**ABSTRACT**: Eggs enriched with n-3 polyunsaturated fatty acids (PUFA) could contribute to dietary intake of these healthful fatty acids (FA). Because n-3 PUFA are highly susceptible to peroxidation, a first part of the study with Leghorn laying hens was carried out to investigate the influence of different levels of fish oil (0, 0.7, 1.4, 2.8, or 5.6%, respectively) in the diet on n-3 PUFA, cholesterol, vitamin E, and lipid peroxidation product contents in eggs. Addition of fish oil to a complete diet based on wheat, rye, tapioca, and soybean constituents containing 11 IU vitamin E/kg resulted in increased n-3 PUFA content in egg yolk, mainly due to accumulation of docosahexaenoic acid. Cholesterol was not altered up to 2.8% fish oil in the diet. The vitamin E content of the yolk was insufficient for the protection of PUFA from peroxidation. Addition of up to 2.8% fish oil to laying hen diets increased the n-3 PUFA content of yolks with a concomitant imbalance between vitamin E and PUFA, leading to increased levels of cytotoxic aldehydic lipid peroxidation products such as malondialdehyde (MDA). In a second part of the studies, the balance between vitamin E, PUFA, and lipid peroxidation was analyzed during the period of storage of n-3 PUFA-enriched eggs produced after feeding the laying hens with 1.5% fish oil diets with different concentrations of vitamin E (0, 5, 10, 20, 40, 80, 160 IU/kg). Storage of eggs resulted in a marked loss of vitamin E in yolk. In stored eggs, the cytotoxic lipid peroxidation products MDA, 4-hydroxynonenal, and 4-hydroxyhexenal were reduced in response to vitamin E supplementation. To prevent the increase of cytotoxic aldehydic lipid peroxidation during production and storage of n-3 PUFA-enriched eggs, a high vitamin E supplementation with at least 80 IU vitamin E/kg is needed.

Paper no. L8563 in *Lipids 36*, 833–838 (August 2001).

As components of membrane phospholipids n-3 polyunsaturated fatty acids (PUFA) play a key role in the structure and function of biological membranes. They influence membrane fluidity, receptor and enzyme activities, ion channel properties, and signal transduction pathways. Additionally, the n-3 PUFA eicosapentaenoic acid (EPA, 20:5n-3) serves as a source for eicosanoid synthesis (1).

However, the typical Western diet provides much more n-6 PUFA than n-3 PUFA. In this diet the content of linoleic acid (LA, 18:2n-6) is especially high. That fatty acid is abundant in vegetable oils, e.g., corn oil, sunflower oil and safflowerseed oil (2). LA undergoes desaturation and elongation to form arachidonic acid (AA, 20:4n-6), which is the principal precursor for prostanoids of the 2 series and leukotrienes of the 4 series. Metabolically active PUFA from the n-3 PUFA family—EPA and docosahexaenoic acid (DHA, 22:6n-3) found in high concentrations in fish oil—are synthesized from α-linolenic acid (α-LNA, 18:3n-3), the major n-3 PUFA in vegetable oils like linseed oil and soybean oil. PUFA of both n-6 and n-3 families compete for the same enzymes for their metabolic pathways. Remarkably, prostanoids of the 3 series and leukotrienes of the 5 series derived from EPA are in general less prothrombotic and proinflammatory than eicosanoids originating from AA. The dietary ratio between n-6 and n-3 PUFA is important for a more or less inflammatory status (3,4). Hence, the changes in dietary habits leading to an imbalance between n-6 and n-3 PUFA in the diet may make a person more vulnerable to inflammatory diseases, e.g., rheumatoid arthritis, asthma, atopic dermatitis, diabetes, cancer, and AIDS (3,5,6). n-3 PUFA also have beneficial effects on a number of diseases associated with civilization, such as coronary heart disease (7). These are likely due to the hypolipidemic, antithrombotic, and antiarrhythmic effects of n-3 PUFA (1,8,9). Therefore, dietary recommendations encourage increased consumption of fish. However, dietary intake has been decreasing; therefore, it is important to raise the dietary intake of n-3 PUFA in populations of Western countries. Because it is difficult and time-consuming to change the nutrition habits of a population and because seasonal availability and consumer preference may limit fish consumption, enriching the n-3 PUFA content of food products is a reasonable approach. The enrichment of hens' complete diet based on wheat, rye, tapioca and soybean meal with n-3 PUFA has been tested (10). Alternatively, eggs enriched with n-3 PUFA also can contribute to the dietary intake of these healthful PUFA, n-3 providing them in a highly bioavailable phospholipid form (11,12).

Since n-3 PUFA are highly susceptible to peroxidation, a study with laying Leghorn hens was carried out to investigate the effects of different supplements of fish oil to the hens' diet on n-3 PUFA, vitamin E, and lipid peroxidation products of freshly laid eggs. The balance between n-3 PUFA, vitamin E, and lipid peroxidation products was also analyzed during the

egg storage for 4 wk. The latter part of the investigations was carried out with eggs produced from hens fed a constant content of fish oil (1.5%) but different contents of vitamin E. Therefore, we addressed the questions whether it is necessary to stabilize a high n-3 PUFA content in eggs to prevent a significant accumulation of cytotoxic aldehydic lipid peroxidation products and whether vitamin E supplementation is sufficient for the stabilization.

## MATERIAL AND METHODS

*Animals.* Experiments were performed in conformance to accepted standards. For part one of the study, on the n-3 PUFA enrichment of eggs produced by hens consuming diets with different levels of fish oil, 120 white Leghorn laying hens with an age of 38 wk were used. For the second part of the study, the influence of different vitamin E contents at one defined fish oil concentration on changes in eggs during 4 wk of storage was investigated with 120 additional Leghorn hens, age 35 wk.

*Diets.* During a 2-wk pre-test period an additional supplementation of 1% arachis oil as a source for LA was given (no linolenic acid). During the actual test period, combined additions of fish oil (12.5% EPA, 9% DHA) and arachis oil (25% LA) (3.5:1) were used to give dietary levels of 0, 0.7 ± 0.2, 1.4 ± 0.4, 2.8 ± 0.8, or 5.6 ± 1.6%, respectively. The test period was 4 wk.

For evaluating the antioxidant effects of added vitamin E on the n-3 PUFA enrichment of eggs with different fish oil contents [a blend of fish-oil (12.5% EPA, 9% DHA) and arachis oil (25% LA) (3.5:1) was used to give dietary levels of 0, 0.7, 1.4, 2.8, or 5.6%, respectively], a supplementation with 5 IU vitamin E/kg was performed. As vitamin E, all-*rac*-α-tocopherylacetate was used. The resulting average vitamin E content was 11 IU/kg diet. After the indicated times eggs were collected and pooled (3 eggs per pool) for analytical procedures. The mean egg weight was 60.2 g. The average amount of an egg yolk is about 16.8 g per fresh egg.

The total length of time for delivery of eggs to the laboratory, sampling, and homogenization of yolk until it had been frozen was less than 24 h. The influence of different vitamin E contents (at one defined fish oil concentration) on the changes in eggs during 4 wk of storage (room temperature, ~25°C; 70% humidity) was investigated by using a complete diet based on wheat, rye, tapioca, soybean meal, 1.5% fish oil, and vitamin E contents of 0, 5, 10, 20, 40, 80, and 160 IU/kg.

*Analytical procedures. (i) Fatty acids*. The extraction of egg yolk for fatty acid determination was carried out according to Brandt *et al.* (13). The fatty acid methyl esters were analyzed by means of gas chromatography according to the scheme of the Association of Official Analytical Chemists (14).

*(ii) Cholesterol*. The cholesterol content of egg yolk was determined spectrophotometrically (15).

*(iii) Vitamin E.* The vitamin E content of egg yolk was measured according to Bassler and Buchholz (16) by means of high-performance liquid chromatography (HPLC) separation and detection.

*(iv) Vitamin E requirement*. The tocopherol equivalent (TE) requirement—a value which is important for the protection of PUFA from peroxidation—was estimated on the basis of mathematical models according to Gassmann and Kübler (17).

*(v) Malondialdehyde (MDA)*. The concentration of MDA was determined according to Wong *et al.* (18). To 25 mg egg yolk, 0.75 mL phosphoric acid (0.44 mol/L) was added. The sample was thoroughly mixed in the presence of 10 mM butylated hydroxytoluene (BHT). The mixed sample (250 µL) was boiled in the presence of 0.25 mL thiobarbituric acid (42 mmol/L), 0.5 mL phosphoric acid, and 0.3 mL water for 60 min. Then the reaction was stopped by cooling the samples in an ice bath. Immediately before analysis on HPLC an equal volume of 1 M NaOH was added. The extract was then centrifuged. The HPLC equipment consisted of a Waters 510 pump and a Shimadzu fluorescence detector RF-530 (525/550 nm) and integrator C-R6A. The column was a Supelcosil 150 × 4 mm LC-18-S (5 µm) (Supelco). As eluent, a 50-mM potassium phosphate buffer solution at pH 6.8 with 40% methanol was used.

*(vi) 4-Hydroxynonenal (HNE) and 4-hydroxyhexenal (HHE)*. The aldehydes were analyzed according to Sommerburg *et al.* (19): 1 g of egg yolk was reacted with 1 mL of dinitrophenylhydrazine (DNPH) solution (1.8 mM in 1 M HCl) in presence of BHT in final concentration of 10 mM for 2 h in the dark. The sample was then kept for 1 h in an ice bath in the dark, extracted three times with 4 mL of dichloromethane, centrifuged at 900 × *g,* and evaporated on a rotary evaporator to dryness at a temperature of 35°C. The residue was transferred with 1.0 mL of dichloromethane into small vials for spotting on thin-layer chromatography (TLC) plates. The TLC plates were developed along with known standard compounds with dichloromethane. In this way the dinitrophenylhydrazones of carbonyl compounds were separated into three zones. Zone I contained the 4-hydroxyalkenals. This zone was scraped off, extracted three times with 5 mL each of methanol and evaporated to dryness. The residue was dissolved in 1 mL of methanol. An HPLC Gold system from Beckman (Unterschleissheim, Germany) was used. The eluent for the isocratic separation was methanol/water (4:1, vol/vol). The flow rate was 1 mL/min. A Supelcosil column LC-18 150 × 4 mm i.d. (5 µm) was used. Peak identification was performed by comparison of the retention times of peaks of samples and of standards, by the coelution of yolk extracts with the reference compound, and by comparison of the spectra. Quantification of HHE and HNE was achieved by separating HHE-DNPH and HNE-DNPH standard solutions of different concentrations.

*Statistical evaluation.* Data were compared and evaluated by means of variance and regression analysis. The analysis of variance and Duncan tests were carried out for six-yolk groups in the experiments with different fish oil contents and with different vitamin E concentrations at defined fish oil content. Mean differences with $P < 0.05$ were considered significant.

## RESULTS

Feeding fish oil to laying hens increased the n-3 PUFA content of egg yolk which is mainly owing to increases in EPA

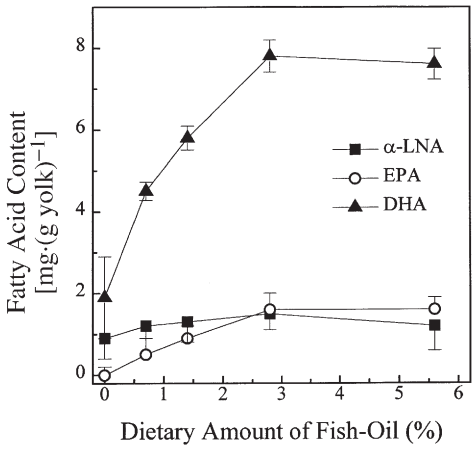

**FIG. 1.** Amount of n-3 polyunsaturated fatty acid (PUFA) as a function in egg yolk of dietary fish oil supplementation to hens. α-LNA, α-linolenic acid; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid. Error bars represent standard deviation.

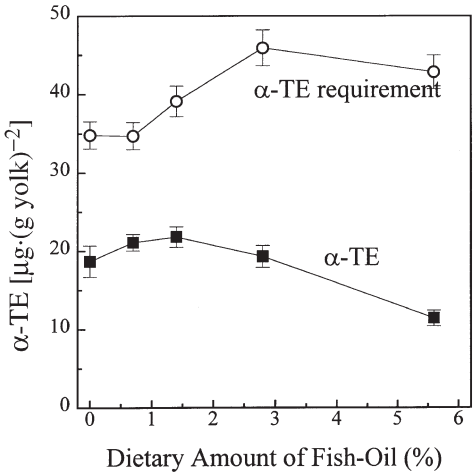

**FIG. 2.** Content of α-tocopherol equivalents (TE) in egg yolk in comparison to the TE requirement, which was calculated according to References 20 and 21. Error bars represent standard deviation.

and DHA. n-3 PUFA content (EPA + DHA) increased owing to fish oil supplementation in the up to 2.8% fish oil in the diet, $P < 0.001$ (Fig. 1). At 5.6% fish oil in the diet there was no further increase in n-3 PUFA content in egg yolk. Even though the EPA content was higher than the DHA content in the original fish oil, the DHA content of egg yolk was five to nine times higher than the EPA content. Because the content of several n-3 fatty acids was influenced by the diet, we decided to check for other lipid components. Table 1 shows that at fish oil contents up to 2.8% the cholesterol concentration of egg yolk and of total egg tissue remained unchanged. Only higher concentrations of fish oil were able to increase the cholesterol by 30%.

Figure 2 shows the content of α-TE in egg yolk compared to the TE requirement, which was calculated according to References 17, 20, and 21. At the highest fish oil concentration in the diet (5.6%), vitamin E content was markedly reduced. About 28% of vitamin E was transferred into the egg yolk at 0.7 to 2.8% fish oil addition. It was reduced to 18% at 5.6% fish oil addition. The vitamin E content was insufficient to protect PUFA from peroxidation as indicated by an imbalance between n-3 PUFA and the calculated physiological TE requirement. The gap between the TE determined and the TE required to balance PUFA became wider with increasing fish oil supplementation (Fig. 2). This imbalance between pro-oxidant and antioxidative defense should result in enhanced oxidation of lipids in the egg. Therefore, we measured MDA, one of the most abduant lipid peroxidation products. At concentrations beyond 1.4% fish oil in the diet, there was an increase in MDA concentration in the egg (Fig. 3).

Owing to the inability of the egg to protect this increased amount of the highly peroxidizable fatty acids, we investigated whether vitamin E supplementation can provide better protection. (Of course, the storage time from egg production to the usage by the consumer can influence the prooxidative-antioxidative balance dramatically.) We tested whether vitamin E supplementation of hens' diet would increase the vitamin E content in the egg and how stable this vitamin E was during storage. There was a 90% increase in vitamin E in yolks from fresh eggs at dietary levels up to 80 IU/kg vitamin E (Fig. 4). A level of 160 IU vitamin E/kg drastically

increased the vitamin E concentration in both fresh and stored eggs. Although at high amounts of vitamin E in the diet a remarkable amount of the vitamin was left after the storage at room temperature, there was also a notable loss of vitamin E in egg yolk (Fig. 4). Since we were able to enrich the eggs with vitamin E with dietary supplementation, we measured the influence of vitamin E on the n-3 PUFA concentrations in egg yolk (Fig. 5). Dietary vitamin E supplementation enhanced PUFA transfer to the egg to a certain degree. The increased PUFA content was mainly due to the accumulation of DHA. Increasing vitamin E supplementation up to 40 IU/kg led to PUFA/DHA increases (Fig. 5). Vitamin E concentrations higher than 40 IU/kg did not lead to further increases of PUFA/DHA contents.

During egg storage, high amounts of aldehydic lipid peroxidation products accumulated. Figure 6 demonstrates the concentrations of MDA, HNE, and HHE in egg yolk of fresh eggs and of eggs which were stored for 4 wk. The largest differences between fresh and stored eggs were for MDA and HNE. In stored eggs, MDA, HNE, and HHE were reduced in response to vitamin E supplementation (Fig. 6). Interestingly, the difference in HHE concentrations between stored and fresh eggs from hens without any vitamin E in the diet was notable, whereas this difference decreased with increasing vitamin E concentrations. Therefore, Figure 6 illustrates that vitamin E concentrations above 80 IU/kg diet are sufficient to protect eggs enriched with n-3 PUFA.

## DISCUSSION

During evolution the human being adapted biologically to foods with a relatively low content of total fat and saturated fatty acids. The n-6/n-3 ratio of unsaturated fatty acids was about one (2). As a result of social, agricultural, and industrial development, the n-6/n-3 ratio in a modern Western diet

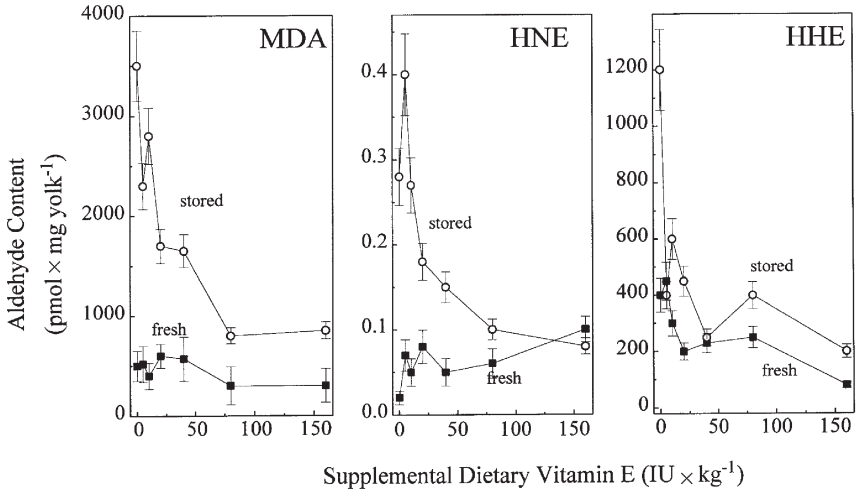

**FIG. 6.** Concentrations of MDA, 4-hydroxynonenal (HNE), and 4-hydroxyhexenal (HHE) in egg yolk of fresh eggs and of eggs stored at room temperature for 4 wk. Eggs were laid by hens fed diets with 1.5% fish oil and different vitamin E contents. Error bars represent standard deviation.

is now 20–25:1 (2). The main sources of EPA and DHA are fish and poultry (22).

It was shown earlier that the n-3 PUFA content of egg yolk may be an important source of n-3 PUFA for human nutrition (11,23). In our study the supplementation of hens' diet with fish oil resulted in increased n-3 PUFA content in egg yolk, mainly from accumulation of DHA. The present study considered DHA content of egg yolk as a function of different fish oil concentrations at one defined vitamin E concentration of the diet. The vitamin E content of the yolk was insufficient to protect PUFA from peroxidation, as calculated from mathematical models and as indicated by an increase of MDA. Therefore, it is reasonable to increase the vitamin E content in the hens' diet to ensure an adequate vitamin E provision for the animals.

That the addition of vitamin E to hens' diet is accompanied by an increased accumulation of vitamin E in the egg yolk was demonstrated Chen *et al.* (24) and Cherian *et al.* (25). The balance between vitamin E, PUFA, and lipid peroxidation in n-3 PUFA-enriched egg yolk was also analyzed. A notable increase in vitamin E content in the egg yolk was found, especially at high levels of dietary vitamin E supplementation. Storage of eggs resulted in a remarkable loss of vitamin E in the yolks. During the period of storage of n-3 PUFA-enriched eggs produced after feeding the laying hens a diet with a defined fish-oil concentration (1.5%) but different concentrations of vitamin E (0, 5, 10, 20, 40, 80, 160 IU/kg), the loss of vitamin E in all vitamin E supplementation groups was comparable. The high vitamin E content in eggs produced by hens supplemented with 160 IU/kg allowed eggs to be stored for 4 wk without a complete loss of the important lipid soluble antioxidant vitamin E. After storage, the amount of vitamin E in the yolk was still higher than the vitamin E content of fresh eggs from hens without any vitamin E supplementation. On the other hand, the supplementation of hens' diet with vitamin E enhanced the accumulation of n-3 PUFA in the egg. Therefore, the supplementation of hens' diet with vitamin E stabilized the antioxidant defense systems of the egg and enriched of n-3 PUFA in the egg.

Since the vitamin E functions in the egg to increase the antioxidant capacity of the yolk compartment, we tested for the protective role against spontaneous lipid peroxidation in the egg. For our measurements we chose three of the major cytotoxic lipid peroxidation products: MDA, HNE, and HHE. These three aldehydes are formed during lipid peroxidation of various fatty acids: MDA is formed from fatty acids with three or more double bonds, HNE is formed from n-6 PUFA with two or more double bonds, and HHE is formed from n-3 unsaturated fatty acids (26). None of the aldehydes detected in fresh eggs was found to change its content significantly due to the supplementation of hens' diet with vitamin E. Cherian *et al.* (25) reported a significant decrease of egg MDA content due to vitamin E supplementation of the hens' diet. However, nothing was said about the storage of eggs in that study. We found a notable accumulation in stored eggs of cytotoxic aldehydic lipid peroxidation products such as MDA, HNE, and HHE. That MDA is formed by peroxidation processes in large amounts during storage of eggs is not remarkable, since this aldehyde may be formed from a number of different PUFA (26). The increases in HHE and HNE during storage of eggs from hens fed with a non-supplemented diet are also obvious, since high amounts of n-3 fatty acids are present in the egg yolk and these are susceptible to oxidation. In the chain propagation of the lipid peroxidation process the n-3 and n-6 fatty acids—the precursors of HNE—are subject to enhanced oxidation (26). MDA, HNE, and HHE formation during storage at room temperature was reduced by vitamin E supplementation. At vitamin E doses of ≥ 80 IU/kg diet, no difference in the content of aldehydic lipid peroxidation products was found after 4 wk of storage. Therefore, these high doses of vitamin E are sufficient to protect high contents of n-3 and n-6 PUFA in eggs.

To produce n-3 PUFA-enriched eggs—so-called DHA eggs—without increased levels of cytotoxic aldehydic lipid peroxidation products, a 1.5% fish oil-containing diet needs a very high vitamin E addition. To produce DHA eggs without an accumulation of lipid peroxidation products, the hens' diet must be supplemented with at least 40 IU vitamin E/kg diet.

# Diferuloylputrescine and *p*-Coumaroyl-feruloylputrescine, Abundant Polyamine Conjugates in Lipid Extracts of Maize Kernels

**Robert A. Moreau[a,*], Alberto Nuñez[a], and Vijay Singh[b]**

[a]USDA, ARS, ERRC, Wyndmoor, Pennsylvania 19038, and [b]Department of Agricultural Engineering, University of Illinois, Champaign, Illinois 61801

**ABSTRACT:** Extraction of corn bran or corn fiber with polar solvents such as methylene chloride, ethanol or chloroform/methanol yielded common lipids and two unknown high-performance liquid chromatography (HPLC) peaks, each with an ultraviolet absorbance maximum at 320 nm. HPLC–mass spectrometry revealed that the unknowns were diferuloylputrescine (DFP) and *p*-coumaroyl-feruloylputrescine (CFP). When compared to extracts of corn fiber (a pericarp-enriched fraction from the wet milling of corn), comparable extracts of corn bran (a pericarp- enriched fraction from the dry milling of corn) yielded three- to eightfold higher levels of DFP and CFP. Extraction of corn bran or fiber with an accelerated solvent extractor revealed that elevated temperatures greatly enhanced the extraction of DFP and CFP by methylene chloride and ethanol. "Corn bran oil," prepared by extraction of corn bran with hot methylene chloride, contained 14 wt% DFP and 3 wt% CFP. However, when hexane was used as a solvent, accelerated solvent extraction of the corn bran or fiber did not extract any DFP or CFP. Extraction of wheat bran or psyllium hulls with hot methylene chloride did not yield any detectable DFP or CFP. Because it has been suggested that polyamine conjugates such as DFP and CFP may function as natural pesticides, a rapid method was developed to purify them so that their biological activity could be evaluated.

Paper no. L8765 in *Lipids 36,* 839–844 (August 2001).

Previously, we reported that high levels of three phytosterol classes (free phytosterols, phytosterol fatty acyl esters, and phytosterol ferulate esters) could be obtained by extraction of corn fiber with hexane, ethanol, or supercritical $CO_2$ (1). The present study was undertaken to investigate other lipids and lipid-like components that are present in lipid extracts of ground corn, corn fiber, and other corn processing streams. In addition to the polar and nonpolar lipids that have previously been reported (2), we now report that when corn kernels are extracted *via* routine organic extractions and analyzed *via* chromatographic methods, high levels of polyamine conjugates such as diferuloylputrescine (DFP) and *p*-coumaroyl-feruloylputrescine (CFP) will also be extracted and will appear as peaks interspersed among common lipids. In the only previous quantitative reports, the levels of DFP in kernels of 62 corn hybrids ranged from 8 to 560 μg/g ground kernel (3); and in a second study of isolated corn pericarp, embryo, and endosperm, the levels of DFP were reported to be 65, 15, and 5 μg/g, respectively (4). DFP was also reported to occur in extracts of gibberella ear rot-resistant corn (5). CFP has not previously been reported in any plant materials.

## EXPERIMENTAL PROCEDURES

*Materials.* Corn fiber [consisting of a combination of coarse fiber (mainly from the pericarp) and fine fiber (mainly from the endosperm)] was obtained from a conventional corn wet-milling plant and kindly provided by T. Carlson, Cargill, Inc. (Dayton, OH). Corn bran (NC02080, Coarse, DIETFIBER, from a corn dry-milling plant) was kindly provided by W. Duensing, Lauhoff/Bunge Foods (Danville, IL). Yellow dent #2 corn kernels, H3361, were kindly provided by Pioneer Hi-Bred International (Johnston, IA). Wheat bran and psyllium (*Plantago ovata*) husk powder (Yerba Prima Botanicals, Ashland, OR) were purchased locally. Corn fiber, corn kernels, and wheat bran were milled to 20 mesh with a Wiley mill (Thomas Scientific, Philadelphia, PA), whereas corn bran and psyllium had already been milled to a comparable particle size.

*Extraction.* Most extractions were performed with a Dionex Accelerated Solvent Extractor, Model ASE 200 (Dionex Inc., Sunnyvale, CA), using hexane, methylene chloride, or ethanol. The sample (2–4 g) was placed in an 11-cc stainless steel extraction vessel, and the remaining volume was filled with sand. The extractor was programmed to extract at a pressure of 1000 psi (69 bar), and a temperature of either 40 or 100°C; each sample was extracted with a total of 22 mL of solvent, delivered in three 10-min extractions. For purification studies, a sample was extracted with methylene chloride, first at 40 and then at 100°C. Alternatively, samples were extracted using the Bligh and Dyer chloroform/methanol extraction method (6), either with or without sample homogenization (Polytron; Brinkman, Westbury, NY), 60 s,

Abbreviations: ASE, accelerated solvent extraction; CFP, *p*-coumaroyl-feruloylputrescine; DFP, diferuloylputrescine; EI, electron impact; ELSD, evaporative light-scattering detector; HPLC, high-performance liquid chromatography; LC/MS-EI, HPLC-mass spectrometry-electron impact ionization; MS, mass spectrometry; PDA, photodiode array detector; SPE, solid-phase extraction.

high speed. Purified pericarp and aleurone layers were prepared by steeping corn kernels (0.2% $SO_2$ and 0.55% lactic acid, at 50°C for 24 h), removing the hull with a scalpel, and separating it into the pericarp and aleurone layers *via* hand dissection with forceps, followed by Bligh and Dyer extraction and high-performance liquid chromatography with evaporative light-scattering detector (HPLC-ELSD) analysis of each. Two separate extractions were performed for each sample, and two HPLC injections were made from each extract.

*HPLC analyses.* HPLC analyses were performed on a Hewlett-Packard Model 1100 HPLC (Agilent Technologies, Palo Alto, CA) with an autosampler, with detection *via* two detectors in series; the effluent first entered a Hewlett-Packard Model 1100 Diode Array ultraviolet (UV)-visible detector, and then a Sedex Model 55 Evaporative Light Scattering Detector (Richard Scientific, Novato, CA) operated at 40°C, with nitrogen as a nebulizing gas, at a pressure of 2.0 bar. The HPLC column was a LiChrosorb Diol 5 micron (3 × 100 mm, packed by Varian/Chrompack, Walnut Creek, CA), and the isocratic mobile phase was hexane/isopropanol/acetic acid, 66.6:33.3:0.1, by vol, at a flow rate of 0.5 mL/min. A sample of purified DFP/CFP mixture (determined to be at least 99% pure by HPLC-ELSD, and estimated to be 85% DFP and 15% CFP by HPLC with UV absorbance measurement 320 nm) was used to construct a calibration curve which exhibited a linear relationship between area of UV 320 nm and mass in the range of 1–30 μg DFP and 1–10 μg CFP.

*HPLC/mass spectrometry-electron impact ionization (LC/MS-EI).* The LC/MS-EI instrument consisted of a Waters HPLC 2690 Separation Module (Waters Co., Milford, MA) connected in series to a Waters 996 Photodiode Array Detector (PDA) and a Waters Thermabeam Mass Detector (Integrity System). The HPLC portion used a Valco LiChrosorb Diol 5 micron column (2 × 250 mm) (Varian/Chrompack) with an isocratic solvent system of hexane (0.1% acetic acid)/isopropanol, 60:40 vol/vol, at a flow rate of 0.3 mL/min. The PDA was set to scan from 200 to 400 nm, and the MS-EI detector was set to scan in the mass range of *m/z* 60–600 at 1 scan/s with an ionization energy of 70 eV, a source temperature of 200°C, and a nebulizer temperature of 44°C.

*High-resolution electrospray MS.* Electrospray-MS was performed using a VG BioQ (Quattro II Upgrade) triple quadrupole mass spectrometer (source) scanning the range of 360–475 *m/z*; dwell 1.0 ms; pause 5.0 ms, calibrated using polyethylene glycol.

*Purification of a DFP- and CFP-enriched fraction* via *solid phase extraction (SPE).* Corn bran (25 g) was extracted by weighing five 5-g samples into accelerated solvent extraction (ASE) vessels as described above. Each vessel was extracted first with 22 mL of methylene chloride at 40°C, and then with an additional 22 mL of methylene chloride at 100°C. The 40°C methylene chloride extract was evaporated, weighed, analyzed for DFP and CFP, and then discarded. The 100°C extract, which was enriched in DFP and CFP, was then applied to an SPE cartridge (Mega Bond Elute, Silica, 10 g/60 mL, Varian), as follows: the cartridge was rinsed with 50 mL methanol and 50 mL chloroform; the sample (112 mL of extract, methylene chloride at 100°C, from 25 g corn fiber) was then applied to the SPE cartridge, and it was then sequentially eluted with 50 mL each of 99:1, 98:2, 95:5, 90:10, and 85:15 chloroform/methanol, vol/vol; and the solvent was evaporated in each fraction and the mass and levels of DFP and CFP were quantitatively analyzed *via* HPLC-UV at 320 nm.

## RESULTS AND DISCUSSION

Extraction of corn bran with hexane yielded an oil that contained only triacylglycerols, phytosterols, and other minor components reported previously (1). Extraction of corn bran with more polar solvents, such as methylene chloride or ethanol, yielded two unknown peaks (at retention times of about 6.5 and 8.5 min), and both peaks exhibited an absorption maximum of about 320 nm (Fig. 1). The UV absorption spectra of both unknowns were very similar to the UV spectrum of ferulic acid (data not shown), suggesting that the unknowns may contain esterified ferulic acid or a similar compound. With LC/MS-EI and the same column and chromatographic conditions as above (Fig.1), the two peaks each possessed unique mass spectra (Fig. 2). The molecular weights of the 6.5- and 8.5-min unknown peaks appeared to be *m/z* 410 and 440, respectively.

High-resolution electrospray-MS analysis of the larger peak fraction (8.5 min) provided an accurate mass for the protonated molecular ion $(M + H)^+$ signal of 441.1996. The mass

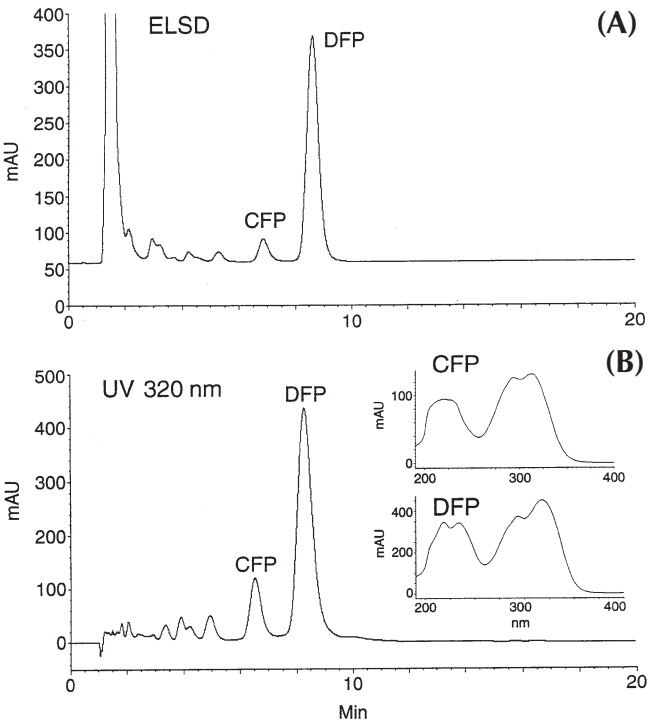

**FIG. 1.** Chromatograms of the 100°C methylene chloride accelerated solvent extraction lipid extract from corn bran (A) with detection *via* evaporative light-scattering detection (ELSD), and (B) with detection in the ultraviolet (UV) at 320 nm. CFP, *p*-coumaroyl-feruloyputrescine; DFP, diferuloylputrescine.

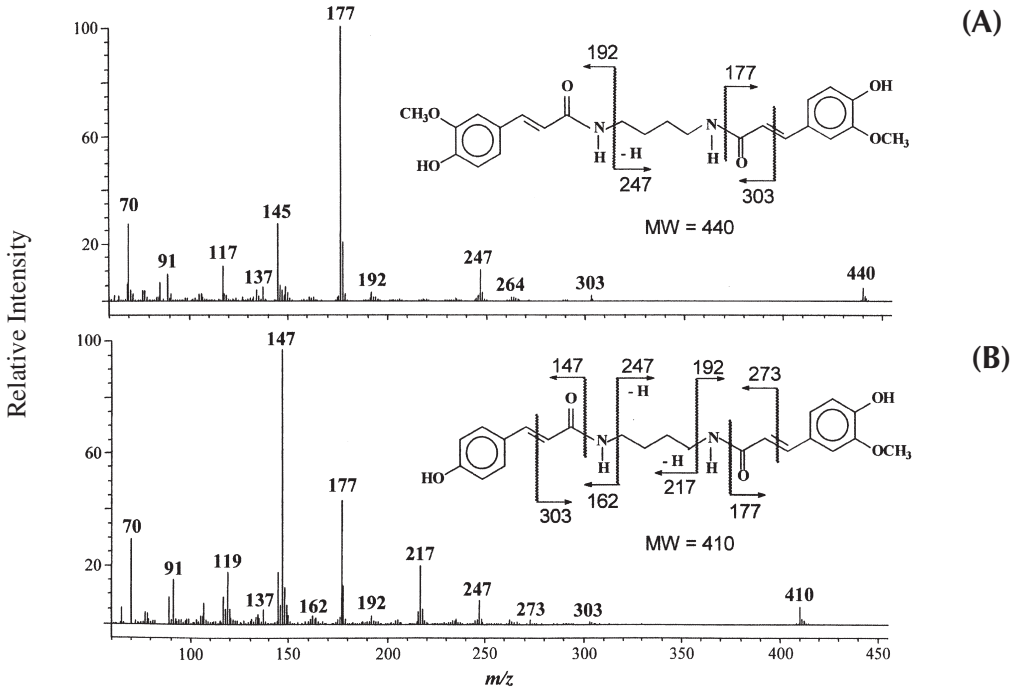

**FIG. 2.** Mass spectra (electron impact) and proposed structures with fragmentation patterns of the two unknown UV (320 nm)-absorbing compounds found in corn bran extracts. (A) DFP and (B) CFP. For abbreviations see Figure 1.

of the 8.5-min unknown compound matches the structure $C_{24}H_{29}N_2O_6$, calculated to be 440.2025620, which corresponds to the structure and MS-EI of diferuloylputrescine (see structure and fragmentation pattern in Fig. 2) as reported in the in the NIST database (*trans N,N′*-diferuloylputrescine, CAS #042369-86-8, molecular formula $C_{24}H_{28}N_2O_6$, National Institute of Standards and Technology, Gaithersberg, MD). Miller *et al.* (5) previously reported similar major MS-EI fragments from DFP at *m/z* 70, 117, 145, 177 (base peak), 191, and 247. The other unknown peak (the 6.5-min peak), with a molecular mass 30 mass units lower, was then proposed to be *p*-coumaroyl-feruloylputrescine, and the MS-EI fragmentation pattern was consistent with this identification (Fig. 2), although no previous reports of the occurrence of a mass spectrum of this compound are known.

DFP was previously reported to occur in tobacco (7), in corn kernels (3–5), and in the male reproductive organs of corn (8,9). This current report is the first evidence of CFP in plants. Sen *et al.* (4) reported that DFP was the most abundant polyamine conjugate in corn embryo, endosperm, and pericarp, but they also reported significant levels of monoconjugates (feruloylputrescine and *p*-coumaroylputrescine) and di-*p*-coumaroylputrescine. In the current chromatograms (Fig. 1) DFP and CFP were the major UV-absorbing peaks (320 nm), and if these other types of polyamine conjugates were present, they occurred in much lower levels than DFP and CFP (perhaps the small peaks at 320 nm and 3–5 min in Figure 1 are polyamine monoconjugates).

Upon identification of DFP and CFP in extracts of corn bran, we next investigated the effect of various extraction conditions on the levels of these compounds in corn bran, corn fiber, and whole ground corn (Table 1). A Dionex Accelerated Solvent Extractor was used to evaluate the effect of elevated temperatures on the levels of DFP and CFP extractable from corn bran. For these studies a constant solvent pressure of 1000 psi (69 bar) enabled the use of temperatures of up to 100°C and was used for all extractions. Extraction of corn bran with hexane, at either 40 or 100°C, yielded 1.27 and 1.44 g oil/100 g bran, respectively, but this oil contained no detectable levels of DFP or CFP. Extraction of corn bran with methylene chloride at 40°C yielded an oil that contained DFP and CFP (6.72 and 1.58 wt%, respectively), and much higher levels of both (approximately 2.5 times higher) were extracted when the temperature was increased to 100°C. Extraction of corn bran with ethanol yielded an oil with even higher levels of CFP and DFP, at both 40 and 100°C. Extraction of corn bran using the Bligh and Dyer (6) chloroform/methanol extraction (commonly used for extraction of polar membrane lipids) at ambient temperature (25°C) yielded DFP and CFP levels that were similar to those obtained with ASE ethanol extraction at 40°C. Polytron homogenization of corn bran during the Bligh and Dyer (6) extraction had no significant effect on the levels of DFP and CFP in the oil. The highest yields of extractable DFP were observed in two slightly different sets of conditions when yields were expressed in two different units: when expressed in units of wt% DFP in the oil, the highest concentration of DFP (13.6%) was recorded with the methylene chloride extraction at 100°C, and when expressed in units of mg DFP per 100 g dry wt of bran, the highest level of DFP (327.85 mg) was obtained with the ethanol extraction at 100°C.

Previously we reported (2) that corn fiber (a pericarp-enriched by-product obtained during the wet milling of corn)

contained higher levels of phytosterols than corn bran (a pericarp-enriched by-product obtained during the dry milling of corn). Extraction of corn fiber with the ASE/methylene chloride, or Bligh and Dyer/chloroform/methanol resulted in oils with similar yields (expressed in g oil/100 g fiber), but the levels of DFP and CFP were much lower (three- to eightfold lower) in these corn fiber oils than in comparably extracted corn bran oils (Table 1). We recently reported ultrastructural evidence (10) that corn bran is primarily composed of only pericarp layers whereas corn fiber is a mixture of pericarp, aleurone layers, and fine fiber (cellular fiber from the endosperm). This report of higher levels of CFP and DFP in corn bran vs. corn fiber suggests that both compounds are primarily localized in the pericarp layers and not in the aleurone layer (cells). To further investigate the possible pericarp localization of the polyamine conjugates, corn kernels were steeped (0.2% $SO_2$ and 0.55% lactic acid at 50°C for 24 h), and the hulls were carefully removed with a scalpel and forceps and hand-dissected to yield separate pericarp and aleurone layers. Extraction and analysis of the lipids in both fractions confirmed that the pericarp layers contains much higher levels of DFP and CFP than the aleurone layers (Table 1).

Extraction of whole ground corn with hot methylene chloride yielded an oil with levels of DFP and CFP that were about twice the levels found in extracts of corn fiber. Additional studies are needed to determine whether all of the DFP and CFP is localized in the outer layers of the corn kernel or if some may occur in the internal portions (i.e., germ and endosperm). It is also possible that some of the differences in the levels of DFP and CFP in Table 2 may be due to hybrid variability, since commercial samples of bran and fiber were obtained from unknown and/or blended hybrids.

Because of the high levels of DFP and CFP in corn bran and corn fiber, we next extracted two other commercial pericarp-enriched grain products from related species—wheat bran and psyllium hulls. Surprisingly, we found that neither of these pericarp-enriched fractions contained any detectable levels of DFP or CFP (Table 1).

[a]Sample applied to SPE cartridge.
[b]Numbers in parentheses are the percent recoveries of CFP or DFP in the SPE fractions, relative to the amount that was applied to the SPE cartridge. For abbreviations see Table 1.

In the only previous quantitative reports, the highest levels of DFP were 560 μg DFP/g in ground kernels (3) and 65 μg/g of corn pericarp (4). Much higher levels of DFP were observed in the current study, with the ASE 100°C ethanol extraction yielding 3279 μg DFP/g of corn bran (equal to the value of 327.85 mg/100 g bran reported in Table 1). These findings suggest that DFP and CFP are difficult to extract quantitatively and that previous reports of these compounds need to be reexamined. It is also possible that additional studies may reveal solvent extraction methods that yield oils with even higher levels of DFP and CFP than are reported herein.

Because corn bran was found to be an abundant source of DFP and CFP, a process was developed to purify these compounds in levels sufficient for evaluation of their biological activity (Table 2). After examining the data in Table 1, it appeared that if corn bran was first extracted with methylene chloride at 40°C (extracting most of the phytosterols and other nonpolar lipids), followed by the same solvent at 100°C, then the latter extract is enriched in CFP and DFP and would be a good starting material for chromatographic purification. Accordingly, when the 100°C methylene chloride extract was applied to a SPE column, the 90:10 chloroform/methanol fraction was a highly enriched mixture of DFP and CFP (at a ratio of about 85% DFP and 15% CFP). HPLC analyses of the preparation with detection by both UV 320 nm and ELSD indicated that it was highly enriched in DFP and CFP. Several very small unidentified peaks were observed in chromatograms of the preparation, but their total area was <1%, even when the polarity of the mobile phase was increased to 44.9:50:5:0.1, hexane/isopropanol/water/acetic acid, by vol (which was sufficiently polar to separate very polar lipids such as phospholipids, if any had been present). We are in the process of developing a preparative HPLC method to further purify DFP and CFP, but we feel that this SPE process to yield a purified mixture of these two structurally related compounds is a rapid method that can be used to purify large quantities of material for evaluation of biological activity of this simple mixture.

The physiological role of DFP and CFP in corn is not known, but this report of their high levels in corn pericarp suggests that their potential physiological role(s) should be investigated. It has been suggested that polyamine monoconjugates may function as fungicidal (5), insecticidal (11), and viricidal (12) compounds. Polyamine monoconjugates have also been reported to occur in wheat (13) and in the barley root-arbuscular mycorrhizal fungi symbiotic system (14). Others have reported that DFP is a radical scavenger and may function as a protectant against ozone damage (15). Treatment of barley leaves with methyljasmonate was reported to cause an elevation of the levels of polyamine monoconjugates (16). Free putrescine and other polyamines have been reported in corn kernels (17), and their levels remained constant during seed storage and showed no correlation with loss of seed viability. Although free polyamines are likely to be metabolic precursors to polyamine conjugates, we are not aware of studies of possible interrelationships between free polyamines and polyamine conjugates in corn kernels. Clearly, more work is needed to elucidate the function and relationship between the polyamine diconjugates that we have herein quantitatively analyzed in corn and the polyamine monoconjugates that others have reported in corn and other plants.

## ACKNOWLEDGMENTS

We would like to thank Karen Kohout and Michael Powell for excellent technical assistance, Dr. Kevin Hicks for helpful insights regarding extractions and corn milling fractions, and Dr. Mark Rogers for valuable assistance with high-resolution electrospray mass spectrometry.

**ABSTRACT:** We describe the results from the isolation and structural identification of the acylglycerol constituents of fruits from wild plants belonging to different species of *Thapsia* (Apiaceae). The isolated lipid fractions were analyzed and characterized by chemical, chromatographic, and spectroscopic means. In particular, $^{13}C$ nuclear magnetic resonance data allowed the identification of petroselinic acid as the major fatty acid esterified to glycerol in the fruit oils from all the plant samples. This was also confirmed by gas chromatography (GC) and GC–mass spectrometry analyses of fatty acid methyl and butyl esters derivatives from *Thapsia* oil. The genus *Thapsia* should be regarded as a useful source for the extraction of petroselinic acid, which represents an important oleochemical raw material.

Paper no. L8695 in *Lipids 36,* 845–850 (August 2001).

The Apiaceae (Umbelliferae) represent one of the best-known plant families, widely distributed in temperate climate regions where they are often used as spices or drugs owing to the presence of useful secondary metabolites such as coumarins, essential oils and sesquiterpenes (1–3).

In addition, more recently the plant family has attracted attention for the high level of petroselinic acid (*cis*-6-octadecenoic acid) produced by some of the genera belonging to it. This unsaturated fatty acid, isomer of oleic acid, represents in fact an interesting oleochemical for the food, cosmetics, and pharmaceutical industries (4–7). In particular, petroselinic acid can be oxidatively split at the double bond into lauric (12:0) and adipic (6:0) acids, both with important applications in the manufacture of soaps and plastics (4–7).

Attempts to engineer industrial oilseed crops, e.g., by introducing genes from coriander, to increase the yield of petroselinic acid have not yet been very successful (4–7). Therefore, we believe that the identification of new plants which can provide high amounts of petroselinic acid is still appropriate.

In recent years, within the Apiaceae family, the genus *Thapsia* has been the subject of several scientific investigations (8–10), especially for the medical properties of *T. garganica*. Phytochemical studies of plants belonging to different species of *Thapsia* have shown that they are an important source of bioactive compounds, and may be useful in providing new insights into the present taxonomy of the genus (11–17). In the present paper we report the results from the isolation and structural identification of the acylglycerol components of fruits from wild plants of different *Thapsia* species.

## EXPERIMENTAL PROCEDURES

*Plant material.* Fruits of *T. garganica* were collected, during 1999, from wild-growing plants at Sammichele (Bari, Italy). Fruits of *T. villosa* (two samples, 88-16, 2n = 44, and 88-9, 2n = 66), *T. laciniata*, *T. minor*, *T. maxima* I and *T. maxima* II were obtained from wild-growing plants as described before (12,16,17). Fruit vouchers are deposited at Dipartimento Farmaco-Chimico, Universitá di Bari (Italy).

*Oil extraction and purification*. Finely pulverized fruits (10 g) of *Thapsia* species were extracted in a Soxhlet apparatus with refluxing petroleum ether (bp 35–60°C) for 3 h. Evaporation of the solvent under vacuum gave an oily product, which was further investigated.

Each oil sample was first characterized by precoated silica gel 60 F254 TLC aluminum sheets ($10 \times 20$ and $5 \times 7.5$ cm; Merck, Darmstadt, Germany) developed in $CHCl_3$. Lipid visualization was obtained with phosphomolybdic acid reagent (10% in EtOH; Sigma, Milan, Italy) and by charring the plates at 110°C.

Oils extracted from *T. garganica* consisted of a nearly pure fraction of acylglycerols; fruit extracts from the other species of *Thapsia* resulted instead in a mixture of acylglycerols plus other compounds (identification not reported here) mainly originating from the terpene pool of metabolites. All extracts were, however, purified by column chromatography (silica gel 60H, Merck) using $CHCl_3$ as the eluent to recover pure triacylglycerols.

*Saponification and methylation*. Triacylglycerols (15 mg) from *Thapsia* species were treated with 5% NaOH in MeOH (3 mL) for 20 min at room temperature. Methanolic 6 N HCl was then added to stop the reaction. After evaporation of the solvent, the residue was further reacted with $CH_2N_2$ according to Reference 18. The methylated fatty acid fractions were then analyzed by gas chromatography (GC) and GC–mass spectrometry (MS). For comparison, commercial tripetroselinin (Sigma) was also subjected to the above reactions. Free fatty acids (stearic, palmitic, oleic, linoleic, petroselinic, and linolenic; Sigma) were also methylated with $CH_2N_2$ and used as reference compounds for GC and GC–MS analyses.

*Preparation of fatty acid butyl esters.* Triacylglycerols (5 mg) from *Thapsia* species and commercial tripetroselinin were reacted with 1 mL 0.1 M Na *tert*-butylate in *n*-butanol

(Fluka, Milan, Italy). The reaction was performed for 1 h at room temperature, and then 5% $NaHSO_4$ in $H_2O$ was added as described (19). The organic layer was used for GC and GC–MS analyses. Standard butyl esters of stearic, palmitic, petroselinic, oleic, and linoleic acids were also prepared and submitted to GC and GC–MS analysis.

*GC analysis.* A Carlo Erba HRGC 5160 gas chromatograph equipped with a flame-ionization detector and an on-column injector was used. Hydrogen was the carrier gas; air and $H_2$ were adjusted to yield optimal separation. Data were processed by a Spectra Physics SP 4290 computing integrator. All the samples were dissolved in $CHCl_3$.

Triacylglycerols from *Thapsia* oil samples, commercial tripetroselinin, triolein, trilinolein, tristearin, and tripalmitin were analyzed with an Easy 1 (Analitica, Milan, Italy) bonded phase fused-silica capillary column (25 m × 0.32 mm i.d.; 0.1–0.15 μm film thickness) either in isothermal conditions at 280°C or under programmed conditions, from 260°C, 7°C/min, up to 360°C. The detector port was kept at 380°C.

Determination of fatty acid methyl esters (FAME) and fatty acid butyl esters was carried out on a DB-5 (Superchrom, Milan, Italy) fused-silica capillary column, 30 m × 0.32 mm i.d.; 0.25 μm film thickness. The chromatographic conditions were as follows: detector temperature 300°C; column temperature was programmed from 70°C, 20°C/min to 170°C and then up to 280°C (5 min isothermal) at 5°C/min. Alternatively, FAME and fatty acid butyl esters from *Thapsia* acylglycerols were analyzed on a DB-23 (Superchrom) fused-silica capillary column (30 m × 0.32 mm i.d.; 0.25 μm film thickness) at the following conditions: 70°C, 15°C/min to 110°C and then up to 230°C (20 min isothermal) at 3°C/min. Detector port was maintained at 300°C.

*GC–MS analysis*. GC–MS analyses of FAME and fatty acid butyl ester derivatives were performed with a Hewlett-Packard 6890-5973 mass spectrometer interfaced with an HP 59970 Chemstation. The chromatographic conditions were as follows: column oven program from 70 (4 min isothermal) to 280°C (20 min isothermal) at 20°C/min; injector, 250°C. Helium was the carrier gas (flow rate, 1 mL/min). An HP-5-MS capillary column (30 m × 0.25 mm; 0.25 μm film thickness) was utilized. MS operating parameters were: ion source, 70 eV; ion source temperature, 230°C; electron current, 34.6 μA; vacuum $10^{-5}$ torr. Mass spectra were acquired over 40–800 amu range at 1 scan/s. The ion source was operated in the electron impact mode. The samples (1 μL) were injected using the splitless sampling technique.

*Spectroscopic methods*. Fourier transform infrared (FTIR) spectra were recorded using NaCl cells on a PerkinElmer Spectrum One.

Proton ($^1$H NMR) and carbon nuclear magnetic resonances ($^{13}$C NMR) were recorded on a DRX500 Avance Bruker instrument equipped with probes for inverse detection and with *z* gradient for gradient-accelerated spectroscopy. Standard Bruker automation programs were used for two-dimensional (2D) NMR experiments. 2D correlation spectroscopy (COSY) experiments were performed using COSYDFTP (double-quantum-filtered phase-sensitive COSY) and COSYG (gradient-accelerated COSY) sequences. Inverse detected normal and long-range $^1$H-$^{13}$C heterocorrelated 2D NMR spectra were obtained by using the gradient-sensitivity enhanced pulse sequences INVIEAGSSI and INV4GPLRND, respectively. $CDCl_3$ was used as the solvent in all the NMR experiments. Residual $^1$H and $^{13}$C peaks of the solvent were used as internal standards to calculate chemical shifts referred to tetramethylsilane.

## RESULTS AND DISCUSSION

Acylglycerols purified by chromatographic techniques from the total lipid extracts of the various species of *Thapsia* were characterized by chromatographic, spectroscopic, and chemical means. Homogeneous results were obtained with all the analyzed plant species, therefore reported spectroscopic assignments from spectra related to a single acylglycerol sample from *Thapsia* apply to all of them as well.

Infrared (IR) spectra of *Thapsia* lipids showed typical absorptions at 3003 (C–H olefins), 2949, 2921, 2852 (C–H), 1744 (C=O), 1464 (C–H), 1179 (C–O) and 721 $cm^{-1}$.

More structural information came from their $^1$H and $^{13}$C spectral data (Fig. 1). 2D proton-proton and proton-carbon correlations also facilitated the assigning of relative signals (Fig. 2).

The $^1$H NMR signals at δ 4.11 (*dd*; glycerol α C$H_2$), 4.28 (*dd*; glycerol α C$H_2$), and 5.29 (*m*; glycerol β C*H*) indicated that the isolated lipids were triglycerides (Table 1). The observed chemical shifts in the $^{13}$C NMR spectra at δ 62.52 (glycerol α-carbon atoms) and 69.32 (glycerol β-carbon atom) and their relative size also confirmed that the isolated compounds were triglycerides (Table 1). This was further supported by the highest chemical shift signals at about δ

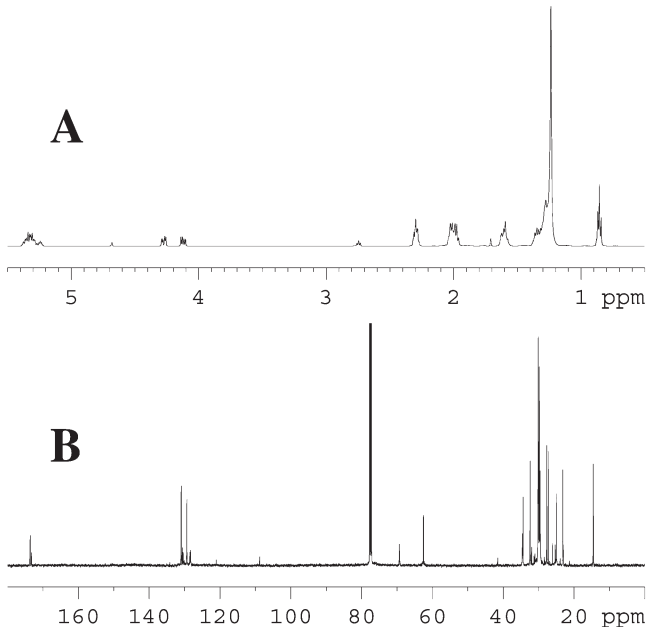

**FIG. 1.** $^1$H (A) and $^{13}$C (B) 500 MHz nuclear magnetic resonance (NMR) spectra of acylglycerol constituents from the fruits of *Thapsia* sp.

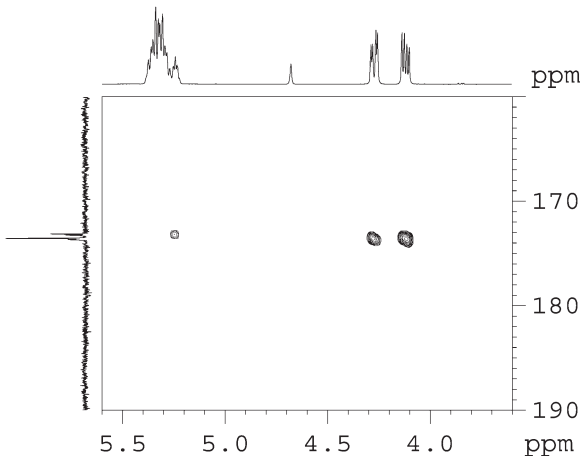

**FIG. 2.** Long-range two-dimensional heteronuclear NMR spectrum of acyglycerols from *Thapsia* sp. Selected region shows cross peaks between carbonyl resonances of C1 α and β chains and glycerol α and β hydrogens. For abbreviation see Figure 1.

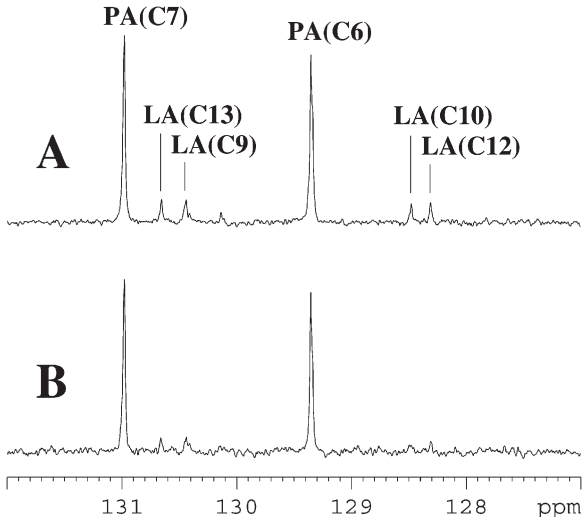

**FIG. 3.** Expansion of the olefin region of $^{13}$C NMR spectra of the acylglycerols from (A) *T. garganica* and (B) *T. villosa* (88-16). PA, petroselinic acid; LA, linoleic acid. For abbreviations see Figure 1.

173.11 (C1 β chains) and δ 173.52 (C1 α chains) in all the lipid samples from *Thapsia* species. The 2D NMR experiments were also useful to corroborate the 1,2,3 substitution pattern of the isolated esters. Cross peaks (Fig. 2) were in fact observed in the long-range $^{1}$H-$^{13}$C heteronuclear correlated spectra between the carbon resonance at δ 173.52 and 173.11 (C1 α and β chains) and proton resonances at δ 2.30 (C2) and δ 4.28, 4.11 and 5.29 (glycerol α and β hydrogens).

Moreover, the multiplet at δ 5.33 in the proton spectrum, together with the signals in the range between δ 128 and 131 in the $^{13}$C NMR spectra, suggested the presence of olefinic structural units. In addition, resonances of allylic and diallylic methylenes can be identified in the spectra (Table 1). The olefin region in the carbon NMR spectrum appears particularly important for the characterization of the oil composition (20–22). A closer inspection of this peak area, in fact, allowed us to distinguish in all the samples, on the basis of their chemical shifts, the following two unsaturated fatty acids esterified to the unit of glycerol: petroselinic acid, δ 130.95 (C7) and δ 129.33 (C6); linoleic acid (*cis*-9,12-octadecadienoic), δ 130.61 (C13), δ 130.37 (C9), δ 128.48 (C10), and δ 128.29 (C12) (Fig. 3).

Identity of the two fatty acids was further confirmed by comparison with NMR spectra of commercial tripetroselinin and trilinolein and with spectra obtained from constructed mixtures of saturated (tripalmitin) and unsaturated (tripetroselinin, trilinolein, and triolein) triacylglycerols. Literature data have also been evaluated for their identification (20–25).

Quantification of the relative proportions of petroselinic and linoleic acids in the NMR spectra according to Mallet *et al.* (22) indicated that petroselinic acid was by far the most abundant (≅90%) unsaturated fatty acid esterified to glycerol

in *Thapsia* fruit lipids. Petroselinic acid represents a positional isomer of oleic acid (18:1n-9*cis*). The two fatty acids often occur in combination as constituents of Apiaceae oils, and they are generally difficult to separate. According to our NMR results, *Thapsia* fruit oils should not contain oleic acid, or only in low amounts (Fig. 3). Oleic acid, as well as petroselinic and linoleic acids, shows well-defined signals related to the olefin region in the $^{13}C$ NMR spectra, namely, at around δ 129.7 (C9) and 130.0 (C10), the latter often overlapping with the C9 peak of linoleic acid (20–22). A weak signal at δ 130.1 attributable to oleic acid was sometimes detectable in our oil samples suggesting a trace quantity of oleic acid in *Thapsia* oils.

To achieve a good quantification of the fatty acids in their fruit oils, lipids from *Thapsia* plants were submitted to transmethylation and transbutylation reactions, and the methyl and butyl esters formed were subjected to GC analyses. Separation on a DB-23 column allowed the best determination and quantification of the fatty acid content in the acylglycerols from *Thapsia* oils (Table 2; Fig. 4). The column produced a good separation of the three isomers—oleic methyl ester (ME), petroselinic ME, and *cis*-vaccenic ME—as well as for the separation of their corresponding butyl esters (Fig. 4), which were used for the quantitative analysis. Neverthless, GC further supported NMR findings, that is, *Thapsia* triacylglycerols were mainly made up of petroselinic (69–82%) and

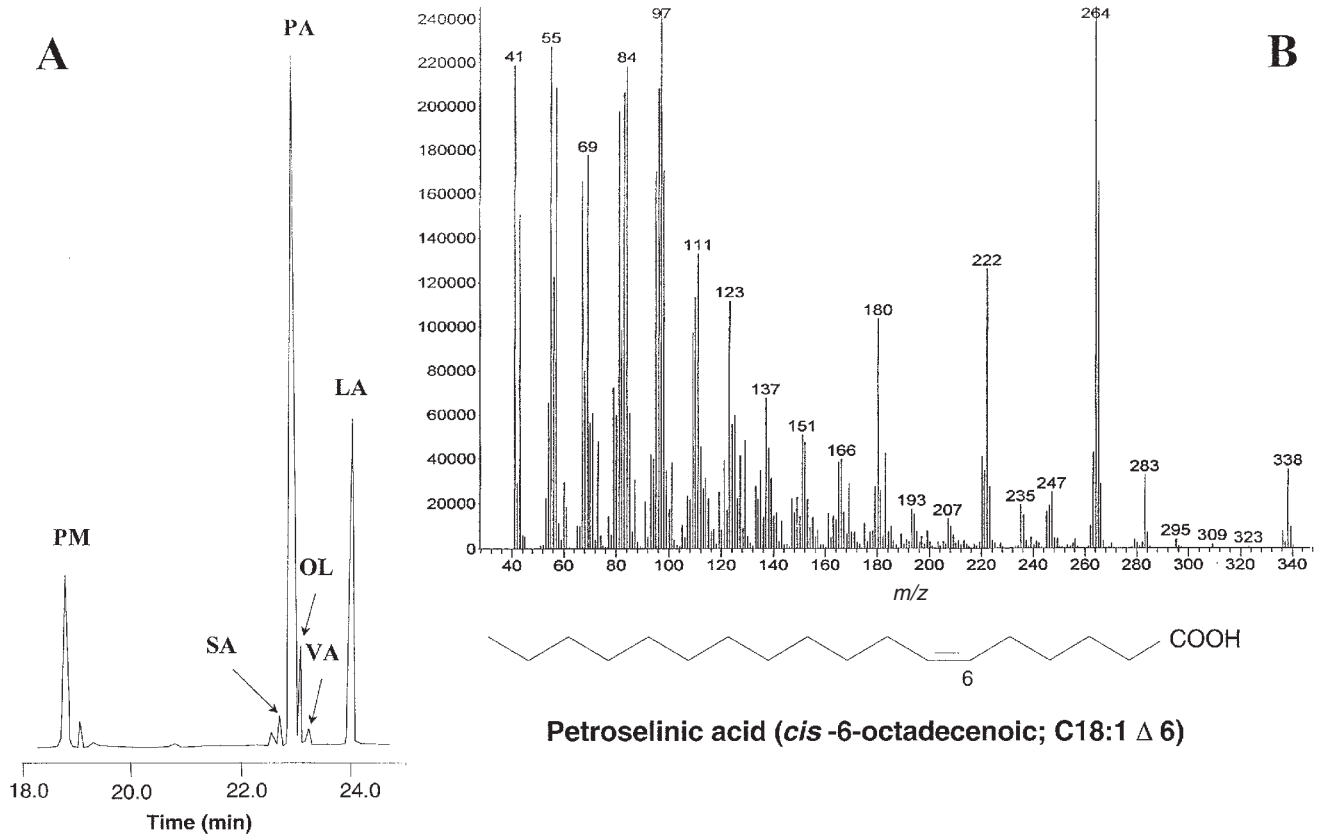

**FIG. 4.** Gas–liquid chromatographic analysis (A) of the butyl esters obtained from the acylglycerols of *T. minor,* and mass spectrum (B) of PA. PM, palmitic acid; SA, stearic acid; OL, oleic acid; VA, *cis*-vaccenic acid. For other abbreviations see Figure 3.

linoleic (trace–16%) acids. The amount of oleic acid generally ranged from 4 to 6%. GC analysis of the butyl ester derivatives from the oils also allowed the quantification of *cis*-vaccenic acid as minor component (from traces up to 1%). The two saturated palmitic (5–8%) and stearic (trace–8%) acids were also identified in the reaction mixtures (Table 2; Fig. 4). Their presence was not further investigated in the NMR spectra, however.

All the derivatized oil fractions were also analyzed by GC–MS; MS fragmentation of petroselinic acid butyl ester was as follows: *m/z* (relative intensity, r.i.), 338, [$M^+$, $C_{22}H_{42}O_2$ (14)], 264 (100) ($M^+ - 74$), 222 (51), 180 (42), 166 (16), 151 (21), 137 (25), 123 (45), 111 (54), 97 (99), 84 (89), 69 (72), 55 (92), 41 (89).

The following MS fragments were obtained for petroselinic (i) and linoleic (ii) ME derivatives, respectively, *m/z* (r.i.): (i), 296, [$M^+$, $C_{19}H_{36}O_2$ (100)], 264 (83) [$M^+ - 32$], 222 (49) [$M^+ - 74$], 180 (33), 123 (40), 110 (46), 96 (92), 84 (93), 74 (100), 55 (99), 41 (75); (2), 294, [$M^+$, $C_{19}H_{34}O_2$ (100)], 263 (15) [$M^+ - 31$], 220 (6) [$M^+ - 74$], 178 (8), 164 (10), 150 (14), 136 (15), 123 (18), 109 (35), 95 (63), 81 (77), 67 (100), 55 (54), 41 (44). Data were in agreement with mass spectra obtained with reference compounds.

Similarly, GC of the intact triglycerides allowed the separation of one main component (80–90%) coeluting with commercial tripetroselinin. Trilinolein resulted in a partially overlapping shoulder to the GC peak of tripetroselinin.

To our knowledge, this is the first extensive study on the distribution of tripetroselinate in the genus *Thapsia*. Petroselinic acid is one of the most common fatty acids in Apiaceae seed oils, thus its isolation from the genus *Thapsia* can be anticipated. Moreover, a previous report (26) showed that petroselinic acid, a component of the oil from *T. villosa*, amounted to 75%. Other studies showed that the different species of *Thapsia* can be distinguished by their phytochemical characters; in particular, the presence/absence of the typical sesquiterpene lactones and the constituents of the essential oils were of chemotaxonomic value in differentiating them (8,9). The most pronounced heterogeneity was found among plants identified as *T. villosa* species, which were divided into five types, corresponding to two distinctly different chemical, cytological and morphological groups (16,17). We cannot know what type of *T. villosa* has been investigated previously (26). However, according to the present investigation, in all the analyzed species belonging to the genus *Thapsia*, the acylglycerols have almost the same composition and tripetroselinate is equally abundant in all of them. Thus, in contrast to other chemical classes synthesized by *Thapsia* plants, this metabolite cannot further contribute to the chemotaxonomy of the genus. Nevertheless, the genus *Thapsia* should be regarded as an important source of petroselinic acid, an oleochemical raw material that is used in cosmetics, pharmaceuticals, or food (6,7,27,28).

## ACKNOWLEDGMENTS

This work was supported by the Italian Ministero dell'Università e della Ricerca Scientifica. The authors are grateful to Giovanni Dipinto (Dipartimento Farmaco-Chimico, Università di Bari) for recording the GC–MS spectra.

# Characterization of Lipoxygenase Oxidation Products by High-Performance Liquid Chromatography with Electron Impact-Mass Spectrometric Detection

**Alberto Nuñez*, Thomas A. Foglia, and George J. Piazza**

USDA, ARS, ERRC, Wyndmoor, Pennsylvania 19038

**ABSTRACT:** Lipoxygenase (LOX) is an enzyme that oxygenates polyunsaturated fatty acids to their corresponding hydroperoxy derivatives. For example, LOX found in plants produce the corresponding 13- and 9-hydroperoxide derivatives of linoleic acid (13-HPOD and 9-HPOD). Identification of the HPOD products is usually accomplished by using gas chromatography with mass spectrometric (MS) detection, which requires extensive derivatization of the thermally unstable hydroperoxy group. Here we report a high-performance liquid chromatographic method in combination with electron impact (EI)-MS detection that separates and characterizes the HPOD isomers generated by soybean LOX type I oxygenation of linoleic (LA) and linolenic acids as well as HPOD products produced by photosensitized oxidation of LA. The method does not required derivatization of the hydroxyperoxide group, and location of its position can be determined by the EI-MS fragmentation pattern. The method has been used for the analysis of HPOD produced by action of partially purified LOX from the micro-alga *Chlorella pyrenoidosa* on LA. The study suggests the presence of two LOX isozymes in the micro-alga that oxygenate LA to its 13-HPOD and 9-HPOD derivatives. Moreover, the 9-LOX isozyme under anaerobic conditions cleaves 13-HPOD to 13-oxo-tridecadienoic acid and pentane but does not cleave 9-HPOD.

Paper no. L8746 in *Lipids 36*, 851–856 (August 2001).

Lipoxygenase (LOX; EC 1.13.11.12) is a lipid dioxygenase enzyme that is widely distributed throughout the plant and animal kingdom. The enzyme catalyzes the regio- and steroselective peroxidation of polyenoic fatty acids, and often the characterization of a particular plant isozyme is made based on its specificity of reaction with linoleic (LA) and linolenic acid (LNA) (1,2). For example, when LOX oxygenates LA and LNA to produce 13-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid (13-HPOD) and 13-hydroperoxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid (13-HPOT), respectively, the enzyme is classified as 13-LOX, whereas when the products are 9-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid (9-HPOD) and 9-hydroperoxy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid (9-HPOT), respectively, the enzyme is classified as 9-LOX (3). Depending on LOX source and reaction conditions, the amounts of the 9- and 13-HPOD isomers formed can vary. In addition, LOX activity in the fungi *Penicillium* sp. is reported to produce the 9-, 10-, 12-, and 13-hydroperoxy derivatives of LA. The HPOD products were racemic, which was attributed to either a low enantioselectivity of the LOX or the presence of isozymes showing complementary enantioselectivity, but no additional evidence for this unusual activity was reported (4).

Zimmerman and Vick (5) initially reported LOX-type activity in *Chlorella pyrenoidosa* in a partially purified $(NH_4)_2SO_4$ fraction, which produced both the 9- and 13-HPOD derivatives (ratio of 1:4) of LA. Later, these same authors reported that the molecular weight of this LOX enzyme was 100 kDa and that it had maximal activity at pH 7.5 (6). Bisakowski *et al.* (7) further investigated LOX present in *C. pyrenoidosa* and showed that the active fractions produced the 9-HPOD derivative together with the 10- and 13-HPOD isomers. In both studies, however, whether the reported activity resulted from the presence of one or more LOX isozymes was not established. In addition to its peroxidation activity, LOX can anaerobically cleave the oxidation products into short volatile fragments and an oxocarboxylic acid (8,9). For example, Nuñez *et al.* (10) recently reported that LOX present in *C. pyrenoidosa* was able to cleave 13-HPOD to an ω-oxo- fatty acid. It was not shown whether other HPOD isomers are substrates for this LOX oxidation reaction.

LOX activity is usually determined by measuring the ultraviolet (UV) absorption of the conjugated double bonds at 234 nm for the 9- and 13-HPOD isomers produced from LA or LNA. However, the method does not distinguish between them (11). The absence of conjugated double bonds in the 10- and 12-HPOD isomers [10-hydroperoxy 8(*E*),12(*Z*)-octadecadienoic acid and 12-hydroperoxy-9(*Z*),13(*E*)-octadecadienoic acid] limits their detection by UV. The position of the hydroperoxy group in HPOD isomers is determined by gas chromatography with mass spectrometric detection (GC/MS). Because of their thermal instability, the GC/MS technique requires reduction of the hydroperoxide group to an alcohol followed by silylation for better GC analysis (12). Finally, unambiguous assignment of

the position of the hydroperoxide group requires saturation of the double bonds by hydrogenation (7,13).

Plattner and Gardner (14) attempted to analyze HPOD compounds directly without prior reduction by mass spectrometry by using a direct exposure probe with chemical ionization (CI) and collision-induced decomposition (CID) techniques. With ammonia gas as ionizing reagent, the CI-MS technique indicated the molecular mass of HPOD derivatives, whereas when isobutane was the ionizing reagent a series of fragmentation ions were produced, the formation of which was consistent with a mechanism proposed for the acid-catalyzed decomposition of HPOD derivatives. Determination of the position of the hydroperoxy group in the HPOD was made from an analysis of the daughter ions of higher-mass ions in the CID spectra (14). Burgess *et al.* (15) studied a series of alkyl hydroperoxides by using MS with electron impact (EI) ionization. The main features of the peroxide fragmentation pattern were inferred by analogy with the fragmentation pattern of the related alcohols. The hydroperoxides studied showed a characteristic elimination of peroxy radical $HO_2^{\cdot}$, since the formation of the alkyl cation radical occured at a lower ionization potential than that for $HO_2^{+}$. Additional characteristic losses from the molecular ion were $HO^{\cdot}$ and $H_2O$, which were explained through formation of a cyclic intermediate (15). However, EI-MS spectra for the 13- and 9-HPOD isomers have not been reported.

Recently we reported an analysis of LOX products using high-performance liquid chromatography (HPLC) with atmospheric pressure chemical ionization-mass spectrometric detection (LC/APCI-MS). This MS technique, however, did not allow identification of the position of the hydroperoxide group in the products; rather, isomer assignments were made on the basis of elution order from a diol chromatographic column (10). In the present study, we developed an LC/EI-MS method that allows for the direct analysis of the methylated products of the HPOD and HPOT isomers and that provides evidence for the position of the hydroperoxide group without pretreatment of the sample. In using this method the HPOD products obtained using partially purified LOX fractions from *C. pyrenoidosa* were analyzed. In addition, anaerobic oxidative cleavage activity found in the same LOX fractions was assayed using pure 9- and 13-HPOD products as substrates.

## MATERIALS AND METHODS

*Materials.* LA and LNA acids were purchased from Sigma Chemical (St. Louis, MO). The 13-HPOD and -HPOT derivatives of LA and LNA acid were prepared as described previously (16). Reduction of the 13-HPOD isomer to its corresponding 13-alcohol was done by using $NaBH_4$ as reducing agent (7). All products were methylated before LC/EI-MS or GC/MS analysis using a hexane/diazomethane saturated solution. The hexane/diazomethane solution was obtained by decomposition of 1-methyl-3-nitro-1-nitrosoguanidine (Aldrich, Milwaukee, WI) added to a bi-layer solvent system consisting of hexane (upper layer, 20 mL) and an aqueous solution of NaOH (20%) (lower layer, 3 mL). All other reagents were of the highest purity available. *Chlorella pyrenoidosa* was obtained from American Type Culture Collection (No. 11469) (Manassas, VA).

*Photosensitized oxidation of LA.* A rose bengal saturated methanol solution was added dropwise to a solution of LA (20 mg) in methanol (120 mL) until the reaction mixture had an absorption of 0.2–0.3 absorption units at 556 nm. The mixture was placed into a 10-cm diameter Pyrex reaction flask and oxygen was bubbled through the solution. The mixture was irradiated with a 500-watt halogen lamp for 10 h at 15°C. The methanol was removed by rotary evaporation and the residue redissolved in 20 mL of methylene chloride, which was washed several times with water until the rose bengal was removed. After removal of the solvent, the oxidation products were methylated and injected into the LC/MS for analysis. The yield of hydroperoxides varied between 30 and 40%.

*Protein extraction and purification. Chlorella pyrenoidosa* cells were grown and harvested as described previously (16). Typically, 3–4 g of wet cells were washed with distilled water, centrifuged at $1,000 \times g$ for 10 min, and resuspended in 30 mL potassium phosphate buffer (50 mM, pH 8.0). Homogenization of the cells was done with a bead-beater apparatus (Biospec Products, Bartlesville, OK) using 30–35 mL of 0.5 mm glass beads at 0°C for 30 s interspersed with 30 s cooling, for a total homogenization time of 2 min. The beads were separated by decantation. Cellular debris in the supernatant was removed by centrifugation at $12,000 \times g$ for 10 min. The supernatant was separated from the pellet and then centrifuged at $100,000 \times g$ for 65 min to remove the microsomal fraction. The supernatant was treated sequentially to 30, 45, and 80% $(NH_4)_2SO_4$ saturation, at 0°C for 30 min. After each $(NH_4)_2SO_4$ addition the precipitate was separated by centrifugation at $15,000 \times g$.

*LOX assay.* The precipitated fractions were resuspended in 5 mL of potassium phosphate buffer (100 mM, pH 8.0), the pH was adjusted at 8.0, and 4 mL were incubated with 50 mL solution of LA or LNA, 1 mM in potassium phosphate (100 mM, pH 8.0) and Tween 20 (0.1%) under oxygen. The oxidation reaction was followed spectrophotometrically at 234 nm. At the end of the reaction the oxidation products were extracted, methylated with diazomethane, and injected into the LC/EI-MS. The anaerobic cleavage activity of the LOX fractions was determined by analyzing the volatile products by GC/MS after incubation of the resuspended fractions (1 mL) with a solution in potassium phosphate (100 mM, pH 8.0) of 9-, 13-HPOD or 13-HPOT (1 mM, 5 mL) as previously described (10).

*LC/EI-MS.* LC was performed with a Waters HPLC 2690 Separation Module (Waters Co., Milford, MA) connected in series to a Waters 996 Photodiode Array Detector (PDA) and a Waters Thermabeam Mass Detector (Integrity System). The LC portion used a Valco LiChrosorb DIOL 5-µm column (2 × 250 mm) (Varian/Chrompack, Raritan, NJ). The linear gradient elution profile used was as follows: hexane (100%) hold for 5 min; to a final composition of hexane/isopropanol (99.5:0.5%, vol/vol) over 30 min, hold for 70 min at a flow rate of 0.3 mL/min. The PDA was set to scan from 200 to 400 nm, and the EI-MS detector was set to scan the mass range *m/z* 90–600 at 1 scan per second with an ionization energy of 70 eV. Ionization source temperature was 200°C, nebulizer

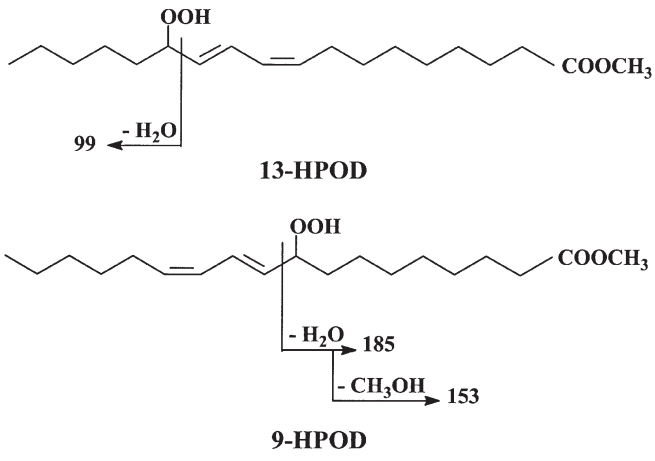
temperature was 42°C, and expansion region temperature was 75°C.

*GC/MS analysis of HPOD isomers.* Methylated HPOD products from soybean LOX and photo-oxidation were reduced with $NaBH_4$ (7) and silylated in pyridine with *N,O*-bis(trimethylsilyl)trifluoroacetamide (Pierce, Rockford, IL) and injected (1 μL) into a gas chromatograph (Hewlett-Packard, Wilmington, DE) model 5890 Series II Plus equipped with a capillary inlet and a Mass Selective Detector model 5972 (Hewlett-Packard) set to scan from *m/z* 45 to 600 at a scan rate of 1.2 scans per second. The capillary column used was an SP-2340 (60 m × 0.25 mm) (Supelco, Bellefonte, PA). The oven temperature was programmed from 130 to 230°C at 2°C/min. The temperature of the injector port was 230°C, and the detector transfer line temperature was 240°C. The carrier gas was He at a flow rate of 1 mL/min and a split ratio of 50:1.

## RESULTS AND DISCUSSION

Soybean LOX type I produces mainly 13-HPOD and minor amounts of 9-HPOD (Scheme 1) (1). The GC/MS spectra of the reduced and silylated LOX products were consistent with those reported by Wu and Robinson (12) with a molecular ion at *m/z* 382 and characteristic ions at *m/z* 311 (40%) for the 13-HPOD adduct and *m/z* 225 (60%) for the 9-HPOD adduct. However, the isomers can be differentiated only in the intensity of the characteristic ion, since both derivatives have ions at *m/z* 311 and 225 (12). When LOX type I products are analyzed on an HPLC diol column using the method described in the Materials and Methods section, the 13-HPOD isomer elutes at about 48 min and the 9-HPOD isomer at 55 min. Both peaks absorb in the UV at 234 nm owing to their conjugated double bonds. The EI spectra for the 9- and 13-HPOD isomers are shown in Figures 1A and B, respectively, together with the 13-alcohol [(13-hydroxy-9(*Z*),11(*E*)-octadecadienoic acid: 13-HOD] product obtained from 13-HPOD (Fig. 1C). The mass spectra of both HPOD isomers have an ion at *m/z* 310 [M – Oxygen], 308 [M – $H_2O$], 293 [M – $O_2H$], and 292 [M – $H_2O_2$], which are characteristic of hydroperoxide fragmentation (14,15). Although a molecular ion is not seen in the spectrum of the 13-HPOD isomer, the spectrum for the analogous 13-HOD isomer does show a molecular ion at *m/z* 310 and an ion at *m/z* 292 formed by loss of $H_2O$ from the parent molecule (Fig. 1C). Loss of a methoxy group from the 13-HOD molecular ion gives the ion at *m/z* 279 [M – $CH_3O$], while the ion at *m/z* 279 [M – 47] in the spectrum of the HPOD isomers suggests the elimination of oxygen and a methoxy group. The ions of the HPOD isomers at *m/z* 277 [M – $H_2O$ – $CH_3O$], and 261 [M – $H_2O_2$ – $CH_3O$] also establish a difference between 13-HOD and the 13-HPOD, but other portions of their spectra are similar.

Additional information on the location of the hydroperoxy group in the HPOD isomers can be obtained by examining the ions formed toward the saturated hydrocarbon portion of the molecule, which produces a series of acyl ions (14). Both 13-HOD and 13-HPOD have an ion at *m/z* 99 (100%), whereas 9-HPOD gives ions at *m/z* 185 (20.2%) and 153 (16.7%) (185 – MeOH) (Fig. 1A). Scheme 1 shows a fragmentation pattern of 13- and 9-HPOD that can account for the formation of these ions.



SCHEME 1

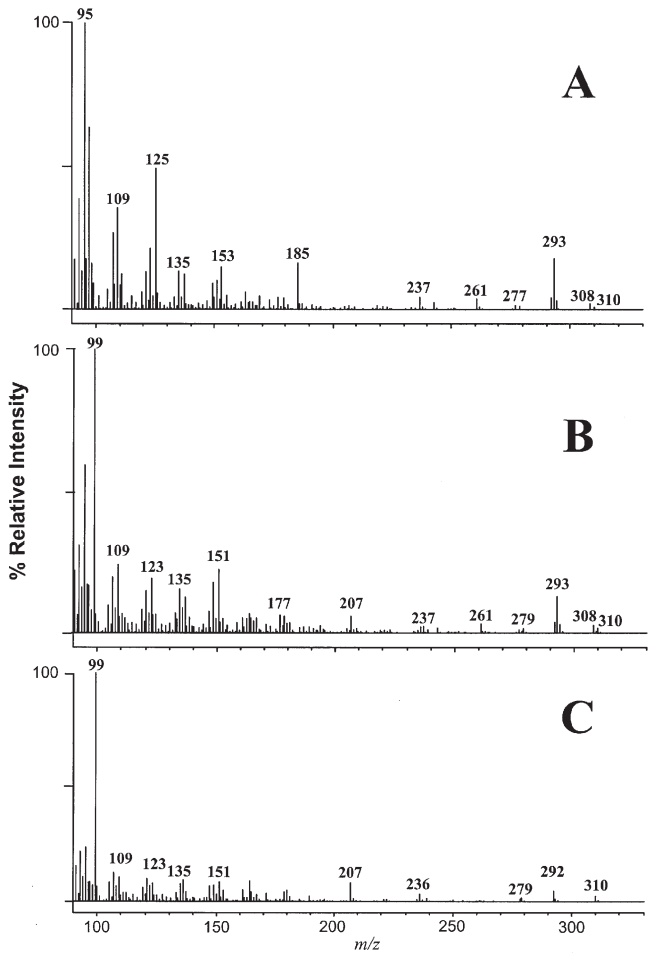


**FIG. 1.** High-performance liquid chromatography (HPLC)/electron impact-mass spectrometry (LC/EI-MS) spectra of the methyl esters of (A) 9-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid (9-HPOD); 13-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid (B) (13-HPOD) produced by incubation of soybean lipoxygenase (LOX) type I with linoleic acid (LA) under oxygen; and (C) reduced and methylated 13-alcohol (13-HOD) of 13-HPOD.

When LNA is incubated with soybean LOX type I under an oxygen atmosphere, the 9- and 13-HPOT isomers are produced in a ratio similar to the HPOD isomers from LA. LC/EI-MS analysis of these products produced the spectra shown in Figure 2. Both EI spectra are characterized by ions at *m/z* 308 [M – Oxygen], 306 [M – $H_2O$], 291 [M – $O_2H$], 290 [M – $H_2O_2$], and 275 [M – $H_2O$ – $CH_3O$]. The presence of a third double bond in the HPOT isomers alters the fragmentation pattern. The location of the hydroperoxide group for the 13-HPOT isomer cannot be established by the presence of an acyl ion at *m/z* 97, which is found in 13-HPOD at *m/z* 99 (see Fig. 1B and Scheme 1). Instead, the 13-HPOT spectrum gives ions at *m/z* 255 (28.5%), 239 (9.1%), 238 (5.1%), and 237 (8.1%) suggesting the fragmentation pattern indicated in Scheme 2, each of which subsequently loses methanol to give the ions at *m/z* 223 (4.2%), 207 (19.3%), 206 (17.3%), and 205 (5.1%). The additional double bond in 9-HPOT also produced an EI spectrum different from that of 9-HPOD; however, the ions at *m/z* 185 (33.4%) and 153 (21.5%) [185 – MeOH] can be used to identify the location of the hydroperoxide group in 9-HPOT in an analogous fashion as for 9-HPOD (Scheme 1).

Rose bengal-photosensitized oxidation of LA inserts oxygen at the double bonds, leading to the formation of the 13-, 12-, 10-, and 9-HPOD isomers (17,18). The GC/MS spectra of reduced and silyated alcohols were consistent with the 9- and 13-HPOD adducts reported earlier (12), and the spectra of the 10- and 12-HPOD adducts after reduction showed a MW of 382, with characteristic ions at *m/z* 271 (100%) for the 10-HPOD adduct and *m/z* 185 (100%) for the 12-HPOD

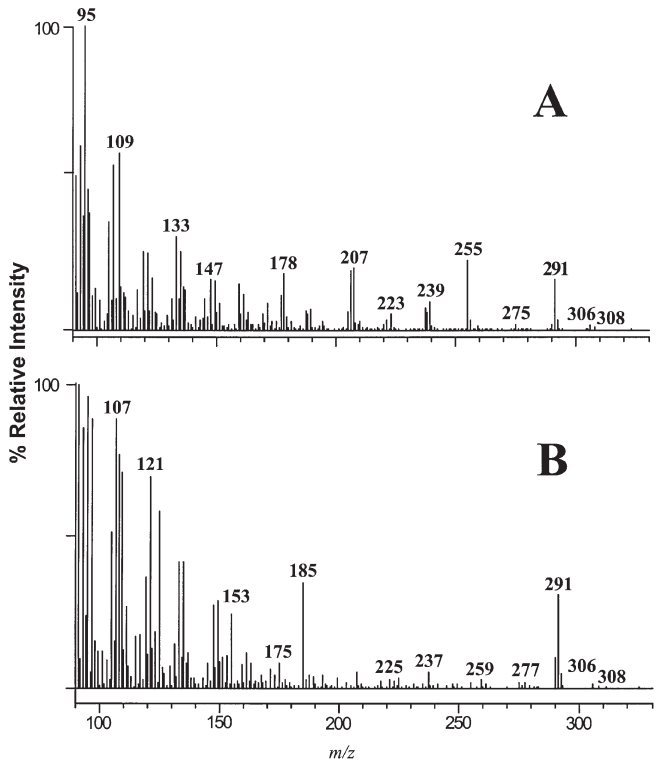

**FIG. 2.** LC/EI-MS spectra of the methyl esters of (A) 13-hydroperoxy-9(*Z*), 11(*E*),15(*Z*)-octadecatrienoic acid; and (B) 9-hydroperoxy-10(*E*),12(*Z*), 15(*Z*)-octadecatrienoic acid produced by incubation of soybean LOX type I with linolenic acid under oxygen. For abbreviations see Figure 1.

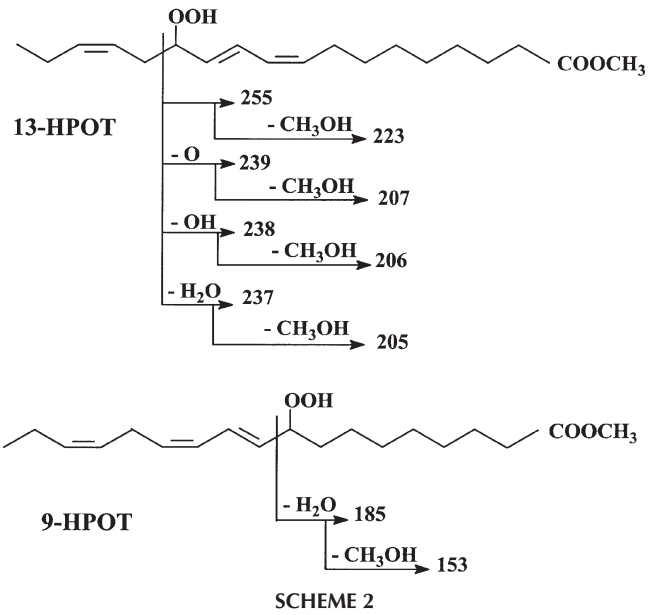

SCHEME 2

adduct as reported previously (18). The 9- and 13-HPOD isomers have *cis-trans* conjugated double bonds as in the LOX-produced products, but the reaction is not stereoselective and gives a racemic mixture of the *R* and *S* HPOD isomer products (18). Separation of the HPOD isomers on the DIOL column with UV and EI-MS detection produced the chromatograms shown in Figures 3A and 3B, respectively. The UV chromatogram shows three major peaks eluting at 48.1, 52.3, and 54.5 min, labeled 1a, 2a, and 3a, respectively, in Figure 3A. Peaks 1a and 3a have UV maxima at 234 nm, which is consistent with a conjugated *trans-cis* double bond, whereas peak 2a has a UV maximum at 228 nm, suggesting a conjugated *trans-trans* double bond (19). The total ion current (TIC) EI-MS chromatogram in Figure 3B shows significant differences from the UV chromatogram. Peaks 1b (48.3 min) and 4b (54.6 min) are not of equal size, which was also confirmed by using an evaporative light-scattering detector (result not shown), suggesting the elution of two products under peak 1b but with only one product absorbing at 234 nm. The mass spectrum of this peak showed a characteristic fragmentation pattern for 13-HPOD, i.e., a significant ion at *m/z* 99 and other characteristic ions at *m/z* 113 and 129. Extraction of the ion chromatograms at *m/z* 99 and 129 indicated two components with retention times of 48.2 and 48.5 min, respectively as shown in the insert of Figure 3B. The EI spectrum of the early portion of the 48.2 min peak is completely consistent with 13-HPOD. The EI spectrum of the later portion of the 48.5 min peak (Fig. 4A) shows ions at *m/z* 310 (>1%), 308 (1%), 293 (10.3%), 279 (2.3%), and 261 (4.6%) that are characteristic for an HPOD isomer. These ions and the lack of UV absorption at 234 nm indicate an HPOD isomer with nonconjugated double bonds. The UV and EI-MS data for this peak and its elution order from the DIOL column suggest this peak is the 12-HPOD isomer. The ions at *m/z* 129 (65.4%), 113 (30%), 112 (23.9%), and 111 (22.4%) (Fig. 4A) also are consistent with a 12-HPOD isomer, as indicated by

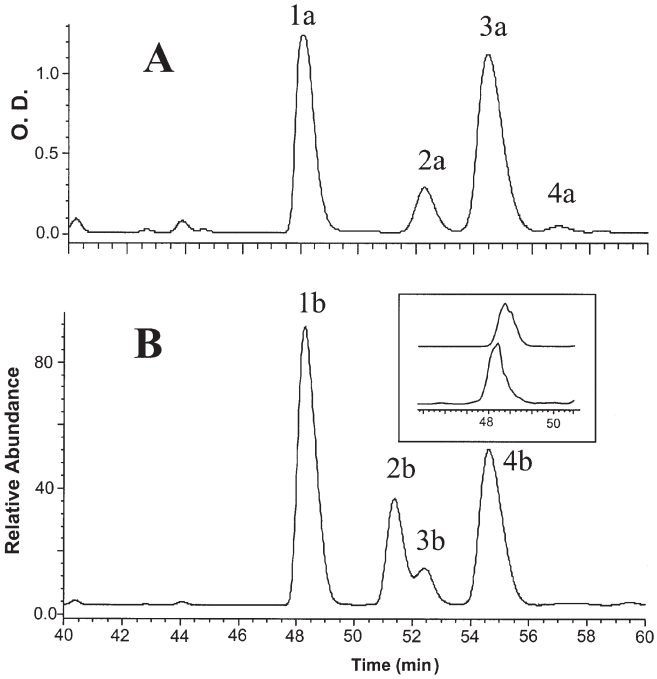

**FIG. 3.** HPLC DIOL column separation of the methylated HPOD products obtained by photosensitized oxidation of LA (see Materials and Methods section). (A) Ultraviolet chromatogram at 234 nm; (B) MS total ion chromatogram. Insert: extracted ion chromatograms for 129 amu (top); and 99 amu (bottom). See Results and Discussion section for peak labeling. O.D., optical density; for other abbreviations see Figure 1.

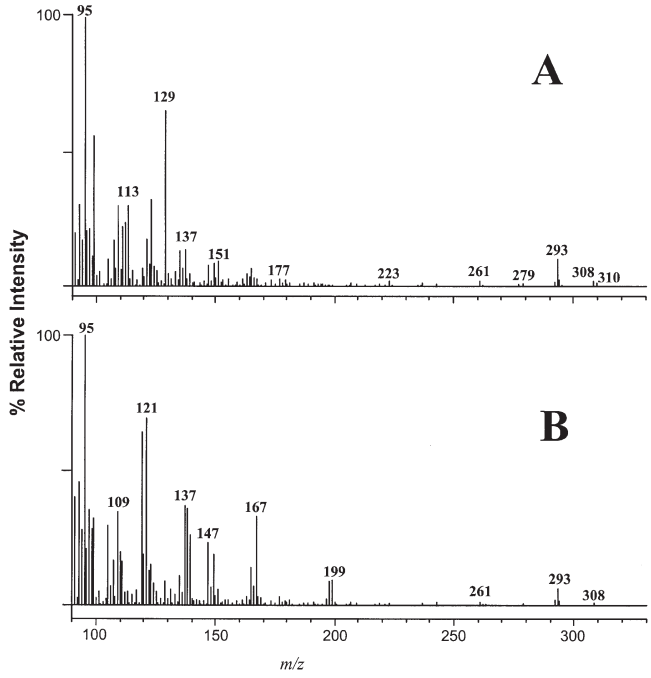

**FIG. 4.** LC/EI-MS spectra of the methyl esters of (A) 12-hydroperoxy-9(*Z*), 13(*E*)-octadecadienoic acid and (B) 10-hydroperoxy-8(*E*),12(*Z*)-octadecadienoic acid produced by photosensitized oxidation of LA. For abbreviations see Figure 1.

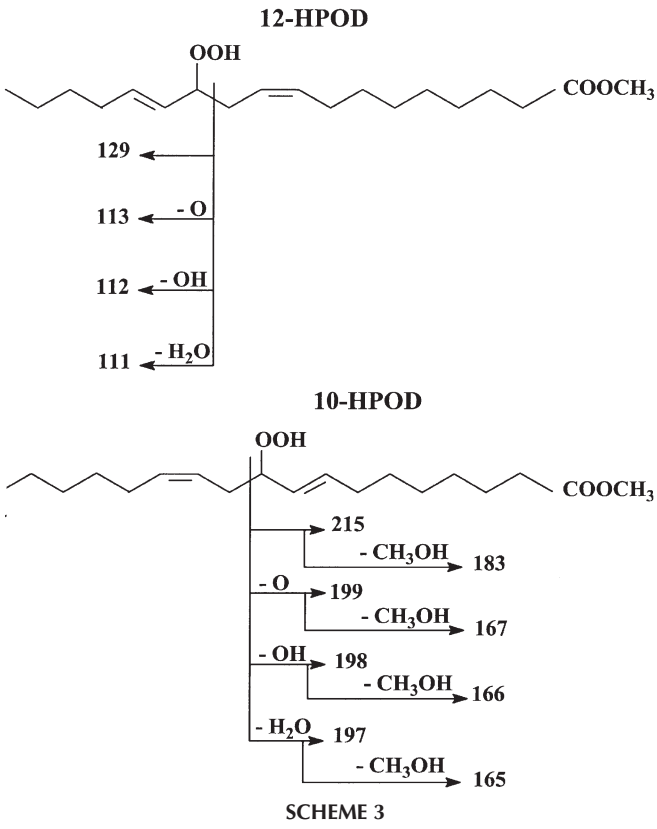
the fragmentation pattern shown in Scheme 3. These ions present a fragmentation pattern similar to that observed for 13-HPOT, in which cleavage toward the proximal *trans* double bond generates the observed ions (Scheme 2). Thus, the EI spectrum for the peak at 48.3 min (insert Fig. 3B) indicates co-elution of the 13- and 12-HPOD isomers.

Peak 2b (51.3 min) in the TIC chromatogram in Figure 3B also does not have UV absorption at 234 nm. However, its EI spectrum (Fig. 4B) has the higher mass ions (*m/z* 308, 293, and 261) that are consistent with an HPOD isomer. Additional ions for this isomer are at *m/z* 199 (14.5%), 198 (12.9%), 197 (2.9%), along with ions at *m/z* 167 (42.2%), 166 (10.9%), and 165 (20.4%). Elution of this isomer after the 12- and 13-HPOD isomers and the absence of UV absorption at 234 nm suggests it is a 10-HPOD isomer, as indicated from the fragmentation pattern shown in Scheme 3.

The unresolved TIC peak 3b (52.3 min, Fig. 3B) had a spectrum consistent with 13-HPOD (Fig. 1A). The elution order of this peak from the column along with its UV maximum at 228 nm supports its assignment as *trans-trans* 13-HPOD (19). The TIC for peak 4b (54.6 min, Fig. 3b) had an EI spectrum and UV maxima consistent with *cis-trans* 9-HPOD. The minor companion peak 4a (57 min, Fig. 3A) had a UV maximum and mass spectrum consistent with the *trans-trans* 9-HPOD isomer (19).

Chlorella pyrenoidosa *HPOD products.* LOX activity present in *C. pyrenoidosa* was isolated by $(NH_4)_2SO_4$ precipitation (45 and 80% saturation). The active fractions were subsequently used to oxygenate LA to HPOD isomers at pH 8.0; after methylation with diazomethane they were separated and analyzed by LC/EI-MS. The chromatogram of the product obtained with the LOX fraction obtained at 45% $(NH_4)_2SO_4$ saturation showed two main peaks with retention times of 48 and 55 min. Both



**SCHEME 3**

peaks had UV maxima at 234 nm, which indicates the presence of conjugated double bonds. The EI spectra of both peaks had ions at *m/z*: 310 [M – Oxygen], 308 [M – $H_2O$], and 293 [M – $O_2H$], which are ions characteristic for HPOD derivatives. The first-eluting peak (>60% of the product) had an EI spectrum with an ion at *m/z* 99 (100%), which is characteristic for the 13-HPOD isomer. The EI spectrum of the second-eluting peak (<45%) had ions at *m/z* 185 (24%) and 153 (18%), which is indicative for 9-HPOD (14). Other minor peaks in the chromatogram were identified as the corresponding 9- and 13-HPOD *trans, trans* isomers. Incubation of LA under oxygen with the LOX fraction obtained at 80% $(NH_4)_2SO_4$ saturation produced the 9-HPOD isomer as the main product (>85%) as determined from its UV and EI spectra.

Previously it was reported that *C. pyrenoidosa* produced 9-, 10-, and 13-HPOD isomers (7). However, the LC/EI-MS analysis presented here did not detect the 10-HPOD isomer. The 45 and 80% $(NH_4)_2SO_4$ LOX fractions produced different HPOD isomers, which suggested the presence of two LOX isozymes in *C. pyrenoidosa*. Moreover, the 45% $(NH_4)_2SO_4$ LOX fraction oxygenated both LA and LNA, whereas the 80% $(NH_4)_2SO_4$ LOX fraction oxygenated only LA (yield near 50%).

We reported (10) that *C. pyrenoidosa* LOX has a cleavage activity on 13-HPOD and 13-HPOT under anaerobic conditions. Both substrates produced a mixture of volatile $C_5$ monomers as well as $C_5$ dimers when 13-HPOT was the substrate. These results are consistent with the LOX anaerobic cleavage mechanisms proposed by Salch *et al.* (9). The 45 and 80% $(NH_4)_2SO_4$ saturated LOX fractions were assayed for their cleavage activity under anaerobic conditions with 13-HPOD and 13-HPOT by using a GC/MS method previously described (20). The 45% $(NH_4)_2SO_4$ LOX fraction showed low cleavage activity, whereas the 80% $(NH_4)_2SO_4$ LOX fraction showed high cleavage activity. However, other factors such as the concentration of free fatty acids in both fractions could play a role, and studies with more highly purified enzyme fractions are planned. In addition, when the 80% $(NH_4)_2SO_4$ LOX fraction was incubated under anaerobic conditions with its own product, 9-HPOD, no cleavage products were detected by GC/MS analysis and no decrease in UV absorption at 234 nm was observed, suggesting that the LOX that produces 9-HPOD does not promote anaerobic cleavage of 9-HPOD.

*Conclusion.* The LC/EI-MS method presented here can effectively identify the 9-, 10-, 12-, and 13-HPOD isomers of LA and the analogous HPOT isomers of LNA. EI-MS fragmentation patterns for the HPOD isomers provide distinctive MS peaks that are characteristics for each HPOD isomers. Co-elution of peaks such as the 12- and 13-HPOD isomers can be detected by analysis of ion chromatogram. Hence LC/EI-MS is a powerful tool for the analysis of mixtures of HPOD isomers. The method is particularly useful for analyzing HPOD isomers produced by LOX isozymes. For example, the assay of partially purified LOX from *C. pyrenoidosa* showed the presence of two LOX isozymes, the characterization of which is currently under study in our laboratory.

**ABSTRACT:** An important role for docosahexaenoic acid (DHA) within the retina is suggested by its high levels and active conservation in this tissue. Animals raised on n-3–deficient diets have large reductions in retinal DHA levels that are associated with altered retinal function as assessed by the electroretinogram (ERG). Despite two decades of research in this field, little is known about the mechanisms underlying altered retinal function in n-3–deficient animals. The focus of this review is on recent research that has sought to elucidate the role of DHA in retinal function, particularly within the rod photoreceptor outer segments where DHA is found at its highest concentration. An overview is also given of human infant studies that have examined whether a neonatal dietary supply of DHA is required for the normal development of retinal function.

Paper no. L8652 in *Lipids 36*, 859–871 (September 2001).

Docosahexaenoic acid (DHA, 22:6n-3) is found in very high concentration in the retina (1,2). DHA may be obtained directly from the diet or synthesized from one of its n-3 precursors (3). The retina possesses an efficient conservation and recycling mechanism that helps preserve retinal DHA concentrations even during prolonged periods of low n-3 dietary intake (4–6). The high concentration of DHA in the retina and existence of the conservation and recycling mechanisms suggest that DHA may be important to retinal function. The growing body of evidence to suggest that DHA performs several important roles within the retina is the subject of this review. We have chosen to focus on recent research that has provided new information regarding the role of DHA in the retina, particularly within the photoreceptors. Key results from early studies that have contributed to our understanding of the role of DHA in the retina are also discussed. A comprehensive review of earlier studies in this field was published previously (7).

A major portion of this review is dedicated to animal studies that have investigated the effect of large reductions in retinal DHA levels on retinal function. An overview is also given of studies with human infants that have sought to determine whether a supply of preformed DHA is required in the diet of human infants to achieve optimal retinal function. A description of the basic structure and physiology of the retina and how its function may be assessed with the electroretinogram (ERG) will preface the review of the human and animal studies.

Abbreviations: AA, arachidonic acid; ALA, α-linolenic acid; DHA, docosahexaenoic acid; E, cGMP phosphodiesterase; EPA, eicosapentaenoic acid; ERG, electroretinogram; IPR, isolated probe response; IRBP, interphotoreceptor retinal binding proteins; ISI, interstimulus interval; LC-PUFA, long-chain polyunsaturated fatty acids; PE, phosphatidylethanolamine; ROS, rod outer segment; RPE, retinal pigment epithelium.

## THE RETINA

The following sections provide a brief overview of basic retinal structure and physiology; more detailed information on these subjects may be found elsewhere (for review, see Refs. 8–10). The process of vision begins with light being focused through the cornea and lens onto the retina. The retina contains the cells responsible for light capture and transduction, the rod and cone photoreceptors. The rod system has high sensitivity at low light levels to provide animals with "night vision," but does not provide color vision or high spatial resolution. The retinas of nocturnal mammals such as rats are rod dominant and have few cones. Cones provide the basis for color vision and the ability to see over a wide range of light intensities in daylight. Higher primates, including humans, apes and old world monkeys, have three classes of cones that respond optimally to either long, medium, or short wavelengths (i.e., red, green, or blue) (11). Cones are tightly packed within the fovea to provide the basis for high visual acuity.

Photoreceptor cells contain two distinct compartments, the inner and outer segments (Fig. 1). The inner segments contain the components necessary for cell metabolism, whereas the outer segments contain the photopigments that absorb photons of light. The rod outer segments (ROS) contain thousands of vertically stacked free-floating disks that are rich in DHA and the photopigment rhodopsin (Fig. 1). The cone photoreceptors also contain disks within the outer segment, but they are not free floating and remain contiguous with the outer plasma membrane.

In the dark, a continuous current flows into the rod photoreceptor outer segments through cation channels kept open by a high cytosolic concentration of cGMP (see Fig. 2). After photon capture, rhodopsin rapidly undergoes a conformational change to form metarhodopsin II (R*), the activated form of rhodopsin. R* activates the trimeric G protein, transducin, by catalyzing the exchange of GDP for GTP, which binds to the α subunit of transducin (Fig. 2). The activated

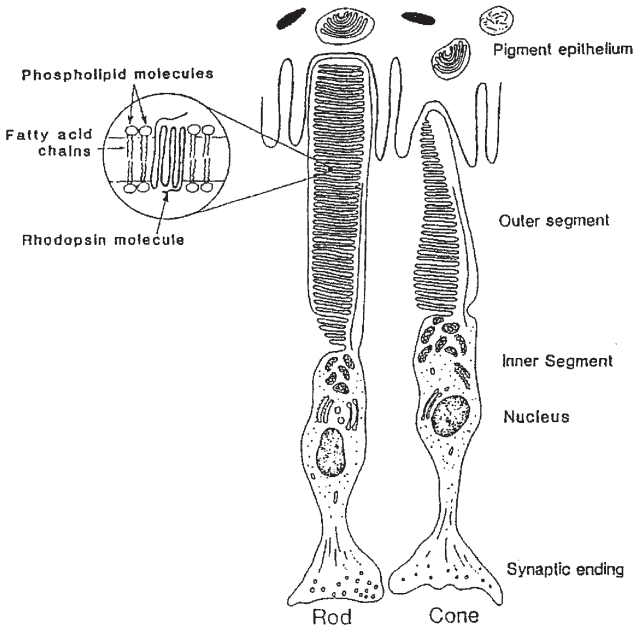

**FIG. 1.** Rods contain thousands of vertically stacked free-floating disks that are rich in docosahexaenoic acid (DHA) and the photopigment, rhodopsin. The cone photoreceptors also contain disks within the outer segment, but they are not free floating and remain contiguous with the outer membrane. Each cone photoreceptor contains one of three photopigments that respond optimally to short, medium or long (red, green or blue) wavelength light. The inner segments contain the components necessary for cell metabolism. The pigment epithelium has several important roles including regulation of the exchange of nutrients and by-products between the photoreceptors and the choroidal blood supply. Inset: The photopigments are surrounded by the DHA-rich phospholipids. Reproduced with permission from Reference 7.

transducin (Gα*) binds to the tetrameric cGMP phosphodiesterase (E), thus removing the influence of one of its inhibitory γ subunits. The activated E (E*) hydrolyzes cGMP to GMP. The resulting fall in cytosolic cGMP after rhodopsin activation closes cation channels causing the photoreceptor to hyperpolarize. The phototransduction cascade has a high gain, so the activation of a single rhodopsin molecule results in the hydrolysis of some $10^5$ cGMP molecules (12).

In the dark, photoreceptors continually release the neurotransmitter glutamate into their synaptic junctions with the bipolar and horizontal cells. Light-induced hyperpolarization of the photoreceptors causes a graded reduction in the release of glutamate, which in turn causes the bipolar cells to either depolarize (ON-bipolars) or hyperpolarize (OFF-bipolars).

## THE ERG AS A MEASURE OF RETINAL FUNCTION

The ERG is a record of the voltage change that occurs across the retina in response to a brief flash of light (for reviews, see Refs. 10,13). The ERG may be recorded using a wide variety of electrodes, but a contact lens electrode placed on the cornea provides the largest and most stable response (14). The following section gives a brief overview of the ERG with particular reference to the components most commonly recorded in studies that have assessed the role of DHA in retinal function. A typical ERG and its characteristic parameters are shown in Figure 3.

*Origin of the ERG.* The leading edge of the ERG a-wave recorded to a bright saturating flash, i.e., one that closes all cation channels, reflects the hyperpolarization of the massed photoreceptor response (15,16). The rod-dominated ERG b-wave recorded in the dark reflects depolarization of the rod bipolar cells (17,18). The cone-dominated ERG b-wave recorded with a bright background is shaped by both ON and OFF bipolar cells and horizontal cells (19). The oscillatory potentials are high-frequency oscillations superimposed upon the b-wave (Fig. 3), and are thought to originate from different levels within the proximal retina, including the amacrine, interplexiform, and ganglion cells (20).

*Factors affecting ERG morphology.* One important determinant of ERG amplitudes and implicit times is the retinal illuminance produced by the flash. Retinal illuminance refers to the number of photons arriving at the retina measured in trolands (Td) (21). Retinal illuminance takes into account not only the intensity and spectral content (color) of the flash but also a number of other factors, including dark adaptation, the length of the eye, and the size of the pupil (21). It has been estimated for dark-adapted humans that a troland of light induces, on average, 8.6 photoisomerizations per rod (22). For the average human rod with 70 million rhodopsin molecules (9), a flash that produces a retinal illuminance of 1.0 log scotopic troland-seconds (scot-Td-sec) will therefore bleach ~0.0001% of the available rhodopsin.

Another important determinant of ERG morphology is the background luminance. Scotopic ERG (rod dominant) are recorded in the dark, whereas photopic ERG (a measure of the massed cone response) are recorded against a background light sufficient to saturate the rods. Photopic ERG are typically smaller and faster than scotopic ERG (23).

*Conventional analysis of the ERG.* The "conventional" method of ERG assessment involves measurement of ERG b-wave amplitude over a range of flash intensities (Fig. 4). The change in amplitude with flash intensity may be described in terms of the Naka-Rushton function (Fig. 5), an adaptation of the Michaelis-Menten equation (24,25):

$$V/V_{max} = I^n/(I^n + K^n) \quad [1]$$

where $V$ is the amplitude (μV), $I$ is the flash intensity, $n$ is the slope of the curve, $V_{max}$ is the maximum amplitude (μV), and $K$ is the intensity that elicits half-maximal response. $V_{max}$ has been interpreted as an index of both the number of rods responding and the gain (μV/quantum captured) for each b-wave generator (26). The parameter $K$ has been interpreted as an index of retinal sensitivity that represents quantal capture (26). Rod threshold, defined as the flash intensity at which an ERG b-wave is just detectable, may also be determined from the Naka-Rushton equation (27).

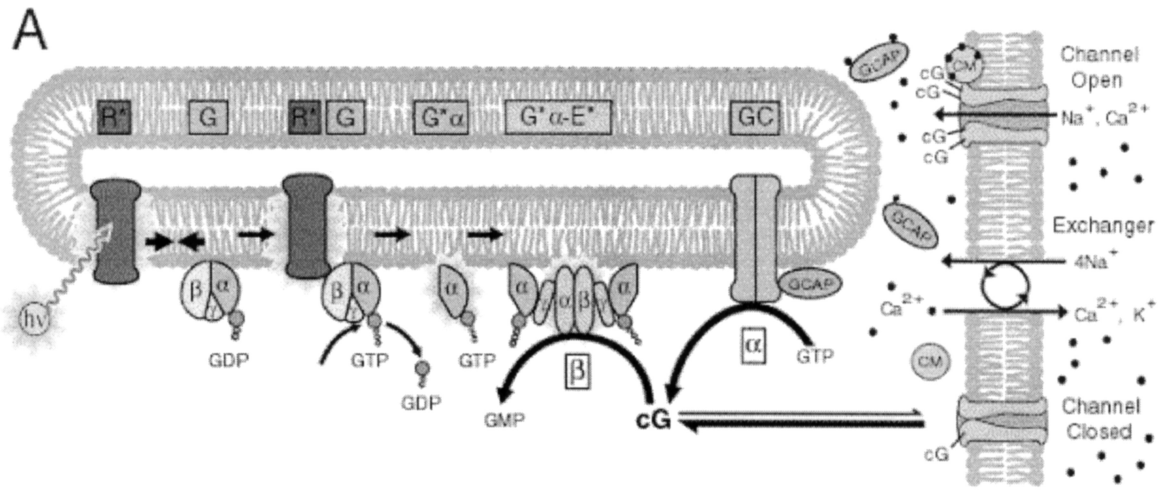

**FIG. 2.** Upon capture of a photon of light (hν), rhodopsin is activated (R*). R* activates the G protein by catalyzing the exchange of GDP for GTP. Upon activation, the G protein separates into two parts; one is the isolated subunit to which GTP is now attached (G*α). G*α binds to cyclic guanosine monophosphate phosphodiesterase (E), releasing the inhibitory influence of one of the E γ subunits. The activated E begins to hydrolyze cGMP (cG) to GMP. The resulting fall in cytosolic cGMP concentration causes cGMP molecules to dissociate from the ion channel, which now closes. Rod recovery occurs in part due to an increase in cGMP concentration, which is synthesized from GTP by guanylate cyclase (GC). Reproduced with permission from Reference 78.

One limitation of conventional ERG analysis is that the ERG waveforms are formed by a composite of generators and thus are nonspecific in terms of cellular origin. For example, the ERG b-wave contains not only bipolar responses but also contributions from the photoreceptor a-wave and oscillatory potentials from the proximal retinal layers (18). The b-wave also includes a substantial corneal negative scotopic threshold response generated by the proximal retina at low-to-moderate flash intensities (18,28). In most of the studies investigating the role of fatty acids in retinal function, the ERG has typically been measured up to flash intensities sufficient to produce maximal ERG b-wave amplitude ($V_{max}$). At this flash intensity, the ERG a-wave does not provide an accurate description of the massed hyperpolarization response of the photoreceptors (16).

*Analysis of phototransduction.* Recent developments in ERG recording and analysis techniques have enabled better isolation of the massed responses from the photoreceptor and bipolar cells. *In vitro* experiments with isolated photoreceptors have enabled the development of a quantitative model describing the G-protein cascade of phototransduction (29). The same quantitative model or slight variants of it (see Eq. 2) have been used successfully to describe the leading edge of the ERG a-wave in response to a high intensity flash that causes a-wave saturation (22,30–32). Figure 6 shows an example of ERG recorded to three different flash intensities (solid lines) and the fit of the model given in Equation 2 to the leading edges of the ERG a-waves (dashed lines). The phototransduction model is given by

$$P3(i, t) \approx \{1 - \exp[-i \cdot S \cdot (t - t_d)^2]\} \cdot R_{maxP3} \qquad t > t_d \qquad [2]$$

where $P3$ is the voltage of the ERG a-wave (μV), at time $t$ seconds, in response to a flash with a retinal illuminance of $i$ scot Td-sec. The $P3$ term describing the ERG a-wave is so named after Granit's classic analysis, in which the ERG was formed by the addition of two cellular responses, $P2$, a single postreceptoral response and $P3$ the response from the pho-

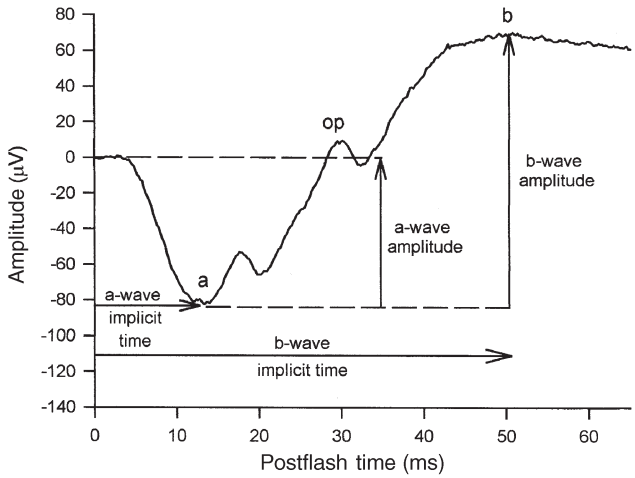

**FIG. 3.** The electroretinogram (ERG) a-wave represents the hyperpolarization of the massed photoreceptor response, whereas the ERG b-wave represents the depolarization of the rod-bipolar cells. Small oscillatory potentials shown superimposed on the rising b-wave originate from interactions among the amacrine, interplexiform, and ganglion cells. ERG a-wave amplitude is measured from the baseline to the trough of the ERG a-wave, and ERG b-wave amplitude is measured from the trough of the a-wave to the peak of the ERG b-wave. Implicit times are measured from flash onset (time 0) to the trough of the ERG a-wave and to the peak of the ERG b-wave.

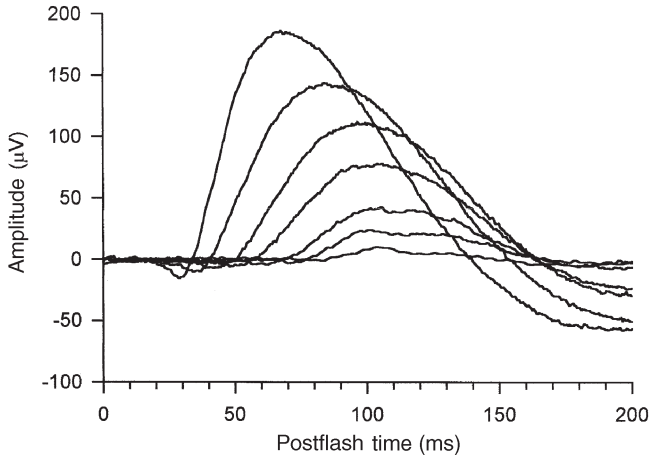

**FIG. 4.** Variation in ERG b-wave amplitude and implicit time over a 4 log unit range of retinal illuminance. With increasing retinal illuminance (bottom to top), ERG b-wave amplitude increases and implicit time decreases. For abbreviation see Figure 3.

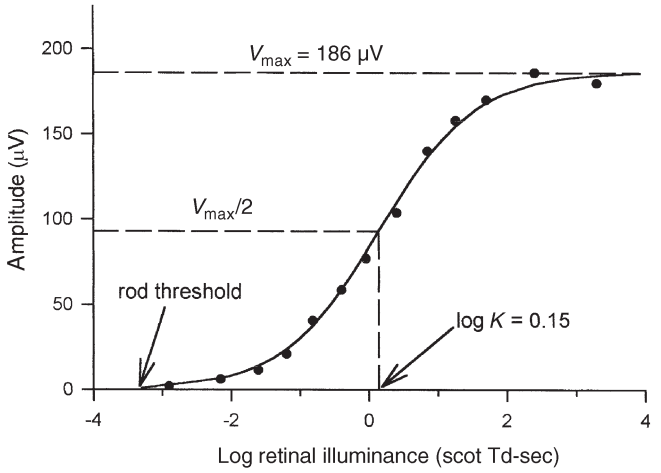

**FIG. 5.** Variation in ERG b-wave amplitude with retinal illuminance from an adult rhesus monkey. The solid line shows the fit of the Naka-Rushton equation (Eq. 1 in text) to the data. The parameters derived from the fit of the Naka-Rushton equation are as follows: $V_{max}$, the maximum amplitude (μV), and *K*, the intensity that elicits half-maximal response. Rod threshold, defined as the flash intensity at which an ERG b-wave is just detectable, may also be derived from the Naka-Rushton equation. For abbreviation see Figure 3.

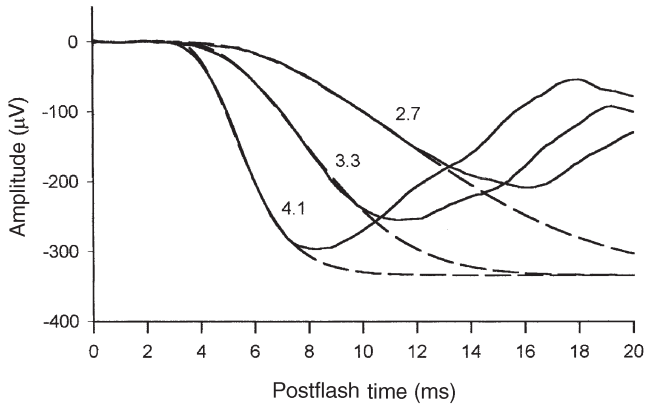

**FIG. 6.** The *P*3 model given by Equation 2 (see main text) provides an excellent fit (dashed lines) to the leading edges of the rod-isolated ERG a = waves (solid lines). The numbers above each ERG a-wave indicate the retinal illuminance in log scot Td-sec used to generate the ERG.

toreceptors (33,34). The parameters of the model that are adjusted to provide the best description of the leading edge of the rod isolated ERG a-wave are as follows: *S*, a sensitivity parameter that scales retinal illuminance [(scot Td-sec)$^{-1}$ sec$^{-2}$]; $t_d$, a delay (sec), and $R_{maxP3}$, the maximum amplitude response (μV) (35). The parameter *S* has been interpreted to represent the gain of the phototransduction cascade, i.e., it is proportional to the number of cation channels closed per molecule of rhodopsin activated (22,30). Alternatively, *S* may also be altered by a change in the local rhodopsin density on the disk membrane (22,30). $R_{maxP3}$ is the change in voltage corresponding to the maximum number of cation channels that can be closed. A reduction in the number of photoreceptors or shortening in the length of the ROS would cause a proportional reduction in $R_{maxP3}$ (22,30). The parameter $t_d$ is a nonphysiologic delay due to instrumentation filtering and finite duration of the flash. One variation to the model given in Equation 2 is to include a term that accounts for membrane capacitance (32,36). Membrane capacitance becomes an important factor when describing the cone photoreceptor ERG a-wave or the rod ERG a-wave recorded to extremely bright flash intensities (31,32,36). Employing the model given by Equation 2 to describe the ERG a-wave thereby provides an *in vivo* method of quantifying the phototransduction process.

To derive the phototransduction parameters, *S*, $R_{maxP3}$, and, $t_d$ Equation 2 is typically fitted simultaneously to multiple ERG a-waves recorded to a series of bright flashes (ensemble fit) (Fig. 6). The highest retinal illuminance used in Figure 6 is ~500 times brighter than the illuminance required to produce ERG b-wave saturation, as used in conventional ERG analysis.

*Assessment of rod recovery.* After light capture, the phototransduction proteins (R*, G*, and E*) are activated, and cytosolic cGMP concentration falls, closing a portion of the cGMP-gated ion channels that are open (Fig. 2). Before the rod can fully respond to subsequent photons of light, the rod must be returned to its dark-adapted resting state. The steps necessary for rod recovery include deactivation of R*, G*, and E* and the return of cGMP concentration to its preflash level. The latter step reopens the same proportion of cGMP-gated ion channels that were closed by the flash. The time course of rod recovery can be assessed using a paired-flash ERG method (35,37). With the paired-flash method, a high intensity "test" flash that forces the rod into saturation is followed by a second "probe" flash at varying interstimulus intervals (Fig. 7). If the probe flash is delivered during the period of rod saturation when all cation channels are closed, there will be no measurable ERG response (Fig. 7, ERG at 6-sec interstimulus in-

terval). Once cation channels begin to reopen, a subsequent probe flash will close all newly opened cation channels, driving the rod back into saturation. The amplitude of the ERG a-wave to the probe flash is proportional to the number of cation channels closed and therefore, the amount of recovery that has occurred since the test flash (35,38). Figure 7 illustrates the recovery of ERG amplitude (thin solid lines) from an adult rhesus monkey at various interstimulus intervals after a bright test flash (5.4 log scot Td-sec). At the end of the recovery experiment, the ERG is recorded in response to a probe flash presented in isolation without a preceding test flash ("Probe only," Fig. 7). The dashed lines in Figure 7 show the fits of the *P*3 model (Eq. 2) to the leading edges of each ERG a-wave. The maximal response derived at each interstimulus interval (ISI), $R_{maxISI}$, is normalized with respect to the maximal response derived from the isolated probe response (IPR), $R_{maxIPR}$. Figure 8 shows the plot of the normalized responses $R_{maxISI}/R_{maxIPR}$ against log interstimulus interval. The solid line is the best fit of the sum of two exponentials to the data. Also shown are two characteristic parameters derived from the analysis, i.e., $T_c$, the time the rod remains saturated after the test flash and $T_{50}$, the time required from $T_c$ to reach 50% of full recovery.

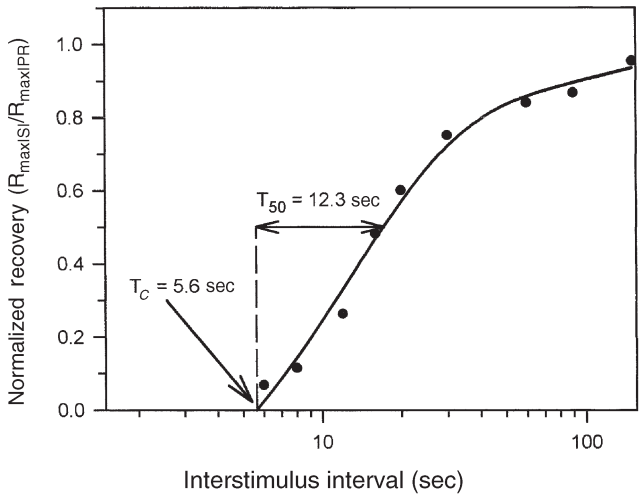

**FIG. 8.** Normalized ERG a-wave recovery plotted against interstimulus interval. The amplitudes of the probe flash ERG at each interstimulus interval (ISI) ($R_{maxISI}$) are normalized with respect to the amplitude of the isolated probe response (IPR) flash ERG recorded at the end of the sequence ($R_{maxIPR}$). The solid line is the best fit of the sum of two exponentials to the data. Also shown are two characteristic parameters derived from the analysis, $T_c$, and $T_{50}$. For abbreviation see Figure 3.

## DHA IN THE RETINA

Within the retina, DHA is incorporated primarily into structural glycerophospholipids of the cell membrane lipid bilayer (39). DHA accounts for 8–20% of total retinal fatty acids in humans and 38–92% of total polyunsaturates within the mammalian retina (2,40–45). DHA is particularly concentrated within the disk membranes of the ROS where it accounts for up to 30% of total fatty acids and 54% of phosphatidylethanolamine (PE) fatty acids (2,42,46,47). The retina is unique in that it contains phospholipids with polyunsaturates at both the *sn*-1 and *sn*-2 positions (dipolyenes). In the monkey, dipolyenes with long-chain polyunsaturated fatty acids (LC-PUFA) in both the *sn*-1 and *sn*-2 positions constitute 16% of the diacyl ethanolamine phosphoglycerides, and 15% of these have DHA in both positions (48).

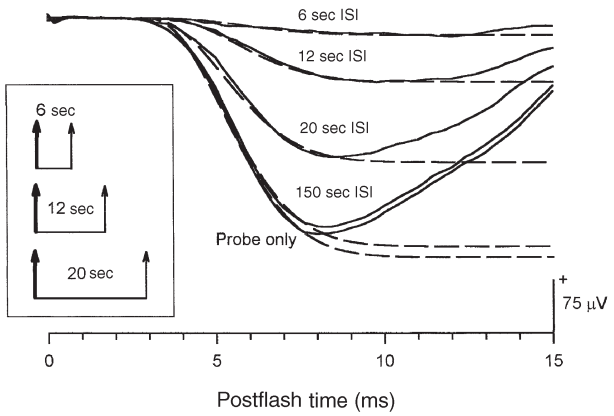

**FIG. 7.** Recovery of the rod ERG a-wave after a saturating flash. The solid lines show the rod isolated ERG recorded to the second (probe) flash (4.1 log scot Td-sec) at a given interstimulus interval (ISI) after a test flash (5.45 log scot Td-sec). The bottom-most response (probe only) is the ERG recorded to the probe flash presented without a preceding test flash 150 sec after the last double flash pair. The dashed curves show the best fits of Equation 2 to the leading edges of the ERG a-waves. Inset: Graphic representation of the separation between the saturating test flash (thick arrow) followed by the probe flash (thin solid arrow) at a given interstimulus interval. For abbreviation see Figure 3.

## LC-PUFA SUPPLEMENTATION IN HUMAN AND NONHUMAN PRIMATES

Birch *et al*. (27) reported an elevation in log *K* and a reduction in $V_{max}$ at 36 wk postconception (~6 wk postnatal age) in preterm infants fed a corn oil-based formula with a low level (0.5%) of α-linolenic acid (ALA) compared with infants fed a fish oil-supplemented formula [0.35% DHA and 0.65% eicosapentaenoic acid (EPA)]. Analysis of the Naka-Rushton function from these infants also revealed an elevation in rod threshold in the corn oil group, which likely reflects the elevation in log *K*. Infants fed a soybean oil-based diet (2.7% ALA) had parameter values that were in between those of the corn and fish oil diet groups. In a follow-up study of term infants by the same group, only log *K* was elevated at 6 wk postnatal age in infants fed a formula with 1.7% ALA as the sole n-3 fatty acid, compared with infants fed a formula supplemented with LC-PUFA [0.36% DHA, 0.72% arachidonic acid (AA)] (49). In both studies, the early differences noted in the ERG between the diet groups were no longer present at 4 mon of age (cor-

rected age for premature infants). However, in the preterm study, infants in the corn oil group had longer latencies for light-adapted oscillatory potentials at 4 mon corrected age (27).

In another study, term infants were randomized to either a control formula containing 2.1% ALA as the sole n-3 fatty acid or one of two formulas supplemented with LC-PUFA, either 0.12% DHA and 0.43% AA, or solely 0.23% DHA. There were similarly no ERG differences between the diet groups at the sole test age of 4 mon (50).

Owing to limitations in ERG methodology used, results from a fourth study are difficult to interpret. Faldella *et al*. (51) recorded ERG from a skin electrode placed on the bridge of the nose. ERG recorded from this position exhibit high variability, are extremely small, and lack the sensitivity even to distinguish different forms of retinal pathology (52). The failure to dilate the pupil or dark-adapt the infants in this study would have further reduced ERG amplitudes and increased variability of the recordings. Given these limitations, it is difficult to draw any conclusions about the effects on retinal function of the diets used in this study.

The preterm infants in the study of Birch *et al*. (27) were born at 28–33 wk gestation. Over the last trimester of pregnancy, there is a 35% increase in retinal DHA level (40), and infants born prematurely are likely to be more susceptible to any reduction in the availability of DHA for accretion by the retina. This greater susceptibility in infants born prematurely may explain the more marked ERG alterations at 6 wk postnatal age in the preterm infants compared with the term infants. Other differences between the term and premature infant studies, notably the level of dietary ALA used, may also account for the greater ERG alterations in the premature infants. The results from both preterm and term infants suggest that retinal function may be altered by the level of n-3 fatty acids supplied in the diet for at least the first six postnatal weeks.

Owing to the difficulty of recording ERG with a contact lens in older infants and young children, the evaluation of retinal function after varying dietary n-3 fatty acid content has been limited to a maximum of 4 mon postterm in humans. The rhesus monkey provides an ideal animal model of the human for the long-term study of the effect of diet on retinal function. The similarities between retinal structure, function, and development in macaque monkeys (e.g., rhesus) and humans are well described (11,53–56). Additionally, rhesus monkeys, like humans, are capable of desaturating and elongating the n-3 and n-6 essential fatty acids to obtain their respective long-chain polyunsaturates (57–60). Adjustments necessary for comparison of humans and macaque monkeys are the different rates of visual development (1 wk for monkeys is equivalent to ~4 wk in humans) and the greater neural and retinal maturity of the monkey at birth.

In a recent study, infant monkeys were raised for the first six postnatal months on either a formula containing 1.7% ALA as the sole n-3 fatty acid or a diet supplemented with 0.8% DHA and 0.8% AA. At 4 and 13 mon of age, there were no significant differences in rod or cone ERG between the two diet groups (62).

In a separate study, retinal function was assessed in monkeys raised their entire lives on either a diet with 8% ALA as the sole n-3 fatty acid or a diet supplemented with 0.6% DHA and 0.2% AA. The mothers of these monkeys consumed diets identical to those of their offspring throughout pregnancy. There were no significant differences in the ERG between the two groups of monkeys when tested as adults (4–6 yr) (62). However, several alterations were found in the ERG of monkeys fed very low ALA diets, and these are described in the following section.

The results from the two monkey studies suggest that a diet with 1.7–8% ALA as the sole n-3 fatty acid does not adversely affect the long-term development of retinal function in higher primates, compared with a diet containing at least 0.6% DHA. The similarity of the rhesus monkey retina to that of humans, together with the data for human infants at 4 mon, suggests that this finding is likely valid for humans. It has not been tested in humans whether a diet with a level of ALA >1.7% would eliminate the alterations in the ERG noted at 6 wk postnatal age compared with infants fed a LC-PUFA-supplemented diet containing 0.35% DHA.

The combined results from the human and monkey studies suggest that the period of vulnerability of the retina to a low supply of dietary n-3 fatty acids is short. If a lowering of retinal DHA level underlies the ERG alterations reported in the human infants, what are the possible mechanisms that result in this early vulnerability? In both rhesus monkeys and baboons, DHA is readily accreted by the retina from the circulating blood supply during the latter stages of fetal development and during the neonatal period (57–59). The retina also has a sophisticated recycling system that ensures conservation of retinal DHA levels even during periods of prolonged dietary n-3 deficiency (4–6). Both term and preterm human infants are capable of synthesizing some DHA from ALA (63,64). However, the above results suggest that infants, particularly preterm infants, fed formulas with <1.7% ALA may not be able to synthesize sufficient DHA to meet their retinal requirements over the early postnatal weeks. The lack of ERG differences at 4 mon of age suggests that any such limitation is transient.

## THE EFFECT OF DHA DEFICIENCY ON RETINAL FUNCTION IN ANIMALS

*Rats and guinea pigs.* Reductions in conventional ERG a- and b-wave amplitudes have been consistently reported in rats and guinea pigs fed n-3-deficient diets in comparison with control animals fed high ALA, n-3-sufficient diets (46,65–70).

The newer methods of ERG recording and analysis have been used in only a few studies. Weisinger *et al*. (70) reported that phototransduction sensitivity, *S*, varies as a saturating function of retinal DHA level at 16 wk of age in guinea pigs (Fig. 9, lower graph). In the same guinea pigs, the maximal rod response $R_{\max P3}$ was reduced by ~0.16 log units when retinal DHA fell below 16% of total fatty acids (Fig. 9, upper graph). Further reductions in retinal DHA did not produce any additional loss in $R_{\max P3}$. The pattern of variation in *S* with

retinal DHA level differs from that of $R_{maxP3,}$ suggesting that two separate mechanisms may be affected in n-3-deficient guinea pigs. In a subsequent study in rats from the same laboratory, a reduction in retinal DHA from 34.1 to 25.5% of total fatty acids was associated with a 0.28 log unit reduction in both $R_{maxP3}$ and $S$ at 35 wk of age (71).

The mechanisms by which lowering retinal DHA levels causes reductions in ERG amplitudes and phototransduction sensitivity in rats and guinea pigs are not yet fully understood. The rate of ROS disk synthesis (42), the number of photoreceptors (46,72), ROS length (42,72), and the width of the outer nuclear layer (42) remain unaltered in n-3-deficient rats. The number of retinal pigment epithelium (RPE) phagosomes is reduced in n-3-deficient rats (66,73), but such changes seem unlikely to alter ERG components generated by the photoreceptors and bipolar cells within the first 70 msec after flash onset. Alteration in the local concentration of rhodopsin within the ROS would likely affect phototransduction sensitivity (30), and the rate of rhodopsin regeneration after a 100% bleach is slowed in n-3-deficient rats (72). However, slower rhodopsin regeneration is unlikely to have caused the ERG alterations in n-3-deficient rats and guinea pigs, given that all studies, with the exception of Watanabe *et al.* (66), allowed sufficient time to achieve full dark adaptation. There are conflicting reports as to the effect of altering the level of dietary n-3 fatty acids on absolute rhodopsin content in the retina after complete dark adaptation. Higher levels of rhodopsin have been reported in rats fed either an n-3-deficient diet (72) or a high DHA/EPA fish oil-supplemented diet (74) compared with rats fed a diet containing ALA as the sole n-3 fatty acid. Further experiments are required to determine whether altered rhodopsin levels underlie the sensitivity changes reported in rats and guinea pigs. Higher rhodopsin levels in n-3-deficient rats might be expected to lead to higher rather than lower sensitivity. However, low DHA in the membrane lipid environment of rhodopsin may reduce its photochemical activity and thus lower sensitivity. This possibility is supported by *in vitro* model membrane studies showing lower metarhodopsin II formation in membranes low in DHA (75–77).

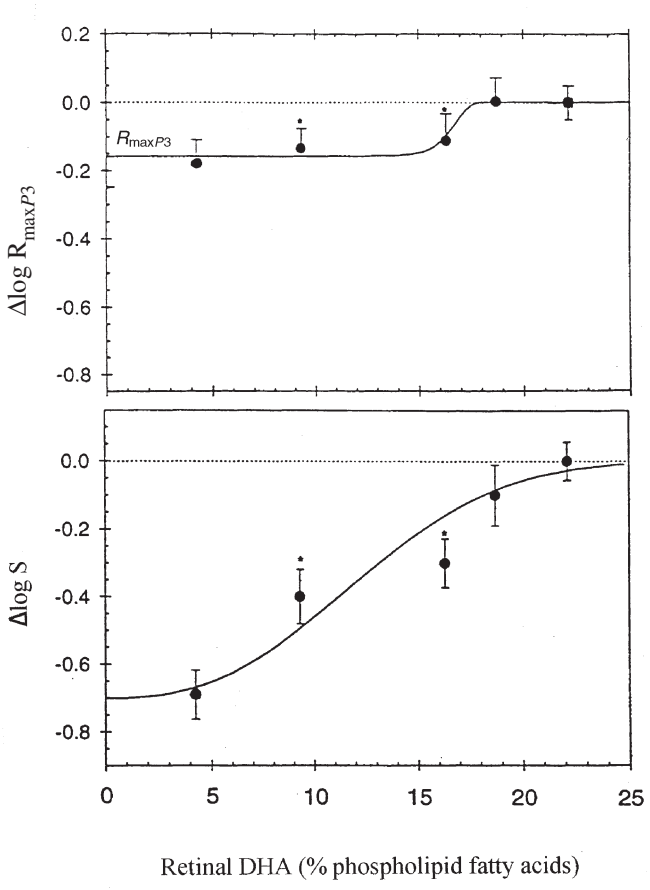

**FIG. 9.** Variation in $S$ (lower graph) and $R_{maxP3}$ (upper graph) with retinal docosahexaenoic acid (DHA) in 16-wk-old guinea pigs. Values are expressed as the change (Δlog value ± SEM) from control guinea pigs fed a canola oil-based diet. *Significantly different from the canola oil group, $P < 0.05$. Data were fit by a Weibell function to emphasize the transitions. Reproduced with permission from Reference 70.

Another possibility is that low retinal DHA affects the ERG through changes in ion channels. $R_{maxP3}$ is proportional to the magnitude of the circulating photocurrent, i.e., the number of open cGMP-gated ion channels within the retina (22). The number of cGMP-gated ion channels open at any given time is regulated by intracellular cGMP concentration, which in turn depends on the rates of cGMP hydrolysis and synthesis. A number of the mechanisms involved in determining the rates of cGMP hydrolysis and synthesis are $Ca^{2+}$ dependent (78). On the basis of the results from experiments in monkeys described below, it is speculated that a reduction in retinal DHA may alter the calcium current flowing into the photoreceptor outer segments through the cGMP-gated ion channels. Whether alteration in cytosolic $Ca^{2+}$ concentration underlies the reduction in $R_{maxP3}$ in n-3-deficient rats and guinea pigs remains to be determined.

No significant alterations in ERG a-wave and b-wave implicit times have been reported in n-3-deficient guinea pigs compared with those fed a high ALA diet (68,70). Rats fed a diet with DHA enriched at the *sn*-2 position of triglycerides had a 3.5–5.5% delay in ERG b-wave implicit times compared with rats fed either rat milk or a diet with DHA distributed equally across the *sn*-1, -2, and -3 positions (79). A caveat in interpreting this study is that the delay in ERG implicit times was present for only one of three flash intensities. Absolute retinal fatty acid levels were not significantly different between the two groups fed the experimental diets, but it would be of interest to know whether the experimental diets altered the dipolyene composition of the retinas. The retina is unique in containing a high level of dipolyenes, and these are known to increase the rate of rhodopsin activation (metarhodopsin II formation) compared with monoenes in recombinant membranes (76,77,80). Delays in metarhodopsin II formation or the rate of activation of the phototransduction proteins could slow the ERG response.

*Cats.* The effects of reducing retinal DHA levels in a single study of cats were quite different from those reported in

rats and guinea pigs. In 12-wk-old cats, ERG a-wave implicit times were delayed by 10% in those fed diets with differing levels of ALA (0.2–1.3%) compared with cats fed diets that contained LC-PUFA (>0.3% DHA, >0.5% AA) (81). There were no significant differences in ERG amplitudes between the groups. Delays in ERG b-wave implicit times in this study were reported, but are difficult to interpret because the ERG was recorded to a red flash that elicited a mixed rod/cone response. The mean ERG b-wave implicit time for the LC-PUFA-supplemented cats was 48.6 msec, consistent with the peak of the cone response (23), whereas the mean ERG b-wave implicit time for the ALA cats was 70.7 msec, consistent with the peak of the rod response (23). These results suggest that different ERG b-wave components were measured for the two diet groups, or that the relative amplitudes of these components were altered.

*Rhesus monkeys.* Neuringer and co-workers (82–85) fed two cohorts of rhesus monkeys diets that contained either 0.3% ALA (Low ALA) or 8% ALA (High ALA) as the sole n-3 fatty acid. The second cohort also included a third dietary group supplemented with LC-PUFA (0.6% DHA, 0.2% AA, and 0.2% EPA). ERG were recorded from the monkeys as infants (3–4 mon), juveniles (1–2 yr), and for the second cohort as young adults (4–6 yr). In the first cohort, Low ALA monkeys had reduced rod and cone ERG a-wave amplitudes as infants compared with the High ALA monkeys (84). This result was not repeated in the second cohort when they were tested at the same age or in either cohort when tested as juveniles or adults (62,84,86). In addition, there was a 5–10% delay in rod and cone ERG b-wave implicit times in the Low ALA monkeys when tested as juveniles and adults compared with monkeys fed the High ALA and LC-PUFA-supplemented diets (62,84,86).

The most marked and consistent alteration in retinal function in monkeys fed the Low ALA diet was a delay in the time required for the rod photoreceptors to recover after a light flash. When moderately intense flashes (2.6 log scot Td-sec) were separated by intervals of 20 sec, ERG amplitudes were not significantly different between the rhesus monkeys fed the Low ALA diet and those fed the High ALA diet. When the interval between flashes was reduced to 3.2 sec, ERG a- and b-wave amplitudes were reduced in both groups of monkeys, but there was a significantly greater reduction in the Low ALA monkeys compared with the High ALA monkeys (83–85). This effect was present in both cohorts of monkeys when tested as infants and juveniles. The reduction in ERG amplitude at short intervals between flashes suggested a delay in recovery of the rod photoreceptors, a conclusion recently confirmed in adult rhesus monkeys by measuring rod recovery with the paired flash method (62,86). The Low ALA monkeys were delayed by ~30% in reaching 50% recovery ($T_{50}$) compared with the 5% delay in ERG implicit times in the same monkeys (62). There was no effect of diet groups on the duration of complete rod saturation, $T_c$ (62).

Results from *in vitro* experiments using recombinant membranes and isolated cells suggest a number of possible mechanisms that could account for the delays in ERG b-wave implicit times and rod recovery in the Low ALA monkeys. Activation of the G-protein cascade involves contact between the activated proteins, R*, G*, and E* as the result of two-dimensional diffusion through the disk membrane lipid bilayer. It has been proposed that the high concentration of DHA and dipolyenes in the disk membrane imparts a number of biophysical properties (77) that should facilitate the diffusion of the phototransduction proteins through the disk membrane. Recent results demonstrate that the diffusion of transducin is faster in model membranes containing DHA at the *sn*-2 position than in membranes with oleic acid at the *sn*-2 position (87). Thus, slower diffusion of the phototransduction proteins through the lipid bilayer of the disk membrane may account for the small delays in ERG implicit times in n-3-deficient animals. The same principle could also apply to proteins such as rhodopsin kinase and recoverin, which are involved in the deactivation of R* and thus could help to explain part of the delay in rod recovery as well. However, the delay in rod recovery in the Low ALA adult rhesus monkeys was ~6 times greater than the delay in ERG implicit times, and this discrepancy suggests a separate mechanism in the recovery process that is altered in the Low ALA monkeys. One possibility is that a larger $Ca^{2+}$ current flows through the cGMP-gated cation channels of the Low ALA monkeys. There are numerous processes required for rod recovery, including the deactivation of the phototransduction proteins and the return of cytosolic cGMP concentration to preflash levels. Higher intracellular $Ca^{2+}$ slows the deactivation of metarhodopsin II and the synthesis of cGMP (88); the net effect of both is to slow the rate of rod recovery. DHA as a free fatty acid suppresses voltage-gated L type $Na^+$ and $Ca^{2+}$ channel currents in isolated neonatal and adult rat cardiomyocytes and in CA1 neurons from the rat hippocampus (89,90). Whether DHA similarly affects the cGMP-gated ion channel of the rod photoreceptor is unknown. A larger transient $Ca^{2+}$ influx through the cGMP-gated ion channels in the Low ALA monkeys could explain the observed delay in rod recovery.

*Comparison of ERG results among animal species.* The studies in rats, guinea pigs, cats, and rhesus monkeys highlight important species differences with respect to the effect of reducing retinal DHA levels on retinal function. It is unclear why these species should exhibit such contrasting ERG alterations in response to an n-3-deficient diet. In the ERG studies, rats and guinea pigs fed n-3-deficient diets had retinal DHA levels reduced by 30–65% in comparison with n-3-sufficient control animals. In the rhesus monkeys, retinal DHA was reduced by 50% at birth and by 80% at 2 yr of age compared with the High ALA control group. In each of the animal studies described, the fall in retinal DHA was largely compensated for by an increase in retinal 22:5n-6 and, to a lesser extent, 22:4n-6. These comparisons highlight the fact that the n-3-deficient diets used in each species induced similar changes in retinal fatty acids.

The timing of retinal development and accretion of DHA to the retina also appear to be unable to explain the different

ERG results between monkeys and guinea pigs. There is substantial growth and differentiation of retinal cells *in utero* in both monkeys and guinea pigs (53,91), and mothers were fed the same n-3-deficient diets in studies using both species. The structure of the monkey retina is quite different from that of rats and guinea pigs. In higher primates, cones account for ~5% of the total photoreceptors and interact with rods in a complex manner (92). The primate retina also has a macula, a central area containing the pigments, lutein, and zeaxanthin (93). At the center of the macula lies the fovea, a region with very high cone density that enables primates to achieve high visual acuity (94). The retinas of rats and guinea pigs by comparison are specialized for nocturnal vision, are dominated by rod photoreceptors, and have no macula or fovea. Therefore, rats and guinea pigs have excellent sensitivity in the dark but poor visual acuity. It is possible that these differences in retinal structure among species may account for the different effects on retinal function of lowering retinal DHA.

## CRITICAL PERIODS FOR ACCRETION OF DHA TO THE RETINA

A number of repletion studies have provided evidence for a "critical period" during retinal development when an inadequate supply of DHA to the retina will result in permanent retinal dysfunction that cannot be normalized even when retinal DHA is returned to normal.

A subset of the monkeys from cohort 1, described previously, was fed the Low ALA diet for 10–22 mon after birth before being switched to a fish oil-based diet containing 9% DHA and 13% EPA (wt% of total fatty acids) (60). After 9 mon of dietary repletion, when DHA levels had increased to above normal, repleted monkeys still had delayed ERG b-wave implicit times and a greater reduction in ERG b-wave amplitude at short interflash intervals compared with control monkeys (84). In this study, repletion was initiated at ages when rhesus monkeys have an adult-like retina (53,95). In one monkey repleted with 1.6% DHA ethyl ester from 4 mon of age, when the retina is not fully developed, the ERG normalized by 2 yr of age (96).

In a study by Armitage *et al*. (71), rats were fed either a safflower oil-based diet with 1% ALA and a LA/ALA ratio of 72:1 or a canola oil-based diet with 8% ALA and a LA/ALA ratio of 2.5:1. At 8 wk of age, half of the rats fed the safflower diet were switched to the canola oil diet for 25 wk. By 33 wk, there were no significant differences in retinal DHA levels between the repleted rats and those fed the canola oil diet. Nevertheless, the repleted rats had a 60% reduction in $R_{\max P3}$ compared with the those fed the canola oil diet. In a similar repletion study using the same diets, no ERG alterations were found in guinea pigs after retinal DHA levels were returned to within 85% of normal after repletion from 5 to 16 wk. In both species, repletion was initiated at an age when the retina has functionally reached adult levels (97).

The above results provide strong support for the existence of a critical period in both monkeys and rats in which DHA must be accreted to the retina to achieve normal development of retinal function. The length of these critical periods with regard to either age or the stage of retinal development has yet to be determined.

## A ROLE FOR DHA IN THE REGENERATION OF RHODOPSIN

Rhodopsin is formed in the disk membrane of the retinal ROS when opsin binds its chromophore, 11-*cis* retinal. The capture of light by 11-*cis* retinal results in its isomerization to all-*trans* retinal and leads to the formation of metarhodopsin II. After deactivation of metarhodopsin II, some of the all-*trans* retinal separates from opsin and is converted to all-*trans* retinol. Regeneration of rhodopsin from these components is a two-step process. First, all-*trans* retinol must be removed from the ROS and transferred to the RPE. Second, a new 11-*cis* retinal molecule manufactured within the RPE must be transferred to the ROS, where it binds opsin to form a new rhodopsin molecule. The mechanism whereby the highly insoluble retinoids, 11-*cis* retinal and all-*trans* retinal, are transferred across the aqueous interphotoreceptor matrix between the RPE and the ROS is known to involve the interphotoreceptor retinal binding proteins (IRBP). The IBRP are the major soluble proteins within the interphotoreceptor matrix, and bind both retinoids and fatty acids (98).

In a single fluorescence study, DHA had the highest affinity for IRBP, twice that of AA and three times that of ALA (99). A subsequent fluorescence study found that DHA hindered the interaction of 11-*cis* retinal at a hydrophilic binding site on IRBP and also facilitated the dissociation of 11-*cis* retinal from this binding site (100). In contrast, DHA did not alter the interaction or dissociation of all-*trans* retinol with IRBP. Preliminary data indicate that AA does not affect the interaction of 11-*cis*-retinal with IRBP (100).

Chen *et al*. (100) reported that the concentration of DHA noncovalently bound to IRBP represented 8.6% of total bound fatty acids in bovine retina. In the same retinas, DHA accounted for 20 and 3.5% of lipids in ROS and RPE, respectively. Thus, there is a DHA concentration gradient between the ROS and RPE. On the basis of the presence of this concentration gradient and the above fluorescence studies, Chen *et al*. (100) proposed the following model for how DHA modulates the transfer of retinoids between the RPE and ROS. When IRBP is located near the RPE, it binds a saturated fatty acid, resulting in high affinity for 11-*cis* retinal at the IRBP hydrophilic binding site. When the IRBP approaches the ROS, DHA will displace the saturated fatty acid from the IRBP because of its higher affinity. The binding of DHA to IRBP will in turn cause a rapid dissociation of 11-*cis* retinal, which moves into the ROS. DHA does not affect the binding affinity of all-*trans* retinol, which moves from the ROS into the hydrophilic binding site on IRBP that was previously occupied by 11-*cis* retinal. When IRBP moves back near the RPE, the process is reversed as DHA is swapped for a saturated fatty acid and the retinoid binding site regains its affinity for 11-*cis* retinal.

There is strong evidence from a single study to suggest that DHA plays an important role in the regeneration of rhodopsin. An 80% reduction in retinal DHA level in n-3-deficient rats was associated with a significantly slower rate of rhodopsin regeneration after a 100% bleach (72). The 11-*cis* retinal necessary for forming rhodopsin is synthesized in the RPE from all-*trans* retinol. The RPE obtains all-*trans* retinol from the choroidal blood supply, and in many mammals, the RPE acts as a secondary store for all-*trans* retinol (9). In rats, the RPE is a relatively weak store for all-*trans* retinol (9), which may make rats more susceptible than other mammals to the effect of lower DHA levels on the rate of rhodopsin regeneration.

## SUMMARY AND CONCLUSIONS

Early studies in this field provided conclusive evidence that a reduction in retinal DHA level was associated with altered retinal function as assessed with the ERG. Recent studies have extended these findings to include specific alterations in photoreceptor function in n-3-deficient animals, including slower rod recovery in monkeys and reductions in the maximal response and phototransduction sensitivity in guinea pigs and rats. On the basis of the experiments in n-3–deficient animals, it has been proposed that DHA serves a number of important roles in photoreceptor function, including regulation of retinoid transport between the RPE and ROS and regulation of the $Ca^{2+}$ photocurrent through the cGMP-gated ion channels. It was also proposed that DHA provides the membrane properties that allow the phototransduction proteins to diffuse rapidly through the lipid bilayer of the disk membranes.

The alterations in phototransduction and rod recovery mechanisms in the retina of n-3-deficient animals may be applicable to similar mechanisms in other tissues with high DHA concentration. DHA is also found at high levels within the brain (83,101), which lacks the same efficient mechanism for DHA conservation present within the retina. Several of the mechanisms studied within the photoreceptor are found elsewhere in the body. For example, the phototransduction cascade has a high degree of commonality with the many other signal transduction pathways mediated by G proteins (12,102). Although the ligands may include light, neurotransmitters or hormones, once initiated, the respective G-protein cascades are remarkably similar (12,102). DHA is also found in high concentration within synapses (103,104) where calcium also plays an important role in the modulation of neurotransmitter release (105). The results from ERG experiments with n-3-deficient animals may therefore be relevant for many other neural and physiologic processes. They may also have implications for human infant nutrition despite the lack of ERG alterations beyond 6 wk of age in human infants fed a diet without DHA supplementation.

# Randomized Trials with Polyunsaturated Fatty Acid Interventions in Preterm and Term Infants: Functional and Clinical Outcomes

**Robert A. Gibson[a,*], Wenxiong Chen[b], and Maria Makrides[a]**

[a]Child Health Research Institute at Flinders Centre and Women's & Children's Hospital, Adelaide, SA Australia, and [b]Department of Paediatrics, Fujian Medical University Affiliated Union Hospital, Fuzhou, Fujian, China

**ABSTRACT:** The role of polyunsaturated fatty acids (PUFA) in infant nutrition has now been well studied through many randomized controlled trials (RCT) that provide us with high-quality evidence, particularly in relation to efficacy. As a result of a systematic search of the literature for RCT of supplementation of formulas of term and preterm infants with long-chain polyunsaturated fatty acids (LC-PUFA), we have identified 21 studies that have physiological responses or growth as outcomes. There have been 11 RCT involving preterm infants, and many of these claim a beneficial effect on visual, neural, or developmental outcomes. There are some reports of negative effects on growth in relation to the addition of n-3 LC-PUFA to preterm formulas but not when AA is added with n-3 LC-PUFA. Small studies have shown no differences in prostanoid formation or peroxidative stress between n-3 LC-PUFA-supplemented and unsupplemented infants. There have been 10 RCT involving term infants; whereas some studies report an effect on visual/neural/developmental outcomes, an equal number report no effect. There have been no reports of negative effects of n-3 LC-PUFA on growth in term infants. In summary, there appear to be few safety concerns relating to the use of LC-PUFA in infant nutrition. The potential medium- and long-term effects of including these compounds in the early diet of infants remain to be assessed.

Paper no. L8724 in *Lipids 36*, 873–883 (September 2001).

Unlike the roles of many other nutrients in infant nutrition, the role of polyunsaturated fatty acids (PUFA) has been well studied through numerous randomized controlled trials (RCT) that provide us with high-quality evidence. For this reason, primary consideration in this review is given to the results of RCT because these studies limit the bias and confounding influences such as those associated with comparisons between breast-fed and formula-fed infants. The aim of this paper is to bring together all the fully published RCT testing the effects of supplementation with PUFA on growth or other physiological measures reported to date. Observational studies, comparisons of breast-fed and formula-fed infants, or controlled trials with only biochemical outcomes have not been included in this review.

A systematic literature search was undertaken using the Medline database. In most cases, the complete database was searched and the date of the last search was June 28, 2001. Search terms used included: infant food, formula or milk, infant, docosahexaenoic acid, arachidonic acid, alpha-linolenic acid, n-3 (omega-3) fatty acid, linoleic acid, n-6 (omega-6) fatty acid, growth, visual acuity, neural development, and randomized controlled trial. The names of authors who had published relevant studies were also used as search terms to identify previous or more recent work that may be appropriate. Search limits included human and English language.

To the nonexpert, reviewing this area can be confusing because many trials have been reported in more than one paper. For example, results from the very first trial with clinical outcomes involving long-chain polyunsaturated fatty acid (LC-PUFA) supplementation to preterm infants have been reported in at least five separate papers (1–5).

## TRIALS INCLUDING LC-PUFA IN PRETERM INFANTS

Our literature search identified 11 RCT reported in 22 separate papers (1–22). These trials were designed to test the efficacy and safety of varying levels of eicosapentaenoic acid (EPA, 20:5n-3), docosahexaenoic acid (DHA, 22:6n-3), and arachidonic acid (AA, 20:4n-6) in the diets of preterm infants. These trials are summarized in Table 1.

All trials involved healthy preterm infants fed preterm formula, and 8 of 11 trials had a breast-fed reference group (1,11–13,15,19–21). Only one (15,16) of these trials reported adequate concealment of allocation, and 9 of 11 trials were either unclear regarding losses to follow-up or failed to follow up ≥20% of infants randomly allocated to treatment groups. Not all trials were analyzed on an intention-to-treat basis, with infants developing complications after randomization either being excluded or withdrawn from the trials. Only one study (9) attempted to specifically address the effect of n-3 LC-PUFA supplementation in preterm infants with bronchopulmonnary dysplasia (BPD), a major cause of medical complication in preterm infants.

Abbreviations: AA, arachidonic acid; ALA, α-linolenic acid; BAEP, brainstem auditory-evoked potential; BPD, bronchopulmonary dysplasia; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; ERG, electroretinogram; LA, linoleic acid; LC-PUFA, long-chain polyunsaturated fatty acid; PUFA, polyunsaturated fatty acids; RCT, randomized controlled trials; VEP, visual-evoked potential.

**TABLE 1**
**Intervention Trials Involving Supplementation with Long-Chain Polyunsaturated Fatty Acids (LCPUFA) from a Variety of Sources in Preterm Infants[a]**

| Trial results reported by: | Age and characteristics at start of study | Type of intervention | How were the groups allocated? | Number of infants enrolled per group | Blinded outcome assessment (yes/no) | Outcome measures and results | Percentage of dropouts (loss to follow-up) | Other comments | Power calculation (yes/no) |
|---|---|---|---|---|---|---|---|---|---|
| Birch *et al.* (1,2), Uauy *et al.* (3), Uauy *et al.* (4), Hoffman and Uauy (5), plus other not listed | Healthy preterm infants | FC1 = LA/ALA, 24:0.5; FC2 = LA/ALA 21:2.7; FFO = LA/ALA, 20:1.4 + FO (0.65% EPA, 0.35% DHA, 0.1% AA); BM. | Random, no details regarding assignment. | 83 enrolled; initial distribution among groups unclear. | Yes | SS VEP acuity and visual acuity cards at 36 and 57 wk PMA: BM and FFO better than FC1; FC2 had intermediate value.<br>Rod ERG at 36 wk PMA:<br>Rod threshold: BM, FFO shorter than FC1; FC2 not diff. from other groups.<br>$V_{max}$: BM; FFO higher than FC1; FC2 not diff. from other groups.<br>Log *K*: BM, FFO shorter than FC1; FC2 not diff. from other groups.<br>Rod ERG at 57 wk: Not diff. among groups for any parameters.<br>Cone ERG: At 36 and 57 wk PMA not diff. among groups.<br>Oscillatory potentials: At 36 wk PMA, not detectable. At 57 wk PMA, dark adapted: not diff. among groups; light adapted: generally implicit times of BM shorter than FC1.<br>Growth: No effect of diet.<br>Bleeding times: All within normal range but FFO longer compared with FC1.<br>Vitamin A and E: No diff. with diet.<br>RBC membrane fluidity: No diff. with diet. | 16% at 40 wk PMA<br>37% at 57 wk PMA | When insufficient breast milk available for BM groups, infants were fed FFO. | Yes for some outcomes |
| Carlson *et al.* (6,7, 22), Werkman and Carlson (8) | Healthy preterm infants exclusively fed formula | FC = LA/ALA, 19:3 up to 1800 g, then LA/ALA; 33:4.8; FFO = FC + FO (0.36% EPA, 0.2% DHA). | Random, no details regarding assignment. | 79 enrolled; unclear distribution between groups at assignment; completed; FC = 34, FFO = 33. | Partial | Visual acuity cards: At 2 and 4 mon CA, FFO better than FC; no diff. between groups at 6.5, 9, and 12 mon CA.<br>Growth (z-scores for weight, length, head circumference): FFO infants lower z-scores at 2, 4, 6.5, 9, 12 mon CA than FC.<br>Fagan test: No diff. in novelty preference at 6.5, 9, and 12 mon CA; FFO compared with FC infants had more and shorter duration looks.<br>Bayley's MDI and PDI: No diff. at 12 mon CA. | Unclear, 10/79 infants replaced post-randomization | 3 of the 67 infants were diagnosed with BPD; size at term was interpolated from 38 and 48 wk PMA data. | Yes |
| Carlson *et al.* (9, 22), Carlson and Werkman (10) | Preterm infants exclusively fed formula | FC = LA/ALA, 21:2.4; FFO = FC + FO (0.06% EPA, 0.2% DHA); these formulas fed to 2 mon CA and then both groups fed LA/ALA = 34:5. | Random, no details regarding assignment. | 94 enrolled; 35 excluded or lost to follow-up; completed to 2 mon CA: FC = 33, FFO = 26. | Yes | Visual acuity cards: at 2 mon CA, FFO better than FC; interaction between BPD and diet. At 2 mon, infants without BPD and fed FFO had better acuity than all other infants.<br>No other acuity differences due to diet at other ages.<br>Growth: Compared with FC, FFO had lower weight z-score at 6 and 9 mon CA, smaller head circumference z-score at 9 mon CA and lower weight-for-length at 2, 6, 9, and 12 mon CA.<br>Fagan test (subgroup): FFO compared with FC had more and shorter duration looks at 12 mon CA; | Unclear, infants replaced post-randomization | 15 BPD in FC and 8 BPD in FFO; more FC infants than FFO infants lost to follow-up. | Yes |

| | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | | | | | | no diff. between groups on novelty preference at 12 mon CA. Bayley's MDI: FFO > FC at 12 mon CA. Bayley's PDI: No diff. between groups at 12 mon CA. | | | |
| Faldella *et al.* (11) | Healthy preterm infants fed formula or breast milk | FC = LA/ALA, 19:0.9; FEPL = LA/ALA, 11:0.7 + 0.3% DHA, 0.05% EPA, 0.44% AA; BM (fed FEPL when necessary). | Random, method of assignment not stated. | FC = 26, FEPL = 23, BM = 17. | Yes | Flash VEP latency for $N_4$ and $P_4$: BM FEPL shorter than FC at 52 wk PMA. BAEP: No diff. between groups. Flash ERG: No diff. between groups. Growth: No diff. between groups. | FC = 4%, FEPL = 10%, BM = 30% | ERG methdology not according to International Standards. Formula-fed infants received <25% intake from BM. | No |
| Bougle *et al.* (12) | Healthy preterm infants fed formula or breast milk | FC = LA/ALA, 14:1.3; FFO = LA/ALA, 18:1.2 + 0.1% EPA, 0.6% DHA, 0.1% AA; BM. All diets fed for 30 d. | Random, double blind, no other details. | FC = 11, FFO = 14, BM = 15. | Yes | VEP latency: No diff. between groups 30 d post-treatment. BAEP: No diff. between groups 30 d post-treatment. Nerve conduction: FFO slower than BM; FC intermediate. Growth: Weight gain greater in FFO than BM or FC. | FC = 18%, FFO = 7%, BM = 27% | Mean weight not diff. between groups. Dietary intake of infants in FFO group > intake of FC and BM groups. | No |
| Clandinin *et al.* (13,14) | Healthy preterm infants fed formula or breast milk | FC = LA/ALA, 13:1.4; FAF1 = FC + 0.24% DHA, 0.32% AA; FAF2 = FC + 0.35% DHA, 0.49 AA; FAF3 = FC + 0.76% DHA, 1.1% AA; BM. All diets fed for 6 wk. | Controlled clinical trial; details of allocation not clear. | FC = 22, FAF1 = 22, FAF2 = 22, FAF3 = 18, BM = 33. | Not stated | Growth: Weight gain and length. gain over the 6-wk study period not diff. between formula groups; some differences noted between breast-fed and formula-fed infants. | FC = 18%, FAF1 = 18%, FAF2 = 18%, FAF3 = 33%, BM = 24% | Comparison of growth: No adjustment for baseline variables. | No |
| Vanderhoof *et al.* (15,16); Field *et al.* (17) | Healthy preterm infants fed formula or breast milk | FC = LA/ALA, 13:1.4; FAF = LA/ALA, 12:1.5 + 0.35% DHA, 0.50% AA; BM. All diets fed to 48 wk PMA. | Formula groups assigned by "a central computerized system of automatic randomization." Stratified by birth weight. Breast-fed reference group was not randomized. | FC = 78, FAF = 77, BM = 33. Subgroup tested for immune outcomes: FC = 12, FAF = 15, BM = 17. | Yes (formula groups only) | Growth: No diff. in weight, length, head circumference or mid-arm circumference between formula groups at full feeds 40, 48, and 92 wk PMA; some differences noted between breast- and formula-fed infants at all ages. Subgroup tested for immune markers: At 42 d, total T cells T-CD4, and CD4/CD8 ratio in BM and FSCO diff. in FC. Mononuclear cell phenotypes: More mature in BM and FSCO compared with FC. | Until 48 wk PMA; FC = 36%, FSCO = 38%, BM = 60%; until 92 wk unclear. | Many withdrawn and excluded infants to ensure healthy study groups. Small sample sizes for immune outcomes. | Yes, for growth at 40 wk PMA only |
| Ryan *et al.* (18) | Healthy low-birth-weight infants (750–2250 g) exclusively fed formula prior to | FC = LA/ALA, 17:2.5 to 43 wk PMA, then LA/ALA, 22.4:2.4 to 59 wk PMA; | Blinded random assignment; each study center had | FC = 45, FFO = 45. | Yes | Growth: Between enrollment and 59 wk PMA, males fed FFO had lower weight, shorter lengths, and smaller head circumferences than FC; no diff. in female infants. | FC = 27%, FFO = 33% | Many withdrawn and excluded infants. 4 SIDS deaths | Yes, for weight gain |

**(Continued)**

| Trial results reported by: | Age and characteristics at start of study | Type of intervention | How were the groups allocated? | Number of infants enrolled per group | Blinded outcome assessment (yes/no) | Outcome measures and results | Percentage of dropouts (loss to follow-up) | Other comments | Power calculation (yes/no) |
|---|---|---|---|---|---|---|---|---|---|
| | enrollment; enrollment was 7–10 d before discharge | FFO = LA/ALA, 16:2.3 + 0.2% DHA, 0.04% EPA to 43 wk PMA, then LA/ALA 21:2.0 + 0.2% DHA, 0.07% EPA to 59 wk PMA. | own randomization schedule; all schedules were prepared in a central location. | | | Male infants in FFO drank less formula than male infants in FC. | | in the FFO group and 0 deaths in the FC group. Investigators and ethics review considered each death unrelated to formula assignment. | |
| Diersen-Schade *et al.* (19) | Healthy very-low-birth-weight infants (846–1560 g) exclusively fed formula; healthy term infants breast-fed for at least 4 mon (85% of nutrition from breast milk) | FC = LA/ALA, 22:3.1; FA = FC + 0.34% DHA; FAF = FC + 0.33% DHA, 0.60% AA. All formulas fed for at least 28 d and then graded onto standard, non-LC-PUFA term formula to 57 wk PMA. BM (term infants). | Randomized study; no details of allocation procedures. | 194 enrolled; unclear about group distributions at enrollment. At 40 wk PMA, FC = 52, FA = 54, FAF = 59, BM = 90. | Yes | Weight: No diff. between formula groups at 40 and 57 wk PMA, but at 48 wk PMA FAF > FA, FC. Length: FAF > FA at 40 and 48 wk PMA but not at 57 wk PMA; no diff. between FC and FAF. Head circumference: No diff. between formula groups at any time. Weight and length of BM group generally greater than all preterm groups. | Unclear over whole study duration; study formula phase, 9% | Number of infants in study groups at each assessment not stated. | Stated for weight, but no details given |
| Stier *et al.* (20) | Healthy preterm infants (<2000 g) fed formula or breast milk | FC = LA/ALA, 19:0.9; FEPL = LA/ALA, 12:0.6 + 0.2% DHA, 0.35% AA; BM. All diets fed for a 3-wk period while infants in hospitals. | Randomized study; no details of allocation procedure given. | FC = 10, FEPL = 10, BM = 10. | Yes | Urinary prostanoid excretion: No diff. between groups at end of diet treatment. Growth: No diff. between groups at end of diet treatment. | Unclear | Small sample sizes. | No |
| Jacobs *et al.* (21) | Healthy preterm infants (30–35 wk gestation) fed formula or breast milk | FC = LA/ALA, 17:1.6; FFO = LA/ALA, 11:1.8 + 0.5% DHA, 0.5% EPA: BM. Diets fed for 6 wk. | Randomly assigned for formula groups; no other details regarding allocation. | Total enrolled unclear. Included in the analysis: FC = 15, FFO = 13, BM = 7. | Yes for formula groups | Growth: Gains in weight, length, and head circumference not diff. between FC and FFO. Weight and head circumference gains were greater in formula-fed infants than BM group. No. diff. between groups for plasma vitamin E and C levels, plasma TBARS, or reduced/oxidized glutathione ratio. FFO group had reduced susceptibility of red blood cells to $H_2O_2$ oxidative stress compared with FC and BM groups. | Unclear | Small sample sizes. | No |

[a]Abbreviations: BM, breast milk fed; FC, control (standard) infant formula; FFO, formula supplemented with fish oil; FEPL, formula supplemented with egg phospholipid; FO, fish oil; FA, formula supplemented with algal oil; FAF, formula supplemented with algal and fungal oils; FSCO, formula supplemented with single-cell oils; ALA, α-linolenic acid; LA, linoleic acid; AA, arachidonic acid; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid; BAEP, brainstem auditory-evoked potential; ERG, electroretinogram; BPD, bronchopulmonary dysplasia; VEP, visual-evoked potential; SS, steady-state; TBARS, thiobarbituric acid-reactive substances; CA, corrected age; PMA, postmenstrual age; MDI, Mental Developmental Index; PDI, Psychomotor Developmental Index; RBC, red blood cell; d, days; mon, months; wk, weeks.

Up until 1996, fish oil of the MaxEPA type containing more EPA than DHA (15 vs. 11% of total fatty acids) was used as a source of DHA, whereas in breast milk the proportion of EPA rarely exceeds that of DHA. EPA is the precursor to 3-series eicosanoids which may suppress some effects of the 2-series eicosanoids originating from AA. Some studies (9,18) have avoided the addition of excessive EPA by using fish oils high in DHA, such as tuna oil. Other studies used other sources of LC-PUFA such as fractions of egg phospholipids (11,20) or fungal and algal oil (15,16,19). It is doubtful whether the source of LC-PUFA has much effect on LC-PUFA status of the infant (23).

Most workers investigating the potential benefits of LC-PUFA supplementation of preterm infants have assessed infant sensory modalities. Most trials have assessed aspects of visual function, including the sensitivity of the retina to light (2,11), visual-evoked potential (VEP) latency (11,12), or visual acuity measured by VEP or tested by behavioral means (cards) (1,6,9). More complex visual behaviors such as novelty preference and infant looking behavior to paired comparisons have also been assessed (8,10). Other efficacy assessments have included brainstem auditory-evoked potential (BAEP) (11,12), nerve conduction studies (12), and the Bayley Scales of Infant Development (22). In most trials, infant growth has been employed as a measure of safety, although some trials have used other surrogate markers of safety such as vitamin A and E levels (4), bleeding times (4), prostanoid formation (20), and measures of oxidative stress (4,5,21).

Benefits of adding n-3 LC-PUFA to preterm infant formulas (with or without AA) on electroretinographic responses and VEP acuity have been reported in one study (1,2). Benefits have also been reported on visual acuity assessed *via* cards (Teller) in all trials that used this outcome (1,6,9). One study (11) detected a benefit of LC-PUFA supplementation on VEP (flash) latency, whereas another study (12) showed no benefit of LC-PUFA supplementation on VEP (transient) latency. Visual recognition memory (novelty preference) and visual attention (number and duration of discrete looks) were determined with the Fagan Test of Infant Intelligence by two trials (8,10) from one center, which reported that the DHA-supplemented group compared with the control group had more and shorter-duration looks in comparisons of familiar and novel stimuli.

Studies investigating other sensory modalities have reported no effect of dietary LC-PUFA on BAEP (11,12). The only potential negative finding relating to LC-PUFA–supplementation of preterm infants has come from somatosensory assessments where preterm infants fed n-3 LC-PUFA–supplemented formula had slower peripheral nerve conduction than infants in the human milk group (12).

The immune consequences of adding AA and DHA to preterm infant formula have been reported in a small subgroup of one trial (17), which found that adding AA and DHA to a preterm infant formula resulted in lymphocyte populations, cytokine production, and antigen maturity that were more consistent with those in human milk-fed infants. This may affect the ability of the infant to respond to immune challenges.

Two initial trials (7,9) and one more recent study (18) that supplemented infant formula with fish oil suggested negative effects on growth, although other studies (4,12,21) reported no effect of fish oil supplementation on growth. The possibility that fish oil treatment had negative effects on growth through a lowering in infant AA status remains a significant cause for concern, although all the studies assessing fish oil supplementation and growth of preterm infants had flaws that could have influenced growth outcomes. Nevertheless, most recent trials have attempted to add AA with n-3 LC-PUFA to avoid the decline in plasma and erythrocyte AA caused by fish oil supplementation. The five trials (11,13,15,19,20) that added both n-3 and n-6 LC-PUFA reported no adverse effects on growth. In fact, one of these five trials claimed benefits of both AA and DHA supplementation on growth, although shortcomings in the design and analysis may have contributed to these findings.

Stier *et al.* reported that neither conventional formula nor supplementation of a preterm formula with LC-PUFA for a period of 3 wk substantially influenced prostanoid formation in healthy infants (20). In addition, other trials found that supplementation of n-3 LC-PUFA had no effect on vitamin A, E, or C levels, plasma thiobarbituric acid-reactive substances (TBARS), and reduced/oxidized glutathione ratio but found reduced susceptibility of erythrocyte membranes to $H_2O_2$ treatment (4,5,21). All three trials had relatively small sample sizes and thus had limited power (4,5,20,21).

Although there are still some concerns on safety issues regarding the addition of LC-PUFA to preterm infant formula, the evidence in support of a beneficial effect of such supplementation on visual function is relatively compelling. Moreover, it seems that the possible negative effects of n-3 LC-PUFA on growth of preterm infants have been overcome through improved study design and/or the addition of a balance of n-6 and n-3 LC-PUFA.

## TRIALS INVOLVING LC-PUFA SUPPLEMENTATION OF TERM INFANTS

Our literature search identified 10 RCT (24–38) that were designed to test the efficacy and safety of adding either n-3 LC-PUFA or a combination of n-3 LC-PUFA and AA to formulas for term infants. These trials are summarized in Table 2.

All trials involved healthy term infants fed formulas from near birth, and all but one had a breast-fed reference group (Table 2). Most trials appeared to have adequate randomization and masking procedures, and most presented power calculations for their primary outcome measurements. Five of 10 trials reported less than 20% loss to follow-up among the randomly allocated formula-fed infants.

VEP acuity was an outcome measure in five studies, while acuity was tested through the use of cards in three studies. Various standardized and unstandardized developmental tests were used as outcome measures in six studies. Growth was assessed in most trials.

There have been no negative findings in relation to growth in term infants regarding LC-PUFA supplementation of in-

**TABLE 2**
**Intervention Trials Involving Supplementation with LC-PUFA from a Variety of Sources in Term Infants[a]**

| Trial results reported by: | Age and characteristics at start of study | Type of intervention | How were the groups allocated? | Number of infants enrolled per group | Blinded outcome assessment (yes/no) | Outcome measures and results | Percentage of dropouts (loss to follow-up) | Other comments | Power calculation (yes/no) |
|---|---|---|---|---|---|---|---|---|---|
| Makrides *et al.* (24) | Healthy term infants exclusively fed formula or breast milk | FC = LA/ALA, 17:1.6; FFO + EPO = LA/ALA, 17:1.5 + 0.58% EPA, 0.36% DHA, 0.27% GLA; BM. Diets fed from <5 d to 30 wk. | Random; method not stated. | 89 enrolled; completed: FC = 19, FFO + EPO = 13, BM = 23, partial BM = 24 | Yes | VEP acuity: FFO + EPO, BM better than FC at 16 and 30 wk.<br>Growth: No effect of diet. | Overall dropout = 11% | Uneven randomized groups due to unavailability of test formula | Yes |
| Auestad *et al.* (25); Scott *et al.* (26) | Healthy term infants exclusively fed formula or breast milk | FC = LA/ALA, 22:2.2; FEPL = LA/ALA, 22:1.9 + 0.12% DHA, 0.43% AA; FFO = LA/ALA, 21:1.9 + 0.23% DHA, 0.07% EPA; BM ≥ mon. Diets fed from <7 d to 12 mon. | Central preparation of randomization schedules; separate randomization at each of 3 centers; details of allocation not stated. | FC = 65, FEPL = 68, FFO = 65, BM = 76 | Yes | Sweep VEP and acuity cards: No diff. with diet at 2, 4, 9, and 12 mon.<br>Growth: No diff. with diet at 2, 4, 6, 9, and 12 mon.<br>Bayley's MDI and PDI: No effect of diet at 12 mon.<br>McArthur CDI: In one sub-scale, FFO < FC, FEPL, and BM at 14 mon. | FC = 31%, FEPL = 32%, FFO = 34%, BM = 17% | Each of the 3 sites had different visual acuity protocols | No |
| Carlson *et al.* (27) | Healthy term infants exclusively fed formulas or breast milk | FC = LA/ALA, 22:2.2; FEPL = LA/ALA, 22:2.0 + 0.1% DHA, 0.43% AA; BM ≥ 3 mon. | Random, double-blind study; details of allocation not stated. | FC = 31, FEPL = 28, BM = 35 | Yes | Card visual acuity: BM, FEPL groups better than FC at 2 mon but no diff. between groups at 4, 6, 9, and 12 mon. | FC = 35%, FEPL = 32%, BM = 46% | Well-balanced groups; well-designed study | Yes for card acuity |
| Agostoni *et al.* (28, 29) | Healthy term infants exclusively fed formula or breast milk | FC = LA/ALA, 11:0.7; FEPL + EPO = FC + 0.3% DHA, 0.44% AA, 0.05% EPA, 0.3% GLA; BM. Diets fed from 3 d to 4 mon. | Random—no details on method of allocation. | FC = 31, FEPL + EPO = 29, BM = 30 | Yes | Brunet–Lezine DQ: FEPL + EPO and BM groups higher scores at 4 mon. No diff. between groups at 24 mon. | At 4 mon: No losses to follow-up.<br>At 24 mon: FC = 3%, FEPL + EPO = 10%, BM = 17% | Well-balanced groups; well-designed study | Yes for DQ at 4 mon |
| Makrides *et al.* (30,31) | Healthy term infants fed formula or breast milk | FC = LA/ALA, 17:1.5; FFO = LA/ALA, 17:1.2 + 0.35% DHA, 0.1% EPA; FEPL = LA/ALA, 17:1.0 + 0.34% DHA, 0.34% AA; BM. Diets fed from <7 d to 12 mon. | Randomization and allocation adequately concealed. | FC = 28, FFO = 27, FEPL = 28, BM = 63 | Yes | VEP acuity: No diff. in formula groups at 16 and 34 wk; BM better than formula groups at 34 wk.<br>Bayley's MDI and PDI: No diff. between formula groups at 1 or 2 yr; BM better at 2 yr.<br>Growth: No diff. between formula groups in weight, length, or head circumference at 6, 16, and 34 wk, 1, 2 yr. BM group had lower weight and length at 34 wk and 1 yr than formula groups. | FC = 25% FFO = 15%, FEPL = 14%, BM = 27% | Well-designed study | Yes for VEP acuity and growth |

| | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| Lucas *et al.* (32) | Healthy term infants fed formula or breast milk from birth | FC = LA/ALA, 12:1.1; FEPL = LA/ALA, 16:1.4 + 0.32% DHA, 0.30% AA for 6 mon, then formula of choice; BM ≥ 6 wk. | Random permuted block design stratified by site and gender; concealed assignment. | FC = 155; FEPL = 154, BM = 138 | Yes | Bayley's MDI and PDI: No effect of diet at 18 mon. Language, motor, and social scales: No effect of diet at 9 mon. Growth: No diff. between formula groups. Infection and atopy to 9 mon: No diff. between formula groups. | FC = 19%, FEPL = 19%, BM = 25% | | Yes for Bayley's MDI and PDI |
| Jorgenensen *et al.* (33) | Healthy term infants, fully formula feeding at 1 mon, 2 BM groups, one cross-sectional and one prospective | FC = LA/ALA, 12:1.2; FFO = FC + FO, 0.32% DHA, 0.39% EPA, 0.60% AA; FFO + BO = LA/ALA, 13:1.2 + 0.32% DHA, 0.37% EPA, 0.06% AA, 0.54% GLA; BM (2 groups). | Random and masked assignment. | FC = 11, FFO = 12, FFO + BO = 14, BM1 = 17 (prospective for growth), BM2 = 25 (cross-sectional for sweep VEP reference) | Yes | Sweep VEP acuity: No diff. between formula groups at 4 mon, BM2 better acuity than FC group. Growth: No diff. in weight length, or head circumference between groups at 1, 2, and 4 mon. | Unclear | Successful VEP tests: 18/26 (combined FFO and FFO + BO) and 8 (FC) | Yes for sweep VEP acuity; did not reach estimated sample size in all groups |
| Willatts *et al.* (34, 35) | Healthy term infants exclusively fed formula from birth | FC = LA/ALA 11:0.7; FEPL = LA/ALA, 12:0.63 + 0.2% DHA, 0.35% AA. Diets fed to 4 mon. | Randomized using computer-generated schedule; no details about concealment at allocation. | FC = 38, FEPL = 34; some inconsistency between the two reports | Yes | Means–end problem solving: No diff. between groups at 9 mon; more solutions in FEPL group compared with FC at 10 mon. Growth: No diff. in weight length, head circumference, skinfolds at 3 mon. | Unclear as inconsistent between the two reports | Developmental test unvalidated | Yes for problem-solving task |
| Birch *et al.* (36,37) | Healthy term infants fed formula or breast milk from birth | FC = LA/ALA, 15:1.5; FA = FC + 0.35% DHA; FAF = FC + 0.36% DHA, 0.72% AA; BM. Diets fed from <5 d to 17 wk. | Randomized from single center; masked assignment. | FC = 26, FA = 26, FAF = 27, BM = 29 | Yes | Sweep VEP acuity: FA, FAF, BM better scores at 6, 17, and 52 wk but not 26 wk compared with FC. FPL acuity: No effect of diet. Growth: No effect of diet. Bayley's test: FAF better MDI than FC at 18 mon; FA had intermediate value; no effect of diet on PDI. | At 52 wk: FC = 19%, FA = 23%, FAF = 29%, BM = 31% | Small sample size for MDI and PDI, but small SD allowed a result | Stated for VEP and card acuity and MDI |
| Gibson *et al.* (38) | Healthy term infants exclusively fed formulas or breast milk from birth | FC = LA/ALA, 18:1.4; FAF1 = FC + 0.2% DHA, 0.2% AA; FAF2 = FC + 0.2% DHA, 0.32% AA; FAF3 = FC + 0.25% DHA, 0.4% AA; BM. All diets fed for 6 wk. | Randomization and allocation were concealed; allocation from central location. | FC = 29, FAF1 = 31, FAF2 = 29, FAF3 = 29, BM = 40 | Yes | Growth: No diff. between groups at 6 wk. | FC = 24%, FAF1 = 32%, FAF2 = 24%. FAF3 = 28%, BM = 35% | | Yes for plasma DHA and AA |

[a]Abbreviations: BO, borage oil; EPO, evening primrose oil; GLA, γ-linolenic acid; DQ, Developmental Quotient; CDI, Communicative Developmental Inventory; FPL, Forced Preferential Looking. See Table 1 for other abbreviations.

fant formulas. This is despite the fact that four trials have supplemented formulas with DHA alone (tuna oil or MaxEPA) without added AA, resulting in the AA, status of infants being depleted (24,25,30,33). It should also be noted that, in most of these trials, infants were fed the test formulas for one year. Thus, there is little evidence for n-3 LC-PUFA supplementation of term infant formulas causing perturbations in growth. The safety of LC-PUFA–supplemented formulas for term infants has been further highlighted by the trial of Lucas *et al*., who reported similar rates of infection and atopy in infants fed either standard or LC-PUFA–supplemented formulas (32).

Benefits of adding DHA to formulas (with or without AA) on VEP acuity have been reported in some studies (24,36), whereas other studies have failed to detect a benefit of LC-PUFA supplementation (25,31,33). Benefits have also been reported on visual acuity assessed *via* cards (Teller) in one study (27) but not in others (25,36). There is also mixed evidence for the support of an effect of dietary LC-PUFA on more global measures of development (Bayley's Scales of Infant Development or Brunet–Lezine test). Agostoni *et al.* (28) and Birch *et al.* (37) both reported benefits of dietary LC-PUFA, as did Willatts *et al.* (35) using an unstandardized test of infant problem-solving ability. However, the larger studies conducted by Auestad *et al.* (25), Lucas *et al.* (32), and Makrides *et al.* (31) all failed to detect effects of LC-PUFA supplementation on Bayley's Scales of Infant Development. Possible interpretations of these data include a small individual effect (type 2 error) or that only a proportion of infants will benefit or the presence of confounding variables. Further studies are needed to elucidate this issue.

## TRIALS INVOLVING LINOLEIC ACID AND α-LINOLENIC ACID IN TERM AND PRETERM INFANTS

Our literature search identified three RCT involving term infants (39–41) and one involving preterm infants (1–5) designed to test the efficacy and safety of varying levels of linoleic acid (LA) and α-linolenic acid (ALA) and thus varying LA/ALA ratios. The trials with term infants are summarized in Table 3; the trial involving preterm infants is included in Table 1 because this study involved both PUFA and LC-PUFA interventions.

All three RCT involved healthy term infants fed infant formulas from near birth and had a breast-fed reference group (Table 3). Two trials appeared to have adequate randomization and masking procedures, and both presented power calculations for their primary outcome measurement (40,41). The study by Ponder *et al*. (39) did not state the method of randomization or power calculations. Makrides *et al.* (40) attempted to test the benefit of increasing ALA intake (or lowering the LA/ALA ratio) by measuring VEP acuity, whereas Jensen *et al.* (41) used VEP latency, which cannot yield an acuity determination. All studies measured growth using standard procedures.

