These reductions in hepatic cholesterol have been related to up-regulation of apo B/E receptor activity, which in turn draws LDL cholesterol from plasma (34). However, in this study, after guinea pigs were fed the TEST and control diets for 12 weeks, no significant effects were observed on plasma cholesterol levels, which suggests that the up-regulation of hepatic apo B/E receptors is not taking place after longer feeding periods. Guinea pigs fed the TEST diet had lower hepatic TAG concentrations than animals fed the control diet. The mechanism causing decreased hepatic TAG concentrations may be related to the capacity of soluble fiber to delay their absorption in the intestinal lumen (35). Inhibition of lipogenesis in the liver may also account for the observed reduction of hepatic TAG in conjunction with delayed intraluminal absorption (36).

In addition, in rats a higher concentration of hepatic cholesterol has been correlated with higher concentration of hepatic TAG (37). This is due to a decreased synthesis of carni-

tine, which may result in less mobilization of fatty acids to mitochondria for β oxidation and increased fatty acid and TAG synthesis (36). In the present study, the higher hepatic cholesterol concentrations in the control groups may reflect a similar situation to that observed in the rat. The higher levels of hepatic cholesterol in control guinea pigs may affect carnitine synthesis and promote TAG accumulation in the liver. Thus, in guinea pigs fed the TEST diets, the lower concentrations of hepatic TAG could also be related to the lower concentration of hepatic cholesterol observed in the TEST groups.

*Effects of diet and gender on plasma TC and TAG levels.* Previous studies have shown that pectin and psyllium lower plasma cholesterol and TAG in guinea pigs (11,14) and other animal models (15,38). In addition, isolated soy protein lowered plasma TC in cynomolgus monkeys (9), and hamsters and guinea pigs fed soybean protein for 4 wk also had plasma cholesterol lowering (24). Contrary to these findings, in the present study, soluble fiber in conjunction with soy protein had no effect on plasma cholesterol or TAG after a longer feeding period of 12 wk. These results were unexpected and

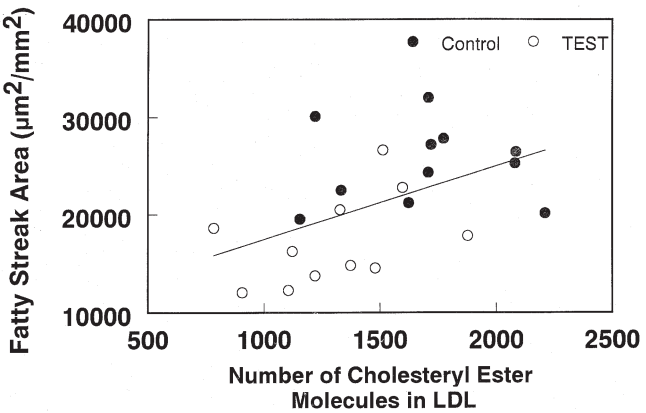

**FIG. 1.** Correlation between low density lipoprotein (LDL) number of molecules of cholesteryl ester and lesion involvement in male, female, and ovariectomized guinea pigs fed control (●) and TEST (○) diets ($r$ = 0.495, $P < 0.05$).

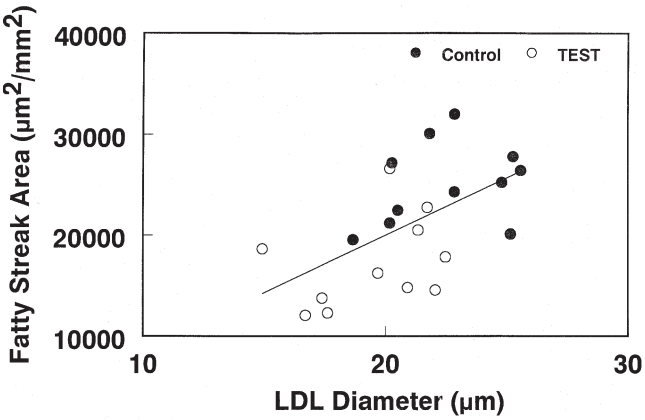

**FIG. 2.** Correlation between LDL diameter and lesion involvement in male, female, and ovariectomized guinea pigs fed control (●) and TEST (○) diets ($r$ = 0.56, $P < 0.01$). See Figure 1 for abbreviation.

can only be related to the longer feeding time in the present study compared to the earlier studies (11,14,24). Similar to the lack of correlation between plasma cholesterol and early atherosclerosis development found in the present study, Calleja *et al.* (39) also did not find changes in plasma cholesterol concentrations in apo E knockout mice eating different types of oils, whereas atherosclerotic lesions differed according to the type of fat and the sex of the animals.

In this study a group effect in TC was observed because ovariectomized guinea pigs had higher plasma cholesterol levels than males or females. Similar elevated plasma cholesterol and TAG levels have been observed in our previous study (18), and they could be attributed to the lack of estrogen. These results are in agreement with human studies that have shown postmenopausal women have significantly higher risk factors for CHD, such as higher plasma LDL cholesterol, apo B, and TAG levels (4).

Plasma TAG were highest in ovariectomized guinea pigs fed the TEST diet. It is possible that soluble fiber, similar to what has been observed in subjects treated with the bile acid-binding resin, cholestyramine (40) increased the release of VLDL from liver. Because VLDL is the major carrier of TAG in the preprandial state, an increased release of VLDL by the liver could cause an increase in plasma TAG. Vega-Lopez *et al.* (41) showed similar results in a crossover study with humans fed psyllium or control cookies for 4 wk. In this study, postmenopausal women had higher plasma TAG levels during the psyllium compared to the control period (41).

However, in female guinea pigs, plasma TAG were not increased by dietary fiber intake. These lower levels could be related to the lower hepatic TAG in females since higher hepatic triglycerides have been related to increased VLDL secretion rate (42). Endogenous estrogen may also play a role in the lowering of plasma TAG as well, although mechanisms are unclear.

*Effects of diet and gender on atherosclerosis and lipoprotein composition.* VLDL, intermediate density lipoprotein, and LDL are linked in a delipidation cascade in which TAG-rich VLDL, released from the liver, is converted into cholesterol-rich LDL. There could be a relationship between the composition of the TAG-rich VLDL being secreted by the

liver and the LDL formed in the plasma compartment. VLDL particles that are high in CE may be the precursors of LDL with a high number of CE molecules.

The TEST diet induced a lower relative percentage of CE in VLDL from male, female, and ovariectomized animals. In addition, the CE/protein ratio, which reflects the amount of esterified cholesterol compared to surface area, was higher in the control groups suggesting a larger VLDL. The VLDL particles rich in esterified cholesterol from the control guinea pigs will eventually become LDL also rich in esterified cholesterol, which are known to be more atherogenic (43). In agreement with our observations, CE-enriched VLDL have been shown to be more readily converted to LDL through the delipidation cascade in African green monkeys (44).

Epidemiologic research suggests that small, dense LDL particles may be atherogenic (45). Alternatively, there is evidence suggesting that a high-fat diet results in the predominance of larger LDL particles in humans (46) and saturated fat results in the formation of large LDL particles, which have been associated with increased atherosclerotic events (47) in nonhuman primates. In this study, intake of the control diet resulted in a higher number of CE molecules in LDL. An association between the number of CE molecules and aortic fatty streak was also observed suggesting a potential role of CE amount in early atherosclerosis development, similar to the observations in nonhuman primates (46).

In the present study, there was a reduction in LDL diameter in guinea pigs fed the TEST diet when compared to controls. In addition, an association between LDL diameter and fatty streak formation was found, implying that large LDL could be more atherogenic. Larger LDL particles were seen in the males and ovariectomized guinea pigs than the females. As a result, female TEST animals had the least amount of aortic fatty streak when compared to male and ovariectomized animals. It has also been shown in humans that large LDL particles have a reduced affinity for the LDL receptor compared with intermediate size LDL (48). This property of large LDL particles might enhance their uptake by nonreceptor-mediated pathways and thus increase their atherogenic potential (49). Interestingly, estrogen supplementation in postmenopausal women reduces levels of large LDL particles (50). The role of estrogen in reducing atherosclerosis could be related to a reduction of CE-enriched LDL particles. Honore *et al*. (51) reported that intravenous administration of genistein 30 min prior to administration of acethylcholine, a known constrictor of the artery, resulted in dilation of the artery in female monkeys. These results suggest that the higher concentrations of isoflavones present in the TEST diet might have contributed to the observed reduction in atherosclerotic lesions in guinea pigs.

In the present study we demonstrated that guinea pigs develop atherosclerosis when challenged with hypercholesterolemic diets and that sex and hormonal status mediate early lesion development. In addition, we showed a potential role of LDL composition and size in fatty streak accumulation, which is more significant than plasma LDL cholesterol concentrations. In addition, it was demonstrated that the contribution of dietary cholesterol to atherosclerosis could be greatly reduced in the presence of high levels of dietary soluble fiber and soybean protein. The influence of sex/hormonal status on lipoprotein metabolism and atherosclerotic lesions was also demonstrated. Female guinea pigs had the most beneficial responses, which might be associated with the presence of estrogen.

# Incorporation of Dietary Linoleic and Conjugated Linoleic Acids and Related Effects on Eggs of Laying Hens

**Klaus Schäfer[a,*], Klaus Männer[a], Angelos Sagredos[b], Klaus Eder[c], and Ortwin Simon[a]**

[a]Institut für Tierernährung, Freie Universität Berlin, D-14195 Berlin, Germany, [b]TrocoCell Research and Trade GmbH, D-20249 Hamburg, Germany, and [c]Institut für Ernährungswissenschaften, Martin-Luther-Universität Halle, D-06108 Halle (Saale), Germany

**ABSTRACT:** In the present study, laying hens received 29 g per kg diet of a preparation containing either 70% linoleic acid (LA) or approximately the same amount of conjugated linoleic acid (CLA) in the control and experimental treatments, respectively. The CLA preparation consisted predominantly of *cis*-9,*trans*-11 and *trans*-10,*cis*-12 fatty acid isomers as free fatty acids in a ratio of 1:1. The diets were fed for 8 wk to determine the effect of dietary CLA on quality characteristics of eggs. In addition, the fatty acid composition of liver and heart was analyzed. Performance parameters (egg weight, feed efficiency) were not significantly affected by feeding the diets supplemented with CLA. The overall amount of CLA that was incorporated into yolk was 7.95 g CLA/100 g total fatty acids, or approximately 400 mg CLA/egg. The transfer efficiency of the *cis*-9,*trans*-11 isomer was higher than that of the *trans*-10,*cis*-12 isomer; however, the transfer rate of CLA isomers into yolk and tissues was significantly lower than that of linoleic acid. Dietary CLA increased the concentration of saturated fatty acids in yolk and tissues at the expense of monounsaturated fatty acids. The proportions of myristic, palmitic, and stearic acids in yolk lipids were also changed by dietary CLA. Additionally, long-chain polyunsaturated fatty acids (arachidonic acid and docosahexaenoic acid) were decreased without changing the balance of the n-6/n-3 ratio in egg yolk. The inclusion of CLA in layer diets altered the shape of the yolk and various egg parameters (albumen height, foam index, and yolk index). The results of this study indicate that CLA induces various changes in lipid and fatty acid metabolism of laying hens and affects quality characteristics of eggs.

Paper no. L8771 in *Lipids 36*, 1217-1222 (November 2001).

Conjugated linoleic acid (CLA) is a common term for a group of dienoic isomers of linoleic acid that are present as minor constituents in certain foods. Naturally occurring CLA is produced as an intermediate product of microbial metabolism of linoleic acid in the rumen. CLA isomers are incorporated into the fat of milk and meat of ruminants, which explains their relatively high concentration in these products (about 3 to 8 mg CLA/g fat). On the other hand, foods derived from nonruminants such as poultry products have relatively low CLA levels: Edible parts of chicken and eggs, for example, contain approximately 0.9 and 0.6 mg of CLA/g fat, respectively (1). Naturally occurring CLA therefore enters human diets mainly from ruminant food fats. Animal studies have demonstrated that CLA isomers might have beneficial effects, including inhibition of carcinogenesis, modulation of the immune system, prevention of atherosclerosis, and reduction of body fat accumulation as reviewed by Belury (2) and Pariza (3). This has stimulated interest in dietary treatment with CLA and the production of foods enriched with CLA.

Ip *et al.* (4) estimated on the basis of a rat model study that, to obtain health benefits, a person weighing 70 kg should consume 3.0 g of CLA per day. The actual CLA intake, however, is less than that recommendation. In Germany, the actual CLA intake has been estimated at 0.36 g per day for women and 0.44 g per day for men (5). This raises the question as to possible ways of increasing CLA intake. In nonruminants such as pigs and chickens, the fatty acid composition of tissue lipids can be significantly altered by dietary fat; it is well known that dietary fatty acids are incorporated into tissue lipids. Enrichment of animal products with CLA is a means of raising the intake of CLA. The content of CLA in ruminant milk fat can also be enhanced [see review by Griinari and Baumann (6)], but in many regards it might be more promising to produce CLA-enriched food from broilers, pigs, and, as recently shown, from eggs. Champruspollert and Sell (7) reported that eggs from hens fed diets containing 5% CLA will contain 310 to 365 mg of CLA per egg. Consumer acceptance of fatty acid–modified eggs also depends on the quality characteristics of the treated eggs. Dietary lipids are known to affect the fatty acid composition of yolk lipids. The effect of CLA on egg quality parameters would therefore be an important consideration if eggs were to serve as a source of CLA in foods.

The objectives of this research were to determine whether dietary CLA free fatty acids consisting predominantly of two isomers could be transferred efficiently into egg yolk and to measure the effect of this CLA on egg quality parameters (yolk fatty acid composition, egg shell strength, albumen height, foam and yolk indices).

## MATERIALS AND METHODS

*Animals and diets.* A total of 60 laying hens (Lohmann Selected Leghorn, LSL), 31 wk of age, were housed individually in single-cage batteries. The birds were allocated to two

Abbreviations: CLA, conjugated linoleic acid; FAME, fatty acid methyl ester; LA, linoleic acid; LDL, low density lipoprotein; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids; TAG, triacylglycerols.

groups of 30 hens each. The basal diet of the hens was supplemented with 29 g per kg of a preparation containing either predominantly linoleic acid (control group) or CLA (treatment group). The composition of the diets (g/kg) was as follows: wheat, 639; soybean meal, 200; limestone grit, 87; monocalcium phosphate, 18; soybean oil, 12; premix [containing vitamins, minerals, and amino acids according to requirements given by the National Research Council (8)], 16; LA (control diet) or CLA preparation (treatment diet), 29. Nutrients of the diets were as follows: metabolizable energy (MJ/kg), 11.9; crude protein (g/kg), 174; crude fiber (g/kg), 28; crude fat (g/kg), 57. The fat preparations containing LA or CLA were donated by TrocoCell (Hamburg, Germany). The LA preparation consisted of (in g/100 g fatty acids): palmitic acid, 7.8; stearic acid, 2.6; oleic acid, 12.8; linoleic acid, 73.4; others 3.4. The CLA preparation consisted of (in g/100 g fatty acids): palmitic acid, 7.2; stearic acid, 2.7; oleic acid, 13.2; linoleic acid, 1.1; *cis*-9,*trans*-11 CLA, 32.5; *trans*-10,*cis*-12 CLA, 32.2. The major difference between the two preparations was therefore the replacement of linoleic acid by CLA isomers, whereas concentrations of the other fatty acids were similar in both preparations. The fatty acids of both preparations were present as free fatty acids. The fatty acid composition of total lipids of the diets is shown in Table 1. The hens were given free access to food and water. Body weights, feed intake, and egg production were recorded weekly.

At the end of the 8-wk feeding trial (39 wk of age) five hens per treatment were randomly selected and slaughtered. Livers and hearts were removed and washed with saline. The organs were weighed and frozen at –20°C pending analysis. Dry matter, protein, and fat content of yolk and organs were determined, as was the fatty acid composition. Additionally, various egg characteristics, the major individual lipid fractions (triacylglycerols, phospholipids, cholesterol) and minerals were analyzed for determination of treatment effects. Egg quality was determined with reference to specific parameters (egg shell breaking strength, albumen height, yolk index, and foam index).

*Determination of crude nutrient contents.* Crude protein, crude fiber, and crude fat were analyzed according to standard procedures (9).

*Analysis of fatty acid composition.* Details of the method have been described previously (10). Total lipid was extracted from freeze-dried and finely ground animal tissues using chloroform/methanol 2:1 (vol/vol). Quantitation of fatty acids was done after preparation of fatty acid methyl esters (FAME) with trimethylsulfonium hydroxide (0.2 M in methanol; Macherey-Nagel, Düren, Germany). A Hewlett-Packard (HP) gas chromatograph, equipped with a 50 m Sil 88 capillary column (Chrompack, Middelburg, The Netherlands) of 0.25 mm i.d. and a coating thickness of 0.20 μm was used to separate FAME. Helium carrier-gas column flow rate was 0.85 mL/min. The injector temperature was maintained at 250°C. A temperature program with total run time of 68 min was used. The column temperature, after an initial isothermal period of 5 min at 60°C, was increased to 180°C in increments of 5°C/min, and was maintained at this temperature for 16 min. The temperature was increased again to 220°C and was maintained at the final temperature for 15 min. Samples (1 μL) were introduced with an automatic sampler HP 7673A. CLA *cis*-9,*trans*-11 and *trans*-10,*cis*-12 were separated as distinct peaks without any serious interference or overlaps. Fatty acid standards including CLA methyl esters and 13:0 as an internal standard were purchased from Sigma (Deisenhofen, Germany). The integration of chromatograms was performed using an HP 3365 II Chem Station. All results are given in g/100 g total fatty acids.

*Determination of total cholesterol, triacylglycerols (TAG), and phospholipids.* For the determination of yolk lipids, eggs were cooked. Lipids of cooked egg yolks were extracted using a mixture of hexane and isopropanol (3:2, vol/vol). An aliquot of the extract was pipetted into a reaction vial and the solvent evaporated under vacuum. The lipids were dissolved in a small volume of a mixture of chloroform and Triton X-100, and the solvent was evaporated again. Commercially available kit reagents for cholesterol and TAG assays were added and the concentrations of TAG and total cholesterol assayed by colorimetry (11).

*Analysis of minerals and trace elements.* To determine the concentrations of minerals in yolk, 0.5 g of dried samples were mineralized with 5 mL of 65% nitric acid in a 25-mL flask in a microwave oven at 180°C and topped up with demineralized water to 25 mL. Concentrations of minerals were determined by plasma emission spectrophotometry (inductively coupled plasma; Spectro Analytical Instruments, Klewe, Germany). Phosphorus was measured spectrophotometrically by the molybdate-vanadate method (9).

*Determination of egg quality parameters*. Eggshell breaking strength was determined on five eggs per treatment using a testing machine. Eggs were compressed between two plates with the major axis perpendicular to the compression surface. Breaking strength was defined as the force in N required to fracture the shell. To measure albumen height, the egg was cracked at room temperature on a reflector measuring plate. The height of albumen and yolk was measured in two eggs from each hen using a height gauge. The yolk index is defined as the ratio of yolk height (×100) to yolk width. The foam index was determined by pooling the whites of three eggs from each hen and beating air into 100 mL of liquid egg white for 120 s. The foam index is defined as the ratio of foam volume to volume of liquid egg white.

**TABLE 1**
**Fatty Acid Composition of Total Lipids of the Experimental Diets (g/100 g fatty acids)**

| | | LA diet | CLA diet |
|---|---|---|---|
| Palmitic acid | 16:0 | 10.1 | 9.0 |
| Stearic acid | 18:0 | 4.5 | 3.8 |
| Oleic acid | 18:1 | 22.1 | 21.2 |
| Linoleic acid | 18:2 | 55.5 | 19.0 |
| CLA isomers | 18:2 *cis*-9,*trans*-11 | —[a] | 18.1 |
| | 18:2 *trans*-10,*cis*-12 | — | 18.6 |
| | 18:2 others | — | 1.8 |

| Others | | 3.9 | 4.6 |

[a] —, less than 0.1 g/100 g fatty acids. LA, linoleic acid; CLA, conjugated linoleic acid.

*Calculation of transfer rates.* Transfer rates of CLA isomers and LA from diet into yolk or liver and heart were calculated as a proportion of the respective concentration ratios [as proposed by Pettersen and Opstvedt (12) for *trans* fatty acids and by Bee (13) for CLA of milk lipids in pigs]:

$$\text{transfer rate} = \frac{[\text{CLA}]/[\text{PUFA}] \text{ in the tissue}}{[\text{CLA}]/[\text{PUFA}] \text{ in the diet}} \quad [1]$$

where PUFA means polyunsaturated acids. Tissue (CLA values used in these calculations are reported in Table 7 ($n$ = 5), whereas diet values for CLA are taken from Table 1.

*Statistical analysis.* Data are presented as means ± SD. The level of significance for differences between groups was tested using either Student's *t*-test (parametric test) or the Wilcoxon-Mann-Whitney test (nonparametric test).

## RESULTS

*Animal performance data and egg quality parameters.* Performance parameters are shown in Table 2. Performance of hens was measured from 36 to 38 wk of age (test period 21 d). Body weights, egg performance (number of eggs, egg weights, and total egg mass), and feed efficiency for egg production did not differ between the two treatment groups. However, hens fed the CLA diet consumed slightly less food than those fed the LA diet. Weights of liver and heart were similar in both groups; however, the relative weight of the liver (as a percentage of body weight) was slightly higher in the hens fed the CLA diet, whereas the relative weight of heart was slightly lower than in the hens fed the LA diet (Table 3).

Eggshell stability was not significantly affected by the dietary treatment (Table 4). However, eggs from hens whose diet was supplemented with CLA had a higher yolk index and a higher foam index than eggs from hens fed the control diets. Albumen height did not differ significantly between the two groups. The concentrations of various minerals (the minerals and trace elements were identical with those shown in Table 5) in egg shells were also similar for both treatment groups (data not shown). In contrast, yolks of hens fed CLA had higher concentrations of phosphorus and zinc than yolks of hens fed the control diets (Table 5).

**TABLE 2**
**Parameters of Laying Hens Receiving a Diet Supplemented with an LA Preparation or a CLA Preparation Between the Test Period of 36 and 38 wk of Age[a]**

| | Units | LA | CLA |
|---|---|---|---|
| Initial body weight (36th wk) | kg | 1.96 ± 0.13 | 1.99 ± 0.15 |
| Final body weight (38th wk) | kg | 1.97 ± 0.18 | 2.00 ± 0.12 |
| Feed intake | kg | 2.59 ± 0.01[b] | 2.42 ± 0.03[c] |
| Eggs/hen | n | 23.9 ± 1.4 | 23.1 ± 1.6 |
| Egg weight | g | 65.6 ± 3.7 | 63.9 ± 4.2 |
| Total egg mass | g | 1568 ± 125 | 1477 ± 246 |
| Feed efficiency | kg feed/kg egg mass | 1.65 ± 0.09 | 1.64 ± 0.10 |

[a]Results are means ± standard deviations (SD) with $n$ = 27 for both groups. Means with different superscript letters differ significantly by Student´s *t*-test ($P < 0.05$). For abbreviations see Table 1.

**TABLE 3**
**Weights of Liver and Heart of Laying Hens Receiving a Diet Supplemented with an LA Preparation or a CLA Preparation at the 39th Wk of Age[a]**

| | LA | CLA |
|---|---|---|
| Liver, absolute (g) | 53.0 ± 4.7 | 58.4 ± 5.3 |
| Relative to body weight (%) | 2.62 ± 0.13[b] | 2.85 ± 0.19[c] |
| Heart, absolute (g) | 17.6 ± 1.1 | 16.6 ± 0.9 |
| Relative to body weight (%) | 0.87 ± 0.02[b] | 0.81 ± 0.06[c] |

[a]Results are means ± SD with $n$ = 5 for both groups. Means with different superscript roman letters differ significantly by Student´s *t*-test ($P < 0.05$). For abbreviations see Tables 1 and 2.

*Concentrations of lipids and protein in egg, liver, and heart.* The effect of CLA on the lipid concentrations of egg yolks is summarized in Table 6. Feeding the CLA diet reduced the concentrations of TAG, phospholipids, and total lipids; the concentration of total cholesterol, however, did not differ between the two treatments. Crude protein levels were higher in eggs from hens fed the CLA diet than in eggs from hens fed the control diet. In contrast, the concentrations of crude protein and crude fat in liver and heart did not differ between the two treatments (data not shown), but the ratio of fat to protein in both liver and heart was slightly reduced by feeding the CLA diets (liver: 0.48 ± 0.05 vs. 0.42 ± 0.03; heart: 1.40 ± 0.13 vs. 1.22 ± 0.12).

*Fatty acid composition of yolk, liver, and heart lipids.* The fatty acid composition of lipids from egg yolk, liver, and heart was significantly modified by the CLA diets (Table 7). Feeding the CLA diet caused extensive incorporation of both CLA isomers into yolk and tissue lipids. Moreover, yolk and tissue of hens fed the CLA diets had higher concentrations of saturated fatty acids (SFA) and lower concentrations of monounsaturated fatty acids (MUFA) than yolk and tissues of hens fed the control diets. The ratio of palmitic to stearic acid was reduced from 2.7 (control group) to 1.8 (treatment group) by feeding the CLA diet, and the concentration of arachidonic acid in yolk and liver was also lowered. The concentration of docosahexaenoic acid was decreased in yolk but increased in heart with the CLA diet. The ratio of n-6 to n-3 PUFA was not affected by feeding the CLA diet.

*Transfer efficiency of CLA isomers and LA into yolk, liver, and heart lipids.* On the basis of calculated transfer rates (Table 8), the incorporation of LA into yolk and tissues was higher than that of CLA isomers. Of the two CLA isomers, the transfer efficiency of the *cis*-9,*trans*-11 isomer was higher than that of the *trans*-10,*cis*-12 isomer. Moreover, the results indicate tissue-specific features in the CLA isomer profile. The relative transfer efficiency of the *cis*-9,*trans*-11 isomer into yolk is higher (up to 0.88) than into liver (up to 0.66) and heart (up to 0.32).

## DISCUSSION

*Chemical properties of CLA-enriched eggs.* The growing focus on the biological and health benefits of CLA has stimulated interest in producing CLA-enriched foods. The results presented here show that laying hens fed a CLA-enriched diet accumulated CLA in yolk lipids. The overall amount of CLA that was incorporated into yolk was 7.95 g CLA/100 g total fatty acids, or approximately 400 mg CLA/egg. An amount similar to that of hens fed 5% CLA (365 mg CLA/egg) was reported by Chamruspollert and Sell (7). Supplementing the diet with CLA had no adverse effects on the laying performance of hens. This is in agreement with results of other studies (7,14–16).

CLA has been reported to modulate energy metabolism and body composition. Animals that were fed diets supplemented with CLA deposited less body fat, and the ratio of fat to protein was modified in favour of the protein fraction. The effect of CLA in reducing body fat accretion was most conspicuous in growing animals such as mice (17), pigs (18), and

**TABLE 8**
**Transfer Rate of LA and CLA Isomers from the Diet into Heart, Liver, and Egg Yolk[a]**

| | LA | $CLA_{total}$ | *cis*-9,*trans*-11 | *trans*-10,*cis*-12 |
|---|---|---|---|---|
| Heart | 2.16 | 0.30 | 0.32 | 0.26 |
| Liver | 1.55 | 0.55 | 0.66 | 0.40 |
| Yolk | 1.60 | 0.64 | 0.88 | 0.42 |

[a]Details of calculations are given in the Materials and Methods section. For abbreviations see Table 1.

fast-growing chicks (19). A major objective of the present study was to investigate whether dietary CLA treatment of laying hens also influenced the fat-to-protein ratio in eggs. The results of this study demonstrate that this is the case. Feeding a diet supplemented with CLA also reduced the ratio of fat to protein in the liver and heart. Thus, a fat-to-lean partitioning effect of CLA was evident in laying hens as well.

Yolk lipid composition depends on the rate of liver lipid neosynthesis, hepatic uptake of fatty acids from the blood, and incorporation of lipid components from the diet (20). This study shows that the rate of incorporation varies for different CLA isomers. A higher transfer rate of the *cis*-9,*trans*-11 isomer compared with that of *trans*-10,*cis*-12 isomer as observed in this study was also reported for rodents (17), pigs (13,21), broilers (19), and cows (22). The efficiency with which the *cis*-9,*trans*-11 isomer is transferred from the diet into the egg seems to be similar to the rate of transfer from the diet into sow's milk (13). The calculated transfer rates show, however, that the transfer rate of both CLA isomers is much lower than that of LA. Incorporation of dietary fatty acids into tissues depends on several factors such as rate of absorption from the diet, metabolic utilization for β-oxidation, desaturation to highly unsaturated fatty acids, and incorporation into specific lipid fractions. Little is known to date about the absorption of CLA isomers from the diet, their utilization for β-oxidation, and their desaturation. The incorporation pattern of CLA isomers and LA is quite different, however. The majority of CLA is incorporated into the TAG fraction of eggs, whereas only a small proportion is incorporated into phospholipids (23). LA, on the other hand, is incorporated at similar levels into TAG and phospholipids, in particular phosphatidylcholine (24).

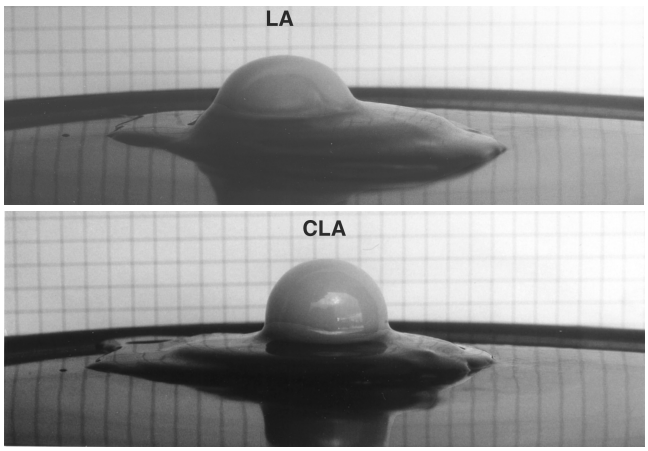

**FIG. 1.** Shape of yolks of eggs from by a laying hen receiving a diet supplemented with a linoleic acid (LA) preparation or a conjugated linoleic acid (CLA) preparation. The effect of CLA was observed after storage of eggs under refrigeration conditions (4°C).

*Effects of CLA-enriched eggs on blood lipids in humans.* This study shows that feeding CLA-supplemented diets is a means of enriching eggs with CLA. According to the literature, CLA might provide human health benefits, particularly with regard to cancer prevention. This study shows that incorporation of CLA into eggs is associated with a general alteration of the fatty acid composition of egg yolk lipids. Compared with the LA group, significantly more SFA and less MUFA were deposited in yolk lipids. Additionally, long-chain PUFA (arachidonic acid and docosahexaenoic acid) were decreased without changing the balance of the n-6/n-3 ratio in egg yolk. The increase in the SFA concentration and the decrease in PUFA in yolk lipids as a result of dietary CLA might be relevant with regard to cholesterol concentration in plasma and the low density lipoprotein (LDL) fraction in humans consuming these eggs. The ratio of PUFA to SFA decreased from 0.68 of yolk in group LA to 0.36 of yolk in group CLA. Dietary SFA are known to increase the cholesterol concentration, whereas PUFA, particularly of the n-6 type, are known to reduce it. Thus, the incorporation of CLA into egg yolk results in a fat with an increased atherogenic index. On the other hand, studies with model animals, particularly hamsters, indicate that CLA isomers could lower cholesterol concentrations in plasma and LDL, thus reducing the ratio of LDL cholesterol to high density lipoprotein–cholesterol, which is also a strong atherogenic indicator (25). It is as yet uncertain whether CLA also lowers cholesterol levels in humans. We are therefore unable to draw a firm conclusion as to whether CLA-enriched eggs would have beneficial effects on blood lipids of humans.

*Physical characteristics of CLA-enriched eggs.* The present study has demonstrated that feeding diets supplemented with CLA modifies some egg quality characteristics such as eggshell breaking strength, albumen height, foam index, and yolk index. The changes in the yolk index could be due to alterations of the lipid composition of egg yolk. The concentration of SFA in egg yolk is generally kept at a constant level, regardless of the fat in the hen's diet (26). CLA caused a marked increase of SFA in yolk at the expense of MUFA as a result of a reduced activity of Δ9 desaturase (27). This large increase in SFA and the reduction of available MUFA could be associated with alterations of physical properties, particularly the shape of the yolk. At room temperature, yolk is slightly higher in eggs of hens fed diets supplemented with CLA than in eggs of control hens. At a low temperature of 4°C, the increase in yolk height is very pronounced (Fig. 1). Feeding diets supplemented with cottonseed oil to hens also causes a marked increase in the stearic acid concentration in yolk (28). This effect might be due to reduced Δ9-desaturation caused by cyclopropene fatty acids present in cottonseed oil (29). The increased SFA concentration was also associated with alterations in the shape and physical properties of egg yolk similar to those observed with dietary CLA in the present study.

This suggests that increasing the content of SFA at the expense of MUFA affects physical properties of egg yolk.

There are potentially several different ways in which CLA can affect the physical properties of eggs. Evaluation of eggs during storage at 4°C confirmed that CLA-enriched eggs differ from typical eggs (30). Storage of CLA-enriched eggs increased the firmness and texture (elastic properties) of hard-boiled egg yolk. Also, the possibility of CLA-induced alterations of eggshell matrix proteins cannot be ruled out. Eggshell matrix proteins are thought to influence the mechanical properties of the eggshell (31). In the present study CLA treatment marginally increased eggshell stability. However, current knowledge of CLA-related effects on eggshell quality parameters is limited, and further studies on the effects of CLA isomers on physical properties of eggs are needed.

# *Trans*-10,*Cis*-12 Conjugated Linoleic Acid Reduces Triglyceride Content While Differentially Affecting Peroxisome Proliferator Activated Receptor γ2 and aP2 Expression in 3T3-L1 Preadipocytes

**M. Evans[a], Y. Park[b], M. Pariza[b], L. Curtis[c], B. Kuebler[c], and M. McIntosh[a,*]**

[a]Graduate Program in Nutrition, University of North Carolina at Greensboro, Greensboro, North Carolina 27402, [b]Department of Biology, High Point University, High Point, North Carolina 27410, and [c]Food Research Institute, University of Wisconsin at Madison, Madison, Wisconsin 53706

**ABSTRACT:** A series of experiments was conducted using 3T3-L1 preadipocytes as the cell model to determine: (i) whether the triglyceride (TG)-lowering effects of a crude mixture of conjugated linoleic acid (CLA) isomers were due to a specific isomer of CLA and the timing of treatment, (ii) if CLA reduced TG content by inhibiting a key regulator of adipogenesis, (iii) if CLA incorporated into either neutral lipid or phospholipid cell fractions, and (iv) whether the effects of CLA treatment were reversible. *Trans*-10,*cis*-12 CLA reduced TG content, whereas the *cis*-9,*trans*-11 isomer increased TG content compared to vehicle [bovine serum albumin (BSA)] controls. Treatment with 50 μM *trans*-10,*cis*-12 CLA during the entire 6 d of differentiation reduced TG content to a greater extent than treatment during either the first 3 d or last 3 d of differentiation. *Trans*-10,*cis*-12 CLA treatment of preadipocyte cultures for 48 h increased peroxisome proliferator activated receptor γ2 (PPARγ2) protein expression compared to cultures treated with linoleic acid (LA) or the BSA controls. CLA had no effect on adipose P2 (aP2), a fatty acid-binding protein regulated by PPARγ2. Both the *cis*-9,*trans*-11 and the *trans*-10,*cis*-12 isomers of CLA were incorporated into neutral lipids and phospholipids. However, *cis*-9,*trans*-11 CLA levels were one- to twofold higher than *trans*-10,*cis*-12 CLA levels. Moreover, *trans*-10,*cis*-12 CLA treatment reduced *cis*-11 18:1 concentrations in both neutral lipids and phospholipids while increasing *cis*-9 18:1 and 18:2 concentrations. Palmitoleic acid (16:1) levels were also lower in the neutral lipid fraction of cultures treated with *trans*-10,*cis*-12 CLA. Supplementing *trans*-10,*cis*-12 CLA-treated cultures (50 μM) with increasing levels of LA resulted in a dose-dependent increase in TG content compared to cultures treated with 50 μM CLA alone. LA supplementation also prevented some of the morphological changes associated with *trans*-10,*cis*-12 CLA treatment as seen with scanning electron microscopy. Treatment with 50 μM *trans*-10,*cis*-12 CLA for 6 d decreased PPARγ2 levels, and supplementation of CLA-treated cultures with LA increased PPARγ2 levels compared with cultures treated with CLA alone. Taken together, these data indicate that in cultures of 3T3-L1 preadipocytes: (i) *trans*-10,*cis*-12 CLA is the TG-lowering isomer of CLA, and its effects are dependent on dose, duration of treatment, and the amount of LA in the cultures; (ii) *trans*-10,*cis*-12 CLA treatment alters the monounsaturated fatty acid profile of neutral- and phospholipids of the cultures; and (iii) although acute (2-d) *trans*-10,*cis*-12 CLA treatment increased PPARγ2 protein levels, chronic (6-d) treatment decreased PPARγ2 levels.

Paper no. L8756 in *Lipids 36*, 1223–1232 (November 2001).

Conjugated linoleic acid (CLA) consists of a group of positional and geometric fatty acid isomers that are derived from linoleic acid (LA; 18:2n-6). Food sources of CLA, such as ruminant meats, pasteurized cheeses, and dairy products, are rich (~80%) in the *cis*-9,*trans*-11 isomer. Commercial sources of CLA used in many research studies contain predominantly *cis*-9,*trans*-11 (~40%) and *trans*-10,*cis*-12 (~40%) isomers. In rodents, CLA has anticarcinogenic (1), antiatherogenic (2,3), antidiabetic (4), and antiobesity properties (4–9). As an antiobesity agent, mice, pigs, and hamsters fed low levels of CLA (<1.5%, w/w) had less body fat and more lean body mass than controls (5–8,10–14). In addition, CLA treatment (3.4–6.8 g/d) for 3 mon reduced body fat mass of obese and overweight adult men and women (15). In contrast, Zambell *et al.* (16) found that CLA consumption (3 g/d mixed isomers) over 3 mon did not affect fat mass, fat-free mass, percent body fat, or body weight in normal weight human subjects.

*In vitro*, several studies have shown that treatment with a mixture of CLA isomers alters the lipid content of (pre)adipocytes (6,8,17–19). For example, Park *et al.* (6) showed that mature murine 3T3-L1 adipocytes treated with 20–200 μM of a mixture of CLA isomers for 2 d had less triglyceride (TG) content and lower lipoprotein lipase (LPL) activity compared to control cultures. Moreover, the *trans*-10,*cis*-12 isomer of CLA was determined to be the bioactive isomer that reduced LPL activity and TG content (8). However, another study (17) found that differentiating 3T3-L1 preadipocytes treated with a mixture of CLA isomers had greater rates of lipogenesis and more TG than

Abbreviations: AA, arachidonic acid; ANOVA, analysis of variance; BCA, bicinchoninic acid; BSA, bovine serum albumin; CLA, conjugated linoleic acid; DMEM, Dulbecco's modified Eagle's medium; FBS, fetal bovine serum; HMDS, hexamethyldisilazane; IBMX, isobutylmethylxanthine; LA, linoleic acid; LPL, lipoprotein lipase; PBS, phosphate buffered saline; PPARγ2, peroxisome proliferator activated receptor γ2; SCD-1, stearoyl-CoA desaturase-1; SEM, scanning electron microscopy; TBP,TFII basal transcription factor; TBS-T, medium containing Tris HCl + NaCl + Tween 20; TG, triglyceride.

nontreated cultures. In contrast, Brodie *et al.* (18) demonstrated that 25–100 μM of mixed CLA isomers inhibited both proliferation and differentiation and reduced mRNA levels of peroxisome proliferator activated receptor γ2 (PPARγ2) and adipose P2 (aP2) in cultures of 3T3-L1 preadipocytes. A recent study also found that *trans*-10,*cis*-12 CLA reduced stearoyl-CoA desaturase (SCD-1) activity and mRNA levels without affecting PPARγ or aP2 mRNA, suggesting that CLA may be interfering with the desaturation of long-chain fatty acids and their subsequent esterification into TG (20).

The aforementioned studies suggest that the antiobesity actions of a crude mixture of CLA isomers may be due to the direct influence of a specific isomer of CLA (i.e., *trans*-10,*cis*-12 CLA) on preadipocyte differentiation. However, the specific mechanism behind CLA's antiadipogenic actions remains to be determined. Therefore, the purpose of this study was to investigate: (i) the effect of various doses of *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA isomers and treatment periods on TG content (Exp. 1), (ii) the influence of these two CLA isomers on the expression of a key transcription factor that regulates adipogenesis (Exp. 2), (iii) the impact of CLA on neutral lipid and phospholipid fatty acid profile (Exp. 3), and (iv) the ability of LA to block CLA's reduction of TG content in differentiating cultures of 3T3-L1 (pre)adipocytes (Exp. 4).

## MATERIALS AND METHODS.

*Cell model and culture conditions.* Postconfluent monolayers of differentiating 3T3-L1 preadipocytes were used as the cellular model for these studies. 3T3-L1 preadipocytes are a nontransformed cell line, which is a continuous substrain of Swiss albino 3T3 murine cells developed through clonal expansion (21). The cells and protocols for differentiating the cultures were generously provided by Dr. Howard Green (Harvard University, Boston, MA).

Both isomers of CLA and LA were complexed to 1 mM fatty acid–free bovine serum albumin (BSA; 1 mM BSA: 4 mM fatty acid) and added to the cultures on day 1 of differentiation (Fig. 1) as previously described (19). LA (99% pure according to the manufacturers) was obtained from Nu-Chek-Prep (Elysian, MN). The *trans*-10,*cis*-12 CLA and *cis*-9,*trans*-11 CLA isomers (98+% pure, according to the manufacturers) were obtained from Matreya Inc. (Pleasant Gap, PA). Since we did not analyze CLA and LA for their purity, we realize that other isomers could be present in each fatty acid. All treatments contained 0.2 mM α-tocopherol (Sigma Chemical Co., St. Louis, MO) to prevent lipid peroxidation as previously described (19). Media were changed at 2-d intervals and fresh fatty acids added each media change until the day of harvest.

Cells were seeded at a density of $3.3 \times 10^3/cm^2$ in 12-well plates and cultured in Dulbecco's modified Eagle's medium (DMEM), 10% bovine calf serum, and antibiotics until confluent. Unless otherwise indicated, cells were cultured and treated in 12-well plates (Falcon Labware; Becton Dickinson & Co., Franklin Lakes, NJ). Two days postconfluence, the cells were stimulated to differentiate with DMEM containing 10% fetal bovine serum (FBS) (charcoal-stripped to remove endogenous fatty acids), 10 μg/mL insulin, 0.5 mM isobutylmethylxanthine, 0.1 μM dexamethasone, 0.2 mM α-tocopherol, and 1% antibiotics. On day 3 of differentiation, the above medium was replaced with DMEM, 10% stripped FBS, 2.5 μg/mL insulin, 0.2 mM α-tocopherol, and 1% antibiotics. From day 5 onward, medium containing DMEM, 10% stripped FBS, 0.2 mM α-tocopherol, and 1% antibiotics was used.

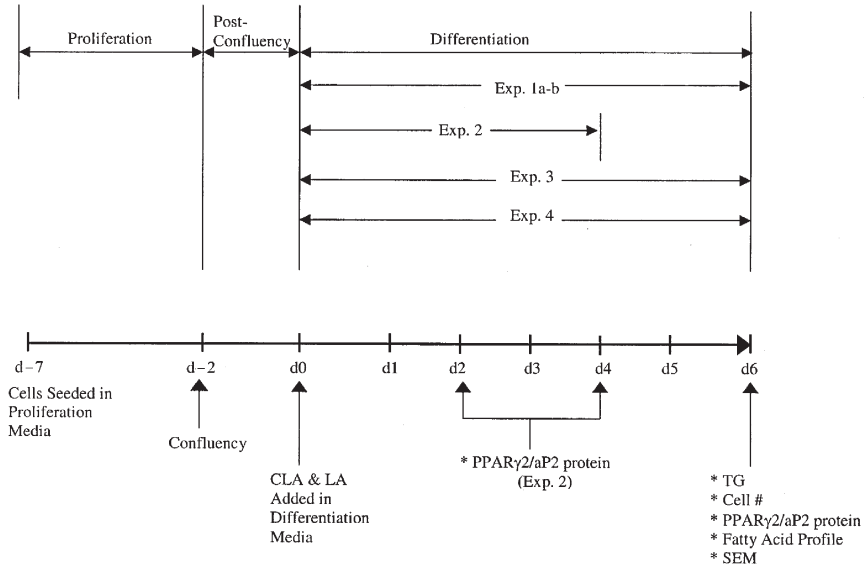

**FIG. 1.** Design of experiments. Abbreviations: CLA, conjugated linoleic acid; LA, linoleic acid; TG, triglyceride; SEM, scanning electron microscopy; PPARγ2, peroxisome proliferator activated receptor γ2; aP2, adipose P2.

*(i) TG content (Exp. 1a–b; Exp. 4a).* TG content was measured using a commercially available colorimetric kit (Sigma #339-10; Sigma Chemical Co.) modified for cell culture as previously described (22). This procedure employs enzymatic hydrolysis of glycerol and fatty acids and the glycerol is quantified spectrophotometrically at 520 nm.

*(ii) Cell number (Exp. 1a–b; Exp. 4a).* Adherent cells were harvested in a cell counting solution (25 mM glucose, 0.154 M NaCl, 0.01 M $NaH_2PO_4$ [monobasic], 5 mM 2% albumin, pH 7.4) and counted on a Coulter Multisizer IIE (Coulter Corp., Miami, FL).

*(iii) Protein content (Exp. 2; Exp. 4c).* Protein was measured using the bicinchoninic acid (BCA) assay (Pierce, Rockford, IL). This assay measures the reduction of $Cu^{2+}$ to $Cu^{+}$ by protein and can be quantified spectrophotometrically at 542 nm.

*PPARγ2 and aP2 expression (Exp. 2; Exp. 4c).* PPARγ2 and aP2 protein levels were assessed 48 and 96 h following treatment with vehicle (BSA), 50 μM LA, *cis*-9,*trans*-11 CLA, or *trans*-10,*cis*-12 CLA (Exp. 2) or 6 d posttreatment with vehicle (BSA) or increasing doses of LA (0–100 μM) in the presence or absence of 50 μM *trans*-10,*cis*-12 CLA (Exp. 4c). Cultures were grown in 10-cm dishes (Falcon Labware) with $n = 3$ for each experiment unless otherwise indicated. Cells were harvested according to the directions provided by Santa Cruz Biotechnology, Inc. (Santa Cruz, CA). Briefly, the cells were washed twice with phosphate-buffered saline (PBS) and lysed with 0.3 mL radioimmunoprecipitation assay (RIPA) lysis buffer [1 ml RIPA stock (PBS buffer at pH 7.5 containing 1% detergent NP40, 0.1% sodium dodecylsulfate, and 0.5% sodium deoxycholate) plus 30 μL/mL aprotinin, 10 μL/mL of 10 mg/mL phenylmethylsulfonyl fluoride, and 10 μL/mL of 100 mM sodium orthovanadate made fresh at each harvest]. Cells were scraped into one corner of the dish, transferred to a microfuge tube, and placed on ice for 20 min. Whole cell lysates were recovered by centrifugation at 15,000 × *g*, 4°C for 20 min, and stored at –80°C. The protein concentration was determined using the BCA assay. Twenty micrograms of protein was fractionated by electrophoresis using 12% NOVEX Tris-Glycine precast gels (Invitrogen Corp., Carlsbad, CA) for PPARγ2 and TFII basal transcription factor (TBP). TBP proteins are constitutively expressed during 3T3-L1 preadipoctye differentiation and therefore are more reliable as a loading control protein than cytoskeletal proteins that are differentially expressed during differentiation (23; Mandrup, S., University of Southern Denmark, personal communication). One microgram of protein was fractionated by electrophoresis on 16% Tris-Glycine Novex precast gels for aP2 protein expression. Separated proteins were transferred electrophoretically to Novex polyvinylidene difluoride membrane. Membranes were incubated in TBS-T (25 mM Tris-HCl at pH 8.0, 125 mM NaCl, and 0.5% Tween 20) containing 5% nonfat dry milk to block nonspecific binding. The blots were then incubated with primary antibody, a polyclonal anti-PPARγ2 (1:2500) (the generous gift of Dr. P. Pekala, East Carolina University), anti-TBP (sc-273; Santa Cruz Biotechnology) (1:500), or anti-aP2 (a generous gift of Dr. D. Bernlohr, University of Minnesota) (1:30,000) antiserum in blocking solution (TBS − T + 5% dry milk) for 1 h at room temperature. After washing twice with TBS-T for 10 min, the blots were incubated with a secondary antibody, horseradish peroxidase-conjugated rabbit antirabbit immunoglobulin G (1:2000 dilution; Santa Cruz Biotechnology) for 1 h. After washing four times with TBS-T for 5 min, the blots were developed using an enhanced chemiluminescence system (ECL Plus, Amersham, Arlington, IL) and visualized by exposure to X-ray film (ECL Hyperfilm; Amersham). The bands were quantified by densitometry using an Imaging Densitometer (Bio-Rad Laboratories, Hercules, CA).

*Fatty acid extraction and gas chromatography analyses (Exp. 3).* Cultures were grown in 10-cm Falcon dishes ($n = 4$ per treatment). Cellular lipids were extracted with chloroform/methanol (2:1) (24). Neutral and polar lipids were separated using Sep-Pak silica cartridges (Waters Corp., Milford, MA) (25). Lipid extracts were dried under nitrogen and converted to fatty acid methyl esters using 4% HCl/methanol at 60°C for 20 min. Fatty acid methyl esters were extracted into hexane and analyzed on a Hewlett-Packard 5890 series II gas chromatograph (Hewlett-Packard, Wilmington, DE) fitted with a flame-ionization detector and 3396A integrator. A Supelcowax-10 fused-silica capillary column (60 m × 0.32 mm i.d., 0.25 μm film thickness) was used, and oven temperature was programmed from 50 to 200°C, increased 20°C per min, held for 50 min, increased 10°C per min to 220°C, and held for 50 min. Fatty acid methyl esters were identified by comparison with standards (Sigma Chemical Co. and Nu-Chek-Prep).

*Scanning electron microscopy (SEM)* (Exp. 4b). 3T3-L1 monolayers were grown and treated until day 6 of differentiation on inserts with 0.2-μm pore size (Falcon Labware) that fit into individual wells, where the media and solutions for processing were applied as previously described (19). Cells on inserts were fixed with 2% glutaraldehyde in 0.1 M cacodylate in 0.1 M sucrose buffer for 1 h. Cells were rinsed with cacodylate-sucrose buffer prior to postfixation for 1 h in 1% osmium tetroxide. Inserts were then rinsed with 0.1 M piperazinc-*N,N′*-bis(2-ethanesulfonic acid) buffer and refrigerated until they were processed for SEM. The inserts with attached cells were processed for SEM by chemically drying with hexamethyldisilazane (HMDS). They were dehydrated in a series of ethanol dilutions (70, 85, 95, and 100%) for 5 min each. Next, they were placed in HMDS and dried overnight under vacuum. After drying, the insert membranes with attached cells were placed on aluminum stubs and coated with gold in an SPI Module Sputter coater. Samples were examined with a JEOL JSM-35CF scanning electron microscope (Japan Electron Optics Limited, Peabody, MA). Images at 480 and 2000× magnification were recorded on Type 52 Polaroid film.

*Statistical analyses.* Data were analyzed for analysis of variance (ANOVA) using commercially available software (SuperAnova; Abacus Concepts, Inc., Berkeley CA). For experiments 1a–b, two-way ANOVA were conducted, and their interactions (fatty acid × dose in Exp. 1a; fatty acid × time

[a]Values are means ± SEM, $n = 4$. Values in a row with different roman superscripts are significantly different at $P < 0.05$. BSA, bovine serum albumin; CLA, conjugated linoleic acid; SEM, standard error of the mean.

period in Exp. 1b) were compared for significance at the $P < 0.05$ level. For experiment 2, a three-way ANOVA (fatty acid, treatment duration, replication) was conducted, and the fatty acid × treatment duration interactions were compared for significance at the $P < 0.05$ level. In experiment 3, a two-way ANOVA was conducted and their interactions (fatty acid × dose) were compared for significance at the $P < 0.05$ level. For each fatty acid, an additional analysis was computed in which the treatment sum of squares for fatty acid dose was subdivided into linear response curves and tested for significance. In experiments 4a and 4c, a two-way ANOVA (fatty acid × replication) was conducted, and the effects of fatty acid treatments were compared for significance at the $P < 0.05$ level. The means ± standard errors of the means of the treatment interactions and their statistical differences are presented in the figures and Table 1.

## RESULTS

*Experiment 1 a-b: Dose response and time periods (Figs. 2,3). (i) Dose response (Fig. 2).* The TG content of the cultures treated with 50 μM *trans*-10,*cis*-12 CLA was lower than control cultures. In contrast, the TG content was higher in cultures treated with 50 μM *cis*-9,*trans*-11 CLA compared to the BSA controls.

*(ii) Time periods (Fig. 3).* Cultures treated with *trans*-10, *cis*-12 CLA during the entire 6-d period of differentiation had 38 and 43% less TG than LA- and *cis*-9,*trans*-11 CLA-treated cultures (days 1–6), respectively. Cultures treated during only the last 3 d of differentiation (days 4–6) with *trans*-10,*cis*-12 CLA contained 13 and 18% less TG than LA- and *cis*-9, *trans*-11 CLA-treated cultures, respectively. In contrast, there was no difference in the TG content between the three fatty acid treatments during the first 3 d of differentiation.

*Experiment 2: PPARγ2 and aP2 protein expression after 48 h and 96 h of treatment (Figs. 4,5). (i) PPARγ2 protein expression.* Cultures treated with 50 μM *trans*-10,*cis*-12 CLA had 35% higher PPARγ2 protein levels than BSA controls after 48 h of treatment (Fig. 4). In contrast, *cis*-9,*trans*-11

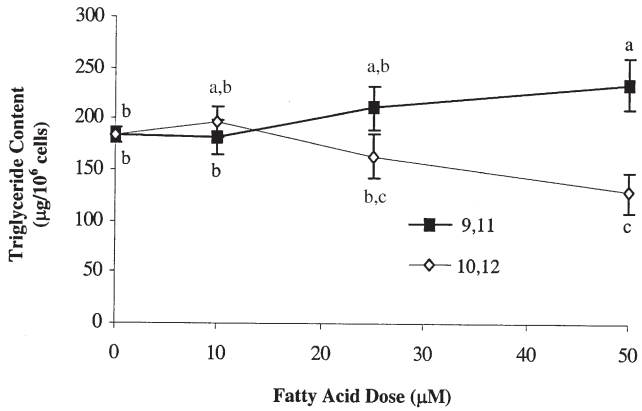

**FIG. 2.** The effect of increasing doses of *cis*-9,*trans*-11 CLA or *trans*-10, *cis*-12 CLA on TG content on day 6 of postconfluent cultures of differentiating 3T3-L1 preadipocytes (Exp. 1a). Cultures were treated continuously and harvested after 6 d of treatment. Means (±standard errors of the means; $n = 6$) not sharing a common superscript are significantly different ($P < 0.05$). For abbreviations see Figure 1.

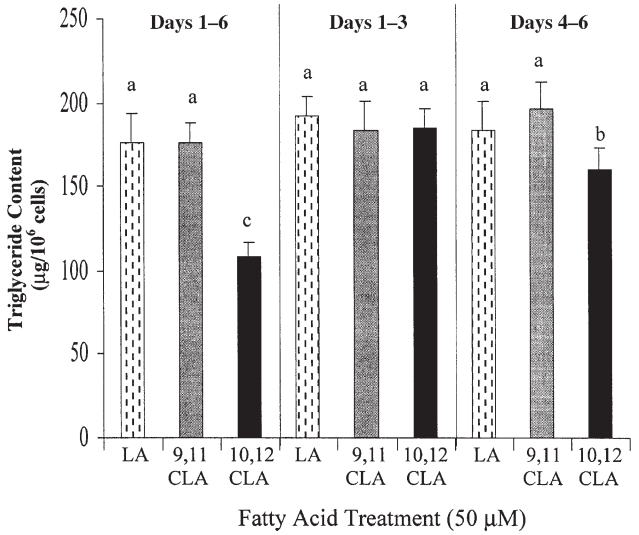

**FIG. 3.** The effect of time and fatty acid treatment [(LA, *cis*-9,*trans*-11 CLA, or *trans*-10,*cis*-12 CLA] on TG content on day 6 of post-confluent cultures of differentiating 3T3-L1 preadipocytes (Exp. 1b). Cultures were treated continuously and harvested after 6 d of treatment. Means (± standard errors of the means; $n = 6$) not sharing a common superscript are significantly different ($P < 0.05$). For abbreviations see Figure 1.

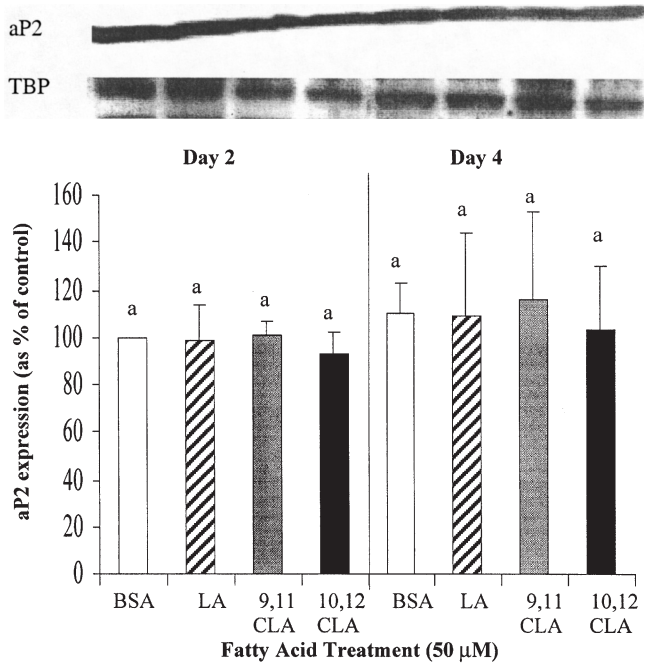

**FIG. 5.** Effect of BSA (vehicle control), 50 μM LA, *cis*-9, *trans*-11 or *trans*-10, *cis*-12 CLA for 48 or 96 h on aP2 protein expression after normalization for TBP (Exp. 2). Protein levels are expressed as a percentage of control (BSA) levels on day 2 of differentiation. Means (±standard error of the mean; $n = 3$) not sharing a common superscript are significantly different ($P < 0.05$). For other abbreviations see Figures 1 and 4.

CLA-treated cultures had similar PPARγ2 protein levels as the BSA controls, while LA-treated cells had lower PPARγ2 protein levels than BSA controls. After 96 h of treatment, there were no significant differences in PPARγ2 protein expression due to fatty acid treatment.

*(ii) aP2 protein expression.* After 48 and 96 h of treatment there was no significant difference in aP2 protein expression due to fatty acid treatment (Fig. 5).

*Experiment 3: Influence of CLA on cellular lipids (Table 1).* Both isomers of CLA were detected in the neutral and polar lipid fractions of the cultures. However, more *cis*-9, *trans*-11 CLA than *trans*-10,*cis*-12 CLA was detected in the fatty acids of each fraction. Both CLA isomers incorporated into the neutral and polar lipid fractions in approximately equal proportions. For example, cultures treated with 50 μm *cis*-9,*trans*-11 and 50 μM *trans*-10,*cis*-12 CLA isomers had 1.29 and 1.51 g/100 g *cis*-9,*trans*-11 CLA and 0.61 and 0.57 g/100 g *trans*-10,*cis*-12 CLA in their phospholipid and neutral lipid fractions, respectively. *Trans*-10,*cis*-12 and *cis*-9,*trans*-11 CLA treatment caused a dose-dependent decrease in *cis*-11 18:1 in fatty acids from both the neutral and polar lipid fractions (linear dose, $P < 0.05$). Cultures treated with 50 μM *trans*-10,*cis*-12 CLA had the lowest amount of *cis*-11 18:1 in the phospholipid fraction. In contrast, 50 μM *trans*-10,*cis*-12 CLA treated cultures had increased amounts of *cis*-9 18:1 in both the neutral and phospholipid fractions, whereas 25 and 50 μM *cis*-9,*trans*-11 supplementation reduced *cis*-9 18:1 levels in the phospholipid fraction only. Interestingly, cultures treated with 50 μM *trans*-10,*cis*-12 CLA had more LA in both the neutral and phospholipid fractions and more 18:0 in the neutral lipid fraction compared to controls.

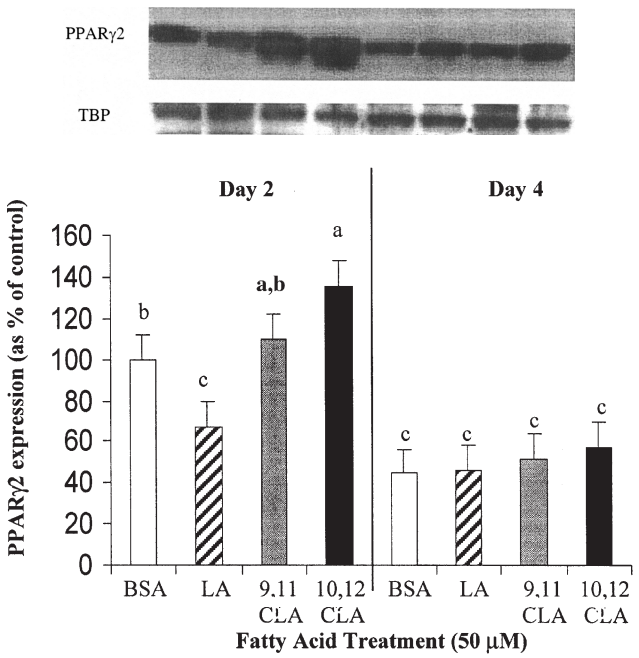

**FIG. 4.** Effect of bovine serum albumin (BSA) (vehicle control), 50 μM LA, *cis*-9,*trans*-11 or *trans*-10,*cis*-12 CLA for 48 or 96 h on PPARγ2 protein expression normalized for TFII basal transcription factor (TBP) expression (Exp. 2). Protein levels are expressed as a percentage of BSA levels on day 2 of differentiation. Means (±standard errors of the means; $n = 3$) not sharing a common superscript are significantly different ($P < 0.05$). For other abbreviations, see Figure 1.

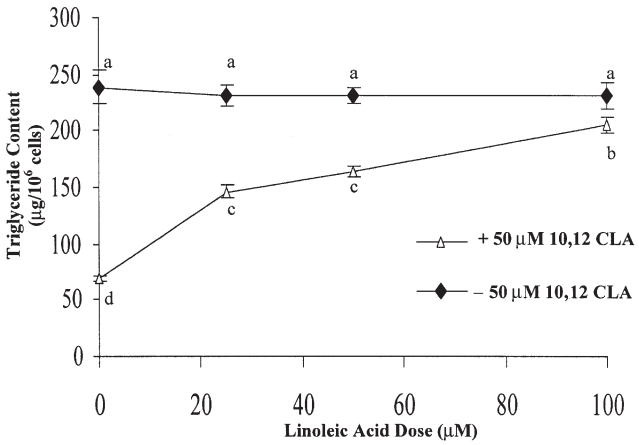

**FIG. 6.** The effect of increasing doses of LA with and without *trans*-10, *cis*-12 CLA supplementation on TG content on day 6 of postconfluent cultures of differentiating 3T3-L1 preadipocytes (Exp. 4a). Cultures were treated continuously and harvested after 6 d of treatment. Means (± standard error of the means; $n = 6$) not sharing a common superscript are significantly different ($P < 0.05$). For abbreviations see Figure 1.

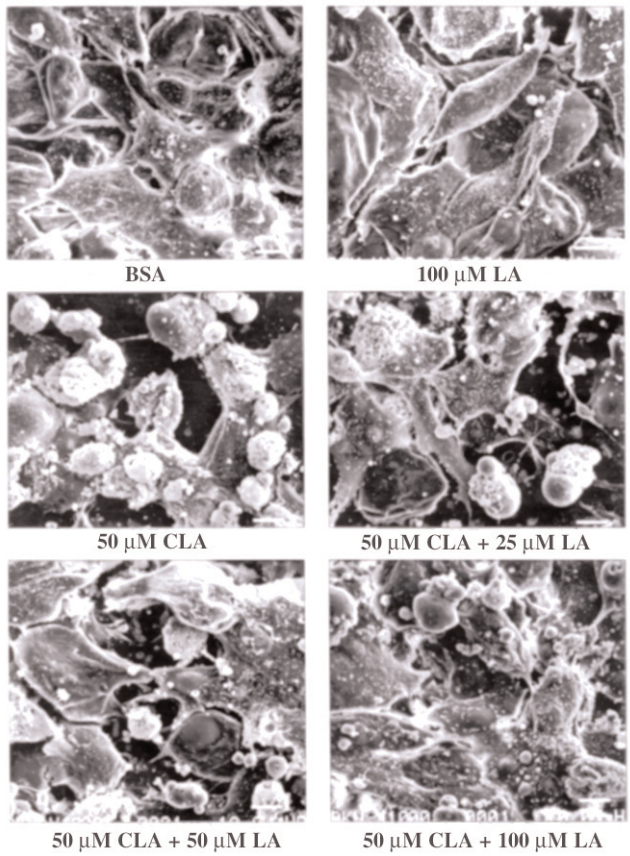

**FIG. 7.** Scanning electron micrographs of postconfluent cultures of differentiating 3T3-L1 preadipocytes treated with increasing doses of LA in the presence or absence of 50 μM *trans*-10,*cis*-12 CLA for 6 d (Exp. 4b). Magnification (480×) is the same in all photographs. Representative samples that were taken from at least two different cultures in each treatment group were similar in appearance. For abbreviations see Figures 1 and 4.

*Experiment 4a-c: trans-10,cis-12 CLA + LA supplementation (Figs. 6–9). (i) TG content*. LA supplementation of CLA-treated cultures increased TG content of the cultures in a dose-dependent manner (Fig. 6). Although this increase was significant, it did not reach the level of the BSA controls or the LA only-treated cultures.

*(ii) SEM micrographs (1000×).* SEM of the cultures revealed normal cell morphology for the BSA control cultures (Fig. 7). Cells were fibroblastic in shape with numerous microvilli and sharp-pointed lamellipodia. At 100 μM LA, some cells still retained a flattened fibroblastic appearance. However, number and length of microvilli per cell appeared decreased. In cultures treated with 50 μM of *trans*-10,*cis*-12 CLA, there were still some flattened cells, but there were large numbers of small, rounded cells that appeared lumpy in appearance. Cells that appeared to be blebbing, a characteristic of apoptotic cells, were also seen in the CLA-treated cultures. Addition of LA to cultures treated with 50 μM *trans*-10,*cis*-12 CLA seemed to offset the rounding and blebbing seen with CLA treatment. Furthermore, the number of small, rounded cells and the degree of blebbing seemed to decrease as the dose of LA increased.

*(iii) PPARγ2 and aP2 protein expression.* Cultures treated with 50 and 100 μM LA had lower PPARγ2 protein levels on day 6 of differentiation compared to BSA controls (Fig. 8). In contrast to what was observed after 48 and 96 h of treatment, treatment with 50 μM *trans*-10,*cis*-12 CLA for 6 d decreased

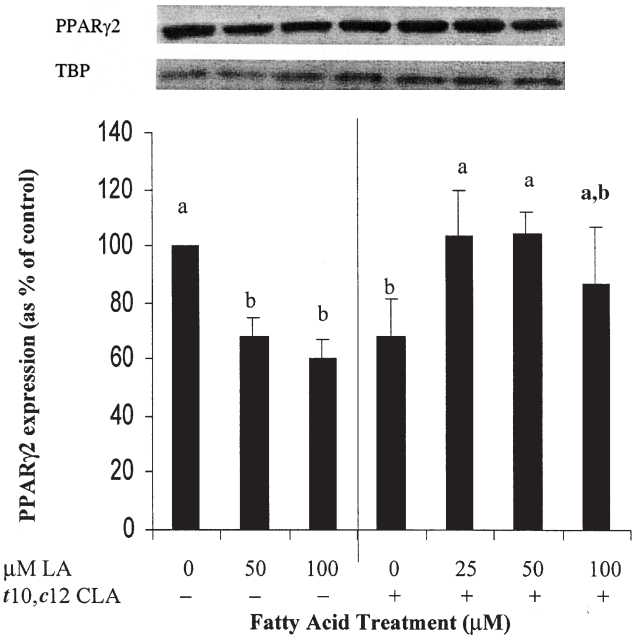

**FIG. 8.** Effect of increasing doses of LA in the presence or absence of 50 μM *trans*-10,*cis*-12 CLA on PPARγ2 protein expression normalized for TBP protein expression on day 6 of differentiation (Exp. 4c). Protein levels are expressed as a percentage of vehicle control (BSA) levels on day 6 of differentiation. Means (±standard errors of the means, $n = 2$) not sharing a common superscript are significantly different ($P < 0.05$). For abbreviations see Figures 1 and 4.

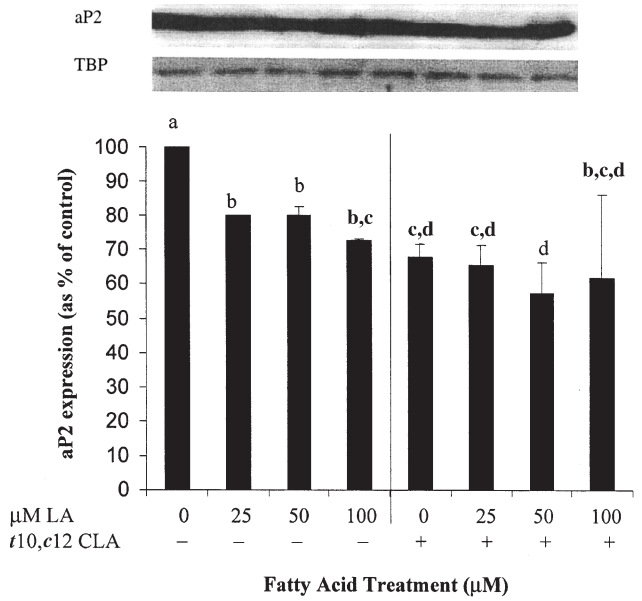

**FIG. 9.** Effect of increasing doses of LA in the presence or absence of 50 μM *trans*-10,*cis*-12 CLA on aP2 protein expression normalized for TBP protein expression on day 6 of differentiation. Protein levels are expressed as a percentage of control (BSA) levels on day 6 of differentiation. Means (±standard errors of the means, $n = 2$) not sharing a common superscript are significantly different ($P < 0.05$). For abbreviations see Figures 1 and 4.

PPARγ2 levels, and supplementation of CLA-treated cultures with 25 or 50 μM LA increased PPARγ2 expression compared to CLA alone. As with PPARγ2 expression, treatment with 25–100 μM LA reduced aP2 protein expression on day 6 of differentiation (Fig. 9). Supplementation with 50 μM *trans*-10,*cis*-12 CLA reduced aP2 protein expression, whereas addition of 25–100 μM LA to CLA-treated cultures did not affect aP2 protein expression.

## DISCUSSION

We have confirmed that *trans*-10,*cis*-12 CLA is responsible for the TG-lowering effects of a commercially available crude mixture of CLA isomers using 3T3-L1 preadipocytes as the cell model. However, the effects of *trans*-10,*cis*-12 CLA were dependent on dose, duration, and time period of treatment, as treatment throughout the first 6 d of differentiation was more effective than treatment during either the first 3 d or the last 3 d of differentiation. Our results substantiate the reports of previous research demonstrating that *trans*-10,*cis*-12 CLA is the antiadipogenic isomer of CLA. *In vivo*, ICR mice consuming 0.25% *trans*-10,*cis*-12-enriched CLA had lower body fat percentages than controls or mice fed 0.25% *cis*-9,*trans*-11-enriched CLA (8). Furthermore, Baumgard *et al.* (26) found that only the *trans*-10,*cis*-12 isomer of CLA reduced milk fat percentage and yield in Holstein cows, suggesting this CLA isomer may reduce *de novo* lipogenesis. *In vitro*, Park *et al.* (8) showed that 3T3-L1 preadipocytes treated for 48 h with *trans*-10,*cis*-12 CLA contained less intracellular TG and glycerol than *cis*-9,*trans*-11 CLA-treated cultures. More recently, Choi *et al.* (20) found that *trans*-10,*cis*-12 CLA inhibited the production of SCD-1 without reducing PPARγ2 or aP2 mRNA levels in 3T3-L1 preadipocytes.

To our knowledge, our results are the first to show that the impact of *trans*-10,*cis*-12 CLA on 3T3-L1 preadipocytes depends on the time period of treatment. Data in Figure 2 clearly show that treatment during the entire period of differentiation reduced TG content to a greater extent than treatment during the last 3 d of differentiation. However, *trans*-10,*cis*-12 CLA treatment during only the first 3 d of differentiation was not sufficient to lower TG concentrations. Park *et al.* (8) showed that 3T3-L1 preadipocytes treated with mixed isomers of CLA for 48 h on day 4 of differentiation had lower TG levels than LA controls, results that correspond to our effects seen with treatment during the last 3 d of differentiation.

In an attempt to elicit a mechanism through which *trans*-10,*cis*-12 CLA inhibits TG accumulation, we assessed the expression of PPARγ2 and aP2 protein. In contrast to our hypothesis that *trans*-10,*cis*-12 CLA decreases TG content by reducing the expression of PPARγ2, we found that *trans*-10,*cis*-12 CLA had differential effects on PPARγ2 expression throughout differentiation. Specifically, PPARγ2 expression increased on day 2 of differentiation compared to BSA controls, whereas PPARγ2 protein expression on day 4 was unchanged. aP2 protein levels were unaffected by either 2 or 4 d of CLA treatment. In contrast, the expression of PPARγ2 and aP2 proteins decreased after 6 d of treatment with *trans*-10,*cis*-12 CLA, suggesting that *trans*-10,*cis*-12 CLA has different effects on the regulation of differentiation depending on the time period of treatment.

Interestingly, LA treatment reduced PPARγ2 protein expression. In support of this unexpected result, LA has previously been suggested to inhibit preadipocyte differentiation and SCD-1 gene expression (27). Furthermore, we have consistently found that LA treatment increased cell number (data not shown), which would correlate with a suppression of PPARγ2 expression to allow clonal expansion during the early phase of differentiation (21,28).

To our knowledge, this is the first report of the impact of *trans*-10,*cis*-12 CLA treatment on PPARγ2 protein levels in 3T3-L1 preadipocytes. Brodie *et al.* (18) found that 50 μM of a crude mixture of CLA isomers reduced PPARγ mRNA expression in 3T3-L1 preadipocytes treated for 2–7 d. However, these researchers used a general probe for PPARγ, not one that was specific for PPARγ2—the isoform that is abundant in adipose tissue and generally mediates fatty acid-induced gene expression (29). Furthermore, the combination of CLA isomers found in a crude CLA mixture may have differential effects on PPARγ isoform expression. In contrast to the results of Brodie *et al.* (18), Choi *et al.* (20) reported that, although a crude mixture of CLA isomers reduced PPARγ2 mRNA expression, 45 μM *trans*-10,*cis*-12 CLA did not affect PPARγ2 mRNA levels. Furthermore, Houseknecht *et al.* (4) found that 100–200 μM of a crude mixture of CLA isomers activated the expression of PPARγ in CV-1 cells transiently transfected with a human PPARγ reporter gene construct.

We also found that *trans*-10,*cis*-12 CLA did not affect aP2 protein expression after 2 or 4 d of treatment but decreased its expression after 6 d of continuous treatment. Similar to our early results, Choi *et al.* (20) found no effect of *trans*-10,*cis*-12 CLA on aP2 mRNA levels. In contrast, *in vivo,* Houseknecht *et al.* (4) found that 1.5% (w/w) of a crude mixture of CLA isomers increased aP2 mRNA levels in prediabetic ZDF rats. However, the effect of the individual CLA isomers on aP2 expression is unknown. Furthermore, these researchers used epididymal adipose tissue that contains a mixture of stromal vascular cells, including preadipocytes and adipocytes in various stages of differentiation, making the interpretation of these results unclear.

For the lipid-lowering effects of CLA to be physiologically relevant, CLA must incorporate into cellular lipids or alter lipid composition. To this end, we found that both *trans*-10, *cis*-12 CLA and *cis*-9,*trans*-11 CLA incorporated into neutral lipid and phospholipid fractions; however, the *cis*-9,*trans*-11 CLA isomer was one- to two-fold more abundant than the *trans*-10,*cis*-12 isomer. Interestingly, Comb White Leghorn laying hens fed mixed isomers of CLA had higher levels of *cis*-9,*trans*-11 CLA than *trans*-10,*cis*-12 CLA in their egg yolks (30). In addition, albino rats fed 0.5–1.5% (w/w) of a crude mixture of CLA isomers for 60 d had almost twice the amount of *cis*-9,*trans*-11 CLA in their adipose tissue as *trans*-10,*cis*-12 CLA (31).

CLA's antiadipogenic actions have been proposed to be due to inhibited elongation and/or desaturation of saturated fatty acids such as palmitic acid and stearic acid into monounsaturated fatty acids (20). In support of this hypothesis, we found that 50 μM *trans*-10,*cis*-12 CLA-treated cultures had lower amounts of palmitoleic acid (16:1) (in the neutral lipid fraction) and *cis*-11 oleic acid (18:1) (in both the neutral and polar lipid fractions) compared to BSA controls. However, *trans*-10,*cis*-12 CLA increased the amount of *cis*-9 oleic acid as well as the level of LA (18:2). These results differ from those of Satory and Smith (17), who found that 3T3-L1 preadipocytes cultured with 5–10 mg/L of mixed isomers of CLA had increased amounts (g/100 g total fatty acid) of palmitic acid (16:0) and palmitoleic acid (16:1) and decreased stearic acid (18:0) and oleic acid (18:1) concentrations. However, these researchers treated their preadipocytes with the crude mixture of CLA isomers, dissolved their fatty acids in ethanol as the delivery vehicle, evaluated a combination of neutral and polar lipids, and used lower amounts of CLA, all of which could account for the differences from our results. More recently, Choi *et al.* (20) showed that 3T3-L1 preadipocytes treated with 45 μM *trans*-10,*cis*-12 CLA had lower levels of both 16:1 and 18:1 in their cellular lipids, similar to our results in neutral lipids where TG is stored (20). Finally, Δ-6 desaturation of linoleic acid in rat hepatic microsomes was decreased in the presence of both *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA (32). However, only the *trans*-10,*cis*-12 isomer of CLA inhibited Δ-9 desaturation of stearic acid.

CLA treatment has also been theorized to inhibit the production of adipogenic fatty acids such as arachidonic acid (AA) and its subsequent eicosanoid metabolites. A reduction in AA and other adipogenic fatty acids may decrease TG esterification, conversion into phospholipids that are critical for cellular metabolism, and/or synthesis into lipid second messengers, such as prostaglandin $J_2$ ($PGJ_2$), that may regulate adipogenesis. In contrast to this theory, our data showed no difference in AA levels in the phospholipid fraction with either *cis*-9,*trans*-11 or *trans*-10,*cis*-12 CLA treatment. Our results conflict with those of Satory and Smith (17) who found that 3T3-L1 preadipocytes cultured with 5–10 mg/L of a crude mixture of CLA isomers had lower levels of AA. However, Choi *et al.* (20) found that, while mixed CLA treatment had no effect on 20:4 concentrations in 3T3-L1 preadipocytes, treatment with *trans*-10,*cis*-12 CLA increased 20:4 concentrations. Thus, our results, along with those of Choi *et al.* (20), dispute the suggestion that CLA's antiadipogenic actions may be the result of an inhibition of adipogenic fatty acid production. However, since we did not assess the production of eicosanoid metabolites and lipid second messengers such as $PGJ_2$ that may impact adipogenesis, it is still possible that *trans*-10,*cis*-12 CLA may be inhibiting TG production through these pathways.

Last, in a fourth set of experiments, we examined the impact of LA supplementation on TG content, morphology, and adipogenic protein expression of *trans*-10,*cis*-12 CLA-treated cultures. To our knowledge, we are the first to report that concurrent treatment with LA (18:2n-6) was able to prevent the TG-lowering effects of *trans*-10,*cis*-12 CLA in cell culture. Furthermore, the increase was dose-dependent and almost reached the level of LA-only supplemented cultures. These results may indicate that *trans*-10,*cis*-12 CLA's TG-lowering effects can be overcome by supplementation with polyunsaturated fatty acids, at least in cultures of preadipocytes. Further research to determine if other fatty acids have differential rescue effects dependent on structure are in progress.

