

Two major difficulties were encountered in the synthesis work. First, the yields of the products from the reactions between ω-azido fatty esters and [60]fullerene were very low (a range from 5–9% based on the amount of [60]fullerene initially used or 22–35% based on the amount of [60]fullerene

reacted). In fullerene chemistry it is the practice to calculate the yields based on the amount of [60]fullerene consumed rather than on the actual amount of [60]fullerene used at the start of the reaction. Second, the separation and purification of the products by silica column chromatography were a very tedious exercise, but unavoidable. The optimal reaction condition was to reflux 1.3 molar equivalent amounts of ω-azido fatty ester with 1 molar equivalent of [60]fullerene for 16 h in chlorobenzene in high dilution. Attempts to increase the relative molar amount of ω-azido fatty ester in the reaction led to the production of [60]fullerene derivatives with multiaddends. This result complicated the separation process even further. All purified products (aza-fullerene derivatives) appeared as dark brown solids with m.p. higher than 350°C and are soluble in diethyl ether, benzene, toluene, chloroform, or dichloromethane. However, these derivatives could not be crystallized from any of these solvents.

Despite the fact that a mixture of [60]fullerene and aza-[60]fullerene fatty ester derivatives appeared to be readily separated on an analytical silica TLC plate, the removal of unreacted [60]fullerene from the isolated crude product could only be accomplished by eluting the silica column with a large quantity of *n*-hexane/toluene (1:1, vol/vol). The requisite product could then be isolated using toluene as the eluant. The column chromatographic separation process was closely monitored by TLC analysis of subfractions (50 mL) of eluant, in order to ensure high purity of the desired aza-[60]fullerene ester derivatives.

Attempts to use preparative high-performance liquid chromatography or preparative TLC to isolate aza-[60]fullerene fatty ester derivatives were unsuccessful. The reactions of saturated ω-azido fatty esters (6:0, 8:0, and 12:0) with [60]fullerene gave aza-[60]fullerene ester derivatives (**2a–2c**) with a "[5,6]-open" type aza substructure in the cage (13,17). The presence of the "[5,6]-open" aza substructure in these products was evident from the $^{13}C$ NMR spectral analysis, which showed the appearance of 30–31 $sp^2$ carbon signals in the region of $\delta_C$ 133–147. All carbon atoms of the [60]fullerene cage were therefore of the olefinic nature ($sp^2$ hybridized).

In the reaction between methyl 6-azido-hexanoate and [60]fullerene, the mass spectral analysis (APCI) of the isolated product (**2a**) showed a weak molecular ion peak at *m/z* = 863.5, which corresponded to the molecular formula of $C_{67}H_{13}O_2N$ (calc. *m/z*: 863.846). This result indicated the presence of a single fatty ester addend attached to the [60]fullerene unit. The IR spectrum confirmed the presence of the ester function and the [60]fullerene cage by the absorption bands at 1734 and 526 $cm^{-1}$, respectively. The proton spectrum of compound **2a** further confirmed the presence of the aza-ester addend from the proton shift of the methylene group adjacent to the nitrogen atom at $\delta_H$ 3.81. The carbon shift of the methylene group adjacent to the nitrogen atom appeared at $\delta_C$ 51.62. These shift values agreed with data reported by Prato *et al.* (13) and those by Hawker *et al.* (18) for aza-fullerene derivatives. The assignment of the shifts of the various carbon atoms of the fatty ester moiety was readily achieved. The reactions of methyl 8-azido-octanoate and methyl 12-azido-dodecanoate with [60]fullerene also gave the corresponding "[5,6]-open" type aza [60]fullerene derivatives (**2b, 2c**).