The level of essential fatty acids tested in term infants ranged from 11 to 34% LA and 0.4 to 4.8% ALA (note that all fatty acid data are expressed as percent total fats) with LA/ALA ratios varying from 5:1 to 44:1. The data indicate that LA/ALA ratios as low as 5:1 and as high as 44:1 have no clinically relevant effect on growth. Although Jensen *et al.* (41) reported a lower weight in infants fed a 5:1 ratio formula compared with higher LA:ALA ratio formulas at 120 d of age, this group had excessive losses to follow-up at this age that prevented adequate interpretation. Thus, there appear to be few safety concerns in regard to the addition of oils rich in LA or ALA to infant formulas.

Whereas infants fed formulas with the lowest LA/ALA ratios (5:1) have higher plasma DHA levels than those fed formulas with higher LA/ALA ratios (10:1 and above), no study has demonnstrated a clear clinical benefit of one LA/ALA ratio over another with respect to effects on either VEP acuity, latency, or amplitude. No LA/ALA ratio raises the plasma or erythrocyte level of DHA to that of breast-fed infants.

Claims have been made by Heird *et al.* (42) that beneficial effects of supplementing formulas with LC-PUFA have only been seen when the level of ALA is less than 2% of total fats. The underlying hypothesis is that ALA levels of <2% total fatty acids do not allow adequate synthesis of n-3 LC-PUFA, and hence infants fed such formulas are more likely to benefit from dietary LC-PUFA. However, this hypothesis cannot be entirely substantiated. For example, the reference formula used in the large study by Lucas *et al.* (32) contained 1.1% ALA, and they reported no effect of LC-PUFA supplementation on Bayley's Developmental Indices at 18 months or on growth, infection, or atopy rates. Justification of an exact level of ALA in the dietary fats of term infants must await further studies. Although breast milk contains about 1% ALA, it must be remembered that breast milk also contains n-3 LC-PUFA.

There has been only one preterm trial (1–5) designed to test the efficacy and safety of varying levels of LA and ALA. The levels of essential fatty acids in different groups were 24% LA and 0.5% ALA in one group and 21% LA and 2.7% ALA in the other (Table 1). The ratios of LA/ALA were 48:1 and 8:1, respectively. These investigators reported that LA/ALA levels as low as 8:1 and as high as 48:1 have no effect on growth. The preterm infants fed 8:1 ratio formula had levels of visual acuity and electroretinogram (ERG) responses intermediate between those of infants fed a 48:1 ratio formula and those of infants fed a 14:1 ratio formula supplemented with n-3 LC-PUFA. This preterm infant trial (1–5) did not adequately report the randomization and allocation procedure, although investigators and participants were blinded to the treatment group. Furthermore, there were significant losses to follow-up (37%) by the time infants were 57 wk postmenstral age (PMA). Although an important trial, the quality of reporting does not allow firm conclusions to be drawn regarding LA/ALA ratios in infants formulas and their effects on preterm infants.

The strategy of improving the PUFA blends of infant formula by adding LC-PUFA is probably the preferential method to meet the requirement of n-3 fatty acids for preterm infants.

## SUMMARY AND CONCLUSIONS

*Preterm infants.* Four of the five trials assessing retinal sensitivity and visual acuity in response to dietary LC-PUFA

**TABLE 3**
**Intervention Trials of Changes in the Balance of n-6 and n-3 Essential Fatty Acids, Linolenic Acid, and α-Linolenic Acid in Term Infants[a]**

| Trial results reported by: | Age and characteristics at start of study | Type of intervention | How were the groups allocated? | Number of infants enrolled per group | Blinded outcome assessment (yes/no) | Outcome measures and results | Percentage of dropouts (loss to follow-up) | Other comments | Power calculation (yes/no) |
|---|---|---|---|---|---|---|---|---|---|
| Ponder *et al.* (39) | Healthy term infants exclusively fed formula or breast milk | F7:1 = LA/ALA, 34:4.8; F39:1 = LA/ALA, 31:0.8; BM. Diets fed from 3 d to 8 wk. | Randomly assigned; no details regarding allocation | Not stated; number completed per group: F7:1 = 11, F39:1 = 14, BM = 18 | Not stated | Growth: No diff. between groups at 4 and 8 wk. | Not reported | | No |
| Makrides *et al.* (40) | Healthy term infants fed formula or breast milk | F10:1 = LA/ALA, 17:1.7; F5:1 = LA/ALA, 17:3.3; BM. Diets fed from <5 d to 34 wk. | Randomization and allocation adequately concealed | F10:1 = 36, F5:1 = 37, BM = 103 | Yes | VEP acuity: No diff. between dietary groups at 16 and 34 wk. Growth: No diff. between formula groups at 6, 16, 34 wk, after adjustment for birth size; BF infants less weight and length gain at 16 and 34 wk than formula groups. | F10:1 = 17%, F5:1 = 24%, BM = 17% | Well-designed study. Birth weight and birth length of F5:1 group was greater than F10:1 group. | Yes |
| Jensen *et al.* (41) | Healthy term infants fed formula or breast milk from birth | F44:1 = LA/ALA, 18:0.4; F18:1 = LA/ALA, 17:0.95; F10:1 = LA/ALA, 17:1.7; F5:1 = LA/ALA, 16:3.2; BM. Diets fed from 1 to 120 d. | Random and masked assignment | F44:1 = 20, F18:1 = 20, F10:1 = 20, F5:1 = 20, BM = 19 | Yes | VEP latency and amplitude: No diff. between groups at 120 and 240 d. Growth: Weight of F5:1 group less than other formula groups at 120 d; no other diff. in weight; no diff. in length, head circumference, and skinfolds at 21, 60, 120, and 240 d. | At 120 d: F44:1 = 15%, F18:1 = 15%, F10:1 = 20%, F5:1 = 35%. At 240 d: F44:1 = 35%, F18:1 = 15%, F10:1 = 25%, F5:1 = 40% | Difficult to assess growth effects due to small numbers in F5:1 group. At 120 and 240 d, numbers were less than estimated sample size. | Yes for growth, VEP latency, and amplitude |

[a]See Table 1 for abbreviations.

supplementation of preterm infants reported a measurable benefit, whereas the fifth reported no effect.

Two trials also reported a measurable benefit in visual attention in n-3 LC-PUFA–supplemented infants compared with controls, while a subgroup of infants from one trial showed more mature immune markers compared with unsupplemented infants.

There are some reports of negative effects on growth in relation to the addition of n-3 LC-PUFA to preterm formulas but not when AA is added with n-3 LC-PUFA. Small studies have shown no differences in prostanoid formation or peroxidative stress between n-3 LC-PUFA–supplemented and unsupplemented infants.

*Term infants.* There appear to be few safety issues regarding the addition of LC-PUFA to term formulas, but there is controversy about their efficacy.

Five of nine trials with at least one efficacy outcome reported a measurable benefit in either visual or global development as a result of adding LC-PUFA, while four trials reported no effect in either visual or global development.

While a proof of essentiality may be lacking, there is some evidence of benefit of LC-PUFA to term infants. There is no evidence from RCT that AA must be added along with DHA in term infant formula. The fact that AA and DHA are in a balance of about 2:1 in the breast milk of most Western countries is due to the nature of the Western diets rather than a reflection of any requirement of the infant. We note that breast milk of fish-eating communities (such as most Asian countries) has AA/DHA ratios of 1:1 or lower.

*LA/ALA ratio.* While there appear to be few functional benefits of one LA/ALA ratio over another, there also appear to be few safety issues in relation to the LA/ALA ratio.

While infants fed low LA/ALA ratios have higher DHA levels, no LA/ALA ratio raises the level of DHA to that of breast-fed infants.

Justification of an exact level of ALA in the dietary fats of term infants and preterm infants must await further studies.

**ABSTRACT:** Essential fatty acids are structural components of all tissues and are indispensable for cell membrane synthesis; the brain, retina and other neural tissues are particularly rich in long-chain polyunsaturated fatty acids (LC-PUFA). These fatty acids serve as specific precursors for eicosanoids, which regulate numerous cell and organ functions. Recent human studies support the essential nature of n-3 fatty acids in addition to the well-established role of n-6 essential fatty acids in humans, particularly in early life. The main findings are that light sensitivity of retinal rod photoreceptors is significantly reduced in newborns with n-3 fatty acid deficiency, and that docosahexaenoic acid (DHA) significantly enhances visual acuity maturation and cognitive functions. DHA is a conditionally essential nutrient for adequate neurodevelopment in humans. Comprehensive clinical studies have shown that dietary supplementation with marine oil or single-cell oil sources of LC-PUFA results in increased blood levels of DHA and arachidonic acid, as well as an associated improvement in visual function in formula-fed infants matching that of human breast-fed infants. The effect is mediated not only by the known effects on membrane biophysical properties, neurotransmitter content, and the corresponding electrophysiological correlates but also by a modulating gene expression of the developing retina and brain. Intracellular fatty acids or their metabolites regulate transcriptional activation of gene expression during adipocyte differentiation and retinal and nervous system development. Regulation of gene expression by LC-PUFA occurs at the transcriptional level and may be mediated by nuclear transcription factors activated by fatty acids. These nuclear receptors are part of the family of steroid hormone receptors. DHA also has significant effects on photoreceptor membranes and neurotransmitters involved in the signal transduction process; rhodopsin activation, rod and cone development, neuronal dendritic connectivity, and functional maturation of the central nervous system.

Paper no. L8639 in *Lipids 36,* 885–895 (September 2001).

Studies over the past five decades have evaluated the effects of nutrition on central nervous system (CNS) development in experimental animals and humans. The results reveal that a reduction in the supply of energy and/or several essential nutrients during the first stages of life has profound effects on the structural and functional development of the nervous system. Malnutrition impairs brain growth and development by decreasing the number of cell replication cycles, reducing total brain DNA, and restricting dendritic arborization, thus reducing neuronal connectivity. Intrauterine and early postnatal malnutrition affect cell number and hyperplastic growth as measured by DNA content (1). Development of the cerebellum is most affected by nutritional deprivation around the time of birth in humans. Synaptic connectivity is particularly affected if malnutrition occurs after birth but before year 3 of life. Alterations in dietary precursors may affect tissue levels of neurotransmitters (serotonin, norepinephrine, dopamine, and acetylcholine) in specific brain regions (2). The supply of essential fatty acids (EFA) affects the structural composition of the brain and myelin sheaths in particular. The functional correlates of these biochemical changes induced by malnutrition include alterations in the waking electroencephalographic activity, visual- and auditory-evoked responses, motor and cognitive development, and social abilities. Sleep-wake cycle organization as well as autonomic nervous system functioning during sleep are perturbed by early human malnutrition (3,4). Most of these effects are potentiated by other environmental factors that interact with poor diet in defining the adverse consequences.

The traditional point of view, that protein and energy deficits *per se* directly affect brain structural development and cognitive performance, has been challenged because protein energy malnutrition coexists with multiple micronutrient deficiencies and with psychosocial deprivation that interact to disrupt brain development. This makes it particularly difficult to tease out the role of specific nutrients such as EFA from multiple deprivations that act in tandem, contributing to the final outcome in terms of growth and mental developmental (5). The major effects on growth and brain development associated with EFA deficiency are explained by the role of fatty acids (FA) as basic components of biological membranes, precursors of eicosanoids, and regulators of gene expression. The effect on growth is most likely linked to the role of EFA in energy balance and eicosanoid-mediated growth factors. The effects on CNS development are likely mediated by the role of EFA on gene expression, membrane structures, and electrophysiologic responses. The purpose of this review is to examine the effects of dietary EFA on the development of the brain and vision and the potential mechanisms by which modulation occurs.

[a]Abbreviations: ALA, α-linolenic acid; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; ERG, electroretinogram; PCA, postconceptional age; LA, linoleic acid; HM, human milk; VEP, visual evoked potential; FPL, forced-choice preferential looking; PDI, Psychomotor Development Index; NP, novelty preference; AA, arachidonic acid; ABER, auditory brainstem evoked response. F1, F2, and F3 correspond to different formulas.
[b]First value refers to content during the period up to the gestational age (40 wk); second value is the content after 40 wk.

## EFFECT OF EFA ON BRAIN DEVELOPMENT

*Preterm infants (randomized controlled trials).* Very-low-birth-weight infants born with a birth weight of <1500 g are considered particularly vulnerable to EFA deficiency given the virtual absence of adipose tissue at birth, the possible insufficiency of FA elongation/desaturation enzymatic pathways, and the inadequate intake of long-chain polyunsaturated fatty acids (LC-PUFA) provided by formula. Randomized controlled clinical trials that have included formula feeding with or without LC-PUFA and functional assessment of visual/neurodevelopment in preterm infants are summarized in Table 1.

Over the past decade, we and others have conducted studies to evaluate the effect of n-3 FA in preterm infant development. These studies examined the effects of α-linolenic acid (ALA), ALA plus docosahexaenoic acid (DHA), or ALA plus DHA and arachidonic acid (AA) supplementation on plasma and tissue lipid composition, retinal electrophysiologic function, maturation of the visual cortex, and on other measures of infant growth and development (6–14). In our initial work, we showed that retinal function, as determined by the electroretinogram (ERG), is affected by n-3 supply in preterm human infants. Infants fed an n-3–deficient corn oil diet (standard formula at the initiation of the study in 1987) had significantly higher rod ERG thresholds (i.e., more light was necessary to elicit a threshold rod ERG response, resulting in a less mature ERG response) than infants receiving either human milk or n-3–supplemented formula. An analysis of the amplitude–intensity behavior of the responses (Naka-Rushton functions) from the infants in the study revealed that the threshold elevation in the n-3–deficient infants was due primarily to a shift in log *k* (i.e., the sensitivity of the rod system was lower). In addition there was a modest but significant de-

crease in the amplitude in the maximal amplitude ($V_{max}$) that could be elicited from infants in the deficient group. An analysis of the leading edge of the a-wave showed that the decreased sensitivity in the infants fed n-3–deficient formula originated in the rod photoreceptors (7). The results of dietary FA modification on the function of the visual cortex, as measured by pattern reversal visual-evoked potential (VEP) acuity and behaviorally by the forced-choice preferential looking (FPL) visual acuity response, demonstrated that infants in the human milk and marine oil groups (both receiving DHA) had improved maturation of VEP relative to infants fed formulas devoid of DHA (corn and soy oil groups) at the 4-mon adjusted-age followup (8). No differences were found between soybean- and marine oil-containing formula if acuity was assessed by FPL. Visual acuity tests measure the integrity of the neural pathway from the retina to the occipital cortex and provide a surrogate measure of CNS function. The long-term significance of the improved retinal and visual function on later neurodevelopment is presently being explored.

Carlson's first randomized clinical study in preterm infants supplemented with LC-PUFA demonstrated better visual acuity in infants up to 4 mon of age using FPL measurements. After this time, control infants "caught up" in visual function measures. These investigators report evidence of more rapid visual processing as measured by shorter look duration in the Fagan test of visual recognition at 6 and 12 mon of age in LC-PUFA–supplemented infants (9–11). The reduction in AA in blood lipids, when marine oil was provided as a source of n-3 fatty acids, was associated with reduced weight and linear growth (10–13). In a second preterm infant study using low eicosapentaenoic acid (20:5n-3) marine oil for up to 2 mon corrected age, Carlson demonstrated improved visual development at the 2-mon followup; at 12 mon of age, there was a 10-point Bayley Mental Development Index (MDI) difference favoring the DHA-supplemented group (11,12). Furthermore, the DHA-supplemented group had shorter look times in the novelty preference test at 9 mon, suggesting better visual processing (12).

In our recent studies, conducted in Chile, no LC-PUFA effect on auditory brain stem-evoked responses (ABER) was demonstrated; this coincides with the results of a preterm infant study by Faldella (14). One of our centers (INTA) recently participated in a collaborative multicenter study of a large group of preterm infants. This study included 470 preterm infants fed LC-PUFA formula supplemented with different AA and DHA sources, i.e., marine oil and egg phospholipids or fungal oil. The level of DHA was 0.25% of total fat in preterm formulas and 0.15% in follow-up formula; both formulas contained 0.4% AA (15). Significant differences were found in sweep VEP at 6 mon favoring the LC-PUFA–supplemented formula group compared with the control formula group. There were no diet-induced differences in behavioral tests of visual acuity (determined using Teller acuity cards). Mean novelty preference was significantly better at 6 mon in the LC-PUFA–supplemented group. No differences in MacArthur vocabulary tests were found, but an improved 14-mon score was noted in the supplemented group when non-English-speaking subjects were excluded from the analysis. For infants <1250 g at birth, an advantage of 8.8 points in the LC-PUFA–supplemented group in the Bayley II Psychomotor Development Index was observed at 12 mon (15).

*Significance of LC-PUFA for term infants (randomized controlled trials).* The question of whether healthy full-term infants require LC-PUFA in their formula has received considerable attention over the past decade. The finding of lower plasma DHA and red blood cell (RBC) concentrations in infants fed formula compared with breast-fed infants suggests that formulas provide insufficient ALA or that chain elongation–desaturation enzymes are not sufficiently active during early life to support optimal tissue accretion of DHA. Full-term infants also may be dependent on dietary DHA for optimal functional maturation of the retina and visual cortex (16–38). Controlled trials that have included formula feeding with or without LC-PUFA and functional assessment of visual and neural development are summarized in Table 2.

Makrides *et al.* (25) conducted the first controlled randomized study in term infants using a formula supplemented with 0.36% DHA and 0.27% γ-linolenic acid (GLA) compared with a formula providing ample ALA (1.6%) but no DHA as well as a breast-fed reference group. They demonstrated delayed visual acuity at 4 and 6 mon of age in the formula group lacking DHA. Infants who received breast milk for >16 wk had better VEP acuity than those breast-fed for shorter times or given formula without LC-PUFA. A separate study showed better visual acuity at 2 mon but no benefits after 6 mon of life in breast-fed or 0.1% DHA formula-fed infants relative to control formula (26). Biochemical indices of DHA status and visual acuity maturation of infants receiving only ALA were delayed relative to those receiving formula supplemented with ALA + DHA; these latter infants had maturational indices similar to those of the breast-fed group (27).

Auestad *et al.* (28) compared infants fed standard formula, formula supplemented with 0.2% DHA (from marine oil), or formula with 0.12% DHA and 0.43% AA. No significant differences could be detected among the three diet groups using ERG at 4 mon, visual acuity, or the Bayley Scales of Infant Development test at 12 mon. Furthermore, negative correlations were found between RBC and DHA at 4 mon and language development assessed by the MacArthur Communicative Development Inventory given at 14 mon ($r = -0.20$ to $-0.37$ depending on the specific item, $P < 0.05$) (29). A beneficial effect of DHA, AA, and GLA supplementation on psychomotor development assessed by the Brunet-Lezine method was reported at 4 and 12 mon but not at 24 mon of age (30,31). This study reported a strong association between the erythrocyte phosphatidylcholine (PC) AA/linoleic acid (LA) ratio and the developmental quotient at 24 mon, but there was no relation to the dietary intervention in the first 4 mon of life (31). In an attempt to control for confounding variables that could affect visual and neural development, Gibson *et al.* (32) supplemented mothers with LC-PUFA to produce DHA-enriched breast milk with concentrations ranging from 0.1 to 1.7% of total FA. The plasma and erythrocyte-phospholipid DHA level

| | HM (138) | | | |
| 40 | F1 (24) | DHA 0.34, AA 0.34 | Flash VEP, 16, 34 wk | Not different |
| | F2 (23) | DHA 0.35 | | |
| | F3 (21) | LA 16.8, ALA 0.13 | Bayley Mental and Psychomotor Developmental Index at 12, 18 mon | Not different and not related to plasma DHA levels |
| | HM (46) | DHA 0.2, AA 0.4 | | |

[a]Abbreviations: GLA, γ-linolenic acid; MDI, Mental Development Index; RBC, red blood cell; for other abbreviations see Table 1.

of these infants was related to breast milk DHA in a saturable manner; no significant increases were noted in blood DHA levels when the breast milk content of DHA was >0.6%. Infant VEP acuity had no relationship to DHA content of breast milk; the developmental quotient at 12 mon was significantly but weakly correlated with breast milk DHA. At 24 mon, this effect was no longer evident.

Recently, Birch *et al.* (33) showed a persistent benefit in visual acuity development for year 1 of life in DHA-supplemented formula-fed infants compared with infants fed formula with ample ALA but devoid of LC-PUFA. The formula given for the first 17 wk of life contained 0.35% DHA, with or without 0.72% of AA; both LC-PUFA were derived from single-cell oils in the supplemented groups. The dietary effects on vi-

sual acuity development were evident using sweep VEP acuities but absent if the FPL behavioral measure of acuity was used. Supplemented groups receiving DHA or DHA + AA and the breast milk group had better acuity. The differences were significant during the periods of rapid change in development of VEP acuity, i.e., in the first 20 wk and near 12 mon of life. The developmental outcome of these infants was reported recently (34). Scores on the Bayley MDI II at 18 mon of age for the DHA + AA group were significantly better than those observed in the non–LC-PUFA formula-fed infants. A 7-point normalized MDI score difference was highly significant despite the relatively small sample size ($n$ = 20/group). The small variability in developmental score obtained was likely due to the highly homogeneous population studied and the fact that one observer evaluated mental development in all subjects. The DHA-only group had marginally higher MDI scores than controls. This is the first randomized controlled study that reports an LC-PUFA effect on mental development at 18 mon of age. Moreover, positive significant correlations between blood DHA levels at 4 mon with measures of visual acuity at 1 yr and mental development at 18 mon were noted (34). The existence of a relationship between early biochemical and later functional data suggests that visual function and neurodevelopmental phenomena may be related but do not constitute proof of a causal relationship.

A behavioral study of 44 term infants fed a combined DHA- and AA-supplemented formula or a control formula during the first 4 mon demonstrated that visual habituation performance scores of infants at 4 mon of age were better in the LC-PUFA–supplemented formula group (35). Infant cognitive behavior was assessed at 10 mon of age by a means-end problem-solving test (36). The LC-PUFA–supplemented group had significantly more intentional solutions and scored higher than infants fed the non–LC-PUFA–containing control formula. Higher problem-solving scores in infancy have been shown to relate to higher childhood intelligence quotient scores (37). These studies provide a solid indication of efficacy but are limited in their extrinsic validity because of small sample size and rather homogeneous infant populations.

Lucas *et al.* (38), in the largest controlled term-infant study to date, did not find a beneficial effect of LC-PUFA supplementation in a group of 309 infants randomized to formula diets with or without LC-PUFA. A reference group of 138 infants included for comparative purposes were breast-fed. No biochemical data on FA composition of plasma or tissues were obtained in this study, limiting the assessment of compliance to the test formula. Follow-up studies at 18 mon revealed no benefit in cognitive or motor development. No adverse effects of LC-PUFA supplementation were noted in terms of infection, atopy, or formula tolerance. However, the interpretation of these data is limited by the fact that study formulas differed not only by the presence or absence of LC-PUFA but also by several other fatty acids. The expected higher MDI score in breast-fed infants compared with standard formula-fed infants was not apparent in this study, and because there was no plasma or tissue biochemical evaluation of infant EFA status, a relationship between LC-PUFA status and neurodevelopment could not be established (38). In addition, the maternal population studied had a low educational level, i.e., ~20% had no formal education at all and ~70% had not completed a high school education. Mean MDI values for all groups of infants were 4–6 points below the norm, suggesting that these groups may not be representative of the normal population in the United Kingdom but rather a group subjected to an environmental factor that restricted their neurodevelopment. The possible effect of maternal education or ethnicity is raised from the analysis of confounding variables (39). Using the same LC-PUFA–enriched and control formulas, Makrides *et al.* (40) also did not find diet-induced differences in VEP acuity or Bayley MDI scores during year 1 of life. In this case, breast-fed infants had higher MDI scores than formula-fed infants at 2 yr, even after adjusting for environmental variables. No correlations between plasma LC-PUFA levels and neurodevelopment indices were found by these investigators.

Other studies have attempted to optimize ALA to DHA conversion by providing sufficient ALA (>0.7% of total energy) as well as lowering the LA to ALA ratio in the formula (<10:1). This alternative strategy for the formulation of infant diets would be simpler and less expensive to produce than the addition of n-3 LC-PUFA (21,24). Unfortunately, results from infants fed formula with a ratio of 4.8:1 demonstrated poorer growth, possibly due to the lower AA levels found with this dietary regimen (24).

*Recent systematic reviews of LC-PUFA supplementation.* The results of two recent meta-analyses conducted on the effect of LC-PUFA on visual acuity maturation in preterm and term infants are summarized in Figures 1 and 2. As can be observed in the figures, most studies demonstrated a positive effect for assessments conducted during the first 2–4 mon of life; the results at 6 mon were equivocal and again, at 12 mon, some studies were positive. The conclusions by San Giovanni *et al.* (41,42), in their two reports, is that there is a significant overall advantage for the LC-PUFA–supplemented infants in terms of visual acuity. The main differences in experimental design, subject selection, dietary supplementation, other nutrition-related factors, and the primary outcomes of these studies are summarized in Table 3. Most studies have chosen the prospective, randomized, controlled, double-blind design, but some studies included in the systematic reviews compared human milk-fed with formula-fed infants. This comparison has limited validity because infants of breast-feeding mothers and formula-fed infants usually vary in terms of maternal education, birth weight, home environment, socioeconomic level, and other confounders. To evaluate efficacy, most studies have used "healthy" subjects controlling for birth weight, gestational age, socioeconomic status, and maternal characteristics. These well-controlled studies have strong intrinsic validity. However, these studies cannot be generalized for all infants because the study groups in the controlled studies may not be representative of the population at large. The diets studied have provided 0.1–0.35% DHA in both preterm and term infant studies. These values are in the middle-to-lower

range of mean DHA content found in breast milk as derived from combined data of omnivorous women around the world. No formal controlled DHA dose-response studies evaluating visual maturation and/or mental development at varying levels of supplementation have been conducted in preterm (8–15) or term infants (25–31,33–40).

The duration and reversibility of diet-induced effects is another important consideration in assessing outcome. In evaluating diet-induced changes in visual/neural development, the selection of outcomes is crucial. The sensitivity and variability of the measurements are vital to detect an effect given the presence of multiple known and unknown confounders. The timing of the measurement is also of great importance; most LC-PUFA effects are evident only over the period of rapid development and do not persist once functional maturation has been achieved. The visual acuity results suggest that transient effects reflect the acceleration or the slowing of a maturational process with a fully normal final outcome. Several studies have demonstrated significant effects of dietary LC-PUFA on visual maturation in the first 4 mon of life, but in most studies, visual acuity normalized by 6 mon or at most by 1 yr of age (41,42). However, we need to consider whether this phenomenon can truly be dismissed as transitory and of limited significance and instead consider that we may have failed to detect a significant change later in life. This may be explained by the limitations in our tools, which may not be sufficiently sensitive; moreover, other related functions may indeed have been affected. As an example of this problem, in term infants, we failed to detect differences in visual acuity of breast-fed compared with formula-fed infants at 6 mon but stereo-acuity responses were different at 3 yr of age (16). In this study, most breast-fed infants (92%) had mature operant preferential looking stereo acuity, whereas only 35% of the infants in the formula-fed group met the maturity criteria. Visual recognition in the breast-fed group was also better; only 61% of the formula-fed infants had a perfect score, whereas 93% of the breast-fed group had a perfect score (16). This illustrates the need to select sensitive outcome measures and provide for sufficient follow-up of cohorts in these randomized clinical trials. It is impossible to fully discard the possible long-term consequences of early developmental delays in function unless followup is conducted over a sufficient period of time.

## MECHANISMS FOR EFA EFFECTS ON GROWTH AND BRAIN DEVELOPMENT

*Molecular regulation of gene expression by nutrients*. Regulation of gene expression by nutrients can occur at multiple levels (43,44). For example, FA can bind to specific or nonspecific ligands that interact with response elements in specific DNA motifs usually present in the promoter region of the gene, affecting gene transcription. DHA and other PUFA interact with nuclear factors modulating the activation of specific nuclear proteins such as peroxisome proliferator-activated receptors (PPAR), which in turn act as transcription regulators (45). In this case, the nutrient effect is indirect because it is the activated transcription factor that binds *cis*-regulatory elements of DNA found in target genes. Another form of nutrient ligand interaction includes changes in phosphorylation mediated by the nutrient. At the posttranscriptional level, once mRNA are formed, nutrients may act by modifying native RNA processing, mRNA transport and stability, and breakdown rates. Nutrients may also modify the rate of mRNA translation by the activation of protein synthesis in the polyribosomal complex. Nutrients such as vitamin K can affect gene expression at the posttranslational level beyond the synthesis of protein by modifying the gene products formed. Vitamin K-dependent amino acid carboxylation, which is necessary for active prothrombin synthesis, represents an example of nutrient-induced posttranslational modification of gene products. Finally, nutrients can modify the turnover rates of proteins including enzymes, thus affecting their activity level. In many cases, the nutrient-induced changes in gene expression are part of the adaptive response to a given level of nutrient exposure (43,44). Thus, nutrients may affect the uptake, metabolism, storage, or excretion of the nutrient that triggered the gene regulatory response.

LC-PUFA are involved in the regulation of cell growth and differentiation by modulation of gene expression. For example, the effect of DHA on the functional maturation of the retina observed in several animal species including primates may now be potentially related to a direct effect on photoreceptor differentiation. Studies using primary culture of retinal neuronal cells have revealed a potential mechanism by which this conditionally essential nutrient affects gene expression critical to retinal function and survival (46). In cultured cells from rats, DHA significantly increased the differentiation of apical processes in rod outer segments, the locus for rhodopsin and opsin-dependent light transduction. This was paralleled by an increase in opsin expression and content in the rod photoreceptor apical processes (46). The molecular mechanisms underlying these effects have not been fully clarified, but these data suggest an effect of DHA on opsin gene expression and possibly on other proteins required for the assembly of disc membranes. Recent studies from Bazan's group (47) have demonstrated that the transport of opsin and rhodopsin to the apical process *via* post-Golgi membranes is coupled to DHA transport. The close molecular interaction between these key photoreceptor proteins and DHA suggests that DHA influences retinal photoreceptor structural development as well as function.

Regulation of gene expression by LC-PUFA also occurs at the transcriptional level and is mediated by transcription factors that bind *cis*-regulatory elements found in target genes. These transcription factors, which are activated by FA, have a structure similar to that of the steroid-thyroid supergene family of nuclear receptors, which includes the steroid hormone receptors, glucocorticoid receptor, vitamin D receptor, thyroxine receptor (TR), and the retinoic acid receptor (RxR) (48–50). PUFA-responsive transcription factors recently have been characterized; for example, PPAR can be activated by clofibric acid and other peroxisome proliferators (45,48,50). Recent studies have identified a number of proteins and co-activators that in-

teract with nuclear receptors involved in the regulation of transcriptional activity. The formation of the binding site for the co-activator in the nuclear receptor is ligand dependent.

The activation of PPAR by FA was first characterized in *Xenopus laevis*; α-, β-, and γ-isoforms were able to respond to FA with overlapping specificity (45). However, few studies have systematically explored the differential activation of PPAR by FA of different chain length or unsaturation. Yu *et al.* (49) compared the ability of FA to activate the different PPAR isoforms using chimeric constructs. The tetR/PPARα chimeric receptor was activated to almost the same extent by LA and DHA, whereas the γ-isoform was activated by DHA but not by LA and the β-isoform was responsive to DHA > LA. PPARα is apparently also activated by medium- and long-chain unsaturated FA. This evidence has been used to support the notion that reduction of hepatic expression of lipogenic enzymes induced by dietary n-3 and n-6 PUFA is mediated by PUFA-activated PPARα (45,48,50). In this chimeric PPAR expression model, DHA was the most potent activator, whereas saturated myristic acid (14:0) was a considerably poorer inducing agent (48). The net effects of PPAR on cellular processes and metabolism include enhanced peroxisomal proliferation, increased FA oxidation, decreased FA synthesis, and enhanced glucose oxidation (50). Additional work will be necessary to better characterize the intracellular FA metabolites that regulate transcriptional activation and responsiveness of target genes critical for retinal and brain development.

*EFA effects on neural structures and functional properties.* Lipids, such as various phospholipids and cholesterol, serve as components of specialized cell membranes and organelles. The overall quantity and relative composition of these lipid species may affect membrane fluidity and protein/lipid interactions, resulting in changes in overall cell function. The FA composition of structural membrane lipids can affect membrane function by modifying overall membrane fluidity (order parameter), membrane thickness, lipid phase properties, membrane microenvironment, or by interaction of FA with membrane proteins (51–53). These effects may modulate receptor activity, transport of metabolites in and out of cells, and hormonal or other signal transduction processes. Most dietary n-3 FA–induced membrane changes are not reflected by an overall change in membrane fluidity, but result in selective changes in specific domains of membrane microenvironment (54). The replacement of DHA by docosapentaenoic acid (22:5n-6) observed in n-3 deficiency results in a very similar overall lipid unsaturation level because only one double bond has been lost. Thus, on average, membrane fluidity as measured by fluorescent probe polarization remains unchanged. Furthermore, the major changes in the physical state induced by the FA composition of lipid bilayers occur when mono- or diunsaturated moieties are introduced; namely, when a saturated FA such as stearic acid (18:0) is replaced by oleic acid (18:1n-9) or by LA (18:2n-6) (52,53). Others have suggested that the DHA supply modifies the phospholipid molecular species present in neural tissues, thus affecting overall function (55).

One of the most significant membrane effects of DHA is its role in photoreceptor signal transduction processing. Recently, Litman and Mitchell (56) reported that LC-PUFA present in membrane phospholipid molecular species have profound effects on rhodopsin activation and related structural modifications. Rhodopsin is a membrane protein present in rod outer segment disk membranes, accounting for 90% of the protein content. It functions as a photon receptor coupled to a G protein. The light-induced conformational change of rhodopsin triggers a biochemical cascade finally leading to an increase in phosphodiesterase activity and a decrease in cGMP that closes sodium ion channels in the photoreceptor disk membrane. The result is a hyperpolarization that is reflected in the ERG as the leading edge of the a-wave and that ultimately leads to the release of synaptic neurotransmitters. Membrane FA composition affects the ability of photons to transform rhodopsin to the activated state (56–58). The rhodopsin activation in response to light involves a transformation of metarhodopsin I (M I) to metarhodopsin II (M II).

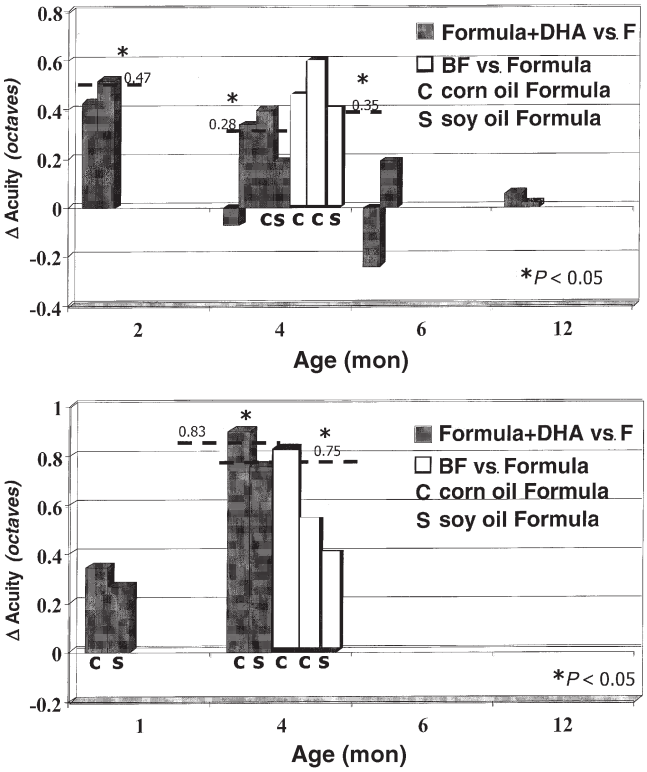

**FIG. 1.** Meta-analysis of visual acuity differences in preterm infants; solid bars represent randomized comparisons [group fed formula with long-chain polyunsaturated fatty acids (LC-PUFA) compared with group fed formula without LC-PUFA]. Open bars represent nonrandomized comparisons (group fed human milk compared with formula without LC-PUFA). Dashed line represents mean of estimate from combined data for various studies for given month. C and S refer to comparison formulas containing corn and soy oil, respectively. (A) Acuity differences measured by behavioral tests (acuity cards); (B) acuity differences measured by visual-evoked potentials; all values expressed in octaves (one-octave difference is a 50% reduction in width of stimulus element). Data obtained from Reference 41. DHA, docosahexaenoic acid; F, formula; BF, breast feeding.

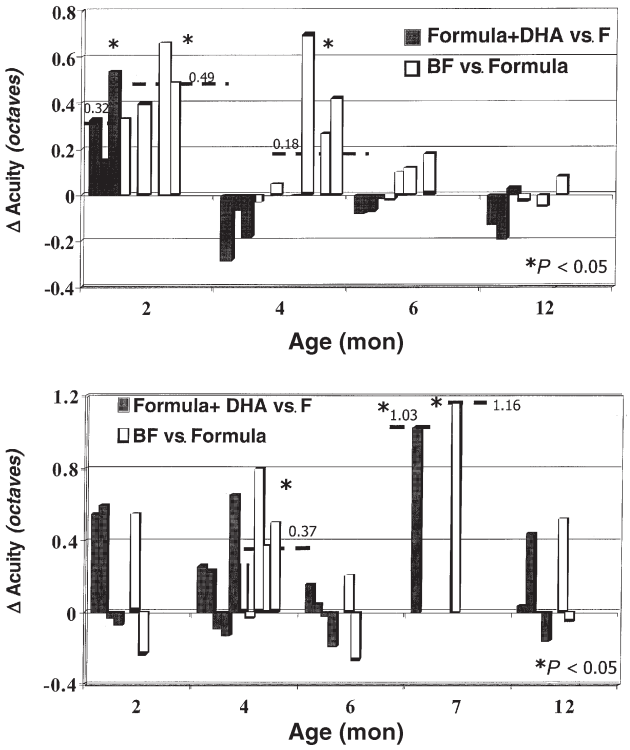

**FIG. 2.** Meta-analysis of visual acuity differences in term infants; solid bars represent randomized comparisons (group fed formula with LC-PUFA compared with group fed formula without LC-PUFA). Open bars represent nonrandomized comparisons (group fed human milk compared with formula without LC-PUFA). Dashed line represents mean of estimate from combined data for various studies for given month. (A) Acuity differences measured by behavioral tests (acuity cards); (B) acuity differences measured by visual evoked potentials; all values expressed in octaves (one-octave difference is a 50% reduction in width of stimulus element). Data obtained from Reference 42. See Figure 1 for abbreviations.

The MI → MII equilibrium constant is six times higher with di-DHA acylated PC than with di-myristoyl (14:0) PC. The di-DHA PC has an equilibrium constant that is almost identical to that of phospholipids extracted from native rod disks. The effect is explained mainly by the increase in membrane free volume. This greater mobility of rhodopsin within the lipid microenvironment most likely explains the change in G protein activation and the corresponding enhanced signal transduction to photon stimuli (58). The corresponding physiologic phenomenon is an increase in retinal sensitivity to light, such as we observe by providing DHA in the infant diet.

*EFA effects on electrophysiologic responses*. The role of membrane lipid composition in determining the electrical properties of cultured neuronal cells exposed to exogenous FA has also been investigated (59). Both n-3 and n-6 FA reduce the rate of rise and lower the amplitude of $Na^+$ action potentials. The opposite effects were observed when saturated or *trans* monoenoic FA were added to the culture (60). These effects are likely mediated by a change in the number of active $Na^+$ channels. A change in membrane composition or altered FA availability to the cells may explain this effect. Free LC-PUFA have been shown to modulate the inactivation of calcium and sodium channels in rat neural cells (61). There are also changes in cation currents in hippocampal neurons (60) and a higher seizure threshold in rat cortex (62). These effects appear to depend on free extracellular LC-PUFA concentrations and not on membrane phospholipid composition (61). The responsiveness of free LC-PUFA to dietary interventions, which alter tissue composition, remains unclear. The release of free LC-PUFA from membranes could have widespread effects on neurosensory function.

At the CNS level, interest in the effect of EFA on the maturation of visual function is based on their role as key structural components of cell membranes and their accumulation in visual and neural structures. Data from breast-fed infants who received DHA indicate that a higher content of this FA is present in brain cortex relative to infants fed formula (63). Neuringer and colleagues (64) established the need for n-3 FA in the diet, utilizing infant rhesus monkeys as a model system for n-3 FA deficiency. Following prenatal (maternal) and

**TABLE 3**
**Critical Aspects in Experimental Design of Studies of Long-Chain Polyunsaturated Fatty Acid (LC-PUFA) Supplementation on Visual and Neurodevelopment in Infants[a]**

| Design | Diet |
|---|---|
| Prospective randomized, controlled, double blind study | Content and balance of EFA: LA and ALA |
| Nonrandomized, formula compared with breast-fed reference group | Content and balance of each LC-PUFA |
| Descriptive, nonrandomized trial | Source of LC-PUFA: egg, single cell, marine |
| Preplanned or *post-hoc* analysis | Energy balance and content of critical nutrients (I, Fe, Zn, vitamin A, folate) |
| Sample size to detect effect | Digestibility and utilization |
| | Duration of the dietary intervention |
| **Subjects** | **Outcome** |
| Term or preterm infants | Sensitivity of selected outcome |
| Birth weight and gestational age | Variability in measurement of outcome |
| Special groups or representative population | Age of evaluation, time of day of evaluation |
| Socioeconomic and ethnic group | Time of effect relative to critical period |
| Maternal education | Biological and clinical significance |
| Home environment | Duration and reversibility of effects |
| Pre- and postnatal growth | Safety of intervention and side effects |

[a]Abbreviation: EFA, essential fatty acids. For other abbreviations see Table 1.

postnatal diets deficient in n-3 FA, the DHA concentrations in both the occipital cortex and the retina were reduced to 20% of that in control monkeys. The n-3 FA deficiency also impaired visual acuity as measured by preferential looking techniques. By 12 wk of age, the deficient monkeys presented Snellen acuities of ~20/125 vs. 20/50 in controls (20/20 is the average adult acuity; 20/50 is the average for 12 wk of age in monkeys). In addition, the b-wave amplitudes of ERG were reduced by 30% in the n-3 FA–deficient rhesus monkeys (64).

Several potential mechanisms by which early dietary EFA supply may affect visual and brain maturation and long-term function can be outlined on the basis of the available experimental data. The potential role of DHA as a modulator of membrane properties is supported by the *in vitro* studies of membrane fluidity and transport in neural cells modified in their membrane FA. The putative role of DHA in amplifying the phototransduction cascade is supported by the electrophysiologic findings in animals and humans. Dietary n-3 supplementation in these studies resulted in decreased retinal rod threshold and higher maximum amplitude, meaning that less light is required to trigger a retinal response and that more signal is being transmitted to the visual pathway, respectively. Moreover, the discovery of biochemical differences in phosphorylated microtubular-associated proteins in neurons from the visual cortex of light-deprived kittens during early development provides a mechanism for the classical observations by Hubel and Wiesel (65,66). The expression of microtubular proteins in the visual cortex induced by light plays a key role in establishing the dendritic arborization and interconnections necessary for visual perception; darkness inhibits the expression of this gene product (67,68). Thus the role of light-mediated stimuli in triggering cortical differentiation offers a plausible explanation for the phenomenon of a critical period for ocular dominance that has a biochemical basis as well as structural and functional correlates (65–70). We speculate that the effect of DHA on light transduction in the retina early in life may have lasting effects (i.e., imprint) on the organization and function of the visual cortex. The alternative possibility is that DHA has an effect on photoreceptors as well as an independent effect on cortical maturation itself. No definitive answer can be established from the available data. As previously indicated, the fact that human milk-fed infants exhibited more mature stereo acuity at 3 yr relative to formula-fed infants suggests that this phenomenon may be relevant to humans (16). Additional supportive evidence on the possible long-term effect of early DHA supply on maturation of the visual cortex comes from a large population-based prospective study of determinants of stereo acuity development conducted in Bristol, United Kingdom in collaboration with one of us (E.B.). The results indicate that a maternal antenatal diet rich in DHA is associated with enhanced stereopsis of infants at age 3.5 yr after adjusting for other environmental as well as maternal and infant factors (71).

In conclusion, evidence for a beneficial effect of AA + DHA supplementation on CNS development is strong. The followup of supplemented infants beyond infancy should help to address the question concerning the persistence of effects beyond early life. Studies summarized in this review provide evidence supporting the view that dietary EFA supply affects visual development of preterm and term infants. The preliminary information on cognitive development is insufficient to fully establish a claim for an LC-PUFA effect on mental development. Human infants require dietary AA and DHA to maintain normal FA composition of plasma and RBC membrane lipids, and presumably of brain and retina. Differential gene expression induced by EFA and changes in membrane biophysical properties are likely responsible for the observed functional effects. Further work should lead to a better understanding of the mechanisms by which EFA affect visual and brain development and allow for a better definition of optimal nutrition in early life. Optimal in this context implies the right amount and balance of nutrients to obtain a desirable outcome (i.e., enhanced cognitive development or decrease in burden of disease in adult life) considering that there are inherent risks from excesses as well as deficits.

# Perinatal Characteristics May Influence the Outcome of Visual Acuity

**Maria Makrides[a], Mark A. Neumann[b], and Robert A. Gibson[a,*]**

[a]Child Nutrition Research Centre, Child Health Research Institute and Women's & Children's Hospital, North Adelaide, SA 5006, Australia, and [b]Department of Paediatrics & Child Health, Flinders Medical Centre and Flinders University, Bedford Park, SA 5042, Australia

**ABSTRACT:** Visual-evoked potential (VEP) acuity has been used to assess the effects of dietary fats on the integrity of the visual pathway of infants. We investigated prognostic determinants of VEP acuity at 16 wk of age. The results of two randomized dietary intervention trials designed to assess the effect of dietary fatty acids on the visual development of term infants were combined. At entry to both trials (~day 5 of life), a blood sample to assess polyunsaturated fatty acid (PUFA) status was collected along with sociodemographic and perinatal characteristics. At 16 ± 0.9 wk of age, infants underwent VEP testing to measure acuity. There was no effect of dietary treatment on these outcomes within or between trials. Multiple linear regression models were constructed to investigate the effect of perinatal and nutritional variables at study entry on VEP acuity of 185 infants. Higher birth weight was associated with an ability to resolve smaller checkerboard patterns [$r^2$ = 0.05; 95% confidence interval (CI), –0.10, –0.04 log units]. Male gender ($r^2$ = 0.03; 95% CI, 0.01, 0.07 log units), day 5 plasma 22:5n-6 ($r^2$ = 0.04; 95% CI, 0.02, 0.20 log units), day 5 red cell membrane 20:3n-9 ($r^2$ = 0.03; 95% CI, 0.03, 0.13 log units), and the number of smokers in the household ($r^2$ = 0.02; 95% CI, 0.00, 0.04 log units) were all associated with poorer VEP acuity scores. It is possible that a combination of perinatal factors could accumulate to either mask or enhance effects of diet on VEP acuity, given the relatively modest effects of long-chain PUFA on visual outcome.

Paper no. L8799 in *Lipids 36*, 897–900 (September 2001).

Intervention trials with dietary long-chain polyunsaturated fatty acids (LC-PUFA), such as docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (AA, 20:4n-6), have generally used visual acuity as a primary outcome measure. Studies of dietary n-3 fatty acid deficiency in rhesus monkeys documented that reduced n-3 LC-PUFA status was linked with impaired visual acuity and altered retinal function associated with reduced brain and retinal LC-PUFA composition (2,3). Randomized trials involving preterm infants have also consistently demonstrated that infants allocated to LC-PUFA–supplemented diets have improved visual acuity and retinal sensitivity compared with infants fed unsupplemented diets (4–6). However, trials involving term infants have demonstrated equivocal results, with some trials reporting modest positive effects of LC-PUFA supplementation on visual acuity and others reporting no effect (1).

Various factors have been put forward as possible explanations for these disparate results, including dose of DHA, the background level of α-linolenic acid (ALA, 18:3n-3) (7), sample size, and different methodologies. However, none adequately explains the differences in the results of the six current published trials of LC-PUFA intervention and visual outcome. We hypothesized that the inconsistent results of LC-PUFA randomized trials in term infants may be related to confounding effects from baseline perinatal factors, sociodemographic characteristics, and/or a relatively small LC-PUFA effect size (1).

We recently reported two randomized controlled trials that were designed to test the effect of dietary fatty acids on visual acuity as assessed by visual-evoked potential (VEP). One trial assessed the effect of an LC-PUFA intervention (8), whereas the other evaluated the effect of altering the ratio of essential fatty acids (9). Neither trial demonstrated an effect of dietary intervention on VEP acuity when infants were 16 wk of age (8,9). This is in contrast to a previous trial we conducted, where LC-PUFA supplementation of term infants resulted in improved VEP acuity compared with unsupplemented infants (8,9). Because of these conflicting results, we undertook a retrospective analysis of our two trials to identify prognostic variables of VEP acuity in healthy, term infants at 16 wk of age.

## METHODS

The data from two randomized controlled trials of formula feeding as well as their breast-feeding reference groups were combined (8,9). The trials had the same inclusion and exclusion criteria as well as the same data collection protocol. The only difference between the two trials was the dietary intervention. In one trial, infants were randomly allocated to either an infant formula with a linoleic acid (LA, 18:2n-6) to ALA ratio of 17:1.5 and no LC-PUFA or an identical formula but with 0.35% DHA from tuna oil or 0.34% DHA and 0.34% AA from egg phospholipid (8). In the other trial, infants were allocated to either a standard formula (LA/ALA ratio of 16.9:1.7) or one with high ALA (LA/ALA ratio 16.6:3.3) (9). In both trials, we also recruited a parallel group of breast-fed infants (8,9). Information on sociodemographic and perinatal

Abbreviations: AA, arachidonic acid; ALA, α-linolenic acid; DHA, docosahexaenoic acid; LA, linoleic acid; LC-PUFA, long-chain polyunsaturated fatty acid; MAR, minimum angle of resolution; VEP, visual-evoked potential.

characteristics was collected at study entry (approximately day 5 of life) as was a baseline blood sample by heel prick to assess plasma and erythrocyte membrane fatty acids (8,9). Infants had an ophthalmic examination at 10–12 wk of age and were excluded if their refraction was outside the range of –3 to +5 diopters or they had severe astigmatism (≥1.75 diopters) or strabismus. Infant VEP to different checkerboard patterns (7, 10, 14, 20, 28, 42, and 55 min arc) was tested at 16 wk of age (8,9). The peak-to-peak amplitude of the VEP (N1–P1) response was measured and plotted against the log of the angle subtended by each check size. The linear portion of the plot was extrapolated to 0 μV to give the theoretical value that would just elicit a response [log of the minimum angle of resolution (log MAR)]. Hence, lower log MAR values represent better visual acuity, as they indicate detectable responses to smaller checkerboard patterns. Points were excluded from the regression if they were not on the linear portion of the stimulus–response function or represented amplitudes of ≤2 μV (8,9). VEP acuity extrapolations were accepted as valid only if there were at least three points and the regression line was significant ($P < 0.05$). There were no differences in VEP acuity values between dietary groups within either trial or between the two trials.

*Statistics.* Multiple linear regression models were constructed to evaluate the possible effects of baseline sociodemographic and perinatal variables on VEP acuity at 16 wk of age. The independent variables considered for the regression model were gender, gestational age, birth size, birth order, parental smoking, education and social scores, number of siblings, and infant plasma and erythrocyte membrane polyunsaturated fatty acids measured on day 5 of life. Infants with incomplete data sets were excluded. The models were constructed using the independent variables that were associated ($P < 0.2$) with the dependent variable. Independent variables were removed if the independent variable's presence or absence did not influence the model. The regression-standardized residuals of the dependent variable, VEP acuity, were normally distributed. All analyses were performed using SPSS for Windows 7.5 (SPSS Inc., Chicago, IL).

## RESULTS

In the original trials, a total of 261 infants underwent VEP testing at 16 ± 0.9 wk of age [95% confidence interval (CI), 15.2–17.7 wk]. The age bracket of testing was narrow, and, as a result, there was no association between age at testing (postnatal age) and VEP acuity.

Among the 261 infants tested, 194 had successful VEP acuity extrapolations (Table 1). These 194 infants had significantly lower mean birth weight and lower mean birth length compared with infants with unsuccessful VEP acuity extrapolations, even following adjustment for gender (Table 1). There were no other significant differences in sociodemographic or perinatal characteristics between infants with successful and unsuccessful VEP acuity determinations.

[b]Median score; education was ranked using a six-point scale: 1 = primary school level, 2 = mid secondary school level, 3 = completion of secondary school, 4 = completion of a certificate or diploma, 5 = tertiary degree, 6 = higher degree.
[c]Median score; the highest rank (1) was assigned to professionals and academic occupations and the lowest rank (6) was assigned to unskilled occupations.

Of the 194 infants with successful extrapolations, 185 were included in the regression model to predict VEP acuity. Eight infants were excluded because they had incomplete data sets, and the ninth one excluded was an outlier (>3 SD from the mean acuity). A combination of perinatal factors explained 17% of the variance in VEP acuity at 16 wk of age (Table 2). Birth weight explained 5% of the variance in VEP acuity, and a 1-kg increase in birth weight was associated with an ability to resolve smaller checkerboard patterns by 0.07 log units (Table 2). Male gender, day 5 plasma 22:5n-6, day 5 red cell 20:3n-9, and the number of smokers in the household were all associated with poorer VEP acuity scores (Table 2). Day 5 DHA status was not associated with VEP acuity at 16 wk.

## DISCUSSION

The use of VEP acuity as a test of visual/neural development in infants has been extensive in the area of LC-PUFA research although the long-term relevance of this test is yet to be fully assessed. The modest and inconsistent differences reported to date between infants receiving LC-PUFA–supplemented formula and those fed unsupplemented formula make it important to ensure that the data are free from potential confounders or effect modifiers so that the full effect of dietary LC-PUFA can be determined.

It is interesting to note the similarity of reported VEP acuity values across study centers, despite the diversity of VEP acuity testing procedures. The actual VEP acuity values of breast-fed and formula-fed infants at 16 wk of age observed in the combined data from our two trials were similar to values observed in the placebo formula-fed infants in our original study measured using different hardware (10). Other trials have demonstrated VEP acuity values in breast-fed and formula-fed infants similar to the data reported here (11). The VEP acuity values recently reported by Birch *et al.* (12) at 17 wk of age are approximately 1 SD lower than our data (8,9) and those of Auestad *et al.* (11). However, it should be noted that all trials report acuity values within the expected normal range.

Importantly, we could find no direct effect of DHA status near birth on VEP acuity. It has been suggested that the n-3 LC-PUFA status of infants at birth may be prognostic (antecedent variable) of later visual and neurological development (13,14). This postulate has been put forward as a possible explanation for inconsistent findings of randomized trials of formula feeding of term infants with and without LC-PUFA supplementation. It is proposed that n-3 LC-PUFA status near birth may confound any subsequent effect of dietary LC-PUFA on visual outcomes (13). In other words, those infants born with the highest DHA status may be less responsive to dietary supply. In our data, DHA was not a predictor of VEP acuity and only 22:5n-6 (which may be an indirect index of n-3 LC-PUFA status) predicted VEP acuity at 16 wk of age. This may be an insignificant association, as the regression model predicts that a 1% change in plasma 22:5n-6 level would be required for a 0.109 log unit change in acuity, which is unlikely even in infants fed n-3-deficient diets (15). Therefore, our data do not provide support for the hypothesis that n-3 LC-PUFA status at birth is a significant prognostic variable of visual outcome.

In our regression model to predict VEP acuity, higher birth weight emerged as a small but significant influence on improved acuity. This finding is similar to that reported by Jorgensen *et al.* (16). It is interesting to note that infants without VEP acuity extrapolations had higher birth weights compared with infants included in the regression model. This may indicate that the maximum of the spatial tuning curve of these infants occurred at the smaller checkerboard patterns, hence leaving too few points on the linear portion of the curve for extrapolation to the threshold (acuity) value (9). It is therefore likely that the infants excluded from the regression model had acuity values beyond the sensitivity of the test and that the effect of birth weight on VEP acuity is thus underestimated in our regression model. In any event, it may be important to adjust for birth weight in any analysis of VEP data.

Male gender also emerged in the regression model and was associated with poorer outcome. These findings are consistent with the negative association between male gender and global measures of neurodevelopment (17,18) and highlight the need for adequate gender stratification in randomized trials. Similarly, parental smoking was associated with poorer VEP acuity, independently of birth weight.

It is possible that the factors that have emerged as being prognostic of acuity in our data set may have confounded the outcome of previous trials. A combination of the independent variables birth weight, gender, and the number of smokers in the household can predict VEP acuity, and the magnitude of this association is similar to the postulated difference in VEP acuity between LC-PUFA–supplemented and unsupplemented infants at about 4 mon of age (1). It is therefore possible that a number of perinatal factors could be additive and

thereby mask or enhance dietary effects on VEP acuity, particularly since the effects of LC-PUFA on visual outcome are likely to be modest.

It should be noted that mothers and infants in our trials might have had different social and demographic characteristics from study samples in other trials. The infants in our trials were from families where, on average, both parents completed secondary education and infants had birth characteristics indicative of well-nourished and uncomplicated pregnancies. Thus, it is reasonable to suppose that the perinatal factors that are predictive of outcomes in other study populations may be different from those reported here.

So what do our results mean to researchers in this area? The effects of gender and birth weight may be balanced in any trial but only if adequate randomization and stratification procedures are in place. The other effects we have seen may be too small to be clinically important or even strong enough to influence an effect of diet. However, it is important for researchers to conduct their own tests of their data, *post hoc*, in order to assess actual power and whether or not they may have confounding influences in their data sets.

In summary, using the largest sample of VEP reported to date on healthy term infants and tested at the same postnatal age, we have demonstrated that a variety of perinatal characteristics including birth weight, gender, and number of smokers in the household need to be considered in relation to VEP acuity.

# Polyunsaturated Fatty Acids and Infant Growth

**Alexandre Lapillonne[a] and Susan E. Carlson[b,*]**

[a]USDA/ARS Children's Nutrition Research Center, Department of Pediatrics, Baylor College of Medicine, Houston, Texas, and [b]Departments of Dietetics and Nutrition and Pediatrics, University of Kansas Medical Center, Kansas City, Kansas

**ABSTRACT:** Because of the rapid rate of growth during infancy, and the potentially deleterious effect of differences in the availability of dietary essential nutrients, growth is an important outcome variable in any study assessing a diet designed for infants. Nearly 10 yr after the first demonstration of reduced growth in preterm infants fed a fish oil-enriched formula, there is very little additional information to confirm or refute the finding that long-chain n-3 polyunsaturated fatty acid (LC-PUFA) intake can modulate growth in infants. To evaluate the issue of a possible relationship between PUFA intake and growth of infants, we reviewed a total of 32 randomized studies, 13 in preterm infants and 19 in term infants. From the data published to date, it seems clear that long-chain n-3 fatty acids can reduce growth achievement in preterm and term infants under some experimental conditions. However, the effect of n-3 PUFA supplementation on the growth of preterm and term infants appears to be minimal and of questionable clinical and/or physiologic relevance. Nonetheless, n-3 fatty acids have an effect on gene transcription, at least in some species, and this finding may provide important clues to the mechanism by which n-3 and n-6 fatty acids regulate growth.

Paper no. L8796 in *Lipids 36*, 901–911 (September 2001)

Despite the common use of growth assessments, the interpretation of these assessments is not necessarily straightforward. In retrospect, this could be said to be the case for several randomized studies in prematurely born human infants who were fed very long chain n-3 fatty acids [eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA)] and showed lower growth in supplemented vs. control groups (1–3). Lower growth in preterm infants was perceived as an adverse or potentially adverse outcome. Nearly 10 yr after the first such study was reported, however, there is very little additional information to confirm or refute the finding that long-chain n-3 polyunsaturated fatty acid (LC-PUFA) intake can modulate the growth of infants. Surprisingly, few data are available to help evaluate the clinical significance of the growth effects that were observed (4).

Studies evaluating LC-PUFA supplementation in infants were designed primarily to assess the effects of supplementation on PUFA status and visual, cognitive, and/or behavioral development. It has become clear that supplementation of formulas with n-3 and n-6 LC-PUFA is desirable for visual and/or neural development. However, only a few studies were designed specifically to evaluate growth, even if virtually all have included reports of anthropometric measures. These studies utilized formulas with a variety of linoleic acid (LA)/α-linolenic acid (ALA) ratios, as well as various amounts and/or sources of LC-PUFA. Among the studies, the duration of supplementation and/or followup, the outcome variables evaluated, and the number and birth weights of infants included in each group were also quite variable. Furthermore, the effect of gender has seldom been studied, and the growth of infants not always normalized to reference growth curves. Without these considerations, and in the absence of normalization to an established standard of growth, it is difficult to conclude that supplemented infants who grew less well than their own controls were at any real risk for growth impairment.

To address the issue of a possible relationship between PUFA intake and infant growth, we reviewed 13 randomized studies in preterm infants and 19 randomized studies in term infants. We included those studies that examined growth data of at least two groups of infants fed formulas with different fatty acid patterns, i.e., either different LA/ALA ratios or different amounts of LC-PUFA. Few of the studies were designed as growth trials, *per se*. Not all had enough power to detect an effect of PUFA supplementation on growth. If we assume that a difference of 1 SD in weight and/or length is of physiologic relevance, then the sample size required to observe such a difference in growth between two groups ($\alpha$ 0.05, power 0.80) is, theoretically, 16–18 infants/group. If the expected effect on growth is smaller, 0.7 SD or 0.5 SD, for example, then ~34 or ~66 infants, respectively, must be included to detect an effect on growth with the same power and $\alpha$. Because effects of n-3 fatty acid supplementation on growth of preterm infants have not been observed before ~10 wk of feeding (1), we may postulate that studies of <10 wk duration and with 16 infants cannot be used to conclude that there were not effects of n-3 supplementation on growth.

Because of the need to present a complete perspective on this subject and to evaluate all potential indicators, we provide here a summary of the evidence from the relevant studies. The data for preterm and term infants are delineated separately and results obtained in the larger studies are emphasized. The final section reviews molecular effects of n-3 fatty acids that may hold clues to the mechanism by which n-3 and/or n-6 fatty acids regulate growth.

Abbreviations: AA, arachidonic acid; ALA, α-linolenic acid; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; LA, linoleic acid; LC-PUFA, long-chain n-3 polyunsaturated fatty acids; NCHS, National Center for Health Statistics; PG, prostaglandin; PMA, postmenstrual age; PPAR, peroxisome proliferator-activated receptor.

## PUFA INTAKE AND GROWTH OF PRETERM INFANTS

Three studies in human preterm infants have reported effects of n-3 fatty acid intake on growth (1–3). In each of these studies, DHA was fed without a source of arachidonic acid (AA, 20:4n-6) although the formulas contained large amounts of the essential fatty acid linoleic acid (LA), the precursor of AA.

In the human infant study that found the most pronounced effect on growth of feeding an n-3 LC-PUFA–enriched formula (1), all anthropometric assessments from 0 to 12 mon corrected age were lower in the supplemented vs. the control group. Infants had an average birth weight of ~1.1 kg. There were a number of factors in the design that likely contributed to the size of the effect. First, infants were fed a large total amount of long-chain n-3 fatty acids because the fish oil supplement contained 0.3% EPA as well as 0.2% DHA, the intended additive, and the formula already contained a high amount of ALA. Second, the supplemented formula was fed for 11 mon. Third, the formula did not contain AA to balance the long-chain n-3 fatty acids, although it did contain a large amount of LA. Plasma concentrations of phosphatidylcholine AA (the average at 2, 4, and 6.5 mon) were used as the measure of infant AA status. AA status explained 7–23% of weight and length attainment during the time interval from 0 to 12 mon adjusted age (5). It was speculated that the greater decline in normalized growth in infants randomized to receive high-EPA fish oil supplementation compared with control formula was related to the effects of fish oil n-3 fatty acids on AA status (1).

The two other studies that involved the finding of an adverse effect of fish oil–supplemented formula on the growth of preterm infants had close to 30 infants/group (2,3). In both of these studies, however, the design should have mitigated the effects of fish oil on infant AA status. In one of these (2), the n-3 fatty acid–supplemented formula was fed for ~19 wk to ~1 kg birth weight infants (until 2 mon adjusted age). The source of DHA was low-EPA fish oil, which effectively reduced the intake of long-chain n-3 fatty acids by half compared with the first study (1) but provided the same amount of DHA. Normalized weight, length, and head circumference of the infants showed no overall effect of diet. However, n-3 LC-PUFA–supplemented infants had a lower normalized weight at 6 and 9 mon, lower weight-for-length at 2, 6, 9, and 12 mon, and lower head circumference at 9 mon. In particular, the lower weight-for-length of the infants fed the n-3 fatty acids suggested they might be somewhat leaner than the infants fed the commercially available formulation.

Ryan *et al.* (3) reported data of infants fed a low-EPA fish oil for 24 wk. Mean birth weight of infants was ~2 kg, considerably higher than that in all but one (6) of the studies involving the feeding of experimental formula supplemented with fish oil without AA (1,2,7,8). The data were normalized for age, but males and females were studied independently so that the actual comparison groups included ~15 infants of the same gender. Compared with males who were given the control formula, males fed the experimental formula had consistently lower Z-scores for weight, length, and head circumference throughout the study to 4.5 mon corrected age, but the differences were not significant. Absolute weight and length of the male infants, but not the female infants, were statistically lower in the experimental group than in the control group at 4.5 mon. In addition, n-3 fatty acid–supplemented male infants had a lower head circumference at 2.5 and 4.5 mon. Estimates of body composition, determined by total body electrical conductivity, indicated that males fed the supplemented formula had significantly lower fat-free mass at 2.5 and 4.5 mon. A lower fat mass also was observed for those in the fish oil-fed group, but the difference was not significant.

Three other studies reported growth of preterm infants fed fish oil without additional AA (Table 1). One was conducted at the same time as the first study discussed above. In this study, supplemented infants received slightly greater amounts of LC-PUFA, and the experimental formula was fed for only 25 wk (7) compared with 48 wk (1). There was no effect of the fish oil-supplemented formula on normalized weight, length, or head circumference at 0, 1, 2, 3, or 4 mon corrected age in infants with an average birth weight of 1.3 kg. The study had adequate power to detect a difference in growth of ~1 SD.

Growth data were also reported in a study in which low-EPA fish oil was fed to one group of 29 infants for only 4.5 wk (6), as well as in a study in which low-EPA fish oil was fed for 23 wk to a group of 11 infants (8). Neither study was intended as a growth study, and the studies lacked either a sufficient number per group, or a long enough duration of feeding to reach conclusions about growth.

Other studies in preterm infants provided both DHA and AA in the experimental formula (Table 2). The sources of LC-PUFA have included egg lipids (9), egg phospholipids (10), egg triglycerides (11), single-cell oils (11–16), and fish oil (11). Two of these studies (11,16) found lower growth rates in infants supplemented with DHA and AA compared with those in a control group but no significant effects on actual weight, length, or head circumference. In one study (16), a lower mean increase in length from 0 to 12 mon corrected age was observed in the group fed the single-cell–enriched formula. In the second study (11), a lower length gain between study entry and 4 mon corrected age and a lower head circumference gain (females only) were observed in the group fed the enriched formula with egg triglycerides and fish oil. In contrast to these studies, however, another study (14) found higher growth during the period from enrollment (30 wk postmenstrual age, or PMA) until 56 wk PMA (4 mon corrected age) with DHA and AA supplementation. None of these three studies (11,14,15), which included large groups of infants ($n$ = 58–144) that should have been adequate to detect differences in growth of <0.5 SD, demonstrated a significant effect of DHA + AA supplementation on the actual weight, length, or head circumference in the supplemented groups. The remaining four studies that provided DHA and AA to preterm

infants were not designed to measure growth as an outcome. One (10) had sufficient power to detect a difference of 1 SD in growth, but the three other studies (9,12, 13), were too small, or of too limited duration, to permit detection of anything other than extremely large effects of diet on growth.

In summary, three of six reports of preterm infants supplemented with n-3, but not n-6, LC-PUFA showed lower growth. The other three studies in this group may have had too few subjects to detect an effect on growth (7,8) or have provided an experimental formula for only a short period of time (6). It seems clear that long-chain n-3 fatty acids can reduce growth achievement in preterm infants under some experimental conditions. One may speculate from the combined results of these studies that growth is more likely to be affected under conditions that would have the largest effect on the already marginal AA status of preterm infants (17). The most recent trials (11,14,15) have provided substantial data on the effect of balanced addition of DHA and AA to preterm formulas. Excepting some inconsistent effects on rates of growth, they have not demonstrated significantly different absolute growth in the experimental groups compared with the control group (Table 2).

## PUFA INTAKE AND GROWTH IN TERM INFANTS

Because of concern about the effect of dietary manipulations of n-3 LC-PUFA on growth in animals as well as in preterm infants, the Expert Panel of the Life Sciences Research Office (LSRO) of the American Society for Nutritional Sciences (18) did not recommend the addition of AA or DHA to term infant formula.

Because of the variable LC-PUFA content of human milk, one might suggest that differences in the PUFA composition of human milk could affect the postnatal growth of term infants. No study to date has addressed this issue, but several studies have provided postnatal growth data on infants of mothers randomly assigned to a DHA supplement from microalgae, fish oil, or high-DHA eggs (19–21). These supplements significantly modified the fatty acid composition of breast milk and the plasma or erythrocytes of the infants, but growth of the various groups of breast-fed infants did not differ. These findings suggest that changes in the diet of the mother do not significantly alter the fatty acid status of their infants to an extent that would be sufficient to influence postnatal growth. However, because these studies included only a small number of infants, further studies are required to evaluate this issue.

To examine the possibility of a relationship between PUFA intake and growth of term infants, we reviewed 19 randomized studies that included growth data on at least two groups of term infants fed formulas with different fatty acid patterns, i.e., either different LA/ALA ratios or different amounts of LC-PUFA (Tables 3 and 4). Only one of the 19 studies suggests that the amount of n-3 fatty acids significantly affected the growth of term infants (22). In that study, infants were fed formulas containing ~16% of total fatty acids as LA, and 0.4, 0.95, 1.7, or 3.2% of total fatty acids as ALA (LA/ALA ratios from 5:1 to 44:1). The group of infants fed the highest ALA intake had the highest plasma phospholipid ALA, EPA, and DHA concentrations. Equally importantly, this group had the lowest plasma phospholipid AA and 22:5n-6 concentrations. At 120 d of age, and only at this study point, the mean weight of the group that received the formula with 3.2% of total fatty acid as ALA was significantly lower than that of the group that received the formula with 0.4% ALA. There was no significant difference among feeding groups in weight before or after 4 mon of age. There also was no significant difference among groups in length, head circumference, triceps, or subcapsular skinfold thickness, although all of these measurements tended to be lower in the infants who received the highest ALA intake. This study suggests that the differences in growth pattern could be related to differences in ALA intake. However, it does not differentiate between the effects of ALA intake *per se* vs. differences in the LA/ALA ratio. The absence of any significant effect of ALA intake or the LA/ALA ratio on growth in three other studies (23–25) is further evidence that large differences in n-3 PUFA intake are needed to affect growth.

In contrast to studies in preterm infants, no significant reductions in weight or length have been reported among groups of term infants fed formulas supplemented with egg lipid (26–29), egg phospholipid and/or triglyceride (30–33), various fish oils (31–38), or single-cell sources of DHA and/or AA (33,39,40). One study, however, reported a significantly lower head circumference at 4 mon of age in infants fed a formula enriched with low-EPA fish oil vs. the unsupplemented formula (35). However, the head circumference of the infants fed the enriched formula was within the normal range for age and also similar to that of a reference breast-fed group. In addition, Morris *et al.* (40) reported that the subscapular skinfold thickness of infants fed a formula enriched with single-cell oils (DHA + AA) was significantly lower than that of controls at both 6 wk and 3 mon of age. The triceps skinfold thickness and mid-arm circumference also were slightly lower than in controls, although the differences were not significant. These findings suggest a decreased fat deposition in infants fed an LC-PUFA–enriched formula.

In one of the largest studies published to date (33), an increase in weight gain for male infants was observed between enrollment and 4 mon in the group fed a fish oil + fungal oil–enriched formula compared to a control.

It should be noted, however, that with few exceptions (30–33,39,40), either small numbers of infants were included and/or the duration of supplementation was short, so it cannot

be concluded that term infants might not show effects of n-3 LC-PUFA on growth like those that have occurred in some studies of preterm infants.

A relationship between n-3 PUFA intake and growth in formula-fed infants may exist in term infants, as indicated by the study of Jensen *et al.* (22). However, the data reported to date suggest that the effects of n-3 PUFA supplementation on the growth of term infants are observed only when comparisons are made between infants fed a formula supplemented with low vs. very high levels of n-3 PUFA. These effects were small and have questionable clinical relevance. Just as has been observed in preterm infants, the trials in term infants with balanced addition of DHA and AA did not result in findings of lower growth in the experimental group compared with the control group (Table 4). A difference in skinfold thickness in one of these studies suggests, however, a lower rate of fat deposition in infants fed an n-3 and n-6 LC-PUFA–enriched formula. In the absence of any direct data on body composition, and because of the small number of studies actually designed to validly assess the effect of LC-PUFA on growth, studies are needed to monitor the long-term growth and quality of growth (i.e., body composition) of term infants fed an LC-PUFA–enriched formula.

## DOES THE COMPARATIVELY REDUCED GROWTH RATE OF INFANTS FED n-3 PUFA–SUPPLEMENTED FORMULAS HAVE ANY CLINICAL RELEVANCE?

In general, any adverse effect on weight gain or achieved weight in infants, particularly preterm infants, is considered undesirable. However, it is not clear that this is the case with respect to the effect of n-3 PUFA on growth. The supplemented groups that grew more slowly than randomized controls appeared to experience excellent growth when held to an established standard of growth (4). Given these considerations, it is difficult to conclude that supplemented infants who grew less well than their own controls are at any real risk. For example, the observed effect of n-3 PUFA on growth was rather small in the study of Jensen *et al.* in term infants (22). The mean weight of infants who received the highest ALA intake was only 0.1 SD below the National Center for Health Statistics (NCHS) 50th percentile value for weight at 120 d of age, whereas the mean weights of the other groups were above the 50th percentile.

To evaluate the clinical relevance of the effect of high- or low-EPA fish oil supplementation on the growth of preterm infants, the data on the growth of preterm infants published by Carlson *et al.* (1,2) were compared with NCHS data (41) on growth of term infants to generate percentiles for norms. However, a possible limitation of the preterm studies that showed effects of feeding long-chain n-3 fatty acids alone on growth is that all were conducted with populations having a high proportion of infants of African descent (1–3). The growth of term infants from one of the study sites indicated that first-year growth of term infants of primarily African descent may have been at a slower rate than that of infants included in the NCHS (Z-score 0 means growth at the 50th percentile for the reference group, here the NCHS group) (42; Carlson, S., unpublished data). Therefore, growth data of term infants (*n* = 61) enrolled in the same hospital and followed over the first 12 mon of life were also used to create other normative data from the same population (called the reference group) and are reported with growth data of preterm infants fed control and high-EPA fish oil–containing formulas (Fig. 1) or control and low-EPA fish oil–containing formulas (Fig. 2).

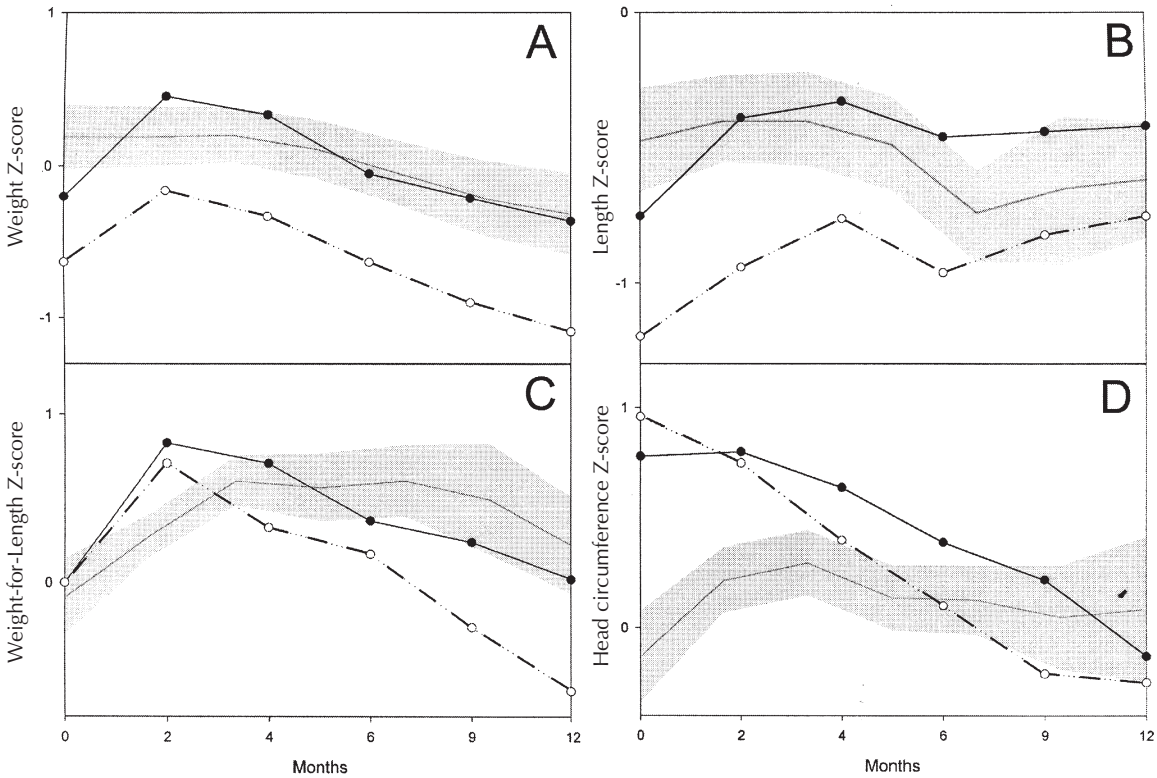

**FIG. 1.** The shaded areas are the normalized (±SEM) weight (A), length (B), weight-for-length (C), and head circumference (D) for 61 normal term infants enrolled from the same hospital and with similar demographics compared with the preterm infants fed control formula (●) and formula containing high-eicosapentaenoic acid (EPA) fish oil (○). See Reference 1 for population characteristics of preterm infants and other aspects of study design.

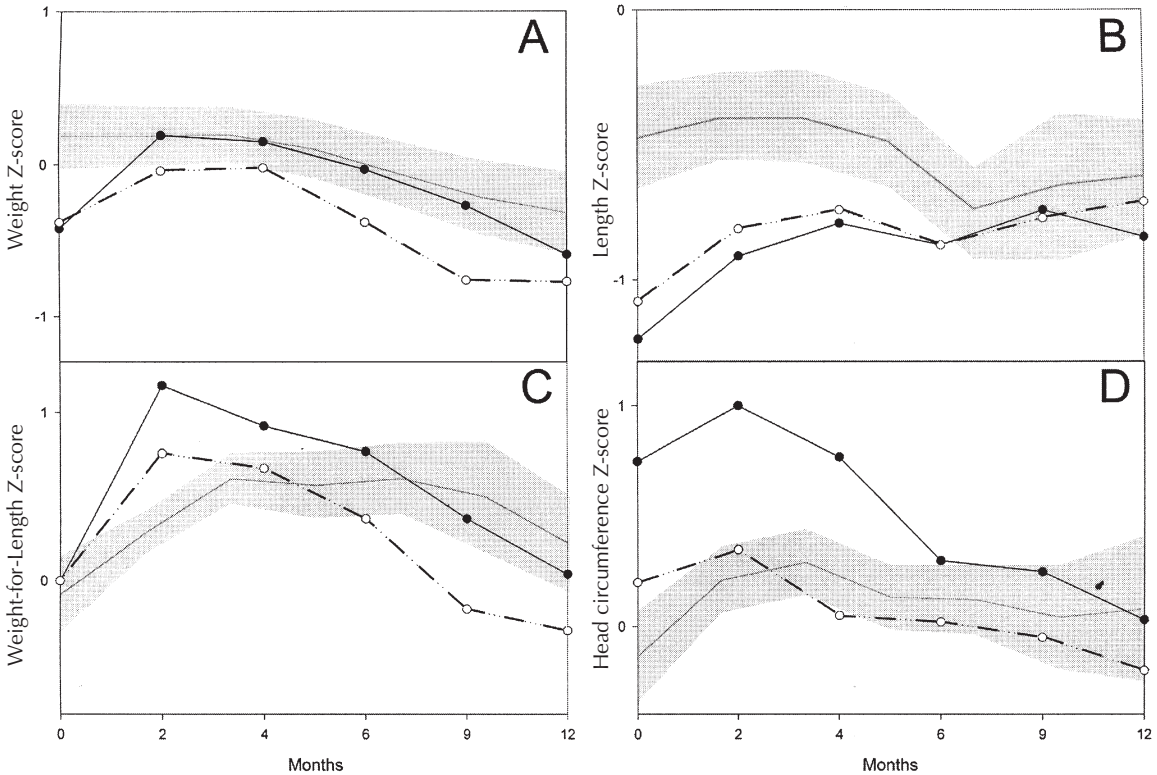

**FIG. 2.** The shaded areas are the normalized (±SEM) weight (A), length (B), weight-for-length (C), and head circumference (D) for 61 normal term infants enrolled from the same hospital and with similar demographics compared with the preterm infants fed control formula (●) and formula containing low-EPA fish oil (○). See Reference 2 for population characteristics of preterm infants and other aspects of study design, and Figure 1 for abbreviation.

Figures 1A and 1B illustrate the weight and length, respectively, of preterm infants fed the high-EPA fish oil–containing formula or the control formula. The randomized control group had caught up to and exceeded the 50th percentile for weight of the reference group of term infants by 2 and 4 mon. From 6 to 9 and from 9 to 12 mon, the mean normalized weight of the preterm control group declined progressively but was virtually identical to that of the reference group. Normalized length of the preterm control group exceeded that of the reference group by 4 mon corrected age and remained greater for year 1 of life. The normalized weight of infants fed the high-EPA fish oil–enriched formula showed the same pattern as the reference group and was significantly lower than the randomized control group of preterm infants at every age studied (0.4–0.8 SD). The linear growth of the experimental group was 0.2–0.3 SD below that of the reference group by the corrected age of 12 mon, but it was 0.5–0.6 SD below that of the randomized control group. Compared with the growth of the reference group from the same population, it is clear that the control randomized preterm group grew as well (weight) or better (length) than infants born at term. If catch-up growth in the supplemented group was slower than in the controls, it was also clear that the linear growth achieved by 12 mon corrected age in the experimental group was only slightly less than that of the reference group. In fact, growth of these ~1.1 kg birth weight infants was as good as or better than that reported for much larger infants studied in a multicenter trial during the same period (43).

The linear growth of preterm infants fed the low-EPA formula was unaffected by diet at any age (2; Fig. 2B). It can be seen from Figure 2A that a difference in weight began to emerge at the adjusted age of 2 mon, when the experimental formula was stopped. At 12 mon corrected age, the weight of preterm infants fed the experimental and control diet was the same but was 0.3–0.4 SD lower than the reference group. Linear growth of the two preterm groups was virtually identical from 0 to 12 mon of age. By 6 mon of age, both groups were 0.2 SD lower than the linear growth of the reference group, and at 9 and 12 mon, both groups were within the SEM for linear growth of the reference group (Fig. 2B). It can therefore be concluded that, compared with the growth of healthy term infants recruited from the same hospital and having the same demographic characteristics, the growth of preterm infants randomized to receive n-3 fatty acids from a low-EPA fish oil appeared to be only minimally compromised.

Head circumference data (Figs. 1D and 2D) indicate the rather remarkable variance of head circumference of preterm infants from both the NCHS reference and the term reference group from the same population. It is not clear at which point the variance in head shape due to prematurity might give way to the actual size of the brain as a predictor of head circumference in these preterm infants, if ever. It can be stated simply that head circumference of all four study groups fell within 1 SEM of the reference group by 12 mon corrected age.

Taking into account the observations described above, it can be argued that the apparent effects of ALA intake on weight gain of term infants, and of fish oil on the weight (Figs. 1A and 2A) and weight-for-length (Figs. 1C and 2C) of preterm infants are of questionable clinical and/or physiologic relevance (4). The effect of n-3 PUFA on growing infants may prove to be desirable in certain aspects of body composition, particularly if it reflects a lower rate of fat deposition, as the lower skinfold thickness and the reduced weight-for-length ratio suggest. Regardless of whether infants were fed high-EPA fish oil for 11 mon (Fig. 1C) or low-EPA fish oil for 5 mon (Fig. 2C), weight-for-length fell below 1 SEM of the reference group at 6, 9, and 12 mon corrected age. This was not the case for the randomized control group. With the increasing incidence of obesity in infants, older children, and adolescents, it seems wise to begin devising strategies for reducing fat deposition without reducing deposition of lean body mass, even during infancy. Modification of the quality of dietary fat, with or without a modest decrease of nonprotein energy as fat, conceivably could modify weight gain of infants without adversely affecting linear growth.

## PHYSIOPATHOLOGY

The mechanism whereby PUFA may affect the rate and/or composition of weight gain in infants is not clear. None of the studies performed in either term or preterm infants provide specific clues to address this issue. In general, differences in rates of growth among groups of similar infants reflect differences in nutrient intake, nutrient absorption, and/or nutrient utilization/deposition. Most of the studies cited included an assessment of intake, and differences between groups were minimal. None included an assessment of nutrient absorption, but there is little reason to expect differences in this area. How n-3 fatty acids affect nutrient utilization and/or deposition is not known, but data recently obtained, primarily in rodent models or cell cultures, offer potential clues.

Some studies have shown that growth is significantly correlated with the plasma and/or erythrocyte phospholipid content of AA and other n-6 fatty acids (1,2,22). Others have shown a negative association between DHA status and growth (31), but most have shown no significant correlation between any fatty acid and growth (24,38). Moreover, the correlations that have been reported, although significant, were usually quite weak. These discrepancies among studies raise the question whether the correlations between fatty acids and growth represent a cause-and-effect relationship. Because the mean AA content of erythrocyte phospholipid is usually lower in n-3 fatty acid–supplemented vs. unsupplemented groups, correlations between AA status and growth would be expected even if the effects of n-3 fatty acids on growth and on the AA content of plasma and/or erythrocyte phospholipid were independent. Therefore, it remains controversial whether the decrease in n-6 PUFA status (i.e., AA) or the increase in n-3 PUFA intake plays a major role in lowering weight gain and skinfold thickness in infants fed a formula supplemented with n-3 fatty acids, and the mechanism of the growth effects remains unclear. On the other hand, it should be noted that a decreased rate of growth is a prominent feature

of n-6 fatty acid deficiency (44,45). Indeed, infants who were fed a formula based on skim milk, or who were kept on lipid-free parenteral nutrition, developed growth retardation with dermatitis. The role of n-6 PUFA deficiency in growth was confirmed when growth failure and other symptoms could be prevented or cured if LA or AA were added.

A large body of literature suggests that the fatty acid composition of dietary lipid and, hence, tissue lipid membranes influence both hormonal signaling events and the molecular events governing gene expression (46,47). Numerous studies, performed primarily in rodents, have demonstrated that the ingestion of fats rich in n-3 PUFA (e.g., a large amount of fish oil) suppresses hepatic lipogenesis (47,48), reduces hepatic triglyceride output (49), enhances ketogenesis (50), and induces fatty acid oxidation in both liver and skeletal muscle (51,52). Further, these changes in fuel metabolism are accompanied by a decrease in body fat deposition (51,53). Although the repartitioning of fatty acids away from triglyceride synthesis and toward oxidation may explain the lipid-lowering effects of dietary n-3 PUFA, it cannot explain why fat deposition is less efficient in animals fed diets that are rich in n-3 LC-PUFA (46). Such an explanation requires the induction of biochemical processes that enhance heat production and are inducible by dietary PUFA. In this regard, peroxisomal fatty acid oxidation and the uncoupling of mitochondrial oxidative phosphorylation appear to fulfill this requirement. Indeed, there are data suggesting that PUFA induce the thermogenic pathways of peroxisomal fatty acid oxidation and uncoupled mitochondrial oxidation, and also reduce weight and fat deposition (46,47,54). The mechanisms by which PUFA are responsible for these metabolic outcomes appears to be exerted largely at the genomic level. Peroxisome proliferator-activated receptor (PPAR), particularly PPARα, which is expressed primarily in the liver, appears to be the major transcription factor that coordinately up-regulates genes encoding proteins involved in lipid oxidation and thermogenesis. Of major interest is the finding that several fatty acids bind to PPARα. In this respect, oils that are rich in n-3 PUFA (e.g., fish oils) appear to be even more efficacious than vegetable oils rich in n-6 PUFA. Thus, the activation of PPARα by n-3 PUFA, with up-regulation of the transcription of genes involved in lipid oxidation and thermogenesis, if it occurs *in vivo* in infants, could explain the lower rates of weight gain and/or skinfold thickness observed in infants fed a formula supplemented with n-3 PUFA.

In addition to their role in the expression of genes involved in lipogenesis and fat oxidation, PUFA appear to function in the control of adipogenesis. In this regard, adipogenesis is influenced more by n-6 PUFA than n-3 PUFA because PUFA themselves appear to have moderate effects on this regulation compared with various arachidonate metabolites. Mature adipocytes and cultured preadipocytes produce significant amounts of prostaglandins (PG) from AA ($PGE_2$, $PGD_2$, $PGF_{2\alpha}$, and $PGI_2$). PG have been shown to modulate preadipocyte differentiation by either promoting or inhibiting differentiation (55). This suggests that the balance between the two pathways is important and could determine the net effect of PG on the differentiation program. In this regard, it has been observed that 20:5n-3 inhibits fat cell differentiation, which suggests that 20:5n-3 may give rise to a biologically less potent activator of adipose differentiation (56). To date, there is more evidence to suggest that AA metabolites may promote rather than inhibit preadipose differentiation (55). Specifically, some of the PG were shown, at micromolar concentrations, to stimulate adipose differentiation *in vitro* through their interaction with PPARγ (56,57). Possibly in coordination with other transcription factors, PPARγ activates target genes, which promote differentiation of preadipocytes to adipocytes, and appears to play a key role during the last steps of differentiation (55). On the basis of these findings, we may postulate that a decrease in AA status in infants may reduce adipocyte status, whereas an increase in AA status may promote adipocyte differentiation, and hence, fat accumulation and deposition. Furthermore, the observation that plasma and/or erythrocyte content of 20:5n-3 is higher in all studies showing a negative effect of n-3 fatty acids on growth of infants supports the hypothesis that a biologically less potent activator of adipose differentiation was produced from 20:5n-3.

To our knowledge, the proposed mechanisms described above (i.e, up-regulation of genes encoding for fat oxidation, thermogenesis, and regulation of adipose differentiation) have not been shown to occur *in vivo* in humans, although they have been shown to occur in rodents and cell cultures. It is also possible that several other mechanisms may explain how n-3 and n-6 PUFA can modulate growth. Indeed, AA and its bioactive metabolites mediate the secretion of several hormones associated with growth and metabolic functions. These include luteinizing hormone, prolactin, adrenocorticotropic hormone, and corticotropin-releasing hormone (58). The hypotheses described above are consistent with the lower rates of weight gain and possibly fat deposition observed in infants fed formulas supplemented with n-3 PUFA. Discrepancies in the possible effects of n-3 PUFA on growth among the studies may be explained by the observation that effects of n-3 PUFA on growth were observed in studies utilizing relatively large amounts of total n-3 PUFA (ALA alone or ALA + fish oil). This raises the possibility of a dose response or threshold value for the n-3 fatty acids to reduce rates of weight gain and fat deposition in infants. In this regard, data in rodents support the possibility of a dose response of n-3 PUFA on fat deposition. On the basis of the difference in magnitude of the effects of n-3 PUFA supplementation on growth and/or fat deposition between rodents and humans, it may be postulated that the intensity of the cellular effects of PUFA in rodents and humans may differ, with a much higher response in rodents than in humans (59). Nonetheless, it seems reasonable to postulate that the mechanisms involved are similar in both species.

In conclusion, it is clear that there are significant effects of n-3 fatty acids on growth of both term and preterm infants from the above summary of published sets of data. A more relevant issue, however, is the biological significance of this effect. It appears that the mean rates of increase in both weight and length of all groups (i.e., control or supplemented) in some studies were close to, or actually greater than the mean rates of normal

control term infants. This raises the question whether the growth effects observed have any biological significance (4).

The primary effect of n-3 fatty acids on growth appears to be inhibition of the rate of weight gain rather than the rate of increase in either length or head circumference. It could be argued that this effect may be desirable if it reflects a lower rate of fat deposition. Some biological data from both animal models and cell cultures suggest that n-3 PUFA reduces fat deposition and n-6 PUFA induces adipogenesis. These mechanisms, theoretically, result in lower rates of fat deposition in infants receiving an n-3 PUFA–enriched formula. In this regard, the lower skinfold thickness or weight-for-length ratio in some studies may be biologically relevant. However, the lack of information concerning the effects of n-3 fatty acids on body composition and energy expenditure of human infants makes it very difficult to suggest a precise mechanism for the apparent inhibitory effect of n-3 fatty acids on growth of infants.

Although such an effect on fat deposition is clearly desirable for adults, it is not clear that it would be desirable for infants, especially preterm infants. One could argue that different rates of growth between two groups of preterm infants could impose some risk for the slower-growing group. To achieve the same subsequent size as the term infants, the preterm infants must experience more rapid rates of growth (4). In this situation, any dietary factor that inhibits growth for any period of time decreases the likelihood of the preterm infant's achieving the same size as the infant born at term. But even in these infants, there are, to date, few data to support this argument, and the consequences of the lower rates of growth of infants fed n-3 fatty acid–supplemented vs. –unsupplemented formulas are not known.

From this review, it is obvious that further studies are warranted not only to elucidate the mechanisms involved in the regulation of growth by LC-PUFA, but also to assess the quality (i.e., body composition) of early growth in infants fed LC-PUFA–supplemented formulas and to determine the long-term effects of various n-3 and/or n-6 LC-PUFA supplements on adiposity and growth.

## ACKNOWLEDGMENTS

This work is a publication of the USDA/ARS Children's Nutrition Research Center, Department of Pediatrics, Baylor College of Medicine, Houston, Texas. This project was funded in part with federal funds from the USDA/ARS under Cooperative Agreement No. 58-6250-6001. This work was also supported in part by National Institutes of Health Grant HD-02528, University of Kansas Medical Center. The authors thank Dr. William C. Heird for reviewing the manuscript, Dr. E. O'Brian Smith for helpful discussion, and Leslie A. Loddeke for editorial assistance (USDA/ARS Children's Nutrition Research Center, Houston, TX). They are also grateful to the KUMC Mental Retardation Resources Center for help with graphics.

# Models and Methods for Studying Behavior in Polyunsaturated Fatty Acid Research

**David I. Mostofsky***

Boston University, Boston, Massachusetts 02215

**ABSTRACT:** This report examines a range of models and procedures applicable to polyunsaturated fatty acid (PUFA) research and considers their relative merits. Considerations pertaining to cost, efficiency, and scientific rigor are of particular interest. Parallel activities in other areas of behavioral neuroscience, such as behavioral pharmacology and toxicology, that have profitably exploited various behavior designs for the study of human and animal cognition are noted. Special attention is given to the utility of operant conditioning models and schedules of reinforcement, which are currently underrepresented in PUFA research. Investigations of analogs of complex human behavior as well as implications for generalizing laboratory results to clinical phenomena are addressed.

Paper no. L8651 in *Lipids 36*, 913–917 (September 2001)

The study of fatty acids (FA), particularly the essential fatty acids (EFA), has generated numerous investigations relative to behavioral correlates in sensory, cognitive, learning, and similar systems. There are constant reminders of the need to focus on establishing functional and/or behavioral implications of insufficient levels of EFA or their balance (ratio). From the perspective of the long historical developments in biochemistry and the neurosciences, behavioral studies in FA research are relatively new, and the participation of behavioral scientists is sorely underrepresented. Although diverse designs have been employed, it would seem useful to pause and reflect on the rationale that underlies the selection of a particular animal or human subject, or the specific assessment protocol that is chosen. It may also be useful for nonbehavior specialists to appreciate how the practitioners of experimental psychology are likely to evaluate a protocol of choice. Important works by leaders in the field of nutrition and FA research (e.g., 1–6) have already properly noted the conceptual issues that confront the execution of behavior studies, the caution required in interpreting the findings, and the frequent failure to establish evidence for behavior deficit in the face of known changes in membrane or neurochemical composition. This report will not attempt to provide a definitive summary of all of the published work nor to extricate conflicting findings. Rather, it will attempt to sketch the outlines of domains of concern, to reflect on the utility and failings of different animal and infant human analogs, and to clarify the advantages that might be realized by adopting alternative strategies. Elegant and sophisticated experimental investigations by physiologists, biochemists, biophysicists, and neurobiologists often appear to reflect an incomplete appreciation of some of these issues, and it is for them as well that some basic review of established experimental psychology methodologies is provided.

Abbreviations: DRL, differential reinforcement of low rate; EFA, essential fatty acids; FA, fatty acids; PUFA, polyunsaturated fatty acid(s); VI, variable interval; VR, variable ratio.

## SELECTED CRITERIA FOR MODEL SELECTION

Initially, the dependent variables for assessing behavior changes are arrived at by creating a test condition analogous to an anecdotal report by a patient, or from observations in an otherwise uncontrolled environment. Behaviors of interest are also defined by reasonable expectations of functional change, when chemical or structural changes appear in an experimental or clinical preparation. It is quite reasonable therefore to expect some changes involving visual function when phospholipid changes in the retinal membranes are noted secondary to a FA-deficient diet. However, the varieties of measurements that can describe "visual function" are many, and not all visual behaviors may be sensitive to the physiological change. The design of a test to establish changes in more complex forms of functioning, such as "cognitive functions," becomes even more difficult, not least because of the difficulty to operationally define "cognitive function," a problem that has been recognized not only among behaviorists but also by other neuroscientists (7,8). When extrapolation to clinical conditions is undertaken and clinical efficacy is predicted from an animal study, there is the additional major problem and complication of a lack of resemblance between the models used and the clinical condition, as well as the diversity of the potential mechanisms of action of the test compounds (9). In an issue related to the EFA, when the subject studied is the fetus or infant, it was noted by an expert panel that "mechanisms appear to exist in a normal fetus and infant that can compensate for some nutritional and environmental diversity, which may obscure some of the effects of *trans* fatty acids" (10). Similarly, the attribution of behavior deficits or restorative effects to the presence or absence of EFA is thereby complicated as well.

Primarily problematic to the behavior researcher is the ambiguity of terms used to describe a function or ability for which the model was created. Deficits in "visual function," "memory," or "learning" are examples of performances of

interest; yet, depending on the conception of the investigator, each of these hypothetical states or functions can be assessed by a variety of procedures and the respective outcomes may not necessarily agree with one another. We have learned our lesson from years of "IQ" testing or "anxiety" research that the multivariate nature of the concept cannot be comfortably assessed by any single test result. Similarly, to evaluate the role and utility of FA in behavior, it is essential that the specific features of the concept or treatment in question be sufficiently operationalized to permit a translation for an experimental protocol. For example, before claiming any global advantages for nutritional "supplementation," it is necessary to distinguish among three conditions (at least) in which "supplementation" can be used: (i) as a prophylactic and protective agent, (ii) as a restorative agent to reverse or compensate for deficient diet or levels of FA or docosahexaenoic acid, for example, or (iii) as a facilitative agent to improve some aspect of behavior in otherwise nondeficient organisms. Especially problematic is the lack of precision with regard to discussions pertaining to cognitive function or chronic disorders, in which the implementation of an animal or human infant model that is able to integrate the biological, clinical, and behavioral aspects efficiently is a challenge of long standing (11,12).

It is also worth noting the obvious truism that significant findings in animal models may not translate to humans, and that an outcome in one animal species does not ensure similar outcomes for all species or even for members of the same order. Perhaps counterintuitive are the findings of different responses to an n-3 FA deficiency between rats and mice. For example, water maze learning was significantly different between mice fed n-3 FA-deficient diets and those fed sufficient diets (13), a result that was not reproduced for rats (14). Some inconsistencies in experimental reports may be attributable in part to diets in which n-3 alone is rendered deficient, compared with diets in which both n-3 and n-6 are deficient. In the latter case, several reports have shared the view that "we are afraid that these maze tests are too simple to evaluate behavioral changes induced by n-3 fatty acid deficiency in the presence of n-6 fatty acids" (13). In the case of the "dual deficiency" condition, the effectiveness of the introduction of the experimental intervention may depend upon the developmental stage of the animal, thereby adding yet another complication to understanding the deleterious effects of an n-3 deficiency, such that a deprivation of these fatty acids during the gestational phase led to irreversible impairment in Y-maze learning, whereas lactational deprivation led to impairment that could be remediated, and postweaning deficiency had no observable effect on learning performance (15). In the case of human studies, the selection of preterm vs. healthy term infants is a critical consideration in establishing the full EFA requirements and the ultimate influence on subsequent development and cognitive function (16,17). Above all, investigators are often challenged to ensure that any learning, memory, or cognitive changes attributable to the status of FA cannot readily be explained by alterations in maturational, visual, or motivational systems.

## EXTRAPOLATION TO COMPLEX BEHAVIOR

To the extent that biochemical pathways may implicate several behavior systems concurrently, it is quite reasonable to undertake a study whose outcome is expected to approximate behaviors that would be encountered in a clinical or "real world" setting. For example, given that FA deficiency has reliably been shown to affect certain visual performance measures, selected changes in the immune system, and modulation of serotonin, for example, one would be justified to expect observable changes in performances for tasks in which the separate biological systems are known to exert their influence. As such, studies of maze learning performance, memory, avoidance, visual discrimination, and a host of other comparable behavioral performances are essentially extrapolations from laboratory tasks or contrived experimental settings. The interpretations derived from those data are then employed as support for reflecting the patency of a biological/behavioral system, which is itself a hypothetical construct. Often elegant attempts are devised to simulate a "memory" task to be presented to an infra-human or infant human subject, and to interpret the outcome in a manner consistent with our appreciation of what is intended and understood by the concept of "memory." To be sure, "memory" is a requisite condition even for the simplest model of conditioning, far more complicated than what is popularly presented in the introductory psychology textbook. It is quite clear that an animal's conditioned response to a signal does not depend simply on the contiguity between the stimuli in the experiment, but does depend largely on the predictive value of that stimulus to alert the performing subject that something of consequence is about to happen. Without a doubt, the subject must be capable of remembering the critical features of earlier trials, and must be able to "process information" relevant to its success in the experiment. But conditioning models by themselves generally do not qualify as tests for memory or cognitive abilities, although there are options for conducting such tests. The literature dealing with the design and execution of different behavior models, species-specific characteristics, selection of dependent variables, and a theoretical framework for undertaking the behavioral experiment is vast. Publications abound with discussions and guidelines for properly understanding the experimental results, to ensure some measure of validity and to generalize to performance outside the laboratory setting. Separate discussions relevant to research in mice, rats, primates, and humans are available, and although a complete review or list of bibliographic citations is beyond the scope of this paper, a few publications can be offered as representative and as a valuable resource to provide an entry to the larger library of publications (18–23). Common to most of these scientific efforts is the utilization of operant conditioning protocols. Because operant conditioning dominates many of the activities surrounding animal research (in particular), and because it often serves as the basis for the study of many cognitive skills in animals and infants, it is useful to examine the essential nature of both the experimental proce-

dures and some of the underlying theory that define this methodology.

## SCHEDULES OF REINFORCEMENT, TIMING, AND IMPULSIVITY

The familiar Skinner box is, generically, a relatively restricted environment that contains provisions for the subject to respond (a manipulandum), for the response datum to be collected (counted, measured, recorded, depending on the nature of the data), for signals or cues to be presented, and for rewards (reinforcers) or noxious stimulations to be presented. It serves as the popular experimental setup for examining behavior under a wide variety of conditions. In addition to the study of basic principles of learning, the Skinner box allows for investigating behaviors that seem to meet the requirements for modeling more complicated constructs. Rather than discrete trials, the conventional operant design allows the experimenter to examine a stream of behavior as the subject engages in responding throughout the session. The strength of the correlation between the occurrence of a stimulus or environmental event and a subsequent response, together with the absence of the response in the absence of the stimulus or event, is described as "stimulus control." A powerful tool in the world of stimulus control derives from an observation made by Humphreys over 60 years ago, and for a while known as Humphreys' paradox, that learning trials orchestrated under conditions in which rewards are administered continuously whenever a correct response is made leads to extinction (or decrease) in the learned response at a faster rate than decreases in comparable learning when rewards are made available on some (but not every) occasion in which a correct response occurs. In other words, there is a greater resistance to extinction and forgetting following learning under conditions in which rewards are made available only some of the time. True for all organisms, this phenomenon, the Partial Reinforcement Effect, which was further developed by the work of B.F. Skinner, established formal paradigms of reward parameters for implementing partial reinforcement, i.e., Schedules of Reinforcement. Each of the schedules, or rules that govern the conditions when an experimenter will make reinforcers available, is an instance of Partial Reinforcement. Interestingly, however, the nature of the reinforcement schedule generates a pattern of responding, i.e., a "style of learning," that is characteristic for the respective schedule. Rate of responding, frequency and duration of interresponse pausing, and local changes in response rate are but some of the molecular aspects of an operant performance that may be observed in the visual record of a cumulative response graph or in the digitized information that can be presented as a table. In addition, by imposing restrictions, linkages, or conditional criteria, each schedule offers possibilities for examining analogs of complex human and animal behaviors, including but not limited to extrapolations to functions such as choice, counting, memory, and timing. Other cognate disciplines in the neurosciences such as pharmacology and toxicology have profitably investigated the effects of various compounds, stimulations, or extirpations on the separate properties that are derived from schedule performances.

A particularly sensitive index of operant performance concerns the role of time. The study of time in animals has been examined aggressively by experimental psychologists (24,25). To be sure, there are studies designed to examine time estimation (which itself can take a variety of procedural forms), whereas others purport to enable the study of elapsed time, and so forth. In particular, when demands are placed on the performing subject to learn to increase or decrease the response rate (i.e., frequency of responses per unit of time), one commonly observes a degradation of behavior in the presence of a chemical or surgical intervention. Although deserving of more examples in the FA areas, this variable has previously been shown to yield significant results for nutritional variables (26). The fact that time can play such an important role in modulating behavioral performance is indeed a testament to the "cognitive" nature of the task under study (27). The potential for meaningful assessments of FA effects on the separate aspects of operant responding and temporal stimuli would appear most promising and worthy of future research.

In addition to providing opportunities for evaluating molecular aspects of the learning task, schedules of reinforcement often set the occasion for behaviors that analogously reflect complex human activities. For example, if we consider a simple variable interval (VI) or variable ratio (VR) schedule of reinforcement, the subject will learn to respond at a fairly steady rate with rewards presented irregularly as programmed by the schedule. If we then add to this schedule a conditional restriction such as a differential reinforcement of low rate (DRL), the subject will learn to respond at a steady rate, but slowly enough to satisfy the conditions of the DRL requirement, i.e., the interresponse times will be increased. Response rates that exceed the DRL requirement are "not counted" toward the criterion needed to produce a reward. For many values of VI, VR, or DRL, subjects will usually be able to optimize performance on this amended schedule, as will be confirmed by distributions of the interresponse times and by noting that the responses produced the maximal amount of reinforcers that were programmed for the session under the conditions of the VI-DRL (or VR-DRL). The interpretation of successful DRL performance has often been offered in evidence to suggest an intact memory function or, of greater interest with poor DRL performance, to present evidence for impaired memory function. Such attributions have been offered for the effects of aging (28,29) as well as for the administrations of toxic compounds or diet and nutritional deficiencies (30). A more interesting, if somewhat anthropomorphic, interpretation of DRL performance has been offered to suggest that the subject is exercising "self control," i.e., refraining from responding at too fast a rate. When the subject is unable to meet the demands of the schedule, the interpretation takes the form of suggesting that the behavior gives evidence of "impulsivity." The experimental study of impulsivity has been of interest to the students of psychology, psychiatry, and

pharmacology (31,32), and the ability to provide an animal model constitutes a significant achievement. Although the DRL schedule focuses attention on the issues of environmental control with the attending power of reinforcement, considerable theoretical interest has been concerned with the role of the underlying neurobiology of this phenomenon (33). Perhaps most interestingly, the implications of impulsivity as a clinical disorder and its relationship to FA have not gone unnoticed (34). Other examples of using schedules (with variations) to represent complex and cognitive behaviors can be found.

## EPILOGUE

The armamentarium of behavior technologies for assessing the role of FA in sensory learning and higher functioning ("cognitive") in both humans and animals is far richer than the limited number of designs that have appeared in the published literature. Simple, one-trial or single-session tests for visual discrimination, maze, attention, or avoidance and escape performance may suffice for many conditions. However, if the concern is genuinely with relatively permanent changes that take place with exposure to rehearsal and practice (i.e., learning), there is much to be gained by adding other experimental protocols to the use of the T-maze or spatial maze, specifically to consider operant schedule performance. If the research question is directed at "cognitive" abilities, it is probably wise not to rely on maze performance for an answer. Schedules of reinforcement together with other laboratory procedures already exist for more directly assessing the effects of experimental variables on such behaviors as choice, fear, probability estimation, or the cost and utility of a reward. Such paradigms are more likely to approximate the investigator's intention of describing "cognitive" function and, in the context of the underlying FA biochemistry, are more likely to demonstrate the profound effects of lipid chemistry on behaviors that are essential for quality living

# Recent Advances in Infant Cognition: Implications for Long-Chain Polyunsaturated Fatty Acid Supplementation Studies

**John Colombo***

Schiefelbusch Institute for Life Span Studies, Department of Human Development, University of Kansas, Lawrence, Kansas 66045

**ABSTRACT:** The assessment of cognitive function in early life has recently become an issue for consideration in long-chain polyunsaturated fatty acid (LC-PUFA) supplementation studies. This article reviews the various means by which such assessment has been done in past LC-PUFA supplementation studies and provides some background on recent advances in the measurement of infant cognition that may need to be considered when planning or designing future supplementation studies. These include (i) consideration of the specificity of LC-PUFA effects on cognition, (ii) inclusion of multiple tasks or levels of measurement as outcome measures, and (iii) a stronger emphasis on developmental processes in the design of such studies.

Paper no. L8646 in *Lipids 36*, 919–926 (September 2001).

Given the putative importance of some long-chain polyunsaturated fatty acids (LC-PUFA) to central nervous system (CNS) integrity and function, it has long been suspected that LC-PUFA play some role in mammalian behavior and behavioral development. The contribution of LC-PUFA to learning and cognition has been investigated in both animals (1–3) and humans (4,5). In addition, LC-PUFA deficiencies have been theoretically linked with a range of behavioral disorders from sudden infant death (6), to dyslexia (7), to schizophrenia (8).

For some time now, an understanding of the science of infant behavior and development has been relevant to scientists investigating the effects of LC-PUFA on behavioral development. There is an intriguing and plausible theoretical case to be made for the importance of LC-PUFA for the development of the CNS and retina during the pre- and postnatal periods (9–16). Thus, it has been hypothesized that early manipulations (either supplemented or deprived diets) of LC-PUFA should affect visual and cognitive development. Rather than wait until subjects reach maturity, many of these investigators have chosen to assess the effects of such manipulations with measures of visual and cognitive function in infant participants. As such, the period of infancy has served as a preliminary "proving ground" for such early nutritional manipulations.

## INFANT COGNITION AND LONG-CHAIN POLYUNSATURATED FATTY ACIDS (LC-PUFA)

A critical point in studies of this sort is the choice of the dependent measure. Studies of infant visual function have been widely conducted in this area for some time (e.g., Ref. 17), showing both positive (18–26) and null (27–31) effects for LC-PUFA supplementation. The choice of dependent variable within this realm is perhaps facilitated by the fact that there is a finite set of such measures for visual function (e.g., acuity or contrast sensitivity), and that the standardized measures that do exist (e.g., Ref. 32) possess good validity and reliability. However, other investigators have chosen to examine whether manipulations of LC-PUFA early in life affect broader cognitive functions. In choosing dependent measures designed to reflect early manifestations of cognition in infancy and toddlerhood, these investigators face a number of difficult issues (see Ref. 33), many of which remain unresolved among those in the field of early cognitive development. The purpose of this article is to try to address some of these fundamental issues on this topic for the audience that may be interested in the effect of LC-PUFA on cognition and behavioral development in early infancy. Although some data on standardized tests will be reviewed briefly, the primary focus of the paper is on recent advances in laboratory tasks of infant cognition. The aim is to provide a current description of this field and to explicate the implications of recent advances in this area for researchers interested in applying these tasks as outcomes in studies of early nutrition. Although the article will make reference to the extant data from clinical studies of LC-PUFA and behavior in infancy, methodological differences among those studies that may have given rise to differential outcomes on such measures will not be addressed here.

## MEASURES OF INFANT COGNITIVE/INTELLECTUAL FUNCTION

The first issue facing investigators interested in this topic of research is that there is no one widely accepted measure for assessing cognition or cognitive development in the infant/toddler age range. There are two broad classes of assessment tools. One class is comprised of normative, standardized tests of general behavioral or developmental function. The second class is comprised of laboratory tasks that have been designed to tap a specific cognitive process. In the sections that follow,

these two classes of assessment are generally described, along with a brief review of studies of LC-PUFA manipulations that have employed them.

## Standardized Normative Measures of Infant Development

There are a number of traditional standardized measures of infant cognitive or "mental" development. These include tests such as the Bayley Scales of Infant Development (34), the Kaufman Assessment Battery for Children (e.g., Ref. 35), the Battelle Developmental Inventory (e.g., Ref. 36), and the Denver Developmental Screening Test (e.g., Ref. 37). Many of these tests are derived from infant scales constructed during the 1920s or 1930s; their construction is based on the assumption that developmental outcome can be characterized as some aggregate of the infant's attainment of normative developmental milestones across a number of domains (motor, imitation, language). The summing of items across domains to achieve a single score is perhaps attributable to an implicit assumption that a construct of "general intelligence" exists in infancy (38–40).

Other more recent normative tests for the infant/toddler age ranges are constrained to a particular domain. Most prominent among these are tests of language or communicative development. These include the Sequenced Inventory of Communicative Development (41), the Reynell Developmental Language Scales (42), and the MacArthur Communicative Development Inventory (43). These tests avoid the pitfalls associated with the assumption of a general intelligence factor, but still calculate the optimality of outcome based on the comparison of the infant's performance against some standardized norms.

*LC-PUFA effects on laboratory-based tasks.* Standardized tests have been used in a number of follow-up studies of infant LC-PUFA supplementation. These include both positive and null findings. Carlson *et al.* (44) reported an advantage on the Bayley Mental Development Index (MDI) for preterm infants who were fed a LC-PUFA-supplemented formula. In a series of follow-up reports, Agostoni *et al.* (45,46) reported a strong correlation between LC-PUFA composition of the red cell membrane and improved neurodevelopmental performance on a standardized psychomotor developmental test (Brunet-Lexine Scale) at 4 mon of age. In a large-scale clinical trial, Scott *et al.* (47) reported no effects of LC-PUFA supplementation on Bayley MDI scores at 12 mon of age in a clinical trial, and in fact reported negative effects for LC-PUFA supplementation on some standardized language measures. Birch *et al.* (48) report an advantage of nearly half a standard deviation on the new Bayley scale at 18 mon for infants supplemented with docosahexaeonic acid (DHA) and DHA plus arachidonic acid (AA) until 17 wk of age. In contrast, Makrides *et al.* (49) found no differences among infants assigned to placebo, DHA supplementation, and DHA + AA supplementation groups at 12 and 24 mon on the Bayley Scales. In the last-mentioned study, however, it may be worth noting that breast-fed infants outperformed all three of the formula-fed groups on the Bayley at 24 mon of age. Clearly, the results of these studies are mixed; although positive outcomes were observed in a majority of the studies, these are tempered by null findings in larger-scale clinical trials.

## Laboratory Measures of Infant Cognition

Along with the standardized tests, some researchers have adapted a number of specific laboratory tasks as cognitive outcome variables in experiments and clinical trials of LC-PUFA. In general, such tasks were developed initially for purposes of conducting basic research on early cognitive development, and were designed explicitly to assess specific components of information processing or CNS function in infancy. As such, they are advantageous relative to the standardized tests because they presumably tap more specific cognitive domains with greater depth and accuracy, and their interpretation does not rest on assumptions about the structure of the intellect in infancy. Their disadvantage, however, is that they are not standardized in either their administration or interpretation (39,40). As a result, the outcomes of different studies may vary as a function of how the tasks are conducted. Furthermore, some ambiguity may exist in the interpretation of results. Let us first consider those tasks and/or measures that have been used in prior research with LC-PUFA research.

*Visual habituation.* In this task, a visual stimulus is repetitively presented to the infant, and the duration of the infant's looking is measured over the course of these presentations. The presentations may proceed on the basis of parameters chosen by the investigator ("fixed trial" habituation procedures), or may be provisional upon the infant's looking ("infant-controlled" procedures; see Ref. 38 for a procedural review). The duration of infants' looking declines across such repeated presentations, and this decline (or "habituation curve") is generally taken to reflect the infant's visual learning. The procedure is appropriate for infants from birth through ~10 mon of age. Many variables have been culled from this habituation curve that are thought to represent some index of the efficiency or rapidity of this learning. These variables include the slope or magnitude of the decline, trials to some criterion of decrement, or some measure of the infant's duration of looking (50).

*Paired-comparison tasks.* In novelty preference tasks, the infant is presented ("familiarized") with a visual stimulus to study for some amount of time, and then tested for whether s/he is able to recognize the stimulus by simultaneously pairing the familiarized stimulus with a novel one and allowing the infant to compare between the two. Recognition is generally indicated by some systematic preference for looking at one of the stimuli during this "paired-comparison" phase. Most typically, this is a preference for the novel stimulus, but under conditions of insufficient familiarization or increased cognitive demands, this preference may be expressed in terms of a preference for the familiarized stimulus (see Ref. 38). The initial familiarization period may be conducted using a habituation procedure. More commonly, however, the familiarization is

conducted by allowing the infant to study the stimulus for some fixed amount of time. A set of paired-comparison tasks (in which stimuli, familiarization times, and tasks protocols were standardized) comprised the Fagan Test of Infant Intelligence (FTII; 51). The FTII was a popular instrument through most of the 1990s in followup studies of various sorts, including some studies manipulating dietary LC-PUFA. This procedure is appropriate for infants from 2 to ~12 mon of age.

It is worth noting that some of the variables that can be culled from the habituation curve (most notably measures of look duration) are also available from an analysis of infant looking during the familiarization phase (52).

*Problem-solving tasks.* A number of tasks that tap higher-order cognitive functions have also been used in evaluating the effects of LC-PUFA supplementation. One is the "A-not-B" task (e.g., Ref. 53). Here, the infant is shown an object (e.g., a toy) being hidden under a cup or in a well at some location ("A"), and is then allowed to search and retrieve the object from the location. A brief delay (e.g., 5–15 s) may be imposed between the hiding and search. After several successful retrievals, the object is then hidden at a second location ("B"). Between 8 and 12 mon of age, infants will generally search at the first location rather than the second, that is, the infant searches at location A, not at B, thus giving rise to the name of the task. This perseverative error is generally attributed to the infant's inability to inhibit the previously successful response of searching at location A, and it has been taken to reflect immaturity of the dorsolateral frontal cortex.

Other problem-solving tasks have been used as well. These typically involve having the infant pull a string to retrieve an object or move one object out of the way to get to another. Thus, the infant must engage in some goal-directed behavior ("means") to attain a satisfactory outcome ("ends").

*LC-PUFA effects on laboratory-based tasks.* Several studies have documented significant differences between infants whose diets were supplemented with LC-PUFA (particularly DHA) in performance of such tasks. In general, the most consistent finding has been demonstrated for infant look duration culled from paired-comparison tasks. This finding has been generally interpreted as reflecting more rapid or more efficient visual learning. Werkman and Carlson (54) first observed this effect in preterm infants fed a DHA-supplemented diet through 9 mo of age. Assessment points were at 6.5, 9, and 12 mo of age. Carlson and Werkman (55) subsequently reported the same effect in 12-mon-old infants whose supplementation ended at 2 mon of age. Reisbick *et al.* (56) experimentally deprived infant monkeys of DHA and observed the opposite effect; the DHA-deprived infants looked for significantly longer durations. It is worth noting that, in each case, dietary supplementation affected look duration, but did not affect subjects' novelty preference performance.

Willatts *et al.* (57) also observed briefer duration looks during habituation in DHA-supplemented infants, but only in infants whose attentional patterns were characterized as more "disorganized" (i.e., with nonlinear/nonmonotonic declines). Willatts *et al.* (58) subsequently reported that DHA-supplemented infants performed better on means-ends tasks at 10 mon of age (see also Ref. 59).

## RECENT ADVANCES IN THE MEASUREMENT OF INFANT COGNITION

These findings are provocative and intriguing, and are generally in line with other results that suggest that cognitive function is affected positively by dietary LC-PUFA. These results have been obtained with procedures that might have been considered advanced or experimental in the early 1990s. However, infants' performance in each of the procedures outlined above may be interpreted in various ways (38,39). Indeed, there have been significant advances in the field of infant cognition since the mid-1990s to which researchers interested in using these tasks may profitably attend.

### Tasks for More Specific Processes and Underlying Substrates

The first advance is attributable to the growing influence of cognitive neuroscience in the field of developmental psychology. The scope of cognitive neuroscience is to identify and understand the neural substrates to which cognitive/behavioral processes may be attributed. The elucidation of such substrates is complicated by developmental processes (60), but substantial progress has been made in many areas, such as the development of the ability to plan and execute motor responses in infancy (53) and in the development of visual attention in infancy (61).

A by-product of this progress is a proliferation of tasks that tap specific processes and that presumably represent the function of specific underlying neural substrates. For example, in the area of visual attention, research has identified two separate neural substrates (see Fig. 1). One of these mediates the broadband detection of visual objects, the direction of attention to (and disengagement from) the location of such objects. The other mediates analysis of visual features and object recognition. These are sometimes referred to, respectively, as the "where" and "what" systems of visual attention. There is some crosstalk between the systems, but a primary pathway through which the systems interact is located in the frontal lobe. This frontal input may be thought of as providing "top-down" control over the two systems. For example, frontal areas probably provide the voluntary "holding" or maintenance of attention that is colloquially referred to as "attention span." A number of different functions have been identified for each of these systems, and for many of these functions, tasks have been adapted for use with human infants (see Table 1).

This point has several implications for follow-up research, such as LC-PUFA supplementation studies, that seeks to employ measures of infant cognition. First, some of the results of previous studies may be open to reinterpretation. For example, look duration in infants (which has been linked to DHA manipulations) has been interpreted as an index of rapidity or efficiency of learning. Recent work (62,63),

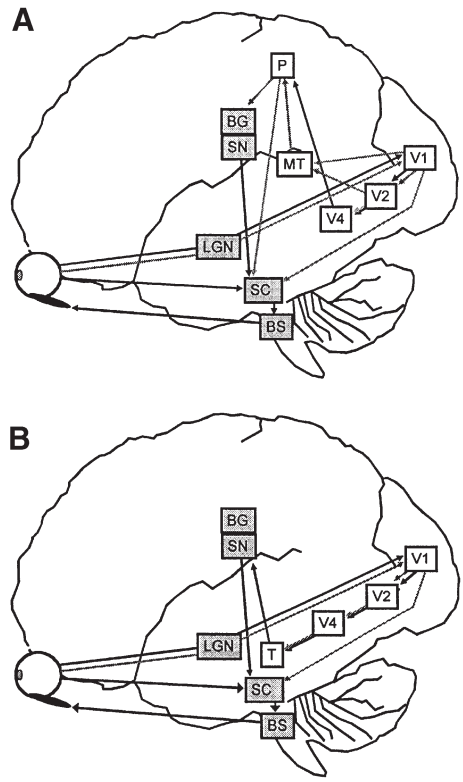

**FIG. 1.** Attention systems in the brain: (A) the dorsal or "where" pathway; (B) the ventral or "what" pathway. The figures represent schematics redrawn from various sources (78–81). Unshaded structures are cortical structures; shaded structures are subcortical. Legend: BG, basal ganglia; BS, brain stem; LGN, lateral geniculate nucleus; MT, medial temporal lobe; P, parietal lobe; SC, superior colliculus; SN, substantia nigra; T, temporal lobe; V1, V2, V4, areas of visual cortex.

however, suggests that look duration (at least during the middle portions of the first year) may reflect the infant's ability to disengage attention from visuospatial loci (a function of the dorsal, or "where" system). Interestingly, it has been argued that the paired-comparison task is mediated by the ventral attentional system (60). The finding that LC-PUFA affect look duration but do not improve paired-comparison performance (e.g., Ref. 56) supports the dissociability of the tasks, and also the possible specificity of the LC-PUFA effect.

**TABLE 1**
**List of Visual Attention Components Tested in Infancy[a]**

| |
|---|
| Spatial orienting |
| Smooth pursuit |
| Fast (involuntary/express) saccades |
| Disengagement of attention |
| Inhibition of return |
| Attention to visual object features |
| Sensitivity to color/form |
| Attention to color/form compounds |
| Intrastimulus shifting |
| Object cue dominance |
| Endogenous (voluntary) control of attention |
| Interstimulus shifting |
| Inhibition of saccades |
| Sustained attention |

[a]Adapted from Ref. 61.

A side implication of such a high degree of "modularity" of cognitive measures in infancy is that it is entirely possible to obtain effects that are not readily reconcilable. For example, how could Carlson and colleagues (54,55) and Reisbick *et al.* (56) observe improvements in look duration as a function of DHA status, but Scott *et al.* (47) observe significantly lower language outcome at 14 mon of age in DHA-supplemented infants? If one holds to a unitary approach to intellectual function, these findings make no sense at all. If, however, one considers the possibilities that the substrates reflected in attention are different from the one reflected in language, and may thus be differentially affected, then the findings appear far less anomalous.

A final implication to be discussed here arises from the fact that the number of dependent variables now available to researchers interested in conducting follow-up studies is indeed quite large. Unlike the standardized normative tests, whose construction and scoring rest on the assumption that the infant's performance can be reduced to a single score that reflects general intelligence or overall cognitive function, research suggests that these different functions are dissociable in terms of their underlying neural substrates and developmental course (61). As such, the choices that followup researchers make in evaluating the effects of LC-PUFA with such new tasks should be based on a strong theoretical position as to what function LC-PUFA might be expected to affect, and at what age point this effect might be expected to be manifest (39).

## Multilevel Measurement

A second major change in the field of measuring infant cognition that has occurred at the cutting edge of the field is that researchers no longer rely solely on behavioral measures, i.e., 5–10 yr ago, it would have sufficed to measure infant looking in the habituation or paired-comparison paradigms. However, it has become more common to see such behavioral paradigms bolstered with convergent measures (64). Such convergent measures can be psychophysiologic (e.g., heart rate; HR) or electrophysiologic (e.g., evoked response potentials; ERP) in nature. The increasing availability of high-density ERP systems (with measurement from as many as 128 electrodes on the scalp) nearly approximates neuroimaging (65,66), although the choice of paradigms is constrained to some degree with such increasingly sophisticated measurement systems.

The addition of such multilevel measurement allows for two things. First, it is possible to observe internal reactions to events within paradigms that heretofore have not yielded data. For example, in a recent study (67), 4-mon-olds were observed in a fixed-trial habituation procedure; measurement of looking was augmented by simultaneous recording of HR. It was observed that infants routinely showed brief but significant accelerations to stimulus presentations; that is, upon illumination of the stimulus, infants' HR increased. One striking finding was that infants who looked for long durations had

significantly greater HR accelerations than infants who looked for brief durations. Thus, the simultaneous measurement of HR provided a finding that would not have been available with only behavioral measures of attention.

Second, the addition of measures allows for a much finer and more precise analysis of cognitive components during attention. In particular, Richards and Casey (e.g., Refs. 64,68,69) have taken the characteristic HR deceleration that occurs during infant looking and have parsed the looking into three distinct phases, each of which putatively reflects different types of information processing (see Fig. 1). "Orienting," which is the initial portion of the deceleration, reflects a simple reaction to the detection of the stimulus. "Sustained Attention," which is the asymptotic portion of the decelerative response, is presumed to reflect the voluntary maintenance of attention to the stimulus. Finally, "Attention Termination" is a period during which HR begins to increase from its decelerative asymptote, and reflects the end of processing. The hypothesized characteristics of the latter two phases have been supported by research over the 1990s (64,68,69). Such a framework has been useful in studying individual differences in infant cognition; indeed, one of the defining characteristics of infants exhibiting prolonged durations during an infant-controlled habituation, relative to their shorter-looking counterparts, was increased amounts of attention termination (70). That is, longer-looking infants spent more time looking when their HR patterns suggested that they were probably not processing very much information.

It goes without saying that access to new measures and the ability to conduct finer-grained analyses in familiar paradigms has great potential for followup work of the type that LC-PUFA supplementation studies might take.

### An Emphasis on Developmental Process

One last advance that is relevant to the use of measures of infant cognition in short-term outcome research is not the direct result of improvements in technology or the influence of other sciences. It is, rather, an advance that may be attributed to a growing theoretical shift in the field of developmental psychology.

The study of development is, by definition, the study of change. Over the past 20 yr, there has been a growing emphasis on the consideration of developmental processes, rather than a simple focus on behavioral products at particular points in time (71–73). In the 1990s, researchers working with LC-PUFA dietary manipulations were attracted to measures of infant cognition largely because those measures had been observed to be correlated to some degree with performance on standard tests of intelligence (i.e., IQ) and language during childhood and adolescence (38). Thus, habituation and novelty preference measures were used primarily as substitutes for, or facsimiles of, a cognitive product (i.e., IQ); the attraction, however, was that these measures could be taken during infancy.

This mind-set reflects a focus on static cognitive "products" that might simply be "tapped" in some emergent or precursor form early in the lifespan. In this way of thinking, it should be possible to implement an intervention (here, some dietary manipulation of LC-PUFA), choose a measure of early cognition, and then take a "snapshot" at one point during infancy to see whether the intervention makes a difference. This approach is inspired by a "psychometric approach" to infancy that was encouraged in some earlier publications (e.g., 38,50). The psychometric approach is attractive in its parsimony and simplicity, in that it leans heavily on the assumption that there will be a putatively direct causal relationship between early and mature cognitive function. A major drawback to this approach, however, is that it essentially ignores the processes by which cognitive functions develop and evolve over the lifespan. Indeed, one particular study of the paths through which the continuity of cognitive function travels from infancy to childhood has revealed that the significant relationships between early and later measures are not direct, but are rather mediated through a series of complex variables across age (74).

The consideration of such complex and cascading causal effects in development is generally within the realm of developmental systems theory (e.g., Ref. 75). The growing importance of this approach in understanding behavioral development has several implications for research in the area of LC-PUFA supplementation.

First, there will be an emphasis on measuring the developmental course of cognitive function in infancy, rather than simply taking such measures in a "snapshot" or "slice" at one particular age point. Indeed, researchers will have to conduct more extensive longitudinal measurements and use measures of the developmental course of variables in assessing whether nutritional supplementation affects cognitive outcome. Our own recent work on the development of look duration (76) suggests that the developmental course of look duration is complex, and that different phases of the course may reflect the functional onset of different neural substrates. As such, an LC-PUFA supplementation follow-up study that assesses look duration at one (or perhaps even two or three) particular age points will not provide an adequate means to evaluate the effects of the supplementation over all of these phases. It should be noted, however, that relatively intensive longitudinal measurement is more the norm than the exception in the literature on early manipulation of dietary LC-PUFA. Most of the studies on infant visual function and infant visual attention have collected data at three or more age points.

A second methodological implication of adopting a broader, developmental systems approach is that researchers should consider whether variables other than LC-PUFA manipulations interact with the manipulations themselves. For example, it is possible that LC-PUFA supplementation has larger effects in populations in which environmental quality (e.g., socioeconomic status or caregiver responsiveness) is poor, compared with populations in which environmental conditions are more optimal. Many other examples of such variables can be proposed (e.g., individual differences in metabolism or reactivity), all of which might interact with nutritional supplementation.

A third and final implication is that small or transient effects observed at one age point may not be unimportant. For example, in a recent meta-analysis, SanGiovanni *et al.* (77) concluded that DHA supplementation produces an early but transient improvement in visual acuity. Such transience has caused some to dismiss the finding. However, the fact that a control group will show the same visual acuity as a supplemented groups at 10 mon of age ignores the possibility that the acceleration of the visual acuity curve experienced by the supplemented group may have a longer-term effect. For example, the improvement in visual acuity in DHA-supplemented infants appears during a time period in which it has been shown that the visual substrates of the CNS can be greatly affected by environmental input. The maintained focus upon the acuity variable misses the possibility that even a small early advantage in lower-order function may serve to affect higher-order functions at some later point.

**ABSTRACT:** We have recently shown that docosahexaenoic acid (DHA) is necessary for survival and differentiation of rat retinal photoreceptors during development *in vitro*. In cultures lacking DHA, retinal neurons developed normally for 4 d; then photoreceptors selectively started an apoptotic pathway leading to extensive degeneration of these cells by day 11. DHA protected photoreceptors by delaying the onset of apoptosis; in addition, it advanced photoreceptor differentiation, promoting opsin expression and inducing apical differentiation in these neurons. DHA was the only fatty acid having these effects. Mitochondrial damage accompanied photoreceptor apoptosis and was markedly reduced upon DHA supplementation. This suggests that a possible mechanism of DHA-mediated photoreceptor protection might be the preservation of mitochondrial activity; a critical amount of DHA in mitochondrial phospholipids might be required for proper functioning of these organelles, which in turn might be essential to avoid cell death. Müller cells in culture appeared to be involved in DHA processing: they took up DHA, incorporated it into glial phospholipids, and channeled it to photoreceptors in coculture. Both Müller cells, when cocultured with neuronal cells, and the glial-derived neurotrophic factor (GDNF) protected photoreceptors from cell death. These results suggest that glial cells may play a central role in regulating photoreceptor survival during development through the provision of trophic factors. The multiple effects of DHA on photoreceptors suggest that, in addition to its structural role, DHA might be one of the trophic factors required by these cells.

Paper no. L8640 in *Lipids 36*, 927–935 (September 2001).

The enrichment in docosahexaenoic acid (DHA) of membrane lipids in the nervous system has stimulated the search for the possible functions of this fatty acid in brain and retinal neurons. In the retina, DHA is the major fatty acid of photoreceptor phospholipids (1), and several pieces of evidence suggest that a close correlation exists between this high content of DHA and correct photoreceptor function. A decrease in DHA content in retinal lipids is associated with alterations in the electroretinogram (2,3) and impairment of visual acuity (4,5). DHA plays an important role during the development of the vertebrate retina. A deficiency of this fatty acid or its precursors in infant formulas affects human retinal development (6–8), and supplementation of infant diets with long-chain polyunsaturated fatty acids improves visual development (9). The puzzling question regarding the roles of DHA in the development, structure, and functionality of the retina, and particularly photoreceptor cells, has been the subject of considerable research and has mainly been studied from a structural point of view. Several studies suggest that DHA-enriched membranes can favor rhodopsin conformational changes and function (10–12). However, the precise functions of DHA in the retina are far from being established.

Recent reports from our laboratory have shown a novel role for DHA as a survival factor for photoreceptor cells. This fatty acid is able to rescue photoreceptors from apoptosis, the most frequent pathway of programmed cell death, during the early stages of their development *in vitro* (13–15). Elucidation of the molecular and cellular mechanisms involved in the regulation of photoreceptor apoptosis is one of the major aims in this area of investigation, particularly with the recognition that apoptosis is the main mode of photoreceptor death in mouse models of retinitis pigmentosa (16,17). However, until now the identification of specific trophic molecules able to effectively prevent photoreceptor degeneration has been elusive. Three trophic factors, namely, epidermal growth factor, basic fibroblast growth factor, and ciliary neurotrophic factor, along with other molecules such as laminin, taurine, and retinoic acid have been shown to have either protecting or differentiating effects on photoreceptor cells (18). More recently, the glial-derived neurotrophic factor (GDNF), produced and released by glial cells, has been added to the list of survival-promoting molecules (19).

The mechanism of action involved in DHA protection remains to be established. It is also unclear how retinal cells, and particularly photoreceptors, get the DHA required for building their membrane phospholipids. It has been proposed that DHA is transported from the liver, bound to plasma lipoproteins to reach photoreceptor cells in the retina (20). Non-neuronal cells in the retina may also synthesize and/or process DHA and deliver it to photoreceptors. Glial cells appear to have multiple functions in the retina and have been shown to be a source of trophic factors, including GDNF, required for the survival and maintenance of neuronal cells (21,22).

In the present paper, we review DHA survival- and differentiation-promoting effects; show that GDNF and glial cells,

Abbreviations: BSA, bovine serum albumin; DAPI, 4,6-diamidino-2-phenylindole; DHA, docosahexaenoic acid; DME, Dulbecco's modified Eagle's medium; FBS, fetal bovine serum; GDNF, glial-derived neurotrophic factor; GFAP, glial fibrillary acidic protein; PI, propidium iodide.

when cocultured with retinal neurons, can also rescue photoreceptors from cell death; and present evidence suggesting that glia may modulate photoreceptor survival through the provision of DHA and GDNF.

## MATERIALS AND METHODS

*Materials.* Albino Wistar rats bred in our own colony were used in all the experiments. Plastic 35-mm culture dishes and multichambered slides (Nunc) were purchased from Inter Med. Fetal bovine serum (FBS) was from Centro de Virología Animal (Cevan). Dulbecco's modified Eagle's medium (DME) (Gibco) was purchased from Life Technologies. Bovine serum albumin (fraction V; fatty acid-free; low endotoxin, tissue culture tested) (BSA), poly-DL-ornithine, trypsin, trypsin inhibitor, transferrin, hydrocortisone, putrescine, insulin, polyornithine, selenium, gentamicin, 4,6-diamidino-2-phenylindole (DAPI), fluorescein-conjugated secondary antibodies, propidium iodide (PI), palmitic, oleic, and arachidonic acids, anti-glial fibrillary acidic protein (GFAP) IgG fraction antiserum antibody, and paraformaldehyde were from Sigma Chemical Co. (St. Louis, MO). Secondary antibody, *Alexa 488*-conjugated goat anti-mouse, *Alexa 546*-conjugated goat anti-rabbit IgG, and Mitotracker were from Molecular Probes, Inc. Monoclonal antibody against rhodopsin, Rho-4D2, was generously supplied by Dr. R. Molday (University of British Columbia). Monoclonal antibody HPC-1 was a generous gift from Dr. C. Barnstable (Yale University). DHA was isolated from bovine retinas, by a combination of chromatographic procedures (13). [$^{14}$C]22:6 (specific radioactivity 160 mCi/mmol) was from NEN (Boston, MA). Solvents were high-performance liquid chromatography grade, and all other reagents were analytical grade.

*Retinal neuron cultures.* Purified cultures of rat retinal neurons were prepared by methods previously described (13,23), with slight modifications. In brief, 1–2-d-old rat neuroretinas were dissociated for 12 min with trypsin (0.1%) in $Ca^{2+}$–$Mg^{2+}$-free Hanks' balanced salt solution, and the resulting cell pellet was incubated with trypsin inhibitor. The cells were sequentially rinsed, resuspended in a serum-free, chemically defined neuronal medium, and then subjected to a gentle dissociation with a glass pipette. About $0.8 \times 10^5$ cells/cm$^2$ were seeded on 35- or 100-mm diameter dishes or on coverslips placed in these dishes. Culture dishes and coverslips had previously been sequentially treated with polyornithine and schwannoma-conditioned medium (24).

*Pure glial cell cultures*. Pure glial cell cultures were prepared from 1–2-d-old rat retinas dissociated as described above; retinal cells were then resuspended in DME with 10% FBS and seeded at a density of $2.5 \times 10^5$–$3 \times 10^5$ cells/cm$^2$ on a 35-mm diameter plastic dish, with no pretreatment. The culture medium was routinely replaced every 2–3 d to eliminate neuronal cells.

*Coculture of retinal neurons with glial cells.* To obtain neuron–glia cocultures, the dissociated cells were resuspended in neuronal medium and seeded at a density of $2.5 \times 10^6$–$3 \times 10^6$ cells per 35-mm diameter plastic dish, with no pretreatment, as described above. After 2 d, the culture medium was replaced by DME with 10% FBS, to allow the growth of glial cells.

*Fatty acids and GDNF supplementation.* DHA, palmitic, oleic, and arachidonic acids, complexed with BSA, were added to 35- or 100-mm diameter dishes at day 1 in culture, 4–6.7 mM final concentration (13). The same volume of a BSA solution of the same concentration was added to control cultures. After different incubation times, the cells were thoroughly washed and scraped from the culture dishes, and lipids were extracted as described below.

GDNF was added to the cultures immediately after seeding the cells at a final concentration of 10 ng/mL in DME. A similar volume of DME was added to control samples.

*Lipid analysis.* Rat retinas were excised using a dissecting stereomicroscope and immediately homogenized for lipid extraction (25). To prepare lipid extracts from neurons in culture, the incubation media were removed, and, after the cultures were rinsed, the cells were transferred to glass tubes and centrifuged for 10 min at 1000 rpm (13). Neuronal lipids were then extracted (25). All samples were kept under an $N_2$ atmosphere.

To analyze neuronal fatty acid composition, free fatty acids were separated by thin-layer chromatography (13); the methyl ester derivatives of phospholipid and triacylglycerol fatty acids were then prepared (26) and analyzed by gas–liquid chromatography (13). Distribution of radioactivity among lipids was determined (15). Unlabeled lipids prepared from bovine retina were added to the samples as carriers.

*Labeling of glial and neuronal cells with [$^{14}$C]DHA.* To investigate the possible metabolic coupling between glial cells and retinal neurons, pure glial cell cultures were incubated for 6–10 d until they reached confluence. The serum-containing media were then replaced by chemically defined medium supplemented with [$^{14}$C]22:6 (0.1 μCi, 6.7 μM). Unlabeled 22:6n-3 was also added, in the amount required to reach the desired concentration. After 1 d, this medium was removed, and glial cells were thoroughly washed to eliminate nonincorporated label. Fresh serum-free, chemically defined culture medium was added (1 mL), and pure neuronal cultures, grown on coverslips, were then placed on top of and facing glial cells and cocultured for 3 d. The coverslips were then removed, and both glial cells and neurons were fixed for 1 h with 2% glutaraldehyde in phosphate-buffered saline (0.9% NaCl in 0.01 M $NaH_2PO_4$, pH 7.4) and processed for autoradiographic analysis (23).

*Cytochemical methods.* The cultures were fixed as described above and permeated with Triton X-100 (0.2%). Neuronal cell types were identified by immunocytochemistry with the monoclonal antibodies HPC-1, for amacrine cells (27,28), and Rho-4D2, for photoreceptor cells (29), as previously described (13), using *Alexa 488*-conjugated goat anti-mouse as the secondary antibody. Glial cells were identified by their flat morphology and by their immunoreactivity to GFAP, which selectively recognizes Müller cells in the retina.

Controls for immunocytochemistry were done by omitting either the primary or the secondary antibody. Dead cells were identified by fluorescence microscopy, incubating the cultures with PI (0.5 μg/mL final concentration in culture) for 30 min just before fixation (30). Nuclei integrity was determined with DAPI (14).

Mitochondrial activity was determined by incubating the cultures for 30 min before fixation with the fluorescent probe Mitotracker (0.1 μg/mL), which selectively stains active mitochondria in culture. Active mitochondria, displaying a bright red fluorescence, and damaged mitochondria, showing a pale red fluorescence, were identified by microscopy.

*Statistical analysis.* For cytochemical studies, 10 fields per sample were analyzed in each case. Each value reported from cytochemical, compositional, and lipid labeling studies represents the average of at least three experiments ± SD. Statistical significance was determined by Student's two-tailed *t*-test.

## RESULTS

*Neuronal and glial cultures.* When retinal cells were incubated in chemically defined medium and in the absence of specific trophic factors, they developed and differentiated mainly as photoreceptors and amacrine neurons (13,14). Photoreceptors have a small, round cell body with a single neurite at one end and sometimes display a connecting cilium at the opposite end, but they failed to develop their characteristic outer segments (Fig. 1A). Opsin was diffusely distributed over the cell body, as observed with the Rho4-D2 monoclonal antibody. Amacrine neurons are bigger than photoreceptors and have multiple neurites (Fig. 1B). Both cell types developed normally for 3–4 d. Photoreceptors then started an apoptotic pathway leading to the death of most of these cells by day 14 (14). In contrast, amacrine neurons continued their survival and differentiation for up to 17 d *in vitro*.

Dissociated retinal cells resuspended in 10% FBS in DME and seeded at high density on low adhesive substrata developed mainly as flat cells, with big oval nuclei, that survived in culture for several days. Using the GFAP antibody, these cells were identified as Müller cells (Fig. 1C).

*DHA had multiple effects on photoreceptor survival and differentiation.* Analysis of the fatty acid composition of neuronal lipids showed that DHA amounted to only 4–6% of the total esterified fatty acids; this proportion was the same as found in the 1–2-d-old retinas used for the cultures. While the percentage of DHA in retinal lipids increased steadily during development *in vivo*, it remained constant in neurons *in vitro* (Fig. 2A). However, addition of DHA to the culture medium showed that neurons had active mechanisms for taking up and esterifying this fatty acid, because the proportion of DHA in neuronal lipids increased to over 20%, reaching similar values to those found *in vivo* (Fig. 2A,B).

Unexpectedly, this increase in the proportions of DHA in neuronal lipids was paralleled by an increase in photoreceptor survival (13). Addition of DHA had a protective effect on photoreceptors, rescuing them from the degeneration pathway observed in control conditions. At day 10, about 80% of photoreceptors were apoptotic in control cultures, whereas in DHA-treated cultures this percentage was reduced to nearly 60% (Fig. 3A). This effect was specific for photoreceptors; amacrine cells showed no signs of apoptosis and were unaffected by DHA addition.

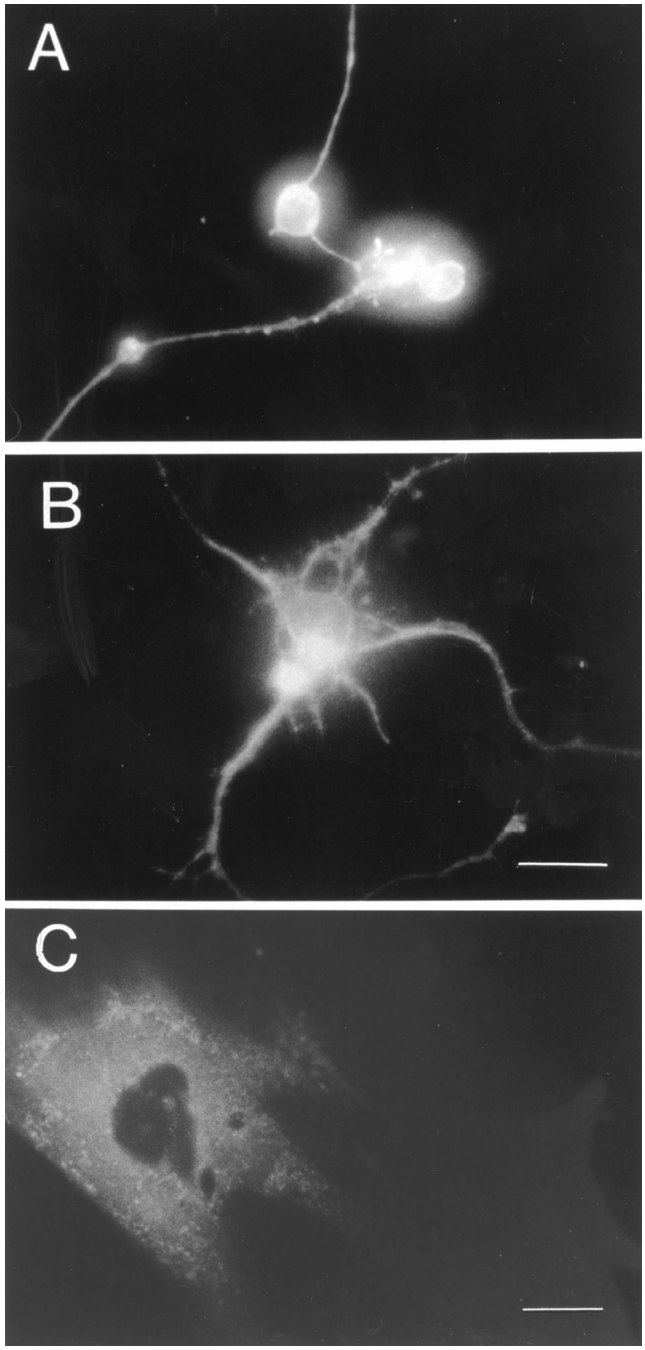

**FIG. 1.** Neuronal and glial cell identification. Fluorescence photomicrographs of (A) photoreceptors labeled with the Rho4-D2 monoclonal antibody, (B) amacrine cells visualized with the HPC-1 monoclonal antibody, and (C) glial cells, identified with antibodies to glial fibrillary acidic protein (GFAP). Rat retinal neurons were cultured for 7 d in a chemically defined medium; glial cells were cultured until they were confluent in 10% fetal bovine serum in Dulbecco's modified Eagle's medium. The bars represent 10 μm (A and B) and 20 μm (C).

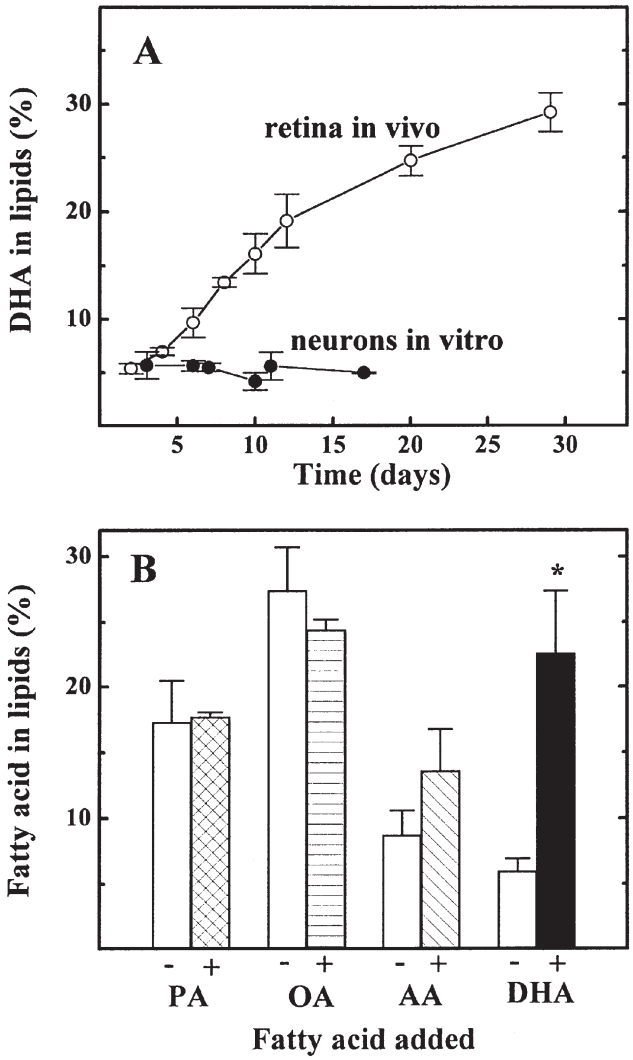

**FIG. 2.** Fatty acid composition of the retina *in vivo* and of retinal neurons in culture. Whole rat retinas were excised at different postnatal days *in vivo*, and retinal neurons were collected at different times of development *in vitro*. In fatty acid-supplemented cultures, the fatty acid (4 μM) complexed with bovine serum albumin (BSA) was added at day 7 *in vitro*; the same volume of a BSA solution was added to control cultures. At day 11, lipids were extracted, and the combined fatty acid composition of phospholipids and triacylglycerols was analyzed. (A) Variations in the percentage of docosahexaenoic acid (DHA) in lipids in the retina *in vivo* and retinal neurons *in vitro* during development. Values represent the means ± SD of three to seven samples. (B) Comparison of fatty acid composition of neuronal membranes in control cultures and cultures supplemented with palmitic acid (PA), oleic acid (OA), arachidonic acid (AA), or DHA. Bars represent the percentage of each fatty acid in lipids of retinal neurons in control cultures (–) and in cultures supplemented (+) with same fatty acid. Mean values ± SD of at least three samples are given. *Statistically significant difference with respect to control cultures ($P < 0.05$).

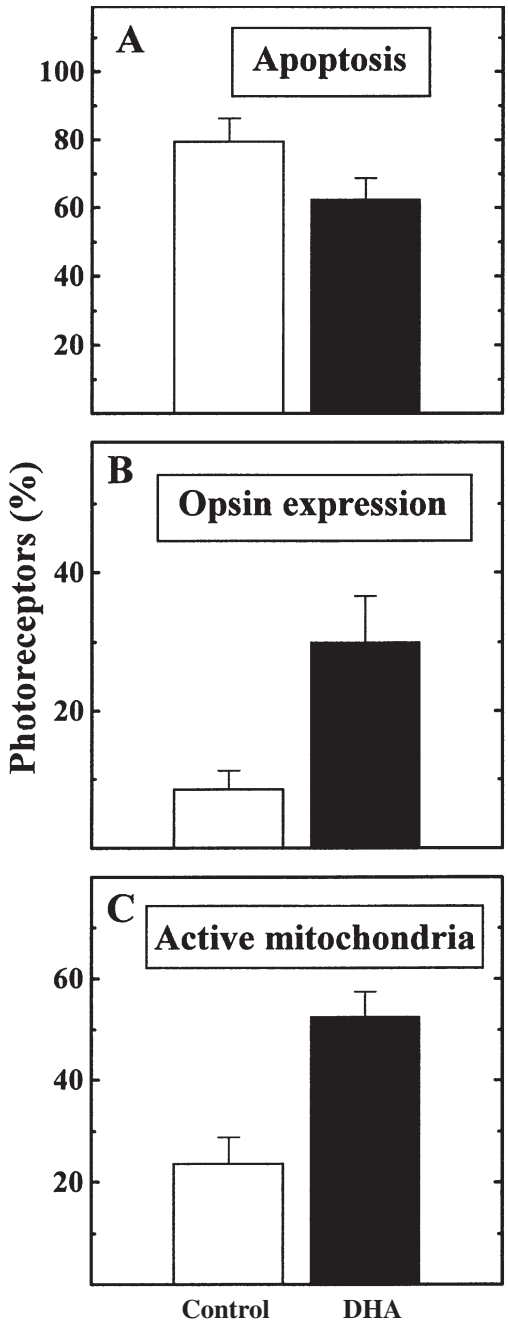

**FIG. 3.** Effects of DHA on photoreceptor survival, differentiation, and mitochondrial activity. Pure neuronal cultures were supplemented at day 1 with either 6.7 μM DHA or with a BSA solution (control), as described in Figure 2. Cells were fixed at day 10, and (A) photoreceptor apoptosis was determined by counting the number of these cells with fragmented nuclei, labeled with 4,6-diamido-2-phenylindole (DAPI); (B) opsin expression was evaluated by counting the number of Rho-4D2-positive photoreceptors; and (C) mitochondrial activity was analyzed with the fluorescent probe Mitotracker. Mean values ± SD of at least three samples are shown. See Figure 2 for abbreviations.

Even when photoreceptors displayed such characteristic apoptotic features as fragmented nuclei, they maintained some basic functions for several days. At early stages of apoptosis, most cells had a normal appearance and even expressed opsin. Depending on the severity of the damage, nonviable cells could be visualized by the pale to bright red fluorescence they exhibited after incubation with PI. At day 1, about 40,000 photoreceptors/dish were nonviable; by day 10, this number had sharply increased, and about 700,000 cells/dish were PI-positive (Fig. 4). Addition of DHA markedly reduced the number of nonviable cells, to about 470,000 photoreceptors/dish (Fig. 4).

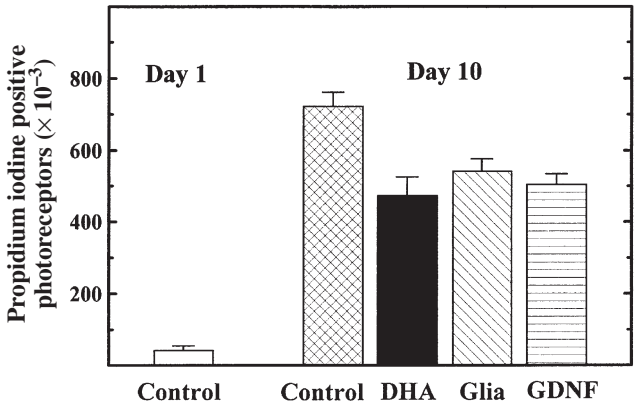

**FIG. 4.** Effect of DHA, glial cells, and glial-derived neurotrophic factor (GDNF) on photoreceptor survival. Pure neuronal cultures supplemented with either DHA, as described in Figure 2, or GDNF (10 ng/mL), added immediately after seeding the cells or neuron–glia cocultures, were incubated for 10 d. Dead photoreceptors were identified with propidium iodide (PI). The bars represent the number of dead, PI-positive photoreceptors in each culture condition, as means ± SD of at least three samples. See Figure 2 for abbreviations.

To find out if these effects were specific to DHA, neuronal cultures were supplemented with other fatty acids, such as palmitic, oleic, or arachidonic acid. The fatty acid composition of neuronal membranes remained the same upon addition of these fatty acids (Fig. 2), because none of them was able to accumulate in membrane lipids. Concomitantly, these fatty acids were unable to stop photoreceptor degeneration and had no effect on apoptosis (14). Hence, DHA was the only fatty acid having an anti-apoptotic effect and this effect, was consistent with its increased proportions in neuronal lipids.

Searching for clues to understand the anti-apoptotic activity of DHA, we analyzed characteristic parameters of photoreceptor differentiation and found that both the development and the differentiation of these cells were enhanced upon DHA addition. As described above, under control conditions, a small percentage of photoreceptors expressed opsin, and the photoceptors did not develop their characteristic outer segments (Fig. 1A). However, upon DHA supplementation, the proportion of photoreceptors displaying apical processes at the end of their cilium (13,15) and showing opsin expression was markedly increased (Fig. 3B). Thus, the percentage of photoreceptor cells expressing opsin at day 10, either in the cell bodies or in their apical processes, increased from 8.6% in control cultures to 30% in DHA-treated cultures (Fig. 3B). In addition, in DHA-treated cultures, opsin tended to lose its axon localization and to concentrate either in photoreceptor cell bodies or in their apical processes. All these changes were indicative of photoreceptor differentiation.

Mitochondria have been proposed to have a central role in triggering apoptotic death (31). Impairment in mitochondrial activity seems to be closely related to the onset of cell death. Looking for possible molecular pathways leading to the protective effect of DHA, we investigated mitochondrial functionality in control and DHA-treated cultures. Most amacrine cells had several active mitochondria at every time studied (not shown). In contrast, mitochondrial activity was severely reduced in photoreceptor cells under control conditions: by day 10, only about 25% of these cells were left with active mitochondria. DHA supplementation seemed to ameliorate mitochondrial damage: after the same time in culture, 53% of photoreceptors still displayed active mitochondria (Fig. 3C). Hence, the anti-apoptotic effect of DHA might be related to the maintenance of mitochondrial activity.

*Glial cells ameliorated photoreceptor cell death* in vitro. We investigated the effects of glial cells on neuronal survival by coculturing retinal glia with neuronal cells. The presence of glial cells led to a significant increase in photoreceptor survival: the amount of PI-positive photoreceptors at day 10 was reduced from 700,000 cells/dish in pure neuronal control cultures to about 550,000 cells/dish in neuron–glia cocultures (Fig. 4). Glial cells seemed to exert this effect by delaying the onset and retarding the progression of apoptosis, in a similar manner to DHA (Insua, M.F., Rotstein, N.P., and Politi, L.E., unpublished data). Moreover, as observed in DHA-supplemented cultures, glial cells increased the formation of apical processes in photoreceptors (Insua, M.F., Rotstein, N.P., and Politi, L.E., unpublished results).

We then analyzed glial cell fatty acid composition and the ability of glia to take up DHA from the culture medium. The major fatty acids present in glia total lipids were oleic and palmitic, with arachidonic as the major polyunsaturated fatty acid; almost 15% of the fatty acids were DHA (Table 1). The proportion of this acid was considerably higher than that found in neuronal lipids. When glial cells were supplemented with 6.7 μM DHA, the percentage of this fatty acid in lipids increased to about 27% with a concomitant decrease of oleic acid. Therefore, glial cells were able to take up DHA and accumulate it in their lipids.

**TABLE 1**
**Effect of Docosahexaenoic Acid (DHA) Supplementation on the Fatty Acid Composition of Glial Cells *in vitro*[a]**

| Fatty acid | –DHA (%) | +DHA (%) |

[a]Glial cells were cultured for 6 d in 10% fetal bovine serum in Dulbecco's modified Eagle's medium until they reached confluence and were then incubated in neuronal medium either with 6.7 μM DHA complexed with bovine serum albumin (BSA) (+DHA) or with the same volume of a BSA solution (–DHA). After 2 d, the cells were collected and centrifuged, their lipids were extracted, and the fatty acid composition was analyzed as described in Figure 2. The values are percentages of total fatty acids and are shown as means ± SD from three or four samples.

*Glial cells can transfer DHA to neurons in coculture*. The question remaining was whether glial cells could channel DHA to neurons. Glial cells previously labeled with [$^{14}$C]DHA were cocultured with neurons grown on coverslips, and then glial cells and neurons were again separated. Autoradiographic analysis showed a diffuse distribution of the silver grains in glial cells, indicating [$^{14}$C]DHA uptake and dispersion over the entire cells (Fig. 5). In contrast, silver grains were more densely concentrated in neuronal cells, preferentially in photoreceptors; moreover, in these cells, the most intense staining was observed in the regions corresponding to apical processes. Overall, these results suggest that glial cells incorporated the fatty acid and managed to convey [$^{14}$C]DHA to neurons in coculture and that photoreceptors avidly took it up and concentrated it in the newly formed apical processes.

*GDNF protects photoreceptors from cell death.* Glial cells might rescue photoreceptors from cell death by releasing trophic factors other than DHA, such as GDNF. The possibility that this molecule might protect photoreceptors from degeneration *in vitro* was investigated. When cell death was evaluated (Fig. 4), the number of PI-positive photoreceptors at day 10 was reduced from about 720,000 cells/dish in control cultures to 500,000 cells/dish in GDNF-supplemented cultures. This reduction was similar to that induced by glial cells and DHA (Fig. 4). Therefore, GDNF, DHA, and glial cells were able to rescue photoreceptors from cell death triggered by the absence of trophic factors.

## DISCUSSION

The mechanisms by which photoreceptor cells avoid natural programmed cell death during normal development in the retina are still unknown. The identification of the possible trophic factors involved in this process is of paramount interest, not only to increase our understanding of retinal functioning but also to prevent or treat human inherited degenerative

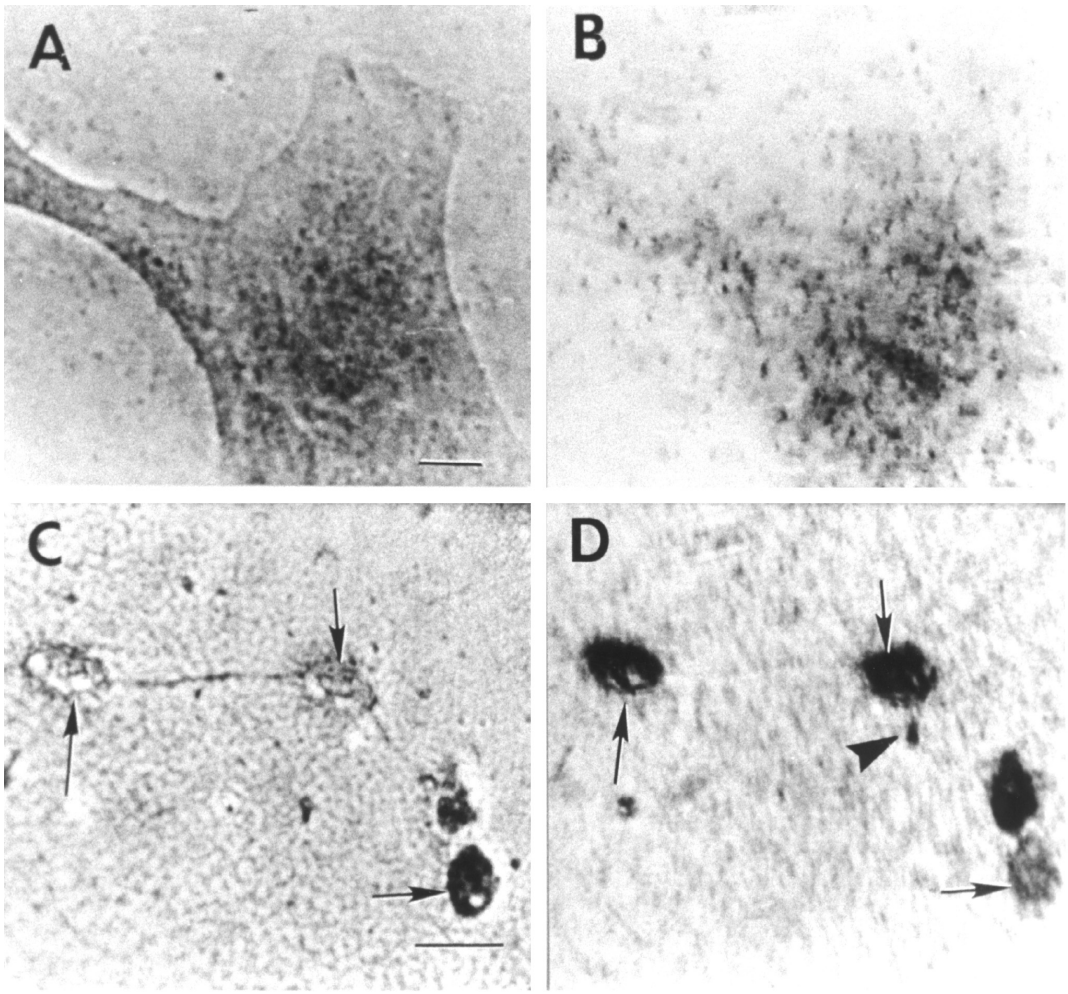

**FIG. 5.** Channeling of [$^{14}$C]DHA from glial to neuronal cells in coculture. Phase-contrast (left) and bright-field (right) pictures of autoradiographies of glial (A, B) and neuronal (C, D) cells. Glial cultures were incubated with [$^{14}$C]DHA for 1 d and, after thorough removal of the fatty acid, cocultured with pure neuronal cultures for 3 d. Both cell types were then separated, and [$^{14}$C]DHA labeling was analyzed by autoradiography. In glial cells, silver grains were diffusely distributed, whereas these grains were concentrated in photoreceptors in neuronal cultures. The bars indicate 10 μm. For abbreviation see Figure 2.

diseases affecting the retina, such as retinitis pigmentosa. The multiple effects of DHA on photoreceptor survival and differentiation shown in the present and previous reports (13–15) suggest a novel role as a neurotrophic factor for this lipid molecule. DHA rescues photoreceptors by delaying the onset and slowing down the progression of apoptosis. Moreover, our present results confirm previous reports that DHA, like other trophic factors, advances the differentiation of this single neuronal cell type. In the mature retina, photoreceptors must have highly differentiated characters at both the molecular and structural levels to accomplish their visual function: they must develop apical processes to fully differentiate the outer segments where opsin is to be concentrated for phototransduction to occur. Under control conditions *in vitro*, the diffuse distribution of opsin over the entire plasmalemma and the lack of apical differentiation mirrored immature stages of photoreceptor differentiation (14,15). DHA addition promoted the formation of apical processes, enhanced opsin expression, and favored its localization in these newly formed apical processes of photoreceptor cells.

The DHA-promoted survival and differentiation of photoreceptors contrast with the well-known harmful and proapoptotic effects of arachidonic acid in other nervous tissues (32). The protective effects of DHA paralleled an increase in its content in neuronal lipids upon DHA supplementation, similar to the accretion of this fatty acid in the retina *in vivo* during early stages of development (Fig. 2). Although the enzymes required for the esterification and turnover of several fatty acids are active in retinal neurons (15), DHA was the only fatty acid able to accumulate in neuronal lipids and modify their acyl chain composition when added to the culture media (Fig. 2). This was consistent with DHA being the only fatty acid having a neurotrophic activity (13–15). This suggests that the ability to form new DHA-containing phospholipids might be somehow related to the survival-promoting and, even more likely, the differentiating actions of DHA. The availability of such phospholipids, essential components of rod outer segments, might help redirect opsin to its correct localization (33,15), and the right combination of protein and phospholipids might allow the formation of apical processes. In patients with retinitis pigmentosa, and in animal models of this disease, a decrease in DHA content in plasma (34) and in both retina and photoreceptors (35) has been described. This decrease might contribute to the failure of photoreceptors to develop their outer segments and the ultimate death of photoreceptors in retinitis pigmentosa.

However, roles played by DHA are probably not only structural. Addition of DHA also has a protective action on monocytes, reducing tumor necrosis factor-induced apoptosis in these cells (36). These protective effects suggest that DHA could induce the release of a survival signal or, alternatively, it could prevent the release of a death signal during apoptosis development. Death signals, such as cytochrome c, are known to be released from damaged mitochondria during apoptotic processes (reviewed in Ref. 31). Our results show that an increase in the number of apoptotic photoreceptors was consistent with increased mitochondrial impairment in these cells. Mitochondrial damage has also been shown in other apoptotic processes affecting photoreceptors (37). Addition of DHA to the cultures partially prevented the loss of mitochondrial activity, suggesting a possible role for this acid in sustaining mitochondrial function. Mitochondrial failure is closely related to alterations in membrane properties, such as transmembrane potential and $H^+$ gradient, mainly due to the opening of a large-conductance channel (31). Polyunsaturated fatty acids have been shown to be involved in the regulation of ion channels, thus regulating neuronal survival in other systems (38,39). Accumulation of DHA in mitochondrial lipids might similarly participate in the modulation of the aperture of mitochondrial channels, partially preventing or postponing the changes in membrane properties and thus slowing down the apoptotic death of photoreceptors. Further research to obtain a better understanding of the mechanisms involved in DHA protection of mitochondrial function by DHA is warranted.

The essentiality of DHA for photoreceptor survival makes it essential for retinal cells to accumulate this fatty acid. DHA is tenaciously retained in the retina, even upon prolonged dietary deprivation (2,40), and efficient mechanisms have been developed to avoid loss of DHA during the daily recycling of photoreceptor discs (41). The liver has been proposed to be in charge of DHA provision to the retina (20). This fatty acid can also be synthesized by both the pigment epithelium (42) and the retina itself (43–45), although experiments conducted with the whole retina have not determined whether this synthesis was performed by neurons or glial cells. In the brain, astrocytes take charge of DHA synthesis and delivery to neurons (46). Our results showed that glial cells had a protective effect on photoreceptors, delaying cell death in a similar fashion to DHA. In addition, the proportion of DHA was higher in glial than in neuronal lipids. This prompted us to investigate whether glia could provide DHA to neurons in coculture, and we found that not only did glial cells transfer [$^{14}$C]DHA to neurons but these cells avidly incorporated it and esterified it in their lipids as well. Radioactive DHA was particularly concentrated in photoreceptors, suggesting that either glial cells preferentially channeled it to these neurons or that photoreceptors had the most efficient mechanisms for the uptake of DHA. Glial cells have been shown to modulate several neuronal functions, including photoreceptor survival through the supply of trophic factors (21,22). Provision of DHA might be at least one of the mechanisms involved in the protective role played by glial cells in the regulation of photoreceptor survival in the retina.

There is growing consensus that a combination of trophic factors is probably required for sustaining photoreceptor survival (47,48). DHA is undoubtedly required at a precise developmental period to postpone the triggering of photoreceptor apoptosis; however, this process eventually starts, with only a small population of photoreceptors being spared from apoptotic death (14). This suggests that other survival factors are required, acting in a sequential or synergistic manner to allow these cells to survive for longer time periods and

acquire fully differentiated characters. Our results show that GDNF was able to protect photoreceptors from cell death in the absence of other trophic factors *in vitro*, having a survival-promoting effect similar to those of DHA and glial cells. We have also shown that GDNF diminished apoptosis, acting coordinately with DHA (49). Since glial cells are known to release GDNF, this trophic factor may provide glia with another way of controlling photoreceptor apoptosis. Hence, glial cells might play a central role in the regulation of photoreceptor survival, by modulating the release of GDNF and DHA during development.

In conclusion, mounting evidence supports the hypothesis that a lipid molecule like DHA, acting in a coordinated, developmentally regulated fashion with other trophic molecules, may behave as a trophic factor essential for sustaining photoreceptor survival and differentiation.

## ACKNOWLEDGMENTS

The present work was funded by grants from the Agencia Nacional para la Ciencia y Tecnologia (ANPCYT) 01-00000-00926 (to Luis Politi), the Consejo Nacional de Investigaciones Cientificas y Técnicas (CONICET), and the Universidad Nacional del Sur, Argentina. Luis Politi, Nora Rotstein, and Néstor Carri are CONICET research career members. We thank Beatriz de los Santos for excellent technical assistance, and Drs. Colin Barnstable (Yale University) and Robert Molday (University of British Columbia) for their generous gift of the monoclonal antibodies Rho4-D2 and HPC-1 used in these studies.

**ABSTRACT:** More and more reports in recent years have shown that the intake of polyunsaturated fatty acids (PUFA) constitutes an environmental factor able to act on the central nervous system (CNS) function. We recently demonstrated that the effects of PUFA on behavior can be mediated through effects on the monoaminergic neurotransmission processes. Supporting this proposal, we showed that chronic dietary deficiency in α-linolenic acid in rats induces abnormalities in several parameters of the mesocortical and mesolimbic dopaminergic systems. In both systems, the pool of dopamine stored in presynaptic vesicles is strongly decreased. This may be due to a decrease in the number of vesicles. In addition, several other factors of dopaminergic neurotransmission are modified according to the system affected. The mesocortical system seems to be hypofunctional overall [e.g., decreased basal release of dopamine (DA) and reduced levels of dopamine $D_2$ ($DAD_2$) receptors]. In contrast, the mesolimbic system seems to be hyperfunctional overall (e.g., increased basal release of DA and increased levels of $DAD_2$ receptors). These neurochemical changes are in agreement with modifications of behavior already described with this deficiency. The precise mechanisms explaining the effects of PUFA on neurotransmission remain to be clarified. For example, modifications of physical properties of the neuronal membrane, effects on proteins (receptors, transporters) enclosed in the membrane, and effects on gene expression and/or transcription might occur. Whatever the mechanism, it is therefore assumed that interactions exist among PUFA, neurotransmission, and behavior. This might be related to clinical findings. Indeed, deficits in the peripheral amounts of PUFA have been described in subjects suffering from neurological and psychiatric disorders. Involvement of the monoaminergic neurotransmission function has been demonstrated or hypothesized in several of these diseases. It can therefore be proposed that functional links exist among PUFA status, neurotransmission processes, and behavioral disorders in humans. Animal models are tools of choice for the understanding of such links. Improved prevention and complementary treatment of neurological and psychiatric diseases can be expected from these studies.

Paper no. L8644 in *Lipids 36*, 937–944 (September 2001).

The presence in the brain of large amounts of polyunsaturated fatty acids (PUFA) from the n-3 and n-6 families is in agreement with their major role in the structure and function of this organ (1). These essential fatty acids (EFA) are exclusively provided by the diet in the form of precursors (18:3n-3 or α-linolenic acid, and 18:2n-6 or linoleic acid) and long-chain derivatives (LC-PUFA, mainly docosahexaenoic acid, 22:6n-3 or DHA; and arachidonic acid, 20:4n-6 or AA).

During the last decade, it has become evident that intake of PUFA constitutes an environmental factor able to act on the central nervous system (CNS) function. This is based on experimental studies that show behavioral abnormalities in animals consuming diets unbalanced in PUFA, and on clinical observations that describe abnormal levels of PUFA in the plasma and/or erythrocytes of subjects suffering from several diseases of the CNS. In agreement with these findings, we recently reported evidence that such behavioral dysfunctions might be related to neurochemical changes, especially in the monoaminergic neurotransmission processes.

This new field of research on the effects of nutrition on the neurotransmission processes opens up perspectives regarding the following: (i) the knowledge of mechanisms involved in the effects of PUFA on the CNS and (ii) the potential preventive and therapeutic use of PUFA in several neurological and psychiatric diseases.

## PUFA AND MONOAMINERGIC NEUROTRANSMISSION: EXPERIMENTAL STUDIES IN ANIMALS

The involvement of PUFA in CNS function can be assessed using dietary manipulation in animal models. It has already been shown that chronic dietary deficiency in α-linolenic acid in rodents greatly affects the fatty acid (FA) composition of cerebral membrane phospholipids (1–5). The main changes comprise reduction in DHA levels and a compensatory rise in n-6 PUFA levels, especially docosapentaenoic acid (22:5n-6). It was shown more recently that the composition of PUFA in cerebral membranes is not homogeneous throughout the brain, and is not modified in a similar way in response to PUFA deficiency. Analysis of specific brain regions showed that in rats and mice consuming a diet balanced in n-6 and n-3 PUFA, the amount of DHA was significantly higher in the frontal cortex than in other regions such as the striatum, hippocampus, and cerebellum (6,7). Moreover, the frontal cortex

Abbreviations: AA, arachidonic acid; ADHD, attention deficit/hyperactivity disorder; CNS, central nervous system; DA, dopamine; $DAD_2$, dopamine $D_2$; DAT, DA transporters; DHA, docosahexaenoic acid; $D_nR$, dopamine receptor; Dopac, dihydrophenylacetic acid; EFA, essential fatty acids; FA, fatty acid; GABA, γ-aminobutyric acid; HPLC, high-performance liquid chromatography; LC, long chain; PUFA, polyunsaturated fatty acids; $VMAT_2$, vesicular monoamine transporter.

seemed to be more affected by α-linolenic acid deficiency than other regions (6-8).

In addition to these biochemical changes, α-linolenic acid deficiency impairs performance in a variety of learning tasks (3–5,9,10). These impaired behavioral responses often involve both learning ability and sensory, motor, or motivational processes (11). In particular, increased responses to several reinforcement factors and slower extinction observed in n-3 PUFA–deficient rats can be interpreted as changes in motivation.

Although behavioral responses cannot be precisely related to specific neurochemical pathways, we proposed that the behavioral effects of n-3 PUFA deficiency might be mediated through dopaminergic systems (6). This hypothesis was based mainly on the known role of dopamine (DA) as a major factor modulating attention, motivation, and emotion (12). This role of DA in behavior modulation is exerted mainly through the mesocortical and mesolimbic systems, whereas the nigrostriatal pathway is essentially involved in locomotor activity. Mesocortical DA neurons are thus involved in cognitive functions such as working memory, and mesolimbic DA neurons play a strong role in motivational behavior and emotional functions (12–14).

We therefore studied the effects of α-linolenic acid deficiency on several parameters of monoaminergic neurotransmission, and more especially, dopaminergic neurotransmission, in cerebral regions under such neurochemical control. In most of our experiments, we compared 2- to 3-mon-old male rats consuming a diet deficient in α-linolenic acid for several generations (the lipid ratio was provided by African peanut oil providing 1200 mg of linolenic acid and <6 mg of α-linolenic acid/100 g of diet) to age-matched rats consuming a diet balanced in n-6 and n-3 PUFA (the lipid ratio was provided by a mixture of African peanut oil and rapeseed oil, providing 1200 mg of linolenic acid and 200 mg of α-linolenic acid/100 g of diet). The n-6/n-3 ratio in the deficient diet was >200, whereas in the balanced control diet it was 6, which is considered as optimal to obtain and maintain a physiological level of DHA in developing and adult rats (15).

In the initial series of experiments, we measured the overall amounts of three monoamines, DA, serotonin, and noradrenaline, in tissue homogenates of the frontal cortex, striatum, hippocampus, and cerebellum obtained from rats consuming the α-linolenic acid–deficient or the control diet. The main modification observed in rats fed the deficient diet was a 40–60% decrease in the amount of DA in the frontal cortex, whereas only a slight decrease was observed in the striatum (6); both abnormalities persisted throughout life, from 2 to 24 mon of age (16). To refine these results, we turned our work to a dynamic approach allowing the study of several parameters of DA neurotransmission in live animals. For this, we used the intracerebral microdialysis technique. This method consists of implanting a probe, terminating with a semipermeable membrane, and perfused with a buffer medium, into a specific region of the brain. The pores of the membrane allow the passage of solutes of suitable size from the extracellular compartment along a concentration gradient (17). Neurotransmitters are thereafter measured in the dialysate fractions collected with an appropriate method, e.g., high-performance liquid chromatography (HPLC) associated with electrochemical detection. This measurement reflects the concentration of neurotransmitters in the fluid surrounding the dialysis probe, which represents a large population of nerve terminals. It must be emphasized that the experimental conditions of microdialysis are of major importance for the correct interpretation of the results (18).

We used microdialysis to study the release of DA and its main metabolites [dihydrophenylacetic acid (DOPAC) and homovanillic acid] in basal conditions and under pharmacological stimulation (drugs being administered through the probe or by systemic injection). This demonstrated that the decrease in DA in the homogenates of the frontal cortex from α-linolenic acid–deficient rats was probably due to abnormalities in the DA storage compartment, rather than to the cytoplasm compartment (19,20). Several findings thus suggest a deficit in the storage of DA in the presynaptic vesicles, which can be due to a decrease in the number of dopaminergic vesicles. Indeed, the vesicular monoamine transporter ($VMAT_2$), which is localized on the vesicle membrane and allows DA entry into vesicles, is decreased in the frontal cortex (21,22) and nucleus accumbens (20) of deficient rats. Although this decrease was found to occur in both regions, the dopaminergic function response to n-3 PUFA deficiency differed between cerebral regions. The results of pharmacologically stimulated release of DA were in accordance with hypofunction in the frontal cortex and hyperfunction in the nucleus accumbens (Fig. 1). The strong functional links existing between the frontal cortex and the nucleus accumbens (14,23,24) could explain in part this last finding. For instance, the enhanced basal level of extracellular DA measured in the nucleus accumbens of awake n-3 PUFA–deficient rats (20) might be related to the reduction in the level of DA in the frontal cortex, thus removing the inhibitory effect exerted by the frontal cortex efferent on the DA level in the nucleus accumbens. This last cerebral area is very involved in reinforcement processes, mainly through DA release soon after a reward (25,26). On this basis, Reisbick and Neuringer (27) recently proposed that the poorer performance in several cognitive tasks observed in n-3 PUFA–deficient rats might be attributed to increased reactivity to reward related to the dopaminergic function of the nucleus accumbens.

In addition to these effects on DA metabolism, it seems that α-linolenic acid deficiency is also able to induce changes in specific molecular targets of DA. The main targets are receptors localized on postsynaptic neurons, and autoreceptors and membrane DA transporters (DAT), both localized at presynaptic levels. Five subtypes of dopamine receptors have been distinguished to date on pharmacological, genetic, and molecular grounds. They belong to two families, i.e., the $D_1$-like family ($D_1$ and $D_5$ receptors), and the $D_2$-like family ($D_2$, $D_3$, $D_4$ receptors). The $D_1$ receptors ($D_1R$) are exclusively postsynaptic (28), whereas $D_2$ receptors ($D_2R$) are both post-

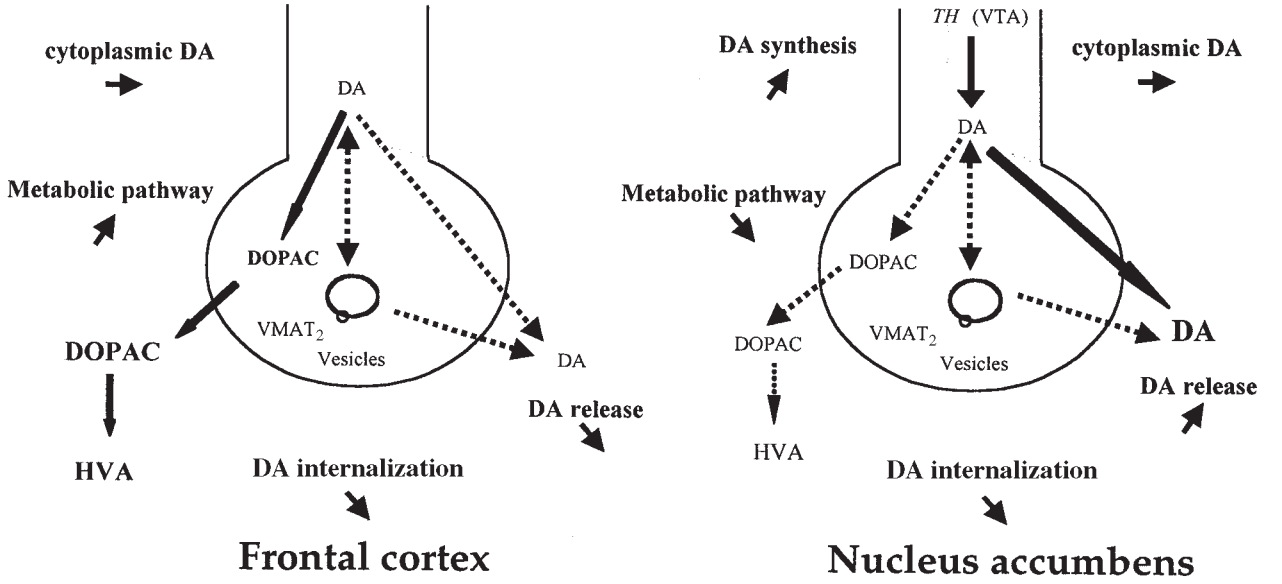

**FIG. 1.** Dopamine metabolism in the frontal cortex and nucleus accumbens of n-3 PUFA–deficient rats: hypothesis. In the frontal cortex as well as in the nucleus accumbens, the cytoplasmic compartment of DA is unmodified and the vesicle storage compartment (DA internalization) is reduced in α-linolenic acid–deficient rats. However, the metabolic pathway is increased in the frontal cortex (decreased DA release and increased DOPAC and HVA release), and increased in the nucleus accumbens (increased DA synthesis, increased DA release, decreased DOPAC and HVA release). This leads to a hypofunction of dopaminergic transmission in the frontal cortex, and an hyperfunction in the nucleus accumbens. Abbreviations: DA, dopamine; DOPAC, dihydroxyphenyl acetic acid; HVA, homovanillic acid, PUFA, polyunsaturated fatty acid; $VMAT_2$, vesicular monoamine transporter; TH, tyrosine hydroxylase; VTA, ventral tegmental area.

synaptic and presynaptic (see Ref. 29 for recent review). The DAT has major physiological roles in regulating neurotransmission processes through rapid removal of DA from the synaptic cleft back into the presynaptic nerve endings. It also mediates the pharmacological effects of drugs such as cocaine and amphetamine (30), and is very involved in a variety of disease processes such as Parkinson's disease (31). It was therefore of great interest to study the potential effects of n-3 PUFA deficiency on these presynaptic and postsynaptic binding sites, which are involved in the physiological function of DA.

We found that neither $D_1R$ nor DAT seemed to be affected by α-linolenic acid deficiency (6,16), whereas $D_2R$ were slightly decreased in the frontal cortex (6,16) and strongly increased in the nucleus accumbens (20). These changes were observed at the following two levels: (i) protein expression measured by quantitative autoradiography using binding experiments with specific ligands, and (ii) mRNA expression measured by *in situ* hybridization. These modifications occurring in deficient rats could result in part from regulatory responses to the neurotransmission abnormalities already described. For example, the increase in $D_2R$ in the nucleus accumbens could be due to hypersensitivity of presynaptic autoreceptors in response to the increased DA levels observed in this cerebral region (20) because this type of regulatory mechanism has been described (32).

Our overall neurochemical findings, which demonstrate that chronic n-3 PUFA deficiency acts on the mesocortical and mesolimbic systems, are in accordance with several studies reporting behavioral effects of such deficiency related to motivation, response to reward, and learning ability. However, the precise mechanisms linking PUFA, neurochemical events, and behavior remain to be clarified. One of these mechanisms might involve the effects of changes in the relative amounts of PUFA in the neuronal membranes on the function of these membranes. Several findings show that changes in dietary PUFA act on membrane fluidity (33–35); it can therefore be hypothesized that membrane changes induced by chronic n-3 PUFA deficiency could decrease the formation of vesicles, which we observed. In agreement with this, it has also been shown that dietary α-linolenic acid deficiency can affect vesicle density in the rat hippocampus (36). As already proposed, biochemical modifications in neuronal membranes might also be involved in abnormalities of the neurotransmitter receptors that are included in these membranes (37).

In addition, neurochemical changes also suggest that modification of the lipid content in the diet is able to act on the regulation of gene transcription. The direct involvement of lipids, particularly PUFA, in the regulation of gene expression, transcription, and mRNA stability in different biological tissues has become increasingly apparent in the last decade. Such phenomena have been studied and described in hepatic, lipogenic, and immune tissues (38,39). We can therefore hypothesize that such regulation takes place in the brain and that dietary modulation of n-3 PUFA content influences gene expression and transcription, thus explaining differences in protein and mRNA expression between control and deficient rats.

Animal experiments therefore suggest that interactions among PUFA, neurotransmission, and behavior exist, and these might have repercussions for the improvement of human health.

## PUFA AND CNS DISORDERS: CLINICAL DATA

Several teams have recently focused on the peripheral amounts (plasma and/or red blood cells) of PUFA in subjects suffering from neurological or psychiatric diseases. It was shown that various neurological disorders such as Huntington's disease, multiple sclerosis, Alzheimer's disease, and adrenoleucodystrophia can be associated with deficits in n-6 and/or n-3 PUFA (40,41). However, little information is available to date. In addition, it is difficult to obtain relevant comparisons between affected and control subjects because peripheral amounts of PUFA seem very heterogeneous among populations (40). Findings are more consistent in the field of psychiatric disorders, and we chose to study three of these diseases in which the involvement of monoaminergic neurotransmission processes are hypothesized, i.e., schizophrenia, depression, and attention deficit/hyperactivity disorders (ADHD).

Schizophrenia is a psychiatric disease that affects ~1% of the population. The predominant hypothesis regarding the pathophysiology of this disease is dysfunction of the dopaminergic systems (see Ref. 42 for review). These systems seem to be unbalanced, thus inducing dysfunction at different cerebral levels under dopaminergic control, such as the frontal cortex, limbic regions, and basal ganglia (43). In addition, other neurotransmitter systems such as the glutamatergic pathways, which have strong interactions with DA, could be involved (44).