In previous research, we showed that treatment with both mixed CLA isomers and *trans*-10,*cis*-12 CLA induced molecular (i.e., increased percentage of cells in the sub-$G_1$ phase) and morphological changes (i.e., nuclear condensation, cellular rounding, and membrane blebbing)—changes that are characteristic of apoptosis (19). In the current research, supplementation of *trans*-10,*cis*-12 CLA-treated cultures with LA inhibited the CLA-induced morphological changes in a dose-dependent manner (Fig. 7). In agreement with these data, CLA-treated cultures supplemented with LA have greater TG content (Fig. 6). A number of studies have also shown that CLA is capable of inducing apoptosis. For example, cells in the adipose tissue of C57BL/6J mice fed 1% (w/w) of mixed isomers of CLA underwent apoptosis (9). Additional studies in primary rat mammary cells (33) as well as NMU mammary cells (34) have also demonstrated that CLA induces apoptosis. However, the mechanism through which LA prevents the induction of apoptosis by *trans*-10,*cis*-12 CLA is unclear.

Finally, we examined PPARγ2 and aP2 protein expression after 6 d of supplementation with *trans*-10,*cis*-12 CLA and LA. Interestingly, concurrent LA and *trans*-10,*cis*-12 CLA

treatment for 6 d increased PPARγ2 protein levels compared to *trans*-10,*cis*-12 CLA treatment alone, an effect that may explain some of LA's ability to reverse CLA's antilipogenic effects. However, the mechanisms through which LA is able to reverse the decrease in PPARγ2 expression and by which LA lowers the effects of CLA remain to be determined.

We found that *trans*-10,*cis*-12 CLA is the TG-lowering isomer of CLA in 3T3-L1 preadipocytes. Furthermore, the effects of *trans*-10,*cis*-12 are time- and dose-dependent and do not appear to depend directly on a reduction in PPARγ2 or aP2 protein expression during the first 4 d of differentiation. However, after 6 d of treatment with *trans*-10,*cis*-12 CLA, PPARγ2 protein levels were lower than control cultures, suggesting that chronic treatment with CLA may reduce TG by downregulating PPARγ2 protein expression. We also discovered that *trans*-10,*cis* 12 CLA decreased the production of certain monounsaturated fatty acids such as 16:1 and *cis*-11 oleic acid, while increasing LA and *cis*-9 18:1 levels. Finally, supplementation with LA was able to prevent some, but not all, of *trans*-10,*cis*-12 CLA's effects on TG content and morphology in cultures of 3T3-L1 preadipocytes.

# Growth Modulation of Low Density Lipoprotein Receptor Sterol Sensitivity in Cultured Human Fibroblasts

**Loukas Tatidis and Sigurd Vitols***

Department of Medicine, Division of Clinical Pharmacology, Karolinska Institute & Hospital, S-171 76 Stockholm, Sweden

**ABSTRACT:** Sterols regulate low density lipoprotein (LDL) receptor and 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase gene expressions by end product repression. Studies on cultured cells have shown that growing cells have a higher LDL uptake than quiescent cells and that incubation of cells with growth factors or mitogenic compounds leads to sterol-resistant upregulation of LDL receptor gene expression. The recent finding that elevated LDL receptor activity in acute myelogenous leukemia cells was characterized by a decreased sensitivity to downregulation by sterols raises the possibility that the mechanism behind this is related to the cellular growth rate. By using cultured human fibroblasts as a model system we therefore studied whether growth modulation of sterol sensitivity takes place in normal actively growing cells. Judging from the ability of sterols (25-hydroxycholesterol + cholesterol) to inhibit $^{125}$I-LDL degradation, we found that the sensitivity to sterols varied markedly between cells of different densities. The lowest sensitivity to sterols and highest $^{125}$I-LDL degradation rate were found in subconfluent cells, whereas sparse and confluent cells were the most sensitive ones. In contrast to the LDL receptor, HMG-CoA reductase sterol sensitivity did not appear to be growth regulated. We conclude that growth-dependent modulation of sterol sensitivity and LDL receptor activity takes place in normal human fibroblasts. Modulation of sterol sensitivity may be an important mechanism to ensure an adequate cholesterol supply in growing cells.

Paper no. L8722 in *Lipids 36,* 1233–1240 (November 2001).

Cells can supply their cholesterol needs by receptor-mediated uptake of the major cholesterol-carrying lipoprotein in plasma, low density lipoprotein (LDL), or by *de novo* synthesis (1,2). The rate-limiting enzyme in cholesterol synthesis is the enzyme 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase. Both pathways are regulated by the cellular cholesterol concentration *via* end product repression (2–4).

Studies on cultured cells have shown that growing cells have a higher LDL uptake than quiescent cells (3,5–7). One reason for this may be that the cellular cholesterol concentration decreases as a result of increased cholesterol requirements during cell growth, which stimulates LDL receptor activity. Another possibility is that factors involved in growth stimulation, e.g., growth factors, directly stimulate LDL receptor expression. Previous studies have shown that LDL receptor expression is enhanced upon incubation of cells with growth factors (8–10) or mitogenic substances (11). Moreover, incubation of cells with growth factors or mitogenic compounds has been demonstrated to cause a resistance to the downregulatory effect of sterols on LDL receptor expression (9,11,12). It has, however, not been demonstrated that cells indeed growth-modulate their own sterol sensitivity.

Elevated LDL receptor activity, compared to the corresponding normal cells or tissues, has been reported in several types of malignant cells, e.g., leukemic cells from patients with acute myelogenous leukemia (AML), lung cancer tissue, and colon cancer tissue (13–16). In a recent study we demonstrated that elevated LDL receptor activity, in leukemia cells from AML patients, was characterized by a decreased sensitivity to sterols (25-hydroxycholesterol + cholesterol) compared with normal mononuclear cells (17). The median sterol concentration for 50% inhibition ($IC_{50}$) of LDL receptor activity was more than five times higher for AML cells than for normal mononuclear cells. We also observed that the LDL receptor activity in these cells correlated with the white blood cell count but not with the cellular free cholesterol content (17), raising the possibility that the mechanism behind the elevated LDL receptor activity and sterol resistance is growth related.

The objective of this study was therefore to investigate whether growth modulation of the LDL receptor sterol sensitivity normally occurs in cells. We studied gene expression in cells at different growth rates and at different densities and investigated the sensitivity to sterols from the ability of 25-hydroxycholesterol and cholesterol to inhibit LDL receptor activity. As a model system we used cultured human fibroblasts.

## MATERIALS AND METHODS

*Materials.* Radiolabeled sodium iodide (Na $^{125}$I, carrier-free, pH 7–11), cytidine 5′-(*a*-$^{35}$S)thiotriphosphate (triethylammonium salt, >1000 Ci/mmol), uridine 5′-(*a*-$^{35}$S)thiotriphosphate (triethylammonium salt, >1000 Ci/mmol), 3-hydroxy-3-methyl (3-$^{14}$C) glutaryl coenzyme A (52 mCi/mmol), and D,L-(2-$^{3}$H) mevalonic acid lactone (1.26 Ci/mmol) were from Amersham Pharmacia Biotech (Uppsala, Sweden). RNase A, RNase T1, proteinase K, transfer-RNA, and salmon sperm DNA were obtained from Sigma Chemical Co. (St. Louis, MO). Formamide (p.a.) was from Merck (Darmstadt, Germany). The plasmid, pGEM4z, restriction endonucleases, and the *in vitro*

Abbreviations: AML, acute myelogenous leukemia; FCS, fetal calf serum; HMG-CoA reductase, 3-hydroxy-3-methylglutaryl coenzyme A reductase; $IC_{50}$, median sterol concentration for 50% inhibition; LDL, low density lipoprotein; LPDS, human lipoprotein-deficient serum; PBS, phosphate-buffered saline; TCA, trichloroacetic acid.

transcription kit (Riboprobe Gemini II Core System) were from Promega (Madison, WI). Sephadex G-50 columns (Nick columns) were from Amersham Pharmacia Biotech.

Lipoproteins. LDL (density 1.020–1.063 g/mL) and human lipoprotein-deficient serum (LPDS) were isolated from serum of healthy blood donors by sequential ultracentrifugation (18). $^{125}$I-LDL (specific activity (150–350 cpm/ng protein) was prepared as described by Langer *et al.* (19). The purity of LDL and LPDS preparations was checked by agarose gel electrophoresis. Less than 1% of the radioactivity in the $^{125}$I-LDL preparation was present as free iodide.

*Cell culture and incubations*. Fibroblasts from normal human foreskin (CRL 2091; American Type Culture Collection, Rockville, MD) were grown in monolayer for not more than 15 passages in RPMI-1640 medium supplemented with 10% fetal calf serum (FCS), 2 mM glutamine, and antibiotics (100 IU of penicillin + 100 µg of streptomycin/mL) in a humidified incubator (5% $CO_2$, 95% air) at 37°C. For experiments, confluent cell monolayers in 162 $cm^2$ stock flasks (Costar Corp., Cambridge, MA) were detached with 0.05% (vol/wt) trypsin and 0.02% (vol/wt) EDTA and cells were seeded into 10 cm Ø petri dishes (Costar Corp.) containing 9 mL of 10% FCS medium. In all experiments lasting more than 3 d the medium was replaced with fresh medium every 3 d. In some experiments the medium was changed at the indicated time points to medium with 10% LPDS with or without 25-hydroxycholesterol + cholesterol (1:20). In the experiments described in Figure 4, the cells were photographed using a 10× magnification lens with a phase contrast microscope (Carl Zeiss, Inc., Thornwood, NY) connected to a video printer (Mitsubishi Electric Chiyoda-ku, Tokyo, Japan).

*Determination of LDL receptor expression and activity*. Cellular degradation of $^{125}$I-LDL was used as a measure of LDL receptor activity. Monolayers were washed three times with 10 mL ice-cold phosphate-buffered solution (PBS; 140 mmol/L NaCl, 2.7 mmol/L KCl, 9.5 mmol/L $Na_2HPO_4$, and 9.5 mmol/L $KH_2PO_4$, pH 7.4) containing 1% LPDS before 8 mL 10% LPDS medium containing 10 µg/mL $^{125}$I-LDL was added. After 4 h, the medium was collected and trichloroacetic acid (TCA)–soluble radioactivity was determined in the medium, which represents degradation of products formed by the cells and released into the medium (1). Following removal of the incubation medium, the monolayers were washed with PBS, after which the cells were solubilized in 0.1 M NaOH for determination of cellular protein concentration.

*Determination of RNA levels*. The monolayers were washed three times with 10 mL ice-cold PBS; the cells were harvested with a cell scraper, and following centrifugation, the pellets were frozen in liquid nitrogen for later RNA analysis. An aliquot of the cells was also frozen for later HMG-CoA reductase activity analysis. LDL receptor and HMG-CoA reductase RNA levels in cells were determined by a quantitative RNA-RNA solution hybridization method (20). Briefly, total nucleic acids were prepared from 10–20 × $10^6$ cells that were homogenized in 4 mL of 1 × SET (1% sodium dodecyl sulfate, 20 mM Tris-HCl, pH 7.5, and 10 mM EDTA) with a Polytrone (Kinematica Type PT 16/35; Kriens, Luzern, Switzerland) for 10–15 s at setting 5–6 and DNA concentration was assayed by Hoechst fluorometry. Antisense and sense probes for LDL receptor RNA were prepared by *in vitro* transcription of a BamHI or HindIII cleaved plasmid, carrying a 265-bp fragment of cDNA encoding the human LDL receptor with T7 (in the presence of $^{35}$S-UTP and $^{35}$S-CTP) and SP6 (in the presence of unlabeled nucleotides only) RNA polymerases, respectively. HMG-CoA reductase RNA antisense and sense probes were prepared by *in vitro* transcription of a HindIII or EcoRI-cleaved plasmid, carrying a 50-bp oligonucleotide encoding human HMG-CoA reductase, with SP6 and T7 RNA polymerases, respectively. The nucleic acid extracts or unlabeled sense RNA were hybridized with the various antisense probes in solution. Following RNase treatment and precipitation with trichloroacetic acid, the RNase resistant precipitate was collected on a GF/C filter and the radioactivity was determined in a liquid scintillation counter (Packard Instrument Company, Downers Grove IL). RNA levels were quantified by comparing the hybridization signal with the linear part of the standard curve, which was generated by hybridizations with different concentrations of sense RNA. RNA values are presented as RNA copies per diploid genome (6 pg DNA).

*Other assays*. HMG-CoA reductase activity in cell-free extracts was determined from the rate of conversion of 3-hydroxy-3-methyl(3-$^{14}$C) glutaryl coenzyme A (25,000 dpm/nmol) to $^{14}$C-mevalonate in detergent-solubilized extracts as previously described (20,21). HMG-CoA reductase activity is expressed as picomoles of $^{14}$C-mevalonate formed per minute per milligram of detergent-solubilized protein. The protein concentration in extracts and whole cells was determined by the method of Lowry *et al.* (22) with human serum albumin as a standard. $^{3}$H-Thymidine incorporation was determined by the addition of 30 µCi $^{3}$H-thymidine (Amersham Pharmacia) to the cell monolayers. After 4 h of incubation at 37°C (simultaneously with the $^{125}$I-LDL degradation assay) the cells were washed with PBS three times and filtered through GF/C filters with ice-cold 10% TCA before radioactivity was determined (23).

## RESULTS

*Gene expressions in continuously growing fibroblasts.* Figures 1 and 2 demonstrate the profound effect of growth on the expression of both the HMG-CoA reductase and LDL receptor genes in cultured human fibroblasts. Although the gene expressions were severalfold higher in cells continuously growing in the absence of lipoproteins (Figs. 2A,B) compared with fetal calf serum, RNA levels and protein activities declined rapidly as the monolayers became confluent

*Sterol sensitivity in cells at different growth rates and cell densities*. We next studied whether LDL receptor sterol sensitivity varied with different growth rates. Two experimental setups were used. In the first experimental setup, concentration–effect curves regarding the inhibitory effect of sterols (25-hydroxycholesterol + cholesterol, 1:20) on LDL receptor

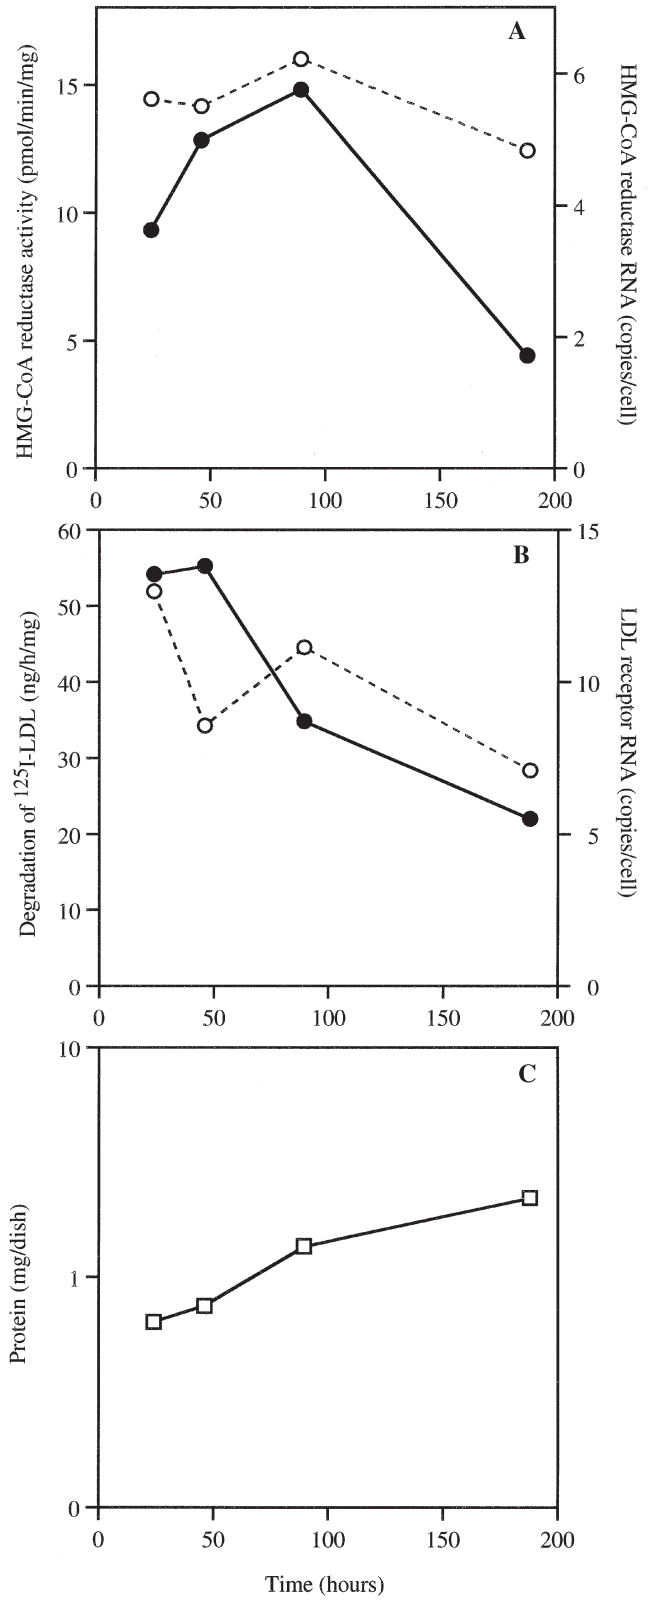

**FIG. 1.** (A) 3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase RNA level (○) and protein activity (●), (B) low density lipoprotein (LDL) receptor RNA level (○) and protein activity (●), and (C) amount of cell protein/dish (log scale) in fibroblasts continuously growing in medium containing 10% fetal calf serum (FCS). Each RNA value represents the mean of three hybridizations and each degradation value represents the mean of duplicate incubations.

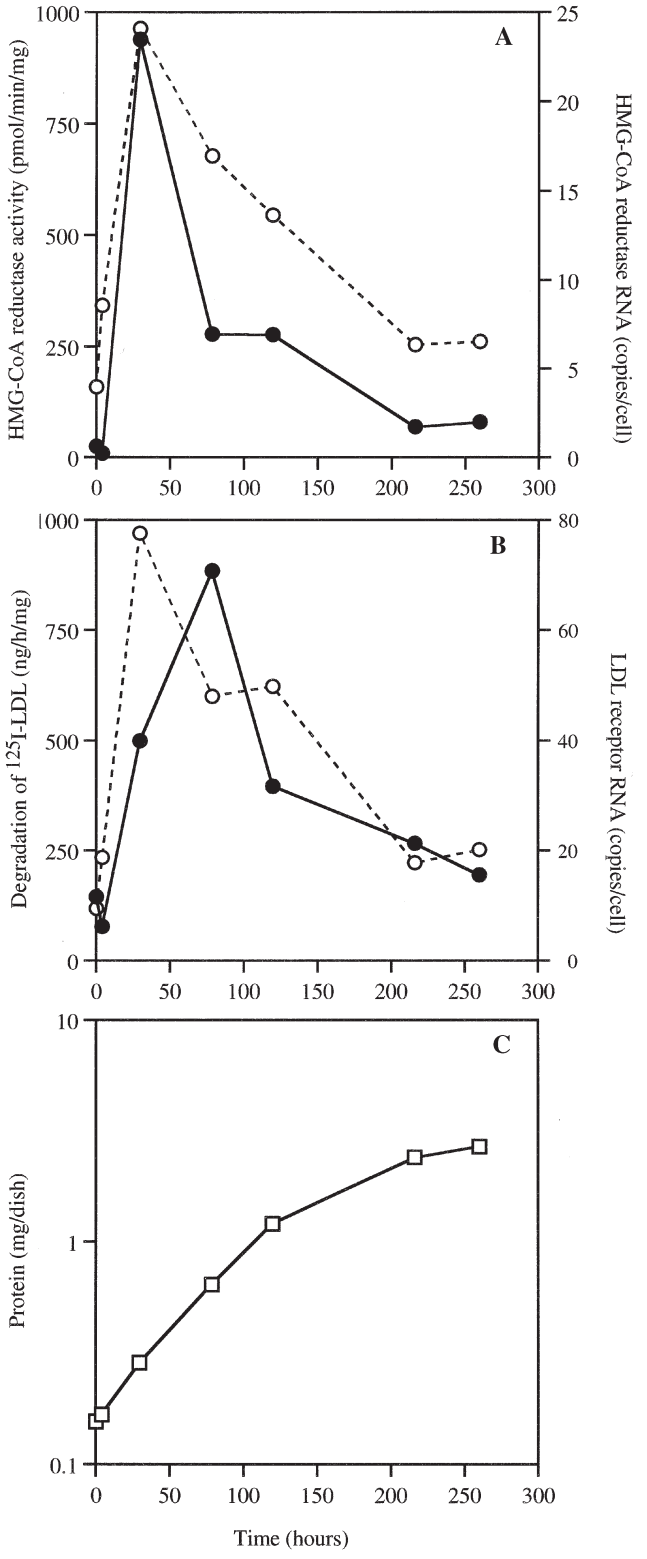

**FIG. 2.** (A) HMG-CoA reductase RNA level (○) and protein activity (●), (B) LDL receptor RNA level (○) and protein activity (●), and (C) amount of cell protein/dish (log scale) in fibroblasts continuously growing in medium containing 10% human lipoprotein-deficient serum (LPDS). The cells were seeded at day 0 in medium containing 10% FCS, and on day 1, when the monolayers still were sparse, the medium was changed to 10% LPDS medium. The number of hybridizations and incubations were as in Figure 1. See Figure 1 for other abbreviations.

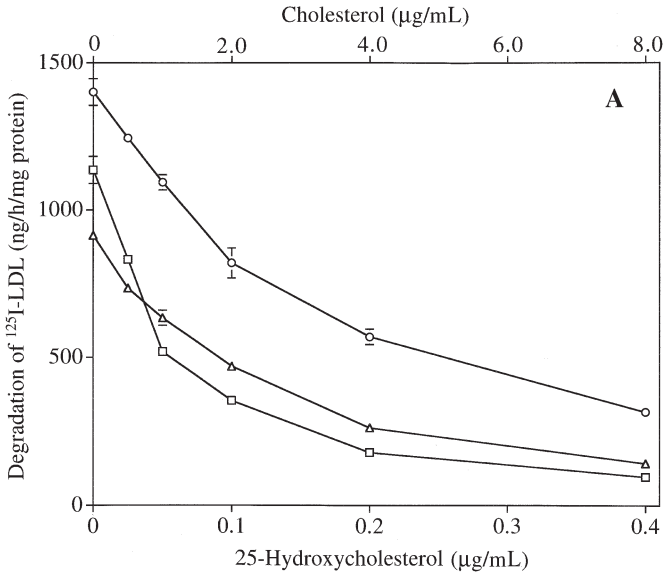
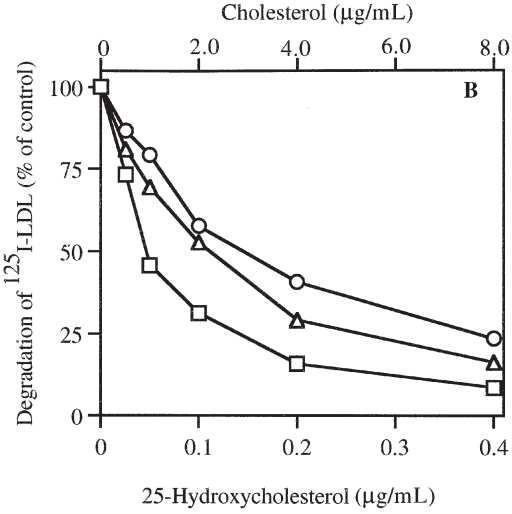
activity were determined from cells plated at the same density but grown for different time periods (Fig. 3). Cells were seeded in 10% FCS medium and after 27, 44, and 99 h of growth, the medium was changed to 10% LPDS medium with or without sterols. The LDL receptor activity was determined after a further 16 h of incubation. The fractional growth (protein content after the 16 h incubation divided by protein content before) during the 16 h incubation in 10% LPDS was 1.8, 1.5, and 1.2 for the cells grown in 10% FCS for 27, 44, and 99 h, respectively. The lowest sensitivity to sterols and the highest LDL receptor activity was found in the cells grown for 44 h, which appeared subconfluent, whereas the more confluent cells grown for 99 h were more sensitive to sterols. The most sensitive cells were the sparse cells grown for 27 h. In a separate experiment we also determined the influence of sterols on HMG-CoA reductase activity in cells grown for 27 and 44 h. In contrast to the LDL receptor activity, the HMG-CoA reductase was equally sensitive to sterols at both cell densities (Fig. 4).

In the second experimental setup, sterol sensitivity was determined in cells seeded at a wide range of densities (from $3 \times 10^3$ to $24 \times 10^3$ cells/cm$^2$) and allowed to grow for the same time period. Thirty hours after seeding, the medium was changed to 10% LPDS medium with either a single concentration of sterols (25-hydroxycholesterol 0.1 µg/mL + cholesterol 2.0 µg/mL) or without sterols. Following a further 16 h of incubation the LDL receptor activity was determined (Fig. 5A). The fractional cell growth, during the 16 h of incubation in 10% LPDS, declined at cell protein contents above approximately 0.9 mg protein/dish (Fig. 5B). Also in this case there was a cell density-dependent decrease in sterol sensitivity up to approximately 0.8 mg protein/dish where the cells appeared subconfluent and LDL receptor activity reached its maximum.





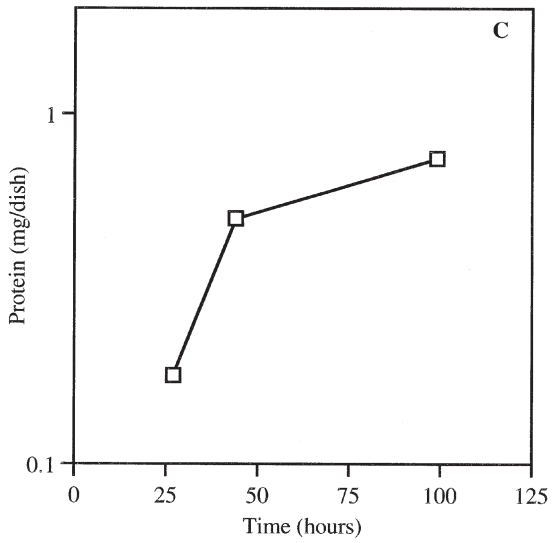


**FIG. 3.** Effect of sterols on $^{125}$I-LDL degradation rate in normal human fibroblasts grown for different time periods. (A) After 27 (□), 44 (○), and 99 (△) h of growth in medium containing 10% FCS, the medium was changed to medium containing 10% LPDS with the indicated concentrations of 25-hydroxycholesterol + cholesterol (1:20), and the cells were incubated for another 16 h before degradation of $^{125}$I-LDL was determined. (B) $^{125}$I-LDL degradation rate expressed as percentage of control cells incubated without sterols. Each degradation value represents the mean of triplicate incubations. (C) Amount of cell protein/dish (log scale) after growth for the indicated periods of time in medium with 10% FCS (27, 44, and 99 h). See Figures 1 and 2 for abbreviations.

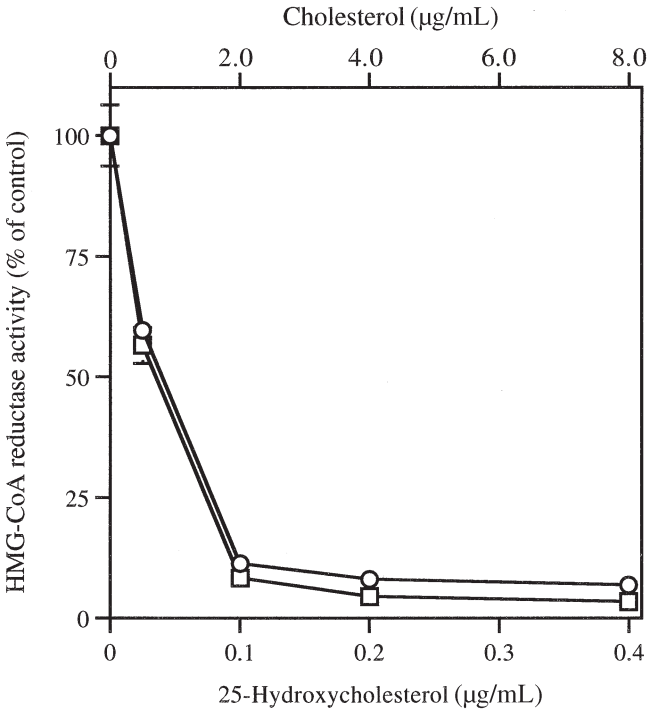

**FIG. 4.** Effect of sterols on HMG-CoA reductase activity in normal human fibroblasts grown for different time periods. After 27 (□) and 44 (○) h of growth in medium containing 10% FCS, the medium was changed to medium containing 10% LPDS with the indicated concentrations of 25-hydroxycholesterol + cholesterol (1:20), and the cells were incubated for another 16 h before HMG-CoA reductase activity was determined. Results are expressed as percentage of control cells incubated without sterols. Each value represents the mean of triplicate incubations. See Figures 1 and 2 for abbreviations.

At higher densities the sterol sensitivity again increased and LDL receptor activity decreased along with declining cell growth (Figs. 5A,B). The photographs in Figure 5C show representative illustrations of cells from the various cell densities.

In order to study in more detail growth modulation of LDL receptor and HMG-CoA reductase sterol sensitivity, we also investigated the RNA levels for both genes. $^3$H thymidine uptake was used as a measure of cell growth rate. This experiment was performed in a similar setup as that presented in Figure 5 but at two densities, sparse (seeded at $5 \times 10^3$ cells/cm$^2$) and medium (seeded at $10 \times 10^3$) density (Table 1). We found a significantly higher sensitivity to sterols at the LDL receptor RNA level in cells at low density (0.33 mg protein/dish) than at medium density (0.55 mg protein/dish), whereas the sterol sensitivity at the HMG-CoA reductase RNA level was similar at both cell densities. There was a trend toward higher $^3$H-thymidine incorporation in the low-density as compared to the medium-density cells ($P = 0.073$, Table 1).

## DISCUSSION

The objective of this study was to investigate if an intrinsic growth modulation of LDL receptor sterol sensitivity takes place in growing cells. The results demonstrate that growth modulation of LDL receptor sterol sensitivity takes place in normal human cells, both at RNA and protein levels. In contrast, HMG-CoA reductase activity was not modulated by cell growth. Essentially the same results were observed for the LDL receptor using two different experimental settings. Sterol sensitivity was determined at different cell densities obtained by either letting the cells grow for different periods of time (Figs. 3,4) or by seeding the cells at a wide range of densities (Fig. 5). Clearly, the highest LDL receptor activity and lowest sterol sensitivity were found in subconfluent cells at protein contents between 0.5 and 0.8 mg/dish (Figs. 5A,B). At cell densities above 0.8 mg protein/dish the LDL receptor activity declined and the sensitivity to sterols again increased.

Why then was LDL receptor activity lower and sterol sensitivity higher in sparse cells compared with subconfluent cells even though the growth rate was not lower in the sparse cells, as shown by data on $^3$H-thymidine uptake and fractional cell growth? One explanation could be that growing cells secrete factors that increase LDL receptor activity and lower the sensitivity to sterols. At low cell densities, the concentration of a putative factor that is secreted into the culture medium is low because of the low number of cells. The concentration of this factor, however, increases in the medium along with the increasing amount of cells resulting in increased LDL receptor activity and decreased sensitivity to sterols in the subconfluent cells.

We cannot rule out that cell to cell contact may be involved in the modulation of sterol responsiveness and LDL receptor activity. When cells come in close contact with each other, as, for example, in dishes with more than 0.8 mg protein, LDL receptor activity falls off and sterol responsiveness increases

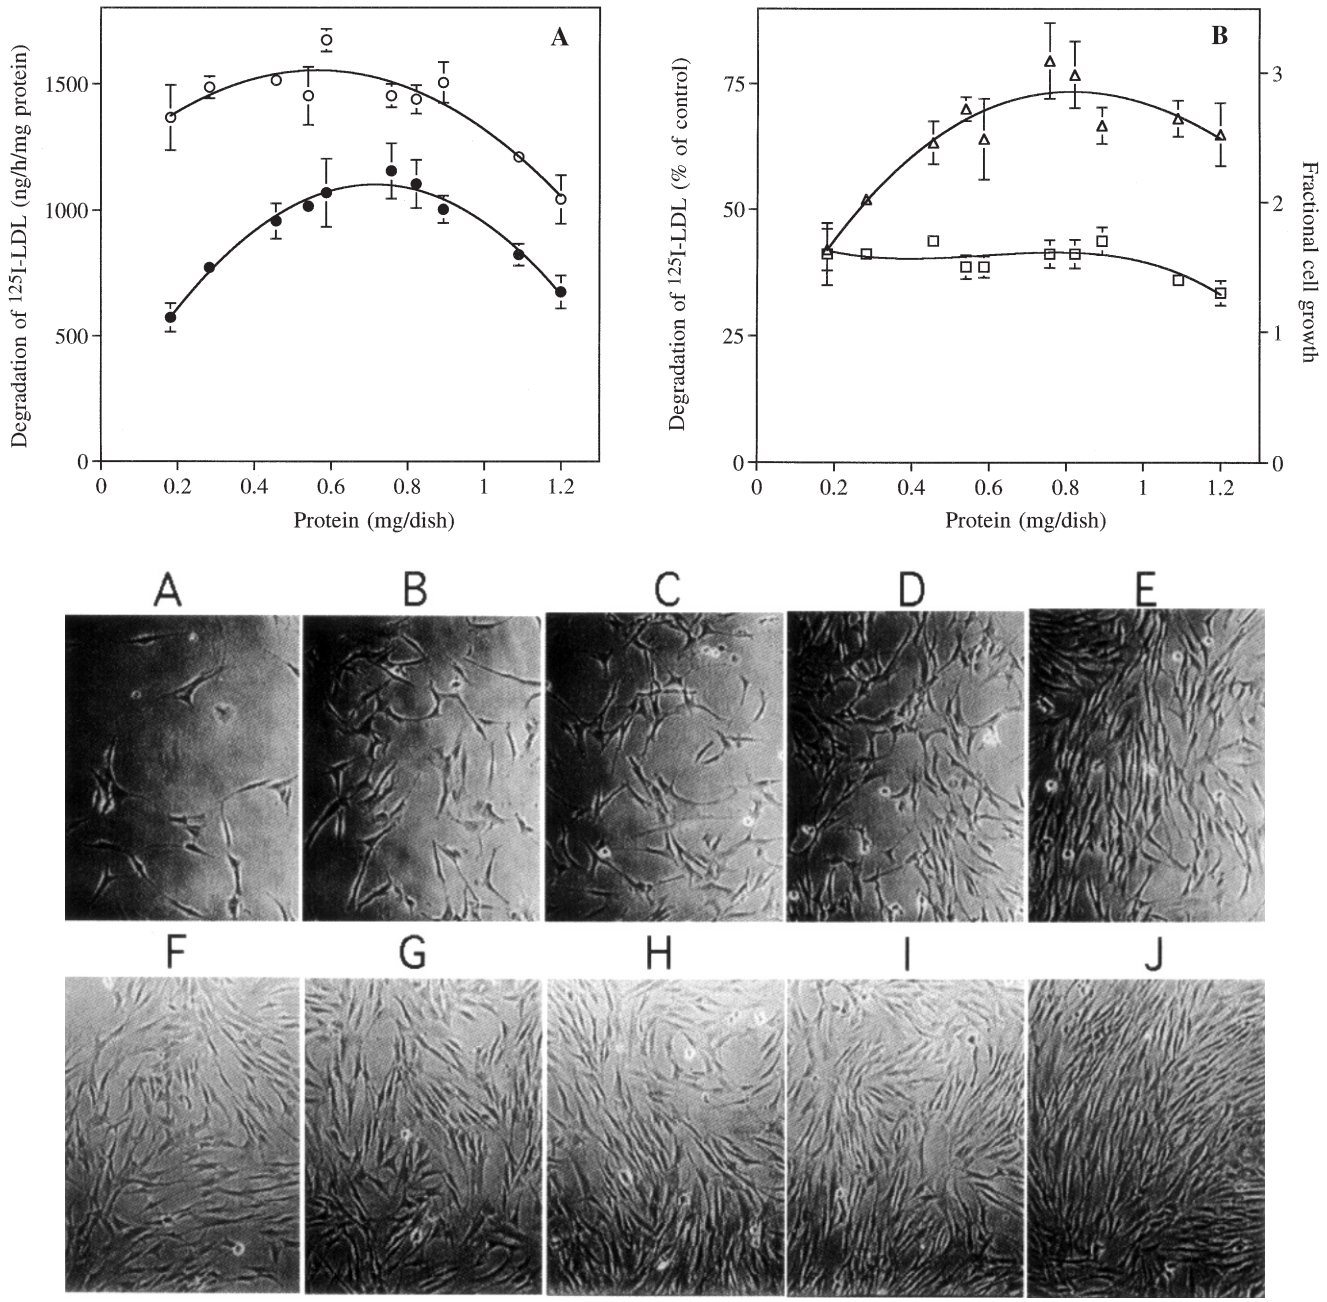

**FIG. 5.** Effect of sterols on $^{125}$I-LDL degradation rate by normal human fibroblasts at 10 different densities. Cells were seeded at 3000 to 24,000 cells/cm$^2$ in medium containing 10% FCS; after 30 h of growth, the medium was changed to medium containing 10% LPDS with (0.1 μg/mL 25-hydroxycholesterol + 2.0 μg/mL cholesterol) or without sterols. Following another 16 h of incubation, the $^{125}$I-LDL degradation rate was determined. Owing to the large number of dishes, the experiment was divided into two; the five lowest densities were seeded one week before the five highest densities. (A) Degradation of $^{125}$I-LDL in cells without (○) and with (●) sterols in the medium. (B) $^{125}$I-LDL degradation rate in the presence of sterols (△) expressed as percentage of control cells incubated without sterols and fractional cell growth (□) (calculated from the amount of protein after the 16 h incubation divided by the amount of protein before the 16 h incubation). Each value represents the mean of triplicate incubations. (C) The photographs show representative cell monolayers in the experiment in Figure 5; the mean protein contents (mg protein/dish) of the dishes are as follows: Picture A, 0.18; B, 0.28; C, 0.46; D, 0.54; E, 0.59; F, 0.76; G, 0.82; H, 0.89; I, 1.09; J, 1.20. For abbreviations see Figures 1 and 2.

rapidly. This explanation is also supported by the rapid decrease in RNA levels for both proteins when cell growth declines (Figs. 1,2). Alternatively, a high cell density may lead to a decreased available surface area of the cells that may add to the steep decrease in LDL receptor activity.

Several studies have shown that mitogenic stimulation by growth factors or phorbol esters activate LDL receptor gene expression (9,11,12,24). Activation with growth factors leads to an increased LDL receptor mRNA expression, and it has been shown that the sterol-responsive elements of the LDL

receptor are modulated by platelet-derived growth factor growth activation in human skin fibroblasts (25,26). Activation of the LDL receptor was also characterized by a decreased sensitivity to sterols, supporting our hypothesis that growth factors modulate LDL receptor sterol sensitivity and stimulate receptor activity in growing fibroblasts. Interestingly, Kenagy *et al*. (27) found that cell medium conditioned by cultured fibroblasts autostimulated LDL receptor activity, supporting the existence of such a factor. The data in the current study support that a growth-dependent autocrine modulation of sterol sensitivity takes place simply as a result of cell growth and that an exogenous addition of stimulants is not necessary in order to achieve a sterol-independent regulation of the LDL receptor.

Previous studies have shown that, in order to reach maximal LDL receptor expression, cells have to be actively growing and deprived of exogenous cholesterol (1,3,28,29). Because growing cells have higher cholesterol demands than nonproliferating cells, it is tempting to explain the strong suppression of LDL receptor and HMG-CoA reductase activities in confluent cells by a decreased cholesterol utilization for membrane synthesis leading to elevated intracellular cholesterol levels and decreased gene expression. However, results presented by Kruth *et al*. (5) show that cells at a higher density contained less cholesterol/mg protein compared to cells at a lower density both in the presence and absence of LDL cholesterol. This also supports the hypothesis that growth-dependent expression of the LDL receptor and HMG-CoA reductase is not mainly governed by the presence of cholesterol. We cannot, however, rule out that the concentration of cholesterol in a "regulatory compartment" differs from the whole cell level. That cholesterol is important for the expression of the LDL receptor and HMG-CoA reductase genes is obvious from the data in Figures 1 and 2, demonstrating that cells growing without an external source of cholesterol exhibited more than 10-fold higher expression levels than cells growing in 10% FCS.

It is possible that the growth-dependent modulation of LDL receptor sterol sensitivity, which in this study we have described in normal cells, could be abnormal in malignant cells and therefore be responsible for the elevated LDL receptor activity in AML cells. This is supported by the fact that previous studies have shown that the LDL receptor activity in leukemia cells from patients with AML has a decreased sensitivity to sterols (17). In addition to this, an *in vitro* autonomous growth that is related to an autocrine formation of growth factors (30,31) is frequently found in leukemia cells from AML patients. Modulation of sterol sensitivity may be an important mechanism to ensure an adequate cholesterol supply in growing cells.

# Production of Docosahexaenoic Acid by *Crypthecodinium cohnii* Grown in a pH-Auxostat Culture with Acetic Acid as Principal Carbon Source

**Colin Ratledge*, K. Kanagachandran, Alistair J. Anderson, David J. Grantham, and Janet C. Stephenson**

Lipid Research Centre, Department of Biological Sciences, University of Hull HU6 7RX, United Kingdom

**ABSTRACT:** *Crypthecodinium cohnii*, a marine alga used for the commercial production of docosahexaenoic acid (DHA), was cultivated in medium containing sodium acetate as principal carbon source; the pH was maintained at a constant value by addition of acetic acid, which also provided an additional carbon source in a controlled manner. The accumulation of lipid by *C. cohnii* in this pH-auxostat culture was significantly greater than previously reported for batch cultures using glucose as principal carbon source. Of six strains tested in pH-auxostat cultures, *C. cohnii* ATCC 30772 was the best, with the cells reaching 20 to 30 g dry weight per liter after 98 to 144 h and containing in excess of 40% (w/w) total lipid, with DHA representing approximately half of the total fatty acids in the triacylglycerol fraction. A productivity of 36 mg DHA $L^{-1}$ $h^{-1}$ was achieved during cultivation for 98 h using a 5% (vol/vol) inoculum, and DHA production was in excess of 3 g per liter of culture. Most of the DHA was present in neutral lipids.

Paper no. L8870 in *Lipids 36*, 1241–1246 (November 2001).

With the current increasing demand for oils rich in docosahexaenoic acid, DHA (22:6 n-3), not only for improved infant nutrition (1–3) but also as a dietary supplement for adults (4–7), attention has increasingly focused on the potential of microorganisms to meet these requirements (8,9). Nonmicrobial supplies of pure DHA are restricted to such sources as the eye-socket of the tuna or to expensive fractionation of fish oils (4), but in the latter case the DHA is nearly always accompanied by notable amounts of eicosapentaenoic acid (20:5n-3) (10), which may detract from the efficacy of DHA as a nutritional supplement (1–7). However, it has long been known that the marine dinoflagellate, *Crypthecodinium cohnii*, produces DHA as its sole polyunsaturated fatty acid (11). Development of this organism as a commercial source of oil rich in DHA has taken place over the past 6 to 8 yr, mainly through the efforts of Martek Co. Inc. (Columbia, MD) (12–14), and numerous patents have been taken out to protect the process and the product (e.g., Refs. 15–17).

In an attempt to improve upon the existing process, which uses glucose as the principal carbon source, we have discovered that the organism will grow to high cell densities, and also produce DHA at high concentrations within its intracellular oil, when it is grown on acetic acid. Preliminary work (de Swaaf, M.E., personal communication) indicated that *C. cohnii* could utilize sodium acetate, but the rise in pH that accompanied growth resulted in poor cell yield (<3 g/L). Also, published work (18) indicated that *C. cohnii*, as well as other microalgae, might be able to grow on acetate, but only if the concentration was kept low (1 g/L or less).

Growth of microorganisms on sodium acetate results in a rise in pH. This is because $Na^+$ remains in the medium and $CH_3COO^-$ is gradually replaced with $OH^-$ and other anions. Sodium hydroxide is a much stronger base than sodium acetate, and hence the pH rises. An increase in pH is characteristic of growth of microorganisms on salts of organic acids, or organic acids that have been neutralized by the addition of alkali. In the present work, we have used a pH-auxostat culture system in which a low initial concentration of sodium acetate is included in the initial growth medium and acetic acid is used to maintain a constant pH value and supply a further carbon source for growth. The concept of the pH-auxostat was first described in 1976 (19), and a pH-auxostat fed with acetic acid has been used to cultivate *Mucor circinelloides* for the production of biomass and an oil rich in γ-linolenic acid (20). In this paper we report the cultivation of *C. cohnii* in a pH-auxostat and DHA production in excess of 3 g per liter of culture.

## MATERIALS AND METHODS

*Growth of* C. cohnii. *Crypthecodinium cohnii* strain ATCC 30772 was used except where stated otherwise. Strains were grown at 27°C for 4–5 d in screw-capped tubes (25 mL) containing 5 mL of medium (ATCC Culture Medium 460 A2E6) and used to inoculate starter cultures. Starter cultures were grown at 27°C for 4 d in static flasks (250 mL) containing 100 mL medium containing (per liter): glucose (9 g), yeast extract (2 g), and sea salts (25 g). Shake-flask cultures were grown in flasks (250 mL) containing 100 mL medium composed of (per liter): glucose (27 g), yeast extract (3.8 g), and sea salts (25 g). These cultures were inoculated (10% vol/vol) with static culture and grown at 27°C for 3 d with shaking at 180 rpm.

Small pH-auxostat cultures were grown in fermenters (1 L) containing 800 mL of medium composed of (per liter): yeast extract (7.5 g), sea salts (25 g), and sodium acetate (1–16 g, as required). The pH of the medium was adjusted to

Abbreviations: ATCC, American Type Culture Collection; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; GC, gas chromatography; TLC, thin-layer chromatography; vvm, volume of air/volume of medium/min.

approximately 6.5 with NaOH, prior to autoclaving for 60 min at 121°C. pH-auxostat cultures were inoculated (10% vol/vol) with culture grown in shake-flasks as described above. The pH was maintained at 6.5 by the automatic addition of acetic acid (50% vol/vol) and, if necessary, KOH (2 M). The temperature was maintained at 27°C. The cultures were stirred at 300–1000 rpm and aerated at 0.2 to 1.0 vol air/vol medium/min (vvm), increasing the stirring speed and aeration as required to maintain a dissolved oxygen concentration above 30% of air saturation. Foaming was controlled by addition of polypropylene glycol (2000 grade). For growth in a fermenter with glucose as principal carbon source, the shake-flask culture medium described above was used and inoculated (10% vol/vol) with culture grown in the same medium. The growth conditions were otherwise as described for pH-auxostat culture except that the pH was maintained at 6.5 by the automatic addition of KOH (2 M) and, if necessary, HCl (2 M).

Larger pH-auxostat cultures were grown in the same medium (3.5 L) in fermenters (5 L) and inoculated (5% vol/vol) with pH-auxostat culture grown for 3 d in a 1-L pH-auxostat culture. The culture was aerated at 1 vvm and the dissolved oxygen concentration was maintained above 30% of air saturation by increasing the stirrer speed as required, from an initial speed of 300 rpm to a maximum of 1000 rpm. The growth temperature was 27°C and the pH was maintained at 6.5 as described above. Foaming was controlled as before.

*Determination of dry weight.* Samples of culture (50 to 100 mL) were centrifuged (4000 × *g* at 5°C for 10 min) and washed twice with water. The resulting cells were freeze-dried until constant weight was achieved.

*Lipid extraction.* Lipid was extracted from freeze-dried cells (usually 250 to 500 mg) by standing overnight in approximately 100 mL chloroform/methanol (2:1, vol/vol) and then following established procedures (21), with the final lipid amount being determined gravimetrically.

*Lipid fractionation.* The total lipid extract (approximately 120 mg) was fractionated following the procedure of Christie (22) using a 70 mL/10 g SPE Isolute $NH_2$ column (International Sorbent Technology, Mid-Glamorgan, United Kingdom) which was washed initially with hexane, and then the lipid extract, in chloroform, was added. Fractions were eluted progressively with diethyl ether (to elute neutral triacylglycerols), acetone/pyridine (1:1, vol/vol) (to elute sterol esters, sterol glycosides, and any digalactosyldiacyl glycerols), methanol (to elute choline-containing lipids), and finally chloroform/methanol/28% (wt/vol) aqueous ammonia/0.05 M ammonium acetate (4:1:0.08:0.02, by vol), to remove polar phospholipids. The solvent from each lipid fraction was evaporated and the residue weighed. The identity of each lipid component was confirmed by standard thin-layer chromatography (TLC) analysis (23).

*Fatty acid analysis.* Fatty acyl groups of the total lipid or the lipid fractions were transesterified using trimethylsulfonium hydroxide (24) and analyzed by gas chromatography (25).

*Determination of polysaccharide.* Samples of culture (100 mL) were centrifuged (4000 × *g* at 5°C for 10 min). The supernatant (25 mL) was mixed with 2-propanol (75 mL) and allowed to stand at room temperature for 30 min. The precipitated material was transferred to a preweighed filter (Whatman GF/A) and dried to constant weight at 65°C.

## RESULTS

*Optimization of the initial nutrient concentrations for growth of* C. cohnii *in a pH-auxostat.* When *C. cohnii* ATCC 30772 was grown in a series of pH-auxostat cultures with the initial concentration of sodium acetate in the medium ranging from 1 to 16 g/L, the growth rate and cell density attained after growth for 140 h were greatest with sodium acetate at 8 g/L (Fig. 1A). This concentration also produced the highest lipid content in the cells (Fig. 1B). The concentration of sodium acetate in the medium had no significant effect on the proportion of DHA, which represented approximately 40 to 50% of the total fatty acids (Fig. 1C).

The effect of independently varying the concentrations of sea salts and yeast extract in the growth medium was tested. No significant improvement in lipid accumulation or DHA production was achieved by modest increases or decreases in concentration (data not shown).

*Performance of other strains in pH-auxostat culture.* The performance of six strains of *C. cohnii*, including ATCC 30772, all grown in pH-auxostat cultures with 8 g sodium acetate/L as the initial concentration, is summarized in Table 1. All the strains tested produced DHA, and the highest productivity was achieved using strain 30772. On the basis of the amount of acetic acid consumed, strain 30772 produced the lowest yield of cells and the highest yield of DHA.

All cultures of *C. cohnii* became viscous toward the end of the growth period, and material, presumably exopolysaccharide, could be precipitated from the supernatant fluid by treatment with 2-propanol (Table 1). The highest concentration of precipitable material was found for strain ATCC 30772.

*Effect of inoculum substrate on pH-auxostat growth.* It is well known that the utilization of acetate requires the induction of several enzymes that are not active in glucose-grown cells. The performance of *C. cohnii* in the pH-auxostat was, however, similar for cultures inoculated with glucose or acetate (pH-auxostat) cultures. No significant differences were seen with respect to growth performance (Fig. 2A), lipid production (Fig. 2B), or DHA production (Fig. 2C), and both lipid and DHA production were substantially greater than achieved during batch fermentation with glucose as carbon source (Figs. 2B, 2C). Presumably the inducible enzymes needed for the utilization of acetate were synthesized soon after exposure of the cells to acetate, and this occurred during the lag period, prior to rapid growth of the culture.

*Lipid fractionation.* The lipid produced by cells grown with glucose as principal carbon source was fractionated into its major components (Table 2). Comparable data for cells grown on acetate in a pH-auxostat are shown in the lipid from

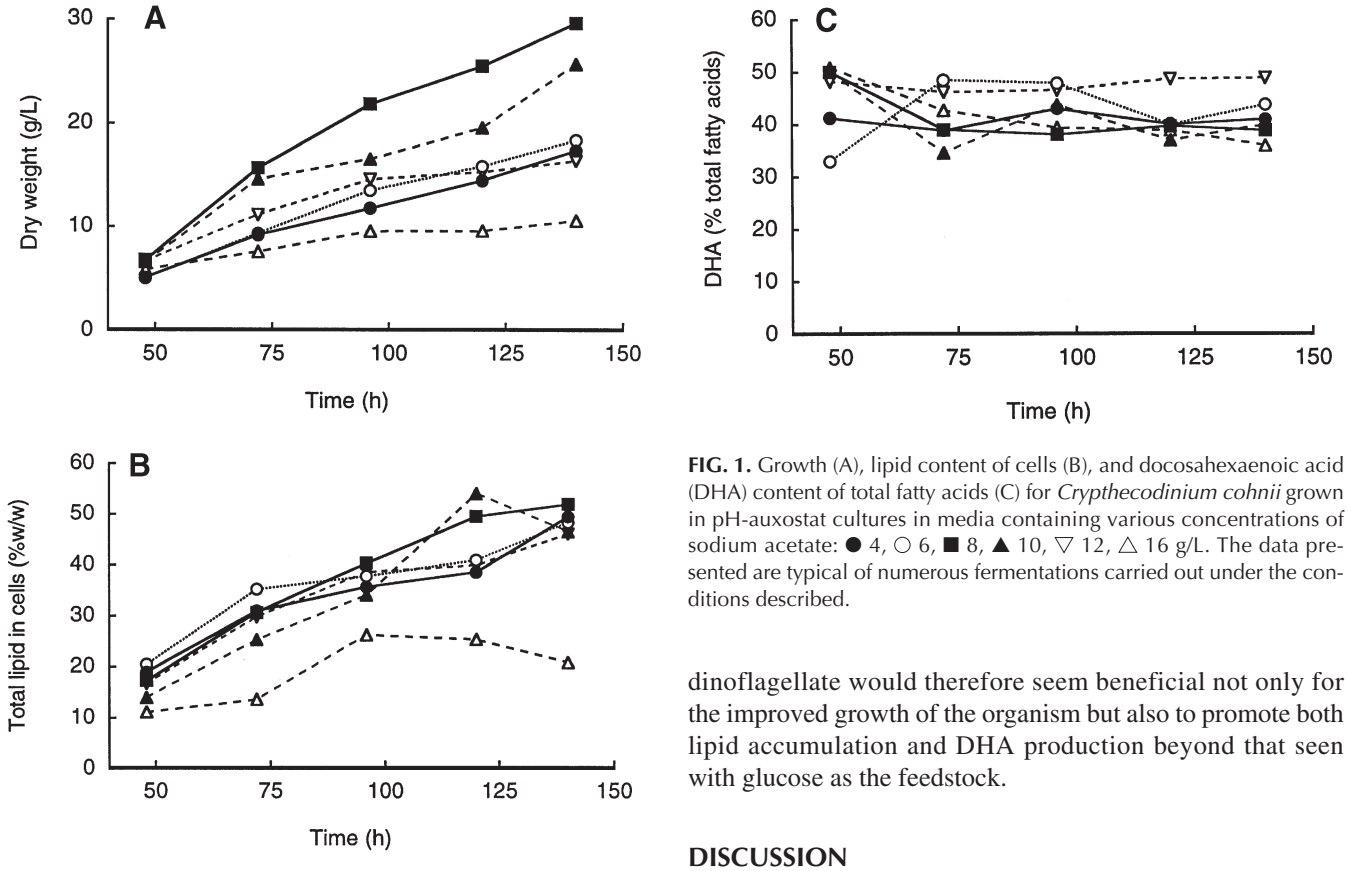

**FIG. 1.** Growth (A), lipid content of cells (B), and docosahexaenoic acid (DHA) content of total fatty acids (C) for *Crypthecodinium cohnii* grown in pH-auxostat cultures in media containing various concentrations of sodium acetate: ● 4, ○ 6, ■ 8, ▲ 10, ▽ 12, △ 16 g/L. The data presented are typical of numerous fermentations carried out under the conditions described.

Table 3. In both cases the major fraction, constituting 75% of the total lipids, was the neutral lipids. These were shown by TLC to be wholly triacylglycerols. The proportion of the other lipid components was also similar for cells produced in glucose and acetate pH-auxostat cultures. Of possible significance, though, was the increased content of DHA not only in the total extracted lipid but also in the triacylglycerol fraction obtained from the acetate-grown cells compared to the glucose-grown cells. The triacylglycerol fraction, which is the commercially most valuable part of the oil, contained over 50% more DHA when isolated from the acetate-grown cells than was in the same fraction obtained from the glucose-grown cells. Acetate as a feedstock for the cultivation of this dinoflagellate would therefore seem beneficial not only for the improved growth of the organism but also to promote both lipid accumulation and DHA production beyond that seen with glucose as the feedstock.

## DISCUSSION

The large-scale production of DHA-rich oil derived from *C. cohnii* has been carried out since the mid-1990s with the oil being offered as an over-the-counter dietary supplement for adults and as a beneficial and important polyunsaturated fatty acid for inclusion in infant formulae. Although technical aspects of the commercial process are obviously restricted, it is nevertheless understood that the organism is cultivated in large stirred fermenters with glucose as principal carbon source (12,13). Yields of biomass, lipid, and DHA are, of course, closely guarded company secrets.

Nevertheless the results being reported here would indicate that an alternative process based on acetic acid as the principal carbon feedstock might seek to rival the traditional glucose feedstock process. The performance of *C. cohnii*

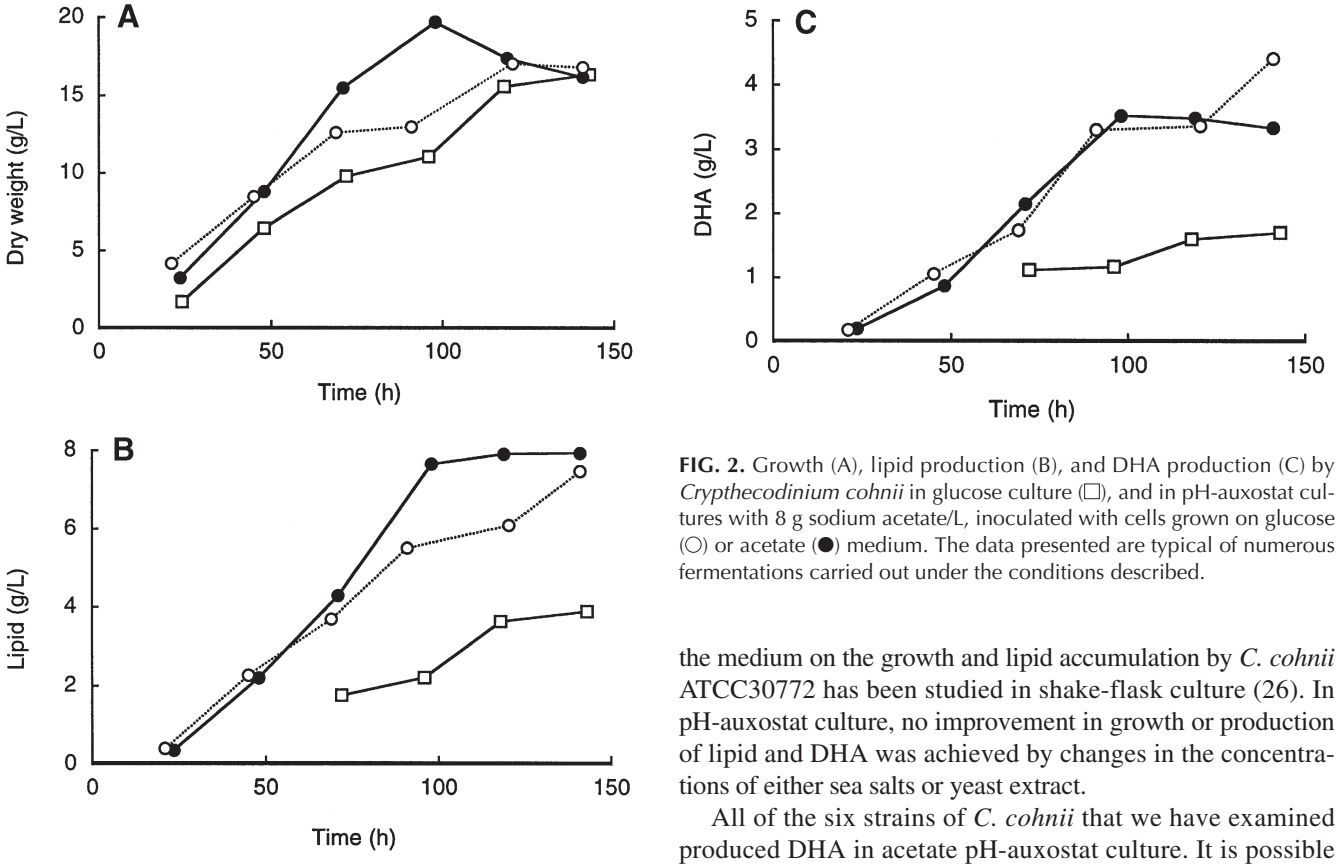

**FIG. 2.** Growth (A), lipid production (B), and DHA production (C) by *Crypthecodinium cohnii* in glucose culture (□), and in pH-auxostat cultures with 8 g sodium acetate/L, inoculated with cells grown on glucose (○) or acetate (●) medium. The data presented are typical of numerous fermentations carried out under the conditions described.

ATCC 30772 in acetate pH-auxostat culture is certainly superior to that achieved with this strain using medium containing glucose as principal carbon source (26). Overall productivities for total lipid and DHA were calculated as 78 and 36 mg $L^{-1}h^{-1}$, respectively, for 98-h cultivation in a pH-auxostat culture using a 5% inoculum taken from a similar culture (Figs. 2B, 2C). The influence of the concentrations of sea salts and yeast extract in the medium on the growth and lipid accumulation by *C. cohnii* ATCC30772 has been studied in shake-flask culture (26). In pH-auxostat culture, no improvement in growth or production of lipid and DHA was achieved by changes in the concentrations of either sea salts or yeast extract.

All of the six strains of *C. cohnii* that we have examined produced DHA in acetate pH-auxostat culture. It is possible that other strains of this organism (the American Type Culture currently lists some 45 strains) might have even better DHA productivity than strain ATCC 30772. The pH-auxostat is clearly a useful method of cultivation of *C. cohnii* on acetate, since the carbon source is delivered in a controlled manner so that its concentration never becomes inhibitory to growth. The pH-auxostat might also be of value for the cultivation of a wide range of oleaginous organisms on acetic acid, which is an inexpensive carbon source.

[a]Trace (<0.5%).

Fractionation of the lipid produced from glucose (Table 2) and acetate (Table 3) cultures confirmed the observations (27) that DHA is present in both neutral and polar lipids of *C. cohnii* and that choline lipids contain the highest proportion of DHA. In the present study, however, most of the DHA is present in neutral lipids, simply because of the much greater lipid accumulation achieved.

The material that could be precipitated from supernatant fluid with 2-propanol has recently been identified as polysaccharide (28). The production of exopolysaccharide is likely to affect yield and is therefore significant for large-scale cultivation of *C. cohnii* for DHA production. Thus, carbon and energy source will be wasted in production of polysaccharide, and it becomes increasingly difficult to supply cultures with sufficient dissolved oxygen as their viscosity increases. The presence of polysaccharide may also interfere with the recovery of the DHA-containing oil.

A patent application (GB 00/02695) covering the main aspects of this work has been filed.

# Regiospecific Analysis of Conifer Seed Triacylglycerols by Gas–Liquid Chromatography with Particular Emphasis on Δ5-Olefinic Acids

**Frédéric Destaillats[a,b], Paul Angers[a], Robert L. Wolff[b,*], and Joseph Arul[a]**

[a]Department of Food Science and Nutrition and Dairy Research Center (STELA), Université Laval, Sainte Foy, Québec, Canada G1K 7P4, and [b]ISTAB, Université Bordeaux 1, 33405 Talence Cedex, France

**ABSTRACT:** Dibutyroyl derivatives of monoacylglycerols (DBMAG) from conifer seed oil triacylglycerols (TAG) were prepared by partial deacylation of TAG with ethylmagnesium bromide followed by diesterification with *n*-butyryl chloride. The resulting mixtures were analyzed by gas–liquid chromatography (GLC) with a 65% phenylmethyl silicon open tubular fused-silica capillary column operated under optimal conditions and separated according to both their fatty acid structures and their regiospecific distribution. Seed oils of 18 species from 5 conifer families (Pinaceae, Taxaceae, Cupressaceae, Cephalotaxaceae, and Podocarpaceae) were analyzed. The chromatograms showed a satisfactory resolution of DBMAG containing palmitic (16:0), stearic (18:0), taxoleic (*cis*-5,*cis*-9 18:2), oleic (*cis*-9 18:1), *cis*-vaccenic (*cis*-11 18:1), pinolenic (*cis*-5,*cis*-9,*cis*-12 18:3), linoleic (*cis*-9,*cis*-12 18:2), α-linolenic (*cis*-9,*cis*-12,*cis*-15 18:3), and an almost baseline resolution of DBMAG containing gondoic (*cis*-11 20:1), *cis*-5,*cis*-11 20:2, sciadonic (*cis*-5,*cis*-11,*cis*-14 20:3), dihomolinoleic (*cis*-11,*cis*-14 20:2), juniperonic (*cis*-5,*cis*-11,*cis*-14,*cis*-17 20:4), and dihomo-α-linolenic (*cis*-11,*cis*-14,*cis*-17 20:3) acids. We have observed that results for *Pinus pinaster* and *P. koraiensis* seed oils obtained with this new simple method compared favorably with literature data established with other usual regiospecific analytical techniques. Δ5-Olefinic acids are esterified mainly at the external positions of the glycerol backbone in all cases, in agreement with data obtained by other methodologies allowing validation of the GLC regiospecific method. To date, 45 gymnosperm species (mostly Coniferophytes) from 21 genera belonging to 9 families have been analyzed, all of them showing a definite enrichment of Δ5-olefinic acids in the external positions of TAG. These fatty acids (FA), with one exception only, represent between ~2 and 8% of FA esterified to the internal positions. For some species, i.e., *P. koraiensis* and *P. pinaster,* this asymmetrical distribution was established by at least three analytical procedures and confirmed by stereospecific analysis of their seed TAG.

Abbreviations: DAG, diacylglycerol; DBMAG, dibutyroyl-monoacylglycerol; FA, fatty acid; GLC, gas–liquid chromatography; HPLC, high-performance liquid chromatography; MAG, monoacylglycerol; NMR, nuclear magnetic resonance; TAG, triacylglycerol; TLC, thin-layer chromatography; UPIFA, unsaturated polymethylene-interrupted fatty acid.

Although gymnosperm seed fatty acid (FA) compositions have been almost completely neglected for decades, ~200 species have been analyzed in our laboratory since 1995. This systematic study followed that of Takagi and Itabashi (1) published in 1982, who established the FA compositions of 20 species. In addition to the presence of Δ5-unsaturated polymethylene-interrupted fatty acids (Δ5-UPIFA, or Δ5-olefinic acids), the seed triacylglycerols (TAG) show a particular regio- and stereospecific distribution of these FA. Both classical and recent procedures have shown that Δ5-UPIFA are esterified mainly at the external [*sn*-1(3)] positions and scarcely at the internal (*sn*-2) position. In the classical procedures, TAG are partially deacylated with a Grignard reagent (2) or pancreatic lipase (3), and FA resulting from the partially deacylated products [isolated by thin-layer chromatography (TLC)] are analyzed by gas–liquid chromatography (GLC). In the recent methods, $^{13}C$ nuclear magnetic resonance (NMR) spectroscopy is used to assess Δ5-UPIFA at the external and internal positions (4–11). Both protocols indicate either a low content of Δ5-UPIFA, or very little Δ5-UPIFA, at the *sn*-2 position, respectively. However, each method has its limitations. With the lengthy classical methods, which include a TLC step, some intra-isomerization of monoacylglycerols (MAG) can occur, whereas $^{13}C$ NMR spectroscopy is unable to detect signals arising from the *sn*-2 position when Δ5-UPIFA are less than ~3% of the total FA at this position.

In more thorough experiments (12), the stereospecific distribution of Δ5-UPIFA was established in a few species. In these experiments, appropriate derivatives of *sn*-1,2- and *sn*-2,3-diacylglycerol (DAG) were separated by high-performance liquid chromatography (HPLC) on a chiral column. This clearly demonstrated that Δ5-UPIFA are essentially esterified at the *sn*-3 position of TAG (>80% of total Δ5-UPIFA). However, it is also possible in this procedure that Δ5-UPIFA may have migrated to some extent from one position to another during separation of DAG by TLC. It is noteworthy that TAG molecular species containing two Δ5-UPIFA were scarce, or even absent in two pine species (13).

To reduce any positional acyl migrations in MAG or DAG, we adopted a new regiospecific analytical procedure that considerably reduces the time of analysis (14,15; Destaillats, F., Angers, P., Wolff, R.L., and Arul, J., unpublished data). Briefly,

TAG are partially deacylated with ethylmagnesium bromide and immediately butylated with *n*-butyryl chloride. Dibutyroyl-MAG (DBMAG) are then directly analyzed by GLC under appropriate conditions (*sn*-1,2-DBMAG coelute with *sn*-2,3-DBMAG, but are separated from *sn*-1,3-DBMAG); thus, no TLC step is involved. The objectives of this study were to compare data obtained with the new method to earlier data obtained with classical procedures, and to determine, using this method, the regiospecific distribution of FA of conifer seed oils from species or genera that have not been analyzed to date.

## MATERIALS AND METHODS

*Samples and reagents.* The conifer species studied for their seed lipids are listed in Table 1. Details of their source, oil extraction, and the FA compositions of some species are found elsewhere (16,17). Phosphatidylcholine and standard TAG (tripalmitin, tristearin, triolein, tri-*cis*-vaccenin, trilinolein, tri-α-linolenin, trigondoin, trieicosadienoin, and trieicosatrienoin) were purchased from Sigma Chemical (St Louis, MO). Ethyl magnesium bromide, *n*-butyryl chloride, and triethylamine were obtained from Aldrich (Milwaukee, WI).

*DBMAG synthesis*. The method of Angers and Arul (14) was followed with only slight modifications. To a stirred solution of oil (10 mg, equivalent to a droplet) in anhydrous diethylether (500 μL), contained in a flame-dried flask under inert atmosphere ($N_2$), a solution of ethyl magnesium bromide in the same solvent (3.0 M, 40 μL) was added. After 30 s of stirring at room temperature, glacial acetic acid (10 μL) was added, followed by boric acid (10% aqueous solution, 300 μL). The mixture was quickly extracted with diethyl ether (3 × 500 μL) and the organic extracts were combined, washed sequentially with $Na_2CO_3$ (10% aqueous solution, 2 mL) and NaCl (saturated aqueous solution, 2 mL), dried over anhydrous $Na_2SO_4$, and concentrated under a stream of dry nitrogen. The residue was dissolved in dry chloroform (500 μL); triethylamine (100 μL) and *n*-butyryl chloride (50 μL) were added sequentially after homogenization, and the mixture was held at 40–60°C for 30 min in a closed vial with constant stirring. After the mixture was cooled to room temperature, distilled water (500 μL) was added, and after homogenization, the mixture was added to *n*-octane (1 mL) and sequentially washed with HCl (0.15 N, 2 mL), $Na_2CO_3$ (10%, 2 mL), and NaCl (saturated aqueous solution, 2 mL). The organic extract was dried over anhydrous sodium sulfate and filtered before GLC analysis.

[b]Also known as *Tsuga mertensiana* (see Ref. 18).

*GLC analyses*. DBMAG were analyzed in a Hewlett-Packard 6890 gas chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a RTX-65TG (65% phenylmethyl silicon) open tubular fused-silica capillary column (30 m × 0.25 mm i.d., 0.10-μm film thickness; Restek, Brockville, CA). The injector (split mode) and the flame-ionization detector were maintained at 400°C. Quantitative data were calculated by a Hewlett-Packard GLC ChemStation.

Three different temperature programs were used to obtain an almost baseline separation of most of the DBMAG containing a Δ5-unsaturated FA. Identifications were performed by comparison with DBMAG prepared with authentic standards of usual TAG. The initial chromatographic runs were performed under conditions described below, which allowed the separation of DBMAG but not baseline resolutions of DBMAG containing a Δ5-unsaturation. The oven temperature was 270°C for 10 min and then increased to 360°C at 20°C/min. The inlet pressure of the carrier gas ($H_2$) was 120 kPa. Satisfactory resolutions of DBMAG of the $C_{18}$ group containing taxoleic (*cis*-5,*cis*-9 18:2), oleic (*cis*-9 18:1), *cis*-vaccenic (*cis*-11 18:1), pinolenic (*cis*-5,*cis*-9,*cis*-12 18:3), and linoleic acids were achieved with isothermal separation at 210°C for 50 min, then to 360°C at 20°C/min for 3 min. The inlet pressure of the carrier gas ($H_2$) was 140 kPa. Separations of DBMAG of the $C_{20}$ group containing 5,11-eicosadienoic (*cis*-5,*cis*-11 20:2), gondoic (*cis*-11 20:1), sciadonic (*cis*-5,*cis*-11,*cis*-14 20:3), dihomolinoleic (*cis*-11,*cis*-14 20:2), juniperonic (*cis*-5,*cis*-11,*cis*-14,*cis*-17 20:4), and dihomo-α-linolenic (*cis*-11,*cis*-14,*cis*-17 20:3) acids were achieved with temperature programming. The oven was programmed from 100 to 300°C at a rate of 5°C/min, then to 360°C at 20°C/min. The inlet pressure of the carrier gas ($H_2$) was 84 kPa. Quantification of *sn*-2- and *sn*-1(3)-DBMAG was performed by normalizing each series to 100% and dividing each peak area by the respective sums. Results are expressed as area percentages, and no response factors were applied.

*GLC of FA methyl esters*. Methylation of FA was carried out in a sealed tube with 0.4 N sodium methoxide in methanol. Analyses of the methyl esters were performed with a Hewlett-Packard gas chromatograph model 5890 Series II, equipped with a flame-ionization detector and connected to a computer with a Hewlett-Packard ChemStation. Samples in hexane (1.0 μL) were injected on an open tubular DB-225

capillary column (30 m × 0.25 mm i.d., 0.25-μm film thickness; J&W). The injector and detector temperatures were maintained at 250°C, and the oven temperature was 190°C. Hydrogen was the carrier gas, with a head pressure of 140 kPa.

## RESULTS AND DISCUSSION

*Sampling.* Eighteen conifer seed oils were analyzed in this study. This sampling contained original species whose regiospecific distribution is not known and six species (*Taxus chinensis*, *Cephalotaxus drupaceae*, *Pinus koraiensis*, *P. sylvestris*, *P. pinaster*, and *Juniperus virginiana*) whose regiospecific profiles have already been determined by literature methods (1,4,6,8,12,19). The latter group was included for the purpose of comparison of the present method. Seed oils were extracted by the method of Folch *et al.* (20) and used without further purification.

*Experimental considerations.* The oil samples were crude and possibly contained components other than TAG, such as phospholipids, which can interfere in DBMAG synthesis. FA profiles of polar lipids and TAG fractions are known, and both fractions contain different proportions of Δ5-UPIFA (1). Egg yolk phosphatidylcholine was submitted to Grignard degradation and derivatization with *n*-butyryl chloride under conditions similar to seed oil as described above. GLC analysis of the resulting products did not exhibit any peaks attributable to DBMAG. Presumably *sn*-1-monoacyl-lysophospholipids and *sn*-2-monoacyl-lysophospholipids resulting from Grignard degradation are removed in the aqueous extract during work-up. Thus, phospholipids do not interfere with the regiospecific analysis of TAG by the present method, which can be performed directly on the crude lipid extracts without further purification of TAG by TLC or other methods.

*Optimization of analytical conditions.* Different GLC conditions were examined for the separation of DBMAG containing Δ5-UPIFA. A systematic search of optimal temperature and pressure conditions revealed that the retention of the $C_{18}$ and $C_{20}$ DBMAG on the stationary phase is different; consequently, they cannot be completely baseline-resolved under the same chromatographic conditions. The $C_{18}$ DBMAG group includes stearic, taxoleic, oleic, *cis*-vaccenic, pinolenic, linoleic, α-linolenic, and coniferonic acids; the $C_{20}$ group encompasses 5,11- 20:2, gondoic, sciadonic, dihomolinoleic, juniperonic, and dihomo-α-linolenic acids, at different regioisomeric positions.

For the $C_{18}$ regioisomers, isothermal conditions were used. The DBMAG elution order was established by comparison with stearic, oleic, *cis*-vaccenic, linoleic, and α-linolenic DBMAG in their *sn*-1(3) and *sn*-2 positions prepared from authentic TAG standards. Figure 1 shows the relative elution of these DBMAG at different temperatures when the gas

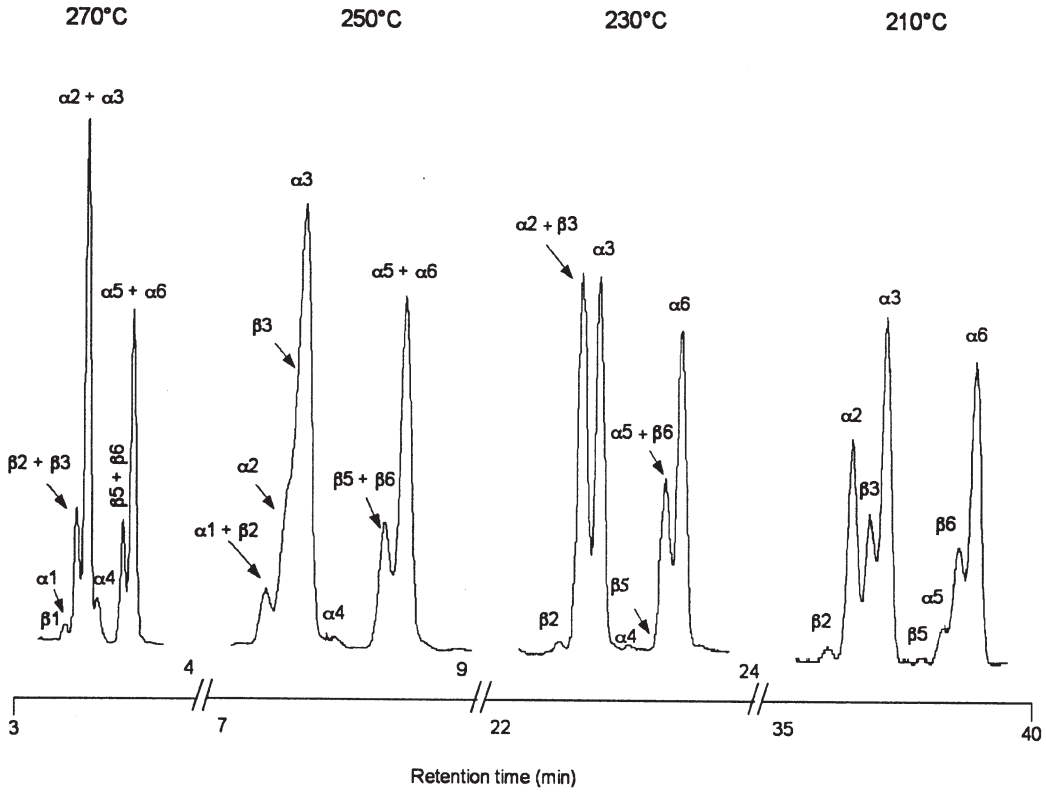

**FIG. 1.** Gas–liquid chromatography of $C_{18}$ dibutyroyl derivatives of monoacyglycerols prepared from *Taxus chinensis* on a 30-m RTX-65TG (Restek, Brockville, CA) column at different oven temperatures (see text for other operating conditions). Peak identification: α is for *sn*-1(3) and β for *sn*-2 positions; (1) stearic (18:0) acid; (2) taxoleic (*cis*-5,*cis*-9 18:2) acid; (3) oleic (*cis*-9 18:1) acid; (4) *cis*-vaccenic (*cis*-11 18:1) acid; (5) pinolenic (*cis*-5,*cis*-9,*cis*-12 18:3) acid; (6) linoleic (*cis*-9,*cis*-12 18:2) acid.

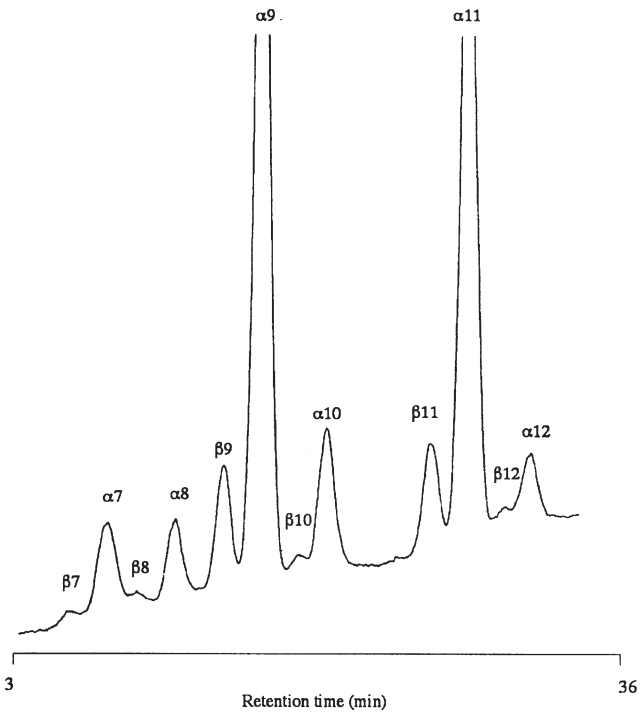

**FIG. 2.** Gas–liquid chromatography of $C_{20}$ dibutyroyl derivatives of monoacyglycerols prepared from *Taxus chinensis* on a 30-m RTX-65TG (Restek, Brockville, CA) column (see text for other operating conditions). Peak identification: α is for *sn*-1(3) and β for *sn*-2 positions; (7) *cis*-5,*cis*-11 20:2; (8) gondoic (*cis*-11 20:1) acid; (9) sciadonic (*cis*-5,*cis*-11,*cis*-14 20:3) acid; (10) dihomolinoleic (*cis*-11,*cis*-14 20:2) acid; (11) juniperonic (*cis*-5,*cis*-11,*cis*-14,*cis*-17 20:4) acid; (12) dihomo-α-linolenic (*cis*-11,*cis*-14,*cis*-17 20:3) acid.

velocity is maintained at 40 mL·cm$^{-1}$. Temperature had a significant effect on the resolution of Δ5-olefinic DBMAG. At 270°C, oleic and taxoleic acids at *sn*-1(3) elute together as well as linoleic and pinolenic acids. The same phenomenon also occurs for all *sn*-2-DBMAG. However, with a gradual temperature decrease, taxoleic acid esterified at the *sn*-1(3) and *sn*-2 positions undergoes a shift to the left-hand side of oleic acid (see Fig. 1, partial chromatograms at 250 and 230°C). Similarly, the elution order becomes *sn*-2 taxoleic, *sn*-1(3) taxoleic, *sn*-2 oleic, *sn*-1(3) oleic, *sn*-2 pinolenic, *sn*-1(3) pinolenic, *sn*-2 linoleic followed by linoleic acid at the *sn*-1(3) positions at 210°C (Fig. 1). This elution order is quite uncommon with medium polar capillary stationary phases because the octadecadienoate-DBMAG with a Δ5-ethylenic bond (*cis*-5,*cis*-9 18:2) elutes before DBMAG containing oleic acid; similarly, the octadecatrienate (*cis*-5,*cis*-9,*cis*-12 18:3) DBMAG elutes before DBMAG containing linoleic acid.