The reaction of methyl 11-azido-7-undecynoate with [60]fullerene furnished two products (compounds **2d** and **2e**), which were isolated in the pure form by silica column chromatography. The molecular ions of compounds **2d** and **2e** (APCI) were identical ($M^+$, *m/z* = 930.2, calc. 929.949 for $C_{72}H_{19}O_2N$), which indicated that these products were monoadducts and of the same molecular weight. The $^{13}C$ NMR spectrum of compound **2d** showed 30 signals in the region of $\delta_C$ 133–147, which confirmed the "[5,6]-open" type of aza substructure of the [60]fullerene cage. The presence of the acetylenic bond [$\delta_C$ 16.75 (C-9), 18.72 (C-6), 79.30 (C-8), 81.15 (C-7)] and the ester group [$\delta_C$ 51.52, $\delta_H$ 3.67] in the addend (fatty ester moiety) was readily confirmed by NMR spectroscopic analysis.

Compound **2e** showed a very different $^{13}C$ NMR spectrum compared to that obtained for compound **2d**. Instead of displaying a multitude of $sp^2$ signals at $\delta_C$ 133–147, compound **2e** gave only 10 $sp^2$ signals in the region of $\delta_C$ 140–145. This reduction in the number of signals showed that the molecule was more "symmetrical" in its structure than those of compounds **2a–2d**. Moreover, in the carbon spectrum of compound **2e**, a signal at $\delta_C$ 85.05 showed the presence of $sp^3$ carbon atoms in the cage (19). From these shift data, compound **2e** contained an aziridine system where the nitrogen atom straddled the carbon atoms of two six-membered rings (hexagons) of the fullerene cage to yield a "[6,6]-closed" type aziridino adduct.

Many reactions between various azides or diazo compounds with [60]fullerene have been reported (13,17–25). Banks *et al.* (19) and Diederich *et al*. (20) found that the "[6,6]-closed" aziridino adduct and the "[5,6]-open" type aza-fullerene appeared to be more stable than the other two possible types ("[6,6]-open" aza-fullerene and "[5,6]-closed aziridino adduct, respectively).

It is interesting that only [5,6]-open monoadducts were found in the reactions of [60]fullerene with saturated ω-azido fatty esters, but both [5,6]-open and [6,6]-closed adducts were obtained substantially when methyl 11-azido-7-undecynoate reacted with [60]fullerene. In order to find out whether compound **2d** could have been derived from **2e** or vice versa, these derivatives were individually refluxed in toluene. It was found that compound **2d** was partially converted to compound **2e** (about 50% as indicated by TLC and NMR analyses) after 50 h of reflux. However, compound **2e** remained unchanged after refluxing in a toluene solution for 50 h. An attempt to heat compound **2e** to a higher temperature (132°C, refluxing a solution of chlorobenzene) led to decomposition of the compound. These experiments showed that the rearrangement reaction (from a "[5,6]-open" aza-fullerene to a "[6,6]-closed" aziridino adduct) appeared to be unidirectional. To explain this unexpected result, we propose that

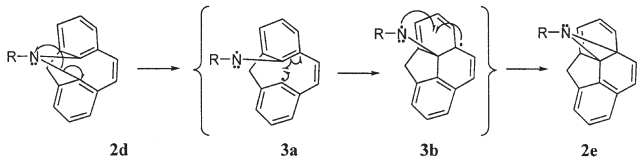

**FIG. 2.** Partial structure of [60]fullerene and the rearrangement of the carbon radical intermediate.

heating of the "[5,6]-open" adduct causes one of the C-N bonds to cleave homolytically to form a very unstable singlet nitrene-carbon free radical intermediate (**3a**). The stability of the intermediate is enhanced by the presence of an acetylenic bond in the alkyl chain. This situation resembles the stabilizing effect of a nitrogen atom on free radical fragments encountered during the electron bombardment of picolinyl esters of unsaturated fatty acids during mass spectrometric analyses (26). To compensate for a more thermodynamically stable intermediate, the nitrene free radical intermediate (**3a**) undergoes ring closure at the 5,6-junction to yield a nitrene with a tertiary carbon free radical (**3b**). Recombination of the singlet nitrene with the tertiary carbon free radical forms the "[6,6]-closed" aziridino adduct (**2e**). The presence of an acetylenic bond in the alkyl chain is therefore vital to stabilize the first step of nitrene free radical formation (Fig. 2). This plausible mechanism appears to be in line with a suggestion made by Banks *et al.* (19) on the mechanistic origin of minor closed "[5,6]-isomers" (aziridino fullerenes).