Horrobin *et al*. (45,46) first proposed that relationships could exist between schizophrenia and changes in the status of EFA, showing a tendency toward lower amounts of plasma PUFA, especially linoleic acid. However, further findings concerning the levels of EFA in erythrocytes suggested that two schizophrenic populations could be distinguished, i.e., one with EFA levels similar to those of controls and another with reduced amounts of n-6 and n-3 PUFA, especially AA and DHA (47–49). Several mechanisms could explain these deficits, including increased activity of phospholipase $A_2$, thus inducing increased extraction of AA and DHA from cerebral membranes (50–52). Another argument in favor of a relationship between schizophrenia and EFA deficit is that dietary supplementation in PUFA is able to alleviate symptoms of the disease (53,54). It seems therefore that schizophrenia might be an example of disease in which PUFA supplementation associated with pharmacological treatment might be beneficial, but extended evaluation of such treatment is still required (see Ref. 55 for review).

Depression is a complex disorder that particularly involves serotoninergic neurotransmission processes, especially serotonin receptors and membrane transporters (56). Several studies have described deficits in plasma and/or erythrocytes of depressed subjects (57–61), e.g., a 45% reduction in the levels of α-linolenic and DHA, thus inducing an overall increase in the n-6/n-3 PUFA ratio (59). However, no clear hypothesis has yet been proposed to explain the relationships between these findings and depression.

Attention deficit/hyperactivity disorder (ADHD) affects mainly boys and is characterized by increased impulsivity and hyperactivity. Several recent findings are in agreement with abnormalities in parameters of dopaminergic neurotransmission, especially the dopamine transporter, associated with this disease (62–65). The first study linking ADHD and PUFA was performed on 48 drug-naïve children compared with age-matched control subjects, and showed plasma decreases in DHA, AA, and dihomo-γ-linolenic acids (66). More recent reports have confirmed these findings (67–69), but the reasons for these deficits remain unclear.

It appears therefore that several psychiatric diseases could be associated with peripheral deficit in n-6 and more often n-3 PUFA. However, several mechanisms might be involved in these abnormalities. They include the following: (i) deficit in the dietary intake or digestive absorption of LC-PUFA or their precursors; (ii), poorer ability to convert the precursors to LC-PUFA; and (iii) incorrect PUFA incorporation into membranes or increased membrane extraction related to enzyme dysfunction such as phospholipase $A_2$ (according to the hypothesis proposed by Horrobin). In addition, it remains to be assessed whether abnormalities in PUFA levels in the plasma and/or erythrocytes are related to changes in the composition of cerebral membranes. Little information is available on this cerebral composition in subjects suffering from neurological or psychiatric diseases. Reduction in the level of total phospholipids (70) as well as decrease in several FA, including AA and DHA (71), was described in various cerebral areas in Alzheimer's disease subjects. Lower levels of PUFA, particularly AA and its precursor linolenic acid, were found *post mortem* in the frontal cortex (72) and caudate (73) in brains of schizophrenic subjects. These findings are in agreement with the possible occurrence of abnormal composition of FA in cerebral membranes of subjects suffering from diseases of the CNS, but remain to be confirmed.

Such clinical findings, which are still sparse, might be put together with experimental studies in animals. Because we have now shown that induced deficiency in n-3 PUFA in animals can cause changes in several aspects of the monoaminergic neurotransmission processes, it can be proposed that a deficit in these PUFA might be able to aggravate human diseases involving these processes. This proposal is therefore in favor of the following: (i) the detection of patients suffering from PUFA deficits and (ii) PUFA supplementation associated with pharmacological treatment in such patients.

## PROSPECTS

There is currently a great need for investigations that would provide understanding of the mechanisms linking PUFA, neurochemical events, and behavioral processes. Such knowledge is necessary to achieve new potency in clinical applications. Animal models are very relevant tools for this aim because dietary manipulation, neurochemical studies, and behavioral tests can be performed and compared. Several specific points would be thus tackled in animal models.

*Dose-effect of n-3 PUFA on monoaminergic neurotransmission.* Most of the above studies involve animals totally deprived of α-linolenic acid. However, less information is available concerning the effects of high dietary intake of n-3 PUFA. It has been shown that this type of diet induces changes in brain PUFA composition, i.e., a rise in n-3 PUFA (DHA, ecosapentaenoic acid) compensated for by lower amounts of n-6 PUFA (74,75). In addition, high dietary fish oil (rich in n-3 LC-PUFA) seems to improve learning ability in specific experimental conditions (76–78). We found recently that a similar diet also induced neurochemical modifications, including slightly reduced (striatum) and slightly increased (frontal cortex) amounts of dopaminergic $D_2R$ and a rise in overall DA levels in frontal cortex tissue (79). These last results might suggest opposing effects of n-3 overload and deficiency on dopaminergic function, but they are still preliminary. It would therefore be of great value to study the simultaneous effects of increasing amounts of n-3 PUFA, especially DHA, from deficiency to overload, on FA membrane composition, dopaminergic parameters, and response to behavioral tests. Few experiments have been performed in this field (80). Such information would be very useful with a view to nutritional supplementation in specific clinical situations as discussed above.

*Reversibility of neurochemical changes induced by n-3 PUFA deficiency.* Another major question is to establish whether the neurochemical changes observed under α-linolenic acid deficiency could be reversed by n-3 PUFA supplementation. It has been shown that, in terms of FA composition, the speed of recovery after deficiency is very slow in rats (81). It has also been shown in mice deficient in α-linolenic acid that intake of n-3 PUFA for 2 mon from the age of 7 wk is effective in reversing the biochemical and behavioral changes induced by the deficiency (82). It would be of great interest now to associate neurochemical parameters with these first biochemical and behavioral findings. In addition, the occurrence and swiftness of reversibility might be dependent on the age at which the supplementation is provided, and thus to a stage of cerebral development.

*Effects of PUFA on other neurotransmission systems.* The results obtained on the effects of n-3 PUFA deficiency on dopaminergic neurotransmission raise the question of the potential effects of such deficiency on other neurotransmission systems. It is not clear whether PUFA act on neurotransmission through membrane, genetic, or other routes that might simultaneously disturb several systems, or specifically disturb particular systems. In the first hypothesis, these effects might be exerted directly by PUFA. A few reports have described the effects of PUFA on various neurotransmitters, such as the reduced effects of DHA on the γ-aminobutyric acid (GABA) response (83), a rise in acetylcholine levels induced by DHA (84), and various effects of n-6 and n-3 PUFA on cerebral peptides (85). In addition to these direct effects, the effect of PUFA on several neurotransmission systems might also be the consequence of dopaminergic changes. It is indeed known that dopaminergic systems have many functional interactions with other systems, such as the serotoninergic, glutamatergic, GABAergic, and cholinergic, all of which are involved in behavioral processes. This therefore opens up a wide range of neurochemical investigations in relation to PUFA dietary intake.

This report brings together extensive evidence showing that PUFA are environmental factors able to act on several aspects of CNS function, such as neurochemical events and behavior. It is proposed that strong links exist among PUFA status, neurotransmission processes, and behavioral disorders. More evidence must be found to reinforce this proposal; the use of animal models is therefore a tool of choice in which diet, neurochemistry, and behavior can be studied simultaneously. The expected repercussions of such experiments are improved prevention and treatment of neurological and psychiatric diseases.

# Mechanisms of Action of Docosahexaenoic Acid in the Nervous System

**Norman Salem, Jr.*, Burton Litman, Hee-Yong Kim, and Klaus Gawrisch**

Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Rockville, Maryland

**ABSTRACT:** This review describes (from both the animal and human literature) the biological consequences of losses in nervous system docosahexaenoate (DHA). It then concentrates on biological mechanisms that may serve to explain changes in brain and retinal function. Brief consideration is given to actions of DHA as a nonesterified fatty acid and as a docosanoid or other bioactive molecule. The role of DHA-phospholipids in regulating G-protein signaling is presented in the context of studies with rhodopsin. It is clear that the visual pigment responds to the degree of unsaturation of the membrane lipids. At the cell biological level, DHA is shown to have a protective role in a cell culture model of apoptosis in relation to its effects in increasing cellular phosphatidylserine (PS); also, the loss of DHA leads to a loss in PS. Thus, through its effects on PS, DHA may play an important role in the regulation of cell signaling and in cell proliferation. Finally, progress has been made recently in nuclear magnetic resonance studies to delineate differences in molecular structure and order in biomembranes due to subtle changes in the degree of phospholipid unsaturation.

Paper no. L8776 in *Lipids 36*, 945–959 (September 2001)

## DHA COMPOSITION

In the 1960s, the very high level of docosahexaenoic acid (DHA, 22:6n3) in the mammalian brain was already appreciated (1,2) although the first description by Thudichum (3) was nearly a century earlier [see review by Salem *et al*. (4)]. Yabuuchi and O'Brien (5) described the positional distribution of brain phosphoglycerides in 1968, detailing both the high concentration of DHA in position *sn*-2 and its concentration in the aminophospholipids, phosphatidylserine (PS), and phosphatidylethanolamine (PE). By the early 1970s, the very high concentration in brain synaptosomal plasma membranes (6) and synaptic vesicles (7) was described by Breckenridge and co-workers. Table 1 presents the DHA composition in the aminophospholipids of brain and other selected mammalian tissues (1,6–18). It is apparent that the DHA content of the nervous system is very high. The retina not only contains a very high level of DHA in the rod outer segment (ROS) membranes, but also contains a very considerable amount of di-DHA species (19) as well as ones with DHA coupled to other highly unsaturated fatty acids (HUFA). The sperm is another compartment enriched in DHA. Every mammalian cell contains DHA, and phospholipids of internal organs and muscles have a significant content. Human milk contains a relatively low content of DHA with a higher percentage in phospholipids than triglycerides, the main lipid component of milk.

It has long been known that when an adult mammal consumes a diet low in DHA and its n-3 precursors, the nervous system content of DHA is much less altered than are other organs, i.e., DHA is said to be tenaciously retained once neural development has occurred (for reviews, see Refs. 4,20). However, animal studies have shown that when n-3 fat sources are inadequate during early neural development, then the levels of brain and retinal DHA decline (4,20–24). This has also been confirmed in autopsy studies of human infants that were fed a vegetable oil-based formula with low n-3 fat sources vs. breast-feeding in which preformed DHA was present (25–27). This has naturally led to an interrogation of the functional consequences of neural DHA loss.

## ANIMAL STUDIES

Representative studies in the animal literature (28–42) concerning the n-3 fatty acid deficiency syndrome are presented in Table 2. Only studies that focus on neural functions, notably brain and retinal functions, have been included here. Typically, these studies involve a two-generation diet regimen in which the mother is raised on an n-3-deficient diet and her offspring are then studied. Such treatment has generally been found to be necessary to induce a marked decline in brain and retinal DHA; a decline of 50–80% is typical of those associated with a change in neural function. A variety of different tasks show impairment, including those in both the visual and olfactory modalities (Table 2). In addition to decrements in performance in simple associative learning types of tasks, losses in spatial memory (39) and olfactory set learning have been reported recently (43). Thus, the loss in brain DHA may be said to affect cognition, at least to the extent that it can be ascertained in the rat.

## DHA RECOVERY

It has long been known that once depleted, the brain recovers its DHA rather slowly (44,45). A recent study in rats provided the time courses of DHA recovery and the reciprocal decline in docosapentaenoic acid (DPAn-6, 22:5n-6) in the retina, brain, liver, and serum when the rats were repleted with a diet containing both α-linolenate (LNA) and DHA (46). The half-times for brain and retinal recovery of DHA were 2.9 and 2.1 wk, respectively, even though the liver and plasma half-times were only 0.3 and 0.5 wk, respectively. This suggests a rather slow transport of DHA into the brain/retina even in the case of a DHA-deficient nervous system (47).

It could be hypothesized then that if the functional consequences of dietary n-3 fatty acid deficiency were due to the loss in DHA, at least some neural functions may be restored as the neuronal and retinal DHA level is restored. Others may not be reversible due to missed opportunities in sequential development or changes in structural features of the brain (48). The first such study of functional recovery by Connor and

| Impaired recovery of dark-adaptation | Neuringer *et al.*, 1986 (42) |

Neuringer (49) indicated that electroretinographic changes associated with low retinal DHA persisted after DHA repletion. However, Moriguchi *et al*. (50) recently presented evidence that spatial task acquisition and memory are reversible and, to a first approximation, correlate well with the level of brain DHA. However, Weisinger *et al*. (51) reported that when n-3-deficient guinea pigs were subsequently given a diet containing LNA, changes in mean arterial blood pressure and electroretinographic changes in the a-wave were not reversed even when the DHA levels were indistinguishable from the control levels. Thus, it appears that there may be no general answer to the question of reversibility of losses in function due to DHA losses in early development; the answer will depend on the type of function involved.

## HUMAN STUDIES

As mentioned above, formula-feeding of infants has been associated with a loss in brain DHA with respect to the level in those breast-fed (25–27). The pre-existing animal literature would predict that formula-fed infants would have a functional deficit if the neural DHA loss were of a sufficient magnitude. Of course, there are many differences between breast-feeding and formula-feeding; these involve not only differences in nutrients, but also maternal contact and care, and the association of breast-feeding with socioeconomic factors. Nevertheless, it appears that the DHA variable can explain a good portion of the benefits associated with breast-feeding.

Studies of preterm infants have generally shown a benefit when DHA is added to the formula in controlled experiments (Table 3) (52–59). The studies included here are limited to controlled studies of formula-feeding with or without addition of DHA or DHA plus arachidonic acid (AA). Also, only those in which neural outcomes were included are listed; studies of growth and other anthropometric measures are not included. Studies of preterm infants (52–58) indicated, with one exception (59), that there was a benefit to adding long-chain polyunsaturates (LCP) to formulas that contain only the 18-carbon essential fatty acids found in vegetable oils. In addition, a meta-analysis of visual acuity differences in premature infants at 2 and 4 mon of age found a benefit of LCP of 0.47 and 0.28 octaves, respectively (60). These observations, in combination with studies indicating the safety of the ingredients used to supply these nutrients, lead us to conclude that preterm infant formulas must contain DHA/AA.

Studies of full-term infants are listed in Table 4 (61–72). In half of these studies, the LCP supplement supported an increased visual acuity (61,63,67), neurodevelopmental score

(62,71), or problem-solving ability (68). In five of the trials, no effect was observed for the LCP supplement (64–66,70,72). In one trial, infants with the LCP supplement appeared to perform more poorly in a vocabulary test administered to 14-mon-old children (69). However, a recent trial with a larger number of preterm infants reported a positive effect of LCP-supplemented formula on vocabulary scores (73). San Giovanni *et al*. (74) performed a meta-analysis of the trials involving visual acuity and concluded that there was a 0.32 octave difference in visual acuity when supplemented and unsupplemented formula groups were compared, with the DHA-fed groups having the higher acuity. A somewhat larger difference (0.49 octaves) was observed when breast-fed infants were compared with unsupplemented formula-fed infants.

In most of these trials, a rather low level (0.1–0.35% of total fatty acids) of DHA supplement was given, corresponding to a "Western" level of DHA in milk. In a recent review, Jensen (75) calculated the average for DHA content in mature milks in Western and non-Western women to be 0.45 and 0.88% of total fatty acids, respectively. Thus, it is likely that more of the trials would have observed a benefit of DHA if given at a higher level that is more consistent with the range of present-day worldwide human milk values. Viewed from this perspective, it is rather surprising that some trials can succeed in demonstrating a benefit of a fat component that is only 0.1–0.2 % of the total fatty acids. This suggests that these LCP are potent and essential nutrients for optimal development.

It was also of interest to note that Jensen (75) found the ratios of AA/DHA to be very close to 1 in his averages of human milk from both Western and non-Western women. The average levels found in non-Western women of ~0.9% each AA and DHA may be a good starting point for future research. This is believed by some to represent a better standard than that of Western women because the composition is strongly influenced by the diet and Westerners have in the last century or two shifted their consumption of fats toward n-6 fats and away from n-3 fats due to the availability of linoleic-rich vegetable oils. Estimates of the Paleolithic diet indicate a much greater intake of LCP and a ratio of n-3/n-6 fats close to 1 (76). Thus, human infants likely received a much higher intake of DHA and other LCP from their mother's milk during human evolution. In modern times, this ensured supply of DHA during neurodevelopment has been abrogated by formula-feeding and by a very low maternal intake of n-3 fats in many modern women. Given the present state of knowledge from human and animal studies of changes in neural function associated with a low DHA status, coupled with biochemical and nutritional studies indicating the loss of DHA in both peripheral tissues and the nervous system when preformed DHA is not fed and the safety of ingredients (70,77) used to supply DHA, it is clear that a prudent course of action would be to supply sources of preformed DHA in the infant diet.

## MECHANISMS OF ACTION OF DHA

From the above, it should be clear that many effects of DHA status have been observed relating to physiologic and behavioral functions of the nervous system. What has been unclear are the mechanisms underlying DHA function. Perhaps the most perplexing aspect of this question relates to the phenomenal degree of specificity that is apparent in this effect. It must be recalled that these studies did not involve essential fatty acid deficiency and that there were adequate and often excessive amounts of n-6 fats present, usually in the form of linoleic acid (LA). There is a well-known reciprocal replacement of DHA with DPAn-6, in this case in the brain (78) and retina (37,46,49). These two fatty acids differ only with respect to the absence of the Δ-19 double bond in the DPAn-6 molecule; both are 22-carbon HUFA with their first five double bonds in the same positions with respect to the carboxyl end of the molecule. There is little in the modern disciplines of biochemistry, biophysics, and neuroscience to offer a conceptual framework to understand this extraordinary specificity.

The first and most reasonable hypothesis was that a cyclooxygenase or lipoxygenase (LO) product of DHA but not DPAn-6 was produced that had an important function in the central nervous system. This hypothesis was explored extensively after the early reports that cyclooxygenase products of DHA were produced in the rainbow trout gill (79). Early investigations indicated that products made by rat brain were sensitive to LO inhibitors (80–83). A correction of the trout gill work indicated that the DHA products were not prostaglandins but rather LO products (84). Aveldano and Sprecher (85) observed that platelet LO produced a monohydroxylated form of DHA, and Bazan *et al.* (86) found a similar product after incubations with rat retinas. However, Kim and co-workers (80,81) demonstrated that the brain DHA products were a racemic mixture and thus unlikely to be enzymatic products. They also demonstrated that many of the products observed in the brain were a result of the failure to remove platelets and other blood cells by perfusion of the brain before *in vitro* experiments. Apparently, what was being measured *in vitro* may have corresponded to the low level of nonenzymatic fatty acid peroxidation that is known to occur. This is not to deny the existence of LO in the capillary beds in the brain, because Moore *et al*. (87) demonstrated 12-*S*-LO activity in a microvessel fraction. Also, Sawazaki *et al*. (82) found a 12-LO product of AA and DHA in the rat pineal gland and Zhang *et al*. (88) subsequently observed that the formation of these products is regulated by the light–dark cycle and melatonin through the modulation of both 12-LO (88) and cytosolic phopholipase $A_2$ expression (89). They also reported that n-3 fatty acid deficiency had profound effects not only on the pineal lipid profile but also on pineal biochemical activity, resulting in significantly fewer LO products (90).

It is still quite possible that a "magic bullet" type of molecule may be found for DHA, i.e., a function for the nonesterified fatty acid or a metabolite that is extremely potent. Physiologic experiments, for example, have demonstrated that DHA or an anandamide analog of DHA has a potent effect on the $K^+$ channel (91–93). Leaf and co-workers showed that the nonesterified form of DHA has a potent effect on $Na^+$ (94–96) and $Ca^{2+}$ channels (96,97). Also, synaptic transmission (98) and long-term potentiation (99,100) in the hippocampus as well as

*N*-methyl-D-aspartate responses in the cerebral cortex (101) are altered by DHA. However, what is not clear is whether these actions of DHA and its analogs are operative *in vivo*. Moreover, the substrate specificity required to explain the n-3 deficiency syndrome has generally not been found in these studies.

The failure of this initial hypothesis led to proposals that are based on the concept that the active form of DHA is in the form of a phospholipid (102–104). Little progress was made on this intractable problem until workers focused on this hypothesis. Several approaches have been used including cell biological, biochemical, and biophysical attacks. Examples of each of these will be summarized in turn below with reference to apoptosis, protein-lipid interactions, and the physical state and membrane properties of DHA-phospholipids.

The first topic that will be taken up is G-protein signaling with a focus on rhodopsin. This line of inquiry is central to an understanding of the function of DHA-lipids in the visual system; it also serves as a model of other G-protein-coupled signaling receptor systems that helps us to understand how DHA may function in the brain.

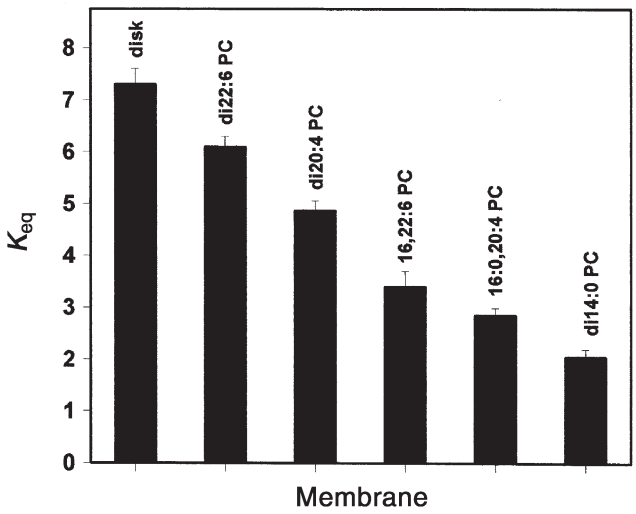

**FIG. 1.** The compositional dependence of the metarhodopsin MI↔MII equilibrium constant, $K_{eq}$, determined for rhodopsin in a series of compositionally defined bilayers varying in degree of unsaturation at 37°C. *Source*: Reference 107. M, metarhodopsin; PC, phosphatidylcholine.

## PROTEIN-LIPID INTERACTIONS: G-PROTEIN SIGNALING

Intercellular signaling is initiated through the activation of ligand-specific receptors imbedded in the lipid bilayers of cellular membranes. An understanding of the factors that govern the efficiency of signaling processes requires elucidating how the lipid composition of the membrane modulates the interactions of these receptors with the other membrane-bound protein components in the signaling pathway. To elucidate the role of n-3 fatty acids in the nervous system and visual process, the phospholipid acyl chain dependence of several steps in the visual transduction pathway was studied (105). This was accomplished by purifying several components of the visual transduction system and reconstituting them in phospholipid vesicles of defined lipid composition (106).

The visual transduction pathway is initiated by the absorption of a photon by rhodopsin, a prototypical member of the family of G-protein-coupled receptors that includes many neurotransmitter receptors such as those for serotonin and dopamine. Metarhodopsin (M)II is the conformation of photoactivated rhodopsin that binds and activates the visual G-protein, $G_t$, which in turn activates a cGMP-specific phosphodiesterase (PDE) (105). Hydrolysis of cGMP by the PDE results in the closing of cGMP-gated channels in the ROS plasma membrane, changing the transmembrane potential and initiating the neuronal response to light. In n-3-deficient animals, a reduced amplitude and delayed response are observed in the leading portion of the a-wave of electroretinograms (37,40,41). This portion of the a-wave is associated with the transduction pathway. To determine whether these observations can be linked to changes in membrane composition, we examined the bilayer dependence of MII formation, the kinetics and extent of MII-$G_t$ complex formation, and resulting PDE activity as a function of phospholipid acyl chain composition and cholesterol content of the bilayer. These topics will be treated in turn below.

$K_{eq}$ measures the extent of MII formation, which represents the formation of the activated ligand-bound receptor state, for the MI-MII equilibrium. This parameter depends critically on the level of acyl chain unsaturation (Fig. 1) (107). For both mixed-chain phosphatidylcholines (PC) and symmetrically substituted PC, the highest levels of MII formation were seen in DHA-containing bilayers. The addition of 30 mol/100 mol phospholipid to these systems lowered the level of MII formation. However, the lowest percentage reductions were obtained in the DHA-containing systems, suggesting that DHA-containing phospholipids are best able to buffer the inhibitory effects of cholesterol.

The first amplification step in the visual cascade is the activation of $G_t$. The initial step in this activation is the binding of $G_t$ to MII and is characterized by the association constant, $K_a$. This process is also affected by acyl chain composition. The value of $K_a$ in 18:0,22:6-PC is more than two times greater than that in 18:0,18:1-PC, indicating that twice as much MII-$G_t$ complex is formed in the DHA phospholipid than in the monounsaturated bilayer (Niu, S., Mitchell, D.S., and Litman, B.J. unpublished results). The number of $G_t$ molecules activated in the two bilayers should be proportional to the amount of complex formed, suggesting that at equivalent levels of MII and $G_t$, a higher signal amplitude will be observed in the DHA-containing bilayer.

Another important aspect of signaling is the response time. This aspect of signaling was addressed by measuring the kinetics of both MII and MII-$G_t$ formation in several bilayers. An important characterizing parameter in these measurements is the ratio of the rate of formation of MII-$G_t$ to that of MII. This parameter represents the lag time in appearance of the

complex after MII has formed and is a measure of the efficiency of the interaction of the receptor and $G_t$ protein. This ratio is 1.4 in the native ROS disk membrane, indicating a rapid complex formation after the appearance of MII (106). Complex formation in 18:0,22:6-PC and 18:0,18:1-PC is characterized by ratios of 3.5 and 4.9, respectively. Although the DHA PC phospholipid is not as efficient as the disk system, it does provide for more efficient MII-$G_t$ formation than the less unsaturated bilayer. Some of the enhanced efficiency of MII-$G_t$ formation in the disk membrane may be attributable to the more complex mixture of phospholipid classes that contribute a net negative surface charge to the membrane.

The overall measure of the signaling pathway is the dose-response curve, generated by determining the level of PDE activity brought about by increasing levels of rhodopsin activation. In these experiments, both $G_t$ and PDE were reassociated with rhodopsin-containing vesicles. At light exposure levels at which 1 in 1000 rhodopsin molecules was activated, ROS disks yielded 87% of their maximal PDE activity. Under similar light exposure conditions, 59 and 26% of maximal disk activity was obtained in 16:0,22:6-PC and 16:0,18:1-PC, respectively (106). Although not reaching the same activity as native disk membranes, the DHA-containing bilayer yields twice the activity of the monounsaturated bilayer. Thus, in the integrated function of the pathway, the DHA-containing bilayer yields higher activity levels than the monounsaturated bilayer.

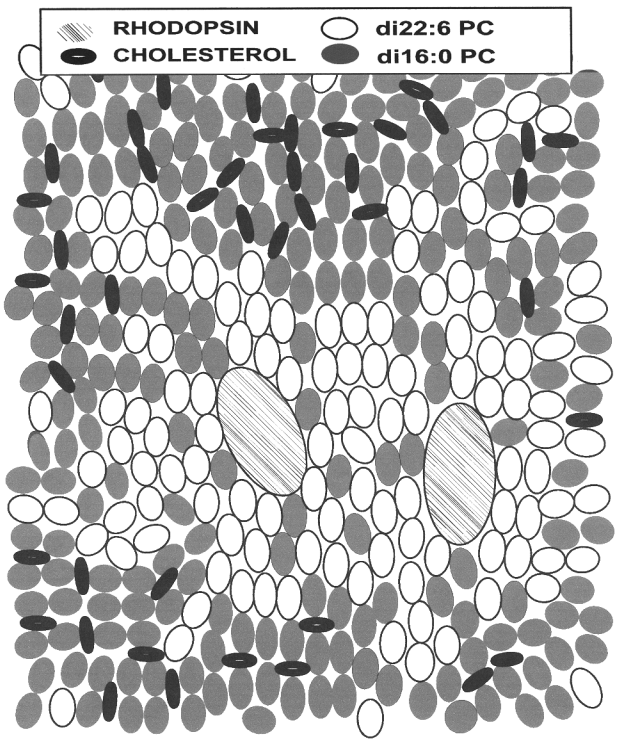

**FIG. 2**. Domain structure of rhodopsin-lipid model membranes. Fluorescence energy transfer studies of model membranes composed of a 3:7:3 mixture of di22:6-phosphatidylcholine (PC)/di16:0-PC/cholesterol and varying levels of rhodopsin show the presence of lateral domains. These domains are composed of a rhodopsin-containing region highly enriched in di22:6-PC and a second region highly enriched in di16:0-PC and cholesterol. The formation of these domains requires the presence of both rhodopsin and cholesterol, demonstrating the complex nature of the molecular interaction responsible for domain formation. These include a rhodopsin preference for docosahexaenoic acid (DHA) acyl chains and a preference of cholesterol for saturated acyl chains (108).

Recent studies suggest that lateral domain formation may play a critical role in the requirements for DHA-containing phospholipids (Fig. 2) (108). Fluorescence energy transfer experiments have provided evidence of the formation of lateral domains in reconstituted membranes consisting of di22:6-PC, di16:0-PC, cholesterol, and rhodopsin. In these domains, the lipid composition around rhodopsin is highly enriched in di22:6-PC, whereas the di16:0-PC is highly enriched in cholesterol. Domain formation requires the presence of both rhodopsin and cholesterol, indicating the complex nature of the interactions that drive lateral segregation of the constituents of this system. If the other components of the signaling pathway have the same preferable partitioning into a DHA-rich lipid domain as rhodopsin, then this would raise their local concentration and provide a greater efficiency for the signaling pathway.

The results presented here demonstrate that the visual signaling pathway is greatly dependent on the acyl chain composition of the bilayer. The steps in this signaling process involve unimolecular conformation changes required for rhodopsin activation and several protein–protein interactions for the activation of $G_t$ and PDE. Both of these types of processes were enhanced in bilayers containing DHA. The studies reported here were carried out in PC bilayers of varying acyl chain composition. The disk membrane contains ~42–45% of both PC and PE and ~10–12% PS. The differences in activity observed between the pure PC system and native disk membrane might be attributable to the lack of a surface potential supplied by the presence of PS or perhaps specific properties contributed by the PE. It should be noted that both PE and PS contain the highest levels of symmetrically substituted di-DHA species in the retina. Despite these differences, the results reported here suggest an explanation for the observations in the electroretinograms of n-3-deficient animals. The delay in the development of the leading edge of the a-wave is likely related to the increased lag time observed in the formation of the MII-$G_t$ complex, whereas the reduced amplitude may be explained on the basis of the reduced association constant observed for MII-$G_t$ complex formation.

## ANTIAPOPTOTIC EFFECT OF DOCOSAHEXAENOIC ACID

Next, we turn to a consideration of the effects of DHA at a cell biological level. Unlike AA, DHA is not easily released from neuronal membranes, but instead is retained by membrane phospholipids (109–111). In contrast, astroglia cells, which are known to support neuronal survival, release this fatty acid readily (110–113). This suggests that DHA fatty acid may act as a trophic factor, and enrichment of this fatty acid in neuronal

membranes may be an important aspect in neuronal survival. In neuronal membranes, DHA is highly enriched in aminophospholipids, especially PS (1,2,4,5–10,114). We and others have previously demonstrated that the enrichment of DHA in cell membranes increases PS synthesis and, conversely, that depletion of this fatty acid by an n-3-deficient diet or by chronic ethanol exposure decreases the accumulation of PS (115–118). Considering the fact that PS is the major negatively charged phospholipid class in many mammalian cell membranes and many of the signaling proteins such as protein kinases are influenced by PS (119–121), this alteration of PS content may have significant implications for cellular function.

In contrast to the well-documented apoptotic effect of DHA (122–127), only a few studies have indicated an antiapoptotic function for this fatty acid (128–131). In each case, an antiapoptotic effect was observed only after preincubation with DHA before the induction of apoptosis. Because DHA is prone to oxidation during the incubation period and much of the apoptotic effect is mediated through oxidative stress (126,127), it is difficult to successfully enrich cultured cells with DHA without accompanying lipid peroxidation. Therefore, to observe the antiapoptotic effect of DHA, it is crucial that an antioxidant such as vitamin E be added along with DHA to the culture medium (130,131).

In studies by Kim *et al*. (131) in which PC-12 or Neuro-2A cells were exposed to AA (1–25 μM) during serum deprivation, apoptosis determined by genomic DNA fragmentation decreased in a dose-dependent manner, but treatment with DHA or oleic acid had no effect. The insensitivity of the protective effect of AA to indomethacin or nordihydroguaiaretic acid indicated that the observed protective effect of AA was not mediated by either cyclooxygenase or LO derivatives, but rather through the direct action of AA (132). In contrast to the effect of AA, DHA became protective only after a prolonged period of incubation. In Neuro-2A cells, the protective effect required at least 24 h of enrichment, and a longer incubation led to an enhancement of the protective action of DHA. During this period, DHA was steadily incorporated into PS, and total cellular PS was increased. The protective effect is related to the extent of cellular PS accumulation. When cells were enriched with DHA in a serine-free medium, the PS content did not increase significantly and the antiapoptotic effect was diminished significantly.

Caspase-3 activity, which has been shown to mediate mammalian apoptosis, increased as the starvation proceeded, with the exception of cells enriched with DHA. Both AA- and DHA-treated cells initially showed less caspase-3 activity in comparison to nonenriched control or oleic acid-enriched cells. However, prolonged serum starvation abolished the protective effect of AA, and only DHA-treated cells maintained caspase-3 activity at a level similar to that of control cells kept in the 5% serum medium. The DNA fragmentation data and DNA ladder formation obtained after at least 48 h of serum starvation showed consistent results (Fig. 3). It was also observed that the 17-kDa active fragment of caspase-3 increased under serum-free conditions, and supplementation of Neuro-2A cells with DHA before serum starvation effectively prevented the increase of the 17-kDa fragment (131).

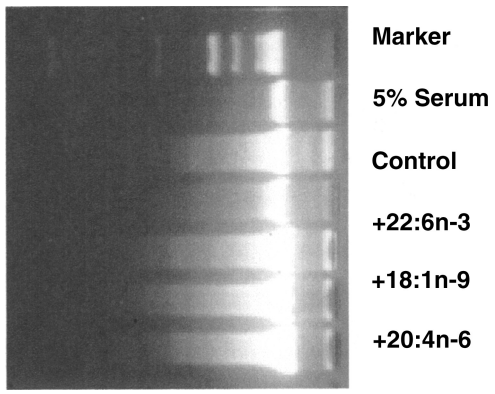

**FIG. 3**. Protection from DNA fragmentation after the enrichment of cells with docosahexaenoic acid for 48 h.

Enrichment of cells with DHA also altered expression of various proteins at the gene level because the levels of mRNA for caspase-3 decreased, whereas mRNA of Raf-1 increased (131,132). DHA has been shown to affect transcriptional activities through nuclear hormone receptors such as the peroxisome proliferator-activated receptor (133) or the retinoid X receptor (134). The antiapoptotic effect of DHA enrichment suggests that ensuring the survival of neuronal cells may be one of the reasons for the high level of DHA in brain. Alterations of the membrane PS content by DHA will influence not only the receptor activities but also the translocation of various signaling proteins as well as their activation (118–120,131). Although the release of DHA in neuronal cells may be minimal, it may be possible to reach a local concentration of intracellular DHA sufficient to activate nuclear receptors involved in transcriptional activity. It is likely that the antiapoptotic effect of DHA is the result of multiple regulations at various signaling stages, ranging from the plasma membrane to nuclear events, most of which have yet to be discovered.

## BIOPHYSICAL PROPERTIES OF POLYUNSATURATED LIPID MEMBRANES

As referred to above, there has been a lack of a conceptual basis in biophysics in which a meaningful difference in function could be predicted with respect to a DHA- vs. a DPAn-6-containing lipid. In fact, there have been few biophysical studies that discern appreciable differences in the properties of various polyunsaturated species. It has often been said that introduction of a double bond into a saturated lipid results in a large change in physical properties. Introduction of a second double bond also results in an additional effect; however, it is of a much smaller magnitude than that of the first double bond. Thereafter, introduction of additional double bonds (for a total of three or more) has little effect. However, the n-3 fatty acid deficiency syndrome described above indicates that there are significant biological effects measurable in the whole organism, e.g., by

behavioral or physiologic means, when DPAn-6 is substituted for DHA. Because these are pentaenoic and hexaenoic lipids, it would appear that a physical basis must exist for the differential biological function of various highly unsaturated fatty acids. Recent studies have begun to demonstrate that all highly unsaturated lipids indeed do not have the same physical properties. Some of the techniques and research approaches as well as data obtained from these investigations are presented below.

## MAGIC ANGLE SPINNING (MAS)

Solid-state nuclear magnetic resonance (NMR) spectroscopy on models of polyunsaturated membranes enables the measurement of dozens of parameters, probing every segment of the lipid bilayer with atomic resolution. This became possible after improving the performance of magic angle spinning (MAS) probes in combination with very high magnetic field strength. MAS NMR reduces the linewidth of lipid resonances to ~10 Hz (135). That is equivalent to or better than resolution of resonances for very small unilamellar liposomes that tumble rapidly enough to eliminate anisotropic interactions. However, in contrast to studies of liposomes, for MAS NMR, the membranes are not required to have small radii of curvature, and water content does not matter as long as the lipids remain in the liquid-crystalline state. Just a few milligrams of sample is sufficient to provide very high signal-to-noise ratios as evidenced by the spectra in Figure 4 (136).

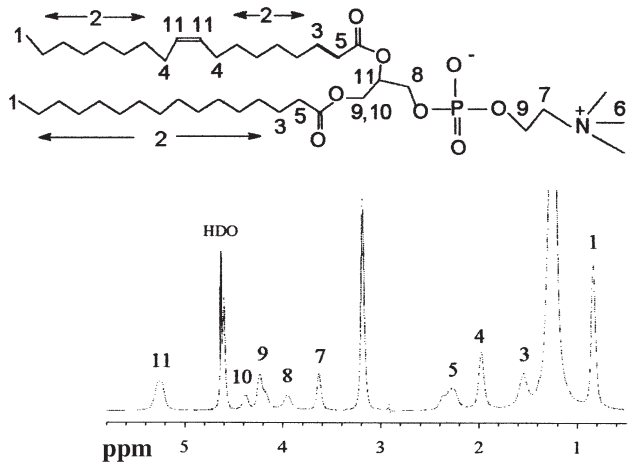

**FIG. 4.** $^1$H magic angle spinning (MAS) nuclear magnetic resonance (NMR) spectrum of 16:0,18:1 PC in 50 wt% $D_2O$ recorded at ambient temperature and a spinning speed of 10 kHz. Signal assignment is provided by numbers in the spectrum and the formula. *Source*: Reference 137.

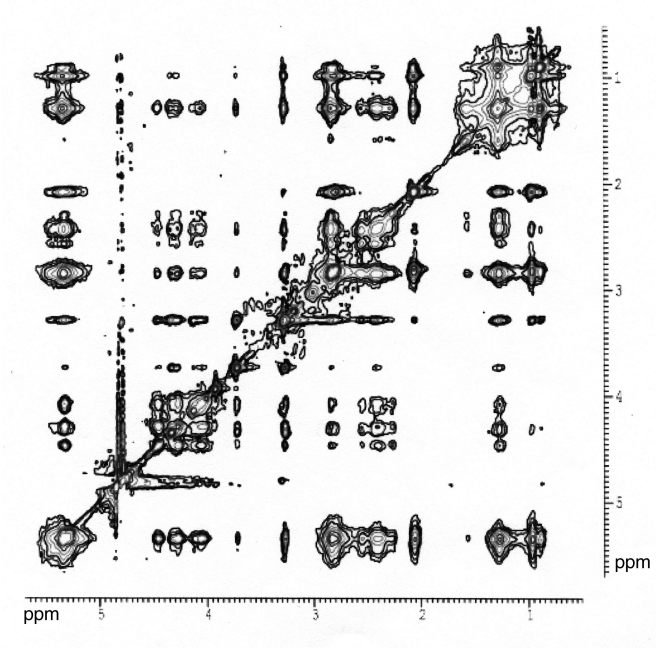

**FIG. 5**. Two-dimensional nuclear Overhauser enhancement spectroscopy (NOESY) magic angle spinning (MAS) nuclear magnetic resonance (NMR) spectrum of an 18:0-22:6 phosphatidylcholine (PC)/18:$0_{d35}$-22:6 phosphatidylethanolamine (PE)/18:$0_{d35}$-22:6 phosphatidylserine (PS)/cholesterol$_{d7}$ (4:4:1:3, by vol) mixture.

## NUCLEAR OVERHAUSER ENHANCEMENT SPECTROSCOPY (NOESY)

The excellent resolution of lipid resonances allows application of techniques that probe magnetization transfer between protons such as nuclear Overhauser enhancement spectroscopy (NOESY), well known for its important contribution to the structural determination of soluble proteins (137).

Magnetization transfer is the result of interactions between the magnetic dipoles of the protons in lipids. Rates of transfer become observable when the protons approach each other to within distances ≤5 Å (138). In the two-dimensional NOESY contour plot shown in Figure 5 (139), the peaks along the diagonal correspond to the one-dimensional resonances shown in Figure 4. The rate of magnetization transfer is reflected by the intensity of the off-diagonal crosspeaks. The surprising observation has been that magnetization is transferred between all lipid resonances, but at different rates. Even the most distant protons such as methyl groups of the choline headgroup and methyl groups at the end of lipid hydrocarbon chains exchange magnetization. For a long time, such surprising transfers were ascribed to a process called spin diffusion. Spin diffusion relays magnetization *via* coordinated flip-flops of magnetization along the proton network of a lipid molecule. In a series of experiments on protonated lipids in deuterated matrices, we demonstrated recently that this interpretation is incorrect (140). In the biologically relevant liquid-crystalline state, membranes are truly disordered to the point that lipid headgroups and ends of hydrocarbon chains meet once in a while, albeit with lower probability than membrane segments that are located closer to each other. The experiments also demonstrated that the unexpected long-range contacts are not taking place within one lipid molecule, but rep-

resent magnetization transfer to neighboring lipid molecules that surround the emitter (141).

Experiments on *sn*-1 chain perdeuterated 1-stearoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (18:$0_{d35}$,22:6-PC) not only confirmed that polyunsaturated chains in membranes are similarly disordered, but also offered evidence that conformational disorder of the remaining degrees of freedom of a polyunsaturated chain is higher (135,142). Furthermore, the intensity of cross- and diagonal peaks as a function of mixing times allows judgment about motional correlation times in the polyunsaturated membranes on the time scale from pico- to milliseconds (138). The spin-lattice and spin-spin relaxation rates of polyunsaturated chains are lower, indicating more rapid motions of these protons. This result is surprising because polyunsaturated chains have long been perceived as rigid and bulky owing to the loss of degrees of freedom.

## DIPOLAR RECOUPLING ON-AXIS WITH SCALING AND SHAPE PRESERVATION (DROSS)

MAS NMR techniques with application of radio-frequency pulses, which are synchronized with the phase of the spinning rotor, enable recoupling of anisotropic interactions, e.g., the magnetic dipolar interaction between $^{1}$H and $^{13}$C nuclei. The strength of this interaction depends on the time-averaged orientation of the $^{1}$H-$^{13}$C bond vector with respect to the lipid bilayer normal.

In the two-dimensional dipolar recoupling on-axis with scaling and shape preservation (DROSS) experiments (Fig. 6), this technique allows assignment of order parameters to resolved $^{13}$C resonances of lipid segments (143). Conducting this experiment on $^{13}$C nuclei benefits from the much greater resolution of $^{13}$C chemical shifts. Throughout the molecule, >20 order parameters can be assigned to specific regions within the polyunsaturated lipid, without isotopic labeling.

The experiments showed unambiguously that order parameters of double bond $^{1}$H-$^{13}$C vectors are close to 0. Because of differences in bond geometry between saturated and unsaturated hydrocarbon chains, this result was not unexpected. However, the very-low-order parameters for the five $^{1}$H-$^{13}$C vectors of the methylene groups that are sandwiched between double bonds were surprising. These order parameters must be low as a result of crankshaft-like coordinated motions within the DHA chain. Such motions are likely because of lower potential barriers for rotations about the vinyl-methylene bonds compared with C-C bonds in saturated chains (144). This enables DHA chains to adapt to looped conformations that have shorter length and larger area per molecule (145).

## $^{2}$H NMR

Although the DROSS technique allows determination of assigned order parameters, for technical reasons, the precision in order parameter determination remains about one order of magnitude lower than the precision of order parameters measured by the classical approach, i.e., analysis of effective quadrupolar splittings in the $^{2}$H NMR spectra of deuterated lipids (146). Quadrupole splittings are measured with a resolution of ~50 Hz, which corresponds to a precision for order parameters of $\Delta S = \pm 0.0004$. Such small changes are of relevance, e.g., to detect the level of stress that is caused in the lipid matrix as the result of a conformational change of a membrane protein (147). We conducted preliminary $^{2}$H NMR experiments on perdeuterated DHA, incorporated at low concentration into bilayers of 18:0,18:1-PC (Fig. 7). Partial assignment of the order parameters to segments of the DHA chain was achieved by taking advantage of the small differences in chemical shift between the deuterium resonances in MAS experiments with partial recoupling of the quadrupolar interaction (Gawrisch, K., Safley, A.M., and Polozov, I.V., unpublished data). The results fully confirmed the observations from the less precise DROSS experiment. Order parameters of all methylene segments between double bonds in the hy-

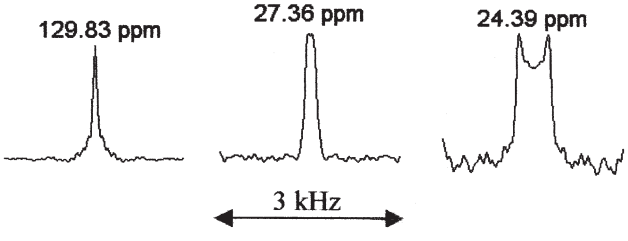

**FIG. 6.** Extracted columns of a two-dimensional dipolar recoupling on-axis with scaling and shape preservation (DROSS) spectrum corresponding to resonance signals of double bonds (129.83 ppm), methylene groups between the double bonds (27.36 kHz), and the C-17 methylene group of stearic acid (24.39 ppm). The peak doublets are the result of recoupling of dipolar interactions between the $^{1}$H and $^{13}$C nuclei. The value of order parameters is directly proportional to the magnitude of splittings.

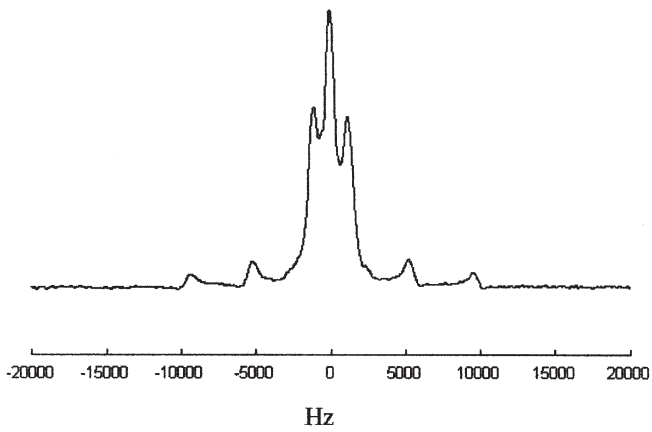

**FIG. 7.** $^{2}$H nuclear magnetic resonance (NMR) spectrum of perdeuterated docosahexaenoic acid in an 18:0,18:1-PC matrix.

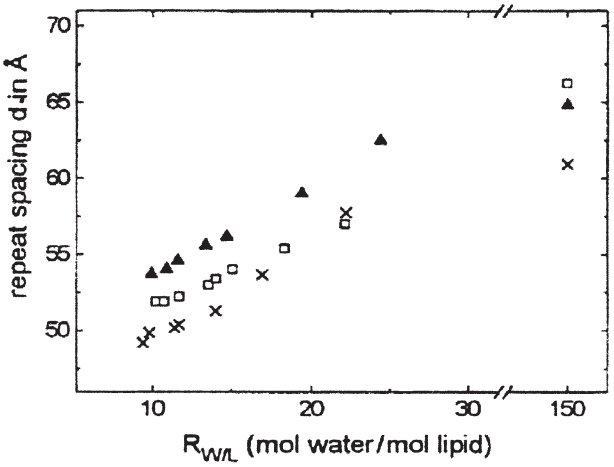

**FIG. 8.** X-ray repeat spacing of lipid bilayers as a function of water content expressed as the number of water molecules per lipid. *Source:* Reference 142.

drocarbon chain, as well as the order of the majority of the double bonds, are very low. Only the two methylene segments near the carboxyl group of DHA have order parameters that are comparable to values of more saturated chains.

## X-RAY DIFFRACTION

Results of X-ray diffraction experiments on 18:0,22:6-PC, recorded as a function of water content, were compared with the results of experiments on 18:0,18:1-PC and di14:0-PC (Fig. 8) (142). The repeat spacing of bilayers with polyunsaturated chains, i.e., the thickness of the lipid layer plus the thickness of the water layer separating two bilayers, is rather similar to the thickness of the di14:0-PC bilayers with only 14 carbon atoms per chain.

Water uptake of polyunsaturated lipids is slightly increased and does not account for this difference (142). We estimated that the polyunsaturated DHA occupies a unit cell with average dimensions of $6 \times 6 \times 14$ Å in the bilayer. Compared with saturated and monounsaturated chains, this is an increase in chain area of ~7 $Å^2$. DHA chains in an extended angle-iron or helical conformation exceed this length by up to 10 Å (148); therefore, they cannot be the only conformation that DHA chains adopt in bilayers. Consequently, we propose that looped conformations, as proposed in a paper by Dolmazon's laboratory (145), are very common in polyunsaturated chains.

We also conducted X-ray experiments as a function of osmotic stress to reduce the sample's water uptake. Controlled dehydration of membranes creates lateral tension, which compresses bilayers laterally. Using a combined NMR and X-ray approach, we followed the changes in area per molecule of saturated and polyunsaturated chains in 18:0,22:6-PC as a function of lateral tension. We observed that 75% of the increase in chain length and reduction in area per molecule was the result of changes in the average conformation of the polyunsaturated chain (142).

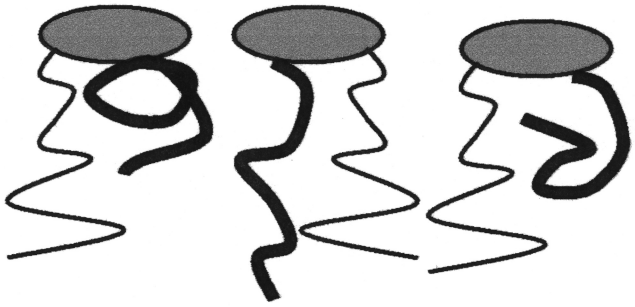

**FIG. 9.** A schematic that highlights the conformational freedom of docosahexaenoic acid (DHA) chains in mixed-chain lipids. DHA converts rapidly between looped and extended conformations. The center of mass of the DHA chain is closer to the lipid–water interface.

## CONFORMATION AND FLEXIBILITY OF THE DHA CHAIN

The alteration of elasticity of neural membranes according to the number of double bonds per fatty acid is one possible role of lipid polyunsaturation. Membranes contain a matrix of lipid molecules with hydrophilic ("water-loving") headgroups (shown in gray motif) and hydrophobic ("water-rejection") fatty acid chains in black (Fig. 9). Membranes respond to external perturbations like elastic rubber bands. With NMR spectroscopy and X-ray diffraction, the elastic deformation of membranes under tension, including the changes in structure and motions of lipid hydrocarbon chains, could be measured. The results suggest that polyunsaturated chains in membranes prefer flexible, looped, and helical structures with rapid transitions among a large number of conformers. This provides increased flexibility to receptor-rich neural membranes that contain high concentrations of DHA. A common perception of polyunsaturated chains is that they are stiff and inflexible due to the presence of motionally restricted double bonds. In contrast, our NMR studies indicate exceptionally high deformability of DHA chains in biomembranes.

## DIFFERENCE IN MEMBRANE PROPERTIES BETWEEN DHA AND DPA LIPIDS

Although there is ample evidence that membrane biophysical properties control membrane protein function to a significant extent, the idea that the loss of a single double bond from DHA to DPAn-6 in lipids is sufficient to alter membrane biophysical properties has been met with some skepticism. We compared deuterated *sn*-1 chain order parameter profiles in mixed-chain 18:0,22:6-PC and 18:0,22:5-PC by $^2$H NMR order parameter experiments.

Saturated chain order of the first half of the chain near the lipid–water interface was high and almost constant (order parameter plateau), whereas order of the second half of the chain decreased with a steep gradient toward the terminal methyl chain end. This order profile has been linked to the probability of gauche-*trans* isomerization in chains (higher at the terminal methyl end).

Changes in hydrocarbon chain length and area per molecule are reflected in order parameter changes. An increase of average chain order by $\Delta S = +0.002$, which can be easily resolved, corresponds to an increase of average bilayer thickness of 0.1 Å and a decrease of area per molecule of 0.2 Å$^2$. Compared with monounsaturated bilayers, the order of *sn*-1 chains that are paired with polyunsaturated chains in the *sn*-2 position is lower, mostly for the second half of the chain, with a maximal decrease by $\Delta S = -0.018$ near carbon atom number 13 for 18:0,22:6-PC (149). We propose that this decrease reflects formation of short looped chain conformations (*vide infra*) with a higher density of polyunsaturated chain segments near the lipid–water interface. As a result of this redistribution of DHA chain density, the lower segments of the saturated chain have more freedom for movement and lower chain order parameters in the second half of the chain. The surprising observation has been that the loss of a single double bond from DPAn-6 to DHA in 18:0,22:5-PC results in order parameters that are much closer to those of a matrix with monounsaturated oleic acid chains in position *sn*-2.

In summary, assigned order parameters and relaxation times related to molecular motions were measured using novel MAS NMR approaches and classical $^2$H NMR order parameter studies on chain perdeuterated, polyunsaturated lipids. In comparison to saturated chains, DHA order parameters were low, reflecting both a change in bond geometry and an increase in chain dynamics. The loss of a single double bond near the terminal methyl group of hydrocarbon chains has a significant influence on lipid matrix properties; therefore, membranes rich in DHA have unique properties. We speculate that the differences are of importance for the function of receptor proteins in retinal and synaptosomal membranes.

# Metabolism and Functions of Highly Unsaturated Fatty Acids: An Update

**Manabu T. Nakamura[a,*], Hyekyung P. Cho[b], Jing Xu[b], Zhongren Tang[b], and Steven D. Clarke[b]**

[a]Department of Food Science & Human Nutrition, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801, and [b]Graduate Program of Nutritional Sciences, University of Texas at Austin, Austin, Texas 78712

**ABSTRACT:** This review briefly examines the recent progress in knowledge about the synthesis and degradation of highly unsaturated fatty acids (HUFA) and their functions. Following the cloning of mammalian Δ6-desaturase (D6D), the D6D mRNA was found in many tissues, including adult brain, maternal organs, and fetal tissue, suggesting an active synthesis of HUFA in these tissues. The cloning also confirmed the long-postulated hypothesis that the same pathway is followed in n-6 and n-3 HUFA synthesis. Dietary n-6 and n-3 HUFA both induce fatty acid oxidation enzymes in peroxisomes when compared to their respective precursor polyunsaturated fatty acids. This suggests that peroxisomes may be the primary site of HUFA degradation when HUFA are supplied in excess from the diet. Peroxisome proliferators strongly induce the enzymes for the HUFA synthesis. The mechanism of this induction is currently unknown. Recent studies revealed new HUFA functions that are not mediated by eicosanoids. These functions include endocytosis/exocytosis, ion-channel modulation, DNA polymerase inhibition, and regulation of gene expression. These new discoveries will enable us to re-examine the underlying mechanisms for the classical symptoms of essential fatty acid deficiency as well as vitamin E deficiency. Progress has also been made in understanding the mechanism by which dietary HUFA reduce body fat deposition. One mechanism is induction of genes for fatty acid oxidation, which is mediated by peroxisome proliferator-activated receptor-α. Another likely mechanism is that HUFA suppress genes for fatty acid synthesis by reducing both mRNA and protein maturation of sterol regulatory element binding protein-1.

Paper no. L8729 in *Lipids 36*, 961–964 (September 2001).

Among the essential fatty acids shown in Figure 1, at least linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3) are required from diets because mammals lack enzymes to synthesize these fatty acids from acetyl CoA. Mammals are able to synthesize other fatty acids from these precursor fatty acids. Δ6-Desaturase (D6D) catalyzes the first and rate-limiting step (1). Products of D6D [highly unsaturated fatty acids (HUFA)] can also be supplied from foods (Fig. 1). We recently succeeded in cloning mammalian D6D using the sequence of the algal D6D (2). The predicted amino acid sequence of the cloned D6D is entirely different from that of the "linoleoyl-CoA desaturase" whose purification was reported nearly 20 yr ago (3). The D6D mRNA is expressed in many human tissues, including adult brain (2,4). We also have shown that the dietary precursor 18:2n-6 (2) and products (HUFA) (4) suppress D6D activity and mRNA when substituted for oleic acid. This feedback regulation of HUFA synthesis is largely at the transcriptional level (Nakamura, M.T., Cho, H.P., and Clarke, S.D., unpublished data).

Tracer studies showed that only a small percentage of dietary precursor fatty acids were converted to HUFA (5,6). These data have raised concern that the HUFA synthesis from precursors may be insufficient, especially in rapidly growing animals. Thus, dietary HUFA supplementation may be necessary for the early stages of development. Indeed, search of the BLAST expressed sequence tag (EST) database shows the expression of the D6D mRNA in human fetus, infant, amnion, uterus, and breast, suggesting active HUFA synthesis by fetus and infant as well as maternal contribution to the HUFA supply. These data imply a possible benefit of HUFA supplementation in infant formula. Nevertheless, these results are not conclusive for the following reasons. First, the synthetic pathway of HUFA is fully activated only in deficient conditions, and the expression and activity of the synthetic enzymes drop quickly when the body HUFA is repleted (2,4). Second, tissue expression detected by EST does not necessarily mean the presence of actual HUFA synthesis in these tissues, nor does it yield any quantitative data.

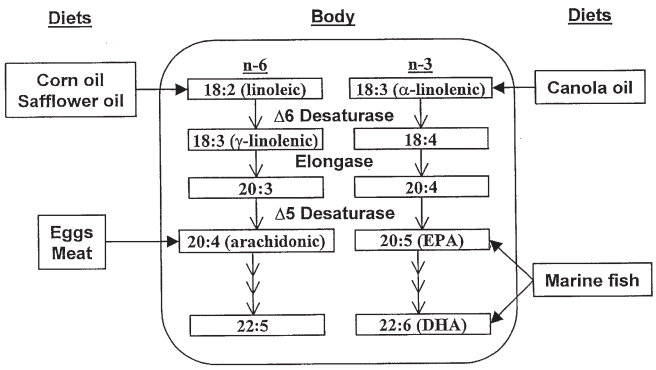

**FIG. 1.** Synthetic pathway of highly unsaturated fatty acids (HUFA). EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

Abbreviations: D6D, Δ6-desaturase; FAS, fatty acid synthase; HUFA, highly unsaturated fatty acids; PPAR, peroxisome proliferator activated receptor; PUFA, polyunsaturated fatty acids; SREBP, sterol regulatory element binding protein; TG, triglyceride.

Another recent development to be noted is that our cloning study demonstrated that the synthesis of both n-6 and n-3 HUFA is catalyzed by the same Δ6- and Δ5-desaturases as shown in Figure 1 (2,4). This strongly supports the importance of a balanced supply of dietary n-3 and n-6 fatty acids to meet the requirement of both n-3 and n-6 HUFA. Also, the studies suggest that an excessive supplementation of either n-3 or n-6 HUFA in the diet may cause a deficiency in the other group because it may shut down the synthetic pathway shared by n-3 and n-6 fatty acids.

## DEGRADATION OF HUFA

There are two known degradation pathways of HUFA. One is the formation of eicosanoids, which is a unidirectional reaction. Eicosanoids are further metabolized to inactive forms and excreted mostly in urine (7). The other pathway is fatty acid β-oxidation. In noneicosanoid functions, the hydrolyzed free HUFA can be re-esterified to phospholipids after forming a thioester bond with coenzyme A (CoA). The HUFA CoA can also be oxidized *via* the β-oxidation pathway in mitochondria and peroxisomes (8,9). Both n-6 and n-3 HUFA induce acyl-CoA oxidase, the rate-limiting enzyme of peroxisomal β-oxidation, when precursor polyunsaturated fatty acids (PUFA) in the diet are replaced with the respective HUFA (10–12). These studies suggest that peroxisomes may be the primary site of oxidization of excess HUFA. Another line of studies has elucidated the molecular mechanism of this induction. Peroxisome proliferator-activated receptor-α (PPARα) plays a key role in the induction of the fatty acid oxidation enzymes in both peroxisomes and mitochondria, and the response elements have been identified in key enzymes such as acyl-CoA oxidase (13) and carnitine palmitoyltransferase 1 (14). Free fatty acids directly bind and activate PPARα (15,16). Taken together, the excess HUFA are likely to induce their own oxidation machinery *via* a feed-forward mechanism, which is mediated by PPARα. However, the quantitative contribution of peroxisomes in HUFA degradation is yet to be determined.

## INDUCTION OF D6D BY PEROXISOME PROLIFERATORS

Kawashima and colleagues (17) found that fibrates, a group of PPARα ligands known as peroxisome proliferators, are potent inducers of D6D activity. We found that Wy 14,643, a PPARα-specific ligand and another peroxisome proliferator, strongly induces the D6D mRNA and that transcriptional activation of the D6D gene largely accounts for the induction (Nakamura, M.T., Cho, H.P., and Clarke, S.D., unpublished data). The mechanism of this induction is presently unknown. The simplest explanation for the activation of D6D transcription by these compounds is that the D6D gene has the PPARα response element and is activated directly by liganded PPARα. However, this mechanism faces some difficulties in explaining results of other studies. First, although both HUFA and peroxisome proliferators are agonistic ligands of PPARα (15,16), these compounds have opposite effects on D6D gene expression: Wy 14,643 activated transcription of the D6D gene, whereas HUFA suppressed the transcription (Nakamura, M.T., Cho, H.P., and Clarke, S.D., unpublished data). Second, in spite of marked activation (16-fold) of D6D activity in rat liver after 7-d feeding of clofibric acid, HUFA in the liver did not increase (17). In contrast, when growth hormone was overexpressed for the same duration (7 d), the liver HUFA was enriched more than 50%, with a much smaller increase (<threefold) in the D6D activity (18). An alternative hypothesis to accommodate these observations is that peroxisome proliferators induce HUFA synthesis by increasing HUFA oxidation because of their ability to induce rate-limiting enzymes of fatty acid β-oxidation. Because functions of HUFA are modulated by the abundance of HUFA in cells (1,7,19,20), it is likely that many cellular functions are affected by the balance between the supply and degradation of HUFA. Therefore, the regulatory mechanism of synthesis and degradation of HUFA would be an important area for future investigation.

## PHYSIOLOGICAL ROLE OF HUFA

HUFA are required for a wide range of physiological functions. The best characterized among them are the functions of eicosanoids that are enzymatically synthesized from HUFA. Eicosanoids work as autocrine/paracrine hormones and mediate a variety of functions such as immune response, blood pressure regulation, and blood coagulation (21). In addition to these eicosanoid-mediated functions, recent studies have uncovered further involvement of HUFA in fundamental cellular functions, including endocytosis/exocytosis (22), ion-channel modulation (23), DNA polymerase inhibition (24), and regulation of gene expression (25). Schmidt *et al.* (22) showed that endophilin, a vital component in neurotransmitter recycling, is a lysophosphatidic acid acyl transferase. Their study suggests that rapid hydrolysis of phospholipids by phospholipase $A_2$ and reacylation by lysophospholipid acyl transferases change the membrane curvature and thus play a critical role in endocytosis and exocytosis. Another important role of HUFA is to help muscle contraction synchronized by slowing down the recovery of ion channels (23). This is the likely mechanism by which dietary fish oil could reduce death rates after myocardial infarction. DNA polymerase inhibition, another potential function of HUFA, is still in the early stage of investigation, and its significance in the regulation of the cell cycle and DNA repair is yet to be elucidated (24). HUFA also regulate many genes involved in lipid metabolism (25). HUFA directly bind and modulate activities of transcription factors such as PPAR (15,16) and hepatocyte nuclear factor 4 (26). Moreover, our recent study suggests that HUFA regulate gene expression by modulating the mRNA stability and proteolytic processing of steroid regulatory element binding protein 1 (SREBP-1) (27,28), which is discussed in more detail below. A common feature in these HUFA functions is that HUFA first need to be hydrolyzed

from membrane phospholipids to perform their functions. This implies phospholipases as a key regulator of these functions.

These discoveries enable us to revisit and examine the potential mechanisms of classical symptoms of essential fatty acid deficiency as well as vitamin E deficiency. For example, the main symptoms of essential fatty acid deficiency are dry skin, dermatitis, and water loss through skin (29). This may be due to the decrease of waxy compound secretion by sebaceous glands, rather than a change in the membrane structure of epidermal cells. Another example is embryo resorption in vitamin E-deficient rats. The resorption occurs on the 13th day of gestation, when nutrient transport by pinocytosis plays a critical role, and vitamin E-deficient rats seem to lose this pinocytosis function (30,31). This observation is in accordance with the role of HUFA in exocytosis/endocytosis.

## REDUCTION OF BODY FAT BY DIETARY HUFA

In a genetic model of obesity, replacing dietary 18:2n-6 with a small amount of its D6D product, 18:3n-6, reduces the development of obesity (32). This effect was observed in a dietary induced model of obesity (12). Dietary fish oil also decreased fat deposition in a dietary induced rat model (33,34) and possibly in humans (35). Taken together, dietary HUFA exert a unique effect of reducing fat deposition compared with the precursor PUFA. As reviewed in the Degradation of HUFA section above, this HUFA effect can be explained, at least in part, by increased acyl-CoA oxidase gene expression (10,11) and the resulting higher β-oxidation capacity in peroxisomes (12). Interestingly, 18:2n-6, 18:3n-6, and 20:4n-6 all activate PPARα with equal potency *in vitro* (15). Thus, the unique effect of HUFA *in vivo* may be due to the difference between these fatty acids as substrates for triglyceride (TG) synthesis. HUFA seem to be a very poor substrate for TG synthesis, whereas the precursor PUFA are readily stored in adipose tissue in humans (36), pigs (37), and rats (38), as fatty acid composition analysis indicates.

In addition to the induction of oxidation enzymes, dietary PUFA suppress hepatic lipogenic genes such as fatty acid synthase (FAS), pyruvate kinase, and S-14 at the transcriptional level (25). SREBP-1 is the likely mediator of this effect. The binding site of SREBP-1 is identified in the proximal promoter of the FAS gene (39), and overexpression of SREBP-1 activates all lipogenic genes, including the FAS gene (40). We found that PUFA suppressed the SREBP-1 mRNA, but the transcription of the SREBP-1 gene was unchanged (27). Our subsequent study has shown that PUFA do indeed increase degradation of the FAS mRNA (28). PUFA also suppressed both precursor and mature SREBP-1 proteins, with suppression of the latter being stronger (27). These results suggest that PUFA suppress the FAS gene by reducing the stability of the SREBP-1 mRNA and proteolytic processing of SREBP-1 protein. At present, it is not clear whether HUFA suppress SREBP-1 expression more strongly than precursor PUFA. Our *in vivo* study using a D6D inhibitor suggests that Δ6-desaturation is required for the suppression of the FAS gene by PUFA (41). It is yet to be determined which mechanism, the induction of fatty acid oxidation or the suppression of fatty acid synthesis, plays a greater role in the reduction of body fat by dietary HUFA.

## SUMMARY

Recent developments have brought new insights into the metabolism and function of HUFA:

(i) Expression of D6D mRNA in many tissues suggests that active synthesis of HUFA occurs in these tissues.

(ii) Cloning desaturase confirmed the postulated shared pathway for n-6 and n-3 HUFA synthesis.

(iii) Peroxisomes may be the primary site of HUFA degradation when HUFA are supplied in excess from the diet.

(iv) Peroxisome proliferators strongly induce enzymes for the HUFA synthesis by a currently unknown mechanism.

(v) Recently found HUFA functions include endocytosis/exocytosis, ion-channel modulation, DNA polymerase inhibition, and regulation of gene expression.

(vi) The likely mechanisms by which dietary HUFA reduce body fat deposition are the induction of genes for fatty acid oxidation and suppression of genes for fatty acid synthesis by reducing both the SREBP-1 mRNA stability and maturation of the protein.

## ACKNOWLEDGMENT

This study was supported in part by an M.M. Love Endowment to Steven D. Clarke.

# Stable Isotope Approaches, Applications, and Issues Related to Polyunsaturated Fatty Acid Metabolism Studies

**E.A. Emken***

Midwest Research Consultants, Princeville, Illinois 61559

**ABSTRACT:** The use of stable isotope tracers for investigating fatty acid metabolism in human subjects has increased substantially over the last decade. Advances in analytical instrumentation, commercial availability of labeled substrates, and safety considerations are major reasons for this increased use of stable isotope tracers. Several experimental design options are available for using either deuterium or carbon-13 as tracers for fatty acid and lipid studies. Options include feeding a pulse dose of labeled fat or a mixture containing two or more labeled fats. Multiple doses of the labeled fat can be fed at timed intervals to increase enrichments. Administration by injection or continuous intravenous infusion is an alternative. Another option is to use diets containing foods from plants that have slightly higher natural carbon-13 enrichment. Each basic experimental design has its specific strengths, and the best choice of experimental design depends on the study objectives. Stable isotope studies have been used to address a variety of questions related to unsaturated fatty acid metabolism in humans. Examples are provided that illustrate the use of stable isotopes to investigate oxidation of docosahexaenoic acid, desaturation of linoleic and linolenic acids in infants and adults, incorporation of long-chain n-6 and n-3 fatty acids, bioequivalency of linolenic acid in primates, $^{13}C$ nuclear magnetic resonance spectra of arachidonic acid in living rat brain, and effect of triacylglycerol structure on absorption. Radioisotope and stable isotope tracer studies in animals and humans are responsible for much of our understanding of fatty acid and lipid metabolism. However, tracer studies have limitations, and there are some unresolved issues associated with isotope studies. Examples of unresolved issues are quantification of isotope data, validity of *in vivo* fatty acid metabolite results, kinetic modeling, subject variability, and use of blood lipid data as a reflection of tissue lipid metabolism. Resolving these issues, developing novel methodology, and applying stable isotope tracer methods to questions related to PUFA metabolism are broad areas of interesting and challenging research opportunities.

Abbreviations: DOB, delta $^{13}C$ values over baseline; dpm, decompositions per minute; %en, percent energy; GC, gas chromatography, GC–C–IRMS, gas chromatography–combustion–isotope ratio mass spectrometry; IRMS, isotope ratio mass spectrometry; High22:6, high docosahexaenoic-acid diet; High20:4, high arachidonic acid diet; LC-PUFA, long-chain polyunsaturated fatty acid; Low20:4, low-arachidonic acid diet; Low22:6, low-docosahexaenoic acid diet; MIDA, mass isotopomer distribution analysis; MS, mass spectrometry; NCI, negative chemical ionization; NMR, nuclear magnetic resonance; PC, phosphatidylcholine; PCI, positive chemical ionization; PUFA, polyunsaturated fatty acid; SIM, selected-ion monitoring; TAG, triacylglycerol; VLDL, very low density lipoprotein.

The theory and application of isotope tracer methods for metabolic studies were validated by radioisotope studies in animals, and the results from these early metabolic tracer studies have provided much of our current knowledge about fatty acid metabolism (1). More recently, stable isotopes have emerged as practical alternatives to radioisotopes. The increased use of stable isotopes has been prompted by advances in analytical instrumentation, increased availability of stable isotope-labeled fats, and the proliferation of misguided regulations and concerns about the safety of radioisotope tracers. A number of good reviews detail the history, theory, methodology, and applications of stable isotopes in biological studies (2–8). The focus of this review is to discuss briefly study design options, associated analytical methods, and recent studies that illustrate use of deuterium and carbon-13 isotope approaches for addressing questions relevant to fatty acid metabolism in infants and mothers. Some issues and research opportunities related to the use of stable isotopes to study polyunsaturated fatty acid (PUFA) metabolism are discussed.

## STUDY DESIGN OPTIONS

Various stable isotope experimental approaches are available, but there is no one best study design. The final choice of the approach to use depends on the information needed, sensitivity and accuracy requirements, and availability of labeled tracers and analytical equipment. The single-labeled experimental design is the most widely used approach and involves administration of a pulse oral dose of one labeled fatty acid. A superior approach is the multiple-labeled design that involves administration of a pulse oral dose of a mixture containing two or more labeled fatty acids (1). These types of tracer experiments are often incorporated into an experimental design that consists of a control and an experimental or treatment group. The advantage of a multiple-labeled experimental design compared to a single-labeled design is that the metabolic fate of two or more fatty acids can be directly compared in the same subject under identical experimental conditions. This design feature enhances confidence in the results because all experimental variables affect each labeled fatty acid equally, and it reduces some interpretation problems due to subject variability. Interpretation of the tracer data is simplified because data for the labeled fatty acids are directly comparable to each other. Other advantages of the multiple-

labeled design are that a labeled fatty acid, such as oleic acid (18:1n-9), can be used as an internal standard or control and each subject can serve as his or her own control. Use of an internal standard fatty acid in a series of experiments provides a common denominator for comparing results from different studies with different fatty acids. Feeding a mixture containing three or four differently labeled fatty acids is the equivalent of combining three or four single-isotope experiments into one, but more information is obtained for essentially the same effort as required for one single-isotope experiment. We typically use labeled 18:1n-9 as an internal control because 18:1n-9 is easy to label with two, four, six, or eight deuterium labels. Using fatty acids with different numbers of deuterium labels is advised because it avoids questions about what fatty acid was the precursor of any fatty acid metabolite detected. Employing a multiple-isotope design is uncomplicated with deuterium-labeled fatty acids and conventional gas chromatographic–mass spectrometric (GC–MS) analysis. It is more complex if a combustion–isotope ratio mass spectrometry (C–IRMS) approach is used because the advantage of different labeling patterns is lost when samples are combusted.

A double-labeling approach is useful for following the metabolic fate of different parts of the same molecule. For example, this approach can be used to determine if a fatty acid acyl group remains attached to the glycerol backbone of a triacylglycerol (TAG) or a phospholipid. Labeling both acyl and double-bond carbons provides an approach to detect specific desaturases, to investigate metabolic pathways, and to measure isotope effects.

Multiple-pulse oral-dose studies involve administering several doses of a labeled fatty acid during an appropriate time interval. This approach can be used to increase the concentration of labeled fatty acid metabolites in lipid pools that are difficult to enrich and to increase the enrichment of metabolites present at low concentrations. The increased enrichment enhances both detection and quantification.

The constant-infusion isotope-dilution technique consists of continuously infusing a labeled fatty acid at a constant rate until an isotopic steady state is achieved. The fatty acid turnover rate is calculated from the isotope dilution data at steady state (9). A bolus injection of labeled fatty acid can also be used to calculate plasma fatty acid turnover rate from the decrease in enrichment of the labeled substrate over time (10). Administration of a pulse-oral dose of a tracer combined with continuous intravenous infusion of a tracer containing a different number of labels is a variation that has been used to measure cholesterol absorption (11). The ratio of the tracers in plasma is determined and used to calculate percent absorption. This design should be applicable to a variety of fatty acid absorption and metabolism problems.

Mass isotopomer distribution analysis (MIDA) is a stable-isotope approach for investigation of *de novo* lipogenesis and is a modification of traditional radioisotope methods used to measure fatty acid synthesis. A good review of the fundamental concepts, applications, and limitations has been published (12). The general experimental approach involves infusion of carbon-13-labeled acetate, extraction of plasma samples, and determination by mass spectrometry of the distribution pattern of newly synthesized fatty acid isotopomers.

## ANALYTICAL METHODS FOR STABLE ISOTOPES

The two most common analytical methods used in biological studies to measure stable isotope-labeled fatty acids are GC–MS and GC–C–IRMS). The GC–MS method uses a conventional mass spectrometer operated in a positive chemical-ionization (PCI) mode to analyze fatty acid methyl esters and in a negative chemical-ionization (NCI) mode to analyze fatty acid pentafluorobenzyl esters. Both chemical-ionization methods normally use conventional selected-ion monitoring (SIM) of masses corresponding to the appropriate fatty ester molecular ions. Natural carbon-13 background is about 2.5% for the $m + 2$ ion of an 18-carbon methyl ester. This background must be subtracted if the molecular ion for the labeled fatty acid is 2 atomic mass units higher than the tracee fatty acid. Errors inherent in this correction can substantially decrease the accuracy of results obtained with dideuterated fatty acids if enrichments are less than about 0.5%. Samples from both deuterium and carbon-13 studies can be analyzed by either NCI or PCI MS methods using SIM. The typical amount of tracer used in a pulse-oral-dose *in vivo* experiment is 30–50 mg/kg body weight of 95% enriched $^{2}$H-labeled fatty acid. Both methods provide molecular-ion data to confirm fatty acid identification based on GC retention times. NCI is about 500 times more sensitive than PCI and is the clear choice when the sample size is less than 0.2 mg of total fatty acid. When sample size is not a limiting factor, both methods have an accuracy of about $0.2 \pm 0.02$% enrichment.

GC–C–IRMS instrumentation has become the method of choice for analysis of carbon-13-labeled fatty esters. Isotope-ratio mass spectrometers have high sensitivity and precision. The accuracy of the $^{13}C/^{12}C$ ratio data is about $0.01 \pm 0.001$% enrichment. Differences between the accuracy of GC–MS and GC–C–IRMS methods may or may not be a major issue because the standard error for the MS data is much smaller than the standard error for the biological part of the study. However, detection limits for $^{13}$C-labeled fatty acids are lower than for deuterium-labeled fats and allow $^{13}$C-labeled fatty acids to be followed for many days. The typical amount of tracer used in a pulse-oral-dose *in vivo* experiment is 2–10 mg/kg body weight of a 99% enriched uniformly labeled $^{13}$C fatty acid. Proportionally more $^{13}$C-labeled fatty acid is fed when enrichments are lower or if only one or two carbons are labeled with $^{13}$C. A disadvantage of GC–C–IRMS is that molecular-ion data are not obtained for confirmation of fatty acid structure. Subtraction of baseline $^{13}$C enrichment is necessary because baseline $^{13}$C levels can vary significantly between subjects owing to the natural variation in the $^{13}$C content of foods. The data also need to be examined to ensure that a significant amount of [$^{13}$C]acetyl CoA is not recycled back into fatty acids by *de novo* synthesis.

Analysis of $^{2}$H- and $^{13}$C-labeled compounds by nuclear magnetic resonance (NMR) methods has been used for

decades to obtain exact structure information for fatty acids extracted from biological samples. However, the relatively low sensitivity of NMR methods compared to MS methods has limited their application for monitoring the metabolism of stable isotope-labeled fatty acids in biological studies. A $^{13}C$ NMR spectrometer equipped with a surface coil has been used in an *in vivo* method to measure incorporation of $^{13}C$-labeled fatty acid into tissues of live animals, but the method is much less sensitive than *in vitro* NMR methods.

## APPLICATIONS OF STABLE ISOTOPE METHODS

Stable isotope tracer studies provided a powerful approach to address questions relevant to PUFA studies in infants and mothers. For example, a variety of stable isotope experimental designs have been used to investigate the conversion of labeled n-6 and n-3 PUFA to their respective n-6 and n-3 long-chain polyunsaturated fatty acid (LC-PUFA) metabolites. These studies with adults, infants, and animal models have provided considerable information about the *in vivo* conversion and PUFA metabolism. The following examples illustrate the general utility of stable isotope tracer studies to investigate desaturation–elongation of linoleic and linolenic acids, TAG absorption, and kinetic parameters related to lipid synthesis, fatty acid oxidation, and *de novo* fatty acid synthesis.

### Synthesis of n-6 and n-3 LC-PUFA by Adults

*(i) Single-labeled pulse-dose design.* The origin of 18:2n-6 and n-6 LC-PUFA in milk lipids and the effect of lactation duration were determined by feeding [U-$^{13}C$]18:2n-6 (1 mg/kg body weight) to six mothers at 4, 6, and 12 wk after starting lactation (13). Milk and breath samples were collected for a 108-h period. The results showed that incorporation into milk lipids and oxidation of [$^{13}C$]18:2n-6 were not related to dietary 18:2n-6 intake. This finding suggests that these processes are separately regulated and noncompetitive. A multiple compartmental model was used to calculate cumulative recoveries of $^{13}CO_2$ (17.7–24%) in breath and [$^{13}C$]18:2n-6 (11.7–13.1%) in milk lipid samples. Accretion of 20:3n-6 was 3–25% of total 20:3n-6 in milk, suggesting a wide variation in 18:2n-6 conversion among lactating mothers. Oxidation, transfer, and conversion of [$^{13}C$]18:2n-6 were not influenced by lactation duration. Conversion of dietary 18:2n-6 to n-6 LC-PUFA was estimated to provide about 11% of the 20:3n-6 and 1.2% of the 20:4n-6 in milk lipids.

*(ii) Single-labeled pulse-dose design.* The effect of dietary n-3 fatty acids on the conversion and oxidation of 18:3n-3 was investigated in male and female adults (21–66 yr) (14). Subjects were fed diets containing different levels of oleic, linolenic, or eicosapentaenoic + docosahexaenoic acids. At the end of the 7-wk diet period, [U-$^{13}C$]18:3n-3 (45 mg) was fed as the methyl ester using an oral pulse dose of a labeled fatty acid. The maximal amounts of [$^{13}C$]20:5n-3 and [$^{13}C$]22:6n-3 incorporated into total plasma lipid were each about three times lower in the 18:3n-3 diet group than in the 18:1n-9 diet group. These results suggest that dietary 18:3n-3 decreased conversion of 18:3n-3 to 20:5n-3 and 22:6n-3 compared to the oleic acid diet. Conversion of [$^{13}C$]18:3n-3 to [$^{13}C$]22:6n-3 was not detected in plasma total lipid of subjects fed the 20:5n-3 + 22:6n-3 diet. Oxidation of [$^{13}C$]18:3n-3 was 24.8% for the 20:5n-3 + 22:6n-3 diet group, 20.4% for the 18:3n-3 diet group, and 15.7% for the 18:1n-9 diet group. The combined results suggest that conversion of 18:3n-3 to LC-PUFA is decreased and oxidation of 18:3n-3 is increased by dietary n-3 fatty acids.

*(iii) Single-labeled pulse-dose design.* The question of retroconversion of 22:6-n-3 to 20:5n-3 and 22:5n-3 was investigated in adult human subjects and rats by feeding a single oral dose of [U-$^{13}C$]22:6n-3 as the TAG (15). Time-course data were presented for plasma and high-density lipoprotein lipid classes, platelet phospholipids, and red cell phosphatidylcholine (PC). Overall, total retroconversion of [U-$^{13}C$]22:6n-3 was 1.4% in humans and 9% in rats. No increase in 20:4n-6 and 22:4n-6 carbon-13 enrichment was observed, which suggests that recycling of [$^{13}C$]acetyl CoA into elongated PUFA products was negligible. Interestingly, a precursor–product relationship for the expected sequence 22:6n-3 $\rightarrow$ 20:5n-3 $\rightarrow$ 22:5n-3 was supported by the rat data but not by the human data. The results provide several other interesting insights into the metabolic fate of 22:6n-3 and show that rats are not a good model for 22:6n-3 metabolism in humans.

*(iv) Multiple-labeled pulse-dose design.* The effect of dietary 22:6n-3 on distribution of 18:2n-6 and 18:3n-3 between lipid classes and on conversion to n-6 and n-3 LC-PUFA metabolites was investigated in male subjects (age 28–39 yr) (16). The subjects were fed a typical U.S. diet (Low22:6) or a typical U.S. diet supplemented with 6.5 g of 22:6n-3 (High22:6) for 90 d. At the end of the 90-d diet period, a mixture of deuterated 18:1n-9 (39–48 mg/kg), 18:2n-6 (29–35 mg/kg), and 18:3n-3 (27–36 mg/kg) TAG were fed. This approach allowed the metabolism of the three deuterated fats to be directly compared within each subject. The relative percentages of 18:1-$d_6$, 18:2-$d_2$, and 18:3-$d_4$ incorporated into plasma lipid classes were similar for all subjects, showing that the selectivity of the various acyltransferases was not influenced by dietary 22:6n-3. Plasma total lipid time-course data for [$^{2}H$]22:6n-3 accretion was 88% lower and [$^{2}H$]20:4n-6 accretion was 71% lower for the 22:6n-3–supplemented diet group compared to the Low22:6 diet group. Overall, dietary 22:6n-3 supplementation reduced the total amount of [$^{2}H$]LC-PUFA metabolites synthesized from 18:2-$d_2$ and 18:3-$d_4$ by about 70%. Based on total plasma lipid data from subjects fed the Low22:6 diet, *ca.* 4% of the 18:2-$d_2$ and *ca.* 5% of the 18:3-$d_4$ were converted to their respective LC-PUFA. The results suggest that inhibition of 18:2n-6 conversion to 20:4n-6 contributes to the physiological effects produced by dietary 22:6n-3 supplementation.

*(v) Multiple-pulse oral-dose design.* Enrichment of a fatty acid in plasma lipids can be increased by administering multiple doses of a labeled fatty acid at timed intervals. Higher enrichments enhance both detection and measurement of

labeled fatty acid metabolites because the increased isotope enrichment of a precursor fatty acid increases the enrichment of the fatty acid metabolites. This multiple-pulse dose approach was used to measure the effect of dietary arachidonic acid on conversion of 18:2n-6 to n-6 LC-PUFA metabolites in adult subjects (17). Male subjects (age 20–39 yr) were provided a typical U.S. diet (Low20:4) or a typical U.S. diet supplemented with 1.5 g of 20:4n-6 (High20:4) for 50 d. The stable isotope experiment consisted of feeding a 3.5 g dose of 18:2-$d_2$ at 8:00 A.M., 12:00, and 5:00 P.M. The deuterated fat was fed as a TAG and included as part of the subject's normal meal. Comparison of n-6 fatty acid metabolite data from the two diet groups showed that in plasma total lipid, 1.5 g/d of additional dietary 20:4n-6 reduced accumulation of both deuterated 20:3n-6 and 20:4n-6 by about 50%. For subjects fed the Low20:4 diet, about 3% or 325 mg of [$^2$H]20:4n-6 was synthesized from the 10.4 g of [$^2$H]18:2n-6 fed.

## Synthesis of n-6 and n-3 LC-PUFA by Infants

*(i) Single-labeled pulse-dose design.* Metabolism of an oral pulse dose of [U-$^{13}$C]18:2n-6 (1 mg/kg body weight) was studied in breast-fed full-term infants during the first week after birth (18). The results show that newborn infants have the capacity to desaturate and elongate 18:2n-6, but the amount of 18:2n-6 converted to 20:3n-6 and 20:4n-6 was low (1.5 and 1.2%, respectively). The authors suggest that conversion of 18:2n-6 may have been inhibited by dietary LC-PUFA since breast milk provides sufficient LC-PUFA to meet requirements. This suggestion is consistent with the observation that dietary 20:4n-6 and 22:6n-3 supplementation (16,17) reduced conversion of 18:2n-6 and 18:3n-3 in adults by 50–70%.

*(ii) Multiple-labeled pulse-dose design.* Premature infants were studied 30 d after birth by using an elegant combined dual-labeled and oral multiple-pulse experimental design (19). This study was the first to use this approach with $^{13}$C-labeled fatty acids. Formula containing about a 10:1 mixture of uniformly $^{13}$C-labeled 18:2n-6 and 18:3n-3 was continuously administered by intragastric infusion for 48 h. This dual-labeled approach with $^{13}$C-labeled fatty acids is possible because the plasma n-6 and n-3 fatty acids can be separated by GC before C–IRMS analysis. Time-course area data were used to calculate the amount of $^{13}$C-labeled 20:4n-6 and 22:6n-3 synthesized. The results provide clear evidence that low-birth-weight premature infants are able to synthesize 20:4n-6 and 22:6n-3. Estimates based on plasma phospholipid data indicate that about 6% of the total [$^{13}$C]18:2n-6 dose was converted to 20:4n-6, and about 14% of the [$^{13}$C]18:3n-3 dose was converted to 22:6n-3.

*(iii) Natural carbon-13-enriched diets.* The average natural abundance of $^{13}$C in foods is about 1.1%, but the percentage varies depending on the food source. Carbon-13 enrichment is about 1.081% for plants that use the $C_3$ photosynthesis pathway (e.g., soybean), and about 1.0975% for plants that use the $C_4$ photosynthesis pathway (e.g., corn). Diets containing mainly carbohydrate, protein, or oil from $C_4$ plants will produce a detectable increase in the $^{13}$C enrichments of breath and tissue samples. This "natural carbon-13 diet approach" has rarely been utilized for PUFA metabolism studies, but the feasibility has been demonstrated by feeding full-term infants a corn oil-based formula for 4 d in place of breast milk or commercial formula (20). By day 4, the $^{13}$C enrichments for 18:2n-6 and 20:4n-6 in plasma total lipid increased by comparison with baseline $^{13}$C enrichments. The increase in 20:4n-6 enrichment showed that these infants (mean age 18 d) were actively synthesizing 20:4n-6 from dietary 18:2n-6.

## Synthesis of n-6 and n-3 LC-PUFA in Animals

*(i) Single-labeled pulse-infusion design.* Accretion in fetal tissue lipids of synthesized 22:6n-3 was compared to that of preformed 22:6n-3 by infusion of [U-$^{13}$C]18:3n-3 (3.9–16 mg total) or [U-$^{13}$C]22:6n-3 (1.7–3.7 mg total) into pregnant baboons over a 1-h period (21). The baboons were in the third trimester of pregnancy. Incorporation of preformed [$^{13}$C]22:6n-3 in fetal brain lipid was about 20 times greater than incorporation of 18:3n-3–derived [$^{13}$C]22:6n-3. This result suggests that dietary 22:6n-3 has about 20 times the bio-equivalency of dietary 18:3n-3 and that an estimated dietary intake of 0.45% energy (%en) 18:3n-3 is needed to meet fetal requirements for 22:6n-3. This tracer study provided a wealth of other information about the incorporation, conversion, and transfer of n-3 and n-6 PUFA between maternal and fetal organs. The information is considered relevant to humans because the studies were conducted with primates.

*(ii) Single-labeled oral-pulse design.* Newborn baboons were fed human infant formula containing a 10:1 ratio of 18:2n-6 to 18:3n-3. At age 4 wk, they were dosed with [U-$^{13}$C]18:3n-3 (7.5 mg) or [U-$^{13}$C]22:6n-3 (4.4 mg) to determine the bioequivalency of dietary 18:3n-3 and 22:6n-3 (22). Two weeks after dosing (6 wk of age), brain, retina, retinal pigment epithelium, liver, plasma, and erythrocytes total lipids were analyzed by GC–C–IRMS. Accretion of preformed [$^{13}$C]22:6n-3 in brain lipids was 1.7% of the total dose, which suggests that 22:6n-3 was not highly conserved. The ratio of preformed [$^{13}$C]22:6n-3 to 18:3n-3-derived [$^{13}$C]22:6n-3 in these tissue lipids ranged from 7 to 51 and was lowest in brain lipid. The results indicate that dietary 22:6n-3 has about seven times the bioequivalency of dietary 18:3n-3.

*(iii) Single-labeled pulse-infusion design.* A single intravenous dose of [U-$^{13}$C]18:2n-6 (*ca.* 20 mg) was used to investigate the metabolism of 18:2n-6 and its LC-PUFA metabolites in maternal plasma and fetal organ lipids of baboons during the third trimester of pregnancy (23). Diets contained no LC-PUFA and an 18:2n-6 to 18:3n-3 ratio of 10:1. Maternal plasma samples were collected hourly for 8 h and daily for 20 d. Fetal samples were collected at eight time points between 1 and 29 d. The maximum amount of [$^{13}$C]20:4n-6 in fetal brain occurred at day 21 and was equal to 0.025% of the total [$^{13}$C]18:2n-6 dose. As a percentage of total label, accretion of [$^{13}$C]20:4n-6 in all

major fetal organs (liver, brain, heart, kidney, lung) continued to increase during most or all of the 29-d study period. Concentration of total n-6 [$^{13}$C]-labeled fatty acids and the percentage of 22-carbon [$^{13}$C]-labeled fatty acids were higher in fetal brain than in other organs. These tracer data suggest that about 50% of the fetal brain requirement for 20:4n-6 is provided by conversion of 18:2n-6 to 20:4n-6 and 50% is supplied by maternal stores.

*(iv) Dual-labeled pulse-dose design.* NMR was used to compare the accretion of 20:4n-6 synthesized from 18:3n-6 and preformed 20:4n-6 in suckling rats administered a mixture of [3-$^{13}$C]18:3n-6 (9.6 mg) and [1-$^{13}$C]20:4n-6 (10.4 mg) ethyl esters (24). Accretion of preformed 20:4n-6 was 7 times higher in liver total-lipid extracts than synthesized 20:4n-6 and 10 times higher in total brain lipid extracts. The results suggest that the source of most of the 20:4n-6 in brain lipids is from diet, tissue stores, and its synthesis by liver. A second part of this study involved injecting about 10 mg/d of [1-$^{13}$C]20:4n-6 for four consecutive days into the stomach of the rat pups. After 3 d, *in vivo* NMR spectra (obtained with a surface coil) of the intact brain and liver of the living rat pups detected [1-$^{13}$C]20:4n-6 in liver but not in brain. This *in vivo* NMR approach is attractive, but sensitivity is a limiting factor at this time.

## TAG Structure

A multiple-labeled oral-pulse-dose design was used to investigate the effect of TAG structure on fatty acid absorption and metabolism in middle-age male subjects fed native or randomized lard diets (25). A mixture of TAG (93–130 mg /kg) that contained both 1,3-dideuteriolinoleoyl-2-tetradeuteriopalmitoyl-*rac*-glycerol (L$d_2$P$d_4$L$d_2$) and 1,3-hexadeuteriopalmitoyl-2-tetradeuteriolinoleoyl-*rac*-glycerol (P$d_6$L$d_4$P$d_6$) was fed. The results shows that [$^2$H]16:0 and [$^2$H]18:2n-6 were equally well absorbed, and [$^2$H]-labeled fatty acids in the *sn*-2 TAG position were 85% retained in chylomicron TAG. After absorption, [$^2$H]16:0 in the chylomicron *sn*-2 TAG position migrated to the *sn*-1,3 positions, and [$^2$H]18:2n-6 in the *sn*-1,3 TAG positions migrated to the *sn*-2 acyl position. Migration was minimal when the labeled fatty acids were initially incorporated at the preferred or usual chylomicron TAG acyl position. The only effect of TAG acyl position on distribution in plasma lipid classes was less (30%) incorporation of [$^2$H]16:0 in the 1-acyl position of PC when [$^2$H]16:0 was fed as a *sn*-2 TAG. TAG structure did not influence conversion of [$^2$H]18:2n-6 to [$^2$H]20:3n-6 and [$^2$H]20:4n-6.

## Kinetic Studies

Radioisotope tracers have been used for more than 30 yr to obtain kinetic data for estimating turnover rates, half-lives, and fractional synthesis rates for TAG, very low density lipoprotein (VLDL), and fatty acids in human subjects. Kinetic information, obtained by continuous infusion and pulse injection of radioisotope-labeled fatty acids, has been reported for palmitic, stearic, oleic, linoleic, and arachidonic acids (26–28). Current stable isotope kinetic methods and theory are patterned after radioisotope methods (2,29,30). Many issues related to the experimental designs, assumptions, and various models used for interpretation of stable isotope kinetic tracer data have been critically reviewed (31). The following examples illustrate some approaches and results obtained using stable isotope tracers to study lipid synthesis, fatty acid synthesis, and fatty acid oxidation.

*(i) Lipid class synthesis.* Continuous infusion of [U-$^{13}$C]16:0 and [U-$^{13}$C]18:2n-6 over a 24-h period was used to determine the kinetics of surfactant PC synthesis in lungs of eight critically ill infants (age 11–149 d) with respiratory failure (32). The fractional synthesis rates for surfactant PC-16:0 and PC-18:2n-6 ranged from 0.4 to 3.4%/h, and from 0.5 to 3.8%/h, respectively. Mean times for maximal enrichments in surfactant PC were 49.2 h for 16:0 and 45.6 h for 18:2n-6. The half-lives of PC-16:0 and PC-18:2n-6 varied widely, and a shorter half-life correlated with the severity of respiratory failure. The results showed that synthesis of lung surfactant is a relatively slow process and demonstrated the application of $^{13}$C-labeled fatty acids for investigation of lipid class synthesis in lung tissue.

*(ii) Fatty acid oxidation in infants and adults.* A carbon-13 breath test was developed as an alternative to the [$^{14}$C]-triolein breath test for assessing fat malabsorption and gastric emptying. The carbon-13 breath test is used as a safe and noninvasive research tool for measuring fatty acid oxidation in children and healthy adults. IRMS methods are used to measure changes in the $^{13}CO_2/^{12}CO_2$ ratios of breath samples and can accurately detect small changes if appropriate corrections for variation in the natural $^{13}$C background are made (33). The "$^{13}CO_2$ Breath Test" has been used in many studies to measure factors that affect fatty acid oxidation. The following recent applications illustrate its general utility.

*(iii) Oxidation of 22:6n-3 and 18:2n-6.* The effect of dietary 22:6n-3 supplementation on oxidation of [$^{13}$C]22:6n-3 was determined in lactating women (34). An oral dose of $^{13}$C-enriched oil (2 mg/kg body weight) containing 50% 22:6n-3 was fed to the 22:6n-3-supplemented (0.3 g/d) and nonsupplement diet groups. Kinetic and cumulative oxidation rate data for the two diet groups were not different. Time-course data from this study were compared with similar data for lactating women fed a pulse dose of [U-$^{13}$C]18:2n-6 (1 mg/kg body weight) after 2, 6, and 12 wk of lactation (13). The 0–4 h time-course data showed that the [$^{13}$C]22:6n-3 oil was absorbed more quickly than [$^{13}$C]18:2n-6 (1 h vs. 3.5 h for maximum absorption) and oxidized much faster. After 4 h, the percent enrichment data for breath $CO_2$ were similar for both fatty acids. These results suggest that increased dietary 22:6n-3 intake did not result in higher oxidation of 22:6n-3.

*(iv) Oxidation of 16:0 and 18:1n-9.* A multiple-pulse-dose approach was used to estimate the relative oxidation for 18:1n-9 vs.16:0 in adult subjects (35). The tracer fatty acids were incorporated into a liquid formula diet containing 16%en each of 16:0 and 18:1n-9. A steady-state plateau in

$^{13}CO_2$ breath samples was achieved by feeding an oral dose (0.6 mg/kg) of [$^{13}$C]18:1n-9 or [$^{13}$C]16:0 at 20-min intervals for 7 h. The $^{13}$C enrichment in chylomicron samples was used to correct $^{13}CO_2$ data for differences in percent absorption of the labeled fatty acids. The $^{13}CO_2$ enrichment data for [$^{13}$C]18:1n-9 were 1.21 ± 0.02 (range 1.01–1.55) times higher than for [$^{13}$C]16:0. These results suggest that the fractional oxidation rate for 18:1n-9 was 21% higher than for 16:0 and may be related to health benefits reported for 18:1n-9.

*(v) Fat digestion.* The fat digestion capabilities of formula-fed term (age 1–234 d) and preterm (age 10–57 d) infants were investigated by measuring the oxidation of an oral pulse dose (10–20 mg/kg body weight) of 1,3-distearoyl-2-[$^{13}$C-carboxy]-octanoyl-glycerol (36). Carbon-13 enrichment did not increase in breath $CO_2$ from three of five preterm infants younger than 20 d. This result suggests impaired fat digestion capability in the preterm infants. For infants 30 d or older, $^{13}CO_2$ enrichment data were within normal ranges for adults and showed that the capacity of infants to digest fat is developed to normal levels by about 1 mon of life.

*(vi) Fatty acid synthesis.* The MIDA approach involves measurement of the stable isotope isomer distribution pattern in the fatty acids synthesized following continuous infusion of [$^{13}$C]acetate. This approach provides a general method for determining the effect of diet and physiological changes on *de novo* lipogenesis. For example, the approach was used in humans to show that the percentage of VLDL-16:0 and VLDL-18:0 produced by *de novo* hepatic lipogenesis is small, 0.9 and 0.37% respectively (37). Carbohydrate and glucose refeeding increased the percentage of newly synthesized VLDL-16:0 and VLDL-18:0 to 1.64 and 0.64%, respectively. This small increase was considered physiologically insignificant. The MIDA approach was used in rats to measure the effect of insulin and supplementation with glucose and fructose on the fractional synthetic rate of VLDL-TAG. Both insulin administration and sugar supplementation were shown to increase greatly the fractional synthetic rate of VLDL-TAG (38).

Injection of $^{3}$H-labeled glycerol is a traditional approach used to measure synthesis of triacylglycerols. As an alternative, use of deuterated glycerol was validated recently as a stable-isotope method for estimating VLDL-TAG fractional catabolic rates (39). The method used a single-pulse infusion of a bolus dose of [$^{2}H_5$]-glycerol. VLDL-TAG was isolated from plasma samples collected over a 12-h period and percent enrichment was measured by mass spectrometry. A fractional catabolic rate (pools/h) of 0.301 to 0.559 (mean 0.378 ± 0.092) was calculated from the monoexponential decrease in VLDL-[$^{2}H_5$]-glycerol for six normolipidemic men.

*(vii) Fractional conversion rates.* Term infants were fed formula containing 0.4, 1.0, and 3.2% of fat as 18:3n-3 from birth until 3 wk old (40). Each infant was then fed 25–40 mg/kg body weight of [U-$^{13}$C]18:2n-6 and 20–25 mg/kg body weight of [U-$^{13}$C]18:3n-3. The tracer/tracee ratios in plasma total phospholipid were determined, and a precursor–product compartmental model was used to calculate fractional conversion rates for synthesis of [$^{13}$C]20:4n-6 and [$^{13}$C]22:6n-3 and fractional incorporation rates. The fractional conversion rate for 18:3n-3 → 22:6n-3 increased 39% and that for 18:2n-6 → 20:4n-6 decreased 64% when the 18:3n-3 content of formula was increased from 0.4 to 3.2% of total fat. Fractional incorporation rates increased 2.4-fold for 22:6n-3 and decreased 55% for 20:4n-6. The fractional conversion rate decrease for 18:3n-3 was not statistically significant because of large variability within and between diet groups. However, the combined results showed that dietary 18:3n-3 influenced both n-6 and n-3 LC-PUFA metabolism. The relevance of these plasma phospholipid results to organ tissue lipids remains to be determined.

## ISSUES

A major issue concerning stable isotope studies is whether plasma lipid data provide a valid quantitative estimate for accretion and synthesis of PUFA. Concerns about the validity of qualitative results are usually not an issue. Examples of some typical questions are:

(i) Is it valid to use human plasma data as a reflection of PUFA incorporation and conversion in organ lipids?

(ii) Do the different methods for expression of isotope data [e.g., percent enrichment, tracer to tracee ratio, weight, percent of total tracer, percent delta over baseline (% DOB)], result in equally valid quantitative conclusions?

(iii) How large is normal subject variability and does it invalidate results from studies with a small number of subjects?

(iv) Is it valid to extrapolate results from animal studies to humans?

(v) Is it possible to obtain valid *in vivo* kinetic data?

These are controversial and complicated questions that have not been satisfactorily resolved. Whether isotope data provide valid quantitative results depends on many factors. Conclusions based on isotope tracer results can lead to misconceptions, and the results from other types of studies should always be considered. The following comments summarize some nuances related to the above questions, but an in-depth discussion of these questions is beyond the scope of this review.

*Validity of stable-isotope results.* Does accretion of n-6 and n-3 LC-PUFA in human plasma lipids provide a valid quantitative measure of LC-PUFA synthesis from 18:2n-6 and 18:3n-3 precursors? The answer is yes, no, and maybe. The presence of labeled n-6 and n-3 LC-PUFA metabolites in human plasma lipids is qualitative evidence that desaturation and elongation of 18:2n-6 and 18:3n-3 have occurred. All recent studies have shown that *in vivo* conversion of 18:2n-6 and 18:3n-3 to LC-PUFA is not trivial. It is clear also from many lines of evidence that increased synthesis of LC-PUFA can increase accumulation in plasma lipids but not necessarily in proportion to the amount synthesized. The reason is that accretion of n-6 and n-3 LC-PUFA metabolites in lipid classes is controlled or regulated by several metabolic pathways. The main pathways are desaturation–elongation, acylation–deacylation–reacylation, and fatty acid oxidation. The amounts and ratios of n-6 and n-3 fatty acids in diet can alter accretion of synthesized LC-PUFA by competing for

acylation of the 2-acyl position of phospholipids and increasing turnover rates. Mechanisms responsible for the transport or transfer of lipids from plasma to other organ lipids are also important. An additional major complication is that most of the enzymes involved in these pathways have a different affinity or selectivity for different fatty acid structures. The result is that the relationship between synthesis and accretion is complex and probably not linear for LC-PUFA.

Stable isotope studies provide quantitative conversion data that are sufficiently accurate for some purposes and not for others. For example, plasma total lipid data are a valid indicator of the minimum amount of 22:6n-3 synthesized from 18:3n-3, but these data are probably not an accurate measure of the total amount synthesized. Comparison of the relative amounts of n-6 and n-3 LC-PUFA in plasma total lipids from subjects fed a mixture of labeled 18:2n-6 and 18:3n-3 provides an accurate reflection of relative synthesis rates for LC-PUFA. However, the results are valid only for the actual set of experimental conditions. The bottom line is that tracer data for human plasma LC-PUFA can provide a valid reflection of LC-PUFA accretion and a useful estimate of total synthesis.

*Expression of isotope data.* The answer to the question of "what is the best or most valid way of expressing stable isotope data?" depends on the experimental design and objective of the study. Stable isotope tracer data can be presented in a variety of ways. Examples are percentage enrichment, tracer/tracee ratio, weight, percentage of total tracer, and change in DOB. Each approach is valid and has advantages, but percentage data are the most likely to be misleading because the numbers are unitless or relative. Exceptions are the percentage total accumulation used to quantify the total amount of fatty acid oxidation and percentage data calculated from concentration data. Percentage of total tracer is useful because the numbers are relative to the total amount of tracer and are not influenced by the amount of tracee present. The standard used in radioisotope studies is specific activity [decompositions per minute (dpm)/unit weight]. If an internal standard is added to the lipid extract, stable isotope data can be expressed in an analogous way. Examples are microgram/mole and microgram/milligram of lipid.

*Subject variability.* Variation between results from different subjects raises questions about the validity of the stable isotope results from studies with a small number of subjects. For most stable-isotope studies in humans, the time and effort involved preclude the use of a large number of subjects. The use of a small number of subjects is not necessarily a major problem if there is reasonable assurance that the subjects reflect the normal distribution within a specific population. Variation between results from different subjects that appear to represent the same population is disconcerting. For control vs. experimental treatment studies, a large variability between data for subjects within the same group prevents conclusions from being drawn unless there are large differences in the stable isotope data for the two groups. When the reason for variation between data for different subjects cannot be explained, it is commonly referred to as "subject variability." However, subject variability is the sum of many experimental variables that either were not controlled or cannot be controlled. When an internal control fatty acid is simultaneously fed along with one or more experimental fatty acids, the variability of the relative data is less because uncontrolled experimental variables influence each fed fatty acid equally. This multiple-labeled isotope approach also facilitates comparisons of metabolic data for different fatty acids because each subject serves as his or her own control and experimental variables affect each fatty acid equally.

Our experience has been that stable isotope tracer data from subjects confined to a metabolic ward are less variable than data from free-living subjects. This observation suggests that experimental variables other than inherent metabolic differences contribute substantially to variation between data from different subjects. Differences in plasma lipid concentration, body weight, and the amount of tracer fed are responsible for much of the variability between data for individual subjects. Adjusting tracer data for these differences usually reduces variability greatly.

*Use and relevance of animal studies.* Can animal metabolism studies be used as valid indicators of human metabolism? Animal studies usually provide valid qualitative information, but extrapolation of quantitative results from animal models to humans without validating the model should be avoided. Small rodents are an example of a poor human model, and quantitative results from PUFA studies with rodents should not be extrapolated to humans. Extrapolation of results from some species of primates may be valid, but additional research is needed in this area. However, PUFA metabolism studies in animals can be very useful because experimental conditions can be rigorously controlled and organs can be sampled. Well-designed animal studies have provided valuable information that could not be obtained with human studies.

*Kinetics.* An elusive goal has been finding an answer to the question of how to use fatty acid isotope tracer data to obtain valid *in vivo* kinetic data in humans. Various approaches that range from classical enzyme kinetic models to multiple compartmental modeling have been used. The real question is whether the kinetic model and assumptions used to simplify the calculations are valid. The problem is that fatty acid metabolism *in vivo* involves interactions between several lipid pools or compartments, and a number of simplifying assumptions must be made that may or may not be totally correct. However, even simple kinetic treatments appear to provide useful information on the relative differences in the metabolism of different fatty acids. Kinetic data for PUFA metabolism in animal models are likely to be valid because the various organs and fatty acid pools can be sampled.

## RESEARCH OPPORTUNITIES

Stable isotope studies can be used to address many questions related to PUFA metabolism in infants and mothers. Each concern or question discussed in the previous section would be a challenging research opportunity. Other obvious examples of questions that provide opportunities for using stable isotope tracers are:

(i) Does percent conversion of 18:2n-6 and 18:3n-3 to LC-PUFA change during pregnancy?

(ii) What factors are responsible for the apparent differences in capacity of individuals to synthesize and accumulate LC-PUFA?

(iii) Does the n-6/n-3 ratio influence PUFA metabolism more than the actual amount of dietary 18:2n-6 and 18:3n-3?

(iv) Are estimates for the bioequivalency of 18:3n-3 and 22:6n-3 in primates valid predictors for humans?

(v) Can blood lipid markers be used to estimate accretion of PUFA metabolites in organs that cannot be sampled?

(vi) How important is dietary TAG structure?

(vii) What is the relative importance of desaturation–elongation and acyltransferase reactions with respect to synthesized LC-PUFA accretion in tissue lipids?

Development of new analytical methodology is another general area of opportunity. Recently developed atmospheric-pressure chemical-ionization MS methods provide molecular-ion information for intact TAG and phospholipids (41). Combining this analytical method with stable isotope tracer studies provides a new approach to investigate the affect of dietary TAG structure and fatty acid acyl position on absorption and metabolism. This approach also could be used to study lipid class synthesis and selective pairing of LC-PUFA with other fatty acids in phospholipids. Quadrupole ion-trap MS systems have potential for use in fatty acid tracer studies because of their inherent high sensitivity, but they have not been used to analyze samples from stable isotope-labeled fatty acid studies. Affordable internal and external ion-trap MS systems are available that should provide sensitivity and accuracy equal to those of NCI methods.

A noninvasive and sensitive analytical method that would provide a real-time quantitative measure of isotope-labeled PUFA metabolism in human subjects is an exciting and fascinating concept. Developments in NMR instrumentation and technology provide hope that this concept can be realized. Early studies showed that $^{13}C$ NMR could detect natural $^{13}C$-labeled fatty acids in liver and adipose tissue of living rats by using a surface coil. These studies showed that the influence of dietary PUFA could be detected in organs of live rats (42). Recent studies have shown that incorporation of $^{13}C$-labeled PUFA in the liver of live rats could be measured by $^{13}C$ NMR with the use of a surface coil (23,43). Continued refinement of this approach provides an intriguing research opportunity.

## SUMMARY

Stable isotope studies are clearly a powerful tool for investigating a variety of questions related to PUFA metabolism in mothers and infants. Several stable isotope experimental study designs are available, and they have been used to provide considerable information related to *in vivo* conversion of n-6 and n-3 PUFA, fatty acid oxidation, TAG absorption, and lipid synthesis. Many other questions could be addressed, but some issues about the validity of stable isotope results need to be resolved. New approaches will be developed as new and improved analytical instrumentation becomes available.

# Application of New Methods and Analytical Approaches to Research on Polyunsaturated Fatty Acid Homeostasis

**Stephen C. Cunnane**

Department of Nutritional Sciences, University of Toronto, Toronto, Canada M5S 3E2

**ABSTRACT:** New methods and analytical approaches are important to challenge and/or validate established beliefs in any field including the metabolism of polyunsaturated fatty acids (PUFA; polyunsaturates). Four methods that have recently been applied toward obtaining a better understanding of the homeostasis of PUFA include the following: whole-body fatty acid balance analysis, magnetic resonance imaging (MRI), $^{13}C$ nuclear magnetic resonance (NMR) spectroscopy, and gas chromatography–combustion–isotope ratio mass spectrometry (GC–C–IRMS). Whole-body balance studies permit the measurement of both the percentage of oxidation of linoleate and α-linolenate and their conversion to long-chain PUFA. This method has shown that β-oxidation to $CO_2$ is normally the predominant metabolic fate of linoleate and α-linolenate. Furthermore, models of experimental undernutrition in both humans and animals show that β-oxidation of linoleate and α-linolenate markedly exceeds their intake, despite theoretically sufficient intake of linoleate or α-linolenate. Preliminary results suggest that by using MRI to measure body fat content, indirect whole-body linoleate balance can be done in living humans. $^{13}C$ NMR spectroscopy provided unexpected evidence that linoleate and α-linolenate were metabolized into lipids synthesized *de novo*, an observation later quantified by tracer mass balance done using GC–C–IRMS. This latter method showed that within 48 h of dosing with $^{13}C$-α-linolenate, >80% underwent β-oxidation to $CO_2$ by suckling rats, whereas 8–9% was converted to newly synthesized lipids and <1% to docosahexaenoate. Further application of these recently developed methods in different models should clarify the emerging importance of β-oxidation and carbon recycling in PUFA homeostasis in mammals including humans.

Paper no. L8648 in *Lipids 36*, 975–979 (September 2001).

Progress in scientific research depends on a mixture of new ideas and new methods. Sometimes new ideas can be tested using existing, and even old, methods. Often, however, a new method may be required to undertake the appropriate experiment. Applying new methods to an old problem can sometimes reveal the information that was hoped for. Unanticipated results that perhaps contradict prevailing concepts may also occur in the process. It takes originality, patience, and luck to optimize experimental and analytical methods to research objectives.

Abbreviations: GC, gas chromatography; GC–C–IRMS, GC–combustion–IRMS; IRMS, isotope ratio mass spectrometry; LC, long chain; MRI, magnetic resonance imaging; NMR, nuclear magnetic resonance spectroscopy; PUFA, polyunsaturated fatty acids.

Research on the metabolism of polyunsaturated fatty acids (PUFA; polyunsaturates) has benefited from new methods almost since the inception of this field in the original studies of Burr and Burr in 1929–1930. Of any single analytical method, gas chromatography (GC) has arguably made the greatest contribution to the fields of fatty acid and sterol analysis. The application of deuterium isotope ratio mass spectrometry (IRMS) to problems in lipid metabolism is older than GC, but refinements in the 1990s have pushed this method into the forefront of PUFA research. Nuclear magnetic resonance (NMR) spectrometry was considered to be a tool of chemists until people began to use it to measure tracer metabolism in isolated tissues and live animals in the 1980s. These methods are by no means the only analytical developments that have contributed to an improved understanding of PUFA homeostasis.

## WHOLE-BODY LINOLEATE AND α-LINOLENATE BALANCE

In a nutritional context, balance methodology refers to comparing "what goes in to what comes out." It has been applied extensively to the metabolism of nutrients that cannot be synthesized, i.e., minerals and indispensable amino acids. Because there is no endogenous synthesis of "essential" nutrients in mammals, the difference between what goes in (dietary intake) and what comes out (excretion and β-oxidation) represents the amount accumulating in some form or other in the organism. If animals are used, what accumulates can be measured directly and compared with intake or excretion under the experimental conditions in question.

This method can be applied to two important questions in PUFA metabolism, i.e., (i) How much dietary linoleate (18:2n-6) or α-linolenate (18:3n-3) is converted to the respective long-chain (LC) PUFA? (ii) How much linoleate or α-linolenate undergoes β-oxidation, i.e., what is their true bioavailability under normal conditions? The only apparent condition on such fatty acid balance studies is that, because linoleate and α-linolenate can both be chain-elongated from their respective 16-carbon precursors, which are present in edible green vegetables, and because each of these precursors can be converted to several LC-PUFA, the dietary PUFA in a whole-body fatty acid balance study should be only linoleate and α-linolenate. This is not usually a difficult condition to meet as long as semipurified diet ingredients are used. PUFA accumulation would then have two components, (i) accumulation of linoleate or α-linolenate and (ii) accumulation of all

n-6 or n-3 LC-PUFA, namely, the percentage of conversion from linoleate or α-linolenate.

If the analysis is done correctly, the difference between intake minus the sum of both excretion and the combined accumulation of linoleate or α-linolenate plus their respective LC-PUFA represents the disappearance of linoleate or α-linolenate from the whole-body pool of n-6 or n-3 PUFA, i.e., their β-oxidation. In growing animals, a balance period of only a few days is sufficient, but it can be several weeks if it is desirable. The advantages of this analytical approach to studying both net desaturation-chain elongation and β-oxidation of PUFA are as follows: (i) No tracers are involved; thus the data are not dependent on isotope equilibration with various pools. (ii) β-Oxidation exceeding intake can be measured, which is a surprisingly common phenomenon (see below). (iii) Whole-body rather than single compartment synthesis of LC-PUFA can be measured. (iv) The analytical method (quantitative fatty acid extraction and analysis by capillary GC) is relatively simple and well established. The single main disadvantage is that LC-PUFA also undergo β-oxidation, although to a lesser extent than linoleate or α-linolenate. This component of the equation can be estimated from published values (1) but cannot be measured directly; thus, there is an inherent although modest error in its estimation.

The whole-body fatty acid balance method provided the first clear indication of the overall capacity to synthesize LC-PUFA in rats. Subcellular preparations, tracer conversion, or changes in precursor to LC-PUFA ratios simply cannot provide this information because they are isolated from the integrated influences on PUFA homeostasis in the whole body. Predictable changes such as increased LC-PUFA synthesis during pregnancy or impaired LC-PUFA synthesis in nutritional deprivation such as moderate zinc deficiency (Table 1) confirm the plausibility of the results obtained using whole-body fatty acid balance methodology. Perhaps most surprising are the relatively low levels of conversion [3–4% to arachidonate (20:4n-6) and 1–2% to docosahexaenoate (22:6n-3)], especially relative to β-oxidation of the parent PUFA.

**TABLE 1**
**Various Nutritional Manipulations Probing Key Aspects of Whole-Body Homeostasis of Linoleate and α-Linolenate, i.e., Conversion to Long-Chain Polyunsaturated Fatty Acids (LC-PUFA) or β-Oxidation**

| | Linoleate | α-Linolenate | Reference |
|---|---|---|---|
| | (% of intake) | | |
| Conversion to LC-PUFA[a] | | | |
| Normal, young rats | 3–4 | 1–2 | 2 |
| Pregnant rats | 8 | 45 | 3 |
| Pregnant + mild zinc deficiency | 4 | 24 | 3 |
| β-Oxidation | | | |
| Normal, young rats | 70 | 80 | 2 |
| Pregnant rats | 62 | 35 | 3 |
| Fasted, refed pregnant rats | 106 | 142 | 4 |
| Weight-cycled male rats | 81 | 89 | 5 |
| Linoleate-deficient male rats | 485 | ND[b] | 6 |

[a]18- to 22-carbon LC-PUFA in each family.
[b]ND, not determined.

This method also shows that whole-body β-oxidation of linoleate and α-linolenate is generally in the range of 70–80% (Table 1), values that are in broad agreement with whole-body tracer data (1). Predictably, β-oxidation of PUFA is reduced by pregnancy and increased by a variety of conditions involving nutritional deprivation (Table 1). One important advantage of this method is that because whole-body analysis is done at two time points to determine accumulation, a net loss over the balance period (negative accumulation) can be measured. Hence, unlike with tracer methods, depletion of PUFA from body stores is easily quantified. A significant degree of whole-body PUFA depletion occurs with weight loss, fasting-refeeding, and dietary linoleate deficiency (Table 1).

Indirect approaches using whole-body fatty acid balance methodology can also be used to estimate requirements for certain PUFA such as docosahexaenoate (7). Docosahexaenoate accumulation at 10 mg/d in the human neonate was estimated from a collation of tissue data. Taking into consideration an estimate that 50% of dietary docosahexaenoate undergoes β-oxidation in neonates (8) left an apparent requirement for docosahexaenoate intake and/or synthesis of 20 mg/d. Although breast milk almost invariably provides at least 60 mg/d docosahexaenoate, no data obtained by balance or tracer methods in an animal or human model suggest that α-linolenate can be converted to docosahexaenoate at the necessary rate of 20 mg/d, i.e., a conversion rate of 5% (7). These results, although preliminary and potentially in need of revision, demonstrate the applicability of whole-body fatty acid balance to important questions in PUFA research in both infants and animal models.

## MAGNETIC RESONANCE IMAGING (MRI) AND *IN VIVO* WHOLE-BODY FATTY ACID BALANCE

One significant limitation to applying whole-body fatty acid balance to understanding PUFA metabolism in humans is the need for an accurate measure of the whole-body content of the fatty acids in question, i.e., the need for tissue analysis. Under some circumstances, MRI may be able to provide the necessary information to estimate the whole-body pool of PUFA such as linoleate in living humans (9). The key requirements of this method can be met without direct lean tissue PUFA analysis, at least under the following experimental conditions: (i) Whole body MRI scans provide accurate lean and fat tissue volumes for the whole body. (ii) Lean and fat tissue densities and water content are known; thus, the actual mass of individual fatty acids in these compartments can be determined. (iii) Linoleate is predominantly in body fat and because fat is the only tissue (besides plasma) that can be routinely biopsied; fatter individuals reduce the error of having only a sample of subcutaneous fat with which to analyze linoleate levels. (iv) Linoleate levels seem to be the same at all fat locations (10), allowing one to generalize that the data obtained from one biopsy site is valid across all fat depots. (v) Studying linoleate β-oxidation during energy deficit and moderate weight loss essentially eliminates the need to

measure linoleate conversion to n-6 LC-PUFA because energy deficit impairs desaturation (11). (vi) Moderate energy deficit leading to <15% weight loss does not change lean tissue linoleate levels in animals (12); thus, only the size of the lean tissue compartment but not a change in its PUFA content must be known.

In our initial experiments with this *in vivo* version of the whole-body fatty acid balance method, it became clear that β-oxidation of linoleate during weight loss of 13 kg in obese men can markedly exceed its intake, despite a nominally adequate linoleate intake (9). This was not evident in the PUFA content of plasma fatty acid profiles. Because of their already large linoleate stores and ongoing "normal" linoleate intake, this whole-body loss exceeding intake by two- to threefold was unlikely to be a significant risk, at least immediately. However, the point is that indirect whole-body linoleate balance can be done in living humans under minimally invasive and ethically acceptable circumstances. This method appears to provide plausible estimates of linoleate β-oxidation and indicates for the first time that under conditions of apparent linoleate adequacy, linoleate β-oxidation can considerably exceed its intake. This may lead to assessment of conditions in which linoleate sufficiency is less certain, i.e., during pregnancy, lactation, early infancy, or chronic risk of undernutrition.

In one such future application, we are beginning an evaluation of fetal MRI to assess the feasibility of determining fat accumulation during the third trimester *in utero*. Fetal adipose tissue accumulates uniquely during the third trimester. Growth retardation *in utero* or premature birth are both associated with a higher risk of compromised neurological development postnatally and with lower fetal fat accumulation. At birth, adipose tissue contains more docosahexaenoate than α-linolenate (7); thus, this depot is potentially important in both normal postnatal development and early postnatal PUFA homeostasis. The PUFA balance methodology is analogous to that used in living adults (9) in which the changes in total fetal fat volumes will be combined with PUFA profiles obtained from separate autopsy samples. In principle, this should allow the estimation of PUFA accumulation in fetal adipose tissue.

## $^{13}$C NMR SPECTROSCOPY: APPLICATION TO A NEW PATHWAY IN PUFA METABOLISM

NMR spectroscopy has several applications in PUFA metabolism, particularly in determining the physiological properties of fatty acids such as docosahexaenoate (13). Our particular interest in this method was in the potential application of $^{13}$C NMR to the noninvasive measurement of LC-PUFA synthesis in organs such as brains of living animals and humans. As detailed elsewhere (14), technical limitations still prevent useful information on this potentially valuable application of NMR to studying PUFA metabolism. However, in the process of attempting to measure LC-PUFA synthesis noninvasively from uniformly $^{13}$C-labeled linoleate and α-linolenate in live neonatal rat pups, we made the serendipitous observation that the tracer was appearing in substantial amounts in brain lipids containing saturated carbons, i.e., cholesterol, saturated, and monounsaturated fatty acids. This was clearly evident in the *in vivo* $^{13}$C NMR spectra because peaks for saturated carbons of all lipids cluster in one region of the spectrum, whereas the peaks containing unsaturated carbons cluster in a separate region distinct from the saturated carbon peaks.

At the time, we were unaware of Andrew Sinclair's seminal work with $^{14}$C-α-linolenate showing essentially the same thing in suckling rats (15); skeptical then of our *in vivo* NMR data, we proceeded with $^{13}$C NMR analysis of brain total lipid extracts (16). Spectra of these extracts unequivocally confirmed the $^{13}$C enrichment in saturated fatty acids and cholesterol that appeared in the poorly resolved *in vivo* $^{13}$C NMR spectra (16). More sophisticated NMR methods, including generating double quantum, two-dimensional spectra, demonstrated the carbon pairing of telltale satellite peaks that indicated exactly which cholesterol carbons came into the molecule as intact $^{13}$C-enriched carbon pairs directly from the dosed $^{13}$C-PUFA (17). Further analysis by continuous flow IRMS confirmed the occurrence of substantial "carbon recycling" from 18-carbon PUFA, probably through ketones, into brain lipids synthesized *de novo* (16).

The point of this example is that our goal, i.e., to demonstrate synthesis of LC-PUFA in an *in vivo* model, had been quite different from the main results it produced. Had we used routine methods to examine LC-PUFA synthesis, the cholesterol fraction would not have been retained and we would not have learned about "carbon recycling" from PUFA into *de novo* lipid synthesis. This is also one of the drawbacks to GC/MS with selected ion monitoring, i.e., the investigator selects the ions, and therefore the molecules of interest, and discards or ignores the others regardless of their information content. In light of the data to be presented in the following section, unfortunately, this is a lost opportunity to evaluate a pathway of PUFA metabolism that appears to be, quantitatively, more important than LC-PUFA synthesis.

Carbon recycling from PUFA into *de novo* lipid synthesis appears to occur *via* β-oxidation of the PUFA, incorporation of the PUFA carbons into ketones, and use of the labeled ketones for *de novo* lipid synthesis in the brain (18). This pathway has not been investigated but would be an ideal subject for $^{13}$C NMR analysis because this method is well suited to identifying the water-soluble products (ketones, but probably other metabolites as well) through which the $^{13}$C enrichment is transferred.

## GAS CHROMATOGRAPHY–COMBUSTION–ISOTOPE RATIO MASS SPECTROMETRY (GC–C–IRMS): APPLICATION TO CARBON RECYCLING OF PUFA

IRMS is the most sensitive and precise way to measure the increase in $^{13}$C (or other tracer) above background during a tracer experiment. Because this method requires that the isotope in question be gaseous, it is limited to low-molecular-weight isotopes, mostly of hydrogen, oxygen, nitrogen, and

carbon. Gaseous samples such as breath require a purification step but can otherwise be sent straight to the mass spectrometer for analysis. Nongaseous samples must be combusted, a process that used to be done manually, with the gaseous sample then being purified and fed through a vacuum system to the mass spectrometer. In the past two decades, "continuous flow" systems have combined automated combustion and purification of the samples with the subsequent MS, thereby greatly reducing the need for manual input. In the past decade, the further refinement of adding a gas chromatograph ahead of the combustion system has been commercialized.

In principle, any organic compounds that can be separated by GC can have isotopic enrichments analyzed by GC–C–IRMS. For instance, it is now reasonably common to measure, in both animal models and humans, synthesis of $^{13}$C-labeled n-3 LC-PUFA after dosing with $^{13}$C-α-linolenate (8,19–22). Following on from our preliminary data showing that carbon recycling into *de novo* lipid synthesis appeared to capture a significant amount of the carbon skeleton of a mixture of linoleate and α-linolenate (16), we applied GC–C–IRMS to quantifying the fate of a physiologic oral dose of $^{13}$C-α-linolenate in suckling rat pups. Total lipids of brain, liver, gut, lung, and remaining carcass were extracted; the $^{13}$C enrichment in fatty acids and sterols was analyzed separately; tissue fatty acid and sterol levels were quantified; and the data were combined so as to determine the distribution of $^{13}$C from α-linolenate in body lipids. In addition, the total recovery of $^{13}$C in body lipids would indicate by mass balance how much $^{13}$C was missing and therefore lost through β-oxidation.

Results for the brain, liver, and gut have already been reported (23), from which it was clear that recycling of α-linolenate carbon into *de novo* lipid synthesis exceeded that going into docosahexaenoate by 5- to 40-fold, depending on the tissue and time of sampling after dosing with the tracer. More recently, we confirmed these data in the lung and are compiling the carcass and whole-body data. A nearly complete whole-body estimate showed that 48 h after dosing, <10% of $^{13}$C-α-linolenate remained in total body lipids in any form, i.e., that ~90% underwent complete β-oxidation. Of the remaining 10%, <5% stayed as $^{13}$C-α-linolenate, and <5% was converted to n-3 LC-PUFA. Less than 1% of the dosed $^{13}$C-α-linolenate appeared to be going into docosahexaenoate in the whole body of the suckling rat. If our remaining analyses and those of others working in this field confirm these preliminary conclusions (Fig. 1), these data will corroborate our whole-body balance data showing that 1–2% of dietary α-linolenate is normally used by the growing rat to make n-3 LC-PUFA (2).

The influence on n-3 LC-PUFA synthesis of preformed docosahexaenoate in the milk consumed by the suckling rats will still have to be assessed; the point remains, however, that IRMS is a reliable and sensitive analytical method for quantitatively assessing the bioavailability and whole-body homeostasis of PUFA.

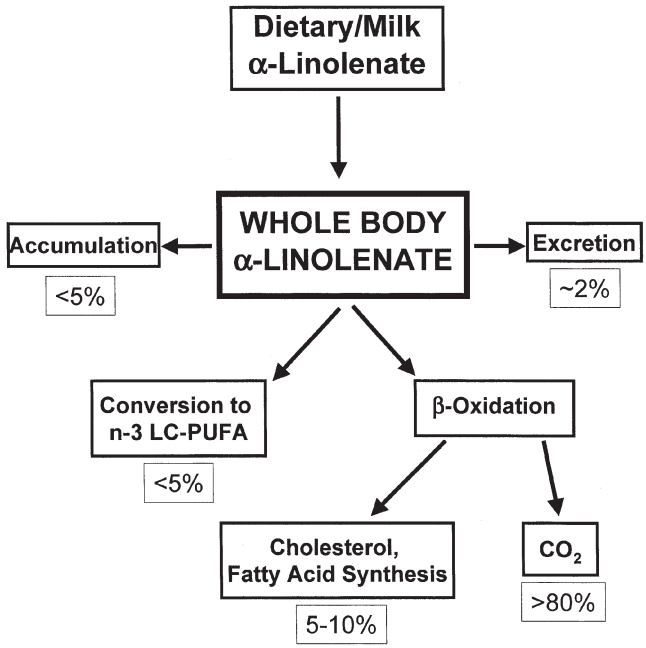

**FIG. 1.** Scheme outlining α-linolenate homeostasis in suckling rats based on metabolism of an oral dose of $^{13}$C-α-linolenate 48 h after dosing in 6-d-old rat pups. The values are derived from published (23) and unpublished data. LC-PUFA, long-chain polyunsaturated fatty acids.

## ACKNOWLEDGMENTS

Several people, including Mary Ann Ryan, Dr. Sergei Likhodii, Dr. Zhen-Yu Chen, Dr. Keith Goodman, Dr. Tom Brenna, Dr. Jilin Yang, Chantale Menard, Rory McDonagh, and Jody (Bannister) Coles, contributed ideas and/or significant physical effort to the data described here. This research was supported by NSERC Canada, MRC Canada, Ontario Ministry of Colleges and Universities, Roche, Martek, Milupa, CIL Isotopes, and Unilever.

# A New Concept of Cellular Uptake and Intracellular Trafficking of Long-Chain Fatty Acids

**Wolfgang Stremmel*, Jürgen Pohl, Axel Ring, and Thomas Herrmann**

Department of Gastroenterology, Ruprecht-Karls-University, 69115 Heidelberg, Germany

**ABSTRACT:** Fatty acids are the main structural and energy sources of the human body. Within the organism, they are presented to cells as fatty acid:albumin complexes. Dissociation from albumin represents the first step of the cellular uptake process, involving membrane proteins with high affinity for fatty acids, e.g., fatty acid translocase (FAT/CD 36) or the membrane fatty acid–binding protein ($FABP_{pm}$). According to the thus created transmembrane concentration gradient, uncharged fatty acids can flip-flop from the outer leaflet across the phospholipid bilayer. At the cytosolic surface of the plasma membrane, fatty acids can associate with the cytosolic FABP ($FABP_c$) or with caveolin-1. Caveolins are constituents of caveolae, which are proposed to serve as lipid delivery vehicles for subcellular organelles. It is not known whether protein ($FABP_c$)- and lipid (caveolae)-mediated intracellular trafficking of fatty acids operates in conjunction or in parallel. Channeling fatty acids to the different metabolic pathways requires activation to acyl-CoA. For this process, the family of fatty acid transport proteins (FATP 1-5/6) might be relevant because they have been shown to possess acyl-CoA synthetase activity. Their variable N-terminal signaling sequences suggest that they might be targeted to specific organelles by anchoring in the phospholipid bilayer of the different subcellular membranes. At the highly conserved cytosolic AMP-binding site of FATP, fatty acids are activated to acyl-CoA for subsequent metabolic disposition by specific organelles. Overall, fatty acid uptake represents a continuous flow involving the following: dissociation from albumin by membrane proteins with high affinity for fatty acids; passive flip-flop across the phospholipid bilayer; binding to $FABP_c$ and caveolin-1 at the cytosolic plasma membrane; and intracellular trafficking *via* $FABP_c$ and/or caveolae to sites of metabolic disposition. The uptake process is terminated after activation to acyl-CoA by the members of the FATP family targeted intracellularly to different organelles.

Paper no. L8624 in *Lipids 36,* 981–989 (September 2001).

## THE OVERALL VIEW

Long-chain fatty acids are the major energy source in the mammalian organism, supplying ATP *via* mitochondrial β-oxidation. As an example, cardiomyocytes represent a cell type that is essentially dependent on efficient and constant energy flow provided by fatty acids. Any extra fatty acid not used for ATP production is stored as triglyceride, preferentially in lipid droplets at the endoplastic reticulum (ER) membrane. All cells are able to synthesize triglycerides for storage of excess fatty acids as well as for rapid recruitment of fatty acids if required. Adipocytes are "professionally" dedicated to fat storing, thus serving as energy providers in times of demand and as banks of triglycerides in times of surplus supply.

In addition to adipocytes, there is one other cell type in the mammalian organism that represents a professional triglyceride producer, i.e., the intestinal mucosal cell. All long-chain fatty acids entering the mucosal cell have to be esterified to triglycerides by the ER before they are bound to apolipoproteins in the Golgi compartment and leave the cell by exocytosis as very low density lipoproteins (VLDL) or chylomicron particles. These are released to the systemic circulation *via* the lymphatic system and thoracic duct (1,2). At the surface of endothelial cells, they are exposed to the action of endothelial lipoprotein lipase for cleavage to unesterified fatty acids. Consecutively they are bound to albumin, the major fatty acid transporting molecule in blood serving to keep fatty acids in solution for sufficient cellular delivery.

Another cell type that is of special interest to fatty acid utilization is the endothelial cell. In the heart, there is a tight barrier of endothelial cells separating blood [where fatty acids are tightly bound to albumin ($K_D$, $10^{-8}$)] from cardiomyocytes. The impervious interendothelial junctions do not allow any paracellular permeation of fatty acids (3) (Fig. 1). Because endothelial cells use only a small fraction of fatty acids for their own energy requirements (4), they channel the bulk of fatty acids unmetabolized from the blood to the subendothelial space from which they are taken up by cardiomyocytes. For uptake and translocation across endothelial cells, it was recently shown that fatty acids enter vesicular compartments that might shuttle unmetabolized fatty acids into the subendothelial space (Ring, A., Pohl, J., Völkl, A., and Stremmel, W., unpublished results). The vesicles represented caveolae as well as clathrin-coated vesicles. This vesicular uptake route of endothelial cells is fast and efficient, and requires dissociation of fatty acid:albumin complexes at the cell surface (see below). In addition, a rather slow pinocytotic transport system could operate with low-affinity albumin binding sites, allowing transcellular translocation and delivery of fatty acid:albumin complexes to the subendothelial space (5). Here the albumin molecules accept fatty acids translocated through the endothelium and present them to the

Abbreviations: ACBP, acyl-CoA binding proteins; ER, endoplasmic reticulum; $FABP_c$, cytosolic fatty acid binding protein; $FABP_{pm}$, plasma membrane fatty acid binding protein; FAT, fatty acid translocase; FATP, fatty acid transport protein; mAspAT, mitochondrial aspartate aminotransferase; PPAR, peroxisome proliferator-activated receptor; VLDL, very low density lipoproteins.

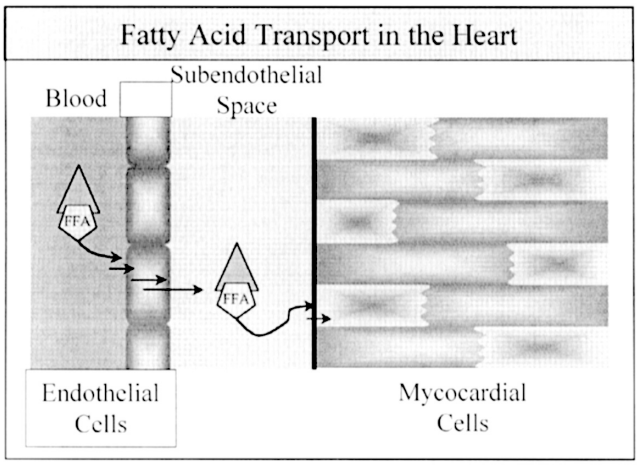

**FIG. 1.** From the vascular system to cardiomyocytes, fatty acids have to pass various barriers. After dissociation from albumin, they enter the endothelial cell layer by specific plasma membrane fatty acid uptake systems. This is followed by transcytosis and release to the subendothelial space. Here, albumin serves again as acceptor and delivery molecule to plasma membranes of cardiomyocytes. Specific membrane transport systems control the entry into parenchymal cells for metabolic disposition in the heart, particularly to β-oxidation for ATP production.

adjacent parenchymal cells for uptake. An alternative hypothesis postulates direct cell–cell contact to shuttle fatty acids from endothelial cells directly to parenchymal cells (6).

## THE MOLECULAR VIEW

The molecular mechanism by which fatty acids enter cells has long been controversial. Theories of passive diffusion across the phospholipid membrane were contrasted by experimental observations compatible with a catalyzed membrane translocation process (7,8). The passive diffusion theory is valid as long as the distribution spaces are lipid compartments, e.g., the inner and outer leaflet of phospholipid bilayers or fused intracellular membranes. Once a fatty acid has entered the outer layer of a phospholipid bilayer, it may be distributed between both membrane compartments according to concentration gradients (9). The solubility of fatty acids in aqueous solutions is very low. Thus only a tiny amount of unbound (free) fatty acids is released from the lipophilic environment into aqueous media. Proteins with defined affinity for fatty acids [e.g., albumin, cytosolic fatty acid binding protein ($FABP_c$)] accumulate fatty acids, thus establishing distribution gradients from lipophilic media toward the aqueous solution. FABP embedded in a membrane can create concentration gradients across phospholipid bilayers and fatty acids can flip-flop accordingly. The presence and concentration of these proteins on both sides of the plasma membrane determine uptake rates in different organs. In the isolated perfused rat heart, single-pass extraction rates of 50% were observed at physiologic fatty acid concentrations (10), whereas in brain, only 1% was extracted.

Because albumin enters cells to a lesser degree than fatty acids, a previous hypothesis postulated high-affinity albumin receptor sites on the plasma membrane, facilitating dissociation of bound fatty acids followed by passive movement across the phospholipid bilayer (11). Several lines of experimental evidence have ruled out this possibility (12,13).

Therefore, the question concerning how fatty acids pass through plasma membranes was of particular interest. The issue was addressed experimentally in different cell types with similar results (14–21). The time course of fatty acid accumulation in hepatocytes revealed a rapid linear initial uptake phase during the first 30 s (22) (Fig. 2). This was followed by a transition phase with declining uptake rates, and a late period characterized by almost linear but low-rate accumulation. The initial uptake phase represents unidirectional (vectorial) fatty acid influx (23). This initial uptake rate was determined as a function of the (calculated) unbound fatty acid concentration applied to the incubation medium (Fig. 3) (22). Modulation of the unbound oleate concentration was achieved by varying the molar ratios of oleate/albumin, leaving either oleate or albumin constant. With increasing unbound oleate concentrations, saturation kinetics were observed with a $K_m$ of 90 nmol/L and a $V_{max}$ of 835 pmol/(min·mg protein) (22). Additional criteria arguing in favor of a carrier-mediated uptake process were as follows: (i) competitive inhibition of uptake by other long-chain fatty acids (24,25) and (ii) inhibition of uptake by protease pretreatment of cells (16). Comparable results were obtained in hepatocytes, cardiomyocytes, intestinal mucosal cells, type II pneumocytes, keratinocytes, and adipocytes (14–20).

For further determination of fatty acid influx, the responsible driving forces were analyzed. In hepatocytes and cardiomyocytes, it was shown that influx was stimulated by $Na^+$ in the medium (16,26,27). Studies using hepatocellular plasma membrane vesicles revealed accelerated fatty acid influx in the presence of a negative intravesicular charge (cation exchange; valinomycin induced $K^+$ depletion) (Fig. 4) (27). Furthermore, it was shown that acidification of the cell inte-

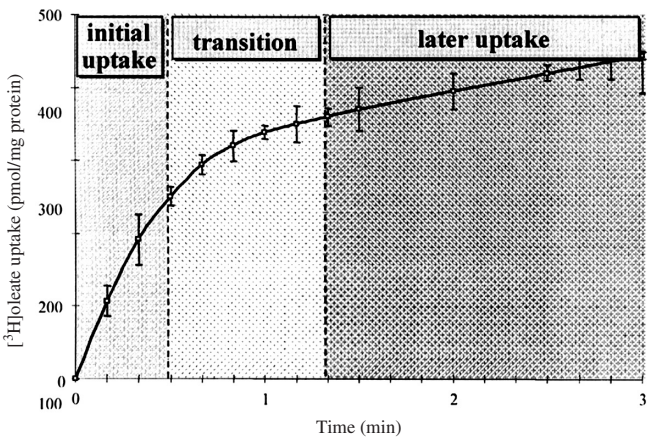

**FIG. 2.** Time course of fatty acid uptake in hepatocytes. Short-term cultured hepatocytes were incubated with [$^3$H]oleate bound to albumin in a molar ratio of 1:1 at 37°C. At the times indicated, the reaction was stopped and uptake determined (22). The initial rapid uptake phase represents cellular influx. This is followed by a transition phase with declining uptake rates. The late uptake period is again almost linear and represents slow intracellular accumulation of fatty acids. (*Source:* Ref. 22.)

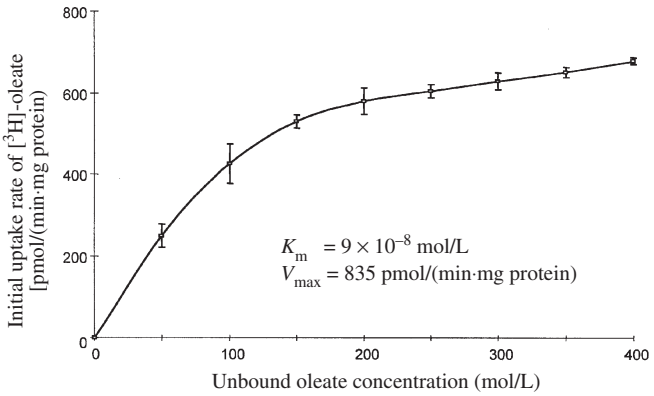

**FIG. 3.** Initial uptake rates of [$^3$H]oleate by short-term cultured hepatocytes as a function of the external unbound oleate concentration. Initial uptake velocities were plotted against the calculated unbound oleate concentration. Saturable influx kinetics indicate the presence of a membrane fatty acid carrier system (22). (*Source:* Ref. 22.)

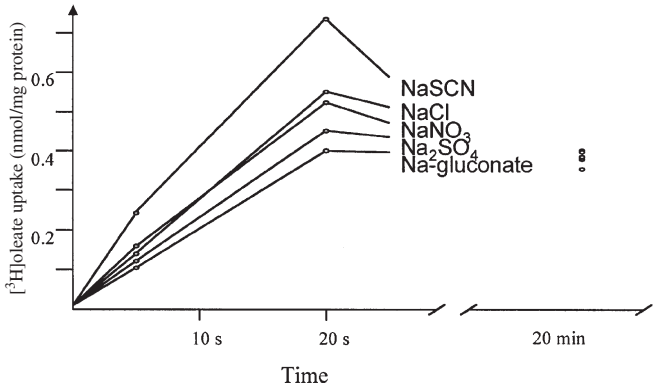

**FIG. 4.** Effect of anion substitution on fatty acid uptake. Hepatocyte plasma membrane vesicles were incubated with 173 µmol/L [$^3$H]oleate:albumin (1:1) at 37°C in the presence of various indicated salts in the medium. In the presence of more permeable accompanying anions ($SCN^- > Cl^- = NO_3^- > SO_4^{2-} >$ gluconate$^-$), $Na^+$-dependent vesicular influx is accelerated (27). It suggests that the translocation of fatty acids across the plasma membrane is stimulated by a relatively more negative intravesicular charge. (*Source:* Ref. 27.)

rior by the $NH_4Cl$ prepulse technique decreased influx velocity, whereas cellular alkalinization stimulated uptake (28). These results are compatible with a $Na^+/H^+$ fatty acid-cotransport system by which fatty acids enter the cell as uncharged or positively charged molecules (Fig. 5).

The next important question was how fatty acids are delivered from the plasma membrane to sites of fatty acid metabolism. Apart from the theory of movement along an intracellular membrane continuum (6), it was shown that they can bind to $FABP_c$ with high affinity (29).Thus, an interaction-mediated transfer of long-chain fatty acids between the cytosolic leaflet of the plasma membrane phospholipid bilayer and $FABP_c$ can be assumed (30). The interactions may occur *via* specific phospholipids and/or membrane proteins, particularly fatty acid translocase (FAT)/CD 36 (30,31). Although only 1–2 mol of fatty acids can be trapped by 1 mol $FABP_c$, the high intracellular concentration of $FABP_c$ seems to be sufficient for operation as a protein-mediated intracellular delivery system (29). This pathway may also play a role in the regulation of intracellular fatty acid metabolism

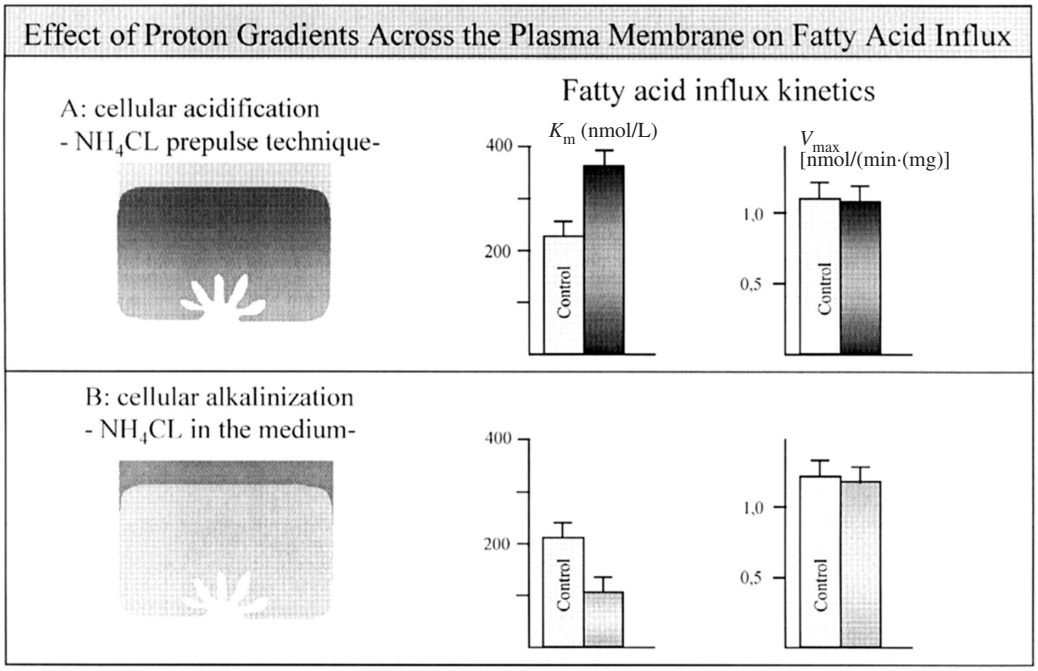

**FIG. 5.** Cellular acidification by the $NH_4Cl$ prepulse technique resulted in a significant $K_m$ increase of fatty acid influx kinetics at unchanged $V_{max}$ values, indicating reduced transporter activity. In contrast, cellular alkalinization decreased $K_m$ at unchanged $V_{max}$ values, indicating increased transport velocity (28). The data are compatible with the hypothesis of a $Na^+/H^+$-fatty acid$^-$ cotransport system by which fatty acids enter the cells as uncharged or positively charged molecules.

(30–32). Indeed, $FABP_c$ can enter the nucleus like the peroxisome proliferator-activated receptor (PPAR) family, which is the main regulator of cellular lipid metabolism (33). As a sensor of the intracellular fatty acid concentration, $FABP_c$ may be involved directly or indirectly *via* PPAR in the transcriptional regulation of responsible genes. Alternatively it was shown that fatty acids bind with high affinity to caveolin-1 at the cytosolic surface of the plasma membrane (34). Caveolins (types 1–3) have been described as integral "hairpin"-like proteins facing the cytosol. They possess an intramembrane region of 33 amino acids anchoring in phospholipid bilayers. Caveolins are essential components of caveolae, which are specific membrane microdomains rich in cholesterol and sphingolipids. Caveolae form typical electron microscopically visible invaginations in the plasma membrane or intracellular vesicular structures, which are functionally involved in important cellular transport processes such as endo- and transcytosis as well as signal transduction pathways (35,36). Their role in cellular cholesterol transport is well established (37). Recently we found that fatty acids taken up by Hep G2 hepatoma cells travel within a vesicular compartment staining positive for caveolin-1. This suggests fatty acid transport by caveolae (Pohl, J., Ring, A., and Stremmel, W., unpublished data). Previously, vesicular uptake was visualized in native rat hepatocytes (38) (Fig. 6). We suggest that fatty acids accumulate within the caveolar membrane and are subsequently delivered to subcellular compartments for further metabolism. Such a caveolin-mediated intracellular delivery system would allow a high number of fatty acids to be transported within the cell.

How fatty acids are incorporated into the caveolae membrane (bound to caveolin-1) remains unclear. The notion that caveolin-1 is anchored within the cytosolic leaflet of the plasma membrane could imply that it may serve as an immediate acceptor protein for membrane translocated fatty acids. This may lead to membrane asymmetry and could eventually induce budding of caveolae from the plasma membrane and formation of vesicles. Alternatively, membrane translocated fatty acids could be incorporated into preformed caveolar vesicles by membrane collision and/or binding to caveolin-1. Most intriguing is the thought that caveolae are loaded with unmetabolized fatty acids *via* direct interaction with $FABP_c$, serving as an intermediate delivery pool.

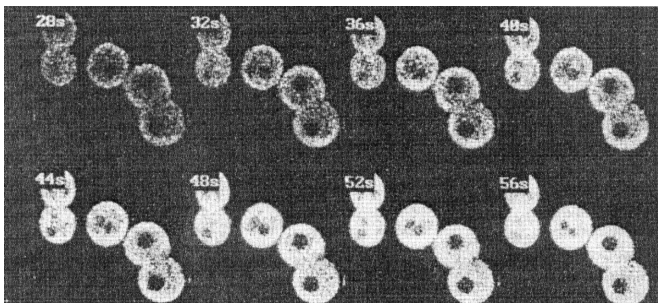

**FIG. 6.** Confocal visualization of 12-*N*-methyl-7-nitrobenzo-2-oxa-1,3-diazol amino stearate (12-NBD stearate) uptake into hepatocytes. Short-time cultured hepatocytes were superfused with the incubation medium containing 50 µmol/L 12-NBD stearate and 25 µmol/L bovine serum albumin. Illustrated is the sequence of pictures obtained between 12 and 56 s of incubation using the frame mode of the confocal laser scanning microscopy system. Uptake into hepatocytes revealed a granular staining pattern starting from the area of the plasma membrane toward the cytosol. It suggests that the bulk of fatty acid uptake is mediated by a vesicular uptake route. (*Source:* Ref. 38.)

The mechanism of interaction between intracellular fatty acids and subcellular organelles is unclear. It is probably controlled by the metabolic demand of the cell, directing fatty acids for ATP production to mitochondria or for storage as triglycerides to the ER. Activation to acyl-CoA is required for any kind of metabolic disposition. It has been long believed that acyl-CoA does not pass biological membranes.

Therefore, it was postulated that native fatty acids first enter the subcellular compartment of destination before undergoing acyl-CoA activation and further metabolism. An alternative hypothesis postulates activation at the outer membrane surface of the organelle. From there, acyl-CoA can be taken up *via* acyl-CoA membrane translocating systems, e.g., by the carnitin shuttle into mitochondria for β-oxidation, or by the ABC transporter assembly into peroxisomes for synthesis of specialized lipids (39). Triglyceride and other complex lipid synthesis can occur at the outer leaflet of the ER membrane, contributing to the formation of lipid droplets. Whether the latter process may also take place at the cytoplasmic site of the plasma membrane is not yet established. Lipid droplet formation can be associated with accumulation of caveolins in their periphery, serving in intracellular trafficking of lipids *via* caveolae (37).

According to the facts presented above and to theoretical considerations, cellular uptake of fatty acids requires a continuous flow down a concentration gradient starting from the amount of fatty acids presented to the plasma membrane until acyl-CoA activation for final metabolic disposition by subcellular compartments. Thus, uptake is eventually regulated by the cellular metabolic demand. The steps in the uptake cascade are as follows: fatty acid:albumin complexes presented to the plasma membrane; dissociation of the complex and binding to plasma membrane proteins with high affinity for fatty acids; flip-flop to the cytosolic leaflet facilitated by an interphospholipid bilayer concentration gradient; binding to $FABP_c$ and caveolin followed by incorporation into caveolae; discharge from the plasma membrane and delivery to subcellular compartments; and activation to acyl-CoA. This overall flow rate represents the total uptake velocity, which is described by saturation kinetics (Fig. 3).

## THE PLAYERS

In the last two decades, most attention has focused on the identification of the responsible membrane fatty acid carrier protein. This question has been difficult, subject to controversies, and may finally be insoluble owing to the complex characteristics of the overall uptake described above. In the following section, we focus briefly on only three of the proposed candidate players (for more details please refer to the cited literature).

*(i) FAT/CD36.* FAT/CD 36 is a 80-kDa protein with two proposed transmembrane spanning domains, very short N- and C-terminal intracytoplasmic domains, and an extracellular glycosylated loop (Fig. 7) (40,41). It may accelerate fatty acid dissociation from albumin and catalyze integration of protonized fatty acids into the outer phospholipid bilayer of the plasma membrane. This accumulation of fatty acids creates a diffusional gradient across the plasma membrane, which is followed subsequently by a flip-flop of fatty acids to the inner leaflet (FAT-catalyzed facilitated diffusion). Expression of this translocase in fibroblasts lacking CD 36 revealed a phloretin-sensitive, very high affinity, saturable fatty acid uptake component ($K_m$, 4 nmol/L) (42). For translocation across the plasma membrane and further on to the cytosol, an interaction with $FABP_c$ has been proposed (30,31).

Also of interest is the observation that the lipoprotein receptor SR-B1, which shares homologies with FAT/CD 36, was shown to co-localize with caveolin (43). This would suggest that FAT might interact with the caveolae-linked uptake route described above. For FAT/CD 36, an intracellular vesicular recruitment compartment has been suggested (44). At least in muscle cells, the protein was shown to reside at the sarcolemma as well as in an intracellular ("endosomal") pool; upon muscle contraction, FAT/CD 36 is redistributed toward the sarcolemma with a concomitant increase in the rate of muscular fatty acid uptake (44). Moreover, hormones such as insulin also can trigger the translocation of FAT/CD 36 to the cell surface (30). These observations indicate that FAT/CD 36–mediated fatty acid uptake can actively be regulated by translocation of the protein from intracellular stores to the plasma membrane.

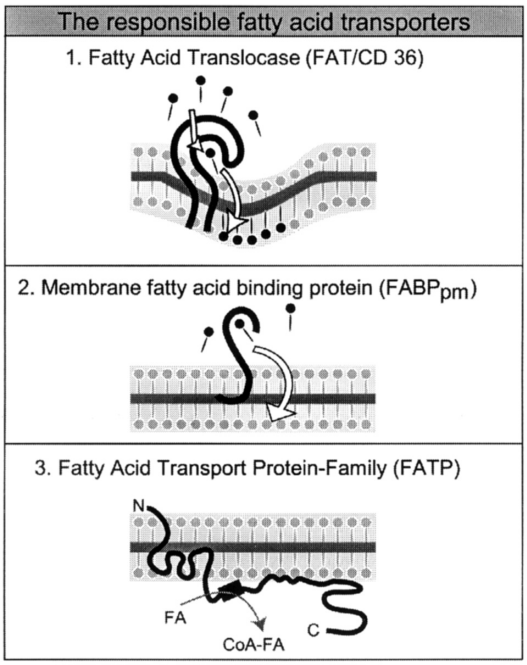

**FIG. 7.** Illustration of three major membrane fatty acid (FA) transport systems. Fatty acid translocase (FAT)/CD 36 is a 80-kDa protein characterized by two transmembrane spanning domains, short intracytoplasmatic tails, and an extracellular glycosylated loop. It translocates native long-chain FA with high affinity across the plasma membrane. Plasma membrane fatty acid-binding protein ($FABP_{pm}$) is a 40-kDa protein, loosely associated with plasma membranes. It represents the membrane-bound form of mitochondrial aspartate aminotransferase (mAspAT). It has an affinity for long-chain FA, and is involved in cellular uptake of long-chain FA. The FA transport protein (FATP) family represents a group of membrane-associated proteins involved in the overall FA uptake process by activating them to acyl-CoA (ACS-activity) at a conserved cytosolic AMP binding site. FATP 1-5/6 have varying N-termini associated with a single transmembrane spanning domain representing different intracellular targeting signals or binding domains for specified proteins.

FAT is not present in hepatocytes but is found at high levels in colon and spleen (40). This differential expression indicates that it is not the only carrier for fatty acids throughout the organism and that it may also be involved in other cellular functions. CD 36–deficient mice reveal impaired fatty acid uptake in the heart, adipose tissue, and muscle, but show normal uptake in liver and intestine (45).

*(ii) $FABP_{pm}$.* is a 40-kDa protein anchored to the outer leaflet of the plasma membrane with its hydrophobic tail (Fig. 7) (46,47). The implication of its involvement in the overall uptake process of fatty acids was documented by antibody inhibition experiments (14–16,20) as well as transfection studies (48,49). The protein is identical to mitochondrial aspartate aminotransferase (mAspAT), thus revealing two different functions in two separate cell compartments (46). It is conceivable that on its passage to the vascular system, the protein is briefly trapped in the outer plasma membrane leaflet with its lipophilic tail binding fatty acids with high affinity, thus facilitating dissociation from albumin (47). After protonization, fatty acids can accumulate in the outer leaflet of the phospholipid bilayer (28). According to the resulting intramembrane concentration gradient, they flip-flop to the inner leaflet. Here they may be bound by $FABP_c$ or caveolin-1 and enter the cells as proposed above. There is a differential distribution of $FABP_{pm}$ throughout the organism, indicating that it does not represent an exclusive fatty acid transport system. It is even possible that other proteins with mAspAT-like properties exist and also operate as FABP on the outer leaflet of the plasma membrane. The requirements are as follows: high abundance, plasma membrane passage, hydrophobic tails for retainment in the outer phospholipid bilayer, and high affinity for fatty acids to mediate dissociation from albumin. Apparently, not too many different proteins meet these criteria because an antibody to $FABP_{pm}$ alone resulted in a 65% inhibition of fatty acid uptake in certain cell types (14–17,21). Nevertheless, the specificity of $FABP_{pm}$ as a fatty acid carrier has to be questioned in view of the rather unspecific characteristics mentioned above. If in the future, proteins with similar characteristics should be identified, this would indicate that the essential function of cellular fatty acid delivery is functionally highly conserved by the option of mutual substitution.

*(iii) FATP family.* The FATP family represents a group of membrane proteins with a molecular weight of 63 kDa. The name was originally created when two proteins leading to cellular enrichment of a fluorescent fatty acid were identified using expression cloning from a murine adipocyte cDNA library (50). One was the known long-chain fatty acid

acyl-CoA synthetase; the other was unknown and was named FATP. In fact, fatty acid uptake studies with stably transfected 293 cells revealed a three- to fourfold increase of fatty acid accumulation over controls.

To date, five members of this family have been described in mice and six in humans (FATP 1-5/6) (51). By hydropathy plot analysis, it was originally proposed that FATP have six transmembrane domains and it was assumed that the N- and C-termini face the cytosolic site of the phospholipid bilayer (50). A more recent detailed analysis of the membrane topology of FATP 1 revealed only one transmembrane domain (52). In addition, the molecule is preferentially oriented toward the cytoplasm with two membrane loops within the inner leaflet, peripheral membrane–associated domains, and two large stretches of nonmembrane-associated residues carrying the highly conserved AMP binding site and the C-terminus (52) (Fig. 7). Only a very short segment of the N-terminus faces the luminal/extracellular site of the membrane bilayer. The N-terminal 51 amino acids of the protein family members are variable (51), and they may represent specific targeting signals for different subcellular compartments. The protein is not glycosylated and does not resemble a typical transmembrane transport protein (52). Binding sites for fatty acids are not defined. The most interesting region of this membrane-anchored protein family is the highly conserved AMP binding region (53). Carefully conducted studies by a number of investigators demonstrated CoA-synthetase activity of FATP 1, 2, 4, and 5 toward various lipid compounds, particularly fatty acids (54–60). Although some substrate specificity was demonstrated, e.g., for very long-chain fatty acids by FATP 1, 2, and 4, this does not rule out the general capability of activating long-chain fatty acids and other related compounds as well. This enzymatic activity could be linked to the conserved AMP binding site of FATP. It is challenging that facilitation of cellular fatty acid uptake may be due to this long-chain acyl-CoA synthetase activity, stimulating fatty acid flow through membranes as described above. In fact, its putative function as direct fatty acid carrier is not well supported by its structural conformation and membrane topology. Another challenging thought relates to the differential subcellular distribution of this protein family. Apart from the initial report localizing FATP 1 to the plasma membrane (50), FATP 2 was found in peroxisomes (55) and the ER (57). FATP 1 (52) and FATP 4 (Herrmann, T., Rost, D., Pohl, J., and Stremmel, W., unpublished observation) were also demonstrated in the ER. This distinct subcellular localization might be mediated by the variable amino termini of the different FATP. From a common origin in the ER as delivery compartment, it could be assumed that the N-terminal assembly with other proteins is capable of directing the complex to subcellular compartments for incorporation into the specific metabolic disposition pathways (61). Accordingly, different cell types with different metabolic requirements could reveal a specific pattern of FATP. By this mechanism, a tuned adaptation and regulation of fatty acid metabolism according to the demands of a cell appears plausible. For FATP 1, a preferential localization at the plasma membrane was shown (50). Its capability to activate fatty acids to acyl-CoA could be utilized for complex lipid synthesis at this site or binding to acyl-CoA binding proteins (ACBP) for intracellular transport. In addition, the preferential activation of very long-chain fatty acids (54) could indicate a role in the intracellular signaling pathways by transfer of fatty acids to PPAR. FATP 4 is preferentially, but not exclusively, detectable in the intestinal mucosal cells and is essentially involved in fatty acid absorption (62,63). Triglyceride and phospholipid synthesis in the ER is a prominent feature of these cells. Therefore, it is conceivable that FATP 4 might play a role in activation of absorbed fatty acids to acyl-CoA for triglyceride synthesis at the ER. In these cells, the ER is closely attached to the microvillous plasma membrane. Such a proposed involvement of FATP 4 in triglyceride formation would indicate a vital function of this protein throughout the organism.

## THE CONCEPT

According to the facts described above and to theoretical considerations, the following working hypothesis can be derived (Fig. 8). At the outer leaflet of the plasma membrane, fatty acids are dissociated from albumin. In different cell types, a concert of different membrane-associated proteins with affinity for long-chain fatty acids facilitates this dissociation process. The best-described candidates of such membrane proteins are FAT (CD 36) and $FABP_{pm}$. Fatty acids dissociated from albumin accumulate in the vicinity of these proteins on the surface of the plasma membrane. Here, fatty acid anions are protonized and rapidly integrate into the external phospholipid bilayer as uncharged molecules. Thus, a concentration gradient toward the inner leaflet is created and fatty acids flip-flop across (passive diffusion component). Here they can be transferred to $FABP_c$.

An interaction of $FABP_c$ with anionic phospholipids and/or FAT/CD 36 has in fact been proposed (30,31,64–67). This could promote the vectorial transport of fatty acids across the plasma membrane. Holo-$FABP_c$ could then serve in intracellular distribution of unmetabolized fatty acids. Because it can also enter the nucleus, a regulatory function has been suggested (see above). It is also quite conceivable that holo-$FABP_c$ can provide fatty acids to preformed caveolar vesicles by protein–phospholipid or protein–protein interaction with caveolins.

Alternatively or complementarily, membrane-translocated fatty acids could bind with high affinity to caveolins (34) embedded in the inner leaflet of the plasma membranes or in the outer leaflet of preformed caveolae colliding with the plasma membrane. A caveolin positive-vesicular uptake component could be visualized in hepatoma as well as in endothelial cells (see above). Caveolae thus may serve as high-capacity intracellular lipid transport vehicles, delivering the bulk of fatty acids to different subcellular compartments for further metabolic disposition. A comparative quantification of both complementary routes of intracellular fatty acid transport ($FABP_c$- and caveolae-mediated) cannot be estimated at present.

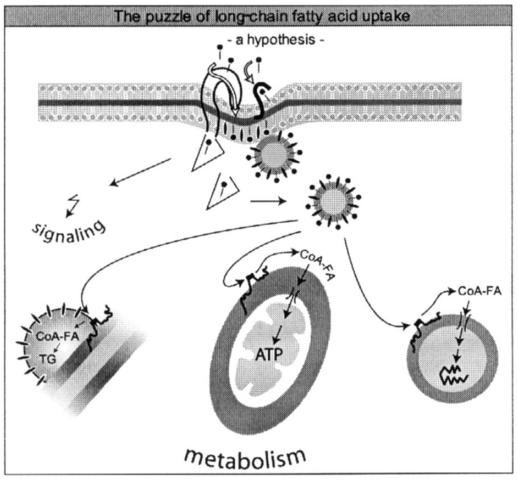

**FIG. 8.** The overall cellular uptake of fatty acids represents a continuous flow from fatty acid:albumin complexes at the cell surface to acyl-CoA formation as the first step in metabolic disposition of fatty acids. At the surface of the plasma membrane, FAT and $FABP_{pm}$ mediate fatty acid dissociation from albumin. After protonization, fatty acids flip-flop across to the inner leaflet of the membrane. Here they are transferred to cytosolic fatty acid binding protein ($FABP_c$) serving as protein-mediated intracellular fatty acid delivery system as well as signaling molecules for fatty acid metabolism. Interaction with caveolins allows incorporation into caveolae. Intracellular trafficking within these vesicles may represent the pathway for uptake of the bulk of fatty acids. At the cytosolic surface of different subcellular compartments, different FATP activate the fatty acids presented to acyl-CoA for channeling to further metabolic disposition. Plasma membrane localized FATP may be responsible for generation of acyl-CoA, which can be loaded onto cytosolic binding proteins (ACBP). Moreover, binding to peroxisome proliferator-activated receptors (PPAR) for signaling or involvement in complex lipid synthesis at this site is a further option. Endoplastic reticulum (ER)-associated FATP may be responsible for lipid droplet formation (triglyceride synthesis), which serves as an intracellular energy storage compartment. At the mitochondria and peroxisomes, FATP may provide acyl-CoA for translocation into the organelles for oxidation and synthesis of specialized lipids (symbols are illustrated in Figure 7). See Figure 7 legend for other abbreviations.

Up to this point, the uptake pathway described apparently does not require energy. It represents a continuous flow of fatty acids, involving membrane binding proteins, rapid flip-flop across the membrane, transfer to $FABP_c$, and possibly integration into caveolin-associated membrane structures. The uptake flow ends at subcellular compartments in which the metabolic disposition of fatty acids is determined. Here the family of FATP enters the stage. By their acyl-CoA synthetase activity, fatty acids are activated as the first step of any kind of metabolism. This could occur exclusively at the plasma membrane level from which acyl-CoA bound to cytosolic binding proteins (ACBP) is transported to sites of metabolic demand. Alternatively it could occur directly at subcellular compartments, which would require special targeting signals of FATP themselves or association with certain proteins directing FATP to the required functional location. The last-mentioned options appear more plausible due to the variable N-terminus of different FATP (signaling sequence) constituting the single transmembrane region of this protein. After physical linking to the site of metabolic disposition, the protein could act as a membrane-associated enzyme facing the cytosol with its catalytic end. Plasma membrane-associated FATP 1 could activate fatty acids for loading of ACBP, or for transfer to PPAR serving the signaling pathways, or for complex lipid synthesis at the cytosolic plasma membrane leaflet. At the ER, FATP might be involved in lipid droplet formation (37) (e.g., for synthesis of triglycerides). Mitochondrial and peroxisomal FATP could activate fatty acids for translocation *via* the carnitine shuttle into mitochondria and for a proposed acyl-CoA transporter in the peroxisomal membrane, respectively. Whether the distinct patterns of FATP distribution in different cell types represent a physiologic adaptation to their respective metabolic demand or are due to an organ-specific, genetically determined transcriptional control of FATP synthesis is unresolved.

The proposed concept relates to the principal mechanism of fatty acid uptake and does not cover specificities of certain cell types, e.g., endothelial cells. It represents hypotheses in addition to a summary of experimentally proven facts and certainly reflects our personal view.

## ACKNOWLEDGEMENTS

# Polyunsaturated Fatty Acid Supply with Human Milk

**T.U. Sauerwald*, H. Demmelmair, and B. Koletzko**

Kinderklinik and Kinderpoliklinik, Dr. von Haunersches Kinderspital, Ludwig-Maximilians-University, Munich, Germany

**ABSTRACT:** Polyunsaturated fatty acids in human milk may derive from diet, liberation from maternal body stores, or endogenous synthesis from precursor fatty acids. The contribution of each of these sources has not been studied in detail. Although maternal diet is a key factor affecting human milk composition, other factors such as gestational age, stage of lactation, nutritional status, and genetic background are known to influence the fat content and fatty acid composition in human milk. Both linoleic and α-linolenic acids, the essential fatty acids, are present in human milk, as are several other n-6 and n-3 longer chain polyunsaturated fatty acids that are required for optimal growth and development of infants. The fatty acid profile of human milk from lactating women of different countries is remarkably stable, but there is variability in some of the components, such as docosahexaenoic acid, which is mainly due to differences in dietary habits. Tracer techniques with stable isotopes have been valuable in assessing the kinetics of fatty acid metabolism during lactation and in determining the origin of fatty acids in human milk. Based on these studies, the major part of polyunsaturated fatty acids in human milk seems not to be provided directly from the diet but from maternal tissue stores.

Paper no. L8642 in *Lipids 36*, 991–996 (September 2001).

Human milk is a unique mixture of lipids that delivers several polyunsaturated fatty acids (PUFA) to the breast-fed infant. With a fat content of about 4% in mature milk, most of these fatty acids are found in triglycerides (98%) and only a minor portion in phospholipids (1%) and other components (1). The amounts of saturated and monounsaturated fatty acids in human milk are large when compared to PUFA. In contrast to saturated and monounsaturated fatty acids, which can be derived from endogenous synthesis, the major part of PUFA in human milk is essential fatty acids, which cannot be synthesized endogenously by mother or infant and, therefore, have to be provided with the diet. The essentiality of both linoleic acid (LA), the precursor of the n-6 series, and α-linolenic acid (ALA), the precursor of the n-3 series, has been known for many years (2,3). Interestingly, both fatty acids compete for the same enzymes for desaturation and elongation (see Fig. 1). Some of their products, including arachidonic acid (AA) and docosahexaenoic acid (DHA), play important roles in infant growth and neurodevelopment (4,5). Furthermore, PUFA in human milk may serve as precursors for eicosanoids, which are potent modulators of processes such as vasoconstriction and immunoreactivity (6). Many studies have focused on human milk fatty acid composition and the effects of different diets. Here we report on different aspects influencing the PUFA composition in human milk and on results of dietary supplementation studies. Furthermore, we present some newer studies using tracer techniques with stable isotopes to assess the origin and metabolism of PUFA during lactation.

## PUFA IN HUMAN MILK

Some 214 different fatty acids have been characterized in human milk, of which 40 are polyunsaturated (7). Usually, only 35 to 40 different fatty acids, including 10 to 15 PUFA, are reported in studies on human milk composition, because they represent the major portion and can be analyzed by the commonly available chromatographic methods. Fatty acids are not randomly distributed within the triglyceride molecules. It is well known that palmitic acid, for example, is preferentially found in the *sn*-2 position and that lipases hydrolyze more of the fatty acids localized at the *sn*-1 and *sn*-3 positions (8). This has been demonstrated to affect absorption of fat and calcium in infants (9). For LA and ALA preferential binding to the *sn*-2 and *sn*-1 hydroxyl groups of the glycerol backbone has been described. Long-chain polyunsaturated fatty acids (LC-PUFA) such as AA and DHA have been found primarily in the *sn*-2 and *sn*-3 positions (8).

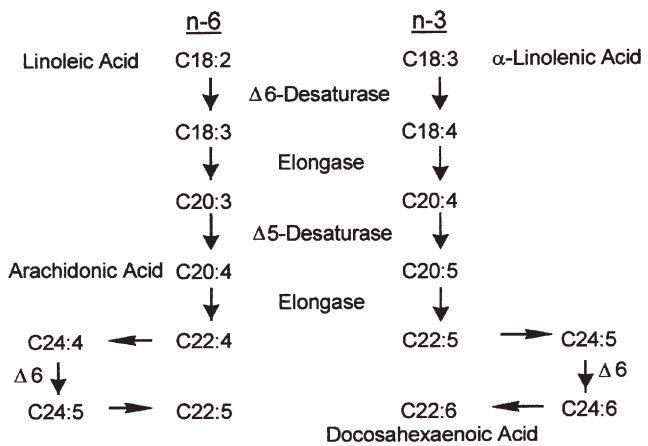

**FIG. 1.** Revised pathways of polyunsaturated fatty acids [based on data from Sprecher *et al.* (50)].

Abbreviations: ALA, α-linolenic acid, 18:3n-3; AA, arachidonic acid, 20:4n-6; DHA, docosahexaenoic acid, 22:6n-3; EPA, eicosapentaenoic acid, 20:5n-3; LA, linoleic acid, 18:2n-6; LC-PUFA, long-chain polyunsaturated fatty acids; PUFA, polyunsaturated fatty acids.

*Changes with lactational stages.* Even during a single feeding, the amount of fat secreted into human milk changes. At the beginning, in foremilk, a fat content of about 1–3% is present, whereas in the last portion of human milk, the hindmilk, the fat content is increased to about 5–8% (10). This phenomenon is related to fat synthesis and its excretion *via* the fat globules in the mammary gland. During breast-feeding, the size of these fat globules increases. In neonatal care units, hindmilk has been used with success for enhancing weight gain in low-birth-weight infants (11). Also with advancing lactation, the fat content increases in colostrum, transitional, and mature milk from about 2% on day 3 postpartum to more than 4% at around 3 mon (12). For single fatty acids, relative changes have also been observed. In a study by Genzel-Boroviczeny *et al.* (13) over the first 30 d postpartum, LA and ALA increased slightly, whereas AA and DHA decreased significantly. No differences were observed between preterm and term mother's milk in that study. A study by Makrides *et al.* (14) that followed lactating mothers until 30 wk postpartum demonstrated a similar decrease of AA and DHA over time. However, because total fat content increases with advancing lactation, the absolute amounts of LC-PUFA excretion remain relatively stable.

*Essential fatty acids.* The most abundant PUFA in human milk is LA. The content of LA in human milk seems to have increased twofold over the last decades (7), which may reflect a shift in the Western world's diet toward higher consumption of n-6 fatty acids. An imbalance of the precursors LA and ALA in the diet might lead to an imbalance of product fatty acids of the n-6 and n-3 series. The influence of the LA/ALA ratio (or different intakes of ALA) on endogenous synthesis of LC-PUFA has been studied in infants (15) and adults (16) with the use of stable isotopes. In the study in infants, a lower LA/ALA ratio (or higher intake of ALA) resulted in a higher incorporation of DHA into plasma phospholipids and, at the same time, in a decreased incorporation of AA into plasma phospholipids. In the study in adults, high vs. low intake of LA also had effects on endogenous LC-PUFA synthesis. Further, an imbalanced ratio of LA and ALA is thought to interfere with an appropriate functioning of the immune system (6,17). The LA/LA ratio is on the order of 5:1 to 15:1 in most milks (18). This ratio has also been proposed by the European Society for Paediatric Gastroenterology and and Nutrition (ESPGAN) for infant formula feeding (19). The LA/ALA ratios found in different studies of human milk composition are presented in Table 1, with some extreme values observed in South Africa (20).

*LC-PUFA.* AA and DHA, the two predominant LC-PUFA in human milk, are known to be required for normal development of infants (4). The amounts of LC-PUFA in human milk in most samples are at least 10-fold lower than those of LA. The most abundant LC-PUFA of the n-6 and n-3 series in human milk and normally reported in compositional studies are 20:2n-6, 20:3n-6, 20:4n-6, and 22:4n-6, and 20:5n-3, 22:5n-3, and 22:6n-3. These fatty acids can also be formed endogenously from precursors, even in the very premature infant (21,22). The absolute amounts of endogenous synthesis and the definite amounts required for optimal development in infants remain to be determined. The amounts of AA and DHA in human milk have been used as some guidelines for infant formula contents of LC-PUFA. PUFA and LC-PUFA profiles in human milk are to some extent remarkably stable (18). On the other hand, there are also quite variable amounts of LC-PUFA, especially DHA, the amount of which varies about 20-fold under certain dietary circumstances (23). Levels reported for DHA in human milk in various countries are presented in Figure 2. Low levels of DHA are found in human milk in the United States (24), and very high levels are found in human milk of mothers consuming marine diets in China (23).

| LA | 14.7 | 10.8 | 13.0 | 15.8 | 16.2 |
| AA | 0.8 | 0.4 | 0.3 | 0.6 | 0.6 |
| ALA | 1.3 | 0.8 | 0.8 | 0.8 | 0.4 |
| DHA | 0.4 | 0.2 | 0.4 | 0.1 | 0.2 |
| LA/ALA ratio | 11.3 | 13.3 | 15.5 | 18.8 | 40.5 |

[a]Abbreviations: LA, linoleic acid; AA, arachidonic acid; ALA, α-linolenic acid; DHA, docosahexenoic acid.

*Human milk samples from different countries.* Most mean or median values for PUFA in human milk in different countries are quite similar. Reported LA values range from a value of 7% (wt% of total) in the United Kingdom (25) to a value of 21% in China (23), with values in most countries falling in the range of 10–15% (see Table 1). Reported ALA values range from 0.4% in South Africa (20) to 3.0% in China (23). Although methodologies might also influence to some extent the detection of LC-PUFA, a remarkably similar content of AA in human milk is found worldwide, with values ranging from 0.3 to 0.9%. More variation is found in the content of DHA (see Fig. 2); as noted above, a 20-fold variation was found in a study conducted within China (23).

*Maternal diet.* Maternal diet is an important factor influencing human milk fatty acid composition. The differences observed in human milk of mothers from different countries therefore appear to reflect primarily different diets. The long-term effects of vegan/vegetarian, high-fish, and omnivorous diets are well known. Because vegans/vegetarians have high intakes of LA and ALA, the levels of these fatty acids in their milk are among the highest values observed in human milk (26). Fish intake is related to eicosapentaenoic acid (EPA) and DHA levels in human milk, with highest values observed in Inuit women (27) and in Chinese women consuming high amounts of marine foods (23). The rapidity of dietary influences on human milk fatty acids has recently been demonstrated in 14 lactating women drinking test formulas containing different fats (28). Increases in human milk of certain marker fatty acids were observed within 6 h of consumption of the test formulas. Maxima were reached at 10 h for ALA (safflower oil), at 14 h for EPA (menhaden oil), and at 24 h for DHA (herring and menhaden oil).

## SHORT- AND LONG-TERM STUDIES OF FATTY ACID SUPPLEMENTATION

The first studies on the influence of dietary alterations on human milk fatty acid composition were reported by Söderhjelm in 1953 (29) and Insull *et al.* in 1959 (30). The methods available at that time allowed only limited detection of individual PUFA. In the study of Insull *et al.*, from one lactating woman the sum of LA and ALA in the milk changed from 10% to well over 40% after a switch to a diet rich in corn oil. Fish oil in a dose of 5, 10, or 47 g was used in a supplementation study by Harris *et al.* (31) and led to increases in the n-3 fatty acids. DHA values increased in that study after a maximum of 4 wk of supplementation from 0.1% at baseline to 0.5, 0.8, and 1.9% of total fatty acids, respectively. Similarly, in another study, fish oil supplementation in a dose of 6 g/d over 3 wk resulted in an increase of DHA from 0.37 to 0.70% at the end of the study (32). In recent studies single-cell oils and DHA-enriched eggs have also been used as sources for DHA supplementation (33,34). Makrides *et al.* (33) reported breast-feeding mothers supplementing with a placebo or 0.2, 0.4, 0.9, or 1.3 g DHA/d (33). After about 11 wk of supplementation, the DHA levels were 0.21, 0.35, 0.46, 0.86, and 1.13 wt% of total fatty acids, respectively, and increased in a dose-dependent manner. Fatty acids other than DHA were not influenced by the dietary intervention. In a recent study, we found about the same effect on human milk DHA levels as reported above for a supplementation with 200 mg DHA/d (35). In the study of Jensen *et al.* (34), three different dietary sources of DHA (single-cell oil, fish oil, and DHA-enriched eggs) were given to lactating mothers, and fatty acid composition of human milk lipids and maternal and infant plasma phospholipids was measured (34). DHA supplementation from 2 to 8 wk postpartum with 170–260 mg/d increased DHA levels in human milk by about 0.07–0.21 mol%. Significant correlations were observed in that study between DHA contents of maternal plasma and human milk and of milk and infant plasma phospholipids

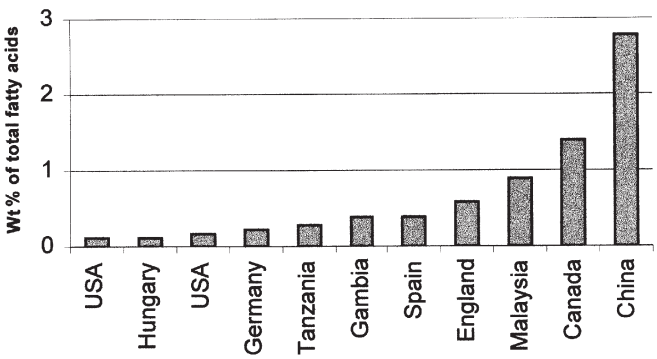

**FIG. 2.** Docosahexaenoic acid (DHA) content in human milk samples of different countries (wt% of total fatty acids; mean or median values): USA (24), Hungary (44), USA (12), Germany (48), Tanzania (51), Gambia (49), Spain (47), England (25) , Malaysia (52), Canada (Inuit) (27), China (23).

## *IN VIVO* STUDIES OF FATTY ACID METABOLISM DURING LACTATION

Methods using stable-isotope-labeled substrates have been increasingly used in the recent past for diagnostic and research purposes (36). The availability of adequate tracers has also contributed to the feasibility of studying metabolic processes *in vivo* during pregnancy, lactation, and the neonatal period. Studies in such individuals with radioactive isotopes would obviously be unethical. In contrast, the use of stable isotopes as tracers has been shown to be safe and without adverse effects.

There are only a few studies investigating the *in vivo* metabolism of fatty acids in lactating mothers. The first report appeared more than 10 years ago and described the transfer of deuterated dietary palmitic, oleic, and linoleic acid into milk in three breast-feeding women (37). There were no differences in the secretion of the individual fatty acids. Tracer fatty acids provided as triglycerides with a defined diet were transported primarily by triglycerides within the chylomicrons and very low density lipoproteins. A delay of about 6 h was observed between maximal enrichments in plasma and human milk. From the tracer transfer into human milk, it was

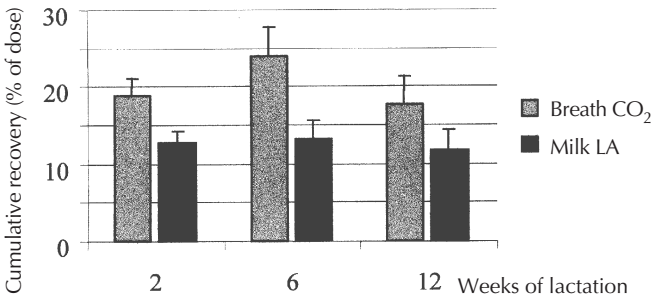

**FIG. 3.** Cumulative recovery of [$^{13}$C]linoleic acid in breath $CO_2$ and in human milk linoleic acid (LA) 5 d after tracer administration in six lactating women at different weeks postpartum (% of dose; mean ± standard error of the mean; adapted from data of Ref. 38)

concluded that long-chain fatty acids such as palmitic, oleic and linoleic acids from the diet contributed to about 30% of the fat in milk.

In a study of six lactating women on their usual diets, we measured the metabolic disposal of orally given $^{13}$C-labeled linoleic acid (38). These women were studied again in the 2nd, 6th, and 12th wk of lactation. No differences were observed between the three time points in oxidation and transfer of linoleic acid to human milk (see Fig. 3). About 20% of $^{13}$C-linoleic acid was recovered in breath $CO_2$ within 5 d. However, the amount of oxidation might even be somewhat underestimated, because some retention of $CO_2$ in the bicarbonate body pools is known to occur but was not taken into account (39). Transfer of dietary linoleic acid into human milk was estimated to reach 13%. From the data, it was calculated that about 30% of linoleic acid in human milk originates from direct dietary transfer and about 70% from maternal tissue stores. Endogenous synthesis of LC-PUFA such as AA occurred only to a low extent. Only about 3% of the AA in human milk was estimated to be derived from endogenous synthesis from LA.

In another group of 10 lactating women, we investigated the metabolism of $^{13}$C-labeled myristic, palmitic, oleic, and docosahexaenoic acids simultaneously at 6 wk postpartum (35). The labeled fatty acid mixture was similar in fatty acid content to the DHA supplement DHASCO™ (Martek Biosciences Corp., Columbia, MD). Oxidation of the fatty acid mixture and transfer from dietary intake to human milk were

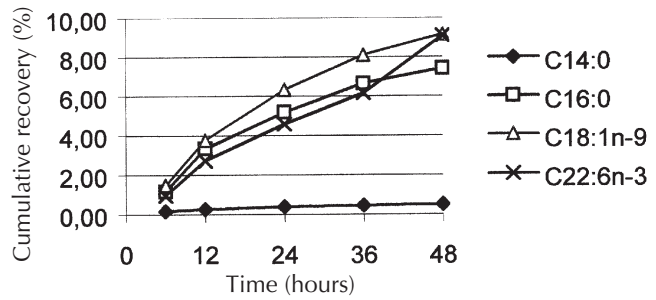

**FIG. 4.** Cumulative recovery of [$^{13}$C]-labeled myristic (14:0), palmitic (16:0), oleic (18:1n-9), and docosahexaenoic acid (22:6n-3) in human milk 48 h after oral tracer administration in 10 lactating women (median values; adapted from data of Ref. 35).

measured over a period of 48 h. Cumulative oxidation of the fatty acid mixture was comparable to our previous observation of linoleic acid oxidation in lactating women (40). The transfer and cumulative recovery of palmitic, oleic, and docosahexaenoic acids in human milk were also comparable and reached about 8% within 48 h. In contrast, the recovery of myristic acid was severalfold lower (see Fig. 4). Medium-chain fatty acids such as myristic acid are readily oxidized, which might explain part of the low direct dietary transfer of this fatty acid (41). Furthermore, extensive *de novo* synthesis of medium-chain fatty acids from carbohydrates has been demonstrated in the mammary gland (42). Our newer studies with $^{13}$C-labeled fatty acids are in good agreement with the earlier study of Hachey *et al*. using deuterated fatty acids (37). Overall, the numerical values obtained from these studies elucidate the flux of different dietary fatty acids during lactation and demonstrate the importance of maternal tissue stores for human milk fatty acid composition. However, long-term dietary intakes affect the tissue fatty acid composition. Therefore, diet remains the key factor in determining the supply of PUFA with human milk.