For the $C_{20}$-containing regioisomers in which the number of ethylenic bonds varies between 1 and 4, the number of corresponding DBMAG peaks may reach 12 for species such as *J. virginiana*, which contains not only sciadonic and juniperonic acids but also their precursors (*cis*-11,*cis*-14 20:2 and *cis*-11,*cis*-14,*cis*-17 20:3, respectively). Because isothermal chromatographic conditions did not permit baseline resolution of all regioisomers, we used temperature programming from 100 to 300°C at a linear rate of 5°C/min. Temperature programming coupled with a low carrier gas pressure of 84 kPa led to satisfactory separation of DBMAG containing $C_{20}$ regioisomers (Fig. 2). The order of elution for the $C_{20}$-DBMAG was the same as that for $C_{18}$-DBMAG (Fig. 2). The polymethylene-interrupted system with a double bond at position Δ5 close to the glyceryl bond is presumably hidden by the two $C_4$ chains of butyroyl groups, thereby leading to reduced solubility on the stationary phase and resulting in the observed elution order.

*Validation of the method.* Regiospecific distribution of Δ5-UPIFA is given in Table 2. Regiospecific distribution of Δ5-UPIFA for *Pinus pinaster* and *P. koraiensis* seed oils obtained with the present protocol is compared with the data published by Wolff *et al.* (12) and Blaise *et al.* (19). They contain four Δ5-UPIFA, two of which belong to the $C_{18}$ group (taxoleic and pinolenic acids) and two to the $C_{20}$ group (5,11-eicosadienoic and sciadonic acids). Blaise *et al.* (19) employed the method of Brockerhoff (2), which involved deacylation with Grignard reagent followed by TLC separation of DAG and FA analysis of their methyl esters by GLC. Wolff *et al.* (12) employed the same method except that DAG generated by partial deacylation were separated by TLC, and their

[a]Values are means of duplicate analyses.
[b]The numbers refer to species listed in Table 1.
[c]Fatty acid composition of O-acylated species in the oil obtained by gas–liquid chromatography analysis of fatty acid methyl esters.
[d]TAG, fatty acid composition of triacylglycerols calculated from *sn*-1(3) and *sn*-2 positions.
[e]Fatty acid esterified to the *sn*-1(3) and *sn*-2 positions of monoacylglycerol derivatives.
[f]Sum of Δ5-UPIFA.

3,5-dinitrophenylurethane derivatives were separated by chiral HPLC. In *P. pinaster* seed oil, we detected 1.1% of taxoleic acid at the *sn*-1(3) and 0.2% at the *sn*-2 positions, whereas Wolff *et al.* (12) and Blaise *et al.* (19) found this FA only at the *sn*-1(3) positions at a level of 1.0%. In *P. koraiensis* seed oil, we detected the same FA at the level of 2.5% at the *sn*-1(3) and 0.3% at the *sn*-2 positions, whereas Wolff *et al.* (12) found 2.3% at the *sn*-1(3) and 0.3% at the *sn*-2 positions and Blaise *et al.* (19) found 2.6% at the *sn*-1(3) and 0.3% at the *sn*-2 positions. With respect to sciadonic acid, we found 6.4% at the *sn*-1(3) and 1.0% at the *sn*-2 positions in *P. pinaster* seed oil. Wolff *et al.* (12) determined a level of 6.5% at the *sn*-1(3) and 1.8% at the *sn*-2 positions, whereas Blaise *et al.* (19) reported 7.2% at the external positions of glycerol and 0.5% at the internal position. The regiospecific distribution of sciadonic acid in *P. koraiensis* seed oil also compares well with that of Wolff *et al.* (12) and that of Blaise *et al.* (19) (see Table 2). Regiospecific distributions of pinolenic and 5,11-eicosadienoic acids in *P. pinaster* and *P. koraiensis* seed oils are similar. Thus, the proposed GLC method compared well with the other two methods, with respect to its accuracy and reliability. The seed oils from these two pine species have also been analyzed by $^{13}$C NMR spectroscopy (4). Regiospecific analysis of Δ5-UPIFA on TAG was based on the chemical shifts of $C_1$ and $C_2$ carbonyl groups. For the $C_1$, two signals at 173.2 ppm in the external position of the glycerol backbone (α-chains) and 172.8 ppm in the internal position are detected. The occurrence of a Δ5-ethylenic bond in the aliphatic chain has the property to modify the $C_1$ and $C_2$ chemical shifts. The $C_1$ on external chains give values in the range of 173.01–173.07 ppm. No studies referred to a signal attributable to Δ5-UPIFA in the *sn*-2 position, which likely has a value slightly lower than 172.8 ppm. Blaise *et al.* (6) indicated that the minimum detection level of Δ5-UPIFA is 3% of fatty acids esterified at the *sn*-2 position.

*Regiospecific distribution of Δ5-UPIFA in conifer seed TAG.* Regiospecific distribution of Δ5-UPIFA is presented in Table 3. Δ5-UPIFA are preferentially located at the *sn*-1(3) positions compared with the *sn*-2 position, in agreement with previous studies. The distribution does not depend on the chain length of FA ($C_{18}$ and $C_{20}$) nor on the number of double bonds (2 to 4). However, certain discrepancies exist compared with the data obtained by methods based on $^{13}$C NMR spectroscopy, which is unable to detect Δ5-UPIFA in the *sn*-2 position of TAG. Unfortunately, all of the species analyzed here were not investigated by $^{13}$C NMR spectroscopy, and only an estimate of the lower value that can be registered by that technique can be made. More than 10 species analyzed here contain <4% Δ5-olefinic acids in their *sn*-2 position, which could not be detected by $^{13}$C NMR spectroscopy. This also holds for *Cedrus brevifolia,* a close relative of *C. atlantica* analyzed by $^{13}$C NMR spectroscopy, which contains

[a]Values are means of duplicate analyses.
[b]The numbers refer to species listed in Table 1.
[c]Fatty acid composition of O-acylated species in the oil obtained by fatty acid methyl esters analyses by gas–liquid chromatography.
[d]TAG, fatty acid composition of triacylglycerols calculated from *sn*-1(3) and *sn*-2 positions.
[e]Fatty acid esterified to the *sn*-1(3) and *sn*-2 positions of monoacylglycerol derivatives.

almost 8% of Δ5-UPIFA in the internal position. There is one species that appears exceptional in our study, *Nageia nagi*, a podocarp, which contains >15% of Δ5-UPIFA in the *sn*-2 position. This species was not examined by $^{13}$C NMR spectroscopy, but our data confirm the observations of Takagi and Itabashi (1) for that species (reported as *Podocarpus nagi*). A realistic limit of detection of Δ5-UPIFA in the internal position by $^{13}$C NMR would thus be 6–8%, rather than 3% as reported earlier for $^{13}$C NMR spectroscopy analyses (6).

*Regiospecific distribution of common FA.* Regiospecific distribution of FA is presented in Table 4. Palmitic and stearic acids are preferentially esterified at the *sn*-1(3) positions, whereas the distribution of monoenoic acids is variable. Oleic (*cis*-9 18:1) acid distribution is random. *Cis*-vaccenic (*cis*-11 18:1) acid appeared to be completely absent from the *sn*-2 position for all species. Except for *Cephalotaxus* spp., in which linoleic acid (*cis*-9,*cis*-12 18:2) was almost equally distributed between the internal and the external positions, this FA was more concentrated in the *sn*-2 position than in the *sn*-1(3) positions for all other species. α-Linolenic (*cis*-9,*cis*-12,*cis*-15 18:3) acid did not seem to follow any rule; however, it was most often equally esterified to both internal and external positions. An exception was *Pseudolarix amabilis*, in which α-linolenic acid was concentrated in the *sn*-2 position. In the few cases in which dihomo-α-linolenic (*cis*-11,*cis*-14,*cis*-17 20:3) acid occurs (Cupressaceae), it appeared to be excluded from the *sn*-2 position.

In conclusion, Table 5 summarizes Δ5-UPIFA regiospecific distribution in all species of conifer seeds analyzed to date, including families and species analyzed here. This table, including two *Ephedra* species (Cycadophytes), is based mainly on the recapitulation by Wolff *et al.* (12) and includes the species analyzed in the present study. Most Coniferophyte families have been screened, and with the exception of

# Sphingophosphonolipids, Phospholipids, and Fatty Acids from Aegean Jellyfish *Aurelia aurita*

**Dimitrios M. Kariotoglou and Sofia K. Mastronicolis***

Food Chemistry Laboratory, Department of Chemistry, University of Athens, Athens, Greece

**ABSTRACT:** The goal of this study is to elucidate and identify several sphingophosphonolipids from *Aurelia aurita,* an abundant but harmless Aegean jellyfish, in which they have not previously been described. Total lipids of *A. aurita* were 0.031–0.036% of fresh tissue, and the lipid phosphorus content was 1.3–1.7% of total lipids. Phosphonolipids were 21.7% of phospholipids and consisted of a major ceramide aminoethylphosphonate (CAEP-I; 18.3%), as well as three minor CAEP (II, III, IV) methyl analogs at 1.3, 1.1, and 1.0%, respectively. The remaining phospholipid composition was: phosphatidylcholine, 44.5%, including 36.2% glycerylethers; phosphatidylethanolamine, 18.6%, including 4.5% glycerylethers; cardiolipin, 5.6%; phosphatidylinositol, 2.6%; and lysophosphatidylcholine, 5.0%. In CAEP-I, saturated fatty acids of 14–18 carbon chain length were 70.8% and were combined with 57.3% dihydroxy bases and 23.4% trihydroxy bases. The suite of the three minor CAEP methyl analogs were of the same lipid class based on the head group, but they separated into three different components because of their polarity as follows: CAEP-II and CAEP-III differentiation from the major CAEP-I was mainly due to the increased fatty acid unsaturation and not to a different long-chain base, but the CAEP-IV differentiation from CAEP-I, apart from fatty acid unsaturation, was due to the increased content of hydroxyl groups originated from both hydroxy fatty acids and trihydroxy long-chain bases. Saturated fatty acids were predominant in total (76.7%), polar (83.0%), and neutral lipids (67.6%) of *A. aurita*. The major phospholipid components of *A. aurita* were comparable to those previously found in a related organism *(Pelagia noctiluca),* which can injure humans.

Paper no. L8759 in *Lipids 36,* 1255–1264 (November 2001).

Phosphonolipids (PnL), in the broad sense of the word, are a class of lipids characterized by the presence of one or more carbon-to-phosphorus (C-P) bonds. The C-P bond(s) provides the molecule with a relative resistance to chemical hydrolysis and thermal decomposition compared with the more reactive N-P, S-P, and O-P linkages. Natural phosphonic compounds are found to exist as glycerol esters (glycerophosphonolipids, GPnL) or sphingosine esters (sphingophosphonolipids, SPnL, and sphingophosphonoglycolipids, SPnGL). The specific effects of the biological functions of PnL depend not only on the chemical stability of the C-P bond but also on the chemical inertness of PnL owing either to the existence of a glycerylether bond in GPnL or to the presence of hydroxy-fatty acids (hydroxy-FA) in SPnL (1–6). Because of the inert character of PnL, an important biological advantage might be conferred by the presence of these PnL in the biological membranes of those organisms that are able to synthesize such compounds. This reasoning may be applicable in the case of ciliated protozoa (*Tetrahymena pyriformis*), which are found in the rumen, an environment rich in hydrolytic enzymes, such as phosphatases (7). It is also generally agreed that PnL contribute to the protection of cellular membranes and survival of aquatic organisms such as cnidaria, mollusks, and sponges, since it has been proposed that PnL provide cationic buffering capacity or facilitate transport of essential ions. PnL were also conserved at the expense of phosphodiester bonds in starved organisms. Possibly, PnL are a storage mechanism for phosphorus in a phosphorus-deficient environment (1–6,8). Cold-temperature studies on the membrane lipid composition of *T. pyriformis* showed that PnL may contribute to its cold acclimation by increasing the level of unsaturated FA, e.g., 18:3n-3 (1,4). Another potential role for the unique structures of the aminophosphonates is in interspecies (or intraspecies) communication or recognition processes. An example of this type of communication is given in a report of a survival-enhancing relationship between the sea anemone *Anthopleura xanthogrammica* and the mussel *Mytilus californianus* (2).

The occurrence of SPnL in cnidaria was first reported in 1963 by Rouser *et al*. (9), with the discovery of ceramide 2-aminoethylphosphonate (CAEP) in the sea anemone *Anthopleura elegantissima* (class Anthozoa). CAEP together with its *N*-methyl analog ceramide 2-methylaminoethylphosphonic acid (CMAEP) is widely distributed in protozoa (10–13), mollusks (1,14–21), and cnidaria (22,23). A number of SPnGL have been identified in lipid extracts from various specific tissues (nervous and muscle tissue, nerve fibers, ganglia, etc.) of some marine mollusc species (24–26). PnL were also found in small amounts in human brain (6). In the milk and liver of cows and goats it has been hypothesized that PnL are exogenous in origin and not

Abbreviations: AEP, 2-aminoethylphosphonic acid; CAEP, ceramide 2-aminoethylphosphonic acid; CCL, carbon chain length; CL, cardiolipin; CMAEP, ceramide 2-methylaminoethylphosphonic acid; ECL, equivalent chain length; FA, fatty acids; GC, gas chromatography; GPC, L-α-glycerylphosphorylcholine; GPE, L-α-glycerylphosphorylethanolamine; GPI, L-α-glycerylphosphorylinositol; GPnL, glycerophosphonolipid; HPTLC, high-performance thin-layer chromatography; LCB, long-chain base; L-PE, lyso-PE; L-PC, lyso-PC; MAEP, 2-methylaminoethylphosphonic acid; MUFA, monounsaturated fatty acids; NL, neutral lipids; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PhL, phospholipid; PI, phosphatidylinositol; PL, polar lipids; PnL, phosphonolipid; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids; SPnGL, sphingophosphonoglycolipid; SPnL, sphingophosphonolipid; TDB, total dihydroxy bases; TL, total lipids; TLC, thin-layer chromatography; TMS, trimethylsilyl; TTB, total trihydroxy bases.

structural components of tissue (4,6). Moreover, PnL also were found in sea-stars, which feed on gastropod and bivalve mollusks, at up to 20% of the total phospholipids (PhL) (1,2,8).

Nakhel *et al*. (22) initiated extensive research into the composition and nature of PnL in jellyfish. They studied the occurrence of PnL in the Aegean jellyfish species *Pelagia noctiluca* (cnidaria), which is toxic to humans because, according to References 1 and 2, this phylum is very rich in PnL. The gastrointestinal tracts of cnidaria are known to contain many hydrolytic enzymes, and cell membranes may benefit from the presence of PnL. In the period 1982–1988, research on PnL species was stimulated by the infestation with swarms of *P. noctiluca*, along most Mediterranean coasts. These lipids were suspected of playing a vital role in the survival of the jellyfish in a very eutrophic environment where other organisms could not survive. The total lipids (TL) content of *P. noctiluca* was 0.19% of the whole body weight. PhL were found to represent 26.2% of TL and to contain 24.3% SPnL. The SPnL class consisted of a major CAEP species (21.0% of PhL) and 3.3% of two other minor SPnL species. However, the structural elucidation of the latter minor SPnL species was not achieved.

The purpose of this study was to elucidate and identify several SPnL species from the scyphozoan *A. aurita*, an abundant but harmless jellyfish of the Aegean Sea. The structural compositions of the PhL and the FA of neutral lipids (NL) and polar lipids (PL) were determined.

## MATERIALS AND METHODS

*Sample description and extraction of TL. Isolation of PL and NL classes.* Jellyfish *(A. aurita)* were collected from Eleusis Bay (Greece) by using a fishing net during August 1996 and May 1998. Four jellyfish (total weight 267 g, diameter 4–6 cm) were collected in 1996 and again in 1998 (total weight 830 g, diameter 10–15.5 cm). The organisms were placed in seawater and transferred to the laboratory alive for lipid extraction. Studies conducted by the Institute of Oceanographic and Fisheries Research in Greece (27) have shown that the salinity of Eleusis Bay is almost constant at 38.5‰ in the water column. The temperature is about 13°C during winter, while during summer, there is a temperature difference of about 10°C between surface and bottom samples (15–25°C). Eleusis Bay is one of the most eutrophic areas in Greece. It is small (67 $km^2$) and shallow (depth max. 33 m) and is subjected to urban and industrial pollution. Each individual jellyfish (1 vol) was drained as thoroughly as possible, transferred to a vessel containing 3 vol of chloroform/methanol (1:2, vol/vol) and immediately blended for 4 min at medium speed in a Sorvall Omni-Mixer. Extraction of lipids was performed according to the method of Bligh and Dyer (28), except that the liquid phase was separated by centrifugation (4°C, 10 min, 1465 × *g*), instead of filtration, and the residue was re-extracted with 1 vol chloroform/methanol (1:1, vol/vol) and centrifuged again. The two extracts were then combined. To the pooled extracts, 1 vol of chloroform and 1 vol of water was added. After phase equilibration, the lower chloroform layer of TL was evaporated to dryness, redissolved in chloroform/methanol (2:1, vol/vol), and stored at 0°C (23). The composite of *A. aurita* TL sample 1996 was recovered from the pooled lipid extracts of all four medusae to make one composite sample. The same procedure was followed for the sample of composite TL of 1998 *A. aurita* (four medusae).

The TL were fractionated into NL and PL classes by solid phase extraction as follows: A portion of TL extract (~10 mg solid) was dissolved in 0.5 mL chloroform/hexane (1:1, vol/vol) and applied to a prewashed 500-mg silica column. NL were eluted four times with 7-mL aliquots of chloroform, and PL were eluted three times with 6.5-mL aliquots of methanol. The apparatus used was a Waters SEP-PAK® Vacuum manifold, and the column used was a Waters SEP-PAK® VAR RC Silica cartridge (29).

*Thin-layer chromatography (TLC) of lipids*. Analysis of *A. aurita* PL by single-dimensional high-performance TLC (1D-HPTLC) was carried out on precoated silica gel 60 HPTLC plates (E. Merck, Darmstadt, Germany) with the following solvent systems: solvent **A**, chloroform/methanol/acetic acid/water (50:25:6:2, by vol); solvent **B**, chloroform/methanol/acetic acid/water (50:37.5:3.5:2, by vol). The PL were further separated by two-dimensional HPTLC analysis (2D-HPTLC) carried out on precoated silica gel 60 plates (10 × 10 cm) with solvent system **C,** which consisted of the following: dimension 1, chloroform/methanol/acetic acid/water (50:25:6:2, by vol); dimension 2, chloroform/methanol/water (65:20:3, by vol). For separation of NL, system **D,** used for 1D-HPTLC was petroleum ether/ether/acetic acid (70:30:1, by vol). Solvent system **E,** used for sphingosine base analysis, was chloroform/methanol/water (65:25:4, by vol). Visualization of spots was effected by exposure to iodine vapor followed by spraying with ninhydrin reagent and/or the phosphomolybdenum blue reagent (30) for PhL, combined with the heating test of Stillway and Harmon (31) for PnL. Dragendorff reagent was used for detection of choline (32). Lipid spots were also visualized by using copper sulfate spray and heating at 180°C for 2–5 min (33,34). Testing for glyco- or sulfolipids was performed by using α-naphtholsulfuric acid reagent (35). The TLC of water-soluble products was carried out on precoated cellulose plates (0.1 mm thickness, Art. 5552, Merck) in the following solvent system: phenol/ethanol/acetic acid/water (80:12:10:20 wt/vol/vol/vol). Hanes and Isherwood spray (36) and ninhydrin spray were used for visualization of phospho- and amino-derivatives, respectively, and Dragendorff spray was used for staining of L-α-glycerylphosphorylcholine (GPC). Additionally, the following were used as lipid standards: synthetic CAEP and synthetic 2-methylaminoethylphosphonic acid (MAEP) were a gift from Prof. Akira Hayashi of Kinki University (Kowakae, Higashi-Osaka, Japan). 2-Aminoethylphosphonic acid (AEP) was purchased from Sigma, 2-dimethylaminoethylphosphonic acid and 2-trimethylaminoethylphosphonic acid were a kind gift from Prof. J. Donald Smith of University of Massachusetts (Dartmouth, MA). Cardiolipin (CL), phosphatidylethanolamine (PE), phosphatidylcholine (PC), phosphatidylinositol, lyso-PC (L-PC), lyso-PE (L-PE), L-α-glycerylphosphorylethanolamine (GPE),

L-α-glycerylphosphorylinositol (GPI), GPC, C18-sphingosine, C18-phytosphingosine, tripalmitin, oleic acid, palmitic acid methyl ester, cholesterol ester, and cholesterol were purchased from Sigma. C16-Sphingosine was purchased from Larodan.

*Fractionation of PL by preparative TLC (solvent B).* Five PhL bands were fractionated after separation of PL (500–800 μg phosphorus/sample) by solvent B on preparative TLC ($n$ = 2–5) carried out on chromatoplates of silica gel G, 0.5 mm thick (20 × 20 cm), activated at 120°C for 1 h, along with PhL standards (CL, PE, CAEP, PC, and L-PC). After visualization by exposure to iodine vapors, each PhL band was scraped off and eluted from silica gel with 31.6 mL chloroform/methanol/water (1:2:0.8, by vol) three times. Then 50 mL of chloroform/water (1:1, vol/vol) was added to the pooled solution, and after mixing, the chloroform extract of each band was taken to dryness and redissolved in chloroform/methanol (2:1, vol/vol).

*Fractionation of SPnL class by preparative TLC (solvent **A**).* The extracted lipid band of SPnL class from the preparative TLC, solvent **B**, was subjected to mild alkaline hydrolysis for removal of the glycerolipids components. The products (530 μg phosphorus) stable to mild alkali from SPnL class were fractionated on preparative TLC by solvent **A**. A major SPnL band and three minor SPnL bands were visualized, scraped off, and extracted as described previously.

*Analytical methods and quantitation of lipid components.* Total phosphorus and phosphonate phosphorus were determined by the methods of Long and Staples (37) and Kapoulas *et al.* (38), respectively. Sugars were determined according to the method of Dubois *et al*. (39). Esters were determined by the method of Snyder and Stephens (40), long-chain bases by the method of Lauter and Trams (41), glycerylethers by the method of Hanahan and Watts (42), and nitrogen according to the method of Hashmi *et al*. (43). Mild alkaline hydrolysis (deacylation) was performed with NaOH (1.2 N) as described previously (21). Each class of NL and PL, in bulk, was quantitated by weight after elution from solid-phase extraction columns.

Individual PhL components were quantitated after separation of PL on 2D-TLC (20 × 20 cm, 0.25 mm thick), scraping each PhL spot directly into digestion tubes, with determination of total phosphorus as described previously (21).

*Preparation of SPnL derivatives.* Acid methanolysis of each isolated and purified SPnL species was performed by a modification of the Vance and Sweely method (44) as follows: 500 μL of 3 N methanolic HCl (10% wt/vol; Supelco Inc.) reagent was added to each SPnL sample (25–70 μg phosphorus), methylation was allowed to proceed (100°C, 5–6 h), and molecular ratios for structural data were determined in each methanolysate aliquot. The SPnL FA methyl esters were extracted from methanolysate with petroleum ether and analyzed by gas chromatography (GC). To the remaining solution of methanolysate, suitable volumes of chloroform, methanol, and water were added to give a ratio of chloroform/methanol/water (8:4:3, by vol) (Folch partition). For the isolation of water-soluble products (aminoalkylphosphonic acids), the upper aqueous layer was evaporated to dryness on a rotary evaporator, and the last traces of HCl were removed under nitrogen by repeated evaporations with water (45). For the isolation of long-chain bases (LCB), the lower chloroform layer was evaporated to dryness in a stream of nitrogen and the residue was dissolved in a small amount of chloroform/methanol (95:5 vol/vol). The LCB were analyzed by GC after silylation.

*GC analysis. (i) FA methyl esters.* To each 1-mg lipid sample (TL, NL, and PL in bulk), 500 μL of 3 N methanolic HCl (10% wt/vol; Supelco Inc.) reagent was added and methylation was allowed to proceed at 100°C for 5–6 h. FA methyl esters were extracted four times with 0.8-mL aliquots of petroleum ether (29), and after drying were redissolved in hexane for GC analysis. The same transesterification procedure was performed for analyzing the FA moieties of individual isolated and purified SPnL species. FA methyl esters were separated using a Hewlett-Packard 6890 gas chromatograph equipped with a flame-ionization detector. The carrier gas and the make-up gas were He. A capillary column SGE BPX-70 (70% cyanopropyl liquid phase; 25 m × 0.32 mm, 0.25 mm film thickness) was used. The oven temperature was programmed from 100 to 200°C at a rate of 4°C/min, with initial and final holding times of 0 and 3 min, respectively. The splitless injector temperature was 250°C, and the detector temperature was 300°C. The FA methyl esters were identified by comparison with three standard mixtures of methyl esters: bacterial FA methyl esters (CP™ Mix, Catalog No. 114; Matreya Inc., Pleasant Gap, PA); mixture special preparation no. 461, Nu-Chek-Prep Inc. (Elysian, MN); and mixture 68 A, Nu-Chek-Prep Inc. Mass spectrometry was not used to confirm any of the FA structures. The FA analysis of each transesterified lipid class was repeated three times (three injections on the gas chromatograph), and the standard deviations of the percentages of FA were between ±0.1 and ±0.5.

*(ii) LCB silylation.* Trimethylsilyl (TMS) derivatives of LCB moieties from each isolated and purified SPnL species were prepared according to the method of Sweeley *et al*. (46) and separated on the same Hewlett-Packard chromatograph using a capillary column HP-5 (5% diphenyl dimethylsiloxane; 25 m × 0.32 mm, 0.25 mm film thickness). The oven temperature was 200°C, the splitless injector temperature was 250°C, and the detector temperature was 260°C. The silylated LCB were identified by their equivalent chain length (ECL), determined relative to C18-sphingosine (47–49).

## RESULTS

*Lipid fractionation and class composition.* By using the TL sample from composite *A. aurita* 1996 we had the opportunity to design initial large-scale experiments in order to provide a deeper insight into the composition and nature of individual SPnL species as well as the rest of the lipid classes present. The above 1996 experiments indicated that *A. aurita* contains a major and several minor SPnL species as well as glycerolipids. In the final large-scale experiment, we used the composite 1998 TL in order to isolate and identify all the individual glycerophospholipids and SPnL classes, together

with the FA composition of PL and NL classes. The extracted TL amounted to 0.031 and 0.036% (w/w) of fresh tissue, and the lipid phosphorus content of the TL accounted for 1.7 and 1.3%, respectively, for 1996 and 1998 composite samples; the coefficients of variation of lipid phosphorus content ($n$ = 4) were 23.5 and 7.6%, respectively. On the basis of phosphonate-phosphorus determinations, the PnL were found to represent 22.3 ± 0.6 and 21.7 ± 0.3% (mol/mol) of total PhL ($n$ = 4), respectively, for both composites. TL samples were separated by solid-phase extraction into PL and NL lipid classes. The PL in bulk recovered from silicic columns were 37.5 and 35.8% of TL, respectively, for 1996 and 1998 composites.

Glycerylether determinations were performed on TL, PL, and NL samples from composite 1998, and the data showed 8.3 ± 0.4, 16.3 ± 0.3, and 3.7 ± 0.2% glycerylethers ($n$ = 4), respectively; furthermore, the carbohydrate content of TL was negligible.

NL were separated by analytical 1D-TLC using solvent system **D**. Based on their TLC behavior along with standards, the NL major component was found to consist mainly of free FA. The NL were also found to contain substantial proportions of cholesterol esters, cholesterol, triglycerides, and trace amounts of glycerylethers and fatty alcohols.

PL were separated into nine subclasses by using analytical 1D-HPTLC with solvent systems **A** and **B**. In system **B** (Fig. 1), all the components of SPnL class, a major and three minor species, had similar $R_f$ values, but they were situated far from PC; therefore, the isolation and extraction of the SPnL class of lipids was more effective on preparative TLC by system **B**. The difference between solvent systems **A** and **B** was that the minor SPnL species were separated into three narrow bands with solvent system **A**, and each one migrated far from the major one, but the slowest minor SPnL spot was at nearly the same $R_f$ as that of PC. By using solvent system **A** on analytical 1D-HPTLC, we observed that the PL fraction contained nine lipid components including eight phosphocompounds. The main phosphorus-positive components were those that co-chromatographed with standards of PC, PE, and CAEP. Below the CAEP position, a group of three minor phosphocomponents, positive to ninhydrin and to the Stillway test, had migrated and were also designated as SPnL species (CAEP II, III, and IV). Two more phosphocompounds co-chromatographed with CL and L-PC standards. Another ninhydrin-positive component free of phosphorus migrated near the origin and was designated *z*. As determined by 2D-HPTLC in system **C**, the PL fraction revealed 11 components, which were designated as CL, $PE_1$, $PE_2$, CAEP-I, PI, CAEP-II, CAEP-III, CAEP-IV, PC, L-PC, and *z* (Fig. 2), namely, two more phosphocomponents than the foregoing 1D-HPTLC fractionation. The spots designated as $PE_1$ and $PE_2$ had the same $R_f$ values as the PE standard by 1D-HPTLC but could be resolved (by 2D-HPTLC) into two phosphorus and ninhydrin-positive spots in the second run. The spots, designated as PI and CAEP-I, had similar $R_f$ values by 1D-HPTLC with the CAEP standard. Component PI was ninhydrin- and Stillway test-negative but was slightly positive

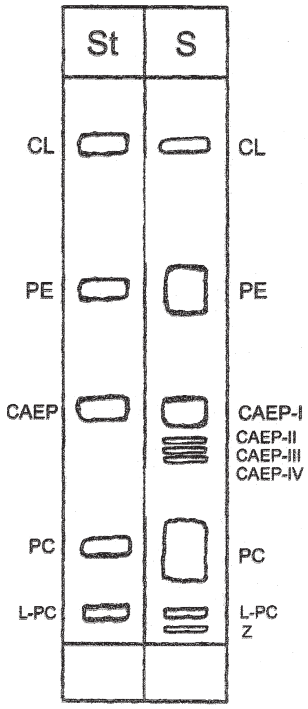

**FIG. 1.** Preparative thin-layer chromatography (TLC) fractionation of *Aurelia aurita* polar lipids on a TLC silica gel 60 plate. The diagram (St) on the left shows these standards: CL, cardiolipin; PE, phosphatidylethanolamine; CAEP, ceramide 2-aminoethylphosphonic acid; PC, phosphatidylcholine; and L-PC, lysophosphatidylcholine. Plates were developed with solvent **B**: chloroform/methanol/acetic acid/water (50:37.5:3.5:2, by vol). Visualization: exposure to iodine vapors. S, sample; St, standard. For explanation of CAEP-I, -II, -III, -IV see text; *z*, unidentified ninhydrin-positive component free of phosphorus.

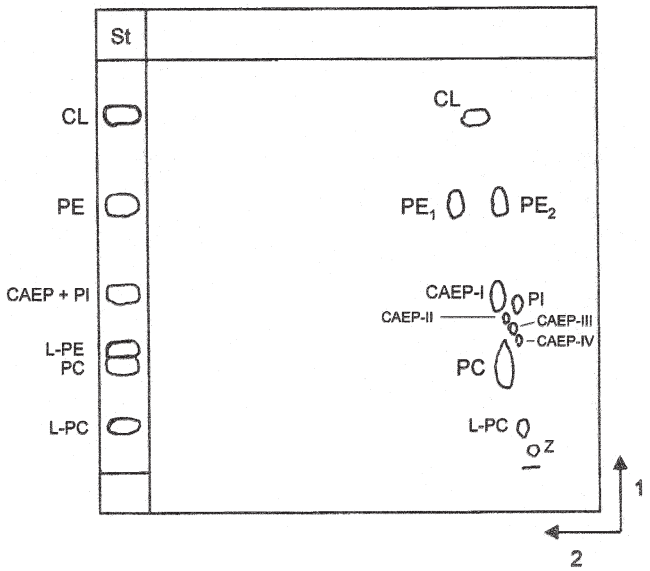

**FIG. 2.** Two-dimensional TLC separation of *A. aurita* polar lipids on high-performance TLC silica gel 60. Plates were developed with solvent **C**: direction 1, chloroform/methanol/acetic acid/water (50:25:6:2, by vol); direction 2, chloroform/methanol/water (65:20:3, by vol). The diagram (St) contains these standards (St): CL, PE, CAEP, PI (phosphatidylinositol), L-PE (lysophosphatidylethanolamine), PC, and L-PC. The plate was stained by copper sulfate/$H_3PO_4$ and charring. Samples contained: $PE_1$ and $PE_2$, two different molecular species of PE; CAEP-I, major sphingophosphonolipid species; CAEP II, III, IV, minor sphingophosphonolipid species of *Aurelia*. The letter *z* denotes an aminolipid component of *Aurelia* as described in the text. For other abbreviations see Figure 1.

| Recovery | 98.2 | 95.5 | Recovery | 98.0 |

[a]Lipid sample (1.0 mg phosphorus/composite 1996; 3.0 mg phosphorus/composite 1998) was fractionated on 20 × 20 cm silica gel plate (solvent **B**).
[b]Values are means ± standard deviations of three replicate phosphorus determinations performed on each lipid band.
[c]Lipid sample (18 μg phosphorus) was separated on 20 × 20 cm two-dimensional thin-layer chromatography (2D-TLC) (solvent **C**).
[d]Values are means ± standard deviations obtained from phosphorus determinations performed on each 2D-TLC plate ($n$ = 3). Abbreviations: CL, cardiolipin; PE, phosphatidylethanolamine; CAEP, ceramide 2-aminoethylphosphonic acid; PI, phosphatidylinositol; SPnL, sphingophosphonolipid; PC, phosphatidylcholine; L-PC, lyso-PC.

to an α-naphthol reagent test, suggesting the presence of PI in this spot. The major SPnL species CAEP-I, as well as the three minor SPnL species groups CAEP II, III, and IV, were, as mentioned above in the 1D-TLC, positive to ninhydrin and the Stillway test (Fig. 2).

Samples of PL originating from composites of either 1996 or 1998 were separated into five PhL bands (CL, PE, SPnL class, PC, L-PC) by preparative TLC with solvent system **B** (Fig. 1). Table 1 shows the lipid-phosphorus distribution of each of the five extracted lipid bands. Alternatively, similar analytical data were obtained by quantitation of total phosphorus using a PL sample (from composite 1998) after separation by 2D-TLC with solvent system **C** into eight PhL components comprising CL, $PE_1$, $PE_2$, the major SPnL (CAEP-I) component, the sum of three minor SPnL spots, which were obtained as one spot, and PI, PC, and L-PC as described in the Materials and Methods section and shown in Table 1.

*FA*. The FA composition of TL, as well as NL and PL FA, was determined using GC as described in the Materials and Methods section. The data on FA and the proportion of the saturated FA (SFA), monounsaturated FA (MUFA), polyunsaturated FA (PUFA), and hydroxy FA are given in Table 2. SFA were predominant in all lipid fractions of *A. aurita*. The *cis*-14:1n-5 fatty acid, included as "other" in Table 2, was not detected in TL and NL. Also, the 17:0 cyclo, 20:0, and *cis*-20:2n-6 fatty acids, included as "other" in Table 2, were not found in the NL and PL.

*Isolation of SPnL class (a major and three minor species)*. After fractionation of PL by preparative TLC (solvent **B**), the lipid band of the SPnL class (including, apart from CAEP-I, three minor SPnL species, CAEP II, III, and IV, and the contaminant glycerolipid of PI) was recovered, and the lipids were extracted (Table 1). A part of the extracted band of the SPnL class (705 μg phosphorus) was subjected to phosphonate-

[a]Mass spectrometry was not used to confirm fatty acid structures.
[b]Abbreviations: TL, total lipids; NL, neutral lipids; PL, polar lipids.
[c]i, iso; a, anteiso; iso and anteiso are isomers of branched saturated fatty acids. "Other" includes all fatty acids present at <0.5 wt%, i.e., 14:1n-5 *cis*, i-15:0, 17:0 cyclo, 20:0, 20:2n-6 *cis*.

phosphorus determination and amounted to 89.3 ± 1.2% of the total phosphorus content. Another part of the extracted lipid band of the SPnL class (650 µg phosphorus) was subjected to mild alkaline hydrolysis in order to remove any glycerolipids (e.g., PI), and the alkali-stable products (576 µg phosphorus) were tested by 2D-HPTLC for purity confirmation. The results confirmed that one major SPnL, CAEP-I, and three minor SPnL species, CAEP II, III, and IV (positive to ninhydrin, to molybdenum blue, and to the Stillway test), were present and their phosphonate-phosphorus analysis showed that 96.1 ± 0.8% of lipid-phosphorus was phosphonate-phosphorus. Individual SPnL species, both the major one and each of the three minor species, were isolated from the alkaline-stable products (530 µg phosphorus) and separated by preparative TLC (system **A**) into CAEP-I (18.3% of PhL) and three CAEP (II, III, IV in the amounts of 1.3, 1.1, and 1.0% of PhL, respectively).

*Identification of major SPnL species, CAEP-I.* After testing the purity of the major SPnL by 2D-HPTLC analysis, a sample of purified major SPnL species (70 µg phosphorus) was subjected to dry-acid methanolysis (see Materials and Methods section). The hydrolysis products contained total nitrogen, LCB, esters, and total phosphorus in molar ratios of 2.1:1.1:1.1:1.0, respectively, and 95.5% of its lipid-phosphorus was phosphonate-phosphorus. FA methyl esters were extracted from methanolysate with petroleum ether and were analyzed by GC (Table 3). After Folch partition of the remaining methanolysate, the water-soluble products were analyzed by TLC on cellulose and found to contain only one component, which co-migrated with the AEP standard and was ninhydrin- and phosphorus-positive (Fig. 3). Therefore, the structure of ceramide aminoethylphosphonic acid was confirmed for the major SPnL species of *A. aurita*, CAEP-I. The chloroform soluble products of Folch partition (LCB) were converted to their TMS derivatives and analyzed by GC. The results are listed in Table 4.

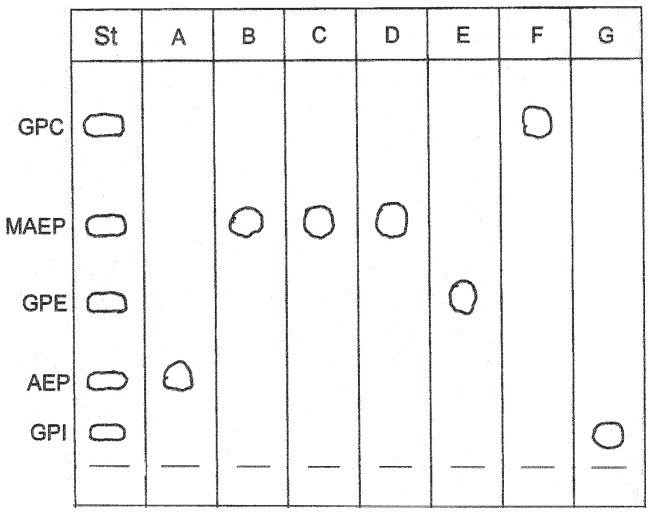

**FIG. 3.** TLC analysis on cellulose TLC of water-soluble components derived from hydrolyses of CAEP-I (A), CAEP-II (B), CAEP-III (C), CAEP-IV (D), PE (E), PC (F), and PI (G) polar lipids of *A. aurita*. The diagram (St) on the left shows these standards: GPC, L-α-glycerylphosphorylcholine; MAEP, 2-methylaminoethylphosphonic acid; GPE, L-α-glycerylphosphorylethanolamine; AEP, 2-aminoethylphosphonic acid; and GPI, L-α-glycerylphosphorylinositol. Developing solvent system: phenol/ethanol/acetic acid/water (80:12:10:20 wt/vol/vol/vol). Visualization: Hanes-Isherwood reagent. For other abbreviations see Figures 1 and 2.

[a]Mass spectrometry was not used to confirm fatty acid structures. "Other" includes all fatty acids present at <0.5%, i.e., i-15:0, 18:3n-3 *cis*, 22:5n-3 *cis*. For abbreviations see Tables 1 and 2.

CAEP-I ceramides were composed mainly of 70.7 % total FA (Table 3), ranging from 14- to 16-carbon chain length (CCL). In contrast, total FA with 18 CCL amounted only to 6.8%. Total LCB of CAEP-I ceramides contained a large amount, 91.9%, of bases with 16–18 CCL, which were distributed primarily in total dihydroxy bases (TDB) (57.3% with a preponderance of C18-sphingosine, 35.6%) and in total trihydroxy bases (TTB) (23.4% with a preponderance of C16-phytosphingosine, 17.6%) (Table 4).

*Identification of three minor species, CAEP II, III, IV.* Each of the three isolated and purified minor SPnL species, CAEP II, III, and IV, was subjected to the same procedure, dry-acid methanolysis, for identification as described above for the major component. The respective molar ratios for

[a]Abbreviations: ECL, equivalent chain length; br, branched; Me, methyl; S, sphingosine; P, phytosphingosine; $SH_2$, dihydrosphingosine; for other abbreviations see Table 1.

total nitrogen, LCB, esters, and total phosphorus were: 2.1:1.2:1.3:1.0 for CAEP-II, 2.0:1.1:1.3:1.0 for CAEP-III, and 2.2:1.2:1.1:1.0 for CAEP-IV. Furthermore, over 96% of lipid-phosphorus of each minor species was found to be phosphonate-phosphorus. Therefore, the structure of ceramide aminoethylphosphonic acid was confirmed for each of the minor SPnL species. FA of each of the minor SPnL species are shown in Table 3. The water-soluble products from each of the minor SPnL species were found to contain only MAEP, which was ninhydrin- and phosphorus-positive (Fig. 3). These data suggest the molecular structure of CMAEP for each. Their LCB compositions are listed in Table 4.

CAEP-II ceramides were composed mainly of 74.3% total FA (Table 3) ranging from 14 to 18 CCL with 52.6% SFA and 21.7% unsaturated FA. Total LCB of CAEP-II ceramides (Table 4) contained a large amount (84.7%) of bases with 14–18 CCL. Their TDB content was 55.1%, and their TTB amounted to 29.6%, mainly C18-phytosphingosine (13.2%).

CAEP-III ceramides were composed mainly of 82.1% total FA (Table 3) ranging from 14 to 18 CCL with 52.3% SFA and 29.8% unsaturated FA plus 4.8% total hydroxy FA. Total LCB of CAEP-III ceramides had a CCL range from 13 to 19, and their TDB was 53.5% with a preponderance of branched C19-sphingosine (39.5%), and their TTB content was 46.5%. Among these, phytosphingosine with 13 and 18 CCL (20.0 and 20.9%, respectively) were predominant (Table 4).

CAEP-IV ceramides were composed mainly of 78.7% FA (Table 3) ranging from 14 to 18 CCL with 51.4% SFA and 27.3% unsaturated FA as well as 15.1% total hydroxy FA. Total LCB of CAEP-IV ceramides (Table 4) contained a large amount (88.0%) of bases with 16–18 CCL. Their TDB content was 29.6% with a preponderance of C18-sphingosine (20.6%), while their TTB amounted to 58.4%, principally C18-phytosphingosine (47.3%).

The i-15:0 fatty acid, included as "other" in Table 3, was not detected in CAEP-IV. Also, *cis*-18:3n-3 was not detected in the three minor SPnL species. Finally, *cis*-22:5n-3, which is also included with "other" in Table 3, was not found in CAEP-III and CAEP-IV.

*Glycerol lipids*. After extraction of the lipid bands that co-chromatographed with PC, CL, and PE standards on preparative TLC (Table 1) of PL (system **B**), each one was repurified by one more preparative TLC step. Upon testing the purity of the PE lipid band by 2D-HPTLC, two species ($PE_1$, $PE_2$) were found. A sample of each PC, CL, and PE lipid band (19.3, 3.0, and 11.2 μmol phosphorus, respectively) was subjected to mild alkaline hydrolysis. The bulk of the lipid phosphorus of the CL band was distributed in the water-soluble products; therefore, this finding suggests a basic molecular structure of CL. The alkali-stable products of PC and PE lipid bands were found to contain 7.0 and 6.5 μmol lipid-phosphorus, respectively, which were co-chromatographed on 2D-HPTLC with L-PC and L-PE standards, respectively. The saponifiable products of the PC and PE lipid bands were analyzed by TLC on cellulose, and only one component was found to co-chromatographed with both GPC and GPE standards (Fig. 3). Therefore, by combining the data, the basic molecular structure of PC and PE was confirmed for PC and PE lipid bands of *A. aurita*. Glyceryl ether determination of PC and PE lipid classes indicated that PC contained 36.2 ± 0.9% glycerylethers (16.1 ± 0.6% of PL), while PE contained glycerylether analogs in a proportion of 4.5 ± 0.2% (0.8 ± 0.1% of PL).

The identification of PI was based on the analysis of water-soluble products derived from mild alkaline hydrolysis of extracted lipid band of SPnL class from the preparative TLC (system B) of PL. The 11.4% of lipid-phosphorus (2.6% of PhL) was distributed in the water-soluble products corresponding to the PI component. This finding is in agreement with the result of quantitative analysis of this lipid spot after separation of PL on 2D-TLC (Fig. 2, Table 1). Furthermore, the water-soluble products were found to contain only one component that co-chromatographed with the GPI standard and also was Hanes-Isherwood positive (Fig. 3). Therefore a molecular structure of PI could be suggested for the PI component of *A. aurita*.

## DISCUSSION

*Lipid content*. The TL contents found in extractions of *A. aurita* composites 1996 and 1998 were almost constant, 0.031 and 0.036% (w/w) of the fresh tissue (0.72% of dry mass, assuming 95% water). The above results are comparable to that reported for *A. aurita* from Chesapeake Bay, 0.027% of fresh tissue or 0.54% of dry mass (5), while in *P. noctiluca* from the Aegean Sea (22) and *Chrysaora quinquecirrha* from Chesapeake Bay (5) they were found to be higher, 0.19 and 0.2% of

fresh tissue, respectively, or 3.8 and 4.0% of dry mass. According to an earlier report of Larson and Harbison (50) the average TL content of Antarctic gelatinous zooplankton is approximately 3%, ranging from 0.4 to 6% of dry mass, whereas Arctic gelatinous zooplankton have an average 8% lipid of dry mass, range 1.5–22%. Recently, Nelson *et al*. (51) reported that in several species of Antarctic gelatinous zooplankton, including cnidaria (*Calycopsis borchgrevinki*, *Diphyes antarctica*, *Stygiomedusa gigantea*, *Atolla wyvillei,* and *Dimophyes arctica*) and ctenophora (*Beroe cucumis*, *B. forskalii*, *Pleurobrachia pileus*, *Bolinopsis infundibulum*), the TL content ranged from 0.01 to 0.5% of fresh tissue (0.3–10.2% of dry mass). It is noteworthy that the TL contents of jellyfish from the Aegean Sea such as *P. noctiluca* (22) and *A. aurita* and those from Chesapeake Bay such as *A. aurita* and C. *quinquecirrha* (5) are similar to those Antarctic jellyfish (51), but they are lower than TL contents of Arctic jellyfish.

The PL percentage of Aegean *Aurelia* in each composite sample 1996 and 1998 was nearly the same (37.5 and 35.8% of the TL), and similar results were obtained from Aegean *P. noctiluca* (e.g., 26.2% PL and 73.8% NL) (22). Currently, Nelson *et al*. (51) reported that in Antarctic gelatinous zooplankton, PL are the major lipid class, 59–96% of TL. It is noteworthy that the PL contents of Aegean jelly fish *P. noctiluca* (22) and *A. aurita* are significantly lower than those of Antarctic jellyfish (51). The similarly low relative percentages of Aegean jellyfish PL (*A. aurita* 1996, 1998 and *P. noctiluca* 1988) derived under the same lipid extraction conditions do not permit us to say that these data reflect greater feeding activity. It is notable that the NL of *A. aurita* 1998 composite contained 3.7 ± 0.2% glycerylethers.

*FA*. The FA composition of *A. aurita* TL from the 1998 composite sample is characterized by high percentages of SFA (76.7%), which included three major FA, 16:0 (42.3%), 18:0 (22.2%), and 14:0 (4.1%) (Table 2). The FA profile of the NL and PL fractions was similar to that of TL, containing also high percentages of SFA, 67.6 and 83.0%, respectively. The very high percentage of SFA, 83.0% (Table 2) in PL of *A. aurita* is in good agreement with that of FA from CAEP-I, 82.2% (Table 3). MUFA levels of *A. aurita* TL were 11.4% while PUFA levels were 3.9%. The principal MUFA of *A. aurita* TL was *cis*-18:1n-9 (8.3%).

The FA profile of TL from *A. aurita* of the Atlantic Ocean (which live in the cold waters off North America, particularly Canada) was appreciably different from that of Aegean *A. aurita*, containing a high percentage (62.7%) of unsaturated FA (which included 20:1, 13.7%, and 18:1, 11.8% (5). The TL, PL, and NL of Aegean *A. aurita* exhibited a low 16:1/16:0 ratio, which is characteristic of many shellfish, and is consistent with a phytoplankton diet. This ratio decreases in temperate and tropical waters (5). Nelson *et al*. (51) reported that the high 16:1/16:0 ratio is a characteristic feature of diatom FA profiles, particularly in combination with elevated proportions of the FA 20:5n-3. The differences in the FA composition of medusae could be attributed to the fact that the content in some FA is influenced by the environmental temperature and the diet of jellyfish, i.e., is dependent on whether the diet is predominantly phytoplankton, zooplankton, or small fishes (5).

*Glycerophospholipids*. The PL of *A. aurita* are characterized by the absence of some lipid classes that are widespread in other animals, such as phosphatidylserine, sphingomyelin, and glycolipids. As shown in Table 1, there is no variation in the relative composition of individual phospholipid bands (CL, PE, SPnL class + PI, PC, L-PC) between 1996 and 1998 composite samples ($P = 0.05$, *t*-test). These data are in agreement with those reported for *P. noctiluca* (22). The percentage of glycerylether-type total PhL of *A. aurita* from the 1998 composite was 16.3 ± 0.3%. These glycerylethers were concentrated in the molecular species of the PE class and also in PC (4.5 ± 0.2 and 36.2 ± 0.9%, respectively). The glycerylether-type PhL found in the jellyfish *P. noctiluca* represent 36.1% of total PhL and were distributed in both PE and PC at 55.0 and 62.0%, respectively (22). The low percentage of glycerylether (4.5%) found in PE of *Aurelia* in relation to the high percentage of alkali-stable products (57.9%) after mild alkaline hydrolysis of intact PE ($PE_1 + PE_2$) could suggest the possible presence of alkenylether analogs (plasmalogens) of PE in a proportion of 53.4%. Finally, it is interesting that PI (2.6% of PhL) was found in *A. aurita* PL (Table 1).

*SPnL*. According to the present structural studies, the PL of *A. aurita* are characterized by the presence of a significant amount of PnL (21.7% of PhLs) (Table 1), which belong to the ceramide aminophosphonic acid type. Their chromatographic resolution on TLC showed a faster-moving major CAEP-I (18.3% of PhL) and several minor SPnL species, which consisted of three chromatographically distinguisable *N*-methyl analogs, CAEP II, III, and IV, in percentages of 1.3, 1.1, and 1.0% of PhL, respectively.

CAEP-I ceramides were mainly characterized by a high content of total SFA acids, 70.8%, in the range of 14–18 CCL and a very low content of total unsaturated FA, 6.7% (Table 3). Total LCB of CAEP-I ceramides have a ratio of TDB to TTB, both having primarily 16–18 CCL, equal to 2.45 (Table 4). It is noteworthy that in the CAEP-I molecule, the principal SFA (70.8%) with 14–18 CCL, combine with 57.3% dihydroxy LCB with 16–18 CCL and 23.4% trihydroxy LCB. Theses results are not comparable to those obtained previously from the *P. noctiluca* major CAEP species (21.0% of PhL), which consisted mainly of SFA (about 96%) with 14–16 carbon atoms, and C18-sphingosine, with over 85% of total LCB (22). Only a few reports concerning the occurrence of CAEP species in cnidaria other than in *P. noctiluca* have been published. A major ceramide aminoethylphosphonic acid has been isolated from the lipids of the sea anemone *Metridium senile*. The main FA was found to be palmitic (52%), but 35% of the total FA were branched-chain acids. Moreover, its LCB were found to be D-*erythro*-1,3-dihydroxy-2-amino-*trans*-4,*trans*-8-octadecadiene (95%) and sphingosine (5%) (23).

In comparison to CAEP-I, the CAEP-II methyl analog had reduced mobility on TLC owing to an increase of total unsaturated FA with 16–18 carbons (Table 3) and because the ratio

of TDB/TTB$_{CAEP-I}$ = 2.45 is decreased in it to 1.86 (value of TDB/TTB$_{CAEP-II}$) (Table 4).

CAEP-III methyl analog in comparison to the CAEP-II methyl analog had reduced mobility on TLC mainly because the value 1.86 for TDB/TTB$_{CAEP-II}$ decreased to 1.15 (value of TDB/TTB$_{CAEP-III}$) (Table 4), and because of an increase of + 8.1% total unsaturated FA content, ranging from 16 to 18 carbons (Table 3).

CAEP-IV methyl analog in comparison to CAEP-III also had reduced mobility mainly owing to an increase of hydroxy FA of 12–16 carbons (Table 3), and because the ratio of TDB/TTB$_{CAEPIII}$ = 1.15 decreased to 0.50 (value of TDB/TTB$_{CAEP-IV}$) (Table 4). The CAEP-IV molecule had 15.1% hydroxy FA with 12–16 carbons, together with 51.4% SFA (with 14–18 carbon atoms) and 27.3% unsaturated FA (with 16–18 carbon atoms), which combine with 58.4% trihydroxy LCB (two more hydroxyl groups) and 29.6% dihydroxy LCB (one more hydroxyl group), with 16–18 carbons.

If we compare each one of the three minor CAEP (II, III, IV) methyl analogs with the major CAEP-I, it is obvious that the three minor analogs have the same head group, but they differentiate from the major CAEP-I mainly because of the increase of their FA unsaturation and not because of a different LCB. Indeed, we see that the ratio SFA/unsaturated FA$_{CAEP-I}$ = 8.4 decreases to 2.6 (value of SFA/unsaturated FA$_{CAEP-II}$), 1.7 (value of SFA/unsaturated FA$_{CAEP-III}$), and 1.5 (value of SFA/unsaturated FA$_{CAEP-IV}$); apparently, the polarities of CAEP-III and CAEP-IV in comparison with CAEP-I polarity have no significant differentiation based on the FA unsaturation (ratios 1.7 and 1.5). We see also that the ratio SFA/hydroxy FA$_{CAEP-I}$ = 11.4 is increased 13.7 (value of SFA/hydroxy FA$_{CAEP-II}$) and 12.4 (value of SFA/hydroxy FA$_{CAEP-III}$). In contrast, for CAEP-IV this ratio is decreased 3.4; thus, CAEP-II and CAEP-III polarities in comparison with CAEP-I polarity have no significant differentiation based on the FA hydroxyl groups (ratios 13.7 and 12.4). In relation to the LCB moieties, we see that the ratio TDB/TTB$_{CAEP-I}$ = 2.8 is decreased to 1.9 (value of TDB/TTB$_{CAEP-II}$), 1.2 (value of TDB/TTB$_{CAEP-III}$), and to 0.6 for CAEP-IV; thus, CAEP-IV polarity in comparison with CAEP-I polarity is higher owing to the hydroxyl groups derived from the increased TTB content. Consequently, the three minor phosphonolipids could not be combined as one component in terms of their FA and LCB composition.

In the present study, a diversity of SPnL species was identified from the whole body of Aegean jellyfish *A. aurita,* including a major ceramidephosphonolipid CAEP, as well as three minor methyl CAEP analogs. This is the first report of the occurrence of methyl CAEP analogs in jellyfish. It is known that in marine invertebrates *Aplysia kurodai* and *Turbo cornutus*, CAEP species and its methyl analog are distributed in various tissue types such as the nervous tissue, ganglion, and fibers of *Aplysia* (54), and also in other tissues, such as viscera (52,53) and muscle tissue (16,19) of *Turbo*. Methyl analogs of SPnGL have also been found in skin of *Aplysia* (55). The biological significance of these distributions is not clear, but the differences in the FA and LCB composition may suggest differences in the metabolism of these molecules among the tissues (54). It would be of further interest to determine if the presence of each of the above major CAEP or minor methyl CAEP analogs is localized in specific tissues of *A. aurita*.

## ACKNOWLEDGMENTS

We wish to thank Professor J. Donald Smith (University of Massachusetts, Dartmouth, MA), Professor Akira Hayashi (Kinki University, Kowakae, Higashi-Osaka, Japan), and Dr. Anne Nikolaou (Bradford University, United Kingdom) for providing the phosphonate standards. We are indebted to Dr. Emmanuel Dasenakis (Athens University, Greece) for providing all necessary facilities for the collection of jellyfish. Also, we thank Dr. Mary Mavri (Athens University, Greece) for the fruitful discussions we had on this research.

# Separation and Identification of Phospholipid Peroxidation Products

**Ginger L. Milne and Ned A. Porter***

Department of Chemistry and Center in Molecular Toxicology, Vanderbilt University, Nashville, Tennessee 37235

**ABSTRACT:** The molecular species in mixtures of phospholipid hydroperoxides are difficult to separate and identify by typical chromatographic and mass spectrometric techniques. As reported by Havrilla and coworkers, silver ion coordination ion-spray mass spectrometry (CIS–MS) has proven to be a powerful technique for the identification of mixtures of hydroperoxides. This ionization technique, which involves the formation of $Ag^+$ adducts of the hydroperoxides, provides valuable, unambiguous structural information about the hydroperoxides. Herein, we report a method for the analysis and identification of phospholipid hydroperoxides using CIS–MS. We also report an improved method for the separation of phospholipid hydroperoxides by reversed-phase high-performance liquid chromatography (RP–HPLC), which, for the first time, separates some of the hydroperoxide isomers. CIS–MS can be coupled with this RP–HPLC method by the addition of $AgBF_4$ to the mobile phase or to the HPLC effluent postcolumn, thus allowing powerful HPLC–MS techniques to be used to identify complex mixtures of phospholipid hydroperoxides.

Paper no. L8860 in *Lipids 36,* 1265–1275 (November 2001).

Lipid peroxidation has been widely studied because of its implicit role in the pathogenesis of a number of human diseases including cancer (1), neurodegenerative diseases (2,3), and atherosclerosis (4). Considerable evidence supports the hypothesis that oxidative modification of the lipids in low density lipoproteins (LDL) may play an important role in the onset of atherosclerosis (5). Phospholipids, as the major lipid components of the surface layer of LDL, are a primary target for oxidation (6). Linoleic acid and arachidonic acid are the most abundant unsaturated fatty acids esterified to phospholipids in LDL. Lipids containing these fatty acids are especially susceptible to free radical chain oxidation (7–9).

Some two decades ago, we reported that neat films of 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphatidylcholine (PLPC) and 1-stearoyl-2-arachidonyl-*sn*-glycero-3-phosphatidylcholine (SAPC) react readily with oxygen at room temperature to give a mixture of phospholipid hydroperoxides (10). These oxidized products could be separated from the unoxidized phospholipid using reversed-phase high-pressure liquid chromatography (RP–HPLC). However, separation of the molecular species of the oxidized phospholipid could not be achieved with the chromatographic options available at that time. Since then, improvements have been made in the HPLC separation of intact phospholipid molecular species. The addition of ion-pairing agents, such as ammonium acetate (11) and choline chloride (12), to HPLC mobile phases leads to improved separation and peak shape.

These improvements in chromatography along with advances in mass spectrometry (MS) have helped make the analysis of intact phospholipid hydroperoxides possible. In 1994, Zhang *et al.* (13) reported the first method to analyze intact hydroxyeicosatetraenoyl-*sn*-glycero-3-phosphatidylcholine (HETE PC) species by fast atom bombardment–tandem mass spectrometry (FAB–MS/MS). Subsequently, an HPLC–MS technique (thermospray MS) used to analyze phospholipid hydroperoxides has been reported (14), and electrospray MS (ESI–MS) has been applied to phospholipid hydroperoxide analysis (15–17).

Analyzing phospholipid hydroperoxides by positive ion ESI–MS allows detection of the parent ion, but MS/MS experiments do not give structural information about the position of oxidation on the side chain. Only the mass-to-charge ratio (*m/z*) of the phosphocholine head group can be detected because it is the only part of the molecule that is charged. The negative ion ESI–MS/MS experiments reported by Hall and Murphy (16) do give structural information about the position of oxidation on the side chains when a high orifice potential is applied during the ionization process. The high potential causes in-source fragmentation of the phospholipid species so that the parent ion, as well as two daughter ions that correspond to the *m/z* for the carboxylate anions of the fatty acid side chains, is observed. Collision-induced dissociation (CID) experiments where the ion with the *m/z* for the oxidized fatty acid of interest is activated give fragment ion peaks that are indicative of the position of oxidation on the side chain. These studies only report separation of the

phospholipid species by class according to their head group and not by the position of oxidation on the side chains.

As an alternative to protonation, organic molecules containing hard or soft Lewis basic sites can be ionized by cations such as $Li^+$, $Na^+$, or $Ag^+$ (18–20). This ionization technique involves the formation of charged analyte complexes formed by the addition of a suitable coordination ion to the analyte. Combined with ESI–MS, coordination ion-spray mass spectrometry (CIS–MS) (21) has proved useful for analyzing complex mixtures of cholesteryl ester peroxides (22). Herein we report a method for the analysis and identification of phospholipid hydroperoxides using CIS–MS that eliminates some of the problems associated with ESI–MS. We also report an improved HPLC method that separates some of the isomers of linoleate hydroperoxides derived from PLPC and all of the arachidonate hydroperoxide isomers derived from SAPC.

## MATERIALS AND METHODS

Phospholipids were purchased from Avanti Polar Lipids (Alabaster, AL) or from Sigma Chemical Company (St. Louis, MO) and used without further purification. PLPC was purchased as a powder and SAPC was purchased as a chloroform solution. Solvents, such as methanol, water, and 2-propanol, were HPLC quality and purchased from either Fisher Chemical (Phillipsburg, NJ) or EM Science (Gibbstown, NJ). Hexanes were purchased from Burdick & Jackson (Muskegon, MI). All other reagents were purchased from Aldrich Chemical Company (Milwaukee, WI) and used without further purification.

Reactions involving hydroperoxides were monitored by thin-layer chromatography (TLC) using a stain of 1.5 g of *N,N′*-dimethyl-*p*-phenylenediamine dihydrochloride/25 mL of $H_2O$/125 mL of MeOH/1 mL acetic acid. Hydroperoxides yield an immediate pink color. TLC was carried out using 0.2-mm layer thickness, silica-coated aluminum columns (EM Science) that were visualized at 254 nm, phosphomolybdic acid char, or the peroxide stain. In general, hydroperoxides were stored as dilute solutions with 1 mol% butylated hydroxytoluene (BHT) in benzene at −78°C and never exposed to temperatures >40°C.

*Instruments.* Analytical HPLC was conducted on a Waters model 600 HPLC instrument, with a Waters model 486 tunable absorbance detector operating at 234 nm and with output to a Hewlett-Packard 3396 Series III integrator. Semipreparative HPLC was conducted on a Waters model 600E HPLC instrument with a Waters model 481 variable wavelength detector operating at 234 nm and with output to a Fisher Record-All Series 5000 strip chart recorder. Chiral HPLC was conducted on a Waters model 590 instrument with a Hewlett-Packard 1040A photodiode array detector. Semipreparative chiral HPLC was conducted on a Waters model 600 instrument with an LDC/Milton Roy Spectromonitor 3000 variable wavelength detector operating at 234 nm and with output to a Hitachi D-2500 Chromato-Integrator.

$^1$H Nuclear Magnetic Resonance (NMR) spectra were recorded on a Bruker DRX-400 (400 MHz) spectrometer in $CDCl_3$. Immediately prior to sample preparation, $CDCl_3$ was passed through a plug of basic alumina to remove any HCl.

*Mass spectrometry.* CIS–MS was performed using a Finnigan Thermoquest TSQ-7000 (San Jose, CA) triple quadrupole mass spectrometer equipped with a standard API-1 electrospray ionization source outfitted with a 100-µm deactivated fused-Si capillary. Data acquisition and spectral analysis were conducted using ICIS software, version 8.3.2, running on a Digital Equipment Alpha Station 200 4/166. Nitrogen gas served both as the sheath and auxiliary gas; argon served as the collision gas. The electrospray needle was maintained at 4.6 kV, and the heated capillary temperature was 250°C. The tube lens and capillary voltages were optimized to maximize ion current for electrospray; the optimal values were determined to be 90 and 10 V, respectively, for phospholipid analysis. For MS/MS experiments, the collision gas pressure was typically 2.6–2.9 mTorr. To obtain fragmentation information on the $Ag^+$-phospholipid adducts, the dependence of collision energy on relative abundance was studied. Positive ions were detected scanning from 100 to 1000 amu with a total scan duration of 1 s. Profile data were recorded for 1 min (~60 scans) and averaged from analysis.

Samples were introduced either by direct liquid infusion (DLI) or HPLC. For DLI experiments, samples were introduced with a Harvard Apparatus (Cambridge, MA) syringe pump at a flow rate of 10 µL/min. For HPLC sample introduction, a Waters model 2690 Separation Model instrument was used. The HPLC was equipped with a Discovery octadecylsilane (ODS) column (4.6 × 250 mm, 5 µm; Supelco, Bellefonte, PA) and operated with a mobile phase of methanol/water (95:5, vol/vol) at a flow rate of 1 mL/min. A splitting tee after the column permitted 240 µL/min to be passed through an Applied Biosystems 785A programmable absorbance ultraviolet (UV) detector operating at 234 nm before entering the mass spectrometer. The remainder of the effluent was collected as waste.

*Liquid chromatography (LC)–CIS–MS of phospholipid hydroperoxides.* For these experiments, the hydroperoxides were isolated from the unoxidized phospholipid using analytical HPLC (methanol/water, 95:5, vol/vol, 1 mL/min). The oxidized fraction for PLPC (13.5–15.5 min) or SAPC (20–28 min) was collected, concentrated, and analyzed by LC–CIS–MS. A stock solution of the oxidized lipid was prepared (1–1.25 mg/mL) and 25–50 µL of the solution was injected per analysis. Offset voltages for selected reaction-monitoring (SRM) experiments, 28–33 eV, were determined by optimization in DLI experiments.

*Studies on PLPC, autoxidation.* To a solution of PLPC (25 mg, 0.033 mmol) in 2.5 mL of $CH_2Cl_2$ was added 10 mol% 2,2,5,7,8-pentamethyl-6-chromanol (PMC; 73 µL of a 10 mg/mL stock solution). The solution was evaporated to dryness under vacuum so that the mixture formed a thin layer on the inside of a 10-mL round-bottomed flask. The flask was then heated to 37°C and exposed to an atmosphere of dry air. After 24 h, the mixture was dissolved in benzene and BHT (~1–2 mg) was added to stop the reaction. TLC of the product mixture indicated the formation of hydroperoxides. The hydroperoxide products were then analyzed by HPLC.

*HPLC analysis of the PLPC hydroperoxides (PLPC-OOH).* In order to analyze the peroxidation products of PLPC, it was first necessary to optimize HPLC conditions for their separation. During the optimization process, two different C-18 analytical columns were tried; one was a Supelcosil column (4.6 × 250 mm, 5 μm; Supelco) while the other was a Discovery column (4.6 × 250 mm, 5 μm; Supelco). Mobile phases used in the optimization were mixtures of varying concentrations of methanol, hexanes, and water containing varying concentrations (0–25 mM) of ammonium acetate or choline chloride. The optimal conditions, which gave the best separation and peak shape, were obtained using the Discovery C-18 analytical column with a mobile phase of simply methanol/water (95:5, vol/vol) at a flow rate of 1 mL/min. Analysis of the PLPC-OOH using these HPLC conditions showed the formation of two major fractions at $t_R$ = 14.04 and 14.97 min. Each fraction was collected, concentrated, and rechromatographed to ensure its purity. The fractions were then converted to the corresponding methyl hydroxyoctadecadienoates (HODE), which were previously characterized (23), for identification.

*Conversion of PLPC-OOH to methyl HODE.* Methyl hydroperoxyoctadecadienoates (HPODE) were prepared as described previously (23). This mixture of hydroperoxides and the isolated fractions of PLPC-OOH were treated with an excess of triphenylphosphine ($PPh_3$) to generate the corresponding alcohols (PLPC-OH). To convert the alcohols to the methyl esters, each isolated fraction was dissolved in benzene (0.5 mL) and treated with an excess of NaOMe (1 mL of a 0.5 M solution in methanol) for 2 h. The reactions were worked up by the addition of deionized water (5 mL) and acetic acid (100 μL). The aqueous layer was extracted with hexanes (2 × 5 mL). The combined organic layers were dried, concentrated, and analyzed by HPLC. To analyze the methyl HODE, the HPLC was equipped with two tandem Ultrasphere silica columns (4.6 × 250 mm, 5 μm; Beckman, Fullerton, CA). The compounds were eluted with 0.6% 2-propanol in hexanes containing 0.1% acetic acid at a flow rate of 3 mL/min. The elution order of the methyl HODE from the standard mixture corresponds to that previously reported (24). Injection of the transesterified fractions showed that phospholipid hydroperoxides **1**, **2**, and **3** elute from the HPLC in the first fraction, $t_R$ = 14.04 min. Injection of the transesterified fractions showed that the second fraction, $t_R$ = 14.97 min, contains phospholipid hydroperoxide **4**. $^1$H NMR of each phospholipid fraction and LC–CIS–MS experiments support this assignment.

*$^1$H NMR of the PLPC-OOH.* $^1$H NMR spectra were taken on each of the isolated PLPC-OOH fractions. The vinyl region of the spectrum taken on the first fraction consists of signals at δ 5.45 (*m*, 1H), 5.62 (*m*, 1H), 5.99 (*m*, 1H), and 6.51 (*m*, 1H). These signals are consistent with those signals previously reported for the *cis,trans* isomers of oxidized cholesteryl linoleate (25). The spectrum of this fraction also contains small signals that correspond to the signals due to the *trans,trans* isomer. These signals at δ 5.55 (*m*, 1H), 5.72 (*m*, 1H), 6.03 (*m*, 1H), and 6.21 (*m*, 1H) are the major vinyl signals observed in the second fraction and are consistent with those signals reported for the *trans,trans* isomers of oxidized cholesteryl linoleate. The data support the assignment of compounds **1**, **2**, and **3** in the first fraction, and the assignment of compound **4** to the second.

*Studies on SAPC, autoxidation.* To a solution of SAPC (25 mg, 0.029 mmol) in 2.5 mL of $CH_2Cl_2$ was added 10 mol% PMC (64 μL of a 10 mg/mL stock solution). The solution was evaporated to dryness under vacuum so that the mixture formed a thin layer on the inside of a 10-mL round-bottomed flask. The flask was then heated to 37°C and exposed to an atmosphere of dry air. After 24 h, the mixture was dissolved in benzene and BHT (~1–2 mg) was added to stop the reaction. Analytical HPLC (Discovery line ODS column, methanol/water, 95:5, vol/vol, 1 mL/min, λ = 234 nm) indicated the formation of six major fractions. These fractions were then identified by LC–CIS–MS: **I**, **11**, $t_R$ = 20.93 min; **II**, **9**, $t_R$ = 22.03 min; **III**, **10**, $t_R$ = 22.78 min; **IV**, **7**, $t_R$ = 24.21 min; $\mathbf{V_a}$, **(*R,R*)-8**, $t_R$ = 24.89 min; $\mathbf{V_b}$, **(*S,R*)-8**, $t_R$ = 25.28 min; and **VI**, **6**, $t_R$ = 27.33 min.

*Studies on fractions $V_a$ and $V_b$.* Fractions $\mathbf{V_a}$ and $\mathbf{V_b}$ were isolated from each other using analytical HPLC (Discovery ODS column, methanol/water, 93:7, vol/vol., 1 mL/min, λ = 234 nm). The fractions were concentrated and rechromatographed to ensure their purity. The compounds were then converted to the corresponding methyl HETE in an analogous procedure to that described above for the PLPC-OOH. The transesterified products were purified using the same analytical HPLC system described for the methyl HODE. The collected products were concentrated for analysis by chiral HPLC equipped with a Chiralpak AD column (4.6 × 250 mm, 10-mm; Chiral Technologies, Exton, PA) using a mobile phase of hexanes/methanol (100:2, vol/vol) at a flow rate of 1 mL/min (26). Coinjection of each transesterified fraction with a racemic mixture of methyl 9-HETE confirmed the elution order. The transesterified product from fraction $\mathbf{V_a}$, $t_R$ = 8.65 min, was found to correspond to the *R* enantiomer of methyl 9-HETE; the transesterified product from fraction $\mathbf{V_b}$, $t_R$ = 9.08 min, was found to correspond to the *S* enantiomer of methyl 9-HETE.

*Determination of the elution order of methyl (9*R*)- and (9*S*)-hydroxy-5(*Z*),8(*E*),11(*Z*),14(*Z*)-eicosatetraenoate in chiral HPLC analyses, autoxidation of eicosatetraenoic acid (arachidonic acid).* In a round-bottomed flask, arachidonic acid (500 mg, 1.64 mmol) was dissolved in 1,4-cyclohexadiene (3.2 mL, 34 mmol) and benzene (5 mL) to give a solution 0.20 M in lipid and 4.2 M in 1,4-cyclohexadiene. Di-*tert*-butylhyponitrite (~3–5 mg) was added to the reaction, and the flask contents were allowed to stir at 37°C for 24 h. At this time, TLC indicated the formation of hydroperoxide products. BHT (~2 mg) was added to stop the reaction. Benzene and 1,4-cyclohexadiene were removed by vacuum, and the mixture was rediluted in hexanes for separation by semipreparative HPLC [Dynamax-60 A silica 83-121-C column (Rainin Instrument Co. Inc., Woburn, MA), 21.4 × 250 mm, 8 μm, 2% 2-propanol in hexanes with 1% acetic acid, 10 mL/min]. The elution order for the HPETE is known (27). 9-HPETE was collected, $t_R$ = 32 min, into a round-bottomed flask containing BHT (~2 mg). The solvent was removed *in vacuo,* and the racemic mixture of 9-HPETE was converted to the corresponding alcohols by treatment with excess $PPh_3$ in $Et_2O$.

*Synthesis of methyl 9-hydroxy-5(Z),8(E),11(Z),14(Z)-eicosatetraenoate (methyl 9-HETE).* The crude alcohol, 9-HETE, was dissolved in $Et_2O$ (1 mL) and treated with an excess of diazomethane generated in a Micro Diazomethane Generator (Ace Glass, Inc.) with 1-methyl-3-nitro-1-nitrosoguandine as the precursor. The reaction was stirred at 0°C for 2 h. The reaction mixture was allowed to sit open to the air in a hood for 30 min to allow evaporation of any excess diazomethane. The ether was removed *in vacuo,* and the methyl ester was purified by analytical HPLC (two tandem Beckman silica columns, 1.6% 2-propanol in hexanes, 1 mL/min, $\lambda = 234$ nm).

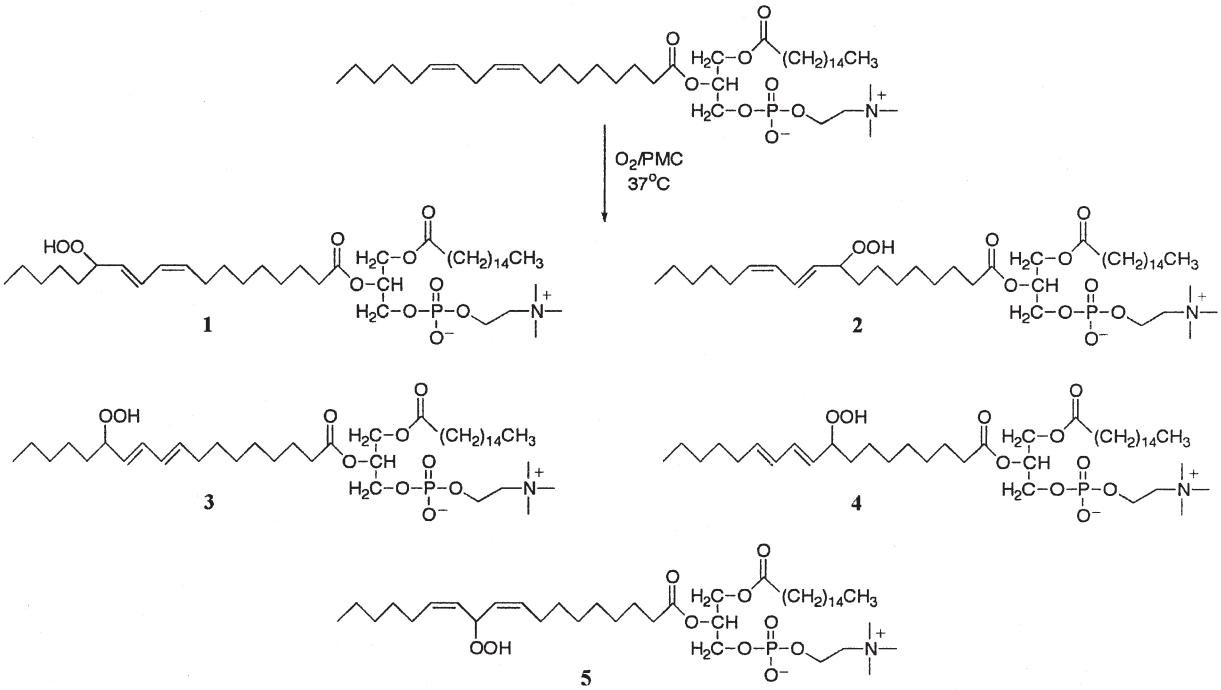
*Separation of racemic methyl 9-HETE by chiral HPLC (26).* The racemic methyl 9-HETE was separated using semi-preparative chiral HPLC. The HPLC was equipped with a Chiralpak AD column (10 × 250 mm, 10-mm; Chiral Technologies) using a mobile phase of hexanes/methanol (100:2, vol/vol) at a flow rate of 3 mL/min. Each enantiomer was collected, concentrated, and reinjected to ensure its purity: $\mathbf{V_a}$, $t_R$ = 13.82 min; and $\mathbf{V_b}$, $t_R$ = 14.47 min.

*Circular dichroism (CD) spectroscopy (28).* Each purified enantiomer was dissolved in 50 µL of dry acetonitrile. One microliter of 1,8-diazabicyclo[5.4.0]undec-1-ene and a few grains of 1-(2-naphthoyl)imidazole were added to the solution. The reaction was kept at room temperature overnight. The solvent was evaporated, and the residue was redissolved in $CH_2Cl_2$ (2 mL). The solution was washed twice with water (1 mL), and the $CH_2Cl_2$ was removed. The naphthoate derivatives were purified by analytical HPLC (two tandem Beckman silica columns, 1% 2-propanol in hexanes, 1 mL/min, $\lambda = 239$ nm). For CD spectroscopy, the purified naphthoate derivatives were dissolved in 400 µL of dry acetonitrile. CD was measured with a Jasco J-720 spectropolarimeter (cell volume 400 µL; cell path length 1 mm). The configuration of the collected enantiomer $\mathbf{V_a}$ was determined to be *R*, whereas the configuration of the collected enantiomer $\mathbf{V_b}$ was determined to be *S*.