In conclusion, we found that reactions of saturated ω-azido fatty esters with [60]fullerene furnished mainly [60]fullerene fatty ester derivatives of the "[5,6]-open" type of aza-fullerene, while the acetylenic ω-azido fatty ester gave a mixture of [60]fullenene ester derivatives containing a "[5,6]-open" aza-fullerene and a "[6,6]-closed" aziridino adduct. The presence of the acetylenic group in the fatty ester moiety appeared to affect the isomerization process of a "[5,6]-open" aza substructure to a "[6,6]-closed" aziridino system of the fullerene unit.

# A New Diacylgalactolipid Containing 4*Z*-16:1 from the Marine Cyanobacterium *Oscillatoria* sp.

**Byeng Wha Son[a,]*, Jung Chul Kim[a], and Hong Dae Choi[b]**

[a]Department of Chemistry, Pukyong National University, Pusan 608-737, Korea, and [b]Department of Chemistry, Dongeui University, Pusan 614-714, Korea

**ABSTRACT:** A new diacylgalactolipid was isolated from the marine cyanobacterium *Oscillatoria* sp., and the structure was elucidated as (2*S*)-3-*O*-β-D-galactopyranosyl-1-*O*-(9*Z*,12*Z*-octadecadienoyl)-2-*O*-(4*Z*-hexadecenoyl)glycerol by enzymatic partial hydrolysis using lipase and physicochemical evidence, which included determining the double bond position in the hexadecenoic acid moiety.

Paper no. L8744 in *Lipids 36,* 427–429 (April 2001).

Cyanobacteria are recognized as a rich source of biologically active natural products, including a variety of glycolipids (1,2). Extracts of several species of *Oscillatoria* have already yielded glycolipids (3) and bioactive peptides (4). As part of an effort to discover biologically active natural products, we report the isolation of a new diacylgalactolipid **1**, along with the known diacylgalactolipids II and IV (3), from the lipophilic extract of the marine cyanobacterium *Oscillatoria* sp.

## EXPERIMENTAL PROCEDURES

*Culture*. The marine cyanobacterium, *Oscillatoria* sp. (strain # KMCC CY-11), was obtained from the Korea Marine Microalgae Culture Center, Pukyong National University. The strain was cultured for 28 d at 23°C in an f/2 medium (5) with aeration (filtered air, 0.3 L/min) under cool-white fluorescent illumination of 5000 lux. After 4 wk, the algal mass was harvested by centrifugation at 10,000 × *g*, filtration on filter paper, and lyophilization. Yields of lyophilized cells were in the range of 100 ± 25 mg/L of culture.

*Isolation of diacylgalactolipid **1**.* The lyophilized algal mass (10.0 g) was extracted with $CH_2Cl_2$/MeOH (1:1, vol/vol) at room temperature and concentrated under reduced pressure to yield an extract (3.0 g). From the extract (3.0 g), seven fractions were obtained by means of silica gel column chromatography (CC) by eluting with *n*-hexane/EtOAc (100% → 0%, vol/vol) and then EtOAc/MeOH (100% → 0%, vol/vol). The eluent with *n*-hexane/EtOAc gave fractions 1-3, and subsequent elution with EtOAc/MeOH yielded fractions 4-7. Fraction 5, containing diacylgalactolipid **1** was eluted with EtOAc/MeOH (5:1, vol/vol). Fraction 5 (140 mg) containing **1** was decolorized by activated-carbon CC using MeOH/$CH_3COCH_3$ (100% → 0%, vol/vol) as the eluent, and purified by high-performance liquid chromatography (YMC, Kyoto, Japan; column 4.6 × 250 mm, refractive index detector, octadecylsilane-A, MeOH) to furnish **1** (20.0 mg). Properties of **1** include the following: colorless viscous solid; $[\alpha]_D$ −6° (*c* 0.2, $CHCl_3$); infrared (IR) (neat): 3420, 1735, 1640, 1245, 1155, 1075 $cm^{-1}$; see Table 1 for nuclear magnetic resonance (NMR) spectral data of **1**.