# Isomeric Fatty Acids: Evaluating Status and Implications for Maternal and Child Health

**Margaret C. Craig-Schmidt***

Department of Nutrition and Food Science, Auburn University, Auburn, Alabama 36849

**ABSTRACT:** "Isomeric fatty acids" is a term that refers to the *trans*- and positional isomers formed during hydrogenation of naturally occurring oils. The purposes of this paper are as follows: (i) to summarize potential exposure of infants to isomeric fatty acids by reviewing estimates of isomeric fatty acids in the maternal diet, in human milk, and in infant formula/infant foods, and (ii) to evaluate the evidence for adverse effects of isomeric fatty acids on infant development with respect to growth and essential fatty acid status. Estimates of the intake of *trans*-fatty acids vary widely both within and across populations. Current estimates of *trans*-fatty acids in the North American population are 4–11% of total fatty acids or 3–13 g/(person·d), whereas in Mediterranean countries in which olive oil is the primary fat and in Far Eastern countries in which little commercially hydrogenated fat is consumed, per capita consumption of *trans*-fatty acids is <1–2 g/d. The *trans*-fatty acid content of human milk reflects the cross-cultural variation in the maternal diet, with *trans*-fatty acids in human milk samples ranging from 6 to 7% in North America to <0.5% in Hong Kong. *Trans*-fatty acids are transferred from the maternal diet through the placenta to the developing fetus or through milk to the breast-fed infant. In some studies, plasma *trans*-fatty acids are inversely related to birth weight and head circumference. The hypothesis that dietary *trans*-fatty acids could inhibit biosynthesis of long-chain polyunsaturated fatty acids with 20 and 22 carbon atoms and thus affect infant development is supported by studies demonstrating an inverse correlation of plasma *trans*-fatty acids with n-3 and n-6 long-chain polyunsaturated fatty acids in infants. However, no such relationship has been observed in human milk. A definitive answer concerning a potentially adverse effect of dietary *trans*-fatty acids on infant development awaits future studies.

Paper no. L8850 in *Lipids 36*, 997–1006 (September 2001).

The polyunsaturated fatty acids (PUFA) found naturally in vegetable oils are modified in structure during the hydrogenation process used in the manufacture of margarine, shortening, and other commercial fats. Similarly, dairy products and meats from ruminant animals contain fat that has been modified by biohydrogenation in the rumen. The term "isomeric" in reference to dietary fat generally refers to those fatty acids in which the double bonds originally present are modified in either conformation (*cis*-/*trans*-) or position by partial hydrogenation. In both the scientific literature and the popular press, however, these fatty acids often are termed "*trans*-fatty acids" with no distinction being made between geometric and positional isomers.

The predominant source of dietary isomeric fatty acids in most Western countries is commercial hydrogenation of vegetable and marine oils (1,2). Although the amount of these fatty acids in products made from commercially hydrogenated fat is highly variable, frying fats can contain up to 40–50% of total fatty acids as *trans*-fatty acids (2). In comparison to commercially hydrogenated fats, meat and dairy products typically contain 1–8% of total fatty acids as *trans*-fatty acids and therefore contribute a smaller proportion of isomeric fatty acids to the Western diet.

Possible detrimental effects of isomeric fatty acids include an unfavorable lipid profile, promotion of cardiovascular disease in adults (3,4), and inhibition of essential fatty acid (EFA) metabolism, influencing infant development (5,6). The purposes of this paper are as follows: (i) to summarize potential exposure of the infant to isomeric fatty acids by reviewing estimates of isomeric fatty acids in the maternal diet, in human milk, and in infant formula/infant foods; and (ii) to evaluate data addressing the effects of isomeric fatty acids on infant development with respect to influences on growth and EFA status.

## EXPOSURE OF THE INFANT TO ISOMERIC FATTY ACIDS

*Estimates of isomeric fatty acids in the maternal diet.* Several methods have been used to estimate isomeric fatty acid intake. These methods include estimates based on "food disappearance" or market share data, analysis of dietary consumption data of a representative population, laboratory analysis of duplicate portion or composite diets, and estimates based on the *trans*-fatty acid content of biological tissues. The advantages and disadvantages of each of these methods have been reviewed (1,2). Briefly, many of the estimates based on food disappearance or market share data do not account for waste and therefore tend to be somewhat larger than estimates obtained by other methods. Analysis of dietary consumption data of a representative population is subject to the errors and uncertainties inherent in performing diet recalls and records, as well as the extreme variability in the isomeric fatty acid content of food items within a single category in composition tables (7). Laboratory analysis of duplicate portion or composite diets can yield accurate values, but the values obtained by this method may not be representative of the population as a whole. Both adipose tissue and human milk samples have been

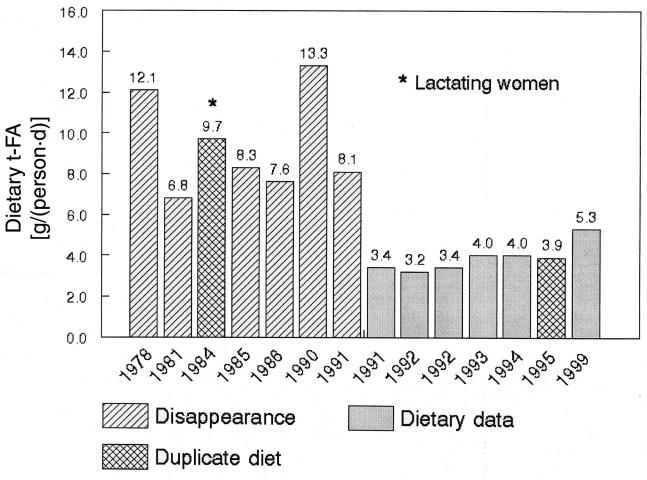

**FIG. 2.** *Trans*-fatty acid (*t*-FA) intake [g/(person·d)] in the United States classified by method used to obtain the data. In some studies, values are reported as dietary 18:1*t*; in others, values represent total *trans*-fatty acids. References are as follows: 1978 (72); 1981 (82); 1984 (8); 1985 (73); 1986 (83); 1990 (84); 1991 (76,85); 1992 (77,78); 1993 (79); 1994 (80); 1995 (86); 1999 (81).

used to estimate isomeric fatty acid consumption; however, this methodology is dependent upon equations expressing the relationship between isomeric fatty acids in the diet and the amount deposited in adipose tissue or secreted in human milk. The efficiency of this "transfer" can be influenced by many factors, most notably, energy intake. Nevertheless, estimates of dietary isomeric fatty acids obtained by all methods taken collectively can give us a measure of the relative values in the maternal diet across populations and thus an idea of the potential exposure to the unborn or breast-fed infant.

Isomeric fatty acid consumption appears to be greatest in North America compared with other parts of the world. In the United States, estimates of *trans*-fatty acid intake range from 4.2 to 8.0% of total fatty acids (Fig. 1) or from 3.2 to 13.3 g/(person·d) (Fig. 2), depending on the year of the study and the methodology used. Isomeric fatty acid consumption specific for lactating women was estimated to be 5.0–7.8% of total fatty acids (8,9). "Consensus" estimates by ILSI expert panels or an ASCN/AIN Task Force are summarized in Table 1. Consumption of *trans*-fatty acids in Canada appears to be just as great, if not greater, compared with the United States, with values ranging from 6.9 to 11.1 g/(person·d) (Fig. 3). For Canadian lactating women, estimates range from 6.9 to 10.6 g/(person·d) (10,11). It is worthy of note that the estimates by Chen *et al.* (10) were based on data obtained using 100-m capillary columns and included a number of minor isomers not generally reported in earlier estimates. According to Innis and King (11), the major sources of *trans*-fatty acids in the diet of Canadian lactating women were bakery products and breads (32%), snacks (14%), fast foods (11%), and margarines and shortenings (11%).

In the United Kingdom (Fig. 4), values reported for *trans*-fatty acid intake are somewhat less than those for North America. For the most part, estimates in the United Kingdom generally range from ~3 to >7 g/(person·d). The estimate of 12.0 g/(person·d) (12) was based on disappearance data and is notably larger than the other values.

*Trans*-fatty acid consumption in European countries is summarized in Figure 5. The southern European and Mediterranean countries, such as Spain, Portugal and Italy, have consumption values less than those in northern European countries. This is probably due to the fact that olive oil, which contains very small amounts of isomeric fatty acids compared with hydrogenated fats, is the major dietary fat used in these

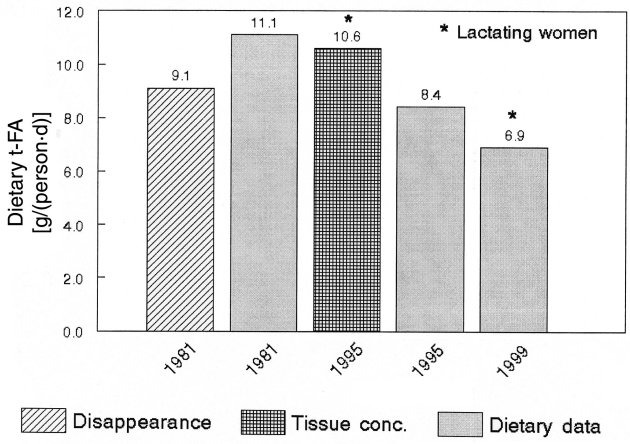

**FIG. 3.** *Trans*-fatty acid (*t*-FA) intake [g/(person·d)] in Canada classified by method used to obtain the data. In some studies, values are reported as dietary 18:1*t*; in others, values represent total *trans*-fatty acids. References are as follows: 1981 (87,87); 1995 (10,88); 1999 (11).

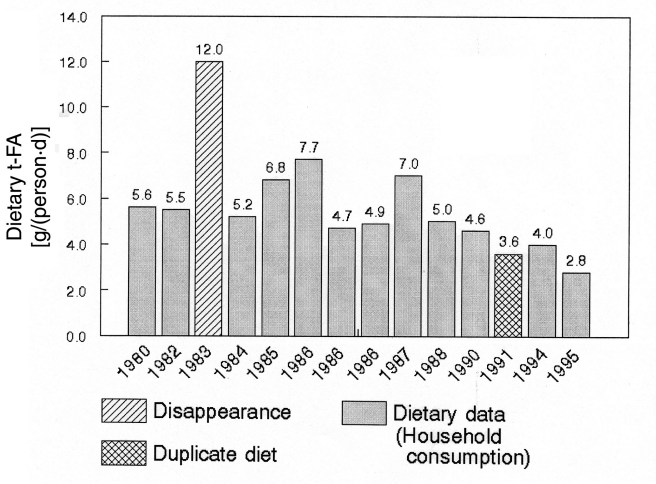

**FIG. 4.** *Trans*-fatty acid (*t*-FA) intake [g/(person·d)] in the United Kingdom classified by method used to obtain the data. In some studies, values are reported as dietary 18:1*t*; in others, values represent total *trans*-fatty acids. References are as follows: 1980 (89); 1982 (89); 1983 (12); 1984 (89); 1985 (90); 1986 (89,91); 1987 (92); 1988 (89); 1990 (89); 1991 (89); 1994 (89); 1995 (13).

countries. The values illustrated toward the front of the graph in Figure 5 are, for the most part, the recent values obtained in the TRANSFAIR study (13). In comparing these values with earlier estimates illustrated toward the back of the graph, it appears that consumption of *trans*-fatty acids in many European countries has decreased. This trend is particularly evident for the Netherlands in which estimates of the consumption of *trans*-fatty acids have decreased from 17 to 4.3 g/(person·d). Thus, exposure of European infants to *trans*-fatty acids appears to be only moderate at the present time. This same trend toward a somewhat lower consumption of *trans*-fatty acids is also evident in all of the Nordic countries except Iceland (Fig. 6).

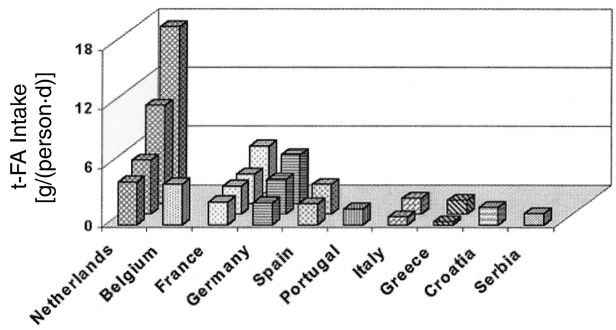

**FIG. 5.** *Trans*-fatty acid (*t*-FA) consumption [g/(person·d)] in European countries. In some studies, values are reported as dietary 18:1*t*; in others, values represent total *trans*-fatty acids. References are as follows: Netherlands (13,86,93,94); Belgium (13); France (13,24,95,96); Germany (13,97–100); Spain (13,25); Portugal (13); Italy (13,86); Greece (13,86); Croatia (86); Serbia (86).

Australia's consumption of *trans*-fatty acids is traditionally less than that of North American and some northern European countries (Fig. 7). This is probably due to the greater availability and use of tropical oils in spreads.

In Korea and Japan, isomeric fatty acid consumption is <1–2 g/(person·d) (Fig. 7). Thus, if the people of these countries continue to consume traditional diets, which contain very little hydrogenated fat, exposure of infants in these countries to isomeric fatty acids would not be a problem.

In summary, there is wide variation among various countries in the amount of isomeric fatty acids consumed. Recent changes in the formulation of fats in the food supply in some European countries have resulted in lower consumption of isomeric fatty acids. At the present time, consumption of isomeric fatty acids due to products containing commercially hy-

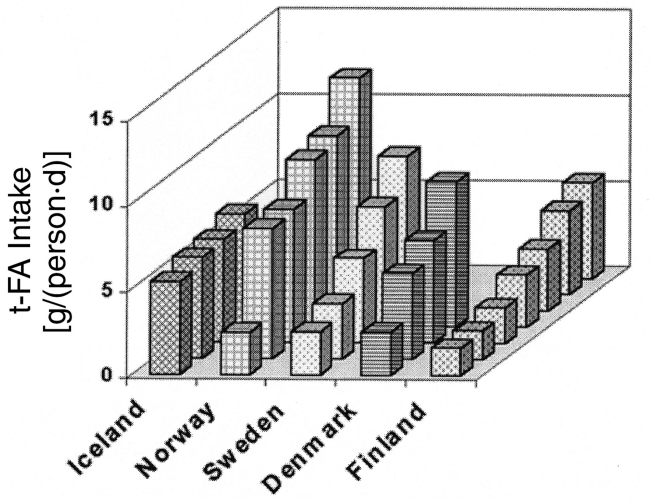

**FIG. 6.** *Trans*-fatty acid (*t*-FA) consumption [g/(person·d)] in Nordic countries. In some studies, values are reported as dietary 18:1*t*; in others, values represent total *trans*-fatty acids. References are as follows: Iceland (13,101,102); Norway (13,103); Sweden (13,101,104–106); Denmark (13,107); Finland (13,108–111).

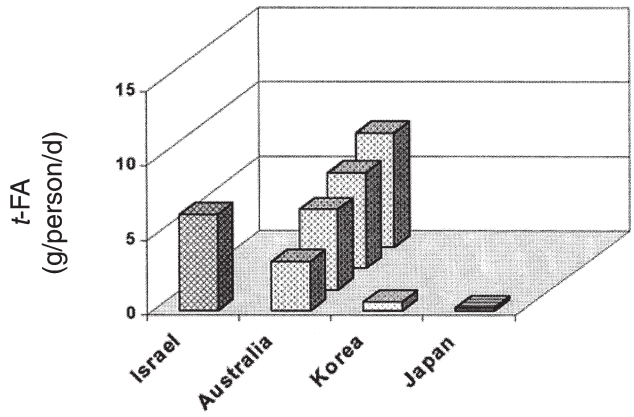

**FIG. 7.** *Trans*-fatty acid (*t*-FA) consumption [g/(person·d)] in other countries. In some studies, values are reported as dietary 18:1*t*; in others, values represent total *trans*-fatty acids. References are as follows: Israel (112); Australia (95,113,114); Korea (115); Japan (86).

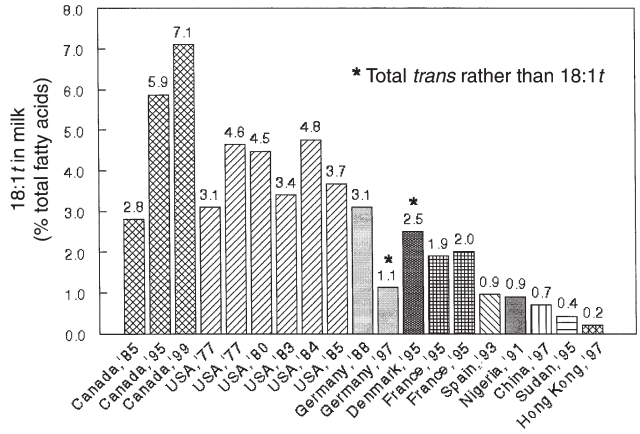

**FIG. 8.** *Trans*-fatty acid (*t*-FA) content of human milk samples from various countries. References are as follows: Canada, 1985 (15); Canada, 1995 (10); Canada, 1999 (11); United States, 1977 (9,16); United States, 1980 (17); United States, 1983 (18); United States, 1984 (8); United States, 1985 (19); Germany, 1988 (20); Germany, 1997 (21); Denmark, 1995 (22); France, 1995 (23,24); Spain, 1993 (25); Nigeria, 1991 (26); China, 1997 (27); Sudan, 1995 (28); Hong Kong, 1997 (27).

drogenated fat appears to be greatest in North America. *Trans*-fatty acids from the maternal diet can cross the placenta (14) or be secreted in human milk (8,9). Thus, developing fetuses and nursing infants in the United States and Canada would be subject to greater exposure to these fatty acids than would infants in other parts of the world.

*Estimates of isomeric fatty acids in human milk*. Isomeric fatty acids are transferred rapidly from the maternal diet to human milk (8,9). The *trans*-fatty acid content of human milk reflects the cross-cultural variation in the maternal diet (Fig. 8). Human milk samples collected from Canada (10,11,15) and the United States (8,9,16–19) contain greater amounts of *trans*-isomers of octadecenoic acid (18:1*t*) than do milk samples from lactating women in Germany (20,21), Denmark (22), and France (23,24). As expected, human milk samples from Spain (25), Nigeria (26), China (27), Sudan (28), and Hong Kong (27) have low amounts of 18:1*t*, reflecting the lack of commercially hydrogenated fat in the maternal diet in these countries. Thus, *trans*-fatty acids in human milk samples range from an average of 6–7% of total fatty acids in North America to <0.5% in Hong Kong.

Chen *et al*. (10) published one of the most complete analyses of the isomeric fatty acid content of human milk. Using a combination of capillary gas chromatography and silver nitrate thin-layer chromatography, these investigators analyzed the geometric and positional isomer distribution of 198 human milk samples collected in 1992 from nine provinces of Canada. Although 18:1*t* was the most prevalent *trans*-isomer group with a mean of 5.87 wt% of total fatty acids, smaller amounts of other *trans*-fatty acids were found. These included 18:2Δ9*c*,13*t*/8*t*,12*c* at 0.36%; 18:2Δ9*c*,12*t* at 0.29%; 18:2Δ9*t*,12*c* at 0.24%; 16:1Δ9*t* at 0.18%; total 18:3*t* at 0.11%; 14:1Δ7*t* at 0.09%; and 18:2Δ9*t*,12*t* at 0.05%. In addition, small amounts (<0.2%) of unusual positional *cis*-isomers were identified.

*Estimates of isomeric fatty acids in infant formula/infant foods.* Small amounts of isomeric fatty acids can be found in infant formula as a result of processing. Published values for the *trans*-fatty acid content of infant formula are given in Table 2. In the United States and Canada (16,29–32), samples of infant formula analyzed contained 0.1–3.1% of total fatty acids, except for one formula analyzed by Hanson and Kinsella (29) which contained 15.7%. In Europe, the content of *trans*-fatty acids in infant formula ranged from 0.2 to 5.0% of total fatty acids (22,33–36).

Infant foods can also contain *trans*-fatty acids (Table 3). In earlier reports (29,37,38), the range of *trans*-fatty acids in baby foods was given as 0.2–7.6%. Holub (39), however, recently reported that Canadian baby biscuits contain up to 37% of fatty acids as *trans*-isomers and that Canadian infant cereals can contain up to 23% *trans*-fatty acids. It is important to note that one must take into account the total fat content and usual consumption of these products before "exposure" to *trans*-fatty acids can be calculated.

*Isomeric fatty acid status based on analysis of blood samples.* Isomeric fatty acids in the diet are reflected in serum/plasma fatty acid profiles (40–43). The concentrations of *trans*-fatty acids have been determined in the plasma of pregnant women, lactating women, newborn infants, and children. Koletzko and Müller (14) were among the first to assess the isomeric fatty acid status of pregnant women. These investigators found that maternal plasma collected from 30 German women at term delivery (38–42 postmenstrual weeks) contained 1.99 ± 0.14% of total fatty acids as *trans*-fatty acids. The major component of this was 18:1*t* at 1.21 ± 0.10%, with smaller amounts of the *trans*-isomers of 18:2 (0.37 ± 0.07%), 16:1*t* (0.35 ± 0.04%) and 14:1*t* (0.06 ± 0.01%). In a more recent study (44), the *trans*-fatty acids in maternal plasma of 41 German women were 0.83% by weight of total fatty acids in triacylglycerols, 0.42% in the phospholipids, 0.28% in the cholesterol esters, and 1.19% in the non-esterified fatty acid fraction. These values are much less than

those in Canadian women studied by Elias and Innis (45) who reported the concentrations of *trans*-fatty acids in maternal plasma lipid fractions of 58 Canadian women at 35 wk of gestation as 3.99 ± 0.21% of total fatty acids with a range of 1.26–7.90% in the triacylglycerol fraction, 2.37 ± 0.10% (1.12–4.47) in the phospholipid fraction, and 1.57 ± 0.10% (0.64–3.70) in the cholesteryl ester fraction. The concentrations of *trans*-fatty acids in all three plasma lipid fractions were significantly related to dietary intake of *trans*-fatty acids adjusted for total energy intake ($r$ = 0.33–0.39).

*Trans*-fatty acids in the maternal plasma of women in the United States have also been reported. In a study of 43 pregnant women in Memphis, Tennessee, Carlson and colleagues (46) demonstrated that intake of *trans*-fatty acids correlated with maternal phospholipid 18:1*t*. The women in this study had relatively high plasma *trans*-fatty acid values, i.e., 18:1*t* was 2.57 ± 1.7% (1.0–7.8) in maternal plasma triglyceride and 1.44 ± 0.50% (0.4–2.6) in maternal plasma phospholipid. As a percentage of *cis*-18:1n-9, 18:1*t* was 8% in maternal plasma triglyceride and 14.2% in the maternal plasma phospholipid. As a percentage of all-*cis*-18:2, the *trans*-isomers (*t*/*t*, *t*/*c*, and *c*/*t*) of 18:2 were 5.4% in maternal plasma triglyceride and 1.7% in maternal plasma phospholipid. Carlson and colleagues (47) also studied 50 pregnant women in Kansas City, Missouri, and found that maternal plasma triglyceride contained 3.81% of total fatty acids as 18:1*t*, a value even greater than that in the Memphis women. In addition, Lammi-Keefe and Makhoul (48; personal communication) analyzed blood collected from pregnant Connecticut women at 24–28 wk gestation ($n$ = 10), 32–35 wk gestation ($n$ = 16), and 36–39 wk gestation ($n$ = 14) and reported that total *trans*-fatty acids were 1.73 ± 0.14, 1.61 ± 0.13, and 1.88 ± 0.13%, respectively, as gestation progressed. Thus, the amount of *trans*-fatty acids in the plasma of women in the United States is roughly comparable to that in Canada but greater than that in German women.

Maternal dietary *trans*-fatty acids can be transferred to the developing fetus (14), and umbilical cord plasma can be used to assess the isomeric fatty acid status of the infant at birth. The amount of *trans*-fatty acids in infant phospholipids correlates with that in maternal phospholipids (45,46). *Trans*-fatty acids were found in umbilical cord plasma at roughly the same percentages as those in maternal plasma by Koletzko and Müller (14). These investigators reported 1.66 ± 0.14 wt% of total fatty acids as *trans*-fatty acids in infant plasma compared with 1.99 ± 0.14 wt% in maternal plasma for 30 German newborn term infants and their mothers. In later studies (44–46), infant plasma *trans*-fatty acids were significantly less in triacylglycerol and phospholipid fractions compared with values in maternal plasma. In contrast, the cholesterol ester fraction of the infant plasma contained a greater concentration of *trans*-fatty acids than did the maternal plasma (44,45).

For Canadian infants ($n$ = 70) (45), values for total *trans*-fatty acids in lipid fractions of umbilical cord plasma ($n$ = 70) were triacylglycerol, 2.83 ± 0.19 (0.63–12.79); phospholipid, 0.67 ± 0.03 (0.11–1.33); and cholesterol ester, 2.04 ± 0.01 (0.86–4.24). A somewhat similar distribution of *trans*-fatty acids in plasma lipid classes was observed by Koletzko (49) who studied 29 preterm German infants on day 4 of life. Total *trans*-isomers were 1.62 ± 0.10 wt% in the triacylglycerols, 1.08 ± 0.07% in phospholipids, and 1.95 ± 0.17% in sterol esters. In a more recent study, Koletzko and colleagues (44) reported values for *trans*-fatty acids in infant plasma that were quantitatively lower, but similar in distribution with respect to lipid class, to the earlier values. For the 41 German term infants in this study, total *trans*-fatty acids in cord plasma were 0.45% in triacylglycerol, 0.21% in phospholipid, and 0.78% in cholesterol esters. The lower *trans*-fatty acid content in the plasma of German infants reported in 1998 compared with 1992 probably reflects a decrease in the overall *trans*-fatty acid content of the German food supply during this time. In the work of Carlson and colleagues (46), 18:1*t* in cord blood was 1.15 ± 0.50% (range, 1.0–7.8%) in triacylglycerols and 0.52 ± 0.25% (range, 0.1–1.2%) in phospholipids. In general, *trans*-

fatty acids appear to be incorporated into the triacylglycerol fraction to a greater extent than into the phospholipid fraction.

If one examines the role of *trans*-fatty acids as inhibitors of EFA metabolism, it is important to express the concentration of *trans*-isomers as percentages of their corresponding *cis*-fatty acids. Carlson and colleagues (46) reported that 18:1*t* isomers, expressed as a percentage of 18:1*c*, were 4 and 7.1% in triacylglycerol and phospholipid, respectively, in cord blood. The *trans*-isomers of 18:2, relative to all-*cis*-18:2, were 6.8% in triacylglycerol and 4.0% in phospholipid. These values were greater in cord blood than in maternal blood, and the investigators suggested that the transfer of *trans*-isomers of 18:2 from mother to fetus was restricted less than the transfer of linoleic acid.

Breast-fed infants receive isomeric fatty acids proportional to these fatty acids in the milk, which reflects the maternal diet (8). Innis and King (11) measured *trans*-fatty acids in the plasma lipids of 62 exclusively breast-fed Canadian infants at 2 mon of age. *Trans*-fatty acids in the triacylglycerol fraction were 6.5 ± 0.33% with a range of 1.9–15.6% and in the plasma phospholipid fraction, 3.7 ± 0.16% of total fatty acids with values ranging from 1.7 to 8.3%. *Trans*-fatty acids in plasma triacylglycerols and phospholipids of the breast-fed infants were significantly correlated ($r = 0.82$ and 0.67, respectively) with *trans*-fatty acids in the milk.

*Trans*-fatty acids in plasma triacylglycerol and phospholipid were found to be less in infants than in young adults (50). Specifically, the *trans*-fatty acid content of plasma at birth in German infants was 1.91% of total fatty acids in triacylglycerols and 0.69% in phospholipids compared with 2.25 and 1.50%, respectively, in young adults (20–26 yr of age). This relationship did not hold, however, for the cholesterol ester fraction. Collective values for German children, aged 1–15 yr, were 1.78, 2.72, and 1.66% for total *trans*-fatty acids in phospholipids, triacylglycerol, and cholesterol esters, respectively. These values were reported in 1994, and on the basis of current estimates of *trans*-fatty acid intake in Germany (13), values would be expected to be lower at the present time.

## EFFECTS OF ISOMERIC FATTY ACIDS ON INFANT DEVELOPMENT

It is clear that in many parts of the world, significant amounts of isomeric fatty acids are being consumed by pregnant and lactating women and that these fatty acids are transferred from the mother to the developing fetus and the nursing infant. The physiologic implications for infants exposed to isomeric fatty acids, however, are not as clear.

Arachidonic acid (AA; 20:4n-6) and docosahexaenoic acid (DHA; 22:6n-3) are important in perinatal growth and neural development (51), and the formation of these long-chain EFA from their shorter-chain precursors is believed to be inhibited by *trans*-fatty acids (52–54). Investigations on the effects of *trans*-fatty acids in development have focused on two general areas, i.e., growth and EFA status. However, because AA status may influence infant growth (55,56), these two areas are not distinct.

*Isomeric fatty acids and growth*. The relationship between *trans*-fatty acids and pregnancy outcome has been investigated by several groups. Koletzko (35,49,57,58) reported that *trans*-fatty acids in the plasma of 29 preterm infants on day 4 of life correlated negatively with birth weight. This relationship was found between birth weight and 18:1*t* in sterol esters ($r = \pm 0.50$; $P < 0.01$), total *trans*-fatty acids in sterol esters ($r = \pm 0.40$; $P < 0.05$), and total *trans*-fatty acids in phospholipids ($r = \pm 0.42$; $P < 0.01$). Similar results were found by von Houwelingen and Hornstra (59), who reported that 18:1*t* in umbilical arterial vessel walls correlated negatively with birth weight ($r = \pm 0.35$; $P = 0.033$). In addition, these investigators found a negative correlation with head circumference ($r = \pm 0.37$; $P = 0.028$). This negative relationship between head circumference and *trans*-fatty acids is consistent with recent preliminary results reported by Lammi-Keefe and Makhoul (48; personal communication). A negative correlation was observed at 32–35 wk gestation between *trans*-isomers of 18:2 in maternal plasma and head circumference of infants ($r = \pm 0.52$; $P = 0.07$). Similarly, Elias and Innis (45) reported that the concentration of *trans*-fatty acids in the cholesterol ester fraction of infant plasma was inversely related to gestational length ($r = \pm 0.33$; $P = 0.006$). Thus, a number of investigators have reported inverse correlations between *trans*-fatty acids and various measures of pregnancy outcome.

The data on the relationship between *trans*-fatty acids and pregnancy outcome must be interpreted with some caution. Koletzko (49) did not find significant negative correlations between birth weight and some fractions of plasma, such as 18:1*t* in triacylglycerols or phospholipids. Moreover, Elias and Innis (45) did not find the relationship between *trans*-fatty acids in various fractions of the umbilical cord plasma lipids and length of gestation, birth weight, and birth length to be significant, except for *trans*-fatty acids in the cholesteryl ester fraction and gestational length. Lammi-Keefe and Makhoul (48; personal communication) did not report a significant negative relationship between *trans*-fatty acids and either birth weight or length at birth. Thus, definitive conclusions on the relationship between *trans*-fatty acids and fetal growth await future investigation.

*Isomeric fatty acids and EFA status*. EFA of both the n-6 and n-3 families play important roles in the perinatal period (51). AA is important as a component of membrane phospholipids, as a precursor for eicosanoids, and as a stimulant of growth and cell division. It also plays a role in second messenger and cell signaling pathways. During perinatal development, DHA accumulates in retinal and neural membrane phospholipids; as such, it is involved in visual and central nervous system function. Both AA and DHA are synthesized from their respective 18-carbon precursors, linoleic acid (18:2n-6) and linolenic acid (18:3n-3) by a series of desaturation and elongation enzymes.

The hypothesis that dietary *trans*-fatty acids could inhibit biosynthesis of long-chain PUFA with 20 and 22 carbon atoms and thus affect infant development is based on studies indicating that *trans*-fatty acids inhibit Δ6-desaturase, and perhaps

Δ5-desaturase activity in animals (60), in *in vitro* systems (52,53,61,62), or in cultured cells (54,63,64). This hypothesis is supported by the work of Koletzko (35,49,57,58) who demonstrated an inverse correlation of plasma *trans*-octadecaenoic acid and total *trans*-fatty acids with n-6 and n-3 long-chain PUFA in 29 preterm German infants at day 4 of life. Specifically, total *trans*-fatty acids in the sterol ester fraction of plasma were negatively correlated with AA and in all three lipid fractions (triglycerides, sterol esters, and phospholipid) with total n-6 long-chain PUFA. In addition, 18:1*t* demonstrated a negative relationship with AA in the sterol ester fraction and with total n-6 long-chain PUFA in triacylglycerols and sterol esters. With respect to n-3 fatty acids, negative correlations were observed for DHA with 18:1*t* and total *trans*-fatty acids in plasma triacylglycerols and sterol esters; total n-3 long-chain PUFA were negatively correlated with 18:1*t* in the triacylglycerol fraction. In addition, total long-chain PUFA (n-6 + n-3) and product/substrate ratios for both n-6 and n-3 long-chain PUFA were negatively correlated with total *trans*-fatty acids and/or 18:1*t* in plasma triacylglycerols and sterol esters. These data were interpreted as indicating a potential impairment of EFA metabolism by *trans*-fatty acids. The safety of high dietary *trans*-fatty acid intake during pregnancy and in the perinatal period was thus questioned.

A similar relationship was demonstrated in 53 German children, aged 1–15 yr, in that plasma phospholipid *trans*-fatty acids were significantly inversely related to AA, total n-6 PUFA, and the AA/linoleic acid ratio (65). Comparable significant relationships for the n-3 fatty acids were not observed in these children.

The recent data of Elias and Innis (45) support, in part, the earlier work of Koletzko (49). Inverse correlations between infant plasma *trans*-fatty acids and DHA concentrations in triacylglycerols and between *trans*-fatty acids and AA concentrations in cholesterol esters were observed in the plasma lipid fractions of 70 North American infants (45).

Similarly, in 50 mother/infant pairs living in Memphis, TN, Carlson and co-workers (66) reported inverse correlations between *trans*-fatty acids in cord venous plasma triacylglycerol and DHA in cord venous phospholipids. Also, positional *cis*-isomers of 18:1 (n-5 to n-7) in cord venous plasma triacylglycerols were inversely correlated with DHA and AA in cord venous phospholipids. In more recent work with 50 mother/infant pairs living in Kansas City, MO, Carlson's group (47) supported the hypothesis that *trans*-fatty acids could compromise the EFA status of infants. These investigators reported that the artery wall was the most robust indicator of an inverse relationship of *trans*-fatty acids with DHA and AA. Significant inverse correlations were found in the umbilical artery wall phospholipids for 16:1*t*, positional *cis*-isomers of 18:1, and 18:2*t*,*c* with both DHA and AA. Additionally, the phospholipids of umbilical vein walls, maternal plasma, cord venous plasma, and cord arterial plasma had significant inverse relationships between AA or DHA and one or more of the isomeric fatty acids mentioned above (16:1*t*, positional *cis*-isomers of 18:1, and 18:2*t*,*c*).

Lammi-Keefe and Makhoul in a preliminary report (48; personal communication) presented further evidence that *trans*-fatty acids may lead to compromised long-chain PUFA status during pregnancy. In a study of 16 Connecticut pregnant women, significant inverse associations between maternal plasma *trans*-fatty acids and n-3 and n-6 long-chain PUFA were demonstrated. For example, *trans*-isomers of 18:2 were inversely correlated with AA and total n-6 long-chain PUFA. Moreover, these investigators found that *trans*-fatty acids were significant covariates for long-chain PUFA during the course of pregnancy.

Further support for inhibition of EFA metabolism during pregnancy by dietary *trans*-fatty acids has been provided by a well-controlled animal study (67) in which rats were fed three levels of *trans*-fatty acids (0, 15, and 30% of total fatty acids) with linoleic acid and α-linolenic acid held constant. These investigators concluded that high intakes of *trans*-fatty acids partially inhibited Δ-6 desaturase in pregnant rats, which may explain, in part, the low concentrations of DHA that they found in tissues of pregnant and fetal rats. They reported, however, that the fatty acid composition of both fetal and pregnant rat brain remained mainly unaffected by dietary *trans*-fatty acids.

Although there is some evidence of a negative relationship between *trans*-fatty acids and long-chain PUFA in plasma, similar negative correlations have not been identified for human milk. Studies by Innis and King (11) did not support the hypothesis that long-chain PUFA in human milk would be suppressed by *trans*-fatty acids in the diet of lactating women. These investigators found that milk *trans*-fatty acids were not inversely related to AA or DHA in milk or infant plasma. In fact, these investigators reported that milk *trans*-fatty acids were inversely related to milk linoleic acid and linolenic acid, but not to their elongated products, AA and DHA. The earlier work of Chen *et al*. (10) was in agreement with that of Innis and King (11) in that they also observed a negative correlation between milk *trans*-fatty acids and 18:2n-6 and 18:3n-3, but not with n-6 or n-3 elongation products. As a possible explanation for these results, Innis and King (11) hypothesized that diets high in *trans*-fatty acids would also be low in all-*cis* n-6 and n-3 fatty acids because hydrogenation reduces the content of the naturally occurring all-*cis* isomers. Moreover, a recent study in rats (68) did not show a relationship between high intakes of *trans*-fatty acids in the maternal diet and long-chain PUFA in rat milk.

In summary, considerable evidence based on relationships among plasma fatty acids exists supporting the hypothesis that *trans*-fatty acids can inhibit EFA metabolism, thereby compromising the AA and DHA status of the developing infant. It must be emphasized that this evidence is correlational in nature and that the physiologic implications of this inhibition are largely unknown.

Only a few investigators have studied the physiologic implications of *trans*-fatty acids on development in humans consuming *trans*-fatty acids within the "normal" range. In a crossover experiment in which lactating women consumed a low *trans*-fatty acid diet and a high *trans*-fatty acid diet made

from commercially available fats, Craig-Schmidt *et al*. (8) found no effect of *trans*-fatty acids on human milk prostaglandins. Although *trans*-isomers of 18:3 can be elongated into *trans*-isomers of long-chain n-3 PUFA and incorporated into rat brain and retina (69), the physiologic implications of the incorporation of such *trans*-isomers into human tissues is not known. Similarly, elongated and further desaturated products of isomeric forms of oleic and linoleic acids have been identified in rats fed partially hydrogenated canola oil (70). Again, the importance of these compounds during perinatal development is unknown. If *trans*-fatty acids in the North American food supply remain greater than that in other parts of the world, the physiologic effects of increased dietary *trans*-fatty acids on the developing infant should be addressed in tightly controlled human studies conducted within the framework of currently available commercial sources of dietary isomeric fats.

# Polyunsaturated Fatty Acids, Inflammation, and Immunity

**Philip C. Calder***

Institute of Human Nutrition, University of Southampton, Southampton SO16 7PX, United Kingdom

**ABSTRACT:** The fatty acid composition of inflammatory and immune cells is sensitive to change according to the fatty acid composition of the diet. In particular, the proportion of different types of polyunsaturated fatty acids (PUFA) in these cells is readily changed, and this provides a link between dietary PUFA intake, inflammation, and immunity. The n-6 PUFA arachidonic acid (AA) is the precursor of prostaglandins, leukotrienes, and related compounds, which have important roles in inflammation and in the regulation of immunity. Fish oil contains the n-3 PUFA eicosapentaenoic acid (EPA). Feeding fish oil results in partial replacement of AA in cell membranes by EPA. This leads to decreased production of AA-derived mediators. In addition, EPA is a substrate for cyclooxygenase and lipoxygenase and gives rise to mediators that often have different biological actions or potencies than those formed from AA. Animal studies have shown that dietary fish oil results in altered lymphocyte function and in suppressed production of proinflammatory cytokines by macrophages. Supplementation of the diet of healthy human volunteers with fish oil-derived n-3 PUFA results in decreased monocyte and neutrophil chemotaxis and decreased production of proinflammatory cytokines. Fish oil feeding has been shown to ameliorate the symptoms of some animal models of autoimmune disease. Clinical studies have reported that fish oil supplementation has beneficial effects in rheumatoid arthritis, inflammatory bowel disease, and among some asthmatics, supporting the idea that the n-3 PUFA in fish oil are anti-inflammatory and immunomodulatory.

Paper no. L8650 in *Lipids 36,* 1007–1024 (September 2001).

## THE IMMUNE SYSTEM

The immune system acts to protect the host from infectious agents that exist in the environment (bacteria, viruses, fungi, parasites) and from other noxious insults. The immune system has two functional divisions, i.e., the innate (or natural) immune system and the acquired (also termed specific or adaptive) immune system. Both components of immunity involve various blood-borne factors and cells (Table 1). These cells are generally termed leukocytes (or white blood cells). Leukocytes fall into two broad categories, i.e., phagocytes, including granulocytes (neutrophils, basophils, eosinophils), monocytes and macrophages, and lymphocytes. Lymphocytes are classified as T lymphocytes, B lymphocytes and natural killer (NK) cells. T lymphocytes are further divided into helper T (Th) cells (these are distinguished by the presence of the molecule CD4 on their surface) and cytotoxic T cells (these are distinguished by the presence of CD8 on their surface). All cells of the immune system originate in bone marrow. They are found circulating in the bloodstream, organized into lymphoid organs such as the thymus, spleen, and lymph nodes, or dispersed in other locations around the body.

### Innate and Acquired Immunity

Innate immunity is the first line of defense against infectious agents. It is present before exposure to pathogens and its activity is not enhanced by such exposures. Innate immunity is concerned with preventing entry of infectious agents into the body and, if they do enter, with their rapid elimination. Elimination can occur as follows: (i) by direct destruction of pathogens by complement, by toxic chemicals (e.g., superoxide radicals and hydrogen peroxide) released by phagocytes, or by toxic proteins released by NK cells; and (ii) by engulfment of pathogens by the process of phagocytosis, which is made more efficient by coating the invading pathogen with host proteins such as complement or antibodies, and their subsequent destruction.

Acquired immunity involves the specific recognition of molecules (antigens) on an invading pathogen, which distinguish it as being foreign to the host. The recognition of antigens is by antibodies (produced by B lymphocytes) and by T lymphocytes. However, in contrast to B lymphocytes, T lymphocytes are able to recognize only antigens displayed on cell surfaces. Therefore, infection of a cell by an intracellular pathogen is signaled to T lymphocytes by cell surface expression of peptide fragments derived from the pathogen. These fragments are transported to the surface of the infected cell and expressed there in conjunction with proteins termed major histocompatibility complex (MHC). It is the combination of the pathogen-derived peptide fragment bound to MHC that is recognized by T lymphocytes. There are two classes of MHC, MHC I and MHC II, and the source of the peptide bound to each differs. MHC I binds peptides that originate from pathogen proteins synthesized within the host cell cytosol; typically, these are from viruses or certain bacteria. The peptides bound to MHC II are derived from pathogens that have been phagocytosed by macrophages or endocytosed by antigen-presenting cells (macrophages, dendritic cells, B lymphocytes).

**TABLE 1**
**Components of Innate and Acquired Immunity**

| | Innate immunity | Acquired immunity |
|---|---|---|
| Physicochemical barriers | Skin | Cutaneous and mucosal immune systems |
| | Mucosal membranes | Antibodies in mucosal secretions |
| | Lysozyme | |
| | Stomach acid | |
| | Commensal bacteria | |
| Circulating molecules | Complement | Antibodies |
| Cells | Granulocytes | B lymphocytes |
| | Monocytes/macrophages | T lymphocytes |
| | Natural killer cells | |
| Soluble mediators | Macrophage-derived cytokines | Lymphocyte-derived cytokines |

The MHC-peptide complex is recognized by the T-cell receptor on T lymphocytes. T lymphocytes expressing CD8 recognize MHC I, whereas T lymphocytes expressing CD4 recognize MHC II. Thus, intracellular pathogens stimulate cytotoxic T lymphocytes to destroy the infected cell, whereas extracellular pathogens stimulate a helper T cell–mediated response.

The acquired immune system includes a component of memory, such that if the antigen is encountered again (i.e., there is reinfection), the response is faster and stronger than the initial response. Although the immune system as a whole can recognize tens of thousands of antigens, each lymphocyte can recognize only one antigen; thus the number of lymphocytes specific for a particular antigen must be very low. However, when an antigen is encountered, it binds to the small number of lymphocytes that recognize it and causes them to divide so as to increase the number of cells that are capable of mounting a response to the antigen; this is the process termed lymphocyte expansion or proliferation. B lymphocytes proliferate and mature into antibody-producing cells (plasma cells), and T lymphocytes proliferate and are able to directly destroy virally infected cells (cytotoxic T lymphocytes) or control the activity of other cells involved in the response (helper T cells). The B lymphocyte response to antigen is termed humoral immunity, and the T cell response is termed cell-mediated immunity.

## Communication Within the Immune System

Communication within the acquired immune system and between the innate and acquired systems is brought about by direct cell-to-cell contact involving adhesion molecules and by the production of chemical messengers. Chief among these chemical messengers are proteins called cytokines, which can act to regulate the activity of the cell that produced the cytokine and/or of other cells. Each cytokine can have multiple activities on different cell types. Cytokines act by binding to specific receptors on the cell surface and thereby induce changes in growth, development, or activity of the target cell.

Tumor necrosis factor (TNF)-α, interleukin (IL)-1 and IL-6 are among the most important cytokines produced by monocytes and macrophages. These cytokines activate neutrophils, monocytes, and macrophages to initiate bacterial and tumor cell killing, increase adhesion molecule expression on the surface of neutrophils and endothelial cells, stimulate T and B lymphocyte proliferation, upregulate MHC, and initiate the production of other cytokines (Fig. 1). Thus, TNF, IL-1, and IL-6 are mediators of both natural and acquired immunity and are an important link between them. In addition, these cytokines mediate the systemic effects of inflammation such as fever, loss of appetite, mobilization of protein and fat, and acute phase protein synthesis (Fig. 1). Production of appropriate amounts of TNF, IL-1, and IL-6 is clearly beneficial in response to infection, but inappropriate amounts or overproduction can be dangerous; these cytokines, especially TNF, are implicated in causing some of the pathological responses that occur in inflammatory conditions (1). The actions of proinflammatory cytokines are antagonized by anti-inflammatory cytokines such as IL-4, IL-10, transforming growth factor-β, and by cytokine inhibitors such as IL-1 receptor antagonist and soluble TNF receptors.

Helper T lymphocytes are subdivided functionally according to the pattern of cytokines they produce (Fig. 2). It is believed that helper T cells that have not previously encountered antigen produce mainly IL-2 upon initial encounter with antigen. These cells may differentiate into a population some-

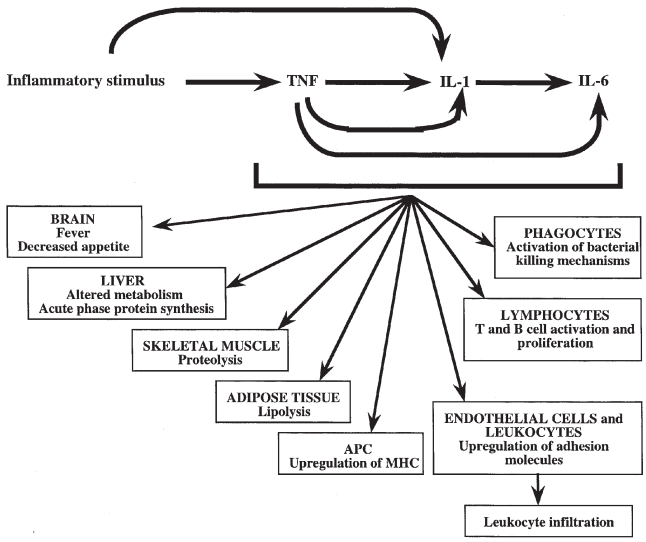

**FIG. 1.** Key roles of proinflammatory cytokines in mediating the host innate immune response and in integrating the innate and acquired immune responses. TNF, tumor necrosis factor; IL, interleukin; APC, antigen-presenting cells; MHC, major histocompatibility complex.

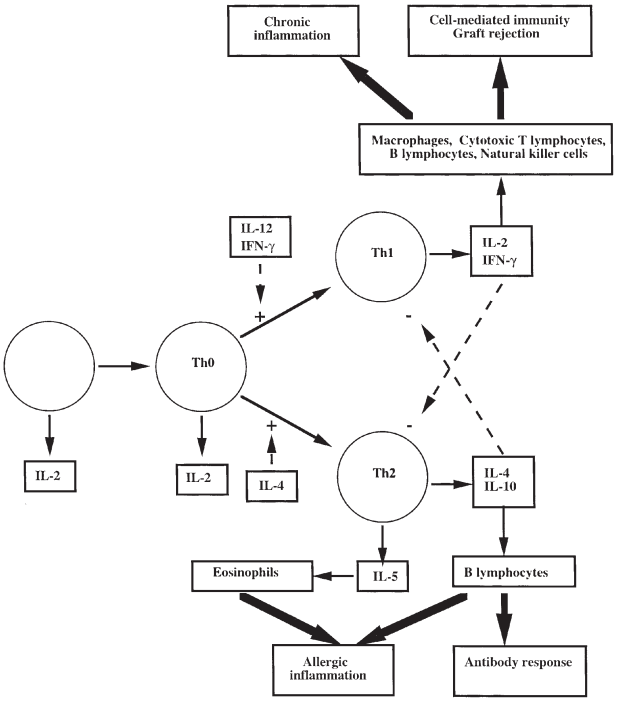

**FIG. 2.** Development and roles of helper T lymphocyte responses. IL, interleukin; IFN, interferon; Th, helper T cells.

times referred to as Th0 cells, which differentiate further into either Th1 or Th2 cells (Fig. 2). This differentiation is regulated by cytokines as follows: IL-12 and interferon-γ (IFN-γ) promote the development of Th1 cells, whereas IL-4 promotes the development of Th2 cells (Fig. 2). Th1 and Th2 themselves have relatively restricted profiles of cytokine production, i.e., Th1 cells produce IL-2 and IFN-γ, which activate macrophages, NK cells, and cytotoxic T lymphocytes and are the principal effectors of cell-mediated immunity (Fig. 2). Interactions with bacteria, viruses, and fungi tend to induce Th1 activity. Because Th1 cytokines activate monocytes and macrophages, these cytokines may be regarded as proinflammatory. Th2 cells produce IL-4, which stimulates immunoglobulin (Ig) E production by B lymphocytes, IL-5, an eosinophil-activating factor, and IL-10, and which together with IL-4 suppresses cell-mediated immunity (Fig. 2). Th2 cells are responsible for defense against helminthic parasites, which is due to IgE-mediated activation of mast cells and basophils. Because Th2 cytokines suppress Th1 responses, these cytokines may be regarded as anti-inflammatory. An imbalance or dysregulation between the Th1- and Th2-type responses is a characteristic of many human diseases (2).

## Inflammation

Inflammation is the body's immediate response to infection or injury. It is typified by redness, swelling, heat, and pain. These occur as a result of increased blood flow, increased permeability across blood capillaries, which permits large molecules (e.g., complement, antibodies, cytokines) to leave the bloodstream and cross the endothelial wall, and increased movement of leukocytes from the bloodstream into the surrounding tissue. Thus, inflammation is part of the normal, innate immune response.

## Integration of the Immune Response

The innate and acquired immune responses are integrated according to the direct cell-to-cell and cytokine interactions that result from the presence of a particular stimulus. The innate response, including its inflammatory component, reacts initially to the stimulus, acting directly to eliminate it by the activities of complement or phagocytosis, for example. Cytokines produced by the cells involved in the innate response, especially monocytes and macrophages, will regulate this response and also act systemically on the liver to promote acute phase protein synthesis, on skeletal muscle and adipose tissue to promote proteolysis and lipolysis, respectively (this is believed to be the body's way of providing fuels to the immune system), and on the brain to reduce appetite and induce fever (Fig. 3). These cytokines will also interact with T lymphocytes. Antigen-presenting cells, which include activated monocytes and macrophages, will present antigen to T lymphocytes and thus the acquired immune response will be triggered (Fig. 3). Now there will be a cell-mediated response to the antigen. T lymphocytes will produce cytokines, which will regulate the activity of the cells involved in the innate response (monocytes, macrophages, NK cells), promote the proliferation of B and T lymphocytes, and promote antibody production by B lymphocytes. By virtue of the integrated innate and acquired responses, the source of the antigen should be eliminated and a component of immunological memory will remain (Fig. 3).

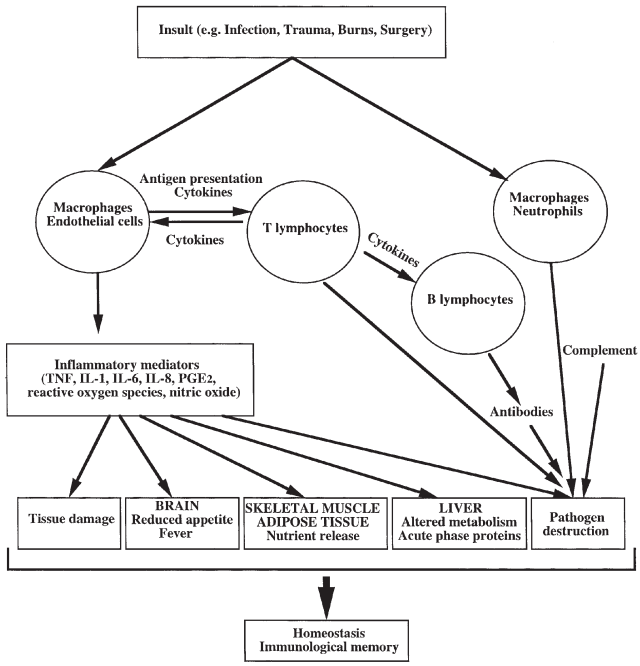

**FIG. 3.** The interrelationship between the innate and aquired immune responses. PG, prostaglandin; for other abbreviations see Figure 1.

### The Immune System in Health and Disease

Clearly, a well-functioning immune system is essential to health. It serves to protect the host from the effects of ever-present pathogenic organisms. Cells of the immune system also have a role in identifying and eliminating cancer cells. There are, however, some detrimental effects of the immune system, including the following:

(i) In the course of its activity to recognize and eliminate foreign antigens, the immune system is responsible for the rejection of transplanted tissues.

(ii) In some individuals, the immune system appears to recognize host antigens as "non-self" rather than as "self." As a result, an immune response to host tissues is generated and this leads to tissue damage. This is the characteristic of so-called chronic inflammatory or autoimmune diseases. Such diseases are linked to genes coding for proteins involved in antigen presentation or recognition such as the MHC II proteins and the T-cell receptor; thus there is a genetic predisposition to these diseases. These diseases are typified by an ongoing chronic inflammation involving the proinflammatory cytokines produced by monocytes and macrophages and by a dysregulated Th1 lymphocyte response. Examples of this type of disease include rheumatoid arthritis, type-1 diabetes, Crohn's disease, psoriasis, and multiple sclerosis.

(iii) The immune system of some individuals can become sensitized to usually benign antigens from the environment and can respond inappropriately to them. Such antigens can include components of foods or of so-called allergens (e.g., cat or dog fur, house dust mite, some pollens), such that this response can lead to allergies, asthma, and related atopic diseases. Although these diseases are often termed chronic inflammatory diseases, they have a different immune basis from the diseases described above, although again they are typified by inappropriate recognition of and/or responses to antigens. However, atopic diseases are characterized by a dysregulated Th2 lymphocyte response such that excessive amounts of IL-4, IL-5, and IL-10 are found. IL-10 suppresses the Th1 response, IL-4 stimulates IgE production by B lymphocytes (IgE promotes histamine release from mast cells), and IL-4 and IL-5 activate eosinophils, which are involved in the persistent inflammation that is a component of these diseases.

(iv) The innate immune system becomes activated as a result of trauma and surgery. This response is characterized by excess production of the proinflammatory cytokines and, if it persists, it can damage organs, causing their failure and leading to complications and sometimes death.

## EICOSANOIDS: A LINK AMONG POLYUNSATURATED FATTY ACIDS, INFLAMMATION, AND IMMUNITY

### Eicosanoid Precursors and Synthesis

Eicosanoids are a second group of chemical messengers that act within the immune system. These compounds provide a link among polyunsaturated fatty acids (PUFA), inflammation, and immune function. Eicosanoids are synthesized from PUFA, in particular dihomo-γ-linolenic acid (DGLA; 20:3n-6), arachidonic acid (AA; 20:4n-6), and eicosapentaenoic acid (EPA; 20:5n-3). Eicosanoids include prostaglandins (PG), thromboxanes, leukotrienes (LT), lipoxins, hydroperoxyeicosatetraenoic acids (HPETE), and hydroxyeicosatetraenoic acids (HETE). The fatty acid precursor for eicosanoid synthesis is released from cell membrane phospholipids, usually by the action of phospholipase $A_2$ activated in response to a cellular stimulus. Because the membranes of most immune cells contain large amounts of AA, compared with DGLA and EPA, AA is usually the principal precursor for eicosanoid synthesis.

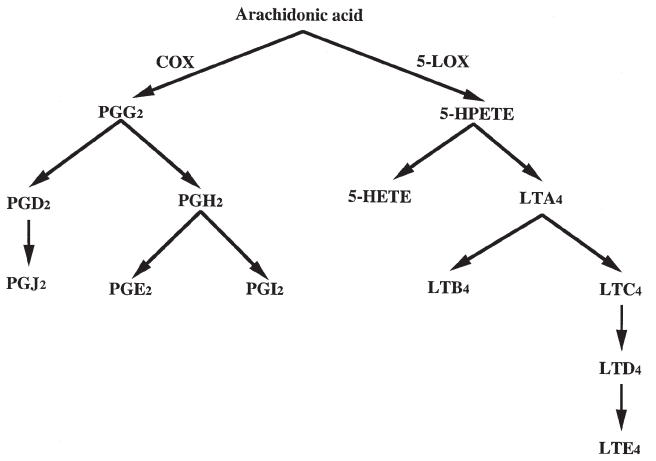

**FIG. 4.** Formation of eicosanoids from arachidonic acid. COX, cyclooxygenase; 5-LOX, 5-lipoxygenase; HPETE, hydroperoxyeicosatetraenoic acid; HETE, hydroxyeicosatetraenoic acid; LT, leukotriene. For other abbreviation see Figure 3.

Metabolism of AA by cyclooxygenase (COX) gives rise to the 2-series PG and thromboxanes (Fig. 4). There are two isoforms of COX; COX-1 is a constitutive enzyme and COX-2, which is induced in immune cells as a result of stimulation, is responsible for the markedly elevated production of PG that occurs upon cellular activation. There are at least 16 different 2-series PG, and these are formed in a cell-specific manner. For example, monocytes and macrophages produce large amounts of $PGE_2$ and $PGF_2$, neutrophils produce moderate amounts of $PGE_2$, and mast cells produce $PGD_2$.

Metabolism of AA by the 5-lipoxygenase (5-LOX) pathway gives rise to hydroxy and hydroperoxy derivatives (5-HETE and 5-HPETE, respectively), and the 4-series leukotrienes (LT), $LTA_4$, $B_4$, $C_4$, $D_4$ and $E_4$ (Fig. 4). 5-LOX is found in mast cells, monocytes, macrophages, and granulocytes. The 12-LOX enzyme is found in platelets and some epithelial cells, and the 15-LOX is found in some epithelial cells.

### Roles for Eicosanoids in Inflammation and Immunity

$PGE_2$ has a number of proinflammatory effects, including induction of fever and erythema, increasing vascular permeability and vasodilation, and enhancing pain and edema caused by other agents such as histamine. $PGE_2$ suppresses lympho-

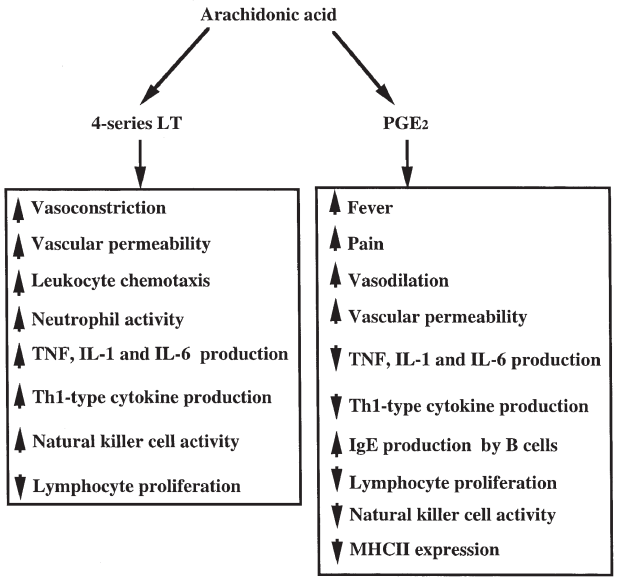

**FIG. 5.** Roles of some arachidonic acid–derived eicosanoids in regulating inflammation and immunity. Ig, immunoglobulin; Th, T helper cell; MHC, major histocompatibility complex; for other abbreviations see Figures 1, 3, and 4.

cyte proliferation and NK cell activity and inhibits production of TNF-α, IL-1, IL-6, IL-2, and IFN-γ; thus, in these respects, $PGE_2$ is immunosuppressive and anti-inflammatory (Fig. 5). $PGE_2$ does not appear to affect the production of the Th2 cytokines IL-4 and IL-10 directly, but it does promote IgE production by B lymphocytes (Fig. 5). $LTB_4$ increases vascular permeability, enhances local blood flow, is a potent chemotactic agent for leukocytes, induces release of lysosomal enzymes, enhances generation of reactive oxygen species, inhibits lymphocyte proliferation, and promotes NK cell activity. LT (4-series) also regulate production of proinflammatory cytokines; for example, $LTB_4$ enhances production of TNF, IL-1, IL- 6, IL-2, and IFN-γ (Fig. 5). 5-HETE enhances whereas 15-HETE inhibits lymphocyte proliferation. Thus, AA gives rise to a range of mediators that have opposing effects to one another so that the overall physiological effect will be governed by the concentration of those mediators, the timing of their production, and the sensitivities of target cells to their effects.

Feeding animals or humans increased amounts of fish oil, which contains EPA and its derivative docosahexaenoic acid (DHA; 22:6n-3), results in a decrease in the amount of AA in the membrane phospholipids of cells involved in inflammation and immunity (Fig. 6). In addition, long-chain n-3 PUFA appear to inhibit the release of AA from membrane phospholipids perhaps by inhibition of phospholipases (4). EPA also competes with AA for the active sites of COX and 5-LOX. Thus, fish oil feeding results in a decreased capacity of immune cells to synthesize eicosanoids from AA (Figs. 7, 8). In addition, EPA is able to act as a substrate for both COX and 5-LOX, giving rise to derivatives that have a different structure from those produced from AA (i.e., 3-series PG and 5-series LT) (Figs. 7, 8). Thus, the EPA-induced suppression in the production of AA-derived eicosanoids is mirrored by an elevation in the production of EPA-derived eicosanoids (Fig. 7). The eicosanoids produced from EPA are considered to be less biologically potent than the analogs synthesized from AA, although the full range of biological activities of these compounds has not been investigated. The best example of differential immunological potencies of eicosanoids produced from AA and EPA is that of $LTB_4$ vs. $LTB_5$. $LTB_5$ is at least 10-fold less potent as a neutrophil chemoattractant than $LTB_4$ and, on this basis, can be considered to be considerably less proinflammatory. One other aspect of the formation of alternative eicosanoids to those produced from AA is that they will share the same receptor on target cells and therefore will act to antagonize the AA-derived mediators (Fig. 8).

## PUFA AND IMMUNE FUNCTION

### Linoleic Acid (18:2n-6) and Immune Function

In vitro *studies*. Linoleic acid enhanced superoxide release from neutrophils and macrophages (7–10) and promoted neutrophil adhesion to endothelial cells (11), suggesting that it possesses proinflammatory effects. In contrast, linoleic acid inhibited the proliferation of rodent and human lymphocytes (12–16) and decreased the production of IL-2 by mitogen-stimulated rat and human lymphocytes (13,14), suggesting that it is potentially immunosuppressive.

*Animal feeding studies*. Essential fatty acid deficiency impaired the ability of mice to produce IgG and IgM in response to sheep red blood cells (17); this response was restored by feeding diets containing 130, 500, or 700 g corn oil/kg (17). In contrast to this apparent enhancing effect of linoleic acid on antibody production, dietary linoleic acid was found to impair the production of antibodies, including IgG and IgM, after antigenic challenges, compared with feeding diets containing low fat or high saturated fat (beef tallow, coconut oil) (18,19). Compared with diets high in saturated fatty acids, feeding rodents high-fat diets rich in linoleic acid decreased mitogen-stimulated lymphocyte proliferation and NK cell activity in some studies (see Ref. 20 for references). These studies suggest that very high levels of linoleic acid in the rodent diet impair cell-mediated and antibody responses. However, modest changes in the amount of linoleic acid in the rat diet did not markedly affect lymphocyte proliferation or NK cell activity (21).

*Human studies*. Surprisingly, few human studies have investigated the immunological effect of linoleic acid. The most detailed of the studies that have been performed are those of Kelley *et al*. (22,23), which involved providing volunteers with low-fat diets (25% energy as fat) that were rich (12.9% of energy) or poor in linoleic acid (3.5% of energy). No differences were observed in the responses of lymphocytes to various T-cell mitogens, in circulating IgM, IgG, IgE, or IgA levels, or in the delayed-type hypersensitivity (DTH) response to seven recall antigens. Yaqoob *et al*. (24) included a group consuming 9 g encapsulated sunflower oil/d for 12 wk in their study. This had no effect on lymphocyte proliferation,

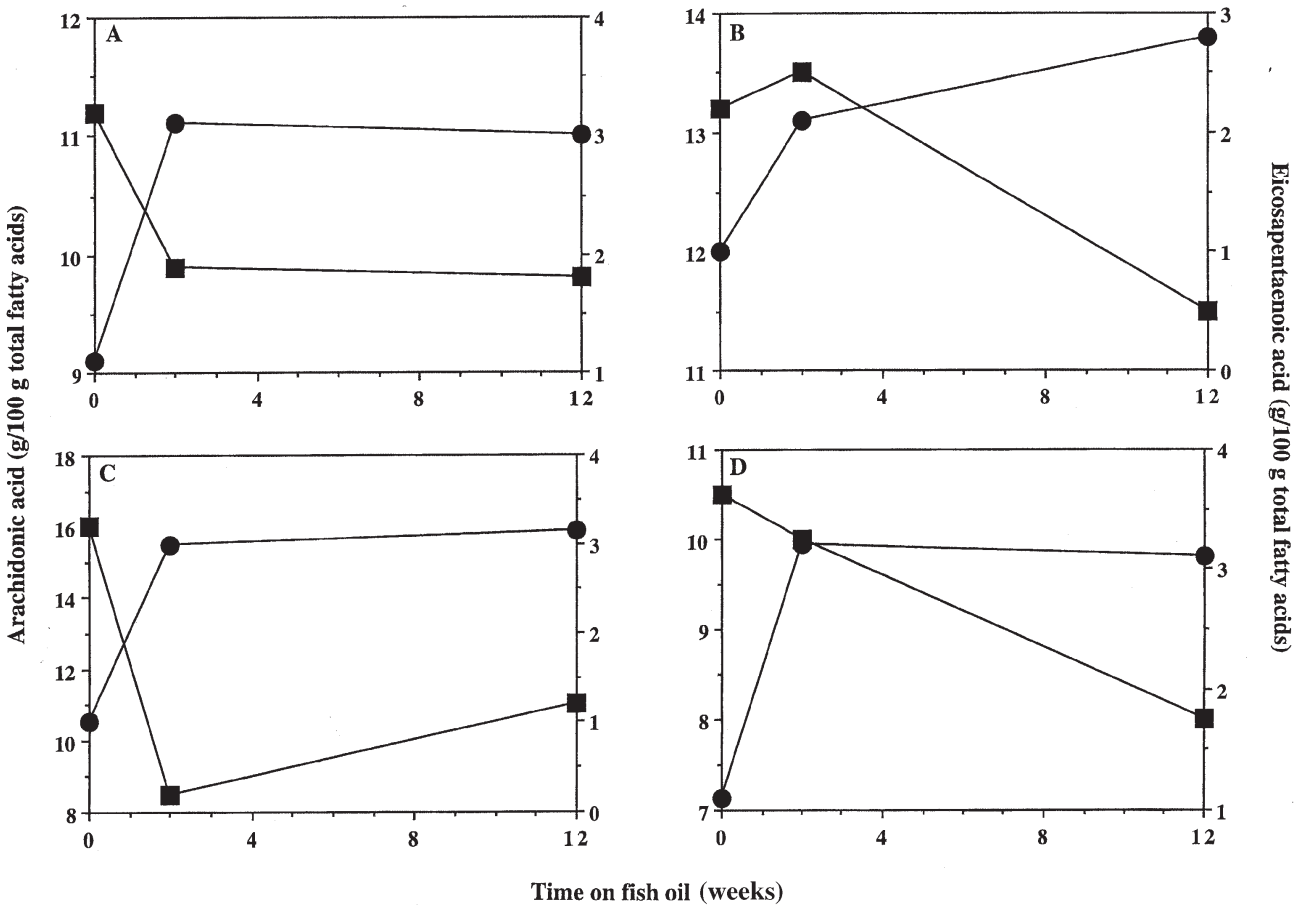

**FIG. 6.** The effect of dietary fish oil on the arachidonic acid (■) and eicosapentaenoic acid (EPA) (●) contents of human immune cell phospholipids. Healthy men aged 22–41 yr supplemented their diets with 10–15 g fish oil/d, providing 2.3–5.6 g EPA plus docosahexaenoic acid/d. After 2 and 12 wk, blood neutrophils (A), monocytes (B), T lymphocytes (C), and B lymphocytes (D) were prepared and the fatty acid composition of their phospholipids determined. Data are from Reference 3.

NK cell activity, or production of TNF-α, IL-1α, IL-1β, IL-2, and IFN-γ by mononuclear cells. These studies suggest a limited effect of linoleic acid (at a level ≥3.5% of dietary energy) on human immune function. However, in another study, the low-fat diet–induced increase in human NK cell activity (25) was reversed by adding 15 g safflower oil/d to the diet for 2 mo (26). Furthermore, the NK cell activity of blood lymphocytes from elderly Danish subjects correlated negatively with linoleic acid intake and with serum levels of linoleic acid (27).

## AA and Immune Function

In vitro *studies*. AA enhanced superoxide release from neutrophils and macrophages (7–10), promoted neutrophil adhesion to endothelial cells (11), and increased IL-1β production by a monocytic cell line (28) and by human monocytes (29). Thus, AA exhibits proinflammatory effects *in vitro*. AA inhibited the proliferation of rodent, pig, and human lymphocytes (12–16,30–32) and decreased the production of IL-2 by mitogen-stimulated rat and human lymphocytes (13,14), suggesting that it is potentially immunosuppressive.

*Animal feeding studies*. Feeding mice a diet containing 20 g safflower oil plus 10 g AA/kg did not affect spleen lymphocyte proliferation or IL-2 production compared with feeding a diet containing safflower oil (30 g/kg) (33). Inclusion of 4.4 g AA/100 g fatty acids in the rat diet did not significantly affect spleen lymphocyte proliferation, NK cell activity, or the graft vs. host response, despite the increased capacity of immune cells from rats fed AA to produce $PGE_2$ (34). These studies suggest that even significant amounts of AA in the rodent diet do not influence cell-mediated immunity.

*Human studies*. Two studies of the influence of dietary AA on human immune function have been performed. In the first, AA (1.5 g/d) was included in a low-fat diet (27% energy as fat) consumed for 8 wk by healthy men aged 20–38 yr (35,36). This level of AA did not alter the proliferation of lymphocytes in response to mitogens, NK cell activity, or the DTH response to seven recall antigens (35) and did not alter TNF-α, IL-1β, IL-6, or IL-2 production by mononuclear cells or the *in vivo* antibody responses to immunization with three strains of influenza virus (36). However, AA did increase production of $PGE_2$ and $LTB_4$ by endotoxin-stimulated mononuclear cells (36). The second study involved supplementing the diet of healthy subjects (men and women) aged 55–75 yr with

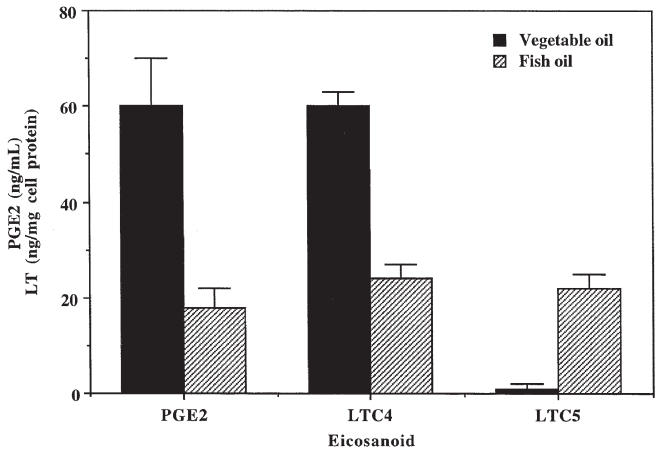

**FIG. 7.** The effect of dietary fish oil on the production of arachidonic acid and eicosapentaenoic acid–derived eicosanoids by murine macrophages. Mice were fed diets containing linoleic acid-vegetable oil or fish oil and thioglycolate-elicited peritoneal macrophages prepared. *Ex vivo* production of prostaglandin (PG)$E_2$, leukotriene (LT)$C_4$, and $LTC_5$ by stimulated macrophages was determined. $PGE_2$ data (ng/mL) are from Reference 5 and LT data (ng/mg cell protein) are from Reference 6.

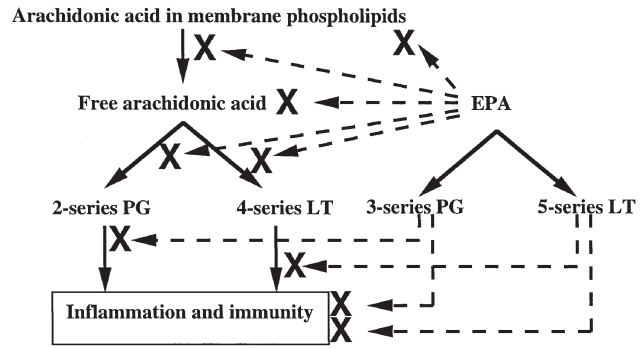

**FIG. 8.** The basis of the anti-inflammatory and immunomodulatory effects of fish oil. Eicosapentaenoic acid (EPA) acts at a number of sites (X) to antagonize the effects of arachidonic acid (AA). EPA replaces AA in immune cell membrane phospholipids, inhibits hydrolysis of AA from membrane phospholipids, and competes with AA for cyclooxygenase (COX) and 5-lipoxygenase (5-LOX). EPA-derived eicosanoids can oppose the effects of those derived from AA by competing for receptor binding. Finally, EPA-derived eicosanoids can have differing effects from those derived from AA. For abbreviations see Figures 3 and 4.

encapsulated AA (~700 mg/d) for 12 wk; there was no effect on NK cell activity (37), mitogen-stimulated lymphocyte proliferation (38), or production of TNF-α, IL-1β, IL-6, IL-2, or IFN-γ by mononuclear cells (38; Thies, F., Newsholme, E.A., and Calder, P.C., unpublished observations). Given that the habitual consumption of AA in free-living Western adults is <300 mg/d, these studies suggest that increasing AA consumption in healthy adults does not have adverse immunological effects. It should be noted, however, that the length of AA administration in these studies was ≤12 wk, and the immunological effects of AA over a longer term are not known.

## α-Linolenic Acid (ALNA; 18:3n-3) and Immune Function

In vitro *studies*. ALNA promoted neutrophil adhesion to endothelial cells (11). ALNA inhibited the proliferation of rodent and human lymphocytes *in vitro* (11–16,30–32), decreased the production of IL-2 by mitogen-stimulated rat and human cells (13,14), and inhibited degranulation of cytotoxic T lymphocytes (39). Thus, ALNA has potentially immunosuppressive properties.

*Animal feeding studies*. Compared with feeding a linoleic acid-rich diet, feeding rats linseed oil (100 g/kg diet) for 8 wk decreased superoxide production by peritoneal macrophages in response to phorbol ester but did not affect superoxide production in response to *Listeria monocytogenes* or phagocytosis of *L. monocytogenes* (40). Studies in rodents indicated that linseed oil increased production of TNF by resident macrophages, but had no effect on TNF production by inflammatory macrophages (41–43). High levels of linseed oil in the rodent diet led to decreased lymphocyte proliferation (44,45), NK cell activity (45), and graft vs. host response (45). The precise effect of ALNA on lymphocyte functions appears to depend on the level of linoleic acid and the total PUFA content of the diet (21).

*Human studies*. A high dose of ALNA (15 g/d for 4 wk) decreased IL-1 and TNF production by lipopolysaccharide-stimulated human monocytes (46). Adding linseed oil (providing ~15 g ALNA/d) to a low-fat diet (total fat provided 29% energy) resulted in a significant decrease in human blood lymphocyte proliferation and in the DTH response to seven recall antigens after 6 wk, but circulating antibody levels were unaffected (47). Supplementing the diet of healthy subjects aged 55–75 yr with linseed oil providing 2 g ALNA/d did not significantly affect NK cell activity (37), mitogen-stimulated lymphocyte proliferation (38), or production of TNF-α, IL-1β, IL-6, IL-2, or IFN-γ by mononuclear cells (38; Thies, F., Newsholme, E.A., and Calder, P.C., unpublished observations). Furthermore, supplementing the diet of healthy young men (aged 20–40 yr) with 4.2 g ALNA/d did not alter superoxide production by neutrophils (48). These studies suggest that a moderate increase in ALNA intake by healthy adults does not affect immunity, but that a marked increase in ALNA intake (e.g. 7- to 15-fold) can induce anti-inflammatory and immunosuppressive effects. It is not clear whether these are exerted by ALNA itself or by EPA, a product of ALNA metabolism.

## Long-Chain n-3 PUFA and Immune Function

Because dietary fish oil leads to decreased $PGE_2$ production (see earlier), it is often stated that it should reverse the effects of $PGE_2$, simply acting as a $PGE_2$ antagonist. If this were so, then fish oil would exert some anti-inflammatory actions (e.g., decreasing fever and vascular permeability) but it would also enhance production of the classic proinflammatory cytokines (TNF, IL-1, and IL-6), enhance production of Th1-type cytokines, increase MHC II expression, lymphocyte proliferation, and NK cell activity, and decrease IgE production

by B lymphocytes. As described below, many studies, especially those conducted in laboratory animals, have demonstrated that although in some situations fish oil does act as a "$PGE_2$ antagonist," it often induces effects that are the opposite to those expected on this basis. Thus, the situation is more complex than fish oil simply being a $PGE_2$ antagonist. $PGE_2$ is not the sole mediator produced from AA, and the range of mediators produced have varying, sometimes opposite, actions (see earlier). Thus, if fish oil was to act as a "4-series LT antagonist," it would be expected to decrease vascular permeability, leukocyte chemotaxis, neutrophil reactivity, production of proinflammatory and Th1-type cytokines, and NK cell activity. EPA itself will give rise to eicosanoids with varying actions, some augmenting the actions of AA-derived mediators and others antagonizing those actions. In addition, long-chain n-3 PUFA may exert a range of eicosanoid-independent effects, especially upon intracellular signaling mechanisms; these are discussed elsewhere (49,50). Thus, the overall effect of fish oil feeding cannot be predicted solely on the basis of an abrogation of $PGE_2$-mediated effects.

In vitro *studies*. Culture with EPA or DHA inhibited superoxide production (51) and phagocytosis (52) by human neutrophils. Incubation with EPA or DHA inhibited cytokine-induced cell surface expression of MHC II (in the mouse these antigens are termed Ia) on mouse peritoneal macrophages (53); DHA was more inhibitory than EPA and other 20-carbon fatty acids and acted by inhibiting the increase in Ia mRNA that occurs after stimulation of macrophages with cytokines (53). Hughes *et al.* (54) examined the effect of incubation of purified human monocytes with either EPA or DHA upon expression of MHC II, which is termed human leukocyte antigen (HLA); both EPA and DHA decreased the proportion of HLA-DR or -DP positive monocytes after incubation with IFN-γ and decreased the level of expression of these molecules on the monocyte surface (54). In accordance with this, the ability of monocytes cultured with EPA or DHA to present antigen (tetanus toxoid) to autologous lymphocytes was diminished (55). EPA and DHA inhibited production of IL-1β and of TNF-α by human monocytes (28,29) and IL-6 production by rat peritoneal macrophages (56). EPA and DHA inhibited mitogen-stimulation proliferation of rodent and human lymphocyte in culture (12–16,31,32,57–60), decreased the production of IL-2 by rat and human lymphocytes (13,14,59), and decreased human NK cell activity *in vitro* (59,61,62). Thus, in cell culture, both EPA and DHA exhibit potent anti-inflammatory and immunosuppressive effects.

*Animal feeding studies*. Feeding fish oil to laboratory animals decreased superoxide and hydrogen peroxide production by macrophages (63–66). Fish oil feeding decreased *ex vivo* production of TNF-α, IL-1β and IL-6 by rodent macrophages (5,67–69) and monocytes (70). Compared with feeding safflower oil, fish oil feeding resulted in lower peak plasma TNF-α, IL-1β, and IL-6 concentrations after intraperitoneal injection of endotoxin in mice (71). Furthermore, parenteral nutrition supplemented with fish oil decreased serum TNF-α, IL-6, and IL-8 concentrations in burned rats compared with n-6 PUFA–rich parenteral nutrition (72,73). Thus, animal studies reveal significant anti-inflammatory effects of dietary fish oil.

One study reported diminished phagocytosis of *Salmonella typhimurium* by murine Kupffer cells after feeding fish oil, although this was not associated with a reduced capacity of the cells to kill the bacteria (65). Another study showed that fish oil administered by gastric tube significantly diminished the ability of neonatal rabbits to clear a challenge of *Staphylococcus aureus* (63). However, there are reports that dietary fish oil does not affect phagocytosis of sheep erythrocytes or yeast particles by murine peritoneal macrophages (66), or of latex beads by porcine alveolar macrophages (74). Feeding fish oil decreased the level of MHC II expression on murine peritoneal macrophages (75) and on rat dendritic cells obtained by cannulation of the thoracic duct (76). Feeding mice an EPA-rich diet for a period of 4–5 wk resulted in diminished *ex vivo* presentation of antigen (keyhole limpet hemocyanin; KLH) by spleen cells (77). Compared with feeding a low-fat diet or a diet containing 200 g safflower oil/kg, feeding rats a diet containing 200 g fish oil/kg diminished *ex vivo* KLH presentation by dendritic cells obtained by cannulation of the thoracic duct to KLH-sensitized spleen lymphocytes (76). A recent study reported that dietary fish oil decreased expression of the IFN-γ-receptor on murine peritoneal macrophages (78). These studies suggest that dietary fish oil might impair the cell-mediated immune response by decreasing the activity of antigen-presenting cells and by decreasing the sensitivity of macrophages to T lymphocyte–derived cytokines. The effect of dietary fish oil on phagocytosis is unclear.

Animal feeding studies indicate that high levels of fish oil decrease NK cell activity (79–82), cytotoxic T lymphocyte activity (80), expression of the IL-2 receptor on activated lymphocytes (82–84), lymphocyte proliferation (82,83,85–90), and the production of IL-2 (74,90) and IFN-γ (90). Recently, Byleveld *et al*. (91) showed that feeding mice fish oil significantly impaired the elevation in lung IFN-γ that follows infection with the influenza virus. Dietary fish oil also decreased expression of the IFN-γ receptor on murine splenocytes (78). Dietary fish oil reduced the DTH response in mice compared with n-6 PUFA–rich or olive oil–rich diets (92), whereas addition of either EPA or DHA to the diet of mice consuming a safflower oil diet decreased the DTH response (93); both n-3 PUFA were equally effective. The DTH response to sheep red blood cells in mice was also diminished after tail-vein injections of emulsions of triacylglycerols rich in EPA or DHA (94). Feeding beagle dogs a diet with an n-6/n-3 PUFA ratio of 1.4 resulted in a reduced DTH response to intradermal KLH compared with diets with n-6/n-3 PUFA ratios of 31 or 5.4 (95); the increased n-3 PUFA content was brought about by replacing linoleic acid with EPA plus DHA. A suppressed host vs. graft response was observed in mice fed a diet containing 160 g fish oil/kg compared with those fed a standard chow diet (96); lower levels of fish oil (25, 50,

100 g/kg) did not significantly affect the response. Significantly diminished graft vs. host and host vs. graft responses were observed in rats fed a diet containing 200 g fish oil/kg compared with those fed a low-fat diet or diets containing 200 g coconut, olive, safflower, or evening primrose oil/kg (97). Taken together, these studies suggest that fish oil impairs cell-mediated immunity and induces a shift in T-lymphocyte response away from the Th1-type response, which is involved in both cell-mediated immunity and chronic inflammation. In accordance with this, fish oil enhanced production of IgE to ovalbumin in rats (98).

Animal studies have often used very large amounts of fish oil in the diet, i.e., a diet in which fish oil contributes 20% by weight will mean that EPA plus DHA comprise up to 30% of dietary fatty acids and up to 12% of dietary energy. Recent studies in rats and mice have indicated that relatively low levels of the long-chain n-3 fatty acids (EPA or DHA at a level of 4.4% of total fatty acids or 1.7% of dietary energy) are sufficient to bring about some of the effects of fish oil (99), that dietary EPA and DHA both inhibit lymphocyte proliferation (33,34) and IL-2 production (33), and that dietary EPA, but not DHA, inhibits NK cell activity (34).

*Human studies*. Fish oil, providing >2.3 g EPA plus DHA/d (and in some studies up to 14.5 g/d), decreased chemotaxis of neutrophils (100–104), decreased neutrophil superoxide production (105–107), and decreased neutrophil binding to endothelial cells (100). A recent study providing up to 2.4 g EPA plus DHA/d to healthy subjects for 12 wk did not detect effects on neutrophil chemotaxis or superoxide production (48).

Fish oil, providing 4.5–5.3 g EPA plus DHA/d, decreased chemotaxis of monocytes (101,102,108). Fish oil supplementation decreased zymosan-induced superoxide production by monocytes (109). A more recent study reported no effect of a low dose of n-3 PUFA (0.55 g EPA plus DHA/d for 12 wk) on monocyte chemotaxis (110).

Supplementation of the diet of human volunteers with 1.6 g EPA plus DHA/d for 3 wk resulted in decreased expression of MHC II (HLA-DP, -DQ and -DR) on the surface of blood monocytes (111). Fish oil providing >2.4 g EPA plus DHA/d has been shown to decrease production of TNF (46,108,112, 113), IL-1 (46,108,112,113), and IL-6 (112) by mononuclear cells. One other study in which subjects consumed a low-fat diet including oily fish daily (providing 1.2 g EPA plus DHA/d) showed decreased production of TNF, IL-1, and IL-6 (114). In addition, parenteral nutrition supplemented with fish oil decreased serum TNF-α and IL-6 concentrations in patients after major abdominal surgery compared with n-6 PUFA–rich parenteral nutrition (115). In contrast to these observations, a number of studies that provided from 0.55 to 3.4 g EPA plus DHA/d failed to demonstrate an effect of fish oil on production of TNF (24,110,116–118), IL-1 (24,110,116–119), and IL-6 (110,117).

Data from studies investigating the influence of fish oil on human lymphocyte functions are also conflicting. Supplementation of the diet of healthy human volunteers with fish oil providing 2.4 g EPA plus DHA/d resulted in decreased proliferation of lymphocytes from older (aged 51–68 yr) but not young (aged 21–33 yr) women and decreased IL-2 production (112). Molvig *et al*. (116) reported decreased lymphocyte proliferation after providing 1.7 or 3.4 g EPA plus DHA/d to men, and Gallai *et al*. (113) reported that 5.2 g EPA plus DHA/d decreased IL-2 and IFN-γ production. Providing 1.2 g EPA plus DHA/d to healthy subjects aged 55–75 yr resulted in decreased NK cell activity (37) and lymphocyte proliferation (38), but did not affect IL-2 or IFN-γ production (38). Finally, inclusion of oily fish providing 1.2 g EPA plus DHA/d in the diet of volunteers consuming a low-fat, low-cholesterol diet decreased lymphocyte proliferation, IL-2 production, and the DTH response to seven recall antigens (114). In contrast to these observations, there are reports of no effect of 3.2 g EPA plus DHA/d on NK cell activity, lymphocyte proliferation, and IL-2 and IFN-γ production (24) and of no effect of 4.6 g EPA plus DHA/d on lymphocyte proliferation and IL-2 production (120).

Taken together these studies indicate that addition of high levels of fish oil to the human diet exerts potent anti-inflammatory effects, particularly decreasing neutrophil and monocyte chemotaxis, superoxide production, and production of proinflammatory cytokines. A high level of dietary fish oil also impairs lymphocyte responses, at least in some studies. Other studies indicated that more modest addition of fish oil to the diet does not affect inflammatory or immune activities. However, there are a large number of studies that fall between the extremes of "modest addition" and "high levels," and these studies provide conflicting results. It is unclear what the reasons for these discrepancies are, but they might be related to different experimental protocols used, particularly those involving cell preparation, cell culture and cytokine assays, and/or to different subject characteristics (e.g., gender, age, habitual diet) (see Ref. 121 for a discussion).

Some recent studies have examined whether the effects of fish oil are due to EPA or DHA. There was no effect of 3.8 g of either EPA or DHA/d for 7 wk on phagocytosis of opsonized or unopsonized *Escherichia coli* by human monocytes (122). Kelley *et al*. (123,124) reported the effects in men aged 20–40 yr of including 6 g DHA/d in a low-fat diet (30% energy as fat) for 90 d. There was no effect of DHA on lymphocyte proliferation, serum IgG concentration, or the DTH response to seven recall antigens (123), or on the serum antibody response to immunization with three strains of influenza virus (124). NK cell activity was unaffected at d 55 but was decreased at d 90 (124). Similarly, the production of TNF-α and IL-1β tended to decrease at day 55 but was significantly decreased at day 80 (124). More recently, 750 mg DHA/d was shown not to affect NK cell activity (37), lymphocyte proliferation (38), or the production of TNF-α, IL-1β, IL-6, IL-2, or IFN-γ (38; Thies, F., Newsholme, E.A., and Calder, P.C., unpublished observations) in healthy subjects aged 55–75 yr. Taken together, these data indicate that high levels of DHA (e.g., 6 g/d) can mimic some of the effects of fish oil but that lower levels (e.g., <1 g/d) do not exert any immunological effects in healthy adults.

## EFFECTS OF n-3 PUFA ON INFLAMMATION AND IMMUNITY: IMPLICATIONS AND APPLICATIONS

As outlined above, a number of animal feeding and human supplementation studies indicate that fish oil can have potent effects on immune function and inflammatory cell responses. Of the two long-chain n-3 PUFA characteristic of fish oil, EPA appears to be more potent than DHA, although high levels of DHA can mimic some of the effects of fish oil. Moderate increases in the intakes of ALNA and AA appear to have little effect on immune function, although high intakes of ALNA have similar effects to fish oil and high intakes of AA have not been studied in humans. The immunological effects of long chain n-3 PUFA are generally termed as anti-inflammatory, and the applications of these effects have been described in terms of chronic inflammatory diseases, allergic inflammation, and acute systemic inflammation in response to trauma. In each of these situations, the benefits of decreased production of 2-series PG (especially $PGE_2$), 4-series LT, and the proinflammatory cytokines, especially TNF-α and IL-1, are evident. The potential detrimental effect on cell-mediated immune responses is often overlooked, although this effect has been demonstrated more easily in animals fed large amounts of fish oil than in humans consuming more moderate amounts. In the following sections, the contrasting effects of fish oil on host responses to live pathogens vs. purified endotoxin and the applications to chronic inflammatory diseases and allergic inflammation are described.

### Fish Oil, Infection, and Endotoxemia

*Animal studies*. The diminished cell-mediated immune responses observed after feeding diets rich in long-chain n-3 PUFA suggest that these fatty acids could impair the host response to infection. Some animal studies support this suggestion. Mice fed a diet containing 200 g fish oil/kg showed lower survival over 15 d (48%) to orally administered *S. typhimurium* than those fed corn oil (62.5%), coconut oil (87.5%), or a low-fat diet (88%) (125); spleens from the fish oil–fed animals contained a greater number of bacteria than those from animals fed the other diets. Similarly, a study of experimental tuberculosis in guinea pigs reported an increased number of bacteria (*Mycobacterium tuberculosis*) in the spleens of fish oil–fed animals, and it was concluded that this represented persistence of the experimental infection (126). Compared with safflower oil, fish oil decreased the clearance of bacteria (inspired *S. aureus*) in neonatal rabbits (63). A diet containing 170 g fish oil/kg decreased survival of mice after an intraperitoneal injection of *L. monocytogenes* compared with feeding 200 g/kg lard, but not compared with feeding 200 g soybean oil/kg, which also resulted in lower survival (127). The spleens from the fish oil–fed mice contained significantly more bacteria than those from the other two groups (127). Recently, fish oil feeding was shown to delay the clearance of influenza virus from the lungs of mice; this was associated with impaired IFN-γ appearance in lung lavage fluid (91). Because the response to microbial and viral infections is predominantly a Th1-mediated response [or at least requires Th1-type cytokines such as IFN-γ (2)], the reduced survival of rodents fed large amounts of fish oil after bacterial challenges confirms that large amounts of fish oil in the diet suppress the Th1 response *in vivo*. In contrast to these observations, some studies show that fish oil feeding does not affect resistance of laboratory rodents to some bacterial (*Pseudomonas aeruginosa*) and viral (murine cytomegalovirus) challenges (128,129). Furthermore, some studies have shown that dietary fish oil enhances survival during some infections. For example, Blok *et al*. (130) reported increased survival of fish oil–fed mice challenged by intramuscular injection with *Klebsiella pneumoniae*; 90% of fish oil–fed mice survived compared with 30, 40, and 0% in groups fed corn oil, palm oil, or chow, respectively. Cerebral malaria induced by intraperitoneal injection of erythrocytes infected with *Plasmodium berghei* occurred in only 23% of fish oil–fed mice compared with 61, 81, and 78% of mice fed corn oil, palm oil, or chow, respectively (130). The latter observation is interesting because in human cerebral malaria, an unrestrained Th1 response is detrimental and a Th2 response is helpful (2). The apparent shift away from a Th1- toward a Th2-type response after fish oil feeding fits with these observations.

In contrast to the detrimental effects of fish oil feeding after challenge with live intact bacteria reported in some studies (see above), intravenous infusion of a 10% (vol/vol) lipid emulsion rich in fish oil into guinea pigs significantly enhanced survival to intraperitoneally injected bacterial endotoxin compared with infusion of a 10% (vol/vol) safflower oil emulsion (131). Furthermore, feeding a diet containing 145 g fish oil/kg to guinea pigs for 6 wk significantly increased survival after an intraperitoneal injection of endotoxin compared with animals fed a diet containing 150 g safflower oil/kg (132). The decreased sensitivity of fish oil–fed animals to endotoxin could be because fish oil decreases the production of the proinflammatory cytokines (see earlier), which are in part the cause of endotoxin-mediated morbidity and mortality. In addition, other studies suggest that fish oil feeding decreases sensitivity to the effects of proinflammatory cytokines. For example, feeding weanling rats a diet containing 100 g fish oil/kg for 8 wk significantly decreased a number of metabolic responses to intraperitoneal TNF-α, i.e., the rises in liver zinc and plasma C3 concentrations, the fall in plasma albumin concentration, and the increases in liver, kidney, and lung protein synthesis rates were all prevented by the fish oil diet (133). Furthermore, fish oil feeding to rats or guinea pigs diminished the pyrogenic (134,135) and anoretic effects (133,136) of IL-1 and TNF-α compared with feeding linoleic acid–containing oils.

It is not entirely clear why fish oil increases susceptibility to pathogens in some studies but not others; this most probably relates to the precise components of the immune response that are required for defense against a particular pathogen, the age of the animals studied, the level of n-3 PUFA in the diet, the mode of administration of the pathogen, and the species

and strain of animal used. What is apparent, however, is that large amounts of fish oil can impair host defense to live pathogens *in vivo* (at least in some experimental animal models), and that they protect against the damage induced by pure bacterial endotoxin. These observations agree with the *ex vivo* measures of immune function. Defense against live bacteria and viruses requires an efficient cell-mediated immune response and this can be impaired by fish oil. In contrast, the damaging effects of purified endotoxin are mediated by macrophage-derived proinflammatory cytokines, whose production is diminished by fish oil feeding.

*Human studies.* There have been no reports of compromised immunity in humans supplementing their diet with n-3 PUFA. However, most studies of PUFA and immune function have been too small and of too short a duration to identify effects on infection rates; they have also not been designed to investigate rates of infection. However, an epidemic of measles in Greenland triggered by its introduction into the naive population by an infected Danish sailor showed the same characteristics (e.g., expected numbers of cases, complications) as previous epidemics recorded in other naive populations (137). This suggests that the traditional, very n-3 PUFA–rich diet of Greenland Eskimos did not worsen their response to the virus.

### Fish Oil and Th-1 Skewed Immunological Diseases

Chronic inflammatory diseases are characterized by a dysregulated Th1-type response and often by an inappropriate production of AA-derived eicosanoids, especially $PGE_2$ and $LTB_4$. The effects of fish oil outlined above suggest that it might have a role in the prevention and therapy of these diseases. Dietary fish oil has been shown to have beneficial clinical, immunological, and biochemical effects in various animal models of human chronic inflammatory diseases. These effects include increased survival and decreased proteinuria and anti-DNA antibodies in mice with autoimmune glomerulonephritis (a model of lupus) (138–141), decreased joint inflammation in rodents with collagen-induced arthritis (142), and less inflammation in rat models of colitis (143,144). The improvements in the model of lupus are associated with abolition of proinflammatory cytokine production and the induction of anti-inflammatory cytokines and antioxidant enzymes (145,146). It was recently reported that both EPA and DHA suppress streptococcal cell wall–induced arthritis in rats, but that EPA was more effective (147); this fits with the more potent effects of EPA than DHA on inflammation and immunity.

There have been a number of clinical trials assessing the benefits of dietary supplementation with fish oil in several inflammatory diseases in humans, including rheumatoid arthritis, Crohn's disease, ulcerative colitis, psoriasis, lupus, and multiple sclerosis. Trials in some of these diseases are summarized in Table 2. Many of the placebo-controlled, double-blind trials of fish oil in chronic inflammatory diseases reveal significant benefit, including decreased disease activity and a lowered use of anti-inflammatory drugs; the evidence for a beneficial effect of fish oil is strongest in rheumatoid arthritis (Table 2). It was recently observed that n-3 PUFA cause a concentration-dependent decrease in expression and activity of the aggrecanase enzymes that degrade cartilage, in expression of COX 2, but not COX 1, and in TNF-$\alpha$ and IL-1$\beta$ expression in cultured articular cartilage chondrocytes (156). These observations may explain in part the benefits of fish oil in rheumatoid arthritis. Trials of fish oil supplementation in systemic lupus erythematosus and multiple sclerosis have failed to show significant clinical improvement.

### Fish Oil and Th-2 Skewed Immunological Diseases

$PGD_2$, $LTC_4$, $LTD_4$, and $LTE_4$ are produced by the cells that mediate pulmonary inflammation in asthma such as mast cells and are believed to be the major mediators of asthmatic bronchoconstriction (Fig. 9). Although its action as a precursor to LT has highlighted the significance of AA in the etiology of allergic inflammation (Fig. 9), a second link with this fatty acid has been made. This is because $PGE_2$ regulates the activities of macrophages and lymphocytes (see earlier). Of particular relevance in the context of asthma and allergic diseases is the ability of $PGE_2$ to inhibit the production of the Th-1 type cytokines IL-2 and IFN-$\gamma$ without affecting the production of the Th-2-type cytokines IL-4 and IL-5, and to stimulate B cells to produce IgE. These observations suggest that $PGE_2$ regulates the development of these diseases (Fig. 9). As a result, there has been speculation that the increased intake of linoleic acid, the precursor of AA, that has occurred since the mid-1960s is causally linked to the increased incidence of asthma and allergic diseases over this period (157,158). Thus, a case has been made for increasing the consumption of n-3 fatty acids by patients with allergic diseases (157,158).

There is some epidemiological evidence to support a protective role of long-chain n-3 PUFA in allergic disease (see Ref. 159 for references). These observations make a compelling argument for trials of fish oil in asthma and related diseases, and a number of such trials have been performed. A fish oil–induced reduction in *ex vivo* $LTB_4$ production by neutrophils from asthmatic patients has been demonstrated (160); most likely, this was accompanied by increased production of 5-series LT. The 5-series LT might be beneficial in asthma because they are unable to elicit an asthmatic response and/or because they block 4-series LT binding to their receptors. Several studies of fish oil supplementation in asthma revealed limited clinical effect, despite significant biochemical changes (e.g., reduced 4-series LT production); details of these studies are discussed elsewhere (see Refs. 159,161). In contrast, some studies have shown significant clinical improvements at least in some patient groups and suggest that this type of approach may be useful in conjunction with other drug- and diet-based therapies (see Ref. 159). A very careful study by Broughton *et al.* (162) found that low n-3 PUFA ingestion resulted in increased methacholine-induced respiratory distress in asthmatic patients. In contrast, high n-3 PUFA ingestion resulted in an improved response in >40% of subjects; all measures of respiratory function were markedly improved in this group of patients who also showed a markedly elevated appearance of the

**TABLE 2**
**Summary of Clinical Trials of Fish Oil in Chronic Inflammatory Diseases[a]**

| Disease | Number of double-blind, placebo-controlled studies | Doses of EPA + DHA used (g/d) | Duration (wk) | Key findings | Reviews |
|---|---|---|---|---|---|
| Rheumatoid arthritis | 14 | 1–7.1 | 4–52 | All studies reported improvements, including reduced duration of morning stiffness, tender or reduced number of swollen joints, reduced joint pain, reduced time to fatigue, and increased grip strength. Twelve studies reported improvement in at least two clinical measures, and five studies reported improvement in at least four clinical measures. Nine studies reported decreased joint tenderness. Three studies reported significant decrease in the use of nonsteroidal anti-inflammatory drugs. | 148–152 |
| Crohn's disease | 3 | 2.7–5.1 | 12–52 | Two studies reported no benefit. One study reported a significiant decrease in relapses. One other study which used oily fish (100–250 g/d for 2 yr) reported a significant decrease in relapses. | 153 |
| Ulcerative colitis | 4 | 1.8–5.4 | 12–52 | One study reported no benefit (this study used the lowest dose of EPA plus DHA). One study reported a nonsignificant decrease in disease activity and a significant decrease in use of corticosteroids. Two studies reported benefit including improved histologic appearance of the colon, decreased disease activity, weight gain and decreased use of prednisolone. Two other "open" studies reported improved symptoms, improved histologic appearance of the rectal mucosa, and decreased use of prednisolone. | 154 |
| Psoriasis | 2 | 1.8 | 8–12 | One study reported significant improvement in itching, scaling and erythema. One study reported no benefit. Three open studies (providing 10–18 g EPA + DHA/d for 6–8 wk) reported mild-to-moderate (two studies) or moderate-to-excellent (one study) improvements in scaling, itching, lesion thickness, and erythema in the majority of patients. One open study,which combined fish oil with a low-fat diet, reported improvements. | 155 |

[a]Abbreviations: EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

EPA-derived 5-series LT in their urine. However, some patients did not respond to the high n-3 PUFA intake. This study suggests that there are patients who respond positively to fish oil intervention and patients who are nonresponders. This suggests that such therapies should be approached cautiously until more is understood about the interaction between fatty acid consumption and disease activity.

## DIETARY PUFA AND IMMUNE FUNCTION IN THE NEONATE

None of the studies described above investigated the influence of altering the fatty acid composition of the maternal diet during pregnancy and/or lactation on immune outcomes in the offspring at birth, weaning, or later in life. Only a limited number of such studies have been reported and these are all in animals (163–165).

In the study by Berger *et al*. (163), female mice were fed before and throughout pregnancy and during lactation diets containing 100 g olive oil, safflower oil, linseed oil, or fish oil/kg. Spleen and thymus weights were determined in the offspring at weaning (d 18). Immune cell functions were determined in the offspring at day 42 but the paper does not indicate the postweaning diet; it is unclear whether it was the same as the maternal diet or was standard chow. At weaning, the offspring of dams fed the olive oil or fish oil diets had smaller spleens than those of dams fed the safflower oil or linseed oil diets. The offspring of dams fed the linseed oil or fish oil diets had smaller thymuses than those of dams fed the olive oil or safflower oil diets. NK cell activity in the offspring at day 42 was decreased by maternal fish oil compared with olive oil and safflower oil. Maternal diet did not affect spleen lymphocyte proliferation or IL-2 production in the offspring.

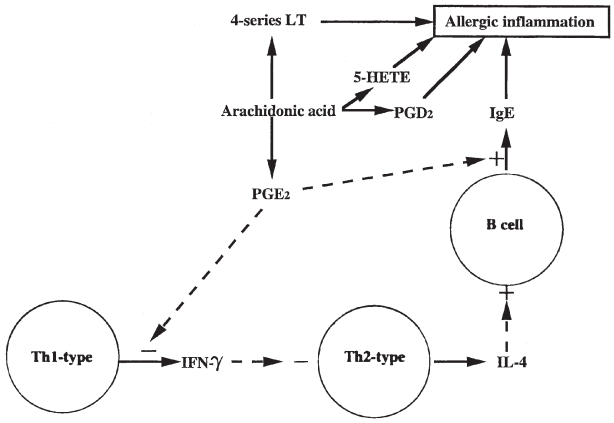

**FIG. 9.** Role of arachidonic acid–derived eicoanoids in allergic inflammation. For abbreviations see Figures 1–5.

Rayon *et al.* (164) fed rats diets containing either 100 g corn or fish oil/kg throughout pregnancy and lactation and then administered live *Streptococcus* to the 7-d-old pups. The offspring of dams fed corn oil were more susceptible to death (50% mortality over 2 d) than those of dams fed fish oil (25% mortality over 2 d).

The influence of feeding rats diets containing 100 g corn oil, 50 g corn oil plus 50 g coconut oil, or 10 g corn oil plus 90 g coconut oil/kg throughout pregnancy on lymphoid tissue weights and immune cell functions in the offspring was determined (165); the rats were transferred to standard laboratory chow once they had given birth. Spleen lymphocyte proliferation in the offspring at birth was higher if the maternal diet contained 90 g coconut oil. Spleen and thymus weight at weaning increased as the amount of corn oil in the maternal diet increased. Spleen and thymus lymphocyte proliferation at weaning were little affected by maternal diet, but tended to be lowest in the offspring of dams fed the 100 g corn oil/kg diet. Spleen NK cell activity at weaning was highest in the offspring of dams fed the 100 g corn oil/kg diet.

These studies indicate that the nature of the fatty acids in the maternal diet during pregnancy can influence lymphoid tissue development in the offspring, immune cell function in the offspring, and the ability of the offspring to withstand infectious challenges. It is not clear how long the influence of the fatty acid composition of the maternal diet affects the offspring. Nor is it clear how the fatty acid composition of the maternal diet affects the subsequent development of Th1- or Th2-type immunological diseases or subsequent resistance to infection. There is a clear need to explore this area further in appropriate animal models and in human epidemiological and intervention studies.

## GENERAL REMARKS

Among the fatty acids, it is the n-3 PUFA that possess the most potent immunomodulatory activities, and among the n-3 PUFA, those from fish oil (EPA and DHA) are more biologically potent than ALNA. Components of both natural and acquired immunity, including the production of key inflammatory mediators, can be affected by n-3 PUFA. Animal studies indicate that diets rich in EPA plus DHA are anti-inflammatory and immunosuppressive *in vivo*, although there have been relatively few good studies in humans. Although some of the effects of n-3 PUFA may be brought about by modulation of the amount and types of eicosanoids made, it is possible that these fatty acids might elicit some of their effects by eicosanoid-independent mechanisms, including actions upon intracellular signaling pathways and transcription factor activity (see Refs. 49,50). Such n-3 PUFA–induced effects may be of use as a therapy for acute and chronic inflammation, and for disorders that involve an inappropriately activated immune response. Moderate levels of AA and DHA do not appear to have any detrimental effects on human immune function, but the effects of these fatty acids have been studied only in healthy adults. The effect of fatty acids during pregnancy upon the maternal immune system and upon that of the infant are not known.

All studies of fatty acids and the human immune system have used adults as subjects, and most studies have used men only or a mixture of men and women. The only study that used women exclusively as subjects was that of Meydani *et al.* (112); in that study, it was found that the immune system of older women is more sensitive to fish oil than is that of young women. This age-related difference in sensitivity to dietary intervention may explain some of the contradictory observations in the literature [e.g., between (24) and (37, 38)]. It is clear that more needs to be understood about the effect of n-6 and n-3 PUFA on the human immune system and on how variations in age, gender, ethnicity, hormone status, antioxidant status, and genetics influence sensitivity to dietary PUFA. Long-chain n-3 PUFA have been used in a range of diseases characterized by dysregulated Th1- or Th2-type responses and, in a small number of studies, in trauma patients at risk of the systemic inflammatory response syndrome. In these situations, long-chain n-3 PUFA have been beneficial as therapeutic agents. It is not clear what the differential roles of n-6 and n-3 PUFA are in regulating the development of the immune system and how they might affect the likelihood of an individual developing a disease with an immunological component. Clearly, the interactions among PUFA intake, environmental factors, and genetics must be established if we are to fully understand the roles of n-6 and n-3 PUFA in the development and action of the human immune system.

# Polyunsaturated Fatty Acids and T-Cell Function: Implications for the Neonate

**Catherine J. Field[a,b,*], M. Thomas Clandinin[a,b], and John E. Van Aerde[c]**

Departments of [a]Agricultural, Food and Nutritional Science, [b]Medicine, and [c]Pediatrics, University of Alberta, Edmonton, Canada

**ABSTRACT:** Infant survival depends on the ability to respond effectively and appropriately to environmental challenges. Infants are born with a degree of immunological immaturity that renders them susceptible to infection and abnormal dietary responses (allergies). T-lymphocyte function is poorly developed at birth. The reduced ability of infants to respond to mitogens may be the result of the low number of CD45RO+ (memory/antigen-primed) T cells in the infant or the limited ability to produce cytokines [particularly interferon-γ, interleukin (IL)-4, and IL-10]. There have been many important changes in optimizing breast milk substitutes for infants; however, few have been directed at replacing factors in breast milk that convey immune benefits. Recent research has been directed at the neurological, retinal, and membrane benefits of adding 20:4n-6 (arachidonic acid; AA) and 22:6n-3 (docosahexaenoic acid; DHA) to infant formula. In adults and animals, feeding DHA affects T-cell function. However, the effect of these lipids on the development and function of the infant's immune system is not known. We recently reported the effect of adding DHA + AA to a standard infant formula on several functional indices of immune development. Compared with standard formula, feeding a formula containing DHA + AA increased the proportion of antigen mature (CD45RO+) $CD4^+$ cells, improved IL-10 production, and reduced IL-2 production to levels not different from those of human milk-fed infants. This review will briefly describe T-cell development and the potential immune effect of feeding long-chain polyunsaturated fatty acids to the neonate.

Paper no. L 8647 in *Lipids* 36, 1025–1032 (September 2001).

Infant survival depends in part on the ability to respond effectively and appropriately to environmental challenges. The required immune response to such a challenge is the result of the interaction among immune cells, signals, and other cells. Neonates are born with some degree of immunological immaturity, affecting both antibody- and cell-mediated function (1–8) and making them highly susceptible to infection (9). The developing neonatal immune system has functional, albeit limited, defensive, homeostatic, and surveillance capabilities; several excellent reviews of the development of the cellular components of the neonatal immune system and their physiologic interrelationships and limitations have been published (1,10). T-lymphocyte (T-cell) function is one of the most poorly developed systems at birth and is central to defense against infectious agents. This review will briefly describe T-cell lymphocyte function, review our current understanding of T-cell development in the newborn, and summarize the work on the effect of dietary long-chain polyunsaturated fatty acids (PUFA) on T-cell function (in the adult). The final section will highlight some work by our group and others that has examined the implications of feeding commercial infant formula with and without added long-chain PUFA on the development of the T-cell function in infants.

## T-CELL FUNCTION

The immune system is defined as part of the host's defense against destructive forces from outside the body (bacteria, viruses, and parasites) or those from within the body (malignant and autoreactive cells). The immune system can be divided loosely into two separate but interacting and interdependent arms, the innate and the acquired immune system (reviewed in Refs. 11,12).

Innate (natural) immune defenses are those components of the immune system (macrophages, monocytes, neutrophils) that do not depend on prior exposure to a particular antigen. This defense system provides the early phase of host defense, protecting the organism during the first 4–5 d before lymphocytes have been activated. Cytokines, growth factors, hormones, and lipid-derived molecules collectively control the proliferation, survival, differentiation, and function of immune cells (11,13,14).

The acquired or adaptive immune system is composed primarily of the cell-mediated and humoral responses (Fig. 1). Acquired immunity develops over the lifetime of individuals as they respond to their environment. T cells are an important part of this arm of the immune system and function by modulating the function of other immune cells and/or directly destroying cells infected with intracellular pathogens. The diverse host defense and immunoregulatory functions of T cells are performed by phenotypically heterogeneous subpopulations within two basic arms, CD4 (helper/inducer) and CD8 (suppressor/cytotoxic) cells. Maturation and expansion of T cells, a process essential to combating invading organisms, begins with the migration of mature T cells from the thymus,

and perhaps the gut, to the periphery. Here the cells encounter antigens by an interaction of their T-cell receptor with an antigenic peptide presented in association with major histocompatibility complex (MHC) class I or II molecules on the surface of a specialized antigen-presenting cell, i.e., a macrophage or B cell (15). Each T cell will generate a unique receptor through rearranging its receptor genes, which enables the cell to respond to a specific antigen.

The CD4 subset has been further subdivided on the basis of the type of cytokines produced and secreted (Fig. 1). The identification of helper T (Th) cell subsets has greatly improved the understanding of the regulation of immune effector functions (16). Th1 cells produce interleukin (IL)-2 and interferon (IFN)-γ, which generally promote a cell-mediated inflammatory response (17). Th2 cells produce IL-4, IL-5, IL-10, and IL-13, which support a humoral response (17). Recently, a cytokine pattern defined as Th0 and Th3 has been described (18,19). Although Th1 and Th2 cytokine profiles are not so clearly defined in humans as they are in mice, it has been hypothesized that the balance between these two responses may explain how the immune system can respond appropriately to different challenges (15). Cytokine secretion is not confined to $CD4^+$ T cells; rather, Type 1 and Type 2 populations of $CD8^+$ T cells have been generated *in vitro* and have been isolated from *in vivo* situations (20).

T cells that reside in mucosal-associated lymphoid tissues are important in the protection against potentially infectious agents and other antigens that might gain entry through mucosal surfaces (21). This system includes immune cells that are found in the skin, the urinary tract, the respiratory tract, and the gastrointestinal tract (22–24). Most important for the neonate is the gastrointestinal mucosal immune system, a complex system with multiple interacting cells. This system is composed of T cells and other immune cells that reside in specialized lymph tissues known as Peyer's patches and in the intraepithelial and lamina propria regions of the gut (22,23). Immune cells work together to limit antigen passage from the gut lumen and thus promote normal antigenic response and ensure systemic tolerance (22,23). Because gastrointestinal infections are a major problem in infants (25), T cells in this region likely play an important role to the outcome of contact with infectious organisms (26). It has been hypothesized that the slow rate of maturation of this immune barrier might contribute to pathological inflammatory conditions that are frequently encountered by infants such as necrotizing enterocolitis, milk-protein enteropathy, and enteric bacterial infections (3,22).

## T-CELL DEVELOPMENT IN THE TERM NEONATE

Technical developments in immunophenotyping and function testing have greatly facilitated studies on the developing lymphocyte system in the infant (reviewed in Refs. 2,27). It is well established that newborn infants (term and preterm) have a higher absolute numbers of white blood cells compared with adults (28). As the infant ages, there is a progressive decline in the peripheral concentration of leukocytes, total lymphocytes and T cells, and natural killer (NK) cells (29–31). However, within the peripheral circulation, the proportion of T cells decreases without any changes in the relative proportion of $CD8^+$ and other cytotoxic cells (29,32,33), resulting in a decrease in the CD4/CD8 ratio (32,33). The following section will review what is known about T-cell maturation in the peripheral blood of term and preterm infants.

*T-cell maturation in the term infant*. The expression of a number of cell surface molecules is different on naïve and mature T cells. In the infant, the most frequently studied markers that delineate antigen naïve and mature T cells are the variant isoforms of CD45 (the common lymphocyte antigen), the CD45RA isoform (molecular weight 190,000–220,000), and the CD45RO isoform (molecular weight 180,000). $CD45RO^+$ T cells are believed to identify primed/memory (antigen-educated) cells and are derived from $CD45RA^+$ (naïve) cells after antigenic or mitogenic stimulation (34). The CD45RA antigen is first expressed late during intrathymic maturation and continues to be expressed by most circulating T cells in the infant (35–37). With increasing age and antigenic exposure, these phenotypically immature cells decline progressively in both absolute numbers and percentages. Recently it has been reported that they do not reach adult values until 2–4 y of age (38). With age, $CD4^+CD45RA^+$ cells have been shown to differentiate into $CD4^+CD45RA^-/CD45RO^+$ "memory" cells. These "primed/memory" cells are the predominant isoform of expressed T cells in the adult (30–40% of adult $CD4^+$ and $CD8^+$ cells) and convey most of the functions associated with T cells (2,34,35,38–40).

Clinical evidence has indicated that the neonatal immune response (cell-mediated) to primary infection is delayed compared with that of adults with the same primary infection (3). Additionally, the functional capacity of T cells (both *in vivo* and *in vitro*) to respond to stimulation in the neonate is reduced compared with adults (1,2,41). There are several possible mechanisms to explain this immaturity. The reduced ability to respond to mitogens may be the result of the low number

of $CD45RO^+$ (memory) cells in the infant (32,36,37). Analyses of the functional capabilities of $CD4^+CD45RA^+$ and $CD4^+CD45RO^+$ cells have shown that proliferative responses to "memory" recall antigens and the ability to provide help for antibody production are functions uniquely performed by $CD4^+CD45RA^-CD45RO^+$ cells (35,42). Extensive phenotypic analysis of naïve and memory T cells shows that the latter express greater amounts of adhesion molecules and low-level antigens indicative of activation (42). Alternatively, the major immunoregulatory functions described for $CD4^+CD45RA^+$ cells (those found in infants) involve suppression of immune responses, either directly or *via* the induction of suppressor activity by $CD8^+$ (35,43). Indeed, a high level of T-cell–mediated suppression has been reported in infant mononuclear cells (44).

It has been suggested that the immunological immaturity and susceptibility to infection of healthy neonates is the result of lower or altered expression of various cytokines (45). Neonatal peripheral T cells produce a limited repertoire of cytokines in response to activation (8,9,31,40,41,45–47), with steady improvement after birth (31). Specifically, the production of IFN-γ and IL-4, which participate in the maturation of cytotoxic cells, activation of macrophages, and maturation and modulation of B cell function and isotype expression, is reported to be reduced as much as 10-fold, compared with cells from adults (31,40,41,48). The higher susceptibility of newborns to fungal, viral, protozoan, and certain bacterial infections has been proposed to be due in part to a decreased IFN-γ production (9). Reports on IL-4 production in the neonate are a little less consistent. Transcriptions of IL-4, as determined by nuclear run-on assays, and IL-4 mRNA-containing cells, as determined by *in situ* hybridization, have been reported to be undetectable in neonatal T cells, whereas both are detectable in adult T cells (40). However, it was found recently that neonatal cells are able to produce IL-4 at levels comparable to that of adults (31). Human neonates exhibit broad immune deficits that parallel actions of IL-10. IL-10 suppresses phagocytic immune responses and accentuates humoral responses (49). In support of this hypothesis, the ability to produce IL-10 has been reported to be diminished in neonatal blood cells (31,50).

Neonatal cells (at least from full-term infants) appear to be able to make IL-2 with mitogen stimulation at levels equal to those of adults (31,40,51). Despite immature CD4 cells being able to make IL-2, only $CD45RO^+$ cells are found to be able to be stimulated by IL-2 (52). This may be due to a lower expression of IL-2 receptors on neonatal T cells (30,36). It has been suggested that the favoring of a type-1 response (increased IL-2 production) early in immune development may contribute to the ontogeny of the infant's immune system (31).

The mechanisms by which T lymphocytes acquire the capacity to produce cytokines during intrathymic and extrathymic development are poorly understood. The difference in cytokine expression in neonatal T cells has been suggested to be due to diminished transcription of these genes (possibly due to differences in essential promoter elements regulating transcription) in response to activation (41). Reduced IFN-γ production by neonatal T cells has been found to correlate with CD45RO expression, suggesting that extrathymic generation of memory T cells during postnatal life may result in an increased capacity for IFN-γ gene expression (40).

T cells do not function in isolation, and there are numerous reports of both humoral (4,7,47,53) and phagocytic (4,6,54) functions being impaired or immature in the neonate. These most certainly contribute to the increased tendency for the infant to develop infections. Owing to the constraints of sampling, little is known about T-cell development at other immune sites in the healthy infant. Additionally, the gastrointestinal immune system is reported to be poorly developed at birth, maturing with both age and antigenic stimulation (3).

*The contribution of human milk to T-cell function and development in the neonate*. Epidemiologic and clinical evidence indicates that there is a lower occurrence of infections (acute respiratory and diarrhea) in breast-fed infants >6 mon of age (25). In support of breast milk providing direct immune protection to the infant, there is considerable evidence that human milk contains a complex mixture of immunologically active components, such as immunoglobulins, immune cells, prostaglandins, cytokines (including IL-2, IL-10, IL-12), soluble cytokine receptors and other proteins (55–62). Many of these immune constituents have been shown in other models to provide both specific and nonspecific defenses against infectious agents in the gastrointestinal tract, but the physiological role of their consumption through breast milk has not been established. Additionally, the T cells found in breast milk may play a functional role in the infant's immunity. $CD4^+$ cells in human milk were found to express mainly the CD45RO isoform and two- to threefold more IL-2R than CD4 cells in adult blood (56). $CD8^+$ cells in human milk were also reported to express more activation markers (HML-1 and VLA-1) than the same population in adult blood (56).

Breast milk may also play a role in regulating the development of antigen-specific T-cell immunity in neonates. Breast-fed infants ingest a wide array of immunologically active ingredients present in maternal milk during a period of rapid maturation of gut-associated and peripheral lymphoid tissues. Although there have been few studies in this area, it is likely that human milk serves an immunodevelopmental role in the infant (reviewed in Ref. 58). At present, infant formula in North America does not contain the immune active substances found in human milk. This suggests that the infant who is not fed human milk is at an immunological disadvantage. As discussed above, there have been a number of papers over the past 20 yr describing the distribution of lymphocyte surface antigens in healthy neonates; more recently this has been extended to compare peripheral blood phenotypes between a large group of formula- and breast-fed infants (60). The concentration and percentage of T ($CD8^+$) and B lymphocytes in the peripheral blood of 6-mon-old infants were found to be the same, regardless of feeding regimen. However, breast-fed infants were found to have fewer $CD4^+$ T cells and more NK cells than the age-matched formula-fed

infants (60). Without maturation or functional data, the physiological consequences of these small changes are unknown; however, these descriptive data do support the hypothesis that diet/feeding regimen can affect the infant's immune system.

## T-CELL DEVELOPMENT IN THE PRETERM INFANT

Considerable maturation of peripheral T lymphocyte populations is believed to occur during the final trimester of gestation (41,63). This suggests that birth before the completion of this maturation process would result in an infant with a less mature immune system. This likely contributes to the increased susceptibility of preterm infants to illness and infection. Few studies have examined immune development in preterm infants.

In our recent study, unlike a number of reports on full-term infants (39,64), the percentage of $CD45RO^+$ T cells in peripheral blood obtained from preterm infants did not increase significantly during the first 42 d of life (33). Delayed expression of this isoform supports the hypothesis that T-cell maturation is delayed in preterm infants. The lower number of $CD45RO^+$ T cells, compared with the full-term infant, likely contributes to the higher susceptibility to infection in these high-risk infants (43). Consistent with the lower proportion of memory/antigen-mature T cells, we found that at 42 d of age, the proportion of $CD4^+CD45RA^+$ cells in preterm infants was higher (33) than that in the literature for full-term infants (2,34,39,64). Contrary to that reported in adults (41) and full-term infants, after 3 mon of age (39,64), ~10–20% of peripheral $CD4^+$ and $CD8^+$ cells in 42-d-old preterm infants did not express either of the CD45 isoforms (33). Lack of CD45 antigen expression (which appears during intrathymic development) further reflects the immaturity of the preterm infant's T-cell immune system (65). It has been suggested that the apparent lack of CD45 expression may be due to the maturation process, which involves a switch of isoform from $CD45RA^+$ to $CD45RO^+$ on peripheral cells (66). It is possible that the cells from the preterm infant may be expressing a very small amount of CD45 RA and RO that was not detectable by immunofluorescence during this process (66).

Compared with full-term infants, IFN-γ production (not due to a decrease in the relative proportion of T cells) in response to mitogens was reported to be even lower in lymphocytes from preterm infants (46). Unlike IFN-γ, IL-2 production by phytohemagglutinin (PHA)-stimulated peripheral mononuclear cells was reported in preterm infants to be higher than that in adults (46,51). The mechanism for these differences is not clear but may be due to alterations in the mRNA for the IL-2 receptor (51).

## PUFA AND T-CELL FUNCTION (ADULT AND ANIMALS)

There is considerable evidence that both the amount and type of dietary fat influence T-cell function (reviewed in Refs. 67,68). Animal studies have clearly demonstrated that the content of long-chain PUFA n-3 fatty acids and/or the ratio of n-6/n-3 fatty acids in the diet modulates many measures of T-cell function. These include the ability to proliferate in response to mitogen/antigen stimulation and to mount a delayed-type hypersensitivity response (68–73). The physiological interpretation of how T-cell function is altered by these lipids is far from clear. This is likely due in part to the wide variation in types of measures and the amounts of PUFA fed to both animals and humans.

Diets rich in n-3 PUFA are generally associated with suppression of cell-mediated immune responses {estimated by [$^3$H]thymidine uptake (71,73)}. Long-chain n-3 PUFA have been demonstrated both *in vivo* (in adult humans and animals) and *in vitro* to reduce IL-2 production (72,74,75). Recently, it was suggested that immunosuppressive and anti-inflammatory effects (delayed-type hypersensitivity response) of feeding fish oil to mice was due to the docosahexaenoic acid (DHA) rather than the eicosapentaenoic acid (EPA) in fish oil (75). Others have shown that the inhibitory effects of DHA on immune cell functions varied with the cell type, and these effects are not mediated through increased production of prostaglandin $E_2$ and leukotriene $B_4$ (76). Results like these have raised questions concerning the efficacy of feeding DHA to infants, particularly preterm infants.

Contrary to many of these studies, we have demonstrated in a healthy animal model that feeding long-chain n-3 PUFA can increase the response to mitogens when measures other than [$^3$H]thymidine incorporation are used (77). For example, we found an increased expression of activation markers (77) and a higher production of IL-2, IFN-γ, and nitric oxide by splenocytes from young rats fed a mixture of EPA and DHA (78). Recently, it was suggested that diets rich in DHA exert some of their immunomodulatory effects by a downregulation of surface expression of CD4 and CD8 and by an upregulation of a co-stimulatory signal [CD28 expression; (79)]. It was also reported that consumption of n-3 fatty acids may have slowed the inflammatory response compared with diets high in n-6 fatty acids, but that feeding n-3 lipids did not compromise overall immune potential (80). From animal and human work, it appears that feeding long-chain n-3 fatty acids is not clearly immunosuppressive. Because the T-cell response is the end point of a number of different components of the immune system and their interaction with other systems, one must examine more closely the type of response rather than simply the magnitude of a single estimate of T-cell function.

## PUFA AND T-CELL DEVELOPMENT/FUNCTION IN THE NEONATE

There are many considerations associated with the development of an optimal formula for infants. Preterm infants have been found to have an essential PUFA status significantly lower than that of term neonates (81). Most recently, emphasis has been placed on inclusion of 20:4n-6 (arachidonic acid; AA) and 22:6n-3 (DHA) fatty acids to promote optimal neurological and retinal function and membrane composition,

particularly in the preterm infant (82,83). As discussed above, a number of studies suggest that DHA added *in vitro* or fed to adults or animals may suppress some measures of T-cell function (67,72–74,84–86). Despite the amount of work done in healthy adults and human diseases and animal models of disease, little work has been done on the effect of PUFA on T-cell development in infants.

We recently attempted, within the limitations of tissue availability, to study the effect of adding long-chain PUFA to a standard infant formula on several functional indices of immune development (33). A large group of medically stable preterm infants were fed human milk, standard preterm infant formula, or a preterm infant formula containing DHA (0.4%) and AA (0.6%) for the first 42 d of life. With blood samples obtained at 14 and 42 d of age, the effect of diet on some parameters of immune development was studied. Compared with standard formula, feeding long-chain PUFA significantly increased the proportion of antigen mature ($CD45RO^+$) $CD4^+$ cells (by ~25%) compared with nonsupplemented formula-fed infants and lowered the proportion of immature ($CD45RA^+$) $CD4^+$ cells to levels not different from human milk-fed infants (33). These changes in the sialylation of the CD45 region (RA/RO) are believed to reflect the maturation of the immune system (87). Our data suggest that adding DHA and AA to preterm formula may have assisted in the maturation of peripheral $CD4^+$ cells.

Because $CD45RO^+$ (memory T cells) differ in their ability to synthesize and respond to a variety of cytokines *in vitro* (52), we also measured the effect of the three dietary treatments on the ability of lymphocytes to synthesize two key cytokines (IL-10 and IL-2) in response to stimulation with PHA. Between 14 and 42 d of age, the ability of peripheral mononuclear cells from unsupplemented formula-fed infants to produce IL-10 was lower than that of infants fed human milk. IL-10 production by cells from infants fed the formula containing DHA + AA did not differ from that of the human milk-fed infants. IL-10 production by stimulated peripheral lymphocytes has been reported by others to be lower for cells from preterm infants compared with adults and has been suggested to be due to differences in cellular maturation (50). IL-10 plays an important regulatory role in both cellular and humoral immunity; after activation, it is synthesized primarily by $CD45RO^+CD4^+$ cells (49,88). IL-10 is produced by T cells ($CD4^+$ Th2 cells), B cells, macrophages/monocytes, and keratinocytes. This cytokine can profoundly alter the expression of MHC class II antigens and the production of cytokines by monocytes, which in turn affect a variety of immunological responses including inhibition of Th1-type functions (anti-inflammatory), promotion of T-cell development, and increased proliferation, differentiation, and activation of B cells (16,49,88). Recently, it was suggested that an increase in IL-10 production, together with a decreased IL-12 production, is important in the induction of oral tolerance (89). To our knowledge, our study was the first to measure IL-10 production by lymphocytes from preterm infants fed different diets and suggests that the addition of DHA + AA to formula improves the ability of peripheral mononuclear cells from formula-fed infants to produce IL-10.

Unlike IL-10 (50) and most other cytokines (31,40, 41,45,48), neonatal cells stimulated with PHA have been reported to produce IL-2 at rates similar to those of adults (41). Feeding formula containing DHA + AA to preterm infants resulted in a significant decrease in the amount of secretory IL-2 receptor (sIL-2R) produced by stimulated peripheral mononuclear cells at 42 d of age compared with 14 d (33). Despite the lower level of sIL-2R compared with the unsupplemented formula, in the (DHA + AA)-supplemented formula group, the amount of sIL-2R produced by the DHA + AA group at both 14 and 42 d of age did not differ from the human milk-fed group. The activation and clonal expansion of T lymphocytes by IL-2 (produced by mitogen- or antigen-activated T cells) is mediated by IL-2 receptors (IL-2R) in such a manner that the level of activation usually corresponds to the level of expression of the IL-2R (90). During activation, sIL-2R is cleaved off and its concentration is used to estimate lymphocyte activation (91). *In vitro*, IL-2 is produced by activated Th1, and more recently, Th0-type CD4 cells [both $CD45RA^+$ and $CD45RO^+$ (40,92,93)]. The precise role of this cytokine *in vivo* is not known; however, a decreased production of IL-2 in response to an *in vitro* mitogen challenge has been interpreted to indicate a reduced capacity to recruit T cells (8,94). Thus, the physiological effect of reduced production between 14 and 42 d of age in the supplemented formula group requires the further study of Th1- and Th2-type cytokines. Despite immature CD4 cells being able to make IL-2, only $CD45RO^+$ cells are able to proliferate in response to mitogens (52). Proliferation was not directly measured in our study; however, the lower production of IL-10 by unsupplemented formula-fed infants, compared with human milk-fed infants, suggests a poorer proliferative response.

The mechanisms for the effects of adding AA + DHA to infant formula on immune maturation and cytokine production have not been established, but changes in fatty acid status (83) and lymphocyte membrane lipid essential fatty acid composition (33) are likely contributors. In lymphocytes, plasma membrane-associated events play an important role in immune functions such as the processing and recognition of antigens, expression of activation marker, and generation of membrane-mediated activation signals (reviewed in Ref. 74).

In conclusion, immunity is the end point of a number of different components of the immune system and their interaction with other systems. T lymphocytes are an important cellular component of this arm of the immune system that can both modulate the function of other immune cells and directly destroy cells infected with intracellular pathogens. At birth, T-cell function is not well developed and contributes to the immune immaturity of the infant, particularly the preterm infant. Interest and energy are currently being directed at identifying the role of specific nutrients in optimizing immune function. Our work suggests that the addition of small amounts of DHA and AA (at levels similar to that in human milk) to preterm infant formula can influence the concentration,

proportion, maturation, and cytokine production of peripheral blood lymphocytes (33). The goal of future studies is to determine whether the addition of long-chain essential fatty acids improves immune development and the ability of the neonate to respond to antigenic (bacterial, viral, parasitic, and dietary) challenges from the environment.

# Polyunsaturated n-3 Fatty Acids and the Development of Atopic Disease

**Karel Duchén[a,*] and Bengt Björkstén[b]**

[a]Division of Pediatrics, Department of Health and Environment, Linköping University Hospital, Linköping, Sweden, and [b]Centre for Allergy Research, Karolinska Institute, Stockholm, Sweden

**ABSTRACT:** The relationship between polyunsaturated long-chain fatty acids and atopy has been discussed for decades. Higher levels of the essential fatty acids linoleic acid and α-linolenic acid and lower levels of their longer metabolites in plasma phospholipids of atopic as compared to nonatopic individuals have been reported by several, but not all, studies. Largely similar findings have been reported in studies of cell membranes from immunological cells from atopics and nonatopics despite differences in methodology, study groups, and definitions of atopy. An imbalance in the metabolism of the n-6 fatty acids, particularly arachidonic acid and dihomo-γ-linolenic acid, leading to an inappropriate synthesis of prostaglandin (PG) $E_2$ and $PGE_1$ was hypothesized early on but has not been corroborated. The fatty acid composition of human milk is dependent on the time of lactation not only during a breast meal but also the time of the day and the period of lactation. This explains the discrepancies in reported findings regarding the relationship between milk fatty acids and atopic disease in the mother. Prospective studies show disturbances in both the n-6 and n-3 fatty acid composition between milk from atopic and nonatopic mothers. Only the composition of long-chain polyunsaturated n-3 fatty acids was related to atopic development in the children, however. A relationship between lower levels of n-3 fatty acids, particularly eicosapentaenoic acid (20:5 n-3), and early development of atopic disease is hypothesized.

Paper no. L8657 in *Lipids 36*, 1033–1042 (September 2001).

Linoleic acid (LA, 18:2n-6) and α-linolenic acid (ALA, 18:3n-3) are essential fatty acids; that is, they cannot be synthesized by humans and thus they must be provided by the food. They compete for the same enzyme systems for desaturation–elongation of the carbon chain and are thus precursors to the long-chain polyunsaturated fatty acids (LC-PUFA) of the n-6 and the n-3 series, dihomo-γ-linoleic (DHGLA, 20:3n-6), arachidonic acid (AA, 20:4n-6), docosatetraenoic acid (DTA, 22:4n-6), eicosapentaenoic acid (EPA, 20:5n-3), docosapentaenoic acid (DPA, 22:5n-3), and docosahexaenoic acid (DHA, 22:6n-3) (1).

For many years, the accepted pathway, i.e., the classical pathway, has been one of alternating desaturation and elongation steps ending in the Δ4 desaturation of 22:4n-6 and DPA to 22:5n-6 and DHA, respectively (Fig. 1). In recent years, an alternative pathway has been suggested involving a Δ6-desaturation, elongation, and further β-oxidation of 22:4n-6 and DPA to 22:5n-6 and DHA, respectively. In fact, the latter has been suggested to be the primary pathway in adults (2). Newborn infants have an immature metabolic system, although desaturation and elongation of PUFA have been shown in formula-fed babies (3). It has been proposed that newborns use an alternative pathway involving an elongation of LA (and ALA) to 20:2n-6 (and 20:3n-3) and subsequent Δ8- desaturation to DHGLA (and 20:4n-3) (Fig. 1).

The desaturation–elongation products from the metabolism of polyunsaturated fatty acids (PUFA) are precursors to com-

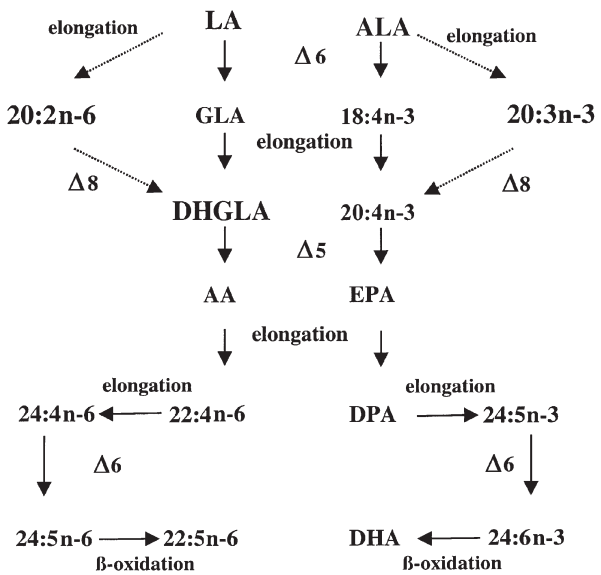

**FIG. 1.** The metabolic pathways of polyunsaturated fatty acids (PUFA). Linoleic acid (LA) and α-linolenic acid (ALA) are metabolized by the classical pathway in adults (arrows). The main metabolic step in the synthesis of 22:5n-6/22:6n-3 is through an elongation and Δ6 desaturation, rather than a Δ4 desaturation. An alternative pathway is used in infancy (dotted arrows) (2). GLA, γ-linolenic acid; AA, arachidonic acid; DHLGA, dihomo-γ-linolenic acid; EPA, eicosapentaenoic acid; DPA, docosapentaenoic acid; DHA, docosahexaenoic acid.

pounds that are important for the structural function of cellular membranes. Thus, the proportion of unsaturated fatty acids in cellular membranes is the main factor regulating membrane fluidity (4). Furthermore, membrane LC-PUFA composition also modulates the activity and conformation of enzymes such as adenylate cyclase and $Na^+/K^+$ ATPase, and it may also influence activity and conformation of membrane-bound receptors (4).

DHGLA, AA, and EPA are the main precursors of prostaglandins and leukotrienes (5). These fatty acids are bound to cell membrane phospholipids. They are released by phospholipase $A_2$ for the generation of prostaglandins $E_1$ ($PGE_1$) and $E_2$ ($PGE_2$) after oxygenation of the n-6 fatty acids DHGLA and AA, respectively (6). Lipoxygenation of AA yields leukotriene $B_4$ ($LTB_4$) (6). Several cell types produce eicosanoids: neutrophils are activated by lipopolysaccharides to the synthesis of $LBT_4$ and induce leukocyte aggregation and adhesion to vascular endothelium, increased vascular permeability in postcapillary venules, and enhanced mucus secretion in inflammatory sites (7). Monocytes and macrophages are significant producers of DHGLA and AA metabolites, particularly $PGE_2$, which inhibits the production of interleukin (IL)-2 and interferon-γ (IFNγ) (8,9) and primes naive $CD4^+$ cells in cord blood to produce IL-5 and IL-4 (9). $PGE_2$ also enhances *in vitro* proliferation and differentiation of mast cells (10) as well as the IL-4-mediated immunoglobulin (Ig) E antibody class switch in uncommitted B-lymphocytes (11). Furthermore, enhanced $PGE_2$ production in antigen-presenting cells (APC) commits naive T helper (Th) cells toward a Th2-like cytokine pattern favoring IgE production (12,13). Furthermore, IL-4 induces CD23 membrane expression in monocytes, partly through the induction of $LTB_4$ synthesis (14). The IL-4-induced IgE production in humans can be further stimulated by $LTB_4$, through an increase of IL-4R positive cells and release of sCD23 from mononuclear cells.

The n-3 fatty acids, especially EPA and DHA, have also been shown to modulate cytokine responses such as IL-1β production by human mononuclear cells after stimulation with endotoxin and *in vitro* lymphocyte proliferation (16). Dietary treatment with n-3 fatty acids in inflammatory disorders such as ulcerative colitis and rheumatoid arthritis provides some clinical improvement of the disease (1), suggesting anti-inflammatory properties, especially of the n-3 LC-PUFA. This could be explained by the competitive inhibition of AA cyclooxygenation by the n-3 fatty acid EPA and production of less inflammatory compounds of the PG and the LT series, e.g., $PGE_3$ and $LTB_5$ (5).

## PUFA AND ATOPIC DISEASE

An abnormal metabolism of essential fatty acids (EFA) and LC-PUFA has been discussed in atopic disease. It has been suggested for decades that atopic disease in adults and children is associated with higher plasma levels of LA (18:2n-6) than in healthy controls (17) while the levels of γ-linolenic acid (GLA, 18:3n-6), DHGLA (20:3n-6), and AA (20:4n-6) are lower than those in healthy controls. Furthermore, disturbances in the n-6 and the n-3 series have been observed in several (18–24) but not all studies (25,26). Only one of these reports confirmed the results of the original study by Hansen (17), i.e., higher levels of EFA and lower levels of LC-PUFA in a small group of children with atopic eczema. In the other studies, there were higher EFA levels (21,23) or lower LC-PUFA levels (19,24) in serum phospholipids from atopic children and adults (Table 1).

The PUFA composition of the phospholipid fraction has also been studied in cord blood and early infancy (20,27–30) (Table 2). Disturbances in the n-6 PUFA composition were observed in cord blood of infants with a family history of allergy (20,27,29). In two prospective studies (24,30), however, there were no disturbances in the composition of n-6 or n-3 PUFA in cord serum phospholipids in children who developed atopic disease later in life. Furthermore, higher levels of n-6 and n-3 LC-PUFA have been found in cord blood phospholipids from babies of allergic mothers, as compared to babies of healthy mothers (31). This suggests that disturbances in the PUFA composition in cord blood phospholipids may merely reflect the atopic status of the mother rather than

predict atopic development. It seems, though, that a disturbed metabolism of IgA and PUFA in atopic individuals can be detected early after birth, during the first months of life (30).

Abnormalities in PUFA composition have been reported consistently in cellular membranes from atopic individuals (21,22,26,32,33), even in studies in which the PUFA levels in plasma phospholids were similar in atopic and nonatopic individuals (26). Although the results vary in different cells, higher LA and lower n-6 LC-PUFA and n-3 LC-PUFA are consistently found in atopic individuals (Table 3).

Thus, despite differences in methodology, age of the study group, and type of atopic manifestations in the various studies, it seems reasonable to conclude that atopy is related to a disturbed metabolism of n-6 and n-3 LC-PUFA. The clinical significance of this relationship is still controversial, however. In a controlled study, clinical improvement of atopic eczema was reported after treatment with a GLA-rich oil from evening primrose (Epogam) (34), whereas in another study there was no effect of the treatment (35). Furthermore, the administration of GLA-enriched diet only partially corrects the differences between patients with atopic eczema and healthy individuals (18).

It has been suggested that a defect in the enzyme activity of Δ6-desaturase is present in atopic diseases (36). This would explain the higher levels of LA and lower levels of its longer metabolites in atopic children and adults (Tables 1 and 3, Fig. 1). It would also explain the high levels of 22:4n-6 and 22:5n-6 in atopics during early infancy when the metabolism is immature (Fig. 1). The disturbed correlations between

PUFA levels in cord serum phospholipids and atopy during childhood (24,28,31) raise the question of whether such a dysfunction is primary or secondary to a sustained allergic inflammation. The important role of AA in $PGE_2$ and $LTB_4$ metabolism and the relation to allergic inflammation (10–14) have led to the hypothesis that there is a dysregulation of AA metabolism in atopy (37). For example, a higher production of $PGE_2$ has been shown in monocytes from atopic individuals (38,39). Furthermore, reduced proliferative responses of peripheral blood mononuclear cells in adults with atopic dermatitis correlate with the IFNγ levels and are inversely related to T-cell production of IL-4 and the production of $PGE_2$ by monocytes (40). Thus, AA products seem to regulate allergic immune responses. Consequently, an abnormal PUFA metabolism could conceivably be associated with either enhanced or decreased susceptibility to allergic disease. An explanatory model has been suggested involving a disturbed n-6 fatty acid metabolism, particularly the balance between DHGLA and AA and between the PG metabolites $PGE_1$ and $PGE_2$, respectively (41).

## HUMAN MILK FATTY ACIDS AND ATOPY—A CLUE TO A FURTHER UNDERSTANDING?

The PUFA composition in human milk has been studied extensively (42). Human milk contains both medium-chain saturated fatty acids (MCSFA) and PUFA. The latter include the essential fatty acids LA and ALA and small amounts of LC-PUFA (42). The fatty acid composition in human milk differs in mothers of term and premature babies (43), and it is influenced by the maternal food habits, especially in mothers consuming fish or vegetarian diets (44). The composition of milk lipids varies over the day (45) and over the lactation period (46). MCSFA ($C_6$–$C_{14}$) are synthesized in the mammary glands and are probably β-oxidized and used as energy by the newborn (47).

Colostrum is characterized by a high percentage of monounsaturated fatty acids and a low proportion of saturated fatty acids, including medium-chain-length acids, low levels of LA and ALA, and high levels of their LC-PUFA (48). The composition of mature milk is the matter of some controversy, as there are only a few longitudinal studies of PUFA in milk from the same mothers through the lactation period (46,49,50). The levels of EFA (LA and ALA) in mature milk increase while the levels of LC-PUFA decrease during lactation in some (49,50), but not all (46), the studies. However, these findings were not confirmed in a cross-sectional study analysis of pooled milk samples (46).

The relationship between breast-feeding and the development of atopic manifestations early in life has been an issue of controversy for the last 50 yr (51). Differences in milk components that might influence infant immunity could possibly explain some of this controversy. The PUFA composition of human milk is one of several factors that have been studied in relation to the atopic status of the mother (50,52–54) and the development of atopic disease in the children (30,55,56).

The results are, at first view, contradictory. Lower levels of LA, ALA, and most LC-PUFA in both PUFA series have been reported in early transitional milk of atopic, as compared to nonatopic, mothers, but not at 3 mon of lactation (30,50,53) (Figs. 2 and 3). These observations partially agree with studies reporting similar PUFA composition (52) or lower levels of AA in milk from atopic mothers as compared to milk from nonatopic mothers (54) (Table 4). Differences in the composition of colostrum, transitional milk, and mature milk during the lactation period (49,50,53) clearly indicate that milk sampling should be standardized not only with regard to sampling procedure (45) but also with regard to period of lactation. The PUFA composition of transitional human milk, however, agrees well with the reported low levels of n-6 and n-3 LC-PUFA (i.e., DHGLA, AA, EPA, DPA, and DHA) in plasma (19,20,24,57) and membrane (19,21,26, 33) phospholipids in atopic children and adults.

It is known that extreme food habits influence the composition of human milk, particularly the levels of LA and ALA (58). Omnivorous diets influence the levels of saturated and monounsaturated fatty acids and LA but have little effect on the composition of 20- and 22-carbon LC-PUFA (44), with the exception of EPA and DHA levels in women with high intakes of fish (44,59). Maternal food habits did not explain the low levels of LA and ALA in transitional milk from atopic mothers (30) (Fig. 2). Although both the LA and ALA levels were lower at 1 mon of lactation in milk from atopic, as compared to nonatopic, mothers, the LA/ALA ratio was similar in the two groups [8.7 ± 2.8 wt% vs. 7.8 ± 1.5 wt% (mean ± SD), nonsignificant]. In contrast, the n-6 LC-PUFA/n-3 LC-PUFA ratio was higher in milk from the atopic mothers (2.1 ± 0.7 vs. 1.8 ± 0.42, $P < 0.01$), suggesting a relationship between maternal atopy and low n-3 LC-PUFA levels in transitional human milk.

The dual composition of colostrum and early milk may suggest a hormonally induced increasing Δ6-desaturase activity in mothers during pregnancy (60), which then later decreases after delivery. This would explain the increasing levels of LA and ALA and decreasing levels of n-6 and n-3 LC-PUFA (30,50,53) during the lactation period. A disturbed Δ6-desaturase activity in lactating atopic mothers might also explain the lower LA and ALA levels in their milk, as compared to the milk of nonatopic mothers, before reaching a stable activity in mature milk. A defect in the Δ6-desaturase activity previously has been suggested in atopic individuals (36,41) because this enzyme desaturates LA to GLA. The low levels of GLA in milk of atopic mothers (30) corroborate this hypothesis. Thus, a disturbance in the desaturation step may be reflected by low levels of most of the LC-PUFA, in both the n-6 and n-3 series, as has indeed been reported (53).

The Δ6-desaturase is also involved in an alternative final step in the PUFA desaturation and elongation (Fig. 1) (61). This could possibly explain the similar 22:4n-6 and 22:5n-6 levels in milk from atopic and nonatopic mothers (30). The limited capacity of the newborn baby to produce LC-PUFA (3) and the newborn's enhanced nutritional requirements stress the importance of breast-feeding for early human development (43,62,63).

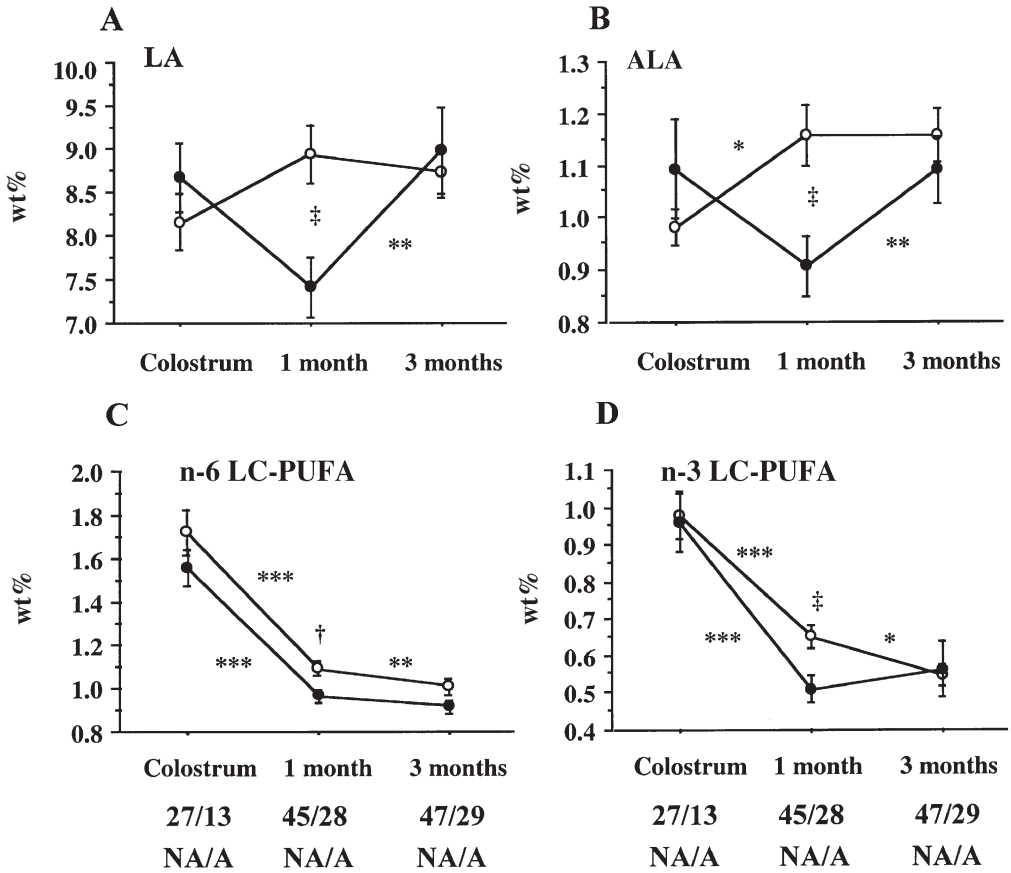

**FIG. 2.** The levels of LA (A), ALA (B), total n-6 long-chain polyunsaturated fatty acids (LC-PUFA) (C), and total n-3 LC-PUFA (D) in milk from atopic (closed circles) and nonatopic mothers (open circles) during 3 mon of lactation. ## MILK PUFA IN RELATION TO ALLERGY DEVELOPMENT IN CHILDREN

Although there seem to be no nutrient abnormalities in the composition of PUFA in the cord blood of atopic infants, various disturbances seem to appear very early in infancy during the lactation period (Table 4). It is well known that the PUFA composition in maternal milk affects the PUFA status of the child (3,64,65). There are only a few studies of the relationship between the PUFA composition of material milk and development of atopy in the children (30,55,56), and only one of them was prospective (30). A different PUFA composition was demonstrated in milk from the mothers of atopic and nonatopic children in all the studies, despite considerable methodological differences (Table 4). In the prospective study (30), in which 160 allergic and nonallergic children were

included, no relationship was found between development of atopy and n-6 PUFA composition in maternal milk. The findings agree with those of one (56) of the cross-sectional studies, but not with those of the other (55). However, the levels of the n-3 LC-PUFA EPA, DPA, and DHA in mature maternal milk seemed to be related to allergic disease in early childhood (Table 4, Fig. 4). Possibly, the composition of milk, as analyzed in cross-sectional studies, merely reflects the milk PUFA composition of the atopic mothers (30,50), rather than being related to atopic disease in their children.

As both n-6 and n-3 PUFA compete for the same metabolic pathway (Fig. 1), the relationship between the two series can be expressed as ratios (Fig. 5). The total n-6/total n-3, LA/ALA, n-6 LC-PUFA/n-3 LC-PUFA, and AA/EPA ratios

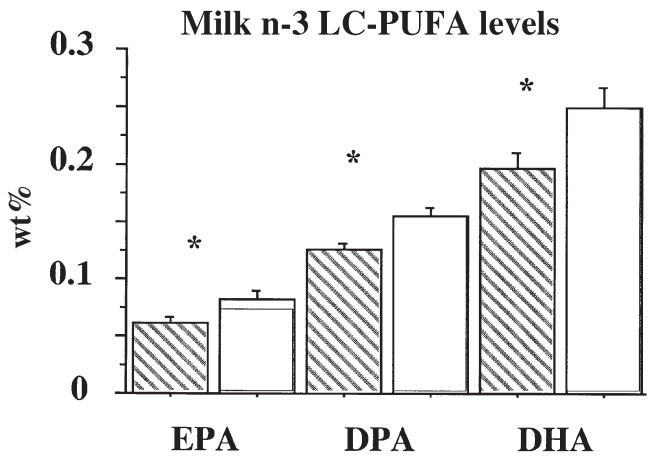

**FIG. 4.** Levels of individual n-3 LC-PUFA in mature milk at 3 mon of lactation, from mothers of 38 allergic (hatched bars) and 70 nonallergic children (open bars) at the age of 18 mon. Mean levels ± SD are given. *$P < 0.05$ for unpaired *t*-test (adapted from Ref. 53). See Figure 1 for abbreviations.

are similar in colostrum from mothers of atopic and nonatopic children. In transitional and mature milk, however, almost all ratios are significantly higher in milk from the mothers of atopic children (Fig. 5). This further strengthens the concept of a relationship between development of atopic disease in the infant and low n-3 LC-PUFA levels in maternal milk.

## MILK PUFA AND THE COMPOSITION OF SERUM PHOSPHOLIPIDS IN CHILDREN

As previously discussed, breast-feeding influences the PUFA composition in newborns (3,64,65). However, the relationship between maternal milk PUFA and serum PUFA composition in infants has been assessed in only one study (30). In this study, the relative fractions of 18:1n-9, LA, and n-6 LC-PUFA were similar in maternal milk and serum phospholipids of the infants, suggesting a relationship. Furthermore, the AA/EPA and AA/DHGLA levels correlated closely in milk and serum at 3 mon in the nonatopic, but not in the atopic infants. This again suggests that the milk PUFA content influences the composition of serum phospholipids in both atopic and nonatopic children and suggests a different ratio of AA and EPA, supporting a relationship between low n-3 PUFA and the development of atopy in childhood.

## IMBALANCE BETWEEN n-6 AND n-3 FATTY ACID METABOLISM IN ATOPY—A NOVEL HYPOTHESIS

The suggestion by Melnik and Plewig (41) that disturbed n-6 PUFA metabolism, particularly low AA and DHGLA levels, would lead to a low $PGE_1$ and $PGE_2$ production has not been corroborated. On the contrary, more recent research has assigned a major role to $PGE_2$ production by APC in the allergic

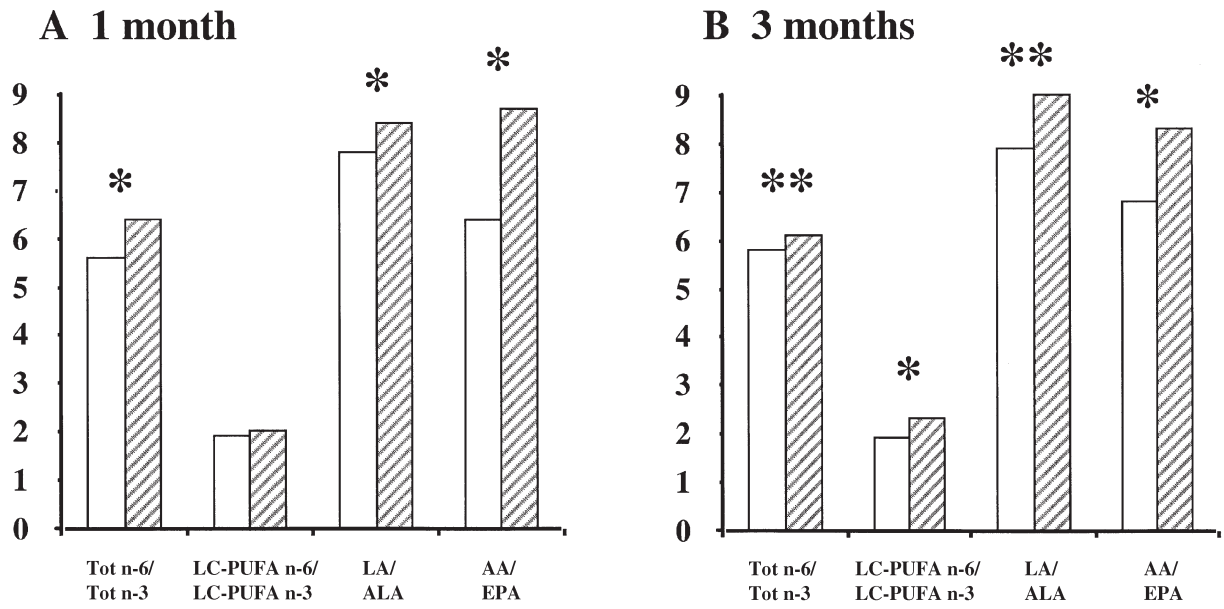

**FIG. 5.** The ratio between different n-6 and n-3 PUFA in milk from atopic (hatched bars) and nonatopic mothers (open bars), at 1 mon (A) and 3 mon (B) of lactation. LC-PUFA = the sum of all metabolites except LA and 20:2 for the n-6 and ALA for the n-3 PUFA. Mean levels ± SD are given. $^*P < 0.05$ and $^{**}P < 0.01$ for unpaired *t*-test (adapted from Ref. 53).

inflammation of $PGE_2$ by APC (8–13) (Fig. 6). Enhanced production of PGE2 by atopic monocytes after *in vitro* stimulation has repeatedly been reported (37,39, 66), corroborating a dysregulation in the synthesis of $PGE_2$ and possibly $LTB_4$ in atopic individuals. Thus, there seems to be a relationship between an abnormal AA metabolism and eicosanoid metabolism in atopic disease. As the clinical trials with PUFA substitution in allergic patients, which were limited to n-6 PUFA (Enfamil/Epogam), did not show any significant clinical efficacy (35), it seems reasonable to conclude that other components of fatty acid metabolism are important.

Recent studies suggest a more complex association between PUFA and atopic disease (30,50,53). The low levels of n-6 and n-3 EFA and LC-PUFA in milk from atopic mothers (30,50) could be explained by a relative Δ6-desaturase deficiency involving both series of PUFA in atopic individuals. Only low levels of n-3 LC-PUFA (EPA, DPA, and DHA) seem to be related to the development of atopic disease, however (30). The AA/EPA ratio, which is consistently higher in milk from mothers of atopic children and in serum phospholipids in atopics, could be a further clue to the relationship between n-3 LC-PUFA metabolism an atopy (30). A disturbed balance in the AA and EPA metabolism would lead to decreased synthesis of the less biologically active $LTB_5$ from EPA as well as an increased synthesis of $PGE_2$ and $LTB_4$ from AA by mononuclear cells. This would result in an overall "pro-allergenic" eicosanoid activity and a reduced synthesis of IL-12 in atopic individuals, leading to a polarization of the immune response toward a sustained Th2-like response (Fig. 6). A combination of an intrinsic dysmaturation of Δ6-desaturase in babies with atopic disease and composition of PUFA in the breast milk could explain both the sustained and transient IgE responses during early childhood.

Animal studies support this hypothesis, as a diet containing 1.3–3.3% of EPA and DHA given to mice significantly increases the proliferative responses of lymphocytes to T-cell mitogens, increases the production of IL-2, and suppresses

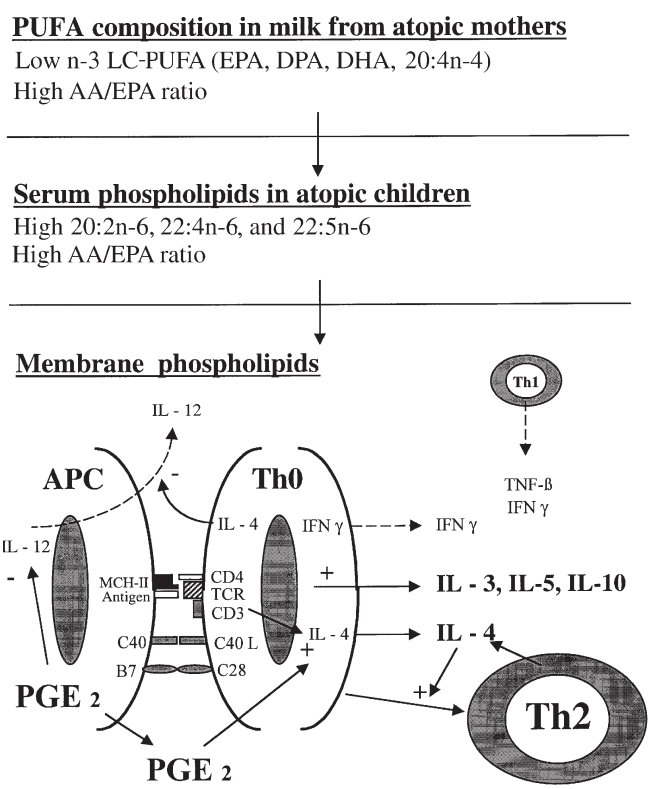

**FIG. 6.** The influence of milk PUFA on the composition of infant serum phospholipids early in life and the hypothesized effect on antigen-presenting cells (APC) and immune responses toward a T helper (Th)2-like response early in life. Abbreviations: TNF, tumor necrosis factor; IFN, interferon; IL, interleukin; PGE, prostaglandin E; MCH, major histocompatibility complex.

the production of $PGE_2$ (67). Dietary n-3 fatty acids also have immunomodulatory properties (15,16), as particularly EPA competes for the same enzymes as AA and is the precursor to the less biologically active $LTB_5$ (5,15,16,67).

The Th2-like immune responses associated with atopic disease (68) are essential for a successful pregnancy (69). Furthermore, Th2-skewed cellular immune responses to common environmental antigens are present already *in utero* (70), suggesting the Th2-like response to be the primary response early in life (71). Prospective studies have shown that human infants synthesize IgE antibodies to both food and inhalant allergens early in life, but only children who develop an allergic disease maintain high IgE responses (72,73). Factors influencing early immune responses, for example, n-3 LC-PUFA in maternal milk, in combination with genetic factors, could then delay or prevent the Th1-skewing, thus promoting transient or sustained IgE synthesis. Breast-feeding is the natural source of PUFA in early infancy. If further research would confirm this hypothesis, dietary manipulation during early infancy might be a feasible way of primary allergy prevention. To corroborate this hypothesis, the composition of maternal diet and membrane phospholipids and their relation to eicosanoid synthesis should be studied in human cord blood monocytes. Such studies are lacking.

We conclude that altered PUFA composition in serum phospholipids and cell membranes is related to atopic disease and that the AA metabolism is disturbed in monocytes from atopics. These findings could be explained by a relating Δ6-desaturase deficiency in allergic individuals. Disturbances in the composition of the n-6 and n-3 fatty acids in milk from atopic mothers and serum phospholipids of their babies could at least be explained by a Δ6-desaturase dysfunction. Furthermore, mothers of atopic children provide their babies with low levels of n-3 fatty acids, and the balance between n-6 and n-3 fatty acids is disturbed. This imbalance, particularly a high AA/EPA ratio, is reflected in the serum phospholipid composition of those babies who develop atopic disease in infancy.

# The Intestinal Mucosa as a Target for Dietary Polyunsaturated Fatty Acids

**A. Donnet-Hughes[a,*], E.J. Schiffrin[a], and M.E. Turini[b]**

[a]Immunology Group and the [b]Nutritional Sciences Group, Nestec Limited, Nestlé Research Centre, CH-1000 Lausanne 26, Switzerland

**ABSTRACT:** Several studies have reported beneficial effects of dietary polyunsaturated fatty acids (PUFA) on various aspects of both human and animal health, and particular reference has been made to their effects on systemic immune responses. Both immune stimulation and immune suppression have been reported, with the outcome dependent on the type of PUFA, the target cell, as well as the immune competence of the cells before exposure. The systemic and the mucosal immune systems are discrete entities, which have evolved specific approaches in the defense of the host. The latter comprises several interconnected tissues, which communicate with one another through the action of soluble mediators and the trafficking of cellular components. After the oral mucosa, the intestinal epithelium and its associated gut-associated lymphoid tissue are the primary targets of dietary components. Absorption of dietary PUFA and its incorporation into intestinal tissues has been well studied, but the consequences of these events in relation to local immune responses have received little attention. This article describes some of the immune mechanisms operating at this barrier and, where possible, pinpoints areas for which a modulatory role for PUFA has already been demonstrated. Although not an exhaustive treatise of the subject, it is hoped that this review will foster research into the specific interaction between dietary PUFA and cell populations comprising the intestinal barrier.

Paper no. L8730 in *Lipids 36*, 1043–1052 (September 2001)

The intestinal mucosa is a dynamic barrier continually adapting to the ever-changing environment in the intestinal lumen and to the factors that are intrinsic to host defense. As such, it has a strategic role to play in the overall immune status of the host. Essentially, its overlying epithelium polices the luminal barrier and surveys which antigens cross the mucosa and gain access to the host's systemic immune system. As a consequence, the intestine has developed a highly organized immune system of its own, i.e., the gut-associated lymphoid tissue (GALT), which allows it to communicate with those in other mucosa. One of the most intriguing attributes of the GALT is its capacity to discriminate between pathogenic microorganisms to which it mounts a response, and the vast array of dietary antigens and commensal microbial flora to which it remains tolerant. This ambivalency is achieved through the precise regulation of pro- and anti-inflammatory mediators, which direct responses during homeostasis and pathological conditions (1). It is a potentially hazardous state, but, in general, the barrier assumes this challenge efficiently without any major detrimental effect to the host. Ordinarily, the chronic physiologic inflammation that ensues (2) is tolerated. However, inappropriate exposure to antigens and/or a failure of the system to restore the "injured" host to homeostasis, can culminate in aberrant immunological responses, which compromise the health of the host.

Dietary fatty acids such as linoleic acid (LA; 18:2n-6) and α-linolenic acid (ALA; 18:3n-3) of the n-6 and n-3 series of polyunsaturated fatty acids (PUFA), respectively, are considered "essential" because they must be derived from the diet. Certain of these are precursors of the eicosanoids, which have well-documented effects on the induction and modulation of immune and inflammatory responses (3,4). The efficacy of dietary PUFA in modulation of such responses will depend on many factors, not least of all, the antioxidant status of the host's gastrointestinal tract. Both immune stimulation and immune suppression have been reported *in vitro* and *in vivo*, but it is clear that outcome is dependent on the admixing of different PUFA in specific proportions, the target tissue, and immune status of the host before exposure. Although a good appreciation of systemic immune effects has been achieved, studies on the modulation of intestinal immunity are lacking.

Because intestinal barrier integrity is a key element in the prevention of infection and clinical disease, this paper will introduce some of the nonspecific and specific immune mechanisms operating locally in the intestinal lumen. It will also briefly describe how the intestinal mucosa communicates with other mucosal tissues. Finally, it will address ways in which these specific mechanisms may be modulated by PUFA.

## ORGANIZATION OF THE INTESTINAL MUCOSAL TISSUE

Host immune defense uses two arms in its battle against pathogens and harmful antigens, i.e., innate immunity and adaptive immunity. Nonspecific innate defenses are initiated the moment the host encounters these antigens, whereas the adaptive responses are specific for individual pathogens and require some days to be fully developed and operational. It is evident therefore that the integrity of the intestinal barrier and selective uptake of molecules are fundamental to the maintenance of homeostasis and the prevention of disease. A number of physical and immunological mechanisms have evolved to regulate antigen exposure at the epithelial surface. Although antigen uptake can be beneficial for sampling the intestinal milieu and providing essential trophic and regulatory factors, uncontrolled passage of antigen predisposes the host to disease (5). One strategy is to limit the antigenic load at the epithelial surface (Fig. 1). Nonimmune elements limiting uptake include gastric acidity, peristalsis, intestinal secretions, proteolytic digestion, the phospholipid layer, and mucus secretion (5). If these fail, the secretory immunoglobulin (Ig)A comes into action and limits the exposure by immune exclusion. For pathogens, an additional strategy is to limit the growth of the pathogen by bactericidal or bacteriostatic mechanisms such as antimicrobial peptides, defensins, and lactoferrin, antibody-dependent cellular cytotoxicity mechanisms or cellular effector mechanisms acting at the mucosal level (6). Yet another possibility is to limit the tissue damage that ensues through the action of antioxidants or complement inhibitors, or by the production of trophic factors.

If the antigen succeeds in overcoming each of these barriers, the mechanisms operating at the epithelium and its underlying lymphoid tissue enter into play. The epithelium itself represents a further physical barrier to antigen uptake, although it is not impenetrable. Unlike the systemic immune response, which is programmed to eliminate all foreign antigens, a differential response operates at the mucosa. Although the uptake of essential growth factors and nutrients is facilitated by specific receptor-mediated uptake (5), harmful antigens must be prevented from breaching the barrier. Some physical protection against large macromolecules is provided by the tight junctions between adjacent epithelial cells. Occludins (7) and claudins (8) are tight junction-specific integral membrane proteins, which are regulated by immune mediators (9) and whose expression restricts paracellular transport of macromolecules. During inflammatory processes, the junctions between the epithelial cells are disrupted, and the passage of luminal antigens across the epithelial layer augmented (10).

The Peyer's patches, lymphoid aggregates that occur along the length of the small bowel, are major inductive sites of the mucosal immune system (Fig. 1). They comprise all of the major lymphoid and accessory cells of the immune system and are covered by the follicular-associated epithelium, which

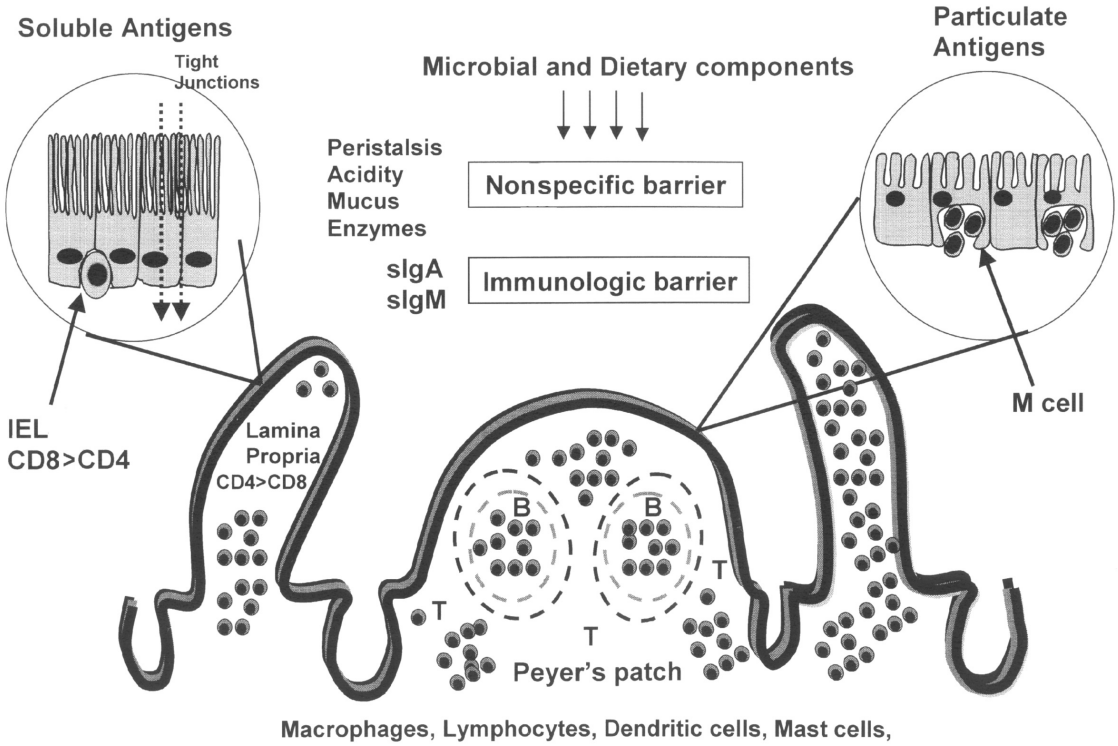

**FIG. 1.** Schematic representation of the intestinal barrier, depicting the physical and immunological mechanisms that regulate antigen exposure at the epithelial surface. Soluble antigens enter the mucosa *via* the villous epithelium, through either paracellular or transcellular routes. The Peyer's patches are the major sites for priming of intestinal lymphocytes. Microorganisms and other luminal antigens bind preferentially to the surface of M cells in the follicular-associated epithelium. These M cells are in intimate contact with immune cells in the underlying tissue. Ig, immunoglobulin; IEL, intraepithelial lymphocyte.

contains a specific epithelial cell type, the M cell (11). This cell facilitates the delivery of antigens, especially particulate antigens, from the lumen to immunocompetent cells, which are situated in its intraepithelial pocket (11). This intimate association favors further dissemination of signals to the macrophages, dendritic cells, and the many B and T lymphocytes underlying the epithelium. Unfortunately, the ease of uptake at this site is exploited by certain pathogens to cross the epithelial barrier and invade the mucosa.

## THE COMMON MUCOSAL IMMUNE SYSTEM

Dietary effects on the host are multifaceted. Specific components may act locally on gut tissues and elaborate immunomodulatory molecules, which then travel to other sites in the host. Alternatively, the dietary components themselves may be transported across the gut barrier to act in distal tissues. A final possibility is that the dietary components influence the phenotype of cells in the gut and that these cells themselves leave the gut environment to exert their effector functions in other tissues.

Lymphocytes continuously migrate through the body to increase the chance of encountering the cognate antigen (12). Labeling studies using Peyer's patch-derived cells injected into rodents demonstrated the phenomenon of the "common mucosal immune system" in which induction of a response in one mucosa-associated lymphoid tissue results in the departure of activated cells to effector sites in the same or other mucosal tissues (13). Once antigenic stimulation takes place in the Peyer's patches, antigen-specific precursor $IgA^+$ B cells and $CD4^+$ T helper cells leave these afferent sites and migrate through lymph to the mesenteric lymph nodes (MLN), then into the thoracic duct to enter into the bloodstream (Fig. 2). Some of the migrating cells express the $\alpha_4\beta_7$ mucosal and L-selectin homing receptors, which interact with the mucosal addressin cell adhesion molecule-1 (MadCAM-1) expressed on the microvascular endothelium and thereby direct the cells back into the lamina propria (14). Others express the integrin $\alpha_E\beta_7$, which interacts with the ligand E-caderin on the basolateral membrane of enterocytes (15) and is responsible for homing of lymphocytes into the intraepithelial compartment. Once lodged in these two sites, these activated cells finish their differentiation and participate in the effector mechanisms, the best known of which is the secretory IgA response. Other adhesion molecules are apparently used by immune cells primed in the bronchus-associated lymphoid tissue (BALT) and nasal-associated lymphoid tissue (NALT) but it is noteworthy that the lactating mammary glands receive immune cells primed in the inductive compartments of both the NALT and GALT (14).

Because activated T cells produce cytokines and express costimulatory molecules, they can induce the nonspecific proliferation of bystander lymphocytes (11). Selectively modifying the survival of these activated cells once they have

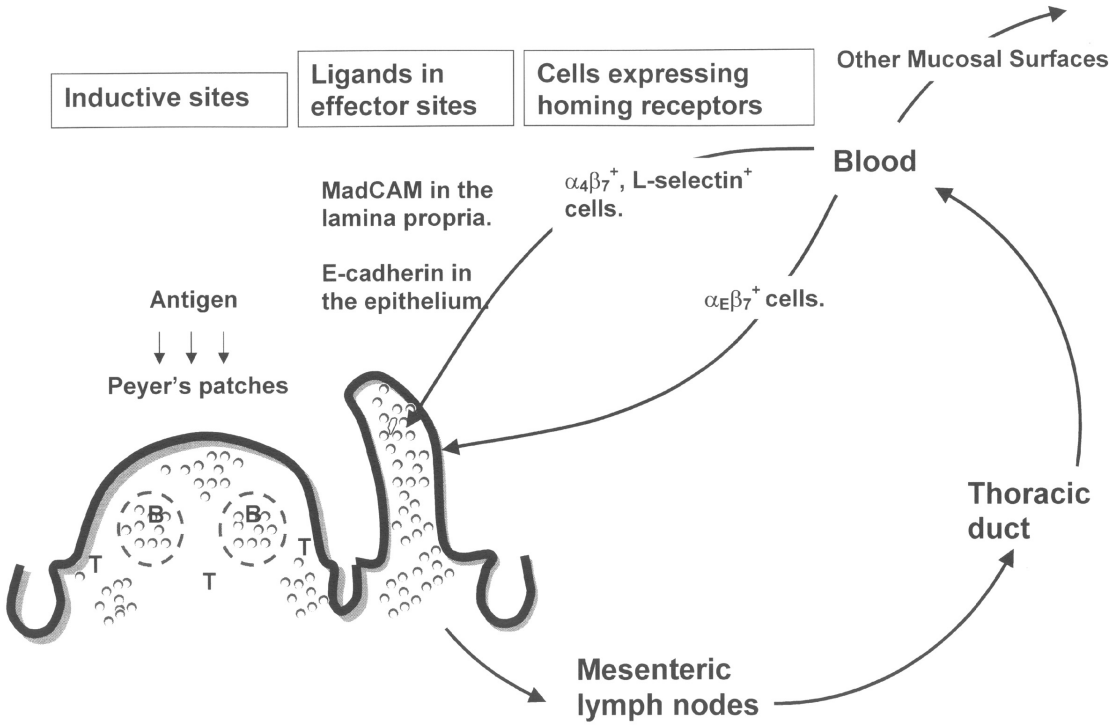

**FIG. 2.** Homing to intestinal tissues. T and B cells, primed in the Peyer's patches, migrate to the mesenteric lymph nodes *via* the draining lymphatics. They then enter into the bloodstream *via* the thoracic duct and finally home to different mucosal compartments depending on their expression of specific adhesion molecules. Cells expressing $\alpha_4\beta_7$ mucosal and L-selectin homing receptors interact with mucosal addressin cell adhesion molecule-1 (MadCAM-1) expressed on the microvascular endothelium and are thereby directed into the lamina propria. Cells that express the $\alpha_E\beta_7$ integrin interact with the ligand E-caderin on the basolateral membrane of enterocytes and are directed into the IEL compartment. For abbreviations see Figure 1.

randomly entered into the tissue or as they leave leads to a preferential accumulation of cells in sites where they are most needed. This might explain how immune responses can spread from the jejunum to the ileum and colon, while remaining confined to the small and large intestine (12).

## THE INTESTINAL EPITHELIUM

Another important component of the effector arm of intestinal immunity is the mucosal epithelium, which is composed of at least two types of immuncompetent cells, i.e., the intraepithelial lymphocyte (IEL) and the intestinal epithelial cell (IEC), which share an intimate association. The nonspecific protective mechanisms mentioned earlier are the first line of protection operating at the mucosa. They are naturally present and do not require prior contact with the antigen. The IEC response against pathogens has been considered part of this process.

IEC migrating from the crypt mature into discrete cell types (enterocytes, neuroendocrine cells, and goblet cells) upon entering into the villus, journey along the length of the villus over a period of 2–5 d, and terminate in apoptosis upon reaching the tip. Thereafter, the dead cells or their fragments are either extruded into the lumen or phagocytosed by macrophages in the lamina propria (16). Under normal conditions, the balance between the opposing forces of cell proliferation and cell death leads to a complete renewal of the epithelial cell population every few days and means that the number of cells within each villus remains constant. IEC produce many of the cytokines (17,18), which are known modulators of crypt cell proliferation. A variety of immune-mediated bowel disorders, including celiac disease and inflammatory bowel disease (IBD), are characterized by accelerated epithelial cell turnover and apoptosis, leading to altered crypt/villous morphology (19).

For many years, the intestinal epithelium was considered to represent a passive barrier and was not thought to participate in the initiation of immune responses until studies performed in the late 1970s revealed that the enterocyte expressed major histocompatibility complex (MHC) Class II (20,21). Later studies showed that this expression was dependent on both age and intestinal location (22), and that it endowed the epithelial cell with antigen-presenting capacity *in vitro* (23). It is now known that the epithelial cell expresses many important immune molecules and has the capacity to elaborate a wide range of cytokines, which modulate its interaction with T lymphocytes (17,18). Presentation can be to both $CD4^+$ helper cells and to $CD8^+$ cytotoxic/suppressor cells. Recent work suggests that presentation to the latter may be through both classical and nonclassical MHC elements such as the CD1 molecule. Although these molecules share similarities to Class I molecules, CD1 have a deeper and more hydrophobic antigen-binding groove (24), which enables them to present microbial glycolipids and synthetic lipids to natural killer (NK) T cells (25). Furthermore, they bind sphingolipid and phospholipid, but it is not known whether these molecules are self- or foreign antigens (26). It is interesting to speculate that dietary phospholipids may modulate immune function through an interaction with CD1.

Taken together, these observations confirm that the Peyer's patch is not the sole site for regulation of intestinal immune responses and that the IEC has a pivotal role to play in host responses to luminal antigen. Indeed, the enterocyte phenotype determines the development of specific subsets of T cells as well as the organization within the Peyer's patch (27).

## INTESTINAL T LYMPHOCYTES

Lymphocytes can be subdivided into various classes on the basis of their phenotype and functional attributes. The main properties distinguishing the various $CD4^+$ T helper cells and $CD8^+$ cytotoxic/suppressor cells are described in detail elsewhere in this volume (28). However, the lymphocytes that reside in the intraepithelial and lamina propria communities have unique characteristics.

The majority of IEL are T cells ($CD3^+$), which are predominantly $CD8^+$ $CD45RO^+$ (memory cells); although both γδ and αβ T-cell receptor (TCR)-bearing T cells are present, the latter are the most abundant (29). However, it has been suggested that IEL at the villous tip are quite distinct from those in the crypt region. Although there is no difference in αβ-$TCR^+$ IEL along the length of the villus, an increased frequency of γδ-TCR-bearing IEL is seen in villous tips (30). The γδ-$TCR^+$ IEL seem to be independent of bacterial challenge, but those with αβ-TCR increase on bacterial colonization of germ-free animals (6).

In contrast to the IEL population, the $CD4^+$ helper T-cell (Th) population predominates in the lamina propria compartment. These cells can be subdivided into functionally distinct phenotypes on the basis of the profile of cytokines they produce (Table 1). Th1 cell-driven responses are exemplified by the delayed-type hypersensitivity reaction for which regulation of phagocytes to fight microbial and viral infections is a major commitment. Th2 cells, on the other hand, promote IgE production and eosinophil activity, both of which contribute to the pathogenesis of allergic reactions. Classification of CD4 cells into these subsets is based on the cytokine profile of the cells. Once activated by allergen, Th2 cells secrete interleukin (IL)-4 and IL-5, which induce the production of IgE and IgG1 by B lymphocytes, and stimulate the recruitment of eosinophils from the bone marrow into inflamed tissues (31,32). Infections, on the other hand, induce Th1-type responses and the release of IL-2, interferon-γ (IFN-γ), and tumor necrosis factor-α (TNF-α) (31,32). It has also been suggested that the environment promoted by Th1 cells may dampen the development of allergen-specific Th2 cells and the development of atopy. Th0 produce all of these cytokines and are considered the precursor of the Th1 and Th2 cells. However, immune responses driven by Th1 and Th2 cells are sometimes influenced by a third type of T helper cell that acts to downregulate the responses mediated by Th1 and Th2. Feeding low amounts of myelin basic protein to mice leads to

**TABLE 1**
**CD4$^+$ T Cell Subsets[a]**

| | Th1 | Th2 | Th3 | Tr1 |
|---|---|---|---|---|
| Cytokine profile | | | | |
| IL-2 | +++ | — | ± | ± |

[a]Abbreviations: IL, interleukin; IFN, interferon; TGF, transforming growth factor; Th, helper T cell; Tr, regulatory T cell.

the induction of immunoregulatory cells, which prevent the development of experimental autoimmune encephalitis (33). These T cells, named Th3 cells, produce high levels of transforming growth factor (TGF)-β but little if any Th1- or Th2-type cytokines (34). Another type of regulatory T cell, named T regulatory cell 1 (Tr1), is distinct from the Th3 cell (35). Tr1 differentiates in the presence of IL-10, has a high production of IL-10, low levels of active TGF-β, and a moderate production of IL-5, IFN-γ, and TNF-α. A deficiency in this particular subset of cells has been suggested to be involved in the pathogenesis of IBD. However, studies on the role of Th3 and Tr1 cells in intestinal immune responses are in their infancy.

Virtually all lamina propria lymphocytes and IEL express chemokine receptors that have been associated with Th1 and Th0 lymphocytes, but chemokine receptors associated with Th2 cells are not expressed (36). Furthermore, these two lymphocyte populations express a specific and similar array of chemokine receptors whose ligands are constitutively expressed in the intestinal mucosa and whose expression is upregulated during intestinal inflammation.

IEC downregulate T cell proliferative and cytokine responses for both Th1 and Th2 within $\gamma\delta^+$ and $\alpha\beta^+$ IEL populations. Such interactions occur *via* cell surface molecules and may exist to prevent inflammatory responses at the intestinal mucosal surface (37). In addition, IEC-derived IL-6 enhances lipopolysaccharide-stimulated IgA secretion by mucosal B cells (38).

It is clear that lymphocyte trafficking, the interaction between IEC and lymphocytes, and the cytokine profile that results will determine the polarization of immune responses. Dysregulation of these processes may well explain the pathogenesis of intestinal inflammatory and allergic conditions.

## THE INTESTINAL BACTERIAL FLORA

The commensal microflora is an integral component of the intestinal milieu; as such, its composition and its contribution to the health of the host cannot be ignored. Specific flora populate each level of the intestine and are prevented from migrating to extraintestinal sites by the intestinal epithelial barrier. The low pH, peristalsis, and luminal secretions of the stomach and upper gut render these tissues sterile or sparsely populated by avirulent, aerobic, gram-positive organisms (6). However, descending toward the distal ileum and colon, gram-negative and anaerobic organisms predominate (39). It seems paradoxical that such a large population of indigenous bacteria establishes itself in this tissue without any adverse effect on the host. Indeed, the physiologic microflora affords protection to the host in two important ways. It functions as a physical barrier to prevent pathogens interacting with the mucosal surface; in addition, it interacts with the host and modulates its mechanisms of defense (6). It is clear that the members of this bacterial community are altered by components in both the diet and the intestinal milieu. Colonization is thought to occur at birth, is different between breast-fed and formula-fed infants, and is altered postweaning, in the elderly, and in clinical disease (6). Dietary components such as fiber and nondigestible oligosaccharides (40), and perhaps cytokines (41) elaborated into the intestinal lumen, may modulate its composition.

## ADAPTIVE CHANGES IN THE NEONATE

After birth, the mucosa undergoes a major adaptive change in the transition of the fetus to the extrauterine environment. This is a major physiologic event with the passage of the intestine from a sterile to a heavily colonized tissue. Clearly, effective barriers are required against the huge bacterial inoculum derived from the mother's genital tract and feces, and from the environment. Beneficial components in breast milk are certainly instrumental in ensuring that the adaptation of the intestine to this massive change occurs without compromising the health of the neonate. However, in the premature, the mucosal barrier is not fully functional and the infants are rendered particularly susceptible to clinical disease states such as necrotizing enterocolitis (NEC) or allergy.

Although immune homeostasis is quickly established in the postnatal period, and neonates are capable of mounting active immune responses, they are nevertheless relatively immunodeficient (42). Neonatal T cells produce mature levels of cytokines *in vitro* but only in response to powerful stimulation (43). Furthermore, both Th1 and cytotoxic T lymphocyte responses are poor or absent. As a consequence of these phenomena, the newborn is vulnerable to potentially hazardous antigens.

## PUFA INTERACTIONS WITH THE INTESTINAL MUCOSA

Uptake of dietary PUFA, past the nonspecific and immunologic barriers, to the intestinal epithelium is well documented. Indeed, there is an energy- and temperature-dependent carrier-mediated transport of ALA and possibly other long-chain fatty acids across intestinal cells (44). Once ingested, the essential fatty acids (EFA) are converted to longer-chain, more highly unsaturated fatty acids, including arachidonic acid (AA) from LA and eicosapentaenoic acid (EPA) and docosahexanoic acid (DHA) from ALA. This process probably already takes place at the level of the epithelium because the enterocyte has the ability to desaturate EFA and incorporate them into jejunal and ileal microsomes (45). Furthermore, the activity of these enzymes is regulated by both the dietary fat intake and cell maturation (45,46). If dietary PUFA are incorporated into IEC membranes, it is feasible that they may have an effect on IEC-intestinal lymphocyte crosstalk in both IEL and lamina propria compartments of the gut, as well as in distal immune responses taking place in the mammary gland.