## RESULTS AND DISCUSSION

As previously reported (10), the peroxidation products, **1–4**, that form when a neat film of PLPC is incubated in an atmosphere of air at 37°C are from linoleoyl side-chain oxidation (Scheme 1). The mechanism by which the four peroxidic products of linoleate form is well understood (7–9). Initial hydrogen atom extraction at the C-11 position on the linoleoyl side chain yields a pentadienyl radical. A molecule of oxygen then adds to this stable radical at either the C-9 or the C-13 positions to give *cis,trans* peroxyl radicals that, in the presence of a good hydrogen atom donor, will be trapped as the *cis,trans* hydroperoxides **2** and **1**, respectively (in the presence of large amounts of a good hydrogen atom donor, such as α-tocopherol, the 11-hydroperoxide of linoleate is formed; 29). In the absence of hydrogen atom donors, the *trans,trans* hydroperoxides **3** and **4** form. The ratio of *cis,trans* to *trans,trans* products formed in a reaction mixture is a good measure of the competition between hydrogen atom abstraction from hydrogen donor molecules and β-fragmentation.

In our previous study, **1–4** were separated from unoxidized PLPC by HPLC, but all four phospholipid hydroperoxides eluted as one broad, tailing peak. There was no separation of the various hydroperoxide isomers (10). Our first goal in this study was to improve chromatography for the separation of phospholipid hydroperoxides by methods that were compatible with CIS–MS techniques. Therond *et al.* (24) achieved



**SCHEME 1**

good separation of the molecular species of soybean PC and their corresponding hydroperoxides, formed from incubation with soybean lipoxygenase, using an analytical Spherisorb C-18 column and a mobile phase of methanol/10 mM ammonium acetate (95:5, vol/vol) at 1 mL/min. Chromatography of a mixture of **1–4** on a Supelcosil C-18 column with a mobile phase of methanol/hexanes/water (100:5:5, by vol) containing 10 mM ammonium acetate gave sufficient separation of the PLPC-OOH from unoxidized PLPC, but there was little separation of the different isomers **1–4**. Better separation was achieved with a mobile phase of methanol/hexanes/water (100:1:5, by vol) containing 10 mM choline chloride. Using choline chloride as an ion-pairing agent resolved the tailing peak observed when ammonium acetate was used. The best separation of the phospholipid hydroperoxides was achieved using a newly marketed HPLC column, the Discovery C-18 column from Supelco, with a mobile phase of methanol/water (95:5, vol/vol) containing no ion-pairing agent.

With the optimal chromatographic conditions, two resolved hydroperoxide peaks with retention times ($t_R$) of 14.04 and 14.97 min were observed by UV detection at $\lambda$ = 234 nm. To determine the elution order of **1–4**, compounds eluting in these two peaks were isolated. The collected phospholipid hydroperoxides in each peak were converted to the corresponding HODE methyl esters by reduction ($PPh_3$) and transesterification ($NaOCH_3$, $CH_3OH$). The HODE methyl esters are well characterized, and the chromatography of these compounds by normal-phase HPLC has been reported (23). This analysis showed that the first-eluting peak, $t_R$ = 14.04 min, contained both of the 13-substituted hydroperoxides, **1** and **3**, and the 9-*cis,trans* hydroperoxide of PLPC, **2**. The second peak, $t_R$ = 14.97 min, contained only the 9-*trans,trans* hydroperoxide, **4**.

It is possible to calculate the *cis,trans* to *trans,trans* product ratio based on the UV absorbance of each eluting peak, assuming that **3** is formed to the same extent as **4**, and that **1** is formed to the same extent as **2.** (This assumption is made based on the calculated extinction coefficients for the *trans,cis* and *trans,trans* hydroperoxides of methyl linoleate; 30.) By using a mixture of hydroperoxides **1–4** that were generated from a standard oxidation of PLPC without a hydrogen atom donor present, the *cis,trans* to *trans,trans* ratio was calculated to be 0.43 by HPLC under the optimal conditions described above. A portion of this oxidation mixture was converted to the corresponding HODE methyl esters, and the *cis,trans* to *trans,trans* ratio was determined by standard normal-phase HPLC–UV analysis. This number was also found to be 0.43, comparable with that calculated using the intact phospholipid hydroperoxides. Being able to determine the product ratio from the intact phospholipid hydroperoxides eliminates the need for converting **1–4** to the methyl esters and may be beneficial in future oxidation studies of complex phospholipid mixtures.

Having developed a chromatographic method that resolved some of the PLPC-OOH isomers, we explored analytical methods that would permit identification of oxidized phospholipid molecular species without conversion or derivatization. CIS–MS has proved to be useful for obtaining structural information for several classes of cholesteryl ester peroxides and hydroperoxides (22), and we therefore turned to CIS–MS for the analysis of intact phospholipid hydroperoxides. In the first experiments, **1–4** were isolated from unoxidized PLPC by HPLC. The collected hydroperoxides were introduced into the mass spectrometer *via* DLI as a mixture in methanol with 4 equivalents of $AgBF_4$. The resulting CIS–MS spectrum is shown in Figure 1A. The dominant ions observed are the $[M + Ag]^+$ adducts at *m/z* = 896 and 898, formed from $^{107}Ag$ and $^{109}Ag$ isotopes that are present in a ratio of ~1:1.

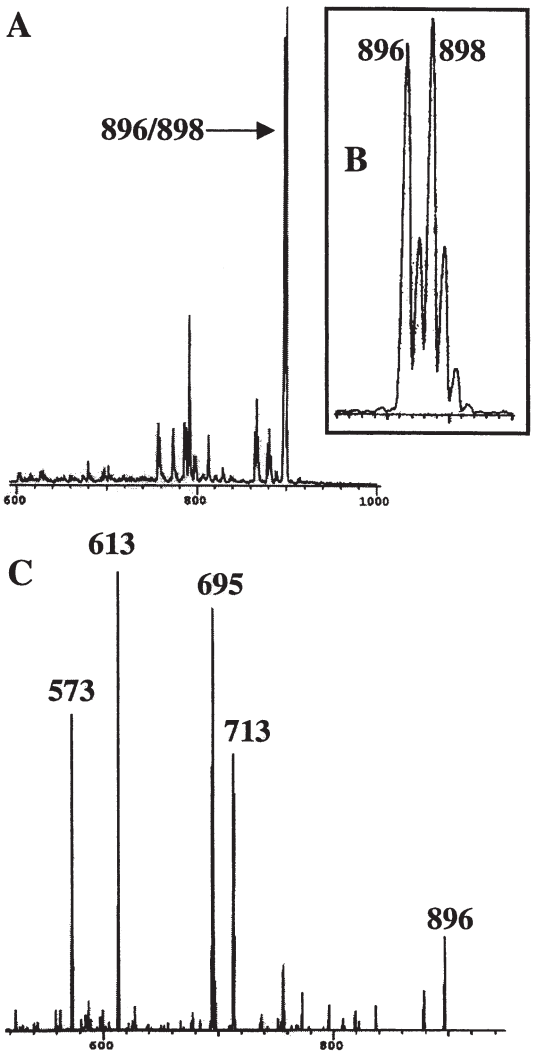


**FIG. 1.** Silver ion coordination ion-spray mass spectrum of a mixture of **1–4** obtained in direct liquid infusion experiments: (A) full scan, (B) blow-up of the $[M + Ag]^+$ region, and (C) collision-induced dissociation spectrum of *m/z* = 896.

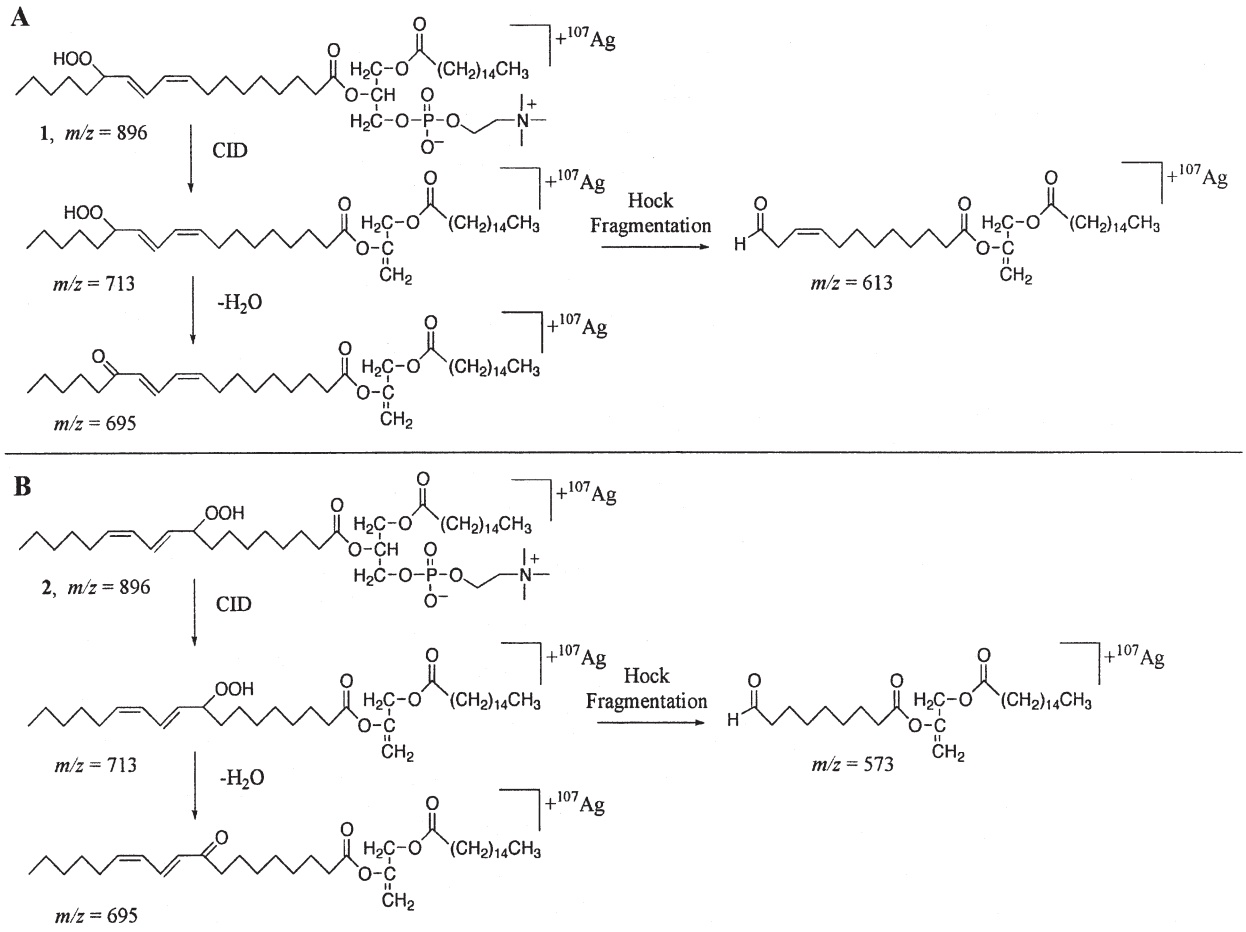
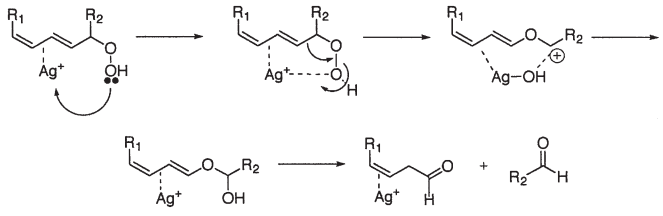
CID experiments on the complex of **1–4** with $^{107}Ag^+$ at *m/z* = 896 gave fragment ions at *m/z* = 713, 695, 613, and 573 (Fig. 1C). The proposed structures for each of the fragment ions are shown in Scheme 2. Each fragment showed loss of the phosphocholine head group as a neutral loss of 183. The fragment at *m/z* = 713 $[M + Ag - 183]^+$ exhibits only loss of the head group, whereas the fragment at *m/z* = 695 $[M + Ag - 183 - H_2O]^+$, in



**SCHEME 2**

addition to head group loss, shows dehydration of the hydroperoxide on the side chain. We suggest that the fragments observed at *m/z* = 613 and 573 are from Hock fragmentation of the silver ion hydroperoxide complex. This fragmentation was the primary mechanism of cholesteryl ester hydroperoxide fragmentation in CIS–MS studies (22). This commonly observed fragmentation (or rearrangement) of lipid hydroperoxides is promoted by protic or Lewis acids in solution at moderate temperatures (31–34). In the collision cell of the mass spectrometer, this fragmentation is most likely catalyzed by the silver ion, a Lewis acid (Scheme 3). The Hock fragments provide valuable information about the position of the hydroperoxide on the linoleoyl side chain. The fragment ion observed at *m/z* = 613 results from collisional activation of the 13-substituted hydroperoxides **1** and **3**, while the fragment at *m/z* = 573 results from activation of the 9-substituted hydroperoxides **2** and **4**.



**SCHEME 3**

Coupling HPLC and LC–CIS–MS was achieved by either postcolumn mixing of 0.50 mM $AgBF_4$ in methanol with the HPLC effluent or by addition of $AgBF_4$ to the HPLC mobile phase to yield a 0.15 mM solution. Chromatography was carried out using the new Supelco Discovery C-18 analytical column with a mobile phase of methanol/water (95:5, vol/vol) at a flow rate of 1 mL/min. A flow splitter was inserted online so that 240 μL/min was directed through a UV detector and into the mass spectrometer while 760 μL/min was collected as waste. Typical chromatograms from the mass spectrometer for a mixture of PLPC-OOH are shown in Figure 2. Panel A shows the total ion current chromatogram for the silver ion adducts. Panel B shows the chromatogram of the 13-substituted hydroperoxides **1** and **3** that co-elute. Panel C shows the chromatogram of the 9-substituted hydroperoxides **2** and **4** that separate under these chromatographic conditions.

These chromatograms result from the mass spectrometer being operated in the SRM mode. In this mode, a specific precursor-to-product mass conversion produced at a characteristic energy in the collision cell is monitored. SRM separates the differently substituted hydroperoxides based on the difference in their Hock fragments. The elution pattern of the hydroperoxides in these SRM experiments is consistent with the elution order determined by separation of the hydroper-

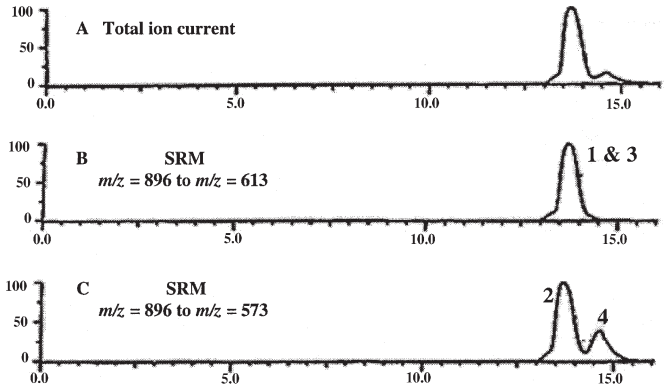


**FIG. 2.** Chromatograms of 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphatidylcholine oxidation mixture formed when oxidized in the presence of 0.1 equivalents of pentamethylchromanol: (A) high-pressure liquid chromatography–coordination ion-spray–mass spectrometry (HPLC–CIS–MS) total ion current is a sum of (B) and (C); (B) HPLC–CIS–MS in selected reaction monitoring (SRM) mode for $m/z = 896 \rightarrow 613$; (C) HPLC–CIS–MS in selected reaction monitoring mode for $m/z = 896 \rightarrow 573$.

oxides by HPLC and subsequent conversion to the corresponding HODE methyl esters.

LC–CIS–MS experiments were also used to identify the 11-substituted hydroperoxide of PLPC, **5** (Fig. 3). The 11-substituted hydroperoxides of methyl linoleate (29) and cholesteryl linoleate (35) were only observed when the oxidation was performed in the presence of large amounts of α-tocopherol. Thus, to identify **5**, PLPC was oxidized as a thin film with 0.75 equivalents of α-tocopherol at 37°C for 24 h. By operating the mass spectrometer in SRM mode and monitoring for the conversion of **5** to its two possible Hock fragments at $m/z = 599$ and 587, the 11-substituted hydroperoxide was identified as the peak eluting at 13.77 min in Figure 3.

With the chromatographic and mass spectrometric techniques developed for analyzing the phospholipid hydroperoxides from PLPC, the hydroperoxides from another phospholipid, SAPC, were studied. The oxidation mixture from SAPC is more complex than that from PLPC because there are more sites of unsaturation on the arachidonoyl side chain. The six hydroperoxides, **6–11**, obtained from oxidizing a neat film of SAPC in the presence of a good hydrogen atom donor, PMC, are shown in Scheme 4. These products, which we previously reported (10), are formed in an analogous way to the hydroperoxides derived from PLPC.

A typical UV chromatogram obtained for **6–11** at λ = 234 nm is shown in Figure 4A, and the corresponding alcohols gave the chromatogram shown in Figure 5. The phospholipid hydroperoxides were then analyzed using LC–CIS–MS with the mass spectrometer being operated in both full-scan and SRM modes. It is of importance to note here that the starting phospholipid used in these studies was purchased from the Sigma Chemical Company. In our initial experiments, SAPC

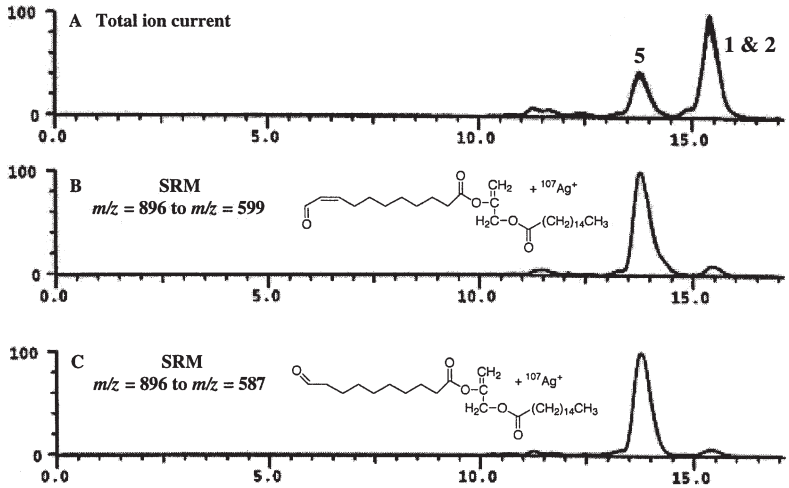

**FIG. 3.** Chromatograms of 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphatidylcholine oxidation mixture formed when oxidized in the presence of 0.75 equivalents of α-tocopherol: (A) HPLC–CIS–MS total ion current is a sum of (B), (C), and the SRM experiments monitoring for the 9- and 13-hydroperoxides (as in Fig. 2); (B) HPLC–CIS–MS in SRM mode for $m/z = 896 \rightarrow 599$; (C) HPLC–CIS–MS in SRM mode for $m/z = 896 \rightarrow 587$. For abbreviations see Figure 2.

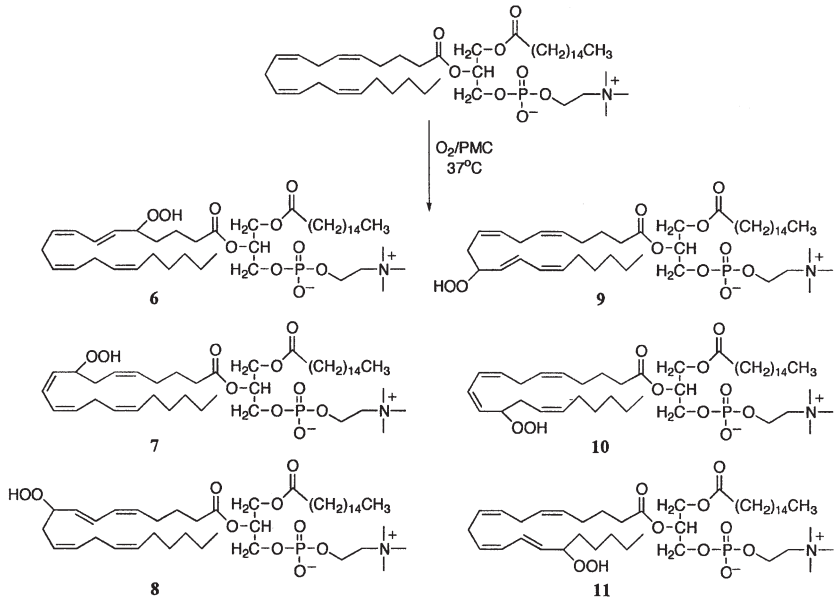

**SCHEME 4**

purchased from Avanti Polar Lipids was used, and a much more complex chromatogram was obtained. We speculate that this complexity was due to oxidation of 1-arachidonyl-2-stearoyl-*sn*-glycero-3-phosphatidylcholine, a positional isomer of SAPC present in the Avanti phospholipid. Avanti reports that the positional purity of their phospholipids can be as low as 80%, but Sigma reports a positional purity of 97%.

In scanning from *m/z* = 600 through 1000, the dominant ions in the LC–CIS–MS spectra for the phospholipid hydroperoxides **6–11** were *m/z* = 948 and 950. The elution order of the phospholipid hydroperoxides from the HPLC was determined using LC–CIS–MS with the mass spectrometer being operated in SRM mode (Fig. 4B–G).

Hydroperoxides **6** and **11** were easily identified as peaks **VI** and **I**, respectively, in Figure 4A because their Hock fragments are unique. However, hydroperoxides **7** and **8**, identified by SRM as peaks **IV** and **V**, have identical Hock fragments, as do hydroperoxides **9** and **10**, identified as peaks **II** and **III**. These hydroperoxides were distinguished from each other by monitoring unique, less abundant fragments from **8** and **10** in SRM mode. These fragments at *m/z* = 780 and 820, shown in Scheme 5, result from cleavage of the C9-C10 bond α to the hydroperoxide in **8** and the C12-C13 bond α to the hydroperoxide in **10**, respectively. This fragmentation pattern, analogous to that observed in the analysis of HETE and HETE PC by negative-ion FAB–MS and ESI–MS (13,16,36,37), helped identify **8** as peak **V** and **10** as peak **III**.

In the UV chromatogram (Fig. 4A), peak **V** actually appears to be two closely eluting peaks. This same pattern for peak **V** is observed in the SRM experiments monitoring for **8** [9-hydroperoxyeicosatetraenoyl-*sn*-glycero-3-phosphatidylcholine (9-HPETE PC)]. This suggested that both of these peaks, $\mathbf{V_a}$ and $\mathbf{V_b}$, are 9-HPETE PC and not a co-eluting contaminant. Unoxidized phospholipids are chiral molecules with a stereogenic center at $C_2$ of the glycerol backbone; the configuration of this center is *R*. When the phospholipid is oxidized to the hydroperoxide, diastereomers are formed because oxygen addition can occur to either face of the pentadienyl radical, and we suspected that these diastereomers of 9-HPETE PC were being separated as peaks $\mathbf{V_a}$ and $\mathbf{V_b}$.

To test the hypothesis that we were observing separation of diastereomers, compounds eluting in peaks $\mathbf{V_a}$ and $\mathbf{V_b}$ were isolated by HPLC and converted to the corresponding methyl HETE. Methyl HETE contain only one stereogenic center at the position of oxygen addition and exist as enantiomers that can be separated using chiral HPLC as reported

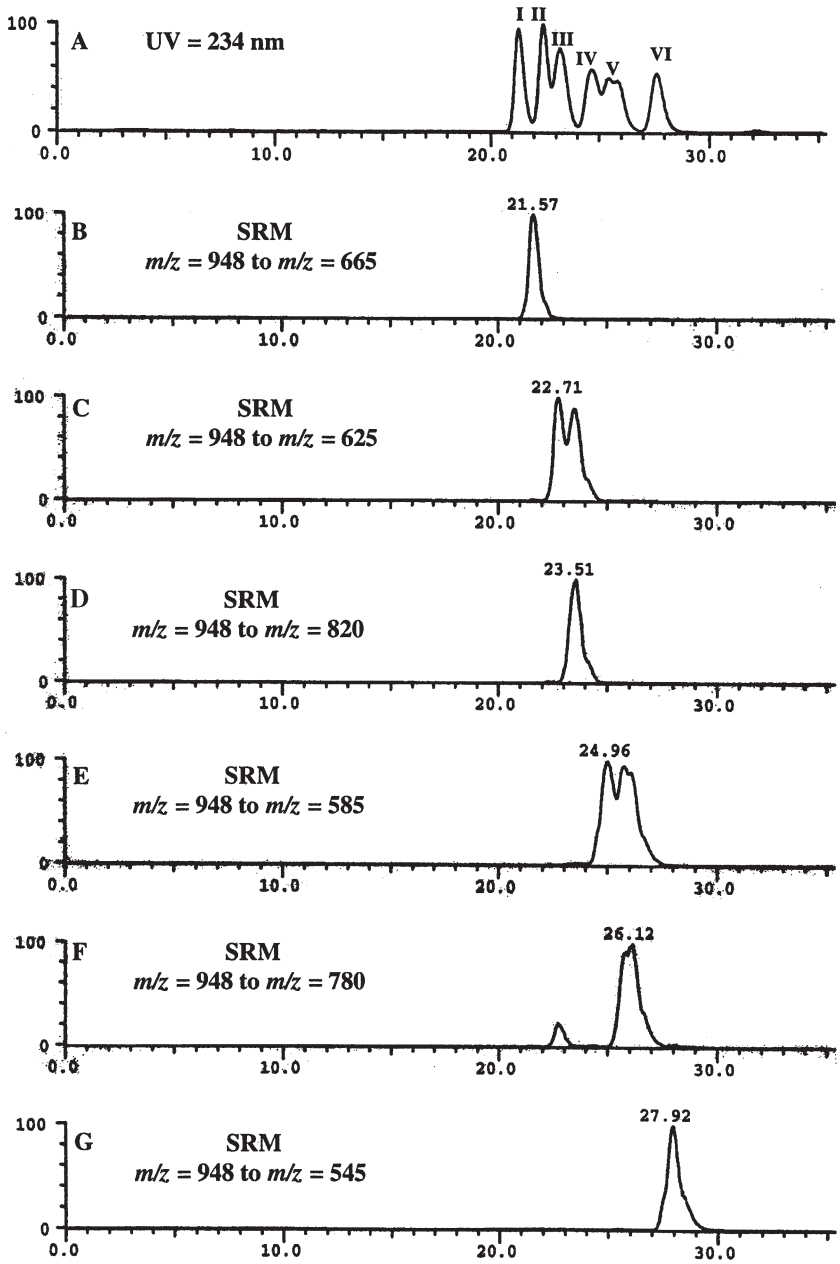

**FIG. 4.** Chromatograms of the product mixture obtained from a 24-h oxidation of 1-stearoyl-2-arachidonyl-*sn*-glycero-3-phosphatidylcholine containing 0.1 equivalents of pentamethylchromanol (mobile phase, methanol/water, 95:5, vol/vol; Discovery C-18 analytical column, Supelco, Bellefonte, PA): (A) ultraviolet detection at λ = 234 nm: **I** = 15-HPETE PC, **II** = 11-HPETE PC, **III** = 12-HPETE PC, **IV** = 8-HPETE PC, **V** = 9-HPETE PC, **VI** = 5-HPETE PC; (B–G) HPLC-CIS-MS in SRM mode. HPETE, hydroperoxyeicosatetraenoic acid; PC, phosphatidylcholine; for other abbreviations see Figure 2.

by Schneider *et al.* The methyl esters derived from collected peaks $\mathbf{V_a}$ and $\mathbf{V_b}$ were analyzed using an analytical Chiralpak AD column with a mobile phase of hexanes/methanol (100:2, vol/vol). Comparison with a standard mixture of racemic methyl 9-HETE supported the notion that the methyl ester derived from peak $\mathbf{V_a}$ was one enantiomer of methyl 9-HETE, and the methyl ester derived from peak $\mathbf{V_b}$ was the other enantiomer (Fig. 6). While it is of importance to report that the diastereomers of 9-HPETE PC are separable by RP-HPLC, we have no explanation for this fact of nature observed for the 9-HPETE PC and not the other HPETE PC.

To determine the elution order of the methyl 9-HETE enantiomers so that configurations could be assigned to the diastereomers of **8** eluting as peaks $\mathbf{V_a}$ and $\mathbf{V_b}$, it was necessary to synthesize derivatives of the compounds and determine their absolute configuration using circular dichroism (CD) spectroscopy. CD spectroscopy uses the interaction of two chromophores at the chiral center in order to define absolute config-

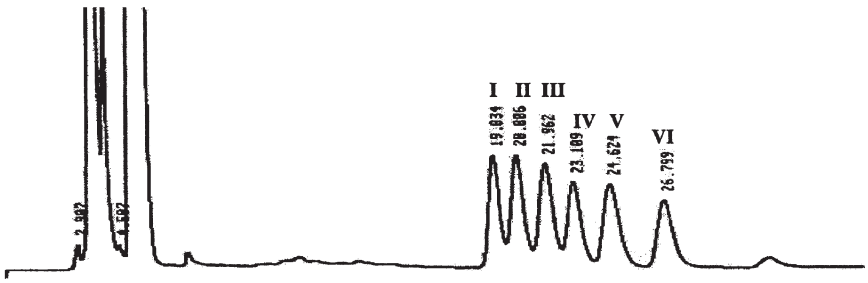

**FIG 5.** HPLC chromatogram of 1-stearoyl-2-arachidonyl-*sn*-glycero-3-phosphatidylcholine alcohol (SAPC-OH) formed by reduction of the SAPC-OOH (Scheme 4, Fig. 4) with triphenylphosphine. The elution order of the alcohols is identical to that of the hydroperoxides. For abbreviation see Figure 2.

uration. Conversion of the isolated 9-HETE methyl esters to their 2-naphthyl esters gave derivatives that provide information about the absolute configurations of the compounds (28).

The derivative of the first-eluting 9-HETE methyl ester enantiomer showed a negative first Cotton effect (CE) at $\lambda$ = 243 nm ($\Delta\varepsilon$ −50.8) and a positive second CE at $\lambda$ = 226 nm ($\Delta\varepsilon$ +41.6) (By definition, if the chirality of the electronic transition moments of the chromophore of highest wavelength to the chromophore of the lowest wavelength is counterclockwise when the molecule is represented in the Newman projection, the CD shows a negative first and a positive second CE and vice versa). Thus, this enantiomer was assigned an absolute configuration of *R*. The derivative of the later-eluting enantiomer showed a positive first CE at $\lambda$ = 243 nm ($\Delta\varepsilon$ +19.6) and a negative second CE at $\lambda$ = 226 nm ($\Delta\varepsilon$ −16.1) and was assigned an absolute configuration of *S*. Using this information, the first-eluting diasteromer of **8** ($\mathbf{V_a}$) has the *R,R* configuration, and the second-eluting diastereomer ($\mathbf{V_b}$) is *S,R*.

CIS–MS is a powerful technique for the identification of phospholipid hydroperoxides. Also, by using the new Supelco Discovery C-18 columns and a mobile phase of only methanol and water, separation of phospholipid hydroperoxide isomers has been achieved for the first time. Currently, we are using these analytical techniques to identify phospholipid hydroperoxides formed in oxidations of low-density lipoproteins.

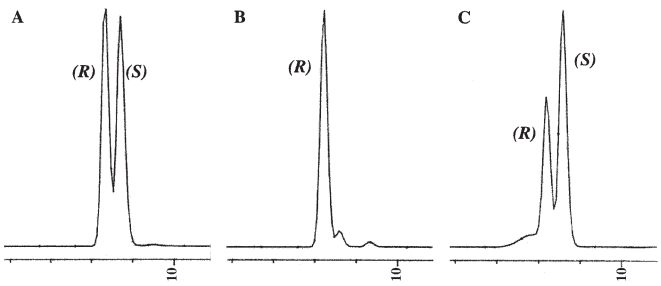

**FIG 6.** Chiral HPLC chromatograms of the 9-HETE methyl ester enantiomers (mobile phase, hexanes/methanol, 100:2, vol/vol; Chiralpak AD analytical column, Chiral Technologies, Exton, PA; UV detection at $\lambda$ = 234 nm): (A) racemic methyl 9-HETE; (B) methyl 9-HETE derived from fraction $\mathbf{V_a}$; (C) methyl 9-HETE derived from fraction $\mathbf{V_b}$. HETE, hydroxyeicosatetraenoic acid; for other abbreviation see Figure 2.

## ACKNOWLEDGEMENTS

Support for this research was provided by NIH (HL17921) and NIEHS (P30ES00267). GLM acknowledges funding from the toxicology training grant NIEHS-T32ES07028 (Vanderbilt University). We are grateful for the assistance of M. Lisa Manier and the Vanderbilt University Mass Spectrometry Research Center and Dr. Claus Schneider and Professor Alan R. Brash.

# Quantitative Determination of $^{13}C$-Labeled and Endogenous β-Carotene, Lutein, and Vitamin A in Human Plasma

**Mark A. Kelm[a], Vincent P. Flanagan[a], Robert J. Pawlosky[a,*], Janet A. Novotny[b], Beverly A. Clevidence[c], and Steven J. Britz[c]**

[a]Food Composition Laboratory, [b]Diet and Human Performance Laboratory, and [c]Phytonutrients Laboratory, Beltsville Human Nutrition Research Center, Beltsville, Maryland 20705

**ABSTRACT:** Quantitative procedures employing liquid-chromatography/particle beam–mass spectrometry (LC/PB–MS) and gas chromatography–mass spectrometry (GC–MS) were applied to the determination of the endogenous and $^{13}C$-labeled β-carotene, lutein, and retinol in plasma of a subject who consumed kale (*Brassica oleracea*) that had been grown in a $^{13}CO_2$-enriched atmosphere. All compounds were analyzed in the negative chemical ionization (NCI) mode using methane as the moderating reagent gas. β-Carotene and lutein were analyzed using LC/PB–MS applying reversed-phase high-performance liquid chromatography (HPLC) separation procedures to resolve the analytes. The concentrations of the β-carotene isotopomers in the plasma over a several-week period were determined using $^2H_8$-β-carotene as an internal standard. The total plasma concentrations of all *trans*-lutein were quantified by HPLC analysis with a photodiode array detector using β-apo-8′-carotenal as an internal standard, and the ratio of the $^{13}C$:$^{12}C$ isotopomers of lutein was determined by PB–MS. The retinol isotopomers were collected from individual HPLC fractions of the plasma extract and then analyzed as the trimethylsilyl ethers by GC–MS in the NCI mode. The $^{13}C$- and $^{12}C$-retinol isotopomers were quantified using $^2H_4$-retinol as an internal standard. These methods demonstrate the application of highly sensitive procedures employing NCI MS for the quantitative determination of carotenoids and vitamin A for the purpose of conducting metabolism studies of phytonutrients.

Paper no. L8831 in *Lipids 36*, 1277–1282, (November 2001).

The nutritional importance of β-carotene and vitamin A has been studied extensively and reviewed recently (1). In addition to the nutritional value of β-carotene as a provitamin A compound, carotenoids and related xanthophylls may possess other beneficial nutritional effects, such as those related to their antioxidant properties. Epidemiologic studies indicate that consumption of foods rich in these compounds may lower the risk of certain types of cancer (2), perhaps through the ability of some carotenoids to form stable radicals by scavenging phenoxyl radicals (3). It was shown recently in an *in vitro* study that lutein and zeaxanthin in the membranes of the retina may protect photoreceptor cells against ultraviolet (UV) light damage and chemically induced lipid oxidation (4). In this regard it has also been proposed that the consumption of foods enriched with these compounds may prevent the onset of age-related macular degeneration (5).

Several analytical methods, employing stable isotopically labeled compounds with mass spectrometry (MS) analysis, have been developed to study the metabolism of phytonutrients (6–11). For example, Pawlosky *et al.* (6) demonstrated the utility of a liquid chromatography/particle beam (LC/PB)–MS procedure to investigate the uptake of $^2H_8$-β-carotene in a human subject. In another example, gas chromatography–combustion interfaced–isotope ratio MS was used to determine plasma concentrations of $^{13}C$-lutein in human subjects who were fed the labeled xanthophyll (7). Although this procedure has a high degree of sensitivity, it is somewhat labor intensive and requires several purification steps as well as saponification and catalytic hydrogenation before mass spectral analysis. An atmospheric pressure chemical ionization LC–MS method was used to determine the bioavailability and conversion of β-carotene to retinol in humans after oral administration of $^{13}C_{10}$-retinyl palmitate and $^{13}C_{10}$-β-carotene (8).

These study designs are limited in their scope in that the compounds were administered in purified form rather than as an integral part of a food substrate. Nutrients that are obtained from foods may be absorbed and metabolized somewhat differently compared with oral administration of purified compounds. For example, Castenmiller and co-workers (12) estimated that the bioavailability of β-carotene from fresh whole-leaf spinach was only ~5% compared with the availability of the carotenoid when given as a dietary supplement. The use of intrinsically labeled foods in metabolism studies has the potential to furnish direct information regarding the uptake and metabolism of nutrients from specific foods and/or from foods that have undergone different means of preparation. The production of plant materials for such purposes by growing them in a $^{13}CO_2$ atmosphere and other methods of labeling plants are discussed in a review (13).

In support of potential human nutrition investigations, three methods utilizing negative chemical ionization (NCI) MS were advanced for the determination of endogenous

($^{12}$C-compounds) and $^{13}$C-labeled β-carotene, lutein, and retinol (derived from the labeled β-carotene) in plasma from a subject who was fed $^{13}$C-labeled kale. In the development of these procedures, modifications were made to two independent HPLC methods employing in-line particle-beam negative ion MS for the determination of the carotenoids and xanthophylls in plasma. The determination of the retinol isotopomers from plasma was carried out using labeled internal standards by GC–MS with NCI detection.

## MATERIALS AND METHODS

*Kale*. For this study, kale (*Brassica oleracea* cv. Vates) was grown in an airtight acrylic chamber with an atmosphere of 400 ppm $^{13}CO_2$ (99%) for 7–9 d after unfolding of the first true leaves, ~5 d after emergence of the seedlings. Growth conditions were 25°C air temperature, 10°C dewpoint, and continuous light at 800 mmol/($m^2 \cdot s$) photosynthetic photon flux density (400–700 nm) from a 50:50 mixture of 400 W metal halide and high-pressure sodium lamps. Plants were cultivated in vermiculite subirrigated with a complete nutrient solution. Only plant parts above the first true leaves were harvested for feeding studies. On the basis of the mass spectrometric analysis of the carotenoids from the labeled kale, there was >98% enrichment of $^{13}$C in β-carotene and lutein, with ~60% of that in the form of the $^{13}C_{40}$ isotopomers, which were the principal isotopes used in the quantitative determination of the nutrients in the plasma in this study.

*Human study design and plasma sample collection*. The protocol for the design of the human study was approved by the Johns Hopkins University, School of Hygiene and Public Health, Committee on Human Research. Plasma from a male subject who had consumed steamed $^{13}$C-kale (400 g) was prepared from blood that was drawn periodically from the forearm. Plasma was separated from blood cells using a clinical centrifuge at 3000 × *g*, frozen in 0.5-mL aliquots, and stored at –60°C until analyzed.

*Plasma extraction procedure*. The internal standards (Fig. 1) were obtained from commercial sources and assayed for their purity using HPLC and either LC– or GC–MS. Standards were stored at –60°C in $CH_2Cl_2$. Individual quantities of the standards were added to the plasma (400 mL) in 130 mL of diethyl ether. The amounts of the internal standards that were added to the samples were as follows: $^2H_4$-retinol (125.2 ng; Cambridge Isotope Labs, Woburn, MA), $^2H_8$-β-carotene (36.56 ng; Cambridge Isotope Labs), and β-apo-8′-carotenal (146.5 ng; (Sigma, St. Louis, MO). The samples were vortex-mixed for 30 s and then allowed to equilibrate with the internal standards for 30 min at 4°C. All solvents that were used were HPLC grade. The analytes were extracted into hexane according to a previously published method (6). The hexane extracts were combined and the solvent was evaporated under a stream of $N_2$. The samples were dissolved in 200 mL of the HPLC mobile phase (65:10:25, acetonitrile/methanol/dichloromethane plus 0.1% diisopropylethylamine) used for the β-carotene analysis and stored at –60°C until analyzed. Aliquots (50 mL) were injected onto an HPLC interfaced with a PB-MS (5989 mass spectrometer, Hewlett-Packard, Palo Alto, CA).

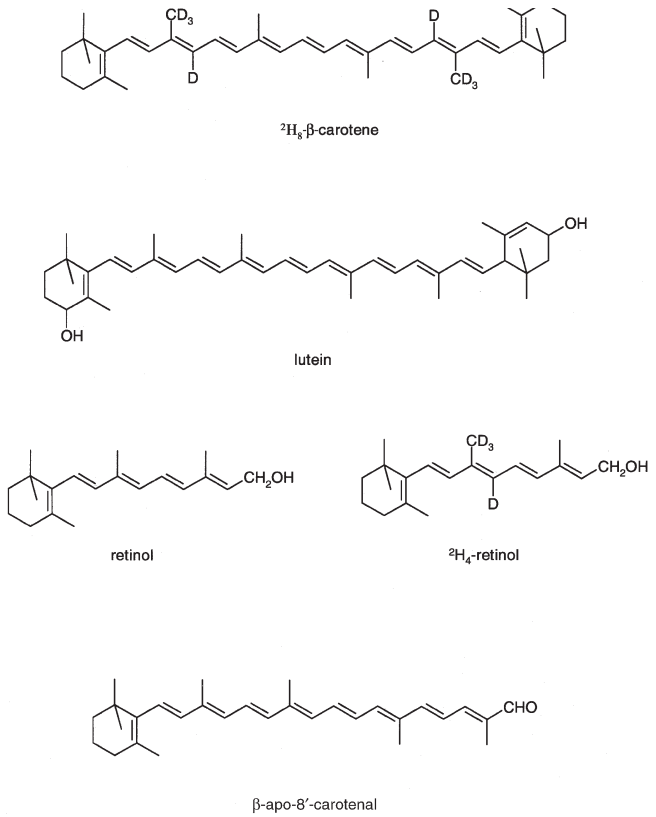

**FIG. 1.** Chemical structures of the analytes and internal standards that were investigated in the study: $^2H_8$-β-carotene, all *trans*-lutein, retinol, $^2H_4$-retinol and β-apo-8′-carotenal.

*Mass spectral analyses. (i) HPLC apparatus*. Separate HPLC procedures were used for the analysis of β-carotene and lutein. The HPLC system consisted of a Beckman Model 114M solvent delivery module equipped with a Beckman Model 421 controller that was interfaced to a Hewlett-Packard 1040M Series II ultraviolet/visible (UV/VIS) photodiode array detector. The data were stored and processed on a Hewlett-Packard 9000 Chem Station data system. Absorption spectra of analytes were recorded between 200 and 600 nm at a rate of 12 spectra/min.

*Analysis of β-carotene isotopomers by LC/PB–MS*. The principal procedures for the determination of β-carotene from plasma using PB–MS may be found elsewhere with the additional modifications that are noted here (6). Briefly, the concentrations of the endogenous β-carotene and $^{13}C_{40}$-β-carotene in the plasma were quantified using $^2H_8$-β-carotene as the internal standard. A standard reference material (SRM) of serum, which consisted of a set of samples certified for β-carotene at two different concentrations (SRM # 968c, National Institute of Standards and Technology, NIST, Gaithersburg, MD) was analyzed together with the samples and used as an internal laboratory control.

(ii) *Fraction collection and HPLC conditions for lutein analysis*. To resolve the all *trans*-lutein isomer from other naturally occurring *cis-trans* isomers of the xanthophyll present in the plasma, specific fractions of the β-carotene HPLC effluent (elution-time fractions from 5.5 to 10.5 min) containing the lutein isotopomers and β-apo-8′-carotenal (~2.5 mL) were collected. The solvent was evaporated under $N_2$ and the sample was brought up in 50 mL of the lutein mobile phase; 35 mL was injected onto a 250 × 4.6 mm, 5 µm VYDAC 201TP column (Phenomenex, Torrance, CA) using acetonitrile/methanol/hexane (86:8:5 with 0.1% diisopropylethylamine) as the mobile phase with a flow rate of 0.7 mL/min. The column temperature was maintained at 15.5°C (Thermo Haake, Paramus, NJ). A standard dilution curve of lutein was prepared using β-apo-8′-carotenal as an internal standard (ISTD) throughout a range of concentrations that incorporated typical plasma values (range: 0.023–0.19 mg/mL). Total plasma concentrations of lutein were then determined using the ratios of the UV absorbances (at 450 nm) of β-apo-8′-carotenal/lutein, which were interpolated from the standard curve ($y = 0.040x + 0.092$, $R^2 = 0.996$). The HPLC effluent was then delivered into the particle beam mass spectrometer and the concentrations of the $^{12}C_{40}$ and $^{13}C_{40}$ isotopomers were determined using the ratios of the ion abundances for $^{12}C_{40}$-lutein (*m/z* 568) and $^{13}C_{40}$-lutein (*m/z* 608).

*(iii) PB–MS conditions*. The mass spectrometer was operated in the negative ion mode using methane as the moderating gas according to a previously published procedure (6). The analytes were detected using selected ion monitoring (SIM) with the quadrupole mass filter focused to transmit the radical anions ($M^{\bullet -}$) for $^{12}C_{40}$-β-carotene (*m/z* 536), $^{13}C_{40}$-β-carotene (*m/z* 576), and the ISTD $^2H_8$-β-carotene (*m/z* 544) and for $^{12}C_{40}$-lutein (*m/z* 568) and $^{13}C_{40}$-lutein (*m/z* 608) that were produced under these conditions.

*(iv) Retinol fraction collection, derivatization, and quantification*. The HPLC fractions containing the retinol isotopomers ($^{12}C_{20}$-retinol, $^{13}C_{20}$-retinol, and $^2H_4$-retinol) were collected from the β-carotene mobile phase effluent (elution times from 5.5 to 6.5 min) for GC–MS analysis. The fractions were reduced to dryness at 40°C under a stream of $N_2$. To the residue was added 20 µL of a 1:1 mixture of *N*,*O*-bis(trimethylsilyl) trifluoroacetamide (BSTFA; Pierce, Rockford, IL) and pyridine. The solution was heated to 60°C for 30 min and the excess reagent was removed under a stream of nitrogen at room temperature. The residue was dissolved in 30 µL of isooctane containing 1% BSTFA/pyridine reagent. The plasma concentrations of $^{13}C_{20}$-retinol and the endogenous retinol were determined by obtaining the ratio of the peak area counts of the internal standard to those of the analytes. Together with the study samples and according to the procedures developed for the β-carotene analysis, the SRM 968c serum samples (NIST) were analyzed for all *trans*-retinol and included as internal controls to determine the overall accuracy of the method. A standard dilution curve of $^{12}C_{20}$-retinol was prepared throughout a range that included typical plasma concentrations of vitamin A (0.105–3.4 mg/mL) using $^2H_4$-retinol as the internal standard ($y = 0.03x - 0.04$; $R^2 = 0.999$).

*(v) GC–MS conditions*. The retinol isotopomers were analyzed on a Varian 3400 gas chromatograph (Walnut Creek, CA) interfaced to a Finnigan-Mat (San Jose, CA) TSQ-700 triple-stage quadrupole mass spectrometer. Samples (1 mL) were injected onto a 14 m × 0.25 mm DB-1701 (J&W Scientific, Rancho Cordova, CA) in the splitless mode. The injection port temperature and transfer line were maintained at 250 and 280°C, respectively. The oven was heated from 100 to 250°C at 21°C/min with helium carrier gas velocity of 70 cm/s. The retinol trimethylsilyl derivatives eluted at 8.9 min. The mass spectrometer was operated in the NCI mode with methane as the moderating gas. The quadrupole mass filter was scanned in the SIM mode for the loss of trimethylsilanol (TMSOH, 90 amu) from the respective analytes of retinol (*m/z* 268), $^2H_4$-retinol (*m/z* 272), and $^{13}C_{20}$-retinol (*m/z* 288).

## RESULTS

*Determination of β-carotene isotopomers in the plasma*. The ion current tracings depicting an illustrative example of an analysis of the three isotopomers of β-carotene ($^2H_8$-β-carotene, $^{13}C_{40}$-β-carotene, and $^{12}C_{40}$-β-carotene) from a plasma extract are given in Figure 2. Under these HPLC conditions, the carotenoids eluted at ~27 min. The somewhat earlier elution time of the $^2H_8$-β-carotene (*m/z* 544) is not unusual because under these chromatographic conditions, a slightly different chemical partitioning of the partially deuterated species takes place between the stationary and mobile phases compared with the protonated analog. The concentrations of $^{13}C_{40}$-β-carotene and $^{12}C_{40}$-β-carotene isotopomers in the plasma were calculated using the ratio of the area counts of the internal standard to that of the analyte as described previously (6). Selected time points for the determinations of the β-carotene isotopomers are given in Table 1. The levels of $^{13}C_{40}$-β-carotene ranged from below the detection limits to 0.0490 nmol/mL (Table 1). The concentration of $^{13}C_{40}$-β-carotene attained a maximum value 48 h after the subject consumed the kale. The mean value for the concentration of endogenous $^{12}C_{40}$-β-carotene in the plasma of this subject over the time period was 0.2945 ± 0.0412 nmol/mL (Table 1).

*Analysis of lutein isotopomers in the plasma*. Figure 3 depicts the UV tracing (at 450 nm) of the elution order profile of an HPLC chromatogram (C-18 VYDAC column) from a plasma extract that contains lutein and β-apo-8′-carotenal. The total concentration of all *trans*-lutein in the plasma over the time course (for the major isotopomers $^{12}C_{40}$, $^{13}C_{40}$, $^{13}C_{39}$, and $^{13}C_{38}$) was interpolated from the standard dilution curve using the ratio of peak area counts of the β-apo-8′-carotenal and lutein. The plasma concentrations for the $^{12}C_{40}$-lutein and $^{13}C_{40}$-lutein isotopomers were then determined from this preliminary value using the isotope ratios of the ions at *m/z* 568 ($^{12}C_{40}$-lutein) and *m/z* 608 ($^{13}C_{40}$-lutein) (Fig. 4). Initially, it was observed that several isomers of the

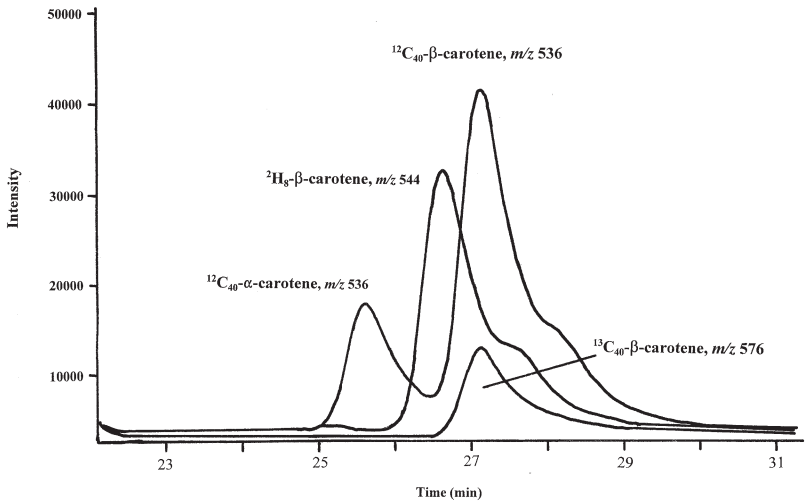

**FIG. 2.** Selected ion chromatographic tracings for $^{2}H_{4}$-β-carotene, $^{13}C_{40}$-β-carotene, and $^{12}C_{40}$-β-carotene from an 8-h plasma extract analyzed by liquid chromatography/particle beam–mass spectrometry.

xanthophyll (presumed to be various *cis-trans* isomers of lutein because of similarities in the UV profiles as well as similar chromatographic and mass spectral characteristics) eluted within a single chromatographic peak using the solvent system developed for the β-carotene analysis. One of these isomers was determined to be zeaxanthin on the basis of comparisons made with an authentic standard. The resolution of the all *trans*-lutein from the other xanthophyll isomers required an additional HPLC procedure, which was optimized to resolve the individual xanthophylls into distinct chromatographic peaks (Fig. 3). The mean plasma concentration of $^{12}C_{40}$-lutein throughout the time course was 0.1347 ± 0.0207 nmol/mL. The earliest time in which $^{13}C_{40}$-lutein was detected in the plasma was 4 h after the subject consumed the kale (Table 1) and $^{13}C_{40}$-lutein was no longer detected in the plasma after day 39.

*Determination of $^{12}C_{20}$-retinol and $^{13}C_{20}$-retinol in the plasma.* As described above, individual fraction cuts of the HPLC effluent from the β-carotene analysis were collected for the determination of retinol by GC–MS. The mean value of the plasma concentration of $^{12}C_{20}$-retinol was 1.4447 ± 0.2690 nmol/mL. The appearance of $^{13}C_{20}$-retinol in the plasma resulted from the metabolism of $^{13}C_{40}$-β-carotene. The $^{13}C_{20}$-retinol was first detected in the plasma 4 h after the subject consumed the kale (0.0052 nmol/mL). The plasma concentrations for $^{13}C_{20}$-retinol reached a maximum value at 8 h and were no longer detected beyond day 43.

## DISCUSSION

Three quantitative procedures employing MS were adapted from existing methods for the analysis of endogenous and $^{13}C$-labeled lutein, β-carotene, and retinol in the plasma of a subject who consumed $^{13}C$-labeled kale. The results reported here demonstrate the usefulness of labeled food substrates together with MS to investigate the metabolism of phytochemicals in humans. No attempt was made here to determine the bioavailability of these nutrients from the labeled kale; however, the stable isotope methods demonstrate the practicality of designing human studies to take advantage of similar approaches. A unique advantage of this study design is that it allows for the determination of carotenoids and xanthophylls derived from a single food. Such an approach may be useful, for instance, in assessing any potential effect that xanthophylls may have on β-carotene metabolism (14).

As reported previously (6), negative chemical ionization of carotenoids using methane as a moderating gas affords the superior degree of sensitivity that is required for the determination of femtomolar concentrations of these compounds in plasma. The application of this procedure has now been extended to the analysis of labeled xanthophylls, which also circulate in picomolar concentrations in the plasma. The low

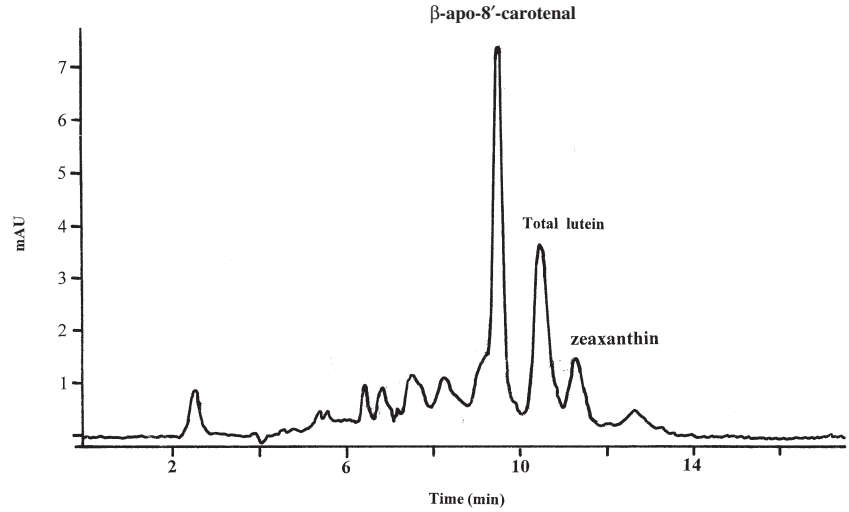

**FIG. 3.** An elution order profile on a high-performance liquid chromatography analysis of a plasma fraction extract containing all *trans*-lutein isotopomers as well as *cis-trans* isomers of lutein and β-apo-8′-carotenal. The compounds were resolved on a VYDAC column using a mobile phase consisting of 86:8:5 acetonitrile/MeoH/hexane 0.1% diisopropylethylamine 0.7 mL/min at 15°C and analyzed with a photodiode array detector (450 nm).

detection limits established for these analyses result from the highly conjugated system of double bonds that occur in these molecules, which have a high affinity for the low-energy thermal electrons that are generated in the methane plasma. This high degree of sensitivity may be required for the analysis of labeled carotenoids in plasma samples from subjects who have consumed a typical serving of labeled food. Moreover, the purification procedures and chemical workup routines do not involve an extensive degree of sample manipulation before mass spectral analysis, which also may have afforded lower detection limits (7,10).

A high degree of accuracy was noted for the determination of both β-carotene and retinol using the isotopically labeled internal standards. For example, there was only a 10% difference in the values determined using the LC/PB–MS method (0.141 mg/mL) compared with the certified value (0.157 mg/mL) for all *trans*-β-carotene in the SRM. Similarly, there was only a 7% difference in the values obtained for retinol compared with the certified concentrations. Moreover, the determinations for both β-carotene and retinol were within the 95% confidence interval established for these analytes by the Institute issuing the reference materials. In the analysis of

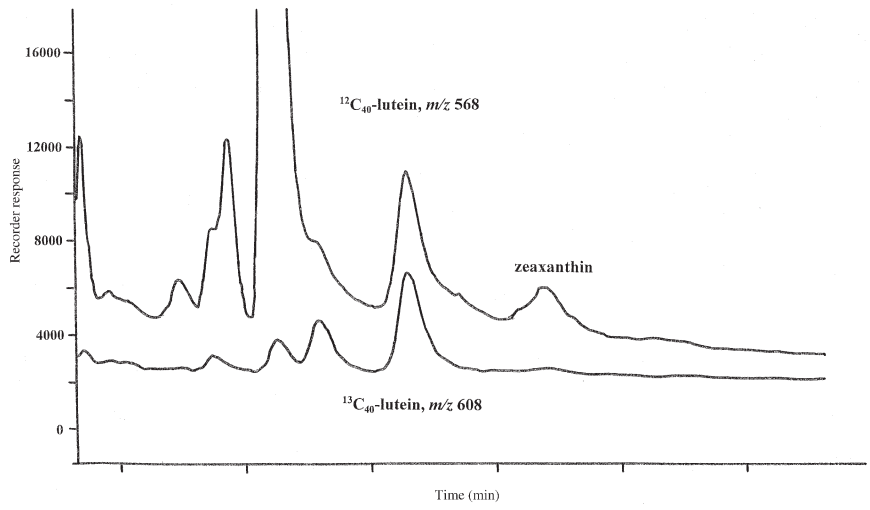

**FIG. 4.** The corresponding selected ion tracing of the plasma extract that appears in Figure 3 using liquid chromatography/particle beam–mass spectrometry analysis. The retention time for all *trans*-lutein is 10.7 min, and chromatographic peaks at *m/z* 568 and 608 represent the all *trans*-$^{12}C_{40}$-lutein and all *trans*-$^{13}C_{40}$-lutein, respectively.

the lutein isotopomers, an additional chromatographic procedure was required to resolve all *trans*-lutein from the other closely eluting *cis-trans* isomers. The resolution of these isomers was essential for establishing the precise identity of the xanthophyll and for the accurate determination of concentration of the *trans*-lutein isotopomers.

The three mass spectral procedures described herein demonstrate the practicability of adapting various analytical strategies to investigate the metabolism of phytonutrients utilizing intrinsically labeled foods. The rapid sample extraction and purification procedures coupled with the superior sensitivity of NCI MS methodology result in a quantitative method for determining trace quantities of analytes in plasma. These methods may be adapted to large-scale human or animal studies for the purpose of assessing the fate of plant nutrients in metabolism studies.

# Comparison of the Bligh and Dyer and Folch Methods for Total Lipid Determination in a Broad Range of Marine Tissue

**Sara J. Iverson*, Shelley L.C. Lang, and Margaret H. Cooper**

Department of Biology, Dalhousie University, Halifax, Nova Scotia B3H 4J1, Canada

**ABSTRACT:** For many studies, it is important to measure the total lipid content of biological samples accurately. The Bligh and Dyer method of extraction was developed as a rapid but effective method for determining total lipid content in fish muscle. However, it is also widely used in studies measuring total lipid content of whole fish and other tissues. Although some investigators may have used modified Bligh and Dyer procedures, rarely have modifications been specified nor has their effectiveness been quantitatively evaluated. Thus, we compared this method with that of the classic Folch extraction in determining total lipid content of fish samples ranging from 0.5 to 26.6% lipid. We performed both methods as originally specified, i.e., using the chloroform/methanol/water ratios of 1:2:0.8 and 2:2:1.8 (before and after dilution, respectively) for Bligh and Dyer and of 8:4:3 for Folch, and with the initial solvent/sample ratios of (3+1):1 (Bligh and Dyer) and 20:1 (Folch). We also compared these with several other solvent/sample ratios. In samples containing <2% lipid, the results of the two methods did not differ. However, for samples containing >2% lipid, the Bligh and Dyer method produced significantly lower estimates of lipid content, and this underestimation increased significantly with increasing lipid content of the sample. In the highest lipid samples, lipid content was underestimated by up to 50% using the Bligh and Dyer method. However, we found a highly significant linear relationship between the two methods, which will permit the correction of reported lipid levels in samples previously analyzed using an unmodified Bligh and Dyer extraction. In the future, modifications to procedures and solvent/sample ratios should be described.

Paper no. L8731 in *Lipids 36*, 1283–1287 (November 2001).

The total lipid content of biological samples is an important quantity used in many biochemical, physiological, and nutritional studies. Thus, reliable methods for the quantitative extraction of lipids from tissues are of critical importance. Natural lipids generally comprise mixtures of nonpolar components such as glycerides (primarily triacylglycerol) and cholesterol, as well as some free fatty acids and more polar lipids. Isolation, or extraction, of lipid from tissues is performed with the use of various organic solvents. In principle, the solvent or solvent mixture used must be adequately polar to remove lipids from their association with cell membranes and tissue constituents but also not so polar that the solvent does not readily dissolve all triacylglycerols and other nonpolar lipids (1). Folch *et al.* (2) were one of the first to recognize this and develop the chloroform/methanol/water phase system (the so-called "Folch" method), which, under various modifications, continues to be considered the classic and most reliable means for quantitatively extracting lipids. In the interest of economy, less exhaustive methods have been developed. By far the best known is the "Bligh and Dyer" method (3), which has become one of the most recommended methods for determining total lipid in biological tissues (4,5) and indeed has become the standard for lipid determination in many studies of marine fish (e.g., 1, 5–12) as well as for other types of samples such as milks (e.g., 13,14).

The primary advantage of the Bligh and Dyer method is a reduction in the solvent/sample ratio (1 part sample to 3 parts 1:2 chloroform/methanol followed by 1 or 2 parts chloroform) (1,3). In contrast, the Folch method employs a ratio of 1 part sample to 20 parts 2:1 chloroform/methanol, followed by several washings of the crude extract (2). Despite this solvent reduction, the Bligh and Dyer method is nevertheless thought to yield recovery of ≥95% of total lipids (1). Although the procedure was developed using cod muscle, it states (1,3) that it can be applied to any tissue containing (or modified to contain) 80% water. Hence, it has been used ubiquitously. Although the Bligh and Dyer method has undergone rigorous and favorable evaluations (e.g., 5,9,16), virtually all of these evaluations have been performed on samples containing less than 1.5% total lipid. Some studies report using a modified Bligh and Dyer method for lipid-rich samples; however, the modifications are often unspecified (e.g., 15), making the evaluation and comparison of results difficult. In other cases, investigators report the use of the Bligh and Dyer method even with samples having high lipid contents, but do not indicate that any modifications have been made. In the course of recent studies in our laboratory, we discovered that samples of a known high lipid content were greatly underestimated using the Bligh and Dyer method compared to the Folch method, although we did not detect any difference in the fatty acid composition under either method. Since much of the data published on the lipid contents of whole fish and other samples have been derived using the Bligh and Dyer method, we undertook a study to evaluate the relationship between these methods in their estimation of total lipid content.

## MATERIALS AND METHODS

Fish and invertebrates were chosen to represent a wide range of lipid contents based on previous species estimates. A total of 36 individuals were used, which included pollock, herring, rock sole, rock fish, sculpin, octopus, and squid. Each whole animal was thoroughly ground and homogenous subsamples were taken for extraction. To increase the range of lipid contents evaluated, we also used weighed aliquots ($n$ = 9) of a homogenous mixture of ground commercial fish (originally containing 2% fat) and commercial fish oil. Weighed quantities of oil were added to produce mixtures ranging from an estimated 21 to 26% lipid. Our primary interest was to evaluate the Bligh and Dyer method compared to the Folch method, but because of the high solvent volumes used in the Folch, we also evaluated the performance of a reduced-solvent Folch using a subset of these samples. Within each method, all samples were extracted and lipid contents were quantified in duplicate.

The Bligh and Dyer extraction was performed as originally outlined using the following ratios (1,3): Briefly, 100 g sample containing (or adjusted to contain) 80 g water (as determined by oven drying separate aliquots) is homogenized with 100 mL chloroform and 200 mL methanol (monophasic system). The solution is rehomogenized with 100 mL chloroform, following which 100 mL of either distilled water (3) or weak salt solution (e.g., 0.88% NaCl or KCl) (1,9) is added. After filtration is performed under suction, the final biphasic system is allowed to separate into two layers and the lower (chloroform) phase is collected. For quantitative lipid extraction (3), the tissue residue is then rehomogenized with 100 mL chloroform, filtered, and the filtrate added to the lower phase collected. Lipid content is then determined gravimetrically after evaporating a measured aliquot of the combined chloroform phase to dryness under nitrogen (see below). As Bligh and Dyer stated (3,16), the above volumes can be scaled down, as long as the critical ratios of chloroform, methanol, and water (1:2:0.8 and 2:2:1.8, before and after dilution, respectively) and of initial solvent to tissue [(3 + 1):1] are kept identical. Thus, we followed the above procedures but reduced the scale of all components (i.e., keeping all ratios the same) for use with a smaller sample amount (4 g sample in a 40 mL conical glass centrifuge tube), to allow both centrifugation of the final biphasic system and collection of the entire lower phase for evaporation and subsequent lipid estimation. Instead of applying manual pressure (3) to the small filter cake, we performed a second chloroform wash to improve removal of residual lipid during filtration.

The Folch extractions were performed as described, using the original extraction ratio of 20 parts 2:1 chloroform/methanol to 1 part tissue, which can be done on any scale that is technically feasible (2). A weak salt solution (e.g., 0.58–0.88% NaCl or KCl) is then added to achieve a final ratio of 8:4:3 chloroform/methanol/water after including the water contained in the tissue (1,2). We also compared the original ratio against a modified version using 30 parts 2:1 chloroform/methanol to 1 part tissue (1). After verifying that the 20:1 and 30:1 solvent/sample ratios produced similar results in our samples ($n$ = 27, all <25% lipid; Fig. 1A), we analyzed the rest of the samples using only the 20:1 ratio as follows: 1.5 g tissue was homogenized with 30 mL 2:1 chloroform/methanol. Although Christie (1) reports improvement by first homogenizing with 10 mL methanol followed by 20 mL chloroform, we have tested both procedures without detecting differences (Iverson, S.J, Lang, S.L.C., and Cooper, M.H., unpublished results). The mixture was filtered and then washed several times with 2:1 chloroform/methanol, and 0.88% NaCl in water was added to the combined filtrate at a final ratio of 8:4:3 chloroform/methanol/water. Finally, we used a "reduced-solvent" Folch, where the ratios of solvent to sample were 7.5:1.0 (i.e., closer to that of the Bligh and Dyer method), but the chloroform/methanol/water ratio was kept the same (i.e., 8:4:3).

In all the above extractions (both Bligh and Dyer and Folch), the final biphasic system was centrifuged, and the entire lower phase (along with washings) was collected into a

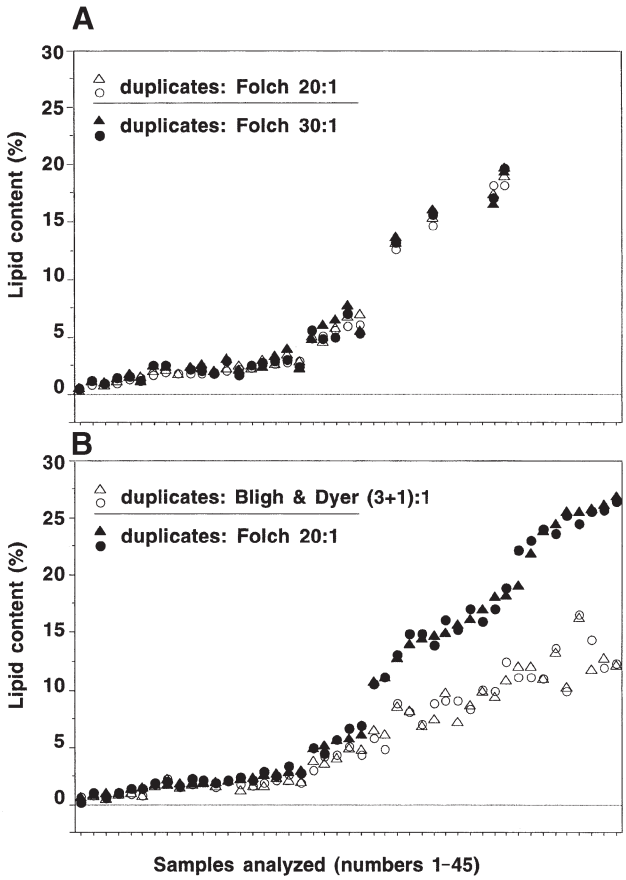

**FIG. 1.** Estimates of total lipid content determined in replicate aliquots: (A) samples ($n$ = 27) extracted using both a 20:1 and a 30:1 solvent/sample ratio Folch and (B) all samples ($n$ = 45) using the Bligh and Dyer method in comparison with the original Folch method. The last nine samples on the x-axis represent the homogenates of commercial fish and oil, which were produced to contain a range of 21–26% lipid. All samples were analyzed in duplicate in each of the extraction methods and are presented in approximate order of increasing lipid content.

preweighed glass tube and evaporated to dryness in an analytical high-speed nitrogen evaporator (24-position N-EVAP 112, Organomation Associates, Inc., Berlin, MA) fitted with stainless steel 14-in. × 19-gauge needles and equipped with a thermostatically controlled water bath maintained at 25–30°C. The nitrogen stream was continually moved so that it actively disturbed the evaporating surface of the sample until all detectable traces of solvent were gone. To remove all final traces of solvent and water, the sample tube was then wiped dry and placed in a sealed glass vacuum tube and flushed with nitrogen, and vacuum suction was applied for 5 min (BOC Edwards model RV3 vacuum pump; Crawley, West Sussex, United Kingdom). Lipid content was then determined gravimetrically. Since results of the Folch method using 20:1 or 30:1 solvent/sample ratio did not differ, we used the results from the 20:1 Folch method as the basis for comparison with and evaluation of the other extraction methods.

## RESULTS

In general, duplicate analyses within each extraction method were very consistent, although more so for Folch extractions ($n$ = 45, Fig. 1B). In samples containing <2% lipid ($n$ = 11), results for the Bligh and Dyer method did not differ from those obtained by the Folch method ($P$ = 0.150, paired $t$-test). However, for samples containing >2% lipid ($n$ = 34), the Bligh and Dyer estimates of lipid content were significantly lower than those of Folch ($P$ < 0.0001). In our nine samples of fish oil–supplemented homogenates, lipid content estimates (20.6–26.6%) using Folch extraction concurred with our estimated lipid contents (21–26%, as discussed in the Materials and Methods section); however, lipid content estimates using the Bligh and Dyer extraction were 50% lower (Fig. 1B). The next-highest lipid contents were found in herring samples ($n$ = 12, 10.7–18.6% lipid by Folch), which were estimated to be about 45% lower (6.1–11.6% lipid) using the Bligh and Dyer method.

The underestimation of lipid content by the Bligh and Dyer method increased significantly with increasing lipid content (Fig. 2A). From 0% to approximately 2% lipid, results of the two methods agreed well. However, with increasing lipid content, the deviation from the one-to-one reference line increased. We were interested in describing the predictive relationship between the two methods to allow correction of previous lipid content analyses that we had performed using the Bligh and Dyer method. Using a log–log plot, we found a highly significant linear relationship between lipid content determined by the Folch method and that determined by the Bligh and Dyer method (Fig. 2B).

The results of the reduced-solvent Folch (7.5:1.0 solvent/sample ratio) were highly correlated with both the 20:1 and 30:1 Folch ($r$ = 0.999, $n$ = 34, and $r$ = 0.987, $n$ = 27, respectively); however, the reduced-solvent method tended to underestimate lipid content as lipid content increased. In samples containing ≤3% lipid ($n$ = 19), there was no significant difference between the Folch extractions using the 20:1 vs.

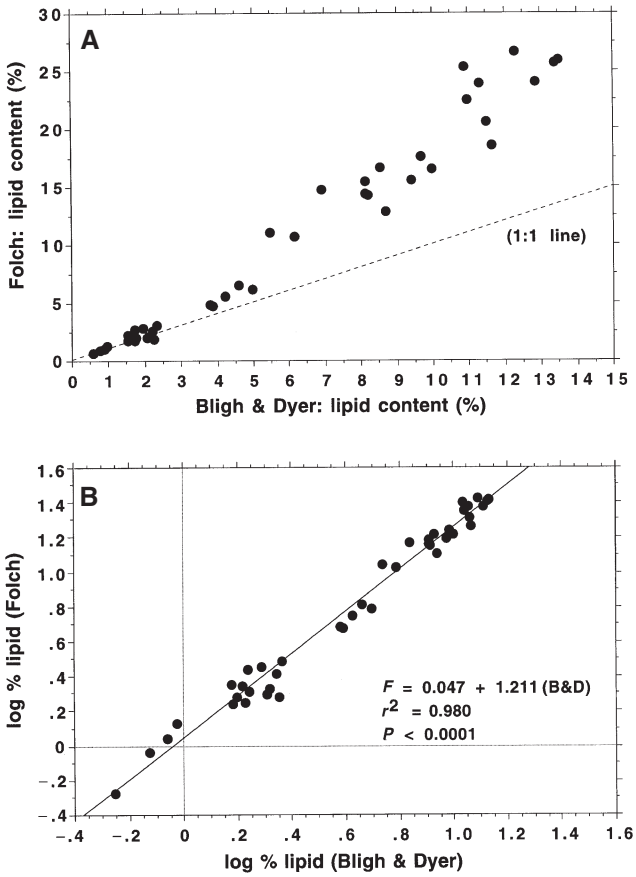

**FIG. 2.** (A) Correlation of the estimates of lipid content (duplicates averaged) in 45 samples using the Folch (20:1) vs. Bligh and Dyer methods ($r$ = 0.9834, $P$ < 0.0001); the dashed line represents the one-to-one reference line. (B) The log–log predictive relationship between estimates of lipid content using the Folch (F) vs. the Bligh and Dyer (B&D) method.

the 7.5:1 solvent/sample ratios (1.9 ± 0.16% vs. 1.9 ± 0.18% lipid, respectively; $P$ = 0.9559, paired $t$-test), but in samples containing >3% lipid ($n$ = 15), the reduced-solvent Folch significantly underestimated lipid content (10.7 ± 1.18% vs. 12.0 ± 1.30%, $P$ < 0.0001). The lipid content estimates of these same 15 samples, using the Bligh and Dyer method, were even lower at 7.2 ± 0.65% lipid. In the highest-lipid natural fish sample tested (herring), lipid content was estimated as 18.6, 16.4, and 11.6% using the 20:1 Folch, the 7.5:1.0 Folch, and the Bligh and Dyer methods, respectively.

## DISCUSSION

In the time since the Folch (2) and the Bligh and Dyer (3) methods for total lipid determination were published, there have undoubtedly been numerous modifications to both methods to improve the efficiency of lipid recovery from various tissues. However, in many publications where these methods have been used, modifications have been neither described nor validated. In other cases, investigators stated that lipids were quantified "according to" one or the other method, but they do not indicate whether any modifications were made,

implying that the methods were applied basically according to the original procedures, even though that may not have been the case. Given that many conclusions about tissue and whole-body lipid and energy values are based on published lipid contents, our purpose was to evaluate these two methods, as originally described, with the aim that investigators could evaluate previously published data and that appropriate modifications would be made and described in the future.

In numerous tests with samples containing <2% lipid, the Bligh and Dyer method has been shown to be very effective and reliable (4,5,9,16). Like other investigators (5), we found that lipid extraction using the Bligh and Dyer method produced estimates of total lipid content identical to those of Folch in samples containing <2% lipid. We also did not detect any differences in the subsequent fatty acid composition of duplicate samples extracted under either method, although this may require further investigation in very low fat samples that contain a higher phospholipid/neutral lipid ratio (e.g., alkali hydrolysis followed by methylation and fatty acid quantitation could also be used to examine any biases in total fatty acid recovery). However, in contrast to low-lipid samples, in all samples containing >2% lipid, the Bligh and Dyer method produced significantly lower estimates of lipid content, and this underestimation increased with increasing lipid content of the sample.

We have several reasons to believe that the total lipid contents of all samples were accurately determined using the Folch extraction method. First, as stated above, in low-lipid samples both the Folch and Bligh and Dyer results were identical. Second, the estimates of percent lipid in the high-lipid fish oil–supplemented homogenates, using the basic Folch extraction, agreed with our calculated lipid contents; furthermore, an increased (30:1) solvent/sample ratio Folch produced the same values. Finally, these homogenates were also analyzed for protein content (by macro-Kjeldahl), as well as dry matter (Cooper, M.H., unpublished data). The amount of dry matter not accounted for by protein and lipid in these samples was reasonably consistent with expectation at 2–4% using the lipid values obtained by Folch extractions, but was quite high (14–20%) using the lipid values obtained by the Bligh and Dyer extractions.

Bligh and Dyer (3) developed their method using fish fillets (i.e., muscle) that generally contained low levels of lipid and a high proportion of phospholipid. In whole animals and in tissue, an increase in total lipid content is due predominantly to increases in triacylglycerol. Indeed, subsets of our isolated lipid subjected to thin-layer chromatography (17) showed that the primary component in the extract was triacylglycerol (especially as lipid content increases), followed by minor amounts of more polar lipid classes. Although Bligh and Dyer (3) stated that their method could readily be applied to other biological tissues, they, as well as others, acknowledged that lipid-rich samples may require modifications. For instance, Christie (1) suggested that very lipid-rich tissues such as adipose tissue and oil seeds should be extracted first with a nonpolar solvent such as diethyl-ether or chloroform, after which the remaining lipid could be recovered effectively using Bligh and Dyer methods. However, this appears to have often gone unrecognized. The total yield of lipids may be more reduced than most investigators have suspected, especially given the widespread use of apparently unmodified Bligh and Dyer extractions for whole fish and other tissues. Even in samples containing 2–10% lipid (which is common for many marine fish and invertebrates), underestimation will still be a significant problem (e.g., Fig. 1), and this has likely been neglected.

The reduced efficiency of the Bligh and Dyer method with increasing tissue lipid contents might be explained from several standpoints. One cause of reduced lipid yield at high lipid concentrations could be the limited solubility of the predominantly nonpolar lipids, such as triacylglycerols, in the seemingly relatively polar solvent solution (1:2 vol/vol chloroform/methanol) employed in the Bligh and Dyer method, which was designed chiefly to extract phospholipid efficiently. However, although the initial solvent ratios are different in the Bligh and Dyer vs. the Folch methods, they do not result in measurably different contents of methanol in the final organic (chloroform) phase (e.g., 16). Hence, this is not likely to be a significant factor. Smedes and Thomasen (16) found that the absorption of the organic phase by the tissue was one of the main causes of incomplete lipid yield. Relatively constant amounts of the organic phase are absorbed by the tissue such that using greater volumes of organic-phase solvents reduces the fraction of the organic phase that is lost in this manner (16). When tissues with increasing lipid contents are extracted (using the same volumes of solvents), the lipid concentration in the organic phase should also increase, assuming that limits of solubility are not reached. This would result in increased loss of lipid in the fraction of organic phase absorbed by the tissue, causing a reduction in final lipid yield. Thus, in addition to maintaining critical solvent and water ratios, perhaps the most important consideration is simply the ratio of solvent to dry-weight sample (and expected fat content), as even with the Folch method, a reduced ratio produced significant underestimates of lipid content.

Our results do indicate that all methods used to estimate lipid contents were highly correlated. Fortunately, there is a highly predictable relationship between the Bligh and Dyer and Folch methods (Fig. 2B), potentially allowing correction of reported values from previous analyses that used an unmodified Bligh and Dyer extraction. It may also be the case that investigators have used a modified Bligh and Dyer extraction employing an increased solvent/sample ratio that produced reliable results and have simply not stated this. It will be important in the future that investigators specify modifications to any of these procedures, especially the precise solvent/sample ratio used. For instance, although an increase in the solvent/sample ratio (i.e., to 30:1) from the original Folch did not appear to alter the estimated lipid content significantly (Fig. 1A), we would not recommend making this assumption for tissues containing greater than 25% lipid (i.e. adipose tissue, milks of many species) unless verified. In such samples,

a further increase in the solvent/sample ratio and/or further multiple extractions may be necessary for quantitative lipid evaluation (e.g., 1), as we have found for marine mammal milks (Iverson, S.J., personal communication).

## ACKNOWLEDGMENTS

This study was supported by grants to Sara J. Iverson from the *Exxon Valdez* Oil Spill Trustee Council, Alaska, and by the Natural Sciences and Engineering Research Council (NSERC, Canada). We thank Lindsay Smith for assistance with some sample analyses and Suzanne Budge for helpful comments. We are also grateful for the suggested improvements to the manuscript by the editor and three anonymous reviewers.