Other features of the experimental procedures include the following.

*Gas chromatography–mass spectrometry (GC–MS).* Conditions of analysis: Hewlett-Packard (Palo Alto, CA) HP-5 capillary column, 0.32 mm × 50 m; gradient temperature increases (3°C/min) from 80 to 150°C and (5°C/min) from 150 to 290°C.

*Properties of **1a.*** High-resolution fast atom bombardment mass spectrometry (FABMS) *m/z* 513.3039 $[M + Na]^+$ (calculated for $C_{25}H_{46}O_9Na$, 513.3040); low resolution FABMS *m/z* 513 $[M + Na]^+$; see Table 1 for NMR spectral data.

*Methyl 9Z,12Z-octadecadienoate*. $^1H$ NMR (400 MHz, $CDCl_3$) δ5.35 (4H, *m*), 3.67 (3H, *s*), 2.77 (2H, *dd, J* = 6.5, 6.0 Hz); 2.07 (2H, *t, J* = 7.5 Hz), 2.04 (4H, *dt, J* = 7.0, 6.5 Hz), 1.62 (2H, *m*), 1.31 (*m*), 0.89 (3H, *dd, J* = 7.0, 6.5 Hz).

*Methyl hexadecenoate. m/z* 268 $[M]^+$ (1), 236 $[M - CH_3OH]^+$ (16), 194 $[M - CH_3COOCH_3]^+$ (45), 179 (5), 166 (12), 152 (34), 138 (11), 123 (17), 110 (22), 96 (69), 84 (59), 74 $[CH_3COOCH_3]^+$ (100); $^1H$ NMR (400 MHz, $CDCl_3$) δ 5.42 (1H, *ddd, J* = 10.7, 7.5, 7.0 Hz); 5.33 (1H, *m*), 2.36 (2H, *m*), 2.03 (2H, *dt, J* = 7.0, 6.5 Hz), 1.58 (*br. s*), 1.26 (*br. s*), 0.88 (3H, *dd, J* = 6.9, 6.7 Hz).

*Dimethyldisulfide (DMDS) derivative of methyl hexadecenoate. m/z* 362 $[M]^+$ (3), 215 $[CH_3(CH_2)_{10}CH{=}SCH_3]^+$ (64), 147 $[CH_3OOCCH_2CH_2CH{=}SCH_3]^+$ (29), 115 (39), 87 $[147 - (CH{=}SCH_3)]^+$ (100).

## RESULTS AND DISCUSSION

Diacylgalactolipid **1** was obtained as a colorless viscous solid. The IR spectrum of **1** revealed absorptions indicative of hydroxyl (3420 $cm^{-1}$), ester (1735, 1245 $cm^{-1}$), and glycosidic moieties (1075 $cm^{-1}$). The $^1H$ and $^{13}C$ NMR spectra of **1** showed signals assignable to monogalactopyranosyl diacylglycerol (Table 1). Alkaline hydrolysis of **1** with 3.0% (wt/vol) NaOMe/dry MeOH gave a galactopyranosyl glycerol **1b** and a mixture of fatty acid methyl esters.

[a]Recorded in $CD_3OD$ at 300 MHz ($^1$H) and 75 MHz ($^{13}$C).
[b–f]Signals within the same column overlapped.
[g–j]Interchangeable in each column.

The galactopyranosyl glycerol, $[\alpha]_D$ −6° ($H_2O$), was shown to be identical in all respects with (2*R*)-3-*O*-β-D-galactopyranosylglycerol **1b** (3). Therefore, the absolute configuration at C-2 of **1** has been determined to be *S*. The fatty acid composition in diacylgalactolipid **1** was analyzed to be a 1:1 mixture of methyl 9*Z*,12*Z*-octadecadienoate and methyl hexadecenoate by GC–MS, but the latter was not identified in the position of double bond.