Several studies have reported regulation of nonspecific barrier function by the products of PUFA, but more emphasis has been placed on the function in the gastric mucosa than in the small intestine. These reports suggest that eicosanoids, particularly those derived from AA, affect intestinal secretions, mucus secretion, phospholipid synthesis, and the density of surfactants in the mucus as well as providing cytoprotection of gastrointestinal mucosa; the majority of studies have provided evidence of upregulation of these phenomena (47–53). However, several studies have challenged the observations on mucous secretion and cytoprotection by finding no relationship between prostaglandin (PG) synthesis and these parameters (54–56). It has also been proposed that intestinal glycosyltransferases involved in cell differentiation and postnatal maturation of the rat small intestine are altered by the global unsaturation index of dietary fatty acids and that any alterations in intestinal glycosylation may result from a decrease in total PUFA (57).

Oleic acid (OA), an unsaturated fatty acid of the n-9 series, induces mucosal injury and increased intestinal permeability in developing piglet intestine that is dependent on both saturation and chain length. However, this can be avoided by using its ethyl ester (58). The authors suggest that ethyl ester forms of fatty acids, which are absorbed and metabolized similarly to free fatty acids, may provide a means of supplying long-chain fatty acids to the intestine without causing mucosal damage. However, a more natural way of providing ester forms of fatty acids is as triacylglycerols.

A diet deficient in EFA increases the incidence of bacterial translocation to MLN (59) and raises the possibility that these fatty acids help maintain a tight intestinal barrier. However, this may be dependent on the type and/or proportion of individual fatty acids. Treatment of endothelial cells *in vitro* with γ-linolenic acid (GLA) has been shown to increase transcellular electrical resistance and reduce paracellular permeability to large molecules. Occludin, which plays a major role in tight junctions, was upregulated by GLA and by EPA but was downregulated by AA and LA (60). The effects obtained may be related to the type of eicosanoids synthesized from these different fatty acids. Because IEC also express these tight junction molecules, it is possible that exposure to specific PUFA may tighten the intestinal barrier. However, more studies are required both *in vitro* with IEC and *in vivo*; in contradiction to the above observations, there is *in vivo* evidence that a safflower oil diet (rich in n-6 PUFA) but not a fish oil (FO; menhaden, rich in n-3 PUFA) diminishes *N*-formyl-methionyl-leucyl phenylalanine-induced permeability and neutrophil infiltration in rats (61).

Studies examining the effect of PUFA consumption on the phenotype and function of cells isolated from the MLN, lymph, or blood give a good indication of modifications to their counterparts in the intestine. Although immunostimulatory effects have been reported, the general consensus is that the n-3 PUFA, such as EPA and DHA, suppress immune responses compared with n-6 PUFA such as LA. However, the precise targets of these dietary PUFA and the mechanisms underlying the observed effects on immunity are not clear. Nevertheless, a modulatory effect of these PUFA on eicosanoid production and the expression of other genes, such as the fatty acid synthase, has been reported.

Consumption of n-3 PUFA, such as that found in FO, can influence the production and the biological effects of a number of cytokines both *in vitro* and *in vivo* (62). Their effects on peripheral blood cells include a decreased lymphocyte response to mitogens, reduced NK cytotoxic activity, and an inhibition of IL-1, IL-2, TNF-α, and IFN-γ production *ex vivo* (28,62,63). A reduction in cytokines such as IL-1, which are known to be co-stimulatory during antigen presentation, suggests that this activity may also be inhibited by n-3 PUFA. Indeed, consumption of FO or consumption of EPA and DHA in the same ratio (3:2) as that commonly found in FO suppresses the expression of MHC Class II and the accessory molecule, intercellular adhesion molecule-1 (ICAM-1) on blood monocytes and thereby inhibits the cells' capacity to present the antigen tetanus toxoid to autologous lymphocytes (64). Furthermore, oil consumption in rats decreases the expression of MHC Class II and CD11a and CD18 on lymph-borne dendritic cells and reduces the ability of the cells to present the antigen keyhole limpet hemocyanin (KLH) to KLH-sensitized responder spleen cells (65). Furthermore, both EPA and DHA inhibit IFN-γ-induced expression of MHC Class II on monocytes/macrophages (66,67). An inhibition of proinflammatory cytokines, MHC Class II expression, and antigen presentation suggest a beneficial role for FO in inflammatory conditions such as IBD, in which these parameters are increased; it also raises the interesting possibility that the absence of MHC Class II on intestinal epithelium (22) and lower immune reactivity during the suckling period may be due, at least in part, to the action of DHA in breast milk.

Although there is an abundance of studies reporting modulatory effects on lymphocytes of the blood or spleen, there have been few studies that have specifically addressed the effect of dietary PUFA on the immune phenotype or function

of intestinal lymphocytes. It is known, however, that these cells incorporate dietary PUFA into their cell membrane. Colonic lymphocytes of rats fed a diet high in corn oil have greater membrane concentrations of LA and AA and higher levels of $PGE_2$ production than those isolated from rats fed menhaden oil (68). As a consequence the cells are refractory to mitogen stimulation.

Miura *et al.* (69) reported that OA stimulates lymphocyte flux and blastogenesis in intestinal lymph and enhances T-cell migration to the Peyer's patches, perhaps through upregulation of homing receptors (70). Dietary fats have also been shown to influence adhesion of lymphocytes to extracellular matrix proteins (71) as well as to macrophage and endothelial cell monolayers (72). Together, these observations suggest that unsaturated fatty acids in the diet may regulate the extravasation of intestinal lymphocytes into the lymph and blood as well as their reentry into mucosal tissues.

Elemental diets reduce the CD4/CD8 ratio in MLN and ileal lamina propria, and the level of IgA positive cells in the lamina propria of rats, but administration of OA reverses all of these changes (73). Although similar studies have not been performed using PUFA, the group of Kleemann *et al.* (74) observed that in diabetes-prone BB rats, feeding a diet enriched with FO altered the IFN-γ and IL-10 levels in the GALT. The authors postulated that the FO had polarized the Th1/Th2 cytokine ratio toward Th2. However, it may be that administration of FO promoted functional development of the Th3 and/or Tr1 cell subsets, which produce high levels of TGF-β and IL-10, respectively (34,35). In support of this, Fernandes *et al.* (75) showed that feeding autoimmune-prone mice menhaden oil led to a higher production of TGF-β. Both IL-10 and TGF-β are well known for their role in the induction of oral tolerance and the prevention of autoimmune disease. Interestingly, dietary PUFA influence the fatty acid composition and secretory activity of lactating mammary epithelial cells (76). Furthermore, high levels of GLA and low levels of ALA and n-3 PUFA in human milk are associated with atopic sensitization during infancy irrespective of the atopic status of the mother (77).

Metabolites of AA have also been implicated in the development and maintenance of intestinal immune homeostasis. Feeding hen egg-white lysozyme (HEL) to mice expressing a HEL-specific transgenic TCR does not result in intestinal pathology. However, simultaneous administration of cyclooxygenase-2 inhibitors and HEL leads to increased proliferation of lamina propria lymphocytes and crypt epithelial cells with resultant crypt expansion and villus blunting (78). The suppression of T-cell proliferative responses could certainly be a result of increased production of IL-10 by Tr1 cells. However, the observations that both n-3 and n-6 fatty acid metabolites lead to increased production of IL-10 and TGF-β and have similar effects in *vivo* are difficult to reconcile, especially in light of the fact that consumption of FO reduces the extracellular release of AA by stimulated T lymphocytes (79). An alternative explanation is that yet another mechanism of control is acting during consumption of n-6 fatty acids. The recent findings that $PGE_2$ selectively inhibits activation and proliferation of human $CD4^+$ memory cells secreting low amounts of both IL-2 and IL-4 and that Th1, Th2, and Th0 clones become sensitive to the $PGE_2$ effects only when IL-2 and IL-4 are removed from the medium support this notion (80).

In inflammatory and pathological conditions, protective mucosal secretions may be limited or not active and production of proinflammatory mediators, including eicosanoids of the n-6 series, increased in inflamed intestine. Furthermore, dysregulation of cell turnover and apoptosis of IEC in the villus may lead to a reduction in the proportion of mature and differentiated cells occupying the upper villus. In this context, dietary n-3 PUFA suppress colonocyte proliferation (81) and increase the number of differentiating and apoptotic cells without modification of crypt morphology or the number of cells per villus (81).

In intestinal pathologies of the premature such as NEC, the increase in the number of goblet cells and enteric defensin expression has been suggested to reflect the pathologic process (82). The observation that the steady-state level of intracellular peptide did not increase in parallel with the increase in defensin mRNA suggested to the authors either that the defensin was actively secreted into the gut lumen or that there was translational regulation of the peptide. However, defensins are believed to be released in an inactive form in the gut and to require activation by particular matrix metalloproteinases (MMP) (83). The predisposition of the premature infant to bacterial overgrowth and infection could therefore be due to inadequate MMP activity in the premature gut. In addition, the increased levels of proinflammatory cytokines, IL-1 and TNF-α, seen in NEC and other intestinal pathologies, such as IBD, promote adherence of gram-negative organisms to intestinal mucosa both *in vitro* and *in vivo* (41). Certain dietary PUFA have been proposed as therapies for intestinal pathologies on the basis of their anti-inflammatory properties. However, the contribution of these dietary components to the colonization of the lumen with beneficial microorganisms and to the integrity of the intestinal barrier provides other target functions. Certainly, diets deficient in EFA increase the incidence of bacterial translocation to MLN (59). EPA significantly inhibits the growth of obligate anaerobes such as *Bacteroides* spp. but not *Escherichia coli* both *in vitro* and *in vivo* (84,85) perhaps through disruption of the outer membrane (86). Diets high in marine oils certainly reduce the anaerobe/aerobe ratio in the colon (87), and some dietary lipids have been demonstrated to increase the number of lactic acid bacteria (LAB) in mice (88) and fish (85). In addition, LAB are major unsaturated fatty acid hydrating bacteria in the rumen (89), whereas human fecal flora can hydrogenate LA and ALA but not AA (90). One interesting possibility that has been observed in fish (91,92) but that has not been tested in humans is that microorganisms colonizing the gut are a source of DHA. Taken together, it would appear that specific dietary PUFA may be used to antagonize potential pathogens and/or encourage health-promoting LAB.

In conclusion, there are numerous studies reporting the effects of the various PUFA and their metabolites on the immune response of peripheral blood cells or splenocytes *ex vivo*. These investigations have greatly increased our perception of how dietary lipids might influence the health of the host. However, to date, understanding the fundamentals of immune regulation in intestinal tissue remains a relatively virgin field of research. The latest work examining polarization of Th1/Th2 responses gave excellent clues as to the events that might be taking place in the intestinal compartment. However, the effect of dietary PUFA on intestinal T-cell subsets and phenotype, IEC phenotype, intestinal cytokine production, and IEC–T cell crosstalk must be known to reinforce the concept that dietary manipulation with specific PUFA not only reinforces immune homeostasis in the healthy individual but also reinstates such homeostasis in a number of immune-mediated disease states.

# The Role of Polyunsaturated Fatty Acid Supplementation in Intestinal Inflammation and Neonatal Necrotizing Enterocolitis

**Michael S. Caplan* and Tamas Jilling**

Department of Pediatrics, Evanston Northwestern Healthcare, Northwestern University Medical School, Evanston, Illinois 60201

**ABSTRACT:** Dietary polyunsaturated fatty acid (PUFA) supplementation has been shown to reduce the incidence of necrotizing enterocolitis (NEC) in a recent randomized, controlled trial. These compounds are known to modulate the inflammatory cascade and to influence intestinal health in a variety of ways. Although the pathophysiology of NEC is not well understood, recent evidence suggests that platelet-activating factor (PAF) is a key endogenous mediator of intestinal necrosis in animals. Using a neonatal rat model of NEC that includes the key risk factors of asphyxia and formula feeding, we investigated the role of dietary PUFA supplementation on the incidence and pathophysiology of NEC. Our findings suggest that PUFA reduce the incidence of NEC by modulating PAF metabolism and endotoxin translocation.

Paper no. L8641 in *Lipids 36,* 1053–1057 (September 2001).

Long-chain polyunsaturated fatty acids (LC-PUFA) are a diverse group of compounds that have been purported to modulate inflammation and immunity (1,2). In high-risk premature neonates, dysregulation of inflammation and immunity may contribute to the pathophysiology of necrotizing enterocolitis (NEC), a serious gastrointestinal emergency that afflicts 10% of infants born weighing <1500 g (3,4). In a recent clinical trial, PUFA supplementation of formula for premature infants was shown to reduce the incidence of NEC in a high-risk population (5). Nonetheless, the specific effects of PUFA on intestinal inflammation and necrosis remain poorly characterized. Studies have shown that n-3 PUFA can reduce the inflammatory response *via* multiple potential pathways (6). Platelet-activating factor (PAF) is an important phospholipid mediator that has been shown to play a crucial role in the initiation and pathophysiology of NEC in several animal models (7). In this report, we will discuss the effect of PUFA on PAF metabolism and delineate the importance of these changes on intestinal inflammation and necrosis.

Abbreviations: AA, arachidonic acid; DHA, docosahexaenoic acid; IL, interleukin; iNOS, inducible nitric oxide synthase; LC-PUFA, long-chain polyunsaturated fatty acids; NEC, necrotizing enterocolitis; NF, nuclear factor; PAF, platelet-activating factor; PAF-AH, PAF-acetylhydrolase; PKC, protein kinase C; $PLA_2$-II, phospholipase $A_2$-II.

## EFFECT OF PUFA ON NEONATAL NEC: CLINICAL TRIAL

Although PUFA supplementation of neonatal formula has been studied extensively for the outcomes of central nervous system development and visual acuity (8), limited information is available regarding PUFA effects on neonatal intestinal inflammation and necrosis. As part of a risk-benefit trial for diet and infant development, Carlson *et al.* (5) performed a prospective, randomized, controlled trial that included neonatal NEC as one of the secondary outcome variables. Using an egg phospholipid preparation of PUFA in experimental formula, they found a reduction of NEC in supplemented patients compared with controls (1 of 34 vs. 15 of 85, $P < 0.05$ using Fisher's Exact Test). The authors discussed several potential mechanisms that could explain the results, but also suggested that due to low numbers of patients in the experimental group, a type I error may have erroneously produced the difference identified between groups. Thus, a larger randomized trial was suggested to confirm these interesting results. Nonetheless, the mechanisms responsible for this potential benefit on neonatal NEC remain speculative.

## PUFA EFFECTS ON INFLAMMATION AND INTESTINAL INJURY

Many recent studies have confirmed that PUFA modulate the inflammatory response. Supplementation in various systems with n-3 PUFA result in anti-inflammatory responses, with recent clinical trials suggesting improvement in rheumatoid arthritis, psoriasis, inflammatory bowel disease, and asthma (9–11). In other studies, n-6 PUFA seem to act in opposition to the n-3 compounds, and activate the inflammatory response *via* interleukin (IL)-1 production and increased tissue responsiveness to additional cytokines (12,13). Further analyses suggest that the balance between n-3 and n-6 PUFA is critical and contributes to the regulation of inflammation *via* cytokine activation and effects. Nonetheless, specific cellular mechanisms responsible for these events have been evaluated, and preliminary evidence suggests multiple effects, including the following: (i) modulation of gene expression, e.g. nuclear factor (NF)-κB (14); (ii) alteration of protein kinase C (PKC) activity (15); (iii) inhibition of apoptosis (16); (iv) inhibition of $Mg^{2+}$-ATPase (17); (v) action on antioxidant system (18); and (vi) modulation of cytokine and prostaglandin metabolite production and receptor activation (2,19).

Additional studies have considered the specific effects of PUFA on intestinal inflammation and necrosis. It is known that multiple cytokines (including IL-1, IL-6, IL-10, IL-11, IL-12, and tumor necrosis factor) and arachidonic acid (AA) metabolites (i.e., prostanoids, leukotrienes, and thromboxanes) influence intestinal health *via* their effects on intestinal blood flow, mucosal permeability, and activation of secondary inflammatory mediators at the mucosal environment (20,21). However, the link between PUFA supplementation and cytokine/prostaglandin modulation leading to alteration of intestinal inflammation and necrosis remains conjectural. One study evaluated the role of n-3 PUFA on hypoxia-induced intestinal injury in mice and found a significant reduction in necrosis with the dietary fish oil supplementation (22). In addition, the results indicated that n-3 PUFA protected against hypoxia-induced leukotriene $B_4$ and PAF production in intestinal homogenates. This study indicated that dietary PUFA may influence local, intestinal mediator production, which in turn could modulate intestinal inflammation and necrosis. The association of intestinal PAF with intestinal injury in this study was of interest because recent evidence has supported a primary role for this mediator in other animal models of neonatal NEC.

## ROLE OF PAF IN NEONATAL NEC

PAF is a potent phospholipid mediator with diverse biological actions (23). PAF is synthesized in most cells and tissues from phosphatidylcholine precursors under the influence of a PAF-specific phospholipase $A_2$-II ($PLA_2$-II) to form lysoPAF, and subsequent acetylation to PAF *via* an acetyltransferase enzyme (see Fig. 1). The half-life of PAF is remarkably short due to rapid degradation catalyzed by the important enzyme PAF-acetylhydrolase (PAF-AH) (24). Of interest, PAF-AH activity is present in breast milk, is deficient in the circulation of neonates, and is significantly reduced in NEC patients compared with age-matched controls (25–27). PAF exerts its biological effects after binding to a G protein-coupled PAF receptor that is present in most tissues, but is highly expressed in intestinal samples (28).

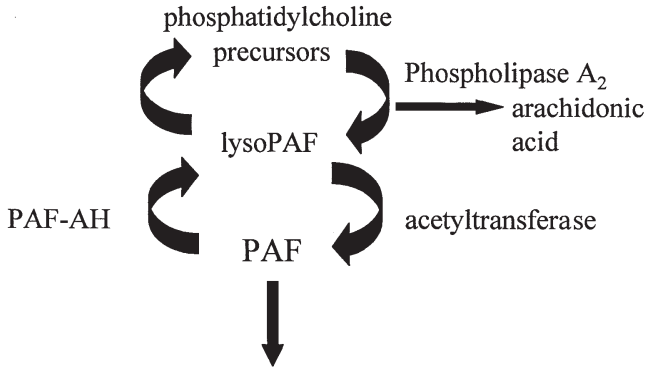

**FIG. 1.** The platelet-activating factor (PAF) cycle. PAF-AH, PAF-acetylhydrolase.

Although PAF is associated with systemic responses of capillary leak, vasoconstriction, platelet and neutrophil activation and degranulation, bronchoconstriction, and myocardial depression, studies suggest that PAF is intimately linked with intestinal necrosis (7,29). Hsueh and colleagues (30–32), using the adult rat model, have confirmed the importance of PAF in intestinal necrosis by showing the following: (i) intravenous PAF results in ischemic bowel necrosis (30); (ii) lipopolysaccharide-induced intestinal injury is blocked by PAF receptor antagonists; and (iii) PAF is increased in intestinal tissue after endotoxin stress (32). In addition, PAF activates several secondary mediators that contribute to the propagation of intestinal necrosis (33). We analyzed the importance of PAF in a neonatal rat model of NEC and showed that PAF receptor antagonists and enteral PAF-AH supplementation reduced the incidence of disease after asphyxia and formula feeding (34,35). Additional experiments have shown that PAF-AH is taken up in the intestinal epithelium, where it remains functionally active but does not translocate into the systemic circulation. Preliminary studies in our laboratory to delineate the cellular mechanisms of PAF-induced injury showed that PAF acts locally on the enterocyte PAF receptor to stimulate chloride transport, intracellular acidosis, and apoptosis, thereby leading to alterations in tight junctional integrity of the intestinal epithelium (Caplan, M., and Jilling, T., unpublished observations). Concurrent studies using the neonatal rat *in vivo* have shown that apoptosis is an important early event that precedes necrosis after asphyxia and formula feeding. Further study of these mechanisms may help clarify the pathophysiology of neonatal NEC, a disease whose etiology has so far remained elusive.

## ROLE OF PUFA SUPPLEMENTATION IN NEONATAL NEC

To investigate the specific role of PUFA supplementation in neonatal NEC, we utilized a well-described model that incorporates the typical risk factors for clinical NEC into the experimental protocol (36). Neonatal rats were fed formula for premature infants and challenged with asphyxia twice daily in a manner that has been shown to produce gross and microscopic NEC in 75% of animals by 96 h of life (37). To evaluate the effect of PUFA supplementation, experimental animals were fed formula supplemented with AA (34 mg/100 mL) and docosahexaenoic acid (DHA; 23 mg/100 mL) to provide an AA/DHA ratio of 1.5:1. Rats were followed up to 96 h for clinical signs of abdominal distention, abdominal wall discoloration, bloody stools, and respiratory distress; as symptoms developed, animals were killed and intestines recovered for gross and microscopic analysis of necrosis and apoptosis. In addition, separate groups of animals were studied at 24 and 48 h; before the development of intestinal injury, samples were frozen for subsequent analysis of mRNA expression of $PLA_2$-II, PAF receptor, and inducible nitric oxide synthase (iNOS), and for apoptosis of epithelial cells. Plasma was collected concurrently at these points for quantification of endotoxin, a crude estimation of bacterial translocation in this model.

We found that PUFA supplementation in this model markedly reduced the incidence of NEC and death compared with control formula (Table 1). Furthermore, PUFA significantly reduced plasma endotoxinemia that occurred by 48 h in animals treated with the protocol (Fig. 2). Analysis of apoptosis suggested no effect of PUFA on programmed cell death of intestinal epithelium. However, using reverse transcriptase-polymerase chain reaction normalized to β-actin, we found that PUFA reduced intestinal gene expression of $PLA_2$-II (at 24 h) and PAF receptor (at 48 h), but had no effect on iNOS at any time point (Figs. 3–5). The results suggest that PUFA reduced the risk for NEC in this model and that altered PAF metabolism might contribute to the beneficial effect of PUFA. The reduction in $PLA_2$-II mRNA lowered local PAF synthesis, and the suppressed PAF receptor expression prevented PAF-induced cellular effects, thereby together contributing to reduced likelihood of PAF-induced intestinal inflammation and necrosis after asphyxia and formula feeding. Although it is thought that bacterial translocation, activation of iNOS, and apoptosis participate in the pathogenesis of NEC (38–40), we found that PUFA had no effect on iNOS or apoptosis but did protect against bacterial translocation. The mechanisms responsible for the effect of PUFA on PAF metabolism and bacterial translocation may include many of those described above because NF-κB activation, PKC inhibition, and modulation of cytokines and prostaglandin metabolites affect PAF, mucosal integrity, and intestinal injury (20,41,42).

In summary, the effects of PUFA on intestinal inflammation and necrosis are complex, but recent studies suggest that these compounds reduce the incidence of NEC in premature infants and prevent NEC in neonatal rats with associated changes in PAF metabolism and bacterial translocation. Nonetheless, interpretation of human and animal studies with PUFA is difficult because differing preparations and ratios of n-3/n-6 fatty acids have been investigated. Additional

**TABLE 1**
**Effect of Polyunsaturated Fatty Acids (PUFA) on Necrotizing Enterocolitis (NEC) and Death**

| | NEC | Death |
|---|---|---|
| Control | 17/24 | 18/24 |
| PUFA | 8/24[a] | 8/24[a] |

[a]$P < 0.05$.

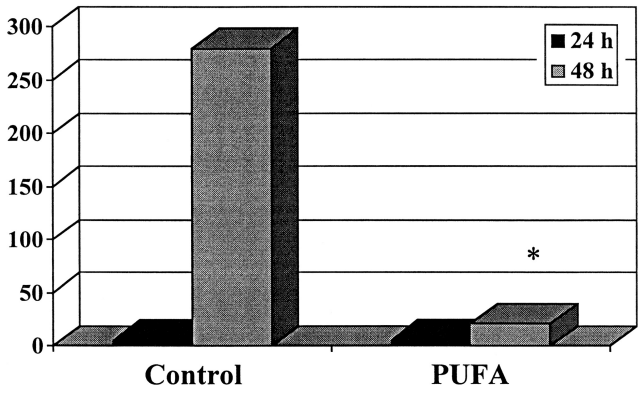

**FIG. 2.** Effect of polyunsaturated fatty acids (PUFA) on plasma endotoxinemia (endotoxin units/mL).

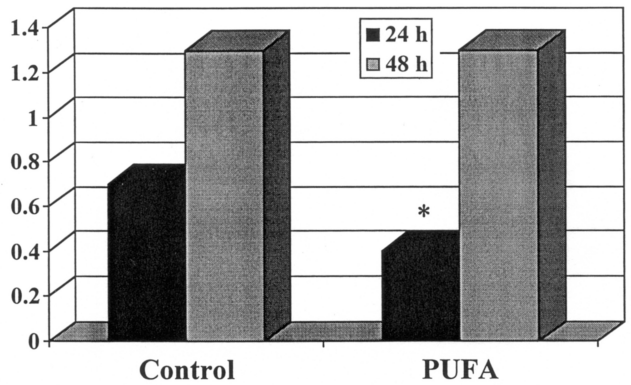

**FIG. 3.** Effect of polyunsaturated fatty acids (PUFA) on phospholipase $A_2$ ($PLA_2$) expression (ratio to β-actin).

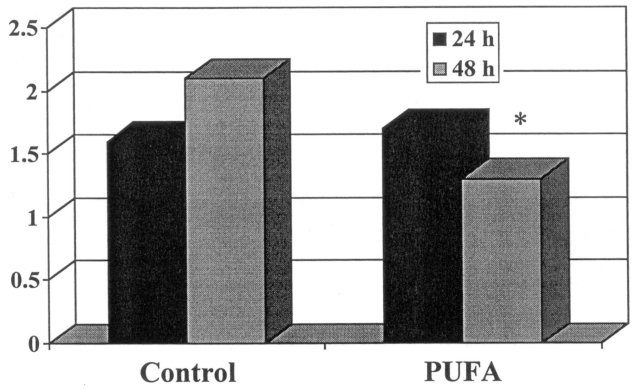

**FIG. 4.** Effect of polyunsaturated fatty acids (PUFA) on platelet-activating factor receptor expression (ratio to β-actin).

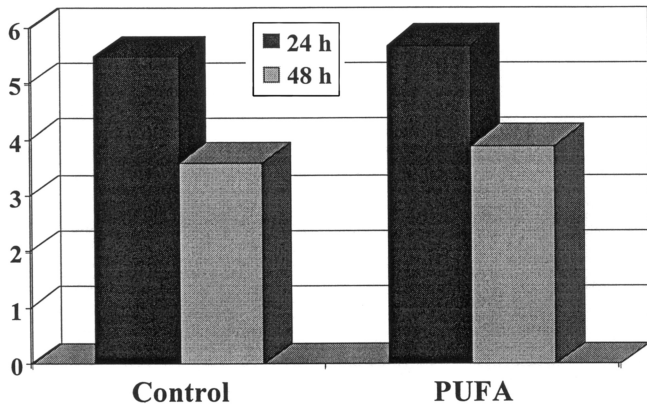

**FIG. 5.** Effect of polyunsaturated fatty acids (PUFA) on inducible nitric oxide synthase expression (ratio to β-actin).

research is warranted to delineate the specific cellular effects of PUFA on intestinal integrity, to clarify the specific components of PUFA responsible for improved intestinal health in animals, and to confirm the beneficial role of these dietary supplements for premature infants.

## A Symposium on PUFA in Maternal and Child Health

■ LCPUFA in Disorders of Protein and Carbohydrate Metabolism. C. Agostoni, E. Verduci, E. Racchi, and E. Riva, Department of Pediatrics, San Paolo Hospital.

In spite of the many trials on the role of LC-PUFA in fat metabolism, few studies are available on their functions in disorders of carbohydrate and protein metabolism. Breast-fed infants show higher percentage levels of DHA and total LC-PUFA in muscle phospholipids with lower plasma glucose levels when compared to formula-fed counterparts. These findings may suggest an early derangement of the insulin axis regulation in formula-fed infants. The relationship between the LC-PUFA synthesis rate and the insulin response seems to be quite complex, however. Obese children with elevated insulin levels and patients affected by type-1 glycogen storage disease, whose dietary regimen provides a high intake of slowly-absorbed carbohydrates, show increased LC-PUFA in plasma lipids. On the other hand, negative correlations between indices of delta-6 desaturase activity and blood insulin levels have been found in obese preadolescents. These data suggest that the insulin-associated stimulatory effects on desaturase activity, shown in earlier experiments, could depend on the individual degree of insulin sensitivity. In inborn errors of protein and amino acid metabolism, the dietary intervention provides semisynthetic diets without LC-PUFA. Dietary LC-PUFA on brain would be of potential utility for those conditions possibly affecting the functional development of the nervous tissues. We have recently investigated the effects of a 12-month supplementation with LC-PUFA in school-age children affected by type-I hyperphenylalaninemia (HPA). These patients follow a low phenylalanine diet, severely restricted in animal foods and LC-PUFA. At baseline HPA children showed a poorer DHA status and prolonged P100 wave latencies than reference children. After 12 months of LC-PUFA, we have found a significant increase in DHA levels of both plasma and erythrocyte lipids and a decrease of the P100 wave latency. In conclusion, LC-PUFA may 1) help regulate carbohydrate metabolism, 2) depend on the individual degree of insulin sensitivity as far as synthesis, and 3) aid brain development in inborn errors of amino acid metabolism that require unusual dietary intakes.

■ n-3 Fatty Acid Deficiency and Hippocampal Morphology. A. Ahmad, M. Murthy, R. Greiner, T. Moriguchi, and N. Salem, Jr., National Institute on Alcohol Abuse and Alcoholism, NIH.

Studies in our lab have previously shown that n-3 deficiency leads to deficits in learning and performance in rats on a number of behavioral tasks. To investigate the anatomical correlates of these deficits, we carried out morphological analysis of the hippocampus in these animals to ascertain the effects of n-3 deficiency. Nineteen adult female rats were raised for three generations on two n-3 deficient and two n-3 adequate diets. Deficient diets (Def and Def+LA) contained low linolenic acid (LNA) or low LNA and elevated linoleic acid (LA), and adequate diets (Adq and Adq+DHA) contained high LNA, or high LNA and docosahexaenoic acid (DHA). Unbiased stereological methods were used to investigate changes in the volume, density, and total number of neurons in the hippocampus of these animals. Cell size of neurons was also measured in CA1-3, granular, and hilar layers of the hippocampus at septal and temporal locations. To confirm the effect of diets on the total and phospholipid fatty acid compositions of the hippocampus, a separate group of 24 rats was used. We found that the cell body size of CA1 neurons decreased in the Def group compared to Adq and Adq+DHA groups at both septal and temporal locations, and the difference was statistically significant ($P<0.01$) between the Def and Adq+DHA groups at the septal location. No significant difference was detected in the size of neurons in other layers except that deficient diets led to a general decrease in the size of hippocampal neurons. No differences were detected in the volume of hippocampal layers, neuronal density, or total neurons across the dietary groups. However, magnitudes of these parameters were marginally higher in both deficient groups. The total fatty acid composition of the hippocampus was indeed dependent on the diets with profound changes in the n-6/n-3 ratios. DHA in the hippocampi of Def and Def+LA animals decreased by about 90% compared with animals on Adq and Adq+DHA diets with a reciprocal increase in docosapentaenoic acid (DPAn-6). The largest decrease in DHA was observed in phosphatidylserine (PS), followed by phosphatidylethanolamine (PE), phosphatidylinositol (PI), and phosphatidylcholine (PC), in Def and Def+LA groups with a similar and reciprocal increase in DPAn-6. Since the size of CA1 neurons decreased, and the density of neurons along with layer volume marginally increased in the deficient groups, it appears that the density of processes in these groups may be altered. Processes in oriens, radiatum, and lacunosum-molecular layers are being labeled with growth-associated protein 43 (GAP-43) to quantify arbor density in the deficient and adequate dietary groups in order to test this hypothesis.

■ Docosahexaenoic Acid (DHA) Mediates Anti-Apoptotic Effects Through Phosphatidylinositol 3-Kinase Pathway: A Novel Observation in Neuronal Apotosis. M. Akbar and H.-Y. Kim, NIAAA.

Neuronal cells contain high levels of long chain polyunsaturated fatty acids, particularly docosahexaenoic acid (DHA). This fatty acid is considered to be essential for many physiological functions of the brain. Recently, we have demonstrated the antiapoptotic effect of DHA enrichment in serum-starvation-induced apoptosis, as pretreatment of Neuro 2A cells for 48 h with DHA (25 μM), but not with oleic acid (OA) and arachidonic acid (AA), significantly inhibited Caspase-3 activity and DNA fragmentation in comparison to non-enriched control cells. In the present study we found that DHA enrichment also prevented apoptotic cell death induced by staurosporine (ST). By using these two model systems, we further investigated the signaling mechanism involved in the antiapoptotic effect of DHA. We found that the protective effect of DHA was abolished by the treatment with a PI3-kinase inhibitor wortmanin (WM), but was not affected by inhibitors of protein kinase A, MEK or MAP kinase. Both serum starvation and ST-treatment significantly decreased phosphorylation of Akt, a well-known downstream kinase of PI3-kinase pathway involved in cell survival, and DHA enrichment restored the phosphorylation status of Akt. In the presence of WM, however, DHA enrichment did not recover the Akt phosphorylation which was suppressed by either serum starvation or by ST-treatment. Taken together, our findings strongly suggest that DHA may exert its antiapoptotic effect through the PI3-kinase/Akt pathway.

Key Words: Apoptosis, PI3-kinase, Akt Phosphorylation

■ The Relationship Between the Essential Fatty Acid Status at Birth and Neurophysiological Function of the Visual System at 8 Years of Age. E.C. Bakker[1,2], J. Reulen[2], F. Spaans[2], C.E. Blanco[2], and G. Hornstra[1], [1]Universiteit Maastricht, Maastricht, The Netherlands, [2]University Hospital Maastricht, Maastricht, The Netherlands.

Our aim was to investigate whether the concentrations of long chain polyunsaturated fatty acids (LCP) in phospholipids of umbilical plasma or umbilical vessel walls are associated with neurophysiological function of the visual system at 8 years of age. Several studies have found an influence of LCP status on the functioning of the visual system in young infants. This study is the first to investigate the long-term effects of LCP

NOTE: The first author was also the presenter; if otherwise, the presenting author has been indicated with an asterisk (*).

on the visual function. The study consisted of a follow-up of 60 children, born healthy and at term, who had been characterized with respect to their LCP status at birth. At 8 years of age, their visual function was assessed by electroretinography (ERG), visual-evoked potentials (VEP), and opthalmological measurements (including visual acuity, stereopsis, and contrast sensitivity). Results of these measurements have been related to the LCP status at birth by means of multiple regression analysis, correcting for potential confounding factors such as gestational age and age at measurement. Based on results of studies in young infants, a positive correlation between LCP status and the functioning of the visual system was expected. However, preliminary results of the 30 children evaluated so far give no evidence for such a correlation. None of the neurophysiological and opthalmological outcome measurements at 8 years was found to be significantly correlated to the LCP status at birth. The results from all 60 children including their essential fatty acid status at 7 years of age will be presented.

Key Words: LCP, Visual Function, Development

■ Distribution of Long Chain Polyunsaturated Fatty Acids in Canine Milk Parallels Changes in Plasma Total Phospholipid Fatty Acids During Lactation. J.E. Bauer[1], K.E. Bigley[1], G.E. Lees[1], and M.K. Waldron[2], [1]Texas A&M University, College Station, TX, USA, [2]Ralston-Purina Co., St. Louis, MO, USA.

Retina and central nervous system of mammals are rich in long chain polyunsaturated fatty acids (LC-PUFA) including arachidonic acid (AA, 20:4n-6) and docosahexaenoic acid (DHA, 22:6n-3). Although human milk contains DHA and AA in amounts high enough for their rapid accumulation in developing nervous tissues, the need for LC-PUFA supplementation of infant formulas to reflect human milk remains controversial. Visual and neurologic development in dogs is not only important, but information obtained using canines may provide useful comparative data. The objective of this study was to investigate fatty acid (FA) profiles and LC-PUFA content of total milk lipid extracts from dogs fed a diet of known fatty acid composition and compare them with plasma phospholipid (PL). Milk and plasma samples were obtained from 11 nursing, adult dogs at <1 week lactation, between 1 and 2 weeks, and >2 weeks lactation. Diet was a mixture of canned and dry puppy growth foods with similar fatty acid profiles. Total lipids were extracted from all samples; lipid classes were fractionated from sera; and FA methyl esters were prepared and subjected to capillary gas chromatography. Total milk fat was determined gravimetrically. Milk FA profiles reflected the diet. Plasma PL fatty acids also reflected the diet although relative amounts of 18:0 and 20:4n-6 were higher in plasma PL, consistent with active *de novo* synthesis, desaturation, and chain elongation during PL synthesis. A decrease in relative amounts of 20:4n-6, 22:5n-3 and 22:6n-3 in milk paralleled a similar decrease in plasma PL from early to later lactation, and total fat dropped slightly. Milk contained approximately 11–12% total fat with moderate amounts of AA, DPA, and DHA. At 1 week, % AA, DPA, and DHA in dog milk were 1.8%, 0.2%, and 0.07%, respectively. Compared to 1 week, total milk LC-PUFA content decreased by 8% at 1–2 weeks lactation and by 12% at >2 weeks; similar to humans. By contrast, recommendations for human infant formula based on human milk are lower for AA (0.3–1.1%) and higher for DHA (0.25–0.76%). Amounts of AA in canine milk in this study are moderately higher, while those of DHA are markedly lower compared with humans. Why these differences exist is unknown. They may initially depend on dietary fatty acid intake but appear to reflect plasma phospholipid profiles. Amounts of n-6 and n-3 LC-PUFA necessary for optimal puppy neonatal development require further study.

■ Essential Fatty Acids and the Development of Childhood Atopic Disease. B. Björkstén[1] and K. Duchen[2], [1]Centre for Allergy Research, Karolinska Institutet, [2]Department of Paediatrics, Linkoping University, Sweden.

The potential relationship between the intake of long chain fatty acids and childhood allergy has been discussed for many years. Conclusive evidence is still lacking, although several recent clinical studies suggest that atopic manifestations in infancy may be associated with a low dietary intake of essential fatty acids (FA), particularly alpha-linolenic acid (LNA). Most often, atopic dermatitis has been linked to an abnormal FA metabolism. Clinical studies of treatment of atopic dermatitis and asthma, by modifying the FA content of the diet have been largely disappointing, however. At least some atopic infants seem to have an imbalance in FA composition. The most consistent findings include lower levels of n-3 PUFA and high ratios of n-6/n-3 FAs in allergic individuals. Also, the relationships between individual FAs of the n-6 and n-3 series are abnormal, indicating disturbances in the FA metabolism. A delta-6 desaturase dysfunction has been suspected in several studies. As the atopic phenotype may be the consequence of any of several genotypes, particularly those related to the regulation of IgE antibody formation, it is not to be expected that allergic disease would be linked to an abnormal FA metabolism in all patients. It is likely, however, that some cases of allergic disease are a consequence of disturbed FA regulation. This would open the possibility for prevention and treatment of some patients by regulation of the diet. Similarly, the allergy preventive properties of human milk are controversial. Recent studies have demonstrated that there are individual variations in the FA composition of human milk, as well as in the content of components of the immune system. Thus, low levels of linoleic acid (LA), LNA, n-6 LCP and particularly LA/LNA and AA/EPA ratios have been reported in human milk of atopic mothers. Furthermore, low levels of n-3, including EPA, DPA, and DHA, as well as altered n-6/n-3 FA and AA/EPA ratios have been found in milk from mothers of allergic babies. It is reasonable to suggest that some of the controversy regarding the role of breast-feeding in allergy prevention is due to individual variations in the composition of human milk. If a relationship between an abnormal FA composition and the development of allergic disease would be confirmed, then this would open for primary prevention of allergies by giving lactating mothers a dietary supplement of n-3 FA.

■ Stable Isotope Studies of Maternal and Infant Polyunsaturated Fatty Acid Metabolism Using Primate Models. J.T. Brenna, Cornell University.

Recent and continuing advances in stable isotope availability and analytical techniques present increasingly powerful tools for investigation of a wide variety of metabolic issues. Specifically, high-precision compound-specific isotope analysis permits the investigation of *in vivo* metabolism at high sensitivity using highly enriched $^{13}C$-labeled tracers and/or by taking advantage of natural variability in $^{13}C/^{12}C$. Tracers are most appropriate for endogenous molecules when it is desirable to label specific parameters involving metabolism of a compound. An example is the labeling of two or more substrates for a single product, such as dietary 18:3 and 22:6 as substrates for brain 22:6. An alternative on this theme is labeling of two forms of the same fatty acid to evaluate utilization efficacy, for example investigating the relative accretion 20:4 consumed as phospholipid or as triglyceride. Other examples include labeling of a route of entry, such as oral and intravenous administration, or labeling of time points using multiple isotopes or isotopomers. Labeling can also be used to investigate the disposition of a single uniformly labeled compound, such as the relative amount of essential fatty acid carbon converted into saturates and monounsaturates, compared with that excreted as $CO_2$. These approaches all have analogues in radiotracer studies, but are often more conveniently accomplished with stable isotopes and do not present the hazards and increasing expense and regulatory burden of radiotracers.

In maternal/infant PUFA nutrition, the question of amount and form of dietary PUFA for long chain PUFA has been under active investigation for several years. Such studies have established that premature human infants can convert 18:3 to 22:6. However, human studies typically suffer from severely limited sampling, typically blood and little or no target tissue, particularly when infants are involved. Kinetic modeling based on blood sampling can provide only rough, tentative estimates of metabolism. In contrast, animal studies permit sampling from critical target tissues such as retina, brain, and liver and deliver direct measurements of tracer concentrations of interest. Quantitative estimates of 18:3 to 22:6 conversion are straightforward using animals. Examples of several of these principles will be presented.

■ The Effect of Dietary Docosahexaenoic Acid (DHA) Supplementation on Human Milk Cytokine Production. D-L. Bryan[1], J.S. Hawkes[2], M. Makrides[3], M.A. Neumann[1], and R.A. Gibson[4], [1]Flinders University of South Australia, [2]Flinders Medical Centre, [3]Women's and Children's Hospital, [4]Child Health Research Institute, Adelaide, Australia.

An increased requirement for dietary DHA (22:6n-3) during pregnancy and lactation has resulted in some expert nutrition committees recommending supplementation for pregnant and lactating women. n-3 PUFA have also been recognized as regulatory agents for inflammatory cytokine production. We have previously reported on levels of the inflammatory cytokines tumor necrosis factor α (TNFα), interleukin (IL) 1β and IL6, in the aqueous fraction of human milk (Hawkes, J.S., *et al*., *Pediatr. Res. 46*, 194–199, 1999). The aim of this study was to examine the effects of dietary DHA supplementation on two of these potentially inflammatory human milk cytokines, TNFα and IL6, as well as the cytokines transforming growth factor (TGF) β1 and TGF β2. Mothers were randomized into three groups and asked to consume a dietary supplement from day 3 postpartum. Group 1 (placebo vegetable oil, *n*=28), group 2 (Lo DHA 300 mg of DHA per day, *n*=27) and group 3 (Hi DHA 600 mg of DHA per day, *n*=28). Milk samples (50mL) were collected by manual expression at week 4 and fractionated by centrifugation to provide fat for fatty acid analysis and the aqueous fraction for measurement of TNFα, IL6, TGFβ1, and TGFβ2. Levels of these aqueous phase cytokines were determined by ELISA, established using matched antibody pairs. Supplementation increased breast milk DHA (mean %±SD) from 0.26±0.08 (placebo) to 0.39±0.08 (Lo DHA) and 0.66±0.18 (Hi DHA) (*P*=0.00). The aqueous phase cytokines TNFα, IL6, TGFβ1, and TGFβ2 were detectable in 60–100% of samples. Preliminary analysis shows no difference between levels of these cytokines in each of the supplementation groups. Our results indicate that increased maternal consumption of n-3 PUFA during lactation does not cause perturbations in these immune mediators in human milk.

Key Words: Docosahexaenoic Acid, Lactation, Cytokines

■ Incorporation of α-Linolenic Acid (ALA) and Linoleic Acid (LA) into Human Epithelial Cell Lines. D.-L. Bryan[1], P. Hart[1], K.F. Forsyth[2], and R.A. Gibson[3], [1]Flinders University of South Australia, [2]Flinders Medical Centre, [3]Child Health Research Institute, Adelaide, Australia.

There have been numerous animal and human studies designed to examine the effects of α-linolenic acid (ALA) and linoleic acid (LA) supplementation on the fatty acid composition of plasma and tissues. A feature of all these studies is the marked difference in incorporation into plasma and tissue phospholipids of these 18-carbon precursors of the long chain polyunsaturates. While dietary LA and ALA are linearly related to tissue phospholipid levels, the levels of tissue LA can be 10-fold higher than tissue ALA even when dietary levels are equivalent. There is some dispute whether this disparity is due to ALA being more rapidly metabolized to its products by the liver or whether LA is preferentially incorporated into cellular phospholipids. We examined the level of incorporation of polyunsaturated fatty acids (PUFA) into human respiratory epithelial cell lines (A549, 16HBE) by determining the dose-dependent incorporation of ALA and LA free fatty acids (5–150 μg/mL FFA) over 24 hours. Cell membrane phospholipid ALA and LA were increased up to ~26–30% total fatty acids with a concomitant decrease in other membrane fatty acids before significant toxicity was observed (50 μg/mL). Analysis of culture media showed little to no conversion of FFA to other lipid classes or of PUFA to their metabolites. Our results indicate that both LA and ALA can be incorporated to similar levels into human cell lines *in vitro* without a concomitant rise in long chain metabolites such as AA, EPA, or DHA. The potential role for LA and ALA to regulate synthesis of mediators of immunity (cytokines, eicosanoids) and other processes per se can thus be explored using this model. Our data support the concept that rather than any inherent inability by human cells to incorporate ALA into membrane phospholipids, the lack of incorporation in human and animal models *in vivo* is due to the rapid metabolism of this fatty acid to other n-3 PUFA in the liver.

■ Relationship Between Spanish Lactating Mothers' Diets and the Antioxidant Vitamin Content in Breast Milk. C. Campoy[1], R.M. Baena[1], A. López-López[2], J. Garrido[1], C. López-Sabater[2], M. Rivero[3], R. Bayés[1], and J.A. Molina-Font[1], [1]Dept. of Paediatrics, School of Medicine, University of Granada, Spain, [2]Dept. of Nutrition and Bromatology, School of Pharmacy, University of Barcelona, Spain, [3]Scientific Dept. of Laboratories Ordesa, Barcelona.

Maternal nutrition during lactation may play an important role in breast milk composition, and thus in the nutrition of their infants. Breastfed newborns depend on maternal milk for their supply of vitamins A (A) and E (E). The aim of this study was to determine if there was a relationship between the lactating mother's food (especially fatty acid) intake and the antioxidant vitamin composition of breast milk. METHODS: 100 samples of breast milk from healthy lactating women between 17 and 37 years of age were collected: 34 colostrum (1–6 days) (C), 32 transition milk (7–14 days) (T), and 34 mature milk (15–41 days) (M). Women were asked to record their food intake for three days before they supplied milk. Evaluation of the questionnaires was accomplished with software developed by Suarez *et al.,* using Wander food composition tables. The milk from each breast was obtained at the beginning and end of each feed throughout the day to minimize any effects of diurnal rhythm on the composition of the milk. The milk samples of one mother were stored individually at -20°C without light and pooled at the end of the day. They were then stored under nitrogen at -80°C until analysis. E and A were measured in mg/dL using HPLC. ANOVA, Student/Welch *t* test and correlation analyses were performed. RESULTS: Significant correlations were found between the different components studied and the days of lactation. Breast milk: E: $r$=-0.49, A:$r$=-0.47. Mother's Intake: MUFAs: $r$=0.34, SFAs: $r$=0.48, CHOL: $r$=0.24, Total Fat: $r$=0.29; Fe: $r$=-0.30, Zn: $r$=-0.53, Carbohydrates: $r$=-0.47. A and E content in breast milk diminished significantly from colostrum to mature milk while the intake of these vitamins by the lactating mother was unaltered in the same period. This effect could be explained by the efficient mechanism of mammary gland E uptake around parturition and related to the higher fat content in colostrum milk. An increase in the mother's intake of MUFAs and SFAs during the periods of transition and mature milk compared to the colostrum was observed. As far as the nutrient content of womens' diets, the mean intake of protein was 109 g/day compared with the RDA recommendation of 65 g/day. The consumption of fats was higher than has been recommended (30%) as a percentage of total energy: 39.2% and 36.8% at the time of providing transition and mature milk, respectively. The profile of fatty acids was also different from that recommended, although possibly due to the high consumption of olive oil (90%). Ca, Fe, and vitamin A and D intake were less than RDA recommendations.

Key Words: Vitamins E and A, Breast Milk, Mother's Diet

■ Docosahexaenoic Acid (DHA) and Arachidonic Acid Content of Breast Milk in Spanish Women: Influence of Mothers' Diets. C. Campoy[1], A. López-López[2], E. Blanca[1], R.M. Baena[1], A. Jerez[1], C. López-Sabater[2], M. Rivero[3], and R. Bayés[1], [1]Dept. of Paediatrics, School of Medicine, University of Granada, Spain, [2]Dept. of Nutrition and Bromatology, School of Pharmacy, University of Barcelona, Spain, [3]Scientific Dept. of Laboratories, Ordesa, Barcelona.

Long chain polyunsaturated fatty acids (LC-PUFA), especially arachidonic (AA) and docosahexaenoic (DHA) acids, are important for normal visual and brain development. PUFAs can be provided to the infant by human milk (HM). HM composition can be affected by different factors such as gestational age, parity, diseases, individuality, and mother's diet. This study analyzed the influence of mother's diet on the HM PUFA composition. METHODS: A total of 100 samples of HM from healthy lactating women—17 to 37 years of age—were collected: 34 colostrum (1–6 days lactation) (C), 32 transition milk (7–14 days lactation) (T) and 34 mature milk (15–41 days lactation) (M). Women recorded dietary intake during the 3 days before C, T, and M milk were obtained. The questionnaires were evaluated using Wander food composition tables. The HM from each breast was obtained at the beginning and end of each feed throughout the day to minimize the effects of diurnal rhythm on the composition of the HM. The sample were kept at -20°C protected from light and pooled and preserved at -80°C under nitrogen at the end of the day. DHA and AA acids were measured in mg/dL by HPLC. ANOVA, Student/Welch *t* test for paired and unpaired data, and correlation analyses were performed. RESULTS: Linolenic acid content in HM increased from C to M milk (days of lactation-

linolenic acid: $r=0.44$, $P<0.0001$). DHA, AA concentrations, and linoleic/linolenic ratio in HM decreased with duration of lactation ($r=-0.45$, $r=-0.47$, and $r=-0.54$, $P<0.0001$, respectively). A correlation between the mother's PUFA intake by the diet and linolenic content in C ($r=0.36$, $P<0.03$) was demonstrated. DISCUSSION: There is a relationship between the maternal dietary DHA and higher concentrations of DHA in the blood of the newborn infant. Our data demonstrate that mother's PUFA intakes in the first days after birth influence the PUFA content in their milk, as well as the supply of these important nutrients to the breast-fed infant. With the progress of lactation and the increase of MUFAs and SFAs in milk, this relationship disappears, and there is a decrease in the DHA, AA, and linoleic acid content of milk. However, the progressive increase of the linolenic acid concentration in mothers' milk with longer lactation suggests a natural mechanism for the infant to obtain the substrate for endogenous production of DHA to meet its needs. CONCLUSION: The levels of PUFAs in the mother's diet can influence her PUFA status, her milk PUFA, and, therefore, the quality of the fat given to the infant.

Key Words: PUFAs, Human milk, Mother's diet

■ Isomeric Fatty Acids in Mothers and Their Infants: A Further Exploration of Relationships to DHA and AA in a New Population with Benefit of Umbilical Vessel Wall Fatty Acids. C.M. Smuts[1]*, M.I. Huang[2], D.C. Mundy[3], and S.E. Carlson[2], [1]MRC, Tygerberg, South Africa, [2]Univ. of Kansas Med. Center, Kansas City, KS, [3]Univ. of Missouri-Kansas City, Kansas City, MO.

Background: We have reported an inverse correlation between cord venous plasma (CVP) triglyceride (TG) *trans* fatty acids and CVP phospholipid (PL) DHA ($n$=50), but stronger inverse correlations between 18:1 *cis* isomers in CVP TG vs. CVP PL DHA and AA in a population studied in Memphis, Tennessee (*Ped. Res. 39,* 304A, 1996). Methods: We studied mothers and babies in Kansas City, Missouri ($n$=50) for whom we prepared PL and TG fatty acid methyl esters (FAMES) with $BF_3$ after TLC separation of CVP, cord arterial plasma (CAP), maternal plasma (MP), and cord umbilical artery and vein walls at delivery. FAMES were analyzed by GLC with an SP-2560 (Supelco) 100-M column. Results: Maternal plasma TG 18:1 *trans* and *cis* isomers were nearly equivalent (3.81 vs. 3.86% of total fatty acids). In comparison, CVP TG had much lower 18:1 *trans* (0.92%) but 4.4% 18:1 *cis*. CAP and CVP TG had similar relative 18:1 *trans* and 18:1 *cis* isomers. Correlations of 16:1 *trans*, 18:1 *cis,* and 18:2 *cis,trans* isomers with DHA and AA in tissues and plasma are shown below. All PL measured (artery, vein, MP, CVP, and CAP) had significant inverse relationships between AA and DHA and one or more of the following: 16:1 *trans,* 18:1 *cis,* and 18:2 *cis,trans* isomers. However, the artery wall was the most robust indicator of these inverse relationships. Conclusion: The artery wall (which carries deoxygenated blood from fetus to placenta) showed the most consistent inverse relationship between isomeric fatty acids and both AA and DHA in PL.

■ Polyunsaturated Fatty Acid Regulation of Gene Expression. S. Clarke, M. Nakamura, and C. Nelson, The University of Texas at Austin.

Dietary polyunsaturated fatty acids (PUFA) function as fuel partitioners in that they direct glucose toward glycogen storage, and direct fatty acids away from triglyceride synthesis and into fatty acid oxidation. 20-Carbon PUFA are more effective than 18-carbon PUFA. PUFA enhance fatty acid oxidation by inducing the transcription of genes encoding proteins involved in fatty acid oxidation (e.g., acyl-CoA oxidase), and PUFA reduce triglyceride synthesis by down-regulating genes encoding proteins of lipid synthesis (e.g., fatty acid synthase). The induction of oxidative genes involves the fatty acid activation of the transcription factor, peroxisome proliferator activated receptor (PPAR). Once activated, PPAR binds to a hexameric repeat (-AGGTCAnAGGTCA-) located within the 5′-flanking region of genes involved in fatty acid oxidation, ketogenesis, and thermogenesis (e.g., UCP-3). PUFA inhibition of lipogenic genes results from the ability of PUFA to reduce the nuclear content of the powerful lipogenic transcription factor, sterol regulatory element binding protein-1 (SREBP-1). PUFA accomplish this by suppressing the proteolytic release of SREBP-1 from its precursor form anchored in the endoplasmic reticulum and by accelerating the rate of SREBP-1 mRNA decay, thereby reducing the amount of precursor SREBP-1. In addition to their effects on lipid oxidation and lipogenesis, PUFA, particularly 20-carbon n-3 PUFA, are strong suppressors of delta-6 and -5 desaturase gene transcription, as well as inducers of skeletal muscle UCP-3 gene expression. The outcome of these coordinated gene events includes decreased blood triglycerides and increased lipid utilization.

■ A Possible Role of Essential Fatty Acids in Pregnancy-Related Cognitive Impairment. R.H.M. de Groot, J.J. Adam, J. Jolles, A.C. van Houwelingen, and G. Hornstra, Maastricht University.

Background: Memory loss is a commonly observed phenomenon during pregnancy. Previous studies have shown that the overall essential fatty acid (EFA) status as well as the functional docosahexaenoic acid (DHA, 22:6n-3) status declines during pregnancy. Moreover, earlier studies also demonstrated that DHA plays an important role in brain functioning. Hence, it is tempting to hypothesize that the decline in DHA status during pregnancy might be functionally related to impaired cognitive functioning. Methods: In order to investigate a possible relationship between the decrease in EFA and/or DHA status during pregnancy and cognitive functioning, 58 pregnant women at week 14 of gestation were compared with different control groups. Two neurocognitive tests were used: the Stroop-Color-Word test as a measure of selective attention, and the spatial finger-precuing task as a measure of response preparation. Findings: Preliminary results at week 14 of gestation suggest a substantial neurocognitive impairment as indexed by performance on the spatial finger-precuing task and the Stroop test. Pregnant women demonstrated impaired reaction times comparable to those observed in elderly people. Nonpregnant controls the same age as the pregnant group were significantly faster (50 msec) on the finger-precuing task. The score on the Stroop test of the pregnant women was delayed, with an average of 3.6 sec compared with a control group of women matched for age and education, suggesting a lack in attention. Interpretation: These results could be taken as evidence to suggest that the decrease in EFA status, particularly DHA, during pregnancy might have a negative effect on neurocognitive functioning. However, randomized, double blind, placebo-controlled intervention studies are necessary to investigate whether a prevention of the pregnancy-associated DHA status decline also prevents neurocognitive impairment during pregnancy. Such studies are presently in progress in our laboratory. Results of an alpha-linolenic acid (18:3n-3) intervention study will be available later this year.

■ The Influence of Body Weight on the Metabolism of $^{13}$C-Linoleic Acid in Newborns. H. Demmelmair[1], P. Szitanyi[2], A. Mydlilova[2], and B. Koletzko[1], [1]Dr von Haunersches Kinderspital, Ludwig-Maximilians-University, Munich, Germany, [2]Thomayer Hospital, Charles University Prague, Czech Republic.

Birth weight is an indicator of endogenous lipid stores and is related to infant health and development. Several studies have shown that post-

natal growth is related to arachidonic acid availability. By comparing the disposal of stable isotope labeled linoleic acid during the first week of life in newborns with appropriate weight for gestational age (AGA) to small for their gestational age (SGA) neonates, we wanted to identify the relationship of birth weight to linoleic acid metabolism. Subjects and methods: Healthy, full-term, breast fed (AGA, $n$=10, birth weight: 3.4±0.2 kg (M±SD); SGA, $n$=9, 2.2±0.3 kg) neonates were enrolled in the study at day 2 of life. Each infant received 1 mg/kg body weight of uniformly $^{13}C$ labeled linoleic acid orally prior to feeding. Expired air (over 6 h) and blood (basal, 24 h, 48 h, and 72 h) samples were taken, and total $CO_2$ production was measured by indirect calorimetry. Fatty acids were quantified by gas chromatography and $^{13}C$ content of expired air and plasma phospholipid fatty acids were determined by isotope ratio mass spectrometry. Using a three-compartment model with assumed bolus injection of the tracer into the plasma phospholipid pool, fractional turnover of linoleic acid and its relative conversion to dihomo-γ-linolenic acid and arachidonic acid were estimated. Results: The concentration of phospholipid linoleic acid was significantly lower in AGA than in SGA infants (81.9±6.8 mg/L vs. 131.9±7.4 mg/L, M±SE), while no significant differences were found for dihomo-γ-linolenic (25.1±1.3 mg/L vs. 27.4±2.0 mg/L, SGA vs. AGA) and arachidonic (133.7±9.3 mg/L vs. 146.1±6.7 mg/L) acids. After 6 hours 7.4±0.6% of administered linoleic acid had been recovered in $CO_2$ in the AGA group and 5.1±1.1% in SGA ($P$<0.05). The fractional turnover of plasma phospholipid linoleic acid not directed towards dihomo-γ-linolenic acid or arachidonic acid was similar in both groups (3.1±0.3%/h vs. 3.3±0.3%/h, NS). Relative conversion of linoleic acid to dihomo-γ-linolenic acid (0.02±0.01%/h) and to arachidonic acid (0.01±0.01%/h) was significantly lower in AGA than in SGA, which showed 0.11±0.04%/h and 0.14±0.05%/h, respectively. Conclusions: Assuming an equal efficiency of tracer absorption in both groups, AGA infants oxidize a higher proportion of exogenous linoleic acid than SGA infants, which might be due to lower plasma concentrations or less exchange with body stores. Overall turnover of phospholipid linoleic acid is similar between groups, but there is a higher relative conversion of linoleic acid to dihomo-γ-linoleic acid and arachidonic acid in SGA infants. The reduced availability of long chain polyunsaturated fatty acids from body stores in SGA infants seems to be counterbalanced by increased endogenous production.

Key Words: Arachidonic Acid Synthesis, Birth Weight, Neonates

■ Investigation of Fatty Acid Metabolism Using Natural Abundance Variation of $^{13}C$. H. Demmelmair and B. Koletzko, Dr. von Haunersches Kinderspital, Ludwig-Maximilians-University, Munich, Germany.

Metabolic fluxes can be studied *in vivo* by the introduction of tracer molecules into the organism. Molecules enriched in a stable isotope, such as $^{13}C$, which naturally contributes only about 1.08% to total carbon in biomass, are very suitable for this purpose. While tracers with a $^{13}C$ content above 99% are available, highly precise gas isotope ratio mass spectrometry offers the possibility to exploit natural variations in $^{13}C$ content. There is a small enrichment difference between biomaterial originating from photosynthesis of $C_4$ plants (about 1.097% $^{13}C$) and carbon fixed by $C_3$ plants (about 1.081% $^{13}C$). In Europe the diet is largely based on $C_3$ plants (e.g., wheat, potato, sugar beet); therefore, lipids from $C_4$ plants (e.g., corn) can be used as tracer substances. In conventional infant formula and breast milk we have found a $^{13}C$ content of 1.077% for linoleic acid, while linoleic acid in corn oil showed 1.093% $^{13}C$. After switching the infant diet from breast milk or regular formula to a corn oil-containing formula, we observed a subsequent increase in the $^{13}C$ content in plasma linoleic acid (+0.012%) and its metabolites dihomo-γ-linolenic acid (+0.006%) and arachidonic acid (+0.002%) during the following 4 days when samples were taken. Since plant oils do not contain long chain polyunsaturated fatty acids, the increased $^{13}C$ contents in products demonstrate their endogenous synthesis from the dietary linoleic acid. The advantage of using naturally $^{13}C$ enriched corn oil is a relatively uncomplicated application as it is an established dietary component and low in cost. On the other hand, the signal to noise ratio is comparatively low with a precision of measurements around 0.0003% $^{13}C$, and dietary amounts rather than tracer amounts have to be fed. This excludes study diets deviating from the natural substrate composition. Furthermore, labeling of defined intramolecular positions is not possible with natural substrates.

While enrichment data obtained after the application of naturally or artificially enriched tracers can demonstrate the activity of a pathway by increased enrichment in the product, it is difficult to obtain quantitative data *in vivo* in humans. Direct measurement of tracer quantities is only possible in excretion products, such as breath $CO_2$, milk, or urine. From tracer concentrations in plasma, only approximate estimates of metabolic activities can be obtained. This usually requires the setup of models with inherent simplifications and assumptions, e.g., plasma concentrations are representative for corresponding pools in metabolically active tissue. Nevertheless, tracer studies elucidate metabolic fluxes, and estimators can be obtained for a comparison between different dietary or physiological states.

■ Transport of Long Chain Fatty Acids Across the Human Placenta: Role of Fatty Acid-Binding Proteins. A.K. Dutta-Roy, Rowett Research Institute, Aberdeen, Scotland, UK.

Essential fatty acids (EFA) and their long chain polyunsaturated fatty acid (LC-PUFA) derivatives play a crucial role in fetal development and pregnancy outcome. The critical importance of maternal dietary intake or synthesis of LC-PUFA and their subsequent preferential transport by the placenta to the fetus is now well recognized. We have identified several membrane-associated (FAT, FATP, and p-FABPpm) and cytoplasmic fatty acid-binding porteins (H-FABP and L-FABP) in human placental trophoblasts. Although the exact roles of the membrane-associated and cytoplasmic fatty acid-binding proteins in complex FFA uptake and subsequent metabolism in the human placenta are yet to be understood, studies suggested that these proteins alone or in tandem may be involved in effective uptake and transfer of LC-PUFA by the placenta. The placental plasma membrane fatty acid-binding protein (p-FABPpm), with a molecular mass of ~40 kDa, preferentially binds LC-PUFA over nonessential fatty acids. The exclusive location of p-FABPpm on the maternal side of the placenta may favor the unidirectional flow of maternal LC-PUFA to the fetus by virtue of preference for these fatty acids, whereas location of FAT and FATP on the both sides of the bipolar placental cells may allow bidirectional flow of all FFA across the placenta. There are significant differences in the properties and regulation of these two FABP types. H-FABP only binds long chain fatty acids, whereas the L-FABP binds heterogeneous ligands such as bile salts, haem, peroxisome proliferators, selenium, lysophosphatidic acid, and eicosanoids. It has been suggested that FABPs may also interact with several fatty acid-mediated cellular processes, such as control of cell growth, cell signaling, and regulation of gene expression (such as PPAR). Studies on the distribution of fatty acids in the cellular lipids of trophoblast cells have shown that DHA is incorporated mainly into the triacylglycerol fraction, followed by the phospholipid fraction, whereas for arachidonic acid (AA) the reverse is true. The greater cellular uptake of DHA and its preferential incorporation into the triacylglycerol fraction suggest that both uptake and transport modes of DHA by the placenta to the fetus are different from that of AA. Certain LC-PUFA upregulate PPARg in human placenta. Since PPARg regulates terminal epithelial differentiation of the trophoblast and fetal cardiac membrane development, and is the only source for embryonic tissues, this indicates importance of placental LC-PUFA transport in feto-placental growth and development.

■ NMR Investigations of Docosahexaenoic Acid Structure and Flexibility. K. Gawrisch, L.L. Holte, B.W. Koenig, I.V. Polozov, A.M.K. Safley, and W.E. Teague, NIAAA, NIH, Rockville, MD.

We investigate conformation and flexibility of docosahexaenoic acid (DHA) chains in lipid membranes by magic angle spinning NMR approaches. Order parameters of all 22 carbon segments are measured. The excellent chemical shift resolution of DHA resonances enables us to partially assign order parameters to specific chain segments. We also measure cross-relaxation rates between the well-resolved DHA proton resonances using the NOESY experiment. In comparison to saturated chains,

DHA order parameters are very low, reflecting both a change in bond geometry and an increase in angular fluctuation amplitudes for some bond angles. DHA is often perceived as rigid due to the presence of six double bonds that eliminate a significant fraction of the internal degrees of freedom for structural transitions. Our NMR results support a very different model. Docosahexaenoic acid is surprisingly flexible with rapid structural transitions between a large number of conformations. The high flexibility of DHA is the consequence of lower potential barriers for rotations around the C-C bonds between methylene- and vinyl groups compared to C-C bonds in saturated chains. This enables these chains to adapt to looped conformations that have shorter length and larger area per molecule. Some neural receptors appear to have a specific requirement for high concentrations of lipids with DHA chains in the membrane. NMR experiments on reconstituted membranes containing the photoreceptor rhodopsin suggest that lipids with polyunsaturated DHA chains preferentially locate near the receptor. Lipid–protein interaction results in minor changes of chain order parameters only. Within the limits of experimental sensitivity, we found no evidence for existence of DHA that is tightly bound to protein. Perhaps low energetic barriers to membrane receptor conformational transitions are essential, making adaptability in structure of lipids with DHA chains a crucial biophysical property.

■ DHA-Deficient Rats Exhibit Learning Deficits in Olfactory-Based Behavioral Tasks. R.S. Greiner[1], J.N. Catalan[1], T. Moriguchi[1], B.M. Slotnick[2], and N. Salem[1], [1]Lab. of Membrane Biochemistry and Biophysics, NIAAA, Rockville, MD, USA, [2]The American University, Washington, DC.

Rats are macrosmatic; this high olfactory acuity is necessary for rats to learn and adapt to their environments and ultimately for their survival. Rats actually demonstrate higher cognitive functions, previously only attributed to primates, when odors are used as the salient cues in behavioral tasks. Development of a learning set or errorless learning is an example of a higher cognitive function that has been demonstrated in rats using the olfactory modality.

We assessed the effects of a chronic n-3 fatty acid (DHA) deficiency on cognitive function in rats using a novel technique based on olfaction. DHA-deficient and DHA-adequate diets were designed and fed to rats over two generations. The dietary treatments were successful in depleting brain DHA as DHA-deficient rats had an average 83% loss of DHA in the total lipid extracts from whole brain or olfactory bulb compared to DHA-adequate rats. In the first behavioral task, rats fed an LNA-deficient diet made significantly more errors compared to LNA-fed rats in a series of seven, two-odor discrimination problems. Furthermore, when tested on a series of 20 two-odor discrimination problems, the number of errors in a DHA-fed group decreased over time. On problems 16–20 this group reached near errorless performance, demonstrating the acquisition of a learning set. DHA-deficient rats did not achieve this near-errorless learning and thus never demonstrated the acquisition of a learning set. These results indicate that DHA is critical for higher level performance associated with acquisition of a learning set when the olfactory modality is employed in the behavioral task.

Key Words: Docosahexaenoic Acid, Fatty Acid, Behavior

■ DHA and AA Supplementation of Infant Formulas Improves Motor Skills and Visual Orientation, Decrease CSF 5-HIAA in Infancy and Improve Heart Rate Variability in Adolescence. Joseph R. Hibbeln[1], Paolo DePetrillo[1], Maribeth Champoux[2], J. Dee Higley[1], Stephen Lindell[1], Courtney Shannon[2], Stephen Suomi[2], and Norman Salem, Jr.[1], [1]National Institute of Alcohol Abuse and Alcoholism, [2]National Institute of Child Health and Human Development.

Cognitive and visual changes result from suboptimal intake of docosahexaenoic acid (DHA) arachidonic acid (AA) during human infancy, but long term neuro-psychiatric consequences have not previously been described. The omega-3 essential fatty acid DHA and AA, are essential nutrients for optimal brain development and are found in both human and rhesus *(Macaca mulatta)* breast milk. Standard infant formulas are virtually devoid of these nutrients. In a well-established animal model, rhesus monkeys fed standard infant formulas, after separation from their mothers at birth, are at increased lifetime risk of lifetime aggressive and depressive behaviors and decreased CSF 5-HIAA concentrations. In this experiment, infant rhesus monkeys were raised under rigorously controlled nursery conditions and fed either standard formula or formula supplemented with physiological concentrations of AA (0.8%) and DHA (0.8%) for the first six months of life. Within 14 days, plasma concentrations of AA and DHA were markedly decreased among the standard formula group. Motor and visual orientation scores were significantly improved among the supplemented infants at days 7 and 14 with a ceiling effect noted by day 21. After 6 months of age, both groups were switched exclusively to diets containing DHA and AA. CSF 5-HIAA concentrations were lower among the DHA/AA supplemented group during formula feeding. At one year of age, heart rate variability (HRV) was markedly greater among the supplemented group. These differences persisted into adolescence, at three years of age. The magnitude of the stable increases in HRV were as great as the transient increases induced with ketamine administration. Low heart rate variability is an indicator of low autonomic arousal and is well established as a longitudinal predictor of disruptive and antisocial behaviors. These data indicate that DHA/AA supplementation results in physiological improvements in heartrate variability that persist into adolescence.

Key Words: Docosahexaenoic, Heart Rate Variability, CSF 5-HIAA

■ Is There a Substrate Preference in Mitochondrial Phosphatidylserine Decarboxylation? J. Hamilton and H.-Y. Kim*, National Institute on Alcohol and Abuse and Alcoholism.

We have previously shown that phosphatidylserine (PS) contents are particularly high in neuronal cells, owing to accumulation of 18:0,22:6-PS, and can be specifically decreased by both n-3 fatty acid deficiency and ethanol. In animal cells PS is synthesized from pre-existing phosphatidylcholine (PC) and phosphatidylethanolamine (PE) by a base-exchange reaction and can then be decarboxylated to PE by phosphatidylserine decarboxylase (PSD). Before PS can be decarboxylated to PE, it must be transported from its site of synthesis in the endoplasmic reticulum to the mitochondria. Specificity in any of these processes will influence the PE and PS status in cell membranes and may attribute to tissue-specific lipid profiles. Although we reported that 22:6n-3 containing phospholipids are preferred in PS biosynthesis, there have been no studies to address the substrate specificity of PSD. In the present study, experiments were designed to determine if PSD has a substrate preference for specific molecular species of PS in liver and brain mitochondria. Unilamellar vesicles containing deuterium-labeled 18:0,18:1-PS, 18:0,22:6-PS and 18:0,20:4-PS were incubated with rat brain cortex or liver mitochondrial fractions, and decarboxylation to the corresponding deuterium-labeled PE was monitored by reversed phase HPLC/electrospray mass spectrometry. Liver mitochondria showed the substrate preference in the order of 18:0,18:1-PS > 18:0,22:6-PS > 18:0,20:4-PS, while in brain cortex mitochondria, the substrate preference was 18:0,22:6-PS > 18:0,18:1-PS > 18:0,20:4-PS. In both tissues PS decarboxylation occurred in a concentration and time-dependent manner. This preference was maintained at all concentrations and time points examined, establishing for the first time that there exists a tissue-specific substrate preference in PSD.

Mitochondrial levels of 18:0,22:6, 18:0,18:1 and 18:0,20:4 PS and PE remained the same after 45 minutes of incubation with the deuterium-labeled PS, indicating that endogenous mitochondrial PS did not significantly interfere with the decarboxylation of exogenously added PS substrates. The levels of 18:0,22:6-PE, 18:0,18:1-PE, and 18:0,20:4-PE in brain cortex or liver mitochondria did not reflect the observed PS molecular species preference, suggesting that the PE status in mitochondrial membranes may be maintained primarily through other pathways such as *de novo* synthesis using a CDP-ethanolamine or ethanolamine base-exchange reaction. Alternatively, it is also possible that not all molecular species of PS are equally transported into the mitochondria, as PS synthesized in microsomes must first be transported to the mitochondria before decarboxylation.

Key Words: Phosphatidylserine Decarboxylase, Docosahexaenoic Acid, Phosphatidylserine

■ Antiapototic Effect of Docosahexaenoic Acid in Neuronal Cells. H.Y. Kim[1], M. Akbar, A. Lau, and L. Edsall, National Institutes of Health, Rockville, MD 20852.

Docosahexaenoic acid (22:6n-3) is the major long chain polyunsaturated fatty acid in neuronal cells. Growing evidence supports the essential role of 22:6n-3 in neuronal function although the underlying biochemical mechanisms are not clearly understood. In this study we investigated the effect of 22:6n-3 on neuronal apoptosis in relation to its capacity to modulate phosphatidylserine (PS) accumulation. When Neuro 2A cells were enriched with 25 μM 22:6n-3, DNA fragmentation induced by serum starvation was significantly inhibited in comparison to nonenriched control, oleic acid (18:1n-9)- or arachidonic acid (20:4n-6)-enriched cells. Consistently, 22:6n-3 enrichment prevented the increase of Caspase-3 activity as well as the cleavage of Pro-Caspase-3 to the active 17-KD fragment upon serum starvation. The protective effect of 22:6n-3 was apparent only after at least 24 h of enrichment, and prolonged treatment for up to 48 h exhibited further protection. During 48 h of incubation, incorporation of 22:6n-3 into PS increased steadily, resulting in a significant increase of the total PS content in Neuro 2A cells. During the same enrichment period, nonenriched control or 18:1n-9-treated cells did not show any significant increases in the PS contents. Membrane translocation of Raf-1 in Neuro 2A cells was significantly enhanced in 22:6n-3-treated cells. *In vitro* biomolecular interaction analysis using PS/PE/PC liposomes and Raf-1 indicated the requirements of PS for their interaction, and this interaction was PS concentration-dependent. When Neuro 2A cells were enriched in a serine-free medium, PS accumulation as well as the protective effect was significantly diminished. Collectively, enrichment of neuronal cells with 22:6n-3 increased the PS accumulation and the membrane localization of Raf-1, down-regulated Caspase-3 activity, and prevented apoptotic cell death under serum-free conditions. The protective potential of 22:6n-3 was sensitive to the extent of PS accumulation, suggesting the observed antiapoptotic effect of 22:6n-3 may be mediated at least in part through the enhanced PS accumulation in neuronal membranes.

Key Words: Docosahexaenoic Acid, Apoptosis, Phosphatidylserine

■ Higher Maternal Docosahexaenoic Acid During Pregnancy Is Associated with More Mature Infant Central Nervous System. C.J. Lammi-Keefe, S.R. Cheruku, H.E. Montgomery-Downs, S.L. Farkas, and E.B. Thoman, University of Connecticut, Storrs, CT, USA.

Functional outcome for the infant with respect to docosahexaenoic acid's (DHA) effect on the developing central nervous system (CNS) during pregnancy remains unexplored. Sleep–wake states of newborns are uniquely appropriate for assessing the functional integrity of the CNS. We hypothesized that the integrity of the infant's CNS measured by sleep recordings during the neonatal period would be associated with maternal long chain polyunsaturated (LC-PUFA), especially DHA, status. Pregnant women ($n$=17) were recruited at parturition; venous blood was collected. Plasma phospholipid (PL) fatty acids were analyzed by gas chromatography. In the hospital, infants' sleep–wake states were measured with the non-intrusive Motility Monitoring System: From a pressure sensitive pad placed under the infants' bedding, infants' body movements and respiratory patterns were logged and scored for sleep–wake states on the first (P1) and second (P2) postnatal days. Maternal plasma PL DHA ranged from 1.91 to 4.5%. Based on previously published data and the median DHA wt% for this population (3.0 wt%), the women were divided into high DHA (Hi) and low DHA (Lo) groups. On P1 infants of Hi had a lower Active/Quiet Sleep Ratio (AS/QS), less Active Sleep (AS), more Quiet Sleep (QS). On P2 they had lower AS/QS, less AS, less Transitional Sleep (T), and more Wakefulness. Maternal n-3/n-6 LC-PUFA (wt%) on P1 was associated negatively with QS and positively with Arousals in Quiet Sleep (Ar/QS). On P2 the n-3/n-6 LC-PUFA was associated positively with AS, T, and AS/QS. Ar/QS is defined as QS fragmentation, and its positive association with higher n-6/n-3 LC-PUFA is significant because Ar/QS is associated with CNS compromise. Thus, the QS fragmentation seen with the higher n-6 to n-3 ratios may be a risk factor for developmental dysfunction. These findings suggest that differences in prenatal supply of LC-PUFA, especially DHA, modify brain PLs and affect neural function. Key Words: Docosahexaenoic Acid, Infant Sleep, Central Nervous System

■ Omega-3 Polyunsaturated Fatty Acids (PUFA) Do Not Affect Growth, Energy Expenditure, Body Composition, or Expression of Genes Controlling Fatty Acid Oxidation and Thermogenesis in Piglets. A. Lapillonne[1], C.M. Nelson[2], J.C. DeMar[1], W.C. Heird[1], and S.D. Clarke[2], [1]USDA/ARS Children's Nutrition Research Center, Baylor College of Medicine, Houston, TX, [2]Division of Nutr. Sciences and Institute for Cell and Mol. Biol., University of Texas, Austin, TX.

Background: Studies in human adults and infants as well as in rodents suggest that n-3 PUFA affect the rate and composition of weight gain as well as rates of fatty acid oxidation and energy expenditure. In addition, carnitine palmitoyl-transferase-1 (CPT-1) and acyl-coA oxidase (AOX) activities as well as transcription of genes encoding for CPT-1, AOX, and thermogenic uncoupling proteins (UCP)-2 and -3 are increased by n-3 PUFA. Based on these findings, we hypothesized that the molecular changes induced by n-3 PUFA increase peroxisomal oxidation and uncoupled mitochondrial oxidation and thus reduce the efficiency of fuel utilization and, thereby, increase energy expenditure. This, in turn, results in a lower energy balance and, hence, lower rates of fat deposition and weight gain. To address this issue, 6-day-old pigs were fed diets differing only in quantity of n-3 PUFA for 2 weeks, and the rates of weight gain and energy expenditure as well as body composition and the skeletal muscle and/or liver contents of mRNAs of CPT-1, AOX, and UCP-3 were determined. Methods: Two groups of 6 piglets were fed isocaloric diets differing only in PUFA composition from day 6 to day 20 of life. Group 1 received a corn oil-enriched diet (18.6% of total fatty acid as 18:2n-6 and 1.0% as 18:3n-3), and group 2 received a flaxseed oil-enriched diet (12.7% of total fatty acid as 18:2n-6 and 9.0% as 18:3n-3). Food intake and body weight were monitored daily. Energy expenditure (24-h indirect calorimetry) was assessed on day 5 and day 18 of life. Body composition (dual energy X-ray absorptiometry), plasma FA composition (gas chromatography), and gastrocnemius muscle as well as liver content of the relevant mRNAs (Northern blot or semiquantitative RT-PCR) were determined on day 20 of life. Results: Plasma 18:3n-3, 20:5n-3, 22:5n-3 and 22:5n-3 were higher in pigs fed the diet enriched with flaxseed oil. Neither weight gain (161 g/kg/d vs. 164 g/kg/d in the corn oil and flaxseed oil groups, respectively), energy expenditure (95 kCal/kg/d vs. 93 kCal/kg/d), nor body composition (fat mass = 5.9% vs. 5.7% of body weight) differed between the 2 groups. The mRNAs of CPT-1 and UCP-3 compared to AOX were low in the muscle of both groups. There were no statistically significant differences between groups in either muscle or liver mRNA levels of AOX, CPT-1, or UCP-3. Conclusions: Feeding piglets a diet with 9.0% vs. 1% of total fatty acids as 18:3n-3 from day 6 to day 20 of life did not affect expression of key enzymes of lipid metabolism, weight gain, energy expenditure, or body composition. The greater expression of AOX vs. CPT-1 in skeletal muscle of both groups suggests that peroxisomal oxidation is much greater than mitochondrial fatty acid oxidation in piglets. These data, in contrast to the data in humans and rodents, raise questions concerning the validity of the piglet as a model for fatty acid oxidation.

Key Words: Gene Regulation, n-3 PUFA, Piglets

■ The Effect of Maternal Fish Oil Supplementation During Lactation. L. Lauritzen[1], M.H. Jørgensen[2], S.F. Olsen[3], and K.F. Michaelsen[1], [1]Research Department of Human Nutrition, The Royal Veterinary and Agricultural University, [2]Department of Neonatology, Copenhagen University Hospital, [3]Danish Epidemiology Science Centre, Statens Serum Institut.

Docosahexaenoic acid (DHA) levels in milk vary considerably, but the effect on the infant is unknown. We have previously, in a small cross-sectional study, observed a significant association between milk DHA and visual acuity in breast-fed infants. We have performed a double-blinded intervention study in which we randomized mothers with a habitual low fish intake to receive 1 g DHA from microincapsulated fish oil or olive oil placebo starting the first week after delivery until 4 months. A control group of mothers with a high habitual fish intake was included. Methods: DHA content of milk samples and infant RBC membranes at 4 months, SWEEP-VEP visual acuity at 2 and 4 months, growth, and parental registration of sleep patterns were measured. Ninety-seven infants completed the intervention (44 olive oil, 53 DHA), and 47 completed examinations in the control group. The mean (SD) ha-

bitual DHA intake during pregnancy was 0.7 (0.4) g/d in the high fish group and 0.2 (0.1) g/d in the low fish group. The last 4 month examination was completed early June 2000. Results. Preliminary data analysis on a subsample ($n$=71) showed that the mean (SD) RBC DHA at 4 months was 9.1% (1.8) of fatty acids in the DHA group and 5.9% (1.9) in the placebo group ($P$=0.001), whereas it was 6.5% (1.9) in the "habitual high fish" group. Visual acuity at 4 months was significantly positively associated with infant RBC DHA ($P$=0.026). Awaiting further analysis, these data suggest an effect on the breast-fed infant of maternal DHA intake. The study was supported financially by The Danish Research and Development Programme for Food Technology (FÿTEK) and BASF Health and Nutrition A/S.

■ Analysis of *in situ* Chemical Constituents of the Retina by Fourier Transform Infrared Microspectroscopy. S.M. LeVine[1], J.D. Radel[1], and D.L. Wetzel[2], [1]University of Kansas Medical Center, Kansas City, Kansas, [2]Kansas State University, Manhattan, Kansas.

Fourier transform infrared (FT-IR) microspectroscopy enables the characterization and semiquantitation of chemical functional groups in microscopic regions of tissue sections. Sections of normal or diseased tissues can be analyzed. In diseased tissues, FT-IR microspectroscopy can reveal chemical changes that are associated with discrete regions of lesion sites, which can provide insights into the chemical mechanisms of disease processes. In the first set of studies, FT-IR microspectroscopy was used to analyze sections of retina from normal (pigmented) and albino rats. The outer segments of pigmented animals were found to have unusually strong absorption values for C=C unsaturation and carbonyl functional groups. Docosahexaenoic acid (DHA), a major constituent of lipids in the outer segments, also had particularly high absorption values for these functional groups, which suggests that it is responsible for those enhanced absorption values. Absorbance values for the unsaturation and carbonyl functional groups were substantially reduced in the outer segments of retinas from albino animals. This finding, together with data from other studies on light-induced oxidative events in the retina, indicates a loss of DHA by a light-induced mechanism in albino animals. In a second set of studies, chemical changes were characterized in the photoreceptor outer segments following exposure to iron-catalyzed oxidative stress. A reduction of unsaturation and carbonyl functional groups was observed in the outer segments of iron-injected eyes compared to vehicle-injected eyes at 3 days following injection, which is prior to major histological changes that occur by 7 days. DHA contains a series of six *cis*-conjugated double bonds, which are vulnerable to free radical attack, and the reduction of these unsaturation group absorptions suggests that DHA was degraded and/or removed from the outer segments of iron-injected eyes. In summary, FT-IR microspectroscopy has been used to detect high concentrations of unsaturation and carbonyl chemical groups in the outer segments of the retina and the concentration of these functional groups' decrease in various disease states that involve oxidative stress.

Key Words: Infrared Microspectroscopy, Retina, Docosahexaenoic Acid

■ Pentadecanoic and Heptadecanoic Acid in Red Blood Cell Phospholipids as Biomarkers of Dietary Milk Fat Intake in School Children. F. Lehner[1], H. Demmelmair[1], J. Linseisen[2], S. Verwied-Jorky[1], G. Wolfram[2], and B. Koletzko[1], [1]Dr. von Haunersches Kinderspital, Ludwig-Maximilians University, Germany, [2]Institut für Ernaehrungswissenschaft, Technische University Muenchen, Germany.

Background: The fatty acid pattern of erythrocyte membranes is widely used as a biomarker of dietary fatty acid intake. Since rumen microorganisms synthesize odd-numbered fatty acids, ruminant milk fat is one of the main dietary sources of pentadecanoic acid (C15:0) and heptadecanoic (C17:0) acid. Aim: To evaluate red blood cell (RBC) C15:0 and C17:0 contents as biomarkers for milk fat intake in children. Subjects and methods: Fasting blood samples were obtained from participants of the "Family Intervention Trial (FIT)" (Erlangen, Germany). Eighty-two 6–7-year-old school children (girls $n$=43; boys $n$=39) and their mothers ($n$=68) completed a 3-d weighed-food record. Food and nutrient intake calculations were performed by means of PRODI 4.4 using the German food composition database Bundeslebensmittelschlüssel II.1. The fatty acid pattern of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) from erythrocyte membranes were analyzed by gas–liquid chromatography. Pairwise associations between RBC fatty acids and dietary intake of milk fat were examined by Spearman's rank correlation analysis (SPSS for windows, Vers. 9.0.1). Results: In girls the dietary intake of fat delivered from milk and milk products (without cheese) was positively related to the proportions of PC 15:0 ($r$=0.58; $P$<0.001), PC 17:0 ($r$=0.33; $P$=0.030) and PE 15:0 ($r$=0.49; $P$=0.001). In boys, the dietary intake of butter showed strong positive correlations with PC 15:0 ($r$=0.63; $P$<0.001), PC 17:0 ($r$=0.43; $P$=0.007), PE 15:0 ($r$=0.53; $P$<0.001), and PE 17:0 ($r$=0.34; $P$=0.037). Moreover, a positive association between milk fat intake and the proportion of PC 17:0 ($r$=0.32; $P$=0.047) was found. In mothers, the dietary intake of milk/milk products and fat delivered from milk/milk products was positively related to PC 15:0 ($r$=0.25; $P$=0.037 and $r$=0.31; $P$=0.011, respectively); significant associations between the intake of butter and butterfat and PC 17:0 were found ($r$=0.29; $P$=0.016), too. In boys and girls, the proportions of PC 15:0 revealed a significant correlation to the dietary intake of C4:0, C6:0, C10:0, and C14:0. PC 15:0 of maternal erythrocytes was positively related to dietary C4:0 and C6:0. In all children, PC 15:0 correlated with consumption of butter ($r$=0.45; $P$=0.001), fat from milk/milk products ($r$=0.42; $P$<0.001), butter fat ($r$=0.45; $P$<0.001), and fat delivered from all milk products ($r$=0.26; $P$=0.020). Less close but significant correlations were also found for PC C17:0 and PE C15:0, while PE C17:0 was only related to fat delivered from milk/milk products. Conclusion: These data demonstrate that C15:0 and C17:0 in red blood cell phospholipids can be used as biomarkers of milk fat intake with C15:0 revealing the strongest correlations. The relationship was found to be closer in children than in adults, probably due to the higher percentage of beef fat in the mothers' diet.

Key Words: Pentadecanoic Acid, Biomarker, Milk

■ Dose Response Effect of Docosahexaenoate Ethyl Ester and Egg-Phosphatidylcholine on Maze-learning Ability and Fatty Acid Composition of Plasma and Brain Lipids in Mice. S.-Y. Lim[1] and H. Suzuki[2], [1]National Institute on Alcohol Abuse and Alcoholism, NIH, [2]National Food Research Institute, Japan.

Our previous work showed that the intakes of docosahexaenoate (DHA, 22:6n-3), ethyl ester (EE), and egg phosphatidylcholine (PC) improved learning ability in both young and old mice but old mice had a poorer performance than young mice. In the present study, we investigated the dose-response effect of dietary DHA and PC on maze-learning ability and fatty acid composition of plasma and brain lipids in mice. Male Crj:CD-1 mice aged 3 mo were fed (i) a diet containing 5 g palm oil/100 g diet (control group); (ii) a diet containing 0.5 g DHA ethyl ester/100 g diet plus 4.5 g palm oil/100 g diet (DHA-EE 0.5% group); (iii) a diet containing 1 g DHA ethyl ester/100 g diet plus 4 g palm oil/100 g diet (DHA-EE 1% group); (iv) a diet containing 2 g DHA ethyl ester/100 g diet plus 3 g palm oil/100 g diet (DHA-EE 2% group); (v) a diet containing 1 g egg-PC/100 g diet plus 4 g palm oil/100 g diet (egg-PC 1% group); (vi) a diet containing 2.5 g egg-PC/100 g diet plus 2.5 g palm oil/100 g diet (egg-PC 2.5% group); (vii) a diet containing 5 g egg-PC/100g diet (egg-PC 5% group) for 4 mo. Maze-learning ability was assessed 3 mo after the start of the experiment. The time required to reach the maze exit and the number of times that a mouse strayed into blind alleys in the maze were measured in three trials carried out at 4-day intervals. In trial one, the DHA-EE 0.5%, 1%, and 2% groups required less ($P$<0.05) time to reach the maze exit, and the DHA-EE 2% and egg-PC 2.5% groups strayed ($P$<0.05) into blind alleys fewer times than the control group. In trial three, performed 4 days after the second trial, the DHA-EE 2% and egg-PC 5% groups needed less ($P$<0.05) time to find the exit and made fewer ($P$<0.05) entries into blind alleys than did the control group. In the total lipids of plasma and brain of mice fed DHA-EE, increasing dietary DHA resulted in an increase in DHA levels with a corresponding decrease in arachidonic acid (AA, 20:4n-6). Improved maze-learning ability in mice fed 2% DHA-EE was associated with higher DHA levels in brain. However, brain DHA was unrelated in the groups with various doses of egg-PC. Our results suggest that the intakes of 2% DHA-EE and 5% egg-PC diets improved learning ability. However, the mechanisms by which the DHA and PC diets improved learning appear to differ.

Key Words: Docosahexaenoic acid (DHA), Egg-phosphatidylcholine (PC), Maze-learning Ability

■ Spatial Task Performance Depends upon the Level of the Brain Docosahexaenoic Acid. T. Moriguchi, J. Loewke, and N. Salem, Jr., National Institute on Alcohol Abuse and Alcoholism, NIH.

Docosahexaenoic acid (DHA) is rapidly deposited during brain development in the perinatal and early postnatal period and appears to play a critical role in the nervous system. Previously, we found that a dietary n-3 fatty acid deficiency resulted in impaired acquisition of a spatial task in adult rats after two generations of n-3 fatty acid deficiency. The present experiments were designed to determine whether the alterations in brain function were reversible at various stages of development from birth through adulthood. Long-Evans hooded rats were fed an n-3-adequate (n-3 Adq) or n-3-deficient (n-3 Def) diet for three generations. When the n-3 Def male rats of the F3 generation were 0 (birth), 3 (weaning), and 7 (adulthood) wks old, the diet was switched to the n-3 Adq diet, a diet that included both 2.6% alpha-linolenic acid and 1.3% DHA. Behavioral experiments (the Morris Water Maze) were conducted when the animals were either 9 or 13 weeks of age. The n-3 Def group exhibited significantly lower brain DHA, longer escape latency, and a delay in the acquisition of this task as compared with the n-3 Adq group. The diet reversal groups that consumed an n-3 Adq diet for less than 6 weeks prior to testing had only partially recovered their brain DHA and spatial task performance. This indicated a good correlation of learning ability with brain DHA concentration. The groups that had diet repletion for more than 9 weeks contained the same level of brain DHA as in the n-3 Adq group irrespective of the age at which diet reversal had occurred. However, a slight difference in performance on the spatial tasks was evident between the various groups that appeared to be related to the age at the time of diet reversal. These results indicated that the recovery effects of the n-3 Adq diet reversal depended not only on the period over which an n-3 Adq diet was consumed but also, secondarily, on the age at which the diet reversal occurred. This reversibility suggests that the learning deficit in the n-3 Def group is directly related to the neuronal membrane fatty acid compositional change. This study has clear relevance to public health, as it demonstrates the importance of adequate n-3 fatty acids in the infant diet in order to achieve optimal brain development. It also demonstrates that DHA feeding subsequent to a deficiency state can potentially restore nervous system function during early development and potentially up to the time of young adulthood.

Key Words: Docosahexaenoic Acid (DHA), Spatial Task Performance, Recovery

■ Effect of DHA and Cholesterol on Receptor-G Protein Coupling. S. Niu, D.C. Mitchell, and B.J. Litman, NIH, Rockville, MD.

The neuronal and retinal tissues are highly enriched with PUFAs, in particular with 22:6n3 (DHA). DHA deficiency in these tissues is associated with impairment of neuronal function and vision. The goal of this study is to characterize the role of DHA and cholesterol on modulating signal transduction in G protein-coupled receptor systems at molecular levels. The visual transduction system, one of the best-characterized members in the superfamily of G protein-coupled signal transduction systems, which consists of receptor rhodopsin (Rh), G protein, and effector PDE, serves as a model in this study. Rh was reconstituted into lipid bilayers consisting of di-22:6PC (DDPC), 18:0,22:6PC (SDPC), and 18:0,18:1PC (SOPC) to vary the levels of DHA and unsaturation in the acyl chains of the phospholipid. Cholesterol levels varied from 0 to 30% (mol) at each lipid composition. The coupling of Rh and G protein was characterized by measuring the equilibrium binding of metarhodopsin II (MII), the active agonist-bound state that binds and activates G protein, to the G protein. In the absence of G protein, a metastable equilibrium between MI and MII is established within a few milliseconds of photon absorption. The equilibrium is shifted toward MII in the presence of G protein due to MII-G complex formation, and the extent of the shift in equilibrium is dependent on G protein concentration. By varying the G protein concentration, the association constant of MII-G can be determined spectroscopically. The association of MII-G, which in fact is a protein–protein interaction, was affected by the lipid composition in such a way that more efficient coupling was observed in DHA containing phospholipids. Weaker association of MII-G was found in all lipid bilayer compositions in the presence of 30% (mol) cholesterol. The nature of the influence on MII-G coupling by lipid bilayer composition and cholesterol needs further investigation, yet it is plausible that lipid bilayer composition and cholesterol can change the conformation of MII and G, which in turn affects the MII-G coupling. The receptor-G protein coupling is an essential step in the signaling cascade. Our findings demonstrate that lipid and cholesterol composition can mediate the extent of receptor-G protein coupling in the visual transduction system. These findings, if extended to other members of the superfamily of G protein-coupled receptors, suggest that a loss in efficiency of signaling is the mechanism whereby cognitive and visual losses occur in DHA deficiency.

Key Words: PUFA, Receptor, Signal Transduction

■ The Nutritional Impact of Including Egg Yolks in the Weaning Diet of Healthy Infants. M. Makrides[1], J.S. Hawkes[2], M.A. Neumann[2], and R.A. Gibson[2], [1]University Dept. Obstetrics and Gynaecology, Women's and Children's Hospital, [2]Child Nurition Research Centre, Flinders Medical Centre, Flinders University.

The primary objective of our trial was to determine the nutritional value of including egg yolks in the weaning diet of healthy breast- and formula-fed infants and to investigate some of the perceived benefits and risks associated with consuming eggs.

At 6 months, healthy breast-fed and formula-fed infants were randomly allocated to receive either no dietary intervention, four regular egg yolks per week or four omega-3 enriched (high in docosahexaenoic acid, DHA) egg yolks per week. Separate randomization schedules were used to allocated breast- and formula-fed infants. Dietary intake, compliance, and growth were assessed at 6, 9, and 12 months of age. Plasma DHA, iron status, plasma cholesterol, and plasma markers of allergy were assessed when infants were 6 and 12 months of age.

Of 82 breast-fed infants recruited, 24/27 (omega-3 eggs), 23/27 (regular eggs), and 23/28 (no intervention) infants completed the trial. Similarly, of 79 formula-fed infants enrolled, 20/26 (omega-3 eggs), 24/26 (regular eggs), and 23/27 (no intervention) infants completed the trial. The egg intervention was well tolerated. Only one breast-fed infant and one formula-fed infant were withdrawn from the trial because the infant appeared to be unsettled on eggs. Mothers with infants allocated to eggs reported a mean (±SD) egg yolk consumption of 4±1 yolks, while mothers with infants in the no-intervention groups reported using 1±1 yolks. Compliance with the dietary intervention was further highlighted by a 40% increase in plasma DHA levels in both breast- and formula-fed infants allocated to omega-3 egg yolks compared with the respective no-intervention (control) groups. In this well-nourished group of infants, consumption of egg yolks had no effect on the clinical markers of iron status nor any effect on growth.

Within the breast-fed and formula-fed cohorts, there were no differences in plasma cholesterol between the three dietary groups at 6 or 12 months. At 6 months and before dietary intervention, breastfed infants had a higher plasma cholesterol level than the formula-fed infants (4.3±0.8 vs. 3.8±0.7 mmol/L, $P<0.005$). This difference disappeared by 12 months of age. At 12 months, when data from all infants were combined and adjusted for mode of feeding and 6-month values, there was no significant effect of egg yolk intervention on cholesterol levels. We could not detect an effect on indices of allergy as a result of increasing the number of egg yolks included in infant diets. Total plasma IgE levels, the percentage of infants with egg yolk-specific antibodies or egg white-specific antibodies were similar between infants allocated to the egg and control groups.

Egg yolks can safely be included into the weaning diets of healthy breast-fed and formula-fed infants. As egg yolks contain a range of vitamins, minerals, proteins, and fats, they can be included as part of a well-balanced diet for infants and toddlers.

Key Words: Docosahexaenoic Acid (DHA), Infant Weaning Diet, Eggs

■ Dietary Polyunsaturated Fatty Acids (PUFA) and Pregnancy Outcome. M. Makrides[1], L. Duley[2], and S.F. Olsen[3], [1]Child Nutrition Research Centre, Child Health Research Institute, North Adelaide, Australia, [2]Resource Centre for Randomised Trials, Institute of Health Sciences, Oxford, UK, [3]Maternal Nutrition Group, Danish Epidemiology Science Centre, Statens Serum Institut, Denmark.

Pre-eclampsia is a common complication of pregnancy and can result in preterm birth and intrauterine growth restriction (IUGR). Pre-

eclampsia, preterm birth, and IUGR are all associated with increased morbidity for both mother and child.

The use of fish oil supplements, and possibly other polyunsaturated fatty acids (PUFA) such as gamma-linolenic acid (GLA), have been proposed as a possible strategy to prevent pre-eclampsia and preterm birth and to increase birth weight. The hypotheses that fish oil could prevent or ameliorate these conditions were initially developed following population comparisons and more recently have been tested in randomized controlled trials.

Our systematic review aims to estimate the overall benefits and hazards of supplementation with dietary PUFA, including n-3 fatty acids and GLA, during pregnancy.

All randomized trials, with adequate concealment of allocation, of dietary PUFA supplementation during pregnancy, were selected for the review. Relevant trials were identified from the Medline database, the Pregnancy and Childbirth Group's Specialized Register and the Cochrane Controlled Trials Register.

We have identified five trials involving over 2,500 women. The intervention in most trials was fish oil with 2.7 g of n-3 fatty acids per day, while one trial had a combination of evening primrose and fish oils (300 mg GLA and 220 mg n-3 fatty acids per day). The individual results of trials suggest that intervention with dietary PUFA had little or no effect on pre-eclampsia and pregnancy-induced hypertension. However, some trials suggest a modest increase in birth weight and length of gestation. The meta-analysis of these trials will be presented and discussed.

Key Words: PUFA, Pregnancy Outcome, Fish Oil

■ Dietary Long Chain Polyunsaturated Fatty Acids Alter Intestinal Fatty Acid Profiles, but Do Not Impact Digestive Function in Neonatal Piglets. M.C. McCarthy[1], A.D. Beaulieu[2], J.K. Drackley[2], H. Mangian[1], K.A. Tappenden[1], and S.M. Donovan[1], [1]Dept. of Food Science Human Nutrition, [2]Dept. of Animal Sciences, University of Illinois, Urbana, IL 61801.

Recent data suggest that dietary arachidonic acid (AA) and docosahexaenoic acid (DHA) benefit brain and retinal development of infants; however, their impact on intestinal function in neonates is less well described. Herein, the effects of dietary AA and DHA on intestinal fatty acid composition and digestive function were assessed. Piglets (2 day old) were randomized to receive formula containing a standard PUFA blend (n-6; $n=6$) or a blend with added 1.2% AA and 0.9% DHA (LC-PUFA; $n=8$) for 12 d. Weight gain, intestinal weight, and intestinal histomorphology were similar between groups. Plasma and red blood cell membrane DHA, but not AA, were increased ($P<0.05$) in piglets fed the LC-PUFA diet. Brush border phosphatidylethanolamine (PE) and phosphatidylcholine (PC) were separated by thin-layer chromatography and fatty acid profiles determined by gas chromatography. The content of DHA in PE but not PC was increased ($P<0.05$) by dietary LC-PUFA, whereas AA content of intestinal brush border PE and PC were unchanged. Transmural resistance and sodium-coupled glutamine and glucose transport were determined in Ussing chambers. Barrier function, nutrient transport, and sodium/glucose co-transporter (SGLT-1) mRNA abundance were not affected by LC-PUFA. Jejunal lactase mRNA abundance and activity were also unaffected. These data suggest that dietary DHA is incorporated into intestinal membrane PE of neonatal piglets, but does not alter digestive function. Therefore, it appears that AA and DHA can be added to infant formulas without detrimentally impacting intestinal development.

■ Arachidonic and Eicosapentaenoic Acid-Derived Prostaglandins Regulate the TH1 Versus TH2 Cytokine Balance: Implications for Atopic Disease. E. A. Miles, L. M. Aston, and P.C. Calder, University of Southampton, Southampton, UK.

T-helper (TH) lymphocytes have been divided into two groups according to the cytokines they produce. Typically, TH1 cells produce interleukin (IL-2) and interferon (IFN)-γ, while TH2 cells produce IL-4, IL-5 and IL-10. TH1 cytokines bias toward a cell-mediated immune response to eliminate intracellular pathogens, while TH2 cytokines promote B cell antibody responses. An imbalance in these cytokines underlies certain diseases such that a bias toward TH1 cytokines is present in patients with chronic inflammatory diseases (e.g., rheumatoid arthritis), while a bias toward TH2 cytokines is present in patients with atopic diseases. Eicosanoids are thought to have a role in regulation of the TH1/TH2 cytokine balance, but this has only been studied in detail for $PGE_2$ and the 4-series leukotrienes. The influence of eicosanoids synthesised from eicosapentaenoic acid on the TH1/TH2 profile has not been well studied. Therefore, in this study we investigate the effects of $PGE_2$ and $PGE_3$ on TH1 and TH2 cytokine production in human whole blood cultures. Whole human blood was diluted 1:5 in RPMI medium containing 0.75 mM glutamine and antibiotics and cultured for 48 h in the presence of concanavalin A (50 μg/mL) with or without the eicosanoids. $PGE_2$ and $PGE_3$ were introduced in ethanol (final concentration 0.1%) at $10^{-6}$, $10^{-7}$, $10^{-8}$, $10^{-9}$, and $10^{-10}$ M. Both prostaglandins suppressed IL-2 production (by between 30–40%) and IFN-γ production (by 70–75%) in a concentration-dependent manner. Conversely, both prostaglandins promoted IL-4 production at concentrations of $10^{-7}$ M and greater with a maximum of 1.5–1.6 times the control level. The addition of prostaglandins to the cultures did not affect IL-10 production when compared with the control. Thus, the addition of $PGE_2$ or $PGE_3$ to concanavalin A-stimulated human whole blood cultures results in reduced production of the TH1 cytokines IL-2 and IFN-γ and increased production of the TH2 cytokine IL-4, so changing the TH1/TH2 balance. This alteration in cytokine profile toward a TH2 bias may have important implications for increasing the development of allergic disorders. Dietary intervention with fish oil containing eicosapentaenoic acid is well known to markedly decrease production of $PGE_2$. There are reports that such an intervention results in only a small increase in production of $PGE_3$. Thus, overall, provision of eicosapentaenoic acid might result in a cytokine environment, which is less favorable toward the development of atopic disease.

Key Words: Prostaglandin, Cytokine, Atopic Disease

■ Effects of Acyl Chain Unsaturation and Cholesterol on the Rate of Receptor-G Protein Coupling. D.C. Mitchell[1], S. Niu[1], and B.J. Litman[1], [1]LMBB/NIAAA/NIH, Bethesda, MD, USA.

Visual signal transduction is a prominent member of the ubiquitous family of G protein-coupled signal transduction systems. In all of these systems an activated receptor passes an external signal to an internal effector enzyme *via* a guanine nucleotide binding protein, or G protein. The G protein is bound to the membrane *via* an isoprenoid tail that is believed to penetrate into the bilayer. Thus, the rate of signal transfer from the activated receptor to the effector depends on the two-dimensional diffusion rates of G protein and receptor. We have utilized rhodopsin and the visual G protein reconstituted in large, unilamellar vesicles to examine the effect of membrane composition on the rate of diffusional coupling of G protein and receptor. The form of photolyzed rhodopsin that binds G protein, meta II, is stabilized by bound G protein in the absence of GTP. Kinetics of both meta II formation and meta II-G protein complex formation at 20°C were measured for rhodopsin in native rod disk membranes and in bilayers consisting of 18:0,18:1 PC, 18:0,22:6n-3 PC, or di-22:6n-3 PC with and without 30 mol% cholesterol. The time constant for meta II in the reconstituted systems was 1 to 3 ms less than that measured in the native bilayer. At a mole ratio of G protein to photolyzed rhodopsin of approximately 1:3, the shortest time constant for complex formation was 7.4 ms in 18:0, 22:6 PC, and the longest time constant was 41 ms in 18:0,18:1 PC/30% cholesterol. Cholesterol increased the time constant for meta II-G protein complex formation in 18:0,18:1 PC by a factor of 4, but increased it by only 15% in 18:0,22:6 PC and di-22:6 PC. In order to isolate the effects of the two-dimensional diffusion process on the overall kinetics of G protein binding, we determined the ratio of the time constants for G protein-receptor complex formation and meta II formation. This ratio, $R_\tau$, indicates the number of periods, equal to its time of formation, that an activated receptor must wait before the diffusion of G protein and receptor results in a G protein-receptor complex. In native disk membranes and di-22:6 PC $R_\tau$ is 2.0, in 18:0,22:6 PC it is 1.5 and in 18:0,18:1 PC it is 2.6. Cholesterol more than doubles $R_\tau$ in 18:0,18:1 PC, but increases it only slightly in 18:0,22:6 PC or di-22:6 PC. These results demonstrate that 22:6 acyl chains in the bilayer increase the rate of meta II-G complex formation, indicating an increase in the rates of lateral diffusion for G protein and/or receptor. In bilayers lacking 22:6 acyl chains, addition of cholesterol severely decreased

the rates of lateral diffusion, however, in bilayers where 50% or more of the acyl chains were 22:6 the effect of cholesterol was minimal. These results demonstrate that acyl chain composition is a critical factor in determining the response time to the appearance of an agonist in a G protein-coupled signaling system.

■ Fatty Acid Composition of Human Milk in Poland. H. Mojska[1], J. Socha[2], and L. Szponar[1], [1]National Food and Nutrition Institute, [2]The Children's Memorial Health Institute.

There are few data on fatty acid composition of human milk in Poland. Subject and methods: The fatty acid composition of human milk was determined by capillary gas chromatography at different stages of lactation. Samples of milk were taken between 3 to 4 days post partum ($n$=50), the 5th to 6th week of lactation ($n$=38) and the 9th to 10th week of lactation ($n$=34). The fatty acid composition was expressed as weight percentage. Results and conclusion: The major fatty acid fraction in milk lipids consisted of saturated fatty acids. The percentage of total saturated fatty acids decreased with duration of lactation from 45.65% to 42.31% to 40.93%. In the same time period, polyunsaturated fatty acids increased from 9.35% to 11.11% to 11.29%. No statistically significant difference in milk monounsaturated fatty acids was seen in colostrum and mature milk. The median value of *trans* fatty acids in mature milk (2.6%) was higher than in colostrum (1.4%). With regard to the essential fatty acids, the linoleic acid (18:2n-6) content of mature milk was 9.61% and alpha-linolenic acid (18:3n-3) was 1.03%. The percentage of linoleic and alpha-linolenic acid increased whereas long-chain polyunsaturated fatty acids decreased in mature milk in comparison to colostrum. The median values of arachidonic acid (0.28%) and docosahexaenoic acid (0.11%)in mature milk were lower than those reported in other studies of lactating women in Europe.

Key Words: Fatty Acids, Human Milk, Stage of Lactation

■ Use of an Artificial Rat Breast and Artificial Rat Milk for the Complete Control of the Rodent Diet; Induction of n-3 Fatty Acid Deficiency in the First Generation. T. Moriguchi[1], R. Greiner[1], B. Lefkowitz[1], S.-Y. Lim[1], J. Loewke[1], J. Hoshiba[2], and N. Salem, Jr.[1], [1]National Institute on Alcohol Abuse and Alcoholism, NIH, [2]Okayama University Medical School, Japan.

Several studies have reported that the level of dietary n-3 fatty acids influence the brain docosahexaenoic acid (DHA) level during postnatal development period when rats are fed using the intragastric method for artificial rearing. However, this method had some disadvantages due to the absence of social interaction and suckling or swallowing behavior. Furthermore, it can begin usually only at day 4–5 of life. Thus, diet cannot be controlled during an important period of neural development. We report here the brain DHA level in newborn rats after exposure to an n-3–deficient diet using a new artificial rearing method that can be employed the first day of life. The newborn rats were separated within 12 hours of birth from their mothers. The dams were maintained on an n-3–adequate diet containing 3% alpha-linolenic acid (LNA) and no DHA. The pups were moved to two rearing chambers and were given an artificial rat milk that was n-3 fatty acid–deficient (n-3 fatty acids were less than 0.002% of total fatty acids) or –adequate (addition of 3% LNA) using an artificial nipple and a nursing bottle after the method of Hoshiba. The n-3 fatty acid content of deficient milk was much lower than that of F-2 n-3 fatty acid–deficient mothers' milk (0.05% total n-3 fatty acid). During the first three days, pups were trained by feeding artificial milk from a nursing bottle with a silicon nipple every 2–3 hours by hand. After three days, the pups were able to find the nipples and suckle by themselves. At various times from day 0 to weaning, animals were killed and the fatty acid composition of various tissues were determined. After about 3 days, rats in the n-3 deficient milk group exhibited a gradually decreasing brain DHA level yielding about a 60% decline by day 17 of life relative to the level of the n-3 adequate milk group. The dam-reared pups were slightly higher in brain DHA than the artificial reared group receiving n-3 adequate milk due to the dams' high DHA intake and the high DHA level in their milk. This method offers a method for obtaining rats with a marked loss of central nervous system DHA in a short period of time and will be useful for the evaluation of alterations in brain function.

■ Differential Effects of Fatty Acid Binding Proteins on Cellular Fatty Acid Uptake and Lipid Metabolism. E. Murphy, University of North Dakota.

Although fatty acid binding proteins have similar binding affinities for fatty acids *in vitro,* these proteins have differential effects on fatty acid uptake and trafficking. Two proteins in particular, I-FABP and L-FABP, demonstrate these differential effects on cellular fatty acid metabolism when stably transfected in L-cell fibroblasts. In these cells, L-FABP stimulates a 1.7-fold increase in fatty acid uptake, whereas I-FABP has no effect on fatty acid uptake. Both proteins target fatty acids to different lipid pools. L-FABP targets fatty acids for esterification into phospholipids and triglycerides, whereas I-FABP only targets fatty acids for esterification into neutral lipids. Both proteins increase the apparent cytoplasmic diffusion coefficient, demonstrating that these proteins are involved in intracellular fatty acid trafficking, supporting the targeting results. In these cells, I-FABP and L-FABP stimulate the apparent cytoplasmic diffusion coefficient 2.6- and 1.9-fold compared to control. Although both proteins stimulate an increase in total phospholipid content, the magnitude of this increase in L-FABP expressing cells is significantly greater than that in I-FABP expressing cells. Similarly, both proteins alter phospholipid acyl chain composition; however, the effect of L-FABP is more robust than that of I-FABP. Hence, expression of I- and L-FABP differentially affect fatty acid uptake, targeting, phospholipid mass, and phospholipid acyl chain composition when expressed in L-cell fibroblasts.

■ Plasma Essential Fatty Acids (EFA), Vitamin E, and Vitamin A in Relation to Alcohol Intake in African American Women at Twenty-Four Weeks Gestation. M. Murthy[1], S. Martier[2], J. Whitty[2], R. Sokol[2], J. Hannigan[2], and N. Salem, Jr.[1], [1]LMBB/NIAAA, National Institute of Health, Rockville, MD, [2]Wayne State University School of Medicine, Detroit, MI.

High levels of alcohol intake affect the metabolism of long-chain polyunsaturated fatty acids (LC-PUFA). More specifically, pregnant women being exposed to alcohol may risk having lower levels of n-3 LC-PUFA in the maternal and fetal circulation. Further evidence from several urban sites suggests that African American women may be at increased risk for fetal alcohol-related birth effects (ARBE) relative to other populations. We hypothesize that alcohol and/or diet low in n-3 LC-PUFA in this population may contribute to lower maternal levels of n-3 fatty acids, suboptimal brain docosahexaenoic acid (DHA) levels in the fetus, and adverse pregnancy outcomes. To address this hypothesis, an inner city African American sample was chosen based on the high incidence of ARBE and a socio-economic profile consistent with potentially suboptimal intake of n-3 fatty acids. Pregnant women presenting at an antenatal clinic were screened and recruited into one of the following three groups based on their self-reported levels of absolute alcohol intake per day (AAD): Light ($0.00<AAD<0.05$ ounces), Moderate ($0.05\leq AAD<1.00$ ounces) and Heavy ($AAD\geq 1.00$ ounces). In this first wave of data at twenty-four weeks gestation, we have attempted to establish statistical correlations between alcohol intake and three nutritional variables, including plasma EFA, vitamin E and vitamin A. In addition, we are collecting data on other dependent variables that reflect both nutritional and perinatal outcomes [e.g., birth weight, head circumference, dysmorphologic features, and fetal alcohol syndrome (FAS) diagnosis], which will be reported in later papers. We expect that results from this study may for the first time lead to a proposal for testing a simple dietary approach to help normalize n-3 LC-PUFA levels in drinking African American mothers and potentially reduce alcohol-related birth effects in the newborn (supported by the Office of Minority Health and NIAAA).

■ Polyunsaturated Fatty Acids and the Ketogenic Diet: Seizure Protection and Tissue Lipids in an Animal Model. K. Musa, C. Dell, S.S. Likhodii, M. Burnham, and S.C. Cunnane, University of Toronto, Toronto, Ontario, Canada.

The ketogenic diet (KD) is a very high fat, very low carbohydrate (CHO) diet that is used to treat children with intractable epilepsy. The anticonvulsant mechanism of the KD is currently unknown. An animal study assessing the effects of an n-3 polyunsaturated fatty acid (PUFA)-enriched KD on tissue lipids and seizure protection was undertaken. Thirty-six male albino Wistar rats were weaned at 20 d of age and randomly assigned to a control or ketogenic diet group. Control rats were fed the AIN-93G diet and ketotic rats were fed a 3.5:1 (ratio of fat:protein + CHO, by weight) KD. After 48 d of dietary treatment, six rats from each group were sacrificed for tissue lipid analysis and the remaining twelve rats in each group underwent a threshold pentylenetetrazol (PTZ) seizure test (50 mg/kg, s.c.). Ketotic rats weighed 6% less than control rats (318 ± 6 g vs. 340 ± 26 g, $P<0.05$). Compared to control rats, ketotic rats had significantly lower blood glucose (6.3 ± 0.3 mM vs. 6.9 ± 0.7 mM, $P<0.01$), and significantly higher plasma β-hydroxybutyrate (0.8 ± 0.3 mM vs. 0.1 ± 0.03 mM, $P<0.001$). The two dietary interventions resulted in significantly different responses to the PTZ threshold testing, where 100% seizure incidence was observed in controls and only 50% seizure incidence was observed in ketotic rats ($P<0.05$). In comparison to controls, the brains of ketotic rats had 6% less stearic acid (18:0), 14% less arachidonic acid (AA, 20:4n-6), and a twofold increase in linoleic acid (18:2n-6) ($P<0.05$). The brains of ketotic rats also contained trace amounts of α-linolenic acid (ALA, 18:3n-6) and eicosapentanoic acid (EPA, 20:5n-3), which were not detected in the brains of control rats. Plasma levels of palmitic acid (16:0) and docosahexaenoic acid (DHA, 22:6n-3) in ketotic rats were twofold lower than in control rats ($P<0.05$). The plasma of ketotic rats contained 30% more stearic acid, seven times more ALA, and six times more EPA ($P<0.05$). The total plasma fatty acid concentration was approximately 1.5 times lower in ketotic rats compared to controls rats (15.9 ± 5.5 mg/dL vs. 24.1 ± 3.9 mg/dL, $P<0.05$). Control and ketotic rats did not differ in plasma concentrations of cholesterol. The greater amounts of brain and plasma n-3 and n-6 PUFA in ketotic rats may be important in conferring seizure protection by acting as more readily oxidized substrates for ketone body formation and by increasing membrane stability and repair. The lower total plasma fatty acids and similar cholesterol levels observed in ketotic rats may implicate a PUFA-enriched KD as being less atherogenic, while eliciting beneficial effects on seizure control. ■ Modulation of the Signaling in the Visual Transduction Pathway by DHA Containing Phospholipids. B. Litman, D. Mitchell, S.-L. Niu, and A. Polozova, National Institute on Alcohol Abuse and Alcoholism, NIH, Rockville, MD, USA.

The retinal rod outer segment disks and the membranes of neuronal tissue contain as much as 50% of the phospholipid acyl chains as DHA, 22:6n-3. We have undertaken a study of the visual transduction system, employing the protein components of this pathway reconstituted in defined lipid systems so as to understand the functional and structural role of the DHA containing phospholipids. The formation of metarhodopsin II (MII), the form of rhodopsin that binds and activates the visual G protein, was greatest in DHA containing phosphatidylcholines (PC), relative to more saturated PC. The kinetic and equilibrium properties for the formation of the MII-G protein complex, were also studied. An important parameter of signaling is the rate of appearance of MII relative to the rate of formation of the MII-G complex, since these relative rates determine the kinetics of initiation of the signaling cascade. These rates were very similar in disk membrane and 18:0,22:6PC bilayers. However, the rate of MII formation exceeded that of MII-G complex formation by about a factor of five in 18:0,18:1PC bilayers at 37°C, indicating a lag time in the initial MII-G protein coupling. Measurements of the cGMP phosphodiesterase (PDE) activity reflect the activity of the integrated pathway. Here again, the PDE activity in a 22:6-containing PC was greater than that measured in a more saturated lipid. In mixed lipid bilayers, rhodopsin was found to separate into microdomains enriched in di22:6PC. The function of the visual pathway, a G protein-coupled system, appears to be optimized in DHA containing bilayers. If the function of other members of the superfamily of G protein-coupled receptors, such as several neurotransmitter receptors, is also optimized in DHA-containing bilayers, then these results provide a basis for explaining the loss of visual and cognitive skills associated with DHA deficiency.

Key Words: DHA, Visual Signaling, G Protein-Coupled Receptors

■ Biophysical Mechanisms of Docosahexaenoic Acid Influence on Membrane Receptor Function—Insights from Deuterium NMR Studies. I.V. Polozov, A.M. Safley, and K. Gawrisch, LMBB NIAAA National Inst. of Health.

Phospholipids of neural and retinal membranes are rich in polyunsaturated fatty acyl chains, particularly in docosahexaenoic acid (DHA, 22:6n3). It is likely that the high content of this fatty acid modulates physical properties of membranes, creating an environment that is optimal for function of neuronal receptors. We investigated this hypothesis by solid-state NMR methods. A unique membrane probe—perdeuterated DHA—was synthesized and incorporated into the lipid matrix. Six distinct order parameters and their corresponding signal intensities were measured. Partial order parameter assignments were made using magic angle spinning NMR techniques. In comparison to saturated chains, DHA order parameters were low, reflecting both a change in bond geometry and an increase in angular fluctuation amplitudes. This is contrary to the current belief that high concentrations of double bonds result in less flexible hydrocarbon chains. Using $^{2}$H-labeled lipids we compared lipid order parameters in the absence, and in the presence of rhodopsin, the primary visual receptor, and a member of G-protein coupled receptor family. Rhodopsin was reconstituted into fully hydrated, solid-supported oriented multi-bilayer samples. With this novel approach we obtained, for the first time, highly resolved spectra from deuterated acyl chains in membranes containing reconstituted integral membrane protein at physiologically sound conditions. Oriented samples also improve NMR sensitivity enabling work with milligram-size samples. The presence of rhodopsin induced differential changes in DHA order parameters along the acyl chain, which suggest a change in the average conformation. We compared rhodopsin effects on the deuterium order parameter profile of saturated chain in mono- and polyunsaturated lipid systems. Protein incorporation decreased the order parameters of polyunsaturated PC, while not affecting that of the monounsaturated PC. The data suggest that rhodopsin preferentially interacts with polyunsaturated lipids resulting in lateral phase separation within the lipid matrix.

Key Words: DHA, Rhodopsin, NMR

■ Role of DHA in Formation of Membrane Domains: Specific Association of Rhodopsin with DI22:6PC. A. Polozova and B.J. Litman, National Institute on Alcohol Abuse and Alcoholism.

It is widely acknowledged that cellular membranes have highly specialized microdomains enriched with specific lipids and proteins. One intriguing hypothesis is that microdomain formation, facilitated by a delicate balance in lipid composition, is critical for proper cell functioning. The goal of this study was to determine the role of polyunsaturated lipids in formation of microdomains. It was shown previously that activation of G-protein coupled photoreceptor rhodopsin is extremely sensitive to lipid polyunsaturation. The lateral segregation of rhodopsin with polyunsaturated lipids was proposed as a possible native mechanism regulating rhodopsin functional activity in retina. To test this hypothesis, we designed a method based on fluorescent resonance energy transfer (FRET). Purified rhodopsin was reconstituted into membranes consisting of phosphatidylcholines (PC) with polyunsaturated (di22:6PC) and saturated (di16:0PC) acyl chains and cholesterol. Trace levels of lipid with similar acyl chains, labeled with fluorophore pyrene (Py), either di22:6-PE-Py or di16:0-PE-Py, were introduced into the membranes. Rhodopsin is a very efficient acceptor of pyrene fluorescence. In reconstituted membranes composed of di22:6PC/di16:0PC/cholesterol at 3:7:3 proportion, the FRET efficiency was significantly higher for di22:6PE-Py, compared to di16:0PE-Py. This result is consistent with presence of microdomains enriched with di22:6PC centered on rhodopsin molecules, as higher FRET efficiency is a direct indication of co-localization of donors and acceptors. Theoretical evaluation of data showed that such microdomains contain at least three lipid layers around each rhodopsin and are enriched

threefold in di22:6PC. Microdomain formation was sensitive to lipid composition. No microdomain formation was found in bilayers containing different proportions of di22:6PC or upon removal of cholesterol. Acute ethanol exposure severely disrupted microdomain structures, as indicated by altered FRET efficiencies for both lipid probes. These results suggest, that DHA lipids, and their proportion are critical for formation of microdomains around receptors. Disruption of such receptor microenviromnents in DHA deficiency may contribute to associated functional losses.

Key Words: Membrane Domains, Rhodopsin, Lipid–Protein Interactions

■ Increasing Dietary Intake of Docosahexaenoic Acid Affects Long-Chain Polyunsaturated Fatty Acid Composition Differently According to Brain Areas in 2-Mo-Old Rat. C. Poumés-Ballihaut[1], S. Vancassel[1], S. Chalon[2], G. Durand[1], Ch. Latgé[3], and G. Guesnet[1], [1]Institut National de la Recherche Agronomique (INRA), [2]Institut National de la Santé et de la Recherche Médicale (INSERM), [3]Blédina S.A., Groupe Danone.

To ensure optimal brain development of the newborn infant, infant formulas in some countries have been supplemented with docosahexaenoic acid (DHA,22:6n-3), the long-chain polyunsaturated fatty acid (LC-PUFA) derived from alpha-linolenic acid (18:3n-3). However, the link between the DHA content in the diet and the fatty acid content of specific regions of the brain has received little study. For this reason, we studied the effects of increasing amounts of dietary DHA on several lipid membrane components in frontal cortex, striatum, hippocampus, and cerebellum in the 2-mo old rat. One week after mating, Wistar female rats deficient in n-3 fatty acids (2nd generation) were randomly divided into eleven groups. Ten groups received DHA from 0 to 1600 mg/100 g diet and one group received 300 mg of 18:3n-3/100 g of diet (control). All diets contained 7% by weight fat and 1.2 g of 18:2n-6/100 g, the precursor of the n-6 family. At weaning, male rat pups continued to receive the same diet as their mother until 2-mo of age. Cholesterol and total phospholipid content of brain regions was not affected by DHA intake, but they differed in concentration among the brain areas studied. Compared to other brain, regions, cholesterol was lowest in frontal cortex and hippocampus (1.0 vs. 1.3 mg/100 mg tissue) and total phospholipids were lowest in hippocampus (3.2 vs. 4.4 mg/100 mg tissue). Neither the cholesterol to phospholipid ratio nor the proportions of phospholipid classes changed or differed among brain areas (weight %): phosphatidylcholine (PC), 47%; phosphatidylethanolamine (PE), 36%; phosphatidylserine (PS), 11%; phosphatidylinositol (PI), 4%; and sphingomyelin (SM), 2%. Whatever the DHA intake, DHA and arachidonic acid (AA, 20:4n-6) levels were specific to the class of phospholipid and the brain area. In PE and PS, the DHA content was similar, higher in frontal cortex and the lower in striatum (31 and 22% of total fatty acids, respectively, in rats fed 1600 mg DHA). In PC, the highest DHA content was in cerebellum (10%). For AA, hippocampus had the highest concentration in PC, PE, and PS. The DHA supply affected proportions of 22:4n-6, 22:5n-6 but mainly DHA and AA. In PC, PE, and PS of each brain area studied, the DHA incorporation followed a logarithmic curve ($P<0.001$) with a rapid increase up to 100 mg DHA/100 g diet, from 7 to 23% in PE of frontal cortex. This increase was followed by a slower one, from 23 to 30% in PE of frontal cortex. During this same interval, AA fell dramatically up to 200 mg DHA/100 g diet, from 14.5% to 11.5% AA in PE of frontal cortex. This decline was followed by a slower decrease, from 11.5% to 7%($P<0.001$). The different DHA and AA contents in brain regions might suggest different needs for those LC-PUFA. All brain areas studied showed an inverse relationship between DHA and AA in PC, PE, and PS as dietary 22:6n-3 increased. This must be carefully considered given the importance of those two LC-PUFA in cerebral functions.

■ Maternal Diet and Human Brain Evolution. S. Robson, University of Utah.

Animal products make up a larger portion of human than non-human diets. Humans also have larger brains, both absolutely and relative to body size. It has often been proposed that increased carnivory during human evolution provided the nutritional support needed to underwrite greater encephalization. Comparative analyses show that at birth, human brains are the same fraction of neonatal weight as the average primate but are a much smaller portion than expected of mature brain size. This means that postnatal, not fetal, growth accounts for our departure from the general primate pattern. During the period of most rapid postnatal brain growth, infants are provisioned primarily (if not exclusively) by lactation. If increased carnivory is responsible for our larger brains, human breast milk should differ from that of other primates by displaying a higher proportion of specific lipids which are critical components of brain matter. Breast milk in humans whose diets vary in meat content should also differ in predictable ways. Multiple lines of evidence suggest that meat in the maternal diet has little impact on breast milk quantity or quality. In addition, human breast milk does not appear to differ in composition from that of other anthropoid primates. If the proportion of meat in maternal diets does not affect breast milk composition (specifically LC-PUFA) among humans, then increased carnivory is unlikely to account for the human pattern of encephalization.

Key Words: Encephalization, Breast Milk, Long-Chain Polyunsaturated Fatty Acids

■ Medium-Chain (MC), Intermediary-Chain (IC) and Polyunsaturated (PU) Fatty Acid (FA) Supplies with Mature Human Milk of Three Different African Populations. G. Rocquelin[1], S. Tapsoba[2], J. Kiffer[1], N. Thiombiano[3], C. Bouda[4], O.N. Zougmoré[5], and A. Traoré[3], [1]IRD, Montpellier, France, [2]ANSA, Ouagadougou, Burkina Faso, [3]FAST, Université de Ouagadougou, Burkina Faso, [4]Faculté de Médecine, Université de Ouagadougou, Burkina Faso, [5]FLASHS, Université de Ouagadougou, Burkina Faso.

Objective: To measure the FA supply from breast milk as part of nutritional surveys of the essential fatty acid (EFA) status of 5-month-old African infants.

Settings: Urban Congo (UC), urban Burkina Faso (UBF), and rural Burkina Faso (RBF).

Subjects: Random samples of healthy mothers nursing 5-month-old infants ($n=100$) living in suburban districts of Brazzaville and Ouagadougou, or in a rural area of Burkina Faso.

Data collection procedures: Mothers were questioned about their socio-econonomic status and dietary habits, and their body mass index (BMI) was measured. Samples of milk (5 to 10 mL) were collected at 2 specific times in the day by manual expression from both breasts. Milk lipid contents were measured and FA analyzed by high-resolution gas chromatography.

Results: Compared with breast milk from various countries, Congolese and Burkinabe women's mature milk was low in lipid. Milk fat content was higher in UBF (33.42 g/L) and RBF (31.42 g/L) than in UC (28.70 g/L). MC and ICFA contents (C8:0–C14:0) were several-fold greater than in most countries, particularly in RBF where they accounted for one third of total FA (33.52%). UC milk was noticeably rich in n-3 PUFA (2.39% of total FA), particularly 18:3 (1.19%) and 22:6 (0.55%) whereas UBF milk was high in n-6 PUFA (21.74%) particularly 18:2 n-6 (19.80%). RBF milk had levels intermediate between UC and UBF milk. In the 3 groups, MC and ICFA were strongly negatively related with oleic acid levels but not related to n-6 or n-3 PUFA. Also a highly significant positive correlation was found between 18:2n-6 and 18:3n-3. Ratios of 18:2n-6/18:3n-3 and n-6/n-3 long-chain PUFA varied respectively from 12:1 in UC to 52:1 in UBF, and from 1:1 in UC to almost 5:1 in UBF. In general, the dietary habits of mothers explained these differences. Data from food frequency questionnaires showed that Congolese and Burkinabe mothers' diets were very high in carbohydrates and low in fat therefore enhancing de novo synthesis of MC and ICFA in the mammary gland. Also in the Congo high consumption of foods providing n-3 PUFA such as green leafy vegetables and fish led to enrichment of milk in these FA. On the other hand, high levels of 18:2n-6 in UBF milk were due to frequent consumption of cottonseed oil (high in linoleic acid) and cereals (millet, sorghum, corn, wheat) higher in 18:2n-6 than tubers (casava) that were preferentially consumed in the Congo.

Conclusions: FA supplies from breast milk to 3 different populations of 5-month-old African infants were much different and their impact on infant EFA status may vary. Studies are needed, for instance, to explore the influence in breast milk of 25% to 33% of total FA as MC and ICFA

on energy balance or else the effect of unbalanced n-6/n-3 PUFA ratios on utilization and metabolism of these PUFA by infants.

■ Synthesis of n-6 Long-Chain Polyunsaturated Fatty Acids in Preterm Infants Fed Medium-Chain Triacylglycerides. M. Rodriguez[1], H. Demmelmair[1], M. Fink[1], S. Kiss[2], M. Turini[3], G. Crozier[3], and B. Koletzko[1], [1]Ludwig-Maximilians University of Munich, Germany, [2]Children Hospital Pecs, Hungary, [3]Nestec, Vevey, Switzerland.

The effects of medium-chain triglycerides (MCT) in preterm infant formulas on essential and long-chain polyunsaturated fatty acid (LC-PUFA) status and metabolism were investigated using stable uniformly $^{13}C$-labeled isotopes. Nineteen premature infants (gestational age≤37 wk) who were exclusively formula fed were enrolled in the study. Infants were randomly assigned to receive for 7 days an infant formula with 40% of fat as MCT ($n$=10) or without MCT ($n$=9), with otherwise similar composition and linoleic and α-linolenic acid contents. At study day 5, infants received 2 mg/kg body weight of uniformly $^{13}C$-labeled linoleic acid. Tracer oxidation was assessed by analyzing $^{13}C$ content in breath $CO_2$. Fatty acid composition of plasma lipids and $^{13}C$ content in plasma phospholipids was determined 48 h after tracer application. The results showed that in the MCT group oxidation of linoleic acid was lower (tracer recovery in breath was 3.0% vs. 5.6% of the applied dose, $P$≤0.01) and plasma linoleic acid concentrations were higher (not significant) than in the control group. LCP concentrations were also higher in infants fed MCT, particularly in plasma triglycerides (57.07±4.36 mol/L vs. 37.93±4.75 mol/L, $P$≤ 0.05). As indicated by the tracer distribution, no significant differences in the relative conversion of linoleic acid to arachidonic acid were observed ($^{13}C$20:4n-6/$^{13}C$18:2n-6 was 0.107 and 0.085 in the control and the MCT group, respectively). Thus, we conclude that MCT have a positive effect on the n-6 LCP status, possibly through a decreased oxidation of linoleic acid and its conversion products.

■ Effect of DHA on Gene Expression in Human Fetal Retinal Explants. C. Rojas[1], D. Hoffman[2], J. Martinez[1], and R. Uauy[1,2], [1]INTA University of Chile, Santiago-Chile, [2]Retina Foundation of the Southwest, Dallas, TX.

Docosahexaenoic acid (DHA) has a profound effect on functional maturation of the retina. To explore the possible effect of DHA on gene expression during human fetal retinal maturation, we compared mRNA expression from retinal explants with and without added DHA using gene microarray methodology. Total RNA was obtained on day 14 from fetal retina (14–18 wk gestation) cultured in serum-free Waymouth's media with 20 μM DHA in BSA. Control explants were cultured in lipid-free BSA. cDNA was synthesized with labeled nucleotides and hybridized to the microarray. Relative expression analysis of 2400 genes was based on signal amplification using fluorescent reporters. The +DHA/Control ratio of expression was unchanged in 80% of genes (i.e., several ribosomal proteins and GADPH). Decreased expression (ratio < 0.33) was observed in 4% of genes (i.e., human brain fatty acid binding proteins, cytoskeletal proteins, PI kinase, leukotriene hydrolase). 15% of the genes showed increased expression (ratio > 3.0). These included genes for fatty acid oxidation and desaturation, PAF acetylhydrolase, LDL receptor, lipoprotein lipase mitochondrial oxidation processes, differentiation and apoptosis-related protein kinases, transcription factors, neurotransmitter receptors, and IGF-binding proteins. We conclude that DHA action during retinal development is mediated not only by its known effects on membrane biophysical properties but also by significant modulation of gene expression. Key Words: DHA, Gene Expression, Retina

■ Docosahexaenoic Acid Protects Retinal Photoreceptors from Apoptosis Induced by Oxidative Stress. N. Rotstein, Instituto de Investigaciones Bioquimicas, UNS-CONICET.

Oxidative stress induces apoptosis both during the normal development of the nervous system and in neurodegenerative diseases. The retina, especially in newborns, is particularly prone to oxidative damage. One of the reasons is its high content of polyunsaturated fatty acids (PUFA). However, it has recently been demonstrated that docosahexaenoic acid (DHA), the most abundant PUFA in photoreceptor cells, can postpone the onset of the apoptosis of these neurons, which otherwise inexorably starts after 4 days in culture (Rotstein *et al.,* 1997, *J. Neurochem. 69*, 504; 1998, *Invest. Ophthalmol. Vis. Sci. 39,* 2750). This protective effect correlates with an active esterification and accumulation of DHA in neuronal lipids. To investigate the effect of oxidative stress on retinal neurons and whether addition of DHA enhanced oxidative damage, 3-day rat retinal neurons were incubated with Paraquat (24 μM), a generator of reactive oxygen species. After 24 hours, this oxidant induced apoptosis in both amacrine and photoreceptor neurons, the two major neuronal types in the culture: the percentages of apoptotic cells raised from 3.2% to 35.0% of the total amacrine neurons and from 23.6% to 67.4% of the total photoreceptors, in control and Paraquat-treated cultures, respectively. Apoptotic death was only slightly affected by a Paraquat concentration ranging from 2.4 to 240 μM. Addition of Paraquat led to the increased expression of the proapototic protein p53 and to the fragmentation of the nuclear lamins, characteristic of apoptotic processes. DHA supplementation at day 1 in culture slightly diminished the percentage of apoptotic photoreceptor at day 4, compared to control conditions. This addition reduced almost by half photoreceptor apoptosis induced by Paraquat: only about 35% of photoreceptors were apoptotic in this condition. This effect was specific for photoreceptors, since induction of apoptosis in amacrine neurons was unaffected by DHA addition. These results suggest that oxidative damage is highly lethal to retinal neurons in the early stages of their development in culture. Surprisingly, a higher content of DHA in their cell membranes does not increase neuronal sensitivity to this damage. On the contrary, it has a protective effect on photoreceptor neurons, enhancing their survival and preventing apoptosis. This suggests that, apart from its well-known structural role, DHA may also act as a signal molecule, triggering intracellular pathways that protect photoreceptors from apoptotic degeneration.

Key Words: Docosahexaenoic Acid, Retinal Photoreceptors, Oxidative Damage

■ Study of Essential Fatty Acid Metabolism Using Multiple Stable-Isotope Labeled Precursors. Y. Lin and N. Salem, Jr., LMBB, NIAAA, NIH, Rockville, MD.

An important issue in nutrition is whether it is adequate to supply only dietary fats like linoleate (LA, 18:2n-6) and alpha-linolenate (LNA, 18:3n-3) or whether it is important to also supply their preformed metabolites. Therefore, comparison was made between 18- and 20-carbon essential fatty acids (EFA) with respect to their metabolism to longer chain, more unsaturated fatty acids (long-chain polyunsaturated fatty acids) in adult rats. A newly developed, multiple stable isotope technique was employed together with isotope dilution gas chromatography/negative chemical ionization mass spectrometry. Deuterium-labeled-LNA (D5-18:3n-3), carbon-13-U-labeled eicosapentaenoate (20:5n-3), carbon-13-U-labeled-LA and deuterium-labeled-dihomo-gamma linolenate (D5-20:3n-6) were used as tracers. These isotope-labeled fatty acids in vehicle oil were simultaneously given as a single oral dose with an 18C/20C ratio of 5:1 (w/w). Rat blood and tissues were collected at various time points after dosing. In rat plasma and liver, the isotopomers of the precursors and their main metabolites, including the 13C-labeled and D-labeled, can be detected simultaneously in the same sample with good resolution due to their differences in mass and retention time. Both 18C and 20C precursors reached their maximal concentration after 4 hr in plasma, but after 8 hr in liver and brain. They were largely eliminated by about 96 hr except in brain, where the precursors were still detectable after 10 d. In plasma, maximal concentrations of D-22:5n-3 and $^{13}C$-22:5n-3 were reached after 8–12 hr, while D5-22:6n-3 and $^{13}C$-22:6n-3 were maximal after 24 hr. However, in the brain, the peak concentrations of isotope-labeled 20:4n-6 and 22:6n-3 occurred at 10 d and were still detected after 30 d. Retroconversion of D-18:2n-6 and D-18:3n-6 from D-20:3n-6 was observed in rat plasma

and liver. Even though the $^{13}C$ enrichment of 20:5n-3 was much greater than that of the deuterium in plasma and liver, the 22:5n-3 metabolite contained a similar enrichment of the two isotopes while the 22:6n-3 had a greater enrichment of deuterium. Similarly, there was evidence that 20:3n-6 molecules that originated from $^{13}C$-18:2n-6 were selectively metabolized to 20:4n-6 in comparison to preformed D5-20:3n-6. This unexpected behavior may be the result of an isotope effect, a different subcellular localization or a different lipid class form of the substrates when derived from either the 18- or 20-carbon fatty acids. It may also indicate coupling between the various desaturase/elongase steps in EFA metabolism.

■ Effect of Increasing Dietary Long-Chain Polyunsaturates (LCP) with High Vitamin E on Lipid Peroxidation and Susceptibility to Oxidation of Piglet Erythrocytes, Plasma and Liver. E. Sarkadi Nagy, M.C. Huang, R. Kirwan, A. Chao, C. Tschanz, and J.T. Brenna, Cornell University, Ithaca, NY.

The purpose of this study was to determine the effects of increasing doses of dietary docosahexaenoic acid (DHA) and arachidonic acid (AA) supplementation on lipid peroxidation and *in vitro* susceptibility to oxidation in piglet tissues. Twenty-four one-day old piglets ($n$=6 per group) were bottle-fed a sow milk replacement formula containing one of four experimental treatments for four weeks: no long-chain fatty acid ("Diet 0") and three different levels of DHA/AA at 1-fold (0.3%/0.6% FA;"Diet 1") 2-fold (0.6%/1.2% FA;"Diet 2") and 5-fold (1.5%/3% FA; "Diet 5") concentration of some human infant formulas. All sow milk formulas had vitamin E at 260 mg/kg diet. Red blood cell (RBC) membrane total lipid DHA and AA increased in a dose-dependent manner while 18:2n-6 (linoleic acid) and 18:3n-3 (linolenic acid) concentrations decreased. These modifications resulted in a concomitant dose-dependent increase in the membrane unsaturation index. Lipid peroxidation was assessed by measuring conjugated diene and glutathione (GSH) levels in the liver, and thiobarbituric acid-reactive substances (TBARS) in plasma. There were no significant differences between the groups in any of these parameters. Oxidative stability was assessed by determination of TBARS concentration after exposure of RBC to 10 mM $H_2O_2$, and liver homogenates to various concentrations of $H_2O_2$ (0, 1, 5, 10 mM) for 30 minutes. TBARS levels of the erythrocyte membranes increased in a dose-dependent manner when *in vitro* oxidation was induced. The TBARS levels of the liver homogenates of the Diet 5 group were significantly different from those of the membranes of the Diet 0 group when the *in vitro* oxidation was induced with only the highest concentration of $H_2O_2$ (10 mM). We conclude that there was no increase in oxidation due to high dietary and tissue LCP with high vitamin E. The susceptibility of RBC and liver of piglets in the Diet 5 group to *in vitro* oxidation was increased compared to the Diet 0 group only under extreme oxidative conditions. Overall, the results suggest that the dietary vitamin E effectively prevented oxidation at the LCP concentrations investigated.

■ The Effect of Essential Fatty Acid Metabolite Supplementation During Pregnancy and Lactation on Growth and Development of Vervet Monkeys *(Cercoopithecus aethiops)*. H.Y. Tichelaar, M.C. Mdhluli, C.M. Smuts*, and A.J.S. Benade, Medical Research Council, Tygerberg, South Africa.

Nonhuman primates are suitable models of human physiology to study the effect of multiple pregnancies on growth and development. We examined the changes in anthropometry and fatty acids of vervet infants from females ($n$=12), aged 6–17 years who had 2–9 previous live births. Vervets were fed a high-carbohydrate diet (low in n-3 fatty acids) that was either supplemented (experimental group) with a DHA-rich oil (Scotia Pharmaceuticals; 320 mg n-3 fatty acids/day, which included 280 mg DHA) for at least one year before and during pregnancy and lactation (based on the Canadian Recommendations for pregnant women), or not supplemented (control group). Following an overnight fast (18 hours), the female vervets were sedated with ketamine HCl (10 mg/kg intramuscular). Blood (2 mL) and anthropometric measurements were taken at birth, after 1, 3 and 6 months when infants were weaned. Plasma and red blood cell (RBC) total phospholipid (TPL) fatty acids were extracted with chloroform/methanol (2:1; vol/vol) and analyzed by GLC for fatty acid composition. Plasma (11.19% vs. 4.92%), RBC (11.14% vs. 4.53%) TPL DHA and milk DHA (3.51% vs. 1.65%) was higher ($P$<0.001) after 6 months of lactation in infants from n-3 fatty acid-supplemented females, compared to the control infants. Experimental infants had higher weights after 3 and 6 months (698 g vs. 573 g and 947 g vs. 722 g, respectively; $P$<0.05); were longer after 1 month (327 mm vs. 312 mm; $P$<0.05); had longer lower leg length after 6 months of lactation (108 mm vs. 101 mm; $P$<0.01) and had larger head circumferences after 3 (202 mm vs. 194 mm; $P$<0.05) and 6 months (208 mm vs. 195 mm; $P$<0.01) than the control infants. The results suggest that n-3 fatty acid supplementation of pregnant and lactating female vervets had profound effects on their offspring. The findings of this study are encouraging and should be used to design a clinical trial of n-3 fatty acid supplementation with pregnant women to measure growth and development of their infants.

■ Relative Effects of Women's DHA Status Entering the Third Trimester of Pregnancy and Third Trimester DHA Intake on Infant DHA Status at Birth. C.M. Smuts[1] and S.E. Carlson[2], [1]Medical Research Council, Tygerberg, South Africa, [2]University of Kansas Medical Center, Kansas City, KS.

Background: The last intrauterine trimester is important for fetal brain docosahexaenoic acid (DHA, 22:6n-3) accumulation, but little is known about the role that maternal DHA status, including the portion related to maternal DHA intake, plays in infant DHA status. Objective: To determine the relative effects of maternal DHA status at the beginning of the 3rd trimester and varied DHA intake during the 3rd trimester on maternal and infant DHA status at birth. Methods: As part of a pilot study to determine if eggs could be used to increase DHA status of women and their infants, we investigated these relationships. Pregnant women were randomly assigned to eat either regular (~27 mg/egg, $n$=19) or high-DHA (~135 mg/egg, $n$=18) eggs (up to 1 dozen per week) during the last trimester of pregnancy. A third group of pregnant women, who indicated in the initial interview that they routinely ate few if any eggs, was included as a non-randomized group ($n$=16). Women in all groups consumed a range of eggs, and, consequently, there was a range of DHA intake from 50 mg/day (obtained from regular diet without eggs) to ~1700 mg/day. Blood was drawn from mothers at enrollment and delivery, and blood was drawn from the cord to determine newborn DHA status at birth. Lipids from plasma and RBC were extracted with chloroform/methanol (2:1; vol/vol) and analyzed by GLC for fatty acid composition. We have already reported that at birth the maternal plasma triglyceride (TG) and total phospholipid (PL), and the RBC PL DHA levels (% wt/wt) did not differ significantly between the treatment groups despite large differences in DHA intake (245.6 and 1445.6 mg/study week). However, the total DHA intake/day (from diet and eggs) was significantly correlated with maternal plasma TG, PL and RBC PL DHA at birth when controlled for weeks in the study ($r$ = 0.475; $r$ = 0.350 and $r$ = 0.294, respectively). Total DHA intake also correlated with the baby plasma PL DHA levels ($r$ = 0.247; $P$ = 0.049). In turn, maternal DHA status at birth (positively) and gravidity (negatively) accounted for 10–39% of the variability in infants' DHA status at birth. Maternal DHA at birth was explained mainly by maternal DHA status at enrollment and dietary DHA intake, which together accounted for 20% (TG), 47.3% (Plasma PL) or 34% (RBC PL) of the variability in maternal DHA at birth. However, maternal DHA at enrollment was the stronger predictor of DHA levels in plasma and RBC PL at delivery. Conclusion: It is important to know and control for prior maternal DHA status in studies of maternal DHA supplementation that test the influence of DHA on outcomes of pregnancy and infant development. ■ Essential Fatty Acids in Maternal and Newborn Phospholipids from a Primarily African American Population in the United States. C.M. Smuts[1], M.I. Huang[2], D. Mundy[3], and S.E. Carlson[2], [1]Medical Research

Council, Tygerberg, South Africa, [2]University of Kansas Medical Center, Kansas City, KS, [3]University of Missouri–Kansas City, Kansas City, MO.

Reports from The Netherlands have established characteristics of maternal and cord blood as well as umbilical arterial and venous vessel wall phospholipid (PL) fatty acids. The purpose of this study was to compare those data to results from a group of predominantly African American, lower SES women from Missouri (USA) who ate a range of DHA (50 to 1620 mg DHA/wk, Block Food Frequency Questionnaire, 24–28 wks gestation) and delivered at term ($n$=39). The women were the first to deliver from a larger group enrolled to study relationships of dietary DHA intake to later DHA status and pregnancy outcome. At delivery, cord and maternal venous blood were obtained and the cord arterial and venous vessel walls were isolated. Lipids from maternal and cord plasma, as well as from umbilical artery and vein vessel walls, were extracted with chloroform/methanol (2:1; vol/vol) and PL isolated and transmethylated ($BF_3$). FAME were analyzed by GLC with an SP-2560 100 meter capillary column. PL fatty acids expressed as g/100 g are shown below. The U.S. women and infants were compared to the range of means from two analogous studies in The Netherlands (*Early Hum. Dev. 24*, 239–248, 1990; *Eur. J. Clin. Nutr. 51,* 232–242, 1997). The mean (SD) maternal age, gestational age at delivery and weights of infants at birth were 19.8 (3.3) years, 39.3 (1.2) weeks, and 3149 (442) g, respectively, in the U.S. group compared with 27–29 years, 40.0–40.2 weeks and 3333–3451 g in The Netherlands groups. For PL fatty acid composition of mother and cord plasma, and the walls of umbilical vessels see table.

| | Mother at birth | | Cord venous blood | |
|---|---|---|---|---|
| | USA | Netherlands | USA | Netherlands |
| 18:2n-6 | 17.3(3.2) | 20.7–23.1 | 7.2(2.1) | 7.3–7.8 |
| 20:4n-6 | 12.8(1.9) | 8.7–9.4 | 21.0(2.0) | 17.1–19.8 |
| 22:6n-3 | 4.4(1.1) | 3.8–3.9 | 6.9(1.5) | 6.5–6.7 |
| ∑n-6 | 40.1(.18) | 34.5–36.8 | 37.6(2.1) | 32.2–35.6 |
| ∑n-3 | 5.3(1.2) | 5.1–5.7 | 7.5(1.7) | 7.3–8.6 |
| ∑n-7≠n-9 | 10.1(1.2) | 13.0–15.7 | 8.6(1.5 | 12.0–15.2 |

| | Vessel arterial wall | | Vessel venous wall | |
|---|---|---|---|---|
| | USA | Netherlands | USA | Netherlands |
| 18:2n-6 | 1.5(0.4) | 1.1–1.9 | 2.5(0.6) | 1.8–2.8 |
| 20:4n-6 | 15.6(2.9) | 11.4–13.6 | 19.8(2.9) | 15.9–18.0 |
| 22:6n-3 | 6.0(1.3) | 4.7–5.3 | 4.7(1.1) | 4.5–5.2 |
| ∑n-6 | 28.3(3.9) | 21.5–22.4 | 34.7(3.8) | 29.2–30.6 |
| ∑n-3 | 6.6(1.2) | 5.2–5.6 | 5.1(1.2) | 5.3–5.5 |
| ∑n-7+n-9 | 19.1(4.0) | 23.5–28.1 | 12.4(2.7) | 16.1–19.4 |

Compared to The Netherlands, USA mothers were much younger, delivered ~1 wk earlier and had infants who were appropriately lighter given an anticipated fetal gain of 30 g/day toward the end of gestation. Despite these differences and the differences in fat intake inferred from lower 18:2n-6 and higher 20:4n-6 in maternal plasma PL, cord plasma and vessel PL fatty acids from the USA and The Netherlands were most remarkable for their similarity. Only Σn-7 and n-9 and 20:4n-6 appeared to differ. The former were much lower and the latter somewhat higher in pregnant women from the USA compared to The Netherlands. Supported by OmegaTech, Inc., Boulder, CO.

■ Low Docosahexaenoic Acid in Brain but Not in Liver, Plasma and Red Blood Cells in Newborn Zellweger Syndrome Mouse. H.-M. Su[1], A.B. Moser[1], H.W. Moser[1], and P.L. Faust[2], [1]Kennedy Krieger Institute, Johns Hopkins Medical Institutions, [2]Columbia University.

Zellweger syndrome is a genetic peroxisomal biogenesis disorder. Peroxisomal β-oxidation plays an important role in the catabolism of very long chain saturated fatty acids, and synthesis of docosahexaenoic acid (DHA, 22:6n-3). We report the fatty acid profiles in newborn, 5, 11, and 13 days old PEX2 peroxisome assembly gene knockout mice, compared with their control littermates. The PEX2 -/- is a model of human Zellweger syndrome. Whole brain, liver, plasma, and red blood cell (RBC) were collected. Lipids were extracted by the Folch method, and fatty acid composition was determined by gas chromatography. At birth, DHA was reduced in the PEX2 -/- brain (10%" vs. 14%"), but normal in RBC (9%"), and, surprisingly, higher than control in plasma (11%" vs. 6%") and liver (14%" vs 12%"). In 5, 11, and 13 days old mice, the DHA was low in all tissues. Ratio of C26:0/C22:0 was higher in PEX2 -/- brain, liver, plasma, and RBC, compared to control littermates at all ages. Plasmalogens were less than 1%" of control in PEX2 -/- brain and RBC at all ages. The brain nervonic acid (24:1n-9) was normal in the newborn and 5-day-old PEX2 -/- mice, and below normal thereafter. Findings in the brain of the PEX2 -/- mouse model in general parallel those in human Zellweger syndrome.

Key Words: DHA, Zellweger Syndrome

■ Dietary n-3 Fatty Acid Alters Rhodopsin Function of Developing Retina. M. Suh and M.T. Clandinin, University of Alberta, Edmonton, Alberta, Canada.

The effect of diets differing in n-3 fatty acid composition on fatty acid content, rhodopsin content, rhodopsin phosphorylation, and rhodopsin regeneration in retina was investigated. Weanling rats were fed diets containing 20% (w/w) fat with either high (5% w/w) DHA or low (1% w/w) n-3 fatty acid without DHA. After 6 wks of feeding, half of the animals in each group were exposed to 48 hrs of continuous light at 850 lux or were kept in complete darkness. After light exposure, animals fed a high n-3 fatty acid diet showed reduction in 22:6n-3 as well as in n-6 and n-3 fatty acid from 24 to 34 carbons (VLCFA) in PC and PS. Diet low in n-3 fatty acid increased rhodopsin content and rhodopsin phosphorylation compared to diet in high n-3 diet. However, low n-3 fatty acid diet caused greater rhodopsin loss after light exposure, resulting in less phosphorylation. Rhodopsin in animals fed a high n-3 fatty acid diet disappeared in a relatively short time with bleaching. Rhodopsin regeneration *in vitro* was increased by feeding a high n-3 fatty acid. It is concluded that the fatty acid composition, rhodopsin content and function in retina is influenced by dietary n-3 fatty acid and light exposure. Feeding a high n-3 fatty diet with DHA may play a role in conserving rhodopsin during or after light exposure.

Key Words: Dietary n-3 Fatty Acid, Rhodopsin, Retina

■ Do Neuronal Receptors Sense Lipid Matrix Curvature Elastic Stress from Polyunsaturated Fatty Acids in Surrounding Lipid Bilayer? W. Teague and K. Gawrisch, National Institute on Alcohol Abuse and Alcoholism. Rockville, MD.

Phosphoethanolamine (PE) comprises more than 40% of retinal and synaptisomal membranes and, within these membranes, more than 50% of all fatty acids in PE are the sixfold unsaturated docosahexaenoic acid (DHA). Increased levels of polyunsaturated PE are known to significantly boost the activation of membrane-bound rhodopsin. PE has the tendency to form phases with small area per molecule near the lipid water interface and larger area per molecule near the terminal methyl groups of the hydrocarbon chains. When forced into a lamellar arrangement, such membranes are under considerable curvature elastic stress. We are investigating quantitatively the influence of polyunsaturation on the coefficient of membrane monolayer curvature elasticity for PE. We alter the membrane curvature of purified polyunsaturated phospholipids by the application of osmotic stress on the inverse hexagonal phase state. The parameters of lipid chain packing and membrane free energy are then determined through solid state NMR and diffraction methods. Preliminary results indicate that PE containing polyunsaturated fatty acids has a tendency to form monolayers with increased levels of curvature elastic stress. This suggests a link between the activity of transmembrane proteins and the degree of polyunsaturation of lipid hydrocarbon chains in the retinal and synaptisomal membranes. We propose that a high concentration of DHA in the PE phospholipids of the retinal and synaptisomal membranes facilitates protein structural transitions during receptor activation. Polyunsaturated PE may serve to balance the curvature stress placed on the membrane due to the presence of tilted transmembrane protein helices.

■ PUFA in Pregnancy and Lactation: New Directions. A.C.v. Houwelingen, S.J. Otto, and G. Hornstra, NUTRIM, Dept. Human Biology, Maastricht University.

Pregnancy is accompanied by maternal hyperlipidemia, which might be a physiological adaptation to meet the increased energy demands due to pregnancy and to improve the fetal access to essential fatty acids (EFA). The fetus needs EFA for incorporation into the proliferating membranes, and especially docosahexaenoic acid (DHA, 22:6n-3) for the CNS and the retina. The fetus must obtain its EFA through placental transfer and is, consequently, dependent on the maternal EFA status. Any limitation in the EFA transfer to the fetus may have functional consequences. Therefore, the maternal EFA status in general, and the n-3 EFA status in particular, has to be adequate to ensure optimum conditions for structural and functional tissue maturation.

The course of the maternal EFA status in the very beginning of pregnancy, until the 10th week of gestation, shows an increase in maternal plasma DHA, probably representing an enhanced incorporation of DHA in phospholipids.

In a prospective longitudinal study performed in pregnant Dutch women it was shown that the overall maternal EFA status steadily declines during normal, uncomplicated pregnancy. This holds for the DHA status also. These data were obtained by measurements of the DHA levels from the 10th week of gestation until delivery.

For most EFA levels, normalization after delivery is complete within 32 weeks. The percentages of plasma 20:4n-6 increased, whereas the percentages of DHA decline significantly after delivery. In contrast to the n-6 EFA status, the normalization of the postpartum course of maternal n-3 EFA status differs between lactating and nonlactating women.

To investigate whether the steady decline in the maternal EFA status during pregnancy observed in pregnant Dutch women is a local or general phenomenon, the EFA status of healthy women from The Netherlands, Hungary, Finland, England, and Ecuador was measured during uncomplicated, singleton pregnancies. Although considerable differences between these groups were observed in the maternal EFA status, the change in the absolute as well as relative amounts of the EFA followed a similar course in the five populations during pregnancy. It seems that the reduction in maternal EFA status during pregnancy is a general phenomenon, and is largely independent of differences in dietary habits and ethnic origin. The neonatal EFA profiles reflected the differences found in maternal plasma during pregnancy and at delivery. Correlations were found, particularly between the neonatal and the maternal n-3 EFA status. The functional implications of the pregnancy-associated reduction in the maternal EFA status for the fetal and neonatal development are not obvious and need to be further elucidated. Since strong correlations were found between the maternal and neonatal n-6 and n-3 EFA at birth, maternal supplementation can be expected to influence the EFA status of the infant.

■ The Effects of Dietary *Trans* Fatty Acids Combined with a Marginal Essential Fatty Acid Status During the Pre- And Postnatal Period on Growth, Brain Fatty Acid Composition, and Behavioral Development in B6D2F2 Mice. I. Wauben, H.-C. Xing, D. McCutcheon, and P. Wainwright, University of Waterloo.

The objective of this study was to investigate whether dietary *trans* fatty acids (TFA) during the pre- and postnatal period would exacerbate the effects of marginal essential fatty acid (EFA) status on growth, brain long-chain polyunsaturated fatty acids (LC-PUFA), and behavioral development in B6D2F2 mice. Pregnant B6D2F1 females were randomly assigned to one of three diets: Marginal EFA (mEFA) plus 22% *trans* 18:1 (mEFA+TFA); mEFA diet; and control diet (CON). The total 18:1 contents in all diets were similar. The offspring were weaned and maintained on the same diets. Sensory and motor development were assessed at d12, and one male from each litter was tested on acquisition and reversal learning in a T-water maze at 7 weeks. Brains were excised and the phosphatidyl-ethanolamine (PE) and phosphatidylcholine (PC) fractions were analyzed for LC-PUFA. mEFA and mEFA+TFA reduced growth and brain weight compared to CON, but did not differ from each other. As expected, mEFA and mEFA+TFA reduced docosahexaenoic acid [DHA (22:6n-3)] and increased 22:5n-6 concentrations in brain PC and PE compared to CON, but again did not differ from each other. Motor and sensory development were not significantly affected by either mEFA or mEFA+TFA compared to CON. Reversal learning in the T-water maze, however, was significantly slower in mEFA+TFA compared to mEFA, and both were slower compared to CON. These findings suggest that TFA do not exacerbate the effects of mEFA on growth or brain LC-PUFA. However, possible long-term effects of dietary TFA on behavioral development and neural function should be investigated in future studies.

■ Perinatal Omega-3 Status Affects Adult Blood Pressure, Body Fluid Homeostasis, and Retinal Function. H.S. Weisinger[1], R.S. Weisinger[2], A.J. Vingrys[3], J.A. Armitage[2,3], P. Burns[2], and A.J. Sinclair[1], [1]RMIT University, [2]Howard Florey Institute of Experimental Physiology and Medicine, [3]University of Melbourne.

The omega-3 fatty acid, docosahexaenoic acid (DHA) is the most prevalent lipid in the nervous system, comprising up to 7% of the dry weight of the brain grey matter and retina. This study investigated the importance of perinatal omega-3 supply in the control of blood pressure, osmotic homeostasis and retinal function in adult Sprague-Dawley rats. Animals raised on an omega-3 deficient diet had higher blood pressure, decreased retinal function and affected osmotic homeostasis, despite subsequent restoration of tissue DHA levels. Our findings indicate that inadequate levels of DHA in the peri-natal period may result in hypertension later in life, possibly as a result of altered osmotic control.

■ Efficacy of Dietary Triglyceride and Phospholipid Arachidonic Acid for Tissue Accretion in Primate Neonates. V. Wijendran[1], G.Y. Diau[1], M.C. Huang[1], G. Boehm[2], G. Sawatzki[2], G. Kohn[2], P.W Nathanielsz[1], and J.T. Brenna[1], [1]Cornell University, Ithaca, NY, [2]Numico Research Group, Germany.

We measured the relative and absolute accretion of dietary arachidonic acid (AA) as a component of phosphatidylcholine (PC) or as triglyceride (TG) in a long-chain polyunsaturate (LCP)-containing formula using $^{13}C$ tracers in baboon neonates. Term neonates were delivered by Caesarean section and immediately placed on formula containing the LCP AA and docosahexaenoic acid, with an n-6/n-3 PUFA ratio of about 10:1. In formula, the fraction of AA in TG was 92% with the remaining 8% in phospholipid (PL). [U-$^{13}C$]-AA (AA*) was chemically synthesized at the *sn*-2 position in either TG or PC, with unlabeled palmitic acid in the remaining positions. TG-AA* ($n$=3) or PC-AA* ($n$=4) was given once orally at 18–19 days of age. Tissues were collected 10 days post-dose, and isotopic enrichment was measured using high-precision isotope ratio mass spectrometry. Results are shown in the Table. As a percentage of dose, AA incorporation from PL-AA was significantly greater than from TG-AA for liver and brain. However, because of the predominance of TG in formula, the total tissue AA accretion was greater from TG-AA expressed by weight. Overall, we estimate that 3.2, 2.3, and 0.002% of dietary AA was incorporated in the liver, brain, and retina, respectively. We conclude that (i) dietary AA as a component of PC is more efficiently incorporated into tissues than AA contained in TG, and (ii) in this fat blend, with a similar TG-AA/PL-AA ratio as human milk, about 5.6-fold more TG-AA appears in tissues compared to PL-AA.

■ The Effect of DHA on Growth and Development of Newborn Rat Cerebral Neurons. J. Zhao[1] and F. Wang[2], [1]Institute of Health and Environment Medicine, [2]Institute of Basic Medical Science.

Docosahexaenoic acid (DHA) normally accounts for greater than one-third of the total fatty acids of the brain gray matter and the retina of the eye. Animal and clinical experiments study have shown that DHA is essential for functional integrity of the visual process, and there is an

impairment of learning ability in rats reared on DHA-deficient diets. We investigated the results of DHA on cellular level. Objective: To study the effects of DHA on the growth and development of cerebral neurons. Methods: Primary cultures of cerebral neurons from newborn rats make out *in vitro* by using serum-free medium (Neurobasal Medium, 1%N2, 2% B27, all were purchased from Gibco). Cells were divided into two groups, experimental and control. DHA (99% cell culture tested, Sigma) was added to the experimental group. After the neurons were cultured, the morphological states of the neurons were investigated. The positive rate of 3-(4,5-dimethythiazol-2yl)-2,5-diphenyl tetrazolium-bromide (MTT), Neurone specific enolase (NSE) and protein value were measured using immunohistochemical method. Results: Both the survival of cells and the outgrowth of neurites were increased by DHA. In the presence of DHA, the diameter and volume of neurons (see Table 1) as well as the content of protein in the cells and the activity of NSE and MTT were markedly increased in image analysis. Conclusion: It is suggested that DHA might play a promotive role in the growth and development of cerebral neurons.

# Mixed-Chain Phospholipids: Structures and Chain-Melting Behavior

**Ching-hsien Huang*,[1]**

Department of Biochemistry and Molecular Genetics, University of Virginia School of Medicine, Charlottesville, Virginia 22908

**ABSTRACT:** It has long been established that diacyl phospholipids isolated from animal cell membranes are predominantly of a mixed-chain variety, meaning that the *sn*-1 and *sn*-2 acyl chains are saturated and unsaturated acyl chains, respectively. In general, monoenoic and dienoic acids are found in the *sn*-2 acyl chain of phosphatidylcholine (PtdCho), whereas polyenoic acids are in phosphatidylethanolamine (PtdEth). These unsaturated chains contain only *cis*-double bonds, which are always methylene-interrupted. In recent years, the structures and the chain-melting behavior of mixed-chain PtdCho and PtdEth have been systematically studied in this laboratory. Specifically, we have examined the effects of chain unsaturation of the *sn*-2 acyl chain on the phase transition temperature ($T_m$) of many PtdCho and PtdEth by high-resolution differential scanning calorimetry (DSC). The $T_m$ values, for instance, obtained from all-unsaturated mixed-chain PtdEth derived from a common precursor can be grouped together according to their chemical formula to form a $T_m$-diagram. Hence, all the $T_m$ values can be compared simply, systematically, and simultaneously using the $T_m$-diagram. In addition, the energy-minimized structures of mixed-chain phospholipids containing different numbers/positions of methylene-interrupted *cis*-double bonds have been simulated by molecular mechanics calculations (MM). In this review, the results of our MM and DSC studies carried out with various mixed-chain phospholipids are summarized. In addition, we emphasize that the combined approach of MM and DSC yields unique information that can correlate the various $T_m$-profiles seen in the $T_m$-diagram with the structural variation of mixed-chain lipids as caused by the introduction of different numbers/positions of methylene-interrupted *cis*-double bonds.

Paper no. L8846 in *Lipids 36,* 1077–1097 (October 2001).

Diacyl phospholipids are amphipathic lipid molecules that can be found in all cell and organelle membranes. These lipid molecules serve not only as a basic structural component of cell and organelle membranes but also as the precursors in lipid-mediated signal transduction. In animal cells, membrane phospholipids are structurally an extremely diverse group of lipid molecules (Fig. 1) which includes principally phosphatidylcholine (PtdCho), phosphatidylethanolamine (PtdEth), phosphatidylinositol (PtdIns), phosphatidylglycerol (PtdGro), cardiolipin ($Ptd_2Gro$), and phosphatidylserine (PtdSer). Of these various classes, PtdCho and PtdEth are quantitatively the most

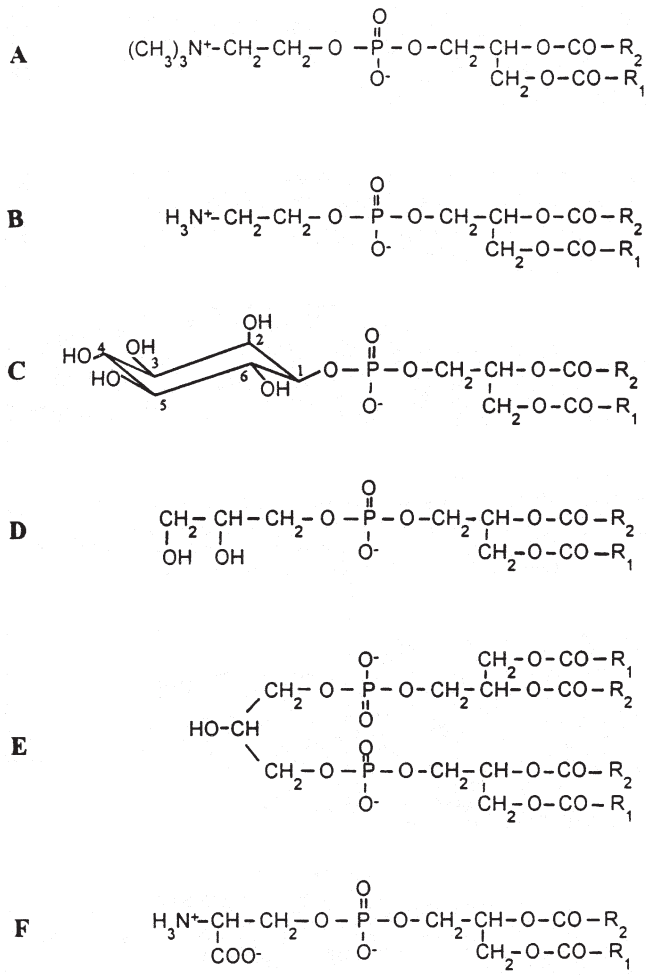

**FIG. 1.** The chemical formulas of diacyl phospholipids that are commonly found in membranes of animal cells. (A) Phosphatidylcholine (PtdCho), (B) phosphatidylethanolamine (PtdEth), (C) phosphatidylinositol (PtdIns), (D) phosphatidylglycerol (PtdGro), (E) diphosphatidylglycerol ($Ptd_2Gro$), and (F) phosphatidylserine (PtdSer). $R_1$ and $R_2$ refer to hydrocarbon chains of fatty acids esterified at carbons 1 and 2 of the glycerol backbone in diacyl phospholipids.

[1]Present address: 2537 Belgreen St., Las Vegas, NV 89135.

Abbreviations: ATS, all-*trans* segment; ΔC, effective chain length difference, as measured in C–C bonds, between the *sn*-1 and the *sn*-2 acyl chains, an indication of chain asymmetry; $\Delta C_{ref}$, effective chain length difference of the reference state [or, effective chain length difference between the *sn*-1 and *sn*-2 acyl chains]; CL, effective chain length of the longer of the two acyl chains; DSC, differential scanning calorimetry; MM, molecular mechanics; N, distance, in C–C bond lengths, between the two carbonyl oxygens of the *sn*-1 acyl chains in a trans-bilayer dimer of C(X):C(Y)PtdCho; PtdCho, phosphatidylcholine; PtdEth, phosphatidylethanolamine; PtdGro, phosphatidylglycerol; $Ptd_2Gro$, cardiolipin (= diphosphatidylglycerol); PtdIns, phosphatidylinositol; PtdSer, phosphatidylserine; $T_m$, main phase transition temperature.

important species. The basic structure of a given class of diacyl phospholipids has customarily been considered to consist of three regions: the polar headgroup, the interfacial region, and the hydrocarbon tail. As shown in Figure 1, the structural features that are common to all classes of phospholipids are the tetrahedrally arranged phosphorus atom in the polar headgroup, the glycerol backbone moiety in the interfacial region, and the long fatty acyl chains in the hydrocarbon tail (1).

In most animal cells, diacyl phospholipids are predominantly of a mixed-chain variety, meaning that the two acyl chains are structurally different. Specifically, the two fatty acids esterified at the *sn*-1 and *sn*-2 positions of the glycerol backbone are originated *in vivo* from saturated and unsaturated fatty acyl-CoA, respectively (2). In particular, the saturated *sn*-1 acyl chain contains an even number of carbon atoms ranging from 14 to 22, predominantly 16 and 18 carbons. The unsaturated *sn*-2 acyl chain may have 16–22 carbons; in addition, it contains 1–6 *cis*-double bonds (Δ-bonds). Interestingly, two or more Δ-bonds in the *sn*-2 acyl chains are always methylene-interrupted, indicating that two neighboring *cis*-double bonds are invariably separated from each other in the *sn*-2 acyl chain by a methylene unit (3). It should be pointed out that (i) methylene-interrupted *cis*-double bonds are the hallmark of membrane lipids originated from animal cells, and (ii) these structural elements are absent in other basic biological molecules such as protein, nucleic acid, and carbohydrate.

Over the last several decades, a wide variety of biochemical and biophysical studies have offered productive approaches for investigating the structure, dynamics, and properties of membrane phospholipids self-assembled, in excess $H_2O$, in the lipid bilayer (4,5). Most of these studies have been concerned with synthetic phospholipids that contain two identical saturated fatty acids. Occasionally, mixed-chain phospholipids containing various polyenoic fatty acids at the *sn*-2 position have been studied (6–12). These studies have been concerned exclusively with mixed-chain PtdCho. In biological membranes, however, mixed-chain PtdCho usually contain one or two Δ-bonds in the *sn*-2 acyl chains. In contrast, polyenoic fatty acids are present most abundantly in mixed-chain PtdEth. Consequently, our current knowledge about the structural and physicochemical properties of naturally occurring phospholipids, particularly mixed-chain PtdEth with saturated *sn*-1 and polyunsaturated *sn*-2 acyl chains, is limited. To approach a broader understanding of the structures/properties of naturally occurring phospholipids, we have in recent years synthesized a large number of mixed-chain phospholipids, including PtdCho, PtdEth, PtdGro, and phosphatidylethanol, that have the same structures as those of naturally occurring phospholipids (13,14). Specifically, these synthesized mixed-chain phospholipids contain the same number and position of methylene-interrupted *cis*-double bonds in the *sn*-2 acyl chain as those that are commonly found in membrane phospholipids of animal cells. Subsequently, we have carried out a systematic and comprehensive study of the structure/chain-melting behavior of the lipid bilayer comprised of the synthesized mixed-chain phospholipids. In these studies, computational molecular mechanics (MM) simulations and differential scanning calorimetry (DSC) are employed. I shall summarize some of our recent studies obtained with mixed-chain PtdCho and PtdEth in this review. These studies give unique information relating the energy-minimized structures of mixed-chain PtdCho and PtdEth to the chain-melting behavior of lipid bilayers composed of the corresponding PtdCho and PtdEth.

## THE STRUCTURE AND PHASE TRANSITION BEHAVIOR OF SATURATED C(X):C(Y)PtdCho

To examine the structure and the chain-melting behavior of the lipid bilayer composed of mixed-chain phospholipids with saturated *sn*-1 and unsaturated *sn*-2 acyl chains, let us first examine the structure and the chain-melting behavior of saturated mixed-chain phospholipids such as C(X):C(Y)PtdCho packed in the lipid bilayer. Here, the abbreviation C(X) designates the total number of carbons in the *sn*-1 acyl chain and C(Y) designates the total number of carbons in the *sn*-2 acyl chain. Both the *sn*-1 and *sn*-2 acyl chains contain only saturated hydrocarbon chains.

Figure 2 shows the energy-minimized structure of C(16):C(16)-PtdCho obtained with MM calculations using Allinger's MM3(92) program (15). The atomic coordinates used as the initial input for MM calculations were derived from experimental data obtained by x-ray diffraction (16). Two conformational features of the acyl chains are revealed by the energy-minimized structure. First, the fully extended *sn*-1 and *sn*-2 acyl chains are aligned in the same direction; however, the zigzag planes of the *sn*-1 and *sn*-2 acyl chains are oriented perpendicularly to each other. Second, although the *sn*-1 and *sn*-2 acyl chains have the same total number of methylene units, there is an effective chain length difference between them. This is due largely to the fact that the *sn*-2 acyl chain is bent 90° at C(2). It should be pointed out that the energy-minimized structure corresponds to the structure of lipid packed in the crystalline state. In the gel-state bilayer, the *sn*-2 acyl chain of C(16):C(16)PtdCho is still bent; however, the effective chain length difference between the *sn*-1 and the *sn*-2 acyl chains is smaller, and, is about 1.5 C–C bond lengths according to neutron diffraction measurements (17). This value can be applied to all saturated identical-chain PtdCho packed in the gel-state bilayer, and we designate it as $\Delta C_{ref}$, the effective chain length difference of the reference state, as shown in Figure 2. The effective chain length of the longer of the two acyl chains (CL) is also introduced in Figure 2. In the case of C(16):C(16)PtdCho packed in the gel-state bilayer, the value of CL is 15 C–C bond lengths, which corresponds to the effective chain length of the *sn*-1 acyl chain.

For saturated mixed-chain C(X):C(Y)PtdCho packed in the gel-state bilayer, three structural parameters are graphically illustrated in Figures 3A and 3B (13). ΔC is the effective chain length difference, in C–C bond lengths, between the *sn*-1 and the *sn*-2 acyl chains. It represents the chain asymmetry. The larger the ΔC value, the greater the asymmetry of the lipid's

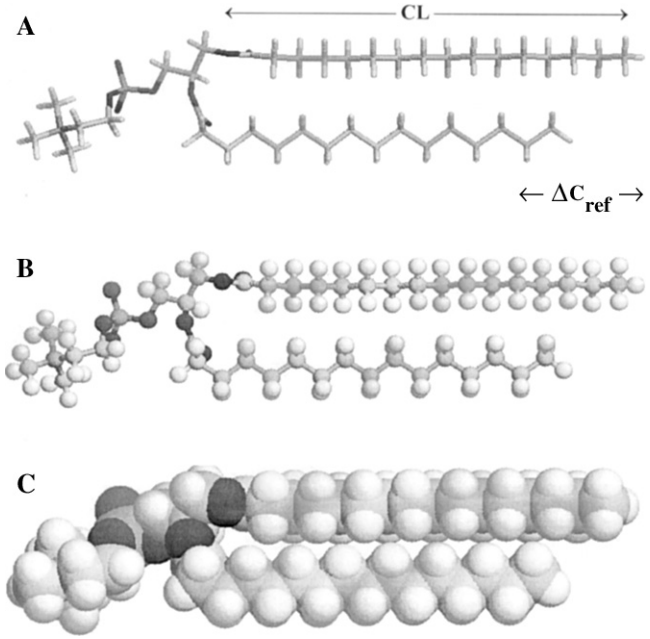

**FIG. 2.** The energy-minimized structure of C(16):C(16)PtdCho obtained by molecular mechanics simulations. This structure corresponds to C(16):C(16)PtdCho packed in the crystalline bilayer. The structural parameter $\Delta C_{ref}$ refers to the effective chain length difference between the *sn*-1 and the *sn*-2 acyl chains, which is about 1.5 C–C bond length for C(16):C(16)PtdCho packed in the gel-state bilayer. This value can, in fact, be applied to all saturated identical-chain PtdCho packed in the gel-state bilayer; hence, $\Delta C_{ref}$ is the effective chain length difference of the reference state. A second structural parameter, CL, refers to the effective chain length of the longer of the two acyl chains. In the case of C(16):C(16)PtdCho packed in the gel-state bilayer, the chain length difference between the two acyl chains, $\Delta C_{ref}$, is 1.5 C–C bond lengths, and the length of the longer chain, CL = X – 1, is 15 C–C bond lengths, or 19 Å, which corresponds to the effective chain length of the *sn*-1 acyl chain. The normalized chain length difference, $\Delta C_{ref}$/CL, is 0.10.

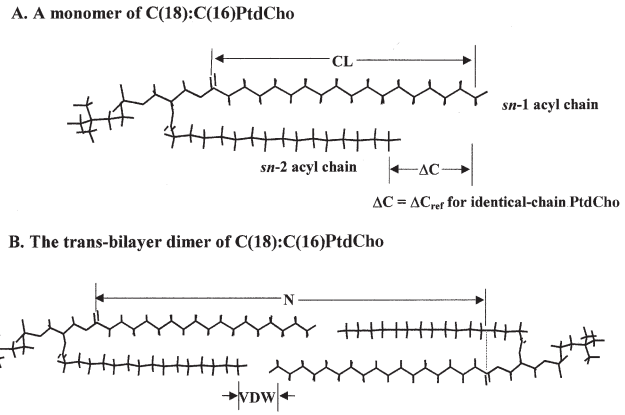

**FIG. 3.** A molecular-graphically depicted diagram illustrating the various structural parameters (ΔC, CL, and N) of C(18):C(16)PtdCho. (A) A monomer of C(18):C(16)PtdCho. ΔC is the effective chain length difference between the two acyl chains along the long molecular axis. The units for ΔC are carbon-carbon bond lengths. $\Delta C_{ref}$ is the ΔC value for identical-chain PtdCho packed in the gel-state bilayer, and $\Delta C_{ref}$ is taken to be 1.5 C–C bond lengths. For C(X):C(Y)PtdCho packed in the gel-state bilayer, $\Delta C = |X - Y + \Delta C_{ref}| = |X - Y + 1.5|$. In the case of C(18):C(16)PtdCho, the value of ΔC is 3.5 C–C bond lengths. CL is the effective length of the longer chain of the two acyl chains, also in units of C–C bond lengths. In the case of C(18):C(16)PtdCho, the value of CL is 17. (B) The trans-bilayer dimer of C(18):C(16)PtdCho with a partially interdigitated packing motif at $T < T_m$, where T is the experimental temperature and $T_m$ is the main phase transition temperature. N is the effective hydrophobic thickness of the dimer, corresponding to the separation distance between the two carbonyl oxygens of the *sn*-1 acyl chains in the two opposing leaflets of the bilayer. VDW is the van der Waals contact distance between the two opposing methyl termini in the bilayer interior, and is assumed to be 3 C–C bond lengths in the gel-state bilayer. The structural parameter N is related to X and Y in C(X):C(Y)PtdCho as follows: N = (X – 1) + VDW + (Y – 2.5) = X + Y – 0.5. For the gel-state bilayer of C(18):C(16)PtdCho, the value of N is 33.5 C–C bond lengths.

acyl chains. The second structural parameter, CL, has the same meaning as that illustrated for C(16):C(16)PtdCho shown in Figure 2. The distance N, in C–C bond lengths, between the two carbonyl oxygens of the *sn*-1 acyl chains in a trans-bilayer dimer of C(X):C(Y)PtdCho is introduced in Figure 3B. N represents the effective hydrocarbon-core thickness of the lipid bilayer composed of C(X):C(Y)PtdCho. These three structural parameters, in C–C bond lengths, are related to X and Y in C(X):C(Y)PtdCho as follows (13):

$$\Delta C = |X - Y + \Delta C_{ref}| \quad [1]$$

$$CL = (X - 1) \quad [2]$$

$$N = X + Y - 0.5 \quad [3]$$

The crystalline structure of C(X):C(Y)PtdCho, as represented by C(18):C(16)PtdCho, is drawn in Figure 3 for the purpose of simplicity. All three structural parameters are actually defined for C(X):C(Y)PtdCho packed in the gel-state bilayer with a partially interdigitated packing motif. In this packing motif, the methyl terminus of the *sn*-1 acyl chain of one lipid molecule in the bilayer is juxtaposed with the methyl end of the *sn*-2 acyl chain of another lipid molecule from the opposing bilayer leaflet as shown diagrammatically in Figure 3B. It is well established that C(X):C(Y)PtdCho with ΔC/CL < 0.42 can, in excess water, self-assemble into the partially interdigitated bilayer at $T < T_m$ where T = experimental temperature and $T_m$ = main phase transition temperature (18).

Figure 4 shows some representative DSC curves obtained with aqueous lipid dispersions prepared from a homologous series of mixed-chain C(X):C(Y)PtdCho. These mixed-chain lipids share a common value of (X + Y), which corresponds to 32 carbons (19). Hence, the N value for the gel-state bilayer prepared from each lipid species of this lipid series is identical. However, the ΔC value obtained with each lipid in this series increases stepwise by 1.0 C–C bond length as the lipid species changes progressively from C(15):C(17)PtdCho to C(10):C(22)PtdCho. Figure 4 clearly shows that the $T_m$ exhibited by C(X):C(Y)PtdCho with ΔC/CL < 0.42 decreases steadily as the value of ΔC increases. This figure demonstrates that, for a series of C(X):C(Y)PtdCho packed in the partially interdigitated bilayer, $T_m$ decreases with increasing ΔC value when N is held constant. In addition, for a homologous series of saturated identical-chain PtdCho (ΔC/CL < 0.42), ranging from C(13):C(13)PtdCho to C(21):C(21)PtdCho, with a common ΔC

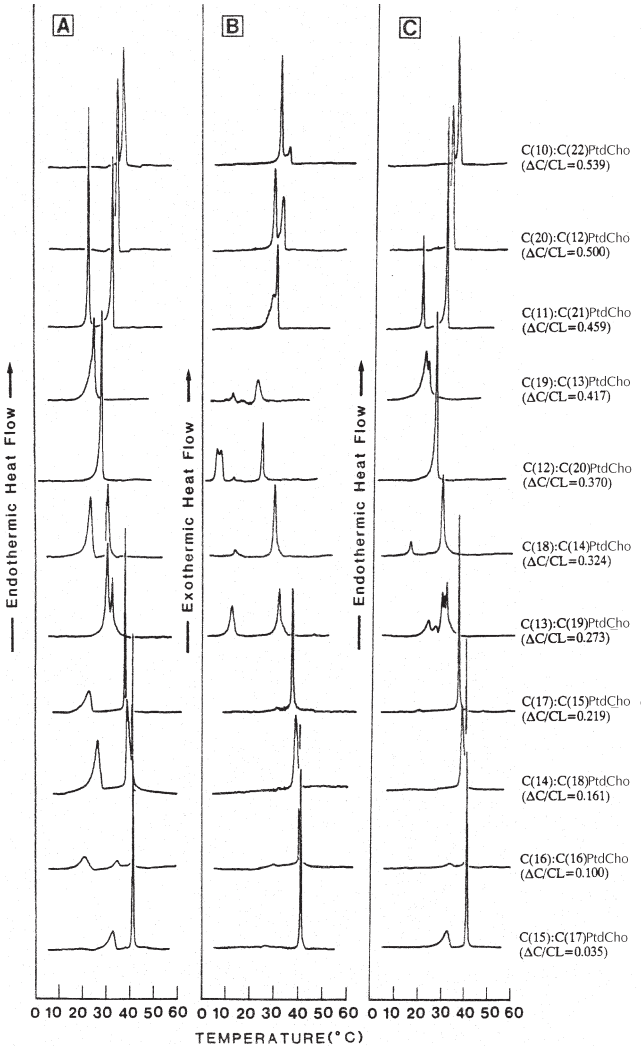

**FIG. 4.** The differential scanning calorimetry (DSC) curves obtained with aqueous lipid dispersions prepared from a homologous series of mixed-chain C(X):C(Y)PtdCho. These mixed-chain lipids share a common value of (X + Y), which corresponds to 32 carbons. The ΔC/CL represents the normalized chain length difference. (A) The initial heating scans, (B) the first cooling scans, and (C) the second heating scans. The DSC scans were obtained from a Microcal MC-2 microcalorimeter (Microcal, Inc., Northampton, MA). Scan rate: 15°C/h. Prior to DSC experiments, each lipid sample was incubated at 0°C for a minimum of 24 h. For abbreviations see Figures 1 and 3.