REVIEW

# Factors Affecting the Storage and Excretion of Toxic Lipophilic Xenobiotics

**Ronald J. Jandacek* and Patrick Tso**

The University of Cincinnati, Department of Pathology, Cincinnati, Ohio

**ABSTRACT:** Lipophilic toxins have been introduced into the environment both as functional compounds, such as pesticides, and as industrial waste from incineration or the manufacture of electrical transformer components. Among these substances are compounds that are carcinogenic and that affect the endocrine system. Accidental high exposures of humans to some lipophilic toxins have produced overt disease symptoms including chloracne and altered liver function. These toxic materials have been the recent focus of international effort to reduce or eliminate classes of halogenated hydrocarbons from the environment. Evidence of the widespread distribution of lipophilic toxins in the biosphere has been obtained by analyses of human tissues and human milk. The principal route of entry of lipophilic toxins into humans is through the food chain, and most of them are stored in adipose tissue. A common route of excretion is in bile, but there is also evidence of nonbiliary excretion into the intestine. Enterohepatic circulation of many of these compounds slows their removal from the body. Substances that interrupt the enterohepatic circulation of compounds that enter the intestine by the biliary and nonbiliary routes increase the rate of their removal from the body and reduce their storage half-lives. Reduction in body fat, along with these dietary substances that interrupt enterohepatic circulation, further enhances the excretion rate. Areas for further research include optimizing regimens for body burden reductions, understanding the nature of nonbiliary excretion, and following the effects of tissue redistribution during loss of body fat.

Paper no. L8918 in *Lipids 36,* 1289–1305 (December 2001).

## BACKGROUND

Many lipophilic xenobiotic compounds enter the body and are deposited in adipose depots and other tissues. Several classes of these chemicals that are known to contribute to the risk of cancer and death enter the environment intentionally as pesticides or unintentionally as industrial by-products. Accidental exposure to high levels of some lipophilic toxins results in chronic disease affecting the liver and skin. An enormous amount of research has focused on the toxicity, carcinogenicity, developmental effects, endocrine effects, and other metabolic alterations by these compounds. For most of these compounds, a "no-effect" level has not been established. These substances have been detected in the tissues of essentially all humans and animals and may contribute to the risk of disease or altered development. The chemical stability of many of these xenobiotics has resulted in environmental accumulation and increasing concentrations in people and animals through dietary and respiratory intakes.

The presence of lipophilic toxins in the environment has received a high level international attention, scientific study, and governmental action. The awareness of the ubiquitous nature of toxic lipophiles has resulted in efforts to minimize their introduction into the environment. There also have been sporadic efforts to intervene at the level of the individual to reduce toxicity.

This paper reviews these interventions to help determine their potential utility as a complementary or alternative approach to environmental efforts to manage lipophilic toxins. The sections that follow first give a brief overview of the types of materials and the current environmental concerns. In addition, brief views of the absorption, tissue distribution, metabolism, and excretion of some representative compounds are presented to give a picture of the paths that lipophiles follow as they enter, move within, and ultimately leave an organism. Although the behavior of the compounds varies among classes and individual molecular species, it is possible to make some generalizations that help establish a basis for consideration of methods of intervention.

### Recent Efforts to Change the Environment

The United Nations (U.N.) sponsored a study of the presence and sources of lipophililic toxins in the environment and concluded that global production of 12 of these materials should be reduced or eliminated. The study led to a multinational treaty imposing reductions in the use and production of these persistent organic pollutants (POP). In May 2001, representatives of 127 countries including the United States agreed to this treaty. The treaty specifies the control of eight pesticides [aldrin, chlordane, DDT (dichlorodiphenyl-trichloroethane), dieldrin, endrin, heptachlor, mirex, and toxaphene], two industrial chemicals [polychlorinated biphenyls (PCBs), once used in electrical transformers; and hexachlorobenzene, formerly used in the manufacture of synthetic rubber and also as a fungicide], and two by-products of combustion and industrial processes (dioxins and furans). Structures illustrating the 12 POP that are the subject of the treaty are given in Figure 1. All of these substances are characterized by carbon-chlorine

Abbreviations: Ah, arylhydrocarbon; DDE, 1,1-dichloro-2,2-bis(chlorophenyl)ethylene; DDT, dichlorodiphenyl-trichloroethane; PBB, polybrominated biphenyl; PCB, polychlorinated biphenyl; POP, persistent organic pollutant; SPE, sucrose polyester; TCDD, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin.

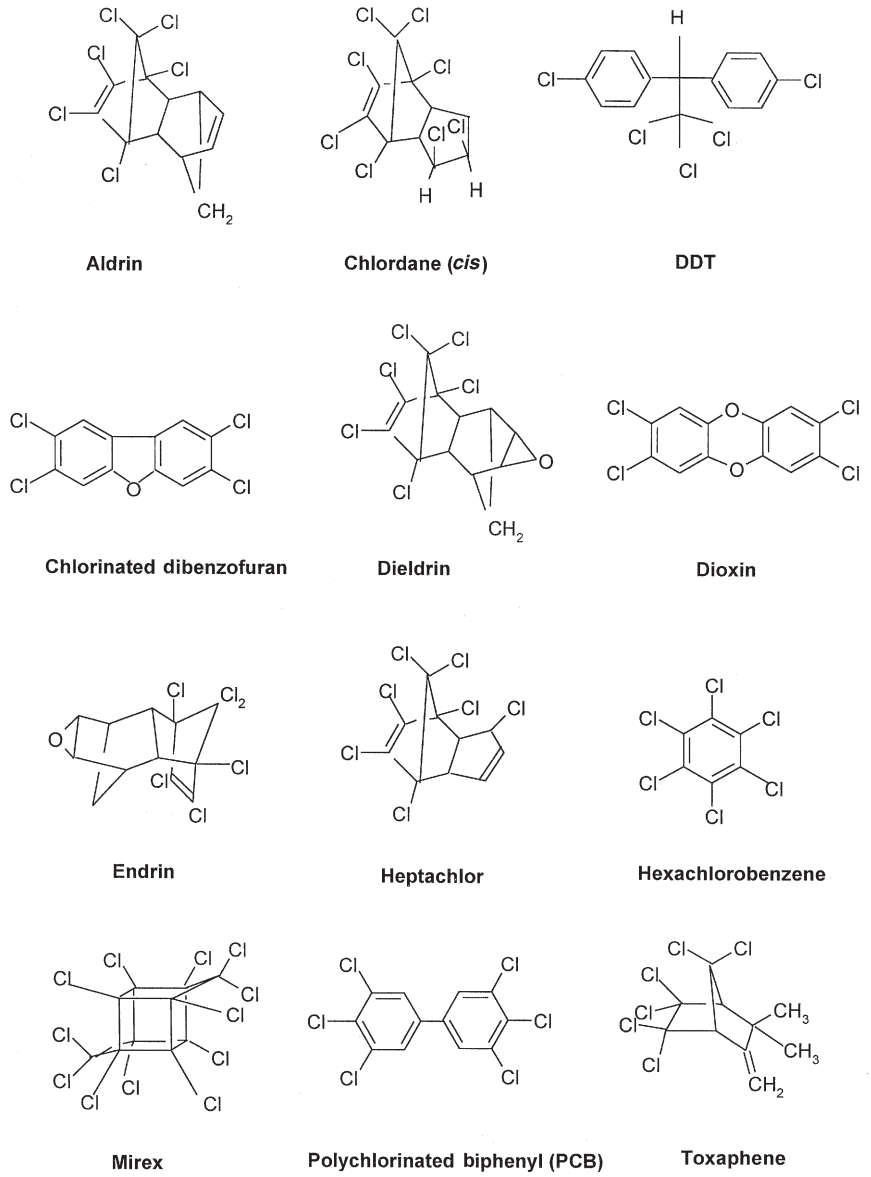

**FIG. 1.** Persistent organic pollutants included in the United Nations treaty.

bonds with stabilities that result in very long half-lives in the environment. Because of their stability and lipophilic character, these materials ascend the food chain from plants to deposition in fat depots and other tissues of higher organisms.

The principal focus for the international management of these materials in the environment has thus become that of elimination and reduction at the sources rather than intervention in individuals or populations with high levels of the materials. This approach does not affect the levels of toxic lipophiles that have already been deposited in the environment. An additional strategy is to find ways to hasten elimination of these substances from the body; to that end, studies have addressed the metabolism and excretion of many of these substances.

This interventional approach is key. The environment and the tissues of virtually all people in all countries already have a considerable burden of these persistent compounds, and it would be desirable to intervene to favorably alter their metabolic course. Finding the best ways to reduce body burdens of these materials is important since there is no consensus about the concentrations in tissues that might result in long-term detrimental health effects. For many of these compounds, a no-effect concentration has not been determined, and the possibility remains that any tissue concentration could increase the risk of disease. In addition to dealing with low-level, long-term exposure, there is a need for optimal treatment of the effects of acute exposure, such as that resulting from accidental ingestion or environmental accidents.

We review here interventions that could affect the absorption, distribution, metabolism, and/or excretion of lipophilic xenobiotic substances. These substances include the chlorinated compounds (POP) cited in the U.N. treaty as well as other lipophilic substances of known or putative toxicity.

## Lipophilic Toxins in the Environment

Numerous studies have determined the presence of various lipophilic materials in the environment and in humans. Since it is beyond the scope of this review to consider studies of lipophilic toxins in the environment, several studies are cited to illustrate the widespread distribution.

One of the most important and most studied substances that provide evidence for the widespread distribution of lipophilic toxins is human milk. A review by Jensen (1) documented the levels of organochlorine compounds including DDT and other contaminants in milk in samples from many countries. Levels in human milk are markedly higher than those in dairy milk as would be predicted from the human position at the top of the food chain. Substances other than DDT also appear in human milk. Hofvander *et al.* (2) reported measurable levels of DDT, DDE (the principal metabolite of DDT), PCBs, dieldrin, and hexachlorobenzene in human milk in Sweden. The primary concern about these toxins in human milk is their potential effect on children's health and development (3,4).

PCBs were used extensively as coolants and lubricants in electric transformers prior to 1977. Although their use was banned that year in the United States, they remain in the environment because of their resistance to chemical decomposition. Evidence for slow disappearance from the body was reported by Wolff and coworkers (5), who longitudinally followed PCB concentrations in capacitor manufacturing workers after PCB use at their manufacturing facility was discontinued. The levels of organochlorine pesticides and PCBs in butter from 23 countries were studied by Kalantzi and coworkers (6). They found a wide range of concentrations, with levels of DDT and its metabolites being highest in countries where this pesticide is still in use. Current levels of PCBs in chicken and pork in Belgium were found to be remarkably high—12% of samples contained more than 50 ng of PCBs/g of fat (7). These levels were unrelated to the contamination of animal feed cited below and were attributed to recycling of fat into animal feed.

The ubiquitous nature of POP is also seen in the very high levels of organochlorines from autopsy samples from Greenland Inuits who consumed high levels of sea mammal fat containing these substances (8). This finding is consistent with an environmental path that begins with an industrial source and ends with humans at the top of the food chain. Another view of the food chain was provided by a study of Kelly and Gobas (9). Organic pollutants in Arctic terrestial animals were traced from lichen to caribou and finally to wolf. They reported evidence for the biomagnification of hexachlorocyclohexane and tetrachlorobenzene *via* this food chain.

Environmental accidents have occurred that have contaminated geographical areas or groups of people. Polybrominated biphenyl (PBB) fire retardants were accidentally introduced into cattle feed that resulted in the contamination of Michigan dairy products and essentially all of the population of Michigan (10). Animal feed was contaminated by PCBs, dioxins, and furans in Belgium in 1999 (11). These exposures resulted in continuing surveillance programs to assess the effects of the toxins on health. In Japan in 1968, cooking oil contaminated with dioxins produced symptoms of chloracne, malaise, and joint pain that were designated as Yusho disease (12). A similar example was the tragic contamination of cooking oil with PCBs in Taiwan in 1979 (13).

Polynuclear aromatic compounds (polycyclic aromatic compounds) are another class of lipophilic toxins/carcinogens. Substances such as benzo(α)pyrene are produced in fossil fuel emissions and are carcinogenic in animals and humans (14,15). Compounds in this class are also found in meats cooked over coals or open flames. Two examples of this class of lipophilic toxins, benzo(α)pyrene and 7,12-dimethylanthracene are shown in Figure 2.

Phthalate esters are plasticizers that are present in numerous plastic/polymeric products around the globe. Phthalate esters are hepatocarcinogens in rats, presumably acting through peroxisome proliferation (16). The relevance of this effect to cancer in humans remains uncertain (17,18). Given the ubiquitous nature of this class of lipophilic compounds, the potential risks of phthalates remain a subject of concern and study (19). A commonly used phthalate ester plasticizer is presented in Figure 2.

These examples represent numerous studies of the widespread distribution of lipophilic toxins. They point out not only the global nature of the problem but also the extent of penetration into the biosphere.

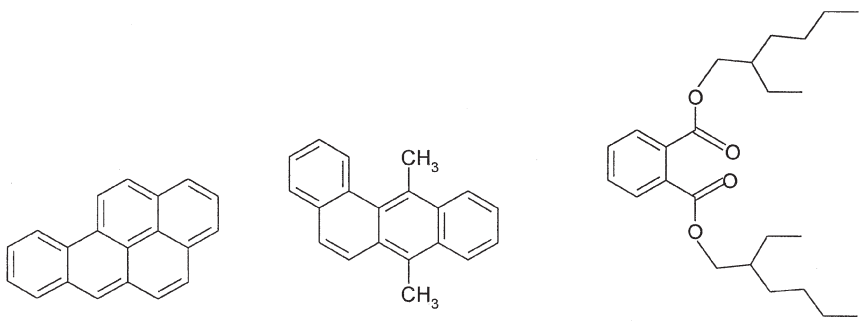

**FIG. 2.** Examples of polycyclic aromatic hydrocarbons and a commonly used phthalate ester plasticizer.

## Toxicity and Carcinogenicity

The results of studies sponsored by the United Nations and the subsequent treaty based on these studies are evidence of consensus about the risk to health of POP in the environment. Chlorinated hydrocarbon pesticides, PBBs, and the class of polycyclic aromatic hydrocarbons are included in the list of substances "reasonably anticipated to be human carcinogens" in the U.S. Department of Health and Human Services *9th Report on Carcinogens* (20). That report upgraded dioxins to the category of "known human carcinogens." Some examples of the many studies that have addressed the toxicity and carcinogenicity of lipophilic compounds are given below.

Among the first reports was that of Fitzhugh and Nelson (21), who studied the oral toxicity of DDT in rats. Mukerjee (22) reviewed the effects of dioxins, which are among the most toxic of the lipophiles, and noted the chloracne, changes in liver function, and associations of increased risk of cancer. Hexachlorobenzene promotes hepatocarcinogenesis in rats (23). Polycyclic aromatic hydrocarbons have been studied extensively and have been shown to cause DNA damage (see, e.g., 24) and to be associated with increased cancer risk (see, e.g., 14,25,26). Estrogenic effects of organochlorine compounds have been suggested to increase the risk of breast cancer, although recent studies have not supported this hypothesis (27). There are indications that other endocrine effects of these compounds may adversely affect health (28).

## Absorption, Distribution, Metabolism, and Excretion

### *Absorption*

Oral ingestion is generally the principal route of entry for lipophiles that ascend the food chain. Absorption by inhalation or through the skin is therefore of less importance when considering methods for intervening in the absorption process.

Studies of oral absorption of toxic lipophiles have utilized techniques and mechanisms associated with the absorption of dietary triacylglycerols, fat-soluble vitamins, and cholesterol. Dietary lipids enter the small intestine, are emulsified to small droplets in the presence of detergent bile salts, are hydrolyzed into more polar products (fatty acid and 2-monoacylglycerol) by pancreatic lipase, and are incorporated into mixed micelles with bile salts. Dietary fat increases the absorption of some lipophilic compounds through the formation of these mixed micelles that can effectively solubilize such compounds as cholesterol and vitamin E. Micelles transport not only the lipid digestion products but also lipophilic solutes to the enterocyte. In the enterocyte triacylglycerols are synthesized and incorporated into lipid-based particles that are stabilized with protein (chylomicrons). These chylomicrons are transported in lymph, which can be studied in thoracic duct-cannulated animals. Chylomicrons carry most lipophilic compounds that are absorbed from the intestine. They enter the blood circulation and are partially degraded to remnant particles by the action of lipoprotein lipase. Some of the components of the chylomicrons and their remnants are delivered to peripheral tissues prior to their uptake by the liver.

The nonpolar character of toxic lipophiles suggests a pathway of absorption and transport similar to that of the dietary fats and fat-soluble vitamins. Studies of the absorption of halogenated hydrocarbons are consistent with this pathway. Some studies of toxic lipophile absorption are summarized in Table 1.

### *Distribution*

Understanding the distribution of lipophilic toxins among tissues is an important area of research and has been the subject

**TABLE 1**
**Studies of the Absorption of Toxic Lipophiles[a]**

| Study design | Results | Reference |
|---|---|---|
| Lymph was collected from rats dosed with [$^3$H]2,3,7,8-tetrachlorodibenzo-*p*-dioxin. | 30% of dose appeared in lymph chylomicrons in 24 h. | 29 |
| [$^{14}$C]DDT in sunflower oil was dosed to thoracic duct-cannulated rats. | 63% of dose was in 72-h lymph collection, and 9% in feces. DDT was transferred to other lipoproteins from chylomicrons. | 30 |
| DDT was administered to rats in corn oil or in ethanol and the appearance in lymph was measured. | DDT absorption from corn oil was twice the absorption from ethanol as the vehicle. | 31 |
| [$^{14}$C]DDT, benzo(α)pyrene, octadecane, and hexadecane were administered to rats with thoracic duct cannulae. Chylomicrons were assayed and injected into recipient rats. | The compounds appeared in the triacylglycerol phase of chylomicrons. The labeled compounds in injected chylomicrons were taken up by high density lipoprotein in recipient animals. | 32 |
| Lymphatic absorption of a moderately lipophilic PCB congener was studied in sheep. | There was little lymphatic absorption. | 33 |
| Pregnant rats were fed hexachlorobenzene with high-fat and low-fat diets. Adipose tissue was assayed. | The amount of hexachlorobenzene found in the high-fat group fat was twice that of the low-fat group. | 34 |
| [$^3$H]Benzo(α)pyrene absorption was studied in rats with cannulated bile ducts and mesenteric lymph ducts. | Low concentration in lymph relative to bile was explained by metabolism of the benzo(α)pyrene to polar metabolites in the enterocyte and absorption *via* the portal vein. | 35 |

[a]Abbreviations: DDT, dichlorodiphenyl-trichloroethane; PCB, polychlorinated biphenyl.

**TABLE 2**
**Studies of the Tissue Distribution of Toxic Lipophiles[a]**

| Study design | Results | Reference |
|---|---|---|
| Autopsy samples from Greenlanders who consumed sea mammals were analyzed. | Chlorinated pesticides and PCBs accumulated in the liver, brain, and fat. | 8 |
| Rats were injected intravenously with [$^{14}$C]-2,3,7,8-tetrachlorodibenzo-*p*-dioxin. | Radioactivity was found in liver, white and brown adipose tissue, thyroid, and adrenals. | 42 |
| Octachlorodibenzo-*p*-dioxin was dosed orally to rats. | There was little conversion of the parent compound to metabolites. Most deposition was in adipose tissue, liver, and skin. | 43 |
| Mice lacking inducible hepatic binding protein, CYP1A2, were dosed orally with dioxin, dibenzofuran, and PCB. | Dioxin and dibenzofuran uptake by the liver was reduced in the knockout animals. | 44 |

[a]For abbreviation see Table 1.

of numerous studies. Although the distribution varies greatly among the compounds of interest, some generalizations can be made. Lipophilic toxins are transported in lipoproteins (36) but may be associated with albumin (37). Uptake and retention of lipophiles and their lipophilic metabolites depends on the lipid content of the tissue or compartment (38). The amount of uptake by the liver can be determined by the induction of systems such as the arylhydrocarbon (Ah) receptor and binding to the cytochrome P450 complex as in the case of dioxins (39). As seen in a study of dioxin pharmacokinetics, the determinants of the compound's disposition include lipophilicity, liver binding elements, diffusion-limited tissue distribution, and metabolic elimination (40). Presumably these determinants apply in varying degrees to most of the lipophilic toxins. The most lipophilic substances are absorbed *via* the lymph, are carried in lipoproteins, accumulate in adipose tissue, and are taken up by the liver and other tissues. Evidence that retention in adipose tissue influences the distribution to other tissues was seen in a study by Rozman *et al*. (41). In rats, hexachlorobenzene excretion decreased with increasing body weight and fat. Studies that illustrate the uptake by fat and liver are listed in Table 2.

### *Metabolism*

The persistence of many lipophilic compounds in the body reflects resistance to metabolism and provides reason for consideration of interventions to increase their rate of elimination. The metabolism of lipophilic toxins varies among the classes and individual compounds. Individual congeners within classes have a wide range of elimination rates (45). People who ingested cooking oil contaminated with PCBs were studied to determine rates of elimination (46). There was a wide range of rates among the individual PCB congeners. In general the hexa- and heptachlorinated congeners were eliminated much more slowly than the tetra- and pentachlorinated compounds. The study was consistent with slower elimination of slowly metabolized congeners. Half-lives for pentachlorinated congeners ranged from 3 to 24 mon. Other classes of lipophilic toxins also are retained for long periods in the body. Dioxins and dibenzofurans have been estimated to have half-lives that range from 4 to 12 yr (47). Half-lives of 12.9 to 28.7 yr have been estimated for PBBs in women (48).

The conversion of lipophilic compounds to more polar species is a common metabolic path for many substances. Aryl hydroxylase catalyzes the hydroxylation of polycyclic aromatic hydrocarbons to produce species that are mobilized for transport in the blood, bile, and urine (49). PCBs and other halogenated hydrocarbons are metabolized by cytochrome P450-dependent monooxygenases to form more hydrophilic species (e.g., 50). The transformation of lipophilic xenobiotics by cytochrome P450 and other systems includes both activation and detoxification, and there have been extensive reviews of these metabolic pathways (51–54).

Hexachlorobenzene and pentachlorobenzene metabolism was studied in the rat after 13 wk of dietary exposure (55). In this study of the more polar derivatives in urine, pentachlorophenol and tetrachlorohydroquinone were formed in addition to sulfur and glucuronide derivatives.

A review of dibenzodioxins discussed the difference in metabolism of the congeners and concluded that the 2,3,7,8-chlorinated species has high toxicity due in part to affinity for the cytosolic Ah receptor protein (39). Another tetrachloro dioxin congener (1,2,7,8-tetrachlorodibenzo-*p*-dioxin) was shown to be converted to polar species in the rat (56). Glucuronides and diglucuronides of the hydroxy derivatives of the congener were identified.

Of relevance to this review are the lipophilic substances that are slowly metabolized to more hydrophilic metabolites and/or those with principal metabolites that are highly lipophilic and slowly excreted. The persistence of organic pollutants in the environment is the result of their stability and is reflected in resistance to chemical alteration by reactions including those that are enymatically catalyzed in the intact organism.

### *Excretion*

*Biliary and nonbiliary*. Lipophilic xenobiotics are excreted in feces and urine. Fecal excretion is the principal route for unchanged lipophilic compounds and their lipophilic metabolites, whereas urinary excretion is the path of more polar metabolites. Biliary excretion can account for a large portion

of the fecal elimination of many compounds; however, there is evidence that some lipophilic substances follow a nonbiliary route.

The excretion of hexachlorobenzene was studied by Ingebrigtsen and coworkers (57). In bile duct-cannulated rats dosed intragastrically with [$^{14}$C]hexachlorobenzene, only small fractions of the dose appeared in bile as the parent compound and as pentachlorobenzene (2.0 and 1.8%, respectively). The data indicated that the major part of biliary excretion of radioactivity was contained in other metabolites. Urinary excretion accounted for 2.1% of the dose during the 4 d after its administration. Urinary metabolites of hexachlorobenzene include pentachlorophenol, sulfur-containing derivatives, and glucuronides (55).

Octachlorodibenzo-*p*-dioxin was studied in rats by Birnbaum and Couture (43). The fecal route was the major pathway for elimination with minimal urinary excretion for both intravenous and oral administration of the $^{14}$C-labeled compound.

Evidence of a nonbiliary route of excretion of lipophilic toxins resulted from studies of the organochlorine pesticide, chlordecone. Excretion data obtained from humans exposed to chlordecone and rats that were administered the compound are consistent with this route as a significant excretory pathway (58,59). The authors observed that fecal excretion of chlordecone was maintained or increased when bile flow was diverted relative to that seen while bile flow was intact.

More evidence for nonbiliary intestinal excretion was reported by Rozman *et al.* (60). A study in the rhesus monkey showed that bile diversion did not alter fecal excretion of hexachlorobenzene. The presence of unchanged hexachlorobenzene in feces when the bile mainly contained metabolites was seen as evidence that nonbiliary excretion *via* exfoliation of the epithelium or exudation across the mucosa was a significant excretory route (61).

Toxic lipophiles in the lumen of the intestine from biliary and nonbiliary excretion routes are a principal target for intervention to accelerate elimination rates. Nonbiliary transport of lipophilic compounds into the lumen of the intestine is poorly understood in terms of their cellular or molecular associations, but as discussed in a later section, there is evidence of enterohepatic circulation of compounds that enter the intestinal lumen *via* a nonbiliary route. Lipophilic compounds that enter the intestine in bile also take part in enterohepatic circulation. Most of the past and current efforts to hasten the egress of toxic lipophiles from the body have focused on interruption of enterohepatic circulation to direct the compounds into fecal excretion instead of reabsorption from the intestine.

*Lactation.* Lipophilic compounds repeatedly have been observed in milk from humans and other species. An important path for the elimination of lipophilic substances from the body is through the lactation process. As discussed below, the mobilization of fat that provides a source of energy for neonates results in the accompanying transport of stored lipophiles into milk.

Patton (62) reviewed ideas about the movement of lipophilic xenobiotics from adipose tissue to the mammary gland. Fatty acid is released by hormone-sensitive lipase in the adipocyte, is transported to the mammary gland bound to albumin, and is re-esterified into triacylglycerol. It is not clear whether lipophilic xenobiotics stored in adipose tissue follow this same path to the mammary gland.

A study of the distribution of PCBs in female mice illustrates the importance of milk as an excretory route (63). The animals were treated with [$^{14}$C]PCB (2,4,5,2′,4′,5′-hexachlorobiphenyl) by intraperitoneal injection in corn oil 2 wk prior to mating. At 20 d postpartum, 98% of the dose was eliminated, and the level in the offspring was consistent with transfer of the mother's entire body burden of PCB to the pups. The level of PCB in virgin mice matched with the mothers maintained through the same time period remained essentially constant.

An example of the removal of lipophilic toxic materials from humans was reported by Schechter and coworkers (64). They followed the levels of lipophilic materials in the blood and milk of a mother who nursed twins for a period of 38 mon. Dioxin and dibenzofuran concentrations in milk decreased from 309 to 173 and from 21 to 9 ng/kg, respectively, during 30 mon. Hexachlorobenzene concentration decreased from 10.7 to 1.8 ng/g. These observations reflect the mobilization of the mother's adipose tissue to provide energy in milk, and the mobilization of stored dioxin, dibenzofuran, and hexachlorobenzene accompanying the fat.

Clearly, milk can be a major excretory route for lipophilic toxins, but the obvious consequence of this route is the introduction of the toxin into the neonate. There have been few studies that have addressed ways to affect the rate or amount of excretion of lipophilic toxins in milk.

## EFFECTS OF DIETARY ADDITIVES

The foregoing discussion is intended to give an overview as a background for the review of methods that alter the residence time and elimination rate of toxic lipophiles in an organism. These interventions include specific dietary additives, changes in energy intake, and variations in dietary fat.

### Nonabsorbable Lipids

#### *Effect on Absorption from the Diet*

Since most toxic lipophiles enter the body orally *via* food and water, the first approach for potential intervention is reduction of absorption from the intestine. As discussed by Jandacek (65) and Patton (62), a large fraction of dietary lipophiles enter the mouth and stomach dissolved in or associated with dietary triacylglycerol. Lipophiles that are adsorbed to other dietary constituents presumably associate with the dietary fat during mastication and mixing in the stomach.

In the small intestine, triacylglycerol is split into fatty acids and 2-monoacylglycerol, which form mixed micelles with bile salts and phospholipid from bile. During this

digestion process, a triacylglycerol oil phase remains mixed with an aqueous micellar phase until its digestion is complete. There is also evidence of liquid crystalline phases in the intestinal lumen during this process (66). Lipophiles are distributed among these phases but are presumably transported to the enterocyte membrane in the bile salt mixed micelles. Entry into the enterocyte and incorporation into chylomicrons presumably occur for many lipophiles. A strong affinity for an oil phase, as is the case for lipophiles with octanol–water partition coefficients of $>10^5$, results in retention of a large portion of the lipophile in the oil.

The triacylglycerol oil phase in the intestinal lumen is relatively transient. Digestion and absorption of dietary fat are efficient and fast, so that the oil phase disappears quickly. It is possible, however, to maintain an oil phase that competes with the micellar phase for lipophile solubilization. Sucrose esterified with long-chain fatty acids is not hydrolyzed by pancreatic lipase, and thereby maintains an intestinal oil phase throughout gastrointestinal transit (67). Sucrose esterified with six or more long-chain fatty acids has been termed "sucrose polyester" (SPE) and is a component of olestra (brand name, Olean®) (68).

*DDT in rats. (i) Olestra.* The effect of olestra (SPE) on the absorption of dietary [$^{14}$C]DDT was studied in the rat by Volpenhein and coworkers (69). When [$^{14}$C]DDT dissolved in soybean oil was intragastrically intubated into rats fitted with thoracic duct cannulas, 67% of the dose was recovered in a 48-h lymph collection. When the dosing oil comprised 50% soybean oil and 50% SPE, 21% of the dose was in the lymph. Data from rats that did not undergo surgery were consistent with the lymph recoveries. After dosing with the same oils used in the thoracic duct experiments, the animals received *ad libitum* semipurified diets without DDT, but which contained 20% by weight soybean oil or the same blend of 50% soybean oil and 50% SPE used in the lymphatic measurements. Animals dosed with soybean oil excreted less than 10% of the radioactivity in 72 h after its ingestion, whereas those dosed with 50% soybean oil and 50% SPE excreted more than 55% of the dose. The recovery of radioactivity from extracted tissues was consistent with the reduction in absorption by SPE. Approximately 60% of the dose appeared in total carcass fat of the soybean oil group compared with 20% in the soybean oil-SPE group. Similar results were obtained from the liver and epididymal fat pads, with recovery from the soybean oil-SPE group equal to one-third that of the soybean oil group.

These data are consistent with the nonabsorbable oil interfering with the absorption of the lipophile from the diet. The apparent mechanism is that of retention of or transport to the nonabsorbable oil, thereby diminishing the concentration of the lipophile in the micellar phase. Since micellar solubilization is obligate for the absorption of lipophiles, absorption was decreased in the presence of a nonabsorbable oil.

*(ii) Mineral oil.* A study of the effect of another nonabsorbable lipophilic material, mineral oil, on absorption from the diet did not provide clear answers. Keller and Yeary (70) tested the effects of mineral oil and sodium sulfate on the intestinal absorption of DDT in rats. Rats were intragastrically gavaged with [$^{14}$C]DDT in either soybean oil, mineral oil, 15% sodium sulfate with acacia, or water with acacia. After an hour the same formulations were intubated without DDT. This procedure was repeated 24 h later. The animals were sacrificed 48 h after the first dosing regimen, and tissues were taken for measurement. Adipose concentration of DDT was used as the principal assay. The authors concluded that the most important observation was the higher absorption observed when soybean oil was ingested. There was minimal difference among the other groups. The data may indicate the facilitation of the absorption of the pesticide by the presence of hydrolyzable dietary fat.

In contrast with the results of Keller and Yeary, another study found that mineral oil reduced markedly the appearance of DDT in lymph collected for 4 h after oral dosing (71). The peak lymphatic concentration after dosing in mineral oil was approximately one-fourth of that seen after dosing in arachis oil. DDT absorption was also determined from plasma areas under the curve in rats that did not undergo surgery. The decrease in absorption seen in the rats fed mineral oil relative to those fed arachis oil was consistent with the measurements of DDT in lymph.

*Lindane in pigs.* Morgan and coworkers (72) studied the effects of dietary additives on the absorption of the lipophilic pesticide lindane (the γ isomer of hexachlorocyclohexane). Anesthetized pigs were gavaged with lindane and various test formulations, and plasma lindane concentrations were followed for 150 min. The formulations that were compared included water (control), activated charcoal, mineral oil, and castor oil. The authors concluded that none of the treatments reliably altered the gastrointestinal absorption of the pesticide.

### *Effects on Stored Lipophiles*

*Olestra. (i) Animal studies.* The effects of three dietary lipids that are either poorly absorbed or not absorbed were studied in rats. Hexachlorobenzene elimination was measured during consumption of diets containing either olestra (SPE), squalane (30-C saturated hydrocarbon; 2,6,10,15,19,23-hexamethyltetracosane, obtained by hydrogenation of squalene), or paraffin (73). [$^{14}$C]Hexachlorobenzene was added to the diet for 4 d, and after 10 additional days the rat diets were supplemented with 8% olestra, paraffin, or squalane. After 3 wk of treatment, measurements of radioactivity in feces were made, and the excretion in each of the treatment groups was found to be three times higher than that of the control groups. Significant reductions in the tissue levels of radioactivity in the treatment groups were consistent with the excretion data. The authors suggested that in light of the absence of biliary excretion of hexachlorobenzene, nonabsorbable oils reduced the effective concentration gradient between blood and the gut lumen.

The effect of olestra on the elimination of [$^{14}$C]DDT (and/or its principal metabolite, DDE) was studied in gerbils

(74). Gerbils were given [$^{14}$C]DDT orally and maintained on chow until a log-linear fecal excretion rate was established. Excreted radioactivity increased more than twofold when 2.5 wt% olestra was added to the diet. Similar increases were seen with 5 and 10% olestra. Animals were changed to diets that provided 50–75% of normal caloric intake, and fecal excretion of radioactivity increased approximately 50% above that of control animals. When olestra was included in the reduced energy diet at a level of 10%, the average increase in fecal excretion was eightfold that of the control animals.

These studies of olestra in animals indicated that olestra could be used to interrupt enterohepatic circulation of lipophilic toxins that had been stored in the body after oral ingestion. Studies in humans discussed below have supported its potential use in removing lipophilic toxins from the body.

*(ii) Human trials.* Olestra has been studied in detoxification of dioxin in human trials. Gesau *et al.* (75) fed olestra to two subjects who had elevated levels of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). Five different dosing regimens were used, and olestra ingestion ranged from 15 to 66 g/d. Fecal excretion of TCDD was markedly increased with olestra consumption. In one patient the increase ranged from 3- to 10-fold above that prior to olestra consumption. In the other patient the increase ranged from three- to eightfold, depending on the specific regimen.

Moser and McLachlan (76) studied olestra in three healthy volunteers with normal exposure to lipophilic pollutants. Fecal excretion of dioxins, dibenzofurans, PCBs, and hexachlorobenzene was measured after 8 d of ingestion of 25 g/d of olestra. The excretion was compared with that of an initial 3-d control phase without olestra consumption. The excretion during the olestra period was 1.5 to 11 times higher than that during the control period, depending on the specific compound. Excretion enhancement (the increase in a compound's excretion relative to its ingestion) increased for all compounds during olestra ingestion. The authors also reported the interesting observation that the excretion enhancement decreased as the octanol/water partition coefficient of the lipophile of interest increased.

*Mineral oil/hexadecane/squalane.* Mineral oil is a cut of petroleum distillates that is dominated by but not limited to long-chain hydrocarbons, including hexadecane. Paraffin/paraffin oil also includes long-chain hydrocarbon compounds. Squalane is defined in an earlier section. These materials are poorly absorbed from the intestine and maintain an intestinal lipid phase during gastrointestinal transit; however, partial absorption may occur and has been implicated in histological lesions in the liver and spleen (77,78). The absorption of trace amounts of mineral oil and its components has not prevented its use as a model lipid sink in elimination studies, but it raises issues relative to its use in long-term human therapy.

Richter (79) reviewed studies that intervened to change the rate of fecal excretion of hexachlorobenzene and cited 12 studies that utilized mineral oil in changing the excretion of hexachlorobenzene, hexachlorocyclohexane, pentachlorobiphenyl, hexabromobiphenyl, chlordecone, mirex, and DDT. Significant enhancement of the rate of excretion was seen with mineral oil in all but one of the cited studies. Five studies with squalane and four with hexadecane were also cited in Richter's review. Both compounds effected increases in the excretion of hexachlorobenzene in the studies reviewed. The review noted that hexadecane is partially absorbed and therefore is not suitable for consideration as a nonabsorbable lipid for therapeutic purposes; there is also evidence for the accumulation of dietary squalane in the liver of rodents (73,80).

Much of the work that was carried out with these poorly absorbed oils was directed by K. Rozman and T. Rozman. Table 3 summarizes the design and results from their studies and from those of other investigators.

Mineral oil (paraffin oil) has been the subject of most studies of intervention in the metabolism of lipophilic toxins. The data are clearly supportive of its interference with the reabsorption of lipophiles that enter the intestinal lumen *via* bile or a nonbiliary mechanism. Although the possibility of absorption of mineral oil limits its applicability in humans, the experiments with animals have demonstrated the validity of an intervention that is based on interruption of enterohepatic circulation of lipophiles.

## Resins

Pharmaceutical cationic ion exchange resins have been used to treat hypercholesterolemia by binding bile salts in the intestine and enhancing their excretion. Since these polymeric resins are not absorbed, bind bile salts, and have lipophilic backbones, they were considered as candidates for intervention in the enterohepatic excretion of some lipophilic toxins. The use of cholestyramine in people contaminated with chlordecone in the study discussed below was the first effective detoxification of a lipophilic toxin that was stored in the body (95).

Cholestyramine binds the pesticide chlordecone *in vitro* and enhances its excretion in rats (96). Rats were given $^{14}$C-chlordecone by stomach tube and after 7 d assigned to diets containing cholestyramine or silica gel/cellulose (control). Measurements of fecal excretion and tissue concentrations ensued. The concentration in the liver was reduced by 39% in the cholestyramine group relative to controls, in fat, by 30%, and in the brain, by 50%. Significant increases in fecal excretion and decreases in body burden were seen in the cholestyramine group relative to the control group.

The reduction of chlordecone from human subjects with a high body burden was reported by Cohn and colleagues (95). Workers in a factory that manufactured chlordecone exhibited symptoms of toxicity attributed to the pesticide. A double-blinded trial of subjects who received either placebo or 24 g/d of cholestyramine was carried out. Cholestyramine increased the fecal excretion by 3- to 18-fold. A significant reduction in the half-life of chlordecone (calculated from longitudinal measurements of blood levels) was seen with cholestyramine. Chlordecone excretion in the bile of a patient fitted with a T-tube was 19 times faster than that in feces,

**TABLE 3**
**Studies with Mineral Oil, Squalane, or Hexadecane[a]**

| Study design | Results | Reference |
|---|---|---|
| Mineral oil and hexadecane were fed to rats and rhesus monkeys that had been dosed with [$^{14}$C]hexachlorobenzene (HCB). Fecal excretion and tissue levels of $^{14}$C were measured. | Hexadecane at a level of 5% in the diet increased $^{14}$C-HCB fecal excretion 4- to 13-fold; mineral oil caused a six- to ninefold enhancement. Blood and adipose tissue levels of $^{14}$C decreased with increased excretion. | 60 |
| Rats were dosed orally with [$^{14}$C]HCB and fed diets containing 8% squalane, paraffin oil, or sucrose polyester. Fecal excretion was monitored. | The half-life, calculated 35–38 d after discontinuation of the HCB diet, was reduced to approximately one-third of that of the control group by all oils. | 73 |
| [$^{14}$C]HCB was dosed to rats in the diet. After 35 and 53 d, animals were sacrificed for analysis. Feces were analyzed. | The fast and slow half-lives of elimination were reduced by 48 and 77% by paraffin oil. There were reductions of HCB in all analyzed tissues; fat concentration was reduced more than 80% by paraffin oil. | 81 |
| [$^{14}$C]PCB (2,4,6,2′,4′-pentachlorobiphenyl) was dosed orally to rats. A control diet was compared with a diet with 8% light paraffin oil. Feces were assayed. | The paraffin oil group excreted 54% of the dose, and the control animals, 43%, during the 4 wk after discontinuation of the PCB-containing diet. | 82 |
| Rhesus monkeys were given mirex and then received a diet containing 5% mineral oil. | Fecal excretion was increased 50% 1 mon after dosing; the increase was 400% 6 mon after dosing. The long-term effect was attributed to "deep" storage in fatty tissue. | 83 |
| Rhesus monkeys were given 5% mineral oil after a dose of 2,4,5,2′,4′,5′-hexabromobiphenyl. | Fecal excretion increased 175% with the addition of mineral oil to the diet. | 84 |
| Rats dosed with [$^{14}$C]HCB were given hexadecane. The effect of bile duct ligation was tested. | Bile duct ligation, dietary hexadecane, and the combination of all treatments increased fecal excretion. The combination of treatments was more effective than each alone. | 85 |
| Orally dosed [$^{14}$C]HCB in intestinal segments was measured; the effect of hexadecane on HCB intestinal excretion in the segments was determined. | The data indicated that hexadecane increased excretion of HCB in the colon. | 86 |
| Rhesus monkeys were dosed orally with [$^{14}$C]HCB with varying doses. Bile flow was diverted, and excretion was measured in animals given diets with and without mineral oil. | Fecal excretion of HCB was raised fivefold by mineral oil. Urinary excretion was not altered by mineral oil. | 87 |
| Rhesus monkeys were dosed orally with [$^{14}$C]DDT and given a diet with 5% mineral oil. Fecal excretion and adipose tissue levels were assayed. | Mineral oil doubled the excretion rate and halved the amount of radioactivity in the adipose tissue. | 88 |
| Hexadecane was injected into ligated intestinal segments of rats previously dosed with [$^{14}$C]HCB; the effect on intestinal excretion was determined. | Intestinal excretion increased in the order jejunum > ileum > cecum and colon. The authors noted that high residency time makes the colon an important site for interaction with hexadecane. | 89 |
| Sheep were fed [$^{14}$C]HCB and then given diets containing 5% mineral oil or 5% hexadecane. Fecal excretion and adipose stores were measured. | Treatment with hexadecane and mineral oil increased fecal excretion threefold. Reductions in adipose tissue corresponded to increases in excretion. | 90 |
| Lactating goats dosed with mirex were given 5% light mineral oil. Fecal excretion, blood, and milk concentrations of mirex were measured. Mineral oil as 3% of the diet was fed to cattle that produced butterfat contaminated with DDT. | Fecal excretion of mirex from goats was increased by dietary mineral oil. There were no changes in concentrations in milk or blood during the period of mineral oil consumption. Fecal DDE excretion from cows increased with mineral oil consumption; milk concentrations did not change with mineral oil treatment. | 91 |
| Rabbits and rats were dosed with [$^{14}$C]HCB and given a diet containing 5% hexadecane. | Half-lives were of HCB in the rat (24 d) and rabbit (32 d) were similar. Hexadecane increased fecal excretion of HCB four- to fivefold. | 92 |
| Chickens with HCB or pentachlorophenol body burdens were given mineral oil, colestipol, and/or reduced caloric intake. | 5 wt% mineral oil in the diet reduced body burden to 36% of dose, compared with 63% of dose with no treatment. | 93 |
| Heptachlor epoxide was given to mink. The effect of diet restriction with a diet containing 10% mineral oil was observed. | Rapid reduction of body burden occurred with control (*ad lib* diet) animals; mineral oil and restricted diet did not accelerate the reduction relative to the control. | 94 |

[a]DDE, 1,1-dichloro-2,2-bis(chlorophenyl)ethylene. For other abbreviations see Table 1.

**Table 4**
**The Use of Resins to Intervene in Toxic Lipophile Excretion[a]**

| Study design | Results | Reference |
|---|---|---|
| Rhesus monkeys were orally dosed with [$^{14}$C]HCB, and 4% cholestyramine was added to the diet. Fecal excretion of $^{14}$C was measured. | Cholestyramine did not increase the rate of fecal excretion above that seen during a period without dietary cholestyramine. | 60 |
| [$^{14}$C]DDT was given to gerbils, and the excretion was followed after diets with and without 4% cholestyramine. | A modest increase in excretion of radioactivity was observed with added cholestyramine. | 74 |
| Rhesus monkeys dosed with 2,4,5,2′,4′,5′-hexabromobiphenyl (PBB) were given 4% cholestyramine in the diet. | Fecal excretion of the PBB increased 50% with the addition of the resin. | 84 |
| Chickens were fed HCB or pentachlorophenol and given colestipol with or without food restriction. | Marked reductions in body burdens were seen for both compounds with colestipol; greater reductions were seen when colestipol was combined with food restriction. | 93 |
| Turkeys and chickens were orally administered [$^{14}$C]dieldrin and fed resins. | Based on carcass analyses, the resins were generally ineffective in reducing the dieldrin levels. | 97,98 |
| Rhesus monkeys dosed with [$^{14}$C]-pentachlorophenol were given a diet containing 4% cholestyramine; fecal excretion was monitored. | Fecal excretion of radioactivity increased 9- to 14-fold with cholestyramine in the diet. | 99 |
| Rhesus monkeys were orally dosed with [$^{14}$C]pentachlorophenol and fed cholestyramine. | Fecal excretion of pentachlorophenol increased by as much as 40%. | 100 |
| PBBs were fed to chickens. Colestipol was fed alone or in combination with a starvation regimen. | Colestipol alone had minimal effect but reduced body burden by 70% in 21 d in combination with starvation. | 101 |
| Patients exposed to PCBs and dibenzofurans were given 8–12 g/d cholestyramine for 24 wk. | In 4 of 6 patients there was no effect of cholestyramine. Fecal excretion of PCBs increased by 36–46% in the other two. | 102,103 |
| Rats fed rice oil contaminated with PCBs and dioxins were given 5% cholestyramine alone or in combination with squalane and rice bran. | Cholestyramine alone enhanced excretion of some congeners by factors of 1.3–3.3. Combinations with rice bran and squalane somewhat enhanced the excretion. Excretion of a heptachlorodibenzodioxin congener was not affected by the resin. | 104 |
| Rats received PBB for 6 mon followed by normal diets for 4 mon. Cholestyramine was included in the diet for 6 mon. | Cholestyramine did not reduce the levels of bromine in the tissues. | 105 |

[a]For abbreviations see Tables 1 and 3.

thereby indicating the existence of an enterohepatic circulation of chlordecone.

Other trials that have studied cholestyramine and colestipol (also a bile salt-binding cationic resin) are summarized in Table 4.

## Activated Carbon

Activated carbon, which is used as an adsorbent in treatment of patients with acute poisoning, has also been studied as a treatment for stored lipophilic toxins. The rationale for its use is that of interference with enterohepatic circulation of compounds that enter the intestine *via* biliary and nonbiliary routes. The use of activated carbon in studies of lipophilic toxin metabolism is summarized in Table 5.

## Protoporphyrin

One study was carried out with dietary protoporphyrin and hemin (108). The rationale for the use of these materials was apparently based on expected low intestinal absorption of protoporphyrin and hemin and predicted high adsorption of lipophilic substances to these substances. Animals that were given the oil that contained polychlorinated dioxin and polychlorinated dibenzofuran were subsequently provided a diet that contained either 0.5% disodiumprotoporphyrin or 0.5% hemin. The protoporphyrin group excreted 2.1 times the amount of the toxins in feces relative to the control group. The group that received hemin was not different from the control group.

## Dietary Fibers/Indigestible Polysaccharides

As noted in Table 4, rice bran fiber in combination with cholestyramine slightly increased the excretion of polychlorinated dibenzofuran congeners relative to cholestyramine alone in rats with body burdens of these compounds (104). The same study included comparisons of rice bran and other fibers (burdock, corn, soybean) that were included in the diet at a concentration of 10% by weight. All of the fibers significantly increased the excretion of all measured dibenzofuran and dioxin congeners except the 1,2,3,4,6,7,8-heptachlorodibenzodioxin relative to the control group. The effect of the rice bran fiber was the greatest, with rates of excretion ranging from 1.9 to 3.3 times that of the control group.

A comparison of the effects of some indigestible polysac-

**TABLE 5**
**The Use of Activated Carbon in Detoxification of Lipophiles**

| Study design | Results | Reference |
|---|---|---|
| 3 patients with body burdens of chlordecone were given 40 g/d of activated charcoal. | Excretion rate was increased by less than twofold by the carbon. | 95 |
| Turkeys and chickens were administered $^{14}$C-dieldrin orally and fed activated carbon. | Activated carbon had no effect on the rate of elimination. | 96,98 |
| Rats received PBB for 6 mon followed by normal diet for 4 mon. Activated charcoal was included in the diet for 6 mon. | Activated charcoal did not reduce the concentration of bromine in tissues. | 105 |
| Activated carbon was fed as 5% of the diet with or after DDT exposure to rats and cows. | Activated carbon decreased DDT absorption but had no effect on rate of elimination. | 106 |
| Mice, rats, and guinea pigs were injected intraperitoneally or subcutaneously with 2,3,7,8-tetrachloro-*p*-dioxin and given chow or chow plus charcoal. | Mortality was reduced from 93 to 53% in mice; 80 to 50% in rats; 64 to 29% in guinea pigs. | 107 |

charides on the accumulation of pentachlorobenzene was performed in rats (109). Rats were fed either cellulose (control), sodium alginate, guar gum, or γ-carrageenan at a level of 5 wt% of the diet. After 2 wk they were dosed orally with 20 mg of pentachlorobenzene, maintained with the experimental diets for seven more days, and then sacrificed to assay tissues. Body weight and adipose tissue mass (as percentage of body weight) were significantly lower in each of the polysaccharide groups relative to the control. The level of pentachlorobenzene was lower in the livers, kidneys, and adipose tissue of the animals that ate the polysaccharides relative to the control group. Fecal excretion of pentachlorobenzene was higher than that from control animals in the groups fed sodium alginate and guar gum. The authors suggested that lower adipose tissue mass seen in the polysaccharide groups was in part responsible for the enhanced excretion of pentachlorobenzene.

### Amount and Type of Absorbable Dietary Fat

Contrasted with the studies of energy deprivation, Nakashima *et al.* (34) studied the effect of a high-fat diet on the elimination of hexachlorobenzene in lactating rats. Pregnant rats fed a high-fat diet transferred hexachlorobenzene more slowly in milk to pups than those fed a low-fat diet. This observation may reflect a reduced rate of mobilization of the adipose stores in the high-fat fed mothers so that the stored hexachlorobenzene also was transported more slowly.

In addition to the effects of nonabsorbable dietary fats, there is evidence that the fatty acid composition of typical dietary fats may influence the metabolism of organochlorine compounds. Umegaki reported that fish oil enhanced the metabolism of pentachlorobenzene in rats relative to the effects of lard or soybean oil (110). Fish oil not only enhanced the levels of the principal metabolite of pentachlorobenzene, pentachlorophenol but also reduced the concentration of pentachlorobenzene in fat. The authors suggest that reduced accumulation of adipose tissue in the animals fed fish oil contributed to its reduced accumulation.

Umegaki and Ikegami (111) studied the influence of dietary fatty acid on hexachlorobenzene metabolism. They reported that relative to soybean oil, fish oil and lard in the diet resulted in a lower total fat mass and higher concentrations of hexachlorobenzene in the blood, liver, and brain. The animals that received fish oil had higher urinary levels of pentachlorophenol, a principal metabolite of hexachlorobenzene. The authors concluded that fish oil increased cytochrome P450 and accelerated hexachlorobenzene metabolism, thereby increasing oxidation to more polar compounds (51).

The absorption of [$^3$H]benzo(α)pyrene was measured in rats that were fitted with bile and lymph duct cannulae and fed 50 or 500 μmol of olive oil (35). There was no effect of the level of dietary fat on the recovery of radioactivity in bile and lymph. The results were consistent with rapid conversion of benzo(α)pyrene to polar compounds in the enterocytes and absorption *via* the portal vein rather than lymph.

## CHANGES IN BODY FAT

Adipose tissue is the principal depot for accumulation of many lipophilic toxins. Therefore, reduction in adipose tissue stores (e.g., from weight loss) can release stored lipophilic toxins into the circulation and expose other sites to them. The following outcomes of this release are possible: storage in tissues that are more affected than adipose tissue by the compounds; increased metabolism resulting from increased uptake by the liver; decrease in body burden; and combinations of these events. Some studies of adipose tissue and weight reduction have examined excretion rates and tissue distribution. There also have been studies in which weight reduction was combined with use of nonabsorbable dietary lipids.

A suggestion of adipose tissue "protecting" more sensitive targets from lipophilic toxins was presented by Geyer *et al.* (112), who suggested that the toxicity of dioxin is inversely related to the amount of body fat in an animal. Based on the relationship between toxicity and body fat among and within species, the authors concluded that body fat is a reservoir that limits the exposure of target organs to toxic lipophiles. This kind of relationship underscores the importance that changes in adipose tissue mass might have on lipophilic toxin metabolism.

## Effects of Weight Loss on Elimination of Lipophiles in Experimental Animals

The study by Davison and Sell (98) of dieldrin in chickens cited in Table 4 included a regimen of severe starvation. The authors observed significant increases in excretion and complementary reductions in carcass levels of dieldrin with reduction in energy intake.

Mitjavila *et al*. (113) studied the effect of restricted food intake on DDT metabolism in the rat. Animals received DDT daily *via* intragastric gavage. They were then subjected to 3 d of starvation followed by 14 d of a fat mobilization period with a diet limited to 2.5 g food/d/rat. Tissue compositions of DDT and DDE were assayed. The half-life of DDT was calculated to be 5 d under these conditions, markedly less than estimates of 2 mon from studies of *ad libitum* feeding. Observation of the animals led the authors to conclude that the rat liver is capable of metabolizing large quantities of DDT that are mobilized by reduction of adipose stores of the pesticide.

In the study by Polin *et al.* (93) (cited in Table 4) of chickens with body burdens of hexachlorobenzene and pentachlorophenol, the effect of reduction of food intake was studied. Treatment with food restriction at 50% of *ad libitum* intake reduced the body burden to 37% of the initial dose of hexachlorophene, compared with a value of 63% for the *ad libitum* diet control group. The analogous figures for pentachlorophenol reduction were 25 and 70% of the dose, respectively. Chickens that were fed 10 wt% colestipol or 10 wt% mineral oil showed a further reduction to 19% of the original dose for each treatment.

As already noted in the summary of the study by Mutter *et al*. (74), caloric deprivation with and without dietary olestra in gerbils increased the rate of excretion of DDT/DDE. This increase was approximately 50% above that from control animals that received an *ad libitum* diet when no other treatment was included. The combination of dietary olestra with caloric deprivation markedly increased the excretion rate to approximately eight times that of the excretion from fed control animals.

A combination of mineral oil and food restriction was studied in the elimination of PBBs from chickens in the study by Polin *et al.* cited in Table 4 (101). Both mineral oil and food restriction treatments resulted in reductions in body burdens greater than those seen in control animals at relatively low doses of the PBBs (0.1 and 1.0 ppb in the diet). At higher dose levels of PBBs, there were minimal effects in terms of percent reduction.

Restricted caloric intake was ineffective in a study of rats with a body burden of PBBs (105). The animals were fed a mixture of PBBs for 6 mon followed by a diet free of PBBs for 4 mon. Reduction in energy intake did not reduce the level of PBBs in adipose tissue.

The study of an interesting lactation process was reported by Polischuk and coworkers (114), who measured the concentration of chlorinated organic compounds in polar bears undergoing an extensive fast and lactating. They found that the concentration of PCBs, chlordanes, and chlorobenzenes in milk lipids increased markedly during the fasting period. The concentrations of DDT and hexachlorocyclohexane did not have a consistent pattern.

## Effect of Weight Loss on Elimination in Humans

Two subjects who were part of the Biosphere 2 project near Tucson, Arizona, participated in measurements of blood levels of PCBs and DDE (115). In the conditions of a closed ecological space and self-sufficient food supply, men and women lost 18 and 10% of body weight during 2 yr, respectively, with most of the loss in the first 6–9 mon. The blood concentrations of the toxicants were reported to increase during the first 12–18 mon and then decrease. The initial increase is consistent with the mobilization of adipose tissue, and the subsequent decrease may reflect reduced body stores.

The effect of modest weight loss on the concentration of hexachlorobenzene and DDT in the breast milk of women with relatively low levels of the contaminants was reported (116). There was no change in the milk concentration of these compounds with a mean weight loss of 4.1 kg.

## Effect of Weight Loss on Tissue Distribution in Experimental Animals

Dale *et al.* (117) studied the effect of caloric restriction in rats that received 200 ppm DDT added to chow for the duration of the study. One group was sacrificed after 90 d of *ad libitum* feeding. A second group was sacrificed after a sequence of 90 d of *ad libitum* followed by 10 d of 50% reduction in normal energy intake. A third group followed the regimen of 90 d of *ad libitum* feeding, 10 d of 50% caloric deprivation, and 40 d of *ad libitum* feeding. A fourth group followed a regimen of *ad libitum* feeding for 140 d before sacrifice. The levels of DDT and its metabolite DDE in tissues were measured. The concentration of DDT and DDE increased in the tissue and the lipid fractions of fat, brains, plasma, livers, and kidneys of animals that were energy-deprived at 100 d relative to those sacrificed at 90 d. Although excretion of DDT and metabolites increased during energy deprivation, the excretion rate did not prevent the increase in concentration of DDT and its metabolites in the examined tissues.

Findlay and deFreitas (118) studied the effect of lipid utilization on the mobilization of DDT in pigeons. Homing pigeons were dosed with [$^{14}$C]DDT in corn oil for 16 d. Some of the birds were maintained at 6°C without food until they had lost 18–20% of their body weight and then sacrificed. The distribution of radioactivity among tissues was measured in the birds and compared with that from a group that was not stressed by the weight loss regimen. The total amount of DDT in the fat in the stressed birds was reduced relative to the unstressed birds at all doses of DDT that were administered. The concentration of DDT in the fat lipids was two- to threefold higher in the stressed birds. The total DDT in breast muscle

increased 172 to 262% in the stressed birds, and the concentration increased 174 to 235%.

Weight loss in female rats that were dosed orally with hexachlorobenzene and restricted to 30% of normal intake for 7 d resulted in a marked increase in hexachlorobenzene in all tissues (119). The levels in the brain and liver were elevated 367 and 496%, respectively.

The effects of restricted feeding on pentachlorobenzene in rats was reported by Umegaki *et al.* (120). The animals that were eating *ad libitum* or with intake restriction received a single dose of pentachlorobenzene in soybean oil. Fecal excretion of dietary pentachlorobenzene was decreased by restriction of feed intake to 50 and 25% of *ad libitum* consumption. Its accumulation in liver, brain, and fat was also reduced by dietary restriction. The authors concluded that the reduced level in these tissues was the result of increased metabolism by the liver resulting from a decrease in adipose tissue mass and mobilization of the compound.

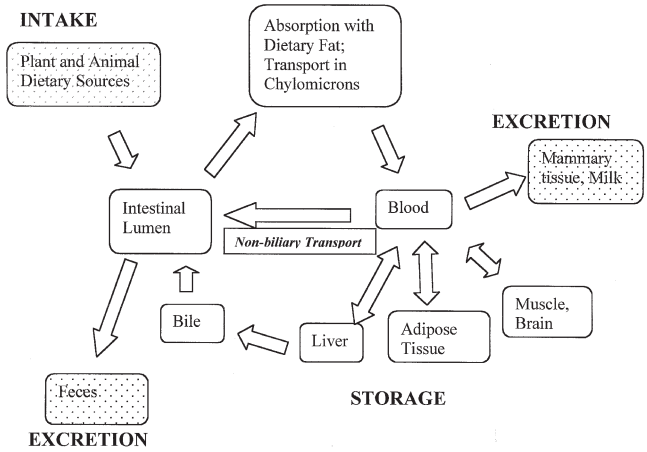
A study of the effect of fasting on the estrogenic effect of DDT and β-hexachlorocyclohexane was studied in mice (121). The animals were injected with the the halogenated compounds and then fasted for 2 d. Uterine weights of fasted and fed animals were compared with those from animals injected with vehicle (control animals). The uterine weights of the animals injected with β-hexachlorocyclohexane were greater than those from fed animals or from fasted control animals. Fasting did not alter the estrogenic effect of DDT. The authors concluded that lipolysis accompanying fasting releases β-hexachlorocyclohexane with subsequent stimulation of estrogen target tissues. The data indicated that DDT was mobilized in a different manner.

There is evidence that energy restriction may make an animal more vulnerable to the toxic effects of lipopohiles. In rats fed hexachlorobenzene, the restriction of energy intake to 50% of a control diet resulted in an increase in liver hypertrophy and hepatocyte foci (23).

## DISCUSSION

### Summary of Lipophilic Toxin Metabolism

The research discussed in the previous sections provides a general view of the metabolism of toxic lipophiles. This view is summarized in the diagram in Scheme 1. Oral ingestion is the principal entry route for most of these compounds. Dietary fat, which facilitates the absorporption of lipophilic xenobiotics, may act as a carrier for the compounds. They are incorporated into chylomicrons, transported to peripheral tissues and the liver, and may exchange with circulating lipoproteins. They are carried in the blood by lipoproteins. The way that they are metabolized varies among the classes of compounds and among the individual congeners within the classes. Metabolism of very lipophilic compounds converts them into more hydrophilic molecules such as glucuronides or hydroxylated derivatives. Molecules that are very hydrophilic are excreted in urine whereas more lipophilic compounds are transported in bile. In addition, there is evidence that lipophilic compounds that are excreted in feces may be of nonbiliary origin. The nature of this excretory route is unclear, but presumably it results from the sloughing of intestinal cells that accumulate lipophilic substances and/or from a hypothetical secretion directly out of the cells. It is clear from several studies that reabsorption of lipophilic compounds from the intestine occurs with subsequent enterohepatic circulation. It is also evident that enterohepatic circulation occurs for compounds both of biliary origin and of nonbiliary origin.



SCHEME 1

There is convincing evidence that many lipophilic xenobiotics and their more lipophilic metabolites are stored in adipose tissue. Uptake by other tissues and organs also occurs, in some cases resulting from induction of and affinity for enzyme systems such as aryldehydrogenase, and in other cases from the lipid content of the tissue.

Lipophilic xenobiotics are mobilized from adipose tissue when the adipose stores are depleted through reduction in energy intake. The fate of these mobilized molecules varies with the compound and with other conditions, including interventions. Some are taken up by other tissues and organs, including muscle and brain. There is some evidence that toxic effects increase with the transport of compounds from adipose tissue to more sensitive organs. Mobilization generally increases biliary and nonbiliary transport into the intestine, which in turn enhances fecal excretion and enterohepatic circulation.

Mobilization of lipophiles from adipose stores accompanies the transport of triacylglycerol from adipose tissue into milk during lactation. Milk fat formed during lactation can remove a large fraction of a body burden of many lipophilic xenobiotics. There are obvious implications of this process for the health of infants ingesting breast milk.

### Summary of Interventions That Alter Storage and Elimination of Lipophilic Toxins

Interventions that can potentially alter the storage and rates of elimination of lipophilic toxins have generally been

directed toward interruption of their enterohepatic circulation. Poorly absorbed materials that adsorb or dissolve lipophilic compounds in the intestinal lumen can reduce absorption that returns them into the circulation and tissues. Nonabsorbable substances that bind lipophiles, such as lipids (olestra, mineral oil), fiber, resins, and activated carbon increase elimination rates in a number of studies, and these results are consistent with interruption of enterohepatic circulation. Nonabsorbable lipids and activated carbon also reduce the initial absorption of dietary lipophilic xenobiotics by the same mechanism of adsorption/dissolution and fecal excretion.

Another approach has been the combination of substances that reduce enterohepatic circulation with a reduction in body fat stores. This combination has been more effective than separate regimens of weight loss or nonabsorbable binders of lipophilic compounds. In addition, there is some evidence that weight loss alone may cause redistribution of toxic compounds to tissues that are more sensitive than adipose tissue. Interruption of the enterohepatic circulation combined with weight loss may reduce this undesirable effect of weight loss alone.

To date there have been no studies of the effects of a high-energy or high-fat diet in combination with substances that interfere with enterohepatic circulation. This regimen could potentially provide a safe method for reducing the body burden of lipophilic xenobiotics by minimizing concentrations in sensitive tissues. The observation by Nakashima *et al.* (34) of a high-fat diet reducing excretion of hexachlorobenzene in milk lends support to this approach.

## Conclusions and Direction for Further Work

There have been numerous attempts to alter the storage and elimination of lipophilic xenobiotics both in animal models and in humans. It is clear that clinically significant changes in elimination rates can be achieved by regimens that reduce the enterohepatic circulation of toxic lipophiles and their metabolites. There have not, however, been systematic approaches that address the combination of regimens to optimize the conditions for the safe and rapid elimination of stored toxic lipophiles.

Many lipophilic substances are known to be toxic and/or carcinogenic, have poorly understood or unknown "no-effect" levels in humans, and are distributed widely in the environment and the biosphere. This scenario warrants continued efforts to develop safe and achievable regimens for reducing body burdens of toxic lipophiles.

In spite of the large amount of work on the elimination of toxic lipophiles, there remain unaddressed areas that warrant further research. An optimal regimen for toxic lipophile removal from the body has not been systematically developed to provide guidance for removal of toxins in situations of acute and of chronic exposure. A better understanding of the nature of nonbiliary excretion in the intestine may provide new ways to control the rate of elimination of toxic lipophiles. There have only been a few studies that have been directed to understand the effect of dietary regimens on the important area of the transport of toxic lipophiles in milk. Since toxic lipophiles are suspected to influence early childhood development, there is a clear need to understand the relationships of lactation, fat mobilization, and toxin transport. Given the known detrimental effects of persistent toxic lipophiles and their widespread distribution in the environment, there is a need to gain better understanding of influences on their elimination from the human body, the top of the food chain for lipophile accumulation.

# Plasma Kinetics of a Cholesterol-Rich Emulsion in Young, Middle-Aged, and Elderly Subjects

**Lígia B. Pinto[a], Mauricio Wajngarten[a], Edson L. Silva[a], Carmen C. Vinagre[b], and Raul C. Maranhão[a,b,*]**

[a]The Heart Institute, Medical School Hospital (InCor-HCFMUSP), and [b]Faculty of Pharmaceutical Sciences, University of São Paulo, São Paulo, Brazil

**ABSTRACT:** Low density lipoprotein (LDL) plasma concentration is increased in the elderly. In this group, the incidence of coronary artery disease (CAD) is greater and LDL remains an important risk factor for CAD development. In this study, the plasma kinetics of a cholesterol-rich emulsion that binds to LDL receptors was studied in 10-subject groups of the elderly (70 ± 4 yr), middle-aged (42 ± 5 yr) and young (23 ± 2 yr). All were normolipidemic, nonobese, nondiabetic subjects who did not have CAD. The emulsion was labeled with $^{14}$C-cholesteryl oleate and injected intravenously into the subjects. Blood samples were drawn at regular intervals over 24 h to determine the plasma decay curve of the emulsion radioactive label and to estimate its plasma fractional clearance rate (FCR, in $h^{-1}$). FCR of the emulsion label was smaller in elderly compared to young subjects (0.032 ± 0.035 and 0.071 ± 0.049 $h^{-1}$, respectively; mean ± SD, $P < 0.05$). FCR of the middle-aged subjects (0.050 ± 0.071 $h^{-1}$) was intermediate between the values of the elderly and young subjects, although not statistically different from them. A negative correlation was found betweeen the emulsion FCR and subjects' age ($r = –0.47$, $P = 0.008$). We conclude that aging is accompanied by progressively diminished clearance of the emulsion cholesterol esters and, by analogy, of the native LDL.

Paper no. L8715 in *Lipids 36,* 1307–1311 (December 2001).

The concentration of low density lipoprotein (LDL) is raised in aged subjects (1,2). Because the incidence of coronary artery disease (CAD) markedly increases in this population and the positive correlation between LDL cholesterol levels and CAD persists in the elderly (3,4), it is important to investigate the mechanisms of LDL elevation. The plasma concentration of LDL is determined by the balance between the lipoprotein production rate and the rates of removal from the plasma. LDL production comprises the hepatic synthesis of the precursor lipoprotein VLDL (very low density lipoprotein) and VLDL catabolism with generation of LDL. Removal from the plasma and LDL uptake by the body tissues are mediated by cell membrane receptors that recognize apolipoprotein B100 (apo B100), which is virtually the only apolipoprotein existing in LDL (5).

Abbreviations: apo, apolipoprotein; CAD, coronary artery disease; LDE, cholesterol-rich emulsion that resembles the lipidic portion of LDL; LDL, low density lipoprotein.

Grundy *et al.* (6), followed by Ericksson *et al.* (7) and Millar *et al*. (8), showed that plasma removal rate of LDL apo B100 is diminished in older compared with younger subjects, confirming the conclusions of the meta-analysis by Miller (1). The study by Grundy *et al.* (6) also found a greater LDL production rate in the elderly, but this was not confirmed in the two other studies. Therefore, the aging process apparently courses along with diminished removal from the plasma of the LDL particles.

Previously, we have studied the metabolic behavior of a cholesterol-rich emulsion that roughly resembles the LDL lipidic structure, which we termed LDE (9). LDE is made without protein, but when injected into the blood stream it acquires apo E and other circulating apo; hence, it is taken up by the cells through the LDL receptors. Those receptors recognize not only apo B but also apo E, which is not found in the LDL fraction (10).

Emulsions can be a practical and efficient tool to study lipid metabolism. The utility of LDE to test LDL metabolism in subjects was shown in dyslipidemia (11) and in cancer patients (12), where its plasma kinetic behavior was as predicted for the native lipoprotein. Those experiments showed that it was feasible to test with LDE the LDL receptor function in subjects. In the current study, LDE labeled with radioactive cholesterol esters was used to verify whether the mechanisms that remove cholesterol from the blood stream indeed become less efficient with aging.

## MATERIALS AND METHODS

*Subjects.* The participants in the study were selected from the outpatient clinics of the Heart Institute of the São Paulo University Medical School Hospital to make up three study groups, each with 10 volunteers: (i) Young subjects: aged 20 to 24 yr (mean ± SD: 23 ± 2 yr), six males and four females. (ii) Middle-aged subjects: aged 36 to 54 yr (mean ± S.D: 42 ± 5 yr), all male. They had no clinical evidence of CAD. (iii) Elderly subjects: aged 65 to 79 yr (mean ± SD: 70 ± 4 yr), six males and four females. Absence of CAD was confirmed by cinecoronary angiography.

None of the participants was obese, addicted to alcohol consumption, or had liver, renal, metabolic, inflammatory, or neoplastic disease. All had total plasma cholesterol <240 mg/dL, LDL cholesterol <160 mg/dL, and triglycerides <250

mg/dL. The experimental protocol was approved by the Ethical Committee of the Heart Institute, and written informed consent was given by all participants. The safety of the radioactive dose intravenously injected into the patients was assured according to the regulations of the International Commission on Radiological Protection (13), as described in our previous study (14).

*Plasma lipids and apo.* Commercial enzymatic methods were used to determine total cholesterol (Boehringer-Mannheim, Penzberg, Germany) and triglycerides (Abbott Park, IL). HDL cholesterol was determined by the same method used for total cholesterol after lipoprotein precipitation with magnesium phosphotungstate. VLDL cholesterol and LDL cholesterol were calculated by the formula of Friedewald (15). Plasma apo A-I and B were assayed by radial immunodiffusion (Lipo-Partigen R-Apo A-I and Nor-Partigen R-Apo B plates, Behring, Marburg, Germany).

*LDE preparation.* LDE was prepared from a lipid mixture composed of 40 mg cholesteryl oleate, 20 mg egg phosphatidylcholine, 1 mg triolein, and 0.5 mg cholesterol. $^{14}$C-cholesteryl oleate was added to the mixture. Emulsification of lipids was done by prolonged ultrasonic irradiation in aqueous media, and the procedure of two-step ultracentrifugation of the crude emulsion with density adjustment by addition of KBr to obtain LDE microemulsion was carried out by the method of Ginsburg *et al*. (16), modified by Maranhão *et al.* (11). LDE was dialyzed against saline solution and passed through a 0.22 µm filter for injection into the patients.

*LDE plasma kinetics.* The participants were fasting for 12 h at the beginning of the test at approximately 9 AM, but they were allowed two standard meals during the study, at approximately 12:30 and 7 PM. LDE containing 37 kBq $^{14}$C-cholesteryl oleate and of 5–6 mg of total lipid mass in a volume of 500 µL aqueous solution was intravenously injected in a bolus. Plasma samples were collected over a 24-h period, in intervals of 5 min and 1, 2, 4, 6, 8, 12, and 24 h. Aliquots (1.5 mL) of blood plasma were extracted with chloroform/methanol (2:1, vol/vol) (17), and the solvent phases were transferred into counting vials and dried under a nitrogen stream. Radioactivity was quantified in a scintillation solution (PPO/dimethyl POPOP/Triton X-100/toluene, 5 g/0.5 g/333 mL/667 mL) using a Beckman LS100C spectrometer.

*Estimation of fractional catabolic rate (FCR).* FCR of the LDE $^{14}$C-cholesteryl oleate was calculated according to the method described by Matthews (18) as FCR, where $a_1$, $a_2$, $b_1$, and $b_2$ were estimated from biexponential curves obtained from the radioactivity remaining in plasma after injection, fitted by the least squares procedure, as $y = (a_1 \cdot e^{-b_1 x}) + (a_2 \cdot e^{-b_2 x})$ where $y$ represents the radioactivity plasma decay.

*Statistical analysis.* The differences in the FCR of LDE, triglycerides, and apo were evaluated by analysis of variance, whereas the Kruskal–Wallis test was used for cholesterol (total and fractions) data analysis. In all analyses, a difference of $P < 0.05$ was considered statistically significant.

## RESULTS

Table 1 shows the plasma lipid and apo data of the two study groups. Total and LDL cholesterol values were about 30% greater in the elderly and middle-aged subjects than in younger individuals ($P < 0.05$). VLDL and HDL cholesterol did not differ among the groups, nor did the values of triglycerides, apo B, and apo A1.

Figure 1 shows the plasma decay curves of the LDE cholesteryl ester radioactive label. It is apparent that the curve of the older subjects was slower than that of the younger ones and that the decay curve of the middle-aged subjects tended to run between that of the two other groups. In fact, the older subjects had a roughly 50% diminution of the emulsion cholesteryl ester FCR compared with the younger group ($0.032 \pm 0.035$ h$^{-1}$ and $0.071 \pm 0.035$ h$^{-1}$, respectively; mean ± SD, $P < 0.05$). The group of middle-aged subjects showed FCR values ($0.050 \pm 0.071$ h$^{-1}$) between the groups of younger and elderly subjects, although not statistically different from either.

Figure 2 shows the negative correlation that was found between the emulsion cholesteryl ester FCR and age ($r = -0.47$, $P = 0.008$).

## DISCUSSION

In this study, while the plasma total and LDL cholesterol values were greater in the elderly and middle-aged than in the young subjects, all the other lipid and apo values were similar in the three groups.

In the studies by Ericksson *et al.* (7) and Grundy *et al.* (6), LDL kinetics were evaluated by $^{125}$I labeling of the apo B100 component and reinjecting it into the subjects. Because apo B100 is not an exchangeable protein and thus remains attached to the LDL particles, its decay curve mirrors the plasma decay curve of the lipoprotein. The use of the autologous lipoprotein is obligatory because of the risk of transmission to recipient subjects of HIV, hepatitis, or other infectious agents by the heterologous preparation. Since LDL is not a homogeneous fraction, comprising subfractions with different compositions, sizes, and densities that show wide interindividual variations, it is conceivable that these factors

**TABLE 1**
**Plasma Lipids and Apolipoproteins in the Young, Middle-Aged, and Elderly Groups of Subjects ($n = 10$ in all groups)**

*Significance at the 0.05 level. HDL, high density lipoprotein; LDL, low density lipoprotein; VLDL, very low density lipoprotein; Apo, apolipoprotein.

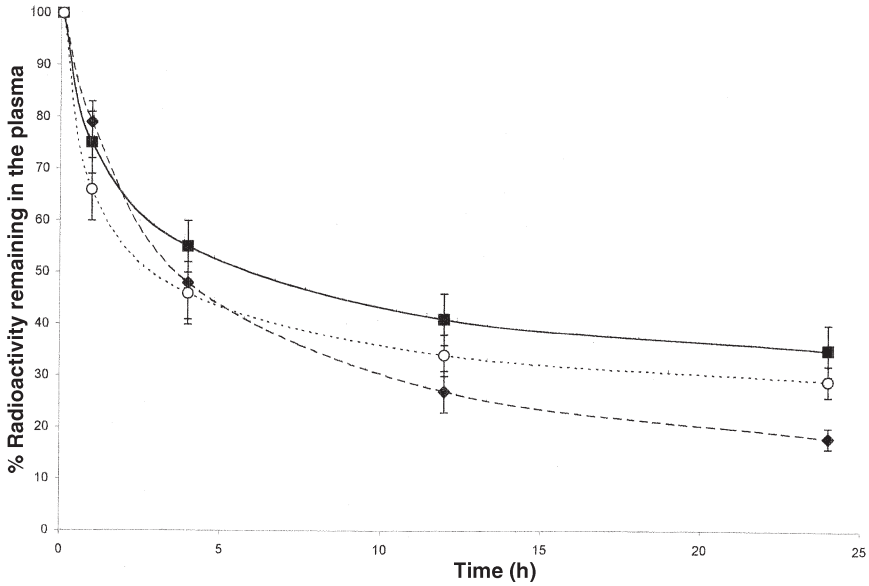

**FIG. 1.** Decaying curves of the emulsion $^{14}$C-cholesteryl oleate obtained from young (♦), middle-aged (○) and elderly (■) subjects ($n$ = 10 in all groups). The labeled emulsion was intravenously injected in a bolus, and blood samples were drawn in preestablished intervals over 24 h for measurement of the radioactivity in a scintillation solution. Points and bars are mean ± standard error of the mean.

may influence the plasma kinetics of autologous $^{125}$I apo B100-labeled LDL when subjects are compared with each other. In fact, smaller, denser LDL subfractions were shown to have poorer affinity for the LDL receptors. Regarding the elderly, it has been shown that LDL from older subjects possessed a higher proportion of cholesterol (19), and significant differences have been found in fatty acid composition of LDL between young and older subjects (20). It could then be possible that the delayed LDL clearance found in the elderly (1,6,7) could be attributed not only to decreased function of the LDL receptors that remove the lipoprotein from the plasma but also to age-related changes in LDL composition. Those changes could presumably decrease the affinity of LDL particles for the receptors, likewise leading to decreased clearance. In the study by Millar *et al.* (8), in which an intravenous infusion of deuterated leucine was used to label apo B100, decreased LDL removal rates were also found. As in the studies mentioned, the possibility that LDL status in the elderly could be implicated in the defect could not be excluded, although Ericksson *et al.* (7) found no differences in LDL isolated from the elderly compared with those from young subjects regarding uptake by lymphocytes.

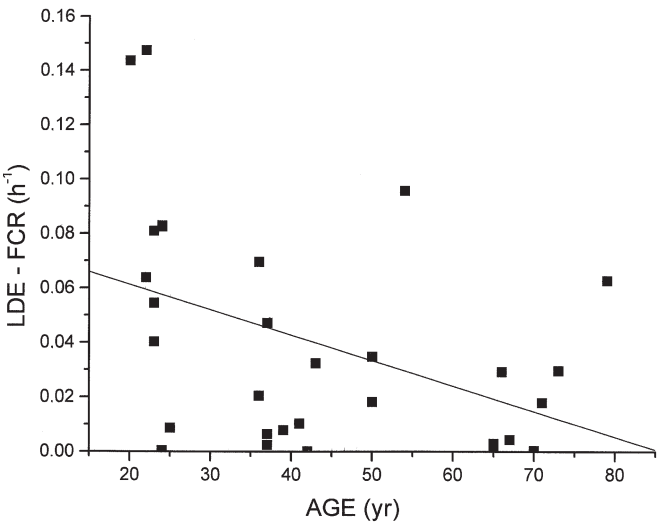

**FIG. 2.** Correlation between the fractional catabolic rate (FCR) of the emulsion radioactive cholesteryl esters and the age of subjects ($n$ = 30, $r$ = –0.47, $P$ = 0.008).