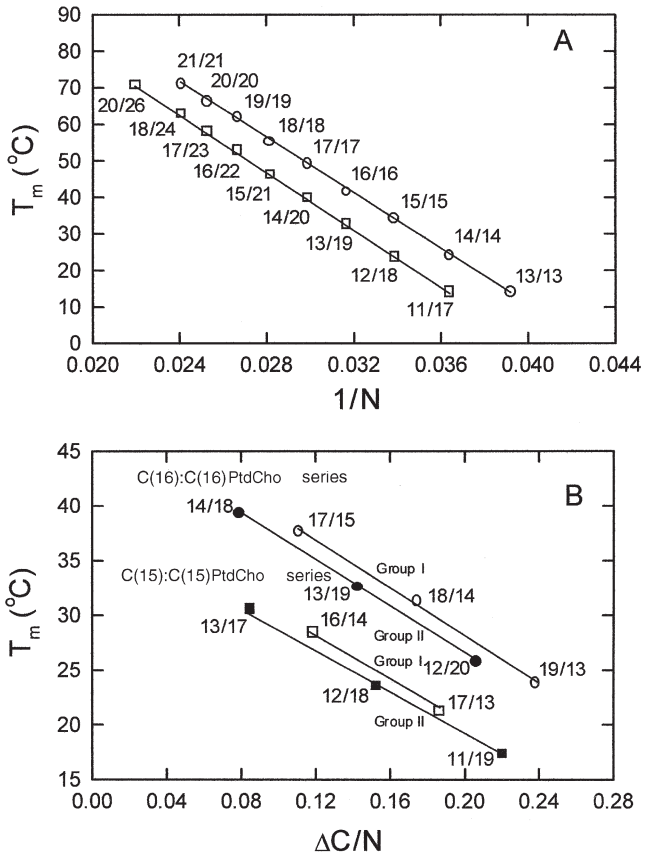

**FIG. 5.** Plots of the phase transition temperature, $T_m$, vs. the structural parameter(s). (A) $T_m$ values from two series of saturated PtdCho with ΔC = 1.5 and 4.5, respectively, are plotted against 1/N. The numerical numbers of X/X or X/Y next to the data points denote the numbers of carbons in the *sn*-1/*sn*-2 acyl chains of the corresponding phosphatidylcholine species. (B) $T_m$ values of lipids with identical N values vs. ΔC/N. The data (○,●) connected by the top two lines were obtained with saturated PtdCho having a constant N value of 31.5 C–C bond lengths. These lipids thus belong to the C(16):C(16)PtdCho series. The data (□,■) in the bottom two lines were obtained with saturated PtdCho having a constant N value of 29.5 C–C bond lengths; hence, these lipids belong to the C(15):C(15)PtdCho series. Within each series, lipids with an effective longer *sn*-1 acyl chain length (X ≥ Y – 1.5) are grouped into Group I lipids, and those with longer effective *sn*-2 acyl chain (Y – 1.5 > X) are classified as Group II lipids.

value of 1.5 C–C bond lengths, the $T_m$ value exhibited by the lipid dispersion prepared individually from them decreases as the value of 1/N increases (Fig. 5). Moreover, the same trend is observed in Figure 5 for another homologous series of mixed-chain C(X):C(X + 6)PtdCho (ΔC/CL < 0.42) with a common ΔC value of 4.5 C–C bond lengths (20). Based on DSC data presented in Figure 5 and elsewhere, the $T_m$ value of C(X):C(Y)-PtdCho (ΔC/CL < 0.42) with X ≥ Y can be related to the structural parameters ΔC and N in a simple first-order manner (13):

$$T_m = 161.75 - 3706.06\,(1/N) - 278.75\,(\Delta C/N) + 239.94\,[\Delta C/(N + \Delta C)] \quad [4]$$

A similar equation (Eq. 5) is also derived for C(X):C(Y)-PtdCho with X < Y (13):

$$T_m = 155.11 - 3534.31(1/N) - 245.78(\Delta C/N) + 199.04\,[\Delta C/(N + \Delta C)] \quad [5]$$

These two equations not only show the fundamental antagonistic effect between N and ΔC in determining the $T_m$ value but also can be employed to predict the $T_m$ value for C(X):C(Y)PtdCho with ΔC/CL < 0.42. The prediction of $T_m$ value based on the chemical formula of C(X):C(Y)PtdCho is possible because the N and ΔC values can be readily calculated from X and Y (Eqs. 1–3). Predicted $T_m$ values ($n$ = 207) for various C(X):C(Y)PtdCho, obtained on the basis of Equations 4 and 5, are presented in Table 1, along with 54 $T_m$ values observed calorimetrically. Clearly, the predicted and the observed $T_m$ values agree well. An important consequence of this excellent agreement is that the number of carbon atoms in the *sn*-1 (or *sn*-2) acyl chain, X (or Y), can be determined

[a]Experimental $T_m$ values are also indicated in boldface italic. Predicted $T_m$ values are calculated in part from Equation 4 (see text) and the relationships between ΔC, N, X, and Y as indicated in Figure 3. Abbreviations: PtdCho, phosphatidylcholine; $T_m$, main phase transition temperature; ΔC, effective chain length difference as measured in C–C bonds; N, distance, in C–C bond lengths, between the two carbonyl oxygens of the *sn*-1 acyl chains in a trans-bilayer dimer of C(X):C(Y)phosphatidylcholine; X, total carbons in the *sn*-1 acyl chain; Y, total carbons in the *sn*-2 acyl chain.

accurately provided that the $T_m$ value and the number of carbon atoms in the *sn*-2 (or *sn*-1) acyl chain, Y (or X), of C(X):C(Y)PtdCho are known. This important relationship will be reiterated later when I discuss the structure/chain-melting behavior of mixed-chain lipids with saturated *sn*-1 and unsaturated *sn*-2 acyl chains.

## THE STRUCTURES AND THE PHASE TRANSITION BEHAVIOR OF PtdCho AND PtdEth WITH SATURATED *sn*-1 AND MONOUNSATURATED *sn*-2 ACYL CHAINS [C(X):C(Y:1$\Delta^n$)PtdCho AND C(X):C(Y:1$\Delta^n$)PtdEth]

The six atoms in the immediate vicinity of a *cis*-double bond, C–CH=CH–C, in a long hydrocarbon chain are coplanar (Fig. 6). Although the rotational flexibility of the *cis*-double bond is highly restricted at physiological temperatures, paradoxically the carbon-carbon single bond preceding or succeeding the *cis*-double bond is rotationally highly flexible, even at –10°C (18). Results of our MM calculations indicate that the carbon-carbon single bond next to the *cis*-double bond prefers to adopt the *skew* ($s^{\pm}$) conformation with torsion angle of about ±110° (Fig. 6). As a result, the most stable structure of a hydrocarbon chain containing a single *cis*-double bond has a twisted boomerang-like conformation with a $s^{\pm}\Delta s^{\pm}$ sequence around the Δ-bond (Fig. 7). Such a twisted boomerang-like conformation, however, is unlikely to be adopted by the *sn*-2 acyl chain in the gel-state bilayer composed of monounsaturated mixed-chain lipids because the all-*trans sn*-1 acyl chain would impose steric constraints on the boomerang-like conformation of the neighboring *sn*-2 acyl chain. Results from our detailed MM calculations indicate that in the presence of an all-*trans sn*-1 acyl chain, the *sn*-2 acyl chain of the monoenoic PtdCho is able to pack favorably in the gel-state bilayer with a kinked crankshaft-like conformation (18,21). Specifically, two parallel chain segments separated by a small kink sequence are observed in this kinked *sn*-2 acyl chain; moreover, these two parallel segments are in close van der Waals contact with the all-*trans sn*-1 acyl chain.

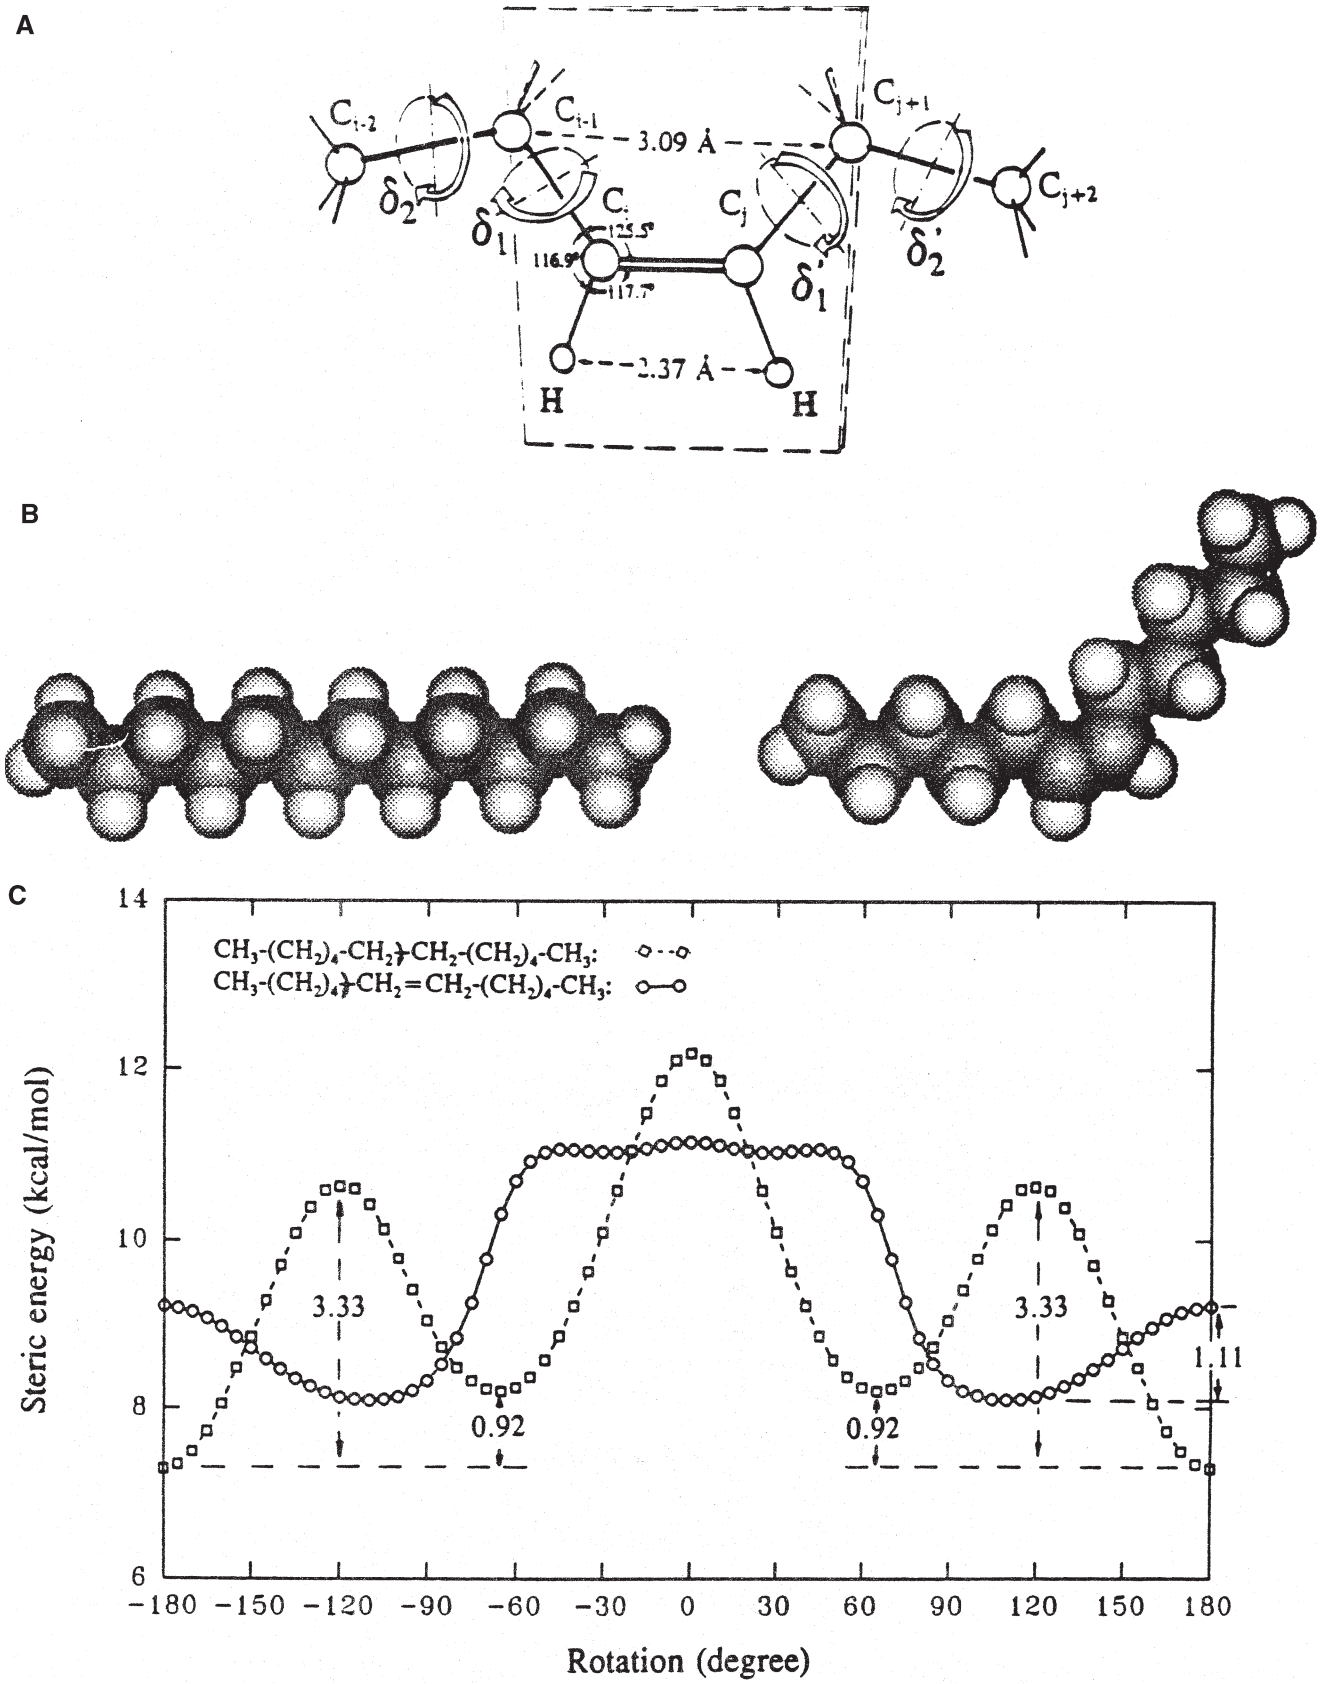

**FIG. 6.** Structure of a *cis*-double bond in a segment of hydrocarbon chain is shown in the top (A). The introduction of a *cis*-double bond into an all-*trans* hydrocarbon chain transforms the linear conformation into a boomerang-like conformation (B). In (C) the energy profiles arising from rotations of a single C(6)-C(7) bond in dodecane (□) and of a single C(4)-C(5) bond in dodecene-6 (○) are shown. Molecular mechanics (MM) calculations were performed with the MM2(85) program (15).

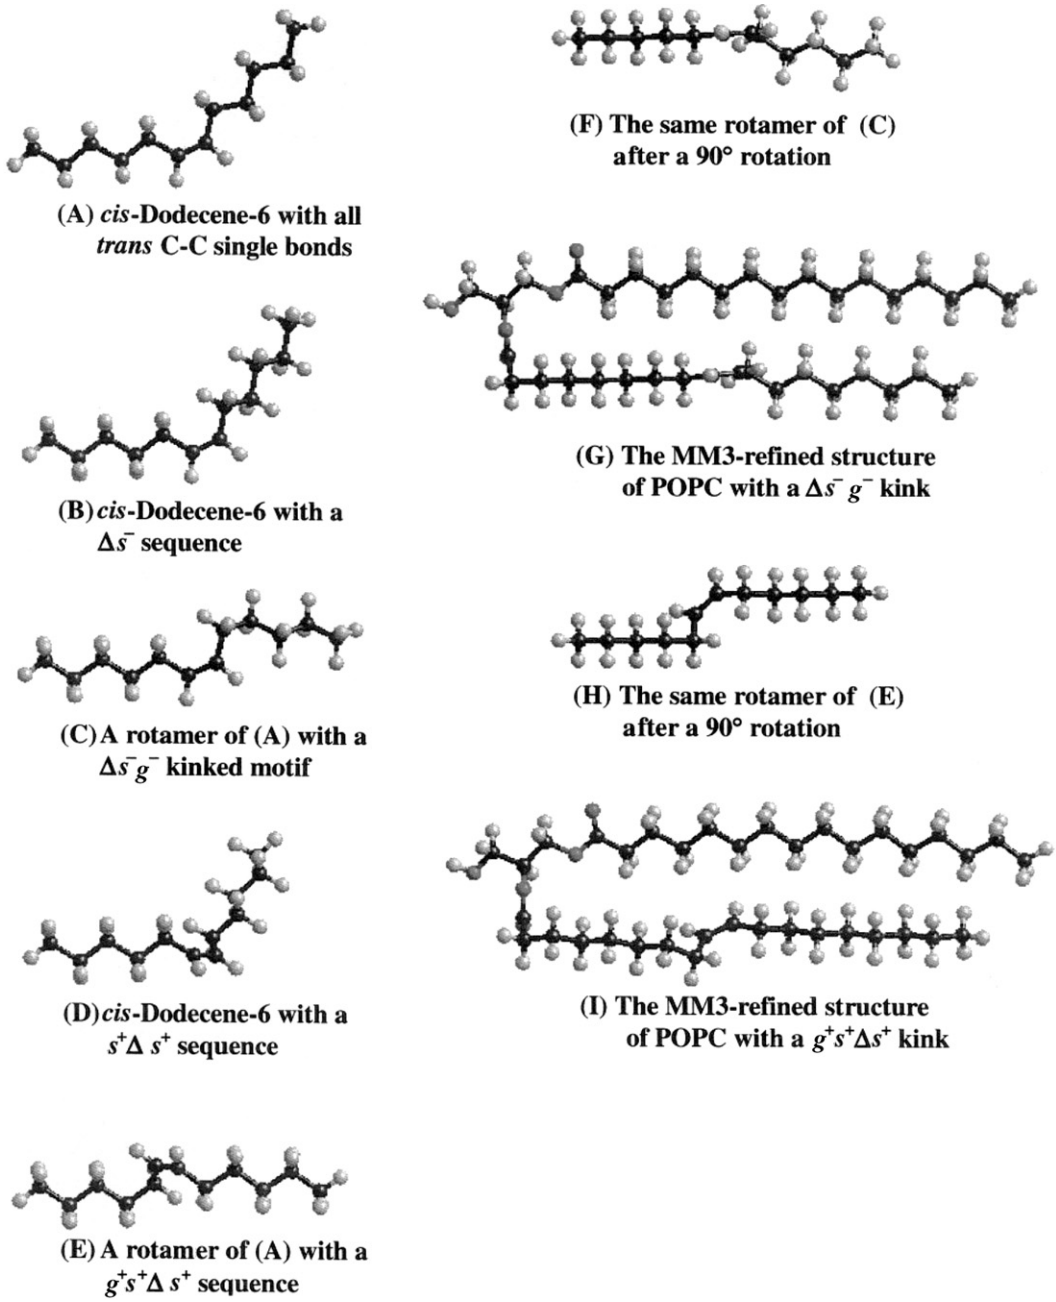

**FIG. 7.** Computer-graphic representations of the hydrocarbon chain with boomerang-like, twisted boomerang-like, and kinked crankshaft-like motifs. Two kinked conformations with identical low-energy for C(16):C(18:1$\Delta^9$)PtdCho as obtained by MM calculations are also shown. POPC, 1-palmitoyl-2-oleoyl-PtdCho; for other abbreviations see Figures 1 and 6.

As a result, such a kinked motif has a low steric energy. As illustrated in Figure 7, a monoenoic hydrocarbon chain with kinked crankshaft-like conformation can be readily obtained by the rotational *trans* → *gauche* isomerizations of the C–C single bond next to the twisted boomerang sequence of $s^{\pm}\Delta s^{\pm}$. However, the overall length of the kinked chain is shortened by 0.8 C–C bond length relative to its saturated all-*trans* counterpart. Two of the kinked crankshaft-like lipid structures obtained with C(16):C(18:1$\Delta^9$)PtdCho, 1-palmitoyl-2-oleoyl-phosphatidylcholine, are also illustrated in Figure 7. Here, the abbreviation C(18:1$\Delta^9$) denotes the *sn*-2 acyl chain with a single *cis*-double bond at the ninth carbon ($\Delta^9$) counting from the carbonyl end. In fact, we have shown by MM calculations that 16 kinked crankshaft-like conformations with a similar low steric-energy may exist normally for C(16):C(18:1$\Delta^9$)-PtdCho at $T < T_m$ (18). Our MM calculations thus indicate that many possible low-energy rotational isomers (rotamers) may be adopted by monounsaturated PtdCho, and these rotamers are likely to interconvert rapidly in the bilayer at $T < T_m$. In addition, these low-energy rotamers share a common structural feature characterized by a kinked crankshaft-like motif.

Examining some representative DSC curves exhibited by lipid bilayers composed of monounsaturated phospholipids demonstrates an interesting point (21,22). In Figure 8, the second DSC heating curves obtained with aqueous dispersions of C(20):C(18)PtdCho, C(20):C(18)PtdEth, C(20):C(18:1$\Delta^9$)-PtdCho, and C(20):C(18:1$\Delta^9$)PtdEth in the presence of 50 mM NaCl, 5 mM phosphate buffer (pH 7.4), and 1 mM EDTA are illustrated (13). A sharp, single endothermic transition with $T_m$ = 75.8°C is observed for C(20):C(18)PtdEth. The introduction of a single $\Delta^9$-bond into the *sn*-2 acyl chain reduces the $T_m$ value of C(20):C(18:1$\Delta^9$)PtdEth to 33.9°C. As shown in Figure 8, this $T_m$-lowering effect of acyl chain monounsaturation is also observed for mixed-chain PtdCho. In particular, the $T_m$ values exhibited by C(20):C(18)PtdCho and C(20):C(18:1$\Delta^9$)PtdCho bilayers are 56.8 and 11.0°C, respectively, showing a marked reduction of 45.8°C in $T_m$ as a single $\Delta^9$-bond is introduced into the *sn*-2 acyl chain of C(20):C(18)PtdCho. Such a $T_m$-lowering effect of acyl chain monounsaturation has been previously observed for PtdCho by other investigators (8,12) but not for PtdEth.

Another distinct characteristic associated with the acyl chain monounsaturation is the $T_m$-lowering effect of acyl chain unsaturation, which is critically dependent on the position of the single *cis*-double bond along the *sn*-2 acyl chain (21). The second DSC heating curves for a series of C(18):C(18:1$\Delta^n$)PtdCho with $n$ = 6, 7, 9, 11, 12, and 13 demonstrate this point (Fig. 9). The minimal $T_m$ is observed when $n$ = 11 or when the *cis*-double bond is positioned near the center of the linear segment of the *sn*-2 acyl chain. Further, the $T_m$ value increases progressively as the *cis*-double bond moves away from $\Delta^{11}$ toward either end of the acyl chain. Specifically, the $T_m$ values of C(18):C(18:1$\Delta^n$)PtdCho with $n$ = 6, 7, 9, 11, 12, and 13 are 24.8, 16.7, 5.6, 3.8, 9.1, and 15.9°C, respectively. As a result, when $T_m$ is plotted against the position of the single *cis*-double bond, a V-shaped $T_m$-profile is seen for the various positional isomers of C(18):C(18:1$\Delta^n$)PtdCho. The second DSC heating curves for C(20):C(20:1$\Delta^n$)PtdCho with $n$ = 5, 8, 11, and 13 are also presented in Figure 9 (21). These data have been extended recently (23). The $T_m$ values of lipid bilayers prepared from C(20):C(20:1$\Delta^n$)PtdCho with $n$ = 5, 8, 11, 13, and 17 are 44.9, 30.6, 19.4, 22.1, and 49.7°C, respectively. Again, a roughly V-shaped $T_m$-profile is observed in the plot of $T_m$ vs. the position of the *cis*-double bond in the *sn*-2 acyl chain for this series of C(20):C(20:1$\Delta^n$)PtdCho (23). Similarly, positional isomers of C(18:1$\Delta^n$):C(18:1$\Delta^n$)PtdCho also display a V-shaped $T_m$-profile in which a *cis*-double bond is present in each of the two acyl chains at the same position (6).

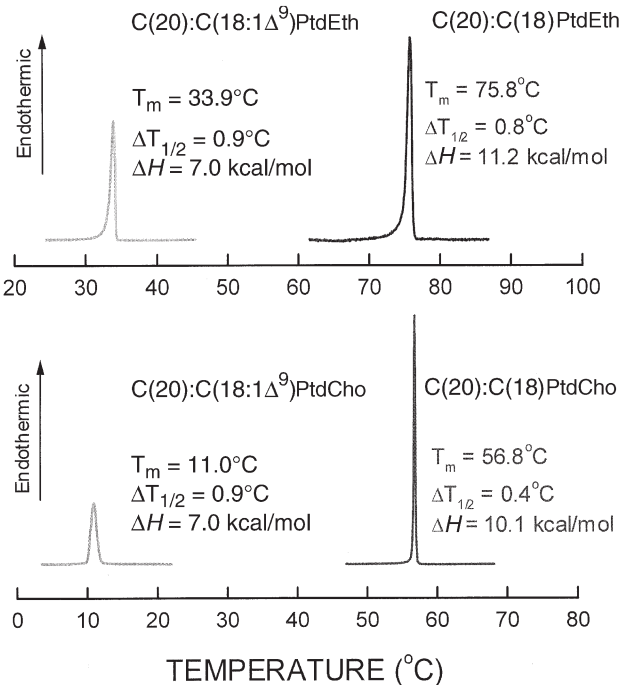

**FIG. 8.** The second DSC heating curves obtained with aqueous dispersions of C(20):C(18)PtdCho, C(20):C(18)PtdEth, C(20):C(18:1$\Delta^9$)PtdCho, and C(20):C(18:1$\Delta^9$)PtdEth. $\Delta T_{1/2}$ represents width of phase transition curve at half-peak height. Scan rate: 15°C/h. Lipid concentration: 3–5 mM. For abbreviations see Figure 1.

Before a molecular model that explains the effects of chain monounsaturation on phospholipids phase transition behavior is presented, let us first examine the energy-minimized structures of some saturated and monounsaturated phospholipids obtained with MM calculations (Figs. 10 and 11). First, compare the monomeric structures of C(18):C(18)PtdCho, C(18):C(17)PtdCho, and C(18):C(18:1$\Delta^{11}$)PtdCho. Clearly, the two acyl chains are more symmetrical, in terms of chain lengths, for C(18):C(18)PtdCho. Quantitatively, the chain-asymmetry parameter, $\Delta C$, is nearly the same for C(18):C(17)PtdCho and C(18):C(18:1$\Delta^{11}$)PtdCho. Based on the relationship between $\Delta C$ and $T_m$ that is known for saturated mixed-chain PtdCho, one would expect the values of $T_m$ exhibited by C(18):C(17)PtdCho and C(18):C(18:1$\Delta^{11}$)-PtdCho to be nearly the same. Yet, the $T_m$ value observed calorimetrically for C(18):C(18:1$\Delta^{11}$)PtdCho is 46.6°C smaller than for C(18):C(17)PtdCho. In comparing the *trans*-dimeric structures of C(18):C(17)PtdCho and C(18):C(18:1$\Delta^{11}$)-PtdCho, the overall *trans*-bilayer thickness is almost indistinguishable, with the structural parameter N being 34.5 and 34.7 C–C bond lengths, respectively. Again, based on the relationship between N and $T_m$ that is known for saturated mixed-chain PtdCho, we would expect a nearly identical value of $T_m$ for these two lipid species. This expectation, however, is not borne out by experimental data as shown in Figure 11. The phase transition behavior observed for unsaturated lipids is thus distinctively different from that of saturated lipids. Therefore, prediction of the chain-melting behavior of unsaturated lipids based solely on the chain-melting behavior of the corresponding saturated lipids cannot be made reliably.

Earlier, it was shown that the $T_m$ value of saturated mixed-chain C(X):C(Y)PtdCho can be quantitatively related to X and Y values (Table 1). Similarly, the value of Y can also be calculated provided that $T_m$ and X are known. The values of $T_m$ and X for C(18):C(18:1$\Delta^{11}$)PtdCho are 3.8°C and 18, respectively. A corresponding saturated mixed-chain PtdCho with a partially interdigitated packing motif can thus be calculated; this fictive

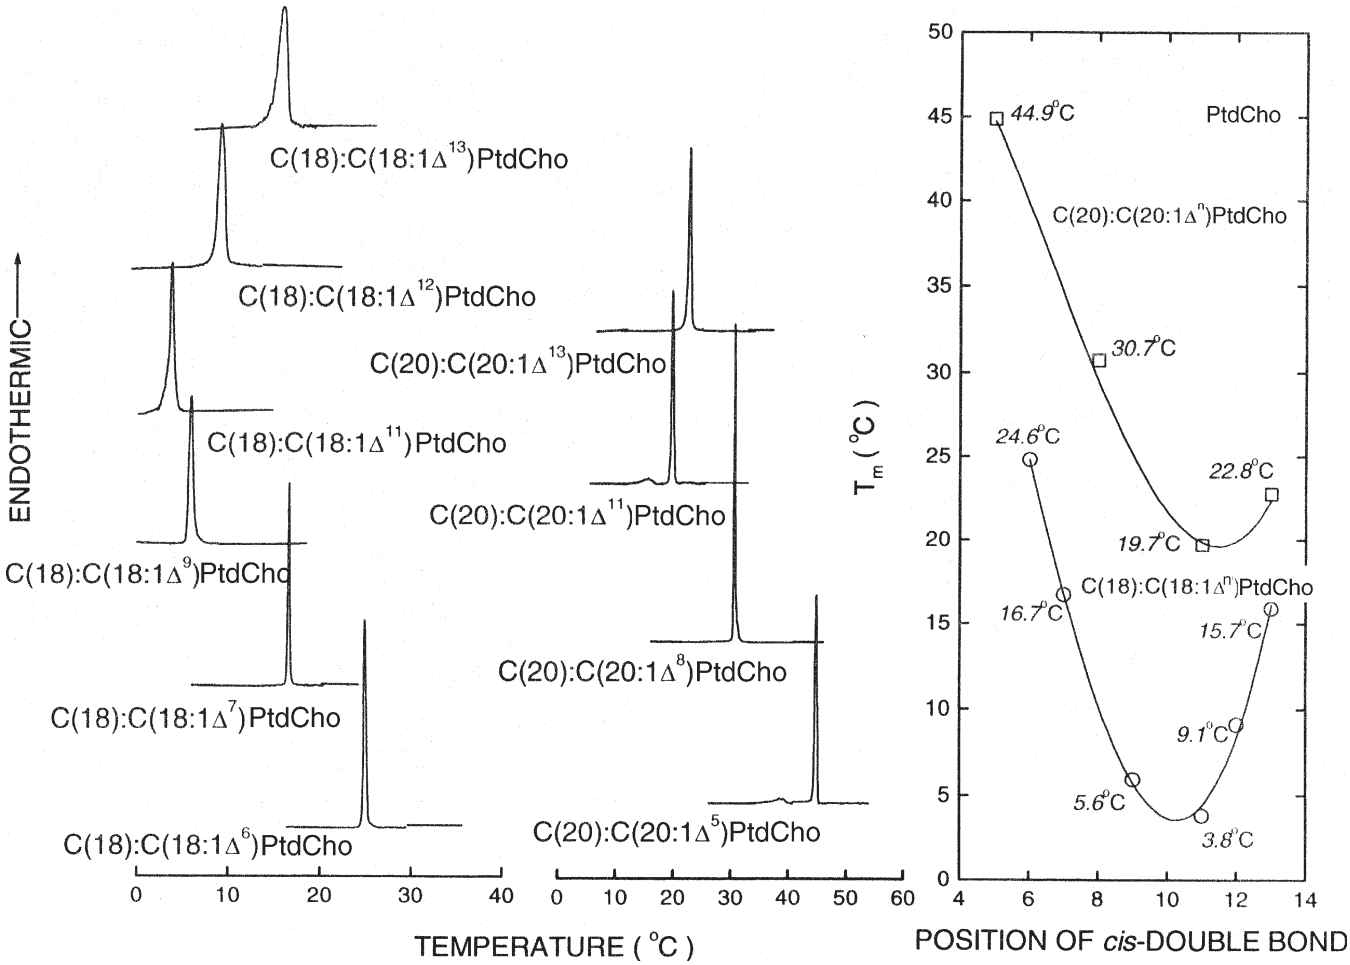

**FIG. 9.** The $T_m$-lowering effect of acyl chain monounsaturation as a function of the position of the single *cis*-double bonds. For abbreviation see Figure 3.

lipid molecule with $T_m$ = 3.8°C is calculated to be C(18):C(11)-PtdCho as illustrated in Figure 12. By comparing the energy-minimized structure of the fictive C(18):C(11)PtdCho with that of C(18):C(18:1$\Delta^{11}$)PtdCho, one can immediately see that the entire length of the *sn*-2 acyl chain of the fictive molecule is virtually identical to the length of the longer upper chain-segment of the kinked *sn*-2 acyl chain in C(18):C(18:1$\Delta^{11}$)PtdCho. At this point, it should be mentioned that the gel-to-liquid crystalline phase transition exhibited by the lipid bilayer at $T_m$ involves fundamentally the rotational *trans* → *gauche* isomerizations of the C–C single bonds in the lipid's acyl chains (24). Based on the energy-minimized structures of the fictive C(18):C(11)PtdCho and C(18):C(18:1$\Delta^{11}$)PtdCho shown in Figure 12, we have proposed a molecular model for monounsaturated phospholipids with the following assumptions (13,21): (i) Monounsaturated lipids are assumed to adopt the kinked crankshaft-like motif at $T < T_m$; hence, the kinked *sn*-2 acyl chain consists of a longer chain-segment and a shorter chain-segment at $T < T_m$. (ii) The short chain-segment is assumed to be largely disordered in the gel-state bilayer due to the presence of appreciable *gauche* bonds at $T \leq T_m$. As a result, this short chain-segment does not contribute significantly to the rotationally disordering process of the *trans* → *gauche* isomerizations of the C–C bonds at $T_m$ (3). (iii) The longer chain-segment in the *sn*-2 acyl chain, at $T < T_m$, is assumed to be composed of *trans* rotamers only and to undergo favorable van der Waals contact interactions with its neighboring all-*trans sn*-1 acyl chains in the gel-state bilayer. Hence, the longer chain-segment in the kinked *sn*-2 acyl chain contributes significantly to the thermally induced chain-melting process at $T_m$.

With the molecular model described above, the drastic $T_m$-lowering effect of acyl chain monounsaturation can be interpreted. Because the short chain-segment is already disordered at $T < T_m$, the total number of *trans* → *gauche* isomerizations of the C–C bonds at $T_m$ is reduced appreciably for a monounsaturated lipid molecule relative to that of the saturated counterpart, leading to a significantly lower $T_m$ value. We can apply the molecular model to predict the V-shaped $T_m$ profile in the plot of $T_m$ vs. the position of the single *cis*-double bond in the *sn*-2 acyl chain. In this molecular model, the longer chain-segment of the kinked *sn*-2 acyl chain is assumed to undergo favorable van der Waals interactions with its neighboring all-*trans sn*-1 acyl chains. The magnitude of this contact interaction depends on the length of the longer chain-segment. When the Δ-bond is positioned at the center of the *sn*-2 acyl chain, the longer chain-segment has a minimal length,

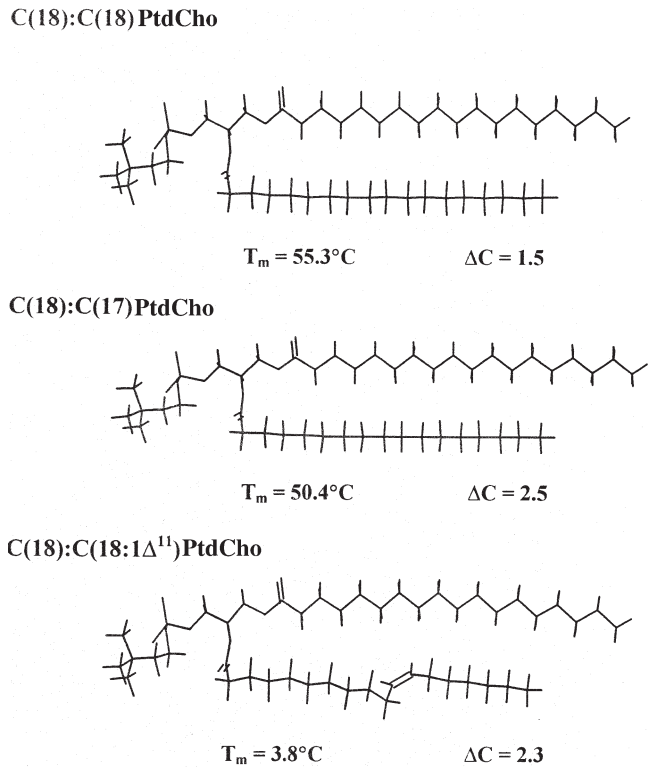

**FIG. 10.** Computer-graphic representations of the energy-minimized structures obtained with the monomers of C(18):C(18)PtdCho, C(18):C(17)PtdCho, and C(18):C(18:1$\Delta^{11}$)PtdCho. For abbreviations see Figure 1.

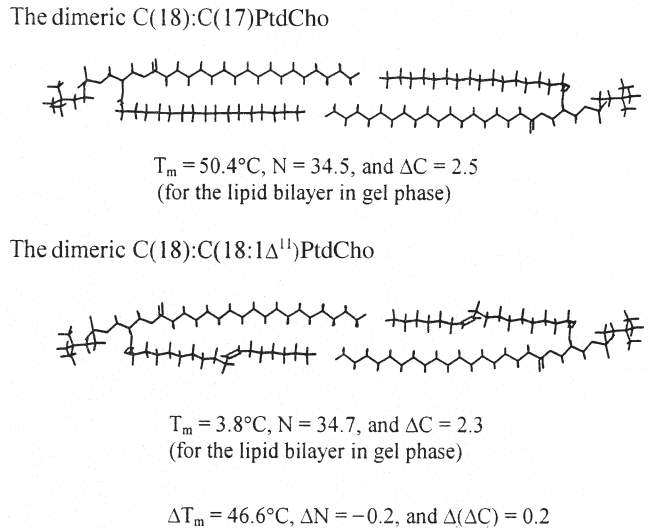

**FIG. 11.** Computer-graphic representations of the energy-minimized structures obtained with the *trans*-dimers of C(18):C(17)PtdCho and C(18):C(18:1$\Delta^{11}$)PtdCho. For abbreviation see Figure 1.

which is almost equal to that of the shorter chain-segment. Consequently, the contact interaction with the all-*trans sn*-1 acyl chain is also minimal. As the Δ-bond moves away stepwise from the chain center toward either end, the length of the longer chain-segment is progressively increased, leading to a proportionally increased van der Waals contact interaction with the all-*trans sn*-1 acyl chain. Because the origin of $T_m$ for the gel-to-liquid crystalline phase transition is largely enthalpic, the $T_m$ can be approximately related to the lateral

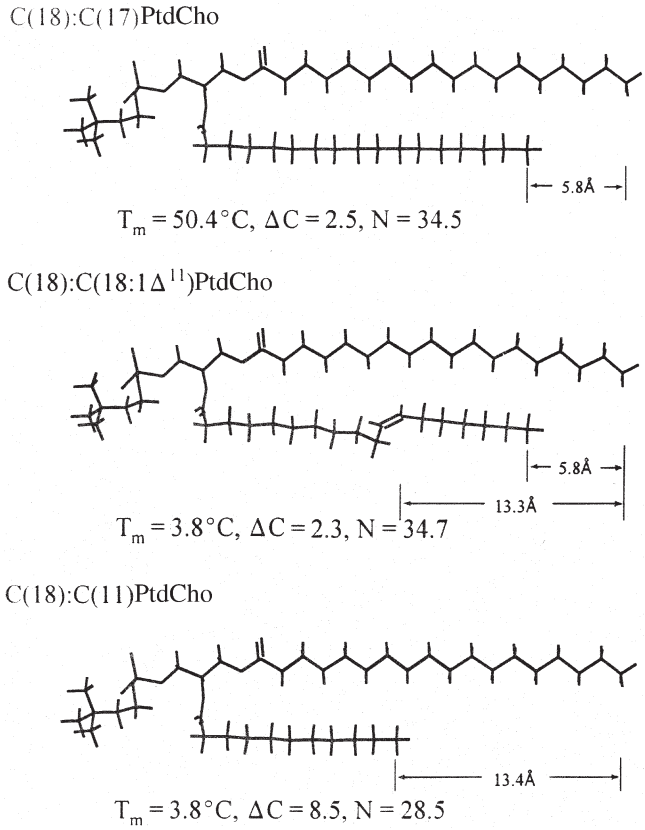

**FIG. 12.** The structure of the saturated fictive PtdCho molecule calculated on the basis of the $T_m$ and X values of C(18):C(18:1$\Delta^{11}$)PtdCho. For abbreviation see Figure 1.

chain-chain contact interaction (13). As a result, the $T_m$ increases as the magnitude of the contact interaction between the *sn*-1 acyl chain and the *sn*-2 acyl chain is increased. Our molecular model thus predicts a V-shaped $T_m$-profile in the plot of $T_m$ vs. the position of the single *cis*-double bond in the *sn*-2 acyl chain, $\Delta^n$, of mixed-chain C(X):C(Y:1$\Delta^n$)PtdCho. Furthermore, the minimal $T_m$ in the V-shaped $T_m$-profile must correspond to the positional isomer of C(X):C(Y:1$\Delta^n$)PtdCho with the Δ-bond positioned at the chain center, because the lateral chain-chain interaction is minimal in this lipid species. Indeed, the $T_m$-profiles observed for the two series of monounsaturated C(18:1$\Delta^n$):C(18:1$\Delta^n$)PtdCho and C(20):C(20:1$\Delta^n$)PtdCho are V-shaped (Fig. 9); in addition, each V-shaped profile is characterized by a minimal $T_m$ corresponding to the anticipated positional isomer.

## THE STRUCTURE AND THE CHAIN-MELTING BEHAVIOR OF PHOSPHOLIPIDS WITH *sn*-1 SATURATED AND *sn*-2 POLYUNSATURATED ACYL CHAINS

As discussed above, the presence of just a single *cis*-double bond in the *sn*-2 acyl chain of a phospholipid molecule is sufficient to exert profound influence on the chain-melting behavior of the lipid bilayer. Now, we shall see how the successive addition of a second, a third, . . . methylene-interrupted *cis*-double bond changes the gel-to-liquid crystalline phase

transition behavior of the lipid bilayer. Specifically, I shall present calorimetric data obtained with mixed-chain PtdEth with saturated *sn*-1 and polyunsaturated *sn*-2 acyl chains, since these lipid molecules are present abundantly in biological membranes of animal cells. Moreover, based on the simple molecular model described earlier for monounsaturated lipids, a more general MM-based molecular model will be described, from which the chain-melting behavior of lipid bilayers composed of polyunsaturated mixed-chain lipids can be rationalized in terms of structural changes of the polyunsaturated acyl chain.

The first and the immediate second DSC heating curves obtained with C(20):C(20)PtdEth and its eight unsaturated derivatives are described (Fig. 13). These unsaturated derivatives with two or more *cis*-double bonds in the $C_{20}$-*sn*-2-acyl chain are seen to contain only methylene-interrupted *cis*-double bonds. The second DSC curves are reproducible upon further repeated reheatings, and the transitions observed in the second heating scans can thus be assigned as the gel-to-liquid crystalline phase transitions. Only the phase transition behavior exhibited by various PtdEth in the second DSC heating scans is discussed in this presentation. For instance, the thermodynamic parameters associated with the gel-to-liquid crystalline phase transition of lipid bilayers prepared from three series of PtdEth are shown in Table 2 (29). More recently, the total numbers of different species of *sn*-1 saturated/*sn*-2 unsaturated PtdEth originated from the common precursors of C(20):C(18)PtdEth and C(20):C(20)PtdEth have been extended in this laboratory to 10 and 15 molecular species, respectively (24,25). In this presentation, I shall limit my discussion of the phase transition behavior of mixed-chain PtdEth to the $T_m$ values of lipid bilayers prepared individually from the 15 lipid species derived commonly from C(20):C(20)PtdEth.

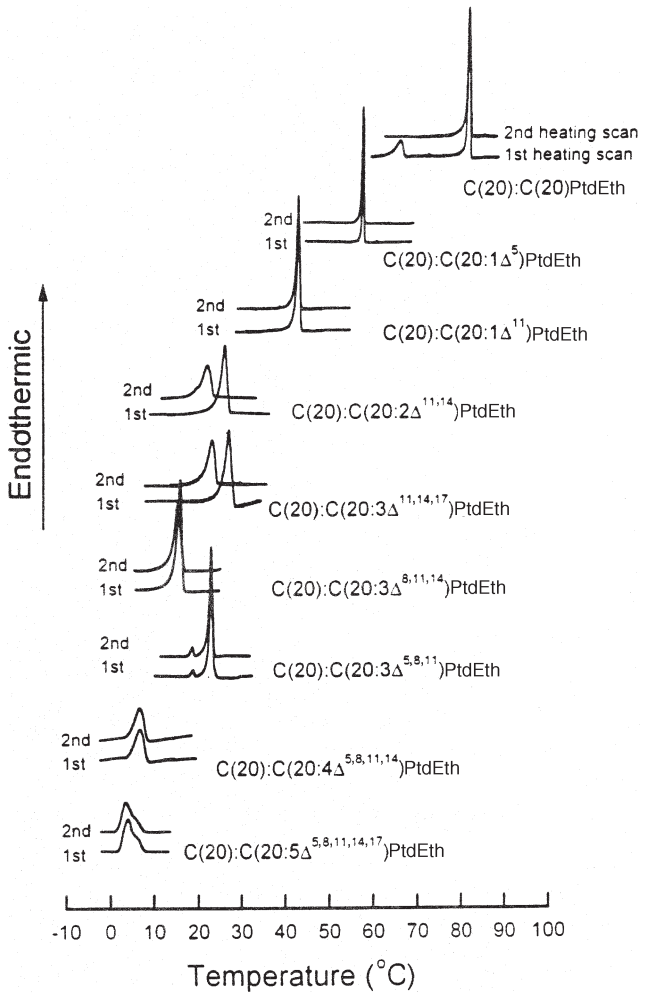

**FIG. 13.** The first and the immediate second DSC heating curves obtained with C(20):C(20)PtdEth and its eight unsaturated derivatives. Scan rate: 15°C/h. Lipid concentration: ~3–5 mM.

The second DSC heating curves for c(20):C(20)PtdEth and its five unsaturated derivatives of C(20):C(20:1$\Delta^{17}$)PtdEth, C(20):C(20:2$\Delta^{14,17}$)PtdEth, C(20):C(20:3$\Delta^{11,14,17}$)PtdEth, C(20):C(20:4$\Delta^{8,11,14,17}$)PtdEth and C(20):C(20:5($^{5,8,11,14,17}$)-PtdEth are illustrated in Figure 14. Here, the first Δ-bond is incorporated at the n-3 (or $\Delta^{17}$)-position in the *sn*-2 acyl chain. The second and all subsequent methylene-interrupted Δ-bonds are introduced into the chain segment located between the n-3-Δ-bond and the carbonyl end. Hence, the *sn*-2 acyl chains of this series of unsaturated PtdEth belong to the n-3-family. In the upper left inset in Figure 14, the $T_m$ value exhibited by each species in the n-3PtdEth series is plotted against the number of Δ-bonds. Clearly, the $T_m$ value decreases continually, but nonlinearly, with increasing number of Δ-bonds. Similarly, like the calorimetric data shown for n-3PtdEth, the $T_m$ value exhibited by each lipid in the unsaturated n-6PtdEth series also decreases

**TABLE 2**
**Thermodynamic Parameters Associated with the Gel-to-Liquid Crystalline Phase Transition of Lipid Bilayers Prepared from Various Phosphatidylethanolamines (PtdEth)**

| Lipid | $T_m$ (°C) | Δ*H* (kcal/mol) | Δ*S* (cal/mol/K) |

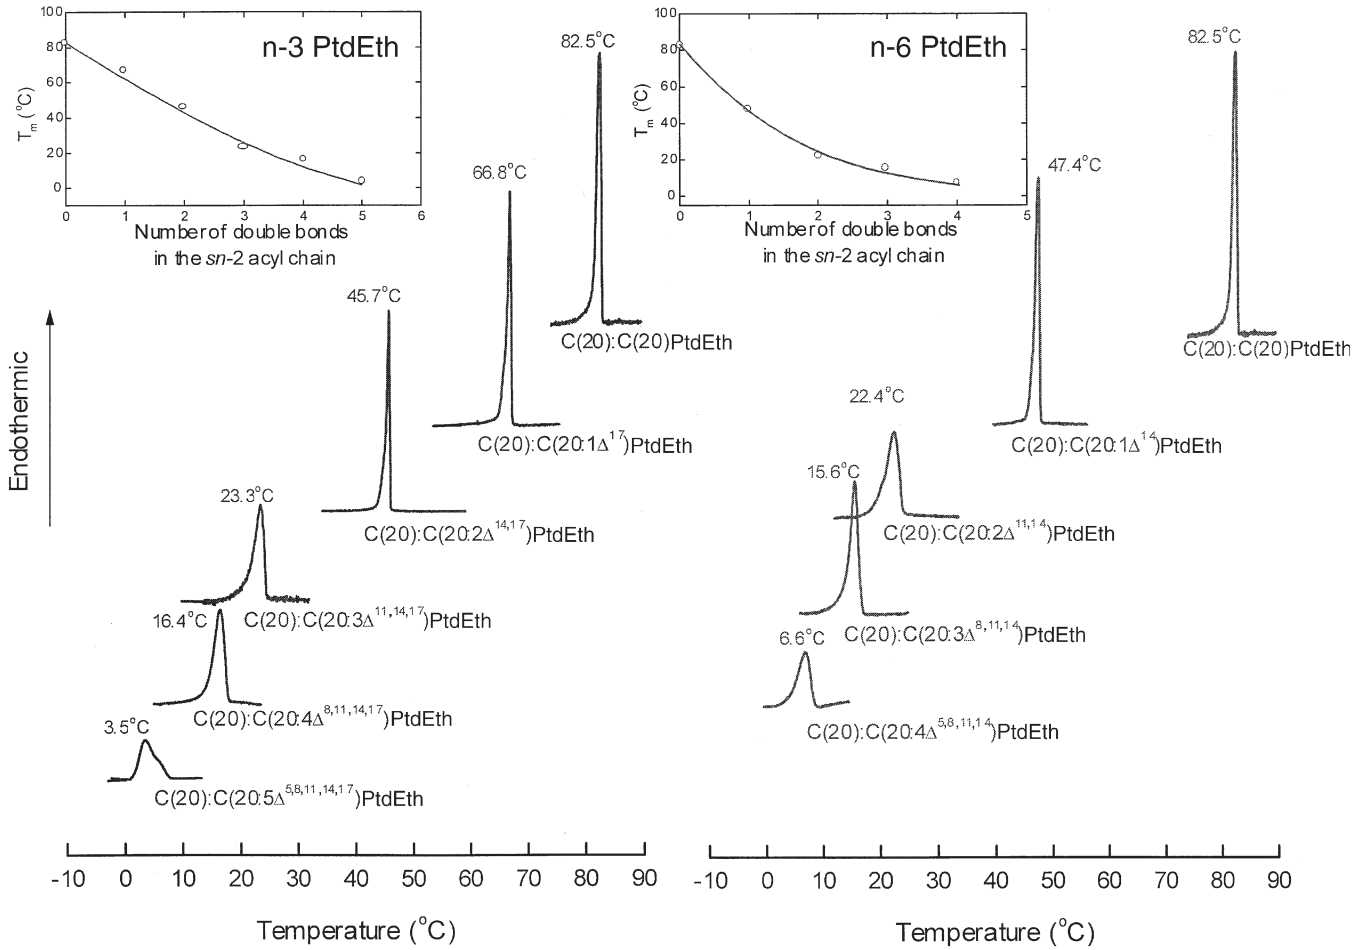

**FIG. 14.** Representative second DSC heating curves for aqueous dispersions prepared individually from C(20):C(20)PtdEth, five unsaturated n-3 derivatives of C(20):C(20)PtdEth, and four unsaturated n-6 derivatives of C(20):C(20)PtdEth. These unsaturated n-3PtdEth containing n-3 fatty acids and n-6PtdEth containing n-6 fatty acids contain 1–5 and 1–4 *cis*-Δ-bonds, respectively, in the lipid's *sn*-2 acyl chain, with the position of the commonly shared double bond being 3 and 6 carbons from the methyl end, respectively. The abbreviated name for each unsaturated lipid species is indicated under each transition curve, and, above the transition curve, the value of $T_m$ obtained with each lipid dispersion is also indicated. Furthermore, the $T_m$ values obtained with unsaturated lipids in each series are plotted against the number of *cis*-Δ-bonds as shown in the two insets.

continually but nonlinearly with increasing number of Δ-bonds, as shown in the upper right inset in Figure 14. It should be noted that the newly added Δ-bond is also placed on the carbonyl side of the existing Δ-bonds in the n-6PtdEth series.

In Figure 15, the DSC curves exhibited by lipids in two additional series of unsaturated PtdEth are depicted. In these two series of unsaturated PtdEth, the first *cis*-double bonds are introduced into the *sn*-2 acyl chain at the $\Delta^8$- and $\Delta^{11}$-positions, respectively. In contrast to the unsaturated lipids shown in Figure 14, the second and subsequent *cis*-double bonds are always inserted into the *sn*-2 acyl chain at positions located between the existing double bond and the methyl end. Hence, the *sn*-2 acyl chains of these two series of unsaturated PtdEth shown in Figure 15 belong to the $\Delta^8$- and the $\Delta^{11}$-series. For the $\Delta^{11}$PtdEth series, the $T_m$ value of C(20):C(20)PtdEth is seen in Figure 15 to decrease from 82.5 to 43.3°C upon the introduction of the first Δ-bond. A further decrease of 20.9°C in $T_m$ is observed in going from C(20):C(20:1$\Delta^{11}$)PtdEth → C(20):C(20:2$\Delta^{11,14}$)PtdEth. In contrast, a slight increase in $T_m$ (0.9°C) is detected as the third methylene-interrupted *cis*-double bond is subsequently added to the dienoic *sn*-2 acyl chain on the methyl end of the $\Delta^{14}$-double bond. Structurally, the C(20):C(20:2$\Delta^{11,14}$)PtdEth → C(20):C(20:3$\Delta^{11,14,17}$)PtdEth conversion, characterized by a small increase in $T_m$, corresponds to an n-6PtdEth → n-3PtdEth conversion. When all $T_m$ values obtained with lipids in this $\Delta^{11}$-PtdEth series are plotted against the number of *cis*-double bonds, a down-and-up $T_m$-profile is observed (upper right inset, Fig. 15). Similarly, for lipids in the $\Delta^8$-PtdEth series, the variation of $T_m$ as a function of the number of Δ-bonds is also characterized by a down-and-up trend (upper left inset, Fig. 15). In this case, the lipid with four Δ-bonds, C(20):C(20:4$\Delta^{8,11,14,17}$)PtdEth, is an n-3PtdEth which displays a higher $T_m$ value than its precursor, C(20):C(20:3$\Delta^{8,11,14,}$)-PtdEth, an n-6PtdEth with three Δ-bonds.

Based on the $T_m$ values shown in Figures 14 and 15 and some other DSC data published previously, a $T_m$ diagram is constructed as shown in Figure 16 (25). Here, nine series of mixed-chain PtdEth with saturated $C_{20}$-*sn*-1 and unsaturated $C_{20}$-*sn*-2 acyl chains derived from the common precursor of

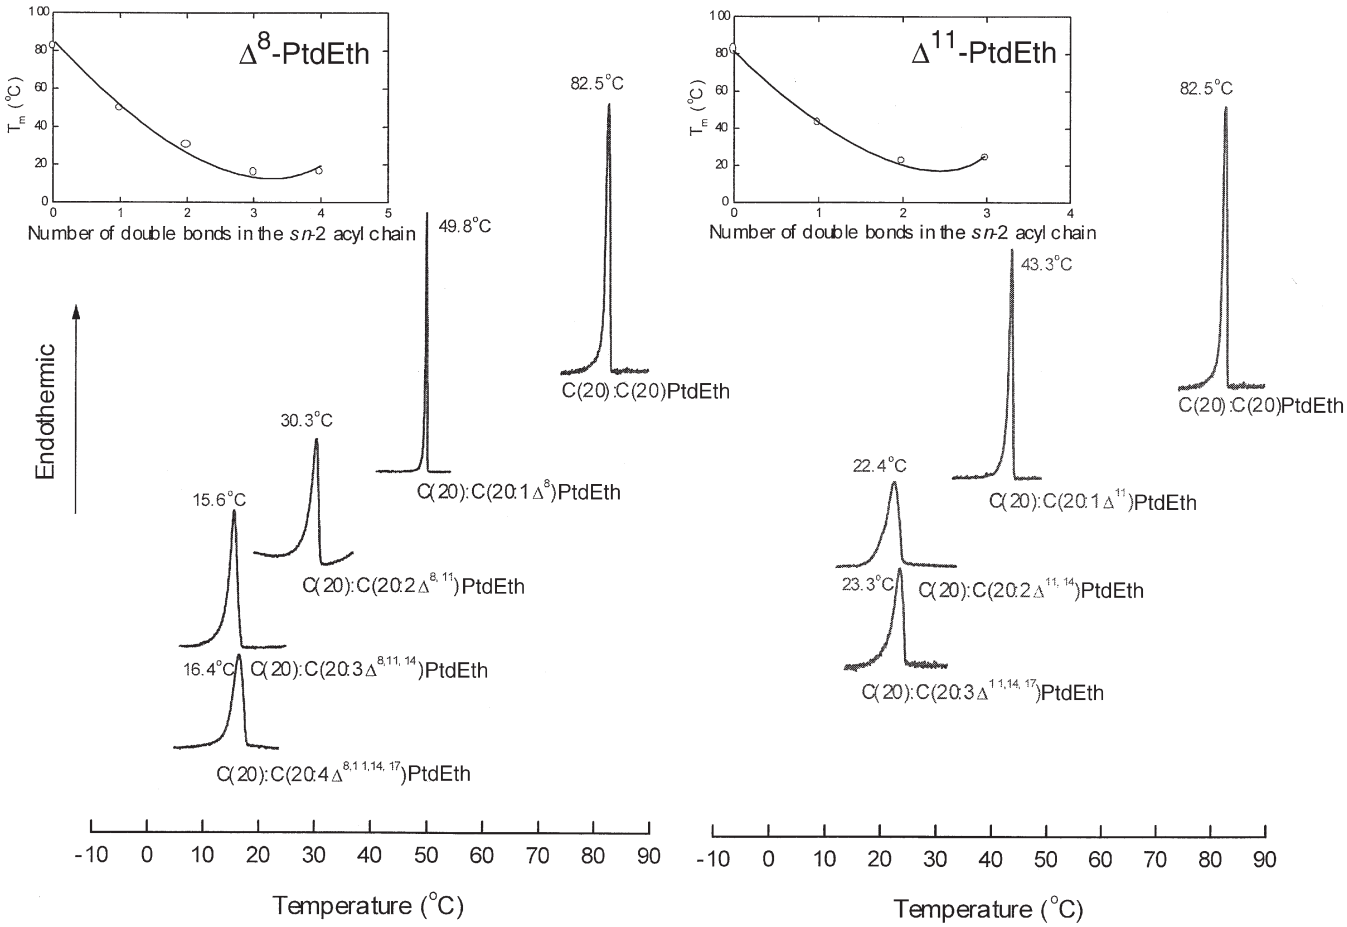

**FIG. 15.** The second DSC heating curves exhibited by lipids in the $\Delta^8$PtdEth- and $\Delta^{11}$PtdEth-series. Here, the superscript number denotes the position of the common *cis*-double bond in the *sn*-2 acyl chain when counting from the carbonyl end.

saturated C(20):C(20)PtdEth are presented. In each of these nine series of PtdEth, there are three or more lipids that share either a common Δ-bond at a fixed position along the *sn*-2 acyl chain or a fixed number of Δ-bonds. In this $T_m$ diagram, all $T_m$ values are placed underneath the appropriate structural formulas. These formulas are arranged systematically in a unifying manner according to their order of complexity. From Figure 16, the effects of the number and position of Δ-bonds on the $T_m$ obtained with lipids in the nine series of mixed-chain unsaturated $C_{20}$-PtdEth can thus be examined simply and simultaneously. Let us first look at the 3-series of PtdEth aligned horizontally in Figure 16; mixed-chain lipids in each of the three n-3 to n-9 PtdEth-series are characterized by a continuously decreasing $T_m$ profile as the number of Δ-bonds increases progressively. Similarly, mixed-chain lipids in the $\Delta^5$-PtdEth series aligned vertically along the rightmost line in the $T_m$-diagram also display a decreasing $T_m$ profile. However, as discussed earlier, the C(20):C(20:2$\Delta^{11,14}$)PtdEth → C(20):C(20:3$\Delta^{11,14,17}$)PtdEth and the C(20):C(20:3$\Delta^{8,11,14}$)-PtdEth → C(20):C(20:4$\Delta^{8,11,14,17}$)PtdEth conversions are coupled with increased values of $T_m$. For the $\Delta^8$- and $\Delta^{11}$-PtdEth series that are also aligned vertically in Figure 16, the $T_m$-profiles are characterized by a down-and-up trend. Finally, three series of mixed-chain PtdEth each with a fixed number of Δ-bonds in the *sn*-2 acyl chain can be seen along the diagonal lines in the $T_m$-diagram (Fig. 16). The monoenoic, dienoic, and trienoic series of mixed-chain PtdEth have five, four, and three positional isomers, respectively. In response to changes in the position of the double bond, the $T_m$ values of mixed-chain lipids with a fixed number of Δ-bonds give rise to a roughly V-shaped profile, a scenario that has been discussed earlier in details for monounsaturated lipids. Interestingly, the two series of positional isomers of PtdEth containing two and three *cis*-double bonds also exhibit V-shaped $T_m$-profiles in the plot of $T_m$ vs. the position of *cis*-double bonds. The most novel feature of the $T_m$-diagram shown in Figure 16 is the following: all the different $T_m$ profiles observed for mixed-chain lipids derived from a common precursor of a saturated lipid species can be seen simultaneously in a simple and unifying manner.

The energy-minimized structures of monounsaturated mixed-chain PtdCho such as C(16):C(18:1$\Delta^9$)PtdCho obtained with MM calculations have been presented. Similar structures can also be simulated for monounsaturated mixed-chain PtdEth based on the single-crystal data of PtdEth (26) and the atomic coordinates of the energy-minimized structures of monoenoic hydrocarbons (22). For instance, a kinked crankshaft-like structure with low energy is simulated for

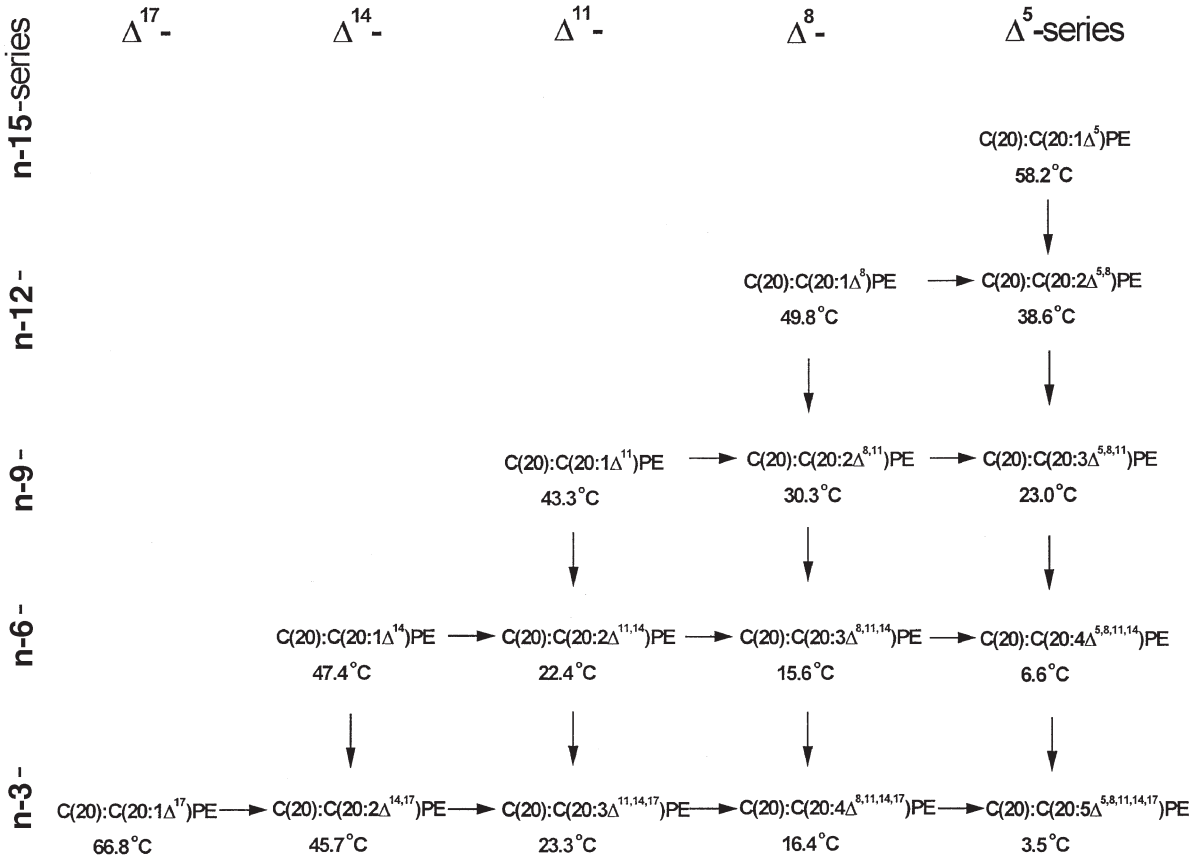

**FIG. 16.** The $T_m$-diagram of *sn*-1 $C_{20}$-saturated/*sn*-2 $C_{20}$-unsaturated PtdEth. Lipids in each row share a common n-carbon, where the n-carbon is defined as the first olefinic carbon atom in the lipid's *sn*-2 acyl chain when counting from the chain terminal methyl end. The five parallel rows of unsaturated lipids from top to bottom are n-15PtdEth, n-12PtdEth, n-9PtdEth, n-6PtdEth, and n-3PtdEth series as indicated. Lipids in each column share a common $\Delta^n$-bond, and lipids in each column thus belong to a $\Delta^n$PtdEth series, where the superscript *n* denotes the position of the common *cis* carbon-carbon double bond in the *sn*-2 acyl chain when counting from the carbonyl end. In this case, the carbonyl carbon is designated as the first carbon of the acyl chain. The five columns of unsaturated lipids from left to right are $\Delta^{17}$PtdEth, $\Delta^{14}$PtdEth, $\Delta^{11}$PtdEth, $\Delta^8$PtdEth, and $\Delta^5$PtdEth series, respectively, as indicated. Altogether, there are 15 molecular species of unsaturated mixed-chain PtdEth in this $T_m$ diagram, and their $T_m$ values are given under the abbreviated names of the corresponding mixed-chain PtdEth.

C(16):C(18:1$\Delta^9$)PtdEth (Fig. 17). Furthermore, the single-crystal structure of linoleic acid, determined by Ernst *et al.* (27), is characterized by a crankshaft-like motif with a kink sequence of $s^-\Delta s^+s^+\Delta s^-$ (–119, –2.3, 123, 124, –3.3, –121°). The most stable structure of dienoic PtdEth in the crystalline-state bilayer can thus be expected to have a kinked conformation. As expected, a rotamer with a kink sequence of $s^-\Delta s^+s^+\Delta s^-$ is indeed found by MM calculations to be energetically the most stable conformation for the s*n*-2 acyl chain of C(16):C(18:2$\Delta^{9,12}$)PtdEth (Fig. 17; 28). MM simulations, in fact, further show that the roughly crankshaft-like conformation is a common motif underlying the energy-minimized structure of other *sn*-2 acyl chains of mixed-chain PtdEth containing three or more methylene-interrupted Δ-bonds (Fig. 18).

The energy-minimized structures of C(20):C(20)PtdEth and its five unsaturated n-3 derivatives are illustrated in Figure 19 (25). These structures, to a first approximation, correspond to the optimal and static structures of PtdEth molecules packed in the crystalline-state bilayer. Here, the zigzag plane of the all-*trans* *sn*-1 acyl chain in each lipid species lies perpendicular to the paper plane, whereas the *sn*-2 acyl chain projects in front of the *sn*-1 acyl chain. For C(20):C(20)-PtdEth, the *sn*-2 acyl chain has an all-*trans* segment extending from C(3) to C(19) with 17 methylene units. This segment is designated as the all-*trans* segment, abbreviated as ATS. For C(20):C(20:1$\Delta^{17}$)PtdEth, the *sn*-2 acyl chain has a crankshaft-like topology with a kink sequence given under the energy-minimized structure in Figure 19. As a result, the *sn*-2 acyl chain can be viewed to consist of two chain segments linked by the kink sequence. The all-*trans* segment in the long-chain segment of the kinked *sn*-2 acyl chain is defined as the ATS. For C(20):C(20:1$\Delta^{17}$)PtdEth, the ATS has 14 consecutive methylene units extending from C(3) to C(16) along the kinked *sn*-2 acyl chain. Note that the ATS is one C–C bond length shorter than that of the long chain segment due to the fact that the C–C single bond preceding the $\Delta^{17}$-bond has an $s^-$ conformation. For the energy-minimized structures of polyunsaturated n-3PtdEth shown in Figure 19, the *sn*-2 acyl chains are seen to adopt roughly an overall kinked motif. The ATS is observed invariably to locate in the upper chain segment in each kinked *sn*-2 acyl chain. Moreover, the length of the ATS is shortened progressively by three methylene

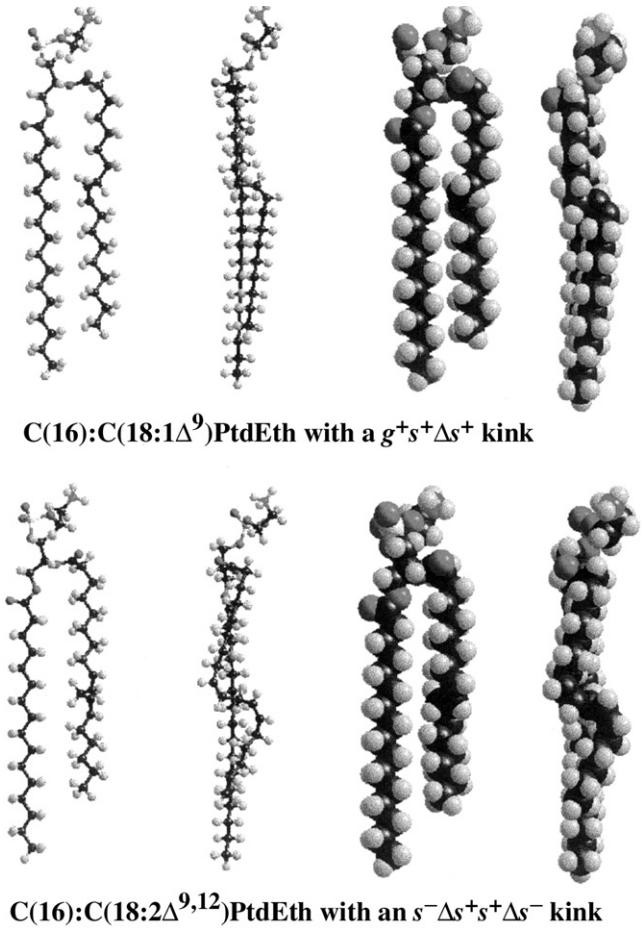

**FIG. 17.** The energy-minimized structures of C(16):C(18:1$\Delta^{9}$)PtdEth and C(16):C(18:2$\Delta^{9,12}$)PtdEth; each is characterized by a kinked crankshaft-like motif.

units as a Δ-bond is added successively on the carbonyl side of the existing Δ-bonds at the methylene-interrupted position. In contrast, the short chain segment succeeding the $\Delta^{17}$-bond is identical in length (Fig. 19). It should be emphasized that the structural features of polyunsaturated n-3PtdEth mentioned above are simulated results obtained with MM computations. These simulated structures do not explicitly provide information about the dynamic nature of lipid molecules in the gel-state bilayer. For instance, the *sn*-2 acyl chains of all unsaturated n-3PtdEth shown in Figure 19 share a common chain terminal segment of C(16)-C(17)=C(18)-C(19)-C(20), in which all C–C single bonds are most likely dynamic in the gel-state bilayer. The assumed flexible nature at $T < T_m$ can be attributed mainly to the large degree of rotational freedom of two single C–C bonds adjacent to the Δ-bond as well as the C–C single bond containing the methyl terminal carbon atom. Hence, it is reasonable to suppose that this disordered methyl terminal segment does not undergo the thermally induced *trans* → *gauche* isomerizations at $T_m$, and it thus makes no contributions to the chain disordering process at $T_m$. The dynamic nature of this short terminal segment, however, is not revealed by any of the MM simulated structures illustrated in Figure 19. On the other hand, as the number of Δ-bonds in this series of n-3PtdEth increases from zero to five, the length of ATS is shortened in each step by a constant length of three methylene units. This variation in ATS, shown clearly in Figure 19, is considered to be a structural feature that persists in the gel-state bilayer.

Similar to lipids in the n-3PtdEth series, the five lipids in the $\Delta^{5}$PtdEth series seen in the $T_m$ diagram also contain up to five methylene-interrupted Δ-bonds in the *sn*-2 acyl chain. The energy-minimized structures of these lipids have also been determined by MM calculations, and a crankshaft-like topology characterizes them all. In these lipids, the short chain segments in the kinked *sn*-2 chains are located near the $H_2O$/hydrocarbon interface, extending from C(3) to C(5). All ATS, however, are located in the lower chain segments; the length of each ATS decreases progressively by three methylene units as a methylene-interrupted Δ-bond is added successively on the methyl side of the existing Δ-bond(s). This decreasing trend in ATS is, in essence, identical to that observed in Figure 19 for the n-3PtdEth series.

In Figure 20, the minimum-energy structures of C(20):C(20:1$\Delta^{11}$)PtdEth, C(20):C(20:2$\Delta^{11,14}$)PtdEth, and C(20):C(20:3$\Delta^{11,14,17}$)PtdEth in the $\Delta^{11}$PtdEth series are illustrated. For C(20):C(20:1$\Delta^{11}$)PtdEth, the $\Delta^{11}$-double bond is located in the middle of the *sn*-2 acyl chain, and the additional Δ-bonds in C(20):C(20:2$\Delta^{11,14}$)PtdEth and (20):C(20:3$\Delta^{11,14,17}$)PtdEth are on the methyl side of the $\Delta^{11}$-bond. Unlike the variable length of ATS shown in Figure 19, all three lipids in this series of $\Delta^{11}$PtdEth share a constant chain length of ATS extending from C(3) to C(10) in the *sn*-2 acyl chain (Fig. 20). It is evident that as the C(20):C(20:2$\Delta^{11,14}$)-PtdEth (an n-6PtdEth) → C(20):C(20:3$\Delta^{11,14,17}$)PtdEth (an n-3PtdEth) conversion occurs, the added $\Delta^{17}$-bond is introduced on the methyl side of the existing Δ-bonds, and the length of the ATS is not affected by the n-6PtdEth → n-3PtdEth conversion. The last two $\Delta^{8}$PtdEth species shown in the $T_m$-diagram are C(20):C(20:3$\Delta^{8,11,14}$)PtdEth and C(20):C(20:4$\Delta^{8,11,14,17}$)-PtdEth, which are n-6PtdEth and n-3PtdEth, respectively. Interestingly, they share a constant length of ATS that is located in the upper chain segment of the kinked *sn*-2 acyl (25). The fourth Δ-bond is added on the methyl side of the existing Δ-bonds as the n-6PtdEth → n-3PtdEth conversion takes place. Hence, this n-6PtdEth → n-3PtdEth conversion is structurally similar to the C(20):C(20:2$\Delta^{11,14}$)PtdEth (an n-6PtdEth) → C(20):C(20:3$\Delta^{11,14,17}$)PtdEth (an n-3PtdEth) conversion seen in Figure 20.

Let me summarize what is known about the structural features of *sn*-1 saturated/*sn*-2 polyunsaturated phospholipids from MM simulations: (i) the *sn*-1 acyl chain has an all-*trans* conformation; (ii) the *sn*-2 acyl chain extending from C(3) to the methyl terminus has a crankshaft-like conformation; hence, it can be considered to consist of two chain-segments linked by a kink sequence; (iii) the relative length of the two chain-segments in the kinked *sn*-2 acyl chain depends on the position of the multiple Δ-bonds; (iv) the consecutive all-*trans* segment in the long chain segment of the kinked *sn*-2 chain can be defined as ATS, and the length of ATS is

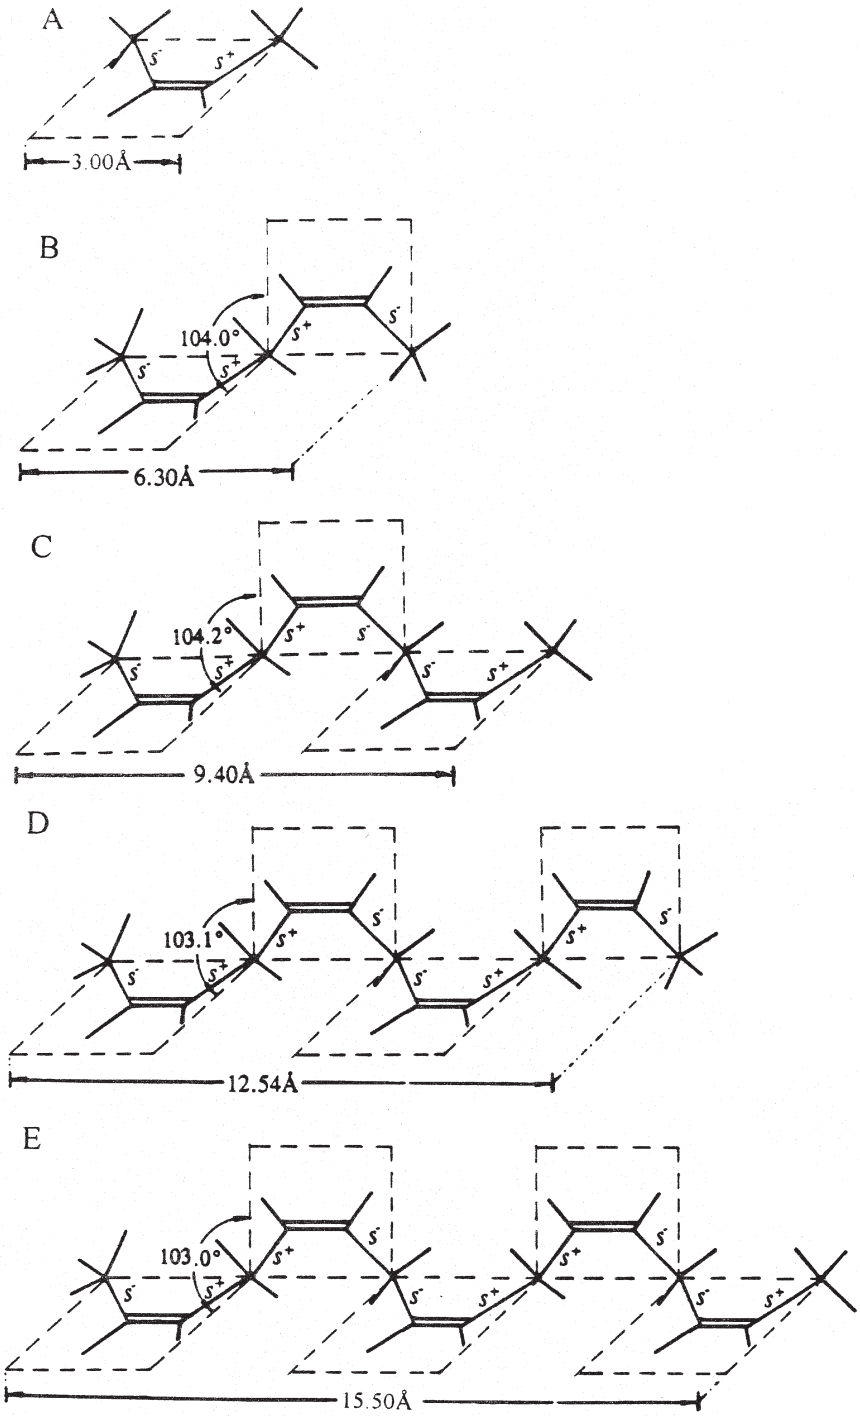

**FIG. 18.** The energy-minimized structure of hydrocarbon chains containing 1–5 methylene-interrupted *cis*-double bonds.

shortened by three methylene units if a methylene-interrupted Δ-bond is incorporated into the ATS; (v) the kink sequence in the dienoic *sn*-2 acyl chain is $s^{-}\Delta s^{+}s^{+}\Delta s^{-}$ or $s^{+}\Delta s^{-}s^{-}\Delta s^{+}$, depending on whether the position of *n* in $\Delta^{n,n+3}$-bond is an odd- or even-carbon atom in the *sn*-2 acyl chain.

Earlier, we presented a simple molecular model that can interpret adequately the large $T_m$-lowering effect of acyl chain monounsaturation and the V-shaped characteristic dependency of $T_m$ on the position of the single Δ-bond along the *sn*-2 acyl chain. We can extend this simple model to interpret the different effects of the *sn*-2 acyl chain polyunsaturation on the phase transition behavior as seen in the $T_m$-diagram (Fig. 16). In this extended molecular model, three basic assumptions are made. (i) The *sn*-2 acyl chain in the mixed-chain PtdEth (or PtdCho) with *sn*-1 saturated/*sn*-2 unsaturated acyl chains is assumed to adopt, at $T < T_m$, an energy-minimized crankshaft-like kink motif. Hence, it consists of a longer and a shorter chain-segment separated by the Δ-containing kink. (ii) At $T < T_m$, the

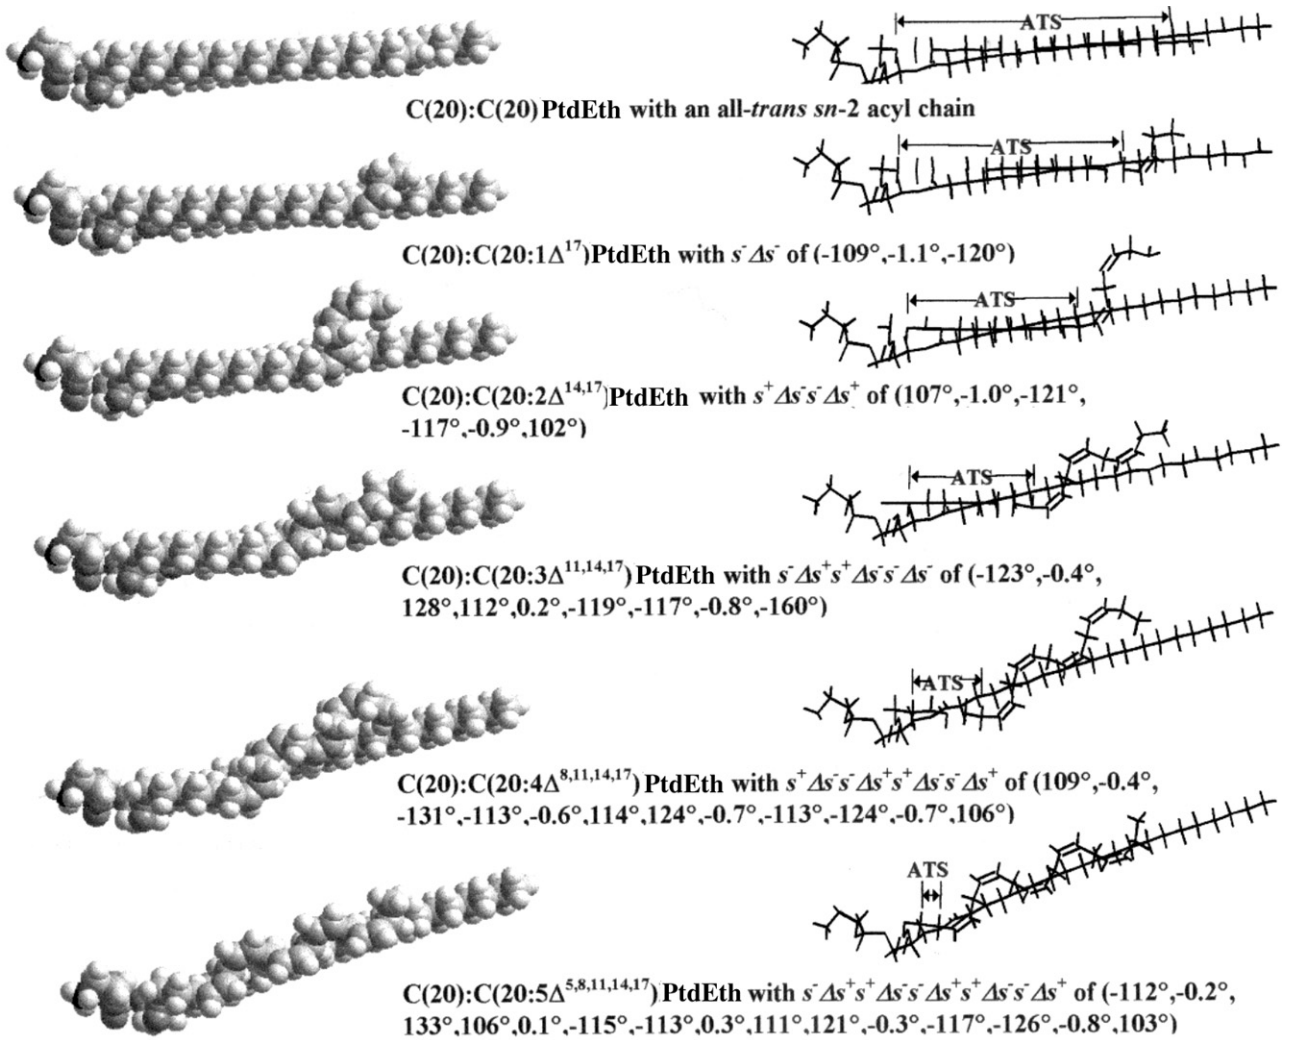

**FIG. 19.** The energy-minimized structures of C(20):C(20)PtdEth and its five unsaturated n-3 derivatives as shown molecular-graphically by space-filling and wire models. These unsaturated n-3PtdEth molecules contain 1–5 *cis*-Δ-bonds. The ATS shown in the wire model denotes the all-*trans* segment (ATS) of the hydrocarbon chain in the *sn*-2 acyl chain. The kink sequence in the *sn*-2 unsaturated acyl chain and a set of optimal torsion angles associated with the kink sequence are presented under each unsaturated lipid species. The length of ATS is shortened progressively by three methylene units as the new methylene-interrupted *cis*-double bond is added successively on the carbonyl side of the $\Delta^{17}$-bond in the *sn*-2 acyl chain of C(20):C(20:1$\Delta^{17}$)PtdEth. In contrast, the short chain segment succeeding the $\Delta^{17}$-bond is identical in length.

ATS in the long chain segment of the kinked *sn*-2 acyl chain and the neighboring all-*trans sn*-1 acyl chain are proposed to undergo attractive van der Waals interaction. In contrast, the shorter chain-segment of the kinked *sn*-2 acyl chain is assumed to be partially disordered. However, if the length of the shorter chain-segment differs from that of the longer one by 1–3 C–C bond lengths, the shorter chain-segment may contribute somewhat to the chain-melting process at $T_m$. (iii) When the number of Δ-bonds in the *sn*-2 acyl chain is larger than two, the methylene-interrupted Δ-bonds act together as a rigid structural unit, which prevents the rotational isomerizations of C–C bonds in the neighboring chains. Hence, the *sn*-2 acyl chain with three or more methylene-interrupted Δ-bonds can facilitate somewhat the lateral chain-chain interactions in the gel-state bilayer.

According to the extended molecular model presented above, the variations of $T_m$ upon successive chain unsaturation in the *sn*-2 acyl chain reflect mainly the changes of the following two opposing effects: (i) the $T_m$-lowering effect caused by the progressive shortening of ATS, and (ii) the $T_m$-elevating effect exerted by the increased rigidity of three to five Δ-bonds. These two opposing effects are brought about, paradoxically, by the same structural change, by the increasing degree of acyl chain unsaturation in the *sn*-2 position. We can now apply this model to explain why two distinct types of $T_m$ profile are observed for lipids upon the successive addition of methylene-interrupted Δ-bonds in the *sn*-2 acyl chain. One type is characterized by a nonlinearly decreased $T_m$-curve and the other is characterized by a down-and-up $T_m$-profile in the plot of $T_m$ vs. the number of Δ-bonds in the *sn*-2 acyl chain.

We begin with the discussion of the $T_m$ profile exhibited by lipids in the n-3PtdEth series derived from C(20):C(20)-PtdEth. This series can be taken as an example to represent all series of PtdEth characterized by a nonlinearly decreased $T_m$ profile. As shown in Figure 21, the length of ATS is short-

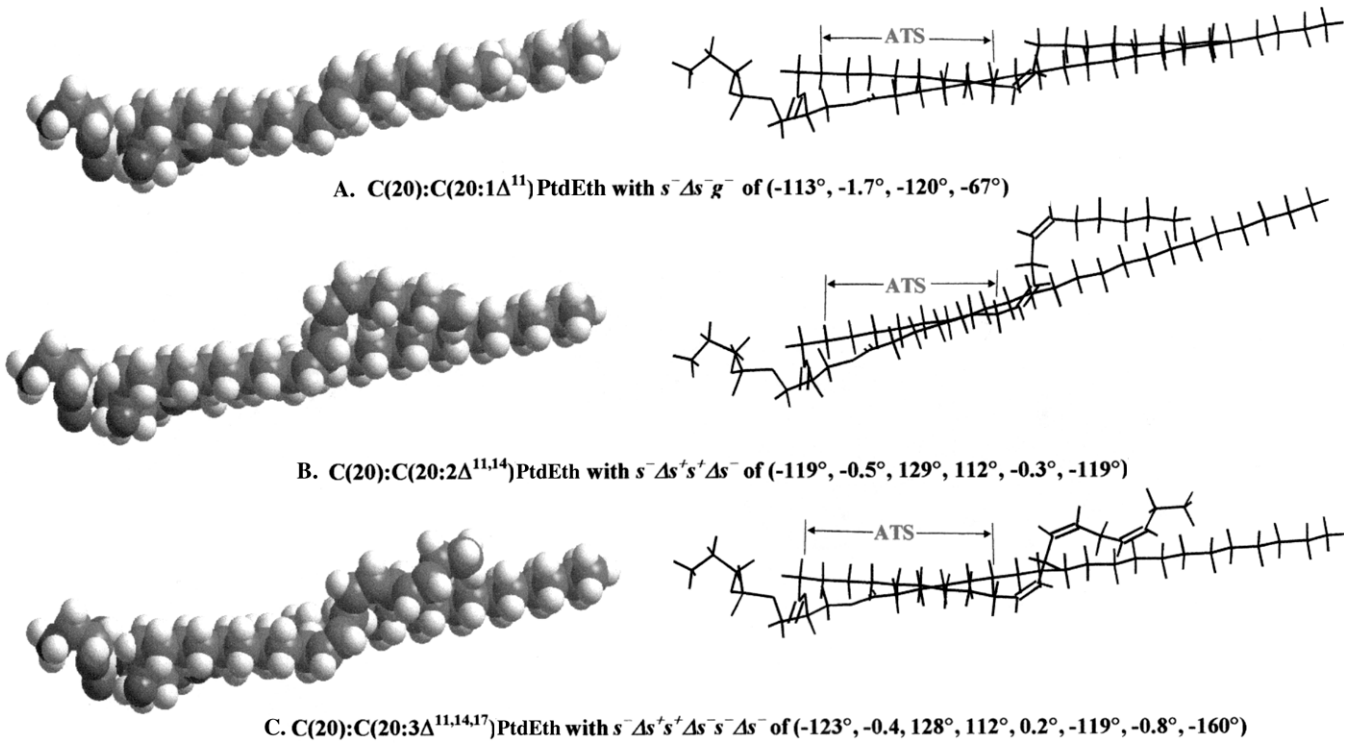

**FIG. 20.** Molecular graphics representations of the energy-minimized structures of C(20):C(20:1$\Delta^{11}$)PtdEth, C(20):C(20:2$\Delta^{11,14}$)PtdEth, and C(20):C(20:3$\Delta^{11,14,17}$)PtdEth in the $\Delta^{11}$PtdEth series as depicted by ball-and-stick and space-filling models. ATS in each lipid species is located in the upper chain-segment of the kinked *sn*-2 acyl chain; moreover, a constant length of ATS is shared by all three lipid species. The added Δ-bond is introduced on the methyl side of the existing Δ-bond. The kink sequence and associated torsion angles for each unsaturated acyl chain are presented under the energy-minimized structure of the corresponding lipid. For abbreviations see Figures 1 and 19.

ened progressively by a constant length of three methylene units as a methylene-interrupted Δ-bond is added successively into the *sn*-2 acyl chain. Based on the observed constant decrease in ATS alone, the $T_m$ values of lipids in the n-3PtdEth series can be expected to fall on a straight line with a negative slope. On the other hand, when the total number of Δ-bonds in the *sn*-2 acyl chain is three or more, the multiple Δ-bonds are proposed to act as a rigid structural unit, thus leading to a gradual increase in $T_m$. However, we assume that this $T_m$-elevating effect is less than the $T_m$-lowering effect exerted by the shortening of the ATS in the *sn*-2 acyl chain. On balance, the absolute value of the $T_m$ increment will be decreased progressively as the third and subsequent Δ-bonds are introduced stepwise into the *sn*-2 acyl chain, with the largest decrease in the $T_m$ increment occurring at the highest number of Δ-bonds. Consequently, the $T_m$ values of lipids in the n-3PtdEth series in the plot of $T_m$ vs. the number of Δ-bonds are expected to fall on a nonlinearly decreased curve; furthermore, the $T_m$ from the lipid species with the highest number of Δ-bonds is expected to deviate most from the straight line. These expectations are indeed borne out by experimental data (Fig. 21). Therefore, we may conclude that the presence of *cis*-double bonds in the *sn*-2 acyl chain contributes to the positive deviation of $T_m$ from the linear $T_m$-profile in the plot of $T_m$ vs. the number of *cis*-double bonds, although its effect vanishes when the total number of Δ-bonds in the *sn*-2 acyl chain is equal to or less than two.

Our proposed model can also explain the down-and-up $T_m$-profile exhibited by lipids in the $\Delta^8$PtdEth- and $\Delta^{11}$PtdEth-series shown in the $T_m$ diagram. Here, the $\Delta^{11}$PtdEth-series is chosen as an example to illustrate our points. The energy-minimized structures of the three lipid species in the $\Delta^{11}$PtdEth-series are shown in Figure 22, in which the ATS is seen to locate in the upper chain-segment. Moreover, the length of ATS remains unchanged among the three lipid species. It should be noted that the lower chain-segment in the C(20):C(20:1$\Delta^{11}$)PtdEth has a length that is only one C–C bond length shorter than the upper chain-segment. According to our proposed molecular model, this short chain-segment may contribute somewhat to the chain-melting process at $T_m$. Consequently, the $T_m$ value for the lipid bilayer composed of C(20):C(20:1$\Delta^{11}$)PtdEth can be expected to be higher than that of C(20):C20:2$\Delta^{11,14}$)PtdEth, although these two unsaturated lipids share a common length of ATS. The introduction of a third *cis*-double bond into the *sn*-2 acyl chain of C(20):C(20:2$\Delta^{11,14}$)PtdEth, an n-6PtdEth, converts the lipid into an n-3PtdEth, or C(20):C(20:3$\Delta^{11,14,17}$)-PtdEth. Based on the constant length of ATS alone, the $T_m$ increment between the n-6PtdEth and the n-3PtdEth would be zero. However, the n-3PtdEth has an additional Δ-bond in comparison to the n-6PtdEth; based on our proposed molecular model, a positive $T_m$ increment is thus expected to associate with the n-6PtdEth → n-3PtdEth conversion in this $\Delta^{11}$PtdEth series. On the basis of our proposed molecular

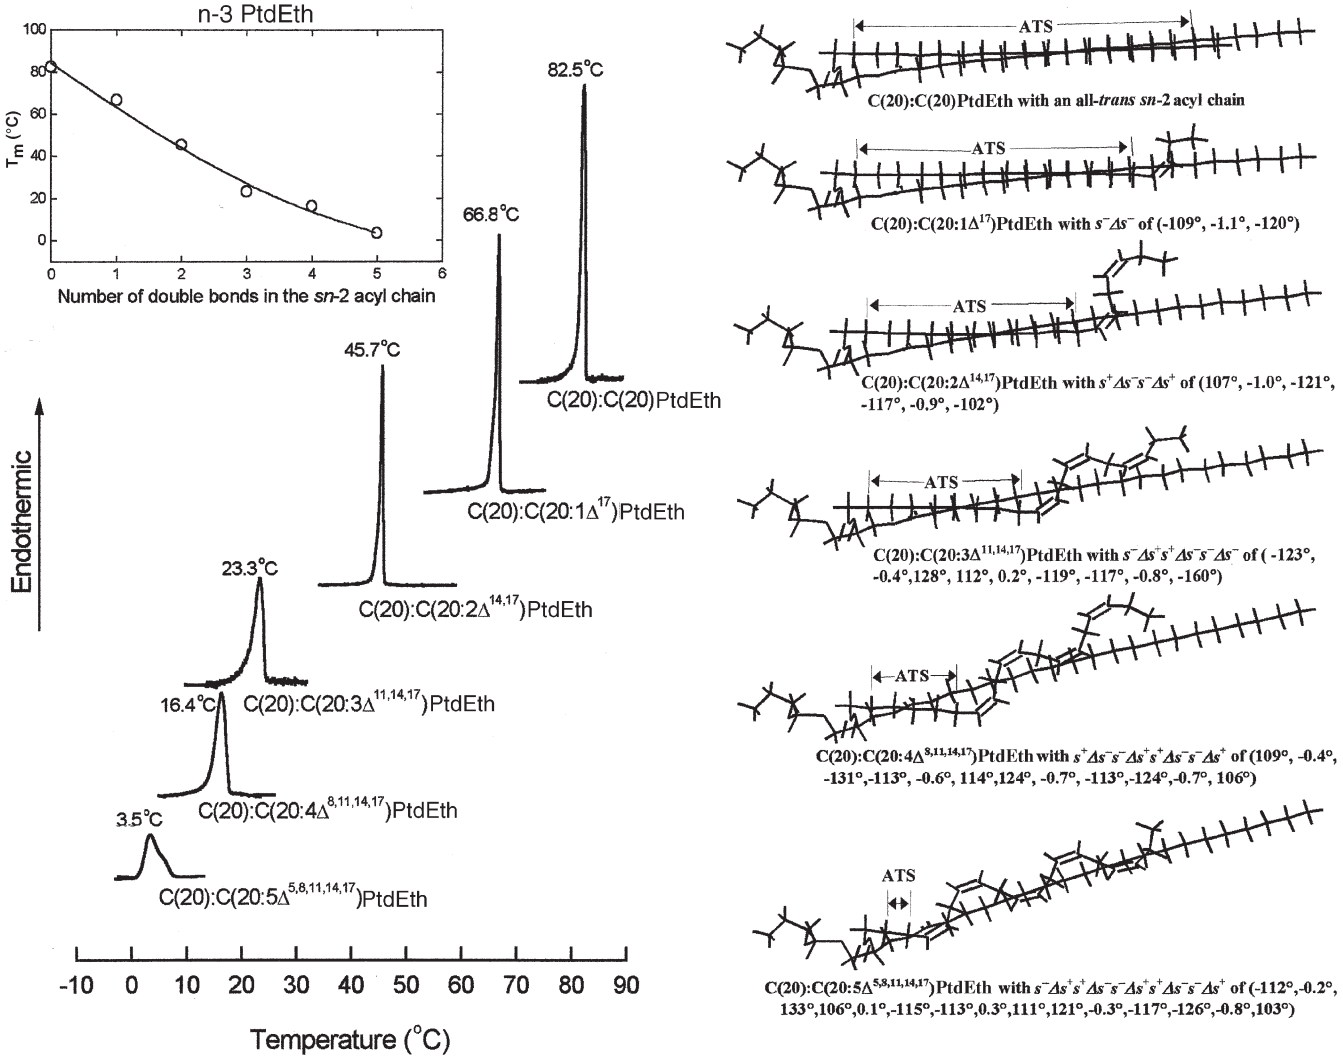

**FIG. 21.** The energy-minimized structures of C(20):C(20)PtdEth and its five unsaturated n-3 derivatives are presented in the presence of the thermograms exhibited by these six lipid species. The $T_m$-profile shown in the inset can be roughly correlated with the variation of the ATS length in the *sn*-2 acyl chains of these six lipid species.

model, the consecutive C(20):C(20:1$\Delta^{11}$)PtdEth $\rightarrow$ C(20):C(20:2$\Delta^{11,14}$)PtdEth $\rightarrow$ C(20):C(20:3$\Delta^{11,14,17}$)-PtdEth conversion should be accompanied by a down-and-up $T_m$-profile. And this is indeed observed calorimetrically as shown in Figure 22. Moreover, such a down-and-up $T_m$-profile has also been observed calorimetrically for PtdCho in two different $\Delta^{11}$PtdCho series (29).

I would now like to conclude by considering once more the $T_m$-diagram (Fig. 16) constructed for mixed-chain phospholipids with saturated and unsaturated *sn*-1 and *sn*-2 acyl chains, respectively, that are originated from a common precursor, C(20):C(20)PtdEth. All unsaturated lipids with two or more *cis*-double bonds shown in this $T_m$-diagram have methylene-interrupted *cis*-double bonds, which are the hallmark of the naturally occurring phospholipids found in animal cells. Moreover, the energy-minimized structures of all the unsaturated *sn*-2 acyl chains of lipids shown in this $T_m$-diagram are characterized by a kinked crankshaft-like motif as obtained by MM calculations. A novel virtue of this $T_m$-diagram is that the $T_m$-profiles exhibited by various series of lipids arranged along the horizontal, vertical, and diagonal lines can be compared simply and simultaneously. In this sense, the $T_m$-diagram is somewhat analogous to the periodic table, in which all chemical elements are arranged simultaneously in a simple and systematic manner. Finally, my emphasis is that a simple molecular model can explain adequately the various shapes of the $T_m$-profiles exhibited by different series of mixed-chain phospholipids shown in this $T_m$-diagram. It is hoped that the experimental and computational results obtained with pure lipids containing well-defined numbers and positions of *cis*-double bonds as summarized in this presentation may lead us to many informative new experiments to be carried out with biological membranes in the future.

## ACKNOWLEDGMENTS

This work was supported, in part, by U.S. Public Health Service Grant GM17452 from NIGMS, National Institutes of Health, and the Department of Health and Human Services. Sincere appreciation

# Inhibitory Effect of Conjugated Linoleic Acid on Linoleic Acid Elongation in Transformed Yeast with Human Elongase

**Lu-Te Chuang[a,b], Amanda E. Leonard[b], Jim-Wen Liu[b], Pradip Mukerji[b], Tammy M. Bray[a], and Yung-Sheng Huang[a,b,*]**

**ABSTRACT:** Conjugated linoleic acid (CLA; 18:2) refers to a group of positional and geometric isomers derived from linoleic acid (LA; Δ9,12-18:2). Using a growing baker's yeast (*Saccharomyces cerevisiae*) transformed with human elongase gene, we examined the inhibitory effect of CLA at various concentrations (10, 25, 50, and 100 μM) on elongation of LA (25 μM) to eicosadienoic acid (EDA; Δ11,14-20:2). Among four available individual CLA isomers, only *c*9,*t*11- and *t*10,*c*12-isomers inhibited elongation of LA to EDA. The extent of inhibition (ranging from 20 to 60%) was related to the concentration of CLA added to the medium. In the meantime, only these two isomers, when added at 50 μM to the media, were elongated to conjugated EDA (*c*11,*t*13- and *t*12,*c*14-20:2) by the same recombinant elongase at the rate of 28 and 24%, respectively. The inhibitory effect of CLA on LA elongation is possibly due to competition between CLA isomers and LA for the recombinant elongase. Thus, results from this study and a previous study suggest that the biological effect of CLA is exerted through its inhibitory effect on Δ6-desaturation as well as elongation of LA which results in a decrease in long-chain n-6 fatty acids and consequently the eicosanoid synthesis.

Paper no. L8797 in *Lipids 36*, 1099–1103 (October 2001).

Conjugated linoleic acid (CLA), a mixture of positional and geometric dienoic isomers derived from linoleic acid (LA, Δ9,12-18:2), has many beneficial effects in animals. It can decrease the development of atherosclerosis in rabbits and hamsters (1,2) and modulate the immune function in rats (3). CLA can also decrease breast cancer cell proliferation and inhibit mammary gland, skin, and stomach tumorigenesis in experimental animals (4–9).

The mechanism by which CLA exerts its biological function is still not fully understood. CLA may modulate the immune function through a modification of eicosanoid synthesis (10–12). Results from our previous study demonstrated that CLA significantly inhibited Δ6-desaturation (13), the rate-limiting step for the production of polyunsaturated fatty acid (PUFA) and eicosanoids in mammalian cells. In these cells, when Δ6 desaturation is suppressed, an alternate metabolic pathway for LA to form PUFA could also take place (see Scheme 1). Some LA could be elongated to form eicosadienoic acid (EDA; Δ11,14-20:2) (14), followed by Δ8-desaturation to form dihomo-γ-linolenic acid (DGLA; Δ8,11,14-20:3) and subsequently to arachidonic acid (AA, Δ5,8,11,14-20:4) by the action of Δ5-desaturase (15,16). Since there was a significant decrease of AA in the CLA-fed animals (11,17), it is reasonable to postulate that CLA can inhibit not only the Δ6-desaturation but also the elongation of LA.

The objective of this study was to examine whether CLA could inhibit the elongation of LA by directly competing with the enzyme elongase, the first step of the alternate pathway. This study was performed in a simple system of an established transformed yeast containing the human PUFA-specific elongase gene without the presence of other enzymes in the metabolic pathway of PUFA synthesis.

## MATERIALS AND METHODS

*Chemicals.* Triheptadecanoin (a synthetic triacylglycerol containing three molecules of heptadecanoic acid, 17:0) LA, EDA, and a mixture of CLA isomers (free fatty acid form, containing 41% of *c*9,*t*11-isomer, 44% of *t*10,*c*12-isomer, and others) were purchased from Nu-Chek-Prep, Inc. (Elysian, MN). Four individual isomers of CLA (*c*9,*t*11; *t*9,*t*11; *c*9,*c*11; and *t*10,*c*12) and a mixture of conjugated eicosadienoic acid (CEDA) isomers (free fatty acid form, containing 53% of *c*11,*t*13 isomer, 29% of *c*11,*c*13 isomer, and others) were obtained from Matreya Inc. (Pleasant Gap, PA). Yeast minimal medium (YMM) was prepared by mixing 26.7 g Dropout base (DOB) medium and 0.69 g complete supplement mixture

Abbreviations: AA, arachidonic acid (Δ5,8,11,14-20:4); CEDA, conjugated eicosadienoic acid; CLA, conjugated linoleic acid; CSM-LEU, complete supplement mixture minus leucine; DGLA, dihomo-γ-linolenic acid (Δ8,11,14-20:3); DOB, Dropout base; EDA. eicosadienoic acid (Δ11,14-20:2); GC, gas chromatography; GLA, γ-linolenic acid (Δ6,9,12-18:3); LA, linoleic acid (Δ9,12-18:2); MS, mass spectrometry; PUFA, polyunsaturated fatty acid; YMM, yeast minimal medium.

minus leucine (CSM-LEU). Both DOB medium and CSM-LEU were from Bio 101, Inc. (Vista, CA). YPD medium containing yeast extract, peptone, and dextrose was from Difco Laboratories (Detroit, MI). Hexane was ultraviolet grade and other solvents were distilled-in-glass quality.

*Plasmids and yeast strain.* The pYX242 expression vector was chosen for the construction of the clone pRAE-58. This expression vector has a strong, constitutive triose phosphate isomerase promoter, leucine selection marker, and ampicillin resistance marker. The pYX242 is a 2μ plasmid, which allows it to replicate autonomously in yeast and be stably maintained at 25–100 copies per cell. In this study, two plasmids, pYX242 (vector only) and pRAE-58 (with human elongase cDNA), were constructed and transformed into a host strain of *Saccharomyces cerevisiae*, SC334 (18). The transformation protocol and growth conditions followed the procedures described previously (18).

*Incubation conditions and experimental design.* Colonies of the transformed yeasts were grown overnight in YPD medium at 30°C. Cultures ($1 \times 10^8$ cells) were then inoculated into 50 mL YMM. Cell numbers were maintained at the same level in all studies. The cultures were grown at 30°C for 48 h. The culture temperature (30°C) has previously been shown to be optimal for expression of the elongase activity (18). Cells were harvested by centrifugation, and cell pellets were washed once with sterile distilled-deionized $H_2O$. The yeast transformed with only vector (pYX242) was used as the negative control.

To confirm whether the activity of elongase (conversion of LA to EDA) was expressed in the transformed yeast, LA (100 μM) was provided as the exogenous substrate in the YMM. To study if CLA could affect the conversion rate of LA to EDA, CLA (as a mixture of four isomers or individual isomers) was supplemented to the medium at different levels (10, 25, 50, and 100 μM) while LA was maintained at 25 μM. To examine whether CLA could be elongated to CEDA, 100 μM of four individual isomers were added to the medium separately. To determine the uptake of substrates (i.e., LA and CLA isomers) and conversion rates of LA to EDA and CLA to CEDA by elongase, LA and two CLA isomers (*c*9,*t*11 and *t*10,*c*12) were supplemented at 50 μM.

*Lipid extraction and fatty acid analysis.* The extraction of yeast lipids was performed according to the procedure described previously (13). Briefly, the rinsed cell pellet was extracted with 20 mL of chloroform/methanol (2:1, vol/vol) containing 16 μg triheptadecanoin (used as the internal standard). After extraction, the yeast lipids were saponified and methylated as described by Yamasaki *et al.* (19). Fatty acid methyl esters were then analyzed by gas chromatography (GC) using a flame-ionization detector and a fused-silica capillary column (Omegawax; 30 m × 0.32 mm, i.d., Supelco, Bellefonte, PA). The identity of CEDA was confirmed by GC–mass spectrometry (MS), using a Hewlett-Packard mass selective detector (model 5972) operating at an ionization voltage of 70 eV with a scan range of 20–500 Da. The mass spectrum of any new peak obtained was compared with that of standard in the database NBS75K.L (National Bureau of Standards). In this study, the conversion of substrates to products was determined based on the ratio of [product]/[product + substrate] × 100%. The amount of LA and CLA isomers taken up by the yeast was calculated from the percentage of LA or CLA isomers in total yeast lipids.

*Statistical analyses.* Data were analyzed by analysis of variance and Fisher's protected least significant difference to determine differences between means of the uptake rates and between means of the conversion rates. Means differences were considered significant at the $P \leq 0.05$ level.

## RESULTS

When the recombinant human elongase, expressed in yeast strain 334(pRAE-58), was incubated with 100 μM linoleic acid (LA) for 48 h, a substantial portion (13%) of LA was elongated to form EDA (Fig. 1B). There were also increases in the levels (relative concentration as well as absolute amount) of Δ11-18:1, the elongation product of palmitoleic acid (Δ9-16:1), and Δ13-20:1, the elongation product of Δ11-18:1. No increases in these elongation products (Δ11-18:1, Δ13-20:1, and EDA) were observed in the control 334(pYX242) yeast (Fig. 1A).

To examine the effect of CLA on elongation of LA to EDA in the transformed yeast, various concentrations of CLA mixture (10, 25, 50, or 100 μM) were added to the growth medium containing 25 μM of LA. Results in Figure 2A show that addition of the CLA mixture inhibited the conversion of LA to EDA in the transformed yeast. Elongation of LA to EDA was inhibited by 50% when equal concentrations of

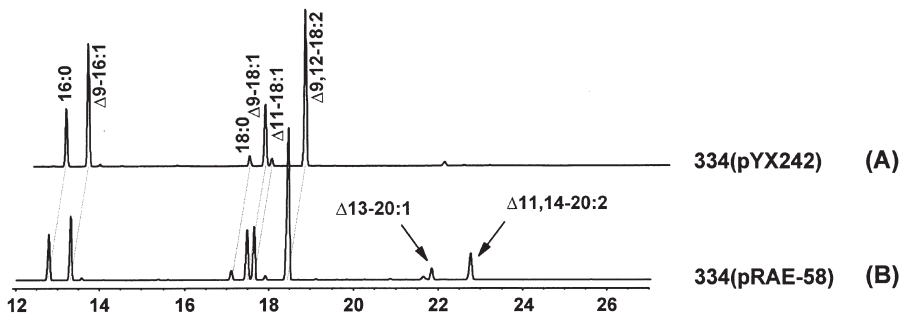

**FIG. 1.** Gas chromatographic analysis of fatty acid methyl esters (FAME) from the total lipids of the transformed yeast with (A) only the vector [334(pYX242)] or (B) the elongase gene [334(pRAE-58)]. All yeast cells were incubated in the medium containing 100 μM linoleic acid (LA). Arrows indicate the appearance of Δ13-20:1, the elongation product of Δ11-18:1, and eicosadienoic acid (Δ11,14-20:2, EDA), the elongation product of LA.

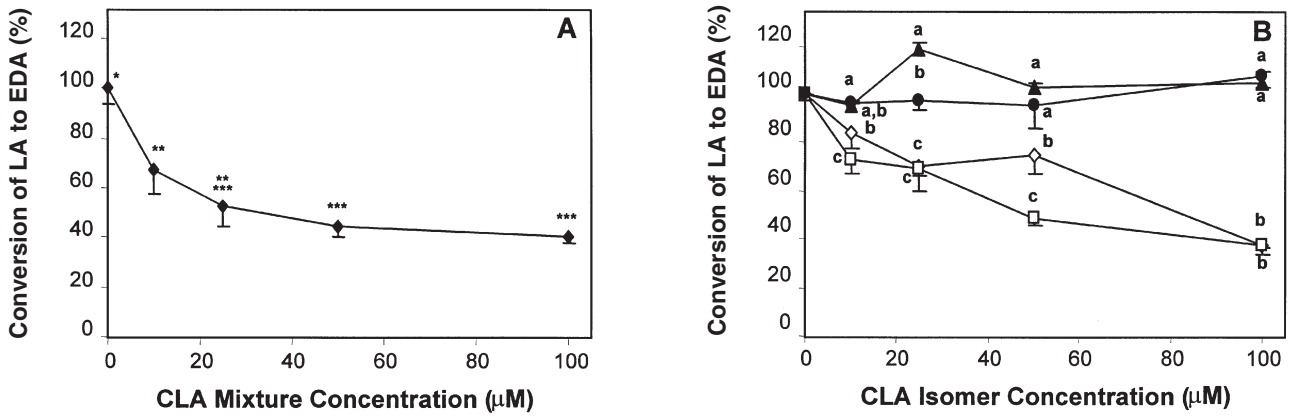

**FIG. 2.** Effect of different concentrations of conjugated linoleic acid (CLA) isomers in mixture (A) or individually (B) on elongation of LA to EDA in yeast transformed with human elongase gene. LA was maintained at 25 μM in the medium. Conversion of LA to EDA was calculated as [product/(product + substrate)] × 100%. Yeasts incubated with medium containing only 25 μM LA were designed as the control (100%). Each value point represents the mean of three incubations. At same substrate concentration, values with different letters (a,b,c) or superscripts (*,**,***) indicate a significant difference ($P < 0.05$) in the decrease in elongation of LA to EDA. *c*9,*t*11-CLA isomer (◇); *t*10,*c*12-CLA isomer (□); *c*9,*c*11-CLA isomer (▲); and *t*9,*t*11-CLA isomer (●).

CLA (25 μM) and LA (25 μM) were added to the medium. No additional inhibitory effect was observed when the concentration of CLA was greater than 25 μM.

The effect of individual CLA isomer on the elongation of LA to EDA was also examined. Figure 2B depicts that only *c*9,*t*11- and *t*10,*c*12-CLA isomers inhibited the conversion of LA to EDA, whereas the other two isomers (*c*9,*c*11- and *t*9,*t*11-CLA) exerted no such effect.

To examine whether CLA itself could be elongated by the same recombinant elongase, the transformed 334(pRAE-58) yeast were incubated with four individual CLA isomers separately for 48 h. Results in Figure 3 show that only two isomers, *c*9,*t*11- and *t*10,*c*12-CLA, could be elongated to form *c*11,*t*13-20:2 and *t*12,*c*14-20:2, respectively (Figs. 3A, 3B). No detectable elongation metabolites were observed in the 334(pRAE-58) yeasts incubated with either *c*9,*c*11- or *t*9,*t*11-CLA isomers (Figs. 3C, 3D).

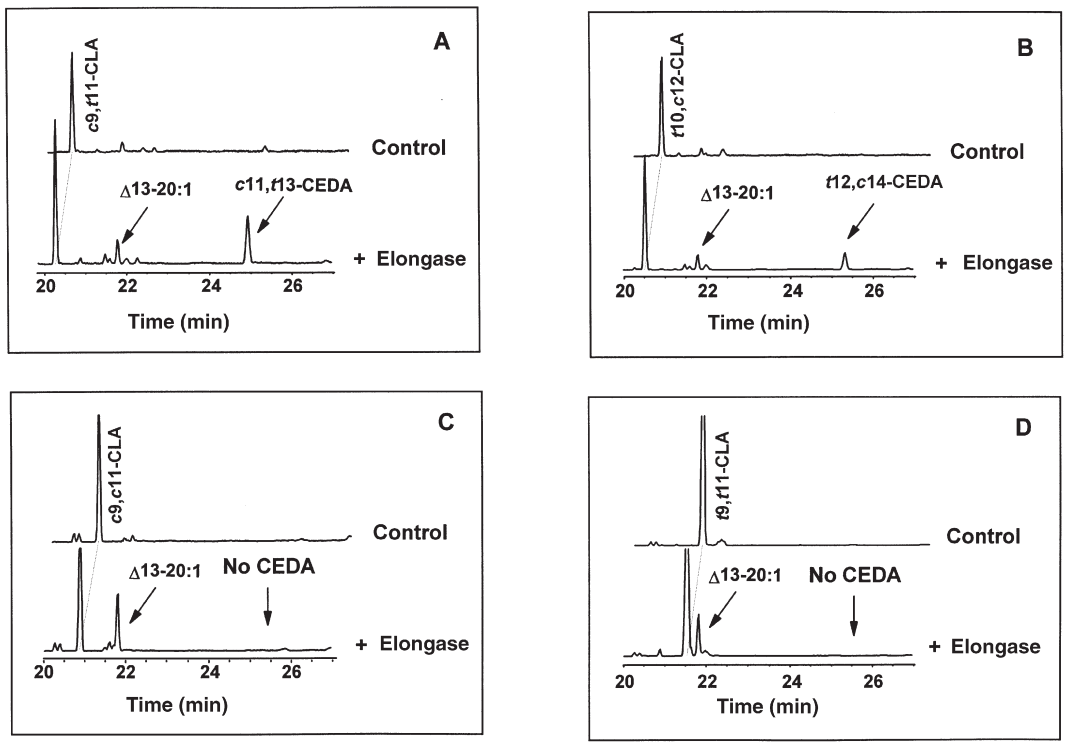

**FIG. 3.** Gas chromatographic analysis of FAME from the total lipids of yeasts transformed with only the vector (Control) or the elongase gene. Yeast cells were incubated in their respective meda containing *c*9,*t*11-CLA (A); *t*10,*c*12-CLA (B); *c*9,*c*11-CLA (C); and *t*9,*t*11-CLA (D). Arrows indicate the appearance Δ13-20:1 and conjugated eicosadienoic acid (CEDA) isomer. For other abbreviations see Figures 1 and 2.

The identity of *c*11,*t*13-20:2, the elongation product of the *c*9,*t*11-18:2, was confirmed by its retention time (25 min) in GC; and the mass peak (*m/z* = 322) and fragmentation pattern in the GC–MS spectrum were identical to the authentic *c*11,*t*13-CEDA standard (data not shown). The elongation product of *t*10,*c*12-CLA also had the same mass peak (*m/z* = 322) and a similar fragmentation pattern, but it was different in intensity from *c*11,*t*13-CEDA (data not shown). Although no authentic standard was available for comparison, evidence from later in this report suggests that the peak was *t*12,*c*14-CEDA.

The uptake of the individual CLA isomers (100 μM) and the elongation of individual CLA isomer were also examined. Figure 4 illustrates that *c*9,*t*11- and *t*10,*c*12-CLA were the two active isomers. Approximately 25% of these isomers were taken up by the transformed yeast, and significant amounts of these isomers were elongated to their respective CEDA. In contrast, approximately 40% of *c*9,*c*11- and 70% of *t*9,*t*11-isomers were taken up, but no detectable amounts of elongation products were observed.

To examine the substrate specificity of the recombinant elongase, equal amounts (50 μM) of LA and the two active forms of isomers (*c*9,*t*11- and *t*10,*c*12-CLA) were added separately into the medium, and the percentage of elongation of each substrate was determined. Results in Figure 5 show that the amounts of LA and CLA taken up by the yeast were similar. Approximately 12% of LA was elongated to EDA, but more than 25% of the two active isomers were elongated to CEDA.

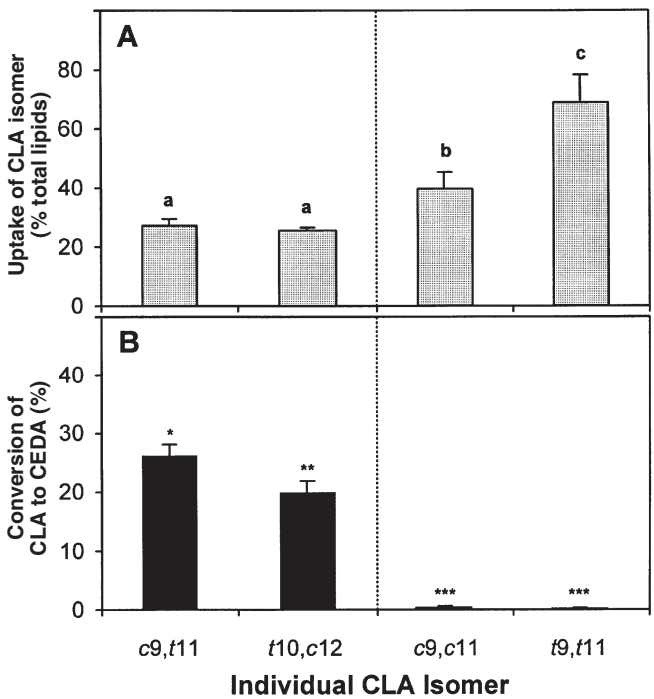

**FIG. 4.** Uptake of CLA (A) and conversion of CLA to CEDA (B) in yeasts transformed with human elongase gene. The yeast cells were cultured in 100 μM of four individual CLA isomers, respectively. The conversion of substrates to products was defined as the same as the legend of Figure 2. The uptake of CLA isomers was calculated based on the sum of CLA and CEDA isomers (% total lipids) in yeast lipids. All results are mean ± SE of three incubations. Values with different symbols or letters significantly differ from each other at $P < 0.05$. For abbreviations see Figures 2 and 3.

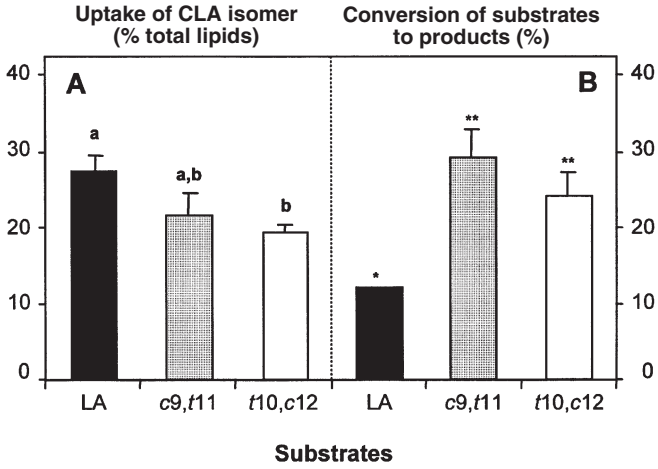

**FIG. 5.** Comparison of uptake of LA and CLA isomers (A) and conversion of LA to EDA and CLA to CEDA (B) in yeasts transformed with human elongase gene. The concentration of LA or CLA in the medium was 50 μM. All results are mean ± SE of three incubations. Values with different symbols or letters indicate a significant difference ($P < 0.05$). For abbreviations see Figures 1–3.

## DISCUSSION

Using a yeast transformed with human PUFA-specific elongase gene, we demonstrated that CLA significantly inhibited the alternate pathway of LA metabolism, i.e., elongation of LA to EDA (Fig. 2A). We also demonstrated that only *c*9,*t*11- and *t*10,*c*12-CLA isomers, among the four available isomers, could inhibit LA elongation and then themselves be elongated (Figs. 3A, 3B). There were no elongation metabolites found from the other two isomers (*c*9,*c*11 and *t*9,*t*11) (Figs. 3C, 3D), despite these two CLA isomers being taken up more readily and incorporated into the 334(pRAE-58) yeast than the two active CLA isomers. Thus, the inability to elongate these two CLA isomers was due to the substrate specificity of the recombinant elongase. It is possible that the recombinant elongase recognize only *cis*-, *trans*- or *trans*-,*cis*- configuration, but not *cis*-,*cis*- or *trans*-, *trans*- configuration of CLA. These findings suggest that the inhibitory effect of CLA on LA elongation was a result of competition between the two *c*9,*t*11- and *t*10,*c*12-CLA isomers and LA as substrate for the recombinant elongase in the transformed yeasts. Interestingly, these two isomers have been previously identified as the most biologically active CLA isomers (9,13, 20,21).

CLA plays an important role in modulating immune functions (10). The decrease of eicosanoid synthesis is attributed to the competitive role of CLA in n-6 PUFA metabolism (10–12). Another hypothesis suggests that incorporation of CLA into the cell membrane might change membrane fluidity which, in turn, influences the mobility of receptors and membrane proteins and affects signal transduction, antigen recognition, receptor-ligand interactions, and cell cycle induction (22). Unfortunately, no direct evidence to support this interesting hypothesis is yet

available. On the other hand, results from the present study and from our previous study (13), demonstrate that the two active forms of CLA (*c*9,*t*11- and *t*10,*c*12-) can inhibit the two metabolic pathways of LA (Δ6-desaturation and elongation) and hence decrease PUFA (e.g., AA) synthesis. This in turn could decrease the amount of AA entering the cyclooxygenase/lipoxygenase pathways for eicosanoid synthesis in mammalian cells.

In conclusion, we demonstrated in this study that CLA can inhibit the elongation of LA to EDA, and thus repress the alternate metabolic pathway of LA. The inhibition is likely due to the competition between LA and two active CLA isomers (*c*9,*t*11- and *t*10,*c*12-) for the enzyme elongase. Only *c*9,*t*11- and *t*10,*c*12-CLA isomers could be metabolized by the transformed yeast with recombinant elongase, and only these two isomers exerted the suppressive effect on conversion of LA to EDA. Together with a previous study, we suggest that the *c*9,*t*11- and *t*10,*c*12-isomers are the two active forms of CLA, and their ability to modulate LA metabolism may be responsible at least in part for their biological effects.

# A Unique Antioxidant Activity of Phosphatidylserine on Iron-Induced Lipid Peroxidation of Phospholipid Bilayers

**Clemente Dique Dacaranhe and Junji Terao***

Department of Nutrition, School of Medicine, The University of Tokushima, Tokushima 770-8503, Japan

**ABSTRACT:** The relationship between the antioxidant effect of acidic phospholipids, phosphatidic acid (PA), phosphatidylglycerol (PG) and phosphatidylserine (PS), on iron-induced lipid peroxidation of phospholipid bilayers and their abilities to bind iron ion was examined in egg yolk phosphatidylcholine large unilamellar vesicles (EYPC LUV). The effect of each acidic phospholipid added to the vesicles at 10 mol% was assessed by measuring phosphatidylcholine hydroperoxides (PC-OOH) and thiobarbituric acid-reactive substances. The addition of dipalmitoyl PS (DPPS) showed a significant inhibitory effect, although the other two acidic phospholipids, dipalmitoyl PA (DPPA) and dipalmitoyl PG (DPPG), did not exert the inhibition. Neither dipalmitoyl PC (DPPC) nor dipalmitoyl phophatidylethanolamine (DPPE) showed any remarkable inhibition on this system. None of the tested phospholipids affected the lipid peroxidation rate remarkably when the vesicles were exposed to a water-soluble radical generator. The iron-binding ability of each phospholipid was estimated on the basis of the amounts of iron recovered in the chloroform/methanol phase after separation of the vesicle solution to water/methanol and chloroform/methanol phases. EYPC LUV containing DPPS, DPPA, and DPPG had higher amounts of bound iron than those containing DPPC and DPPE, indicating that these three acidic phospholipids possess an iron-binding ability at a similar level. Nevertheless, only DPPS suppressed iron-dependent decomposition of PC-OOH significantly. Therefore, it is likely that these three acidic phospholipids possess a significant iron-binding ability, although this ability *per se* does not warrant them antioxidative activities. The ability to suppress the iron-dependent decomposition of PC-OOH may explain the unique antioxidant activity of PS.

Paper no. L8826 in *Lipids 36*, 1105–1110 (October 2001).

The peroxidation of phospholipid bilayers composing biomembranes has been recognized to be one of the primary events leading eventually to the damage of cellular and subcellular membranes. Moreover, the occurrence of phospholipid peroxidation has been observed in degenerative diseases (1,2). Use of liposomal vesicles as a model membrane in the study of antioxidants against the destruction of biomembranes has brought out several important features of their action mechanism (3–5). Because of its availability and convenience, lamellar vesicles prepared from egg yolk phosphatidylcholine (EYPC) frequently have been allowed to oxidize with various prooxidants such as heme compounds (6,7), transition metal ions (8,9), and so on.

The antioxidant activity of phospholipids has been reported to be a consequence of the binding of prooxidant species, often transition metal ions, by the anionic group in their structures (3). Yoshida *et al.* (8) reported the inhibitory effect of phosphatidylserine (PS), and Tadolini *et al.* (10) claimed the inhibitory effect of phosphatidic acid (PA) using EYPC lamellar vesicles as a model system to study the iron ion-induced lipid peroxidation. In both cases, the inhibitory effect was reported to be associated with the anionic charge of the polar head group. However, the mechanism of the interaction of the anionic head group of each phospholipid with iron ion and its efficiency on iron ion-induced lipid peroxidation is still unclear. Therefore, the mechanism of inhibition or promotion of lipid peroxidation by phospholipids is still a subject of argument. The purpose of this study is to clarify whether the ability of binding iron ions by acidic phospholipids can fully explain their antioxidant activity on iron ion-induced lipid peroxidation. To better understand the antioxidant mechanism of acidic phospholipids, their ability to prevent the iron ion-dependent decomposition of PC hydroperoxides (PC-OOH) was also evaluated.

## MATERIAL AND METHODS

*Chemicals.* Dipalmitoyl phosphatidic acid (DPPA), dipalmitoyl phosphatidylcholine (DPPC), dimyristoyl phosphatidylcholine (DMPC), egg yolk phosphatidylcholine (EYPC), dipalmitoyl phosphatidylethanolamine (DPPE), dipalmitoyl phosphatidylglycerol (DPPG), dipalmitoyl phosphatidylserine (DPPS), and desferal were purchased from Sigma Chemical Co. (St. Louis, MO). The purchased EYPC was purified to remove preformed PC-OOH following the method described by Terao *et al.* (11). The PC-OOH content in purified EYPC was lower than 0.14 mol% of the preparation. Iron(III) nitrate and 2,2′-azobis(2-amidinopropane)-dihydrochloride (AAPH) were obtained from Nacalai Tesque, Inc. (Kyoto, Japan). All other chemicals were of reagent grade and were used without

Abbreviations: AAPH, 2,2′-(2-amidinopropane)-dihydrochloride; BBPS, bovine brain phosphatidylserine; DMPC, dimyristoyl phosphatidylcholine; DPPA, dipalmitoyl phosphatidic acid; DPPC, dipalmitoyl phosphatidylcholine; DPPE, dipalmitoyl phosphatidylethanolamine; DPPG, dipalmitoyl phosphatidylglycerol; DPPS, dipalmitoyl phosphatidylserine; EYPC, egg yolk phosphatidylcholine; HPLC, high-performance liquid chromatography; LUV, large unilamellar vesicles; MLV, multilamellar vesicles; PC-OOH, phosphatidylcholine hydroperoxides; TBARS, thiobarbituric acid reactive-substances.

purification. PC-OOH was prepared from EYPC using soybean lipoxygenase (12) and purified by reverse-phase column chromatography by the method described previously (11).

*Preparation of unilamellar vesicles.* A purified EYPC in hexane solution and each phospholipid in chloroform/methanol (95:5, vol/vol) solution added at 10 mol% to EYPC were placed into test tubes, and the solvent was removed completely under a stream of nitrogen gas followed by further removal using a vacuum pump. Then, 0.7 mL of Tris-HCl buffer (10 mM, pH 7.4) was added to the thin lipid film on the glass wall and mixed by vortex for 1 min followed by ultrasonic irradiation for 30 s (Astrason Sonicator W-380, Heat Systems-Ultrasonics, Inc., New York) to obtain the suspension of multilamellar vesicles (MLV). Large unilamellar vesicles (LUV) were prepared from MLV by an extrusion method (13). The suspension was extruded (21 times) through a polycarbonate filter (100 nm pore size diameter) mounted in an extrusion apparatus (Liposofast; Avestin Inc., Ottawa, Canada).

*Oxidation of LUV*. After 5 min of preincubation of EYPC LUV (0.5 mL) with each added phospholipid in the dark at 37°C with continuous shaking, lipid peroxidation was initiated by the addition of 0.1 mL of $Fe(NO_3)_3$ and ascorbate solution or 0.1 mL of AAPH. The final concentrations of the components in the system were as follows: EYPC, 5 mM; phospholipids, 0.5 mM; $Fe(NO_3)_3$/ascorbic acid, 50 μM/500 μM, respectively; and AAPH, 10 mM. The reaction mixture was incubated in the same conditions of preincubation.

*Determination of PC-OOH.* The quantification of PC-OOH was carried out according to Terao *et al.* (11) using a high-performance liquid chromatography (HPLC) methodology. Aliquots of reaction mixture were withdrawn at specific time intervals and injected into an HPLC apparatus (Shimadzu SPD-10 A, Kyoto, Japan) equipped with a column Tosoh TSK gel RP-8 (150 × 4.6 mm) with a flow rate of 1.0 mL/min and detection at 235 nm. The concentration of PC-OOH was calculated from the standard curve of PC-OOH.

*Measurement of thiobarbituric acid-reactive substances (TBARS).* Thiobarbituric acid assay was performed by the method of Uchiyama and Mihara (14), and the amount of TBARS was expressed as (μM malonaldehyde equivalents using an equation obtained from a standard curve of tetraethoxypropane at the appropriate concentration.

*Iron-binding of phospholipids*. EYPC LUV (0.5 mL) containing each phospholipid at 10 mol% were prepared as described. Then, 0.1 mL of $Fe(NO_3)_3$ and ascorbate solution was added to the unilamellar vesicles. The final concentrations of the components in the reaction system were as follows: EYPC, 5.0 mM; phospholipids, 0.5 mM; and $Fe(NO_3)_3$/ascorbic acid, 50 μM/500 μM, respectively. The phase separation was accomplished by adding 2.0 mL of chloroform/methanol (1:1, vol/vol) to the mixture, followed by vortex mixing for 1 min. Afterward, the mixture was left to stand for 5 min to obtain a separation into two phases. The iron contents in aqueous and organic phases were measured using a flame atomic absorption spectrophotometer (Hitachi, Z-6100 Polarized Zeeman, Tokyo, Japan).

*The effect of phospholipids on iron-dependent decomposition of PC-OOH.* PC-OOH (0.1 μmol) and each phospholipid or desferal (0.1 μmol) in 0.8 mL of Tris-HCl buffer (10 mM, pH 7.4) were mixed by vortex and ultrasonicated for 30 s, followed by the addition of 0.2 mL of $Fe(NO_3)_3$ and ascorbate solution in Tris-HCl buffer (10 mM, pH 7.4). The final concentration of the components in the reaction systems was as follows: PC-OOH, 100 μM; phospholipids or desferal, 100 μM; $Fe(NO_3)_3$/ascorbic acid, 10 μM/100 μM, respectively. After 10 min of incubation of the reaction mixture at 37°C, the extent of PC-OOH decomposition was quantified by the measurement of PC-OOH using HPLC as described.

*Ultrafiltration of DMPC LUV.* DMPC LUV containing each phospholipid at 10 mol% to DMPC were prepared by the same procedure described above. Then, DMPC LUV (0.5 mL) was preincubated for 5 min in the dark at 37°C with continuous shaking, followed by the addition of 0.1 mL of $Fe(NO_3)_3$ and ascorbate solution. The final concentration of DMPC, phospholipids, and initiators were the same as of those described in the oxidation of EYPC LUV. Then, the mixture was incubated for 10 min under the same conditions of preincubation. At the end of incubation, DMPC LUV (0.3 mL) was submitted to centrifugal separation at 12,000 rpm for 40 min using ultrafiltrate membrane UFC3TGC00 with pore size of 10 nm (Millipore Co, Tokyo, Japan). The lower filtrate and upper layers were collected for the measurement of volumes.

*Statistical analysis.* Assays were carried out using triplicate samples. Statistical analysis was performed using the one-way analysis of variance followed by the Bonferroni/Dunn *post hoc* multiple comparison test. The level of significant difference was set at $P < 0.05$.

## RESULTS

*Antioxidant activity of phospholipids on iron-induced lipid peroxidation in EYPC LUV.* The antioxidant effect of phospholipids on iron-induced lipid peroxidation in EYPC LUV was estimated either by their ability to inhibit the accumulation of PC-OOH (Fig. 1A) or TBARS (Fig. 1B). During 5 h of incubation, PC-OOH scarcely accumulated in the vesicles containing DPPS. EYPC LUV containing DPPG, DPPC, DPPA, and DPPE showed a fast accumulation of PC-OOH during the first 3 h of incubation. After 5 h of incubation, EYPC LUV containing DPPS provided significantly lower amounts of TBARS (27.8–38.2%) than the other four vesicle solutions.

*Antioxidant activity of phospholipids on AAPH-induced lipid peroxidation in EYPC LUV.* The antioxidant activity of each phospholipid was evaluated on aqueous radical-induced lipid peroxidation, using AAPH (Fig. 2). EYPC LUV containing each added phospholipid showed a rapid increase in the amounts of PC-OOH during the first 3–4 h. During the fifth hour of incubation, PS and the other phospholipids somewhat inhibited the accumulation of PC-OOH. After 5 h of incubation, the amounts of TBARS were similar in all EYPC LUV tested.

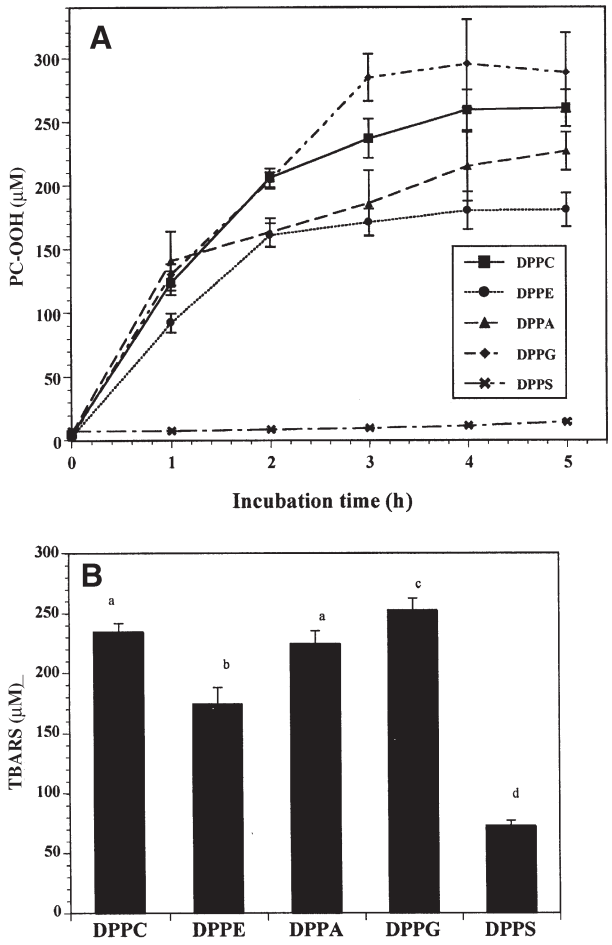

**FIG. 1.** Effect of added phospholipids in iron-induced lipid peroxidation of EYPC LUV. (A) PC-OOH formation; (B) TBARS accumulation after 5 h of incubation. EYPC LUV (0.5 mL) containing each phospholipid at 10 mol% was mixed with 0.1 mL of $Fe(NO_3)_3$ and ascorbic acid. The final concentration of components in the system was EYPC (5 mM), phospholipids (0.5 mM), $Fe(NO_3)_3$/ascorbic acid (50 μM/500 μM, respectively). The reaction was carried out in the dark at 37°C with continuous shaking. Results are means ± standard deviation of three independent measurements. Means not sharing a common letter are significantly different ($P < 0.05$). EYPC LUV, egg yolk phosphatidylcholine large unilamellar vesicles; PC-OOH, phosphatidylcholine hydroperoxide; TBARS, thiobarbituric acid-reactive substances; DPPC, dipalmitoyl phosphatidylcholine; DPPE, dipalmitoyl phosphatidylethanolamine; DPPA, dipalmitoyl phosphatidic acid; DPPG, dipalmitoyl phosphatidylglycerol; DPPS, dipalmitoyl phosphatidylserine.

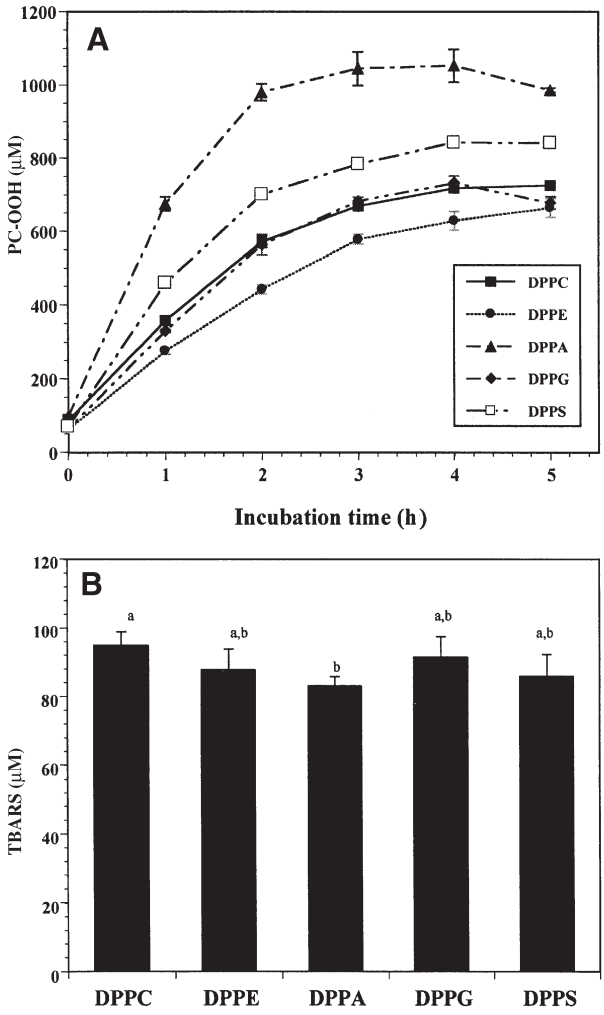

**FIG. 2.** Effect of added phospholipids on AAPH-induced lipid peroxidation in EYPC LUV. (A) PC-OOH accumulation; (B) TBARS formation after 5 h of incubation. Lipid peroxidation in EYPC LUV (0.5 mL) containing added phospholipids at 10 mol% was mixed with 0.1 mL of AAPH solution. The final concentration of EYPC and the phospholipids was the same as those in Figure 1, and the final concentration was AAPH, 10 mM. The reaction was carried out in the dark at 37°C with continuous shaking. Results are means ± standard deviation of three independent measurements. Means not sharing a common letter are significantly different ($P < 0.05$). AAPH, 2,2′-(2-amidinopropane)-dihydrochloride. For other abbreviations, see Fig. 1.

*Iron-binding activity of phospholipids.* The phosphorus assay (15) confirmed that all phospholipids moved to the organic phase (chloroform/methanol phase) after centrifugation of the mixture of LUV solution and chloroform/methanol. Consequently, iron bound to phospholipids should be present in the organic phase and free iron in the aqueous phase (water/methanol phase), respectively. The amount of iron recovered in the chloroform/methanol phase from EYPC LUV containing PS, PA, and PG was higher by far than that from EYPC LUV containing PC and PE (Fig. 3). Meanwhile, EYPC LUV with neutral (PC and PE) phospholipids showed a higher amount of iron in the aqueous phase than the three acidic phospholipids.

*Ability of phospholipids to prevent the iron/ascorbic acid–dependent decomposition of PC-OOH.* The ability of phospholipids to prevent the iron-dependent PC-OOH decomposition was estimated on the basis of the decrease of PC-OOH after the reaction with $Fe(NO_3)_3$/ascorbic acid (Fig. 4). In the absence of any added phospholipids (control), approximately 74% of PC-OOH was decomposed. Phospholipids other than DPPS had little preventive effect on PC-OOH decomposition. However, DPPS significantly prevented the decomposition of PC-OOH and its effect was comparable to that of desferal, a well-known iron ion chelator.

*Water-holding ability and perturbation of DMPC LUV.* The effect of incorporation of each phospholipid into the vesicles on water-holding ability and further perturbation of the

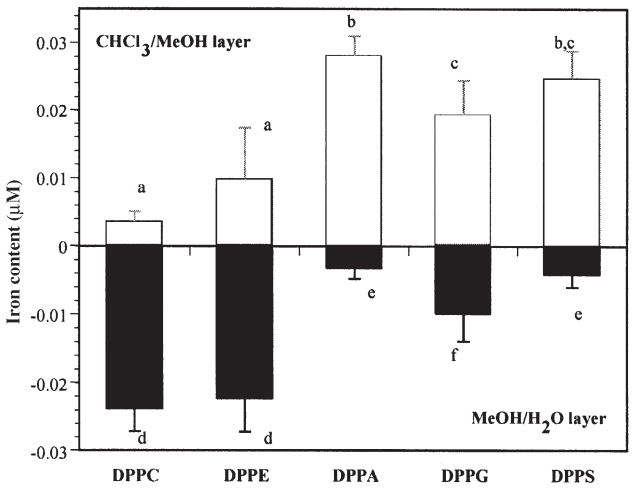

**FIG. 3.** Iron-binding activity of phospholipids. $Fe(NO_3)_3$ and ascorbic acid (0.1 mL) were added to the EYPC LUV (0.5 mL) containing phospholipids at 10 mol%. The final concentration of components in the system was the same as described in Figure 1. The components were separated in two phases by the addition of 2 mL of chloroform/methanol (1:1, vol/vol). Results are means ± standard deviations of three independent measurements. Means not sharing a common letter are significantly different ($P < 0.05$). For abbreviations see Figure 1.

lipid core of LUV was evaluated by submitting the DMPC LUV contents to separation by ultrafiltration. Because of its saturated acyl chain, DMPC was chosen to avoid complication with the formation of lipid peroxidation products during the analysis. After the filtration, the phosphorus assay (15) ensured that phospholipids were present only in the upper phase fraction (data not shown). Therefore the upper phase represented the LUV lipid core. Meanwhile, DMPC LUV containing anionic phospholipids (DPPS, DPPA, and DPPG) produced filtrate volumes higher than those containing neutral phospholipids (DPPC and DPPE) (Table 1). The amounts of collected filtrate volumes increased in the following order: DPPC = DPPE < DPPA < DPPS < DPPG.

**TABLE 1**
**Ultrafiltration of DMPC LUV[a]**

| | Volumes (μL) | | | | |
|---|---|---|---|---|---|
| | DPPC | DPPE | DPPA | DPPG | DPPS |
| Upper phase | 175 ± 10[a] | 165 ± 5[a] | 135 ± 15[b] | 60 ± 5[c] | 100 ± 5[d] |
| Filtrate phase | 125 ± 5[e] | 135 ± 5[e] | 165 ± 10[f] | 240 ± 10[g] | 200 ± 15[h] |

[a]DMPC LUV containing phospholipids at 10 mol% were prepared by the procedure described in the Materials and Methods section. The final concentrations of components in the reaction system were as follows: DMPC (5 mM), phospholipids (0.5 mM), $Fe(NO_3)_3$/ascorbic acid (50 μM/500 μM). At the end of incubation, DMPC LUV (0.3 mL) was submitted to centrifugal separation at 12,000 rpm for 40 min using ultrafiltrate membrane UFC3TGC00 (pore size 10 nm). The filtrate and upper phases were collected for the measurement of volumes. Results are means ± standard deviation of three independent measurements. Means with different roman letter superscripts are significantly different ($P < 0.05$). DMPC LUV, dimyristoyl phosphatidylcholine large unilamellar vesicles; DPPC, dipalmitoyl phosphatidylcholine; DPPE, dipalmitoyl phosphatidylethanolamine; DPPA, dipalmitoyl phosphatidic acid; DPPG, dipalmitoyl phosphatidylglycerol; DPPS, dipalmitoyl phosphatidylserine.

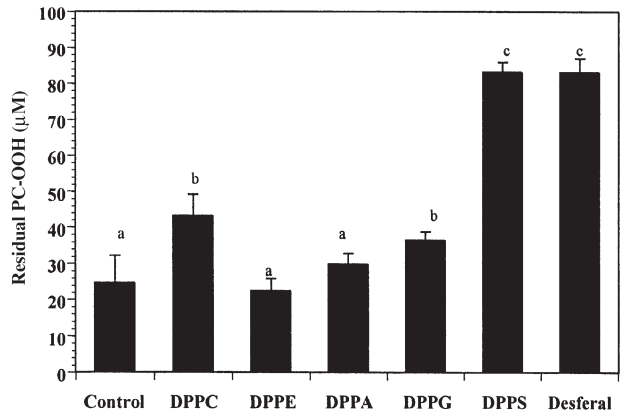

**FIG. 4.** Effect of phospholipids on iron-dependent decomposition of PC-OOH. $Fe(NO_3)_3$ and ascorbic acid (0.2 mL) were added to PC-OOH (0.1 μmol) and phospholipids or desferal (0.1 μmol) in 0.8 mL of 10 mM Tris-HCl buffer (pH 7.4). The final concentration of components in the reaction systems were as follows: PC-OOH, 100 μM; phospholipids or desferal, 100 μM; $Fe(NO_3)_3$ and ascorbic acid, 10 and 100 μM, respectively. The reaction was carried at 37°C for 10 min. Results are means ± standard deviations of three independent measurements. Means not sharing a common letter are significantly different ($P < 0.05$). For abbreviations see Figure 1.

## DISCUSSION

EYPC LUV used in this study were prepared and allowed to oxidize at pH 7.4 in the presence of iron. The increase in PC-OOH amount observed during the incubation of EYPC LUV confirmed the prooxidant role of iron ion/ascorbic acid, as earlier demonstrated by Kunimoto *et al.* (16), Fukuzawa *et al.* (17) and Tadolini *et al.* (18). Moreover, TBARS measurements also confirmed the extent of lipid peroxidation in the vesicles. Among all added phospholipids to EYPC LUV, only the addition of DPPS resulted in a remarkable inhibition of lipid peroxidation (Fig. 1). In contrast, neither DPPS nor other phospholipids tested avoided the accumulation of PC-OOH and TBARS when AAPH was used as a radical generator (Fig. 2). This result indicates that DPPS and other phospholipids tested do not act as radical scavengers.

When the EYPC LUV contents were separated into two phases (organic and aqueous phases), phospholipids were detected only in the organic phase. Thus, phospholipid-bound iron is likely to be dragged into the organic phase whereas free iron seems to remain in the aqueous phase. All EYPC LUV containing added phospholipids with anionic polar head groups (DPPA, DPPG, and DPPS) showed a relatively higher amount of iron in the organic phase, as compared with those with neutral polar head groups (DPPC and DPPE) (Fig. 3). Therefore, it is apparent that the anionic groups of phospholipids are equally responsible for the binding of iron ions. Because the incorporation of phospholipids with anionic groups

in EYPC LUV resulted in a significantly higher amount of trapped irons (DPPA, 92.2%; DPPG, 67.3%; and DPPS, 82.7%) than the incorporation of those containing neutral polar head groups (DPPC, 12.3%; and DPPE, 32.6%), it is expected that all acidic phospholipids contribute to the enhancement of the stability of vesicles against the attack of iron ion. However, this was not the case because two phospholipids with anionic polar head groups, DPPA and DPPG, did not enhance the oxidative stability of LUV (Fig. 1). Earlier, Yoshida *et al.* (8) claimed that the inhibitory effect of PS on iron ion-dependent lipid peroxidation was due to its negatively charged polar head group, which neutralizes the prooxidant action of iron. Present findings suggest that the binding of iron ion by the polar head group of PS does not explain fully the unique antioxidant effect of PS on iron-induced lipid peroxidation.

Prior to this study, we purified the EYPC to eliminate the preformed PC-OOH. However, small amounts of PC-OOH (less than 10 μM) were detected at the start of incubation (Fig. 1A). The iron-induced lipid peroxidation in EYPC LUV is believed to start with the decomposition of preformed PC-OOH by the metal iron, producing unstable species such as peroxyl and alkoxyl radicals, which are later responsible for the propagation of chain reaction (19). Hence, the inhibition of lipid peroxidation rate should be reciprocally associated with the protection of iron-dependent PC-OOH decomposition (Fig. 4). The present study showed the unique ability of DPPS to protect PC-OOH against the attack of iron ion. This protective effect was comparable to that of desferal, a well-known iron ion chelator. The protective mechanism of lipid peroxidation in LUV containing DPPS appears to occur as shown in Scheme 1.

$$Fe^{3+} + AsA^{-} \rightarrow Fe^{2+} + AsA\bullet$$
$$PC\text{-}OOH + Fe^{2+} \rightarrow PC\text{-}O\bullet + OH^{-} + Fe^{3+}$$
$$PC\text{-}O\bullet + PC \rightarrow \text{Radical chain reaction}$$
$$PC\text{-}OOH + Fe^{2+}\text{-DPPS} \rightarrow \text{no decomposition}$$

**SCHEME 1**

$AsA^{-}$: ascorbic acid; PC-O•: alkoxy radical

Other acidic phospholipids (DPPA and DPPG) and neutral phospholipids (DPPC and DPPE) did little to prevent PC-OOH decomposition. Thus, the differences in the reactivity of the phospholipid-bound iron ion toward the PC-OOH preformed in the bilayers should be an essential factor to explain the different behaviors of added phospholipids on liposomal lipid peroxidation. Nevertheless, the mechanisms through which chelators influence the lipid peroxidation reactions are not fully understood (9,20).

While none is bound to the phosphate group in the structure of PA, PG and PS have glycerol and serine moieties, respectively, attached to the phosphate group. The incorporation of charged molecules into phospholipid bilayers may generate an electrostatic charge that is related to the formation of an electrostatic surface potential responsible for a redistribution of cations and anions, including protons and hydroxyl ions at the bilayer–water interface (21). The electrostatic surface at the interface of the membrane may alter the intensity of interaction of iron ion with lipid core. Thus, a stronger barrier at the interface appears to favor the enhancement of the oxidative stability of EYPC LUV. This could also affect the water-holding activity of the bilayers. As shown by changes in water-holding activity (Table 1), the incorporation of acidic phospholipids, DPPA, DPPG and DPPS, seems to cause changes in the size of EYPC LUV and disturb their rigidity. However, this observation does not explain the unique antioxidant activity of PS, because the water-holding ability was nonspecific and not correlated with the suppression of lipid peroxidation.

The role of phosphoserine on lipid peroxidation of EYPC LUV was also examined (data not shown) in order to clarify whether the inhibitory effect of PS depends only on the polar head group. The inhibitory effect of DPPS did not depend only on the action of phosphoserine but may depend on the whole structure of PS as one compound. The acyl chain of PS may play a key role in localization and distribution of phosphoserine in the interface of membrane where the inhibition of iron ion-dependent lipid peroxidation seems to take place.

PS is an essential component of human cellular and subcellular membranes. Several studies have suggested that treatment with PS is effective on the age-related mental decline (22,23). PS is also postulated to function as a regulator of immune and inflammatory responses (24,25). The antioxidant effect of PS shown in this study may be related to some pharmacological activities or physiological activities. Further studies are required to clarify its role in oxidative stress in cellular and subcellular systems.

In conclusion, PS possesses a unique antioxidant activity on iron-induced lipid peroxidation in phospholipid membranes. This effect may originate from its effective prevention of preformed hydroperoxide decomposition.

## ACKNOWLEDGEMENT

We thank to Sayuri Miyamoto for technical advice for the PC-OOH assay.

**ABSTRACT:** The purpose of the present paper is to study and compare *in vitro* the inhibitory effect of 3,4-dihydroxyphenylacetic acid (DOPAC) and caffeic acid (CA) on lipid peroxidation in rat plasma. Rat plasma was oxidized at 37°C by the radical initiators 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH) or 2,2′-azobis(4-methoxy-2,4-dimethylvaleronitrile) (MeO-AMVN). The consumption of endogenous α-tocopherol (α-TOH) and the accumulation of conjugated diene hydroperoxides were measured by high-performance liquid chromatography and by ultraviolet spectroscopy, respectively. α-TOH was consumed at the same rate in the presence of 20 mM AAPH or 2 mM MeO-AMVN. DOPAC and CA suppressed the α-TOH consumption in a dose-dependent manner. A concentration of 50 μM of both phenolic acids was sufficient to induce a lag phase and to delay the rate of α-TOH consumption. The effect was more pronounced in rat plasma oxidation by AAPH than by MeO-AMVN. CA spared vitamin E more effectively than DOPAC in both oxidations. DOPAC and CA suppressed the formation of conjugated diene hydroperoxides. DOPAC and CA at concentration 50 μM suppressed α-TOH consumption during oxidation of soybean phosphatidylcholine (2.8 mM) multilamellar vesicles containing 15 μM α-TOH, in which the lipophilic initiator 2,2′-azobis (2,4-dimethylvaleronitrile) (6 mM) was incorporated. In conclusion, we demonstrated that DOPAC and CA in micromolar concentrations have antioxidant activity in rat plasma, a medium very close to the conditions *in vivo*, suggesting that supplementation with the phenolic acids will provide significant antioxidant protection.

Paper no. L8825 in *Lipids 36*, 1111–1116 (October 2001).

Hydroxybenzoic and hydroxycinnamic acids and their derivatives have been studied recently for their antioxidant activity *in vitro* and *in vivo* in humans and in rats (1–19). Among them, caffeic acid (CA) shows the highest antioxidant activity and the greatest radical scavenging activity (1,2,4–8, 15–17) despite the different experimental conditions. The daily uptake in humans of CA is 206 mg (20), and the major sources are coffee (20–22), black and green teas (23,24), fruits and fruit juices (25–29), tomatoes and tomato juices (25,26), carrots (30), honey (31), red wine (10,32), and olive oil (1,2,33).

3,4-Dihydroxyphenylacetic acid (DOPAC), whose structure is analogous to that of CA but lacks a double bond in the aliphatic chain, also exerts antioxidant activity in lipids (7,34). The daily uptake of DOPAC with food is 7.27 mg, and it is present in nanomolar concentrations in human plasma (35,36), DOPAC has been studied in relation to sympathetic nervous activity (35–37) but not as an antioxidant *in vitro* in plasma or low density lipoproteins (LDL) or *in vivo*. DOPAC has a structure analogous to hydroxytyrosol, the most effective antioxidant in olive oil (38–40), and is used as an antioxidant instead of hydroxytyrosol (34) because it is not commercially available.

Phenolic antioxidants from olive oil protect LDL against oxidative modifications (38–42), and have a beneficial effect against atherosclerosis. They are active in the defense of the cardiovascular, immune, and respiratory systems in humans (38); lower the risk of gastrointestinal diseases (39); and show anticancer potential (1). The antimicrobial properties of honey are attributed to CA and other phenolic compounds contained in it (31).

To elucidate the antioxidant and the biological significance of the phenolic acids, we studied *in vitro* the inhibitory effect of DOPAC and CA on lipid peroxidation in rat plasma. For the purpose, rat plasma was oxidized in the presence of DOPAC or CA at 37°C by the radical initiators 2,2′-azobis (2-amidinopropane) dihydrochloride (AAPH) or 2,2′-azobis (4-methoxy-2,4-dimethylvaleronitrile) (MeO-AMVN). The inhibitory effect of DOPAC and CA on the consumption of α-tocopherol (α-TOH) in soybean phosphatidylcholine (PC) multilamellar vesicles (MLV), containing α-TOH, and oxidized by incorporated 2,2′-azobis (2,4-dimethylvaleronitrile) (AMVN), was also studied in order to distinguish the point where the phenolic antioxidants act.

## MATERIALS AND METHODS

*Materials.* Ascorbic acid (AA), AAPH, AMVN, MeO-AMVN, 2,2,5,7,8-pentamethyl-6-chromanol (PMC), and α-TOH were purchased from Wako Pure Chemical Industries Ltd. (Osaka, Japan). DOPAC and CA were obtained from

Abbreviations: AA, ascorbic acid; AAPH, 2,2′-azobis(2-amidinopropane) dihydrochloride; AMVN, 2,2′-azobis(2,4-dimethylvaleronitrile); CA, caffeic acid; DOPAC, 3,4-dihydroxyphenylacetic acid; HPLC, high-performance liquid chromatography; LDL, low density lipoproteins; MeO-AMVN, 2,2′-azobis(4-methoxy-2,4-dimethylvaleronitrile); MLV, multilamellar vesicles; PBS, phosphate-buffered saline; PC, phosphatidylcholine; PMC, 2,2,5,7,8-pentamethyl-6-chromanol; α-TOH, α-tocopherol.

Sigma Chemical Co. (St. Louis, MO). Soybean PC was purchased from Nichiyu Liposome Co., Inc. (Tokyo, Japan). Ethanol and 2-propanol were from Wako Pure Chemical Industries Ltd. and methanol and *n*-hexane from Kanto Chemical Co, Inc. (Tokyo, Japan). The *n*-hexane and 2-propanol were of high-performance liquid chromatography (HPLC) grades. All other reagents were of analytical grade.

*Animals and diets*. All experimental procedures were conducted in compliance with Teikyo University's policy on animal care and use. Seven male rats, Sprague-Dawley strain, 5 wk old, were purchased from Saitama Experimental Animals Supply Co., Ltd. (Saitama, Japan). They were fed Certified-1 Diet (CRF-1; Oriental Yeast Co., Tokyo, Japan) for 30 wk. During this period, blood from the retro-ocular plexus of each animal was taken at certain intervals. The α-TOH content in the plasma, obtained by centrifugation of rat blood, was in the range 14–17 μM.

*Rat plasma oxidation and its inhibition by antioxidants.* Rat plasma was obtained by mixing the plasma from several rat blood samples centrifuged twice at 2500 rpm for 5 min. Fresh rat plasma (2 mL), without or with the antioxidants DOPAC, CA in ethanol solution, or a water solution of AA added beforehand at appropriate concentration, was incubated for 2–3 min at 37°C in a waterbath shaker before the oxidants AAPH (20 mM) in 1 mM EDTA solution or MeO-AMVN (2 mM) in methanol solution were added to start the oxidation. The final concentration of methanol and ethanol was 1 and 0.5 vol%, respectively. A freshly prepared water solution of AA in 1 mM EDTA was used. Aliquots of 0.2 mL of oxidized rat plasma were withdrawn at measured time intervals. The oxidation was stopped by the addition of EDTA (100 μM) and freezing (43).

*MLV preparation, oxidation, and inhibition of MLV oxidation.* Soybean PC (2.8 mM), α-TOH (15 μM), and AMVN (6 mM) were dissolved in chloroform, mixed, and the solvent was evaporated completely under nitrogen ($N_2$). Phosphate buffered saline (PBS; 10 mM, pH 7.4) containing EDTA (0.1 mM) was added and mixed on a vortex mixer to form an MLV suspension. The MLV suspension was divided into three tubes. DOPAC and CA at concentrations of 50 μM were added to two of them. The MLV suspensions with DOPAC or CA and without antioxidant were placed in a waterbath shaker (37°C, 150 oscillations per minute) to start the oxidation. Aliquots of 0.2 mL were withdrawn at measured time intervals and handled as already described.

*Extraction of α-TOH from rat plasma or MLV and its detection by HPLC with fluorometric detector.* α-TOH was extracted from rat plasma or MLV suspension by the modified method of Abe and Katsui (44), and Abe *et al.* (45), as described by Shabit *et al.* (46). A volume of 15 μL ethanol containing 3 μg PMC as an internal standard was added to oxidized rat plasma or MLV suspension (0.2 mL). The sample was diluted with distilled water (2.0 mL) and ethanol (2.0 mL) after consecutive mixings for 1 min with a vortex mixer. The α-TOH was extracted with *n*-hexane (5.0 mL). A 0.9% NaCl water solution (2.0 mL) was added and mixed 2–3 min with a vortex mixer at which time rat plasma was used (for precipitation of the proteins). The mixture was centrifuged at 3200 rpm for 10 min at 4°C. The upper layer, containing α-TOH, the internal standard, and the lipids, was pipetted. All procedures were performed at 4°C in an ice bath. The *n*-hexane was evaporated under $N_2$. The residue was then dissolved in *n*-hexane (1.6 mL). A volume of 20 μL of this solution was injected into the column of the HPLC system.

The HPLC system contained an injector (Rheodyne Incorporated, Cotati, CA), DGU-4A Shimadzu degasser (Shimadzu Corp., Kyoto, Japan), $NH_2$-1251-N, 4.6 × 250 mm, Senshu Pak column (Senshu Scientific Co., Ltd., Tokyo, Japan), LC –10 AD Shimadzu liquid chromatograph, RF-10 A Shimadzu spectrofluorometric detector, and C-R6A Shimadzu Chromatopac recorder. The α-TOH was detected at an excitation wavelength of 298 nm and an emission wavelength of 325 nm. The mobile phase was *n*-hexane/2-propanol (98:2, vol/vol) at flow rate 1.0 mL/min.

*Ultraviolet (UV) analysis of conjugated diene hydroperoxides formation.* Diluted oxidized rat plasma (plasma/distilled water = 1:80, vol/vol) without or with antioxidants was analyzed by U-3310 Hitachi spectrophotometer (Tokyo, Japan) by scanning from 300 to 200 nm at a rate of 60 nm/min. Eighty times diluted unoxidized rat plasma was used as a reference.

## RESULTS AND DISCUSSION

*Rat plasma oxidation.* Azo compounds generate free radicals by their spontaneous thermal decomposition. They have been used successfully in studies, both *in vitro* and *in vivo*, on the actions of free radicals upon biological molecules and on the protective effect of antioxidants (47).

We found that 20 mM AAPH in 1 mM EDTA water solution or 2 mM MeO-AMVN in methanol induced the oxidation of rat plasma at 37°C. In Figure 1 the kinetic curves of the consumption of endogenous α-TOH (A) and the accumulation of conjugated diene hydroperoxides, measured at 233 nm (B), in oxidized rat plasma are shown. α-TOH was consumed at the same rate in the presence of the initiators AAPH (20 mM) and MeO-AMVN (2 mM). For example, the change in absorbance of 80 times diluted rat plasma, oxidized by AAPH (20 mM), as determined by scanning from 300 to 200 nm at a speed of 60 nm/min, is shown at Figure 2.

*Inhibition of rat plasma and MLV oxidation by DOPAC and CA*. DOPAC and CA in the concentration range of 10–100 μM (Figs. 3A and 3B, respectively) suppressed α-TOH consumption in rat plasma, oxidized by AAPH (20 mM). Nardini *et al.* (15) also showed a dose-response effect of CA on $Cu^{2+}$-mediated and AAPH-induced oxidative modifications of LDL, as measured by formation of conjugated dienes at 234 nm. A concentration of 50 μM of either DOPAC (Fig. 3A) or CA (Fig. 3B) was sufficient to induce a remarkable lag phase and to delay the rate of α-TOH consumption in rat plasma.

DOPAC and CA exogenously added at a concentration of 100 μM delayed the formation of conjugated diene hydroper-

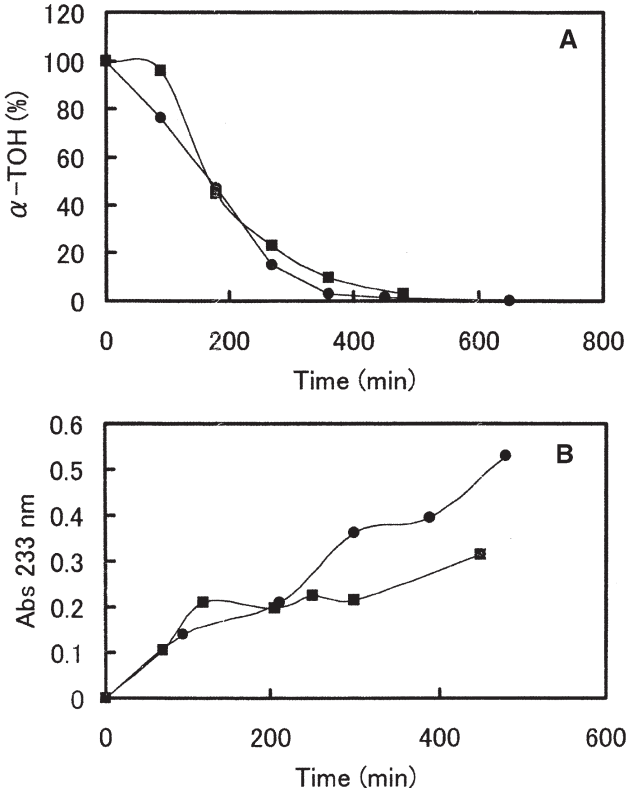

**FIG. 1.** α-Tocopherol (α-TOH) consumption (A) and change in absorbance at 233 nm (B) with time in the oxidation of rat plasma, oxidized by 20 mM 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH) (●) and by 2 mM 2,2′-azobis(4-methoxy-2,4-dimethylvaleronitrile (MeO-AMVN) (■) under air at 37°C.

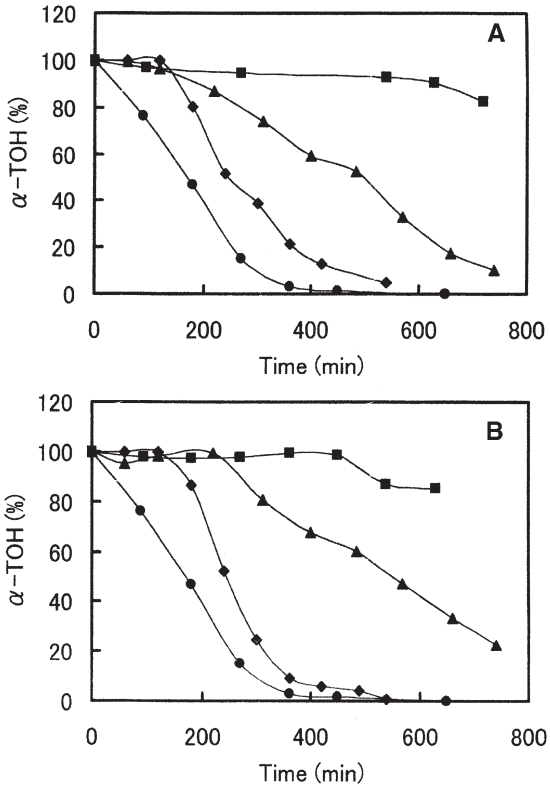

**FIG. 3.** Dose-dependent effect of the antioxidants 3,4-dihydroxyphenylacetic acid (DOPAC) (A) and caffeic acid (CA) (B) on α-TOH consumption in the oxidation of rat plasma induced by AAPH. The antioxidants, at concentrations of 10 (◆), 50 (▲), and 100 μM (■), were added to rat plasma (2 mL) before AAPH (20 mM) was finally added to start the oxidation under air at 37°C. (●) α-TOH consumption without the addition of antioxidant. For abbreviations see Figure 1.

oxides, as shown in Figure 4. AA added at the same concentration also delayed the formation of conjugated diene hydroperoxides but had a smaller effect than the two phenolic acids (Fig. 4).

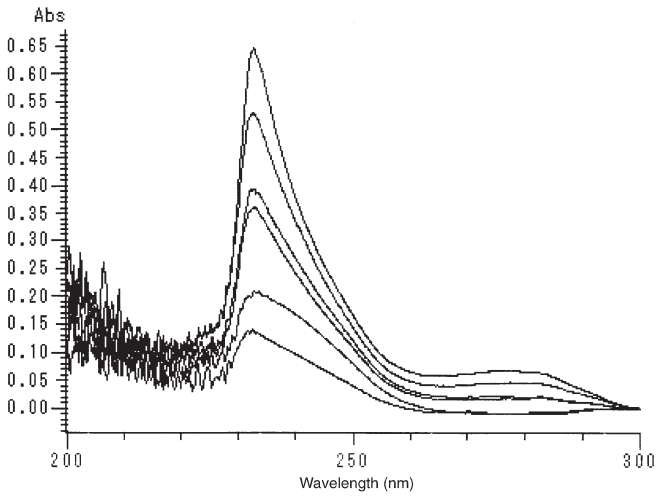

**FIG. 2.** Increase in absorbance of rat plasma, oxidized by AAPH (20 mM). Samples of 0.05 mL of oxidized rat plasma were withdrawn at 95, 210, 300, 390, 480, and 570 min of oxidation time from the reaction mixture and were dissolved in 4 mL of distilled water. The spectrum was scanned from 300 to 200 nm at a speed 60 nm/min. For abbreviation see Figure 1.

Our data showed that DOPAC and CA in micromolar concentrations were inhibitory to lipid peroxidation in rat plasma. This result is relevant because DOPAC and CA are present in human plasma in nanomolar concentrations (32,35,36) and CA is present in rat and rabbit plasma in micromolar concentrations (9,33), indicating antioxidant activity among the other biological activities of both phenolic acids in plasma. We have demonstrated here that DOPAC has antioxidant activity in a natural substrate such as rat plasma, not just in purified food lipids (7,13,34). CA is known to be active against oxidative modifications in LDL at micromolar concentrations (3,5,8,10,14,15,17), but its effect has not been investigated in plasma.

The inhibitory effects of DOPAC, CA, and AA on α-TOH consumption were compared in AAPH- and MeO-AMVN-induced rat plasma oxidations (Figs. 5A and 5B, respectively). DOPAC and CA spared α-TOH more efficiently in AAPH-induced oxidation, where the hydrophilic initiator produced radicals in the aqueous phase, than in MeO-AMVN-induced oxidation, where the initiator produced radicals in the lipid environment and in the aqueous phase. There were a notable lag-phase and delay of the rate of α-TOH consumption in AAPH-induced oxidation (Fig. 5A) compared with the MeO-AMVN-induced oxidation (Fig. 5B).

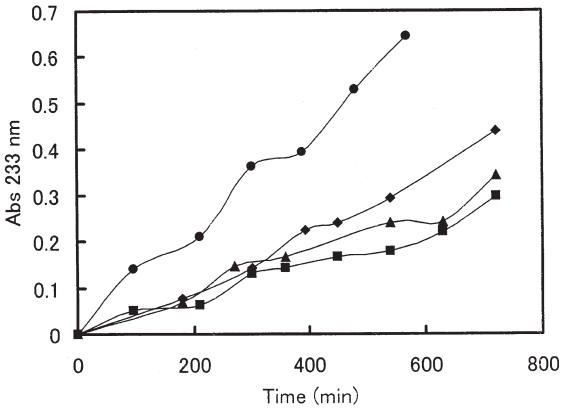

**FIG. 4.** Inhibitory effect of the antioxidants ascorbic acid (AA) (◆), DOPAC (▲), and CA (■) on the formation of conjugated diene hydroperoxides in the oxidation of rat plasma induced by AAPH. The antioxidants, at concentrations of 100 μM, were added to rat plasma (2 mL) before AAPH (20 mM) was finally added to start the oxidation under air at 37°C. (●) Change in absorbance at 233 nm without the addition of antioxidant. For abbreviations see Figures 1 and 3.

To distinguish where the phenolic antioxidants DOPAC and CA act, α-TOH consumption was followed during oxidation at 37°C of soybean PC (2.8 mM) MLV where α-TOH (15 μM) and AMVN (6 mM) were incorporated (Fig. 6). DOPAC and CA at concentrations of 50 μM spared 45% of the α-TOH. α-TOH was consumed almost completely in an MLV suspension without the addition of phenolic antioxidant. In an MLV suspension DOPAC and CA showed identical antioxidant activity: The curve of consumption of α-TOH in the course of oxidation was the same for both phenolic acids, as seen from Figure 6. For comparison, in rat plasma CA was more effective than DOPAC in sparing α-TOH, as shown in Figure 5.

DOPAC and CA spared α-TOH consumption more effectively in rat plasma oxidation induced by a hydrophilic initiator than in rat plasma oxidation induced by a lipophilic initiator and at the same time showed inhibition activity in an MLV system, oxidized by the lipophilic initiator AMVN. It can be concluded that DOPAC and CA most probably acted as antioxidants at the interface of the biological membranes. Laranjinha and Cadenas (3) suggested that the antioxidant activity of CA is largely related to its localization at the bilayer surface where it can encompass the reduction of the α-TOH radical rather than intercept directly any secondary lipid peroxyl radicals. Carbonneau *et al.* (8), investigating the antioxidant effect of CA, sinapic and ferulic acids on LDL oxidation, proposed that phenolic acids are loosely associated with LDL, possibly remaining at least partially at the surface of the particle by virtue of their mainly hydrophilic properties. The antioxidant potential of ferulic acid (11) was associated with its distribution. The major portion of the ferulic acid was found in the albumin-rich fraction of the plasma, and a portion was found to partition between the LDL and the aqueous phase. However, ferulic acid does not associate with the lipid portion of the LDL particle, suggesting that it exerts its antioxidant properties from the aqueous phase.

Our results showed that CA spared α-TOH more efficiently than DOPAC in both AAPH- and MeO-AMVN-induced rat plasma oxidations. Previous results indicated that CA had a greater antioxidant activity than DOPAC during oxidation of lard triacylglycerols at 100°C because the DOPAC radical participated in chain propagation reactions (7). CA has the highest antioxidant activity among the phenolic acids

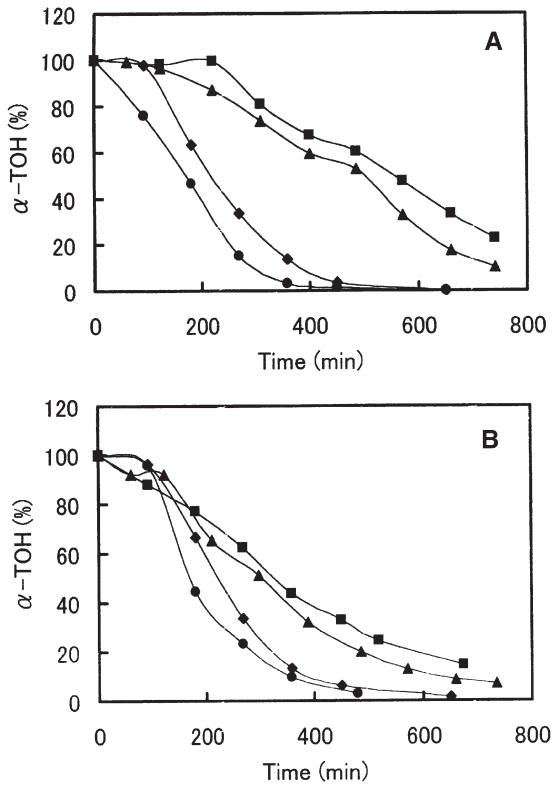

**FIG. 5.** Comparison of the effect of the antioxidants AA (◆), DOPAC (▲), and CA (■) on α-TOH consumption in the oxidation of rat plasma induced by AAPH (A) or by MeO-AMVN (B). The antioxidants, at concentrations of 50 μM, were added to rat plasma (2 mL) before AAPH (20 mM) or MeO-AMVN (2 mM) was added to start the oxidation under air at 37°C. (●) α-TOH consumption without the addition of antioxidant. For abbreviations see Figures 1 and 3.

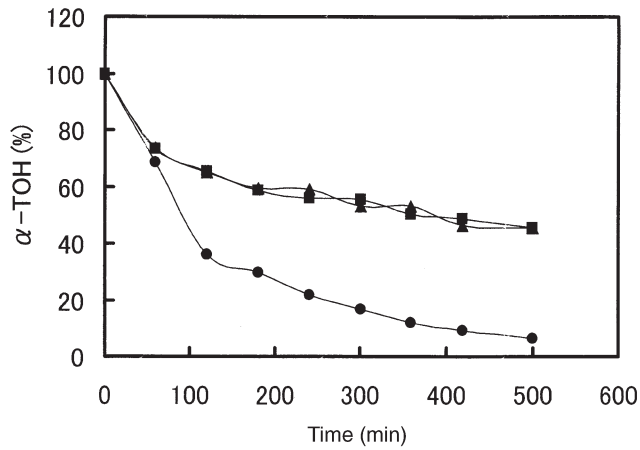

**FIG. 6.** Inhibitory effect of the antioxidants DOPAC (▲) and CA (■) at concentrations of 50 μM on the oxidation of soybean phosphatidylcholine (2.8 mM) multilamellar vesicles where α-TOH (15 μM) and AMVN (6 mM) were incorporated. (●) α-TOH consumption without the addition of antioxidant. For abbreviations see Figures 1 and 3.

(6,12,16) and displays one of the highest reactivities toward peroxyl radicals (19) owing to the presence of two hydroxyl groups in the ortho-position and to the stabilization of the caffeic acid radical by resonance in the aliphatic double bond.

Exogenously added AA in AAPH or MeO-AMVN oxidations also delayed the rate of α-TOH consumption and induced a lag-phase, but its effect was smaller than DOPAC or CA (Fig. 5). It also delayed the formation of conjugated diene hydroperoxides to a lesser extent than the two phenolic acids (Fig. 4). CA and *p*-coumaric acid (3,5) showed a greater antioxidant effect than AA in LDL oxidation mediated by ferrylmyoglobin. Ferulic acid (11) was a more effective antioxidant against LDL oxidation than the hydrophilic AA.

We considered the antioxidant activity of DOPAC and CA in rat plasma, where other natural antioxidants such as α-TOH (14–20 μM), AA (50–90 μM) (9,48–53), ubiquinone (0.5–1 μM) (48,53,54), glutathione (1.2 μM) (49), and uric acid (0.6–20 mM) (9,49) are contained. We evaluated their synergistic action with the antioxidants present in rat plasma. The inhibitory activity of DOPAC and CA in the MLV system must be considered a consequence of their synergistic action with α-TOH. Laranjinha *et al.* (3) demonstrated a synergistic action between CA, α-TOH, and AA and between CA or *p*-coumaric acid and AA (5) in LDL, oxidized by ferrylmyoglobin. Carbonneau *et al.* (8) assumed that flavonoids such as CA, sinapic and ferulic acids played a role similar to that of vitamin C at the surface of LDL particles by regenerating the reduced form of vitamin E from its oxidized form chromanoxyl and by generating phenoxyl radicals. Nardini *et al.* showed that CA spared α-TOH *in vivo* (9) and preserved α-TOH and β-carotene *in vitro* in $Cu^{2+}$ and AAPH LDL oxidations (15).

In conclusion, we demonstrated that DOPAC and CA in micromolar concentrations have antioxidant activity in rat plasma, a medium having conditions very close to those *in vivo*, suggesting that supplementation with the phenolic acids will provide significant antioxidant protection.

**ABSTRACT:** Nonalcoholic steatohepatitis (NASH) is a syndrome frequently associated with obesity, diabetes mellitus, and dyslipidemia. Increased fasting insulinemia and blood glucose levels may trigger a reduced catabolism of lipoproteins rich in triglycerides by lipoprotein lipase (LPL) and an increase in their fasting and postprandial levels. An association between postprandial lipemia and coronary heart disease has been observed, and many studies now support this concept. The most important result of our study is the increase in triglyceride-rich lipoproteins response after a fat load in NASH patients, the increase of incremental area under the postprandial curve, and the duration of the hypertriglyceridemic peaks. The persisting postprandial plasma triglyceride elevation in NASH patients was mostly due to the elevated plasma level of large triglyceride-rich particles. These data are coupled with lower plasma HDL2-cholesterol levels. As for lipoprotein analyses, the number of apolipoprotein B100 (ApoB100) particles is not significantly different between the two groups, and the higher content of triglycerides in NASH very low density lipoproteins (VLDL) increases the triglyceride-to-ApoB ratio and the particle size. A decreased enzymatic activity of LPL or a defective assembly and secretion of VLDL from hepatocytes due to a moderate reduction in microsomal triglyceride transfer protein could be involved in the overloading of VLDL. Moreover, the undetectable levels of ApoB48 in triglyceride-rich lipoproteins fraction A could be related to the synthesis of smaller and denser chylomicrons. NASH patients not only are insulin resistant but also tend to present alterations in fatty meal delivery, suggesting that an increase in fasting plasma insulin and glucose, with insulin resistance, joins with depressed metabolism of triglyceride-rich lipoproteins. An increase in postprandial triglyceride levels with production of large VLDL suggests an atherogenic behavior of lipid metabolism, in accordance with the high prevalence of the metabolic syndrome in NASH patients. This paper suggests that a fat load may be useful in early detection of atherogenic risk in the presence of otherwise normal fasting plasma lipids.

Paper no. L8603 in *Lipids 36*, 1117–1124 (October 2001).

Hyperlipidemia (hypertriglyceridemia, hypercholesterolemia, or both) is a common abnormality in 20 to 81% of patients with nonalcoholic steatohepatitis (NASH) (1), an increasingly recognized chronic liver disease characterized by the histological pictures of alcoholic disease in the absence of significant ethanol consumption (2). Other conditions commonly associated with NASH are obesity and non-insulin-dependent diabetes mellitus (1,3). An increase in fasting blood glucose with reduced glucose tolerance is coupled with depressed metabolism of triglyceride-rich lipoproteins (TRL) and an increase in their fasting and postprandial levels (4,5). The links between glucose and lipoprotein metabolism have received particular attention in the context of the metabolic syndrome (6). Plasma insulin concentration, an indirect index of insulin sensitivity, was shown to be related to the production of large very low density lipoproteins (VLDL) particles (Svedberg flotation rate, Sf, of 60 to 400) in experimental studies with humans (7).

The postprandial phase is regarded as potentially atherogenic (6–8). Investigation of dynamic metabolism after a mixed or a fatty meal provides more complete data about the behavior of other lipoprotein classes. TRL are a heterogeneous population of lipoprotein particles. Those containing apolipoprotein (Apo) B100 are secreted from the liver (VLDL), whereas those with ApoB48 are secreted from the intestine as chylomicrons after fat intake. Several reports have concluded that postprandial alterations in healthy men induce transient compositional alterations of VLDL that link these lipoprotein species to the formation of lipid deposits on arterial walls (4,6,7,9,10). TRL can also trigger an impaired fibrinolysis and endothelial dysfunction (11), which may be ultimately responsible for cardiovascular disease (12). Moreover, the fasting lipid profile may be in the normal range and fail to reflect the atherogenic risk of subjects with impaired postprandial triglycerides (Tg) removal (12,13).

Abbreviations: Apo, apolipoprotein; AUC, area under the postprandial triglyceride curve; BMI, body mass index; Chol, cholesterol; FFA, free fatty acid; FPG, fasting plasma glucose; FSIGT, frequently sampled intravenous glucose tolerance test; HDL, high density lipoproteins; LDL, low density lipoproteins; LPL, lipoprotein lipase; MTP, microsomal triglyceride transfer protein; NASH, nonalcoholic steatohepatitis; OFL, oral fat load; PCR, polymerase chain reaction; SDS, sodium dodecyl sulfate; Sf, Svedberg flotation rate; SI, sensitivity index; Tg, triglyceride; TRL, triglyceride-rich lipoproteins; VLDL, very low density lipoproteins.

The aim of the study was to examine the dynamic postprandial metabolism of TRL and assess its relationship to insulin sensitivity in 11 nonobese, nondiabetic NASH patients and 16 healthy subjects with a normal fasting lipid profile after a standardized oral fat-loading test.

## MATERIALS AND METHODS

*Study subjects.* Lipoproteins from 11 NASH patients and 16 healthy subjects were studied. None of the participants was obese [(body mass index (BMI) 25.9 ± 2.0 kg/m$^2$ for patients and 25.0 ± 2.5 kg/m$^2$ for controls] or diabetic. Fasting plasma lipoprotein lipid concentrations are shown in Table 1. There was no clinical or laboratory evidence of thyroid dysfunction or other conditions leading to secondary hyperlipoproteinemia in either group. Inclusion criteria for the 11 NASH patients (35 ± 9 yr, 10 male/1 female) were as follows: histological feature of alcoholic steatohepatitis with chronically elevated aminotransferases and/or γ-glutamyl transpeptidase; negative history of alcohol consumption (>40 g/wk); negative markers for hepatitis B virus/hepatitis C virus; no recent use of known steatogenic drugs; absence of autoantibodies related to autoimmune liver disease; normal serum iron and copper metabolism profile; absence of serum immunoglobulin M antibodies, anti-Epstein-Barr virus, herpes virus, and cytomegalovirus. The controls were 16 healthy subjects matched for age, sex (33 ± 9 yr, 15 male/1 female), and the main anthropometric parameters. All subjects provided their informed consent. Participants received a questionnaire about fat intake, alcohol intake, and physical activity. Dietary habits were similar between young and elderly subjects (20% of calories of protein, 50% from carbohydrates, and 30% from fat, with a polyunsaturated to saturated fat ratio of 1.50). Mean daily cholesterol (Chol) intake was 200–250 mg.

**TABLE 1**
**Baseline Characteristics, Frequently Sampled Intravenous Glucose Tolerance Test (FSIGT), and Minimal Model Parameters for NASH Patients and Controls[a]**

| | NASH patients ($n$ = 11) | Controls ($n$ = 16) | $P$ |
|---|---|---|---|
| Age (yr) | 35 ± 9 | 33 ± 9 | NS |
| Sex (M/F) | 10/1 | 15/1 | NS |
| BMI (kg/m$^2$) | 25.9 ± 2.0 | 25 ± 2.5 | 0.330 |
| Waist (cm) | 91 ± 6 | 83 ± 5 | 0.002 |
| FPG (mg/dL) | 97 ± 12 | 89 ± 14 | 0.135 |
| IRI (μU/mL) | 13.9 ± 4.5 | 6.9 ± 2.8 | 0.0001 |
| Insulin sensitivity index (min$^{-1}$/μU/mL) | 3.66 ± 2.86 | 9.15 ± 2.94 | 0.000 |
| Triglycerides (mg/dL) | 97 ± 67 | 75 ± 27 | 0.246 |
| Total cholesterol (mg/dL) | 183 ± 40 | 185 ± 22 | 0.868 |
| LDL-cholesterol (mg/dL) | 108 ± 34 | 106 ± 25 | 0.861 |
| HDL-cholesterol (mg/dL) | 52 ± 7 | 59 ± 16 | 0.187 |
| HDL2-cholesterol (mg/dL) | 13.0 ± 5.0 | 18.4 ± 7.5 | 0.047 |
| HDL3-cholesterol (mg/dL) | 39.4 ± 4.1 | 40.5 ± 7.1 | 0.648 |
| Apo AI (mg/dL) | 119 ± 24 | 121 ± 26 | 0.841 |
| Apo B (mg/DL) | 83 ± 30 | 85 ± 21 | 0.840 |

[a]Data are presented as mean ± standard deviation. NASH, nonalcoholic steatohepatitis; BMI, body mass index; FPG, fasting plasma glucose; IRI, immuno-reactive insulin; LDL, low density lipoprotein; HDL, high density lipoprotein; Apo, apolipoprotein; NS, not significant.

*Determination of lipid parameters at baselines.* A hospital medical examination was carried out at 9 A.M. after a fast of 12 h or more. Blood samples drawn from the antecubital vein were used to determine the Tg, total Chol, low density lipoprotein (LDL) Chol, high density lipoprotein (HDL) Chol, HDL2-Chol, and HDL3-Chol, Apo AI, Apo B, glucose, creatinine, albumin, and thyroid-stimulating hormone baselines. The subjects were then asked to return on different mornings for the oral fat load (OFL) test after a fast of not less than 12 h. Blood (1 mg/mL EDTA-$Na_2$) was centrifuged for 30 min at 2500 rpm and 4°C in a J6B centrifuge (Beckman Instruments, Palo Alto, CA) and stored at –20°C until processed. Total Chol and Tg were measured enzymatically (Poli Diagnostici, Milan, Italy). Plasma HDL-Chol was determined after precipitation of ApoB-containing lipoproteins with heparin and manganese chloride (14). Plasma HDL2- and HDL3-Chol levels were determined according to Gidez *et al.* (15): HDL2 and HDL3 were separated after precipitation of ApoB-containing lipoproteins with heparin and manganese chloride, and HDL2 were further precipitated with dextran sulfate. The formula of Friedewald *et al.*(16) was used to calculate LDL-Chol. Plasma ApoAI and ApoB were determined by an automated immunoturbidimetric method (Poli Diagnostici) with a Shimadzu CL-7000 (Shimadzu Instruments, Kyoto, Japan).

*DNA analysis.* APOE (apolipoprotein E) genotypes were determined by polymerase chain reaction (PCR) amplification of genomic DNA using specific oligonucleotide primers (17). Genomic DNA was isolated from frozen EDTA whole blood through the QIAamp Blood Kit (Qiagen-Genenco M-Medical s.r.l., Florence, Italy). Genomic DNA (0.5 μg) was amplified in 25 μL reaction mixture containing 10 mmol/L Tris-HCl (pH 8.3); 50 mmol/L KCl; 200 μmol each of dATP, dCTP, dGTP, and dTTP; 1.5 mmol/L $MgCl_2$; 200 pmol of each primer, and 1.8 U Taq DNA polymerase (Roche Diagnostics S.p.A., Milan, Italy). The amplification cycle was performed in a Gene Cycler (Bio-Rad, Milan, Italy). Five minutes of denaturation at 94°C was followed by 30 cycles of 1 min at 90°C, 1 min at 60°C, and 2 min at 70°C. PCR products were cleaved with 4 U of HhaI restriction endonuclease (New England Biolabs, Ipswich, MA), as recommended by the manufacturer. Subsequently, the samples were electrophoresed through a 10% nondenaturing polyacrylamide gel and visualized by silver staining (Bio-Rad, Milan, Italy). The sizes of HhaI fragments were estimated by comparison with known size markers (MspI-digested pUC18 DNA).

*Frequently sampled intravenous glucose tolerance test (FSIGT).* Insulin sensitivity was assessed by performing an FSIGT. The data were analyzed with the minimal modeling technique to estimate the insulin sensitivity index (SI) as described in detail elsewhere (18).

*Oral fat load.* Five minutes after drawing a blood sample (t0), the subjects consumed a liquid OFL consisting of a mixture of dairy cream (35% fat) and egg yolk. The total amount

of fat was based on the subject's body surface area (77.5 g fat, 0.5 g Chol per $m^2$). The OFL was consumed during a period of 15 min, and the subjects then remained without food for 10 h. A catheter (Venflon Viggo AB, Helsingborg, Sweden) inserted in the antecubital vein and kept patent during the test was used to draw samples after 2, 4, 6, 8, and 10 h (t2, t4, t6, t8, and t10) for the determination of plasma TRL. Strenuous activity was forbidden during the test, because exercise can reduce postprandial lipemia.

*Laboratory analyses.* Plasma total Chol and Tg were measured by means of automated enzymatic methods. The area under the postprandial triglyceride curve (AUC) was evaluated using the trapezoid rule to estimate the overall response of plasma Tg during the entire 10-h postprandial period.

*Separation of VLDL and TRL subfractions.* VLDL were isolated through preparative ultracentrifugation and subsequently assayed for their Tg and total Chol content from all the subjects' blood samples. Briefly, one aliquot of plasma was brought to densities of 1006 g/L by addition of a KBr solution ($d$ = 1330 g/L) and centrifuged at 105,000 × $g$ in a type 50 rotor for 21 h at 10°C in a Beckman L8-70M ultracentrifuge. Concentrations of Tg and total Chol were then determined in lipoprotein fractions enzymatically. The first amount of blood (10 mL) was drawn for subfractionating TRL by ultracentrifugation on a discontinuous density gradient (19). Plasma separated as already described was brought to a density of 1.10 g/mL by the addition of solid KBr. The density gradient was prepared manually by adding to 4 mL of this plasma 3 mL of a 1.065 g/mL solution containing 0.05% KBr/NaCl plus EDTA (pH 7.4); 3 mL of a similar solution at 1.020 g/mL; and 3 mL of physiological saline at 1.006 g/mL. The sample was ultracentrifuged in a SW4O rotor in a Beckman L8-70M centrifuge at 20°C in stages allowing the separation of four VLDL fractions with decreasing Sf values: A > 400; B = 175–400; C = 100–175; D = 20–100. The first centrifugation (28,300 rpm for 43 min) isolated fraction A in a floating volume of 0.5 mL. The volume removed was replaced with physiological saline, and the sample was centrifuged at 40,000 rpm for 67 min to isolate fraction B. This procedure was then repeated at 40,000 rpm for 71 min and at 37,000 rpm for 18 h to isolate fractions C and D, respectively. The automated methods mentioned above were used to determine Chol and Tg on the four fractions.

*ApoB48 and ApoB100 analysis.* ApoB48 and ApoB100 analysis were performed on five subjects with NASH and on five controls matched for age, sex, and the main anthropometric parameters.

VLDL ApoB48 and ApoB100 were separated by sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis using 3.9% gel according to Battula *et al.* (20). Nondelipidated lipoprotein samples were reduced in SDS sample buffer for 4 min at 96°C. Samples were applied to the gel and run at 40 mA in 0.025 M Tris, 0.192 M glycine, and 0.1% SDS. Gel was stained with Silver Stain (Bio-Rad). Since the chromogenicity of ApoB48 is similar to that of ApoB100 (21), a protein standard was prepared from LDL isolated by sequential ultracentrifugation and used to quantify ApoB100 and ApoB48. The bands were quantified by densitometry using Gel Doc equipment (Bio-Rad). Density values were assigned to the ApoB100 bands of the standard LDL and a standard curve was constructed. The values were recalculated by linear regression.

*Statistics.* Means and standard deviations (SD) were calculated for the lipid baseline parameters, and differences between the patients and controls were determined with the $t$ test, or the Mann-Whitney test when comparing postprandial area. Tg levels were log-transformed before testing. Differences in the postprandial responses (plasma Tg and VLDL fraction Tg values) were assessed by connecting Tg plasma levels vs. time with segments. The AUC was computed by the trapezoid method on the area exceeding baseline (incremental area). Spearman's coefficient was used to assess the correlation between parameters concerning insulin sensitivity and basal and postprandial lipid profile.

## RESULTS

*Patients' clinical characteristics and fasting plasma lipids and lipoproteins.* Mean ± SD of clinical anthropometric and basal laboratory determinations of glucose and lipid metabolism in NASH patients and controls are reported in Table 1. Although cases and controls showed similar BMI, there was a tendency to visceral fat accumulation in NASH patients (waist: 91 ± 6 vs. 83 ± 5 cm, $P$ = 0.002). Fasting total plasma Chol (183 ± 40 vs. 185 ± 22 mg/dL, $P$ = 0.618) and Tg (97 ± 67 vs. 75 ± 27 mg/dL, $P$ = 0.246) were not significantly different. HDL2-Chol levels were significantly lower in the patients (13.0 ± 5.0 vs. 18.4 ± 7.5 mg/dL, $P$ = 0.047). The other Chol lipoprotein fractions had similar levels in the two groups as well as ApoAI and ApoB (Table 1). Fasting plasma insulin (13.9 ± 4.5 vs. 6.9 ± 2.8 μU/mL, $P$ = 0.0001) and fasting plasma glucose (FPG) levels (97 ± 12 vs. 89 ± 14 mg/dL, $P$ = 0.135) were increased in the group of NASH patients. There was no difference in ApoE allelic frequency: 12 NASH patients were E3/E3, 2 were 4/3, and 2 were 3/2; 8 controls were E3/E3, 2 were 4/3, and 1 was 3/2. There was no difference in percentage of smokers: 3 patients and 2 controls.

*Insulin sensitivity.* NASH patients had significantly lower insulin sensitivity (SI 3.66 ± 2.86 vs. 9.15 ± 2.94 $min^{-1}$/μU/mL, $P$ = 0.000)

*Postprandial response of plasma Tg.* The total OFL ingested by the NASH group was 390 ± 5.2 g (mean ± SD), and by the control group was 385 ± 4.8 g. It was well tolerated, and there were no instances of gastrointestinal disturbance or steatorrhea during or after the test. The postprandial plasma Tg and VLDL-Tg curves are reported in Figure 1 (right-hand panel). Plasma Tg peaked 4 h after the meal and returned to fasting levels after 8 h in both groups (Fig. 1). Total Chol and LDL-Chol displayed a flat pattern in both groups, and the HDL-Chol levels were unchanged. Plasma Tg were higher in the patients at all time points with a significant difference at 4 h ($p$ = 0.006). The response of VLDL-Tg is illustrated in Figure 1. VLDL-Tg are higher in the

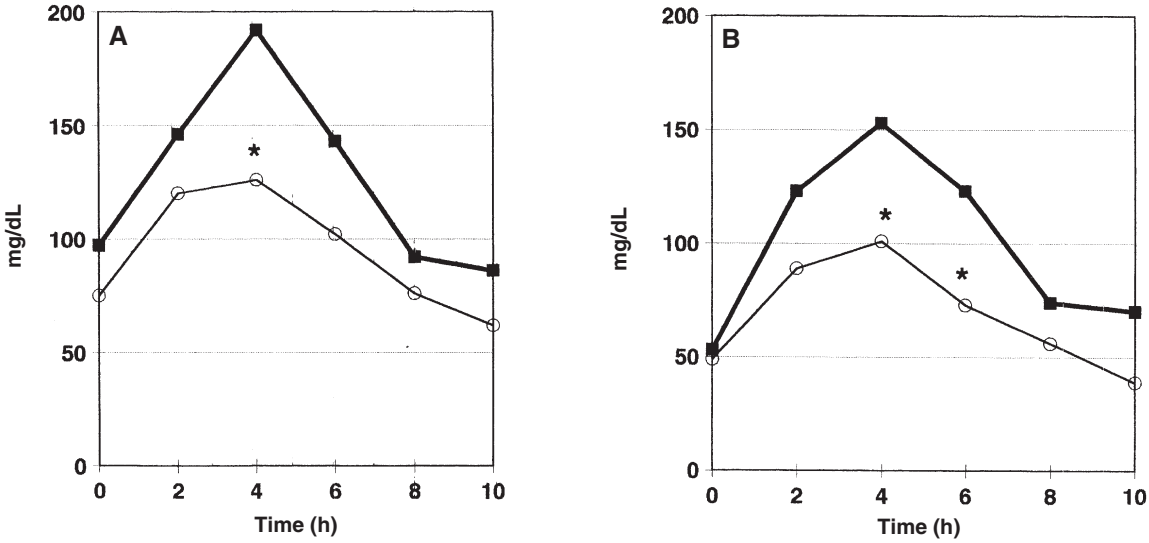

**FIG. 1.** Change in (A) plasma triglyceride (Tg) and in (B) very low density lipoprotein (VLDL) Tg concentrations after the fat load in 11 nonalcoholic steatohepatitis (NASH) subjects (■) patients and 16 controls (○). Results are expressed as mean ± standard error of the mean. *$P < 0.05$. **$P < 0.01$.

NASH group at all time points with significant differences at 4 and 6 h ($P = 0.043$ and $P = 0.019$). There was no significant difference in the incremental AUC for Tg: patients, 1329 ± 596.2 mg/dL × 10 h, $P = 0.063$; controls, 984.6 ± 322 mg/dL × 10 h. The NASH group SI was significantly correlated with the fasting total Tg concentration ($r_s = –0.67$, $P = 0.042$), fasting VLDL-Tg ($r = –0.61$, $P = 0.048$), VLDL-Tg (fraction B) ($r_s = –0.67$, $P = 0.033$), and VLDL-Tg (fraction C) ($r_s = –0.64$, $P = 0.044$), but not with any other basal or postprandial parameter. A correlation between fasting plasma Tg and the AUC was observed in both groups: NASH, $r = 0.835$, $P = 0.0013$ ($r_s = 0.763$, $P = 0.0062$); controls, $r = 0.487$, $P = 0.0551$ ($r_s = 0.633$, $P = 0.0083$). The slope for the regression line between fasting Tg and AUC was less steep in the control group (AUC = 574.67 + 5.46 Tg) than that in the NASH group (AUC = 584.26 + 7.66 Tg).

*Postprandial Tg levels in TRL subfractions.* The lipid content of large and small TRL particles isolated by ultracentrifugation after the OFL is shown in Figure 2. The lipid composition of fraction A showed a transient Tg increase after 4 and 6 h in the NASH group ($P = 0.03$ and 0.04, respectively). The difference was no longer significant during the last postprandial hours. The Tg content of VLDL subfractions B, C, and D displayed similar curves in both groups throughout the postprandial load period. There were no significant differences between the two groups in the total Chol variations at any time.

*ApoB48 and ApoB100 in TRL subfractions.* Absolute postprandial changes of ApoB48 and ApoB100 concentrations in VLDL fractions are shown in Figures 3 and 4, respectively. ApoB48 in VLDL fraction A was detected only in the control group. In VLDL fractions B, C, and D, ApoB48 was at lower levels in NASH patients. In the control group, the ApoB48 concentrations increased significantly in the VLDL fraction D at the baseline and at 2 and 10 h. The ApoB100 concentration in VLDL fraction A, B, and C responded to the OFL in a similar way in both control and NASH individuals. The ApoB100 increased and peaked at 4 h in VLDL fraction D in the control group, but this difference was not significant.

## DISCUSSION

The present study was designed to highlight some mechanisms that potentially link atherosclerosis to an abnormal fat tolerance in NASH patients. NASH is a syndrome frequently associated with obesity, diabetes mellitus, and dyslipidemia (1,3). Elevated levels of free fatty acids (FFA) in the liver are supposed to be responsible for the development of steatohepatitis as a part of the metabolic syndrome (6). Increased fasting blood glucose levels may trigger a depressed metabolism of lipoproteins rich in Tg and an increase in their fasting and postprandial levels (4,5).

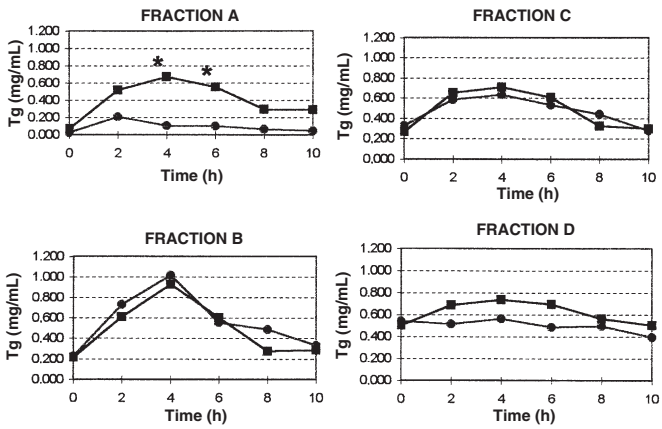

**FIG. 2.** Tg concentrations during the fat load test in the Sf A > 400, Sf B = 175–400, Sf C = 100–175, Sf D = 20–100 lipoprotein fractions (for method see Materials and Methods section) in 11 NASH patients (■) and 16 controls (●). Results are expressed as means. *$P < 0.05$. For abbreviations see Figure 1.

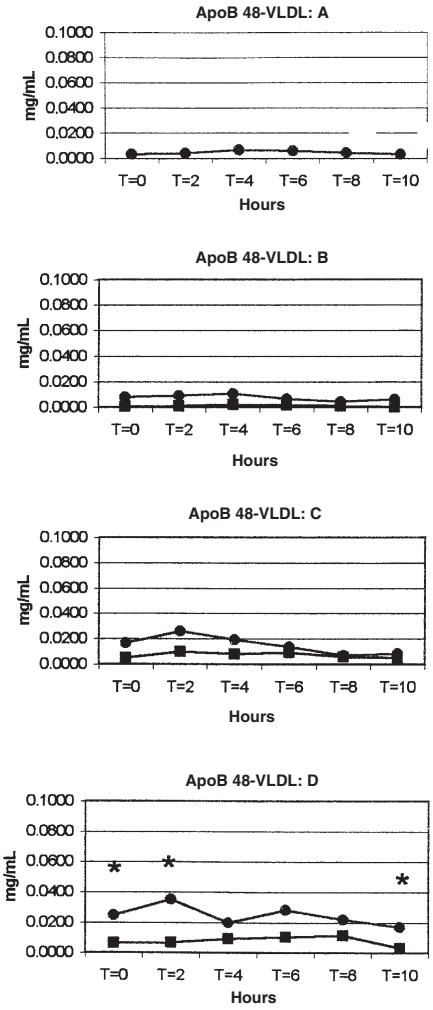

**FIG. 3.** Line plots of changes in plasma apolipoprotein B48 (ApoB48) concentrations during the fat load test in Sf A > 400, Sf B = 175–400, Sf C = 100–175, Sf D = 20–100 lipoprotein fractions (for method see Materials and Methods section) in 5 NASH patients (■) and 5 controls (●). Results are expressed as means. *$P < 0.05$. VLDL, very low density lipoprotein; for other abbreviations see Figure 1.

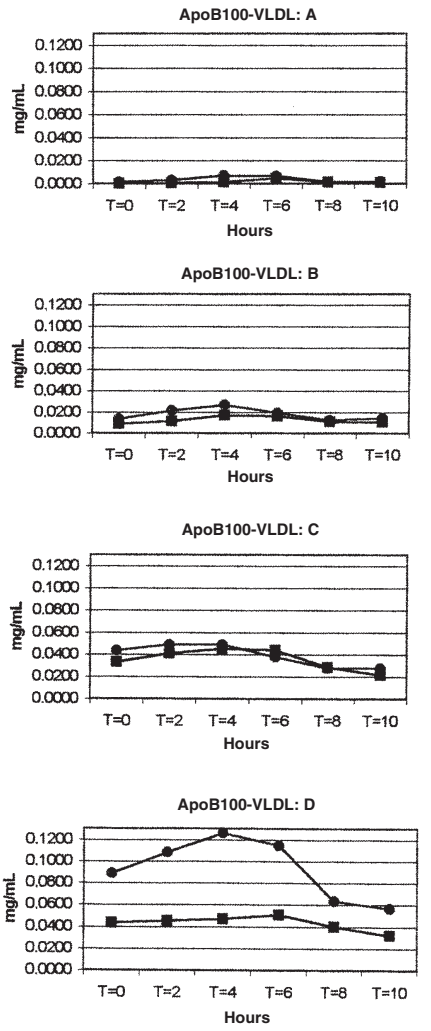

**FIG. 4.** Line plots of changes in plasma ApoB100 concentrations during the fat load test in Sf A > 400, Sf B = 175–400, Sf C = 100–175, Sf D = 20–100 lipoprotein fractions (for method see Materials and Methods section) in 5 NASH patients (■) and 5 controls (●). Results are expressed as means. For abbreviations see Figures 1 and 3.

In our patients, fasting plasma insulin was significantly increased and HDL2-Chol levels were significantly decreased. SI was negatively correlated to fasting total Tg concentration, fasting VLDL-Tg, VLDL-Tg (fraction B), and VLDL-Tg (fraction C) but not to any other basal or postprandial parameter. The most important results of our study are the increase of TRL response after a fat load in the NASH patients, the increase of the incremental area under the postprandial curve, and the duration of the hypertriglyceridemic peaks. Furthermore, we observed a significant correlation between plasma Tg and the Tg AUC in the NASH group. The slope of the regression line between fasting and the Tg AUC was steeper in the NASH group. If the fasting Tg level mirrors the postprandial Tg level, then NASH patients have a higher postprandial Tg level than the control for the same level of fasting Tg.

NASH patients seem to have a disturbance in the metabolism of TRL particles, since they displayed a rapid increase of Tg fraction A levels of lipoprotein and a sustained elevation in the postprandial phase. The curves of both groups for the other VLDL classes were superimposed. The persistent postprandial plasma Tg elevation in NASH patients was mostly due to the elevated level of large TRL particles (fraction A). The production of large VLDL particles (Sf rate of 60 to 400) seems to be regulated by plasma insulin concentrations in experimental studies in humans (7). Some authors have shown that this persistent elevation is ascribable to reduced clearance of postprandial large VLDL, which could also be related to increased competition with chylomicrons for the same lipolytic pathway (22). NASH patients present an impaired metabolism in controlling plasma Tg levels after fat intake, and this may depend on their insulin-resistant state. The role of postprandial insulin in the regulation of postprandial lipid metabolism is still poorly understood. The roles of hyperinsulinemia and insulin resistance in the alteration of lipid metabolism are not clear either (23). Nevertheless, some authors have reported that postprandial lipemia is related to the degree of insulin resistance

even in nondiabetic subjects (24). In the plurimetabolic syndrome the simple fasting hyperinsulinemia is associated with the increased postprandial lipemia even if hypertriglyceridemia and diabetes mellitus are absent (25).

Our data may show that there is no significant difference in the content of ApoB100 in VLDL fraction A between NASH and control subjects. These results mean that the number of ApoB100 particles is not significantly different between the two groups. Because postprandial Tg are higher in NASH subjects, the net effect is to increase the Tg-to-ApoB ratio and to increase particle size. In our study, VLDL fraction A of NASH subjects carry more Tg than VLDL isolated from control subjects, suggesting a decreased enzymatic activity of lipoprotein lipase (LPL), a common abnormality in insulin resistance, or a defective assembly and secretion of VLDL from hepatocytes due to a moderate reduction in microsomal Tg transfer protein (MTP) as a consequence of different gene polymorphism (26).

The most striking result of our study is that ApoB48 in TRL fraction A in NASH subjects is below the sensitivity of the silver stain. ApoB48 levels are extremely low in fraction A, and this fact could be related to an altered functioning of the MTP. Authors have reported that MTP play a key role in the first steps of chylomicron assembly (27). Even if MTP has no effect on ApoB48 synthesis, in the intestine MTP appears to be important in regulating the Tg content of the chylomicron particle (28). Thus, an impaired functioning of MTP in NASH subjects could give rise to smaller and denser chylomicrons, and it could explain why ApoB48 is absent in fraction A and present in the other fractions.

The reduction in ApoB48 and ApoB100 in VLDL fraction D in NASH subjects could be explained with a flaw of lipolysis of larger and less dense lipoproteins.

Since LDL are produced during VLDL catabolism, augmented secretion and availability of the Tg bound to the VLDL and the events subsequent to these metabolic changes may account for the production of altered particles (29). Exaggerated postprandial lipemia has consequences for the particle composition of plasma lipoprotein: Tg-enriched LDL are good substrates for hepatic lipase and the result is smaller and denser LDL ($1.040 < d < 1.063$ g/mL) constituting an atherogenic lipoprotein phenotype (19,29,30). Because the smaller, denser LDL are more susceptible to oxidation (31), the degree of oxidation may also vary in function of the main changes in the metabolism of the Tg bound to the VLDL. Moreover, the greater the degree of LDL oxidation, the greater the atherogenic potential of the particle (32).

These results may suggest that impaired postprandial Tg metabolism in NASH patients is associated with their increased visceral obesity. Reduced SI, FFA elevation (33), and reduced TRL catabolism by LPL are common in the metabolic syndrome (34,35).

An association between postprandial lipemia and coronary heart disease had been observed since the early 1950s (36), and many studies now support this concept (8–10,37).

According to some workers, chylomicrons and their remnants deliver dietetic Chol to the arterial wall, thus contributing to atherogenesis (8); other investigators maintain that the postprandial phase is a critical moment, marked by an abnormal metabolism of Tg transportation, its carriers (38), and other related enzymes or lipoprotein classes (39,40). It has also been suggested that a prolonged postprandial hypertriglyceridemic response alters the coagulation-fibrinolytic balance and favors thrombosis (13).

High plasma Tg is also closely correlated with low HDL-Chol (41–43) and may influence the composition of the HDL; an inverse relationship between HDL2-Chol levels and the postprandial Tg levels is also evident (44). This shows that the substantial alterations in TRL metabolism upstream from the lipolytic and maturative cascade of the lipoproteins have a profound effect on the variations in the other fractions. These observations lead to the conclusion that HDL levels and composition reflect the efficiency of TRL catabolism (38,42,43), and that high HDL-Chol indicates a low production of atherogenic remnants according to a mechanism that also involves the cholesteryl ester transfer protein (45).

It seems appropriate to stress that NASH patients not only are insulin-resistant but also tend to present alterations in fatty meal delivery, suggesting that an increase in fasting plasma insulin and FPG, with insulin resistance, is coupled with lower plasma HDL2-Chol and depressed metabolism of TRL. An increase in fasting and postprandial Tg levels with production of large VLDL suggests an atherogenic behavior of lipid metabolism, in accordance with the high prevalence of the metabolic syndrome in these patients (6,46). Longitudinal studies are needed to confirm this finding.

These findings indicate that the presence of NASH should be systematically sought both in patients with unexplained increase of liver enzymes in the absence of other known mechanisms of liver injury and in subjects with two or more elements of the metabolic syndrome, irrespective of the presence of obesity or visceral adiposity. Owing to the frequent association of the two syndromes, an oral glucose tolerance test and plasma insulin assay together with an OFL should be systematically performed in NASH patients for the early detection of atherogenic risk in the presence of quite normal fasting plasma lipids.

## ACKNOWLEDGMENTS

This study was funded in part from a grant from Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST) 60%, Italy.

# Absorption and Effects of 3-(*N*-phenylamino)-1,2-Propanediol Esters in Relation to Toxic Oil Syndrome

**Daniel Closa, Emma Folch, Rosa Elena Calaf, Joaquin Abián, Joan Roselló-Catafau, and Emilio Gelpí***

Department of Medical Bioanalysis, Institut d'Investigacions Biomèdiques de Barcelona-Consejo Superior de Investigaciones Científicas, Institut d'Investigacions Biomèdiques August Pi Sunyer, Barcelona, Spain

**ABSTRACT:** Toxic Oil Syndrome (TOS) was an epidemic disease related to the consumption of rapeseed oil denatured with aniline that made its sudden appearance in Spain in 1981. The fatty acid esters of 3-(*N*-phenylamino)-1,2-propanediol (PAP), which is a chemical class of by-products resulting from the reaction of aniline with oil components, have shown a strong association with TOS-related oils. These compounds also show some structural similarities to platelet-activating factor (PAF). In search of a toxic agent that could explain the widespread systemic effects observed in TOS patients, we investigated the intestinal absorption and biotransformation of the different PAP esters found in TOS-related oil samples and the possible pathophysiological effect of these mediators and their metabolic products if acting as PAF analogs. Results indicate that PAP esters are absorbed in the gastrointestinal tract and are distributed and stored in different organs, particularly in the liver and brown adipose tissue. PAP in these organs showed different patterns of fatty acids, indicating the ability of the gastrointestinal tract to modify the fatty acid composition of the parent PAP. Thus, the fatty acid profile of the PAP esters found in intestine appears to be related to the type of oil used as vehicle. Some of these PAP esters, when a long acyl chain was present in the *sn*-1 position of the molecule, showed an inhibitory effect on the PAF synthesis. This is an important observation in line with the systemic nature of the disease.

Paper no. L8701 in *Lipids 36*, 1125–1133 (October 2001).

Toxic Oil Syndrome (TOS) was a toxic epidemic disease that made its sudden appearance in Spain in 1981 and affected more than 20,000 people. Epidemiological data revealed that the disease was related to the consumption of rapeseed oil denatured with aniline, illegally refined, mixed with other oils, and sold as edible olive oil (1). Further investigations showed that aniline and fatty acid anilides were present in TOS-related oils, and these compounds became the first markers for toxic oil. More recently, the fatty acid esters of 3-(*N*-phenylamino)-1,2-propanediol (PAP) have shown a strong association with TOS (2). However, no etiological agent has been unequivocally identified for this disease. The main barrier to the identification of the agent(s) has been the absence of an experimental model or bioassay system that fully duplicates TOS.

As for PAP, more than 20 related compounds in TOS-associated oils have been identified. These compounds include monoesters (mPAP) and diesters (dPAP) of PAP (3) (Scheme 1). The toxicity of these compounds is yet to be demonstrated. However, a possible mechanism of toxicity is suggested by the structural similarities of PAP esters to platelet-activating factor (PAF, 1-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) (Scheme 1). This bioactive mediator leads to cell damage by several mechanisms. An excess of PAF has been implicated in a variety of pathologies (4), including ischemia-reperfusion, necrotizing enterocolitis, and asthma.

Significant quantities of PAF-related phospholipids are formed in various cells (6). This fact can be explained on the basis of the relatively low substrate specificity of the enzymes responsible for PAF biosynthesis. Thus, some different enzymes do not discriminate between the alkyl and acyl chains in the *sn*-1 position (5). Keeping this in mind, the structural similarities between PAF (with an alkyl chain at *sn*-1) and PAP esters (with an acyl chain at *sn*-1) and the possible metabolism of the latter into functional PAF analogs provides the incentive for the study of the pathophysiology of these compounds within the TOS context.

In consideration of all these facts, the objectives of this work were (i) to investigate the absorption and distribution of different PAP esters found in TOS-related oil samples, and (ii) to evaluate the possible biological effect of these molecules and their metabolic products as possible PAF analogs.

The availability of these data could provide an insight into the uptake, acyl modifications, and disposition of PAP derivatives. It may also allow us to understand the well-known systemic effects that the toxic oil produced on TOS patients.

## MATERIAL AND METHODS

*Samples and standards.* The structures of the standards for 1-linoleyl PAP [L(1)PAP], 1,2-dilinoleyl PAP [LL(1,2)PAP], 1-stearyl PAP [S(1)PAP], 1-octanyl PAP [Oc(1)PAP], and 1-stearyl-2-acetyl PAP [SA(1,2)PAP] are shown in Scheme 1. L(1)PAP and LL(1,2)PAP were also labeled with $^{14}C$ in the phenylamino group and with $^{3}H$ in the acyl chain: 3-([U-$^{14}C$]phenyl)amino-1,2-propanediyl di[9,10,12,13(n) $^{3}H$]linoleate. All these compounds were synthesized by Guardiola and Messeguer (7). Chemical purity was higher than 93% for all compounds as verified by high-performance liquid chromatography (HPLC) analysis.

*Absorption and distribution.* Radiolabeled L(1)PAP or LL(1,2)PAP, dissolved in 1 mL of olive oil, was administered orally to male Wistar rats (250–300 g body wt) purchased from Iffa Credo (L'Arbreste, France). The dose administered (60 mg/kg) contained 2μ Ci of $^{3}H$ and 1.5 μCi of $^{14}C$. At 4 ($n$ = 4) or 18 ($n$ = 4) h after administration, samples of rat tissues, plasma, and urine were obtained, weighed, dissolved with Soluene-350 (Packard, Canberra, Australia)/$H_2O_2$ and counted in a β-counter for $^{3}H$ and $^{14}C$ channels.

In some samples, the lipidic fraction was extracted by the Bligh and Dyer method (8), and the content of radioactivity in the organic and aqueous fractions was counted in a β-counter for $^{3}H$ and $^{14}C$ channels.

*Biotransformation.* To investigate both the metabolic modifications of mPAP during gastrointestinal absorption and the influence of the vehicle in the biotransformation of PAP, 60 mg/kg of unlabeled L(1)PAP was orally administered to three groups of rats ($n$ = 8 for each group). The vehicle used (1 mL) was olive oil in the first group, coconut oil in the second, and palm oil in the third. Four hours later, the animals were sacrificed, and samples of the intestine (jejunum), liver, brown adipose tissue (BAT), and lung were obtained. Control animals received oil free of PAP esters. The lipid fraction of these samples was extracted by the method of Bligh and Dyer (8). The extracts were evaporated to dryness under a helium stream and stored at –40°C until analysis.

Mass spectrometric analyses were conducted by using a Finnigan TSQ 700 triple quadrupole mass spectrometer. This instrument was provided with an atmospheric pressure ionization source for atmospheric pressure chemical ionization (APCI) from Finnigan (San Jose, CA). Instrument tuning, calibration, and fragmentation studies were performed by continuous infusion of the standards into the spectrometer.

HPLC chromatography was carried out using a Hewlett-Packard model 1100 with a binary pump and an ultraviolet detector (245 nm). Samples were injected with a Triathlon automatic injector (Spark Holland B.V., Emmen, Holland) provided with a 50-μL loop.

Target compounds were separated under gradient conditions using a reversed-phase column (Partisil ODS-3, 5 μm particle size, 2 × 150 mm) from Technokroma (Barcelona,

Spain). The analytical column was preceded by a 2 × 10 mm ODS column (Upchurch Scientific, Oak Harbor, WA). The injection volume was 10 µL, and the flow rate 300 µL/min. The mobile phase was composed of water/methanol (20:80 + 0.1% acetic acid) as solvent A and isopropanol/methanol (20:80 + 0.1% acetic acid + 0.5% hexane) as solvent B. A solvent gradient was used for chromatography. The gradient started at 20% B and increased to 80% in 0.1 min, then increased again to 100% of B in 3.5 min where it was held for 5 min.

Quantification of PAP utilized the precursor ion mode on the TSQ 700 mass spectrometer and selected ion monitoring. The $[M + H]^+$ ions of the PAP targeted for analysis were monitored in the first quadrupole, and the common product ion at *m/z* 132 was monitored in the second analyzer (third quadrupole). The collision energy was set at –25 eV for monoacyl-PAPs and –35 for diacylPAP. The collision gas (argon) pressure was 1.5 mTorr, and the multiplier was set at 1800 V. Ion spray source parameters were: capillary voltage, 4.5 kV; capillary temperature, 250°C; sheath gas (nitrogen) pressure, 70 psi; auxiliary gas (nitrogen) flow, 40 mL/min. APCI source parameters were: corona discharge, 1 kV; vaporizer temperature, 500°C; sheath gas (nitrogen) pressure, 20 psi; no auxiliary gas.

Quantification was carried out using 1-heptadecanoyl-2-oleyl-PAP and 1-heptadecanoyl-PAP as internal standards for diacyl and monoacyl PAP, respectively (9). Total fatty acid levels were determined in palm, olive, and coconut oils by standard gas chromatographic methods [IUPAC 2301 (fatty acid methylation) and IUPAC 2302 (gas–liquid chromatographic analysis): Ref. 10].

*Biological (PAF-like) activity of PAP esters: Changes in vascular permeability. (i) Animal preparation.* Male Wistar rats (200–250 g body wt) were anesthetized with 1 mL/kg of 10% urethane and placed in a supine position. A midline abdominal incision was made to allow a section of mesentery from the midjejunum to be exteriorized. All exposed tissue was covered with saline-soaked gauze to minimize tissue dehydration. The mesentery was superfused at 1 mL/min for 30 min (Harvard "22" infusion pump; Harvard apparatus, Edenbridge, United Kingdom) with phosphate-buffered saline (pH 7.4) containing the different mediators administered (11).

*(ii) Vascular permeability.* Evans blue 1% was used as a marker of vascular permeability (12). In all series of animals, Evans blue (1.8 mL/kg) was injected intravenously into the inferior vena cava 15 min before the start of superfusion. At the end of superfusion, samples of mesentery were obtained, weighed, and put in 1 mL of formamide for 48 h. The amount of Evans blue extracted in formamide was determined by spectrophotometry at a 620 nm wavelength using a Labsystems (Franklin, MA) iEMS plate reader. Results were plotted on a standard curve of Evans blue (1.5–50 µg/mL). The Evans blue content of each sample was expressed as µg/g tissue.

*(iii) Treatments.* Animals were superfused with Lyso-PAF, PAF, S(1)PAP, O(1)PAP, L(1)PAP, and SA(1,2)PAP. Some animals were treated with a PAF antagonist BN-52021 (i.v. 10 mg/kg) (IHB, LePlessise Robinson, France) prior to the superfusion. In addition, some animals were superfused simultaneously with PAF and S(1)PAP at different concentrations in order to evaluate a possible blocking effect of the PAP.

*Effect of PAP on PAF synthesis. (i) Alveolar macrophage isolation.* Alveolar macrophages were obtained by bronchoalveolar lavage (BAL). Lungs were dissected free of the thoracic cavity and a small length of tubing was inserted into the trachea and ligated. BAL was carried out with 10 mL of ice-cold Hank's saline solution instilled four times and withdrawn from the lungs. BAL from 2 or 3 animals was pooled, the cell suspension was centrifuged at 400 × *g*, and the pellet was resuspended in RPMI 1640 medium in presence of penicillin (100 units/mL) and streptomycin (100 mg/mL). Cells were counted, cultured in 24-well plates ($10^6$ cells/well), incubated for 1 h at 37°C under 5% $CO_2$ in air, and then washed twice with warm (37°C) medium to remove nonadherent cells. Supernatants of cultured alveolar macrophages were obtained after 24 h of cell culture at 37°C under 5% $CO_2$ in air (13).

*(ii) Cell treatment.* Synthesis of PAF was stimulated by incubation of alveolar macrophages with lipopolysaccharide (LPS) (10 ng/mL) during 45 min. In addition, mono- or diesters of PAP (100 nM, final concentration), dissolved in dimethylsulfoxide (DMSO), were added simultaneously with LPS in some wells ($n = 4$). Final concentration of DMSO was <0.5%. The same amount of DMSO was added at the start of the procedure in control and LPS wells. At the end of the incubation, 1 mL of cold methanol was added to the wells.

*(iii) PAF extraction.* Supernatants were transferred to 10-mL tubes and methanol, chloroform, and water were added to achieve a final composition of 2:2:2 (by vol). Samples were strongly vortexed and centrifuged (3000 × *g*; 15 min). The lower chloroform phase was collected, and the extraction of the aqueous phase was repeated. The two lipid-containing chloroform phases were pooled, evaporated to dryness, and resuspended in a mixture of methanol/water 15:85 to be processed through C18 Sep Pak cartridges (Waters, Milford, MA). Cartridges were activated with 10 mL of methanol and 10 mL of water, and washed with 10 mL of methanol/water 1:9, 10 mL of water, and 20 mL of petroleum ether. Finally, cartridges were eluted with 4.5 mL of methanol/chloroform (2:1) with 2% of acetic acid. Eluates were vacuum-evaporated to dryness and resuspended in assay buffer (14).

*(iv) PAF assay.* The amount of PAF was quantified with a "Platelet Activating Factor $^3H$ scintillation proximity assay" commercial kit, from Amersham (Buckinghamshire, United Kingdom), according to the supplier's instructions.

## RESULTS

*Studies on absorption, distribution, and excretion of PAP esters.* The distribution of $^3H$ and $^{14}C$ radioactivity found in different organs at 4 and 18 h after administration of radiol-labeled mono- and diesters of linoleyl PAP is shown in Figure 1. These two time periods were selected in order to distinguish

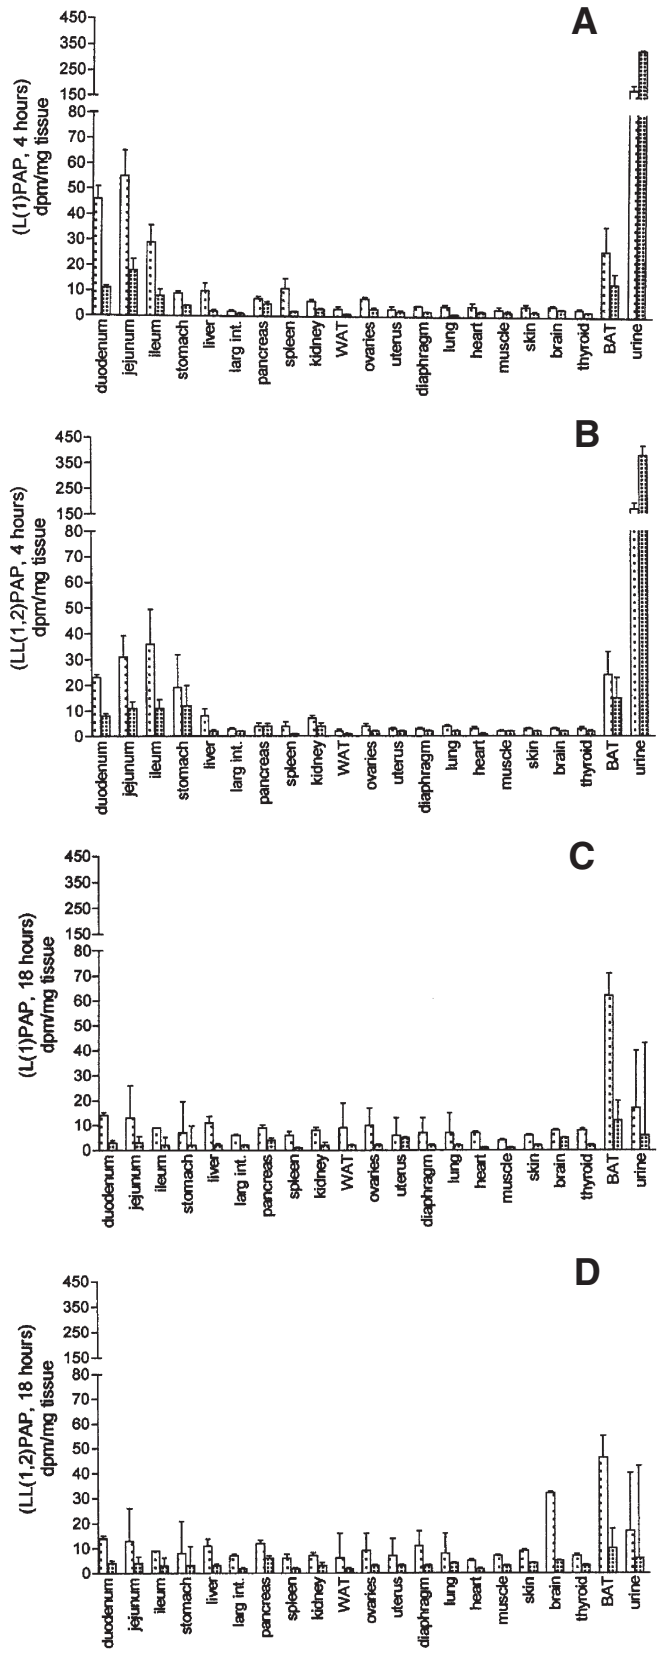

**FIG. 1.** Distribution of radioactivity (expressed as dpm/mg) in different organs 4 and 18 h after oral administration of 1-linoleyl-3-(*N*-phenylamino)-1,2-propanediol [L(1)PAP] or 1,2-dilinoleyl PAP [LL(1,2)PAP]. Dotted bars: $^{3}H$; lined bars: $^{14}C$. WAT, white adipose tissue; BAT, brown adipose tissue. Data are expressed as mean ± SEM.

between the rapid and late fate of the ingested products. Thus, after an initial time period (4 h) that allowed for rapid metabolism and excretion, the second time period, at 18 h, was intended to provide sufficient time for their complete distribution and/or metabolism.

Radioactivity was expressed as dpm measured per mg of tissue (or mL of fluid for urine). The major amount was initially concentrated in the urine. Other organs showing important amounts of radioactivity were the intestine at 4 h and BAT at 4 and 18 h. The mono- and diesters of PAP showed similar distribution profiles.

Figure 2 shows the percentage of radioactivity of $^{3}H$ and $^{14}C$ obtained in different samples compared to the proportion of radioactive forms in the two original oils administered: 35% $^{14}C$/65% $^{3}H$ for monoesters of PAP and 45% $^{14}C$/55% $^{3}H$ for diesters of PAP. All tissue samples at 4 h showed a clear predominance of $^{3}H$ in accordance with the radioactivity pattern of the original oil and in line with the overall lipophilicity of the organ (results are slightly affected by the different quenching present in different samples). On the other hand, the result found in urine at 4 h after administration indicated that the $^{14}C$, originally present in the aniline ring, was preferentially excreted. In urine samples obtained at 18 h after administration, the marked reversal in the proportions of $^{14}C$ and $^{3}H$ was no longer observed.

Figure 3 shows the radioactivity present in the aqueous phase of a Bligh and Dyer extraction of lipids in samples of tissue (liver, BAT, and white adipose tissue), plasma, and urine.

*Gastrointestinal biotransformation.* Figure 4 shows the fatty acid composition of the different PAP measured by liquid chromatography/mass spectrometry (LC/MS) in intestinal samples (jejunum) and liver after administration of L(1)PAP, and the differences observed as a function of the oil used as a vehicle. The

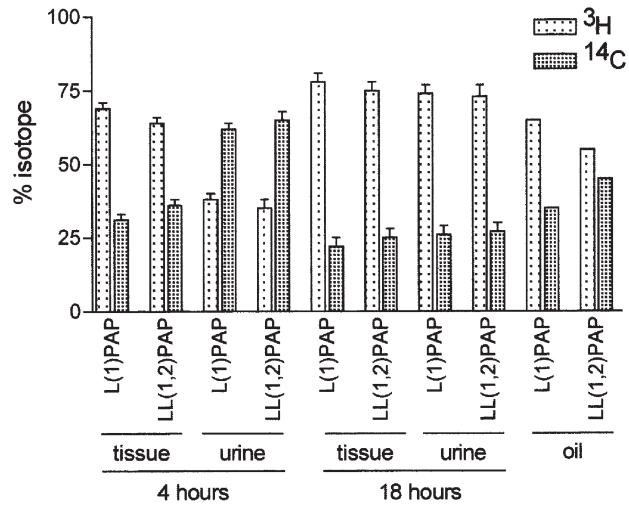

**FIG. 2.** Percentage of radioactivity corresponding to $^{3}H$ and $^{14}C$ obtained in tissue or urine 4 and 18 h after oral administration of radiolabeled L(1)PAP or LL(1,2)PAP. The original oils administered contained 65% $^{3}H$/35% $^{14}C$ for L(1)PAP and 55% $^{3}H$/45% $^{14}C$ for LL(1,2)PAP. For abbreviations see Figure 1. Data are expressed as mean ± SEM.

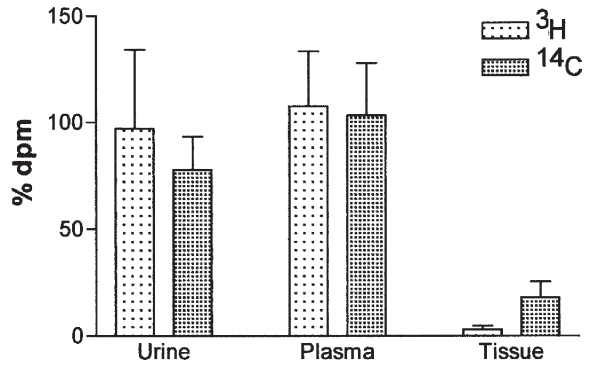

**FIG. 3.** Radioactivity present in the aqueous phase of a Bligh and Dyer (8) extraction of lipids. Results are presented as percentage of the dose administered. Data are expressed as mean ± SEM.

major amount of PAP is present as dPAP, indicating that during intestinal absorption, the monoesters of PAP are esterified in the *sn*-2 position. Lower amounts of mPAP are observed, with the original L(1)PAP predominating. The diesters detected maintain the linoleyl group but incorporate a new fatty acid that can be related to the main free fatty acids present in the oil used as vehicle: oleic acid for olive oil, palmitic acid for palm oil, and lauric and myristic acids for coconut oil. There is a good correlation between the percentage of free fatty acids present in the oils and the fatty acid taken up by the original molecule of L(1)PAP (Fig. 5). The presence of some mPAP species that do not include linoleic acid in their composition demonstrates the hydrolysis of the original linoleic acid moiety of the molecule.

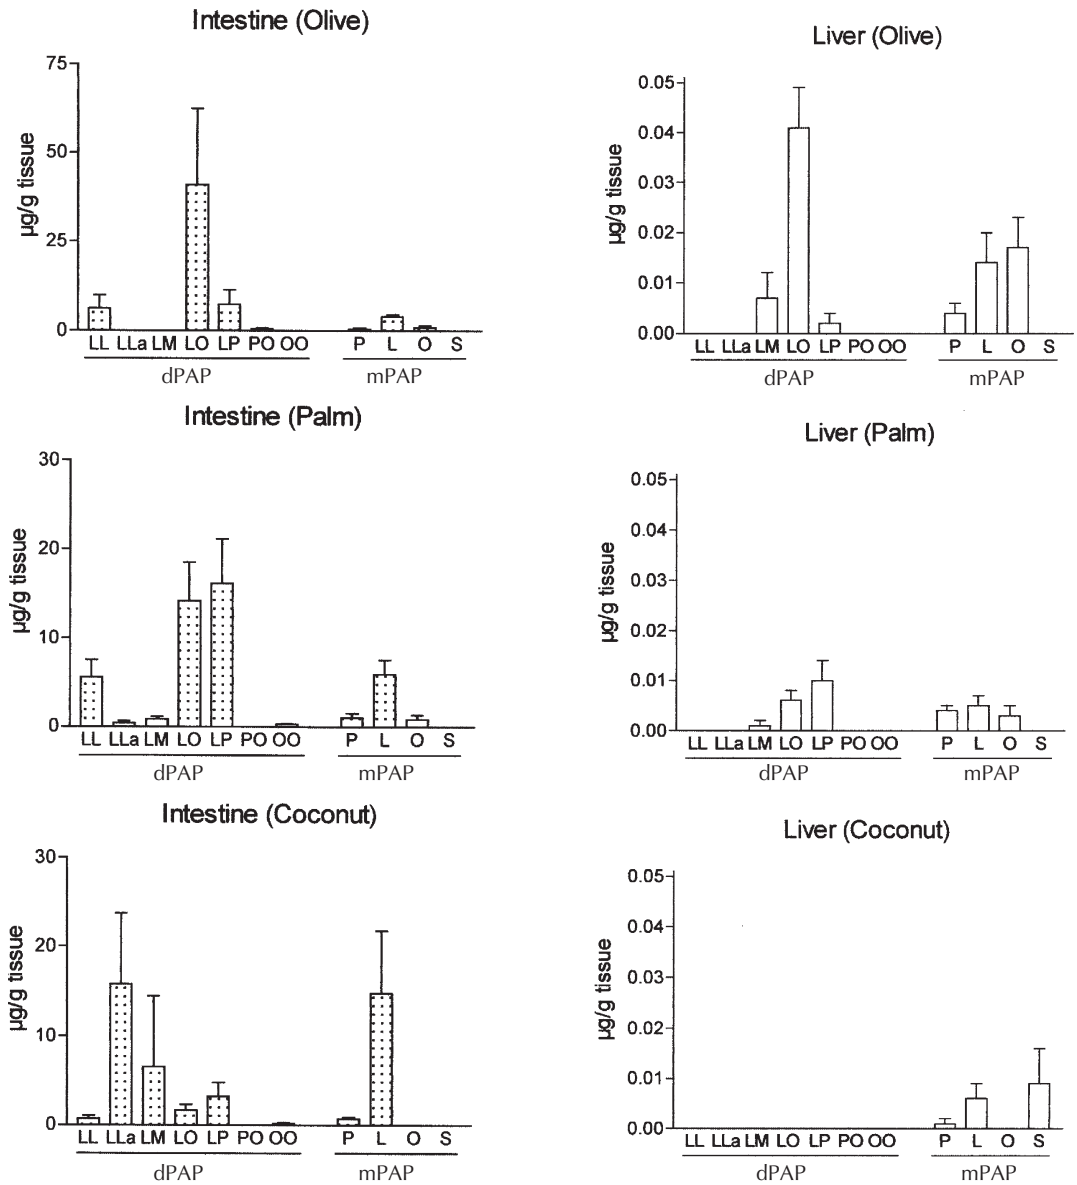

**FIG. 4.** Fatty acid composition of PAP observed in intestinal (left) and liver (right) samples after administration of linoleyl PAP, as a function of the oil administered as vehicle. The fatty acids present in the PAP esters are: P, palmitic; L, linoleic; O, oleic; S, stearic; La, lauric; M, myristic. Thus, LLa indicates that the DPAP incorporates linoleic and lauric acids. dPAP, diester of PAP; MPAP, monoester of PAP; for other abbreviations see Figure 1. Data are expressed as mean ± SEM.

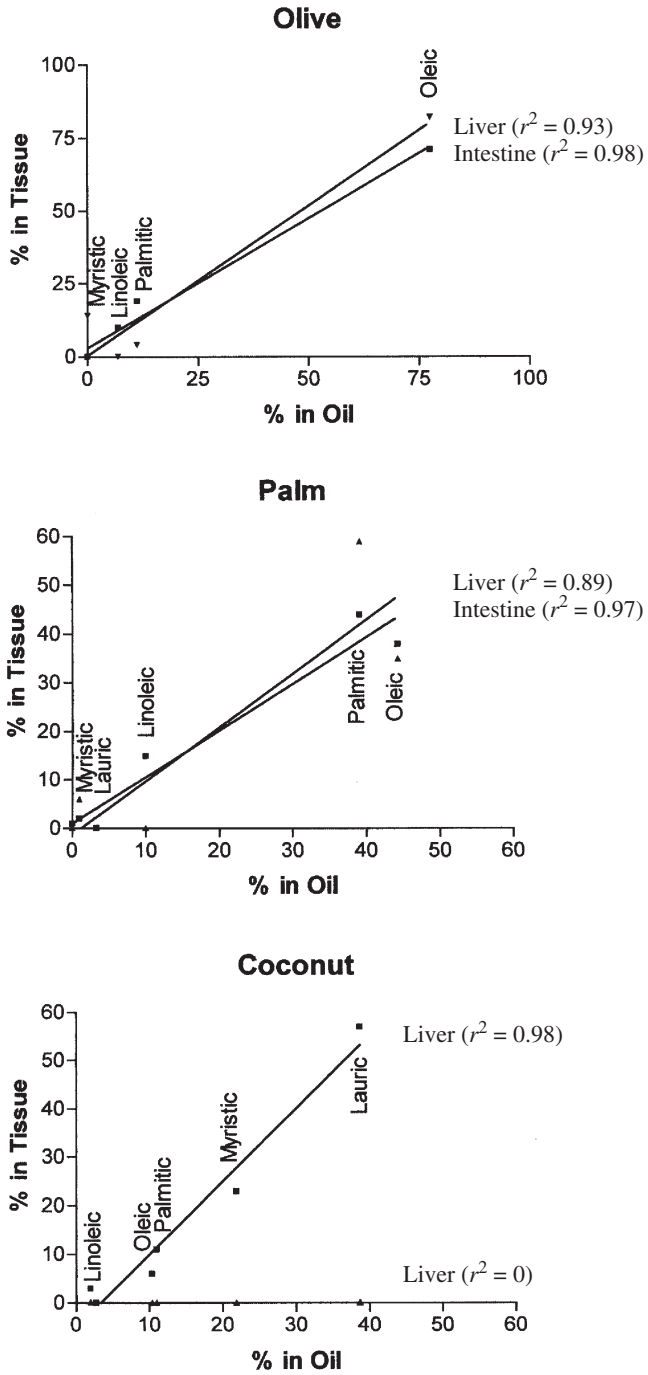

**FIG. 5.** Correlation between the percentage of free fatty acids present in the oils used as vehicle (x axis) and the fatty acid esterified in the original L(1)PAP found in tissue (y axis); intestine (■) or liver (▲). For abbreviations see Figure 1.

In the case of the liver, PAP were present in lower amounts than in jejunum. In this organ we found similar amounts of dPAP and mPAP [with the exception of LO(1,2)PAP for olive oil]. In addition, the predominance of L(1)PAP found in jejunum was not observed in the liver. The profiles found in dPAP in the liver were quite similar to those obtained in the jejunum with the exception of the coconut oil–treated group. In this case, only mPAP were found.

We did not find measurable amounts of any PAP metabolite in lung.

*Biological (PAF-like) activity: Changes in vascular permeability.* Figure 6 shows the changes in vascular permeability induced by superfusion of the different mediators analyzed. Lyso-PAF was used as an inactive control. As expected, superfusion of PAF greatly increased the vascular permeability of the mesentery. All other mediators evaluated showed no effect, except for the monoester of PAP with stearic acid [S(1)PAP]. This product induces a significant increase in vascular permeability. Nevertheless, the effect was very reduced when compared to PAF. To evaluate whether this effect could be related to the PAF receptors, we administered the PAF antagonist BN52021. This product completely inhibited the response to PAF but did not affect the increase in vascular permeability induced by S(1)PAP.

On the other hand, the possible effect of the diesters of PAP as antagonists of PAF was evaluated by cosuperfusion of these products with PAF (Fig. 7). The increase in vascular

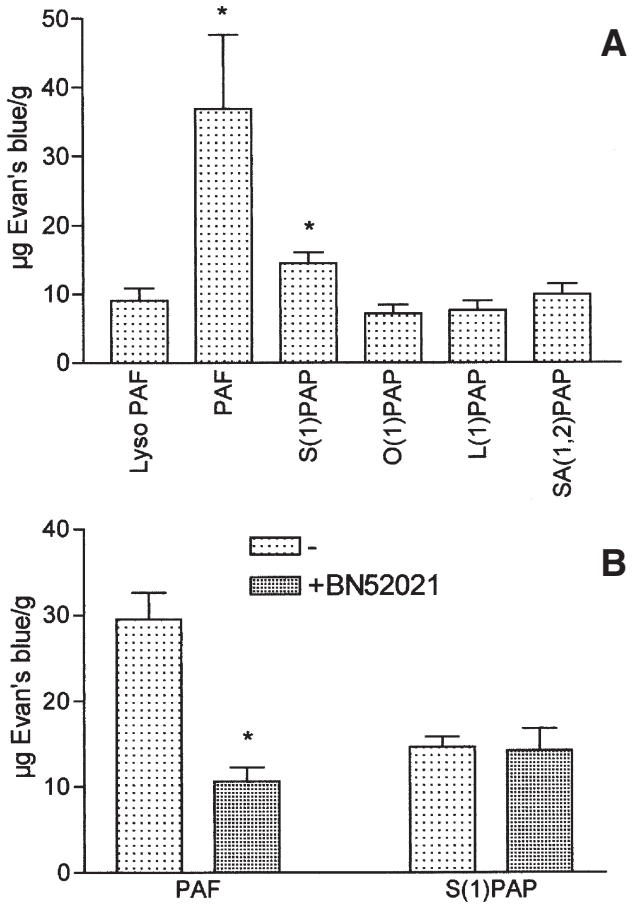

**FIG. 6.** Changes on vascular permeability (A) and effect of a platelet-activating factor (PAF) antagonist (B), measured as the accumulation of Evan's blue, after superfusion (100 nM, 30 min) of the different mediators analyzed. S(1)PAP, 1-stearyl-PAP; Oc(1)PAP, 1-octanyl-PAP; SA(1,2)PAP, 1-stearyl-2-acetyl PAP; for other abbreviations see Figure 1. Data are expressed as mean ± SEM. *$P < 0.05$ vs. Lyso PAF for Figure 6A; *$P < 0.05$ vs. untreated for Figure 6B.

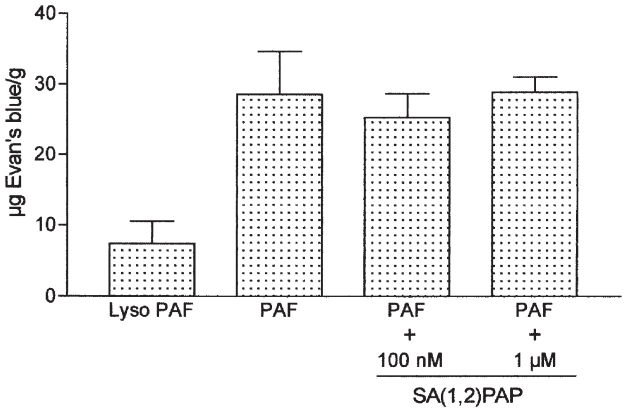

**FIG. 7.** Effect of dPAP on PAF-induced increases in vascular permeability. Effect of PAF (100 nM) was not modified by the presence of (100 nM) or (1 µM) SA(1,2)PAP in the superfusate. For abbreviations see Figures 1, 4, and 6.

permeability induced by 100 nM PAF was not modified by the presence of (100 nM) or (1 µM) SA(1,2)PAP in the superfusate.

*Effect of PAP on PAF synthesis.* The biosynthesis of PAF was induced in alveolar macrophages by LPS (Fig. 8). Mono- and diesters of PAP at 100 nM concentration inhibited the synthesis of PAF, with the exception of the monoester bearing octanoic acid in the *sn*-2 position.

## DISCUSSION

TOS, which occurred in Spain in 1981, was associated with the consumption of refined aniline-denatured rapeseed oil, illegally sold as olive oil (1). Further investigations reported that aniline and fatty acid anilides were present in TOS-related oils, and more recently the fatty esters of 3-(*N*-phenylamino)-1,2-propanediol have shown a strong association with TOS. There is also interest in these compounds because of their relation to the eosinophilia myalgia syndrome (EMS) that occurred in the United States in 1989 (15). That disease was associated with the consumption of L-tryptophan food supplements, and its clinical similarity to TOS suggested that a common biological pathway was affected in the TOS-associated case oils and the L-tryptophan case samples. *In vitro* conversion of (*N*-phenylamino)alanine, an EMS-associated contaminant (16), to 3-(*N*-phenylamino)1,2-propanediol has recently been reported (17). The latter compound forms the basic skeleton of the PAP esters.

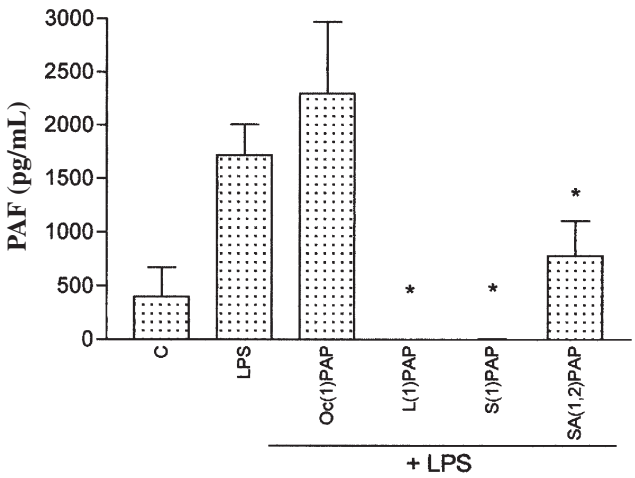

**FIG. 8.** Effect of mPAP and dPAP in the PAF synthesis induced by lipopolysaccharide (LPS) in alveolar macrophages. Oc(1)PAP, 1-octanyl PAP; C, control; for other abbreviations see Figures 1, 4, and 6. Data are expressed as mean ± SEM. *$P < 0.05$ vs. LPS.

The identification of PAP esters (Fig. 2) in TOS-related oil samples (2) suggested possible immunologic or inflammatory responses if these products were to be incorporated into cell membranes. This fact is also supported by the structural similarities of PAP esters and diacylglycerols (DAG). In addition, systemic bioactive phospholipids such as PAF are somewhat similar in structure. In this sense, it is important to understand not only the uptake and distribution of PAP esters but also the modification of these products upon gastrointestinal absorption.

The data obtained from rats after oral administration of radioactive doubly-labeled PAP indicate that these chemical species could be metabolized and distributed to different organs, being rapidly excreted in the urine (Fig. 3). Some organs appeared to be very active in the accumulation of these compounds, particularly the BAT, white adipose tissues, and the liver. The change in the isotopic composition found in urine 4 h after ingestion (Fig. 4) proved that these molecules were catabolized upon gastrointestinal absorption. Moreover, this observation suggests that the aniline-containing part of the molecule was preferentially excreted through urine, while constituent fatty acids were incorporated into the body pool of fatty acids. This observation would be in line with a recent report describing the biotransformation and clearance of the parent PAP, which was found to be highly metabolized in mice and excreted in urine in the form of 2-hydroxy-3-(phenylamino) propanoic acid (18). Results obtained measuring the radioactivity present in the aqueous phase of a Bligh and Dyer lipid extraction (Fig. 5) supported our conclusion. In tissue, radioactivity remained in the lipidic fraction so that little was recovered in the aqueous phase. By contrast, in plasma and urine radioactivity was totally extracted in the aqueous phase, indicating that the radioactivity present in plasma and urine corresponded to polar compounds or metabolic breakdown products. This result indicated that these compounds maintained their lipidic properties in the tissues, whereas in plasma and urine the radioactivity was mainly present in the form of hydrosoluble compounds. As shown in Figure 1, the preferential excretion of the $^{14}C$-labeled aniline ring is evident in the urine samples at 4 h, whereas in the urine collected after 18 h we mainly find $^{3}H$ excretion, probably in the form of catabolized end products of fatty acids, including $^{3}H$-labeled water.

The composition of PAP was found to change during intestinal absorption, and these changes were dependent on the vehicle used for their administration (Figs. 4 and 5). *sn*-1

Monoesters of PAP were esterified in the *sn*-2 position with a second fatty acid. The nature of this fatty acid was a function of the pattern of free fatty acids present in the oil administered as vehicle. The original monoester of the PAP administered was found only in low quantities, indicating that PAP were mostly incorporated in the form of dPAP. In addition, the presence of some esters of PAP that did not contain the original linoleic acid indicated that the intestine was able to hydrolyze the fatty acid originally present in the *sn*-1 position and re-esterify it with another fatty acid. These results suggest that the absorption and intestinal metabolism of PAP could be similar to that of DAG and open the possibility that PAP esters could interfere any of the cell pathways modulated or regulated by DAG.

When measuring the composition of PAP in liver (Figs. 4 and 5), we found that this organ showed a pattern of constituent fatty acids different from that of the PAP detected in the intestine, suggesting that the ability to modify the fatty acid composition of the PAP originally ingested is not restricted to the intestine. As in intestine, the liver showed a different profile of PAP as a function of the oil used as vehicle. For dPAP, changes observed in intestine were maintained in the liver, showing the original linoleic acid and a new fatty acid that was coincident with the fatty acid predominant in the oil. In contrast, mPAP showed clear differences when liver and intestine were compared. It could be suspected that PAP are absorbed by the gastrointestinal tract as dPAP, distributed, and stored in this form in the different organs, whereas mPAP are the result of dPAP metabolism.

On the other hand, the ability to modify the composition of the fatty acids present in the ingested PAP molecule implies that any physiological effects of PAP esters could be induced by PAP esters with a fatty acid composition different from that in the original PAP identified in the toxic oil samples.

When evaluating the potential biological PAF-like effects of PAP, we found a moderate increase in the vascular permeability of the mesentery when it was superfused with the monoester of stearic acid (Fig. 6). This effect was lower than the effect of PAF and was not affected by the presence of PAF receptor antagonists. Therefore, it seems that the effect is not mediated by the structural similarities between S(1)PAP and PAF. On the other hand, the diester of PAP with stearic acid in the *sn*-1 position and acetic acid in the *sn*-2 position (which is the most similar in its structure to PAF), is not able to modify the effect of PAF when assayed at equimolar or ×10 concentrations (Fig. 7).

The most remarkable result found in relation to PAF metabolism is the effect of different PAP on the synthesis of PAF (Fig. 8). When incubating alveolar macrophages with LPS to induce PAF synthesis in the presence of different PAP, we found an inhibitory effect by the esters that contained linoleic or stearic acid in the *sn*-1 position. In contrast, PAP esters containing shorter fatty acids (octanoic) had no effect. The presence of an acetyl group in the *sn*-2 position did not affect the inhibitory effect of the compound, and only the presence of a long ($C_{16}$–$C_{18}$) chain in the *sn*-1 position appeared to be important for this effect.

Some enzymes involved in PAF synthesis show low substrate specificity. For example, acetyltransferases can utilize both acyl-lysoglycerophosphate and acyl-lysoglycerophosphatidylcholine. For this reason, significant quantities of PAF analogs (acyl, alkyl, ethanolamine, and other analogs) have been reported to be formed in various cells (6,19). Taking into account this low substrate specificity, one could hypothesize that some enzymes involved in the pathway of PAF synthesis could be blocked by structurally similar compounds such as PAP esters with $C_{16}$ or $C_{18}$ in the *sn*-1 position.

Despite the low probability that the inhibitory effect could explain the toxic effect of oil samples, these results indicate that these compounds can be effectively incorporated into the lipid metabolic pathways and interfere with some of the enzymes involved in these pathways. However, this fact need not be restricted only to phospholipid analogs, since the incorporation of PAP esters into endogenous lipid metabolic pathways implies the possible generation of other families of mediators, such as modified DAG analogs, that could be suspected to contribute to pathogenesis of TOS. Taken together, the latter consideration plus the data reported herein open the way for new approaches to the study of the metabolically derived physiological effect of PAP esters.

## ACKNOWLEDGMENTS

This work has been supported by FISss grant 96/1815-SAT; E. Folch is recipient of an IDIBAPS predoctoral grant. Thanks are given to Prof. Angel Messeguer (Department of Biological Organic Chemistry, IIQAB-CSIC, Barcelona, Spain) for the synthesis of PAP and PAP derivatives, and Mª Victoria Ruiz and Alvaro Ramos (Instituto de la Grasa, Sevilla, Spain) for the analysis of fatty acids in coconut, palm, and olive oils.

**ABSTRACT:** We have recently synthesized fatty acid bile acid conjugates (FABAC) that were able to reduce and retard cholesterol crystallization in model and human biles. When given orally, they prevented the formation of cholesterol crystals in the bile of hamsters. The aim of the present study was to determine whether the FABAC are cholesterol solubilizers, whether they can dissolve pre-existing crystals, whether they can prevent the formation of cholesterol gallstones, and to investigate the optimal type of bond between the fatty acid and bile acid. The presence of cholesterol crystals was determined by light microscopy, and the total crystal mass of precipitated crystals was measured by chemical means. Inbred (C57J/L) mice on a lithogenic diet were used to evaluate cholesterol crystal formation, dissolution, and gallstone formation *in vivo*. Arachidyl amido cholanoic acid (Aramchol) was the FABAC used in the present experiments. At equimolar amounts, the cholesterol-solubilizing capacity of Aramchol was higher than that of taurocholate and similar to that of phosphatidylcholine. The addition of Aramchol dissolved approximately 50% of pre-existing crystals in model bile solutions. The same phenomenon was demonstrated in human bile *ex vivo*, with a dose–response effect. All inbred mice developed cholesterol crystals in bile after 10–14 d on the lithogenic diet. Thereafter, supplementation of the diet with Aramchol progressively reduced the proportion of mice with crystals to 25% after 28 d. On the lithogenic diet, 100% of inbred mice developed cholesterol gallstones in the gallbladder by day 21. None of the mice whose diet was supplemented with 0.5 mg or 1.0 mg of Aramchol/d developed stones or crystals. FABAC are a new class of molecules that are cholesterol solubilizers and which are able to dissolve cholesterol crystals in bile. Upon oral administration, they dissolve pre-existing cholesterol crystals and prevent the formation of gallstones in gallstone-susceptible mice.

Paper no. L8738 in *Lipids 36*, 1135–1140 (October 2001).

Fatty acid bile acid conjugates (FABAC) are a new class of synthetic molecules produced with the aim of reducing cholesterol crystallization in bile (1). It has been demonstrated that phospholipids, and not bile acids, are the major cholesterol solubilizers in bile (2–5). The FABAC were designed to bring parts of the phospholipid molecule (long-chain saturated fatty acids) into bile, using the very efficient absorption and biliary secretion of bile acids. The whole FABAC molecule has, however, characteristics that are different from those of its components.

The FABAC, and in particular 3-β-arachidylamido-7-α, 12-α-dihydroxy-5-β-cholan-24-oic acid (arachidyl amido cholanoic acid, Aramchol, $C_{20}$-FABAC), were shown to prolong the cholesterol nucleation time markedly and reduce the total crystal mass in model bile solutions (1). In native human gallbladder bile, FABAC were even more effective, preventing crystal formation for weeks and reducing the eventual crystal mass to minute proportions. Aramchol was also shown to prevent *in vivo* biliary cholesterol crystallization in experimental animals (1). Thus, almost three decades after the introduction of chenodeoxycholic acid for gallstone dissolution (6), FABAC raise again the possibility of a medical therapy for the prevention and/or dissolution of cholesterol gallstones. Many questions in relation to the mechanism of action and metabolism of the FABAC remain open. The present study was designed to answer four main questions: (i) Do FABAC act as cholesterol solubilizers in bile? (ii) Can they dissolve formed, pre-existing cholesterol crystals *in vitro* and *in vivo*? (iii) Can they prevent the formation of cholesterol gallstones *in vivo*? (iv) Does the kind of conjugation (ester vs. amide) influence the absorption and biliary secretion of the FABAC?

The experiments were performed with Aramchol, which is a conjugate of arachidic and cholic acid (at position 3) using an amide bond. This compound in particular was found to effectively inhibit *in vitro* cholesterol crystallization in our earlier study (1).

## MATERIALS AND METHODS

*Materials.* Egg yolk phosphatidylcholine (PC), 99% pure, was purchased from Avanti Polar Lipids, Inc. (Alabaster, AL). Free fatty acids (FFA), cholesterol, sodium taurocholate (TC), and cholic acid (CA), >98% pure, were purchased from Sigma Chemical Co. (St. Louis, MO). Cholesterol, TC, and CA were recrystallized prior to use. All other chemicals and

[1]Some of the data in this paper were presented at the 2000 Annual Meeting of the American Gastroenterological Association.

Abbreviations: Aramchol, arachidyl amido cholanoic acid; CA, cholic acid; CSI, cholesterol saturation index; FABAC, fatty acid bile acid conjugates; FFA, free fatty acid; PC, phosphatidylcholine; TC, taurocholate; UDCA, ursodeoxycholic acid.

solvents were American Chemical Society or reagent grade. The glassware was acid washed, thoroughly rinsed in distilled water, and dried.

*Preparation of Aramchol.* Aramchol was prepared as previously described (1) by conjugating cholic acid with arachidic acid ($C_{20}$) in the 3-position, using an amide bond. The conjugation was in the β configuration. For the absorption studies (see below) an ester conjugate was similarly prepared. Both compounds were purified by silica gel chromatography and characterized by $^1$H nuclear magnetic resonance and mass spectrometry.

*Model biles.* The model biles were prepared from a mixture of cholesterol (in chloroform), PC (in chloroform), and TC (in methanol) in various concentrations (specified in the Results section), as previously described (7). The model bile solution was incubated under argon at 37°C, and aliquots were taken for analysis at predetermined times throughout the crystallization process.

*Human bile.* Human gallbladder biles were obtained from gallstone patients at cholecystectomy. The bile was aspirated after needle puncture of the gallbladder prior to mobilization of the gallbladder. Informed consent was obtained according to a protocol approved by the local institutional human subjects committee. Biles were ultracentrifuged (200,000 × *g*, 45 min, 25°C) prior to testing to get rid of crystals and cell debris.

*Solubilization experiments. (i) Cholesterol-solubilizing capacity.* Model biles (30 mM PC, 150 mM Na-TC) were prepared with two different cholesterol concentrations (12.2 and 9.9 mM) to yield a supersaturated [cholesterol saturation index (CSI), 1.1] and an undersaturated (CSI, 0.9) bile solution, respectively. They were then incubated overnight with 10-mM $^3$H-labeled dried cholesterol. The $^3$H-cholesterol solubilization after 24 h of incubation at 37°C was measured. The amount of cholesterol remaining in the supernatant solution after ultracentrifugation for 5 min at 76.000 × $g_{max}$ was the parameter for solubilization. Solubilization of cholesterol in the model bile was compared to that observed in biles that were supplemented with 5 mM Na-TC, PC, or Aramchol.

*(ii) Dissolution of pre-existing cholesterol crystals in bile.* Model bile (as above) or native bile from a cholesterol gallstone patient (after ultracentrifugation for 1 h at 200,000 × $g_{max}$ at room temperature to get rid of debris or crystals) was incubated at 37°C. After crystallization, *in vitro* or *ex vivo*, had progressed and reached an apparent equilibrium (no further increase in crystal mass), incubation was continued without as well as after adding FABAC. Serial microscopic observations and determinations of total crystal mass were performed.

*Evaluation of cholesterol crystal formation and growth. (i) Light microscopy.* Aliquots (5 μL) of bile or model bile were examined by a light microscope (Zeiss, Jena, Germany) under polarized light and with the differential interference mode as previously described (7). Cholesterol crystals were identified by their characteristic morphology and birefringence, and counted per microscopic field at 100-fold magnification.

*(ii) Measurement of crystal mass.* Chemical analyses of cholesterol were performed on model bile samples after *in situ* crystallization, as previously described (8). In human biles the mass of the pelleted crystals was quantitated after ultracentrifugation.

*Animal experiments.* All animal experiments related to cholesterol crystallization were performed with male inbred mice (C57J/L, 4 wk old, approximately 20 g). Cholesterol crystal and gallstone formation was induced by feeding the mice a lithogenic diet containing regular chow (Koffolk, Petach Tikva, Israel), to which butterfat 15%, cholesterol 1%, cholic acid 0.5%, and corn oil 2% (w/w) were added (9).

*Dissolution of preformed crystals.* After 10 and 14 d on the lithogenic diet, a group of mice was sacrificed and gallbladder bile was examined to ascertain the presence of cholesterol crystals. Subsequently, in the remaining animals, Aramchol mixed with saline was administered by gavage (*via* a feeding needle) at a dose of 3 mg/animal/d. Half of the remaining animals were sacrificed after 14 d and the rest after 28 d of Aramchol feeding. The presence of cholesterol crystals and stones in the gallbladder was examined at each time interval.

*Prevention of gallstone formation.* Mice were sacrificed after 3 wk of consuming the lithogenic diet with or without Aramchol (0.5 or 1.0 mg/animal/d). The percentage of animals harboring gallstones (and cholesterol crystals) in their gallbladders was determined by direct inspection and microscopy of their gallbladders.

*Comparison of absorption and biliary secretion of ester- and amide-bonded conjugates.* Male C57Black mice received 3 mg/animal of FABAC by intragastric administration; and heart blood, portal blood, and gallbladder bile were sampled in groups of three animals sacrificed after 1, 2, and 3 h. One group ($n$ = 9) received the regular Aramchol, with an amide (NH) bond between the bile acid and the fatty acid. Another group ($n$ = 9) received the compound with an ester bond. In a separate experiment, animals (3 in each group) were sacrificed 24 h after the intragastric administration of the ester or amide conjugate

*Analytical methods.* Biliary lipids were extracted by chloroform/methanol (2:1, vol/vol) and quantitated as previously described (10–12). Aramchol concentration was determined by high-performance liquid chromatography (Kontron) employing a Phenomenex Luna reversed-phase C-18 column as previously described (1). Samples were applied dissolved in methanol. The running phase was methanol 100%, at a flow rate of 0.9 mL/min. Aramchol was detected at 206 nm.

*Statistical analysis.* Student's $t$ test was used to compare the data. A $P$-value of $<0.05$ was considered significant.

## RESULTS

The cholesterol-solubilizing capacity of Aramchol was studied in two model bile solutions—one undersaturated (CSI, 0.9) and the other supersaturated (CSI, 1.1) with cholesterol. The amounts of cholesterol solubilized by Aramchol in excess of the amount solubilized by the model solutions alone were 0.9 and 1.4 mM, respectively. The corresponding amounts solubilized by NaTC were 0.6 and –0.4 mM, while those by PC were

0.9 and 0.9 mM, respectively. Thus, the cholesterol-solubilizing capacity of Aramchol was higher than that of NaTC and similar to that of PC. The effect was more marked in the supersaturated model.

The ability of Aramchol to dissolve (preformed) cholesterol crystals was studied in two model biles (model A: 15 mM cholesterol, 30 mM PC, 150 mM Na-TC; model B: 18 mM cholesterol, 36 mM PC, 120 mM Na-TC). Aramchol was added at a concentration of 7 mM to model A and at 10 mM to model B, based on the maximal solubility of Aramchol in these models. As shown in Figure 1, the cholesterol crystal mass in both model biles decreased after addition of Aramchol, from 4.4 to 2.7 μmol in model A ($P = 0.28$) and from 7 to 2.9 μmol in bile B ($P = 0.0004$), respectively. Figure 2 shows the effect of Aramchol on preformed cholesterol crystals in human bile. In the native bile, the addition of Aramchol also decreased the crystal mass significantly. The effect was dose-dependent in the dose range studied (10–30 mM). Fourteen days after the addition of Aramchol (10 and 30 mM), the total crystal mass decreased from 2.4 ± 0.1 to 1.5 ± 0.1 μmol ($P < 0.02$) and to 0.1 ± 0.01 μmol ($P = 0.01$), respectively. The decreases corresponded to 38 and 94%, respectively. Three human biles were studied. In all of them, the addition of 30 mM Aramchol resulted in the disappearance of plate-like cholesterol crystals while decreasing the total crystal mass to 6–62% of control. In two-thirds of the cases, the addition of Aramchol converted the plate-like (mature) crystals to filamentous (less mature) crystal forms (13) and reduced the total crystal mass in all three.

The ability of Aramchol to dissolve preformed cholesterol crystals *in vivo* was studied in inbred mice. Two sets of experiments, with a total of 36 mice, were performed. Figure 3 shows the percentage of mice with crystals in their gallbladders as a function of time of feeding the lithogenic diet with and without Aramchol. On days 10 and 14 all sacrificed animals ($n = 7$ and 8, respectively) had crystals in their gallbladders. However, when Aramchol (at 3 mg/animal/d) was then added to the diet, the percentage of animals with crystals gradually dropped to 75% on day 28 ($n = 12$) and to 25% on

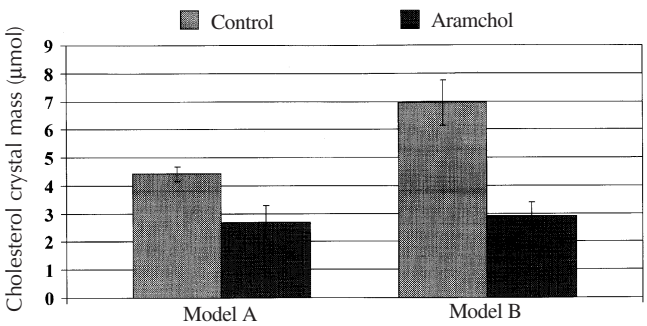

**FIG. 1.** Cholesterol crystal mass after 19 d of incubation of pre-existing crystals in model biles (model A: 15 mM cholesterol, 30m M egg lecithin, 150 mM Na-taurocholate; model B: 18 mM cholesterol, 36 mM egg lecithin, 120 mM Na-taurocholate) in the absence or presence of Aramchol (model A: 7 mM, model B: 10 mM; $n = 3$ for both). The decrease was 39% ($P = 0.28$) in model A and 58% ($P = 0.0004$) in model B.

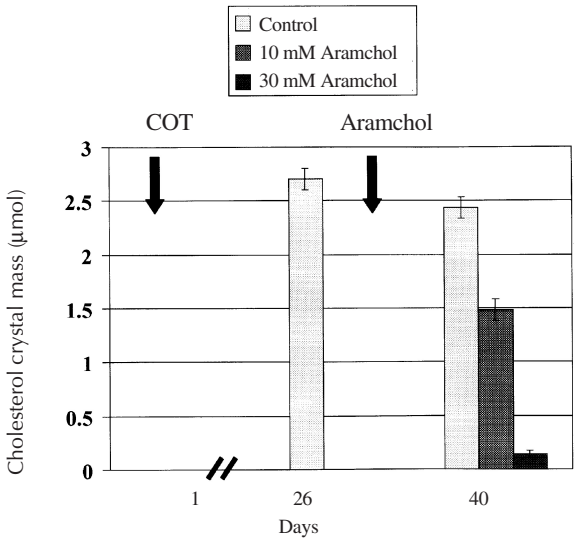

**FIG. 2.** Cholesterol crystal solubilization in human bile *ex vivo* by Aramchol, dose–response effect. Bile from a cholesterol gallstone patient was incubated at 37°C until apparent crystallization equilibrium (day 26). Incubation was then continued for another 14 d in the absence or presence of 10 or 30 mM Aramchol. Microscopic observations and determinations of the final crystal mass were performed. Aramchol decreased the crystal mass by 38 (grey bar: 10 mM) and 94% (black bar: 30 mM). COT, crystal observation time.

day 42 ($n = 9$). This observation contrasts with that following a continuation of the lithogenic diet without any other manipulations, which yields more crystals, and eventually stones (data not shown; Ref. 9).

The ability of Aramchol to prevent gallstone formation *in vivo* was also studied in inbred mice ($n = 17$). As seen in Figure 4, feeding of Aramchol together with the lithogenic diet completely prevented the formation of gallstones (as well as

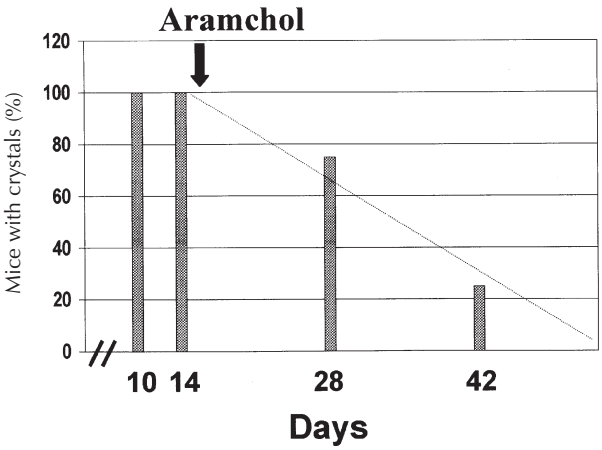

**FIG. 3.** Effect of fatty acid bile acid conjugate feeding on pre-formed cholesterol crystals *in vivo*. All mice ($n = 36$) were fed a lithogenic diet throughout the experiment. Seven animals were sacrificed after day 10 and another 8 after day 14: All had cholesterol crystals in their gallbladders. Thereafter, Aramchol (3 mg/d) was added to their diet. In these Aramchol-supplemented mice ($n = 21$), the proportion with crystals declined progressively to 75% after 14 d and to 25% after 28 d of Aramchol feeding.

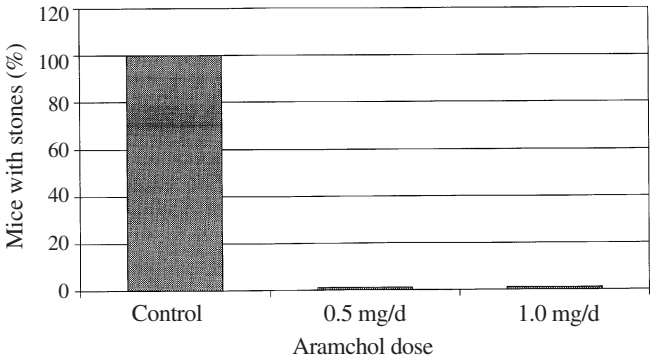

**FIG. 4.** Effect of Aramchol feeding on cholesterol gallstone formation *in vivo*, expressed as a percentage of inbred mice harboring cholesterol gallstones in their gallbladders after 3 wk of feeding a lithogenic diet, with or without Aramchol (0.5 or 1.0 mg/animal/d). At the end of the experiment, none of the Aramchol-fed mice ($n = 10$) had stones (or crystals) in their gallbladders; stones were found in all the controls ($n = 5$).

crystals) in the mice at both doses studied (0.5 and 1.0 mg/animal/d). All control animals developed both crystals and cholesterol gallstones by day 21, whereas none of the Aramchol- supplemented animals had either crystals or gallstones. The concentrations of Aramchol in the gallbladder bile of mice fed 0.5 mg/d varied between 0.03 and 0.17 mM (≥24 h after the last dose).

Bile and heart blood levels of amide- and ester-bonded Aramchol after a single intragastric dose of 3 mg/mouse are shown in Figure 5. In mice receiving the amide-bonded Aramchol, bile levels after 1, 2, and 3 h were 0.3 ± 0.02, 0.4 ± 0.03, and 0.7 ± 0.06 mM, respectively. In mice receiving the compound with an ester bond between the arachidic and cholic acids, bile levels remained below 0.07 mM at all times. Blood levels in the animals receiving the ester-bonded

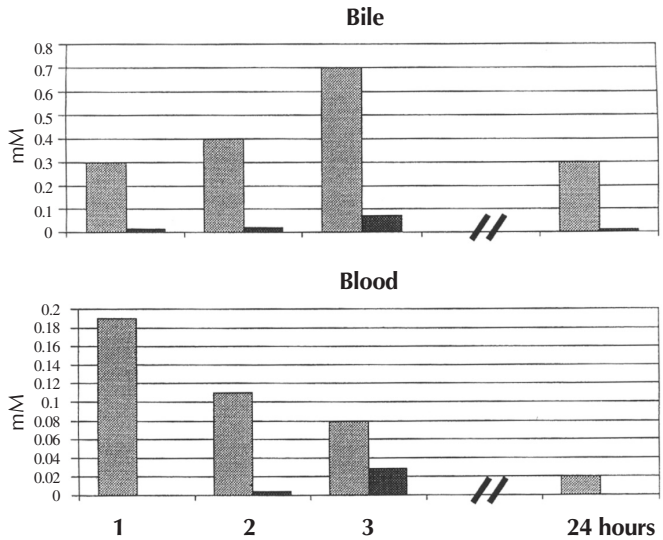

**FIG. 5.** Bile and heart blood levels of amide- (gray bars) and ester- (black bars) bonded Aramchol after a single intragastric administration of 3 mg/animal at 0 time. Three animals were tested at each time point with either conjugate. A separate experiment was performed to test levels at 24 h.

FABAC were below 0.03 mM at all times, whereas in the animals receiving the amide-bonded compound blood levels were mostly between 0.1 and 0.2 mM. Portal blood levels were also significantly higher with the amide-bonded Aramchol (0.1–0.3 mM) compared to the ester-bonded compound (0.001–0.1 mM). Twenty-four hours after an intragastric administration of 3 mg/animal, bile levels were 0.3 ± 0.03 mM with the amide and 0.01 ± 0.001 mM with the ester bond, while heart blood levels were 0.02 ± 0.002 and <0.0001 mM, respectively (Fig. 5).

## DISCUSSION

Aramchol represents a new group of synthetic molecules (FABAC), which were recently shown to inhibit cholesterol crystallization (1). In our previous study we showed that they prolong the crystal observation time and decrease the crystal mass in model and human biles. The FABAC were absorbed after intragastric administration and prevented crystal formation in experimental animals. Their mode of action (solubilization vs. inhibition of crystallization) was not studied. The present study clearly indicates that Aramchol is a cholesterol solubilizer. *In vitro* it dissolves solid amorphous cholesterol when added to either an undersaturated or supersaturated model bile solution. Aramchol dissolves formed cholesterol crystals in model bile and also in human gallbladder bile *ex vivo*. We have now demonstrated, for the first time, that upon oral administration it can dissolve preformed cholesterol crystals *in vivo* and, most significantly, prevent the development of cholesterol gallstones in inbred mice.

Many of the structure/function relationships of the FABAC have now been elucidated. Those with longer-chain fatty acids ($C_{18}$–$C_{22}$) were the most potent in terms of cholesterol solubilization (1). FABAC containing shorter-chain fatty acids ($C_6$–$C_{12}$) were not effective, while those with $C_{14}$, $C_{16}$, and $C_{24}$ fatty acids had a smaller effect (1). The Aramchol used in the present experiments is one of the more effective compounds.

Conjugation with cholic acid (at position 3) results in a dihydroxy compound. Conjugation with a dihydroxy bile acid (e.g., ursodeoxycholic acid) would result in a monohydroxy compound, which could be toxic. However, this is at the moment a speculative consideration, which is being further studied. Our results show that the bond between the fatty acid and the bile acid is very important. An ester bond is easily broken down by intestinal enzymes and bacteria, resulting in the separate absorption of a fatty acid and a bile acid. Thus, little of the intact ester conjugate reaches the bile (Fig. 5). Further breakdown may occur during enterohepatic cycling. Esters of fatty acids with bile acids have been found in the feces (14). These compounds have also been synthesized by Kritchevsky's group (15) in an attempt to delay the intestinal catabolism of chenodeoxycholic and ursodeoxycholic acids. The amide bond used in our experiments is a more stable bond, allowing the absorption and biliary secretion of the intact FABAC. The amide bond is, however, not exclusive. Any stable bond, permitting the absorption and biliary secretion of the intact

FABAC and providing effective cholesterol solubilization, is suitable. The bond between the fatty acid and bile acid can be *via* a bonding molecule, or it can be a direct bond (C=C).

It should be noted that the mechanism of action of the FABAC is quite different from that of chenodeoxycholic and ursodeoxycholic acids. These specific bile acids reduce the mole percentage of cholesterol in hepatic bile by an effect on biliary enzymes and/or cholesterol absorption in the gut (16). They are not cholesterol solubilizers. The direct, *ex vivo* addition of bile salts to human gallbladder bile does not prolong the nucleation time, but the addition of a cholesterol solubilizer, like phospholipids, markedly prolongs the nucleation time. This has been demonstrated by Jungst *et al.* (2). As shown in the present investigation, FABAC are cholesterol solubilizers. This was demonstrated *in vitro* where any potential effects on liver and intestines was excluded.

The cholesterol-solubilizing effect of FABAC was stronger in human bile as compared to model biles. In human bile FABAC have an effect at concentrations of 3–5 mM while in model biles concentrations of up to 30 mM are required (1). This higher effectiveness in human bile has now been confirmed many times, but the explanation is not clear at the moment.

Another major difference was observed in relation to the effect of FABAC on bile *in vivo* and *ex vivo*. To prolong the nucleation time and reduce the crystal mass in bile *ex vivo*, concentrations of 3–5 mM were required (1). To dissolve pre-existing crystals in bile *ex vivo* (using a single addition of FABAC to bile), concentrations of 10–30 mM were required. They dissolved approximately 50% or more of pre-existing crystals, usually converting the remaining crystals to earlier crystal forms (plates to filaments) (Fig. 2). After the administration of a single oral dose of 3 mg/mouse of Aramchol, biliary concentrations were 0.3–0.5 mM after 2 h and 0.1–0.6 mM after 3 h. On chronic oral administration of 3 mg/d of Aramchol, the concentrations in gallbladder bile (≥24 h after the last dose) were of the order of 0.2–0.6 mM. The dissolution of the pre-existing and continuously produced crystals was progressive (Fig. 3), with only 25% of animals having crystals after 28 d. An extrapolation of the curve predicts complete disappearance of crystals approximately 33 d after the start of Aramchol ingestion. The oral administration of 0.5 mg/d prevented the formation of crystals and gallstones in the gallbladder (Fig. 4). This was accomplished with biliary concentrations (≥24 h after the last dose) in the range of 0.03–0.17 mM.

The difference between the 3–5 mM effective in bile *ex vivo* and the 0.1–0.6 mM effective *in vivo* is marked. No definite explanation is presently available. An additional effect of the FABAC on liver, gallbladder, or intestine cannot be excluded. Studies using mass spectrometry demonstrated intact FABAC in blood and bile (Leinkin-Frenkel, A., unpublished data). We have at present no evidence for the presence of metabolites. Further research is ongoing.

The lithogenic tendency in inbred mice on a high-cholesterol diet is very strong. Under these conditions, close to 100% of the mice develop cholesterol crystals in bile within 7–10 d and gallstones within 3–8 wk (9). In human models, the process takes much longer and is less effective. During pregnancy, biliary sludge is formed in almost one-third of women but mostly during the second or third trimester, i.e., 4–9 mon (17). Cholesterol crystals are a major component of biliary sludge. In obese subjects ingesting a very low calorie diet or undergoing gastroplasty, gallstones develop in up to one-third of subjects, although usually only after several months (18). Also, patients receiving octreotide take months to develop gallstones and even then are in only some of the patients (19). The fact that FABAC almost completely prevent the formation of crystals and stones in lithogenic mice and accomplish this within 1–3 wk of ingestion suggests that their solubilizing effect is strong. Moreover, this is accomplished at doses very close to the doses (on a molar equivalence basis) used in bile salt therapy in humans (15 mg/kg/d) (16).

Unlike bile salts, FABAC are found in the systemic circulation at concentrations similar to or higher than those in the portal vein (1). This is probably due to transport *via* the lymph. Moreover, after a single oral dose they circulate in the vascular tree for over 48 h. In view of their cholesterol-solubilizing capacity, this raises the possibility of their applicability in atherosclerosis as well.

The use of chenodeoxycholic acid and ursodeoxycholic acid (UDCA) proved that cholesterol gallstones could be dissolved (16). The process was, however, too long and of low efficacy. It was further shown that for medium- and large-sized stones lithotripsy was needed. The addition of UDCA after lithotripsy did not accelerate fragment evacuation and/or dissolution (20). More importantly, UDCA therapy did not effectively prevent gallstone recurrence after successful non-surgical therapy (21,22). FABAC therapy has the potential for correcting some of these shortcomings.

In summary, the data to date suggest that FABAC may be a potential medical therapy to prevent and/or to dissolve cholesterol gallstones in humans.

# Alterations in Fatty Acid Composition of Tissue Phospholipids in the Developing Retinal Dystrophic Rat

**J.M. Alessandri* and B. Goustard-Langelier**

Nutrition and Food Safety Laboratory, INRA, 78352 Jouy-en-Josas, France

**ABSTRACT:** Alterations in lipid composition occur in the retinal pigment epithelium and photoreceptor cells of the Royal College of Surgeons (RCS) dystrophic rat, a model for inherited retinal degeneration. With respect to lipid composition of nonretinal tissues, the developmental timing of lipid alterations and the incidence of dystrophy are unknown. We determined the fatty acid composition in choline phosphoglycerides (ChoGpl) and ethanolamine phosphoglycerides (EtnGpl) in the brain, liver, and retina from dystrophic RCS rats and from their nondystrophic congenics (controls) at the ages of 3 and 6 wk. At 3 wk, the fatty acid compositions were specific to individual phospholipid classes without any difference between dystrophic and nondystrophic tissues. In plasma phospholipids, there was an age-related increase in the relative contents of monounsaturated and n-3 polyunsaturated fatty acids, with only minor differences between dystrophic and nondystrophic rats. At 6 wk, the fatty acid compositions in ChoGpl and EtnGpl from dystrophic brain and retina were significantly different from those of nondystrophics. The effect of strain on developmental changes in brain fatty acid composition was significant for 18:0 and 22:6n-3 in EtnGpl and for 16:0, 18:0, 18:1n-9, and 20:4n-6 in ChoGpl. The brain ChoGpl fatty acid composition in nondystrophic rats was similar at 6 wk to that of normal rats, and there were almost no postweaning changes in the dystrophics. In retinal phospholipids, the effect of dystrophy was to increase the 20:4n-6 content in EtnGpl and to decrease 22:6n-3 in ChoGpl. The 18:2n-6 and 22:6n-3 contents in dystrophic liver ChoGpl were also significantly affected, while no difference was observed in the EtnGpl fraction. The dystrophy affected the phospholipid fatty acid developmental changes in a tissue- and class-specific manner. Fatty acid metabolism could be selectively altered in neural and nonneural tissues of developing dystrophic RCS rats.

Paper no. L8675 in *Lipids 36,* 1141–1152 (October 2001).

The retinal dystrophy observed in Royal College of Surgeons (RCS) rats is a classically used experimental model for studying a group of recessively inherited retinal degeneration diseases commonly called retinitis pigmentosa (1). The mutation results in the degeneration of the retinal photoreceptor cells and ultimately in blindness. The primary cause of retinal dystrophy in RCS rats is located in the retinal pigmented epithelium (RPE), which is unable to phagocytize the disk membranes of the photoreceptor cell rod outer segments (ROS). In normal conditions, the ROS membranes are shed with a circadian rhythm throughout the lifespan of the animal (2). The nondystrophic congenic RCS rat, which has the same genetic background except for the retinal dystrophy, retains phagocytic functions and serves as a control for the dystrophic animals. A deletion of RCS DNA that disrupts the gene encoding the receptor tyrosine kinase *Mertk* involved in the signaling of phagocytosis was recently discovered in dystrophic RCS rats (3). The phagocytic defect leads to an abnormal accumulation of ROS debris between the outer segment layer of the photoreceptor cells and the RPE that begins within 2 wk after birth (1,4). The defect is accompanied by a breakdown in the RPE cell tight junctions, neovascular formations, cell migrations, and abnormal accumulation of microglial cells (5). In addition, it has been shown that the neutral lipid and phospholipid head group compositions are altered in the ROS membranes of postweaning dystrophic rats (6). At the age of 3–5 wk, at which time the photoreceptor cells become severely damaged, the dystrophic ROS plasma membranes have a twofold lower cholesterol-to-phospholipid ratio than normal membranes, and the phospholipid headgroup composition of the disks differs from those of nondystrophics (6). The ROS fatty acid compositions were not analyzed in these studies. Anomalous phospholipid class distribution and fatty acid composition were reported in the RPE cells from young dystrophic rats (7,8). The dystrophic RPE cell plasma membranes have higher docosahexaenoic acid (22:6n-3) and lower arachidonic acid (20:4n-6) contents than those of nondystrophic rats (8). Moreover, the specific activities of $Na^+K^+$-ATPase and 5′-nucleotidase were found to be higher in the dystrophic RPE plasma membranes (8). These changes may contribute to the degenerative process by modifying the concentration of ions, fluids, and metabolites in the interphotoreceptor matrix (8). The relationship between the dystrophic mutation and the cause of alterations in structural lipids is unknown. Besides, the developmental timing of membrane lipid alterations has not been determined, and it is not known whether other neural or nonneural tissues in RCS rats present some modifications in fatty acid compositions. In this study, we analyzed the fatty acid composition of plasma, retina, brain, and liver phospholipids from dystrophic and nondystrophic rats during the critical period of retinal development. Analyses were performed at 3 wk, when the ROS morphology is still almost normal in dystrophic rats (1), and at a later

Abbreviations: ChoGpl, choline phosphoglycerides; EtnGpl, ethanolamine phosphoglycerides; prcd, progressive rod-cone degeneration; RCS, Royal College of Surgeons; ROS, rod outer segments; RPE, retinal pigmented epithelium.

stage of dystrophy (6 wk), after the inner segments have entirely disappeared and the degeneration has begun to spread through all parts of the visual cells (1). The strain × age interaction was determined for the main fatty acids in choline phosphoglycerides (ChoGpl) and ethanolamine phosphoglycerides (EtnGpl), the two major phospholipid classes in neural and nonneural tissues.

*Animals and collection of tissues.* RCS rats came from breeding colonies supplied by INSERM Unit 450 (Paris, France). Dystrophic rats (rdy/rdy) were black-eyed (p/+) and black-hooded. They were compared to the nondystrophic congenic strain (rdy/+). Rats were housed in an air-conditioned animal room illuminated from 7:00 AM to 7:00 PM and maintained at 21°C. They were given free access to a pelleted diet (Extralabo, Provins, France) containing 4.8% by weight of fats. As shown in Table 1, the dietary lipids contained 20:4n-6 (0.3% of total fatty acids) and 4.3% of n-3 long-chain polyunsaturated fatty acids in the form of 20:5n-3, 22:5n-3, and 22:6n-3 (from fish powders). Rats were killed by decapitation at weaning (3 wk) or at the age of 6 wk. They fasted overnight, with water *ad libitum*. Blood was collected with heparin as an anticoagulant and the plasma was lyophilized after centrifugation. Liver and brain (cerebellum was discarded) were excised, rinsed with 9 g/L NaCl, and drained. The brain and the whole liver were homogenized and lyophilized before extraction of total lipids. The eyes were removed and the anterior segment, lens, and vitreous humor were discarded. The retina was detached from the retinal pigment epithelium, and the eyecups were incubated under gentle stirring at room temperature in a calcium-free Ringer buffer containing 118 mmol/L NaCl, 4.7 mmol/L KCl, 1.17 mmol/L $KH_2PO_4$, 1.17 mmol/L $MgSO_4$, 5.6 mmol/L D-glucose, 35 mmol/L $NaHCO_3$, and 1.0 mmol/L EDTA, pH 7.4 (9). The retinas harvested from one litter (5 to 6 rats) were pooled and stored at –80°C until lipid extraction.

*Determination of fatty acid composition.* Total lipids were extracted from 150 mg of lyophilized tissue with 4 mL of chloroform/methanol (2:1, vol/vol) (10) in the presence of butylhydroxytoluene 0.005 g/100 mL. The plasma total phospholipids were separated from neutral lipids by filtration through silica cartridges (Waters, Milford, MA) (11). The plasma phospholipids, composed of 90% ChoGpl, were not further purified. The two major phospholipid classes in the different tissue samples, ChoGpl and EtnGpl, were separated by solid-phase extraction on a 500 mg prepacked aminopropyl cartridge (J.T. Baker, Deventer, The Netherlands) washed beforehand with 3 mL of hexane and equilibrated with 3 mL of eluent I (isopropanol/chloroform, 1:2, vol/vol) (adapted from Ref. 12). Each sample of total lipids was dried under nitrogen and resolubilized in 250 µL of eluent I. The sample was then applied to the cartridge by elution through the solid phase. In the cases of retina, liver, and plasma samples, the cartridge was eluted successively with 3 mL of eluent I (neutral lipid fraction), 3 mL of diethyl ether/acetic acid (98:2, vol/vol) (free fatty acid fraction), 1 mL of acetonitrile, 8 mL of acetonitrile/*n*-propanol (3:1, vol/vol) (ChoGpl fraction), 2 mL of acetonitrile/*n*-propanol (1:1, vol/vol) (sphingomyelin fraction), and 3 mL of methanol to recover the EtnGpl fraction. Owing to the high cerebral sphingomyelin content, the brain samples were eluted with 3 mL of eluent I, 3 mL of diethyl ether/acetic acid (3:1, vol/vol), 4 mL of acetone (ChoGpl fraction), 4 mL of acetonitrile/*n*-propanol (3:1, vol/vol), 4 mL of acetonitrile/*n*-propanol (1:1, vol/vol) (sphingomyelin fraction), and 3 mL of methanol (EtnGpl fraction).

Fatty acid methyl esters were produced by reacting ChoGpl for 20 min with $BF_3$, 10 g/100 mL, in methanol at 90°C (13) and EtnGpl 4 h with HCl (1:9, vol/vol), and dimethoxypropane, 4 g/100 mL, in methanol at 70°C (14). After adding 2 mL of distilled water, the methyl esters were extracted twice with 1 mL hexane, washed with distilled water, dried under nitrogen, and finally taken up in 30–50 µL isooctane for gas chromatography. An aliquot of 1 µL was injected through the on-column injector of a 9001 gas chromatograph (Chrompack, Middleburg, The Netherlands) equipped with a retention gap and a CP WAX 52 CB bonded fused-silica capillary column (0.3 mm i.d. and 50 m length). The oven temperature was programmed for 79–140–205°C at heating rates of 9°C/min and 3°C/min for the first and second stages, respectively. Peaks attributable to fatty acid methyl esters were automatically integrated and identified by comparing their equivalent chain length with standard compounds. All compositions were expressed as mol% of total fatty acids after subtraction of unidentified peaks and dimethylacetals.

*Statistical treatment.* The significance of fatty acid composition differences between 3- and 6-wk-old rats was individually evaluated within each strain using Statview SE™ (Abacus Concepts Inc., Berkeley, CA) for one-way analysis of variation followed by Fisher's test. The significance of the aging effect was tested at the levels of $P < 0.001$, $P < 0.01$, and $P < 0.05$ in both phospholipid fractions from each tissue.

The interaction of the strain (dystrophic or nondystrophic) with the fatty acid compositional changes with age (strain × age interaction) was then tested for two-way analysis of variance and Fisher's test.

## RESULTS

*Fatty acid composition in plasma phospholipids.* The age-related changes in the fatty acid composition of plasma phospholipids in RCS rats are reported in Table 2. As a whole, the dystrophic and nondystrophic rats presented the same pattern, although differences between 3 and 6 wk of age were globally less significant in the dystrophic group. In both groups, the sum of monounsaturated fatty acids increased between 3 and 6 wk of age (Table 2). The main observation was that plasma 20:4n-6 increased with age by 15% in nondystrophic rats ($P < 0.05$), whereas it did not change in the dystrophic group; the age × strain interaction was not significant. By contrast, the 22:6n-3 plasma content significantly increased with age in dystrophic rats ($P < 0.001$) but not in the nondystrophic ones; the age × strain interaction was significant ($P = 0.04$). The ratio of 22:6n-3 to 20:4n-6 tended to decrease in nondystrophic rats and to increase in dystrophic rats, with a significant interaction ($P = 0.02$). There was no other significant interaction between age and strain effects in plasma phospholipids.

*Fatty acid composition in brain phospholipids.* The developmental fatty acid changes in brain EtnGpl and ChoGpl are reported in Tables 3 and 4. At 3 wk, rats from both strains presented similar fatty acid compositions in EtnGpl (Table 3) and ChoGpl (Table 4). As observed in many other species, both strains presented higher 22:6n-3 contents in the brain EtnGpl fraction than in ChoGpl. The 22:6n-3 content accounted for around 25% of total EtnGpl fatty acids in both strains. However, the 22:6n-3 content decreased by 7% in the brain EtnGpl from the 6-wk-old dystrophic rats ($P < 0.001$), whereas it remained unchanged in the age-matched nondystrophics. The interaction of the age and strain effects was significant ($P = 0.005$, Table 3). Moreover, the 22:6n-3 to 22:5n-3 ratio slightly increased with age in the nondystrophic rats ($P < 0.01$) but not in the dystrophics ($P = 0.004$ for the age × strain interaction). The second major fatty acid in brain EtnGpl was 18:0. This fatty acid slightly decreased with age ($P < 0.01$) in the dystrophic group (Table 3), and this age-related change was strain-specific ($P = 0.007$, Table 3). At 3 wk, the 20:4n-6 content in the brain EtnGpl fractions from both strains was 1.3- to 1.4-fold lower than the content in 22:6n-3 (Table 3). The 20:4n-6 content decreased with age by around 20% in both strains ($P < 0.001$), and the 22:6n-3/20:4n-6 ratio concurrently increased. The 18:1n-9 contents in brain EtnGpl from dystrophic and nondystrophic rats, which both increased

[f]Nonessential polyunsaturated fatty acids (20:3n-9, 20:3n-7, and 22:3n-9).

with age by around 48%, had exactly the opposite age-related changes as 20:4n-6 contents (Table 3). Brain EtnGpl also contained substantial amounts of 22:4n-6, whose molar contents slightly decreased with age (significant in dystrophic rats only). In summary, the data mainly showed that the strain's origin determined the age-related changes of 22:6n-3 and 18:0, the two major fatty acids in brain EtnGpl, whereas the age-related changes in 20:4n-6, the second major polyunsaturated fatty acid, were not altered by the dystrophy.

The brain ChoGpl was much richer in saturated fatty acids than the EtnGpl fraction (Table 4). In the nondystrophic rats, the developmental effect in ChoGpl was a sharp increase of 16:0 ($P < 0.001$) accompanied by a decrease in 18:0 ($P < 0.01$) (Table 4). In this group, the variations of the 20:4n-6 and 18:1n-9 contents were the same as those observed in the EtnGpl fraction, with a 45% decrease and a 43% increase in the 20:4n-6 and 18:1n-9 contents, respectively. In addition, the 22:6n-3 content decreased with age by 37% ($P < 0.001$) in the nondystrophic brain ChoGpl (whereas it remained unchanged in the EtnGpl fraction). The developmental changes in the brain ChoGpl fatty acid composition from the dystrophic rats were very different from those in the nondystrophics. There were in fact only minor changes in the dystrophic brain ChoGpl fatty acid composition between the ages of 3 and 6 wk. The result of this was that the age × strain interaction was highly significant for the changes in 14:0, 16:0, 18:0, 18:1n-9, 18:1n-7, 18:2n-6, and 20:4n-6 (Table 4). Moreover, the age-related changes in the 22:6n-3/20:4n-6 ratio were opposite in the nondystrophic and dystrophic rats ($P = 0.002$, Table 4).

*Fatty acid composition in retina phospholipids.* At weaning, the retinal EtnGpl from dystrophic and nondystrophic rats contained between 40 and 42% of total fatty acids as 22:6n-3 (Table 5). At the age of 6 wk, the 22:6n-3 content tended to increase in nondystrophics, and to decrease in dystrophic rats, but these variations did not reach a significant level. The age × strain interaction was not significant either. At the same time, the retinal EtnGpl 20:4n-6 level decreased by 17% in nondystrophic rats ($P < 0.01$), while it remained almost unchanged in dystrophics; the age × strain interaction was significant with $P = 0.004$. In addition, the 22:5n-3 content underwent a slight but significant ($P < 0.05$) age-related decrease in the nondystrophic EtnGpl fraction; the interaction with the strain effect was significant ($P = 0.01$). The opposite variations of retinal n-3 fatty acids observed in the EtnGpl fraction from nondystrophic and dystrophic rats resulted in opposite age-related changes in the ratio of 22:6n-3 to

22:5n-3. The changes in this product-to-substrate ratio could be indicative of changes in the final steps of metabolic conversion (and EtnGpl acylation) within the n-3 family; from 3 to 6 wk of age, the 22:6n-3/22:5n-3 ratio increased by 50% ($P < 0.05$) in the nondystrophic rats, whereas it decreased by 20% ($P < 0.05$) in the dystrophics, and the age × strain interaction was significant with $P = 0.001$ (Table 5). The 22:6n-3 to 20:4n-6 ratio (Table 5) tended to increase with age in nondystrophics and to decrease in dystrophics, but none of these variations reached a significant level.

In the ChoGpl fraction, the 22:6n-3 content was two- to threefold lower than in the EtnGpl counterpart (Table 6). The ChoGpl 22:6n-3 content significantly increased with age in the nondystrophic rats (from 11.1 to 18.9%, $P < 0.05$), while it tended to decrease in the dystrophic group. As a result of these opposite changes, the age × strain interaction was significant for 22:6n-3 in the ChoGpl fraction ($P = 0.008$). Moreover, the 22:6n-3/22:5n-3 ratio increased with age (by a factor of 2.4, $P < 0.05$) in the nondystrophic group only; the age × strain interaction was slightly significant with $P = 0.025$ (Table 6). As observed in the EtnGpl fraction, the ChoGpl 20:4n-6 content decreased with age only in the nondystrophic rats, but the corresponding age × strain interaction was not significant (Table 6). Thus, the 22:6n-3 and 20:4n-6 ChoGpl contents evolved differently with age in the nondystrophic group, whereas the dystrophic rats had the same ChoGpl fatty acid composition at 3 and 6 wk, resulting in a significant age × strain interaction for the ratios of 22:6n-3 to 20:4n-6 ($P = 0.001$).

In summary, a significant age × strain interaction in the retina was essentially found for 20:4n-6 in the EtnGpl fraction and for 22:6n-3 in the ChoGpl fraction. In both phospholipid classes, the age-related increase of the 22:6n-3/22:5n-3 ratio was significantly altered by the dystrophy, while the 22:6n-3/20:4n-6 ratio increase was altered in the ChoGpl fraction only.

*Fatty acid composition in liver phospholipids.* The changes in liver EtnGpl fatty acid composition between 3 and 6 wk were almost identical in both strains (Table 7). Globally, the fatty acids with 18 carbons significantly increased (18:1n-9, 18:1n-7, and 18:2n-6) or tended to increase (18:0) in the EtnGpl fraction from both strains, while the 16:0 contents decreased. The two major long-chain polyunsaturated fatty acids in liver EtnGpl were 22:6n-3, which significantly decreased with age (by 20–26%) in both strains ($P < 0.001$),

and 20:4n-6, which slightly increased in the nondystrophic group ($P < 0.05$) and tended to increase in the dystrophic one. These variations were apparently not related to the dystrophy, inasmuch as none of the age × strain interactions reached a significant level (Table 7).

In the liver ChoGpl fraction, the fatty acid changes with age were almost the same as those observed in EtnGpl (Table 8). The main observations were that the ChoGpl 18:2n-6 content increased significantly in nondystrophic rats only ($P = 0.003$), and that 22:6n-3 decreased by a greater factor in the nondystrophic group (1.9 vs. 1.4, $P = 0.025$). Besides, minor monounsaturated fatty acids (16:1n-7 and 18:1n-7) increased with age in both strains, with a lower amplitude in the dystrophic group (Table 8). In summary, the origin of the strain had no influence on the variations with age of fatty acid composition in liver EtnGpl, while a slight but significant age × strain interaction was found for 22:6n-3 and for 18:2n-6 in the ChoGpl fraction. Changes in liver phospholipids were mainly determined by development and apparently not related to those observed in neural tissues.

## DISCUSSION

*Brain fatty acid composition.* Two major postweanling fatty acid changes occurred in the nondystrophic brain phospholipids: (i) the relative contents in 20:4n-6 decreased with age both in the ChoGpl and EtnGpl fractions, while those of 18:1n-9 increased in compensation, and (ii) the 16:0 and 18:0 contents also evolved differently in ChoGpl. Opposite changes in 20:4n-6 and 18:1n-9 contents occurred as well in the dystrophic brain EtnGpl, but not in the ChoGpl counterpart. Changes in 16:0 and 18:0 contents were also nearly abolished in the dystrophic brain ChoGpl. Thus, postweanling changes in the brain ChoGpl fatty acid composition were not preserved in dystrophic rats, especially as regards 16:0, 18:0, 18:1n-9, and 20:4n-6.

In developing organs, changes in relative contents with age are likely to arise from differential accretion rates of fatty acids, rather than from losses in their absolute amounts. The finding that the brain ChoGpl fraction from dystrophic rats had the same fatty acid composition at 3 and 6 wk, while the nondystrophics changed their composition, implies that the accretion rates of ChoGpl fatty acids occurred concurrently during the development of the dystrophic brain, whereas they occurred differentially in the nondystrophic. It was recently shown that 22:6n-3 is deposited in the rat fetal brain at a high rate within embryonic days 14 to 17, specifically in the phosphatidylserine and EtnGpl fractions (15), prior to the formation of synapses from growth cones (16). After birth, the accretion of saturated and monounsaturated fatty acids (mainly, 16:0, 18:0, and 18:1n-9) occurs at a low rate, while that of 20:4n-6 and 22:6n-3 remained unchanged up to postnatal day

16 (15). The opposite changes in the relative contents of 20:4n-6 and 18:1n-9 observed in both classes of brain phospholipids from nondystrophic rats could signify that accretion rate of 20:4n-6 in the brain decreased during the 3-wk postweaning period, whereas that of 18:1n-9 increased. Differential deposition rates of 20:4n-6 and 18:1n-9 in brain should be affected by the dystrophy in the ChoGpl fraction only. The low level of 16:0 in EtnGpl at 3 wk (around 8% of total fatty acids) and its high level in ChoGpl (around 32%) suggest that fetal and postnatal deposition of 16:0 in brain phospholipids occurred preferentially in ChoGpl, whereas 18:0 was almost equally distributed in EtnGpl and ChoGpl (22% of total fatty acids in each class being 18:0). Other reports indicate that incorporation of 18:0 in neonatal rat brain phospholipids preferentially occurs in the phosphatidylserine and phosphatidylinositol fractions (17). After weaning, 16:0 continued to accumulate preferentially in ChoGpl, mainly to the detriment of 18:0, whose relative content decreased while that of 16:0 increased. The absence of age-related changes in the 16:0 and 18:0 relative contents in the brain ChoGpl from dystrophic rats may imply that, in this group, both fatty acids were concurrently deposited between 3 and 6 wk of age.

Thus, postweaning changes in fatty acid composition were nearly abolished in the dystrophic brain ChoGpl, while the EtnGpl fraction was much less affected (with a very slight incidence of dystrophy on the 18:0 and 22:6n-3 contents only). Assessment of the impact of these biochemical alterations may be attempted by comparing the brain fatty acid compositions of RCS rats with those from other strains. The fatty acid composition in the brain ChoGpl from 6-wk-old nondystrophic rats was actually very close to that reported for Sprague-Dawley rats of the same age (18) and for Long-Evans rats aged 9 wk (19). In particular, the 16:0 and 18:0 relative contents in the brain ChoGpl fractions were approximately 40–45% and 13–14%, respectively by weight of total fatty acids in nondystrophic RCS, Sprague-Dawley (18), and Long-Evans (19) rats. As presented above, the dystrophic rats of the same age did not match this composition. Therefore, the fatty acid composition in the brain ChoGpl of dystrophic rats appeared to be specifically altered in comparison to normal rats from other strains. In the EtnGpl fraction, the differences in saturated fatty acid contents between dystrophic rats and rats from other strains were of much lower amplitude. Differences in the 20:4n-6 and 22:6n-3 EtnGpl contents exist between both strains of RCS rats (dystrophic and nondystrophic) and rats from other strains that could be attributed to the prevalent influence of the respective rearing diets in composing the brain EtnGpl. Taking into account the fact that

ChoGpl is the major phospholipid class in the brain, it may be supposed that suppression of compositional changes in ChoGpl has an influence on the behavioral development of dystrophic rats. However, the dystrophy-associated alterations in the brain fatty acid composition were not similar to those resulting from dietary deficiencies or imbalances in polyunsaturated fatty acids that are well known to alter the cognitive performance and behavioral development in rodents (20–22). The content in brain ChoGpl 22:6n-3 was not specifically altered by the dystrophy, and it seems unlikely that the 7% decrease in EtnGpl 22:6n-3 that we observed at the age of 6 wk in the dystrophic brains is sufficient *per se* to generate behavioral alterations. However, it should be noted that Christensen *et al.* (23) found that feeding neonatal Wistar rats a structured marine oil–enriched diet induced the brain EtnGpl 22:6n-3 content to increase from 24 to 27% (by weight of total fatty acids) and concomitantly augmented the auditory brainstem response of the adults, the latter event possibly causally related to the former. In their study, learning ability was not modified by the dietary treatment.

*Retina fatty acid composition.* During postnatal development, the normal photoreceptor cells shift their fatty acid composition to more unsaturated species. The photoreceptors rapidly and selectively accumulate 22:6n-3 in nascent outer segments, resulting in much higher 22:6n-3 contents in adult cells than in immature ones (24). High levels of 22:6n-3 are supposed to favor membrane functional dynamics in the renewing photoreceptor disk membranes. The di-22:6n-3 molecular species of ChoGpl normally present in the mammalian retina (25) have been postulated to associate specifically with the seven α-helical segments of rhodopsin and to play an important role in modulating membrane dynamics involved in the rhodopsin-mediated phototransduction process (26,27). In addition, membrane 22:6n-3 can also serve as a precursor for the biologically active docosanoids required in maturing cells (28). It was shown that 22:6n-3 incorporation in retinal phospholipids is lowered in rodent and canine models of inherited retinal degeneration. Photoreceptor cells from the 10-d-old mutant *rd* mouse contained only about two-thirds of the level of 22:6n-3 observed in normal cells (24). In the progressive rod-cone degeneration (prcd) miniature poodle, the ROS 22:6n-3 level was reduced by 20% in prcd-affected dogs as compared to the nonaffected ones (29), although the affected retina retained its ability to synthesize 22:6n-3 from its upstream precursor (30). In dystrophic RCS rats aged 3–5 wk, Boesze-Battaglia *et al.* (6) showed that the distribution of

cholesterol between disk and ROS plasma membranes was detrimental to the ROS membranes. The phospholipid class distribution in the dystrophic disk membranes also differed from that of nondystrophics (6). In addition, anomalous phospholipid class distribution before weaning (7) and fatty acid composition after weaning (8) were reported in dystrophic RPE cells. In particular, the RPE cell plasma membranes of dystrophic rats aged 4–5 wk have 2.2-fold higher and 1.4-fold lower contents of 22:6n-3 and 20:4n-6, respectively, than those from nondystrophic rats aged 5–6 wk (8). In a previous study, Organisciak and Noell (31) compared the fatty acid composition in the EtnGpl and ChoGpl fractions of the ROS debris from adult dystrophic RCS rats with that of normal ROS from Sprague -Dawley rats (with an average age of 3 mon). Their data are summarized in Table 9, where it can be seen that the ChoGpl fatty acid composition in ROS debris was globally more altered at 3 mon than its EtnGpl counterpart. As compared to the normal ROS ChoGpl composition at 3 mon, the contents of 16:0, 18:1n-9, and 20:4n-6 increased in the dystrophic ROS ChoGpl, while those of 18:0 and 22:6n-3 decreased. In the present study we confirm that dystrophic retina fatty acid composition was altered more in the ChoGpl fraction than in EtnGpl, and we show that divergence from normal composition occurred precociously. In fact, the dystrophic retina fatty acid composition that we observed at the age of 3 wk was almost identical to that previously reported (31) for the ROS debris in dystrophic adult rats (Table 9). At 3 wk and 3 mon of age, the main fatty acid contents in dystrophic retina ChoGpl were equal to 37.3 and 38.1% 16:0, 12.7 and 15.9% 18:0, 14.1 and 14.7% 18:1n-9, 2.1 and 1.3% 18:2n-6, 8.1 and 7.3% 20:4n-6, and 15.2 and 17.1% 22:6n-3, respectively (data expressed in mol% of total fatty acids). The very similar ChoGpl fatty acid composition in dystrophic retina at 3 wk and in ROS debris at 3 mon suggests that the ChoGpl fatty acid composition in ROS debris did not differentiate from that of the whole dystrophic retina, whatever the age considered. From the data reported in Table 9, it can be estimated that the ChoGpl 22:6n-3 content increased by only 13% between 3 wk and 3 mon of age in dystrophic rats, whereas it increased by 224% in nondystrophic rats, possibly reflecting the normal accretion of 22:6n-3 in ROS ChoGpl during development. It cannot be excluded that different dietary conditions used in two distinct studies may explain the difference in 22:6n-3 contents observed in nondy-

strophic retinas at 3 wk and 3 mon. However, it is a fact that lower ChoGpl 22:6n-3 contents were related to the dystrophy, and the analysis was precociously performed either on the whole retina (Table 6) or on ROS debris at 3 mon (Table 9). In the EtnGpl fraction, the 22:6n-3 content was also identical in the ROS debris at 3 mon and in the dystrophic retina at 3 wk, i.e., 41.1 vs. 41.8% (Table 9), while, as noted for the ChoGpl fraction, the EtnGpl 22:6n-3 content was higher in 3-mon normal ROS than in 3-wk nondystrophic RCS retina (48 vs. 40.9%). However, the other fatty acids in EtnGpl changed with age in dystrophic as well as in normal rats, suggesting that 22:6n-3 was specifically affected in dystrophic EtnGpl, while most of the fatty acids (including 22:6n-3) were affected in the ChoGpl fraction. In simple terms, the fatty acid composition became globally and precociously fixed in dystrophic ChoGpl, while developmental changes continued to occur in the dystrophic EtnGpl, with the noticeable exception of 22:6n-3. These observations have to be compared to the previous finding of Boesze-Battaglia *et al.* (6) that the ROS disk membranes from 3 to 5-wk-old RCS dystrophic rats contained around 1.3-fold more ChoGpl than those from nondystrophics, while the EtnGpl contents were not statistically different (6). Together, the data imply that phospholipid metabolism in the retina of young dystrophic rats is affected in a class-specific manner. In retina as well as in brain and liver, the ChoGpl fraction appeared more deeply affected than the EtnGpl counterpart.

It is noteworthy that the 20:4n-6 contents significantly decreased with age in both the EtnGpl and ChoGpl fractions from nondystrophic rats, in apparent compensation for the concomitant increase in 22:6n-3. Opposite changes in the 20:4n-6 and 22:6n-3 contents were recently shown to occur in ROS phospholipids during postnatal development of albino Sprague-Dawley rats (32). The data of Suh *et al.* (32) indicate that the 22:6n-3/20:4n-6 ratio in the ChoGpl and EtnGpl fractions from ROS phospholipids increases by around approximately twofold between 3 and 6 wk of age (32). Moreover, the 22:6n-3/20:4n-6 ratio increased with age even though the rearing diet contained 1% of fat as 20:4n-6 (32). The authors suggested that a critical balance between n-3 and n-6 long-chain polyunsaturated fatty acids could be necessary throughout the weanling period for photoreceptor cells to achieve proper fatty acid composition and concomitantly to develop optimal rhodopsin content (32). It should be noted that, in neonatal RCS dystrophic rats reared under ordinary conditions of cyclic illumination, the eye rhodopsin content increases up to 4 wk of age and thereafter sharply decreases (1). Our data indicate that the 22:6n-3/20:4n-6 ratio significantly increased between 3 and 6 wk of age in the nondystrophic retinal ChoGpl and suggest that the dystrophy abolished this change. The comparative data reported in Table 9 also show evidence that the age-related increase of the 22:6n-3/20:4n-6 ratio (3 mon vs. 3 wk) was dramatically reduced in the dystrophic retina glycerophospholipids. Moreover, we found a significant age × strain interaction for the 22:6n-3/20:4n-6 ratio in both classes of brain phospholipids. It is possible that alterations in the retinal balance of n-3 and n-6 fatty acids could be related to the dystrophy-induced alterations in the rhodopsin content. Furthermore, the 22:6n-3/22:5n-3 ratio significantly increased with age in both phospholipid classes of nondystrophic retina, and the dystrophy clearly suppressed this change. Considering that alterations in this product-to-substrate ratio may be indicative of alterations in the terminal steps of n-3 synthesis (33), it could be suggested that dystrophic retina failed to synthesize proper amounts of 22:6n-3. However, lowered phospholipid 22:6n-3 contents may also arise from specific alteration in its uptake, trafficking, acylation, recycling, or turnover, and further experiments are needed to evaluate the impact of dystrophy on these pathways. In addition, alterations of lipid compositions observed in dystrophic RPE and ROS could be associated with the defect in phagocytic and recycling functions (7,8), possibly through damaging lipid peroxidation or anomalous membrane receptor interactions between the RPE and photoreceptor cells (35,36). The recent finding that a receptor tyrosine kinase (*Mertk*) plays an essential role in the signaling of phagocytosis in RCS rats suggests a molecular model in which a Mer-family receptor-binding protein (*Gas6*) mediates the interactions between RPE plasma membranes and phosphatidylserine molecules exposed at the outer leaflet of the shedding disks (3). It is not explained how the dystrophic mutation is involved in alterations of lipid metabolism. Anderson *et al.* (36) assumed that the primary defect ultimately leads to structural and biochemical adaptive changes in photoreceptor cells, possibly in response to the increasing risk of oxidative stress (36). The occurrence of some form of communication between the retina and other tissues is postulated.

Our data show that changes in the phospholipid fatty acid composition of brain and retina of RCS rats were precociously altered in the developmental process. Age-related changes in plasma and liver phospholipids were apparently not linked to those occurring in neural tissues. Our finding that the EtnGpl and ChoGpl compositions were differently affected suggests that the fatty acid uptake by neural tissues and/or fatty acid-acylation activities could be impaired in a phospholipid class-specific manner. Tissue-specific alterations in phospholipid synthesis and fatty acid metabolism could be one of the defects precociously associated to the retinal dystrophy.

## ACKNOWLEDGMENTS

Bénédicte Goustard-Langelier was supported by a postdoctoral fellowship from the Fédération des Aveugles et Handicapes Visuels de France, which is gratefully acknowledged. We especially thank Dr. Yves Courtois (Inserm U450, Paris) for supporting our work and for generously providing the RCS rats. We also thank Jacqueline Thévenoux and Alain Linard for technical assistance in lipid analysis, and Christine Young for correcting the English manuscript.

# Biosynthesis and Tissue Deposition of Docosahexaenoic Acid (22:6n-3) in Rainbow Trout *(Oncorhynchus mykiss)*

**M.V. Bell[a,*], J. R. Dick[a], and A.E.A. Porter[b]**

[a]Institute of Aquaculture and [b]Department of Biological Sciences, University of Stirling, Stirling FK9 4LA, Scotland, United Kingdom

**ABSTRACT:** Rainbow trout *(Oncorhynchus mykiss)* weighing *ca.* 5 g and previously acclimated for 8 wk on a diet comprising vegetable oil (11%), fish meal (5%), and casein (48%) as the major constituents were fed a pulse of diet containing deuterated ($D_5$) (17,17,18,18,18)-18:3n-3 ethyl ester. The synthesis and tissue distribution of $D_5$-22:6n-3 was determined 3, 7, 14, 24, and 35 d after the pulse. The whole-body accumulation of $D_5$-22:6n-3 was linear over the first 7 d, corresponding to a rate of 0.54 ± 0.12 μg $D_5$-22:6n-3/g fish/mg $D_5$-18:3n-3 eaten/d. Maximal accretion of $D_5$-22:6n-3 was 4.3 ± 1.2 μg/g fish/mg of $D_5$-18:3n-3 eaten after 14 d. The amount of $D_5$-22:6n-3 peaked in liver at day 7, in brain and eyes at day 24, and plateaued after day 14 in visceral and eye socket adipose tissue and in the whole fish. The majority of $D_5$-22:6n-3 was found in the carcass (remaining tissues minus the above tissues analyzed separately) at all times. On a per milligram lipid basis, liver and eyes had the highest concentration of $D_5$-22:6n-3. The experimental diet also contained 21:4n-6 ethyl ester as a marker to estimate the amount of food eaten by individual fish. From such estimates it was calculated that the great majority of the $D_5$-tracer was catabolized, with the combined recovery of $D_5$-18:3n-3 plus $D_5$-22:6n-3 being 2.6%. The recovery of 21:4n-6 was 57.6%. The concentration of 22:6n-3 in the fish decreased during the 13-wk period, and the amount of 22:6n-3 synthesized from 18:3n-3 was only about 5% of that obtained directly from the fish meal in the diet.

Paper no. L8823 in *Lipids 36,* 1153–1159 (October 2001).

Docosahexaenoic acid (22:6n-3) is the functional end product of the n-3 series of polyunsaturated fatty acids (PUFA) and has a crucial role in membrane structure and function, being concentrated in excitable membranes, e.g., synapses, retina, sarcoplasmic reticulum (1–3). It is also abundant in sperm (4) where 22:6n-3-rich phospholipids may be crucial to the fusion process during fertilization (5). Docosahexaenoic acid is therefore a critical fatty acid in vertebrates and, in those species that are unable to synthesize 22:6n-3 from its precursor linolenic acid (18:3n-3), it must be supplied in the diet (6), i.e., it is a dietary essential fatty acid.

The extent to which different species can synthesize 22:6n-3 from 18:3n-3 or are reliant on a direct dietary input has been the subject of much debate and study (3,7). It is now recognized that there is a large demand for 22:6n-3 during early development when neural tissue (brain and retina) is being formed and that, in some species that convert 18:3n-3 to 22:6n-3, the rate of conversion may be insufficient to meet demand at this crucial time (7). This has led to the recommendation that infant formula feeds should be supplemented with 22:6n-3 (8).

Marine fish that are obligate carnivores (e.g., gadoids, clupeoids) have an absolute requirement for 22:6n-3 in the diet (9) and normally receive an excess from their prey. Freshwater fish, including salmonids, are able to form 22:6n-3 from 18:3n-3 and are therefore not thought to have such a requirement (10). The pathway whereby 18:3n-3 is converted to 22:6n-3 in fish is inducible and is repressed in the presence of dietary fish oil containing 20:5n-3 and 22:6n-3 (11). However, in spite of the importance of 22:6n-3, there is little quantitative information available on the rate of its formation from 18:3n-3 in vertebrates. *In vitro* assays using hepatocytes and $^{14}$C-labeled fatty acids cannot reliably be extrapolated to living animals because such assays commonly generate major amounts of intermediates in the pathway and minor amounts of end product.

This study measured the rate of formation of 22:6n-3 from 18:3n-3 in rainbow trout *in vivo* using a deuterated tracer and quantitation by gas chromatography–mass spectrometry (GC–MS) as described by Pawlosky *et al.* (12). The tissue deposition of newly formed 22:6n-3 was also determined over a 5-wk period.

## MATERIALS AND METHODS

*Chemicals.* Chloroform, methanol, ethanol, isohexane, and diethyl ether were high-performance liquid chromatography grade from Fisher (Loughborough, Leicestershire, United Kingdom). Diisopropylamine, anhydrous acetonitrile, and pentafluorobenzyl bromide were obtained from Aldrich (Gillingham, Dorset, United Kingdom). $D_5$ (17,17,18,18,18)-linolenic acid was purchased from Cambridge Isotope Laboratories (Andover, MA) as the fatty acid ethyl ester (FAEE). Linseed oil was from ICN (Basingstoke, Hampshire, United Kingdom) and refined olive oil was from Tesco supermarkets. High oleic acid sunflower oil was a gift from Croda Chemicals (Goole, United Kingdom). Fish meal was from Biomar (Grangemouth, United Kingdom). All other chemicals were from Sigma (Poole, Dorset, United Kingdom).

*Synthesis of 21:4n-6.* Heneicosatetraenoic acid (Δ6,9,12,15-

Abbreviations: ANOVA, analysis of variance; $D_n$, deuterated; FAEE, fatty acid ethyl ester; FAME, fatty acid methyl ester; GC–MS, gas chromatography–mass spectrometry; PUFA, polyunsaturated fatty acid; tri23:0, tritricosanoyl glycerol.

21:4) ethyl ester was prepared by a one-carbon addition to 20:4n-6 fatty acid (13). The product was obtained in 51.2% yield and was 98.9% pure by GC and GC–MS of the fatty acid methyl ester (FAME) and pentafluorobenzyl ester (see following).

*Fish and diets.* Rainbow trout, approximately 2 g size, were obtained from a commercial hatchery and kept in a running freshwater aquarium at 6.5 to 12.5°C on a 14 h/10 h light/dark cycle. Fish were fed a diet based on casein and a blend of vegetable oil containing predominantly oleic acid with 18:2n-6 and 18:3n-3 at approximately 1% each to maximize 22:6n-3 synthesis and satisfy the essential fatty acid requirements. The final diet provided 50% crude protein and 11% oil blended to give 0.99% 18:2n-6, 1.02% 18:3n-3, and 0.12% highly unsaturated fatty acids (20:5n-3 and 22:6n-3) from the fish meal that was added to make the diet palatable and readily accepted by the fish. The remaining fatty acids were predominantly 16:0 (1.02%) and 18:1n-9 (7.18%). The full composition of the diet was (g/kg): vitamin-free casein 480, starch 150, fish meal 50, mineral mix 47, vitamin mix 10, arginine 4, methionine 3, cystine 2, leucine 4, orange G 1, chromic oxide 10, α-cellulose 129.6, blended vegetable oil 110, antioxidant mix 0.4. The composition of the mineral mix, vitamin mix, and antioxidant mix were described previously (14). The fish were fed this diet for 8 wk before starting the experiments.

*Preparation of labeled diet.* A small portion of diet containing $D_5$-18:3n-3 FAEE and 21:4n-6 FAEE was prepared as follows. An oil sample containing 10 mg $D_5$-18:3n-3 FAEE, 2.5 mg 21:4n-6 FAEE, 153 mg of high oleic acid sunflower oil, and 61 µg antioxidant was dissolved in 0.82 mL isohexane, and 1.335 g of dry diet mix was added. The isohexane was then removed at 37°C under nitrogen and the diet desiccated *in vacuo* for 18 h. The diet was mixed thoroughly, 0.95 mL water was added, and was mixed to a stiff paste. This was extruded through a 1-mL disposable syringe, dried at room temperature for 2–3 h and cut into 3–4 mm lengths. The diet was stored under argon at –20°C and was used within 3 d.

*Experimental protocol.* Twenty-six fish were acclimated in a 100-L circular tank with running water for 4 d then starved for 24 h. They were then fed the labeled diet, all of which appeared to be eaten. The fish were then fed a known amount of diet twice a day and sampled at days 3, 7, 14, 24, and 35. The temperature rose from 10.5 to 12.5°C over the 5 wk of the experiment. Two fish died on day 27 and were frozen at –20°C.

Fish were anesthetized with ethyl 3-aminobenzoate methane sulfonate and bled from the tail vein into a weighed vial containing heparinized saline (100 U/mL of 0.9% NaCl). The fish were weighed and the following tissues removed: liver, brain, eyes, visceral adipose tissue, and eye socket adipose tissue. The remaining carcass was chopped up. Samples were homogenized in chloroform/methanol 2:1 (vol/vol) using a Potter or Ultra-Turrax homogenizer and an extract according to Folch *et al.* (15) was prepared. Tritricosanoyl glycerol (tri23:0) standard was added to each tissue sample before homogenization. The amount of tri23:0 standard added varied with the weight of the fish and the lipid content of the respective tissues, e.g., for day 7: liver 2.0 µg tri23:0, brain 1.0 µg, eyes 1.0 µg, blood 0.5 µg, carcass 100 µg, eye socket fat 5 µg, visceral fat 20 µg. Samples were kept on ice under nitrogen during workup and were stored at –20°C under argon.

*Quantitation of fatty acids.* One milligram of total lipid was saponified with 2 mL of 0.1 M KOH in 95% (vol/vol) ethanol under nitrogen for 1 h at 78°C. Nonsaponifiable material was removed by extracting with isohexane/diethyl ether (2:1, vol/vol), the aqueous phase was acidified, then free fatty acids were extracted with diethyl ether. Pentafluorobenzyl esters were then prepared from 100 µg free fatty acid using acetonitrile/diisopropylamine/pentafluorobenzyl bromide (1000:10:1, by vol) at 60°C for 30 min under nitrogen as described by Pawlosky *et al.* (12). Excess reagent and solvent were then removed under nitrogen, and samples were dissolved in isohexane and stored at –20°C under argon until analysis.

Calibration standards of individual fatty acids (18:3n-3, 21:4n-6, and 22:6n-3) with 23:0 were prepared by varying the amount of unknown fatty acid while keeping the 23:0 constant and plotting the peak area ratio against the mass ratio of the different fatty acids. Sample volumes for analysis were adjusted such that the amount of 23:0 injected onto the GC–MS was constant. Pentafluorobenzyl esters were chromatographed and quantitated on a Fisons MD 800 GC–MS fitted with an on-column injector and a Chrompack CP wax 52CB column (30 m × 0.32 mm i.d., 0.25 µm film thickness; Burke Analytical, Alva, Clackmannanshire, United Kingdom) using helium as carrier gas (column head pressure 7 psi) and running in negative chemical ionization mode with methane as reagent gas (pressure 7 psi). The temperature program was 80–190°C at 40°C/min, 190–240°C at 1.5°C/min, then 240°C for 10 min. Fatty acids were identified by selective ion scanning for the required masses using a dwell time of 80 ms and cycle time of 20 ms and were quantitated by reference to the appropriate fatty acid calibration curve.

*Fatty acid analysis.* FAME were prepared by acid-catalyzed transesterification using 1% (vol/vol) $H_2SO_4$ in methanol at 50°C for 16 h under nitrogen in the presence of 17:0 free fatty acid standard. FAME were chromatographed on a Fisons GC 8000 gas chromatograph fitted with an on-column injector and a fused-silica capillary column (CP wax 52CB, 30 m × 0.32 mm i.d., 0.25 µm film thickness, Chrompack) using hydrogen as carrier gas (16).

*Analysis of results.* Mean values at different times were compared using one-way analysis of variance (ANOVA) with Tukey's Multiple Comparison Test (Prism statistical package, GraphPad Software Inc., San Diego, CA).

## RESULTS

Twenty-six fish were fed the labeled diet; of those, two died during the experiment while three others were found to have eaten less than 1% of the tracer and were not analyzed further. The size of the fish varied between 3.2 and 15.6 g by the end of the experiment with group means of 5.6 ± 1.0 g at day 3, 6.6 ± 2.1 g at day 7, 7.3 ± 1.9 g at day 14, 7.9 ± 2.4 g at day 24, and 10.4 ± 4.4 g at day 35. A representative range of sizes was

selected at each sample time. Over the whole time course the recovery of deuterated fatty acids as $D_5$-18:3n-3 was 1.2% and as $D_5$-22:6n-3 was 1.4%. The recovery of 21:4n-6 was 57.6%.

The accretion of newly synthesized $D_5$-22:6n-3 with time in the different tissues is shown in Figure 1, where the units are μg $D_5$-22:6n-3/g fish/mg $D_5$-18:3n-3 eaten. Following the pulse of $D_5$-18:3n-3, the rate of accumulation of $D_5$-22:6n-3 was 0.54 ± 0.12 μg/g fish/mg $D_5$-18:3n-3 eaten/d over the first 7 d. Accretion peaked at day 14 in the whole fish (4.3 ± 1.2 μg $D_5$-22:6n-3/g fish/mg $D_5$-18:3n-3 eaten) then plateaued and possibly declined by day 35 (Fig. 1A). Carcass, defined here as the remainder of the fish following removal of the tissues analyzed separately, showed an identical pattern (not shown). The liver accumulated $D_5$-22:6n-3 to a level of 0.5 μg $D_5$-22:6n-3/g fish/mg $D_5$-18:3n-3 eaten by day 7, followed by a sharp decline over the next 4 wk (Fig. 1B). The accumulation of $D_5$-22:6n-3 in both brain and eyes was slow, peaking around day 24 at 0.1 and 0.4 μg $D_5$-22:6n-3/g fish/mg $D_5$-18:3n-3 eaten, respectively (Figs. 1C,1D). The values in adipose tissue plateaued by day 14 at 0.25–0.30 μg $D_5$-22:6n-3/g fish/mg $D_5$-18:3n-3 eaten for visceral adipose tissue (Fig. 1E) and around 0.12 μg $D_5$-22:6n-3/g fish/mg $D_5$-18:3n-3 eaten for eye socket adipose tissue (Fig. 1F).

The deposition of the substrate $D_5$-18:3n-3 showed a very different pattern over time (Fig. 2). Amounts in the whole fish (Fig. 2A), brain (Fig. 2C), eyes (Fig. 2D), visceral adipose tissue (Fig. 2E), and eye socket adipose tissue (Fig. 2F) remained essentially constant throughout the period. Liver showed a sharp decrease from day 3 (0.018 μg $D_5$-18:3n-3/g fish/mg $D_5$-18:3n-3 eaten) onward (Fig. 2B). The amount of $D_5$-18:3n-3 was very low in brain at all times, and in liver from day 14 onward.

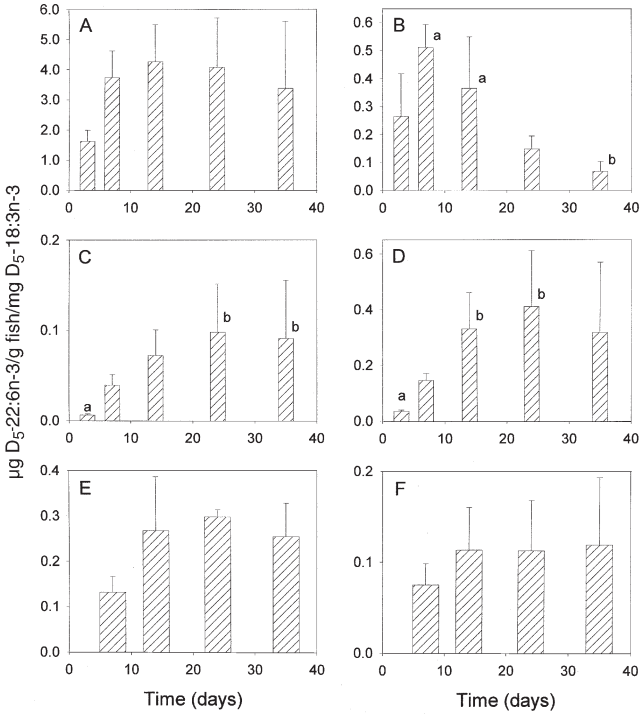

**FIG. 1.** The amount of deuterated $D_5$-22:6n-3 in different tissues with time. Data are expressed as mean ± SD. A = whole fish, B = liver, C = brain, D = eyes, E = visceral adipose tissue, F = eye socket adipose tissue. Note the different scales for different tissues. $n$ = 5 for day 3, 4 for day 7, 5 for day 14, 3 for day 24 and 4 for day 35. One-way analysis of variance (ANOVA) gave differences in mean values of $P$ = 0.0012 for liver, $P$ = 0.0114 for brain, and $P$ = 0.0109 for eyes. Values with different superscripts are significantly different at $P < 0.05$.

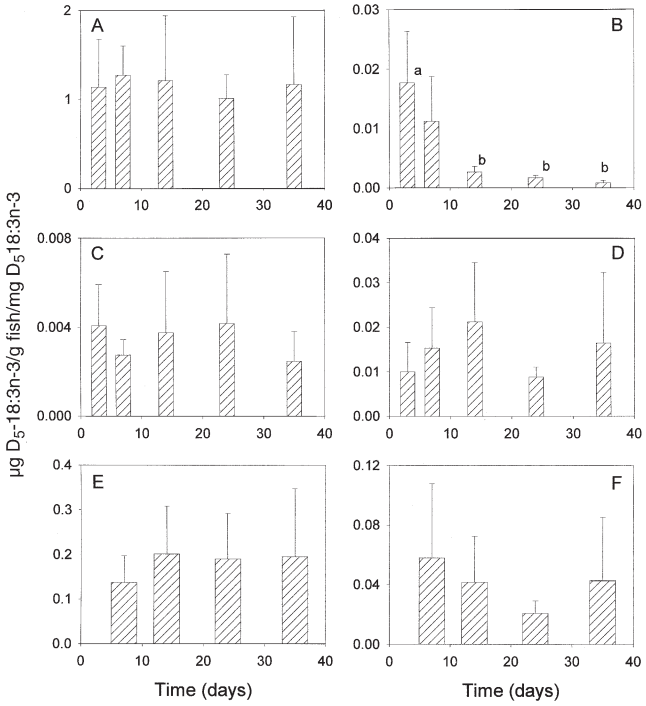

**FIG. 2.** The amount of $D_5$-18:3n-3 in different tissues with time. Data are expressed as mean ± SD. Other details are as Figure 1. One-way ANOVA gave a difference in mean values for liver of $P$ = 0.0009. Values with different superscripts are significantly different at $P < 0.01$. For abbreviations see Figure 1.

When the data are expressed on a per lipid weight basis in the respective tissues, a different pattern emerges (Table 1). The highest concentration of $D_5$-22:6n-3 was found in liver, up to 1.1 μg $D_5$-22:6n-3/mg lipid/mg $D_5$-18:3n-3 eaten at day 7, followed by the eyes, 0.94 μg $D_5$-22:6n-3/mg lipid/mg $D_5$-18:3n-3 eaten at day 24, and the blood, 0.52 μg $D_5$-22:6n-3/mg lipid/mg $D_5$-18:3n-3 eaten at day 14. Brain reached 0.21 μg $D_5$-22:6n-3/mg lipid/mg $D_5$-18:3n-3 eaten after 24 d, whereas both adipose tissues, carcass, and the whole fish contained low concentrations of $D_5$-22:6n-3 on a per milligram lipid basis. The fish grew over the experimental period so that lipid deposition at the later time points diluted the tracer. For $D_5$-18:3n-3 the highest concentrations were in the liver and blood at day 3, 0.038 and 0.051 μg $D_5$-18:3n-3/mg lipid/mg $D_5$-18:3n-3 eaten, respectively, with sharp falls thereafter (Table 2). The levels in the other tissues were similar (about 0.02 to 0.03 μg $D_5$-18:3n-3/mg lipid/mg $D_5$-18:3n-3 eaten) (Table 2), apart from brain where the concentration remained between 0.006 and 0.009 μg $D_5$-18:3n-3/mg lipid/mg $D_5$-18:3n-3 (Table 2).

The majority of the $D_5$-22:6n-3 was found in the carcass at all time points (71–79%) (Fig. 3). Liver was the next most enriched site containing 16.9% at day 3, falling to 2.1% by day

**TABLE 1**

[a]Values are means ± SD. Abbreviations and number of samples as in Table 1. One-way ANOVA gave differences in mean values of $P = 0.0008$ for liver and $P < 0.0001$ for blood. Within columns, values with different superscript roman letters are different at $P < 0.01$.

35. The eyes contained up to 9.7% of the $D_5$-22:6n-3 (day 24). Visceral adipose tissue showed an increase from 3.7% at day 7 to 9.6% at day 35, while eye socket adipose tissue contained 2.2 to 3.6% of the $D_5$-22:6n-3. Accretion into brain was very slow, with 2.6% of total body $D_5$-22:6n-3 by day 35 (Fig. 3). The great majority of the residual $D_5$-18:3n-3 was in the carcass, decreasing from 82.0% at day 7 to 75.2% by day 35 and, in the visceral adipose tissue, increasing from 11.2% at day 7 to 19.7% at day 35 (Fig. 4). Eye socket adipose tissue contained 2.1–4.6% of $D_5$-18:3n-3 with lesser amounts in the eyes, brain, and liver. The tissue distribution of 21:4n-6 was very similar to that of $D_5$-18:3n-3, largely being in the two tissues containing the bulk of body lipid, i.e., the carcass (*ca.* 85%) and visceral adipose tissue (6.4–12.7%). Liver contained up to 4.9% 21:4n-6 at day 7, falling to 0.5% by day 35. Brain, eyes, and eye socket adipose tissue contained under 2% each.

As expected, the ratios of end product fatty acid to substrate fatty acid varied widely in the different tissues. In the liver the ratio of $D_5$-22:6n-3 to $D_5$-18:3n-3 was 8.6 at day 3, increasing to 86 at day 14, then falling back to 55 by day 35.

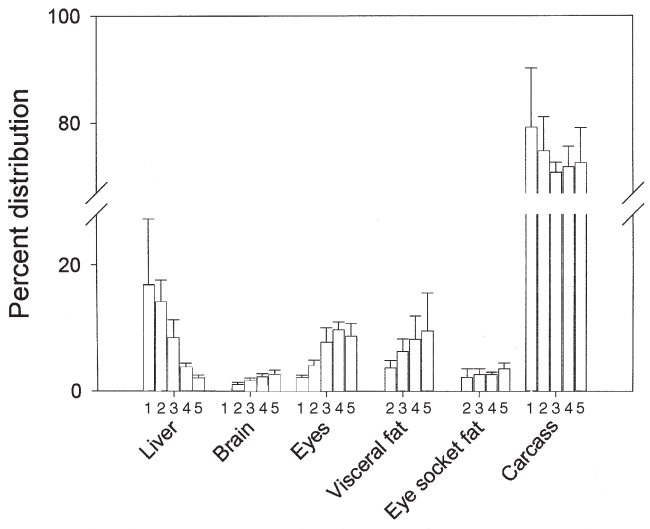

**FIG. 3.** The changes in tissue distribution of $D_5$-22:6n-3 with time. Means ± SD of the number of fish given are in Figure 1. Number key: 1, day 3; 2, day 7; 3, day 14; 4, day 24; 5, day 35. For abbreviation see Figure 1.

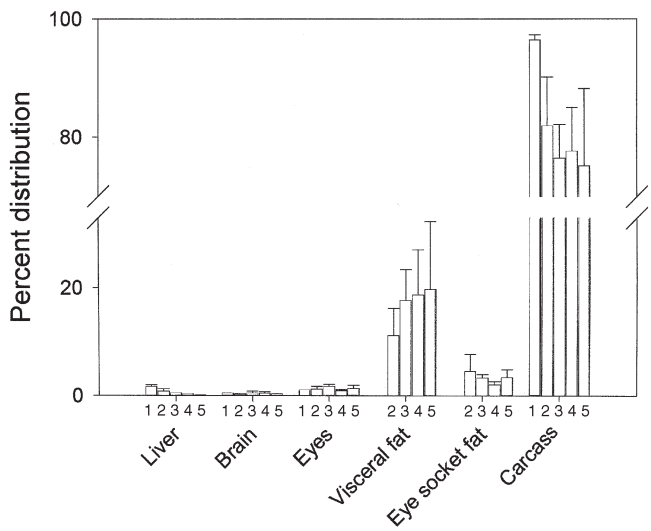

**FIG. 4.** The changes in tissue distribution of $D_5$-18:3n-3 with time. Means ± SD of the number of fish are given in Figure 1. Other details are in Figure 3. For abbreviation see Figure 1.

**TABLE 3**
**Change in the Content[a] of 22:6n-3 with Time in Fish on the Experimental Diet**

| Time on diet (d) | Time post tracer (d) | Number of fish | Weight of fish (g) | 22:6n-3 content (mg) | mg 22:6n-3/g fish |
|---|---|---|---|---|---|
| 0 | — | 5 | 3.04 ± 0.67 | 22.6 ± 7.7 | 7.3 ± 1.1 |
| 62 | 3 | 5 | 5.57 ± 1.03 | 28.3 ± 5.6 | 5.1 ± 0.6 |
| 66 | 7 | 5 | 6.65 ± 2.10 | 24.9 ± 9.1 | 3.8 ± 0.6 |
| 73 | 14 | 5 | 7.33 ± 1.90 | 23.2 ± 5.0 | 3.2 ± 0.4 |
| 83 | 24 | 5 | 7.92 ± 2.43 | 27.7 ± 7.9 | 3.6 ± 1.0 |
| 94 | 35 | 4 | 10.41 ± 4.40 | 30.5 ± 8.9 | 3.1 ± 0.6 |

[a]Values are mean ± 1 SD.

In blood the ratio was 1.9 at day 3, rising to 43 by day 14, then plateauing. Brain and eye showed a preferential accumulation of $D_5$-22:6n-3 with the ratio of $D_5$-22:6n-3 to $D_5$-18:3n-3 increasing to 18.6 by day 35 in brain, and to 44.8 by day 24 in the eyes. The ratio in the visceral adipose tissue and carcass showed little change, remaining between 1 and 2 from day 7 onward. Eye socket adipose tissue showed a slight preferential accumulation of $D_5$-22:6n-3 with a ratio between 3.9 and 5.4 from day 14 onward.

The content of 22:6n-3 in the fish was determined before the fish were fed the experimental diet and for each time point of the tracer experiment (Table 3). The amount of 22:6n-3 rose from 22.6 to 30.5 mg per fish, but the concentration of 22:6n-3 decreased with time (Table 3), giving a regression line with a slope of –0.04747 and a correlation coefficient of 0.870, i.e., the amount of 22:6n-3 decreased at a rate of 0.0475 mg/g fish/d.

## DISCUSSION

Most freshwater fish can desaturate and elongate 18:2n-6 and 18:3n-3 to their $C_{20}$ and $C_{22}$ homologs (17), but these processes have not been quantified. Past studies have used isolated hepatocytes or subcellular fractions, usually with [1-$^{14}$C]-labeled substrate fatty acids. Such assays are complicated because of the difficulties in presenting substrate, and they commonly result in relatively large amounts of pathway intermediates and small amounts of end product 22:6n-3. Therefore, their validity for the whole animal is suspect. Formation of 22:6n-3 from 18:3n-3 by trout hepatocytes was enhanced when fish were reared on diets lacking 22:6n-3 (11). In a study with salmon smolts, borage oil containing γ-linolenic acid (18:3n-6) enhanced the desaturation of both [1-$^{14}$C]18:2n-6 and [1-$^{14}$C]18:3n-3 in hepatocytes (18).

The method used here was developed by Pawlosky (12) to study essential fatty acid metabolism in cats (19). The use of stable isotope tracers offers several advantages over radiolabeled substrates. First, since stable isotopes are a mass tracer, they can be used more easily for quantitative measurements. Second, they are nonhazardous and are more amenable for *in vivo* studies, including those with humans. The metabolism of deuterated linoleic and linolenic acids was studied in human infants (20) and of deuterated linoleic acid in human adults (21). [U$^{13}$C]$C_{18}$ PUFA have been employed to examine PUFA recycling in rats (22) as well as desaturase activity in human infants (23), rats (24), and rhesus monkeys (25).

In this study we used $D_5$ (17,17,18,18,18)-18:3n-3 to determine the rate of formation of 22:6n-3 in rainbow trout *in vivo*. The fish had been reared on a low-PUFA diet (1% each of 18:2n-6 and 18:3n-3 with 0.038% 20:5n-3 and 0.079% 22:6n-3) sufficient to satisfy the essential fatty acid requirements for n-6 and n-3 PUFA (26) and to stimulate the conversion of 18:3n-3 to 22:6n-3 (11). The $D_5$-18:3n-3 tracer was delivered in the diet rather than by injection so that we could minimize stress from handling, which can stop fish eating and alter lipid metabolism, and so that we could feed a group of fish together, again eliminating stress. A marker was required to indicate how much diet individual fish in the experimental group had eaten and for this we used 21:4n-6. The rationale was that a fatty acid mimicking a $C_{20}$ essential fatty acid (arachidonic acid 20:4n-6) would be less likely to be catabolized and, therefore, give a better recovery than a saturated or monounsaturated fatty acid. This proved to be the case in that the recovery of 21:4n-6 in the experimental group as a whole was 57.6% compared with 2.6% for $D_5$-18:3n-3 plus $D_5$-22:6n-3. Other $D_5$-PUFA known to be intermediates in the biosynthetic pathway were not measured. The amount of dietary 21:4n-6 recovered in individual fish varied from 15.9 to 212.9 μg, and the proportion of the total 21:4n-6 recovered in the group as a whole was then used to calculate the amount of diet, and therefore the amount of $D_5$-18:3n-3, eaten by individual fish. The amount of deuterated substrate eaten varied from 0.11 to 1.46 mg per fish, excluding the three fish that did not eat the labeled portion. These values were then used to calculate the amount of $D_5$-22:6n-3 formed per milligram of substrate eaten. We previously used the same methodology to measure the rate of formation of 20:5n-3 in the sea urchin, where the recovery of the marker $D_8$-20:4n-6 was also much higher than that of $D_5$-18:3n-3 and its anabolites (27).

A notable feature of this study was the slow rate at which $D_5$-22:6n-3 was synthesized and deposited in tissues. The amount of newly synthesized $D_5$-22:6n-3 peaked in liver at day 7, whole body accretion peaked at day 14, and brain and eyes continued to accumulate $D_5$-22:6n-3 up to day 24. This suggests that it takes 2 to 4 wk for a pulse of 18:3n-3 to be metabolized to 22:6n-3 in trout.

The highest concentration of $D_5$-22:6n-3 on a per milligram lipid basis was found in liver at day 7 (1.1 μg/mg lipid/mg $D_5$-18:3n-3 eaten), as expected for a tissue actively synthesizing this fatty acid. The concentration in blood followed the trend for liver except that the values for days 7 and 14 were reversed. The eyes accumulated $D_5$-22:6n-3 to day 24, giving

a value of 0.94 μg $D_5$-22:6n-3/mg lipid/mg $D_5$-18:3n-3 eaten, the second-highest value for any tissue or time point, after liver at day 7. The concentration in eye socket adipose tissue at days 24 and 35 was *ca.* 3 times higher than that in visceral adipose tissue, suggesting a preferential deposition of 22:6n-3 for use by the retina. In fish of this size the eyes are still growing, so there is a continuing large demand for 22:6n-3 (28,29). In contrast, brain growth is much slower by this stage, and thus 22:6n-3 accretion by brain was much slower. There was much less tissue variation in the concentration of $D_5$-18:3n-3 on a per milligram lipid basis than for $D_5$-22:6n-3. The concentration of $D_5$-18:3n-3 in brain was notably low at all times, suggesting that either 18:3n-3 does not cross the blood brain barrier or it is metabolized very quickly. The latter seems unlikely since the amount of $D_5$-22:6n-3 was also low in brain and it is, therefore, more likely that 22:6n-3 synthesis in brain is either inherently low or is substrate limited. However, several studies have shown brain to be active in 22:6n-3 biosynthesis. Trout astrocytes in primary culture converted 0.7% of [1-$^{14}$C]18:3n-3 to 22:6n-3 (30) while [U-$^{13}$C]$C_{16}$ and $C_{18}$ PUFA were elongated and desaturated to 22:6n-3 in the brain of rats (31). In the feline, following a dose of $D_5$-18:3n-3, metabolites up to 22:5n-3 were present in liver and plasma, but metabolites from 24:5n-3 onward were only present in brain, suggesting that liver and brain act in tandem to synthesize 22:6n-3 (19). In the present study, the tissue ratios of $D_5$-22:6n-3 to $D_5$-18:3n-3 were highest in those tissues synthesizing 22:6n-3 (liver), transporting newly synthesized fatty acid (blood), and accreting 22:6n-3 (eyes and brain).

The results here clearly show that most of the $D_5$-18:3n-3 was catabolized, the recovery of $D_5$-18:3n-3 plus $D_5$-22:6n-3 being only 2.6% compared with 57.6% of 21:4n-6. This catabolism had largely occurred by the first time point at day 3, since the amount of $D_5$-18:3n-3 recovered in the whole fish was essentially unchanged over the 5-wk time course. The fish were growing, and it was expected that fatty acids would be oxidized extensively to provide energy for growth. However, it was rather unexpected that so much of an essential fatty acid would be oxidized, given that the diet was designed to satisfy the essential fatty acid requirement of the fish and no more (26). However, Cunnane *et al.* (22) showed that there was substantial carbon recycling in rat liver from linoleate into products of *de novo* lipogenesis even under conditions of extreme linoleate deficiency. This suggests that any control over the selection of fatty acids for oxidation is mainly dependent on chain length rather than their potential as key precursors for functionally essential fatty acids. Most of the remaining $D_5$-18:3n-3 was found in tissues other than the liver and was therefore unavailable as a substrate for 22:6n-3 biosynthesis without remobilization from other tissues. We could not determine from this experiment whether the PUFA biosynthetic pathway was substrate limited, but it is possible that if more substrate had been available the rate of formation of 22:6n-3 might have been elevated. The extent to which oxidation and deposition in other tissues controls the amount of substrate fatty acid available to the liver for 22:6n-3 biosynthesis requires investigation.

The synthesis of 22:6n-3 from 18:3n-3 was slow, giving a rate of 0.54 μg 22:6n-3/g fish/mg 18:3n-3 eaten/day over 7 d and peaking at 4.3 μg/g fish/mg 18:3n-3 eaten after 14 d. This can be put into context by considering the amount of 22:6n-3 in the fish and the amount obtained from the diet. The fish increased in size from a mean of 6.65 to 10.41 g over 28 d (from day 7 to day 35). From the regression line, the content of 22:6n-3 was 4.19 mg/g fish and 2.86 mg/g fish, respectively, at days 7 and 35, so for an average fish there was an increase in 22:6n-3 of 1.91 mg $[(10.41 \times 2.86) - (6.65 \times 4.19)]$ over this period. The fish ate 1.66% body weight/day for 28 d, which for an 8.5-g fish is 3.95 g diet containing 37.8 mg of 18:3n-3 and 3.13 mg 22:6n-3. The production of 22:6n-3 was 4.3 μg/g fish/mg 18:3n-3 eaten, giving 0.163 mg 22:6n-3 from 37.8 mg 18:3n-3 ingested. Therefore, for an average fish the total input was 3.29 mg—3.13 mg from the small amount of fish meal in the diet and 0.163 mg from biosynthesis. Thus, the contribution from biosynthesis was only about one-twentieth that from the diet. However, the measured increase in 22:6n-3 from the fatty acid composition was 1.91 mg. Therefore, over the 28 d there was a loss of 1.38 mg (3.29 – 1.91) of 22:6n-3 equivalent to 0.049 mg/d. The fish contained *ca.* 28.5 mg of 22:6n-3, so the turnover of 22:6n-3 was 0.17%/d. A number of assumptions were made in this calculation, and the final values are approximate. However, they are a good starting point for devising experiments to check the extent to which dietary supply and turnover affect the final concentration of 22:6n-3 in the fish.

Our results suggest that the extent to which trout can elongate and desaturate 18:3n-3 to 22:6n-3 may have been exaggerated and that the majority of 22:6n-3 may be obtained from the diet. Freshwater invertebrates that are natural food organisms for salmonids contain 10–15% 20:5n-3 but generally only trace amounts (<0.3%) of 22:6n-3 (32). However, freshwater oligochaetes and gammarids contain 1.0–1.4% 22:6n-3 (32), so it is possible that these species may be important as a source of 22:6n-3 for freshwater fish. Both 18:2n-6 and 18:3n-3 were abundant in all 10 species of invertebrates examined in that study (32). It can be calculated from our data that, in order to maintain the 22:6n-3 level constant in trout flesh, the amount of fish meal in the diet should be increased six- or sevenfold. Thus, a diet comprising vegetable oil and meal consisting of at least two-thirds fish meal should maintain tissue concentrations of 22:6n-3 in rainbow trout.

## ACKNOWLEDGMENTS

This work was funded by the Natural Environment Research Council Aquagene initiative. We thank Dr. Gordon Bell for help in making diets and Prof. John Sargent for constructive criticism of a draft of this manuscript and for many stimulating discussions.

**ABSTRACT:** The relationship between growth and alterations in arachidonic acid (AA) metabolism in human breast (MCF-7) and colon (SW480) cancer cells was studied. Four different fatty acid preparations were evaluated: a mixture of conjugated linoleic acid (CLA) isomers (*c*9,*t*11, *t*10,*c*12, *c*11,*t*13, and minor amounts of other isomers), the pure *c*9,*t*11-CLA isomer, the pure *t*10,*c*12-CLA isomer, and linoleic acid (LA) (all at a lipid concentration of 16 μg/mL). $^{14}$C-AA uptake into the monoglyceride fraction of MCF-7 cells was significantly increased following 24 h incubation with the CLA mixture ($P < 0.05$) and *c*9,*t*11-CLA ($P < 0.02$). In contrast to the MCF-7 cells, $^{14}$C-AA uptake into the triglyceride fraction of the SW480 cells was increased while uptake into the phospholipids was reduced following treatment with the CLA mixture ($P < 0.02$) and *c*9,*t*11-CLA ($P < 0.05$). Distribution of $^{14}$C-AA among phospholipid classes was altered by CLA treatments in both cell lines. The *c*9,*t*11-CLA isomer decreased ($P < 0.05$) uptake of $^{14}$C-AA into phosphatidylcholine while increasing ($P < 0.05$) uptake into phosphatidylethanolamine in both cell lines. Both the CLA mixture and the *t*10,*c*12-CLA isomer increased ($P < 0.01$) uptake of $^{14}$C-AA into phosphatidylserine in the SW480 cells but had no effect on this phospholipid in the MCF-7 cells. Release of $^{14}$C-AA derivatives was not altered by CLA treatments but was increased ($P < 0.05$) by LA in the SW480 cell line. The CLA mixture of isomers and *c*9,*t*11-CLA isomer inhibited $^{14}$C-AA conversion to $^{14}$C-prostaglandin $E_2$ ($PGE_2$) by 20–30% ($P < 0.05$) while increasing $^{14}$C-$PGF_{2\alpha}$ by 17–44% relative to controls in both cell lines. LA significantly ($P < 0.05$) increased $^{14}$C-$PGD_2$ by 13–19% in both cell lines and increased $^{14}$C-$PGE_2$ by 20% in the SW480 cell line only. LA significantly ($P < 0.05$) increased 5-hydroperoxyeicosatetraenoate by 27% in the MCF-7 cell line. Lipid peroxidation, as determined by increased levels of 8-epi-prostaglandin $F_{2\alpha}$ (8-epi-$PGF_{2\alpha}$), was observed following treatment with *c*9,*t*11-CLA isomer in both cell lines ($P < 0.02$) and with *t*10,*c*12-CLA isomer in the MCF-7 cell line only ($P < 0.05$). These data indicate that the growth-promoting effects of LA in the SW480 cell line may be associated with enhanced conversion of AA to $PGE_2$ but that the growth-suppressing effects of CLA isomers in both cell lines may be due to changes in AA distribution among cellular lipids and an altered prostaglandin profile.

Paper no. L8685 in *Lipids 36,* 1161–1168 (October 2001).

Compelling evidence indicates that conjugated linoleic acid (CLA), a derivative of linoleic acid found in milk and ruminant fats, is among the more potent naturally occurring anticarcinogens. *In vivo* model studies of experimental carcinogenesis have revealed that a synthetic mixture of CLA isomers containing 21% *c*11,*t*13, 29% *t*10,*c*12, 29.5% *c*9,*t*11, and 12.3% *c*8,*t*10 (1) possesses powerful inhibitory effects on mammary, colon, forestomach, and skin carcinogenesis in rodents (2–8). Other physiological benefits include a reduction in severity of atherosclerotic plaques, improvement of glucose tolerance in diabetic animals, body fat reduction, enhanced immune responses, and positive effects on bone formation, all of which have been well documented in numerous reviews (9–12). The specific CLA isomers that possess biological activity have not yet been clearly identified. Most of the mechanistic work to explain the potent anticancer effects of CLA has involved a commercial free fatty acid preparation containing up to 16 different CLA isomers (1). The availability of the pure isomers of *c*9,*t*11- and *t*10,*c*12-CLA has paved the way for determining the magnitude of biological responses to these isomers; these two are predominantly present in the synthetic CLA mixture and are produced by ruminants (13), and consequently they are found in the human diet. A study by Ip *et al.* (14) revealed that CLA-enriched butterfat, containing predominantly the *c*9,*t*11-CLA isomer, had a powerful protective effect against the risk of mammary cancer development in rodents.

The mechanisms by which CLA exerts its anticarcinogenic effects have not yet been fully elucidated. Induction of apoptosis by CLA *via* downregulation of a membrane protein bcl-2 has been reported to be the mode of cell death in cultured mammary tumor cells and in differentiated colonies of mammary epithelial organoids (15). The incorporation of CLA isomers into membrane phospholipids of breast, skin, and liver tissue has been reported but with variable levels of displacement from membranes of linoleic acid (LA) and arachidonic acid (AA) (7, 16–19). This suggests that CLA may influence the fatty acid

Abbreviations: AA, arachidonic acid; CLA, conjugated linoleic acid; 5-HPETE, 5-hydroperoxyeicosatetraenoate; $IP_3$, inositol triphosphate; LA, linoleic acid; $LTB_4$, leukotriene $B_4$; MG, monoglyceride; PBS, phosphate-buffered saline; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, prostaglandin; $PGD_2$, prostaglandin $D_2$; $PGE_2$, prostaglandin $E_2$; $PGF_{2\alpha}$, prostaglandin $F_{2\alpha}$; PI, phosphatidylinositol; PKC, protein kinase C; PL, phospholipid; $PLA_2$, phospholipase $A_2$; PLC, phospholipase C; PS, phosphatidylserine; TG, triglyceride; TLC, thin-layer chromatography.

composition of cell membranes, resulting in alterations in eicosanoid production and other signal transduction pathways downstream of the cell membrane. Eicosanoids, comprising prostaglandins and leukotrienes, are a family of membrane-derived lipid mediators that have been an attractive target for cancer chemoprevention (20). Research has shown that CLA can affect the synthesis of eicosanoids, in particular prostaglandin $E_2$ ($PGE_2$) (16), a prostanoid that has been shown to promote growth and metastasis in many experimental tumors (21).

Previously we used mammary (MCF-7) and colon (SW480) tumor cell lines as *in vitro* models to investigate the mechanisms by which CLA may affect breast and colon cancer. The MCF-7 epithelial cell line retains several characteristics of differentiated mammary epithelium including the ability to process estradiol *via* cytoplasmic estrogen receptors (22). The SW480 cell line, which was established from a primary adenocarcinoma of the colon, is a dedifferentiated cell line that expresses elevated levels of the p53 protein and small amounts of carcinoembryonic antigen (23). We previously demonstrated that the mixture of CLA isomers induced a dose- and time-dependent cytotoxicity against both cell lines and provided evidence that this effect may be due in part to increased lipid peroxidation (24). The anticancer effect of CLA may be due in part to a redistribution of AA among cellular lipids, which might influence oxidative susceptibility of particular membrane phospholipids and/or alter eicosanoid synthesis during tumor growth. This study was undertaken to examine the modulatory effects of CLA isomers on cell viability in addition to AA uptake, distribution, release, and conversion to eicosanoid classes in breast (MCF-7) and colon (SW480) human cancer cell lines.

## MATERIALS AND METHODS

*Materials.* $^{14}$C-AA (specific activity, 55 mCi/mmol), Biotrak enzyme immunoassay kit for leukotriene $B_4$ ($LTB_4$), and radioreceptor kit for inositol triphosphate ($IP_3$) were purchased from Nycomed Amersham (Little Chalfort, Buckinghamshire, United Kingdom). The CLA mixture (21% *c*11,*t*13, 29% *t*10, *c*12, 29.5% *c*9,*t*11, and 12.3% *c*8,*t*10) (1) was obtained from Nu-Chek-Prep (Elysian, MN). Individual CLA isomers, *c*9, *t*11 and *t*10,*c*12, were purchased from Matreya (Pleasant Gap, PA). LA, authentic $PGE_2$, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), prostaglandin $D_2$ ($PGD_2$), 5-hydroperoxyeicosatetraenoate (5-HPETE), phospholipid (PL) standards, and Supelclean LC-18 SPE columns were purchased from Sigma Chemical Co. (Poole, Dorset, United Kingdom). Silica Sep-Pak columns were obtained from Waters Corporation (Milford, MA). The Bioxytech immunoassay kit for 8-epi-$PGF_{2\alpha}$ was obtained from Bio-Stat (Stockport, United Kingdom). DC-Alufliien Kiesegel 60 thin-layer chromatography (TLC) plates were obtained from Lennox (Dublin, Ireland). The CellTitre®$AQ_{ueous}$ Non-Radioactive Cell Proliferation Assay kit was purchased from Promega (Southampton, United Kingdom). All other chemicals and solvents used were high-performance liquid chromatography grade.

*Cell culture.* Human breast (MCF-7) and colon (SW480) cancer cell lines were obtained from the American Type Culture Collection (Manassas, VA). Culture media and supplements were purchased from GIBCOBRL (Paisley, Scotland). Both cell lines were maintained in Dulbecco's minimal essential medium supplemented with fetal bovine serum (5% by vol), 0.2 mM L-glutamine, 1 mM HEPES, and 1 unit/mL penicillin and streptomycin. The MCF-7 cells required an additional supplement of 10 mM sodium pyruvate. Cells were grown in Falcon T-25 $cm^2$ flasks and maintained as previously described (24).

*Quantification of cell numbers.* The comparative effects of four different fatty acid preparations on cell viability were evaluated: (i) the CLA mixture of isomers, (ii) the pure *c*9,*t*11-CLA isomer, (iii) the pure *t*10,*c*12-CLA isomer, and (iv) LA. MCF-7 and SW480 cells were seeded in 96-well plates at densities of $1 \times 10^3$/well and $5 \times 10^2$/well, respectively. Cells were cultured for 24 h to allow the cells to attach to the substratum. The medium was then replaced with medium supplemented with either the CLA mixture of isomers, the pure *c*9,*t*11-CLA, the pure *t*10,*c*12-CLA, or LA at two different lipid concentrations: 5 and 16 μg/mL corresponding to 17.8 and 57 μM, respectively. The CLA concentrations used have been reported to be within the physiological range of concentrations of the *c*9,*t*11-isomer in human PL (25), plasma, bile, and duodenal juice (26) and have been previously used in cell culture work (27). The fatty acids were dissolved in ethanol and, therefore, control wells were supplemented with equivalent volumes of ethanol (0.25 or 0.8% by vol). After 24 h and 4 d of incubation, viable cell numbers were quantified using the MTS assay kit (CellTitre®$AQ_{ueous}$ Non-Radioactive Cell Proliferation Assay).

*Lipid extraction and fractionation.* Cells were seeded in T-25 $cm^2$ flasks at a density of $2 \times 10^5$/flask and grown to 90% confluency. The medium was then replaced with medium containing $^{14}$C-AA at 0.2 μCi along with either the CLA mixture of isomers, the pure *c*9,*t*11-CLA, the pure *t*10,*c*12-CLA, or LA, all at a lipid concentration of 16 μg/mL (57 μM). The CLA mixture of isomers at a lipid concentration of 16 μg/mL yielded a *c*9,*t*11-CLA and *t*10,*c*12-CLA concentration of approximately 4.7 μg/mL (17 μM) each. Control flasks were supplemented with an equivalent volume of ethanol (0.8% by vol). After 24 h incubation, cells were harvested using phosphate-buffered saline (PBS) containing trypsin (0.25% by vol). Total lipids were extracted from the cell pellet as described (28), dried under nitrogen, redissolved in chloroform, and applied to a silica Sep-Pak column to separate the triglyceride (TG), monoglyceride (MG), and PL fractions as described (29). An aliquot of each fraction was counted in a Beckman LS6500 scintillation counter before being dried under nitrogen. The PL fraction was separated using normal-phase TLC. Samples were co-migrated with authentic standards of phosphatidylcholine (PC), phosphatidylinositol (PI), phosphatidylserine (PS), and phosphatidylethanolamine (PE). Chloroform/methanol/acetic acid (65:45:4, by vol) was used to separate the PL (30). Iodine vapors were used to identify the position of the PL compared with standards, and these bands were removed from TLC plates and placed in vials for counting by liquid scintillation.

*Phospholipase C (PLC) activity.* $IP_3$ was used as an index of PLC activity. Cells were treated with the four different fatty acid treatments (all at 16 μg/mL) or ethanol as described above. After 24 h incubation the cells were harvested as described above, and $IP_3$ was extracted from cells using a perchloric acid extraction method previously described by Palmer *et al.* (31). A radioreceptor assay kit (Biotrak D-*myo*-inositol 1,4,5-triphosphate assay system) was used to quantify $IP_3$ levels according to the manufacturer's instructions. This assay is based on competition between a [$^3$H]-$IP_3$ tracer and unlabeled $IP_3$ in the samples for binding to a bovine adrenal cortex protein.

*Release of $^{14}$C-AA derivatives.* Cells were seeded in T-25 $cm^2$ flasks at a density of $2 \times 10^5$/flask and grown to 80% confluency. Medium was replaced with medium containing $^{14}$C-AA (0.2 μCi) and incubated for 24 h. After removal of media, cells were washed three times with PBS before addition of medium containing the four different fatty acid treatments (all at 16 μg/mL) or ethanol as described earlier. After 24 h, medium containing the released $^{14}$C-AA derivatives was removed and an aliquot was counted by liquid scintillation.

*Primary PG and 8-epi-$PGF_{2\alpha}$.* Cells were seeded and treated with $^{14}$C-AA at 0.2 μCi along with the four different fatty acid treatments (all at 16 μg/mL) or ethanol as described previously. After 24 h incubation the medium was removed from the flasks, and eicosanoids were extracted twice with ethyl acetate from medium acidified to pH 3.0 with 0.1 N HCl as described (17). Eicosanoid extracts were dried under nitrogen, redissolved in ethyl acetate, and applied onto normal-phase TLC plates. Ethyl acetate/iso-octane/glacial acetic acid/water (55:25:10:50, by vol) was used to separate PG (16). Samples were comigrated with authentic standards of $PGE_2$, $PGF_{2\alpha}$, and $PGD_2$. Iodine vapors were used to identify the position of each PG compared with the standards. Bands of $PGE_2$, $PGF_{2\alpha}$, and $PGD_2$ were removed from TLC plates and placed in vials for counting by liquid scintillation. For the 8-epi-$PGF_{2\alpha}$ assay, culture medium was collected after 24 h incubation with the fatty acid treatments described earlier and 8-epi-$PGF_{2\alpha}$ was extracted as described (32). Briefly, ethanol was added to the medium to a final concentration of 15% (vol/vol) and acidified to pH 3.0 with formic acid (98% by vol). The sample was applied to Supelclean LC-18 SPE columns and washed with water (adjusted to pH 3.0 with formic acid), 15% (vol/vol) ethanol in water (pH 3.0), and hexane. Ethyl acetate containing 1% (vol/vol) methanol was used to elute 8-epi-$PGF_{2\alpha}$. The eluate was dried under nitrogen and resuspended in assay buffer (Bioxytech), and a competitive horseradish peroxidase enzyme-linked immunoassay kit (Bioxytech 8-isoprostane assay system) was used to quantify 8-epi-$PGF_{2\alpha}$ levels according to the manufacturer's instructions.

*$LTB_4$ and 5-HPETE.* Cells were seeded and treated with the four different fatty acid treatments (all at 16 μg/mL) or ethanol as described earlier. For the 5-HPETE assay, cells were lysed using Triton-X 100 (0.1% vol/vol). The assay was initiated by the addition of 50 μL of AA (70 mM prepared in 50 mM Tris-HCl buffer, pH 4) to 50 μL of cell lysate in an ice-cold 96-well plate and incubated at 37°C for 10 min. The reaction was terminated by the addition of 100 μL of the FOX reagent: sulfuric acid (25 mM), xylenol orange (100 μM), iron(II) sulfate (100 μM), methanol/water (9:1 vol/vol) (33). Absorbance was measured at 620 nm using an Anthos 2010 plate reader. For the $LTB_4$ assay, eicosanoids were extracted from the medium as described earlier and dried under nitrogen. An enzyme immunoassay kit (Biotrak $LTB_4$ enzyme immunoassay system) was used to quantify $LTB_4$ levels according to the manufacturer's instructions. This assay is based on the competition between unlabeled $LTB_4$ and a fixed quantity of peroxidase-labeled $LTB_4$ for binding sites on a $LTB_4$-specific antibody.

*Statistical analysis.* Three independent experiments were performed in triplicate. Student's *t* test was used to determine significant differences between treatments.

## RESULTS

*Effect of CLA isomers on cell viability.* MCF-7 and SW480 cells were incubated for 24 h and 4 d with the CLA mixture of isomers, *c*9,*t*11-CLA, *t*10,*c*12-CLA, and LA at two different lipid concentrations (5 and 16 μg/mL corresponding to 17.8 and 57 μM, respectively). None of the fatty acids at either 5 or 16 μg/mL significantly altered cell viability after 24 h. The CLA mixture of isomers (16 μg/mL) caused a reduction in cell viability after 4 d in both cell lines, with a greater reduction noted in MCF-7 cells (58%) (Fig. 1A) compared with SW480 cells (52%) (Fig. 1B). The *c*9,*t*11-CLA isomer caused a similar reduction (~50%) in cell viability to the CLA mixture of isomers following 4 d of incubation at both 5 and 16 μg/mL. In both cell lines, the *t*10,*c*12-CLA isomer at 5 and 16 μg/mL reduced viability by 38–39 and 50–60%, respectively, following 4 d of incubation. Incubation of SW480 cells with LA (16 μg/mL) for 4 d increased cell viability by 23%, but the lower concentration of 5 μg/mL had no effect at either time point (Fig. 1B). LA (5 and 16 μg/mL) had no effect on the viability of MCF-7 cells following 4 d of incubation in this study.

*Effect of CLA isomers on incorporation of $^{14}$C-AA into cellular lipid fractions.* One of the mechanisms involved in growth suppression is an alteration in the AA cascade of events leading to eicosanoid production (17). In order to examine if cellular AA distribution was altered by CLA, we investigated the effect of CLA isomers on incorporation of $^{14}$C-AA into cellular lipid fractions. $^{14}$C-AA was preferentially incorporated into the PL fraction in untreated and CLA-treated MCF-7 cells and SW480 cells (Table 1). Levels of uptake into PL, TG, and MG were 60, 33, and 7%, respectively, in control MCF-7 cells (Table 1). $^{14}$C-AA uptake into the MG fractions was increased in MCF-7 cells treated with the CLA mixture ($P < 0.05$) (7.2%) and the pure *c*9,*t*11-CLA isomer ($P < 0.02$) (16.6%). None of the fatty acid treatments had any effect on uptake of $^{14}$C-AA into the TG and PL fractions of the MCF-7 cell line.