The lipid structure of LDL can be artificially modeled by protein-free emulsions that mimic the lipid physical behavior of native LDL (16,21). LDE particles are composed mainly of a phosphatidylcholine monolayer surrounding a cholesteryl oleate core also containing small amounts of unesterified cholesterol and triolein. When injected into the bloodstream, the metabolic behavior of LDE resembles that of endogenous LDL in rats (9) and in human subjects (11). Similar to triglyceride-rich emulsions (14,22), LDE is capable of assimilating apo from the plasma lipoproteins or from ones free in the plasma. *In vitro* experiments have confirmed that LDE is able to acquire various exchangeable apo, mainly apo E. These apo E molecules endow LDE with the capacity to be recognized and taken up by LDL receptors. In competition studies in cell incubates, it was shown that LDE is dislocated from its cell binding sites by native LDL but not by HDL, as expected, confirming that both LDL and the artificial emulsion share common binding sites. Relative to native LDL, LDE is more rapidly removed from plasma (23). This may be related to the differences in apo profiles on the particle surface. In fact, apo E has been shown to possess several times

greater affinity for the receptor than the unique LDL apo, namely, apo B100 (5). Adequacy of LDE to test LDL metabolism has been proven in clinical studies, wherein the plasma kinetic results obtained with LDE were as expected for native LDL according to the literature. In this respect, removal of LDE was slower in patients with familial hypercholesterolemia (11), wherein LDL receptor function was defective and accelerated in patients with acute myeloid leukemia (12) because in neoplastic cells LDL receptors were upregulated (24). The fact that LDE was removed from the plasma faster than native LDL is an additional methodological advantage because it shortens the period required for performance of the plasma kinetics test.

In our study, by using LDE as an investigation tool we expanded the findings of slowed LDL apo B100 removal, showing also that the removal of cholesterol carried in an LDL emulsion model was delayed. Because we injected the same standard preparation into all study subjects, it can be stated that the delayed emulsion clearance is indeed attributable to a deficiency in the mechanisms of removal from the plasma in the elderly rather than to compositional differences in the LDL fraction between elderly and young subjects.

In both native LDL and the emulsion model, the cholesterol ester moiety tended to shift partially to other lipoprotein classes by the action of the cholesteryl ester transfer protein (see Ref. 25 for a review). Therefore, our results of cholesterol ester-labeled LDE FCR are not strictly specific for the emulsion particles' removal from the plasma, as are those of the other studies mentioned here (5–7), wherein the plasma kinetics of labeled apo B100 were determined to assess the native LDL kinetics. In considering LDE as a tool to model native LDL to explore this metabolism, the negative correlation found between LDE FCR and age implies that with increasing age there is a progressive slowing down of the removal from plasma of this lipoprotein class.

As discussed by Miller (1), decline in the ability to clear LDL from bloodsteam might not be an inevitable consequence of aging in humans, but might result from potentially avoidable environmental factors or lifestyle features related to the aging process. In this regard, we have recently noticed that the LDE clearance is much greater in exercise-trained compared with sedentary subjects (26). If confirmed in the elderly, this observation might lead to novel insights in atherosclerosis prevention.

In conclusion, our study indicates that not only LDL apo B100, as reported by others, but also cholesterol packed in an LDL model emulsion is slowly removed from the plasma in the elderly. This removal deficiency is already manifested in middle-age subjects, who show clearance rates between those of the young and the elderly subjects.

**ABSTRACT:** Liposomes made from a natural marine lipid extract and containing a high polyunsaturated n-3 fatty lipid ratio were envisaged as oral route vectors and a potential α-tocopherol supplement. The behavior of vesicles obtained by simple filtration and of giant vesicles prepared by electroformation was investigated in gastrointestinal-like conditions. The influence of α-tocopherol incorporation into liposomes was studied on both physical and chemical membrane stability. Propanal, as an oxidation product of n-3 polyunsaturated fatty acids, was quantified by static headspace gas chromatography when α-tocopherol incorporation into liposome ratios ranged from 0.01 to 12 mol%. Best oxidative stability was obtained for liposomes that contained 5 mol% α-tocopherol. Compared to the other formulas, propanal formation was reduced, and time of the oxidation induction phase was longer. Moreover, α-tocopherol induced both liposome structural modifications, evidenced by turbidity, and phospholipid chemical hydrolysis, quantified as the amount of lysophospholipids. This physicochemical liposome instability was even more pronounced in acid storage conditions, i.e., α-tocopherol incorporation into liposome membranes accelerated the structural rearrangements and increased the rate of phospholipid hydrolysis. In particular, giant vesicles incubated at pH 1.5 underwent complex irreversible shape transformations including invaginations. In parallel, the absorption rate of α-tocopherol was measured in lymph-cannulated rats when α-tocopherol was administrated, as liposome suspension or added to sardine oil, through a gastrostomy tube. α-Tocopherol recovery in lymph was increased by almost threefold, following liposome administration. This may be related to phospholipids that should favor α-tocopherol solubilization and to liposome instability in the case of a high amount of α-tocopherol in the membranes. A need to correlate results obtained from *in vitro* liposome behavior with *in vivo* lipid absorption was demonstrated by this study.

Paper no. L8781 in *Lipids 36*, 1313–1320 (December 2001).

For several years, n-3 polyunsaturated fatty acids (PUFA) have been investigated for their roles in numerous metabolic pathways and regulation processes. At the membrane level, n-3 PUFA play a role in cellular communication (1) and regulation of the extracellular milieu (2,3). At the physiological level, PUFA are associated with a variety of health benefits, such as alleviated symptoms of rheumatoid arthritis (4) and a reduced risk of coronary heart disease. In this latter case, PUFA influence parameters such as plasma triglyceride level (5), lipoprotein metabolism (6,7), and platelet function (8,9). With the aim to elucidate PUFA benefits, dietary fat modification has been undertaken and is now considered to be an effective tool for modifying physiological parameters (10,11) or cell membrane fatty acid composition (12). Among PUFA, eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) seem to play a major role (1,9,12). Nevertheless, these unsaturated lipids are susceptible to oxidation, the mechanism of which has been thoroughly studied (13,14). As lipid oxidation products are implicated in a number of pathological events (14,15), the presence of antioxidants in biological membranes is essential for lipid integrity. Among the natural antioxidants, α-tocopherol, the main active form of vitamin E, is known to be retained in the membrane and to suppress natural and model membrane oxidation (16,17). It acts by inhibiting the propagation step of the free-radical autoxidation mechanism by reacting with various free radicals (18). In parallel, evidence has accumulated for a protective effect of vitamin E against risk of cancers (19,20) and cardiovascular disease (21,22). In particular, the results of prospective cohort studies and intervention trials have demonstrated that high intake of vitamin E can reduce cardiovascular risk (23).

Nevertheless, absorption of vitamin E depends on various parameters, such as the individual's ability to absorb fat (24) and the identity of the lipids co-ingested (24,25). Up to 70% absorption of α-tocopherol by humans has been reported in the literature (26), but this value seems to be overestimated (24); 50% absorption rate should be considered. Because of increasing interest in its protective effects as well as other beneficial effects, many vitamin E preparations have become widely available. The most marketed form is as gelatin capsules. However, as bile salts are required for its absorption (27), vitamin E administration as a dietary supplement should preferably be taken with food, which consumers may not know. Thus, novel forms of vitamin E preparations have been formulated, i.e., oil, liposome and cyclodextrin preparations (28), self-emulsifying systems (29), or emulsion fat globules (30). However, a normal emulsion preparation is bulky and

suffers from cracking and creaming on storage. Thus, there is an increasing interest in the use of more stable systems.

In this context, we envisaged using liposomes based on a natural lipid mixture extracted from a marine organism, in association with α-tocopherol. First, α-tocopherol incorporation should improve chemical stability of the liposome suspensions. Second, in the case of an oral dosage form, lipid vesicles should provide an adequate binding surface for pancreatic phospholipase $A_2$, and the lysophospholipids generated by phospholipid hydrolysis should favor α-tocopherol absorption. Indeed, fat-soluble vitamins, including vitamin E, are better absorbed in the presence of surfactants or when in emulsified vehicles compared to oily preparations (31). Thus, the purpose of this study was (i) to select the most efficient amount of α-tocopherol to incorporate into PUFA-rich liposome membranes so as to prevent lipids from oxidizing when vesicles are submitted to conditions similar to those of the stomach, i.e., physiological temperature and acid medium, and (ii) to correlate the *in vitro* physicochemical behavior of the obtained liposomes with α-tocopherol recovery in rat lymph. This study was also carried out to determine whether the lipids (chemical and physical forms) associated with α-tocopherol administration affected the bioavailability of the vitamin. For this purpose, α-tocopherol intestinal absorption following liposome administration and sardine oil-based preparation were compared.

## MATERIALS AND METHODS

*Materials.* The natural marine lipid mixture used for liposome preparation was supplied by Phosphotech (Nantes, France). Total lipids contained mainly phospholipids (69 wt%), among which phosphatidylcholine (PC) and phosphatidylethanolamine (PE) were the major classes, 68 and 23 wt%, respectively (32,33). EPA and DHA represented 14 and 31% of PUFA (48% of total fatty acids), respectively (32). Sardine oil was supplied by Pronova Biocare (Sandefjord, Norway). Fatty acid composition of sardine oil determined by gas chromatography (GC) indicated 40% PUFA with 7% EPA and 26% DHA. In marine lipids as well as in sardine oil, α-tocopherol was initially present at 0.01 mol%. HEPES, TRIS, and EDTA were purchased from Sigma (St. Louis, MO). Two buffer solutions were used for liposome preparations: HEPES (10 mM HEPES, 145 mM NaCl, pH 7.4) and TRIS (1 mM TRIS, 10 mM EDTA, pH 7.4). α-Tocopherol (Fisher Scientific, Elancourt, France) was used without further purification. The solvents were of analytical grade or distilled when needed.

*Liposome preparations.* α-Tocopherol-associated liposome suspensions were prepared using the total marine lipid extract. α-Tocopherol and marine lipids were dissolved in chloroform/methanol (2:1, vol/vol) and blended in ratios ranging from 0 to 12 mol%. Organic solvents were removed under a nitrogen stream followed by a lyophilization step overnight. The liposome suspensions were obtained, after a hydration step, by filtration of the lipid suspension through polycarbonate membranes of 5-μm pore diameters (Millipore Corp., Bedford, MA) as described in Reference 34. In the absence of α-tocopherol, this method led to a mixture of vesicles characterized by a variable number of lamellae and a mean diameter equal to 6.3 μm (33,34). Similar results were obtained in the presence of α-tocopherol (results not shown). Adjustments of liposome suspensions to required pH were carried out using HCl (10 N) or NaOH (10 N) solutions.

Giant vesicles were prepared using the electroformation procedure described in Reference 34. α-Tocopherol (5 mol%) was added to the marine lipids. The electrical conditions used were: 10-Hz electric field applied increasingly from 50 to 800 mV $mm^{-1}$ amplitude in 60 min. Then the chamber was left overnight at 10 Hz and 800 mV $mm^{-1}$. Vesicle dispersion was promoted by the application of a low-frequency field (4 Hz).

*Liposome characterization.* Turbidity measurements [optical density (OD) at 400 nm] were performed at 37°C in a thermostated cell support using a PerkinElmer lambda Bio 20 spectrophotometer to follow liposome stability as a function of time. Micromanipulation experiments were carried out on giant vesicles as described in Reference 34. Direct visualization of liposome behavior upon acid stress was performed using a phase-contrast microscope (Axiovert 135 with a water immersion ×40/0.75 objective; Zeiss, Jena, Germany).

*Liposome chemical hydrolysis.* Liposome dispersions (1.5 mg $mL^{-1}$) incubated at 37°C in neutral (pH 7.4) and acid (pH 1.5) solutions for 3 and 24 h were tested for diacylphospholipids and lysophospholipids. The different lipid classes were assayed after lipid extraction using the procedure of Folch *et al.* (35) and two-dimensional thin-layer chromatography (34). The different spots were scraped off and analyzed for total phosphorus (36).

*Lipid oxidation.* Propanal (secondary oxidation product of n-3 PUFA) was analyzed by static headspace GC using a DB1701 column (30 m × 32 mm; J&W Scientific, Folsom, CA) (34). Liposomes (1 mg) were incubated up to 48 h at 37°C in 1 mL HEPES solution at pH 1.5 or pH 7.4. The quantity of propanal formed upon lipid peroxidation was determined from a calibration curve using a pure aldehyde standard solution.

*α-Tocopherol analysis.* α-Tocopherol present in the liposome membrane and in the lymph was quantified by high-performance liquid chromatography (HPLC) on the corresponding lipid extracts. The HPLC system consisted of an HPLC pump (Spectra system P4000) and an automatic sample injector (Spectra system AS3000). A column (Ultrasphere ODS, 25 × 0.46 cm, Beckman) was used with methanol as mobile phase (flow rate of 1 mL $min^{-1}$). α-Tocopherol was detected by fluorescence spectrophotometry (excitation wavelength 292 nm; emission wavelength 330 nm). Quantification of α-tocopherol was carried out using a calibration curve made with pure α-tocopherol standard solutions.

*Animals and surgical procedures.* Official French regulations for the care and use of laboratory animals were followed. Male Wistar rats weighing 250–300 g were obtained from Elevage Janvier (Saint-Berthein, France). They were housed for 1 wk in a controlled environment, with constant

temperature and humidity. They were fed a fat-free diet (UAR, Epinay, France) and allowed free access to water until 24 h before the surgery. Under pentobarbital anesthesia (0.05 mg $g^{-1}$ body wt), a polyethylene catheter (i.d. 0.86 mm, o.d. 1.27 mm; Biotrol, Paris, France) was inserted into the main thoracic lymph duct of each rat for collecting the lymph (37,38). After surgery, the rats were placed in individual restraining cages in a warm environment with tap water freely available. A few hours after the surgical procedure, 0.4 g of lipids (liposome suspension or sardine oil) was administered through a gastric feeding tube followed by 1 mL water in the case of sardine oil. The lymph was collected for 24 h without fractionation in tared tubes maintained in an ice bath. During the collection period, lymph flow averaged 0.6 mL $h^{-1}$. Total lipids of lymph were immediately extracted using the method of Folch *et al.* (35), and α-tocopherol content was quantified. At least five cannulated rats were used for each lipid ingestion condition studied.

*Statistical analysis.* Differences between the two groups were tested for significance using Student's *t*-test. Data were expressed as mean values ± standard deviations.

## RESULTS AND DISCUSSION

*Influence of α-tocopherol on chemical stability.* Oral administration of lipid-soluble molecules in liposomal form provided an alternative route for active compound delivery that might be more efficient. By virtue of their lipid composition, liposomes could be effective for PUFA delivery because phospholipase $A_2$ was able to hydrolyze the phospholipids present in the marine lipid-based membranes even after a 3-h incubation in acid medium that mimicked the gastric residence time (33). However, a significant amount of propanal as secondary oxidation product of n-3 fatty acids was detected after 24 h of storage (33,34). In the present study, all oxidation experiments were performed at 37°C, which corresponded to the physiological temperature. Figures 1A and 1B present lipid oxidation as a function of time. Liposomes containing different ratios of α-tocopherol were incubated in neutral (Fig. 1A) and acid (Fig. 1B) pH media. A significant increase in the rate of propanal formation was observed at pH 7.4 and at low α-tocopherol concentration (0.01 mol%) after a 10-h induction period. This increase corresponded to the propagation phase of the free-radical autoxidation mechanism. Less than 12% of the potentially oxidizable n-3 PUFA was degraded in 24 h; 80 nmol of propanal per μmol of total lipids was the maximum propanal amount that could be produced (Fig. 1B). This result agrees with the fact that liposomes containing high amounts of PUFA can demonstrate great oxidative stability (39). Antioxidant properties of phospholipids have been reported (40,41). They may arise from (i) amine groups of PC and PE that would act *via* a nucleophile reaction as decomposers of hydroperoxides to alcohols (40) and (ii) the selective distribution of PUFA at the *sn*-2 position in marine lipids. In addition, liposome oxidative stability could also result from phospholipid conformation in the membrane (42) and/or the presence of additional lipids, such as cholesterol. Through the condensing effect of cholesterol on the bilayer arrangement over the lipid phase transition temperature (43), PUFA present in the marine lipid-based membranes could be less accessible to the attack of free radicals and/or oxygen. In Figure 1A, pro- and antioxidant properties of α-tocopherol are illustrated for different vitamin amounts added up to 12 mol%. For 2 mol% ratio, the induction period lasted 16 h. At 10 h, for 0.01 mol% α-tocopherol concentration, the rate of propanal formation decreased. When α-tocopherol content was increased up to 5 mol%, aldehyde formation was prevented for 38 h. Thus, the antioxidant activity of α-tocopherol was influenced by its concentration within the membrane, in agreement with previous studies (18,39). The antioxidant activity of tocopherols is

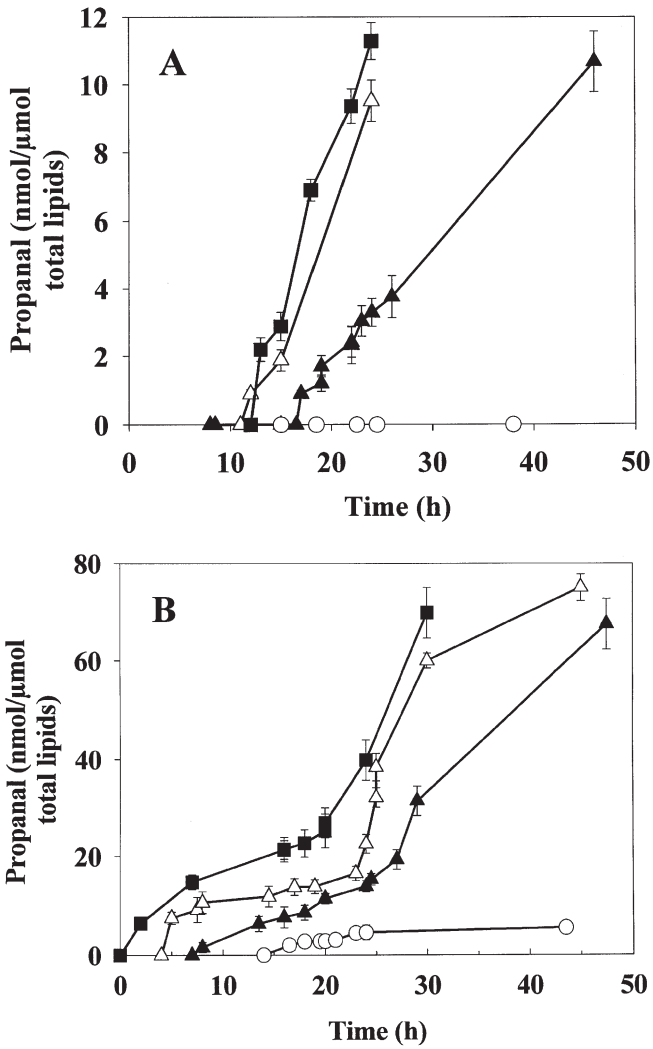

**FIG. 1.** Time-course oxidation curves showing propanal concentration (nmol/μmol total lipids) determined by headspace capillary gas chromatography as a function of α-tocopherol membrane concentration: 0.01 mol% (△), 2 mol% (▲), 5 mol% (○), 12 mol% (■), for liposomes incubated at pH 7.4 (A) and pH 1.5 (B). Lipid peroxidation was studied on liposomes prepared by filtration on 5-μm diameter filters ($[lip]_{tot}$ = 1 mg · $mL^{-1}$) incubated at 37°C. All the experiments were performed in triplicate with a standard deviation of ±8%.

mainly due to their ability to donate their phenolic hydrogens to lipid free radicals. The α-tocopheroxyl radical formed should be inactive toward stable molecules and should limit its reaction only to donation of hydrogen(s) to radicals and to radical–radical coupling (18). Moreover, an antioxidant synergy between α-tocopherol and phospholipids was reported that could involve amino groups in the regeneration of α-tocopherol by hydrogen transfer (41). For the 12 mol% α-tocopherol ratio (Fig. 1A), the vitamin antioxidant effect vanished and propanal formation was similar to that measured for 0.01 mol%. High concentrations of α-tocopherol favor side reactions, and can lead to a pro-oxidant effect in vegetable oils (18) and liposomes (39). The pro-oxidant effect of α-tocopherol was related to high concentrations of its tocopheroxyl radicals, which could be involved in reaction mechanisms described in Reference 18. Reversible reactions of the tocopheroxyl radicals with unperoxidized lipids and with lipid hydroperoxides were suggested to occur in membranes.

To be effective as an oral drug delivery system, liposomes have to clear the obstacles presented by gastrointestinal digestive fluids, especially pH variations from 1–2 (in the stomach) to 7–8 (in the intestine). Thus, the influence of α-tocopherol incorporation into the liposomes incubated in an acid medium (pH 1.5) for times up to 48 h was investigated (Fig. 1B). At a low α-tocopherol concentration (0.01 mol%), after a 5-h induction phase, the propanal formed increased to about 15% of the maximum aldehyde production. Then, the oxidation process held stable for about 15 h and then rapidly reached the maximum value of 80 nmol/μmol of total lipids. A similar profile was obtained for 2 mol% α-tocopherol, although the induction phase was slightly longer and the curve was shifted toward lower propanal values. For 5 mol% α-tocopherol incorporated into liposome membranes, the induction phase lasted 12 h. The pro-oxidant role of α-tocopherol at 12 mol% was again demonstrated when liposomes were stored under acid conditions. On the whole, the pro- and antioxidant activities of α-tocopherol for liposomes incubated in an acid medium were similar to those evidenced in a neutral medium. However, medium acidification acted to shorten the induction phase and increase the amount of propanal produced, whatever the α-tocopherol incorporation ratio. These results are in agreement with the fact that lipid peroxides decompose faster at high temperatures and low pH in the presence of transition metals (18). Moreover, marine lipid-based liposomes placed in acid conditions are subjected to vesicle aggregation and complex supramolecular and/or morphological changes as a function of time (see below; Ref. 34). These structural rearrangements could influence lipid oxidative stability (39,44).

Chemical degradation of liposome diacylglycerophospholipids was assayed looking at lysophospholipid levels, i.e., lysophosphatidylcholine (LPC) and lysophosphatidylethanolamine (LPE) resulting from carboxy ester hydrolysis (Table 1). At low α-tocopherol concentration (0.01 mol%), 1-d storage at 37°C favored hydrolysis, as evidenced by a significant increase in lysophospholipid amounts. The hydrolysis process was favored by acid medium conditions. We already showed that hydrolysis in the marine lipid-based liposomes was more pronounced in acid medium than in neutral medium at 25°C (34) in agreement with ester cleavage being catalyzed in the presence of acid (45). In addition, the hydrolysis process was significantly amplified when physiological pH and temperature conditions were combined (33). The influence of 5 mol% α-tocopherol incorporation on chemical vesicle behavior was studied because this concentration corresponded to the maximal oxidative stability observed for the marine lipid-based liposomes (Fig. 1A,B). α-Tocopherol presence slightly increased the amount of LPC and LPE of liposomes stored in neutral medium, whereas phospholipid degradation was more pronounced in acid storage conditions. The influence of α-tocopherol incorporation on liposome membrane properties has been widely reported in the literature. The role of vitamin E on membrane behavior appears to be very dependent on the lipid composition. For PC-based liposomes, the best stability, assayed by the release of an entrapped water-soluble dye, was obtained for 15 mol% α-tocopherol and was similar to that observed with 37 mol% cholesterol (46). In this case, α-tocopherol decreased membrane fluidity for lipids over their phase transition temperature as reported for cholesterol (43). However, the condensing effect of α-tocopherol progressively vanished as fatty acid unsaturation increased (47). In this study, in which the PUFA content of the lipids used was high, α-tocopherol could have favored lipid hydrolysis by increasing membrane permeability to protons when liposomes were incubated in acid medium. As a consequence, the ester cleavage rate could be increased by increasing the amount of catalyst. The fact that the presence of α-tocopherol also accelerated lipid hydrolysis under neutral storage conditions remained unexplained.

*Influence of α-tocopherol on structural stability.* The influence of 5 mol% α-tocopherol incorporation on liposome morphological stability was studied for two types of vesicles,

i.e., giant oligolamellar liposomes prepared by electroformation and multilamellar vesicles obtained by simple filtration. Liposome micromanipulations were performed to change the outside environment of isolated giant vesicles. Figures 2A–D show a typical shape transformation sequence observed by phase-contrast microscopy when the medium outside the vesicle was acidified from 7.4 to 1.5. Vesicle diameter drastically decreased during the first 5 min. Simultaneously, granulations appeared in the liposome internal volume. No significant membrane rearrangements were observed after 5 min. Neutralization of the external medium did not reverse the structural rearrangements (results not shown). The possible roles of pH in liposome membrane rearrangements were already discussed (34). The present results pointed out the specific influence of α-tocopherol on structural stability. α-Tocopherol incorporation into liposomes accelerated the kinetics of membrane rearrangements compared to the behavior of α-tocopherol-free liposomes (34).

Figure 3 shows the evolution of turbidity with time of α-tocopherol-associated liposomes obtained by the filtration technique and stored at two different pH values. The turbidity remained stable for about 1 d, for liposomes containing 0.01 mol% α-tocopherol and stored at pH 7.4. In contrast, turbidity slowly decreased with time for a 5 mol% α-tocopherol ratio. Incorporation of the lipophilic vitamin into the bilayer altered the liposome stability, suggesting a modification in membrane characteristics with time. When liposomes were placed in an acid medium (pH 1.5), turbidity drastically increased, indicating vesicle aggregation as confirmed by optical microscopy observation (results not shown). Increasing the α-tocopherol amount in the liposomes seemed to enhance the aggregation phenomenon, as suggested by the turbidity values. Whatever the α-tocopherol concentration, turbidity decreased with time. This turbidity pattern was already observed for α-tocopherol-free liposomes (33), although the decrease was more pronounced in the presence of 5 mol% vitamin E. Study of α-tocopherol-free liposomes showed that the turbidity decrease could be interpreted in terms of membrane rearrangements and small aggregate formation (33). These structural modifications were also probably implied in the behavior of α-tocopherol-associated liposomes. In the physiological digestion process, liposomes stay about 2–3 h in acid medium (stomach) before moving to a neutral environment (intestine). To mimic this change in pH, an α-tocopherol-associated liposome sample previously stored under acid conditions for 3 h was further neutralized. Medium neutralization induced a decrease of suspension turbidity correlated, at least partly, with a dispersion of the aggregated liposomes. However, in contrast with results observed for α-tocopherol-free liposomes (33), the resulting OD was slightly lower than that of the untreated sample, suggesting the occurrence of enhanced membrane rearrangements. On the whole, in acid conditions, it seemed that the incorporation of 5 mol% α-tocopherol reflected the morphologic instability already observed for vesicles in neutral conditions.

Membrane chemical asymmetry between the monolayers may be responsible, at least partly, for structural rearrange-

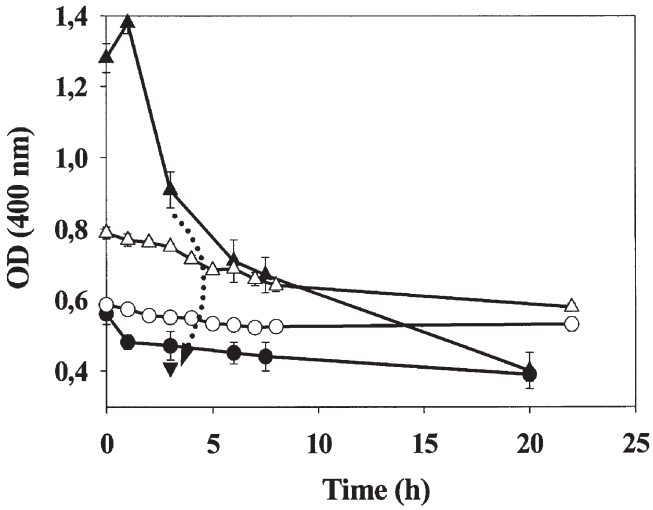

**FIG. 3.** Variations of optical density (OD) at 400 nm as a function of time for α-tocopherol-associated liposomes incubated at different pH values and 37°C: 0.01 mol% α-tocopherol, pH 7.4 (○); 0.01 mol% α-tocopherol, pH 1.5 (△); 5 mol% α-tocopherol, pH 7.4 (●); 5 mol% α-tocopherol, pH 1.5 (▲). Liposomes were prepared by the filtration technique using 5-μm pore diameter filters ($[lip]_{tot}$ = 0.25 mg · $mL^{-1}$). Acidification was performed using HCl (10 N) solution. A sample corresponding to 5 mol% α-tocopherol-associated liposomes stored during 3 h in acid medium (pH 1.5) was neutralized with NaOH (10 N) solution (▼). All the experiments were performed in triplicate with a standard deviation of ±10%.

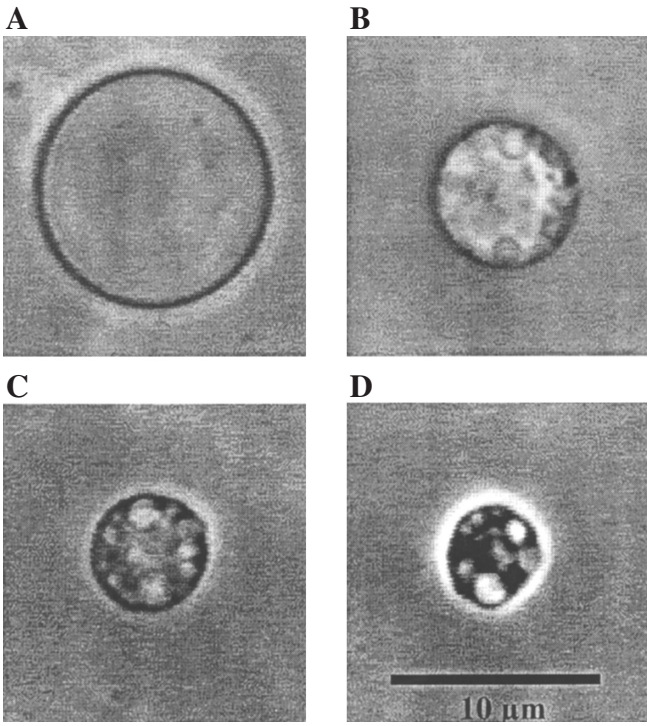

**FIG. 2.** Morphological changes observed by phase-contrast microscopy of a 5 mol% α-tocopherol-associated giant vesicle. The vesicle was swollen in TRIS buffer at pH 7.4 (A) and transferred in acid TRIS solution (pH 1.5). The incubation time in the low-pH medium was 30 s (B), 1 min (C), and 5 min (D). The temperature was 25°C. The bar corresponds to 10 μm.

ments such as invaginations or buddings that can occur both in multilamellar vesicles and giant unilamellar liposomes (48,49). In our case, these rearrangements were actually observed by optical microscopy for giant vesicles and evidenced by turbidimetry for filtered liposomes associated with 5 mol% α-tocopherol and stored in acid medium. The morphologic instability observed may be correlated with high amounts of lysophospholipids and/or increased membrane permeability to water and protons due to α-tocopherol presence in PUFA-rich membranes. The difference in the rearrangement kinetics between filtered liposomes and giant vesicles may arise from a higher lamellarity in filtered liposomes and the existence of aggregated vesicles.

In vivo *α-tocopherol lymphatic absorption.* Vitamin E absorption depends on an individual's ability to absorb fat (24,50). Fractional absorption of α-tocopherol is often overestimated (24). Rats can be considered as a good model for humans as far as digestion processes are concerned. Rat lymphatic absorption rates ranging from 40 to 65% of total ingested α-tocopherol have been found (51,52). Whether α-tocopherol absorption is influenced by unsaturation of the administered oil remains controversial (53–55). However, α-tocopherol absorption is largely influenced by the co-ingested lipids (25,56) as well as by α-tocopherol concentration (53). In this work, the intestinal absorption of α-tocopherol could not be precisely determined because lymph recovery was not quantitative. Thus, efficiencies of the liposome form or sardine oil to deliver α-tocopherol were only compared and discussed on the lymphatic vitamin concentration basis.

α-Tocopherol was not detected in lymph of rats fed a fat-free diet. Figure 4 shows that liposomes facilitated α-tocopherol uptake after oral delivery to rats compared to sardine oil ingestion. The vitamin recovery in lymph increased twofold after liposome administration compared to sardine oil ingestion when both were associated with low α-tocopherol concentration (0.01 mol%). This result was in agreement with α-tocopherol recovery in liver being highest after oral ingestion of liposomes rather than oil (25). It was reported that high levels of linoleic acid in diets (54) and linolenic acid in the form of fatty acids (55) or natural oils (53) decreased the absorption rate of vitamin E. In this study, the PUFA amount in sardine oil was about twice that in liposomes. This could partly explain the lower recovery of α-tocopherol in rats fed sardine oil. Nevertheless, liposome phospholipids might promote vitamin uptake in rats. Indeed, phospholipase $A_2$ was able to catalyze *in vitro* marine phospholipid hydrolysis even when liposomes were previously submitted to an acid treatment (33). Consequently, the higher amount of lysophospholipids may facilitate α-tocopherol incorporation into bile salt–lipid mixed micelles, in agreement with lymphatic absorption of α-tocopherol enhanced by LPC (56). Thus, the relative α-tocopherol lymphatic absorption obtained in rats fed sardine oil or liposomes may account for different parameters, in particular, the lipid composition (PUFA amount, phospholipid presence, etc.). However, when α-tocopherol was increased up to 5 mol% in both ingested lipid forms, α-tocopherol lymphatic recovery was three times higher in rats

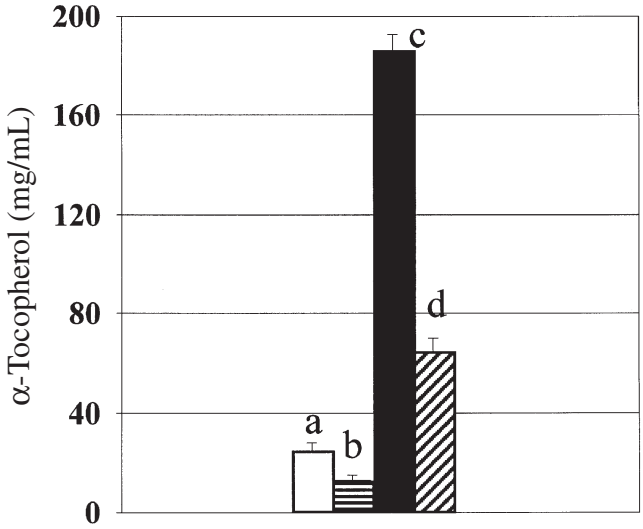

**FIG. 4.** α-Tocopherol lymphatic recovery (mg · $mL^{-1}$ lymph) in rats after oral administration of different lipid forms: α-tocopherol-associated liposomes, 0.01 mol% (empty bar) and 5 mol% (solid bar), and sardine oil containing α-tocopherol, 0.01 mol% (striped bar) and 5 mol% (hatched bar). Liposomes were prepared by the filtration technique using 5-μm pore diameter filters. Lipid ingestion by rats corresponded to 0.4 g liposome suspension or oil. Marine lipids and sardine oil initially contained 0.01 mol% of α-tocopherol. Data are means ± standard deviations of at least five rats. Letters a, b, c, and d indicate statistical difference, $P < 0.05$.

fed liposomes compared to rats fed sardine oil. In other words, increasing the α-tocopherol/lipid ratio led to higher absorption efficiency from liposomes than from oil. In the case of liposomes, this result may account for physicochemical membrane instability of 5 mol% α-tocopherol-associated vesicles compared with vesicles containing only 0.01 mol% α-tocopherol, as pointed out by the *in vitro* studies. Membrane destabilization, suggested by turbidity measurements and visualized by optical microscopy in the case of giant liposomes, associated with increased formation of lysophospholipids might favor liposome solubilization by bile salt and thus, α-tocopherol incorporation into the mixed micelles. A similar threefold increase of α-tocopherol absorption also has been measured for a self-emulsifying vitamin E preparation tested and compared to soft gelatin vitamin E capsules (29). The extent of absorption under fasting conditions has been found satisfactory. Because bile salts are required for vitamin E absorption, vitamin administration should be associated with food to ensure the best vitamin bioavailability. Moreover, results concerning the kinetic behavior of α-tocopherol administered in oil and in liposome forms have suggested that liposome formulation might result in longer persistence of the vitamin in plasma compared to oil preparation (28). This result was obtained after oral administration to heifers and has to be verified in rats and humans.

α-Tocopherol (5 mol%) incorporated into the membranes acted on the physicochemical behavior of the liposome structures. α-Tocopherol prevented the lipid membranes from peroxidation by increasing the induction phase and reducing the

propanal production even in drastic conditions such as low pH. However, it induced structural rearrangements and favored chemical hydrolysis in liposomes, especially when the suspensions were stored in acid conditions. This last phenomenon presumably occurred through increased membrane permeability. Membrane integrity was not totally maintained. *In vivo* α-tocopherol lymph recovery evidenced that liposomes acted by improving the vitamin uptake compared to a classical fish oil administration. The extent of α-tocopherol absorption from liposome formulation may arise from lysophospholipids generated through phospholipase $A_2$ hydrolysis and vesicle physicochemical instability due to α-tocopherol incorporation. These results could be useful with a view to promoting α-tocopherol absorption in bile-duct-obstructed patients or in the case of chronic cholestatic liver disease. Moreover, combination of α-tocopherol in liposomes may also enable administration of mixtures of lipid-soluble vitamin and PUFA in a single dose.

**ABSTRACT:** A novel vitamin E derivative, (6″-hydroxy-2″,5″,7″,8″-tetramethylchroman-2″-yl)methyl 3-(2′,4′-dihydroxyphenyl)propionate (TM4R), which has a chromanoxyl ring and 4-substituted resorcinol moieties, was synthesized; and its inhibitory effects on tyrosinase, antioxidant ability, and lightening effect of ultraviolet B (UVB)-induced hyperpigmentation were estimated. TM4R showed potent inhibitory activity on tyrosinase, which is the rate-limiting enzyme in melanogenesis. The scavenging activities of TM4R on 1,1-diphenyl-2-picrylhydrazyl and hydroxyl radicals were found to be nearly the same as those of α-tocopherol. Furthermore, an efficient lightening effect was observed following topical application of TM4R to UVB-stimulated hyperpigmented dorsal skin of brownish guinea pigs. These results suggest that TM4R may be a candidate for an efficient whitening agent, possibly by inhibiting tyrosinase activity and biological reactions caused by reactive oxygen species.

Paper no. L8618 in *Lipids 36,* 1321–1326 (December 2001).

A number of factors determine the color of mammalian skin and hair. The most important factor is the degree and distribution of melanin pigmentation. Compounds that inhibit melanin synthesis are useful not only in cosmetics as skin-whitening agents but also as a remedy for disturbances in pigmentation. Tyrosinase (phenol oxidase) is known to be a key enzyme for melanin biosynthesis in plants, microorganisms, and mammalian cells (1). Therefore, many tyrosinase inhibitors have been tested in cosmetics and pharmaceuticals as a way of preventing overproduction of melanin in epidermal layers (2).

Also, various types of stimulation, including exposure to ultraviolet (UV) radiation, induce lipid peroxidation in the skin, which may in turn cause damage to epidermal cells, leading to postinflammatory hyperpigmentation. One of the biggest causative agents of hyperpigmentation is probably oxidative stress caused by UV (3). To date, however, research on the regulation of melanogenesis has focused on factors that affect tyrosinase, the rate-limiting enzyme in the melanogenic pathway, including research on chemicals that inhibit tyrosinase function. Furthermore, considering the importance of counteracting oxidative stress caused by UV as a means to prevent skin damage, it is important to design a multifunctional skin-whitening agent with both antioxidant and anti-tyrosinase abilities.

Oral intake of vitamin E (α-tocopherol) has been reported to be effective for the treatment of facial hyperpigmentation (4). Also, α-tocopheryl ferulate, which is a compound of α-tocopherol and ferulic acid connected by an ester bond, has been reported to suppress melanogenesis and inhibit biological reactions induced by reactive oxygen species (5). α-Tocopherol is known to act as an inhibitor of oxidative attack of free and membrane-bound unsaturated fatty acids and also scavenges active oxygen species such as superoxide anion radicals, singlet molecular oxygen, and hydroxyl radicals (6) and thus has been proposed to improve facial hyperpigmentation (4). The antioxidant properties of vitamin E are based on the ability of the chromanoxyl ring to interact with different free radicals (7).

Also, 4-substituted resorcinols have been reported as a potent tyrosinase inhibitor (8), and their structure–activity relationships and inhibition mechanisms were examined in detail (9–11).

Based on these findings, we designed and synthesized a novel vitamin E derivative linking two biologically active moieties (chromanoxyl ring and 4-substituted resorcinol), named (6″-hydroxy-2″,5″,7″,8″-tetramethylchroman-2″-yl)methyl 3-(2′,4′-dihydroxyphenyl)propionate (TM4R) (Fig. 1). The antioxidant and tyrosinase inhibitory activities and skin-lightening effect on UVB-induced pigmentation of TM4R were evaluated.

## EXPERIMENTAL PROCEDURES

*Materials.* 2-Carboxy-2,5,7,8-tetramethylchroman-6-ol [(*R,S*)-Trolox] was purchased from Aldrich Chemical Co. (Milwaukee, WI). 3-(2′,4′-Dihydroxyphenyl)propionic acid (DPPacid) was purchased from Fluka Chemie AG (Buchs, Switzerland). *N,N′*-Dicyclohexylcarbodiimide (DCC) and 4-dimethylamino-

*To whom correspondence should be addressed at Laboratory of Forest Chemistry and Biochemistry, Department of Forest Products, Faculty of Agriculture, Kyushu University Graduate School, 6-10-1 Hakozaki, Higashi-ku, Fukuoka, 812-8581, Japan. E-mail: kondo@agr.kyushu-u.ac.jp

Abbreviations: COSY, correlation spectroscopy; DCC, *N,N′*-dicyclohexylcarbodiimide; DMAP, 4-dimethylaminopyridine; DMSO, dimethylsulfoxide; DOPA, dihydroxyphenylalanine; DPPacid, 3-(2′,4′-dihydroxyphenyl)propionic acid; DPPH, 1,1-diphenyl-2-picrylhydrazyl; ESR, electron spin resonance; HMBC, heteronuclear multiple bond connectivity; HR–FAB–MS, high resolution–fast atom bombardment–mass spectrometry; $IC_{50}$, concentration at which 50% inhibition occurs; NBA, 3-nitrobenzyl alcohol; NMR, nuclear magnetic resonance; TM, 2-hydroxymethyl-2,5,7,8-tetramethylchroman-6-ol; TM4R, (6″-hydroxy-2″,5″,7″,8″-tetramethylchroman-2″-yl)methyl 3-(2′,4′-dihydroxyphenyl)propionate; Trolox, 2-carboxy-2,5,7,8-tetramethylchroman-6-ol; UV, ultraviolet; UVB, ultraviolet B.

Trolox, 2-carboxy-2,5,7,8-tetramethylchroman-6-ol; TM, 2-hydroxymethyl-2,5,7,8-tetramethylchroman-6-ol; TM4R, (6″-hydroxy-2″,5″,7″,8″-tetramethylchroman-2″-yl)methyl 3-(2′,4′-dihydroxyphenyl)propionate; and DPPacid, 3-(2′,4′-dihydroxyphenyl)propionic acid.

pyridine (DMAP) were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Kojic acid and arbutin were purchased from Tokyo Kasei Kogyo Co. (Tokyo, Japan). All other reagents were of analytical grade.

*Spectral analysis.* UV spectra were measured with a Beckman DU 640 spectrophotometer. High resolution–fast atom bombardment–mass spectrometry (HR–FAB–MS) was done with a JMS-HX 110A instrument (Jeol, Tokyo, Japan) with a xenon fast atom bombardment gun with 3-nitrobenzylalcohol (NBA) as the matrix. Nuclear magnetic resonance (NMR) spectra were recorded at 25°C on a JMS-HX 110A FT-NMR spectrometer (Jeol) using acetone-$d_6$ as solvent and tetramethylsilane as internal standard. Electron spin resonance (ESR) spectra were measured using a Jeol JES-FE1XG spectrometer operating at 9.5 GHz with 100 kHz field modulation, a microwave power of 5mW, and a modulation amplitude of 0.1 mT.

*Preparation of 2-hydroxymethyl-2,5,7,8-tetramethylchroman-6-ol (TM).* TM was prepared as described (12).

*Preparation of TM4R.* To a solution of TM (1.50 g), DPPacid (1.15 g), and DMAP (0.238 g) in dry benzene was added DCC (1.30 g), and the solution stirred for 3 h at 50°C. After leaving overnight, the solvent was evaporated and the solid residue was macerated with acetone. The acetone-soluble fraction was filtered, and the crude mixture was separated by column chromatography on silica gel with hexane/diethyl ether (1:4, vol/vol) as the eluent. Thus, pure TM4R was obtained as colorless oil (625 mg yield), subsequent to identification by NMR and MS analysis.

TM4R: colorless oil, HR–FAB–MS (NBA): $[M]^+$ *m/z* 400.1886 ($C_{23}H_{26}O_6$ requires 400.1885). $^1$H NMR (acetone-$d_6$): δ = 1.25 (3H, *s*, 2″-$CH_3$), 1.76 (1H, *m*, 3″-$CH_{2a}$), 1.90 (1H, *m*, 3″-$CH_{2b}$), 2.04 (3H, *s*, 8″-$CH_3$), 2.09 (3H, *s*, 5″-$CH_3$), 2.13 (3H, *s*, 7″-$CH_3$), 2.59 (2H, *m*, 4″-$CH_2$), 2.63 (2H, *m*, 2-$CH_2$), 2.83 (2H, *m*, 3-$CH_2$), 4.05 (1H, *d*, *J* = 11 Hz, 2″-$CH_{2a}$-O), 4.10 (1H, *d*, *J* = 11 Hz, 2″-$CH_{2b}$-O), 6.25 (1H, *dd*, *J* = 2.3, 8.2 Hz, 5′-CH), 6.39 (1H, *d*, *J* = 2.3 Hz, 3′-CH), 6.89 (1H, *d*, *J* = 8.2 Hz, 6′-CH). $^{13}$C NMR (acetone-$d_6$): 11.8 (5″-$CH_3$), 12.0 (8″-CH), 12.7 (7″-$CH_3$), 20.8 (4″-$CH_2$), 22.3 (2″-$CH_3$), 26.1 (3-C), 29.4 (3″-C), 35.1 (2-C), 68.6 (2″-$CH_2$O), 73.9 (2″-C), 103.3 (C-3′), 107.1 (5′-C), 117.5 (10″-C), 118.5 (1′-C), 120.4 (5″-C), 122.4 (8″-C), 123.0 (7″-C), 131.0 (6′-C), 145.2 (9″-C), 146.4 (6″-C), 156.5 (2′ -C), 157.6 (4′-C), 173.1 (1-C).

*Tyrosinase assays.* Mushroom tyrosinase [EC 1.14.18.1] activities were determined by using L-tyrosine (13) or DL-dihydroxyphenylalanine (DL-DOPA) (9) as the substrate, as previously described. L-Tyrosine oxidation assay was done as follows: mushroom tyrosinase solution (0.05 mL, 625 U/mL; Sigma Chemical Co. St. Louis, MO), 1.0 mL of L-tyrosine (5.52 mM), 0.35 mL of McIlvaine buffer (pH 6.8), and 0.1 mL of dimethylsulfoxide (DMSO) with or without sample were mixed and then incubated at 37°C. This solution was immediately monitored for the formation of dopachrome by measuring the linear increase in optical density at 475 nm up to the appropriate time (usually not longer than 20 min). DL-DOPA oxidation assay was done as follows: mushroom tyrosinase solution (0.1 mL, 625 U/mL), 0.7 mL of DL-DOPA buffer solution (2.0 mM), 0.1 mL of McIlvaine buffer (pH 6.8), and 0.1 mL of DMSO with or without sample were mixed and incubated at 25°C. The absorbance was measured at 475 nm between the incubation time of 0.35 and 0.45 min. The extent of inhibition by the addition of samples is expressed as the percentage necessary for 50% inhibition ($IC_{50}$). Michaelis constant ($K_m$), maximal velocity ($V_{max}$), and inhibitor constant ($K_i$) of tyrosinase were determined by Lineweaver-Burke's plot using various concentrations of DL-DOPA. Kojic acid and arbutin were used as positive standards.

*Estimation of hydroxyl radical scavenging activity.* Hydroxyl radical scavenging activities were estimated by the ESR spin-trapping method (14). Seventy-five microliters of 5 mM $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$ (Mohr's salt) solution, 50 μL of DMSO with or without compounds, and 20 μL of 0.1 M 3,3,5,5-tetramethyl-1-pyrroline-*N*-oxide were mixed. Then, 75 μL of 5 mM $H_2O_2$ was added to the resulting solution and shaken on a vortex mixer. After 60 s, ESR spectra were measured. Mn(II) doped in MgO was used as standard.

*Scavenging of 1,1-diphenyl-2-picrylhydrazyl (DPPH).* Free radical scavenging activity of each compound was assayed using a stable free radical, DPPH, according to the method previously reported (12) with modification. Thus, the reaction mixture contained 0.5 mL of 60 μM DPPH in ethanol and 0.5 mL of sample solution in ethanol. After the reaction was carried out at room temperature for 20 min, the free radical–scavenging activity of each compound was quantified by the decolorization of DPPH at 514 nm.

*Pigmentation assays.* UVB-induced hyperpigmentation was elicited on the backs of brownish guinea pigs (Kyudo Co., Ltd., Saga, Japan) using a modification of the method of Yokota *et al.* (15). Animal care was in accordance with institution guidelines. Guinea pigs were gently tethered without anesthesia and four separate areas (2.2 × 2.2 cm) on the back of each animal were exposed to UVB radiation (Toshiba FL40S-BLB; Tokyo, Japan). The total energy dose of UVB was 1350 mJ/cm$^2$ per exposure. Groups of eight animals were used in each experiment. The animals were exposed to UVB radiation once a day for 3 d. Then, 0.25 M sample solution (base solution: propylene glycol/ethanol 1:6) was topically applied to the irradiated areas (20 μL/cm$^2$) five times per week for five successive weeks, while the base solution without sample was applied to the other area as a control. Each sample-applied area was assigned using the table of random sampling numbers. Once every week from the beginning of sample application, the degree of pigmentation was assessed as the absolute value of ΔL*, calculated by the L* value measured with a chromameter (Minolta CR-200; Osaka, Japan) as follows: ΔL* = L* (at each day measured) – L* (at day 0). An increase in the absolute value of ΔL* values indicated the UVB-induced pigmentation of the skin. Kojic acid (16) and arbutin (17) were used to compare with TM4R. Differences between mean values were assessed for statistical significance by using the two-tailed paired Student's *t*-test.

## RESULTS

*Synthesis of TM4R.* TM4R was synthesized in two steps from (*R,S*)-Trolox as shown in Scheme 1. The carboxyl group of Trolox was reduced with $LiAlH_4$ to produce the corresponding TM at 80% yield. Condensation of TM with DPPacid in the presence of DCC and a catalytic amount of DMAP in benzene affords TM4R at 25% yield. The structure of TM4R, and its assignments of $^1$H and $^{13}$C NMR were confirmed by HR–FAB–MS, $^1$H-$^1$H COSY (correlation spectroscopy), $^{13}$C-$^1$H COSY, and HMBC (heteronuclear multiple bond connectivity).

*Inhibitory effect by TM4R on tyrosinase.* The mushroom tyrosinase inhibitory activities of TM4R and some other compounds were determined using L-tyrosine or DL-DOPA as substrate (Table 1). When L-tyrosine was used as a substrate, TM4R and DPPacid showed stronger inhibitory activities than those of kojic acid (18) and arbutin (19), which are known tyrosinase inhibitors. On the other hand, TM, Trolox, and α-tocopherol did not show any tyrosinase-inhibitory activities. Therefore, potent tyrosinase-inhibitory activity of TM4R should be caused by 4-substituted resorcinol moiety, which is the structure common to TM4R and DPPacid (Fig. 1). The Lineweaver-Burke plot of TM4R for DL-DOPA as a substrate on mushroom tyrosinase is shown in Figure 2. TM4R and DPPacid increased the $K_m$ values of tyrosinase in a dose-dependent manner but did not change the $V_{max}$ values and, thus, were the competitive inhibitors with $K_i$ values of 2.74 and 11.5 μM, respectively (Table 1). These results supported our previous notions about the structure–activity relationship, that the 4-substituted resorcinol moiety is most important to reveal the potent tyrosinase inhibitory activity, and that the mode of inhibition is competitive (9). It should be added that, unexpectedly, condensation of DPPacid with the hydrophobic chromanoxyl ring to TM4R increased its inhibitory activity.

**TABLE 1**
**Effects of Compounds on Mushroom Tyrosinase[a]**

| Compound | Substrate: L-Tyrosine $IC_{50}$ (μM) | Substrate: DL-DOPA $IC_{50}$ (μM) | DL-DOPA $K_i$ (μM) | DL-DOPA Type of inhibition |
|---|---|---|---|---|
| TM4R | 0.325 | 23 | 2.74 | Competitive |
| DPPacid | 3.02 | 62 | 11.5 | Competitive |

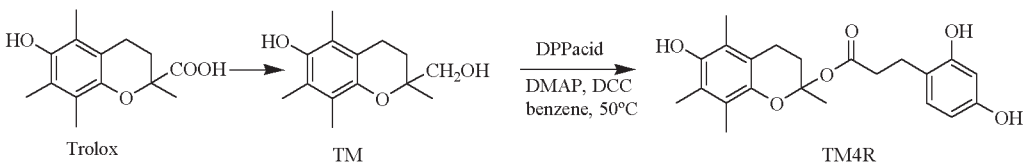
*Antioxidant activity.* The free radical–scavenging activities of TM4R and some other antioxidants were determined by the use of a stable free radical, DPPH, and hydroxyl radical (Table 2). Determination of the reducing activity of the DPPH radical was carried out by spectrophotometer, and the $IC_{50}$ value of TM4R was 3.9 μM, which was nearly the same as those of α-tocopherol, Trolox, and TM (Table 2). Taking no activity of DPPacid into consideration, the chromanoxyl ring moiety should be important for radical-scavenging activity of TM4R (Fig. 1). Determination of the hydroxyl radical–



**SCHEME 1**

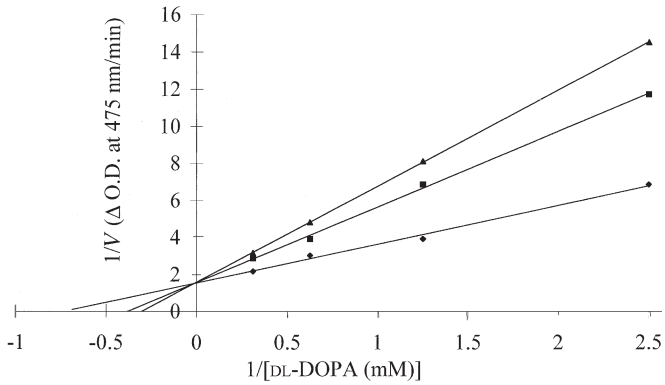


**FIG. 2.** Lineweaver-Burke plots of mushroom tyrosinase and DL-DOPA in the absence or presence of TM4R. ♦ Control, ■ 1.88 μM, ▲ 3.75 μM. O.D., optical density; DOPA, dihydroxyphenylalanine; for other abbreviation see Figure 1.

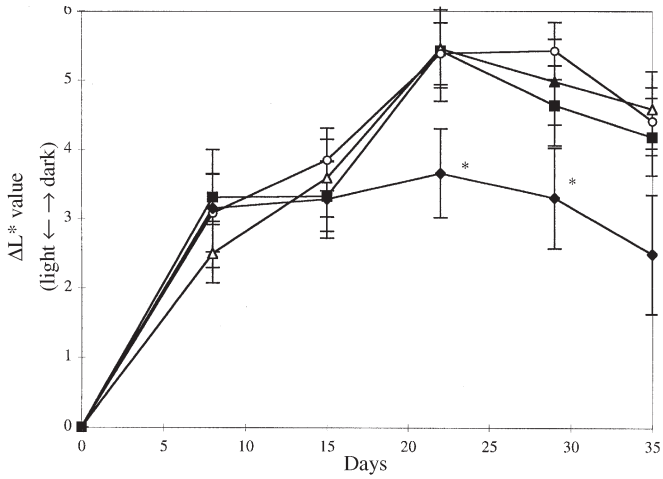

**FIG. 3.** The degree of pigmentation (ΔL* value) before and after daily topical applications (five times per week) of base solution [propylene glycol/ethanol (1:6)] (control, ○), TM4R (0.25 M in base solution, ♦), kojic acid (0.25 M in base solution, (■), or arbutin [0.25 M in base solution, ▲). The applications were continued for 35 d. Data are expressed as mean value ± standard error of the mean ($n$ = 8). L* values at day 0 are 49.9 ± 2.7 (control), 48.9 ± 3.4 (TMR), 50.1 ± 2.9 (kojic acid), and 49.9 ± 2.8 (arbutin). Student's $t$-test was used for the statistical analysis of the data. (*$P < 0.05$, vs. control). See Figure 1 for abbreviations.

scavenging activity of TM4R was carried out by the ESR spin-trapping method, and its scavenging activity at 1.0 and 10 mM (91 and 100%) was nearly the same as that of α-tocopherol (Table 2).

*Pigmentation assays.* To study mammalian melanogenesis *in vivo*, and particularly to evaluate the effects of chemical and physical agents on skin pigmentation, guinea pigs have been widely used (15) because they have similar pigmentary systems and their skin bears a morphologic resemblance to human skin (20). An increase in the absolute values of ΔL*, shown in Figure 3, were indicated by the UVB-induced pigmentation of the skin before and after up to 35 d of daily topical applications of TM4R, kojic acid, and arbutin. The ΔL* values of the only TM4R-treated skins of the eight guinea pigs (3.66 ± 0.64 at 22 d, 3.30 ± 0.73 at 29 d) were significantly lower than those of the base solution-treated skins (5.38 ± 0.44 at 22 d, 5.42 ± 0.41 at 29 d). The ΔL* values of arbutin- and kojic acid-treated skins were not significantly different from those of the control treatment (Fig. 3). It should be noted that both arbutin and kojic acid have been reported to show skin-whitening effects (16,17). However, it is not easy to relate our data precisely to those of earlier reports because of differences in test methods (e.g., dose of UV radiation, the applied concentration, etc.). During the course of these experiments, TM4R never induced erythema.

**TABLE 2**
**Antioxidant Activity of the Compounds**

| Compound | Hydroxyl radical (%)[a] 1.0 mM | 10 mM | DPPH [$IC_{50}$ (μM)][b] |
|---|---|---|---|
| TM4R | 91 | 100 | 3.9 |
| TM | ND | ND | 3.2 |
| Trolox | ND | ND | 3.3 |
| α-Tocopherol | 70 | 93 | 3.9 |
| DPPacid | ND | ND | No activity at 50 μM |

[a]Hydroxyl radical–scavenging activity was expressed as % inhibition concentration of hydroxyl radicals generated by Fe(II) and $H_2O_2$ (Fenton reaction).
[b]The $IC_{50}$ values were calculated from regression lines where the abscissa represented the concentration of tested compound and the ordinate the average percent reduction of DPPH radical from three separate tests. For abbreviations see Table 1.

## DISCUSSION

In this study, we designed and synthesized a novel vitamin E derivative, TM4R, linking two biologically active moieties (4-substituted resorcinol moiety for tyrosinase inhibitory activity and chromanoxyl ring moiety for antioxidant activity). TM4R showed more potent tyrosinase inhibitory activity than kojic acid, which is known as a potent tyrosinase inhibitor. The scavenging activities of TM4R on DPPH and hydroxyl radicals were found to be nearly the same as those of α-tocopherol, which is known as a potent antioxidant. Furthermore, an efficient lightening effect was observed following topical application of TM4R to UVB-stimulated hyperpigmented dorsal skin of brownish guinea pigs.

4-Substituted resorcinols have been reported as potent tyrosinase inhibitors (8), and their structure–activity relationships and inhibition mechanisms were examined in detail (9–11). Therefore, potent tyrosinase inhibitory activity of TM4R should be caused by 4-substituted resorcinol moiety. Unexpectedly, condensation of DPPacid with hydrophobic chromanoxyl ring to TM4R increased its inhibitory activity (Table 1). For 4-substituted resorcinol-type inhibitors, the resorcinol moiety may bind to the binuclear active site and its side chain may be associated with the hydrophobic protein pocket close to the active site (21). In other words, in addition to the stabilizing effect of resorcinol moiety to the binding site, the side chain of the 4-substituted resorcinol-type inhibitor seems to relate to its binding affinity by the enzyme. On the basis of the above assumptions, it is reasonable to conclude

that TM4R is harder to enfold in the protein pocket than DPPacid owing to the higher hydrophobicity of the side chain of TM4R (chromanoxyl ring) than that of DPPacid (carboxyl group). As a result, condensation of DPPacid with a hydrophobic chromanoxyl ring to TM4R increases its inhibitory activity. This assumption may give a hint to the interaction of 4-substituted resorcinol inhibitor with the tertiary structure of the enzyme, but this remains unclear because the structure of tyrosinase has not yet been established. It should be noted that mushroom tyrosinase differs somewhat from that from other sources (22,23), but this fungal source was used for the entire experiment because it is readily available. Also, the tyrosinase inhibitory activity has been assessed only in a test tube assay, not in a cell-based assay using, e.g., melanocyte cultures.

Vitamin E is regarded as the major lipid-soluble antioxidant preventing oxidative attack of membrane lipids and other membrane compounds. The chromanoxyl ring of vitamin E is responsible for the radical-scavenging activity, and, in particular, the hydroxyl group at the C-6 position is essential for this activity (7). TM4R exhibited a scavenging activity against a stable free radical, DPPH, and hydroxyl radical to the same extent as those of α-tocopherol, Trolox, and TM. Taking no activity of DPPacid into consideration, the chromanoxyl ring moiety should be important for radical-scavenging activity of TM4R. It is known that when human skin is exposed to UV, various reactions are induced (24). The skin tissue, especially membrane phospholipids, is known to be damaged by UV-induced active oxygen. With less melanin, DNA damages to keratinocytes following UV irradiation are more severe, and the risk of UV carcinogenesis may increase (25). Thus, whitening agents, if they lighten the basal skin color in addition to hyperpigmented spots, might increase the risk of UV carcinogenesis. However, topical application of α-tocopherol and its derivatives has been shown to protect against UV-induced chronic cutaneous damage including cancer formation (26), wrinkle formation (27), and acute cellular and cutaneous reactions such as immune suppression (28), growth arrest, and cell death (29). Taken together, our results suggest that TM4R, one of the vitamin E derivatives, could be a good candidate for a skin-whitening agent and could also prevent skin damage by UV.

Finally, it is worth adding that melanin formations, caused enzymatically and nonenzymatically, are considered to be deleterious to the color quality of plant-derived food. Therefore, TM4R should be useful as a food additive, acting as an antioxidant and tyrosinase inhibitory agent in food, as dodecyl gallate acts (30).

# β-Oxidation of Conjugated Linoleic Acid Isomers and Linoleic Acid in Rats

**Jean-Pierre Sergiel[a], Jean-Michel Chardigny[a], Jean-Louis Sébédio[a,*], Olivier Berdeaux[a], Pierre Juaneda[a], Olivier Loreau[b], Bruno Pasquis[a], and Jean-Pierre Noel[b]**

[a]INRA, Unité de Nutrition Lipidique, 21065 Dijon Cedex, and [b]CEA-Saclay, Service des Molécules Marquées, 91191 Gif sur Yvette, France

**ABSTRACT:** To assess the oxidative metabolism of conjugated linoleic acid (CLA) isomers, rats were force-fed 1.5–2.6 MBq of [1-$^{14}$C]-linoleic acid (9*c*,12*c*-18:2), -rumenic acid (9*c*,11*t*-18:2), or -10*trans*,12*cis*-18:2 (10*t*,12*c*-18:2), and $^{14}CO_2$ production was monitored for 24 h. The animals were then necropsied and the radioactivity determined in different tissues. Both CLA isomers were oxidized significantly more than linoleic acid. Moreover, less radioactivity was recovered in most tissues after CLA intake than after linoleic acid intake. The substantial oxidation of CLA isomers must be considered when assessing the putative health benefits of CLA supplements.

Paper no. L8753 in *Lipids 36*, 1327–1329 (December 2001).

In animals, conjugated isomers of linoleic acid (CLA) have been reported to have beneficial effects on a range of health parameters, including cancer (1), body composition (2), diabetes (3), immune function (4), and atherogenesis (5,6). However, the last is still controversial as results in mice (7) indicate a proatherogenic effect of CLA, whereas previous data on hamsters and rabbits suggest a preventive effect.

Few studies on the effects of CLA in humans have been published. Vessby and Smedman (8) reported a reduction of fat mass and an increase in urinary excretion of isoprostanes, suggesting enhanced lipid peroxidation (9). On the other hand, Zambell *et al.* (10) reported that CLA had no effect on body composition and energy expenditure in healthy women.

In food, CLA is present as rumenic acid, i.e., 9*cis*,11*trans*-18:2 (9*c*,11*t*-18:2), but synthetic materials are mixtures containing different isomers, 10*trans*,12*cis*-18:2 (10*t*,12*c*-18:2) being one of the major ones. This isomer seems to have specific metabolic effects, mainly on body composition and on desaturase activities (11,12) and related gene expression (13).

However, the effective dosage of CLA is not clearly known. The oxidative metabolism of CLA isomers represents a metabolic pathway that may reduce the bioavailability of CLA for further effects. In the present work, we compared the metabolic oxidation of 9*c*,11*t*- and 10*t*,12*c*-18:2 in rats. The data show that a substantial portion of both CLA isomers is oxidized more than linoleic acid (9*c*,12*c*-18:2).

## MATERIAL AND METHODS

Male rats (Janvier, Le Genest Saint Isle, France) weighing 259 ± 6 g (mean ± SEM) were used. The animals were housed under controlled conditions of temperature (22 ± 1°C) and relative humidity (55–60%). A 12-h light–dark cycle (lights on 7:00 A.M.–7 :00 P.M.) was maintained. The animals were fed *ad libitum* with commercial pellets (Extralabo, Provins, France) and had free access to tap water. The day before the experiment at 5:00 P.M., they had access to only 10 g of commercial pellets, for the researchers to get animals at the same fasting status. All the experiments started at the same time (9:00 A.M.). Animal maintenance and handling were performed according to the French guidelines for animal studies (Authorizations A21200 and 3273).

[1-$^{14}$C]Linoleic acid (2.20 GBq · mmol$^{-1}$) was purchased from NEN (Le Blanc Mesnil, France). The detailed synthesis of [1-$^{14}$C]-9*c*,11*t*- (1.97 GBq · mmol$^{-1}$) and [1-$^{14}$C]-10*t*,12*c*-CLA (2.00 GBq · mmol$^{-1}$) isomers is described elsewhere (14). Each fatty acid was dissolved in triolein (Sigma Chemicals, L'Isle d'Abeau, France) and then administered by gastric tubing.

Immediately after intubation, the rats were placed in an airtight Plexiglas metabolic chamber, as described previously (15). Briefly, the $^{14}CO_2$ expired was trapped in a bottle containing Carbosorb (Packard, Groningen, the Netherlands). Air flow (950 mL · mmol$^{-1}$) was provided by a peristaltic pump.

Without interrupting the bubbling of the expired air through the trapping agent, 1 mL was removed every 30 min during the first 6 h of the experiment, hourly during the next 10 h, and hourly again from 18 to 24 h. As the density of the trapping agent increased during the experiment, the weight of each sample and of the bottle at each sampling time was measured to determine the exact radioactivity expired.

Scintillation cocktail (9 mL; Permafluor E, Packard) was added to each sample, and the radioactivity was determined using a Tri Carb 2000 CA liquid scintillation counter (Packard).

At the end of the 24-h experimental period, the animals were anesthetized. Blood was withdrawn into a heparinized syringe. Tissues (brain, heart, liver, gastrocnemian muscle, lung, kidneys, spleen, adrenals, testes, and epididymal adipose tissue)

Abbreviations: CLA, conjugated linoleic acid; GBq, gigaBecquerel; MBq, megaBecquerel.

were removed, blotted on filter paper, and weighed. The gastrointestinal tract was divided into two parts, as previously described (15). The first part included the stomach and the small intestine. The second part was the large intestine. The carcass of each animal was weighed before homogenization.

Three finely minced portions (30–80 mg) of each tissue finely minced, and five portions of the carcass (50–100 mg) as well as the two parts of the gastrointestinal tract were digested overnight at 50°C using 1 mL of Soluene (Packard). The radioactivity of the samples was then determined by liquid scintillation counting as described previously, after addition of Hionic Fluor (Packard) scintillation cocktail. The radiaoctivity in blood and urine was determined as described (15).

*Statistical analysis.* Data are presented as means ± SEM of three independent determinations. Analyses of variance were carried out using the SAS software (Cary, NC). *P* values of <0.05 were considered significant.

## RESULTS

The weights of rats before administration of the radiolabeled fatty acids were similar. The radioactivity administered to the animals was 2.55 ± 0.04, 1.52 ± 0.04, and 1.57 ± 0.02 GBq for 9*c*,12*c*-, 9*c*,11*t*-, and 10*t*,12*c*-18:2, respectively. At the end of the experiments, 85–95% of the ingested radioactivity was recovered.

$^{14}CO_2$ production was similar for both CLA isomers. At the end of the 24-h experimental period, 71.8 and 70.3% of the dose of radioactivity from 9*c*,11*t*- and 10*t*,12*c*-18:2, respectively, were found in $^{14}CO_2$. These values were significantly higher than that obtained with 9*c*,12*c*-18:2 (60.3%, $P < 0.05$). The cumulative $^{14}CO_2$ production over 24 h is shown in Figure 1. The three curves exhibit a similar pattern with asymptotic profiles. They reached a plateau about 8 h after feeding the labeled fatty acids. The difference between CLA isomers and linoleic acid is borderline significant from 1.5 to 2 h after administration. The *P* values were less than 0.05 from 2.5 h after admistration to the end of the experiment.

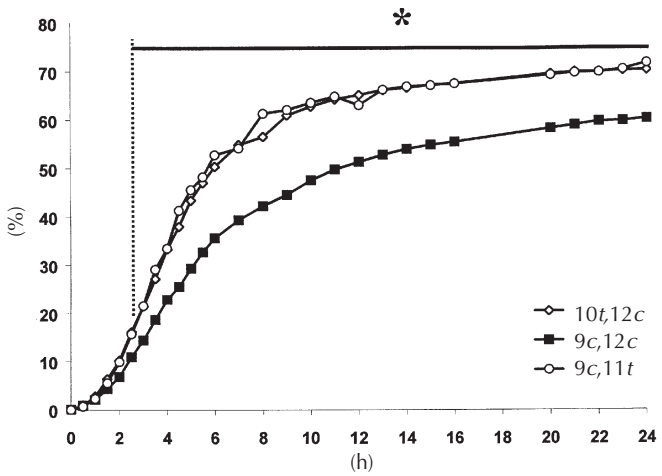

**FIG. 1.** $^{14}CO_2$ recovery after oral administration to the fasting rats of [1-$^{14}$C]-linoleic acid (9*c*,12*c*), -rumenic acid (9*c*,11*t*), or -10*trans*,12*cis*-18:2 (10*t*,12*c*). Data were obtained from three male Wistar rats for each fatty acid. Results are expressed as means of the percentage of radioactivity administered, recovered as $^{14}CO_2$, ± SEM. Asterisk (*) indicates period during which the $^{14}CO_2$ production was significantly different between conjugated linoleic acid (CLA) isomers (9*c*,11*t* and 10*t*,12*c*) and the corresponding values for linoleic acid (9*c*,12*c*) ($P < 0.05$).

The incorporated radioactivity per 100 g of tissue and as a fraction of the radioactivity administered at 24 h after the oral administration of the labeled fatty acids is presented in Table 1. In most tissues, the radioactivity recovered was similar whatever the fatty acid administered. However, the incorporation of radioactivity was different between linoleic acid and both the CLA isomers in brain, heart, adrenals, testes, and carcass (Table 1).

## DISCUSSION

In animal models, CLA isomers have been reported to have beneficial effects on some physiological parameters related to health. Their efficacy in humans is still controversial (10). However, the mechanisms by which these fatty acids may act, as well as their metabolic fate, is still unknown. As with linoleic acid, CLA isomers are converted by desaturation and elongation pathways to conjugated 18:3, 20:3, and 20:4 fatty acids (16–18). Besides these conversions to longer and more unsaturated metabolites, the incorporation of CLA in tissues is generally low. Another possible metabolic pathway involves oxidation, either complete or partial. A 16:2 conjugated fatty acid isomer has been detected and identified in rat tissues fed pure CLA isomers (20).

Using radiolabeled CLA, we compared the oxidative metabolism and tissue incorporation of the two major CLA

**TABLE 1**
**Recovery of Radioactivity (% of the administered dosage) per 100 g of Tissue 24 h After Oral Administration of the [1-$^{14}$C]-Radiolabeled Fatty Acids to Fasting Rats[a]**

isomers in semifasting rats. Our data showed that CLA isomers produced more $^{14}CO_2$ than linoleic acid. This pattern was close to what we reported for α-linolenic acid, where 70% of the ingested radioactivity was recovered in $CO_2$ (15). As CLA seemed to be as well absorbed as linoleic acid (19), this difference between linoleic acid and CLA may be due to a higher metabolic utilization by cellular oxidation systems.

In the present study, the radioactivity incorporated in different tissues was similar after intragastric feeding of the three fatty acids. Some differences were observed only in brain, carcass, heart, adrenals, and testes, in which linoleic acid seemed to be better incorporated than CLA isomers. Moreover, our data do not explain why 9*c*,11*t*-18:2 is generally incorporated more than 10*t*,12*c*-18:2 into tissues (20).

When added to the diet, CLA have been reported to induce different physiological effects in several animal models. The mechanisms by which CLA act are not understood. The present data indicate that the catabolism of ingested CLA has to be taken into account with regard to their tissue bioavailability and emphasize that CLA are lipids that may also contribute to energy production.

Further studies have to be carried out to know the CLA metabolic pattern in humans.

# Dietary α-Linolenic Acid Lowers Postprandial Lipid Levels with Increase of Eicosapentaenoic and Docosahexaenoic Acid Contents in Rat Hepatic Membrane

**Hye-Kyeong Kim and Haymie Choi***

Department of Food and Nutrition, Seoul National University, Seoul 151-742, Korea

**ABSTRACT:** This study was designed to examine the effects of dietary n-3 and n-6 polyunsaturated fatty acids (PUFA) on postprandial lipid levels and fatty acid composition of hepatic membranes. Male Sprague-Dawley rats were trained for a 3-h feeding protocol and fed one of five semipurified diets: one fat-free diet or one of four diets supplemented with 10% (by weight) each of corn oil, beef tallow, perilla oil, and fish oil. Two separate experiments were performed, 4-wk long-term and 4-d short-term feeding models, to compare the effects of feeding periods. Postprandial plasma lipid was affected by dietary fats. Triacylglycerol (TG) and total cholesterol levels were decreased in rats fed perilla oil and fish oil diets compared with corn oil and beef tallow diets. Hepatic TG and total cholesterol levels were also reduced by fish oil and perilla oil diets. Fatty acid composition of hepatic microsomal fraction reflected dietary fatty acids and their metabolic conversion. The major fatty acids of rats fed the beef tallow diet were palmitic, stearic, and oleic. Similarly, linoleic acid (LA) and arachidonic acid in the corn oil group, α-linolenic acid (ALA) and eicosapentaenoic acid (EPA) in the perilla oil group, and palmitic acid and docosahexaenoic acid (DHA) in the fish oil group were detected in high proportions. Both long- and short-term feeding experiments showed similar results. In addition, microsomal DHA content was negatively correlated with plasma lipid levels. Hepatic lipid levels were also negatively correlated with EPA and DHA contents. These results suggest that n-3 ALA has more of a hypolipidemic effect than n-6 LA and that the hypolipidemic effect of n-3 PUFA may be partly related to the increase of EPA and DHA in hepatic membrane.

Paper no. L8780 in *Lipids 36*, 1331–1336 (December 2001).

The study of risk factors for cardiovascular disease has focused on the concentration and composition of plasma lipids and lipoproteins present during the fasting state (1–3). However, the fed state represents a major portion of the body's metabolic time, and the alimentary state is determined by typical eating patterns. Moreover, several studies have linked alterations in postprandial lipemia with coronary vascular disease (4–6). The study on postprandial lipemia will be valuable to elucidate the effect of dietary components on fat metabolism.

Dietary fats containing different fatty acids alter the extent and character of postprandial lipid metabolism (7–9). Chronic feeding of polyunsaturated fatty acids (PUFA), both n-3 and n-6, reduce postprandial lipemia produced by a meal containing other fatty acids. Williams *et al.* (10) reported that moderate n-3 fatty acid supplementation reduced postprandial triacylglycerol (TG) response following a standard meal. However, in these studies, fish or fish oil (FO) rich in long-chain n-3 fatty acids, such as eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3), was provided as an n-3 PUFA source, and vegetable oil rich in linoleic acid (LA; 18:2n-6) was used as an n-6 PUFA source, without considering the degree of unsaturation and chain length. So, it would be more reasonable to provide vegetable oils rich in either LA or α-linolenic acid (ALA; 18:3n-3) for comparison of the effect of n-3 and n-6 PUFA. But a study on the comparison of the effects of LA and ALA has not been performed, and little information exists on the relative effectiveness among n-3 fatty acids.

Plasma TG and lipoproteins are synthesized mainly in the liver. Microsomes contain fatty acid desaturases and the enzymes catalyzing the synthesis of phosphatidic acid, thus synthesizing new membrane lipids. The fatty acid component in the membrane serves as a modulator of the biological processes such as eicosanoid production and activation of membrane-bound enzymes (11–13). Therefore, the study on the fatty acid composition of the cell membrane is thought to be important for understanding the effect of dietary fats on plasma lipids.

Perilla oil (PO), a commonly used cooking oil in Korea, contains as much as 60% ALA in its total fatty acid composition, which makes it suitable for an ALA source. Contrary to the numerous studies on FO with long-chain highly unsaturated fatty acids, little is known about the effectiveness of ALA in lowering plasma lipids. The purpose of this study is to compare the effect of dietary PO on postprandial plasma lipid level and the fatty acid composition of hepatic membrane lipid with other fats.

Abbreviations: AA, arachidonic acid; ALA, α-linolenic acid; BT, beef tallow; CO, corn oil; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FF, fat free; FO, fish oil; HDL-C, high density lipoprotein-cholesterol; LA, linoleic acid; PO, perilla oil; PUFA, polyunsaturated fatty acid; TC, total cholesterol; TG, triacylglycerol.

## MATERIALS AND METHODS

*Animals and diets*. All animal procedures were approved by the Laboratory Animal Center of Seoul National University. Two separate experiments were conducted to compare the effects of dietary fat feeding periods. Sprague-Dawley rats, supplied by the Laboratory Animal Center of Seoul National University, were individually caged throughout the entire experimental periods and had free access to water.

In experiment I, weanling rats were fed one of the five experimental diets for 4 wk and sacrificed. In order to facilitate control of diet intake, all animals were adapted to a meal-eating regimen in which one meal allowed access to food for a 3-h period (9:00 A.M.–12:00 P.M.). The amount of basal diet was determined according to the lowest consumption of rat (in the experimental block) the previous day; it was kept constant among the experimental groups.

In the second part of this study, animals were fed the diet containing 5% corn oil (CO) until they weighed about 140 g and then they were divided into five groups. For 7 d prior to the experimental period of fat supplementation, all rats were adapted to the 3-h feeding regimen, receiving a fat-free (FF) diet so that they would have similar fatty acid status after exhausting stored fatty acids. The diet was prepared by mixing 1% (w/w) CO with the basal diet to prevent essential fatty acid deficiency. The basal diet contained the following percentages of ingredients according to weight: casein 20, sugar 34.85, corn starch 34.85, α-cellulose 5, AIN mineral mixture 4, AIN vitamin mixture 1, and DL-methionine 0.3. After that, rats were fed one of the five experimental diets for 4 d: the FF diet, or one of four diets supplemented with 10% (w/w) each of CO, beef tallow (BT), PO, and FO. The fatty acid compositions of dietary fats are shown in Table 1. To prevent autoxidation, α-tocopherol was supplemented in PO (0.015%) and FO (0.019%) based on peroxidizability index (14). In addition, meals were offered daily and diets were stored in the freezer under $N_2$ gas to minimize the opportunity for peroxidation of lipids.

[a]Values are expressed as percentage of total fatty acids. ΣSFA, sum of saturated fatty acids; ΣMUFA, sum of monounsaturated fatty acids; Σn-6, sum of n-6 fatty acids; Σn-3, sum of n-3 fatty acids; n-6/n-3, ratio of n-6 to n-3 fatty acids.

*Preparation of samples*. Animals were sacrificed by decapitation at 90–120 min after completion of the final meal. Blood was collected in a heparinized tube and centrifuged at 1,500 × *g* for 20 min to separate the plasma. Plasma for high density lipoprotein-cholesterol (HDL-C) analysis was obtained by precipitating non-HDL with dextran sulfate and magnesium sulfate followed by centrifugation. Livers were removed, finely minced, and homogenized in 5 vol of ice-cold homogenizing buffer solution (154 mM KCl, 50 mM Tris-HCl, 1 mM EDTA buffer, pH 7.4). The homogenate was centrifuged at 10,000 × *g* at 4°C for 20 min, followed by recentrifugation of the supernatant at 105,000 × *g* at 4°C for 1 h. The resulting pellet was considered the microsome and resuspended in cold storage buffer (homogenizing buffer/glycerol, 80:20). The entire fractionation procedure was conducted at 0–4°C.

*Lipid analyses*. Lipids were extracted from livers of rats in experiment I by the method of Folch *et al.* (15). The extracted lipids were evaporated under nitrogen and weighed to determine the total fat content of the liver. TG and cholesterol contents in the liver extract and plasma were assayed by using commercial enzymatic kits (Youngdong Pharm. Co., Seoul, Korea). To analyze the fatty acid composition of hepatic microsomal fraction, lipid extraction and transesterification were carried out simultaneously by the method described by Lepage and Roy (16). Fatty acid methyl esters were measured by gas chromatography (Hewlett-Packard model 5890) using an EC wax packed capillary column (EC-1 0.32 mm × 30 m; Alltech, Deerfield, IL) equipped with an HP GC ChemStation data system, an autosampler, and a flame-ionization detector. The fatty acids were identified by comparison of retention time of standard esters under the same conditions, and the composition of fatty acids of each fraction was calculated as a percentage of total area.

*Statistical analysis*. All statistical analyses were carried out using analysis of variance and Duncan's multiple range test. A $P$ value of $<0.05$ was selected as a limit of statistical significance. The statistical program used was SAS package (Cary, NC).

## RESULTS

*Body weight and liver lipid contents.* No significant differences in diet intake, final body weight, or weight increase rate were noted among fat-feeding experimental groups. Diet intakes were not different within a group because animals were individually caged and adapted to the 3-h feeding regimen. All groups consumed the same amount of carbohydrate each day because food intakes were matched. The lipid content of liver is shown in Table 2. Even though there was no significant difference in total lipid content of liver tissue, hepatic TG and total cholesterol (TC) levels were affected by the di-

**TABLE 2**
**Effect of Dietary Fats on Lipid Contents in Rat Liver[a]**

| Group | Total lipid | Triacylglycerol | Total cholesterol |

[a]Expressed as mg/g liver and mean ± standard error of the mean ($n$ = 9). Values with different roman superscripts (a, b, and c) are significantly different at $P < 0.05$ by Duncan's multiple range test. Weanling Sprague-Dawley rats were fed each of the experimental diets for 4 wk by a 3-h feeding protocol. FF, fat-free diet; BT, 10% beef tallow diet; CO, 10% corn oil diet; PO, 10% perilla oil diet; FO, 10% fish oil diet.

etary treatment. Hepatic TG content was low in PO- and FO-fed groups compared with other groups. The TC content was the lowest in the PO group followed by the FO group; other groups showed no significant differences.

*Postprandial plasma lipid levels.* The postprandial plasma lipid was affected by dietary fat as shown in Table 3. In experiment I, the concentration of plasma TG was lowest in the FO group, followed by other groups in the order of PO, BT, and CO. The FF diet group showed an intermediate level between the FO and PO groups. TC content was low in the PO and FO groups compared with groups fed other fats. HDL-C concentration showed a similar tendency to that of TC. However, the relative ratios (HDL/TC) were not significantly different among the dietary fat groups. Similar plasma lipid profiles were found even in a 4-d feeding trial, with the lowest plasma TG and TC levels in FO fed, followed by PO fed and BT fed groups.

*Fatty acid composition of rat liver membrane.* Fatty acid composition of hepatic microsomal fraction is shown in Table 4 as the percentage of total fatty acids. It reflected the fatty acid composition of dietary fats. The major fatty acids in rats fed the BT diet were palmitic, stearic, and oleic. Similarly, LA in the CO group, ALA in the PO group, and palmitic acid and DHA in the FO group were detected in high proportion. In addition, fatty acids not detected in dietary fat itself were shown in hepatic microsomal fractions in substantial amounts. In the CO group, a high content of arachidonic acid (AA; 20:4, n-6) was detected, while low AA content was shown with the increase of EPA and DHA in the PO group. The PO and FO groups fed n-3 fatty acid sources showed significantly high contents of total n-3 PUFA, and the CO group showed high contents of total n-6 PUFA. Similar fatty acid composition was found in a 4-d feeding (experiment II), although the extent of difference was not so great as in experiment I.

## DISCUSSION

Numerous studies have documented that long-chain n-3 fatty acids, such as those present in FO, lower plasma lipid levels in both the fasting and postprandial states (7–9,17). Consistent with these findings, the present study demonstrates that consumption of FO markedly reduced postprandial lipid levels in both long- and short-term feeding experiments, indicating that the hypolipidemic effect of FO was apparent even in a 4-d feeding.

Another n-3 PUFA source, PO, was also effective to reduce postprandial lipemia. Plasma TC and HDL-C levels were similar to that of the FO group. Moreover, the extent of TG reduction was greater than in the CO group, although that was not so great as the FO group. In contrast to many studies on fasting plasma lipid levels, there have been only a few studies on the comparison of n-6 and n-3 fatty acids in the postprandial state. Long-chain n-3 PUFA such as EPA and DHA resulted in less postprandial plasma triglyceridemia compared with the n-6 LA diet (18,19). Thus, it can be suggested that all the n-3 PUFA (ALA, EPA, and DHA) have beneficial effects on plasma TG compared with n-6 PUFA (LA).

In addition, long-term experiment I showed low levels of plasma HDL-C in the FO and PO groups compared with the CO and BT groups. Parks and Rudel (20) demonstrated that the decreased plasma TC levels in n-3 fatty acid diets result in decreased synthesis of nascent HDL and apoprotein A-1. Thus, the high plasma HDL-C levels in the CO and BT groups seem to be related to the significantly high plasma TC levels.

In contrast to the lower TC level of the PO group in experiment I, a significant difference was not observed between PO and CO groups in experiment II. This discrepancy might be ascribed to the duration of feeding. Ihara *et al.* (21) compared the effect of diets high in LA or ALA on fasting lipid metab-

[a]Expressed as percentage of total fatty acids and mean ± standard error of the mean ($n = 9$). Values with different superscripts (a, b, c, d, and e) are significantly different at $P < 0.05$ by Duncan's multirange test. Sprague-Dawley rats were fed each of the experimental diets for 4 wk in long-term and 4 d in short-term feeding. For abbreviations see Tables 1 and 2.

olism in time-course (3, 7, 20, and 50 d) experiments and reported that the levels of serum TC and phospholipid in the rats fed the PO diet were markedly lower than those fed the safflower oil diet after the seventh day. Thus, as in the fasting state, a 4-d feeding in experiment II is thought to be insufficient to make a significant decrease in TC levels between PO and CO diets.

Another interesting result was that CO feeding did not result in any significant decrease in plasma lipid levels. This is contrary to previous reports (9,22–24) that unsaturated fat reduced the plasma lipid levels over saturated fat but consistent with the result of Sanders *et al.* (18). Postprandially, plasma triglyceridemia was greater on the n-6 LA diet and lower on the long-chain n-3 diet, with the saturated diet being intermediate. The 3-h feeding protocol and matched feeding in our study enabled us to feed exactly the same amount of total fat content and other nutrients, such as protein and carbohydrate, so the results can be considered as the sole effect of different dietary fats, compared with other reports. Even though this does not fully explain the different results, it is still questionable that n-6 LA has a plasma lipid-lowering effect.

Although there was no significant difference in total hepatic lipid, hepatic TG and TC levels were low in the PO and FO groups. This shows that the concentrations of hepatic TG and TC were lower in the n-3 PUFA diet than in the n-6 LA diet. Considering that the low serum TG concentration is due to the decreased synthesis and secretion of hepatic very low density lipoprotein-TG (25), the reduction of hepatic TG levels as well as plasma TG levels observed in the PO and FO groups suggests the significance for application to human coronary heart disease.

Hepatic microsomes are predominantly smooth microsomes participating in lipid synthesis and intracellular membrane traffic (26). According to the report of Bernasconi *et al.* (27), the fatty acid composition of total hepatic microsomal lipids and that of phosphatidylcholine, the principal lipid of the microsomal membrane, showed similar results. In addition, they were correlated with the changes in desaturase activities (27,28). Total fatty acid composition in hepatic microsomal fraction was measured in our study as supporting data for the lipid level. As shown in Table 4, the significant differences in hepatic microsomal fatty acid content among groups reflected the dietary fatty acid composition. The major fatty acids in the BT group were palmitic, stearic, and oleic. Similarly, LA in the CO group, ALA in the PO group, and long- chain PUFA (EPA and DHA) in the FO group were detected in high proportion. In addition to the direct incorporation of dietary fatty acids into membrane lipids, there must be a considerable amount of metabolic conversion of fatty acids. In the CO group, a significantly high content of AA was detected, in contrast to the PO group in which the AA content was reduced with concomitant increases of EPA and DHA. It is likely that this result was due to the suppressed biosynthesis of AA from LA by the presence of ALA. The biosynthesis of AA from LA competes with that of EPA from ALA for $\Delta^6$-desaturase, with the relative rate of enzymatic elongation and desaturation in the order n-3 > n-6 > n-9 (29). The resulting high concentration of EPA and DHA in

the PO group might have controlled plasma and hepatic lipid levels. Both EPA and DHA were reported to have a marked hypotriglyceridemic effect, although DHA was more pronounced (30). Thus, the hypotriglyceridemic effect of PO compared with CO can be ascribed to the resulting high concentration of EPA and DHA.

In our study, microsomal DHA content was negatively correlated with plasma TG and TC levels ($r = -0.613$ for TG; $r = -0.458$ for TC, $P < 0.05$), but no significant correlation was observed between other n-3 fatty acids and plasma lipids. These results explain why FO rich in DHA was more effective in reducing plasma TG than PO. In addition, the contents of hepatic TG and TC were negatively correlated with the EPA and DHA contents in microsomal fraction ($r = -0.548$ in EPA, $r = -0.629$ in DHA, for hepatic TG; $r = -0.629$ in EPA, $r = -0.560$ in DHA, for hepatic TC), by which the significant decrease of hepatic lipids in the PO and FO groups can be explained.

It is generally accepted that dietary fat is a normal determinant of membrane fatty acid composition and a constant modulator of the biological process that may be regulated through membranes (31). With young rats, approximately 4–10 wk were required to approach a new steady state in most tissue lipids after a change in dietary lipid (14). Even though the change in fatty acid content occurs most rapidly in the liver, some studies have shown that dietary lipid brings changes of fatty acid profile in plasma and hepatic membrane after 10 d (11,32). Thus, it was assumed that biochemical and physiological changes in the short-term feeding trial would be caused by factors other than fatty acid composition of membrane. Contrary to our expectation, a 4-d feeding protocol in experiment II was sufficient to reflect the dietary fatty acids, even though the extent of change was not as great as in long-term experiment I. From this result, the change of microsomal fatty acid composition seems to be achieved in less time than expected, although a more sophisticated time-course study is needed.

Dietary PO as well as FO was effective to reduce postprandial lipemia and hepatic lipid level. This result suggests that n-3 ALA has considerable hypolipidemic effect compared with n-6 LA. The increase of EPA and DHA in hepatic membrane may be partly related to the hypolipidemic effect of n-3 PUFA.

# Effect of Dexamethasone on the Fatty Acid Composition of Total Liver Microsomal Lipids and Phosphatidylcholine Molecular Species

**Rodolfo R. Brenner*, Sixta Ayala, and Horacio A. Garda**

Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), CONICET-UNLP, Facultad de Ciencias Médicas, 1900-La Plata, Argentina

**ABSTRACT:** Dexamethasone depresses Δ6 and Δ5 and increases Δ9 desaturase and synthase activities. Therefore, we investigated the effect on the fatty acid composition of microsomal liver lipids and phosphatidylcholine (PtdCho) molecular species. After 15 d of treatment we found a notable decrease in arachidonic acid, a small decrease in stearic acid, and increases of linoleic, oleic, palmitoleic, and palmitic acids in liver microsomal total lipids and PtdCho. The study of the distribution of the PtdCho molecular species indicated that 18:0/20:4n-6, 16:0/20:4n-6, and 16:0/18:2n-6 predominated in the control animals. Dexamethasone, as expected because of its depressing effect on arachidonic acid synthesis and activation of oleic and palmitic acid synthesis, evoked a very significant decrease in 18:0/20:4n-6 PtdCho ($P<0.001$) and an important increase in 16:0/18:2n-6. The invariability of 16:0/20:4n-6 PtdCho could be related to the antagonistic effect of arachidonic and palmitic acid synthesis. PtdCho species containing oleic acid were not significant. The bulk fluidity and dynamic properties of the microsomal lipid bilayer measured by fluorometry using the probes 1,6-diphenyl-1,3,5-hexatriene and 4-trimethylammonium-phenyl-6-phenyl-1,3,5-hexatriene showed no significant modification, probably owing to a compensatory effect of the different molecular species, but changes of particular domains not detected by this technique are possible. However, the extremely sensitive Laurdan detected increased lipid packing in the less-fluid domains of the polar-nonpolar interphase of the bilayer, possibly evoked by the change of molecular species and cholesterol/phospholipid ratio. The most important effect found is the decrease of arachidonic acid pools in liver phospholipids as one of the corresponding causes of dexamethasone-dependent pharmacological effects.

Paper no. L8712 in *Lipids 36*, 1337–1345 (December 2001).

Polyunsaturated fatty acids derived from linoleic and α-linolenic acids play important roles in the biological functions of mammals, including human beings. The Δ6 desaturase (1) is the key enzyme that regulates polyunsaturated fatty acid biosynthesis at the level of 18-carbon fatty acids. A second step in this regulation at the level of 20-carbon fatty acids is produced by the Δ5 desaturase.

Since 1966, when we discovered that the Δ6 desaturase was depressed in experimental diabetes and could be recovered by insulin injection (2,3), we have enlarged the study regarding the effect of nearly all other hormones, not only upon the Δ6 but also upon the Δ5 desaturase. Several reviews have been published (4,5), and we have found that except for insulin, all hormones for example, glucagon, adrenaline, glucocorticoids (corticosterone, hydrocortisone, dexamethasone, triamcynolone), 11-deoxycorticosterone, aldosterone, estradiol, estriol, testosterone, and ACTH inhibit both enzymes. Progesterone, cortexolone, and pregnanediol were inactive.

When we compared the effects of these hormones *in vivo* upon the hepatic Δ9 desaturase activity, we found (2,3,6), as Gellhorn and Benjamin (7) showed that experimental diabetes depressed Δ9 desaturation of palmitic and stearic acids, and insulin injection recovered the activity. Unlike what happened to the Δ6 and Δ5 desaturases, glucocorticoids, 11-deoxycorticosterone, testosterone, estradiol, and L-triiodothyronine also enhanced Δ9 desaturase activity (Brenner, R.R., unpublished data).

In the case of glucocorticoids, our pioneering experiments done in 1979 (8) showed that *in vivo* hydrocortisone and the synthetic glucocorticoids triamcynolone and dexamethasone were depressors of Δ6 and Δ5 desaturation activity in liver microsomes and activators of Δ9 desaturase, although both synthetic products were more active than hydrocortisone. The strongest effect was found 24 h after the injection. The depressing effect of dexamethasone on [1-$^{14}$C]eicosa-8,11,14-trienoic acid conversion to arachidonic acid was also shown by direct incubation of the isolated rat hepatocytes or hepatoma tissue culture (HTC) cells with this synthetic glucocorticoid (9). Moreover, *in vivo* experiments demonstrated (10) that this modulation of Δ6 and Δ5 desaturation was produced by the biosynthesis of a cytosolic protein sensitive to trypsin that loosely binds to the microsomes. By incubating rat liver hepatocytes and HTC cells with labeled eicosa-

Abbreviations: DPH, 1,6-diphenyl-1,3,5-hexatriene; Δτ, differential polarized phase lifetime; ELSD evaporative light-scattering detector; GLC, gas–liquid chromatography; GP, generalized polarization; HPLC, high-performance liquid chromatography; HTC, hepatoma tissue culture; Laurdan-6-lauroyl-2,4-dimethyl aminonaphthalene; PtdCho, phosphatidylcholine; PtdEtn, phosphatidylethanolamine; PtdIns, phosphatidylinositol; $r_\infty$, limiting anisotropy; $r_0$, fundamental anisotropy; $r_s$, steady-state fluorescence anisotropy; S, order parameter; τ lifetime; $\tau_P$, phase lifetime; $\tau_M$, modulation lifetime; $\tau_R$, rotational correlation time; TAT, tyrosine aminotransferase; TMA-DPH, 1-(4-trimethylammonium phenyl)-6-phenyl-1,3,5-hexatriene.

8,11,14-trienoic acid in the presence of various corticoids, it was shown that not only dexamethasone but also corticosterone and the mineralocorticoids 11-deoxycorticosterone and aldosterone depressed the biosynthesis of arachidonic acid (11). Similarly, both mineralocorticoids depressed Δ6 desaturation *in vivo* (12). However, the mechanisms of action of each one of these hormones were different, and only the effect of 11-deoxycorticosterone, like dexamethasone, was mediated through a soluble protein of approximately 18 kD present in the liver cytosolic fraction. This protein was induced by the occupancy of the glucocorticoid receptor (13). The inhibitory effect of aldosterone was mediated by a different mechanism. Like dexamethasone (14), 11-deoxycorticosterone induced a cytosolic protein that stimulated Δ9 desaturase activity in rat liver microsomes (15).

Since the above-mentioned corticoids alter the biosynthesis of monoenoic acids and polyunsaturated acids of the n-6 and n-3 families, it was important to recognize the corresponding changes evoked in the composition of tissue lipids. To explore these effects, we investigated the changes produced by a long-term (15 d) administration of dexamethasone on the fatty acid composition of total rat liver microsomal lipids and specifically on phosphatidylcholine (PtdCho), which is the principal component of this membrane and a good change detector in polyunsaturated fatty acids. Moreover, considering that the real effect is evoked in the distribution of the different molecular species of this phospholipid, we studied them as well. In addition, we checked the possible changes in the biophysical properties of the microsomal membrane lipid bilayers by fluorescence techniques.

## MATERIALS AND METHODS

*Animal treatment.* All studies performed with animals were carried out in accordance with accepted international standards. Male Wistar rats weighing between 180 and 200 g were separated into two groups. They were fed a commercial diet (Nutrimento, type 3; Escobar, Argentina). The relative percentages of the fatty acids in the diet were 17.0 palmitic, 0.2 palmitoleic, 5.9 stearic, 25.6 oleic, 1.7 vaccenic, 46.2 linoleic, and 3,4 α-linolenic. One group was used as control. The treated animals were injected daily intraperitoneally for 15 d with 0.5 mg/kg weight dexamethasone phosphate (Sidus, Buenos Aires, Argentina). Thereafter, the injected animals had a mean weight of 165 g, and those in the control group had a mean weight of 250 g. All the animals were killed by decapitation without anesthesia. The liver from each animal was rapidly excised and received in ice-cold homogenizing solution (1:3 wt/vol) which was composed of 0.25 M sucrose, 1 mM EDTA, and 10 mM phosphate buffer (pH 7.2). Microsomes were obtained by differential ultracentrifugation at 100,000 × *g* (Beckman Ultracentrifuge) as described elsewhere (16). They were kept frozen at −80°C. The protein concentration was measured according to the procedure of Lowry *et al.* (17).

To check the effect of the glucocorticoid injection, tyrosine aminotransferase (TAT) activity was determined in the 100,000 × *g* supernatants (cytosol fraction) from both control and dexamethasone-treated rats. All measurements were performed according to the method of Dradmonstone (18). The specific activity in noninduced rat liver cytosol ranged from 5.9 to 8.1 TAT units/mg protein and in treated animals from 32.4 to 44.7 TAT units/mg protein. Only those animals with more than 32.4 TAT units/mg protein were used in the present experiments.

*Lipid analysis.* Lipids were extracted from microsomes according to the procedure of Folch *et al.* (19). Total lipid content was measured by aliquot evaporation to constant weight. Cholesterol content was determined by the procedure of Huang *et al.* (20) and total phosphorus by the method of Gomori (21).

Phosphatidylcholine (PtdCho) and other phospholipid classes were separated from total lipids by high-performance liquid chromatography (HPLC) using an evaporative light-scattering detector (ELSD) (22). An Econosil silica column of 10 μm and 250 × 4.6 mm from Alltech Associates (Deerfield, IL) was used. Elution was performed at a flow rate of 1 mL/min by a gradient of hexane/isopropanol/dichloromethane (40:48:12 by vol) to hexane/isopropanol/dichloromethane/water (40:42:8:8 by vol) for 15 min followed by additional elution with the latter solvent for 30 min.

Nebulization in the ELSD was set at 90°C drift tube temperature and 2.20 L/min of nitrogen gas flow to the nebulizer. PtdCho peaks were collected manually from the column effluent using a flow splitter. The solvent was evaporated under $N_2$ and redissolved in methanol/triethylamine (2:1 vol/vol).

The fatty acid compositions of total lipid PtdCho as well as its molecular species were determined by capillary gas–liquid chromatography (GLC) in a Shimadzu Chromatograph, model GC-R9A. A 30 m × 0.25 mm internal diameter with 0.25 μm thickness Omega Wax 250 column (Supelco Inc., Bellefonte, PA) was used. Temperature was programmed for a linear increase of 3°C/min after 3 min at the starting temperature of 185°C and 19 min at the final temperature of 230°C. Helium was used as carrier gas. The chromatographic peaks were identified by comparison of the retention times with those of standards.

*PtdCho molecular species separation*. The separation of the molecular species was done using the method of Browers *et al.* (23). Resolution of molecular species was performed on two 5-μm endcapped Lichrosphere 100-RP18 columns in series (Merck, Darmstadt, Germany). Isocratic elution was applied using a solvent composed of methanol/acetonitrile/triethylamine (58:40:2 by vol) at a flux of 1 mL/min. The detection and quantification were done in an ELSD using $N_2$ as nebulizer at a flux of 1.8 L/min and temperature of 100°C (23). A sample of 1 mg of PtdCho was injected; 5 of 100 parts went to the detector and the remaining materials of the peaks were collected and identified by GLC analysis.

*Fluorescent probes*. 1,6-Diphenyl-1,3,5-hexatriene (DPH) was purchased from Sigma Chemical Co. (St. Louis, MO). 6-Lauroyl-2,4-dimethylaminonaphthalene (Laurdan) and 1-(4-trimethylammonium-phenyl)-6-phenyl-1,3,5-hexatriene

(TMA-DPH) were purchased from Molecular Probes (Eugene, OR).

*Preparation and labeling of lipid vesicles*. Microsomal lipids (1 mg) in chloroform solution were added to a round-bottomed glass tube. The solvent was evaporated under an $N_2$ stream, and 1 mL of buffer A (50 mM sodium phosphate pH 7.4) was added. After 15 min at room temperature to allow hydration, samples were vigorously vortexed for 2 min. Then, the lipid suspensions were extruded 11 times through a 100-nm pore polycarbonate filter using a Liposo-Fast extruder (Avestin, Inc., Ottawa, Canada). For labeling, 0.25 mL of the extruded vesicles was mixed with 0.25 mL of a 4-μM suspension of the fluorescent probe (DPH, TMA-DPH, or Laurdan) in buffer A and vigorously vortexed. Then, samples were kept at room temperature for at least 30 min and diluted five times with buffer A before the fluorescence measurements were made. The final concentration of the samples was 0.1 mg/mL of lipids and 4 μM of the fluorescent probe.

*Fluorescence measurements.* All measurements were made in an SLM 4800 spectrofluorometer in 1 × 1 cm cuvettes. DPH or TMA-DPH steady-state fluorescence anisotropy ($r_s$), lifetime ($\tau$), and differential polarized phase lifetime ($\Delta\tau$) were measured using an excitation wavelength of 361 nm and observing the total emission at wavelengths >389 nm through a sharp cut-off filter (KV389) according to Lakowicz *et al.* (24,25) with some modification (26–28). For the $\tau$ and $\Delta\tau$ measurements, the exciting light was modulated sinusoidally in amplitude at 18 or 30 MHz with a Debye-Sears modulator and vertically polarized with a Glan-Thompson polarizer. For $\tau$, the emission was observed through a Glan-Thompson polarizer oriented 55° to the vertical to eliminate the effect of Brownian rotation (29). The phase shift and demodulation of the emitted light were measured relative to the reference standard 1,4-bis(5-phenyloxazol-2-yl)benzene in ethanol ($\tau$ = 1.35 ns) (30) and used to compute the phase ($\tau_P$) and modulation ($\tau_M$) lifetimes of the samples (31). $\Delta\tau$ was obtained from the phase shift between the parallel and perpendicular components of the emission observed with the emission polarizer vertically or horizontally oriented, respectively. Data were interpreted according to the model of hindered wobbling rotation (32). As described elsewhere (33,34), the values obtained for $r_s$, $\tau$, and $\Delta\tau$ were used to compute (i) the rotational correlation time ($\tau_R$), which is inversely related to the rotational rate and reflects the local viscous resistance to the probe rotation; and (ii) the limiting anisotropy ($r_\infty$), which is related to the order parameter $S$ ($S^2 = r_\infty/r_0$) and reflects the limitation imposed by the local environment to the extent or range of the probe wobbling.

Fluorescence spectra of Laurdan were taken with monochromator bandpasses of 8 nm in excitation and emission as previously described (34–36). All spectra were corrected for background contribution by subtracting the signal of unlabeled samples. Generalized polarization spectra were obtained by measuring the excitation intensity spectra using 440 nm ($I_{440}$) and 490 nm ($I_{490}$) for the emission and the emission intensity spectra at 340 nm ($I_{340}$) and 410 nm ($I_{410}$) excitation wavelength. Generalized polarization in the excitation (exGP) and emission (emGP) bands were obtained from $exGP = (I_{440} - I_{490})/(I_{440} + I_{490})$ and $emGP = (I_{410} - I_{340})/(I_{410} + I_{340})$, respectively. Laurdan emission lifetime was measured as for DPH and TMA-DPH by exciting at 360 nm and isolating the emission with a KV389 filter.

## RESULTS

*Effect of dexamethasone on the lipid and fatty acid composition of liver microsomes.* The effect of a daily injection of 0.5 mg/kg weight dexamethasone phosphate for 15 d on rat liver microsomal lipid composition is depicted in Table 1. First, it shows that the cholesterol/phospholipid ratio was somewhat increased by the glucocorticoid treatment. However, only very small changes were observed in the relative proportions of the different glycerophospholipids. There was a small decrease in the percentage of PtdCho, whereas the proportions of phosphatidylethanolamine (PtdEtn), phosphatidylinositol, and phosphatidylserine were slightly increased. By far, PtdCho was the predominant phospholipid of the liver microsomal membrane.

The fatty acid composition of rat liver microsomal lipids is shown in Table 2. The 15-d dexamethasone treatment evoked significant increases of palmitic, palmitoleic, oleic, linoleic, and eicosatrienoic n-6 acids and a decrease of stearic and arachidonic acids.

When we analyzed the general fatty acid composition of liver microsomal PtdCho, a similar effect was found as expected (Table 3). The percentages of palmitoleic, oleic, and linoleic acids were increased. Palmitic acid increased and stearic acid decreased, but without statistical significance, whereas arachidonic acid decreased significantly.

Therefore, these results correspond rather well to a decrease of Δ6 and Δ5 fatty acid desaturation activity that inhibits linoleic acid conversion to arachidonic acid and to an increase of the Δ9 desaturation activity that enhances the conversion of palmitic and stearic acids to palmitoleic and oleic acids, respectively, as already demonstrated (8–11,13,15).

*Effect of dexamethasone on microsomal PtdCho molecular species.* In fact, the fatty acid analysis of the microsomal PtdCho only gives an average composition of the lipid. The

real situation in the membrane is that PtdCho constitutes an entire family of different molecular species, each one having different pairs of fatty acids. The molecular species of rat liver microsomal PtdCho and the changes induced by dexamethasone treatment are given in Table 4.

Eleven major molecular species were separated, characterized, and quantitated by the method of Browers *et al.* (23) in both control and treated rats.

As reported in other experiments (34,36,37), the predominant liver microsomal PtdCho species in control rats was found to be 18:0/20:4n-6 followed by 16:0/20:4n-6 and 16:0/18:2n-6.

These three species, constituted by one saturated and another unsaturated acid, represent 70.6% of all molecular species of PtdCho in the microsomes. Therefore, they mainly determine the contribution of this phospholipid to the general biophysical properties of this lipid bilayer.

Dexamethasone treatment evoked changes in the proportion of some PtdCho molecular species (Table 4). The most noticeable modification was a sharp decrease of 18:0/20:4n-6 and an important increase of 16:0/18:2n-6 species. Other changes were a decrease of 18:1n-9/20:4n-6 and an increase of 18:0/18:2n-6 and 16:0/18:1n-9 species. However, the proportion of 16:0/20:4n-6 species was not modified. Despite this last important peak and the small 18:2n-6/20:4n-6 peak, which were not altered, the decrease of the other 20:4n-6 containing peak and the notable increase of 16:0/18:2n-6 and 18:0/18:2n-6 species confirm the changes of polyunsaturated fatty acid mean compositions found in PtdCho (Table 3). They also correspond well to a decrease of dietary linoleic acid conversion to arachidonic acid already shown in glucocorticoid-treated rats (8–11).

No significant changes were found in the 22:6n-3 containing species. The expected small increase of 18:1n-9 containing species was only found in the 16:0/18:1n-9 peak but not in the 18:1n-9/20:4n-6 and 18:1n-9/18:2n-6 peaks.

*Effect of dexamethasone on the order and dynamics of microsomal lipids*. The effect of dexamethasone administration on the biophysical properties of the microsomal lipids was studied in large unilamellar vesicles of these lipids using three different fluorescent probes. The rotational behavior of DPH and TMA-DPH was studied by using phase and modulation fluorometry (Table 5). These probes sense the order and dynamics of the lipid bilayer at different depths. The neutral DPH probe locates deeply into the bilayer, whereas the amphipathic TMA-DPH is anchored through its positive charge to the phospholipid polar groups and locates the fluorescent moiety more externally than DPH. Thus, TMA-DPH senses a more polar environment, which is indicated by its shorter lifetime in comparison with DPH. The lifetimes of these probes obtained by phase ($\tau_P$) and modulation measurements ($\tau_M$) at 18 MHz excitation frequency are shown in Table 5. No effect of dexamethasone administration was observed, indicating no change in the polarity in both sensed bilayer regions. Similar lifetime values were obtained by measurements at 30 MHz (data not shown). This fact and also the small differences be-

[a]TMA-DPH, 1-(4-trimethylammonium phenyl)-6-phenyl-1,3,5-hexatriene; DPH, 1,6-diphenyl-1,3,5-hexatriene.
[b]The values given are the mean ± standard deviation of four animals for the control group and five animals for the treated group. Student's tests do not indicate a significant difference at the 5% probability level for any of the measured parameters.
[c]The indicated values for phase ($\tau_P$) and modulation ($\tau_M$) lifetimes, rotational correlation time ($\tau_R$) and limiting anisotropy ($r_\infty$) were obtained using 18 MHz excitation modulation frequency.

tween $\tau_P$ and $\tau_M$ indicate that there is no large heterogeneity in the probe distribution into different microdomains in the vesicle bilayer. The fact reasonably allows us to apply the hindered wobbling rotation model (32) assuming a unique rotamer population to calculate the rotational correlation time ($\tau_R$) and limiting anisotropy ($r_\infty$) parameters. The $\tau_M$ and $r_\infty$ parameters calculated from measurements at 18 MHz (shown in Table 5) indicate that dexamethasone treatment does not significantly affect the rotational behavior of these probes in the microsomal lipid vesicles.

The effect of dexamethasone administration on the lipid dynamics in vesicles of microsomal lipids was also studied by using the fluorescence properties of Laurdan. This probe locates its fluorescent moiety at the polar-nonpolar interphase of the lipid bilayer, and its emission spectra are highly sensitive to solvent relaxation (38). Small changes in the lipid packing can influence both the amount and mobility of water molecules in the bilayer. An increased water amount at the interfacial region of the bilayer would result in a shorter lifetime and a red-shifted emission of Laurdan fluorescence, whereas an increased mobility of water molecules would produce a red-shifted emission without affecting the fluorescence lifetime (38). Spectral shifts of Laurdan are generally expressed with the generalized polarization (GP) parameter (39). Figure 1 shows the influence of dexamethasone administration on the lipid composition of microsomal membranes and the effect on the GP values calculated from the Laurdan emission spectra at different excitation wavelengths at 25 and 37°C. The observed decrease in GP with increasing excitation wavelength is typical of liquid-crystalline bilayers (40). It is clear from the figure that dexamethasone treatment produces an increase in the GP values when lower excitation wavelengths are used. At lower excitation wavelengths, the less fluid lipid domains should be preferentially selected (40). It is important to note that there was no significant effect of the treatment on the Laurdan fluorescence lifetime because $\tau_R$ was 3.81 ± 0.06 and 3.81 ± 0.03 for control and treated groups, respectively; $\tau_M$ was 4.21 ± 0.03 and 4.20 ± 0.08 for control and treated groups, respectively, measured at 37°C and 18 MHz, indicating no change in the amount of water in the interfacial region. Thus, the observed increase in GP produced by dexamethasone administration can be attributed to an increased lipid packing, which results in reduced water mobility in the less fluid lipid domains preferentially selected at lower excitation wavelengths.

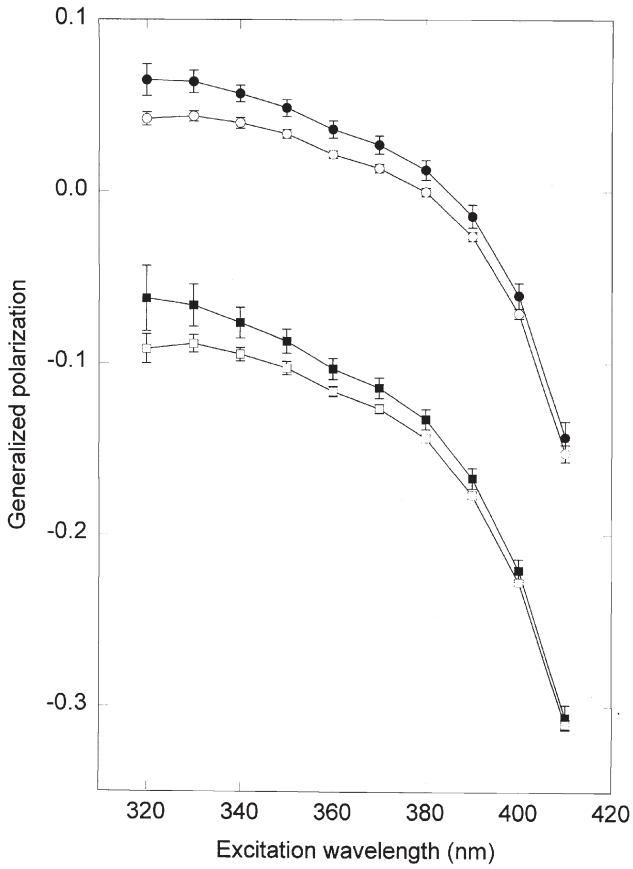

**FIG. 1.** Effect of dexamethasone administration on the Laurdan generalized polarization in microsomal lipid vesicles. Measurements were made on liver microsomal vesicles of control (○,□) and treated animals (●,■) at 25°C (○,●) and 37°C (□,■) as described in the Materials and Methods section. The values are the mean of four and five animals for the control and treated groups, respectively. The standard deviations are indicated by bars.

## DISCUSSION

It is now well accepted that glucocorticoids perform very important functions in glucose and fatty acid metabolism. As already indicated, these hormones depress liver microsomal fatty acid Δ6 and Δ5 desaturase activity and enhance Δ9 desaturase. These changes in the activity of the desaturases are apparently evoked through the biosynthesis of a cytosolic

protein (10,12,13). In the case of Δ9 desaturase, it is important to indicate that the enhancing effect of the hormone has been shown on both [1-$^{14}$C]palmitic and [1-$^{14}$C]stearic acid desaturation. This clarification is pertinent because of the two Δ9 desaturases detected in rodents (41); only one, $SCD_1$ (stearoyl-CoA desaturase 1), is present in liver (42,43), and it is able to desaturate both saturated acids. It could be differently regulated from $SCD_2$, also found in adipose tissue (44). This last isoform is also an exclusive component of other organs.

The biological changes evoked by the alteration of these fatty acid desaturase activities are, in general, the consequence of the alteration produced in the proportion of polyunsaturated fatty acids of n-6 and n-3 families, mainly arachidonic and docosahexaenoic acids, and the monounsaturated acids of n-9 family (oleic acid) in liver and in other organs.

To evaluate these changes evoked by dexamethasone, a very efficient synthetic glucocorticoid that modifies Δ6, Δ5, and Δ9 desaturase activity (8–10,15), we analyzed the fatty acid composition of liver microsomes after 15 d of treatment. This target membrane readily responds to alterations in the availability of polyunsaturated acids of n-6 and n-3 series. This scheme of evaluation is pertinent because the only source of these acids in our experimental conditions was the biosynthesis from the precursor acids, linoleic and α-linolenic. They are the only n-6 and n-3 acids provided by the diet.

As shown in Tables 2 and 3, significant increases in the proportion of linoleic acid and decreases of arachidonic acid of the n-6 family were found in both total lipids of liver microsomes and PtdCho, the main compound (≅80% of the membrane phospholipids) of this bilayer. These facts are in agreement with and apparently the consequence of the decrease of microsomal Δ6 and Δ5 desaturase activities evoked by dexamethasone treatment. In spite of that, it can be argued that the changes produced in the arachidonic and linoleic acid proportions might be due to a redistribution between microsomes and other organelles; the fact that dexamethasone also evokes similar changes in total lipids of cultures of Morris 7288c rat cells confirms our interpretation (45). Moreover, it has also been shown (14) that the corticoid-11-deoxycorticosterone, which similarly to dexamethasone depresses Δ6 and Δ5 desaturases, evoked similar decreases in arachidonic and increases of linoleic acid proportions in liver microsomes, total liver homogenate, cytosol, and plasma lipids.

No significant decrease was detected in the proportion of docosahexaenoic acid of the n-3 family even though its biosynthesis from α-linolenic acid is also mainly controlled by the same enzymes at the level of 18- and 20-carbon fatty acids. However, a difference is found in relation to arachidonic acid because its synthesis requires further steps of elongation to 22 and 24 carbons, a new desaturation by a poorly characterized Δ6 desaturase, and β-oxidation at the peroxisomes (31) that could modify or mask the effect on the mentioned desaturases. Another difference found in our experiments between the mentioned n-6 and n-3 polyunsaturated fatty acid biosynthesis in the animal is that the rats received a diet very rich in linoleic acid (46.2%) but poor in α-linolenic acid (3.4%). Also, less than 3% of 22:6n-3 is found in the total lipids of the membrane compared to more than 20% of 20:4n-6. As a consequence, the possibility is that arachidonic acid, in addition to being a major component of the membrane, is constantly deacylated and reacylated into PtdCho whereas docosahexaenoic acid is more likely to remain in the membrane. Therefore, it is possible that the effect found on the desaturases and transmitted to the arachidonic acid content would be more easily detected than in the n-3 polyunsaturated fatty acid.

However, we must consider that when we studied the effect of experimental diabetes (29), in which the activity of both liver Δ6 and Δ5 desaturases is decreased, we found that, although the amount of arachidonic acid detected in liver microsomal lipids dropped, a significant increase in docosahexaenoic acid was recorded. This last result has not been properly explained yet, but we suggested (29) it could be due to a specific effect on the decreased oxidation of docosahexaenoic acid. It may indicate that the amount of 22:6n-3 acid in the liver microsomes is regulated by an additional mechanism besides that of 20:4n-6 acid.

A remarkable conclusion from these composition studies is that, at least in rat liver microsomal membranes, 15-d glucocorticoid treatment decreases quantitatively the proportion of the biologically very important arachidonic acid of the n-6 family, but it does not alter the amount of the also very important docosahexaenoic acid of the n-3 series.

The increase evoked by dexamethasone in liver microsomal Δ9 desaturase (15) correlates well with the increase of palmitoleic and oleic acid percentages found in microsomal total lipids and PtdCho fatty acids (Tables 2 and 3). However, whereas the decrease of stearic acid found in total lipids (Table 2) also agrees with that effect, a significant change of this acid was not found in PtdCho fatty acids. As well, the increase in the percentage of palmitic acid in both total lipids and PtdCho would not correlate with an increase of Δ9 desaturation activity. However, this result is not an important objection because the relative amount of palmitoleic acid compared to palmitic is extremely low in these lipids, and any possible effect of increased Δ9 desaturation on the palmitic acid amount would pass undetected. Moreover, an even more important explanation for this result is that the increase of palmitic acid in total microsomal lipids and PtdCho is undoubtedly due to the already demonstrated dexamethasone stimulation of fatty acid synthase activity (46,47). This is apparently evoked through an increase of the synthase mRNA transcription and by posttranscriptional events, too (48).

The increase of synthase mRNA evoked by dexamethasone may be also considered, at least in part, as a consequence of the decrease of Δ6 desaturase activity produced by the same glucocorticoid. The decrease of the Δ6 desaturase activity lowers the synthesis and hepatic content of arachidonic acid that, as it is known, suppresses the synthase mRNA transcription (49). The authors (49) also showed that this effect is

not produced by linoleic acid if it is not previously desaturated by the Δ6 desaturase.

*PtdCho molecular species.* The important change evoked by dexamethasone *in vivo* on the molecular species of PtdCho, which are basic structural components of rat liver endoplasmic reticulum bilayer membranes, is clearly shown in Table 4.

As already found in other experiments (34,36,37), the highly predominant PtdCho species in the rat liver microsomes were 18:0/20:4n-6, 16:0/20:4n-6, and 16:0/18:2n-6. They were the principal determinants of the contribution of this phospholipid to the general biophysical properties and some of the chemical properties of the bilayer. Similar predominant molecular species were also shown in rat liver microsomal PtdEtn (37). In PtdIns, 18:0/20:4n-6 and 16:0/20:4n-6 were nearly exclusive components (37).

The decrease in the proportion of arachidonic acid and the increase of linoleic acid shown in PtdCho (Table 3) and evoked by dexamethasone are the consequence of the significant decrease of the predominant 18:0/20:4n-6 and small 18:1n-9/20:4n-6 PtdCho molecular species, and the increase of the predominant 16:0/18:2n-6 and also important 18:0/18:2n-6 PtdCho molecular species. However, other minor species containing 18:2n-6 or 20:4n-6 acids as 18:2n-6/20:4n-6 and 18:1n-9/18:2n-6 are little changed. But what is really remarkable is that the very important 16:0/20:4n-6 PtdCho species is not lowered compared to 18:0/20:4n-6. This undoubtedly indicates that the decrease of arachidonic acid biosynthesis evoked by the inactivation of Δ6 and Δ5 desaturases by dexamethasone determines less availability of this acid for modeling the fatty acids at the 2-position of PtdCho molecules, but the other fatty acids at position 1, and other factors as mechanisms of phospholipid synthesis and specificity of enzymes, also determine the final molecular compositions. The effect of glucocorticoids on phospholipase $A_2$ activity may be an additional factor contributing to the remodeling of PtdCho molecular species.

In the specific case of 16:0/20:4n-6 and 18:0/20:4n-6 species changes, the difference might be due, at least in part, to the different ways 16:0 and 18:0 are affected by dexa-methasone. In the case of 16:0 it has been repeatedly shown that fatty acid synthase is activated by glucocorticoids (46,47).

As expected from the fatty acid composition of microsomal lipids displayed in Tables 2 and 3, no significant modification in the amounts of both 16:0/22:6n-3 and 18:0/22:6n-3 species was evoked by dexamethasone. Although these species are minor components of PtdCho, the reason for no modification is not clear, as previously discussed.

Oleic acid-containing species are not abundant in the liver microsomes of rats fed a linoleic acid rich-diet, and only 16:0/18:1n-9 was nearly doubled by dexamethasone treatment, the consequence of the increase of Δ9 desaturase activity. Indeed, they are unimportant species for the determination of PtdCho contribution to the dynamic properties of the lipid bilayer.

*Effect on dynamic properties of microsomal lipid bilayer.* The changes in the lipidic composition and PtdCho molecular species of rat liver microsomes and the small increase of the cholesterol/phospholipid ratio evoked by dexamethasone administration showed no significant effect on the rotational behavior of DPH and TMA-DPH in vesicles made with these microsomal lipids (Table 5) in spite of testing different depths of the bilayer. The lack of effect on the fluorescent lifetimes of these probes as well as those of Laurdan indicate no change in the environment polarity of these probes at their different locations. However, as indicated by the increased Laurdan GP at lower excitation wavelengths, dexamethasone produces an increased lipid packing in the preferentially selected less fluid domains, resulting in a decreased mobility of water molecules present in the interfacial region of the bilayer in these domains.

It is not surprising that the increased lipid packing as detected by Laurdan does not result in any detectable change in the rotational mobility of DPH and TMA-DPH. We previously showed that higher sensitivity of Laurdan detected small changes in the lipid packing that were not detected by DPH or TMA-DPH, for instance those produced by streptozotocin diabetes (36) or polyunsaturated fatty acid deficiency (35) in rat liver microsomes. The high sensitivity of Laurdan was attributed to the fact that it senses the rotational mobility of a very small molecule, such as water (35). Small changes in the lipid packing that do not appreciably alter the rotational behavior of relatively large molecules like DPH or TMA-DPH can change the motion rate of smaller molecules such as water. Moreover, DPH and TMA-DPH would sense the motion in the different lipid domains, which, on average, were apparently not greatly changed by dexamethasone administration. On the contrary, Laurdan detects an increased lipid packing after dexamethasone treatment only in the less fluid lipid domains, and this might be related to the change of the molecular species of PtdCho and/or to the small increase of the cholesterol/phospholipid ratio. This effect of dexamethasone in the less fluid lipid domains contrasts with the effects produced in the more fluid domains (i.e., at longer wavelengths) by streptozotocin diabetes (36) (which decreases GP) and polyunsaturated fatty acid deficiency (35) (which increases GP). The relationship between compositional changes and these effects on particular lipid domains is not yet easily interpretable.

The main effect evoked by the glucocorticoid in liver is a decrease of arachidonic acid in the membrane phospholipids that alters the proportion of the molecular species of PtdCho, decreasing the 18:0/20:4n-6 species. However, since the proportion of saturated/unsaturated acid molecules is roughly maintained in spite of a small increase in the cholesterol/phospholipid ratio, no important change is evoked in the bulk fluidity of microsomal bilayer as tested by fluorometric techniques. Only a small packing increase is found in the less fluid lipid domains. However, fluorometric techniques used cannot detect changes in specific particular lipid domains that are very probably produced.

The decrease of arachidonic acid stores in liver evoked by dexamethasone would result in lower availability of this acid for its main biological functions. An inadequate availability

of arachidonic acid is associated with impaired nerve transmission, reduced eicosanoid synthesis, and impaired fetal growth. It exerts vital functioning effects in key steps of cell signaling and the expression of a wide array of genes, including those encoding proteins involved in lipid metabolism, thermogenesis, and cell differentiation.

Moreover, the decrease of arachidonic acid biosynthesis and its pools and the depression of phospholipase $A_2$ activity (50) evoked by dexamethasone are cooperative factors that prevent generation of arachidonic-acid derived prostaglandins and other eicosanoids and produce the well-known anti-inflammatory effect of glucocorticoids.

# Analysis of Molecular Species of Peroxide Adducts of Triacylglycerols Following Treatment of Corn Oil with *tert*-Butyl Hydroperoxide

**O. Sjövall[a,b], A. Kuksis[a,*], and H. Kallio[b]**

[a]Banting and Best Department of Medical Research, University of Toronto, Toronto, Canada M5G 1L6, and [b]Department of Biochemistry and Food Chemistry, FIN-20014 University of Turku, Finland

**ABSTRACT:** We recently demonstrated that exposure of synthetic mono- and diunsaturated triacylglycerols to *tert*-butylhydroperoxide (TBHP) leads to formation of stable adducts of the oxidizing agent and the unsaturated esters (Sjövall, O., Kuksis, A., and Kallio, H., Reversed Phase High-Performance Liquid Chromatographic Separation of *tert*-Butyl Hydroperoxide Oxidation Products of Unsaturated Triacylglycerols, *J. Chromatogr. A 905*, 119–132, 2001). In the present study we isolated and identified the TBHP adducts of corn oil triacylglycerols. The much wider range of molecular species available in the corn oil permitted us to demonstrate that the yield of the adducts varies with the degree of unsaturation of the triacylglycerol. The highest yields were obtained for the linoleate (20% of linoleoyl-containing residual triacylglycerols) and the lowest ones for the oleate (5% of oleoyl-containing residual triacylglycerols) triacylglycerols, whereas the saturated triacylglycerols did not give TBHP adducts in readily detectable amounts. Normal-phase thin-layer chromatography along with reversed-phase high-performance liquid chromatography/mass spectrometry (LC/MS) with electrospray ionization was used to isolate and separate the major molecular species of polyunsaturated triacylglycerols and corresponding TBHP adducts. As an extreme example, the dilinoleoylmonooleoylglycerol was identified as the mono-, di-, tri-, tetra-, and penta-TBHP adduct. LC/MS with electrospray ionization at elevated capillary exit voltage (pseudo tandem mass spectrometry) was used to confirm structures of the $[M - RCOOH]^+$ ions and the absence of TBHP adducts of $[M - RCOOH]^+$. It is concluded that stable adduct formation is an unavoidable complication of preparation of oxotriacylglycerols by oxidation with concentrated TBHP solutions and care must be taken to resolve the adducts from the desired oxidation product.

Paper no. L8877 in *Lipids 36*, 1347–1356 (December 2001).

*tert*-Butyl hydroperoxide (TBHP) is a popular lipid-oxidizing agent (1) and has been extensively utilized for the preparation of hydroperoxides and epoxides of unsaturated fatty acid methyl esters (2,3), triacylglycerols (4,5), cholesteryl esters (6,7), and glycerophospholipids (8,9). We have recently detected significant peroxide bridging during preparation of hydroperoxide reference compounds, especially when more concentrated solutions of the hydroperoxide are employed (10). We observed that the oxotriacylglycerols included both chain desaturation and chain cleavage products, many of which formed peroxide bridges with TBHP. Since this reagent is commonly used for the hydroperoxidation of natural lipid mixtures for subsequent biochemical and physiological studies, the formation and recovery of the TBHP adducts during a simple lipid extraction of the reaction mixture is of interest, as is the identification of the adducts.

In the present report we describe the isolation and identification of the TBHP adducts from the residual triacylglycerol mixture recovered from rapid peroxidation of corn oil. Reversed-phase liquid chromatography/electrospray ionization/mass spectrometry (LC/ESI/MS) analysis of the molecular species established that the yield of the adducts varies with the degree of unsaturation of the triacylglycerol. The linoleates yielded the most and the oleates the least, whereas saturates usually failed to give any TBHP adducts.

## MATERIALS AND METHODS

*Materials*. TBHP as 70% solution in water and 2,4-dinitrophenylhydrazine (DNPH) were purchased from Sigma Chemical Co. (St. Louis, MO). The solvents were of chromatography grade or of reagent grade and were dried over anhydrous sodium sulfate.

Synthetic hydroperoxides, epoxides, hydroxides, and core aldehydes of the common palmitoyl, oleoyl, and linoleoyl triacylglycerols were prepared in the laboratory as described in previous studies (4,5). The corn oil (Mazola, Englewood Cliffs, NJ) was obtained from a local grocer. The corn oil triacylglycerols were isolated by thin-layer chromatography (TLC) as previously described (5).

*Oxidation*. The oxidation of corn oil was performed by adding 1 mL of 35 to 70% TBHP in water to 10 mg of purified triacylglycerols in the presence of 10 μM $FeSO_4$ and 100 μL of 0.2% taurocholic acid (5). The reaction mixture was incubated on a mechanical agitator in darkness for 90 min at

Abbreviations: 16:0, palmitic acid; 18:0, stearic acid; 18:1, oleic acid; 18:2, linoleic acid; 18:3, linolenic acid; 20:0, arachidic acid; CapEx 300, capillary exit voltage of 300 V; DNPH, 2,4-dinitrophenylhydrazine; ELSD, evaporative light-scattering detector; ESI, electrospray ionization; HPLC, high-performance liquid chromatography; LC, liquid chromatography; M, molecular ion; MS, mass spectrometry; Rt, retention time; TBHP, *tert*-butyl hydroperoxide; TCN, theoretical carbon number; TLC, thin-layer chromatography.

37°C. The reaction was stopped by adding to the mixture 5 mL of chloroform/methanol (2:1, vol/vol), 100 μL of 2% in water, and 10 μL of 2% butylated hydroxy toluene in methanol. The extracts were washed three times with water (3 × 1 mL). The solvent was evaporated under nitrogen at 38°C and the lipid residue was saved for TLC, high-performance liquid chromatography/evaporative light-scattering detection (HPLC/ELSD), and LC/ESI/MS.

*Preparation of DNPH derivatives*. The DNPH derivatives of triacylglycerol core aldehydes were synthesized by adding freshly prepared DNPH in 1 N HCl (0.5 mg/mL) to an aliquot of dry sample (5). The mixture was shaken vigorously and kept in the dark at room temperature for 4 h and overnight at 4°C. The lipids were extracted by 5 mL of chloroform/methanol (2:1, vol/vol), the chloroform phase was blown down under nitrogen, and the residue was taken up in an appropriate solvent for chromatography and MS as described next.

*TLC.* Normal-phase TLC was used to purify triacylglycerols and to resolve the oxotriacylglycerols and their DNPH derivatives. Silica gel H (Merck & Co., West Point, PA) plates were prepared in the laboratory and heptane/isopropyl ether/acetic acid (60:40:4, by vol) solution was used as a mobile phase (5). The complex mixture resolved into a total of nine yellow bands and a band for residual triacylglycerols (TLC Band 10), which were present mostly as the TBHP adducts (see below). The DNPH derivatives of the core aldehydes were seen as yellow bands on the chromatoplates (in daylight). The compounds were recovered from the silica gel scrapings by extraction with chloroform/methanol 2:1 (vol/vol). Extracts were washed with distilled water, dried with anhydrous $Na_2SO_4$, and saved for subsequent HPLC/ELSD and LC/ESI/MS analysis.

*HPLC/ELSD and LC/ESI/MS.* Procedures for HPLC and LC/ESI/MS were as described previously (5,11). Triacylglycerols and oxidation products were resolved by reversed-phase HPLC on a Supelcosil LC-18 column (Bellefonte, PA; 250 × 4.6 mm i.d.), using a linear gradient of 20–80% 2-propanol in methanol (0.85 mL/min) in 30 min. A Hewlett-Packard model 1050 liquid chromatograph was coupled to a Varex ELSD II light-scattering detector (Varex, MD) using nitrogen as nebulization gas and an evaporation temperature of 85°C. LC/ESI/MS was performed using a Hewlett-Packard model 1090 liquid chromatograph interfaced with a nebulizer-assisted ESI source connected to a Hewlett-Packard model 5989A quadrupole mass spectrometer (10). The HPLC conditions were the same as described above except that ammonia/isopropanol (1%) was added postcolumn at a flow rate of 0.15 mL/min in order to enhance ionization (10).

*Peak identification*. The chromatographic peaks of the oxotriacylglycerols were identified on the basis of reversed-phase HPLC retention times of standards and estimated elution factors for functional groups and their positional distribution as previously described (5). The identification of major peaks was confirmed by single-ion mass chromatograms extracted by computer from the total positive ion current spectra.

*Quantification.* The yields of the major oxidation products were quantified by HPLC/ELSD. The results were compared to those obtained with LC/ESI/MS. The ammonia, sodium, and potassium adducts were summed to obtain a total estimate for the mass of species in each mass spectrum. The TBHP adducts were estimated separately as they were clearly resolved from other species during TLC and the reversed-phase HPLC/ELSD and LC/ESI/MS.

## RESULTS

*LC/ESI/MS profiles of total corn oil and total oxidized corn oil.* Figure 1 compares the total ion current profiles of natural corn oil and corn oil exposed to TBHP for 90 min as obtained by reversed-phase LC/ESI/MS. Corresponding peaks are assigned the same numbers in the elution profiles and the peak identities are listed in Tables 1–3. The native oil gives seven major peaks ranging in theoretical carbon number from 42 to 54, along with seven minor ones mostly of lower carbon number. Owing to extensive peak splitting, the oxidized oil gives a somewhat larger number of peaks, which, however, are eluted over the same range of retention times. The peaks

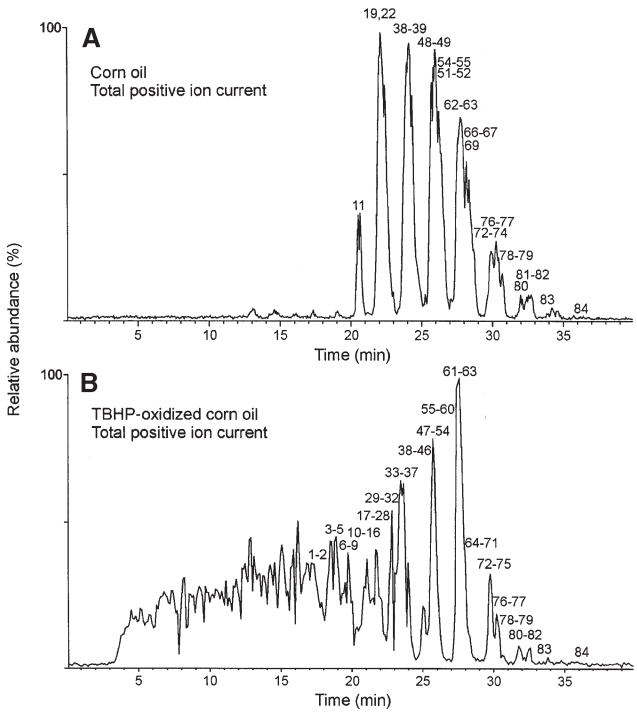

**FIG. 1.** Total liquid chromatography/electrospray ionization/mass spectrometry (LC/ESI/MS) ion current profiles of native (A) and oxidized (B) corn oil. Oxidized corn oil obtained by exposure to *tert*-butyl hydroperoxide (TBHP) for 90 min. Peak identities are given in Tables 1–3. LC/ESI/MS conditions are as follows: Supelco (Bellefonte, PA) LC-18 column (250 × 4.6 mm i.d.) installed in a Hewlett-Packard Model 1090 liquid chromatograph interfaced with a nebulizer-assisted ESI source connected to a Hewlett-Packard Model 5989A quadrupole mass spectrometer (10). The high-performance liquid chromatography column was developed with a linear gradient of 20–80% 2-propanol in methanol (0.85 mL/min) in 30 min. Ammonia (1%) in isopropanol was added postcolumn at a flow rate of 0.15 mL/min in order to enhance ionization.

[a]Abbreviations: LC, liquid chromatography; ESI, electrospray ionization; MS, mass spectrometry; Rt, retention time; TCN, theoretical carbon number; ACN, acyl carbon number; DB, double bond number; TBHP, *tert*-butylhydroperoxide; TLC, thin-layer chromatography; TAG, triacylglycerol.
[b]Numbers of the compounds refer to peaks in Figures 1 and 4.
[c]Nominal mass of $[M + NH_4]^+$.
[d]Abundance of an ion in the first-mentioned TLC band.
[e]The most abundant band mentioned first. Minor amounts of residual TAG were detected also in other bands.
[f]The most likely structure is given, although the positional order of fatty acids may not be as presented.

eluted over the range of 3 to 15 min are due to oxidation products of molecular weights below those of triacylglycerols and were not further examined at this time. Although many of the peaks overlap in retention time, they differ greatly in composition of molecular species because of the exposure to TBHP. Figure 2 compares the total positive ion current mass spectra averaged over the elution time of the native and oxidized corn oil. The major difference in the spectra is the great proportion of the *m/z* 963, 989, and higher (e.g., *m/z* 1019–1075) masses in the mass spectrum of the oxidized oil.

*Isolation of residual triacylglycerols.* Figure 3 shows the TLC separation of the corn oil triacylglycerol oxidation products following derivatization with DNPH. A total of nine yellow bands were obtained along with a colorless 10th band migrating ahead of the others. Since the yellow color was due to dinitrophenylhydrazone formation, it was obvious that most, if not all, of the oxidized triacylglycerol bands contained at least one triacylglycerol with a carbonyl function. On the other hand, TLC Band 10 was not expected to contain carbonyl esters, the bulk of the material presumably representing the unoxidized (residual) triacylglycerols. An LC/ESI/MS examination of TLC Band 10, however, revealed that it contained ion masses far exceeding those anticipated for the simple oxidation products of corn oil triacylglycerols.

Table 4 compares the fatty acid composition of the original corn oil and of TLC Band 10 of the oxidized oil. There was extensive destruction of linoleic acid and, to a lesser extent, oleic acid during the oxidation, as indicated by a fourfold decrease in the proportion of the linoleate and a twofold increase in the proportion of the oleate. The proportion of palmitate doubled, and that of the stearate tripled. The minor saturated long-chain fatty acids proportionally increased.

Figure 4 shows the total positive ion current profile of TLC Band 10 as obtained by reversed-phase LC/ESI/MS, along with the full mass spectrum (*m/z* 700 to 1400) averaged over the entire elution profile. The total ion current profile of native corn oil overlaps partly with that of the total oxidized corn oil, suggesting the presence of residual triacylglycerols,

[a]For abbreviations see Table 1.
[b]Numbers of the compounds refer to peaks in Figures 1 and 4.
[c]Nominal mass of $[M + NH_4]^+$.
[d]Abundance of an ion in the first-mentioned TLC Band.
[e]The most abundant band mentioned first.
[f]The most likely structure is given, although the *sn*-positional order of fatty acids may not be as presented. Underlined double bond shows the *sn*-position of TBHP group for calculation of TCN value.

although the splitting of the peaks is much deeper. The peak numbers are assigned as explained above and their identities are given in Tables 1–3. The mass spectra of the individual HPLC peaks revealed that the masses of the ions corresponded to the mono- and di-TBHP adducts of the residual corn oil triacylglycerols as well as to nonoxygenated triacylglycerols, which, however, had undergone desaturation of fatty chains and conjugation of double bonds. The individual HPLC peaks were identified on the basis of the molecular and fragment ions recorded under each of the peaks and from the relative retention times of standard normal and oxygenated triacylglycerols.

*Identification of residual triacylglycerols.* Figure 5 gives the single-ion chromatograms for the six major residual triacylglycerol masses. In order of decreasing retention time they are *m/z* 933 (18:0/18:1/20:1), 931 (a, 18:1/18:1/20:1; b, 20:0/18:2/18:1), 929 (20:0/18:2/18:2), 877 (a, 16:0/18:1/18:1; b, 16:0/18:2/18:0), 875 (16:0/18:2/18:1), and 873 (16:0/18:2/18:2). Several of these ion peaks are double peaks or possess advance or tailing shoulders. These can be readily attributed to homologs that possess the same total carbon and double bond number but differ in the distribution of the double bonds. Thus, the presence of two double bonds in the same fatty chain shortens the retention time more than the presence of two double bonds in separate fatty chains. Similar single-ion mass chromatograms were obtained for other homologous series of residual triacylglycerols as shown in Table 1. The structures proposed on the basis of relative retention times of standard triacylglycerols were confirmed by the finding of the corresponding $[M - RCOOH]^+$ ions as minor peaks in the total ion spectrum of each peak or as major fragment ions following reanalysis of the sample at a higher

positive exit voltage [capillary exit voltage of 300 V, (CapEx 300)] (data not shown).

*Identification of mono-TBHP adducts*. Figure 6 gives the single-ion chromatograms for the mono-TBHP adducts of the six major residual triacylglycerol masses shown in Figure 5. In order of decreasing retention time they are: *m/z* 1021 (a, 18:0/18:1/20:1 + TBHP; b, 18:0/18:1/20:1 + TBHP), 1019 (a, 18:1/18:1/20:1 + TBHP; b, 18:1/18:2/20:0 + TBHP), 1017 (a, 18:1/18:2/20:1 + TBHP; b, 20:0/18:2/18:2 + TBHP; c, 20:0/18:2/18:2 + TBHP), 965 (a, 16:0/18:1/18:0 + TBHP; b, 16:0/18:1/18:1 + TBHP; c, 16:0/18:2/18:0 + TBHP; and d, 16:0/18:0/18:2 + TBHP), 963 (a, 16:0/18:2/18:1 + TBHP; b, 18:2/18:1/16:0 + TBHP), and 961 (a, 16:0/18:2/18:2 + TBHP; b, 16:0/18:2/18:2 + TBHP). Several of these ion peaks are double peaks or possess advance or tailing shoulders. These can be readily attributed to homologs that possess the same total carbon and double bond number but differ in the distribution of the double bonds. The location of the TBHP groups is indicated by underscoring the appropriate fatty chain. Thus, the presence of two double bonds in the same fatty chain shortens the retention time more than the presence of two double bonds in separate fatty chains. The mono-TBHP adducts migrate slightly ahead of the parent triacylglycerols. Similar single-ion mass chromatograms were obtained for other homologous series of residual triacylglycerols as shown in Table 2.

Table 2 indicates that some of the adducts were also found in TLC Bands 9 and 8. The structures advanced on the basis of the molecular masses of presumed TBHP adducts of the triacylglycerols were confirmed by finding the corresponding $[M - RCOOH - TBHP]^+$ ions of the parent triacylglycerols as minor peaks in the total ion spectrum of each peak or as major fragment ions following reanalysis of the sample at a higher positive exit voltage (CapEx 300) (data not shown). Fragment ions carrying the adducted TBHP moiety, however, were not found. In several instances, the minor diacylglycerol-like fragment ions possessed one double bond more than anticipated from the masses of the major residual triacylglycerols. This suggested that a double bond had been introduced during the adduct formation.

*Identification of di-TBHP adducts.* Figure 7 gives the single ion chromatograms for the di-TBHP adducts of the six major residual triacylglycerol masses. In order of decreasing retention time they are: *m/z* 1109 (a, 18:0/18:1/20:1 + 2×TBHP; b,

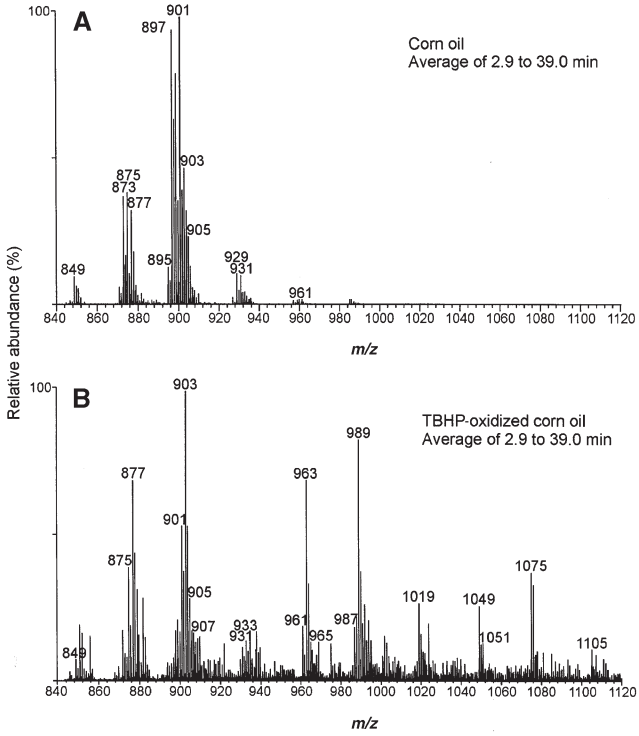

**FIG. 2.** Comparison of total positive ion current mass spectra averaged over the elution times of native (A) and oxidized (B) corn oil. Ions are identified in Tables 1–3. LC/ESI/MS conditions are as given in Figure 1. For abbreviations see Figure 1.

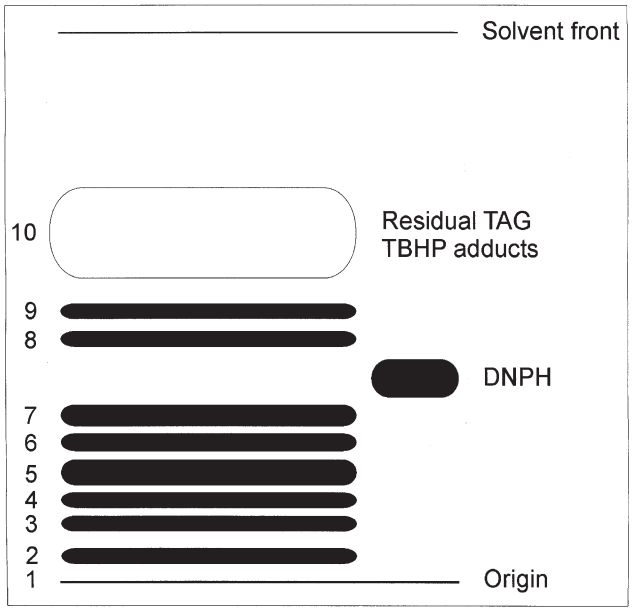

**FIG. 3.** Thin-layer chromatography (TLC) separation of the oxidation products of corn oil triacylglycerols (TAG) following derivatization with dinitrophenylhydrazine (DNPH). Silica gel H (Merck & Co.) plates (20 × 20 cm) were prepared in the laboratory and developed with heptane/isopropyl ether/acetic acid (60:40:4, by vol). DNPH derivatives of TAG containing core aldehydes appeared as yellow bands; other bands were stained with 2,7-dichlorofluorescein. Aldehyde-containing bands (Bands 2–9) are identified in Reference 10. For other abbreviation see Figure 1.

20:0/18:1/18:1 + 2×TBHP), 1107 (a, 18:1/18:1/20:1 + 2×TBHP; b, 20:0/18:2/18:1 + 2×TBHP), 1105 (a, 18:1/18:2/20:1 + 2×TBHP; b, 20:0/18:2/18:2 + 2×TBHP), 1053 (a, 16:0/18:1/18:1 + 2×TBHP; b, 16:0/18:2/18:0 + 2×TBHP), 1051 (16:0/18:2/18:1 + 2×TBHP), and 1049 (a, 16:0/18:2/18:2 + 2 × TBHP; b, 16:0/18:2/18:2 + 2×TBHP). Several of these ion peaks are double peaks or possess advance or tailing shoulders. These can be readily attributed to homologs, which possess the same total carbon and double bond number but differ in the distribution of the double bonds, as explained previously. In some instances, both TBHP groups were assigned to the same fatty chain. Similar single-ion mass chromatograms were obtained for other homologous series of residual triacylglycerols as shown in Table 3.

Table 3 indicates that some of the adducts were also found in TLC Bands 9 and 8. The structures proposed on the basis of the molecular masses of presumed TBHP adducts of the triacylglycerols were confirmed by finding the corresponding $[M - RCOOH]^+$ ions of the parent triacylglycerols as minor peaks in the total ion spectrum of each peak or as major fragment ions following reanalysis of the sample at a higher positive exit voltage (CapEx 300) (data not shown). Fragment ions carrying the adducted TBHP moiety, however, were not found. In several instances, the minor diacylglycerol-like fragment ions appeared to possess one double bond more than anticipated for the mass of the $[M - RCOOH - 2 \times TBHP]^+$ generated from the major corn oil triacylglycerols. This indicated that an extra double bond had been introduced during the TBHP adduct formation.

Figure 8 compares the retention times of one of the major residual triacylglycerols (18:2/18:2/18:1) as the mono-, di- , tri-, tetra-, and penta-TBHP adducts as obtained by single-ion mass chromatograms. In order of increasing retention time they are: *m/z* 1340 (18:2/18:2/18:1 + 5×TBHP), 1251 (a, 18:2/18:2/18:1 + 4×TBHP; b, 18:2/18:2/18:1 + 4×TBHP), 1163 (a, 18:2/18:2/18:1 + 3×TBHP; b, 18:2/18:2/18:1 +

the overall chromatographic retention time of each triacylglycerol derivative. Each additional TBHP group decreases the retention time with respect to the parent triacylglycerol by an amount that is related to the location of the fatty chain involved in the adduct formation. This is indicated by the split and/or multiple peaks in the single-ion mass chromatograms. A complete alignment of the peaks, however, is not possible because the various derivatives represent different homologous series despite similar incremental increases in the total number of the TBHP groups.

*Quantification.* Table 5 gives quantitative estimates for the residual triacylglycerols and the mono-, di-, and tri-TBHP adducts isolated. The results are expressed as percentage of total positive ion current. TLC Band 10 was estimated to represent over 10% of the total ion current of the oxidized corn oil in the present experiments.

**TABLE 5**
**Yield of Residual TAG and Mono- and Di-TBHP Adducts of Corn Oil TAG[a]**

| | Mol% of TLC band 10 | Mol% of total ion current |
|---|---|---|
| Residual TAG | 80.1 | 10–15 |
| Mono-TBHP | 11.7 | 1.5–2 |
| Di-TBHP | 8.7 | 1–1.5 |
| Tri-TBHP | Trace | Trace |
| Tetra-TBHP | Trace | Trace |
| Penta-TBHP | Trace | Trace |

[a]Average ± range/2. Estimated from selected ion intensities by allowing an additional 50% for isotope effect. For abbreviations see Table 1.

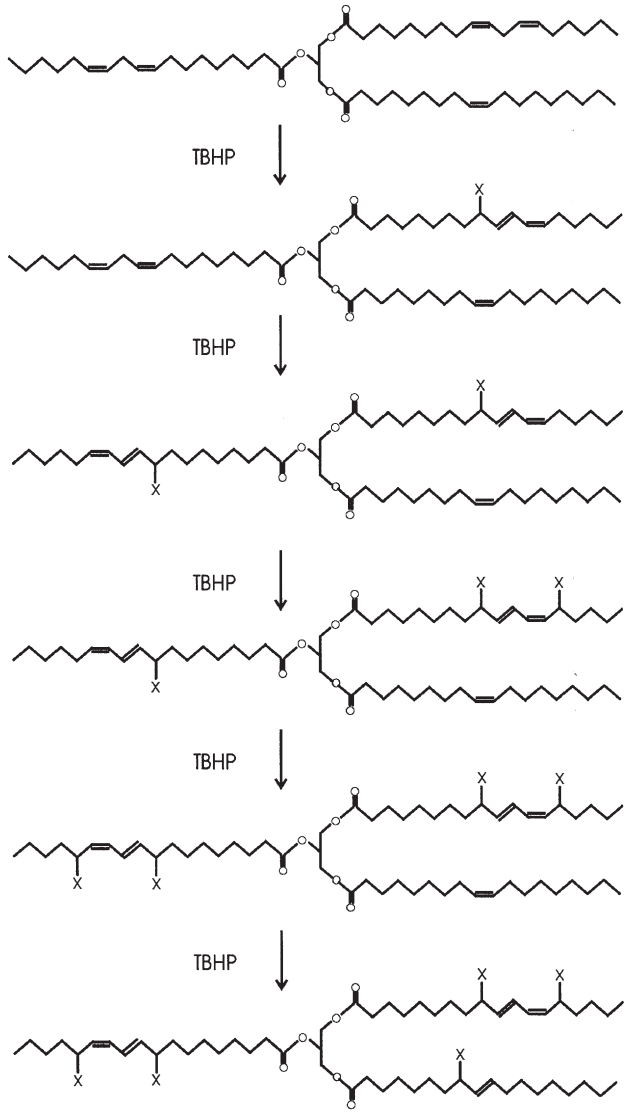

**FIG. 9.** Hypothetical location of TBHP groups in an oxidized corn oil TAG (18:2/18:2/18:1) based on Figure 8. The locations of the TBHP groups are marked with ×. Only one of several bis-TBHP isomers is shown (9,14-bis-TBHP).

## DISCUSSION

The present study demonstrates the formation of significant amounts of TBHP adducts of polyunsaturated corn oil triacylglycerols under experimental conditions commonly employed to generate model oxolipids (4,5,9) to serve as standards for the isolation and identification of autoxidation products of natural fats and oils. The TBHP adducts apparently are of two types, one type resulting from the addition of TBHP functions [X = $(CH_3)_3COO$] to individual fatty chains, the other from addition of two TBHP functions per chain (Fig. 9). The formation of the TBHP adducts can be attributed to free radical termination or annihilation reactions (12) where the *tert*-butyl alkoxy radical reacts with a radical of the fatty chain formed by abstraction of the bis(allylic) hydrogen atom.

Alternatively, TBHP adduct could be formed by reacting a hydroperoxide radical with a *tert*-butyl radical.

The presence of the $Fe^{2+}$ ions is believed to catalyze the formation of the *tert*-butyl alkoxy radical responsible for initiating removal of a bis(allylic) hydrogen atom from the polyunsaturated fatty acids found esterified to the glycerol backbone. The addition of molecular oxygen to the free radical site on the fatty acid would then form an initial hydroperoxide radical, which either abstracted a hydrogen atom to yield a hydroperoxide or became reduced to the hydroxy fatty acyl-substituted triacylglycerol. More complex reactions, however, are also possible as demonstrated previously with oleic (2,3) and linoleic (13) acid methyl esters and polyolefins (14). The dehydration of the hydroperoxides during TBHP oxidation appears to be similar to that reported during autoxidation (15) and would result in introduction of unsaturation, which would become subject to further oxidation. The present study confirms and extends our earlier work on the high molecular weight products of TBHP oxidation of standard mono- and diunsaturated triacylglycerols (10).

The study shows that the TBHP adducts of corn oil triacylglycerols can be readily isolated by normal-phase TLC where they migrate ahead of the other oxotriacylglycerols. The TBHP adducts of polyunsaturated corn oil triacylglycerols overlap with the residual triacylglycerols, which are enriched in the more saturated species of triacylglycerols. The TBHP adducts of some of the more unsaturated triacylglycerols, however, were found to migrate with the less polar oxotriacylglycerols recovered in TLC Bands 8 and 9. The TBHP adducts were stable to strong acid as evidenced by their isolation following preparation of the dinitrophenylhydrazones in 1 N HCl. The adducts decomposed on storage in organic solvents.

The triacylglycerols were identified in the positive ion mode as the ammonia adducts of the molecular ions and the $[M - RCOOH]^+$ ions, which were detected as minor ions during routine ESI and as major ions during the more intense ionization brought about by increased capillary exit voltage (16), although this may lead to possible dehydration of the hydroperoxides (17). The triacylglycerols were identified on the basis of the masses of the molecular ions and the corresponding fragment ions obtained by increasing the capillary exit voltage. There were no adducts found for the $[M - COOH]^+$ ions for any of the triacylglycerols examined in this way. Apparently, the TBHP adducts were readily decomposed at elevated capillary exit voltage. However, in several instances the $[M - RCOOH]^+$ ions with one of two additional double bonds could be recognized.

The proportion of adducted triacylglycerol in relation to the total residual corn oil triacylglycerol was similar to that previously observed during peroxidation of synthetic triacylglycerols with TBHP (10).

In preliminary studies (5) we noted that TBHP oxidation at laboratory scale can yield milligram quantities of oxoacylglycerols, but by-product formation constitutes an undesirable complication. The present work identifies the by-products as mainly the adducts of TBHP. The TBHP adducts are readily resolved from the hydroperoxides and epoxides of simple triacylglycerols by normal-phase TLC and reversed-phase HPLC, but the oxidation products of more complex triacylglycerols overlap extensively with the more complex oxidation products. Because the peroxide bridge formation constitutes a part of the reaction mechanism, it may not be entirely avoided; however, milder reaction conditions minimize the bridge formation.

# Sterol Biosynthesis by the Arbuscular Mycorrhizal Fungus *Glomus intraradices*

**Joël Fontaine[a], Anne Grandmougin-Ferjani[a,*], Marie-Andrée Hartmann[b], and Michel Sancholle[a]**

[a]Laboratoire de Mycologie/Phytopathologie/Environnement, Université du Littoral Côte d'Opale, 62228 Calais, France, and [b]Institut de Biologie Moléculaire des Plantes, CNRS UPR 2357, Département des Isoprénoïdes, 67083 Strasbourg, France

**ABSTRACT:** Ri- T-DNA-transformed carrot roots were used for investigating sterol metabolism by the arbuscular mycorrhizal (AM) fungus *Glomus intraradices* under three distinct experimental conditions: (i) a symbiotic stage (fungus still attached to the host roots); (ii) a detached stage (fungus physically separated from the roots); and (iii) a germinating stage (germinating spores). In all three stages, *G. intraradices* was found to contain a mixture of 24-alkylated sterols, with 24-methyl and 24-ethyl cholesterol as the main compounds, but no ergosterol, the predominant sterol in most fungi. Feeding experiments with [1-$^{14}$C]sodium acetate were performed to check the ability of the fungus to synthesize sterols. Whatever the experimental conditions, *G. intraradices* was able to actively take up exogenous acetate and to incorporate it into sterols and their precursors. Our data provide first evidence for *de novo* sterol synthesis by an AM fungus.

Paper no. L8795 in *Lipids 36,* 1357–1363 (December 2001).

Arbuscular mycorrhizal (AM) fungi of the order Glomales (Zygomycota) form a mutualistic symbiosis with the roots of most land plants. These fungi are obligate biotrophs and colonize the root cortex in order to obtain carbon from the host plant. They also develop a network of external hyphae, which play a pivotal role in the acquisition by the plant of mineral nutrients from the soil (1). The complex association of the two organisms makes the study of the fungal partner difficult. The mechanism or mechanisms by which fungal growth is regulated remain unclear. In the absence of the host plant, the growth of AM fungi is limited to a relatively short period of time (2). During this period, the production of a mycelium by germinating spores triggers gluconeogenesis (3) as well as hydrolysis of storage lipids (i.e., triacylglycerols) (4,5). After establishment of the symbiosis, the fungus becomes able to metabolize glucose in carbohydrates (glycogen and trehalose) and lipids (6,7). These data highlight the versatility of lipid metabolism, which is closely related to the physiological stage of the fungus.