Levels of uptake into PL, TG, and MG were 76, 21, and 3%,

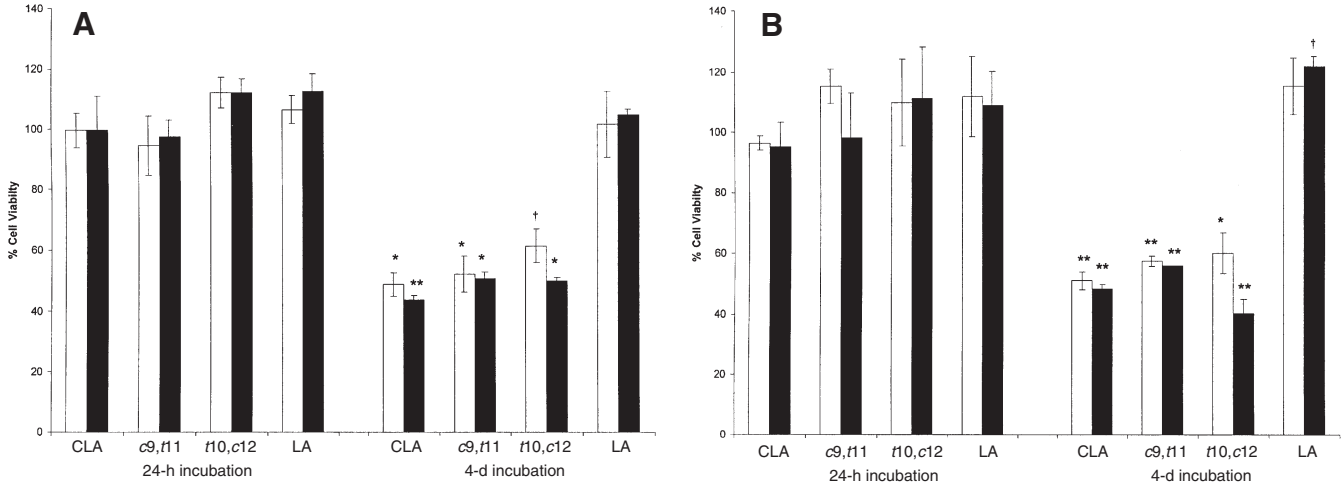

**FIG. 1.** Cell viability for (A) MCF-7 (human breast cancer) and (B) SW480 (human colon cancer) cells incubated with 5 (open bar) or 16 μg/mL (solid bar) conjugated linoleic acid (CLA) mixture, *c*9,*t*11-CLA, *t*10,*c*12-CLA, linoleic acid (LA), or ethanol control for 24 h and 4 d. Data represent cell viability expressed as a percentage of the control, which was taken to be 100% (**$P < 0.001$, *$P < 0.02$, and $^{\dagger}P < 0.05$). Error bars represent standard deviation.

respectively, in control SW480 cells (Table 1). In contrast with MCF-7 cells, uptake of $^{14}$C-AA into PL was significantly lowered ($P < 0.02$) (~25%) in the SW480 cells treated with the CLA mixture and *c*9,*t*11-CLA, while both the CLA mixture and *c*9,*t*11-CLA increased AA uptake into TG (25–30%) ($P < 0.05$). These data suggest that $^{14}$C-AA uptake into TG occurred at the expense of PL in the SW480 cell line. None of the fatty acid treatments had any effect on uptake of $^{14}$C-AA into the MG lipid fraction of the SW480 cells. The *t*10,*c*12-CLA isomer and LA (both at 16 μg/mL) had no effect on $^{14}$C-AA incorporation into any of the lipid fractions in either cell line.

*Effect of CLA isomers on $^{14}$C-AA distribution among PL fractions.* Having shown that $^{14}$C-AA was preferentially incorporated into the PL fraction of CLA-treated cells, we examined the effect of CLA isomers on $^{14}$C-AA distribution among individual PL. PC and PE were the predominant PL classes in which $^{14}$C-AA was taken up by control cells. Levels of uptake into PC, PI, PS, and PE were 45, 8, 6, and 41%, respectively, in the MCF-7 control cells and 34, 3, 3, and 60%, respectively, in the SW480 control cells (Tables 2 and 3). Of all the treatments, only incubation with the pure *c*9,*t*11-CLA isomer altered the distribution of $^{14}$C-AA among PL classes in the MCF-7 cells (Table 2). The *c*9,*t*11-CLA treatment at 16 μg/mL significantly ($P < 0.05$) reduced uptake of $^{14}$C-AA into PC (32%) and increased uptake into PE (41%). The CLA mixture at 16 μg/mL (which yielded a *c*9,*t*11-CLA isomer concentration of 4.7 μg/mL) had no effect. The *t*10,*c*12-CLA isomer at 16 μg/mL had no effect on the incorporation of $^{14}$C-AA into any of the PL fractions in the MCF-7 cells.

Incubation of the SW480 cell line with the *c*9,*t*11 CLA isomer (16 μg/mL) decreased uptake of $^{14}$C-AA into PC by 24% ($P < 0.01$) and increased uptake into PE by approximately 20% ($P < 0.01$) (Table 3). In contrast with MCF-7 cells, both the CLA mixture at 16 μg/mL (which yielded a *t*10,*c*12-CLA isomer concentration of 4.7 μg/mL) and the *t*10,*c*12 isomer (16 μg/mL) increased uptake into PS by 12–15% ($P < 0.05$) in the SW480 cell line. LA treatment had no effect on $^{14}$C-AA distribution among PL fractions in either cell line. None of the CLA isomers or LA had any effect on the uptake of $^{14}$C-AA in PI.

*Effect of CLA isomers on AA release.* AA can be released by two major pathways, the first through the action of phospholipase $A_2$ ($PLA_2$), which catalyzes the hydrolysis of *sn*-2 fatty acyl bond of membrane PL to liberate free AA (34), and the second by sequential cleavage of PI by PLC and diacylglyceride lipase (35). $IP_3$ levels were used as an index of PLC

[a]Data represent the mean percentage incorporation of total cellular phospholipids. Superscript roman letters indicate values that are significantly different compared to controls ([a] denotes $P < 0.05$ and [b] denotes $P < 0.02$). PC, phosphatidycholine; PI, phosphatidylinositol; PS, phosphatidylserine; PE, phosphatidylethanolamine; for other abbreviations see Table 1.

activity in this study. The CLA mixture of isomers, the pure *c*9,*t*11- and *t*12,*c*10-CLA isomers, and LA did not affect $IP_3$ in either cell line (data not shown). Total $^{14}$C-AA derivatives were increased by 28% ($P < 0.05$) in SW480 cells treated with LA only, whereas none of the CLA isomers had any effect on the total level of $^{14}$C-AA derivatives released by cells (Fig. 2).

*Effect of CLA isomers on eicosanoid synthesis.* The effects of various fatty acid treatments on enzymatic conversion of AA to primary eicosanoids ($PGD_2$, $PGE_2$, $PGF_{2\alpha}$, $LTB_4$, and 5-HPETE) and on its nonenzymatic, free radical-catalyzed conversion to 8-epi-$PGF_{2\alpha}$, were examined. Following incubation of MCF-7 and SW480 cells in the presence of the CLA mixture and the pure *c*9,*t*11-CLA isomer at 16 µg/mL, it was found that $^{14}$C-AA conversion to $^{14}$C-$PGE_2$ was decreased by 20–30% ($P < 0.05$) whereas conversion to $^{14}$C-$PGF_{2\alpha}$ was increased by 17–44% relative to control (Figs. 3A,B). CLA treatments had a negligible effect on $^{14}$C-$PGD_2$. The *t*10,*c*12-CLA isomer had no effect on the three PG examined in either cell line. LA significantly ($P < 0.05$) increased $^{14}$C-$PGD_2$ by 13–19% in both cell lines and increased ($P < 0.05$) $^{14}$C-$PGE_2$ by 20% in the SW480 cell line only. Incubation of cells with either the CLA mixture of isomers or the pure *c*9,*t*11- or *t*10,*c*12-CLA isomers did not alter 5-HPETE or $LTB_4$ levels in the cells (data not shown), suggesting that CLA may mediate its effect *via* the cyclooxygenase component of the AA cascade. LA significantly increased 5-HPETE levels by 27% ($P < 0.05$) in the MCF-7 cell line (data not shown) but had no effect in the SW480 cells compared with untreated controls. The *c*9,*t*11-CLA isomer significantly increased ($P < 0.02$)

| LA | 36.7 ± 9.6 | 3.7 ± 1.1 | 3.2 ± 0.4 | 56.4 ± 8.5 |

[a]Data represent the mean percentage incorporation of total cellular phospholipids. Superscript roman letters indicate values that are significantly different compared to controls ([a] denotes $P < 0.01$ and [b] denotes $P < 0.05$). For abbreviations see Tables 1 and 2.

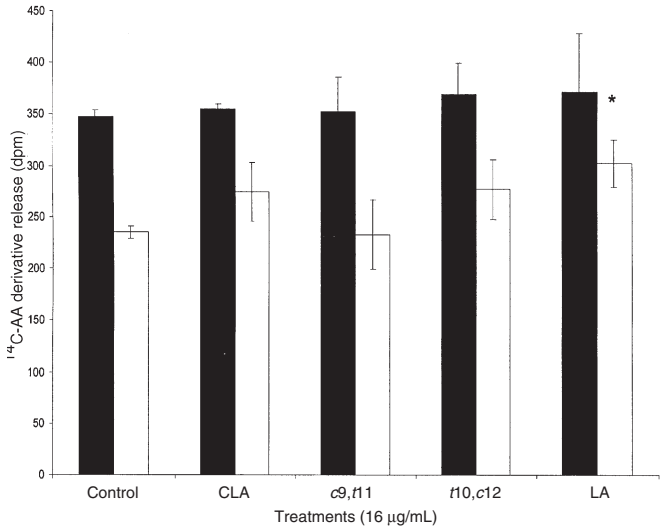

**FIG. 2.** The effect of treatments on total $^{14}$C-arachidonic acid (AA) release in MCF-7 (solid bars) and SW480 (open bars) cells. Cultures were treated with $^{14}$C-AA at 0.2 µCi for 24 h after which medium was replaced to contain either CLA mixture, LA, *c*9,*t*11-CLA, *t*10,*c*12-CLA (16 µg/mL), or ethanol (control) and then incubated for 24 h. Medium containing the released $^{14}$C-AA was removed, and an aliquot was counted by liquid scintillation. Results were expressed as mean $^{14}$C-AA released (dpm). Error bars represent standard deviation. *Values that are significantly different ($P < 0.05$) compared to controls. For abbreviations see Figure 1.

8-epi-$PGF_{2\alpha}$ in MCF-7 and SW480 cells by 38 and 48%, respectively (Figs. 3A,B). The *t*10,*c*12-CLA isomer increased ($P < 0.05$) levels of 8-epi-$PGF_{2\alpha}$ by 30% in the MCF-7 cell lines but had no effect in the SW480 cells (Fig. 3B). However, treatment of both cell lines with the mixture of CLA isomers and LA treatments had no relative effect in either cell line.

## DISCUSSION

This study shows that the MCF-7 and SW480 cell lines were sensitive to growth-inhibitory effects of not only the CLA mixture but also both the *t*10,*c*12-CLA and the *c*9,*t*11-CLA isomers following 4 d of incubation with physiological levels of CLA (5–16 µg/mL) (27). The CLA mixture of isomers at 16 µg/mL (yielding a *c*9,*t*11-CLA and *t*10,*c*12-CLA concentration of approximately 4.8 µg/mL each) was equally effective in inhibiting growth of both cell lines as the pure *c*9,*t*11-CLA and *t*10,*c*12-CLA isomer added at 16 µg/mL. This suggests that a plateau effect was reached or that one or more of the other isomers present in the mixture may be capable of altering cell viability. It is imperative, however, that more basic research be undertaken to determine the specific biological effects of other isomers present in the mixture, particularly *c*11,*t*13, which has recently been detected in natural products (36) and in liver microsomes (37). The growth-stimulatory effect of LA previously reported (27,38) was also seen in this study in the SW480 cell line treated with LA, but no effect was seen in the MCF-7 cells at the concentrations used.

This study provides an insight into the early responses of breast and colon cancer cell lines before growth is altered. Inter-

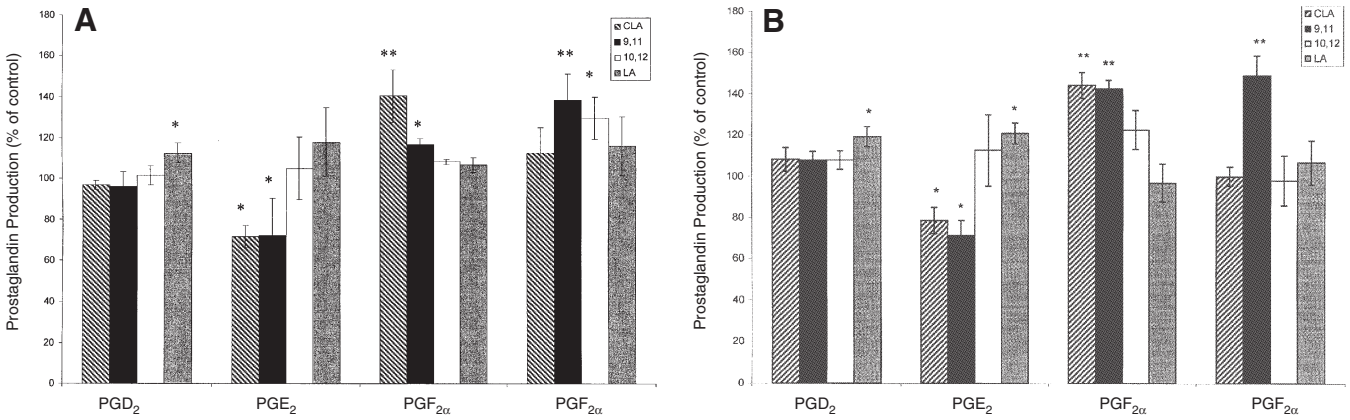

**FIG. 3.** Effect of treatments on primary prostaglandins (PG) and 8-epi-$PGF_{2\alpha}$ synthesis in (A) MCF-7 and (B) SW480 cells. Cultures were treated with 0.2 μCi/mL $^{14}$C-AA along with either the CLA mixture, *c*9,*t*11-CLA, *t*10,*c*12-CLA, and LA (16 μg/mL) or ethanol control for 24 h. Eicosanoids were extracted from medium, and PG were separated using thin-layer chromatography and counted by liquid scintillation. Data represent the mean $^{14}$C-PG synthesis expressed as a percentage of the control, which was taken to be 100%. 8-Epi-$PGF_{2\alpha}$ levels were quantified using an enzyme immunoassay kit from Bioxytech (Bio-Stat, Stockport, United Kingdom). Error bars represent standard deviation. Asterisks indicate values that are significantly different compared to controls (**$P < 0.02$; *$P < 0.05$). For abbreviations see Figures 1 and 2.

estingly, the CLA mixture of isomers containing 4.7 μg/mL *c*9,*t*11-CLA was less effective than the pure *c*9,*t*11-CLA isomer (16 μg/mL) at redistributing AA among lipid fractions in the MCF-7 cell line and had no effect in altering AA content of individual PL of these cells. Our data demonstrate that the *c*9,*t*11-CLA isomer decreased AA uptake into PC while increasing uptake into PE in both cell lines. The decrease in uptake into PC is very significant as this is the PL preferentially hydrolyzed by $PLA_2$ to provide AA for eicosanoid synthesis (39). None of the other treatments had any effect on PS in the MCF-7 cell line, but in the SW480 cell line the CLA mixture and the *t*10,*c*12-CLA isomer both increased uptake of AA into PS. Although PS is a biosynthetic precursor of PE, it is in itself an important membrane lipid as it is an activator of membrane-associated protein kinase C (PKC), an enzyme that phosphorylates serine and threonine residues of an extremely diverse group of proteins regulating cell proliferation, activating cellular function, differentiation, and even apoptosis (40). It has been postulated that CLA may modulate PKC (41). However, activation of this enzyme is also dependent on diacylglycerol, a product of PLC activity, and $Ca^{2+}$ released from intracellular stores by $IP_3$. None of the treatments investigated altered the levels of $IP_3$ in the cells or uptake of AA into PI, suggesting that growth modulatory effects of various treatments in this study were not associated with PLC-mediated signal transduction. Other reports also indicate that physiological concentrations of CLA did not mediate changes in either PLC or PKC activity in MCF-7 cells (42) or in normal rat mammary epithelial cell organoids (43).

Interestingly, none of the CLA treatments influenced AA release from cells, yet both the CLA mixture and the *c*9,*t*11-CLA isomer decreased $^{14}$C-$PGE_2$ synthesis and increased $^{14}$C-$PGF_{2\alpha}$ in both cell lines, suggesting that a modulation of cyclooxygenase and/or downstream isomerase or reductase gene expression may be responsible. By contrast, LA stimulated $PGD_2$ production in both cell lines while stimulating $PGE_2$ production in the SW480 cell line. These changes in PG synthesis may have been responsible for the differential effects of LA and CLA treatments on growth. Levels of $LTB_4$ and 5-HPETE were not altered by any of the CLA treatments, suggesting that the anticancer effect of CLA may be mediated independently of the lipoxygenase component of the AA cascade as has been already proposed (44, 45).

A differential effect between physiological levels (0.5–5 μg/mL) of *c*9,*t*11 CLA and LA on growth of MCF-7 cells after 4 d has been reported (42). Growth inhibition by the CLA isomer was not mediated through PLC, PKC, or $PGE_2$-dependent signal transduction pathways, suggesting that another inhibitory mechanism may be involved. Because our study did show that $PGE_2$ synthesis was reduced by higher but near-physiological concentrations of CLA, it is apparent that there may be a threshold requirement for CLA and LA to affect cellular $PGE_2$ synthesis. A similar inhibitory effect of CLA on $PGE_2$ synthesis was observed in keratinocytes (17) and mouse epidermis (46). More recently CLA has been shown to inhibit prostaglandin H synthase activity in ram seminal vesicle microsomes (47).

Basu and coworkers (48) reported that CLA induced lipid peroxidation in humans by using urinary 8-iso-$PGF_{2\alpha}$ excretion as a biomarker of nonenzymatic lipid peroxidation. We showed that incubation of both cell lines with the *c*9,*t*11-CLA isomer led to significantly increased 8-epi-$PGF_{2\alpha}$ in both cell lines, while incubation with the *t*10,*c*12-CLA led to increases in 8-epi-$PGF_{2\alpha}$ levels in the MCF-7 cell line only. These isomers may be promoting nonenzymatic oxidation of AA at the expense of the formation of enzymatically derived eicosanoids. The mixture of CLA isomers (at 16 μg/mL) had no effect on 8-epi-$PGF_{2\alpha}$ levels, suggesting that a concentration of *c*9,*t*11-CLA higher than 4.7 μg/mL is needed to induce nonenzymatic oxidation of AA. A number of studies have now shown that the production of reactive oxygen species

serves to trigger an apoptotic signal transduction pathway (reviewed in Ref. 49). Further studies to investigate the effects of CLA isomers on the expression of cyclooxygenase isoforms and other signal transduction pathways are warranted to explain the potential inhibitory role of CLA on *in vitro* growth. Intervention studies have shown that increasing CLA intake led to increases in the CLA content in human milk (50), plasma (51), and adipose tissue (52). Although it is attractive to speculate that CLA may be useful in nutritional prevention of cancer in humans, evidence of beneficial effects in cancer patients receiving CLA as a dietary supplement is required. To this end, appropriate molecular and biochemical markers of both CLA nutritional status and of tumorigenesis are currently being sought.

METHOD

# An Octaethylene Glycol Monododecyl Ether-Based Mixed Micellar Assay for Determining the Lipid Acyl Hydrolase Activity of Patatin

**Mercedes Jiménez*, Josefa Escribano, Manuela Pérez-Gilabert, Soledad Chazarra, Juana Cabanes, and Francisco García-Carmona**

Departamento de Bioquímica y Biología Molecular A, Universidad de Murcia, Espinardo 30071, Murcia, Spain

**ABSTRACT:** Patatin was extracted from potato tubers (*Solanum tuberosum* L. cv. Spunta) and purified to homogeneity by ammonium sulfate salt fractionation and one sole chromatographic step. A spectrophotometric mixed micellar assay for patatin lipid acyl hydrolase (LAH) activity was designed with the detergent octaethylene glycol monododecyl ether ($C_{12}E_8$). Patatin LAH used *p*-nitrophenyl butyrate (PNP-butyrate) as substrate when solubilized in ($C_{12}E_8$) micelles. In the mixed micellar system, patatin LAH responds to the PNP-butyrate surface concentration expressed as mol% (= [PNP-butyrate]·100/([detergent] – critical micellar concentration)) and not to the molarity of PNP-butyrate. The kinetic parameters were determined; $V_{max}$ was independent of the mixed micelle concentration, as was $K_m$, when expressed as mol%. However, $K_m$ was dependent on $C_{12}E_8$ concentration when expressed in molar concentration. $C_{12}E_8$/PNP-butyrate proved to be a reliable system for assaying patatin LAH activity and is superior to the commonly used Triton X-100 and SDS methods. It permits investigation of the substrate requirements of patatin LAH activity because the concentration-independent $K_m$ can be determined both in mol% and as the absolute number of substrate molecules per micelle. In addition, the detergent did not affect the enzyme activity.

Paper no. L8769 in *Lipids 36,* 1169–1179 (October 2001).

Patatin is the trivial name given to a group of immunologically related glycoproteins with a molecular weight of 40 kDa found in practically all potato (*Solanum tuberosum* L.) cultivars thus far examined. Patatin accounts for up to 40% of the total soluble protein present in tubers (1,2) and owing to its high accumulation in the tuber, it is considered to be a storage protein (3). In several instances the storage proteins of plants have been found to have a function other than serving merely as a protein reserve. For example, several seed proteins act as proteinase inhibitors or have an antifungal or antibacterial activity (4). Patatin itself has been reported to show esterase activity with a large number of lipid substrates. By using a baculovirus system to express protein from the patatin cDNA, it has unambiguously been shown that the patatin coded by this DNA shows lipid acyl hydrolase (LAH) activity (5). The enzyme is active with phospholipids, monoacylglycerols, and *p*-nitrophenyl (PNP) esters, moderately active with galactolipids, but is apparently inactive with di- and triacylglicerols (6). This esterase activity may play a role in the plant defense mechanisms, although at present its physiological function is not understood (7).

In the literature, there is limited information on the kinetic characteristics of LAH activity of patatin, probably due to the poor solubility of its substrates in an aqueous medium. Lipids usually form several sorts of aggregates that either remain as a colloidal solution (normally turbid or opaque) or separate from the aqueous medium to form a lipid-rich phase (8). Because of the low solubility of these substances, the particular conditions, i.e., the environment in which the interaction and reaction between enzyme and substrate takes place, are unknown. It is even difficult therefore to define the concentration of a substrate because it is not homogeneously distributed in the reaction medium.

Surfactants may stabilize the lipid suspensions by forming mixed micelles, which are transparent, thermodynamically stable aggregates (8). In this way, a homogenous distribution of the lipid in the reaction medium can be achieved. Whenever the surfactant forms micelles with a stable aggregation number, it is possible to establish both the concentration of lipids relative to the concentration of surfactant and the absolute number of lipid molecules per micelle (9).

The term"surface dilution kinetics" has been widely applied to the study of kinetics of enzymes that act on lipids/interface substrates; and the theory, experimental considerations, and applications of surface dilution kinetics have been discussed (10). This kinetic model introduced the important concept that both the surface concentration of lipid and the bulk concentration in solution play critical roles in defining the kinetic parameters of lipid-dependent enzymes.

To routinely assay LAH activity, the most commonly used detergents by far have been Triton X-100 (11) or the combination of Triton X-100 and SDS (5,12–14). Although they form transparent mixed micelles with *p*-nitrophenyl esters (the most frequently used LAH substrates), they present important disadvantages; for example, they are not chemically pure substances, and thus their aggregation number is not well defined.

Abbreviations: BSA, bovine serum albumin; CMC, critical micellar concentration; LAH, lipidacyl hydrolase; PNP, *p*-nitrophenyl; SDS, sodium dodecyl sulfate.

In the present work, a method of purifying patatin to homogeneity is presented. This procedure uses two phase-partitions, one with the detergent Triton X-114 and the other with salts, and only one chromatographic step. A system for measuring the LAH activity of patatin using the nonionic detergent octaethylene glycol monododecyl ether ($C_{12}E_8$) is also described. $C_{12}E_8$ is a chemically pure detergent, which has been well characterized physichochemically (15). It has been shown to solubilize several kinds of lipids such as palmitoyl CoA, phosphatidylglycerol and cardiolipin. López-Nicolás *et al.* (16) were able to determine lipoxygenase activity at neutral pH by using linoleic acid solubilized in $C_{12}E_8$ micelles as substrate.

The mixed micellar assay ($C_{12}E_8$/PNP butyrate) reported in this work enabled us to perform a kinetic analysis of the reaction with respect to the substrate (surface) concentration, which, until now, has not been carried out.

## EXPERIMENTAL PROCEDURES

*Plant materials.* The potatoes used, *Solanum tuberosum* L. cv. Spunta, were obtained from the local market.

*Reagents.* Triton X-114 (TX-114) was from Fluka (Madrid, Spain). Bovine serum albumin (BSA), Bradford reagent, acrylamide, bis-acrylamide, *N,N,N′,N′*-tetramethylethylenediamine, ammonium persulfate, and silver stain chemicals were obtained from Bio-Rad (Madrid, Spain). PNP butyrate, ascorbic acid, and molecular weight markers were from Sigma (Madrid, Spain). Octaethylene glycol monododecyl ether ($C_{12}E_8$) was a product from Fluka. All other chemicals were of analytical grade.

*Enzyme extraction.* After removing the peel and eyes, the potatoes (200 g) were chopped ($1 \times 1 \times 5$ cm, approximately) and homogenized with 200 mL of cold 200 mM acetate buffer pH 4.0, 20 mM EDTA, 6% (wt/vol) Triton X-114. Ascorbic acid (5 mM) was also used as an additional measure.

The homogenate was filtered through four layers of cheesecloth and kept at 4°C for 90 min to allow the precipitation of starch grains. It was then centrifuged at $100,000 \times g$ for 30 min at 4ºC. The supernatant was collected, and the concentration of TX-114 was increased by an additional 4% (wt/vol) and kept at 4°C for 15 min. This was then subjected to temperature-induced phase partitioning by warming to 35°C for 15 min (17).

The solution was then centrifuged at $10,000 \times g$ for 15 min at 25°C. The detergent-rich phase was discarded, and the clean supernatant containing patatin was collected. This solution, referred to as crude fraction, represents the starting material.

The supernatant was brought to 30% saturation with solid ammonium sulfate under continuous stirring at 4°C. After 1 h, this was centrifuged at $120,000 \times g$ for 30 min and the pellet was discarded. The ammonium sulfate concentration of the supernatant was increased to 60% and again stirred for 1 h at 4°C and centrifuged. The precipitate, which contained all the patatin lipid acylesterase activity, was redissolved in 10 mL of 10 mM phosphate buffer, pH 7.0, and dialyzed against the same buffer overnight to remove the ammonium sulfate.

*Anion exchange chromatography.* Aliquots (0.4 mL) of the enzyme extract following salt fractionation treatment were loaded onto a 1-mL Resource-Q column connected to an Äkta purifier (Pharmacia Biotech; Barcelona, Spain). The chromatography was run by the Buffer Prep method, which allows a buffer of any pH and salt concentration to be prepared on-line from four stock solutions. These four solutions were $A_1$: 0.1 M Tris; $A_2$: 0.1 M HCl; $B_1$: $H_2O$; and $B_2$: 2 M NaCl. Patatin was eluted from the column with a NaCl gradient from 0 to 1 M NaCl at 1.5 mL/min. To routinely determine LAH activity in all the collected fractions (2 mL), the assay used was that of Racusen (13), except that 2.6 mM PNP butyrate instead of PNP laurate was used as substrate.

*Affinity chromatography.* The fractions from anion exchange chromatography containing the highest esterase activity were pooled and concentrated. Aliquots of 0.2 mL were loaded onto a 1-mL HiTrap Concanavalin A column (Pharmacia Biotech) equilibrated with 20 mM Tris-HCl, 0.5 M NaCl, 1 mM $MnCl_2$, and 1 mM $CaCl_2$, pH 7.4, at 0.2 mL/min. Patatin was eluted from the column by a linear gradient of methyl-α-D-glucopyranoside (0–1 M) in the same buffer. Fractions (1 mL) with the highest level of LAH activity (determined as described above) were pooled, concentrated, and either used immediately or stored at –80°C.

*Protein determination.* Protein concentration was determined according to Bradford's dye-binding method (18) using BSA as a standard.

*Electrophoresis.* Sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis of purified proteins was run on a 12% acrylamide mini-slab according to Laemmli's method (19). Protein samples were diluted (1:4) in a denaturing sample buffer containing SDS and β-mercaptoethanol and heated at 95°C for 4 min. The gel was run at 200 V for approximately 45 min. Proteins were visualized by silver staining with a Bio-Rad kit, according to the recommended protocol. The SDS gels were scanned using micron image processing (MIP4) from Digital Image Systems (Madrid, Spain).

*Preparation of $C_{12}E_8$/PNP butyrate mixed micelles.* Mixed micelles were prepared by dissolving the detergent in 0.1 M Tris-HCl buffer, pH 8, followed by addition of the substrate, PNP butyrate dissolved in absolute ethanol. In all preparations, the final concentration of ethanol was 1% (vol/vol).

*Mixed micellar assay for lipid acylesterase activity of patatin.* Lipid acylesterase activity was assayed at 25°C by monitoring the increase in absorbance of the forming *p*-nitrophenol in a Kontron Uvikon 940 spectrophotometer at 410 nm. The reaction was started by adding 10 μL of purified patatin to 1 mL of mixed micelle preparation.

## RESULTS AND DISCUSSION

*Enzyme isolation and purification.* Patatin was extracted and purified from potato tubers (*S. tuberosum* L. cv. Spunta) as described in the Experimental Procedures section. The purifi-

**Purification of Patatin from Potato Tuber**

| | Total protein (mg) | Total activity[a] (units) | Specific activity (units/mg) | Purification (fold) | Recovery (%) |
|---|---|---|---|---|---|
| Crude extract | 187 | 935 | 5 | 1 | 100 |
| 30–60% ammonium sulfate | 104 | 755 | 7.3 | 1.5 | 81 |
| Anion exchange chromatography | 34 | 462 | 13.6 | 2.7 | 50 |
| Affinity chromatography | 17 | 231 | 13.6 | 2.7 | 25 |

[a]Lipid acyl hydrolase activity was determined by the assay of Racusen (13), except that 2.6 mM *p*-nitrophenyl-butyrate was used as substrate.

cation stages used in the present work are summarized in Table 1. Eighty-one percent of the LAH activity of potato tubers was recovered in the 30–60% ammonium sulfate fraction. This step increased the specific activity 1.5- fold. These results were similar to those reported by Bohac (14), who obtained a 1.3-fold increase in specific activity in the 40–70% ammonium sulfate fraction from *S. tuberosum* L. cv. Superior. As Table 1 shows, there was no increase in specific activity with the additional affinity chromatographic step. The specific activity value obtained was higher than that obtained by other authors (13,14). The purification achieved in both chromatographic steps was also the same (2.7-fold), although the recovery decreased by up to 25% with the additional step. An estimate of esterase protein as a fraction of all soluble protein can be obtained by dividing the specific activity of the enzyme in the patatin fraction by its specific activity in the homogenate. Thus, 5 U/mg divided by 13.6 U/mg equals 0.37, or 37%, which is about the same as the percentage of patatin in the soluble fraction, as determined here and in earlier studies (13,20).

SDS electrophoresis revealed the purity of the enzyme fractions obtained from the different purification stages (Fig. 1). Samples subjected to anion exchange chromatography (lane 2) and to sequential anion exchange and affinity chromatography (lane 3) showed a very similar protein pattern. Apparently no further purification was achieved when the enzyme was subjected to an additional chromatographic step. This agrees with the results in Table 1, because both enzyme fractions showed the same specific activity. A closely spaced double zone was made visible by silver staining. The presence of these two patatin zones was already described by Racusen and Racusen (21), who reported the existence of two types of patatin (the low- and high-carbohydrate forms) in tuber extracts from the potato species *S. berthaultii*. The heterogeneity of patatin due to different glycosylation states is widely referenced in the bibliography (12,22–24).

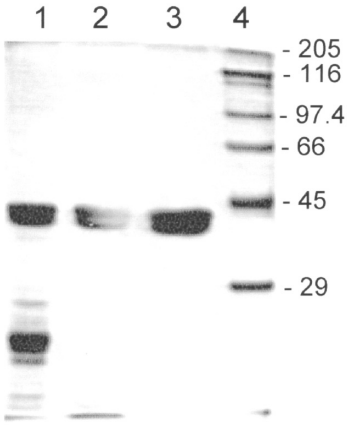

**FIG. 1.** Sequential extracts of protein purification on 12% sodium dodecyl sulfate polyacrylamide gel electrophoresis, visualized with silver staining. (Lane 1) Total crude extract; (lane 2) extract from Resource-Q column; (lane 3) extract from HiTrap Con A column; (lane 4) molecular weight markers with mass indicated in kDa. Each lane contained 10 µg of protein.

The enzyme used in the kinetic experiments described below was purified up to the anion exchange chromatography step; the recovery was twice that obtained after the affinity chromatography stage (50%), and the specific activity was the same (13.6 U/mg).

*$C_{12}E_8$-based mixed micellar assay for patatin esterase activity—characteristics of the detergent.* To measure enzyme activity by a mixed micellar assay, the choice of the detergent is the first consideration, because not every surfactant may be useful. For example, the surfactant must not inhibit, inactivate, or activate the enzyme. Detergents such as SDS and Triton X-100 have been described as stimulating patatin LAH activity (11,13). A choice must also be made on the basis of the aggregation behavior of the surfactant. Although the detergent critical micellar concentration (CMC) value is flexible, it should be low. A high aggregation number ($N_{ag}$) is preferable to a low number, but it is important that both the CMC and the $N_{ag}$ are experimentally known and stable under the working conditions.

The mixed micellar system is characterized by the percentage concentration of lipid with respect to the concentration of aggregated surfactant,

$$\text{mol\%} = \frac{[\text{lipid}]}{[\text{detergent}] - \text{CMC}} \times 100, \quad [1]$$

and by the number of lipid molecules per micellar aggregate ($N_{lpm}$),

$$N_{lpm} = \frac{N_{ag} \times \text{mol\%}}{100} \quad [2]$$

A surfactant that fulfils all the preceding requirements and that is commercially available in a very pure state is $C_{12}E_8$ (CMC = 0.11 mM, $N_{ag}$ = 120–123 monomers/micelle determined between 15 and 25°C in 0.1 M NaCl) (15). According to Equations 1 and 2, 1 mol% of lipid corresponds to 1 lipid molecule per 100 $C_{12}E_8$ aggregated molecules. For instance,

in 3.11 mM $C_{12}E_8$ there are (3.11 – 0.11) = 3 mM aggregated $C_{12}E_8$ and thus 3/121.5 = 0.025 mM micelles, each containing 1.21 lipids per molecule on average.

*pH optimum.* In order to characterize patatin esterase activity in this mixed micellar assay, the effect of pH was analyzed. As shown in Figure 2, the activity varied with the pH, the optimal value being 8. This optimal pH was similar to that reported to measure esterase activity in systems using Triton X-100 and SDS as detergents (5,13,14). At acid pH values there was no detectable activity according to studies carried out on the structural stability of patatin. In a study of the pH dependence of patatin stability and conformation, Pots *et al.* (25) showed that patatin unfolds following heat or very acidic pH treatment and that, below pH 4, the tertiary stabilization of patatin decreases.

A slow rate of enzyme-independent PNP butyrate hydrolysis was observed at alkaline pH values. At pH = 8, this rate was 4% of the PNP butyrate hydrolysis in the presence of the enzyme; however, at pH = 8.5, the enzyme-independent hydrolysis was much higher, up to 18% of the enzymatic hydrolysis rate. This enzyme-independent hydrolysis rate was deducted from the patatin hydrolysis activity determined experimentally.

*Response of patatin esterase activity to the mixed micelles.* The aim of an enzymatic assay based on a mixed micellar system is to homogeneously supply a hydrophobic substrate to an enzyme able to act on it. In such a system, the variables that depend on substrate concentration and that affect the reaction rate can be controlled in a precise way (16).

The mixed micellar assay should satisfy two criteria: (i) dependence of the enzymatic activity on the mole fractions of the substrate and (ii) independence of the enzymatic activity from micelle concentration at fixed mole fractions of substrate (26). As can be seen in Figure 3, both criteria are satisfied by patatin esterase activity acting on $C_{12}E_8$/PNP butyrate mixed micelles: on the one hand, the enzyme shows no response to the overall substrate concentration but responds to the surface concentration (represented by the mole fraction); on the other hand, patatin esterase activity is independent of surfactant concentration at a fixed substrate mole fraction. For example, the overall PNP butyrate concentration at 20 mol% PNP butyrate in 4 mM $C_{12}E_8$ is half that in 8 mM $C_{12}E_8$, although the enzyme activity is the same. If there were any inhibition or inactivation, the activity would not be independent of surfactant concentration at a fixed substrate mole fraction. It might also be thought that the enzyme is already saturated in 4 mM $C_{12}E_8$ at 20 mol%, but this is not the case because an increase in substrate concentration from 20 to 40 mol% brings about a further increase in enzyme activity.

A simple explanation of these results is that the available concentration of substrate is not the overall concentration but that displayed at the surface of the mixed micelles. The constancy of the reaction rate when the mixed micelle concentration is changed confirms the hypothesis that the enzyme "feels" the amount of substrate by reference to the surface area and not the volume unit.

The usefulness of the mixed micellar assay has been demonstrated in the case of diglyceride kinase in octylglucoside/diacylglycerol mixed micelles (27). It has also proved reliable with other enzymes that act or depend on lipids, such as cholinephosphotransferase in Triton X-100/diacylglycerol/phosphatidylcholine (9) and sodium cholate/diacylglycerol (28) and glycerol-3-phosphate acyltransferase in $C_{12}E_8$/palmitoyl-CoA/car-

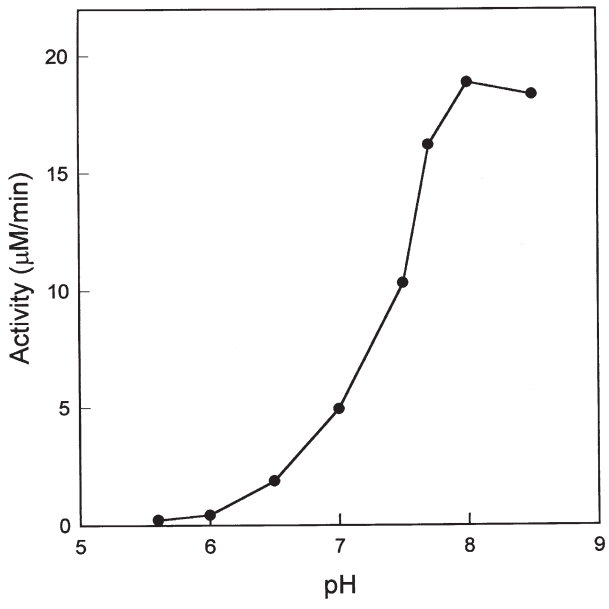

**FIG. 2.** pH response curve for lipolytic acyl-hydrolase activity in 5 mM octaethylene glycol monododecyl ether ($C_{12}E_8$)/*p*-nitrophenyl-(PNP) butyrate mixed micelles. The assay medium contained 50 mol% PNP butyrate in 0.1 M sodium phosphate buffer (pH values 5.6–7.5) or 0.1 M Tris-HCl buffer (pH 7.7–8.5). The reaction was started by the addition of purified patatin (11.5 μg/mL).

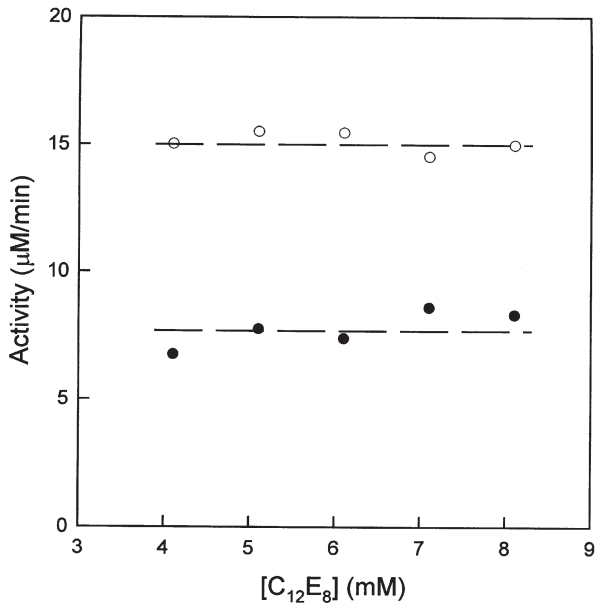

**FIG. 3.** Effect of $C_{12}E_8$ concentration on patatin lipid acyl hydrolase activity at fixed PNP butyrate mol%, (●) 20 mol% and (○) 40 mol%, in 0.1 M Tris-HCl buffer, pH 8, at 25°C. The reaction was started by the addition of purified patatin (11.5 μg/mL). For abbreviations see Figure 2.

diolipin (29). By using $C_{12}E_8$/linoleic acid, a mixed micellar assay for lipoxygenase activity was designed (16).

According to the results presented in Figure 3, the mixed micellar assay can be applied to enzymological studies of patatin esterase activity.

*Dependence of the patatin esterase activity on the substrate concentration. Evaluation of kinetic constants.* The effective substrate concentration for patatin esterase activity is that referring to the aggregated surfactant concentration expressed as mol%; therefore, we studied the dependence of enzyme activity on substrate concentration (Fig. 4). As can be seen, the enzyme showed cooperativity. The sigmoidal curves obtained at different bulk $C_{12}E_8$ concentrations were practically coincident. By fitting the data to the Hill equation, the corresponding kinetic parameters were evaluated. The results summarized in Table 2 show that $V_{max}$ was independent of surfactant concentration in every case, whereas $K_m$ varied proportionally to surfactant concentration when overall substrate concentration was taken into account ($K_m$ expressed in mol%), again demonstrating the surface dependence of the reaction. We can go further in the determination of $K_m$ by taking into account the absolute number expressed by the number of lipids per micelle ($N_{lpm}$). Since the substrate-containing surface forms discrete micelle units with a defined $N_{ag}$, the number of substrate molecules present in each micelle at each mol% of substrate can be evaluated. Through a simple calculation, it can be determined that at a $K_m$ value of 25.9 mol%, there are about 31 molecules per micelle.

To our knowledge, there are very few data concerning the evaluation of kinetic parameters for patatin esterase activity.

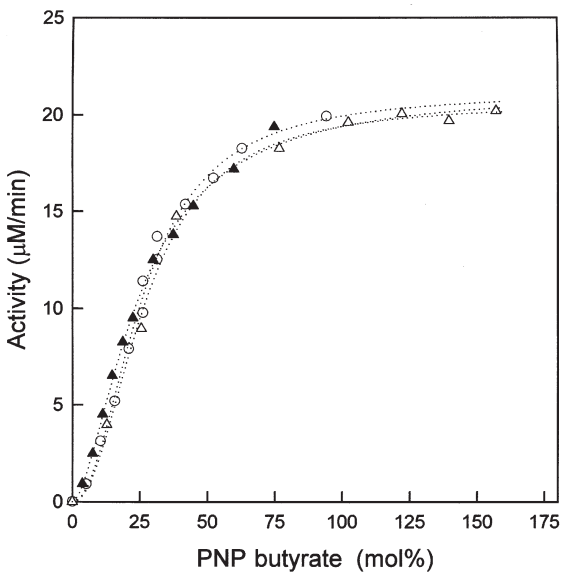

**FIG. 4.** Substrate concentration curves for patatin esterase activity at different bulk $C_{12}E_8$ concentrations, (△) 4 mM, (O) 5 mM, and (▲) 7 mM, in 0.1 M Tris-HCl buffer, pH 8. Enzyme concentration = 11.5 μg/mL. PNP butyrate surface concentration was expressed as mol% {= [PNP-butyrate]·100/([detergent] – critical micellar concentration)}. According to this expression, when mol% = 100, there is 1 molecule of PNP butyrate per 1 molecule of detergent.

**TABLE 2**
**Kinetic Constants of Patatin Lipid Acylesterase Activity in $C_{12}E_8$/*p*-Nitrophenyl-Butyrate Mixed Micelles, Evaluated at Different Bulk $C_{12}E_8$ Concentrations[a]**

| $C_{12}E_8$ (mM) | $V_{max}$ (μM/min) | $n_h$ | $K_m$ (mol%) | $K_m$ (mM) | $K_m$ ($N_{lpm}$) |

[a]$C_{12}E_8$, octaethylene glycol monododecyl ether.

Earlier attempts to determine the $K_m$ for patatin esterase activity used Triton X-100 as dispersing agent, yielding values of 0.5 and 0.7 mM with PNP palmitate and PNP stearate, respectively, as substrates in potassium phosphate buffer pH 7.5 (12). In those experimental conditions, the LAH enzyme activity was inhibited by high substrate concentrations. When 1% Triton X-100 and 0.017% SDS were used as detergents, the $K_m$ value for the substrate PNP laurate was 0.1 mM (14). As we have demonstrated that the patatin esterase reaction depends on the surface concentration of the substrate, the above-mentioned results as determined by volume unit in Triton X-100 or in Triton X-100 and SDS may be meaningless, especially if they were determined at one particular surfactant concentration.

In this work, patatin was extracted and purified from *S. tuberosum* L. cv. Spunta potato tubers. Although all tested potato cultivars and species have patatin, the total amount they contain as well as the esterase activity they show with specific substrates differs among cultivars. We used the cultivar Spunta, a variety that has not been previously used as enzyme source. The three-step purification procedure described here resulted in a 2.7-fold increase in esterase specific activity. This increase was similar to that obtained by Racusen (13). Since patatin has been estimated to be 30–40% of the total soluble tuber protein, the maximum purification can only be 3–4 times that of the crude extract. Hasson *et al.* (30) and Bohac (14) reported a 25- and 21-fold increase, respectively, in esterase specific activity; this greater increase in specific activity was attributed to the removal of an inhibitor or to a change in protein conformation.

This paper also demonstrates the applicability of a procedure that uses the nonionic detergent $C_{12}E_8$ for measuring patatin esterase activity. This mixed micellar system is superior to the assays that use Triton X-100 and SDS as surfactants because it allows the determination of the kinetic parameter $K_m$ independently of detergent concentration and, furthermore, does not affect enzyme activity.

# *Trans*- and *cis*-Octadecenoic Acid Isomers in the Hump and Milk Lipids from *Camelus dromedarius*

**Robert L. Wolff[a,*], Dietz Precht[b], Boubker Nasser[c], and M'hamed Said El Kebbaj[c]**

[a]ISTAB, Université Bordeaux 1, Talence, France, [b]Bundesanstalt für Milchforschung, Kiel, Germany, and [c]Faculté des Sciences Aïn Chock, Université Hassan II, Casablanca, Morocco

**ABSTRACT**: The distribution profiles of individual *trans*- as well as *cis*-18:1 isomers from the fat prepared from the hump adipose tissue and the milk from *Camelus dromedarius* (the single-humped Arabian species) are described. Gas–liquid chromatography on two capillary columns with different polarities and lengths were used for this purpose in combination with argentation thin-layer chromatography. A comparison of the profiles established is made with that of true ruminant fats. In the fats from the dromedarius as well as from true ruminants, the *trans*-18:1 isomers have their ethylenic bonds in all positions between Δ4 and Δ16. The prominent *trans* isomer is the 11-18:1 (vaccenic) acid in all species, and the complete distribution profiles are quite similar. Concerning the *cis* isomers, the prominent isomer is oleic acid, followed by *cis*-vaccenic acid, as in true ruminant fats. Other *cis* isomers encompass the Δ6-8 and the Δ12 to Δ15 isomers. Camelidae (suborder *Tylopoda*) and Bovidae (suborder *Ruminantia*) have evolved independently since the Eocene, that is for approximately 50 million years. Despite this considerable period, and the profound differences in anatomy, morphology, physiology, ecological and dietary habits between the extant species of these suborders, the rumen microflora has continued to synthesize the same *trans*- and *cis*-octadecenoic acid isomers, in comparable proportions, at least as deduced from their composition profiles. We conclude that the *trans*-18:1 acid profile is not intrinsically species-dependent, but it can be affected by the nature and the proportions of dietary unsaturated fatty acids that themselves depend on the feed, and that may be species-specific.

Paper no. L8794 in *Lipids 36,* 1175–1178 (October 2001).

Among artiodactyls, true ruminants, or Ruminantia, and Tylopoda, with the single family Camelidae, have a multi-compartmentalized stomach. In species from the first suborder, the stomach encompasses the rumen, the reticulum, the omassum, and the abomassum. The omassum is lacking, however, in Tylopoda. The rumen microflora is well known to lipid researchers for its biohydrogenation activity on dietary polyunsaturated fatty acids. The acids transform into stearic acid, leading in particular to a great number of intermediary metabolites with *trans* ethylenic bonds that are absorbed and appear in organ lipids, adipose tissues, and milk fat. The main intermediates found in ruminant fats are *trans*-octadecenoic acids, though many other minor *cis*-octadecenoic acids and geometrical and positional isomers of hexadecenoic and octadecadienoic acids also are present.

Among true ruminants, the *trans*-octadecenoic acid distribution profile in triacylglycerols is rather well documented (1), though mostly limited to a few common Bovidae, *Bos taurus* in particular, and to a lesser extent, to *Ovis* and *Capra*. Most data relate to milk because of its economical and dietary importance. Sketchy data on total *trans*-18:1 acids also are available for the meat from *Bison bison* (buffalo) and *Rangifer tarandus* (reindeer) (1) and on total *trans*-unsaturated acids for the fat from some Cervidae, e.g., *Dama dama* (fallow deer) and *Cervus unicolor* (sambur) (2).

A perusal of the available literature shows that no Tylopoda species have yet been examined with regard to the presence of *trans*-fatty acids in their tissues, and therefore their distribution profiles are unknown. This suborder presents only two genera, *Camelus* and *Lama*. Ruminantia and Tylopoda were quite well differentiated during the Eocene (*ca.* 50 million years), and their evolution was mostly accomplished in distinct geographical areas (New World and Old World, respectively). It was thus interesting to investigate the *trans*-fatty acid profile in lipids of a Tylopoda species, and we chose *Camelus dromedarius* from North Africa. We report here on the *trans*- and *cis*-octadecenoic acid profiles of lipids from hump adipose tissue and milk of this species. A comparison between lipids from the dromedarius and true ruminants shows that there are no gross differences between the two suborders Tylopoda and Ruminantia, thus excluding any effect of the species on the *trans*-octadecenoic acid profile.

## EXPERIMENTAL PROCEDURES

*Samples and standards.* Fatty tissues from the humps of six animals were obtained from a slaughterhouse in South Morocco immediately after the animals were killed. The milk was obtained from three lactating females. The tissues were transported to the laboratory at 4°C. Hump adipose tissue and milk samples were frozen at –30°C until analyzed.

*Fat extraction.* Fat was extracted from each individual sample mainly according to Folch *et al.* (3). Representative portions of the adipose tissue were minced with scisors and homogenized in methanol with an Ultra-Turrax T25 (Janke & Kunkel GmbH & Co. KG, Staufen, Germany) before adding chloroform and performing a second dispersion with the

Abbreviations: Ag-TLC, argentation thin-layer chromatography, FAME, fatty acid methyl ester; GLC, gas–liquid chromatography.

Ultra-Turrax. Aliquots of milk were treated in the same manner. After removal of the solvents in a rotary evaporator at 45°C, the fat was weighed and transferred into 5-mL vials and stored at 4°C until used.

*Fatty acid methyl ester (FAME) preparation*. FAME were prepared by vigorously shaking for 1 min a mixture of 3 mL hexane, 1 droplet of melted fat, and 300 µL of a 0.5 N sodium methoxide solution in methanol. After centrifugation, the supernatant was directly used for gas–liquid chromatography (GLC) analysis. For argentation thin-layer chromatography (Ag-TLC), equal amounts of the six FAME solutions were mixed. Data reported here are thus for composite samples.

*Fractionation of FAME by Ag-TLC*. FAME were fractionated according to the number and geometry of double bonds by TLC on silica gel plates impregnated with $AgNO_3$. The plates were prepared by immersion in a 5% solution of $AgNO_3$ in acetonitrile as described by Wolff *et al.* (4). The developing solvent was the mixture hexane/diethyl ether (90:10, vol/vol). At the end of the chromatographic runs, the plates were briefly air-dried, lightly sprayed with a solution of 2′,7′-dichlorofluorescein, and viewed under ultraviolet light (234 nm). The *trans*- and *cis*-monoenoic acid bands were scraped off separately and eluted using a biphasic solvent system (4). The extracts from each fraction were dried under a light stream of $N_2$ and the residues were dissolved in an appropriate volume of *n*-heptane or hexane for further GLC analysis.

*Analysis of FAME by GLC*. The total fatty acid composition covering fatty acids in the range 4:0 to 24:0, including polyunsaturated fatty acids, was determined by GLC analysis of the methyl esters on a CP 9001 chromatograph (Chrompack, Middelburg, The Netherlands) equipped with a split injector (split ratio, 1:50) and a flame-ionization detector, using a 25-m capillary CP-Wax 58 CB column (0.25 mm i.d., 0.20 µm df; Chrompack). The operating conditions were as follows: $H_2$ as the carrier gas at an inlet pressure of 40 kPa; injector and detector temperature, 265°C; and oven program of 50°C for 1 min, then 5°C/min to 225°C, then 15 min isothermal, and finally 5°C/min to 260°C. Calibration of the individual fatty acids was achieved using a standard of methyl esters of all major fatty acids in bovine milk fat.

Analyses of the *cis*- and *trans*-18:1 isomers in total FAME as well as in 18:1 isomer fractions isolated by Ag-TLC were performed using a gas chromatograph CP 9000 (Chrompack) with a split injector, a flame-ionization detector, and a fused-silica capillary column (100 m × 0.25 mm i.d.) coated with 0.20 µm CP-Sil 88 (Chrompack) under the following conditions: $H_2$ as the carrier gas; injector temperature 255°C; and detector temperature 280°C. The unfractionated FAME were analyzed isothermally at 172°C with a column head pressure of 160 kPa (split ratio, 1:50). Monoenoic TLC fractions were analyzed isothermally at a lower temperature, 120°C, with a column head pressure of 220 kPa (split ratio, 1:25) (5). Under these conditions, elution of *cis*- as well as *trans*-18:1 isomers was achieved in approximately 3.5 h.

The calibration of positional isomers of *trans*-18:1 acids present in the *trans*-monoenoate fraction was achieved with the isomer *trans*-Δ11 18:1 that had been quantitated by stearic acid in the isothermal chromatography of the unfractionated FAME on the CP-Sil 88 column. Before, stearic acid was determined by total FAME analysis on the CP-Wax 58 CB column. Further, *cis*-18:1 isomers found in the *cis*-monoenoate fraction were calibrated by *cis* 9-18:1 acid that could be determined in the isothermal chromatogram of unfractionated FAME (5).

Identification of individual isomeric *trans* octadecenoates was achieved by comparison of retention times with FAME standards of the 18:1 isomers Δ6, Δ7, Δ9, Δ11, Δ12, Δ13, and Δ15 (Sigma, St. Louis, MO). *Trans*-18:1 acids isolated from butterfat were used as a secondary standard (6). Integration and quantitation were accomplished with an HP 3365 II ChemStation system (Hewlett-Packard, Palo Alto, PA). Calibration of GLC data included the conversion from FAME to free fatty acids. Thus, results expressing absolute concentrations are given as g/100 g of total fatty acids.

## RESULTS AND DISCUSSION

Quantitative data for the absolute amounts of *trans*- and *cis*-18:1 acid isomers are displayed in Table 1. Total *trans*-18:1 isomer content in hump fat (5.5%) is not significantly different from that found in beef tallow (range, 3.6–6.2%) (7). This also holds for milk fat (4.0%). It resembles that of cow milk fat during pasture feeding (4.3%) (1). The percentages of each individual isomer relative to their respective totals are described as bar graphs in Figure 1. There are no gross differences between either *cis*- or *trans*-18:1 isomers in milk and hump lipids, which would indicate that there are no discriminations in the deposition of 18:1 isomers between adipose tissue and milk fats.

[a]*t, trans; c, cis.*

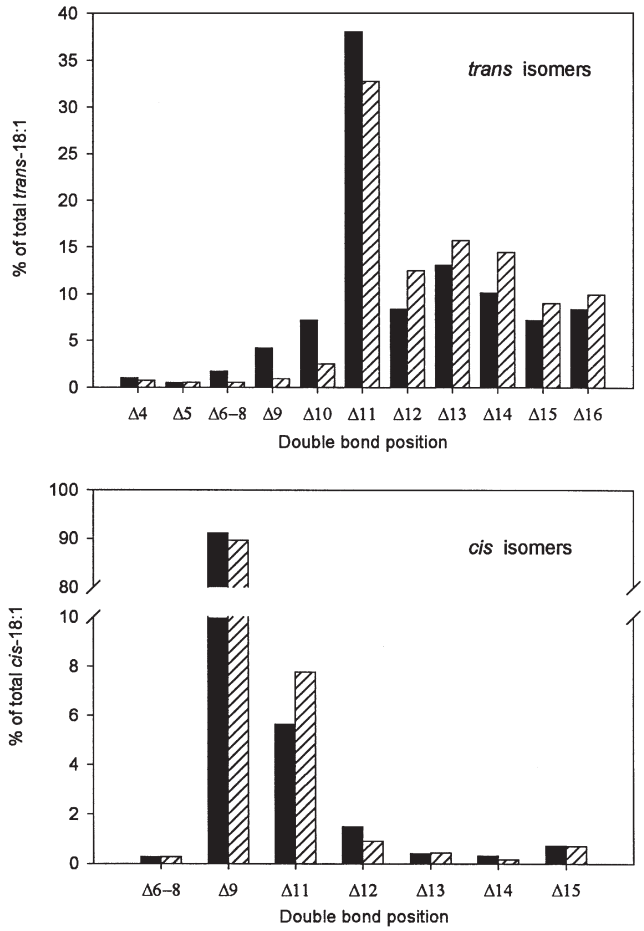

**FIG. 1.** Relative *trans*- and *cis*-18:1 isomeric profile derived from fat of dromedarius milk (black bars) and hump (hatched bars) fat.

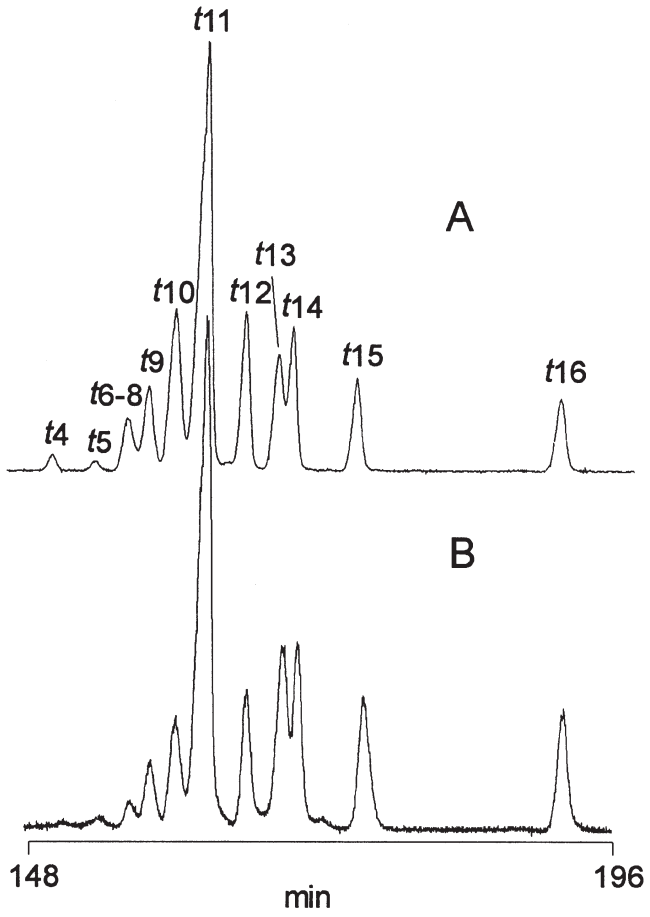

**FIG. 2.** Partial chromatograms of *trans*-18:1 acid methyl esters isolated by argentation thin-layer chromatography from dromedarius (A) and bovine (B) milk fat (see text for analytical conditions).

As found in beef tallow, meat, or milk; ewe milk or sheep meat; and goat milk (1,5), the ethylenic bonds in *trans*-octadecenoic isomers span from position Δ4 to Δ16 in dromedarius hump and milk fats. The major isomer is *trans*-11 18:1 (vaccenic) acid: 33% of total *trans*-18:1 isomers is in hump fat and 38% in milk fat. From comparison of data displayed in Table 1 with data for true ruminants (1,5), it is apparent that no gross differences exist between true ruminants and dromedarius fats, an observation that can be made by simple visual observation of the chromatograms in Figure 2. It is worthwhile to note that the *trans*-Δ16 isomer content, the latest-eluting component of *trans*-18:1 isomers, and possibly derived from dietary α-linolenic acid, is similar for the milk of dromedarius (8.4%) and other ruminants (7–10% of total *trans*-18:1 acids) (1). Also, it should be emphasized that the *trans*-18:1 acid isomer profile is also variable in bovine milk, though the general patterns remain generally comparable (1,5), provided no experimental dietary manipulations are made. The same observations can be made for *cis*-18:1 isomers.

Despite the fact that the dromedarius is not a true ruminant, biohydrogenation by its rumen microflora leads to the same *trans*- and *cis*-18:1 isomers in approximately the same proportions as in true ruminants (e.g., cattle). Thus, it can be deduced that the microflora has undergone little or no evolution during the past 50 million years, whereas the animals themselves differ considerably.

An important point is that *trans*-fatty acids are not limited to ruminants among mammals. They were shown a long time ago—in 1955—also to occur in the depot fat from marsupials, the wallaby (*Thylogale eugene*) and the quokka (*Setonix brachyurus*), a member of the kangaroo family (2), in exceptionally high amounts (approximately 20% of total fatty acids). The latter species at least would have a ruminant-like digestion, as its stomach contains a microbial flora more or less resembling that of ruminants. The *trans*-18:1 as well as the *cis*-18:1 isomers have been characterized and their profiles determined in subcutaneous fat of the monogastric xylophage rodent *Castor canadensis* (Canadian beaver) (8). They were shown to be rather similar to those of bovine milk fat (9), with vaccenic acid being the prominent isomer among *trans*-18:1 isomers. Other isomers included the Δ9 to Δ16 positional isomers.

Though the aim of the present study was not to assess the rumenic (*cis*-9,*trans*-11 18:2) acid content of hump and milk fats, the following values were determined: hump, 0.51%; and milk, 0.74%. The value for hump fat is slightly lower than

for edible beef tallow [0.60–1.67% (7)], whereas the value for milk fat lies well within the range determined for cow milk fat, 0.10–1.89% (10). Other data for ruminant milk fats are limited to ewe and goat milk fats: 0.77–1.04%, and 0.27–0.69%, respectively (11). The beaver would also contain rumenic acid in its subcutaneous fat (8), but there are no data available for marsupials.

# Transforming Growth Factor Beta in Human Milk Does Not Change in Response to Modest Intakes of Docosahexaenoic Acid

**J.S. Hawkes[a], D-L. Bryan[b], M.A. Neumann[a], M. Makrides[c], and R.A. Gibson[a,*]**

[a]Child Nutrition Research Centre, Flinders Medical Centre, Bedford Park, South Australia 5042, [b]Department of Paediatrics and Child Health, Flinders University of South Australia, Bedford Park, South Australia 5042, and [c]Child Health Research Institute, North Adelaide, South Australia 5006, Australia

**ABSTRACT:** Long-chain polyunsaturated fatty acids have been associated with aspects of immune regulation including cytokine production. The purpose of this study was to investigate the effect of maternal dietary supplementation with tuna oil, rich in docosahexaenoic acid (DHA), on the concentration of transforming growth factor beta 1 (TGFβ1) and TGFβ2 in breast milk. In this randomized, dietary intervention trial, mothers of term infants consumed a daily supplement of 2000 mg oil containing either placebo ($n$ = 40), 300 mg DHA ($n$ = 40), or 600 mg DHA ($n$ = 40). The DHA increase in milk and plasma was proportional to dietary DHA. There was no relationship between milk DHA status and TGFβ1 and TGFβ2 levels.

Paper no. L8751 in *Lipids 36*, 1179–1181 (October 2001).

The cytokine family present in the largest amounts in human breast milk is transforming growth factor β (TGFβ), primarily represented by the isoforms TGFβ1 and TGFβ2 (1,2). The primary role of TGFβ in milk is thought to be immunosuppression, as TGFβ "knockout" mouse pups born to heterozygous mothers develop an excessive inflammatory response after weaning, leading to death at 3–5 wk of age (3,4). Other potentially relevant functions that may be of benefit to the breast-fed infant include stimulation of IgA isotype switching in B cells (5), maintenance of epithelial barrier function in the gut (6,7), and involvement in the induction of oral tolerance (8,9).

The inclusion of fish meals in the diet or the consumption of fish oil supplements, both rich in n-3 long-chain polyunsaturated fatty acids (LC-PUFA), leads to changes in tissue composition of n-6 and n-3 fatty acids, which in turn have been associated with immune regulation (10,11). There are conflicting data on the effect of changing the n-6/n-3 ratio on the production of TGFβ. Animal models of autoimmunity have shown that fish oil feeding is associated with significantly higher TGFβ mRNA expression and protein levels (12,13), whereas data obtained from experiments using the spontaneously hypertensive rat model describe a decrease in expression of TGFβ mRNA following supplementation with n-3 PUFA (14,15).

In this component of a larger randomized, dietary intervention trial (16), we examined the effect of supplementation with tuna oil, rich in the n-3 LCPUFA docosahexaenoic acid (DHA), on the concentration of TGFβ1 and TGFβ2 in milk from lactating women at 5 wk postpartum.

## SUBJECTS AND METHODS

One hundred twenty women, who had no history of inflammatory disorders, were not taking anti-inflammatory medication, and had delivered full-term singleton infants and intended to breast-feed, were enrolled in this double-blind, randomized, prospective study (16). The study was approved by the Flinders Clinical Research Ethics Committee, and written informed consent was obtained from all participants. Because primary outcome variables related to breast milk cytokines, women who ceased lactating by the time of sample collection were excluded. Mothers were randomly allocated to one of three groups assigned to take either (i) placebo ($n$ = 40), (ii) 300 mg DHA/d and 70 mg eicosapentaenoic acid (EPA)/d from tuna oil ($n$ = 40, LoDHA), or (iii) 600 mg DHA/d and 140 mg EPA/d from tuna oil ($n$ = 40, HiDHA). The placebo capsules (a highly monounsaturated sunflower seed oil) were identical in appearance to the tuna oil capsules and contained no DHA and no EPA. All capsules were provided by Clover Corporation Pty. Ltd. (Altona North, Victoria, Australia).

In the fourth week of the study mothers were asked to express a small sample (2 mL) of breast milk daily for 5 d. Samples were frozen and retained for fatty acid analysis as described elsewhere (16). At 5 wk postpartum (after 4 wk of dietary supplementation), a breast milk sample (30–50 mL) expressed on the morning of the appointment and peripheral blood (20 mL) were collected. The fresh 50-mL milk samples were centrifuged at 890 × $g$ for 30 min at 4°C, and the aqueous fraction was frozen at –80°C for later analysis of TGFβ1 and TGFβ2 using double antibody sandwich enzyme-linked immunosorbent assay (ELISA) as described previously (1). The limit of detection for each ELISA was 16 pg/mL, the intra-assay precision was 4%, and the interassay precision was 17%. Samples were analyzed in duplicate, and all analy-

Abbreviations: AA, arachidonic acid; ANOVA, analysis of variance; DHA, docosahexaenoic acid; ELISA, enzyme-linked immunosorbent assay; EPA, eicosapentaenoic acid; LC-PUFA, long-chain polyunsaturated fatty acid; TGFβ, transforming growth factor beta.

ses were completed within 3 mo of sample collection. Peripheral venous blood (1 mL) was placed into lithium heparin for separation of plasma and erythrocytes, and each component was retained for fatty acid analysis.

One-way analysis of variance (ANOVA) and *post-hoc* analysis by Newman-Keuls test were used to determine differences in plasma and breast milk fatty acids between diet groups. Because the distributions of the cytokine values were asymmetric, data were log-transformed, and significant differences between dietary groups were calculated by Kruskal-Wallis ANOVA. Data are expressed as medians (5th–95th percentiles) or as individual data points. Associations between fatty acid levels and cytokine concentration were tested using Spearman's rank correlation coefficient. All analyses were completed using SPSS for Windows 10.0 (SPSS Inc., Chicago, IL).

## RESULTS

Of those who were enrolled, 27/40 Placebo, 26/40 LoDHA, and 29/40 HiDHA were still breast-feeding their infants at the 5 wk appointment, and 93% of these mothers were providing >80% of feeds as breast-feeds. Peripheral blood (82/82) and breast milk (81/82 samples for fatty acid analysis and 80/82 fresh samples) were collected from lactating mothers on day 35 (33.6–36.1) (mean, 95% confidence interval). All 50-mL expressions were completed in the morning, and a majority of mothers expressed before a feed (67%) and from a single breast only (62%).

Compliance with the dietary intervention was confirmed by significant increases in n-3 PUFA (16). DHA increased in plasma and milk in a linear manner in response to dietary DHA whereas EPA concentration increased at the highest intake only (HiDHA, 600 mg DHA + 140 mg EPA/d). Tuna oil consumption caused a marginal decrease in plasma arachidonic acid (AA) levels, but changes were not significant in milk.

TGFβ1 and TGFβ2 were detected in all samples collected in the study. There was a wide range of concentrations in each dietary group with TGFβ2 present in two- to threefold higher amounts than TGFβ1 (Table 1). There was no difference in mean rank concentration between the dietary groups for either of the cytokines measured. In addition, there were no correlations between human milk DHA (Fig. 1), EPA, or n-3 PUFA and cytokine concentrations; however, there was a positive correlation between the two isoforms of TGFβ in the aqueous phase of human milk ($r = 0.51$, $P < 0.001$).

## DISCUSSION

Very few human studies have reported the effects of dietary LCPUFA on TGFβ production, a known immunomodulatory cytokine present in high concentrations in human milk throughout lactation. Consumption of n-3 PUFA results in decreased AA levels in cell membranes and increased levels of EPA and DHA, fatty acids that competitively inhibit the conversion of AA to its metabolites, such as prostaglandin $E_2$ and leukotriene $B_4$ (10,17). One mechanism by which n-3 fatty acids may act is suggested by studies that have shown that different chemical inhibitors of AA metabolism can potentiate the effects of TGFβ1 on cellular differentiation and proliferation (18,19). Thus it is possible that a lack of some AA-derived eicosanoids modulates TGFβ effects.

In this study, we could not detect a difference in human milk TGFβ concentration at 5 wk postpartum despite increasing

milk and plasma DHA and, to a lesser extent, EPA levels following dietary supplementation with tuna oil. At this level of supplementation, there was no change in the concentration of AA in human milk. Tuna oil is rich in DHA (~30%) but contains little EPA (~6%) and it may be the latter fatty acid that plays a key role in the regulation of inflammatory mediators such as TGFβ. The wide range of concentrations of both isotypes of TGFβ detected in the milk samples collected in this study is comparable to that described in our previous study (1). Given this, and the relatively low doses of DHA and EPA in the supplement, it is not surprising that we were unable to detect any effects of diet on the cytokines in question, should they exist.

A number of commercial nutritional supplements are designed to meet the needs of pregnant and lactating women for additional n-3 PUFA as recommended by at least one nutrition committee (20). The appearance of specific supplements such as these and increasing community awareness of the benefits of including fish in the diet will result in lactating mothers choosing to increase their n-3 PUFA intake. The levels of human milk DHA described in this study cover the range expected in mothers following healthy diets that include fish. The results of this study suggest that the consumption of moderate doses of DHA (equivalent to consuming 4–5 meals of salmon per week), although increasing DHA, does not appear to cause changes in the level of TGFβ1 and TGFβ2 in human milk.

## ACKNOWLEDGMENTS

We thank Glenda Dandy, Jo Collins, Jenny Osmond, Jane Armstrong, Robyn Polman, Lyn Pullen, and Ela Zielinski for administrative and technical support. We are grateful to the staff of the postnatal wards at FMC for their support in recruitment of mothers for the study. The study was supported by The Channel 7 Children's Research Foundation of South Australia and Clover Corporation Ltd., Sydney, Australia. Robert A. Gibson was partly supported by the MS McLeod Research Trust. M. Makrides was supported by an Applied Health Sciences National Health and Medical Research Council Fellowship.

**ABSTRACT:** Greatly increasing the amounts of flaxseed oil [rich in α-linolenic acid (ALNA)] or fish oil (FO); [rich in eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA)] in the diet can decrease inflammatory cell functions and so might impair host defense. The objective of this study was to determine the effect of dietary supplementation with moderate levels of ALNA, γ-linolenic acid (GLA), arachidonic acid (ARA), DHA, or FO on inflammatory cell numbers and functions and on circulating levels of soluble adhesion molecules. Healthy subjects aged 55 to 75 yr consumed nine capsules per day for 12 wk. The capsules contained placebo oil (an 80:20 mix of palm and sunflowerseed oils) or blends of placebo oil with oils rich in ALNA, GLA, ARA, or DHA or FO. Subjects in these groups consumed 2 g ALNA; approximately 700 mg GLA, ARA, or DHA; or 1 g EPA plus DHA (720 mg EPA + 280 mg DHA) daily from the capsules. Total fat intake from the capsules was 4 g per day. None of the treatments affected inflammatory cell numbers in the bloodstream; neutrophil and monocyte phagocytosis or respiratory burst in response to *E. coli*; production of tumor necrosis factor-α, interleukin-1β, and interleukin-6 in response to bacterial lipopolysaccharide; or plasma concentrations of soluble intercellular adhesion molecule-1. In contrast, the ALNA and FO treatments decreased the plasma concentrations of soluble vascular cell adhesion molecule-1 (16 and 28% decrease, respectively) and soluble E-selectin (23 and 17% decrease, respectively). It is concluded that, in contrast to previous reports using higher amounts of these fatty acids, a moderate increase in consumption of long-chain n-6 or n-3 polyunsaturated fatty acids does not significantly affect inflammatory cell numbers or neutrophil and monocyte responses in humans and so would not be expected to cause immune impairment. Furthermore, we conclude that moderate levels of ALNA and FO, which could be incorporated into the diet, can decrease some markers of endothelial activation and that this mechanism of action may contribute to the reported health benefits of n-3 fatty acids.

Paper no. L8763 in *Lipids 36*, 1183–1193 (November 2001).

Inflammatory cells such as neutrophils, monocytes, and macrophages form part of the innate immune response that is responsible for the early host response to invading bacteria (1). Bacterial cell wall components such as lipopolysaccharide (LPS) stimulate the production of cytokines by monocytes and macrophages. These cytokines include tumor necrosis factor (TNF)-α, interleukin (IL)-1, and IL-6, which act to induce upregulation of adhesion molecules on vascular endothelial cells, so facilitating the adhesion of neutrophils and monocytes at the sites of infection, which is followed by migration, local accumulation, and activation of inflammatory cells (1). The inflammatory cells recognize bacteria in a nonspecific way and act to destroy them by phagocytosis and/or by production of superoxide and related reactive oxygen species (1). This production of reactive oxygen species is referred to as respiratory burst. The inflammatory cytokines also provide one link between inflammatory cells and specific immunity because they can stimulate T and B lymphocytes (1). Among the adhesion molecules upregulated on the endothelial cell surface in response to cytokines and other inflammatory stimuli, such as LPS and reactive oxygen species, are vascular cell adhesion molecule-1 (VCAM-1), E-selectin, and intercellular adhesion molecule-1 (ICAM-1), although the latter is also expressed on monocytes, macrophages, and lymphocytes (2). These adhesion molecules can be shed from the cell surface and appear in the circulation as soluble forms (sVCAM-1, sE-selection, and sICAM-1, respectively) (2). The plasma concentrations of these molecules are elevated during inflammatory conditions (2), increase with age (3–5), are higher in individuals with cardiovascular disease (3,5,6), and are predictive of future myocardial infarction (7).

Abbreviations: ALNA, α-linolenic acid; ANOVA, analysis of variance; ARA, arachidonic acid; DGLA, di-homo-γ-linolenic acid; DHA, docosahexaenoic acid; ELISA, enzyme-linked immunosorbent assay; EPA, eicosapentaenoic acid; FACS, fluorescence-activated cell sorter; FITC, fluorescein isothiocyanate; FO, fish oil; GLA, γ-linolenic acid; ICAM, intercellular adhesion molecule; IL, interleukin; LPS, lipopolysaccharide; MFI, median fluorescence intensity; PBMC, peripheral blood mononuclear cell; PBS, phosphate-buffered saline; PUFA, polyunsaturated fatty acid; RPMI, Roswell Park Memorial Institute; s, soluble; TNF, tumor necrosis factor; VCAM, vascular cell adhesion molecule.

There is now much evidence that the activity of inflammatory cells and the expression of adhesion molecules can be influenced by the availability of various fatty acids; differential effects of n-6 and n-3 polyunsaturated fatty acids (PUFA) have been identified in cell culture studies. Linoleic acid (18:2n-6) and arachidonic acid (ARA; 20:4n-6) enhanced superoxide release from neutrophils and macrophages (8–11), whereas eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3) either inhibited superoxide production (12) or were less potent stimulators than ARA (11). ARA increased IL-1β production by a monocytic cell line (13) and by human monocytes (14). In contrast, EPA and DHA inhibited production of IL-1β and of TNF-α by human monocytes (14,15). EPA and DHA diminished expression of some adhesion molecules on the surface of cultured human endothelial cells (16–19), monocytes (20), and lymphocytes (17). The EPA- and DHA-induced decrease in adhesion molecule expression was accompanied by decreased binding of lymphocytes and monocytes to endothelial cells (17,18). In contrast, several n-6 PUFA [linoleic acid, γ-linolenic acid (GLA; 18:3n-6), di-homo-γ-linolenic acid (DGLA; 20:3n-6), and ARA] promoted neutrophil adhesion to endothelial cells (21). These studies suggest that ARA, and perhaps other n-6 PUFA, enhance inflammatory cell responses whereas the n-3 PUFA, EPA and DHA, diminish these responses. Animal feeding studies support the idea that n-3 PUFA diminish inflammatory cell responses. Feeding fish oil (FO), which contains EPA and DHA, to laboratory animals decreased superoxide production by neutrophils (22,23) and macrophages (24–26) and decreased hydrogen peroxide production by macrophages (25,27). FO feeding also decreased *ex vivo* production of TNF-α, IL-1β, and IL-6 by LPS-stimulated rodent macrophages (28–31) and monocytes (32).

A number of studies have investigated the influence of supplementing the diet of healthy human volunteers with encapsulated FO on inflammatory cell functions. FO decreased superoxide production by human neutrophils (33–35) and monocytes (36), and decreased neutrophil binding to endothelial cells (37). These studies provided between 3.1 and 9.6 g EPA plus DHA per day and were of 3 to 6 wk in duration. One study reported that increasing the amount of α-linolenic acid (ALNA; 18:3n-3) in the human diet to about 14 g per day for 4 wk resulted in a significant decrease in TNF-α and IL-1β production by LPS-stimulated mononuclear cells (38). Supplementation of the diet of healthy humans with FO providing between 2.4 and 5 g EPA plus DHA per day for 4 to 24 wk has been reported to decrease the production of TNF-α, IL-1β, and IL-6 by LPS-stimulated mononuclear cells (38–41).

Thus, there is a wealth of data from *in vitro*, animal feeding, and human supplementation studies that suggests that n-3 PUFA diminish inflammatory cell functions. There is also a limited amount of data, mainly from *in vitro* studies, that suggests that n-6 PUFA enhance inflammatory cell functions. Most often the idea that n-3 PUFA diminish inflammatory cell functions is interpreted in a favorable way, with the conclusion that n-3 PUFA are anti-inflammatory and so will be beneficial to health. However, because inflammatory cells are key components of the early host response to invading pathogens and because they produce mediators that promote the specific immune response, a reduction in inflammatory cell functions could compromise host defense. Indeed, compared with ARA, EPA and DHA decreased the ability of cultured murine macrophages to phagocytose (42), whereas dietary FO diminished rat macrophage phagocytosis (25).

There are recommendations to increase the intake of n-3 PUFA in adults because of their beneficial health effects, especially with respect to cardiovascular disease (43–45). However, the studies described above suggest that potentially detrimental immunological effects can occur at high n-3 PUFA intakes. Infants require ARA and DHA for optimal mental and visual development (46), and a case has been made to include these fatty acids in infant formulae. However, the immunological impact of these fatty acids in humans is not clear. Kelley *et al.* (47,48) reported that 6 g DHA per day for 12 wk decreased circulating granulocyte (and so total leukocyte) numbers and decreased the production of TNF-α and IL-1β by LPS-stimulated mononuclear cells from healthy adults, suggesting that a high level of this fatty acid diminishes some inflammatory cell numbers and responses. The same workers earlier demonstrated that 1.5 g ARA per day increased circulating granulocyte numbers (49).

As indicated previously, many of the studies in humans have been perfomed using large doses of n-3 PUFA (14 g ALNA or >2.4 g EPA plus DHA per day). The habitual intake of ALNA among adults in the United Kingdom is 1 to 2 g per day, whereas that of EPA plus DHA is <150 mg per day (44). Thus, the amounts of these fatty acids provided in the supplementation studies performed to date are greatly in excess of habitual intakes and greatly in excess of intakes that are recommended or that could be achieved in most individuals through dietary change. It is not clear what influence lower levels of these or other polyunsaturated fatty acids have on human inflammatory cell functions. Therefore, the current study investigated the effect of moderate supplementation of the diet of healthy subjects with encapsulated oil blends rich in ALNA, GLA, ARA, DHA, or EPA on circulating leukocyte numbers, *ex vivo* neutrophil and monocyte phagocytosis and respiratory burst, *ex vivo* production of inflammatory cytokines, and circulating levels of soluble adhesion molecules as an *in vivo* indicator of endothelial inflammation. The results presented here form part of a larger study, from which some findings have already been published (50,51).

## MATERIALS AND METHODS

*Materials.* Phosphate-buffered saline (PBS) tablets were obtained from Unipath Ltd. (Basingstoke, United Kingdom). Histopaque, bovine serum albumin (fatty acid-free), HEPES-buffered Roswell Park Memorial Institute (RPMI) medium, glutamine, antibiotics (penicillin and streptomycin), *Escherichia coli* 0111:B4 LPS, and propidium iodide were purchased

**TABLE 1**
**Characteristics of the Treatment Groups**

| Treatment[b] | Number of subjects | Males/females | No. of smokers | Age[a] (yr) | Body mass index[a] (kg/m$^2$) |
|---|---|---|---|---|---|
| Placebo | 8 | 5:3 | 1 | 62 (56–69) | 25.1 (21.3–29.7) |
| ALNA | 8 | 4:4 | 0 | 66 (60–74) | 25.5 (22.2–28.0) |

[a]Values for age and body mass index are mean values with ranges shown in parentheses.
[b]Abbreviations: ALNA, α-linolenic acid; ARA, arachidonic acid; DHA, docosahexaenoic acid; FO, fish oil; GLA, γ-linolenic acid.
[c]Excludes values for one female subject who dropped out during the study.

from Sigma Chemical Co. Ltd. (Poole, Dorset, United Kingdom). Fluorescein isothiocyanate (FITC)-labeled mouse antihuman CD45 (clone Immu19.2) in combination with phycoerythrin-labeled mouse antihuman CD14 (clone RMO52) was purchased from Coulter Corp. (Hialeah, FL). Fluorescence-activated cell sorter (FACS)–lysing solution was purchased from Becton Dickinson (Mountain View, CA). Kits for measurement of phagocytosis and respiratory burst in whole blood (PHAGOTEST® and BURSTTEST®, respectively) were purchased from Orpegen Pharma (Heidelberg, Germany). EASIA™ cytokine enzyme-linked immunosorbent assay (ELISA) kits and Cytoscreen™ sICAM-1 and sVCAM-1 ELISA kits were obtained from BioSource Europe SA (Nivelles, Belgium). Quantikine™ sE-selectin ELISA kits were obtained from R & D Systems Europe Ltd. (Abingdon, Oxon., United Kingdom).

*Subjects and study design.* Ethical permission for all procedures involving human volunteers was obtained from the Central Oxford Research Ethics Committee (COREC No. 96.182). All volunteers completed a health and lifestyle questionnaire prior to entering the study, and physician's consent for inclusion in the study was obtained. Volunteers were excluded if they were taking any prescribed medication; had diagnosed hypercholesterolemia, hypertriglyceridemia, coronary heart disease, diabetes, or a chronic inflammatory disease; took aspirin regularly; were vegetarian; consumed FO, evening primrose oil, or vitamin capsules; were blood donors; had undergone recent weight loss; or smoked more than 10 cigarettes per day. The characteristics of the 46 subjects who completed the study are given in Table 1; mean age and body mass index did not differ among the treatment groups. All subjects were Caucasian and free-living; all lived in their own homes and none was disabled or immobile in any way. All female subjects were postmenopausal and none was taking hormone-replacement therapy. None of the subjects participated in intense or vigorous exercise. Subject height was measured to the nearest millimeter and weight to the nearest kilogram.

Forty-eight subjects were randomly allocated to receive one of the six types of encapsulated oil blends in a double-blind fashion ($n$ = 8 per treatment group); these blends are referred to as placebo, ALNA, GLA, ARA, DHA, and FO. The placebo was an 80:20 mixture of palm and sunflowerseed oils (both supplied by Loders Croklaan, Wormerveer, The Netherlands). The fatty acid composition of this blend closely resembles the fatty acid composition of the average British diet (43). The ALNA blend was a 50:13:37 mixture of palm, sunflowerseed, and super refined flaxseed oils (flaxseed oil supplied by Loders Croklaan). The GLA blend was a 21:5:74 mixture of palm oil, sunflower seed oil, and a GLA-rich triacylglycerol (supplied by Scotia Pharmaceuticals, Stirling, United Kingdom). The ARA and DHA blends were 43:11:46 mixtures of palm oil, sunflower seed oil, and ARASCO® or DHASCO®, respectively (ARASCO® and DHASCO® supplied by Martek Corp., Columbia, MD). The FO used was a Chilean FO (supplied by Loders Croklaan) containing 26 g EPA plus DHA per 100 g total fatty acids. The fatty acid composition of the oil blends (determined by gas chromatography on total lipid extracts) is shown in Table 2. The capsules were gelatin-coated, nontransparent, and green colored. Each capsule contained 445 mg of the oil blend, and subjects con-

[a]g/100 g total fatty acids; EPA, eicosapentaenoic acid. For other abbreviations see Table 1.

sumed nine capsules per day (i.e., 4 g encapsulated oil per day) for 12 wk. Therefore, subjects in the ALNA group consumed an extra 2.0 g ALNA per day; subjects in the GLA, ARA, and DHA groups consumed an extra 700 mg (approximately) GLA, ARA, or DHA per day, respectively; and subjects in the FO group consumed an extra 1 g EPA plus DHA per day (720 mg EPA + 280 mg DHA). All capsules contained 300 μg α-tocopherol-equivalents plus 180 μg ascorbyl-palmitate per gram of oil. Thus, all subjects consumed an extra 1.2 mg α-tocopherol per day.

The capsules were provided to the subjects in blister packs (nine capsules per pack) with seven blister packs per box along with clear instructions of how they should be administered (three capsules three times daily immediately prior to breakfast, lunch, and dinner); during the supplementation period subjects received fresh blister packs of capsules every 4 wk.

Two female subjects dropped out of the study once it was underway, one from the GLA group, due to illness, and one from the FO group, due to inability to comply because of stomach upsets.

A supplementation period of 12 wk was selected because almost all previous studies that reported effects of dietary PUFA on human inflammatory cell numbers or functions were of a duration of 3 to 12 wk (33–41,47–49). Blood was sampled immediately prior to beginning supplementation, every 4 wk during supplementation, and after a 4-wk washout period. Throughout this manuscript week 0 represents the baseline measurements, weeks 4, 8, and 12 represent the supplementation period, and week 16 represents the end of the washout period. Blood samples were collected into heparinized vacutainer tubes between 0800 and 1000 after a fast of at least 12 h. All treatment groups completed the study in parallel. The study ran from June 1997 (early summer) to December 1997 (early winter).

Compliance was assessed biochemically by determining the fatty acid composition of plasma and mononuclear cell phospholipids (see 50,51).

*Analysis of leukocyte numbers and subpopulations.* Leukocyte numbers and subsets were analyzed in the blood samples collected at weeks 0 (baseline), 12 (end of supplementation), and 16 (washout).

To determine total leukocyte numbers, whole blood (40 μL) was incubated with 2 mL Becton Dickinson FACS-lysing solution for 30 min to lyse the erythrocytes and fix the leukocytes. The leukocytes were then stained with propidium iodide (10 μL of a 1 mg/mL solution) and counted in a Coulter XL/MCL flow cytometer (Coulter Corp., Hialeah, FL) using a 60-μL volume stop setting.

For the determination of leukocyte subsets, whole blood (100 μL) was incubated with a combination of fluorescently labeled monoclonal antibodies to CD45 and CD14 (20 μL) for 40 min at 12°C. Erythrocytes were then lysed and leukocytes fixed with 3 mL Becton Dickinson FACS-lysing solution for 10 min. Leukocytes were collected by centrifugation ($250 \times g$, 5 min), resuspended in 3 mL PBS, and then centrifuged again. Finally, they were resuspended in 1 mL PBS and analyzed in a Coulter XL/MCL flow cytometer (Coulter Corp.). Fluorescence data were collected on $10^4$ cells and were analyzed using System II software. Neutrophils, eosinophils, and basophils were distinguished by side scatter properties after staining with anti-CD45; lymphocytes were distinguished as $CD45^+CD14^-$ cells; and monocytes were distinguished by side scatter properties after staining with anti-CD14.

*Measurement of leukocyte phagocytic activity.* Phagocytosis of neutrophils and monocytes was determined using the blood samples collected at weeks 0 (baseline), 12 (end of supplementation), and 16 (washout); PHAGOTEST® kits were used. A sample of whole blood was cooled on ice for 10 min. Prior to use in the PHAGOTEST® assay the cooled blood was vortexed. Aliquots (100 μL) were then incubated on ice (control) or in a preheated water bath at 37°C for 10 min with opsonized FITC-labeled *E. coli* (20 μL). The reaction was then stopped by adding ice-cold quenching solution (100 μL). The erythrocytes were then lysed, the leukocytes fixed, and the DNA stained according to the manufacturer's instructions. Cell preparations were then analyzed by flow cytometry in a Coulter XL/MCL flow cytometer (Coulter Corp.). Fluorescence data were collected on $10^4$ cells and were analyzed using System II software. Neutrophils and monocytes were identified by forward and side scatter. Both the percentage of neutrophils or monocytes having taken up *E. coli* (% positive; determined by subtracting the % positive cells in the control tube incubated on ice from the % positive cells in the tube incubated at 37°C) and the median fluorescence intensity (MFI) (a measure of extent of phagocytosis per leukocyte) were determined.

*Measurement of leukocyte respiratory burst.* Respiratory burst of neutrophils and monocytes was determined using the blood samples collected at weeks 0 (baseline), 12 (end of supplementation), and 16 (washout); BURSTTEST® kits were used. A sample of whole blood was cooled on ice for 10 min. Prior to use in the BURSTTEST® assay, the blood was vortexed. Aliquots (100 μL) were then incubated in a preheated water bath at 37°C for 10 min with opsonized *E. coli* or washing solution as control (20 μL in each case). The samples were then incubated for a further 10 min at 37°C with a solution (20 μL) containing the fluorogenic substrate dihydrorhodamine 123. The erythrocytes were then lysed, the leukocytes fixed, and the DNA stained according to the manufacturer's instructions. Cell preparations were then analyzed by flow cytometry in a Coulter XL/MCL flow cytometer (Coulter Corp.). Fluorescence data were collected on $10^4$ cells and were analyzed using System II software. Neutrophils and monocytes were identified by forward and side scatter. The concentration of *E. coli* used resulted in 100% of neutrophils and >85% of monocytes in all samples undergoing respiratory burst. Therefore, only the MFI values (a measure of respiratory burst activity per leukocyte) are reported here.

*Preparation of peripheral blood mononuclear cell (PBMC).* Blood was diluted 1:1 with PBS, layered onto Histopaque (density 1.077 g/L; ratio of diluted blood to Histopaque, 4:3), and centrifuged for 15 min at $800 \times g$ at 20°C. The PBMC were collected from the interphase, washed

once with PBS, resuspended in 2.5 mL PBS, and layered onto 5 mL Histopaque. They were centrifuged once more to achieve a lower degree of erythrocyte contamination, washed with PBS, and finally resuspended.

*Measurement of the production of proinflammatory cytokines by PBMC cultures.* Proinflammatory cytokine production by LPS-stimulated PBMC cultures was determined at all time points (i.e., weeks 0, 4, 8, 12, and 16). PBMC ($2 \times 10^6$) were cultured for 24 h in HEPES-buffered RPMI medium, supplemented with 2 mmol/L glutamine, 2.5% (vol/vol) autologous plasma, antibiotics, and 15 μg/mL LPS; the final culture volume was 2 mL. At the end of the incubation, the plates were centrifuged and the culture medium collected and frozen in aliquots. The concentrations of TNF-α, IL-1β, and IL-6 were measured by specific EASIA™ ELISA. Limits of detection for these assays were 3 pg/mL (TNF-α), 2 pg/mL (IL-1β), and 2 pg/mL (IL-6) (data supplied by the manufacturer of the kits). The inter- and intra-assay coefficients of variation were <10% for all cytokine ELISA.

*Measurement of plasma soluble adhesion molecule concentrations.* Plasma sICAM-1, sVCAM-1, and sE-selectin concentrations were measured only in plasma collected at weeks 0 (baseline) and 12 (end of supplementation). Soluble adhesion molecule concentrations were measured using commercially available ELISA kits. Limits of detection were 0.04 ng/mL (sICAM-1), 0.5 ng/mL (sVCAM-1), and 0.1 ng/mL (sE-selectin) (data supplied by the manufacturers of the kits). Inter- and intra-assay coefficients of variation were both <5% for sICAM and sVCAM-1 assay kits; the interassay coefficient of variation for the sE-selectin assay kit was <10%, whereas the intra-assay coefficient of variation was <5%.

*Statistical analysis.* Sample size (i.e., number of subjects per treatment group) was calculated on the basis of measurements made previously in our laboratory using the same methods as those employed in this study and of existing data from the literature. It was determined that a sample size of 8 would detect a difference in cytokine production of ≥25% at $P \leq 0.05$ with 80% power.

Unless otherwise indicated, results are expressed as mean ± standard error of the mean for seven or eight subjects per treatment group. Statistical significance of treatment, time, and the interaction of treatment and time were determined using two-factor repeat-measures analysis of variance (ANOVA). Where the interaction between treatment and time was significant, differences among treatment groups at a given time were examined by one-factor ANOVA using Bonferroni's correction for multiple comparisons, and differences within a treatment group between time points were examined by one-factor ANOVA (if data for more than two time points were available) or by paired Student's *t*-test (if data for only two time points were available). The effects of treatment on absolute and percentage changes during treatment (i.e., week 12 minus week 0) were analyzed by one-factor ANOVA using Bonferroni's correction for multiple comparisons. All statistical tests were performed using SPSS version 10.0 (SPSS Inc., Chicago, IL), and a value of $P < 0.05$ was taken to indicate statistical significance.

## RESULTS

*Fatty acid compositions of plasma and PBMC phospholipids.* The fatty acid compositions of plasma and PBMC phospholipids from this study have been published elsewhere (50,51), and will be summarized here only briefly. The fatty acid compositions of plasma and PBMC phospholipids were not affected by the placebo or ALNA treatments. However, supplementation of the diet with GLA resulted in an increase in the proportion of DGLA (63% increase in plasma phospholipids and 45% increase in PBMC phospholipids at week 12). Supplementation with ARA resulted in an 85% increase in the proportion of ARA in plasma phospholipids and a 15% increase in the proportion of ARA in PBMC phospholipids. Supplementation with DHA resulted in an increase in the proportion of DHA in plasma and PBMC phospholipids (91 and 80% increases at week 12, respectively). Finally, supplementation with FO caused increases in the proportions of EPA (230% increase at week 12) and DHA (33% increase at week 12) in plasma phospholipids. Likewise, FO supplementation increased the proportions of EPA and DHA in PBMC phospholipids (220 and 16% increases, respectively).

*Effect of treatments on leukocyte numbers and subsets.* The number of total leukocytes and of neutrophils, eosinophils, basophils, lymphocytes, and monocytes did not differ among the treatment groups at baseline (Table 3). There were no significant effects of treatment or time on the numbers of eosinophils or lymphocytes (Table 3). There was a significant effect of treatment, but not time, on the numbers of total leukocytes and monocytes ($P$ for effect of treatment = 0.001 and 0.007, respectively), but there were no treatment × time interactions (Table 3). There were significant effects of both treatment and time on the number of neutrophils ($P = 0.001$ and 0.042, respectively) but there was no treatment × time interaction (Table 3). There were no differences among the treatment groups with respect to the absolute changes (i.e., week 12 − week 0) in circulating cell numbers (Table 3).

*Effect of treatments on phagocytosis.* The percentage of neutrophils and monocytes carrying out phagocytosis of *E. coli* (approximately 80% of neutrophils and approximately 70% of monocytes) and the activity of those cells (MFI) did not differ among the treatment groups at baseline or at the end of supplementation (data not shown). Likewise, there were no differences among the treatment groups with respect to the absolute changes (i.e., week 12 − week 0) in neutrophil and monocyte phagocytosis (data not shown).

*Effect of treatments on respiratory burst.* The respiratory burst of neutrophils and monocytes in response to *E. coli* (expressed as MFI) did not differ among the treatment groups at baseline or at the end of supplementation (data not shown). There were no differences among the treatment groups with respect to the absolute changes (i.e., week 12 − week 0) in respiratory burst (data not shown).

*Effect of treatments on proinflammatory cytokine production.* Production of TNF-α, IL-1β, and IL-6 by PBMC stimulated with 15 μg/mL LPS did not differ among the treatment

groups at baseline (Table 4). There were no significant effects of treatment or of time on production of TNF-α or IL-6. There was a significant effect of time on the production of IL-1β ($P = 0.020$), but there was no effect of treatment or a significant treatment × time interaction. The absolute changes in production of these cytokines (i.e., week 12 – week 0) did not differ among the treatment groups (Table 4), and there were no differences in cytokine production among the treatment groups at the end of supplementation (Table 4).

*Effect of treatments on soluble adhesion molecule concentrations.* Plasma sICAM-1, sVCAM-1, and sE-selectin concentrations did not differ among the treatment groups at baseline (Table 5). There were no significant effects of treatment or of time on the concentrations of sICAM-1 or sE-selectin (Table 5). However, there were significant effects of time ($P = 0.038$) and treatment ($P = 0.027$) and a significant treatment × time interaction ($P = 0.014$) for sVCAM-1 concentration, and so these data were analyzed further. The concentration of sVCAM-1 was significantly lower after FO supplementation than at week 0 ($P = 0.034$). Placebo, GLA, ARA, or DHA supplementation did not affect sVCAM-1 concentration.

The absolute changes in sVCAM-1 concentration in the ALNA and FO groups were significantly different from the change in the placebo group ($P = 0.034$ and 0.019, respectively) and in the GLA group ($P = 0.027$ and 0.016, respectively). The percentage change in sVCAM-1 concentration in the FO group (–28.3 ± 8.1) was significantly different from the percentage change in the placebo group (0.9 ± 7.2; $P = 0.033$) and in the GLA group (11.9 ± 11.1; $P = 0.006$). The percentage change in sVCAM-1 concentration in the ALNA group (–15.6 ± 9.3) was significantly different from the change in the GLA group ($P = 0.046$).

The absolute change in sE-selectin concentration in the ALNA group was significantly different from that in the placebo group ($P = 0.022$; Table 5). Furthermore, the percentage change in sE-selectin concentration in the ALNA group (–22.8 ± 9.1) was significantly greater ($P = 0.035$) than that in the placebo group (–4.8 ± 3.5). Although the absolute

(Table 5) and percentage (–17.0 ± 10.1) changes in sE-selectin concentration in the FO group tended to be greater than those in the placebo group ($P = 0.075$ and 0.082, respectively), these were not significantly different.

## DISCUSSION

Cell culture and animal feeding studies have shown that the long-chain n-3 PUFA found in FO decrease the production of reactive oxygen species and of inflammatory cytokines and decrease the expression of adhesion molecules (11–32). These findings suggest that FO could compromise host defense. These observations are supported by a number of studies in healthy human volunteers, which have examined the influence of long-chain n-3 PUFA on inflammatory cell functions *ex vivo* (33–41,47,48). However, these human studies have used FO providing more than 2.4 g, and up to 9.6 g, of EPA plus DHA per day. Because current habitual intakes of EPA plus DHA are <150 mg per day (44), these studies represent a 15- to 60-fold increase in EPA plus DHA consumption. Likewise, the only study in healthy humans to examine the effects of ALNA on inflammatory cytokine production used about 14 g ALNA per day (38), which is at least sevenfold higher than habitual intake of this fatty acid (44). In fact, relatively little is known about the effects of more moderate consumption of n-3 PUFA on human inflammatory cell functions. Because there are recommendations to increase intake of both ALNA and long-chain n-3 PUFA (44), it seems important to ensure that there is no adverse immunological impact of a moderate increase in the consumption of these, and other, PUFA. Therefore, in the current study the effects of moderate supplementation with ALNA or FO were investigated, and this was combined with an examination of the effects of 700 mg DHA (in the absence of EPA), GLA, or ARA per day. Habitual intakes of GLA and ARA are <20 and <200 mg per day, respectively (see 50). A supplementation period of 12 wk was selected because almost all previous studies that reported effects of dietary PUFA on human inflammatory cell numbers or functions were of a duration of 3 to 12 wk (33–41,47–49).

The effects of the dietary supplementation on inflammatory cell numbers, on phagocytosis and respiratory burst by neutrophils and monocytes in response to *E. coli*, and on production of inflammatory cytokines by monocytes stimulated with LPS are reported because these have been shown to be affected by higher levels of n-3 PUFA or ARA than used here. In addition, the concentrations of plasma soluble adhesion molecules were measured because these provide a measure of longer-term endothelial activation *in vivo*, and because cell culture studies have shown that cytokine-induced upregulation of VCAM-1, E-selectin, and ICAM-1 on endothelial cells can be inhibited by n-3 PUFA (16–19).

The supplements represented significant increases in consumption of the fatty acids under study (see 50). Compliance of subjects to the supplements was assessed by determining the fatty acid composition of plasma phospholipids; according to this measure, compliance was good (see 50).

None of the treatments altered circulating inflammatory cell numbers (or proportions), suggesting that even marked increases in consumption of the fatty acids examined will not alter the numbers and types of inflammatory cells in the circulation. However, Kelley *et al.* (47) reported that 6 g DHA per day induced a 10% decrease in circulating total leukocyte numbers, which was largely due to a 21% decrease in granulocyte numbers; the total numbers of monocytes and lymphocytes did not change nor did the proportion of leukocytes as monocytes, but the proportion of lymphocytes was increased. In the current study 700 mg DHA per day did not alter circulating leukocyte numbers or types. Combined, these observations suggest that large intakes of either DHA or of long-chain n-3 PUFA in general [but not of ALNA, because 18 g ALNA per day did not alter the numbers of granulocytes, lymphocytes, or monocytes in the circulation (52)] might affect circulating leukocyte, especially granulocyte, numbers. Most of the studies using high levels of FO have not reported leukocyte numbers, and so it is not clear whether this is an effect of both EPA and DHA or of DHA alone. In the current study 700 mg ARA per day did not alter circulating leukocyte numbers or types. In another study, 1.5 g ARA per day was found to increase total leukocyte and granulocyte numbers but not to

affect the numbers of monocytes or lymphocytes (49). Thus, 1.5 g, but not 700 mg, ARA per day can affect circulating granulocyte numbers. It is not clear how the effects of elevated consumption of DHA and ARA on circulating granulocyte numbers occur; the fatty acids could affect either the rate of appearance of the cells into the bloodstream or the rate of removal of the cells from the bloodstream or both. Whatever the mechanism(s) involved, it appears that high intakes of ARA and DHA have opposing effects (47,49) but that more moderate intakes are without effect.

None of the treatments altered phagocytosis by neutrophils or monocytes, expressed as either % of active cells or as MFI. The lack of effect of FO and DHA observed in the current study is consistent with a study that used 3.8 g of either EPA or DHA per day and found no effect on phagocytosis by monocytes (53). To our knowledge there are no previous dietary studies of the effects of GLA, ALNA, or ARA on phagocytosis by human cells. None of the treatments altered respiratory burst by neutrophils or monocytes. Previous studies in humans reporting significant inhibition of respiratory burst by FO have used ≥3.1 g (and up to 9.6 g) EPA plus DHA per day (33–36). The lack of effect of FO (and DHA) observed in the current study extends previous studies showing no effect of 0.55 g EPA plus DHA per day on reactive oxygen species production by neutrophils (35) and monocytes (54). Thus, it appears that a moderate increase in intake of n-6 or n-3 PUFA, including ARA and those found in FO, will not affect phagocytosis or respiratory burst by neutrophils or monocytes.

The only study that investigated the influence of increased consumption of ALNA on cytokine production by human cells showed a marked decrease in production of TNF-α and IL-1β by LPS-stimulated PBMC after providing human volunteers with 14 g ALNA per day (38). The current study indicates that increasing ALNA intake by 2 g per day will not affect human inflammatory cytokine production. The lack of effect of 700 mg ARA per day on cytokine production in the current study is consistent with the observations of Kelley *et al.* (55) who reported no effect of 7 wk supplementation of the diet of young males with 1.5 g ARA per day on production of TNF-α, IL-1β, or IL-6 by PBMC stimulated by LPS. Similarly, the lack of effect of 700 mg GLA per day on cytokine production in the current study is consistent with the observations of Wu *et al.* (56), who reported no effect of 8 wk supplementation of the diet of elderly subjects with 675 mg GLA (plus 650 mg ALNA) per day on production of IL-1β by PBMC stimulated by LPS or *Staphylococcus epidermidis*. Thus, even significant increases in consumption of the longer-chain n-6 PUFA do not affect the production of these cytokines, which contrasts with the effects of these fatty acids seen *in vitro* (13,14). The current study observed no effect of 700 mg DHA per day on inflammatory cytokine production. However, a much larger dose of DHA (6 g per day), as part of a low-fat diet, caused a time-dependent decrease in production of TNF-α and IL-1β by LPS-stimulated PBMC (48).

The current study observed no effect of FO providing 1 g EPA plus DHA per day on production of TNF-α, IL-1β, and IL-6 by LPS-stimulated PBMC. This observation appears to contrast with previous studies (38–41). However, these studies used larger amounts of EPA plus DHA (2.4 to 5 g per day) than used here. Some other studies using low amounts of EPA plus DHA (0.55 to 1.6 g per day) report no effects on LPS-stimulated production of TNF-α (54,57), IL-1β (54,57,58), or IL-6 (54,57). However, the current study differs from each of these earlier studies. The study of Schmidt *et al.* (54) was conducted in younger subjects (24 to 52 yr of age) than the current study and used a very low dose of FO (0.55 g EPA plus DHA per day) in a population with a higher habitual intake of n-3 PUFA than in the current study. The study of Cooper *et al.* (57) also used younger subjects (18 to 36 yr of age) and was not controlled, and the study of Molvig *et al.* (58) used much younger subjects (mean age 27 yr) than the current study. The relevance of subject age is illustrated by the study of Meydani *et al.* (40), who found that *ex vivo* production of TNF, IL-1, and IL-6 by PBMC was much more strongly affected by 2.4 g EPA plus DHA per day for up to 12 wk in older women (51 to 68 years of age) than in young women (22 to 33 yr of age). Taken together these observations suggest that low to moderate doses of EPA plus DHA do not affect inflammatory cytokine production and that the threshold to exert an effect in older subjects is somewhere between 1 and 2.4 g EPA plus DHA per day.

To our knowledge this is the first study investigating the effects of ALNA, GLA, ARA, and DHA on plasma soluble adhesion molecule concentrations. GLA, ARA, and DHA had no significant effects, but ALNA decreased the concentrations of sVCAM-1 and sE-selectin by 16 and 23%, respectively. FO significantly decreased the concentrations of sVCAM-1 and sE-selectin by 28 and 17%, respectively. Because FO providing EPA plus DHA affected the concentrations of some soluble adhesion molecules but DHA alone did not, we conclude that the effects of FO are due to EPA not DHA. Whether the effects of ALNA are due to ALNA itself or relate to its conversion to EPA are not clear from this study.

The origin and roles of soluble adhesion molecules are not well understood. VCAM-1 and E-selectin are almost exclusively expressed by activated endothelial cells (2). Thus, the most likely origin of sVCAM-1 and sE-selectin is from activated endothelial cells, and this is believed to occur as a result of proteolytic shedding from the endothelial cell surface (2). ICAM-1 is expressed at basal levels on monocytes and endothelial cells and its expression can be strongly induced on a variety of cell types, including endothelial cells and monocytes, by stimuli such as cytokines, LPS, and reactive oxygen species (2). As for sVCAM-1 and sE-selectin, the appearance of sICAM-1 is believed to be a result of shedding from the cell surface (2). Thus, increased concentrations of sICAM-1, sVCAM-1, and sE-selectin in the circulation are considered to reflect upregulation of the molecules on the cell surface, and they appear to be biomarkers of chronic inflammation (2). The ability of FO and ALNA to lower the

concentrations of sVCAM-1 and sE-selectin, but not to influence that of sICAM-1, suggests that the n-3 PUFA act *in vivo* to decrease endothelial activation rather than monocyte activation. This accords with the lack of effect of FO and ALNA on *ex vivo* monocyte functions. The different effects of FO and ALNA on the concentrations of sICAM-1 and sVCAM-1 suggest that VCAM-1 and ICAM-1 are upregulated by different mechanisms and that these are not equally sensitive to n-3 PUFA intervention. This is supported by the cell culture observations that show that cytokine-induced upregulation of VCAM-1 expression on human endothelial cells is markedly inhibited by culture in the presence of long-chain n-3 PUFA (16–19), whereas upregulation of ICAM-1 is less affected (16,19) or not affected at all (17,18) by the n-3 PUFA.

Plasma concentrations of sICAM-1, sVCAM-1, and sE-selectin are higher in individuals with cardiovascular disease than in controls (3,5,6), and there is a positive correlation between the extent of atherosclerosis and these concentrations (5). The ability of dietary n-3 PUFA to lower plasma soluble adhesion molecule concentrations indicates a novel mechanism that might contribute to the protective effects of these fatty acids upon cardiovascular and inflammatory diseases.

The current study suggests that moderate levels of a range of n-6 and n-3 PUFA do not influence circulating inflammatory cell numbers or the *ex vivo* functional responses of inflammatory cells. Thus, it appears that consumption of n-3 PUFA could be increased in line with recommendations without inducing adverse effects on the innate immune response. Furthermore, this study also suggests that increased consumption of the n-6 PUFA GLA and ARA will not have such adverse effects. However, the current study was conducted in subjects aged 55 to 74 yr and the findings should not be extrapolated to other groups such as pregnant women or infants. Furthermore, the *ex vivo* measurements reported here were made using a single concentration of *E. coli* or LPS to challenge the cells. This concentration was that which induced optimal cell responses, and it cannot be determined from this study what effect, if any, the PUFA might have on cellular responses to a suboptimal challenge. The current study also found that moderate levels of GLA, ARA, and DHA do not influence circulating adhesion molecule concentrations, suggesting that they do not influence endothelial or monocyte activation *in vivo*. In contrast, moderate levels of ALNA and FO decreased the concentrations of endothelial-derived soluble adhesion molecules, suggesting that they diminish endothelial activation *in vivo*. How this might happen is unclear, but these observations indicate a novel mechanism of action of n-3 PUFA that could contribute to human health.

## ACKNOWLEDGMENTS

This research was supported by a grant to E.A. Newsholme and Philip C. Calder from the Ministry of Agriculture, Fisheries and Food, Unilever Research Colworth Laboratory and Nutricia Research under the Agri-Food Quality LINK Programme (Grant no. AFQ51). sICAM-1 and sVCAM-1 concentration measurements were funded separately by a grant to Philip C. Calder from the Biotechnology and Biological Sciences Research Council (Grant no. 51/F05696), and sE-selectin concentration measurements were funded separately by Unilever Research Colworth Laboratory. The authors wish to thank Drs. Paul Quinlan (Unilever Research Colworth Laboratory), Gert Meijer (Unilever Vlaardingen Laboratory), and Jacques Bindels and Monique Al [Nutricia (now Numico) Research].

# Effects of Dietary Virgin Olive Oil Phenols on Low Density Lipoprotein Oxidation in Hyperlipidemic Patients

**Roberta Masella[a,*], Claudio Giovannini[a], Rosaria Varì[a], Roberta Di Benedetto[b], Ettore Coni[b], Roberto Volpe[c], Nadia Fraone[d], and Antonello Bucci[d]**

Departments of [a]Metabolism and Pathological Biochemistry and [b]Food, Istituto Superiore di Sanità, 00161 Rome, Italy, [c]Servizio Prevenzione e Protezione, Consiglio Nazionale delle Ricerche, 00161 Rome, Italy, and [d]Istituto di Terapia Medica Sistematica, University of Rome "La Sapienza," 00161 Rome, Italy

**ABSTRACT:** The aim of this study was to assess the effects of the dietary intake of extra virgin olive oil on the oxidative susceptibility of low density lipoproteins (LDL) isolated from the plasma of hyperlipidemic patients. Ten patients with combined hyperlipidemia (mean plasma cholesterol 281 mg/dL, triglycerides 283 mg/dL) consumed a low-fat, low-cholesterol diet, with olive oil (20 g/d) as the only added fat, with no drug or vitamin supplementation for 6 wk. Then they were asked to replace the olive oil they usually consumed with extra virgin olive oil for 4 wk. LDL were isolated at the beginning, and after the 4 wk of dietary treatment. LDL susceptibility to $CuSO_4$-mediated oxidation was evaluated by measuring the extent of lipid peroxidation. We also determined fatty acid composition and vitamin E in plasma and LDL and plasma phenolic content. Extra virgin olive oil intake did not affect fatty acid composition of LDL but significantly reduced the copper-induced formation of LDL hydroperoxides and lipoperoxidation end products as well as the depletion of LDL linoleic and arachidonic acid. A significant increase in the lag phase of conjugated diene formation was observed after dietary treatment. These differences are statistically correlated with the increase in plasma phenolic content observed at the end of the treatment with extra virgin olive oil; they are not correlated with LDL fatty acid composition or vitamin E content, which both remained unmodified after the added fat change. This report suggests that the daily intake of extra virgin olive oil in hyperlipidemic patients could reduce the susceptibility of LDL to oxidation, not only because of its high monounsaturated fatty acid content but probably also because of the antioxidative activity of its phenolic compounds.

Paper no. L8668 in *Lipids 36,* 1195–1202 (November 2001).

The dietary intake of natural compounds with antioxidant activity may play a key role in the prevention of cardiovascular diseases and other conditions whose pathogenesis is based on oxidative processes (1). Diets rich in vegetables and fruit provide protection against such diseases, most likely owing to their high content of antioxidants, including not only vitamin E, C, and β-carotene but also phenolic compounds, a large class of molecules characterized by a number of hydroxyl groups attached to a ring structure responsible for the antioxidant activity (2). Epidemiological and experimental evidence associates the more common hyperlipidemias [high low density lipoprotein (LDL)-cholesterol levels, high triacylglycerol levels, and/or low high density lipoprotein (HDL)-cholesterol levels] with the increased risk of developing cardiovascular diseases (3).

LDL modified by oxidative processes (ox-LDL) have been suggested to be involved in the pathogenesis of atherosclerosis (4). The susceptibility of LDL to oxidation depends on several factors such as their fatty acid composition and the concentration of some antioxidant vitamins, e.g., vitamin E (5–7). Epidemiological studies positively correlated the intake of dietary phenolic compounds with a lowered risk of coronary heart disease (8,9). Experimental studies support the hypothesis that several phenolics can be absorbed through the gastrointestinal tract (10–13).

Extra virgin olive oil (EVOO), a typical component of the Mediterranean diet, has been associated with a reduced incidence of coronary heart disease. This is likely due in part to the high amount of monounsaturated fatty acids (14,15) but may also be the result of several phenolic compounds (16,17). The content of phenolic compounds in EVOO can vary greatly depending on the kind of cultivar, fruit ripening, and, above all, oil extraction process (18,19). Its mild extraction process renders EVOO richer in phenolic compounds than olive oil (OO) prepared by the standard method. This suggests the hypothesis that EVOO may exert a protective effect against oxidation of LDL similar to that of green tea and red wine (20,21).

Although the antioxidant properties of EVOO phenolic compounds have been extensively discussed, little is known about their absorption and metabolism and, to the best of our knowledge, very few data are available on *in vivo* studies in humans (22). The aim of this study was thus to assess the *in vivo* effects of dietary EVOO on the oxidizability of LDL isolated from hyperlipidemic patients.

## SUBJECTS AND METHODS

The study was performed with free-living patients, who were given specific dietary advice. Informed consent was obtained

*To whom correspondence should be addressed at Dept. of Metabolism and Pathological Biochemistry, Istituto Superiore di Sanità, Viale Regina Elena, 299, 00161 Rome, Italy. E-mail: masellar@iss.it; biogast@iss.it

Abbreviations: BHT, butylated hydroxytoluene; DAD, diode array detector; EVOO, extra virgin olive oil; FAME, fatty acid methyl ester; HDL, high density lipoprotein; 4-HNE, 4-hydroxy-2(*E*)-nonenal; HPLC, high-performance liquid chromatography; HRGC, high-resolution gas chromatography; LDL, low density lipoprotein; MDA, malondialdehyde; OO, olive oil; ox-LDL, oxidized LDL; PBS, phosphate-buffered saline; PUFA, polyunsaturated fatty acid; SEM, standard error of the mean; SPE, solid phase extraction.

from 10 patients (8 males and 2 females, aged 42–67) with combined hyperlipidemia, who were nonsmokers and leading a sedentary life (Table 1). For a period of at least 6 wk before the beginning of EVOO consumption, the patients were trained individually by a dietitian to achieve or maintain an acceptable body weight and to consume a diet low in total fat (<30% energy) and saturated fat (<10% energy) with a daily cholesterol intake below 300 mg. Recommendations adhered to the dietary goals established by the American Heart Association Step I diet (23). OO (20 g/d) was the only added fat in meals. After 6 wk, OO was replaced by the same amount of EVOO containing 238 ± 20 mg/kg of phenolics. OO and EVOO were purchased by us and were, consequently, the same for all the subjects. The oils derived from the same production and were prepared according to our request so that vitamin E content and fatty acid composition were the same in both of them. Moreover, all these parameters were controlled experimentally in our laboratory, giving the following values: vitamin E (expressed as mg α-tocopherol/kg, calculated using activity coefficients for individual tocopherols), 189 ± 7 (mean ± SD, $n = 5$) in OO and 192 ± 10 in EVOO; and total phenol compounds (expressed as tyrosol concentration, mg/kg), 11 ± 5 in OO and 238 ± 20 in EVOO. The treatment with EVOO lasted 4 wk.

The dietary intake was assessed at the beginning and at the end of the EVOO treatment by means of a 7-d food record: Patients were asked to record detailed descriptions of all foods and beverages consumed (ingredients, methods of preparation, cooking). None of the patients had coronary artery disease, hypertension, diabetes, or obesity. All subjects had normal fasting glucose levels, and they exhibited normal liver, renal, and thyroid functions. No patient used drugs with documented lipid-modifying effects such as diuretics, beta-blockers, corticosteroids, sex steroids, or antifungal agents. The Local Ethics Committee approved the experimental design.

*Blood sampling and laboratory analysis.* Blood was taken at the end of 6 wk of OO consumption and after 4 wk of EVOO consumption. After an overnight fast, blood was collected by venipuncture and divided into two tubes. One of them, containing $Na_2$ EDTA (1 mmol/L), was used for plasma isolation, and the other one to prepare serum for specific determinations. Serum total cholesterol, HDL-cholesterol, and triacylglycerol were determined enzymatically with commercial kits (Boehringer Diagnostica). LDL-cholesterol was determined according to Friedewald's formula.

*LDL isolation and oxidation.* LDL, isolated from plasma by discontinuous density gradient ultracentrifugation (24) and extensively dialyzed against phosphate-buffered saline (PBS) at 4°C, were diluted in PBS to 0.2 g protein/L and incubated with 10 μmol/L $CuSO_4$ for 5 h at 37°C. Oxidation was stopped by refrigeration and the addition of 20 μmol/L butylated hydroxy toluene (BHT) and 100 μmol/L EDTA. The extent of LDL oxidation was evaluated on the basis of the increase in hydroperoxides and end products of lipid peroxidation and the decrease in polyunsaturated fatty acids (PUFA) content. These parameters were determined in triplicate for each patient before and after EVOO treatment, both on native and oxidized LDL.

*Hydroperoxide determination.* The hydroperoxide content in the LDL fraction was determined by iodometric titration according to the method proposed by El-Saadani *et al.* (25), except that reaction time was changed from 30 to 60 min (26). Results were expressed as μmol/mg of LDL protein using $\varepsilon_{mM} = 24.6$.

*Malondialdehyde (MDA) and 4-hydroxy-2 (*E*)-nonenal (4-HNE) determinations.* End products of lipid peroxidation were measured as MDA plus 4-HNE content using a commercial kit based on a colorimetric assay (LPO-586; Bioxytech, Oxis International Inc., Portland, OR). Results were expressed as μmol/mg of LDL protein using tetramethoxypropane as standard.

*Fatty acid analysis.* Fatty acid composition was determined, before and after oxidation, in lipid extracts of plasma and LDL isolated from the patients before and after EVOO consumption. Lipids were extracted from 0.5 mL plasma using 20 mL of chloroform/methanol mixture (2:1 vol/vol). The lipid extracts, washed with 0.88% KCl (1 mL), were completely evaporated under a gentle flow of nitrogen and dissolved in *n*-hexane. An aliquot of the extracted lipids was transesterified by adding an equal volume of 3 N methanolic hydrogen chloride followed by incubation for 12 h at 60°C. Fatty acid methyl esters (FAME) were separated and quantified by high-resolution gas chromatography (HRGC). A PerkinElmer 8320 gas chromatograph (Norwalk, CT) was used, equipped with a split (50:1) injector, a flame-ionization detector, and a 30 m × 0.25 mm i.d. Omegawax 250 capillary column (Supelchem, Milano, Italy). The fatty acid composition of lipids was estimated as percentage of total fatty acids.

*LDL oxidation kinetics.* The kinetics of LDL oxidation was measured by spectrophotometrically monitoring the increase in absorbance at 234 nm due to conjugated diene formation

**TABLE 1**
**Plasma Lipid Concentration and Body Mass Index of Hyperlipidemic Patients[a] Before and After Extra Virgin Olive Oil Consumption**

| Parameter[b] | Before | After | Δ (%) | *P* | 95% CI |
|---|---|---|---|---|---|
| Total cholesterol (mg/100 mL) | 281.4 ± 45.2 | 272.9 ± 38.2 | −3.0 | 0.4 | −47.8 + 30.8 |
| LDL-cholesterol (mg/100 mL) | 172.4 ± 23.0 | 165.9 ± 23.1 | −3.8 | 0.6 | −31.2 + 18.2 |
| HDL-cholesterol (mg/100mL) | 46.6 ± 11.2 | 41.3 ± 9.1 | −5.3 | 0.5 | −11.9 + 7.3 |
| Triacylglycerols (mg/100mL) | 283.1 ± 121.0 | 293.7 ± 105.0 | −3.7 | 0.2 | −95.8 + 117.0 |
| Body mass index (kg/m$^2$) | 25.1 ± 2.3 | 25.0 ± 2.3 | −0.1 | 0.9 | −2.2 + 2.1 |

[a]Values were measured in triplicate before and after extra virgin olive oil consumption in 10 hyperlipidemic patients.
[b]Values are expressed as mean ± standard deviation. LDL, low density lipoprotein; HDL, high density lipoprotein.

[b]Limit of detection (LOD) calculated on the basis of the 3-σ criterion.
[c]Relative standard deviation (RSD) calculated on 10 replicates at the following concentrations: 50 ng mL$^{-1}$ for oleuropein, 3,4-dihydroxyphenylethanol, *p*-hydroxyphenylethanol, *p*-hydroxyphenylethanol aglycone, gallic acid, *p*-coumaric acid, ferulic acid, and luteolin; and 100 ng mL$^{-1}$ for oleuropein aglycone, protocatechuic acid, vanillic acid, caffeic acid, and apigenin.
[d]Performed by recoveries obtained from spiked (four levels) in-house standard (freeze-dried human plasma).

induced by 1.6 μmol/L $CuSO_4$, according to Puhl *et al*. (27). The length of the lag phase, expressed in minutes, was calculated by measuring the intercept of the slope of absorbance in the propagation phase with the extrapolated line for the slow reaction.

*Vitamin E determination.* The plasma and LDL contents of vitamin E, as α-, β-, δ-, and γ-tocopherols, were determined by extracting the analyte from the matrix and then separating it by means of high-performance liquid chromatography (HPLC) as reported by Cavina *et al*. (28). Results were expressed as mg/L for plasma determination and μg/mg protein for LDL determinations, using α-tocopherol acetate as internal standard.

*Determination of phenolic compounds.* In OO and EVOO total phenolic compounds were determined by means of the Folin-Ciocalteau reagent as reported by Swain and Goldstein (29). The concentrations of phenolics in plasma samples were determined by HPLC after extraction and purification procedures. The procedure was similar to that described by Tsimidou *et al.* (30) with some modifications in the extraction procedure and chromatographic conditions; their method refers solely to olive oil, whereas in this study the method was applied to plasma. Briefly, solid-phase extraction (SPE) cartridges (Spe-ed SPE $C_{18}$ 500 mg-6 mL, Applied Separations, Allentown, PA), previously conditioned by passing 2 mL of a *n*-hexane/ethyl ether solution through the cartridge (98:2 vol/vol), were used for the extraction and purification of the phenolic compounds. One milliter of the sample, acidified with 10 μL of phosphoric acid, was then deposited on the top of the cartridge, which was subsequently washed with 10 mL of the conditioning solution. The phenolic fraction was eluted with 8 mL of methanol, filtered through disposable Teflon filters, and evaporated in Rotavapor at 35°C. The dry residue was then dissolved in 0.5 mL of methanol, and 10 μL of this solution was injected into an HPLC chromatograph (Waters, Milford, MA) fitted with a Lichrosorb column (RP18, 250 × 4.6 mm, 5 μm) and a diode array (ultraviolet-visible) detector set at 280 nm. The eluents were (A) acetonitrile/methanol (50:50 vol/vol) and (B) phosphoric acid/water (1:99 vol/vol). The gradient was 4% A at $t$ = 0 min, 20% A at $t$ = 20 min, 50% A at $t$ = 40 min, 60% A at $t$ = 50 min, and 100% A at $t$ = 60 min. Peak identification was made on the basis of retention times and further confirmed by spectrum analysis with a diode array detector. The modified method was validated in a previous study (31) and the analytical performance is reported in Table 2.

Total phenolic content was expressed as tyrosol concentration (mg/L).

*Statistical analysis.* Results were presented as mean ± standard error of the mean. Three determinations were performed for each patient.

The statistical analysis was performed using paired Student's $t$-test. A probability value ≤0.05 was considered significant. The possible relationship between the modification in plasma phenolic and oxidative parameters was evaluated using correlation coefficients and their statistical significance. Data were processed with the Statgraphics software package (v. 7 for DOS, Manugistic, Rockville, MD).

## RESULTS

The 7-d food records assessed at the end of the study showed a high level of compliance with the dietary goals established by the American Heart Association Step I diet and no differences from the 7-d food record assessed before EVOO consumption. Mean body mass index and plasma lipid values remained stable during the study (Table 1), which confirms that

the dietary recommendations were observed during EVOO consumption. The quantitative analyses of the lipid extracts from plasma and the LDL fraction isolated from the patients did not show any significant difference in the content of the various lipid moieties and fatty acid composition after EVOO treatment. In particular, oleic, linoleic, and arachidonic acid contents in the LDL fraction were unchanged (Table 3).

In vitro *susceptibility of LDL to oxidative modification.* The dietary intake of 20 g/d EVOO by dyslipidemic patients resulted in a reduced susceptibility of LDL to oxidation induced by cupric ions. After the LDL isolated from patients were oxidized with 10 µmol/L $CuSO_4$, the amount of lipid peroxidation products, e.g., hydroperoxides and MDA + 4-HNE, was significantly lower in samples collected after EVOO consumption (Fig. 1). The hydroperoxide content, measured at the end of a 5-h oxidation period, was 0.54 ± 0.06 and 0.26 ± 0.04 µmol/mg protein LDL before and after EVOO consumption ($P < 0.01$), respectively.

The content of end products of lipid peroxidation, expressed as MDA + 4-HNE, was also reduced from 0.21 ± 0.01 to 0.17 ± 0.02 µmol/mg protein before and after EVOO treatment, respectively ($P < 0.01$).

*Fatty acid composition.* Figure 2 shows the content of linoleic and arachidonic acids determined before and after the oxidative treatment. Following EVOO consumption, a greater percentage of linoleic and arachidonic acid content remained in LDL oxidized by cupric ions. Linoleic acid content was 18.5 vs. 14.4% in LDL, oxidized after and before EVOO consumption ($P < 0.05$), respectively, showing a lower decrease with respect to the value determined before the oxidative treatment (35 vs. 50%). Arachidonic acid showed an even more marked difference. In fact, residual content of arachidonic acid was 1.9% after and only 0.9% before EVOO treatment ($P < 0.01$), corresponding to a 77 vs. 94% decrease.

*Diene formation during the oxidative treatment.* The kinetics of conjugated diene formation, continuously monitored at 234 nm, allowed us to evaluate the increased resistance of the LDL fraction to oxidation by the increase in the length of the lag phases observed after 4 wk of EVOO consumption. The mean value ± SEM of the lag phase rose from 88 ± 6 min to 101 ± 5 min ($P < 0.01$) after EVOO consumption. (The length of the lag phase was calculated from the curve of conjugated diene formation, by the intercept of the propagation phase tangent with the extrapolated line for the slow reaction.) No differences were obtained either in the maximal propagation rate or in the maximal concentrations of conjugated dienes, as shown in the plot of mean curves of LDL oxidation before and after EVOO consumption (Fig. 3).

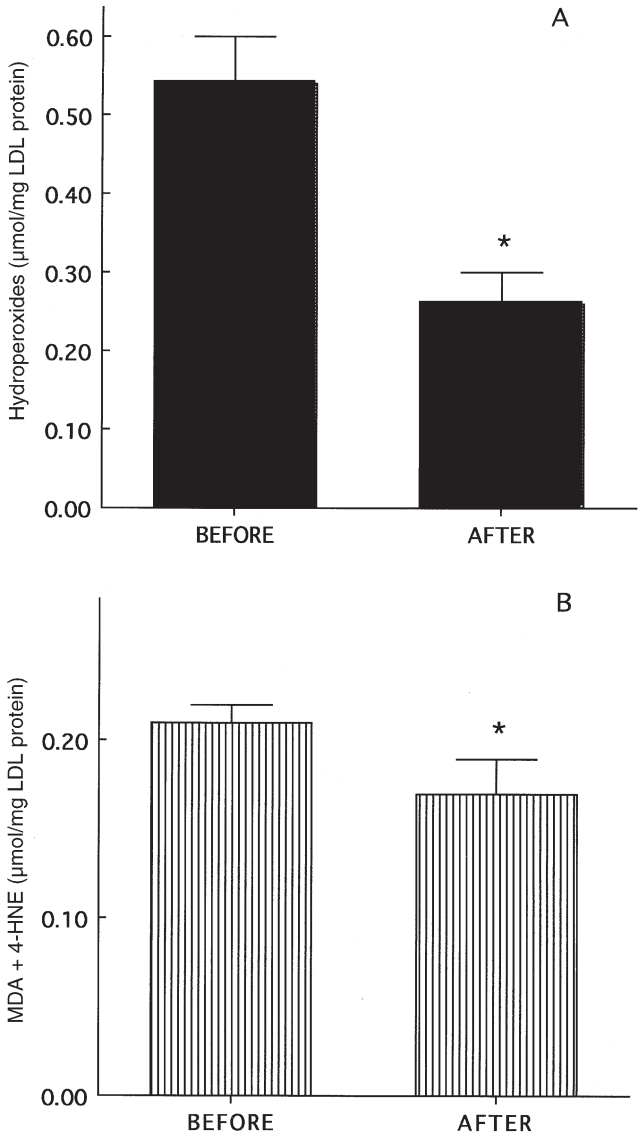

**FIG. 1.** Effect of dietary extra virgin olive oil (20 g/d) on the susceptibility of low density lipoproteins (LDL) to *in vitro* oxidation by 10 µmol/L $CuSO_4$. Plasma LDL were isolated from hyperlipidemic patients before and after 4 wk of extra virgin olive oil (EVOO) consumption. LDL oxidation was evaluated as hydroperoxide content (panel A), and as malondialdehyde (MDA) plus 4-hydroxy-2(*E*)-nonenal (4-HNE) content (panel B) by spectrophotometry. Results are given as mean (µmol/mg LDL protein) ± standard error of the mean (*$P < 0.01$).

**TABLE 3**
**Percentage of Fatty Acids in LDL[a] Fraction Before and After Extra Virgin Olive Oil Consumption**

| | Before | After |
|---|---|---|
| Palmitic acid, 16:0 | 24.4 ± 1.6 | 24.3 ± 1.5 |
| Palmitoleic acid, 16:1 | 4.4 ± 1.1 | 3.7 ± 1.0 |
| Stearic acid, 18:0 | 6.7 ± 1.3 | 5.8 ± 0.8 |
| Oleic acid, 18:1 | 27.8 ± 1.0 | 29.5 ± 0.9 |
| Linoleic acid, 18:2 | 29.5 ± 0.8 | 30.0 ± 1.7 |
| Eicosatrienoic acid, 20:3 | 1.3 ± 0.3 | 1.5 ± 0.6 |
| Arachidonic acid, 20:4 | 5.7 ± 0.5 | 6.2 ± 0.5 |

[a]Values are the percentage of the total fatty acid content measured before and after extra virgin olive oil consumption. Values are expressed as mean ± SEM. See Table 1 for abbreviation.

*Vitamin E and phenolic compounds determination.* Vitamin E content in plasma and LDL did not show significant changes associated with EVOO consumption (14.1 ± 1.0 and 16.7 ± 1.7 mg/L in plasma; 4.4 ± 0.6 and 5.0 ± 0.8 µg/mg LDL protein, before and after EVOO treatment, respectively).

The mean content ± SEM of total phenolic compounds in plasma was remarkably increased after consumption of 20 g

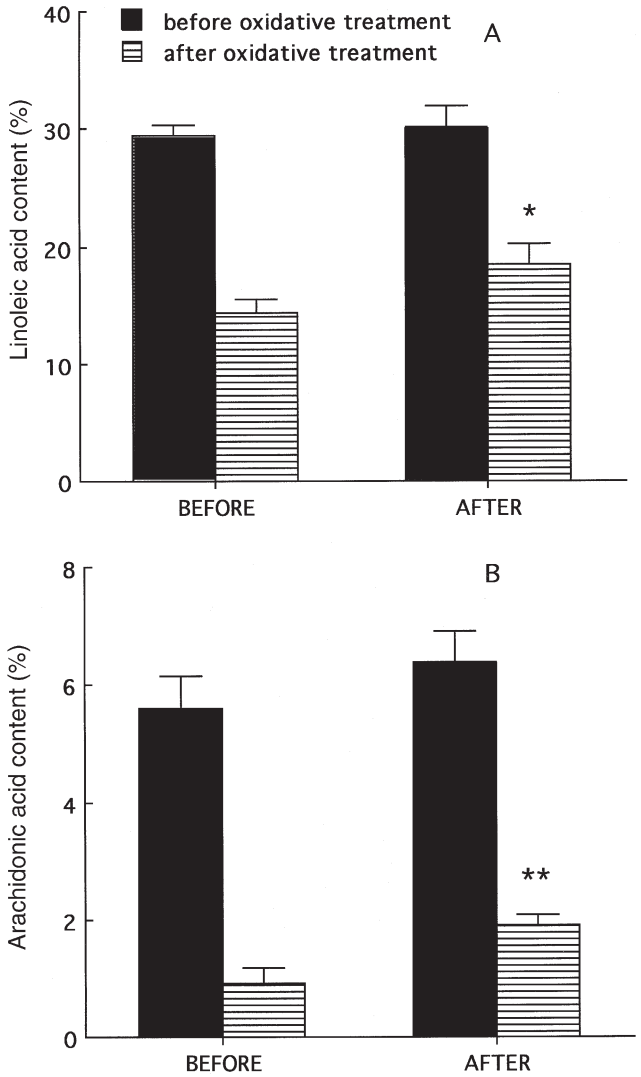

**FIG. 2.** Polyunsaturated fatty acid content of plasma LDL particles before and after oxidation by cupric ions. The figure reports the mean ± standard error of the mean of the residual percentage (% of total fatty acids) of linoleic acid (panel A) and arachidonic acid (panel B) in oxidized LDL before and after 4 wk of EVOO treatment (*$P < 0.05$, **$P < 0.01$). See Figure 1 for other abbreviations.

EVOO/d (23.0 vs. 11.3 mg/L, expressed as tyrosol concentration $P < 0.02$); in particular, oleuropein and its derivatives (oleuropein aglycone, 3,4-dihydroxyphenylethanol, *p*-hydroxyphenylethanol aglycone) increased more than 90% (data not shown). To demonstrate the phenol content differences before and after EVOO consumption, Figure 4 shows a chromatogram obtained by subtracting the chromatogram of hyperlipidemic patient plasma obtained before the treatment from that derived after 4 wk of EVOO consumption. This increase in phenol content appeared statistically correlated with the increase in the length of lag phase ($r = 0.6819$) as well as with the decreased production of hydroperoxides ($r = -0.6923$) and MDA + 4-HNE ($r = -0.8507$), and with the residual content of linoleic and arachidonic acid ($r = 0.6846$ and $r = 0.6541$, respectively) in LDL after the oxidative treatment.

## DISCUSSION

Phenolic compounds have recently been the focus of growing attention because of their antioxidative properties and their possible beneficial role in the prevention of several pathologies such as cancer and cardiovascular disease (32). The antioxidative activity of phenols seems to result from several mechanisms, such as chelation of metal ions, free radical scavenging ability, lipoperoxide chain-breaking, and antioxidant vitamin regeneration (33,34). There is some evidence that they can be directly absorbed through the small intestinal mucosa, but little is known about the efficiency of such uptake and the catabolism of phenolic compounds or their derivatives in the body (35).

This study suggests that the daily consumption of EVOO protects LDL against *ex vivo* oxidation. Like other researchers, we had previously shown the strong antioxidative power of several phenols naturally present in EVOO, capable of protecting LDL from *in vitro* oxidative modifications induced by cupric ions (36,37). The present results are consistent with our previous findings of increased resistance to oxidation of LDL isolated from rabbits fed standard diets modified by the addition of EVOO or a specific EVOO phenolic compound, namely, oleuropein (31). We also demonstrated that tyrosol, the major EVOO phenolic compound, exerted a wholly protective effect against LDL-induced injury in an *in vitro* enterocyte-like system, preventing both cytostatic and cytotoxic events (38).

The present study expanded those previous findings, suggesting that the reduced susceptibility of plasma LDL to lipid peroxidation in humans, as a result of the daily consumption of EVOO, could be mainly related to phenolic antioxidants, rather than to monounsaturated fatty acids as previously suggested (39–41). It is noteworthy that the plasma phenolic content in the patients significantly increased after the consumption of EVOO, in particular that of oleuropein and derivatives, which are compounds peculiar to olives and the most effective antioxidative phenols. This suggests that phenols are absorbed in the gut, become available in blood and are then excreted in the urine as recently reported (22). It could be hypothesized that the phenolic compounds contribute to antioxidative defenses, exerting their activity on plasma components such as LDL, as demonstrated for similar compounds contained in red wine (21).

Other mechanisms might be responsible for the increased resistance of LDL to oxidation, such as changes in the lipid composition of the lipoprotein particles or in plasma antioxidant content (42). The LDL fatty acid composition may affect LDL susceptibility to oxidative modification (43). The formation of oxidized LDL depends on their PUFA content, which is the main target of oxidative reactions, and it was shown that oleate-enriched LDL containing less PUFA were more resistant to oxidative modifications (44). Our results clearly show that the fatty acid composition of plasma LDL particles was unmodified as far as PUFA and monounsaturated fatty acids are concerned. It is worth noting that the

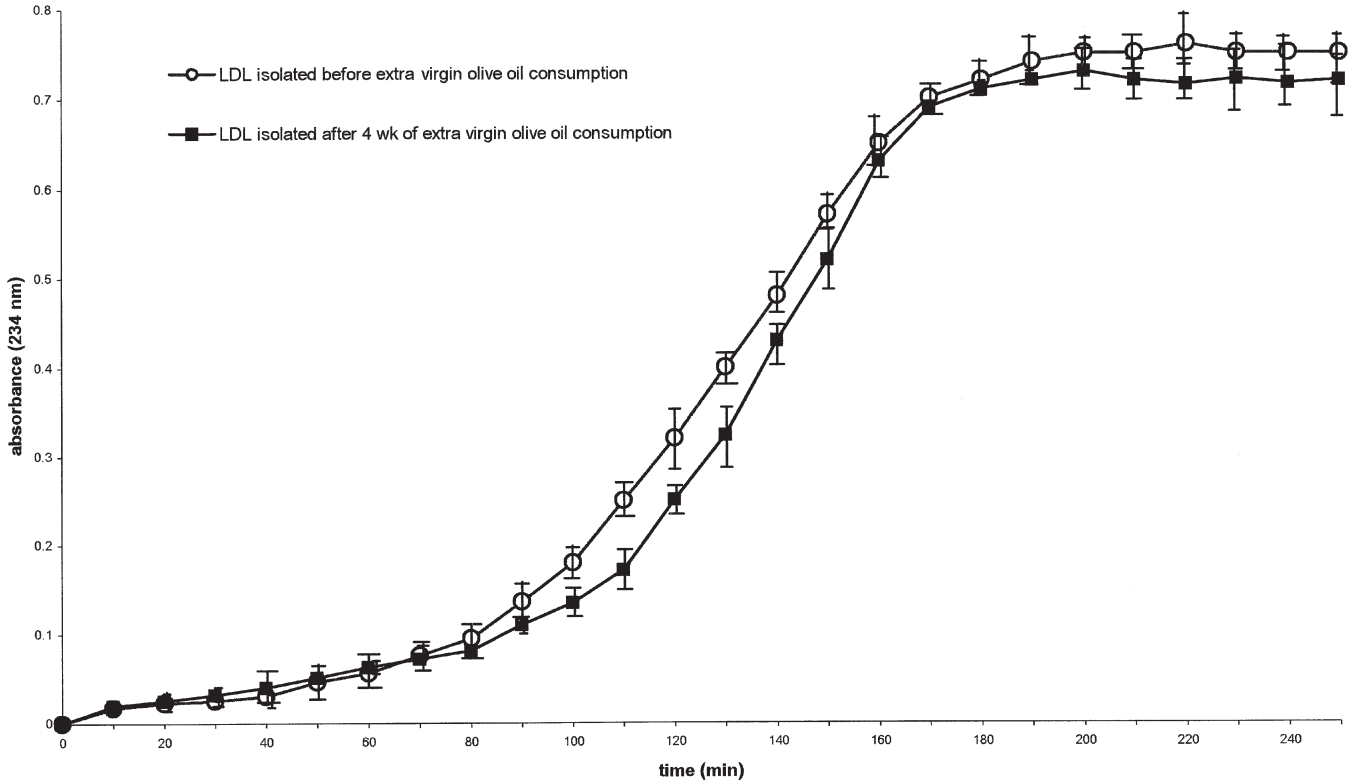

**FIG. 3.** Effect of dietary EVOO on the length of lag phase of plasma LDL. Mean curves of conjugated diene formation induced by copper in LDL isolated from patients before and after dietary intervention are presented. The change in absorbance at 234 nm was continuously monitored for 4 h. See Figure 1 for abbreviations.

intake of monounsaturated fatty acids remained unchanged throughout the study. In fact, before the beginning of the experimental period, the patients consumed OO daily, which differs from EVOO in that it features a lower amount of phenolic compounds, but the same monounsaturated fatty acid content. The progress of the conjugated diene formation curve might suggest that the additional antioxidants in the plasma of patients after the dietary treatment could be bound to LDL as reported for other phenols (21,45), delaying the propagation of the lipoperoxidation in LDL. Once these additional antioxidants were depleted, the rate of the oxidation reaction of LDL was the same at both times owing to their similar fatty acid composition. On the other hand, plasma and LDL α-tocopherol content were not significantly modified during the observation period.

Our investigation indicates that the antioxidative minor components of EVOO might play a relevant role in the prevention or attenuation of pathologies associated with redox imbalance, such as atherosclerosis and other chronic degenerative diseases.

**ABSTRACT:** Electrospray/tandem mass spectrometry was used to quantify lipid remodeling in mouse liver and plasma during inhibition of polyunsaturated fatty acid synthesis by the Δ6 fatty acid desaturase inhibitor, SC-26196. SC-26196 caused increases in linoleic acid and corresponding decreases in arachidonic acid and docosahexaenoic acid in select molecular species of phosphatidylcholine, phosphatidylethanolamine, and cholesterol esters but not in phosphatidylserine, phosphatidylinositol, or triglycerides. For linoleic acid-, arachidonic acid-, and docosahexaenoic acid-containing phospholipid species, this difference was, in part, determined by the fatty acid at the *sn*-1 position, namely, palmitic or stearic acid. An understanding of phospholipid remodeling mediated by Δ6 desaturase inhibition should aid in clarifying the contribution of arachidonic acid derived *via de novo* synthesis or obtained directly in the diet during inflammatory responses.

Paper no. L8754 in *Lipids 36,* 1203–1208 (November 2001).

Arachidonic acid (20:4n-6) is incorporated into lipoprotein particles after being synthesized *de novo* from linoleic acid (18:2n-6) in the liver (Scheme 1) or ingested directly in the diet (1–4). The arachidonic acid in lipoprotein particles is taken up by peripheral tissues and leukocytes where, upon incorporation into phospholipids and release by phospholipases, it serves as the substrate for the synthesis of proinflammatory prostaglandins, leukotrienes, and hydroperoxy or hydroxy fatty acid derivatives (5–9). Past studies have shown that arachidonic acid supplied exogenously to cells is mobilized into different lipid pools of which a select subset is utilized for eicosanoid production (10–16) or regulation of cell division (17). Understanding the remodeling of arachidonic acid in lipids would be significant because of its pivotal role in inflammation. Remodeling of docosahexaenoic acid would also be significant because of its ability to compete with and reduce the tissue level of arachidonic acid (18,19).

*In vivo* studies on the remodeling of phospholipids and the ensuing effect on the metabolism of arachidonic acid and other bioactive lipids have been limited by the lack of selective fatty acid desaturase inhibitors (20,21). This is especially true when attempting to delineate the role of polyunsaturated fatty acids (PUFA) derived from the diet vs. synthesized *de novo*. Recently, SC-26196 was described as a selective inhibitor of the Δ6 fatty acid desaturase (22). In this study, electrospray and tandem mass spectrometry (ES/MS/MS) were used to quantify changes in lipid remodeling following the dosing of mice with SC-26196. A further degree of biological sophistication was observed in that changes in the levels of linoleic and arachidonic acids occurred in specific molecular species within a given lipid class.

## MATERIALS AND METHODS

*Materials and reagents.* Authentic lipids used as standards in MS/MS methods development and as internal standards for quantification were purchased from Avanti Polar Lipids, Inc. (Alabaster, AL). The vehicle for intraperitoneal (ip) dosing consisted of 0.5% methylcellulose + 0.025% Tween-20 (polyoxyethylene-sorbitan monolaurate) + 5% dimethylsulfoxide (DMSO), all purchased from Sigma Chemical Co. (St. Louis, MO). Organic solvents were Optima grade from Fisher Scientific (Pittsburgh, PA). Routine laboratory chemicals were purchased from Sigma Chemical Co. or Fisher Scientific. Sample preparation of lipids/fatty acids was done in glass test tubes having Teflon-lined caps.

*Dietary regimen and dosing.* Animal studies were approved by the Monsanto Institutional Animal Care and Use Committee and conformed to its guidelines. Female Balb/C mice were purchased at 8–10 wk of age and upon arrival were fed a standard rodent chow diet (Teklad 2215 [W] rodent diet 8640, Harlan, Madison, WI). Two days prior to initiating dosing, the mice were switched to a corn oil diet (AIN-76-based corn oil diet, DYETS, Inc., Bethlehem, PA). The switch in diets was made because approximately 0.5 mg of arachidonic acid is consumed per day in the standard chow diet by a 20-g mouse (Lab Diet™, The Richmond Standard™, Animal Diet Reference guide, PMI Feeds, Inc., St. Louis, MO). This level of arachidonic acid may be high enough to circumvent partial depletion of arachidonic acid during chronic inhibition of Δ6 desaturase activity by SC-26196. In contrast, the corn oil diet contains linoleic acid (18:2n-6) and oleic acid (18:1n-9) but not arachidonic acid (23). Furthermore, the high level of linoleic acid in the corn oil diet provides substrate for the *in vivo* synthesis of arachidonic acid, which, in the presence of SC-26196, would be inhibited.

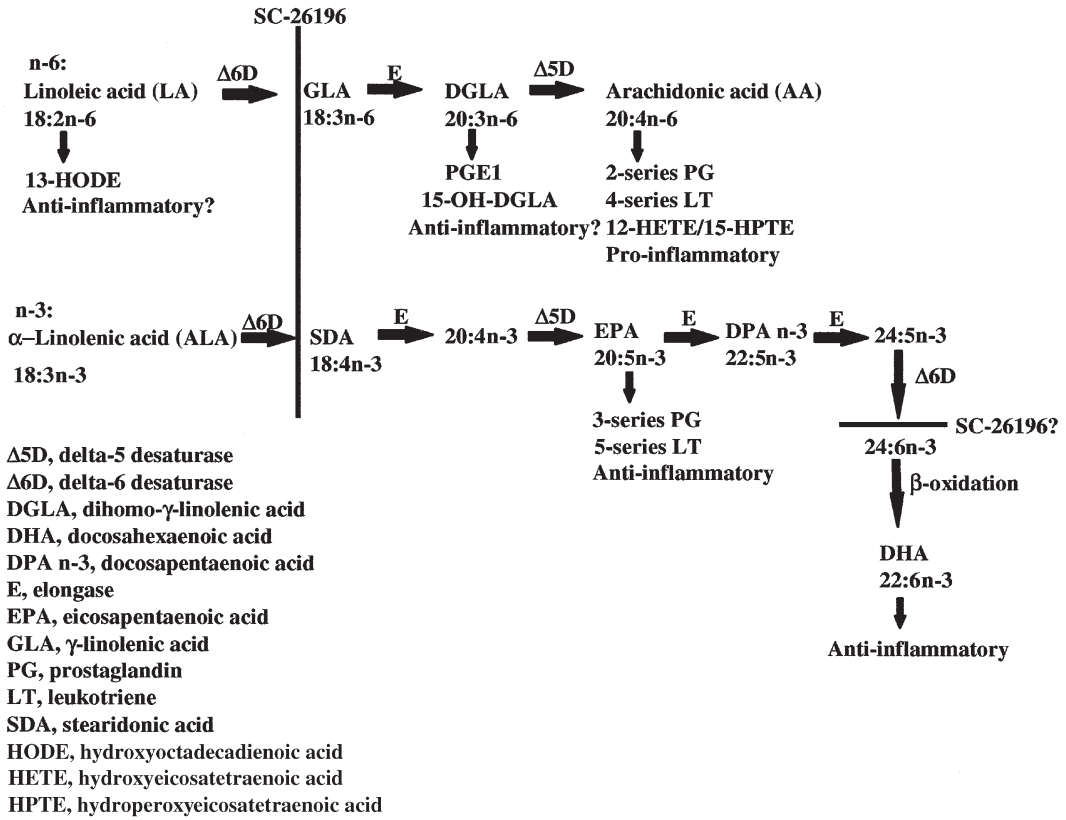
Abbreviations: DMSO, dimethylsulfoxide; ES/MS, electrospray mass spectrometry; ip, intraperitoneal; mpk, milligram per kilogram body weight; MS/MS, tandem mass spectrometry; PUFA, polyunsaturated fatty acid.



SCHEME 1

SC-26196 was prepared as a suspension in vehicle (methylcellulose/Tween-20/DMSO) by wet milling (Retsch, model MM2 wet miller, Haan, Germany). SC-26196 was administered as 0.1 mL bolus doses of 100, 30, or 10 mg/kg body weight (mpk) by ip injections twice daily (approximately 7:00 AM and 5:00 PM) for a total of 9 d. Control groups were administered vehicle using the same dosing regimen. Five mice were included per group.

*Lipid extraction.* At the end of the dosing regimen, the mice were anesthetized with $CO_2/O_2$ (80:20), blood samples were obtained by retroorbital bleeding, and plasma was prepared. The mice were then sacrificed by $CO_2$ inhalation, and liver tissue was removed and blotted. Liver and plasma samples were frozen immediately in tubes placed on dry ice and stored at −80°C until analysis.

Total lipids from liver tissue and plasma were prepared for ES/MS/MS according to a modified Bligh and Dyer procedure (24). Extraction of lipids from liver tissue was described previously (23). For extraction of lipids from plasma, 500 μL of $CHCl_3$/MeOH/$H_2O$ (1:2:0.3) was added to 25 μL plasma. The mixture was centrifuged at 10,000 × *g* for 5 min at room temperature. A second extraction was performed on the pellet by adding 300 μL of $CHCl_3$/MeOH/$H_2O$ (1:2:0.8), vortexing vigorously, and then centrifuging at 10,000 × *g* for 5 min at room temperature. The supernatant was decanted and pooled with the first supernatant. The pooled supernatants were diluted with 250 μL of chloroform, yielding a final lipid extract from 25 μL plasma solubilized in 1.1 mL of $CHCl_3$/MeOH/$H_2O$.

*ES/MS/MS.* For lipid quantification by ES/MS/MS, the liver or plasma lipid extract in $CHCl_3$/MeOH/$H_2O$ was added to an equal volume of $CHCl_3$/MeOH (1:1, vol/vol) containing 10 mM ammonium acetate and a specific concentration (10–50 μg/mL) of internal standard. Lipid extracts were introduced directly into a Sciex API III+ electrospray triple quadrupole mass spectrometer (Sciex, Inc., Thornhill, Canada) operated in the positive ion mode. Specific details of mass spectrometer operating conditions and lipid identification and quantification were published previously (23).

*Statistics.* All doses of SC-26196 and the vehicle were included in a one-way analysis of variance for each fatty acid and lipid species (Figs. 2–4). Because plasma samples were taken only from animals injected with vehicle or 100 mpk SC-26196, the focus was restricted to a comparison between the mean response for vehicle vs. 100 mpk SC-26196 in both liver and plasma samples. If the *P* value was less than 0.05 (two-tailed), the means were considered to be significantly different.

## RESULTS AND DISCUSSION

Fatty acid remodeling within particular lipid classes is critical to understanding the role of the Δ6 desaturase in inflammation because arachidonic acid is found in specific phospholipid species and can be released by phospholipases and converted to proinflammatory eicosanoids by cyclooxygenase and lipoxygenase (6,9–16,25–28). As an initial step in gaining an understanding of the role of *de novo* synthesis of PUFA in lipid remodeling, ES/MS/MS was used in a direct and

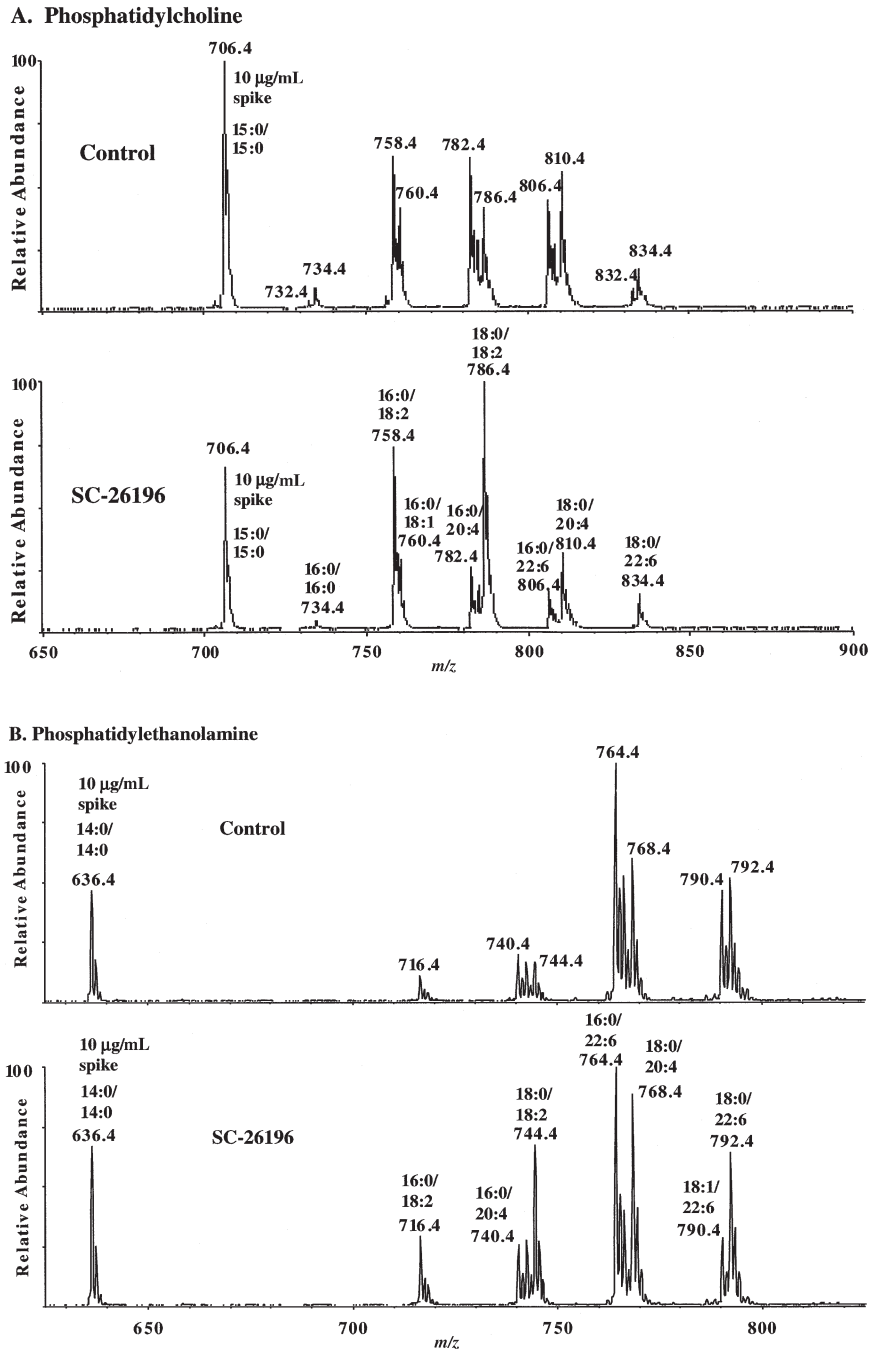


**FIG. 1.** SC-26196-mediated changes in the mass spectra of mouse liver lipids. Shown are representative electrospray mass spectra of liver phosphatidylcholine (A) and phosphatidylethanolamine (B) from a mouse injected with vehicle (control) or 100 mg/kg body weight (mpk) SC-26196 [twice daily intraperitoneal (ip) dosing for 9 d]. Liver lipids were extracted and analyzed by electrospray tandem mass spectrometry (ES/MS/MS) (see the Materials and Methods section for details). SC-26196 is a selective inhibitor of the Δ6 fatty acid desaturase.

facile way to evaluate changes resulting from inhibition of Δ6 desaturase activity by SC-26196, a selective Δ6 fatty acid desaturase inhibitor. Given that SC-26196 was not profiled for its specificity in all aspects of lipid metabolism, its precise mechanism of action *in vivo* remains uncertain.

Dosing of mice with SC-26196 caused quantitative changes in linoleic acid-, arachidonic acid-, and docosahexaenoic acid-containing phospholipid and cholesterol ester species in liver and plasma that were indicative of Δ6 desaturase inhibition, *viz.*, increased substrate (i.e., linoleic acid) and decreased products (i.e., arachidonic acid and docosahexaenoic acid) (Scheme 1, Figs. 1,2). Specifically, SC-26196 caused changes in the fatty acid composition of phosphatidylcholine, phosphatidylethanolamine, and cholesterol esters (Fig. 2) but did not change the fatty acid composition of phosphatidylinositol or phosphatidylserine (data not shown). The most significant changes were seen in linoleic acid-, arachidonic acid-, and docosahexaenoic acid-containing species (Fig. 2). In liver and plasma phosphatidylcholine, the linoleic acid-containing species increased, whereas the arachidonic

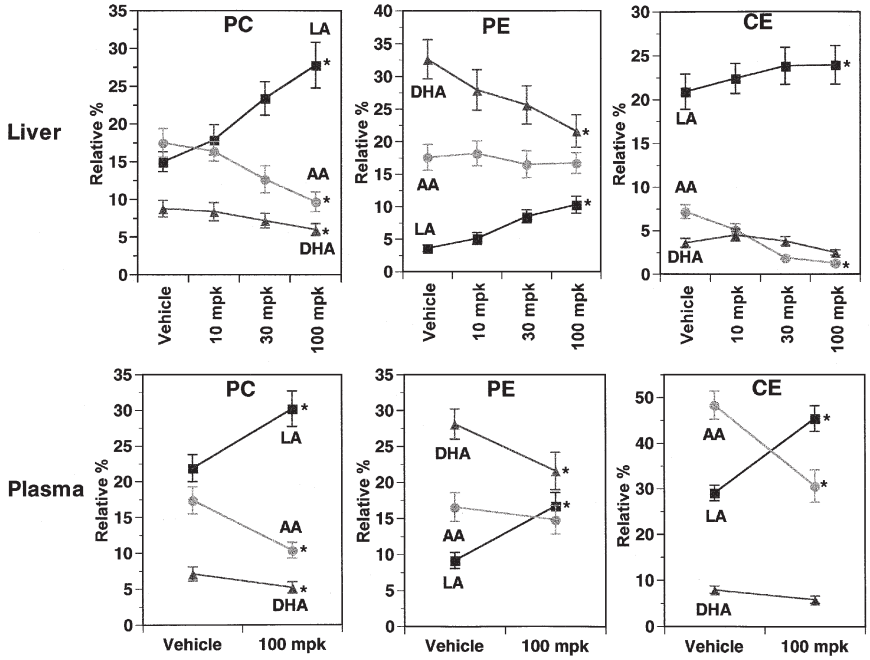

**FIG. 2.** SC-26196-mediated changes in the relative amounts of linoleic acid (LA), arachidonic acid (AA), and docosahexaenoic acid (DHA) in phosphatidylcholine (PC), phosphatidylethanolamine (PE), and cholesterol esters (CE) in mouse liver and plasma. Liver samples were taken from mice injected with vehicle (control) or 10, 30, or 100 mpk SC-26196 (twice daily ip dosing for 9 d). Plasma samples were taken from mice injected with vehicle (control) or 100 mpk SC-26196 (twice daily ip dosing for 9 d). Plasma was obtained by retroorbital bleeding. Plasma and liver lipids were extracted and analyzed by ES/MS/MS (see the Materials and Methods section for details). Results are expressed as the mean ± standard error of the mean ($n$ = 5/group). *$P < 0.05$ at 100 mpk dose. For abbreviations see Scheme 1.

acid- and docosahexaenoic acid-containing species decreased. The results were not as uniform in phosphatidylethanolamine and cholesterol esters of liver and plasma: (i) In phosphatidylethanolamine, linoleic acid-containing species increased and docosahexaenoic acid-containing species decreased, whereas arachidonic acid-containing species were unchanged, and (ii) in cholesterol esters, linoleic acid-containing species increased and arachidonic acid-containing species decreased, whereas docosahexaenoic acid-containing species were unchanged. In plasma, the most significant change in fatty acid composition of the individual lipid classes was observed in the cholesterol ester fraction in which the ratio of arachidonic acid/linoleic acid decreased from approximately 1.7 to 0.7 (Fig. 2).

Further quantitative analyses were performed on the individual fatty acid species of phosphatidylcholine and phosphatidylethanolamine in liver and plasma. A notable observation was that SC-26196 mediated changes in phosphatidylcholine and phosphatidylethanolamine lipid species that depended on the identity of the fatty acids acylated at the *sn*-1 and *sn*-2 positions. Phosphatidylcholine- and phosphatidylethanolamine-containing linoleic acid acylated at the *sn*-2 position increased in abundance more dramatically when stearic acid (18:0), as opposed to palmitic acid (16:0), was acylated at the *sn*-1 position in liver (Fig. 3) and plasma (Fig. 4). Conversely, phosphatidylcholine-containing arachidonic acid and phosphatidylcholine- and phosphatidylethanolamine-containing docosahexaenoic acid acylated at the *sn*-2 position decreased in abundance more dramatically when palmitic acid, as opposed to stearic acid, was acylated at the *sn*-1 position in liver (Fig. 3). In plasma, this difference was only observed with phosphatidylcholine-containing docosahexaenoic acid (Fig. 4). With phosphatidylethanolamine-containing arachidonic acid species in the liver there was not a significant change when palmitic acid or stearic acid was acylated at the *sn*-1 position (Fig. 3). Instead, arachidonic acid-containing species were reduced most significantly when oleic acid (18:1n-9) was acylated at the *sn*-1 position (Fig. 3).

These data suggest that the regulation of liver fatty acid metabolism by Δ6 desaturase inhibition involves differential turnover or selective synthesis of molecular species of phosphatidylcholine, phosphatidylethanolamine, and cholesterol esters, but not phosphatidylinositol or phosphatidylserine. Arachidonic and docosahexaenoic acids appear to be remodeled similarly in liver following treatment of mice with SC-26196. This observation is consistent with the requirement for Δ6 desaturation for *de novo* synthesis of both fatty acids (Scheme 1) (23). For linoleic acid-, arachidonic acid-, and docosahexaenoic acid-containing phospholipid species, remodeling, in part, appears to be determined by the fatty acid at the *sn*-1 position, most often palmitic acid or stearic acid. The specificity of *sn*-1 and *sn*-2 positioning could regulate acylase- and transacylase-mediated lipid remodeling, which could ultimately determine the lipid species that serve as sources of arachidonic acid for eicosanoid metabolism (10–16,20). Lipid species selectivity could also explain why SC-26196 did not decrease the relative amount of arachidonic acid in liver total lipids (22) or why only a small decrease occurred in liver phospholipids and cholesterol esters (Fig. 2). Only when specific liver lipid species were quantified by ES/MS/MS, *viz.,* phosphatidylcholine, phospha-

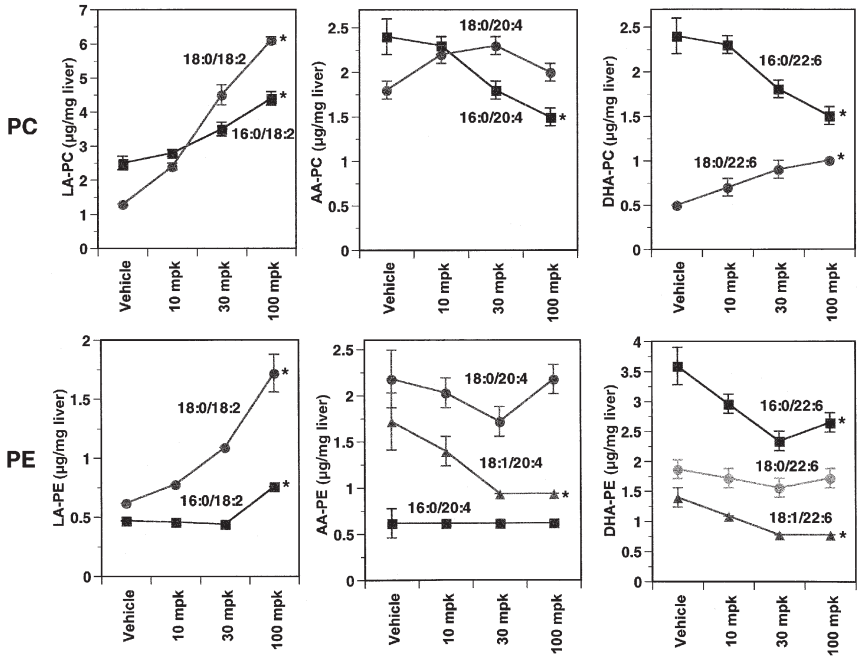

**FIG. 3.** SC-26196-mediated changes in the absolute amounts of major liver PC and PE molecular species containing LA (18:2), AA (20:4), and DHA (22:6). Liver samples were taken from mice injected with vehicle (control) or 10, 30, or 100 mpk SC-26196 (twice daily ip dosing for 9 d). Liver lipids were extracted and analyzed by ES/MS/MS (see the Materials and Methods section for details). Results are expressed as the mean ± standard error of the mean ($n$ = 5/group). *$P < 0.05$ at 100 mpk dose. Other notations: 18:0, stearic acid; 16:0, palmitic acid; and 18:1, oleic acid. For abbreviations see Figures 1 and 2.

tidylethanolamine, and cholesterol esters, did SC-26196 cause a decrease in arachidonic acid (Fig. 3).

Given that the liver is a major source of PUFA-containing lipid species transported *via* the vasculature as very low density lipoprotein and low density lipoprotein particles, it was anticipated that lipid remodeling in liver would reflect that in plasma and, generally, that was the case (Fig. 2). There were exceptions with select lipid species, *viz*., 16:0/18:2- and 18:0/20:4-phosphatidylcholine and 16:0/22:6- and 18:1/22:6-phosphatidylethanolamine (Figs. 3,4). Of the phospholipids, arachidonic acid was affected most in phosphatidylcholine (16:0/20:4) and phosphatidylethanolamine (18:1/20:4), two classes that serve as substrates for its release and metabolism to various eicosanoids (25–28). A notable caveat, however, is that lipid remodeling in liver and plasma may not be indicative of lipid remodeling in eicosanoid-producing cells (e.g., circulating leukocytes, resident macrophages, fibroblasts, and endothelial cells). Additionally, the specific arachidonic acid-containing phospholipid pool for eicosanoid biosynthesis has been difficult to define in any cell (10–16). Future work should thus address the effect of Δ6 desaturase inhibition on remodeling in eicosanoid-producing cells. Furthermore, an understanding of phospholipid remodeling in inflammatory cells mediated by Δ6 desaturase inhibition should clarify the contribution of arachidonic acid derived *via de novo* synthesis or obtained directly in the diet.

**ABSTRACT:** These studies were undertaken to assess guinea pigs as potential models for early atherosclerosis development. For that purpose, male, female, and ovariectomized (to mimic menopause) guinea pigs were fed a control or a TEST diet for 12 wk. Differences between diets were the type of protein (60% casein/40% soybean vs. 100% soybean) and the type of fiber (12.5% cellulose vs. 2.5% cellulose/5% pectin/5% psyllium) for control and TEST diets, respectively. Diet had no effect on plasma cholesterol or triacylglycerol (TAG) concentrations; however, there were significant effects related to sex/hormonal status. Ovariectomized guinea pigs had higher plasma cholesterol and TAG concentrations than males or females ($P < 0.01$). In contrast to effects on plasma lipids, hepatic cholesterol and TAG were 50% lower in the TEST groups ($P < 0.01$) compared to controls. Low density lipoproteins (LDL) from guinea pigs fed the TEST diet had a lower number of cholesteryl ester (CE) molecules and a smaller diameter than LDL from controls. Atherosclerotic lesions were modulated by both diet ($P < 0.0001$) and sex ($P < 0.0001$). Guinea pigs fed the TEST diet had 25% less lesion extension whereas males had 20% larger occlusion of the arteries compared to both female and ovariectomized guinea pigs. Significant positive correlations were found between LDL CE and atherosclerotic lesions ($r = 0.495$, $P < 0.05$) and LDL size and fatty streak area ($r = 0.56$, $P < 0.01$). In addition, females fed the TEST diet had the lowest plasma and hepatic cholesterol concentrations, the smallest LDL particles, and the least atherosclerosis involvement compared to the other groups. These data indicate that dietary factors and sex/hormonal status play a role in determining plasma lipids and atherosclerosis in guinea pigs.

Paper no. L8764 in *Lipids 36,* 1209–1216 (November 2001).

Coronary heart disease (CHD) is the leading cause of death among men and women in the United States (1). Several lines of evidence indicate that elevated serum concentrations of low density lipoproteins (LDL) promote atherogenesis and increase the risk for CHD (2). Gender is a strong predictor of CHD susceptibility, and reports from the Registrar's mortality data indicate that men are more likely to develop CHD than premenopausal women (3). Postmenopausal women are at a greater risk than premenopausal women for CHD owing to detrimental changes in plasma lipids and lipoprotein levels occurring after menopause (4).

Recent reports have linked dietary soy protein and soy-based food products with a reduction in CHD and improvement in a number of related risk factors. Asian women, who consume primarily soy protein, have a lower CHD mortality than women eating a Western diet (5). Soy protein has also been shown to reduce atherosclerosis in cynomolgus monkeys (6) and rabbits (7,8). Soy protein seems to have its greatest and most consistent effect on LDL. Greaves *et al.* (9) reported that isolated soy protein containing naturally occurring isoflavones was associated with LDL cholesterol lowering in cynomolgus monkeys. Compared to a casein diet, soy protein has been shown to reduce apolipoprotein (apo) B synthesis and stimulate LDL receptors (10).

Viscous soluble fibers such as pectin or guar gum, as well as viscous nonfermentable fibers such as psyllium, lower plasma cholesterol concentrations (11). These fibers reduce cholesterol absorption in the small intestine resulting in plasma very low density lipoproteins (VLDL) and LDL cholesterol lowering in response to depletion of hepatic cholesterol and induction of apo B/E receptors (12). Soluble fibers have been shown to lower plasma cholesterol levels in humans (13) and in various animal models (11,13–16).

The present study had the following objectives: (i) to evaluate the potential use of guinea pigs as models for early atherosclerosis development, (ii) to investigate whether diets high in vegetable protein and soluble fiber reduce atherosclerotic lesions resulting from a high intake of cholesterol, and (iii) to determine whether sex and hormonal status modulate the extent of the atherosclerotic lesions. Our TEST diet (100% soybean protein, 10% soluble fiber) was used to ensure significant differences in atherosclerotic lesions between groups and to demonstrate that vegetable protein and soluble fiber have a beneficial effect on atherosclerosis development even in the presence of high levels of dietary cholesterol. In addition to lipid levels, composition and size of VLDL and LDL were determined to evaluate potential atherogenic factors within subclasses of lipoproteins. Our hypothesis was that dietary factors and sex/hormonal status would interact to determine atherosclerosis development.

Guinea pigs were used as the experimental animal model because their lipoprotein profile and response to dietary factors are similar to humans (17). We also hypothesized that guinea pigs would be a good model to evaluate fatty streak

Abbreviations: ANOVA, analysis of variance; apo, apolipoprotein; CE, cholesteryl ester; CHD, coronary heart disease; FC, free cholesterol; LSD, least significant differences; LDL, low density lipoproteins; PL, phospholipids; TC, total cholesterol; TAG, triacylglycerol; VLDL, very low density lipoproteins.

accumulation resulting from intake of hypercholesterolemic diets. Male, female, and ovariectomized guinea pigs, a model for menopause established by our laboratory (18), were used to observe any unique gender differences in lipid metabolism and atherosclerosis development.

## MATERIALS AND METHODS

*Materials*. The source for the enzymatic assay kits for plasma free cholesterol (FC) and phospholipids (PL) was Wako Pure Chemical Industries (Osaka, Japan). Cholesterol enzymatic assay kits, cholesterol standards, triacylglycerol (TAG) enzymatic kits, TAG standards, cholesterol oxidase, and cholesterol esterase were from Boehringer Mannheim (Indianapolis, IN).

*Diets.* Control and TEST diets were prepared and pelleted by Research Diets, Inc. (New Brunswick, NJ). The TEST diet was designed to produce differences in plasma cholesterol concentrations and lipoprotein composition compared to the control diet and to determine whether these alterations in the measured parameters would relate to early atherosclerosis development. In addition, one goal was to demonstrate that high intake of dietary cholesterol in combination with vegetable protein and soluble fiber would result in a more favorable lipoprotein profile and fewer atherosclerotic lesions. Both diets had the same composition except for the type of fiber and the type of protein (Table 1). They both contained 0.33% cholesterol, equivalent to 2475 mg/d in humans (19), and the fatty acid mixture was high in lauric and myristic acids, fatty acids known to be hypercholesterolemic in guinea pigs. The fat mix was olive oil/palm kernel oil/safflower oil in a proportion 1:2:1.8 (20). The control diet contained 12.5% cellulose as the fiber source and the protein portion was made up of 60% casein and 40% soybean. The TEST diet was formulated with 2.5% cellulose, 5% pectin, and 5% psyllium as fiber sources and 100% soybean as protein source. The soybean protein used was intact, containing naturally occurring isoflavones. The control diet had 40% soybean and 60% casein because higher concentrations of casein result in the development of kwashiorkor in guinea pigs (Fernandez, M.L., and McNamara, D.J., unpublished observations).

**TABLE 1**
**Composition of Experimental Diets**

| Components | g/100 g Control | TEST |
|---|---|---|
| 40% soybean/60% casein | 23.0 | — |
| Soybean protein | — | 22.5 |
| Methionine | — | 0.5 |
| Sucrose | 25.0 | 25.0 |
| Corn starch | 15.0 | 15.0 |
| Fat mix[a] | 15.1 | 15.1 |
| Cellulose | 12.5 | 2.5 |
| Pectin | — | 5.0 |
| Psyllium | — | 5.0 |
| Mineral mix[b] | 8.2 | 8.2 |
| Vitamin mix[b] | 1.1 | 1.1 |
| Cholesterol | 0.33 | 0.33 |

[a]Fat mix contained 7.8% myristic, 23.8% lauric, 9.2% palmitic, 8.6% stearic, 19.9% oleic, 26.4% linoleic acids, and 4.3% others.
[b]Mineral and vitamin mixes were adjusted to meet National Research Council requirements for guinea pigs.

*Animals*. Forty-four male, female, or ovariectomized guinea pigs from Harlan Sprague-Dawley, Inc. (Indianapolis, IN), weighing between 300 and 400 g, were randomly assigned to either control or TEST diets. Ovariectomized female guinea pigs were incorporated to mimic menopause. The number of guinea pigs used was 14 males (8 control and 6 TEST), 13 females (7 control and 6 TEST), and 17 ovariectomized (11 control and 6 TEST). Animals were caged in pairs in a light cycle room (light from 7:00 A.M. to 7:00 P.M.). They were gradually adapted to their respective diets with nonpurified diet over a period of 7 d and then fed the experimental diet for a period of 12 wk. All experimental protocols were performed in accordance with U.S. Public Health Service and U.S. Department of Agriculture guidelines. Experiments were approved by the University of Connecticut Institutional Animal Care and Use Committee.

*Plasma cholesterol and TAG assays*. Blood samples were taken by cardiac puncture from nonfasted guinea pigs after they were anesthetized with halothane vapors. Blood was collected with a syringe containing EDTA (anticoagulant) at a concentration of 1.5 mg/mL and was centrifuged at 2000 × *g* for 20 min. Plasma was separated from red blood cells, and plasma total cholesterol (TC) and TAG concentrations were measured by enzymatic methods (21,22). High density lipoprotein cholesterol was measured after precipitation of apo B–containing lipoproteins according to Warnick *et al*. (23) with a slight modification consisting of the use of $MgCl_2$ at a concentration of 2 mol/L (24).

*Lipoprotein isolation and composition*. A preservation cocktail was added to individual plasma samples to ensure minimal changes in composition during isolation. The cocktail consisted of sodium azide ($NaN_3$) (0.1 mL per 100 mL of plasma), phenyl methyl sulfonyl fluoride (0.1 mL per 100 mL of plasma), and aprotonin (1000 IU/mL; 0.5 mL per 100 mL of plasma). VLDL and LDL were isolated by ultracentrifugation in a subset of animals (3 males, 3 females, and 5 ovariectomized per dietary group) at densities of 1.019 and 1.09 kg/L, respectively. Compositions of these fractions were determined by measuring PL (25), TAG (22), and free and total cholesterol (21). Protein was determined by a modification of the Lowry procedure (26). The number of molecules in the LDL subfraction was calculated based on one apo B for each LDL with a molecular mass of 412,000 kDa (27). The number of molecules of TAG, FC, esterified cholesterol, and PL was calculated using molecular weights of 885.4, 386.6, 645, and 734, respectively (28). LDL diameter was calculated according to Van Heek and Zilversmit (29).

*Hepatic lipids*. Samples were suspended overnight in chloroform/methanol 2:1 to extract lipids from liver. With this extract, TC and FC were determined by enzymatic methods (21). Hepatic cholesteryl ester (CE) was calculated by subtracting free from total hepatic cholesterol. Hepatic TAG were determined by an enzymatic method after blanking for glycerol (22).

*Atherosclerotic lesion assessment*. Following removal of the liver, the chest cavity of the guinea pigs was opened, exposing

the heart. The heart was perfused with 10% formalin for 30 min at a pressure that supported slow but steady flow. Hearts were removed from guinea pigs with attached ascending and thoracic aorta and covered with 10% formalin at 4°C for 24 h. Hearts were placed in a container with phosphate-buffered saline (10 mmol/L sodium phosphate, $Na_2HPO_4$), 0.15 mol/L sodium chloride, and pH adjusted to 7.4 until analysis. Prior to quantification of atherosclerosis, the aortic arch was separated from the heart above the aortic valve. Lesions were evaluated as previously reported (30,31). Briefly, the portion of the aorta located between the third neck vessel and 1 mm above the aortic valve was used. The section was cleaned of adventitia and rinsed in 60% isopropanol, and then the inner aortic surface was stained with oil red O saturated 60% with the isopropanol solution. The section was then rinsed with distilled water and the luminal surface was stained with Gill's type hematoxylin (1:20 dilution) for 1 min. The aorta was then rinsed again and opened longitudinally and mounted on a glass slide with a glass coverslip and an aqueous mounting medium. The segments were then photographed using bright field microscopy. Images from the whole mounts were captured and digitized using a Color-Space II video digitizer (Massa Micro Systems, Sunnyvale, CA). The oil red O–stained area was analyzed using a Mac II computer and Image 1.23 software. Measurements are expressed in $\mu m^2/mm^2$.

*Statistics*. Data are presented as mean ± standard deviation. Differences in plasma lipids, lipoprotein composition, hepatic lipids, and aortic fatty streaks were evaluated by two-way analysis of variance (ANOVA) with diet and gender being the two variables. Fisher's least significant differences (LSD) *post-hoc* tests were used to determine significant differences among groups. Significant correlations between variables were determined by linear regression. $P < 0.05$ was considered significant.

## RESULTS

*Preliminary study.* A preliminary study was conducted to determine the percentage of cholesterol that would most effectively develop early atherosclerosis in guinea pigs. For that purpose, male guinea pigs were used. Three guinea pigs were fed the diet described in Table 1 with 0.25% dietary cholesterol, and three were fed the same diet with 0.33% cholesterol. Results from the preliminary study to test the efficacy of the diets on atherosclerosis were: 8.08 ± 0.87 mmol/L and 6.54 ± 1.0 mmol/L for TC, 6.85 ± 2.38 μmol/g and 8.79 ± 2.74 μmol/g for hepatic FC, and 23,240 ± 5,539 $\mu m^2/mm^2$ and 12,374 ± 3,512 $\mu m^2/mm^2$ for fatty streak area of guinea pigs fed the 0.33 and 0.25% dietary cholesterol, respectively. Thus, there were no significant differences in plasma cholesterol or hepatic lipid concentrations between groups. However, the aortic fatty streak was significantly lower ($P < 0.001$) in guinea pigs fed 0.25% than in those fed 0.33% cholesterol. Based on these results, the diet containing 0.33% dietary cholesterol was used to evaluate diet and gender effects on lipoprotein metabolism and atherosclerosis development.

*Plasma and lipoprotein cholesterol and TAG concentrations.* There were no significant differences between groups in food consumption or weight gain (data not shown). Plasma TC and TAG concentrations for male, female, and ovariectomized guinea pigs fed control and TEST diets are presented in Table 2. Plasma TC concentrations were significantly higher ($P < 0.0001$) in the ovariectomized guinea pigs compared to the males and females. Surprisingly, plasma cholesterol and TAG concentrations were not different between guinea pigs fed the control or TEST diets. No interactive effect was observed for plasma cholesterol (Table 2). However, plasma TAG concentrations were higher in ovariectomized guinea pigs fed the TEST diets ($P < 0.05$), indicating that hormonal status (lack of estrogen) and dietary soluble fiber and soybean protein interacted to induce the highest plasma TAG concentrations in this group of guinea pigs.

Plasma lipoprotein cholesterol levels of male, female, and ovariectomized guinea pigs are shown in Table 3. There were no significant effects of diet or gender or an interaction on plasma VLDL or HDL cholesterol values. In contrast, plasma LDL cholesterol concentrations, similar to the observations for plasma TC, were significantly influenced by gender ($P < 0.01$), with ovariectomized guinea pigs having the highest values. No diet or interaction effect was observed for plasma LDL cholesterol (Table 3).

*Hepatic cholesterol and TAG concentrations*. There was a significant diet effect ($P < 0.001$) on hepatic TC, but there was no gender or interaction effect, as shown in Table 4. Likewise, FC and esterified cholesterol were influenced by diet ($P < 0.01$). Guinea pigs fed the TEST diet had 50% lower hepatic cholesterol concentrations than those fed the control diet. No gender or interaction effects were observed for TC, FC, or esterified cholesterol in liver (Table 4). There was a diet and a gender effect on hepatic TAG; however, there was no interaction effect as shown in Table 4. Male, female, and ovariectomized controls had an average 54% higher hepatic TAG ($P < 0.01$) than the male, female, and ovariectomized TEST guinea pigs. There was a gender effect because the males and ovariectomized guinea pigs had higher ($P < 0.01$) hepatic TAG than females.

| Male ($n$ = 3) | 0.23 ± 010 | 7.17 ± 0.39$^{c,d}$ | 0.41 ± 0.30 |
| Female ($n$ = 3) | 0.37 ± 0.17 | 6.59 ± 1.50$^{c}$ | 0.34 ± 0.35 |
| Ovariectomized ($n$ = 5) | 0.18 ± 0.06 | 10.99 ± 4.1$^{d}$ | 0.36 ± 0.24 |
| Two-way ANOVA | | | |
| Diet effect | NS | NS | NS |
| Group effect | NS | $P < 0.01$ | NS |
| Interaction | NS | NS | NS |

[a]Values are expressed as mean ± SD for the number of guinea pigs indicated in parentheses. Numbers in the same column with different roman superscript letters are significantly different as determined by Fisher's LSD *post-hoc* test. VLDL-C, very low density lipoprotein cholesterol; LDL-C, low density lipoprotein cholesterol; HDL-C, high density lipoprotein cholesterol; for other abbreviations see Table 2.

*Lipoprotein composition*. VLDL composition data are presented in Table 5. No significant gender or interaction effects in the relative percentage of FC, CE, PL, TAG, or protein or in the CE/protein ratio of VLDL were observed. However, there were diet effects on the relative percentage of CE, PL, and CE/protein ratio. The relative percentage of CE in VLDL was higher in guinea pigs fed control diets ($P < 0.01$), whereas the relative percentage of PL was higher in guinea pigs fed the TEST diet (Table 5). The ratio of CE to protein was significantly higher in guinea pigs fed the control diet ($P < 0.05$), suggesting that VLDL particles are larger in size since they have a higher core-to-surface ratio (Table 5). Fisher's LSD *post-hoc* test indicated that female guinea pigs fed the test diet had the lowest CE/protein ratio (Table 5).

LDL composition (FC, CE, PL, and TAG), in terms of number of molecules and LDL diameter, is presented in Table 6. There was a significant diet effect ($P < 0.05$) on the number of molecules of CE. Guinea pigs fed the control diet had a higher number of CE molecules than those fed the TEST diet. In addition, the number of TAG molecules was lower in the TEST groups ($P < 0.05$) compared to the control groups (Table 6). Diet and gender effects were observed when LDL diameter was evaluated. Guinea pigs fed the control diet had significantly larger ($P < 0.001$) LDL diameters than the groups fed the TEST diet. Females also had significantly smaller ($P < 0.05$) LDL diameters when compared to male or ovariectomized groups (Table 6).

*Aortic fatty streak*. Aortic fatty streak values were influenced by both diet and gender as shown in Table 7. Two-way ANOVA indicated that there was a significant diet effect ($P < 0.0001$), as fatty streaks in the control guinea pigs were larger than in those fed the TEST diet. A significant gender effect ($P < 0.01$) was also observed. Male animals had larger fatty streaks than female or ovariectomized animals. Female TEST guinea pigs presented less ($P < 0.01$) aortic fatty streak than any other group. Ovariectomized guinea pigs fed the TEST diet were different only from male control animals (Table 7).

To further assess whether LDL composition affected the deposition of CE for foam cell formation, correlations between LDL composition and size and atherosclerosis were evaluated. There was a positive correlation ($r = 0.495$, $P < 0.05$) between number of CE molecules in LDL and fatty streak area as shown in Figure 1. The size or diameter of the LDL particle was also correlated ($r = 0.56$, $P < 0.05$) with fatty streak area. Larger LDL particles appeared to be more atherogenic as depicted in Figure 2.

## DISCUSSION

These studies suggest that guinea pigs develop atherosclerosis with hypercholesterolemic diets and that the extension of the atherosclerotic lesion is closely associated with sex and hormonal status. This is an important finding because animal models for lipid metabolism need to respond to lipid accumulation in plasma by similar physiological and pathological

[a]Values are expressed as mean ± SD for the number of guinea pigs indicated in parentheses. Numbers in the same column with different roman superscript letters are significantly different as determined by Fisher's LSD *post-hoc* test. For other abbreviations see Tables 2 and 4.

events leading to atherosclerotic lesions to make them appropriate models that mimic the human situation (32).

In addition, plasma LDL cholesterol concentrations were not related to the extent of the lesion; rather, LDL particle size and CE content appeared to be more important determinants of fatty streak formation in guinea pigs. Also, sex and hormonal status apparently play a major role in atherosclerotic lesion formation.

*Effects of diet and gender on hepatic cholesterol and TAG metabolism.* Hepatic FC and esterified cholesterol were lower in male, female, and ovariectomized guinea pigs fed the TEST diets. This hepatic cholesterol lowering could be a direct effect of soluble fiber interfering with absorption of dietary cholesterol. It could also be due to the mobilization of cholesterol from liver to synthesize bile acids to compensate for bile acid loss through interruption of the enterohepatic circulation (11). In addition, soy protein has also been shown to reduce absorption of dietary cholesterol and increase bile acid excretion; thus, the increased amount of soy protein in the TEST diet may have contributed to the lowering of cholesterol in liver (33).