The recent development of monoxenic culture systems (8–11) offers unique advantages for investigating fungal lipid metabolism. This approach involves the use of *in vitro* cultures of transformed plant roots colonized by the AM fungus. In particular, the use of divided petri plates, in which the spores and the mycelium are physically separated from the mycorrhizal roots, allows the selective addition of labeled substrates to either compartment and the straightforward isolation of each of these tissues (10).

The present work is an attempt to investigate sterol metabolism by *Glomus intraradices*. Little attention has been paid to this class of lipids in AM fungi, which have been reported to belong to a primitive taxon (12). Whereas ergosterol is by far the predominant sterol in most fungi (13), AM fungi contain cholesterol as well as 24-methyl and 24-ethyl cholesterol, but no ergosterol (14–17). Higher plants also have 24-alkylated sterols, mainly represented by sitosterol, stigmasterol, and 24-methyl cholesterol (18). Thus, the question of whether these biotrophic fungi are able to synthesize their own sterols or have to take them up from the plant partner remains open.

To investigate the ability of the AM fungus *G. intraradices* to synthesize sterols, labeling experiments using [1-$^{14}$C]sodium acetate as a precursor were performed. Monoxenic cultures of Ri- T-DNA-transformed carrot roots colonized by *G. intraradices* were maintained in two-compartment petri plates for 3 or 4 mon. The radioactive precursor was added only to the fungal compartment. Three distinct experimental stages of the fungus have been taken into account: (i) a symbiotic stage, corresponding to the fungus still attached to the host plant roots; (ii) a detached stage, consisting of the fungus physically separated from the host roots; and (iii) a germinating stage (germinating spores). Our data provide first evidence for a *de novo* sterol synthesis by the AM fungus *G. intraradices* in the three stages. A preliminary communication of the present work was previously presented (19).

## MATERIALS AND METHODS

*Chemicals*. [1-$^{14}$C]Sodium acetate (60 mCi mmol$^{-1}$) was purchased from Amersham (Buckinghamshire, United Kingdom). Mevinolin was from Sigma (St. Louis, MO). Before use, the lactone was converted to the open-acid form according to the procedure described by Kita *et al.* (20).

*Fungal growth conditions and labeling experiments*. Ri T-DNA-transformed carrot (*Daucus carota* L.) roots colonized

by *Glomus intraradices* Schenck & Smith (DAOM 197198) were grown in two-compartment petri plates (10) containing a medium M (9), in the dark at 27°C. The two compartments were separated by a watertight plastic wall. The mycorrhizal roots were confined in one compartment, but the fungus was allowed to grow over the central separation and into the other compartment. The cultures were examined weekly, and roots were cut when needed. After 4 mon, the fungus completely filled the distal compartment and sporulated extensively. These monoxenic culture systems were usually maintained for 4 mon.

The ability of the fungus to synthesize sterols was investigated using [1-$^{14}$C]sodium acetate as a precursor under three distinct experimental conditions: (i) a symbiotic stage (fungus still attached to the host roots), (ii) a detached stage (fungus detached from roots), and (iii) a germinating stage (germinating spores). For each experimental condition, 11 petri plates were used. For symbiotic and detached stages, 10 μCi of [1-$^{14}$C]sodium acetate was added to each plate, in the fungal compartment only. In the case of the detached stage, carrot roots were removed just before addition of acetate. For the germinating stage, fungal material was collected from the fungal compartment by blending the solidified medium in sodium citrate solution (10 mM) (21). Spores were collected by filtration on a 53-μm sieve, rinsed with sterile water, and applied onto two plates with 55 μCi of sodium acetate per plate. Then, spores were allowed to germinate on M medium (in 2% $CO_2$, in the dark) (9). In all cases, after addition of sodium acetate, the plates were kept at 27°C in the dark for 12, 24, 48, 72, and 96 h, respectively. After incubation, the culture media were solubilized with sodium citrate (21), and the fungal material was recovered by filtration and frozen at –80°C. These experiments were done in triplicate.

*Incubation with mevinolin*. The ability of *G. intraradices* to synthesize sterols in the symbiotic stage was also investigated in the presence of mevinolin, a potent inhibitor of 3-hydroxy-3-methylglutaryl coenzyme A reductase. For this experiment, fungal material from 4-mon-old cultures, applied onto three petri plates, was used. Mevinolin was added to each plate at a concentration of 20 μM 6 h before radioactive acetate (10 μCi). Fungal material was collected after 48 h, and sterols and their precursors were isolated as described below.

*Sterol analysis.* Sterol analyses were performed on the fungal material collected at 0, 12, 24, 48, 72, and 96 h after addition of [1-$^{14}$C]sodium acetate. After being freeze-dried, fungal material was ground and extracted by refluxing three times with dichloromethane/methanol (2:1, vol/vol) for 3 h. Extracts were combined and dried under reduced pressure. Free sterols (FS) and sterols in their esterified forms (ES) were separated on silica gel thin-layer chromatography (TLC) plates (60F254; Merck, Darmstadt, Germany) with hexane/diethyl ether/glacial acetic acid (78:20:4, by vol) as the solvent. The radioactivity was detected on TLC plates by using a linear radioactivity analyzer (Berthold LB 2820-1, Wilbach, Germany). Bands corresponding to squalene and ES ($R_f$ 0.97), 4,4-dimethylsterols ($R_f$ 0.40), and 4α-methyl- and 4-demethylsterols ($R_f$ 0.35) were scraped off and eluted with dichloromethane. ES were saponified with 6% (wt/vol) KOH in methanol at 90°C for 1 h. Sterols and 4,4-dimethyl- and 4α-methylsterols from free and esterified forms were acetylated (22). Acetate derivatives were then purified and analyzed with the use of a PerkinElmer Autosystem gas chromatograph (GC) equipped with a flame-ionization detector (Norwalk, CT) and a DB-5 (J&W Scientific, Folsom, CA) capillary column (30 m × 0.25 mm i.d.), with hydrogen as the carrier gas (2 mL min$^{-1}$). The temperature program included a fast rise from 60 to 270°C at 30°C/min and then a rise from 270 to 310°C at 2°C/min. Cholesterol (not acetylated) was used as an internal standard. Sterol acetates were identified by gas chromatography–mass spectrometry (GC–MS Varian, Walnutcreek, CA) (23,24). Major 4-demethylsterol acetates were separated from each other by reversed-phase high-performance liquid chromatography (HPLC; Waters, Milford, MA) using a $C_{18}$ ODS Ultrasphere column (4.6 × 250 mm). The eluent was methanol/$H_2O$ (99.7:0.3, vol/vol), at a flow rate of 1 mL min$^{-1}$. An evaporative light-scattering detector (Eurosep Instruments DDL 31, Cergy Pontoise, France; 700 mV, 55°C) was used. Each compound was identified by GC–MS and quantified by GC. Elution times for 24-methyl and 24-ethyl cholesterol acetates were 36 and 42 min, respectively. After addition of carriers, acetates of 4,4-dimethylsterols were separated on TLC plates impregnated with 10% $AgNO_3$ and diluted using cyclohexane/toluene (6:4, vol/vol) (3 runs) as solvent system. Radioactivity was determined by liquid scintillation counting.

## RESULTS

*Sterol composition of* G. intraradices. We first determined the sterol composition of *G. intraradices* in the three experimental conditions corresponding to symbiotic, detached, and germinating stages. Sterol analyses were performed as described in the Materials and Methods section on the fungal material collected after 0, 12, 24, 48, 72, and 96 h. As only low amounts of fungal material were recovered, reliable quantitative data for sterol contents could not be obtained. Because no change in the relative sterol composition of the various samples was observed between 0 and 96 h, results are given as mean values (Table 1). Whatever the experimental conditions, sterols occurred in their free forms (FS) (60%) and as esterified conjugates (ES). Predominant fungal sterols were found to be 24-methyl cholesterol and 24-ethyl cholesterol. The other identified compounds were cholesterol, 24-ethylcholesta-5,22-dien-3β-ol, 24-ethylidene cholesterol, and ergosta-7,24(24)$^1$-dien-3β-ol. No ergosterol was detected. Traces (less than 0.5% of total sterols) of 4,4-dimethylsterols (lanosterol and 24-methylene lanosterol) were also found. Both FS and ES contained the same sterols, but a higher proportion of 24-methyl cholesterol was observed in ES. Table 2 gives the sterol composition of Ri- T-DNA-transformed carrot roots colonized or not colonized by *G. intraradices*. In the absence of the fungus, sterols of carrot roots were identified

as stigmasterol, sitosterol, 24-methyl cholesterol, and isofucosterol, i.e., the typical plant $\Delta^5$-sterols. Carrot roots also contained an unusual sterol, which exhibited a GC relative retention time (RRT) of 1.32, very close to that of sitosterol (RRT 1.34). Based on the MS for the acetate derivative [*m/z* 394 ($M^+$ – AcOH) (100), 379 (22), 352 (3), 310 (7), 296 (19), 281 (25), 255 (14), 253 (33), 228 (13), 213 (20), 211 (14)], this sterol was identified as 24-epiclerosterol, the 24α epimer of 24-ethyl-24(25)-methylene cholesterol, in agreement with data reported by Akihisa *et al.* (25). We also detected other compounds such as cycloartenol, 24-methylene cycloartanol, obtusifoliol, and cycloeucalenol, which correspond to usual precursors of the plant sterol pathway. After colonization by *G. intraradices*, carrot roots were found to contain a higher sterol content than control roots, but the same compounds were detected. However, the symbiosis appears to trigger a significant increase in the relative percentage of 24-methyl cholesterol and/or 24-methylene cholesterol, which were not separated under our GC conditions. Traces of lanosterol and 24-methylene lanosterol were also detected, probably originating from the fungus. Because of low sterol contents, the stereochemistry at C-24 of fungal sterols could not be determined. In higher plants, most 24-ethylsterols have a 24α configuration whereas 24-methylsterols are mixtures of both 24α and 24β epimers. Ergosterol and fungal sterols usually have a 24β configuration (26). Under our GC experimental conditions, epimers at C-24 were not separated. Thus, it was not possible to discriminate between plant and fungal 24-alkylated sterols. However, the presence of traces of lanosterol and 24-methylene lanosterol suggested the existence of a fungal sterol biosynthetic pathway.

*Labeling experiments with [1-$^{14}$C]acetate.* In order to investigate the ability of the fungus *G. intraradices* to synthesize sterols, feeding experiments with [1-$^{14}$C]acetate were conducted as described in the Materials and Methods section. The three experimental situations (i.e., symbiotic stage, detached stage, and germinating stage) were taken into account, with incubation periods ranging from 12 to 96 h. In all three stages, exogenous acetate was found to be actively taken up by the fungus with very similar kinetics. Indeed, only 15–35% of the initial radioactivity remained in the external medium after 12 h, and almost complete absorption of the precursor was observed after 96 h.

Sterols in their free and esterified forms were separated from each other, quantified, and their radioactivity determined as described in the Materials and Methods section. Figure 1A shows the distribution of the radioactivity incorporated into FS and ES of the fungus in the three situations. In all cases, most of the acetate radioactivity was recovered in FS, mainly after 72 and 96 h, giving clear evidence that the fungus was able to synthesize sterols whatever the experimental stage. However, some differences between the three stages were apparent. Whereas the fungus in the symbiotic stage exhibited the most active ability to synthesize sterols, a lower capacity was observed for the fungus in the detached stage, with a maximum at 48 h instead of 96 h. Germinating spores were found to display an intermediate ability for sterol synthesis. In all the stages, labeled ES were presumably formed but were not detectable before 48 h.

It was interesting to check whether the ability of the fungus to synthesize sterols could be affected by an inhibitor. We chose to use mevinolin, a competitive inhibitor of 3-hydroxymethyl-3-glutaryl coenzyme A reductase (27), an enzyme located early in the sterol biosynthetic pathway. The effect of

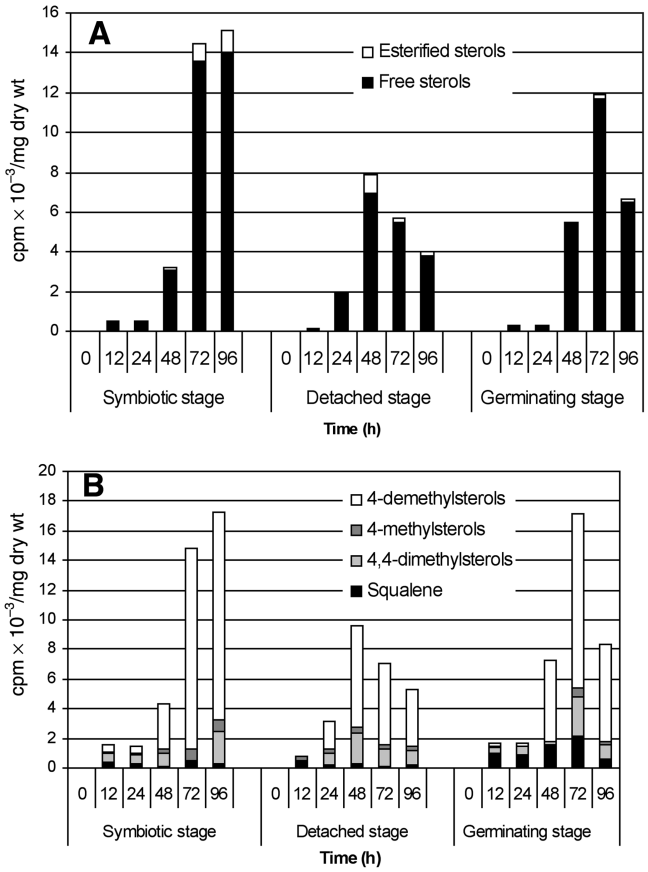

**FIG. 1.** (A) Incorporation of radioactivity from [1-$^{14}$C]acetate into free and esterified sterols of *Glomus intraradices* in symbiotic, detached, and germinating stages after periods of time ranging from 0 to 96 h. (B) Distribution of radioactivity from [1-$^{14}$C]acetate in free sterols and their precursors of *G. intraradices* in symbiotic, detached, and germinating stages after periods of time ranging from 0 to 96 h.

mevinolin on sterol synthesis by *G. intraradices* in the symbiotic stage was tested. Radioactive acetate was given to the fungus after 6 h of contact with the inhibitor, and the fungal material was recovered after 48 h. A strong decrease (85%) in the amount of radioactivity incorporated into sterols was observed (data not shown), indicating that mevinolin was able to inhibit the fungal sterol synthesis. This result also indicates that *G. intraradices* synthesized sterols *via* the classical acetate/mevalonate pathway.

*Distribution of radioactivity among the different classes of free sterols.* Figure 1B gives the distribution of radioactivity among the different classes of FS: 4-demethylsterols and their precursors, (i.e., squalene, 4,4-dimethylsterols, and 4α-methylsterols). The height of each bar in the histograms corresponds to the total radioactivity incorporated into FS. All the classes of sterols were labeled, but most of the acetate radioactivity was recovered in 4-demethylsterols, the end products of the pathway. A relatively higher proportion of squalene was found in germinating spores, suggesting a less active sterol metabolism.

The 4,4-dimethyl- and 4-demethylsterol fractions were analyzed in more detail. The early biosynthetic precursors, 4,4-dimethylsterols, of FS fractions isolated from the fungus in the symbiotic stage were separated from each other as acetate derivatives by argentation TLC in the presence of carriers as described in the Materials and Methods section. Only lanosterol and 24-methylene lanosterol were found to incorporate radioactivity, with the labeling of these compounds increasing as a function of the time of contact with the precursor (Fig. 2). Lanosterol was more labeled than 24-methylene lanosterol, in agreement with the precursor-to-product relationship between the two compounds. As significant amounts of α-amyrine were previously found in spores of AM fungi (17), we checked for the occurrence of radioactivity in the band corresponding to the position of α-amyrine on argentation TLC plates. Whatever the labeling period of time, no radioactive α-amyrine was detected, indicating that although this compound was present in the fungus, it might originate from the plant partner.

The end products, 4-demethylsterols, were separated from each other by reversed-phase HPLC and quantified by GC as reported in the Materials and Methods section. The major compounds, 24-methyl cholesterol and 24-ethyl cholesterol, were clearly found to incorporate radioactivity from acetate in all the experimental situations (Fig. 3).

*Distribution of radioactivity among sterol classes of ES.* Sterols (4-demethylsterols) and their precursors (4,4-dimethylsterols) were recovered from ES and analyzed for their radioactivity. As shown in Figure 4, both classes of compounds were found to contain significant amounts of radioactivity in the case of the fungus in the symbiotic and asymbiotic stages. In contrast, germinating spores exhibited only a low ability to synthesize ES.

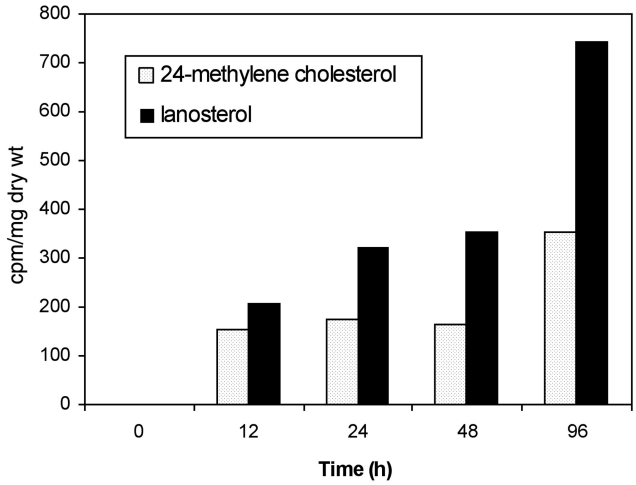

**FIG. 2.** Incorporation of radioactivity from [1-$^{14}$C]acetate into major free 4,4-dimethylsterols of *Glomus intraradices* in the symbiotic stage after periods of time ranging from 0 to 96 h.

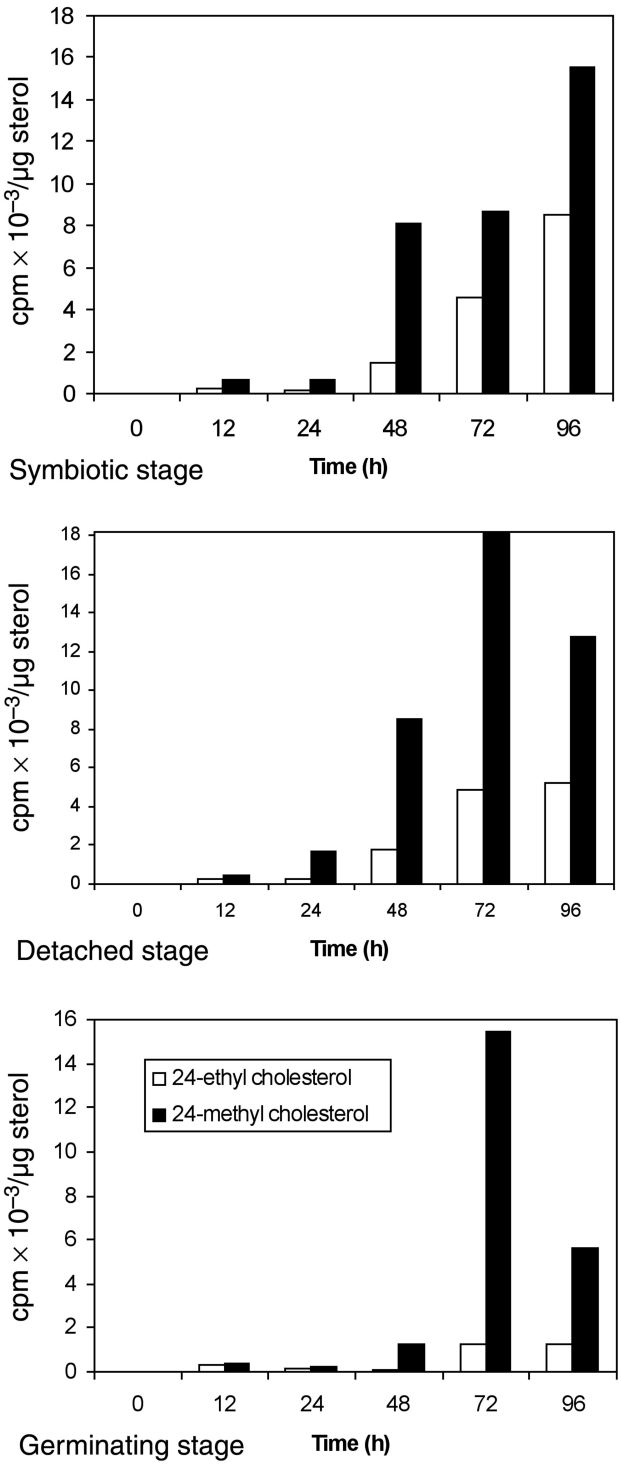

**FIG. 3.** Incorporation of radioactivity from [1-$^{14}$C]acetate into free 24-methyl and 24-ethyl cholesterol of *Glomus intraradices* in symbiotic, detached, and germinating stages after periods of time ranging from 0 to 96 h.

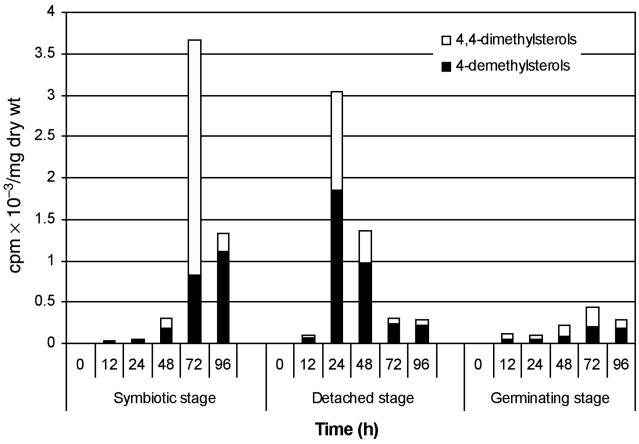

**FIG. 4.** Distribution of radioactivity from [1-$^{14}$C]acetate in 4,4-dimethyl- and 4-demethylsterols from esterified conjugates of *Glomus intraradices* in symbiotic, detached, and germinating stages after periods of time ranging from 0 to 96 h.

## DISCUSSION

The use of monoxenic cultures of transformed carrot roots colonized by the AM fungus *G. intraradices* allowed us to investigate the sterol metabolism of this fungus at three different stages. In contrast to most fungi, *G. intraradices* was found to contain no ergosterol but a mixture of 24-alkylated sterols, represented mainly by 24-methyl and 24-ethyl cholesterol. Other compounds such as cholesterol, 24-ethylidene cholesterol, 24-ethylcholesta-5,22-dien-3β-ol, and ergosta-7,24(24)$^1$-dien-3β-ol were also detected in very low amounts. All these compounds were present as both free sterols and esterified conjugates. The sterol composition did not appear to depend on the fungal experimental situations. The occurrence of 24-ethylsterols in fungi is relatively unusual. These sterols were identified in primitive organisms Chytridiomycota and Hyphochytridiomycota (13). However, 24-ethylsterols were also found in spores of AM fungi, which are classified as Zygomycota (14–17), and also in other typical Zygomycetes such as *Phycomyces blaskesleeanus* (Mucorales) (28,29) and *Umbelopsis nana* (Mucorales) (12). Finally, 24-ethylsterols were also found in "higher fungi." They were detected in pathogenic fungi such as rust fungi (Uredinales, Basidiomycota) (30,31,13) and *Blumeria graminis* f. sp. *tritici* (Erysiphales, Ascomycota) (32), the agent of wheat powdery mildew and also in *Pneumocystis carinii* (Pneumocystidales, Ascomycota), a mammal opportunistic fungus (33). Triterpenoids with 24-alkyl groups are present in mycelia of *Pisolithus tinctorius* (Gasteromycetes, Basidiomycota), an ectomycorrhizal fungus (34).

Because of the low amounts of the fungal sterols, the stereochemistry at C-24 of these sterols could not be determined. However, a 24β configuration is expected (26). As shown in Table 2, control carrot roots were found to contain the usual plant $\Delta^5$-sterols represented by stigmasterol, the predominant sterol, 24-methyl cholesterol, and sitosterol. In higher plants, 24-ethylsterols usually have a 24α configuration whereas 24-methylsterols are a mixture of both epimers (24α, i.e., campesterol, and 24β, i.e., 22-dihydrobrassicasterol) (18). Carrot roots colonized by *G. intraradices* exhibited a sterol

composition similar to that of control roots. However, an increase in the relative percentage of 24-methyl cholesterol was found in mycorrhizal roots. A careful examination of this fraction by GC–MS revealed the presence of 24-methylene cholesterol, which could not be detected in control roots or in spores of *G. intraradices*. A similar observation was previously reported for mycorrhizal roots from other plants (35,36). Another effect of symbiosis was an increase in the total sterol content (in mg $g^{-1}$ dry wt) of carrot mycorrhizal roots. Because epimers at C-24 were not separated under our GC conditions, it was not possible to discriminate between plant and fungal sterols in mycorrhizal roots.

In order to check whether the fungus was able to synthesize its own sterols, labeling experiments were performed using [1-$^{14}$C]sodium acetate as a precursor. The behavior of the fungus was examined in the symbiotic, detached, and germinating stages. In all these stages, the fungus was found to actively take up exogenous acetate and to incorporate it into sterols. Thus, clear evidence for *de novo* synthesis of sterols by *G. intraradices* was obtained for the first time. Radioactivity was mainly recovered in free sterols. The symbiotic stage appeared to be the most active one. Radioactivity was associated with the two main fungal sterols—24-methyl cholesterol and 24-ethyl cholesterol—but also with the early biosynthetic intermediates, lanosterol and 24-methylene lanosterol.

Sterol biosynthesis by the fungus in the symbiotic stage was almost completely inhibited by 20 μM mevinolin, a competitive inhibitor of 3-hydroxy-3-methylglutaryl coenzyme A reductase. This result indicates that in *G. intraradices* acetate is metabolized into sterols by the classical mevalonate pathway as in the filamentous fungus *Aschersonia aleyrodis* and the yeast *Rhodotorula glutinis*. (37).

Our results show that we could detect a less active sterol metabolism of free sterols and a low synthesis of esterified sterols in germinating spores of *G. intraradices*. Nevertheless, the growth of the germinating tubes needs a strong synthesis of membranes. This leads to the hypothesis that sterols required for this membrane synthesis may be provided by hydrolysis of the many sterol esters that are present in *G. intraradices*. These esters are considered to be a storage form for sterols in fungi (38). Such a sterol synthesis by *G. intraradices* even in the absence of symbiosis clearly indicates that the inability of the fungus to complete its life cycle cannot be explained by a lack of sterols and the consequent need to take them up from the plant partner.

## ACKNOWLEDGMENTS

This work was supported by a grant from the Conseil Régional Nord-Pas-de-Calais. We wish to thank Professor Guillaume Bécard (Université de Toulouse, France) for providing us Ri- T-DNA-transformed carrot roots colonized by *Glomus intraradices*.

# A New Trihydroxy Fatty Acid from the Ascomycete, Chinese Truffle *Tuber indicum*

**Jin-Ming Gao[a,b,*], Chen-Ying Wang[b], An-Ling Zhang[a], and Ji-Kai Liu[b]**

[a]College of Life Sciences, Northwest Science & Technology University of Agriculture and Forestry, Yangling, Shaanxi 712100, People's Republic of China, and [b]Department of Phytochemisty, Kunming Institute of Botany, Chinese Academy of Sciences, Kunming 650204, People's Republic of China

**ABSTRACT:** From the chloroform/methanol extract of the fruiting bodies of the ascomycete Chinese truffle *Tuber indicum* Cooke et Massee, a new trihydroxylated monounsaturated fatty acid (**1**) has been isolated. The structure of this new linoleic acid–derived metabolite was established as 9,10,11-trihydroxy-(12*Z*)-12-octadecenoic acid by means of spectroscopic and chemical methods. The fatty acid composition of the chloroform-soluble fraction of this fungus was analyzed by gas chromatography–mass spectrometry. The content of the predominant unsaturated fatty acids (oleic and linoleic acids) is as high as 68%. The use of dimethyl disulfide adduct was effective in the determination of the position of the double bond, and the glycol oxidation fission reaction with sodium metaperiodate supported on silica gel was helpful in establishing the location of the trihydroxylic groups in the new fatty acid.

Paper no. L8843 in *Lipids 36,* 1365–1370 (December 2001).

Truffles, also known as "black diamonds," are subterranean edible fungi of the family Tuberaceae (order Tuberales) that grow in symbiosis with certain trees. There are more than 60 different kinds of truffles around the world (1), most of which grow in various parts of Europe, particularly in France. They are thought to be a "miracle of nature" and have been since ancient times the ultimate in gastronomy because of their superior nutritional attributes. In addition to their use as a costly food, truffles have been used in making liqueurs, for scenting tobacco, and in certain perfumes.

Recent studies have proven that some truffles contain steroids as major components (2,3) as well as volatile organic compounds for mushroom aroma (4–6). The white truffle (*Tuber magnatum* Pico) and the black truffle (*T. melanosporum* Vitt) are highly appreciated for their unique aroma, which is characteristically sulfurous. The predominant sulfur compounds in white truffle aroma are dimethyl sulfide and bis(methylthio)-methane and dimethyl sulfide in black truffle aroma (4). Interestingly, the ability of pigs to detect truffles underground has been linked to the presence of trace amounts of odorous steroidal pheromone in both black and white truffles (5).

Abbreviations: CC, column chromatography; DMDS, dimethyl disulfide; EI–MS, electron impact–mass spectrometry; FAB–MS, fast atom bombardment–mass spectrometry; GC–MS, gas chromatography–mass spectrometry; HPODE, hydroperoxyoctadecadienoic acid; IR, infrared; LA, linoleic acid; LOX, lipoxygenase; MS, mass spectrometry; NMR, nuclear magnetic resonance; OA, oleic acid.

The lipid content of mushrooms has been the object of many investigations in relation to studies in subjects as varied as metabolism, nutrition, and medicine. In the past decades, it has been proven that fatty acids with 16 and 18 carbons in higher fungi are most abundant and that linoleic and/or oleic acids as principal unsaturated fatty acids (6–8) occur in complex bonding forms. Several higher mushrooms are also found to contain polyhydroxylated $C_{18}$ fatty acids in the free acid forms (9–11).

About 25 species of the genus *Tuber* are found in China. Chinese truffles, *T. indicum* Cooke et Massee, are distributed mainly in the provinces of Yunnan and Sichuan. This truffle strongly resembles the black truffle. As part of our search for naturally occurring bioactive secondary metabolites of higher fungi in the Yunnan Province, we reported a rare polyhydroxylated ergosterol glycoside in the preceding paper (2). In continuation of our investigation on chemical constituents of *T. indicum*, a new fatty acid (**1**) was isolated from the fruiting bodies of this fungus, along with known compounds adenosine, uracil, 5-hydroxypyrrolidin-2-one, D-allitol, ergosterol, and nonanedioic acid (azelaic acid). The present report deals with the structural elucidation of this new metabolite, and the fatty acid composition of its chloroform-soluble fraction is briefly described.

## EXPERIMENTAL PROCEDURES

*Chromatographic and instrumental methods.* Melting points were obtained on an XRC-1 apparatus (Sichuan University, Sichuan, People's Republic of China). Optical rotations were taken on a Horiba SEPA-300 automatic polarimeter (Horiba, Tokyo, Japan). The nuclear magnetic resonance (NMR) one- and two-dimensional NMR spectra were acquired on Bruker AM-400 and Bruker DRX-500 instruments (Karlsruhe, Germany); tetramethylsilane was used as an internal standard and coupling constants were represented in hertz. Mass spectrometry (MS) spectra were measured with a VG Autospec-3000 mass spectrometer (VG, Manchester, England). Infrared (IR) spectra were obtained in KBr pellets on a Bio-Rad (Richmond, CA) FTS-135 infrared spectrophotometer. Gas chromatography (GC)–MS was performed with a Finnigan 4510 GC–MS spectrometer (San Jose, CA) employing the electron impact (EI) mode (ionizing potential 70eV) and a capillary column (30 m × 0.25 mm) packed with 5% phenyl/95% methylsilicone on HP-5 (Hewlett-Packard, Palo Alto, CA). Hydrogen was

used as carrier gas and other conditions were as follows: hydrogen gas flow (30 mL/min), air flow rate (300 mL/min), hydrogen gas carrier flow rate (1.0 mL/min), and column temperature (160–240°C, rate of temperature increase: 5°C/min).

*Materials.* Column chromatography (CC) was performed over silica gel (200–300 mesh; Qingdao Marine Chemical Ltd., Qingdao, People's Republic of China). Reversed-phase chromatography was carried out on LiChroprep$^R$ RP-8 (40–63 μm) (Merck, Darmstadt, Germany). Thin-layer chromatographic analysis was carried out on plates precoated with silica gel $F_{254}$ (Qingdao Marine Chemical Ltd.), and detection was achieved by spraying with 10% $H_2SO_4$ followed by heating. All solvents were distilled before use.

*Fungal samples.* The dried fruiting bodies of *T. indicum* were purchased in Yunnan Province in April 2000 and identified by Profs. P.G. Liu and X.H. Wang (Kunming Institute of Botany, Chinese Academy of Sciences, Kunming, Yunnan, People's Republic of China). A voucher specimen was deposited at the Herbarium of Kunming Institute of Botany.

*Extraction and isolation.* The dried and powdered fruiting bodies (4.7 kg) were extracted successively three times with $CHCl_3$ and four times with $CHCl_3$/MeOH (1:1, vol/vol) at room temperature. These extracts were concentrated to dryness *in vacuo*, respectively, to give both $CHCl_3$ (154 g) and $CHCl_3$/MeOH extracts (122 g). The $CHCl_3$/MeOH (1:1, vol/vol) extracts were chromatographed over silica gel using $CHCl_3$ by using increasing concentrations of MeOH in $CHCl_3$ as eluent. The fractions (3.5 g) eluted with $CHCl_3$/MeOH (95:5, vol/vol) were subjected to silica gel CC using $CHCl_3$/MeOH (9:1, vol/vol) to provide a residue (139 mg), which was rechromatographed on silica gel with cyclohexane/acetone (7:3, vol/vol) to furnish pure compound **1** (18.7 mg).

*Fatty acid analysis.* Two milliliters $Et_2O$/*n*-hexane (2:1, vol/vol), 2 mL MeOH, 2 mL 0.8 mol/L KOH-MeOH, and 19 mL $H_2O$ were added to the 110 mg $CHCl_3$ extract containing fatty acids in a 25-mL volumetric flask; after shaking for 5 min, the supernatant obtained was subjected to GC–MS.

*9,10,11-Trihydroxy-(12Z)-12-octadecenoic acid (**1**).* White amorphous crystals ($CHCl_3$); m.p. 73–75°C; $[\alpha]_D^{22}$ = +10.0 (*c* 0.008, $CHCl_3$); IR (KBr) *v* 3368 (OH), 2928, 2852 (aliphatic C-H), 1713 (acidic C=O), 1464, 1399, 1242, 1075, 1017 (C-O), 940, and 723 $[(CH_2)_n]cm^{-1}$; EI–MS (70 eV) (relative intensity %) *m/z* 330 $[M]^+$ (0.5), 302 (1.0), 285 (1.5), 275 (1.0), 273 (1), 271 (1.2), 203 (7.0), 187 (4.5), 185 (41), 173 (7.5), 168 (50), 155 (29), 143 (2.5), 139 (12), 127 (19.5), 121 (5), 110 (14), 109 (35), 98 (24), 97 (29.5), 83 (68), 71 (29), 69 (58.2), 57 (77.5), and 55 (100); and $^1H$ and $^{13}C$ NMR data are given in Table 1. High-resolution fast atom bombardment (FAB)–MS (negative ion mode*s*) at *m/z* 329.2264 $[M-1]^-$, calcd. for $C_{18}H_{33}O_5$, 329.2328; FAB–MS (positive ion mode) *m/z* 331 $[M+1]^+$ (10), 313 $[M+1-H_2O]^+$ (23), 173 (100), 109 (25.5), 81(29.5).

*Acetylation of **1**.* Compound **1** (8.0 mg) was treated with $Ac_2O$/pyridine (1:1) for 36 h at room temperature to yield a crude product, to which 3 mL of water was added and then extracted with EtOAc (3 × 3 mL). The resulting residue was chromatographed on silica gel with *n*-hexane/EtOAc (10:1–8:2 vol/vol) to afford 8.9 mg of its triacetate derivative (**1a**) as a colorless oil. $^1H$ NMR 400 MHz ($CDCl_3$) δ ppm **1a**: 5.70 (1H, *dt*, *J* = 4.2, 6.7, 10.7 Hz), 5.64 (1H, *dd*, *J* = 11.0, 7.4 Hz), 5.29 (1H, *br d*, *J* = 9.7 Hz), 5.17 (1H, *t*, *J* = 5.0, 6.2 Hz), 4.95 (1H, *dd*, *J* = 2.9, 9.8 Hz), 2.20 (2H, *t*, *J* = 7.6 Hz), 1.98 (3H, *s*, $COCH_3$), 1.99 (3H, *s*, $COCH_3$), 2.04 (3H, *s*, $COCH_3$), 1.58 (4H, *m*), 1.22–1.27 ($[CH_2]_n$, *br s*), 0.86 (3H, *t*, *J* = 6.6 Hz, terminal methyl); EI–MS (70 eV) (relative intensity %) *m/z* 456 $[M]^+$ (1), 439 $[M-OH]^+$ (8), 411 (0.5), 410 (0.5), 399 (1), 397 $[M-AcO]^+$ (25), 336 $[M-2\times AcOH]^+$ (41), 294 $[M-2\times AcOH-Ac+1]^+$ (72), 287 (8), 277 (40), 276 $[M-3\times AcOH]^+$ (57), 248 (21), 241 (8), 233 (5), 227 (80), 219 (8.5), 215 (4), 182 (86), 169 (72), 168 (80), 155 (53), 143 (3), 140 (84), 139 (48), 127 (86), 122 (15), 110 (18), 109 (59),

[a]Assignments were made by distortionless enhancement by polarization transfer and heteronuclear multiple quantum coherence analysis; COSY, correlation spectroscopy.

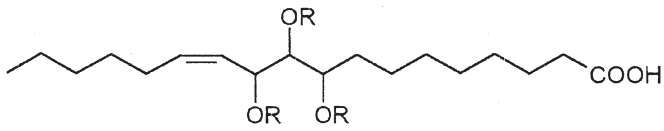
98 (43), 97 (39), 95 (55), 83 (75), 69 (60), 57 (75), 55 (100); high-resolution EI–MS *m/z* 456.2693 $[M]^+$ (calcd. for $C_{24}H_{40}O_8$, 456.2723).

*Sodium periodate oxidation of **1***. Sodium periodate (0.26 g in 1.2 mL water) was heated, with stirring, to 75°C over a period of 25 min. Silica (1.0 g) was added to the stirred solution. The mixture was then cooled and shaken vigorously for 20 min to give a coarse powder. $CH_2Cl_2$ (6 mL) was added and then, after stirring, a solution of **1** (6.4 mg) in 6 mL of $CH_2Cl_2$/MeOH (1:1, vol/vol). The reaction mixture was stirred at room temperature for 90 min, then filtered and washed with $CH_2Cl_2$. The combined supernatant was concentrated *in vacuo* to afford a mixture of aldehydes, which was subjected to EI–MS and $^1$H NMR. EI–MS (70 eV) *m/z* 126 $[M]^+$ for 2-*cis*-octenal **2**, 172 $[M]^+$ for 9-oxo-nonanoic acid **3**; $^1$H NMR 500 MHz ($CDCl_3$) δ ppm **2**: 9.51 (1H, *d*, *J* = 7.8 Hz, 1-H), 6.21 (1H, *dd*, *J* = 11.0, 7.8 Hz, 2-H), 6.85 (1H, *dd*, *J* = 11.0, 7.0 Hz, 3-H), 2.09 (2H, *dt*, *J* = 7.2, 7.8 Hz, 4-H), 0.88 (3H, *t*, *J* = 7.0 Hz, 8-H); and **3**: 9.76 (1H, *t*, *J* = 1.8 Hz, 9-H), 2.42 (2H, *t*, *J* = 7.3 Hz, 8-H), 2.34 (2H, *t*, *J* = 7.5 Hz, 2-H). $^1$H NMR data were in agreement with those of authentic samples.

*Dimethyl disulfide (DMDS) derivative **4** of compound **1a***. To the solution of **1a** (3.1 mg) dissolved in DMDS (0.2 mL), DMDS (0.2 mL) and iodine (1 mg) were added. The mixture obtained was kept at 60°C for 44 h in a small-volume sealed vial. The reaction was quenched with aqueous $Na_2S_2O_3$ (5%), and the reaction mixture was extracted with *n*-hexane (0.6 mL). The extract was concentrated, and the residue was purified by silica gel CC using *n*-hexane/EtOAc (8:2, vol/vol) to give the DMDS adduct **4**. EI–MS (relative intensity %) (70 eV) *m/z* 550 $[M]^+$ (5), 533 (1), 506 (1.5), 452 (2), 419 (4), 404 (4), 390 (9), 355 (4), 340 (8), 323 (16), 309 (31), 239 (10), 226 (19), 183 (14), 167 (22), 154 (37), 131 (56), 111 (28), 97 (49), 83 (47.5), 69 (58), 57 (68.5), 55 (100); high resolution EI–MS *m/z* 131.0898 $[M]^+$ (calcd. for $C_7H_{15}S$, 131.0894).

## RESULTS AND DISCUSSION

Compound **1** was obtained as white amorphous crystals ($CHCl_3$), m.p. 73–75°C. The molecular formula of **1** was determined to be $C_{18}H_{34}O_5$ by high-resolution negative ion FAB–MS (*m/z* 329.2264 $[M - 1]^-$, calcd. 329.2328 for $C_{18}H_{33}O_5$) and $^{13}$C NMR spectra. Upon treatment with $Ac_2O$/pyridine, **1** was acetylated to furnish its acetate **1a** (Scheme 1), which showed a molecular ion at *m/z* 456, corresponding to the molecular composition of $C_{24}H_{40}O_8$ as determined by high-resolution EI–MS at *m/z* 456.2693 (calcd. for $C_{24}H_{40}O_8$, 456.2723). The IR spectrum of **1** revealed the absorption bands of hydroxyls at 3368 and 1017 $cm^{-1}$, and a carboxylic carbonyl at 1713 $cm^{-1}$. Also, the bands appearing at 2928, 2852, 1464, 1420, and 723 $cm^{-1}$ revealed its paraffinic nature (12). Compound **1** was considered to be a straight-chain compound due to a terminal methyl group at δ 14.1 ppm (13) in its $^{13}$C NMR spectrum. The $^1$H NMR spectrum of **1** showed the presence of one terminal methyl at δ

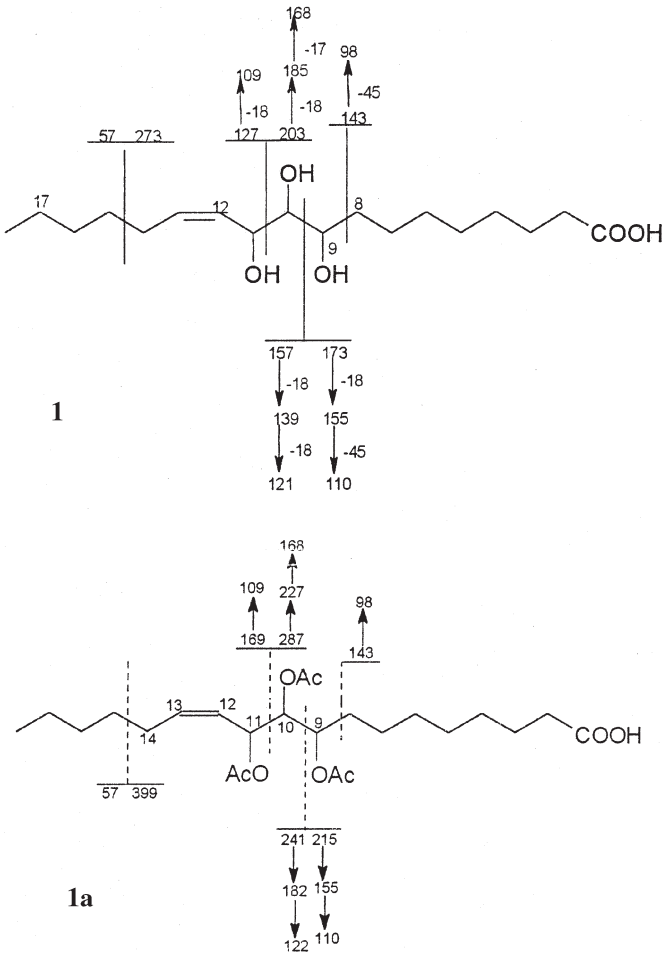


**1** R = H
**1a** R = Ac

**SCHEME 1**

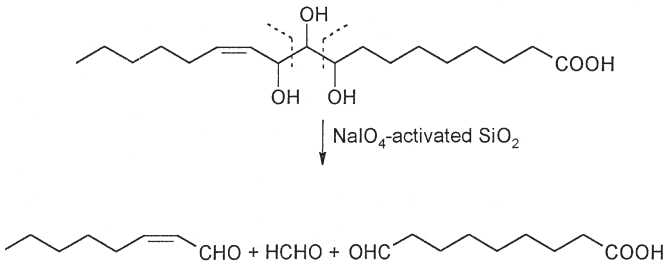
0.80 (3H, *t*), and methylenes at δ 1.19–1.38 (*br m*). The $^{13}$C NMR (distortionless enhancement by polarization transfer) spectrum of **1** further furnished a quaternary carbon, 5 methines, 11 methylenes, and 1 methyl (Table 1), in which one carboxylic carbon (*C*OOH) at δ 175.9 was given. These data revealed that **1** was an unbranched fatty acid.

The $^{13}$C NMR spectral signals at δ ppm 67.8 (CH), 72.6 (CH), and 78.6 (CH) and the $^1$H NMR resonances at δ ppm 5.30 (1H, *dd*, *J* = 9.1, 3.4 Hz), 4.26 (1H, *dt*, *J* = 9.1, 2.6 Hz), and 3.93 (1H, *dd*, *J* = 6.7, 3.4 Hz) infer the existence of three hydroxy groups in the molecule. This conclusion was further confirmed by the presence of the nine-proton (3H, each) singlets of three ester methyl groups at δ 1.98, 1.99, and 2.04 in the $^1$H NMR spectrum of **1a** as well as by a typical ion peak at *m/z* 276 due to the loss of three molecules of AcOH from the molecular ion of **1a**, respectively. A set of diagnostic fragment ions of *m/z* 173→155 and 157→139→121, 203→185→168, and 127→109 in the EI–MS of **1** (Scheme 2) showed these hydroxyls to be located at C-9, C-10, and C-11. This assignment was in turn supported by a series of characteristic mass spectral fragment ions at *m/z* 215→155 and 241→182→122, 287→227→168, and 169→109 in the EI–MS of **1a** (Scheme 2). To further prove the positions of trihydroxylic groups, two short-chain aldehydes, **2** and **3,** along with a formaldehyde (Scheme 3) were prepared by the $NaIO_4$-activated silica gel oxidation of **1**. The aldehydes thus obtained were analyzed by $^1$H NMR and EI–MS without further separation. The conjugated aldehyde **2** with an adjacent double bond gave three typical low-field protons at δ ppm 9.51 (1H, *d*, *J* = 7.8 Hz, H-1), 6.21 (1H, *dd*, *J* = 11.0, 7.8 Hz, H-2), and 6.85 (1H, *dd*, *J* = 11.0, 7.0 Hz, H-3), which was in agreement with the spectrum of an authentic sample. The assignment of H-2 appearing at δ 6.12 ppm is based on the conjugated effect in **2**. Because the olefinic protons of **2** had the coupling constant of $J_{2,3}$ = 11.0 Hz, the double bond was deduced to be *cis*, and the position of this double bond turned out to be at C-2/C-3 due to the coupling between the olefinic proton (H-2) and the aldehydic proton (H-1) by $J_{1,2}$ = 7.8 Hz. Additionally, the aldehyde protons of **3** were recognized as a triplet at δ ppm 9.76 (*t*, *J* = 1.8 Hz, H-9). The absence of a methyl group and the presence of two methylenes as triplets at δ 2.34 and 2.42, respectively, indicate that the carboxyl group was present in **3**. These data show that the oxidation products had key structures **2** and **3**. The precursor of **3**, namely, 9-oxononanoic acid, was found to be 9-hydroperoxy-10,12-octadecadienoic acid (9-HPODE) (14).



**SCHEME 2**

Furthermore, the $^1$H NMR signals at δ 5.60 (1H, *dt*, *J* = 11.0, 7.4 Hz) and 6.16 (1H, *dd*, *J* = 11.0, 9.1 Hz) and $^{13}$C NMR signals at δ 131.5 (CH) and 132.6 (CH) indicated the presence of a disubstituted double bond in **1**. The location and configuration of the double bond were determined as follows. The corresponding fragment ions at *m/z* 57, 127, and 203 due to the formation of $[C_4H_9]^+$, $[CH_3(CH_2)_4CH{=}CHCH(OH)]^+$, and $[CH(OH)CH(OH)(CH_2)_7COOH]^+$ species arising from allylic cleavages between C-14 and C-15 and between C-10 and C-11 supported the location of the olefinic linkage between C-12 and C-13 in the molecule, as evidenced from allylic cleavages of **1a** at *m/z* 57 $[C_4H_9]^+$,169 $[CH_3(CH_2)_4CH{=}CHCH(OAc)]^+$, and 287 $[CH(OAc)CH(OAc)(CH_2)_7COOH]^+$ fragment ions.



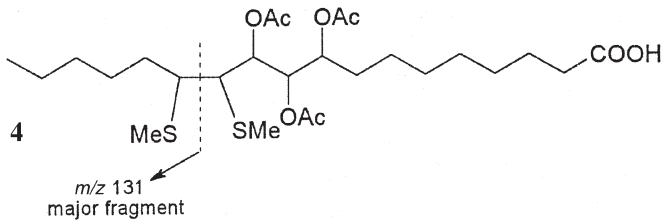
**SCHEME 3**

Moreover, the high-resolution EI–MS spectrum of the DMDS derivative **4** of **1a** showed a remarkable fragment-ion peak at *m/z* 131.0898, corresponding to the chemical composition of $C_7H_{15}S$ (calcd. 131.0894) due to cleavage of the bond between the carbons bearing a methylthio group (Scheme 4). This result also supports the location of the double bond between C-12 and C-13 in **1**.

It is known, on the other hand, that the geometry of the double bond in a long-chain alkene can be determined from the $^{13}$C NMR chemical shift of the methylene carbon next to the olefinic carbon, namely, the carbon signal observed between δ 27–28 ppm in *cis* type and between δ 32–33 ppm in *trans* type (15). The *cis* stereochemistry of this double bond was deduced from the chemical shift of C-14 (δ = 28.2 ppm). This *cis* configuration was also supported by the large vicinal coupling constant ($J_{12,13}$ = 11.0 Hz) displayed between H-12 and H-13. From the $^1$H-$^1$H correlation spectroscopy spectrum, the correlations between H-8 at δ 1.91 (*m*) and H-9 at δ 4.26 (*m*), H-9 and H-10 at δ 3.93 (*dd*), H-10 and H-11 at δ 5.30 (*dd*), H-11 and H-12 at δ 6.16 (*dd*), H-12 and H-13 at δ 5.60 (*dt*), and H-13 and H-14 at δ 2.10 (*m*) were observed in **1**. It strongly confirmed that **1** contained the partial structure -$CH_2$-HC=CH-CH(OH)-CH(OH)-CH(OH)-$CH_2$- (C-8 to C-14). Consequently, the preceding evidence led to the establishment of the structure of **1** as 9,10,11-trihydroxy-(12*Z*)-12-octadecenoic acid (Scheme 1).

The major fatty acids from a $CHCl_3$-soluble extract of *T. indicum* were linoleic acid (LA) (61.6%), stearic acid (16.0%), palmitic acid (13.7%), and oleic acid (OA) (6.66%). The high level of unsaturated fatty acids (68%) may contribute in part to explaining the nutritional quality of this mushroom.

Lipid peroxidation processes induced by lipoxygenase (LOX; EC 1.13.11.12), a nonheme iron-containing dioxygenase enzyme, are reported to occur in plant systems; they were observed, for instance, in *Rudbeckia fulgida* (16), in wheat flour suspensions (17), and in rice plants (18). The oxidation of the two unsaturated acids, LA and linolenic acid, is then catalyzed by LOX to lead, *via* an antarafacial process, to the hydroperoxide 9-HPODE or 13-hydroperoxy-9,11-octadecadienoic acid (13-HPODE), and to mixtures of 9- and 13-HPODE depending on LOX type and appropriate conditions (14). Subsequently, HPODE are metabolized in the presence of various enzymes to mono-, epoxy-, and trihydroxy fatty acids and even a cascade of catabolic products. According to the pathway of metabolism, it is possible that the previously unknown metabolite reported in the present study is biosyn-



**SCHEME 4**

thetically derived from LA *via* the intermediate 9-HPODE (Scheme 5) in *T. indicum*. Hermann and Erwin (19) found that 9,10,11-trihydroxy-12-*trans*-octadecenoic acid from LA, a geometrical isomer of the title compound **1**, was present in the bee and may be considered one of the components responsible for stale bee flavors. There is no doubt that the first discovery of **1** could be required for an understanding of the role of *T. indicum* in mushroom metabolism.

The unsaturated fatty acids possess a broad spectrum of biological properties in both animals and plants. In particular, LA-derived hydroxylated unsaturated C-18 fatty acids have attracted considerable attention. Some of these compounds show biological activity, e.g., 9,10-dihydroxy-8-oxo-12*Z*-octadecaenoic acid exhibits cytotoxicity against HeLa cells and an inhibitory effect on tea pollen growth (9); 9*S*,12*S*,13*S*-trihydroxyoctadeca-10*E*-enoic acid is active against rice blast fungus (18); 9,10,13-trihydroxy-*trans*-11-octadecaenoic acid has prostaglandin E-like activity (20); and 13*S*-hydroxy-9,11-octadecadienoic acid (*S*-coriolic acid) shows nematocidal action (11). A fatty acid mixture consisting of linoleic, oleic, and palmitic acids as main components showed nematocidal activity, and the most active compound was LA with 50% inhibition lethal dose ($LD_{50}$) values between 5 and 10 μg/mL (11). LA and OA displayed antibacterial activity, the former inhibiting the growth of all the Gram-positive bacterial species with a minimum inhibitory concentration between 0.01 and 1.0 mg/mL, whereas the latter is active against three of the five Gram-positive bacteria at a minimum inhibitory concentration of 1.0 mg/mL. A synergistic effect between the two fatty acids was observed against *Staphylococcus aureus* and *Micrococcus kristinae* (21). The fungal metabolites that may be formed in the fruiting bodies of macrofungi constitute their chemical defense system against parasites as well as various predators such as bacteria, fungi, animals, and insects (22). This newly isolated fatty acid, in combination with LA and OA, might be presumed to act as phytoalexins existing in hypogenous fungi. Further investigation will be performed.

LA inhibits the activities of mammalian DNA polymerases; the addition of ergosterol peroxide to a polymerase reaction mixture led to selective enhancement of the inhibitory effect of LA on DNA polymerase β (23). Fortuitously, we have previously reported finding this sterol in this mushroom (2). The occurrence of LA and the sterol further offers the possibility of gaining insight into the biological functions of truffles.

[a]Laboratory of Bioresources Chemistry, Division of Marine Biosciences, Graduate School of Fisheries Sciences, Hokkaido University, Hakodate, Hokkaido 041-8611, Japan, [b]Toyama Prefectural Fisheries Research Institute, Namerikawa, Toyama 931-8536, Japan, and [c]Toyama Food Research Institute, Toyama, Toyama 939-8153, Japan

**ABSTRACT:** Fatty acids of Ophiuroidea (brittle star) *Ophiura sarsi* have been investigated by gas–liquid chromatography (GLC). About 2–13% of four unidentified fatty acids were found in total fatty acids from a sample caught at a depth of 1,100 m. Structural analyses were undertaken after partial hydrogenation of their concentrates with hydrazine hydrate and subsequent isolation of the monoenoate products by argentation thin-layer chromatography. The structures of the unidentified fatty acids were determined as 7*E*,13*E*-eicosadienoic (20:2), 7*E*,13*E*,17*Z*-eicosatrienoic (20:3), 9*E*,15*E*,19*Z*-docosatrienoic (22:3), and 4*Z*,9*E*,15*E*,19*Z*-docosatetraenoic (22:4) acids by gas chromatography–mass spectrometry of dimethyl disulfide adducts and GLC of the monoenoates on a polar column. These fatty acids belong to a family of nonmethylene-interrupted (NMI) polyunsaturated fatty acids frequently observed in marine invertebrates and conifer seeds. As far as the authors know, however, these NMI fatty acid types with mixed geometry of ethylenic bonds have not been reported previously.

Paper no. L8857 in *Lipids 36*, 1371–1375 (December 2001).

Some species of marine invertebrates contain remarkable levels of distinctive fatty acids. In Ophiuroidea (brittle star), 6,9,12,15,18,21-tetracosahexaenoic acid (24:6n-3) has been observed at concentrations of 3–15% in total fatty acids from all of the samples examined (1–3). This fatty acid has anti-inflammatory and antiallergic properties similar to those of 22:6n-3 (4). Because Ophiuroidea are widely distributed with a high density in the upper bathyal zone around Japan, they are useful as a source of 24:6n-3 (2). However, there have been only a few studies on other fatty acid components. The present research on an additional sample of Ophiuroidea *Ophiura sarsi* revealed the occurrence of four unidentified fatty acids (2.2–12.7% of total fatty acids) along with the following major fatty acids: 14:0 (3.8%), 16:0 (6.6%), 16:1n-7 (3.3%), 18:0 (3.1%), 18:1n-9 (13.1%), 18:1n-7 (2.5%), 20:1n-11 + 20:1n-13 (4.3%), 20:5n-3 (4.5%), and 24:6n-3 (5.9%). This paper reports the structural assignments of the unidentified components as nonmethylene-interrupted (NMI) polyunsaturated fatty acids 7*E*,13*E*-20:2, 7*E*,13*E*,17*Z*-20:3, 9*E*,15*E*, 19*Z*-22:3, and 4*Z*,9*E*,15*E*,19*Z*-22:4.

## MATERIALS AND METHODS

Ophiuroidea *Ophiura sarsi* were caught at a depth of 1,100 m in Toyama Bay, the Sea of Japan (37°15′N, 137°35′E) on March 18, 1999, and kept frozen at –30°C for a month until analyzed. Total lipids were extracted from whole bodies by the method of Bligh and Dyer (5). The extracted lipids were converted to fatty acid methyl esters by direct transesterification with 7% $BF_3$/methanol for 1 h at 100°C in a screw-capped test tube under nitrogen. Methyl esters were purified by thin-layer chromatography (TLC) on a Kieselgel 60G plate (Merck, Darmstadt, Germany) with toluene for development (6).

The methyl esters were fractionated according to the degree of unsaturation by argentation TLC (Ag-TLC) on 10% (w/w) silver nitrate-impregnated layers of Kieselgel 60G with hexane/ethyl acetate (95:5, vol/vol) and double developments. The methyl esters were further fractionated according to their carbon number by reversed-phase TLC on a Whatman KC18F plate (Whatman International Ltd., Maidstone, England) with acetonitrile and double developments.

Hydrogenation of fatty acid methyl esters was carried out over palladium black in hexane.

Partial reduction of unsaturated fatty acids was carried out by the method previously described (7,8). A mixture of 1 mg of fatty acids and 10% (vol/vol) hydrazine hydrate in methanol (1 mL) was stirred in the presence of air at 50°C for 5–8 h. The products extracted with diethyl ether were converted to methyl esters with 7% $BF_3$/methanol. The resulting monounsaturated fatty acids were separated from other products by Ag-TLC on 30% (w/w) silver nitrate-impregnated Kieselgel 60G plates with hexane/benzene (50:50, vol/vol) and double developments.

Dimethyl disulfide (DMDS) adducts of the monounsaturated fatty acids were prepared by the procedure of Shibahara

*et al.* (9–11). Methyl esters were reacted with DMDS (1 mL) in the presence of $I_2$ (13 mg) as the catalyst for 1 h at 35°C.

Fatty acid methyl esters were analyzed by gas–liquid chromatography (GLC) with a Shimadzu GC-17A instrument (Shimadzu Seisakusho Co., Kyoto, Japan) equipped with a flame-ionization detector and a Supelcowax 10 capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness; Supelco Inc., Bellefonte, PA). The column temperature was either isothermal at 200°C or programmed from 180 to 240°C (1°C/min). The injector and detector temperatures were 250 and 260°C, respectively. The carrier gas was $H_2$ (95 kPa). Peak area percentages were obtained with a Shimadzu C-R6A integrator.

Monounsaturated fatty acids isolated from the hydrazine reduction products were analyzed by GLC with the same instrument equipped with a polar "CP-Sil 88 for FAME" capillary column (50 m × 0.25 mm i.d., 0.20 μm film thickness; Chrompack, Middelburg, The Netherlands) for separation of geometrical isomers. The column temperature was 200°C. The injector and detector temperatures were 250 and 260°C, respectively. The carrier gas was $H_2$ (125 kPa).

Gas chromatography–mass spectrometry (GC–MS) analyses of fatty acid methyl esters were carried out with a GCQ system (Thermo Quest Co., Tokyo, Japan) equipped with an SPB-1 (dimethylsiloxane) capillary column (30 m × 0.32 mm i.d., 0.25 μm film thickness; Supelco Inc.). Chemical ionization with methane reagent gas was used. The column temperature was programmed as follows: isothermal at 120°C for 1 min, increased from 120 to 220°C (25°C/min) and held for 5 min, increased from 220 to 230°C (0.5°C/min), and increased from 230 to 270°C (25°C/min) and held for 10 min. The injector temperature was 270°C. All spectra were obtained at an ionization energy of 70 eV and at a source temperature of 200°C.

GC–MS analyses of the DMDS adducts were carried out with the GCQ system and the SPB-1 capillary column described above. Electron ionization was used. The column temperature was programmed to increase from 120 to 275°C (25°C/min) after holding the initial temperature of 120°C for 2 min.

Fourier transform infrared spectra were measured in a $CCl_4$ solution with a JASCO FT-IR 5300 spectrometer (JASCO Co., Tokyo, Japan).

## RESULTS AND DISCUSSION

GLC analysis of the fatty acid methyl esters from the Ophiuroidea showed four large peaks of A (2.2% of total fatty acids), B (12.7%), C (5.6%), and D (3.0%) (Fig. 1). Their equivalent chain lengths (ECL) were 20.51 (A), 21.13 (B), 23.08 (C), and 23.28 (D) on Supelcowax 10 at 200°C. With 10% (w/w) Ag-TLC, the peak component of A was concentrated to 5.2% in a fraction along with ordinary monoenoic fatty acids; B and C were concentrated to 51.3 and 22.2%, respectively, in a fraction along with dienoic and trienoic fatty acids; D was concentrated to 19.3% in a fraction along with pentaenoic (primarily 20:5n-3) and tetraenoic (primarily 22:4n-3) fatty acids. Reversed-phase TLC of these Ag-TLC fractions gave further concentrates of A (8.6% of total fatty

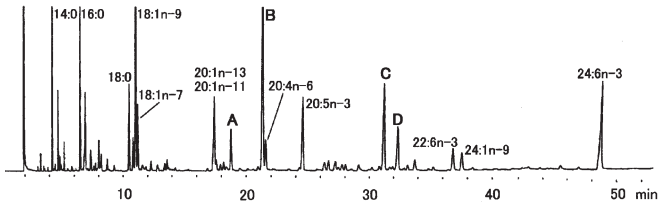

**FIG. 1.** Gas chromatogram of fatty acid methyl esters from the total lipids of Ophiuroidea (Supelcowax 10; Supelco, Bellefonte, PA; 180 to 240°C at 1°C/min). Peaks A–D: fatty acids identified as 7*E*,13*E*-20:2 (A), 7*E*,13*E*,17*Z*-20:3 (B), 9*E*,15*E*,19*Z*-22:3 (C), and 4*Z*,9*E*,15*E*,19*Z*-22:4 (D) in the present study.

acids), B (87.8%), C (75.6%), and D (79.6%). The concentrate of A included 18:1 acids (87.6%) and 19:1 acids (0.8%); concentrate of B included 18:2 acids (5.9%) and 20:2 or 20:3 acids (2.8%); concentrate of C included 20:2 acids (13.7%) and 22:2 or 22:3 acids (9.2%); and concentrate of D included 22:4n-3 acids (12.4%). Total hydrogenation of the concentrates yielded *n*-20:0 from A and B, and *n*-22:0 from C and D, indicating that these four components are fatty acids having straight carbon chains. Figure 2 shows the mass spectrum of fatty acid A. Chemical ionization mass spectrometry of the fatty acid methyl esters gave $[M - H]^-$ and $[M - H - 32]^-$ ions. Two prominent ions at *m/z* 321 and 289 indicated that fatty acid A is eicosadienoic acid (20:2). Prominent peaks observed at *m/z* 319 and 287 for B, at *m/z* 347 and 315 for C, and at *m/z* 345 and 313 for D indicated eicosatrienoic (20:3), docosatrienoic (22:3), and docosatetraenoic (22:4) acids, respectively.

Each concentrate of A–D was partially reduced by hydrazine to produce monoenoic fatty acids. The concentrates of A and B gave two and three isomers of 20:1, respectively, and C and D three and four isomers of 22:1, respectively. All of the monoenoic fatty acid isomers were separately recovered by 30% (w/w) Ag-TLC. DMDS adduct of each isomer was analyzed by GC–MS using an SPB-1 column. Figure 3 shows the mass spectra of the DMDS adducts of 20:1 isomers originated from fatty acid B (20:3). All of the spectra gave a molecular ion at *m/z* 418 and a series of characteristic key fragment ions showing the double bond position in the 20:1 isomers. In Figure 3A, the fragment ions at *m/z* 189 and 229 corresponded to cleavage between the methylthio-substituted

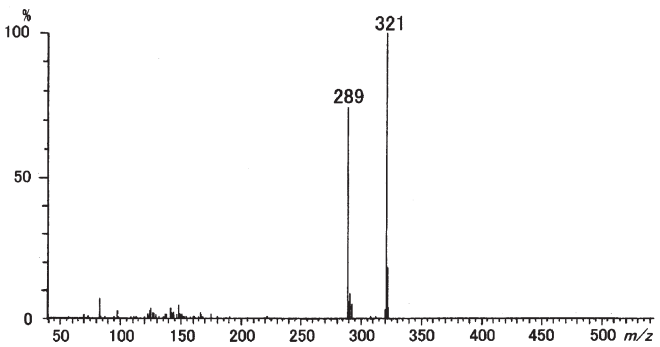

**FIG. 2.** Chemical ionization mass spectrum of methyl ester of fatty acid A, 7*E*,13*E*-20:2.

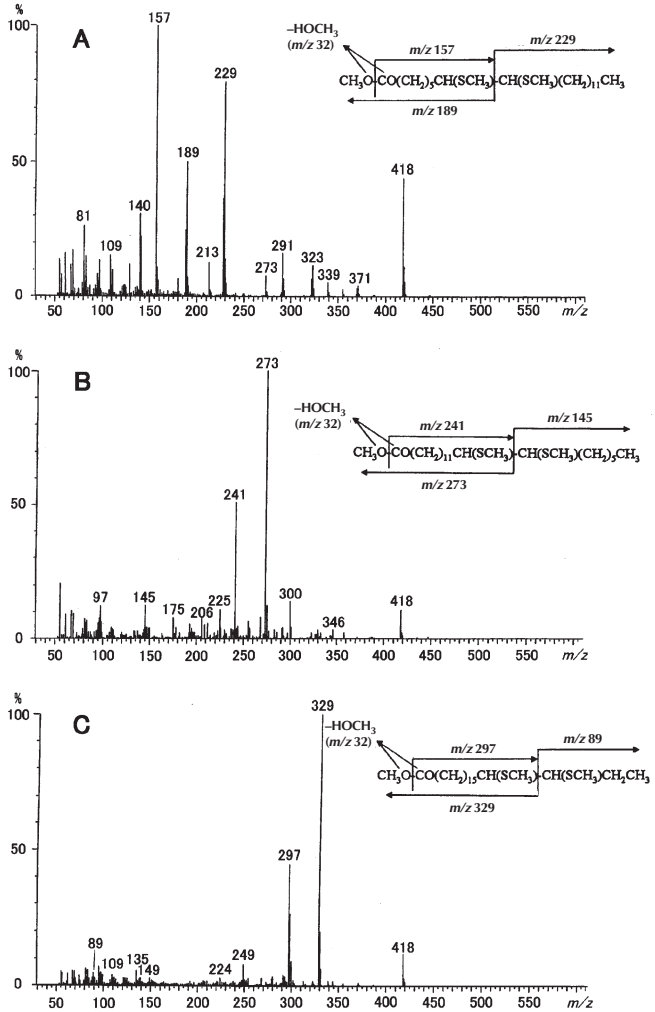

**FIG. 3.** Mass spectra of dimethyl disulfide adducts of 20:1 isomers formed by hydrazine reduction of fatty acid B, 7*E*,13*E*,17*Z*-20:3.

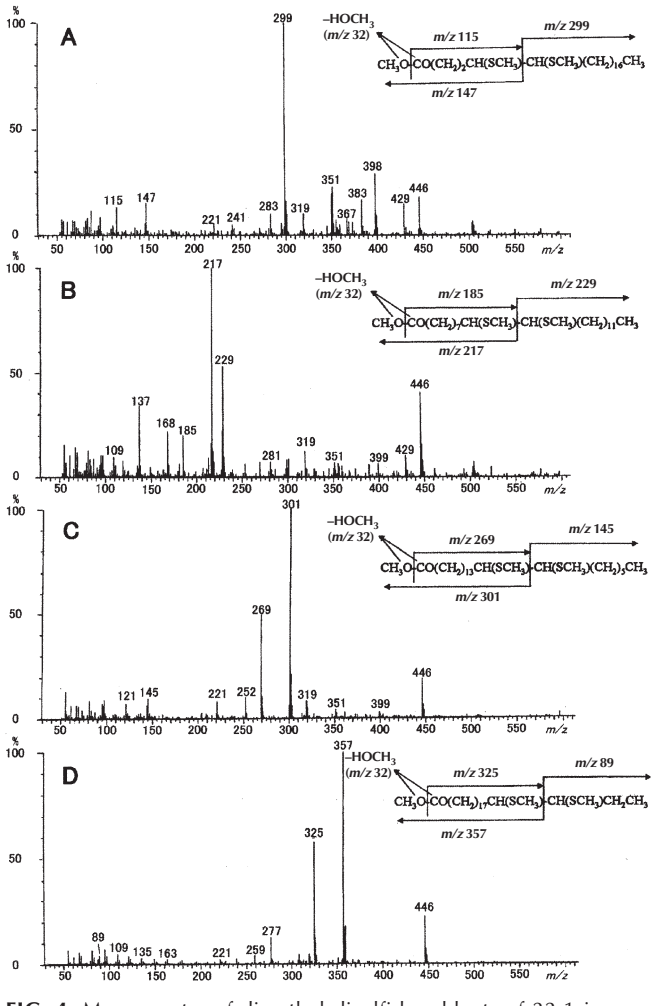

**FIG. 4.** Mass spectra of dimethyl disulfide adducts of 22:1 isomers formed by hydrazine reduction of fatty acid D, 4*Z*,9*E*,15*E*,19*Z*-22:4.

carbons of C-7 and C-8, and the ion at *m/z* 157 was due to loss of methanol (*m/z* 32) from the ion at *m/z* 189. A set of three fragment ions indicated the structure of 7-20:1. In the same manner, structures of 13-20:1 and 17-20:1 were indicated on the basis of key fragment ions at *m/z* 273, 145, and 241 (Fig. 3B), and at *m/z* 329, 89, and 297 (Fig. 3C), respectively. The DMDS adducts of 20:1 isomers originated from fatty acid A (20:2) showed mass spectra similar to those of Figures 3A and 3B. Figure 4 shows the mass spectra of the DMDS adducts of 22:1 isomers originated from fatty acid D (22:4). The structures of isomers 4-22:1, 9-22:1, 15-22:1, and 19-22:1 were indicated on the basis of sets of key fragment ions at 147, 299, and 115 (Fig. 4A); at 217, 229, and 185 (Fig. 4B); at 301, 145, and 269 (Fig. 4C); and at 357, 89, and 325 (Fig. 4D), respectively. The mass spectra of the DMDS adducts of 22:1 isomers originated from fatty acid C (22:3) were similar to those of Figures 4B–D. Hydrazine reduces olefinic bonds without positional and geometrical isomerization of the remaining olefinic bonds (8,12). Consequently, these results indicate that fatty acids A, B, C, and D are 7,13-20:2, 7,13,17-20:3, 9,15,19-22:3, and 4,9,15,19-22:4, respectively.

The infrared spectra of the concentrates of A–D showed a strong absorption near 970 $cm^{-1}$ indicating one or more *trans*-olefinic bonds. The positions of the *trans*-olefinic bonds were determined by GLC of the hydrazine-reduced monoenoate products on a polar capillary column CP-Sil 88 (13–15). Tables 1 and 2 compare the ECL values of the monoenoates with those of *cis*- and *trans*-monounsaturated fatty acid standards obtained from flathead flounder fatty acids (16), hydrazine-reduced products of 20:5n-3 and 22:6n-3, and their geometrical $NO_2$-isomerized products (17,18). ECL of 7-20:1 and 13-20:1 originated from fatty acids A and B were 20.39 and 20.51, whereas those of corresponding *cis*-isomers were 20.54 and 20.73, respectively. Early elution of 7-20:1 and 13-20:1, originated from fatty acids A and B, on this liquid phase indicated that both contained *trans*-olefinic bonds at positions C7 and C13 (i.e., 7*E*- and 13*E*-olefinic bonds) of the original. Table 2 shows corresponding 9*E*- and 15*E*-olefinic bonds in fatty acids C and D. In contrast, ECL values of 17-20:1, 4-22:1, and 19-22:1 originated from fatty acids B, C, and D were close to those of corresponding *cis*-isomers and higher than those of *trans*-isomers, indicating 17*Z*-, 4*Z*-, and 19*Z*-olefinic bonds.

[b]Calculated from the analysis of commercially available authentic standard.
[c]Calculated from the analysis of partially hydrazine-reduced products of 20:5n-3.
[d]Calculated from the analysis of $NO_2$-isomerized products of *cis*-isomer.

In this study, fatty acids A–D were identified as 7*E*,13*E*-20:2 (A), 7*E*,13*E*,17*Z*-20:3 (B), 9*E*,15*E*,19*Z*-22:3 (C), and 4*Z*,9*E*, 15*E*,19*Z*-22:4 (D). These fatty acids belong to the family of NMI polyunsaturated fatty acids. NMI fatty acids and particularly C20 and C22 dienoic acids have been found in lipids of many marine invertebrates (19,20), e.g., chiton (21), gastropods (21–23), mussels (22), oysters (22,24), quahaug (22,25), sea urchin (26), starfish (22), sand shrimps (23), and crab (27). Takagi *et al.* (1) detailed fatty acid compositions of two species of Ophiuroidea, *Ophioplocus japonicus* and *Asteronyx loveni,* caught at the coast of Usujiri near Hakodate, Japan and at a depth of 200 m in the Okhotsk Sea, respectively. Typical NMI dienoic fatty acids, 5,11-20:2 and 5,13-20:2, and their chain extension products, 7,13-22:2 and 7,15-22:2, were found in total lipids of *O. japonicus* at concentrations of 1.67, 0.63, 0.18, and 0.21% of total fatty acids, respectively. In *A. loveni*, 5,11-20:2 and 5,13-20:2 were found at concentrations of 0.49 and 0.04%, respectively. However, there was no information on the occurrence of 7,13-20:2, 7,13,17-20:3, 9,15,19-22:3, and 4,9,15,19-22:4 in their report.

Ackman (28) listed $C_{16}$–$C_{30}$ NMI polyunsaturated fatty acids of miscellaneous aquatic organisms including seaweeds, sponges, and marine invertebrates. Gunstone (29) also listed $C_{18}$–$C_{22}$ NMI fatty acids of plants (particularly conifer seeds) and marine origin. When the lists were combined, $C_{20}$ and $C_{22}$ NMI fatty acids listed were 5,11-20:2, 5,13-20:2, 7,11-20:2, 7,13-20:2, 5,11,14-20:3, 7,11,14-20:3, 5,11,14,17-20:4, 5,11-22:2, 5,13-22:2, 7,13-22:2, 7,15-22:2, 7,17-22:2, 9,13-22:2, 9,15-22:2, and 7,13,16-22:3. Of these fatty acids, 7,13-20:2 corresponds to fatty acid A identified in the present study, although configurations of the olefinic bonds were not determined. This fatty acid was found in white shrimp *Penaeus setiferus* together with 7,11-20:2, 7,13-21:2, 7,13-22:2, 7,15-22:2, 9,13-22:2, 9,15-22:2, and 7,17-22:2 (30). To the best of the authors' knowledge, 7*E*,13*E*,17*Z*-20:3, 9*E*,15*E*,19*Z*-22:3, and 4*Z*,9*E*,15*E*,19*Z*-22:4 identified in the present study have not been reported in previous papers. The first-mentioned trienoic acids seem to be derived from 7*E*,13*E*-20:2 by insertion of an additional *cis*-olefinic bond at the 17 position and subsequent chain extension. The tetraenoic acid is probably formed from 9*E*,15*E*,19*Z*-22:3, although direct insertion of a *cis*-olefinic bond at the 4 position is obscure. Biosynthesis of 22:6n-3 proceeds by way of 7,10,13,16,19-22:5 → 9,12,15,18,21-24:5 → 6,9,12,15,18,21-24:6→ 4,7,10,13,16,19-22:6 (31).

[a]Minor component of the peak.
[b]Fatty acid identified in the present study.
[c]Each of unidentified components was less than 0.5% of total fatty acids.

Fatty acid composition of the Ophiuroidea sample is shown in Table 3. Lipids of Ophiuroidea contain high levels of 24:6n-3. About 3–15% of 24:6n-3 was found in total fatty acids from all of the samples previously reported (1–3). The Ophiuroidea sample analyzed in the present study also contained 5.9% of 24:6n-3 in total fatty acids. The other sample caught at a depth of 258–642 m in Toyama Bay contained 11.2% of this acid. Takagi *et al.* (1) suggested that 24:6n-3 in Ophiuroidea does not originate from diets. In contrast, 7*E*,13*E*-20:2, 7*E*,13*E*,17*Z*-20:3, 9*E*,15*E*,19*Z*-22:3, and 4*Z*,9*E*, 15*E*,19*Z*-22:4 have not been observed in Ophiuroidea at a significant level except for the sample analyzed in this study. Unidentified minor components amounting to 6.3% of total fatty acids were also found in the present sample (Table 3). NMI fatty acids identified in this study or their precursors seem to be related to diets characteristic of each sample.

**ABSTRACT:** Tandem mass spectrometry based on ammonia negative ion chemical ionization and sample introduction *via* direct exposure probe was applied to analysis of regioisomeric structures of octanoic acid containing structured triacylglycerols (TAG) of type MML, MLM, MLL, and LML (M, medium-chain fatty acid; L, long-chain fatty acid). Collision-induced dissociation of deprotonated parent TAG with argon was used to produce daughter ion spectra with appropriate fragmentation patterns for structure determination. Fatty acids constituting the TAG molecule were identified according to $[RCO_2]^-$ ions in the daughter ion spectra. With the standard curve for ratios of $[M - H - RCO_2H - 100]^-$ ions corresponding to each $[RCO_2]^-$ ion, determined with known mixtures of *sn*-1/3 and *sn*-2 regioisomers of structured TAG, it was possible to determine the proportions of different regioisomers in unknown samples. The method enabled quantification of MML- and MLM-type structured TAG. In the case of MLL- and LML-type TAG, it was possible to determine the most abundant regioisomer in the unknown mixture and estimate the proportions of regioisomers when there were more than 50% MLL-type isomers in the mixture.

Paper no. L8733 in *Lipids 36*, 1377–1382 (December 2001).

There is a great interest in research and production of structured triacylglycerols (TAG) such as cocoa butter equivalents, human milk fat substitutes, or lipids with enhanced nutritional properties (1,2). Methods for analysis of structured lipids are important in production process development and quality control (1–4) and may also be of importance when detecting adulterations of commercially valuable fats and oils such as cocoa butter (5,6). Structured TAG containing short- or medium-chain fatty acids have special properties that are often desired in food, nutritional, or pharmacological applications. TAG possessing short- or medium-chain fatty acids in *sn*-1/3 positions and a long-chain fatty acid in the *sn*-2 position are rapidly hydrolyzed by pancreatic lipase. The resulting short- or medium-chain fatty acids are effectively absorbed into the portal blood as free fatty acids, and the long-chain fatty acid containing monoacylglycerol is efficiently absorbed into mucosal cells. Such TAG have been reported to be useful in the treatment of lipid malabsorption and also to have beneficial effects on immune function, nitrogen balance, and lipid clearance from the bloodstream (1). On the other hand, these short- or medium-chain fatty acid–containing structured TAG have special mass spectromeric properties, which have to be considered when analyzing such samples. Mass spectrometry with ammonia negative ion chemical ionization has been used for analysis of TAG molecular weight distribution and regioisomeric structure in various natural fats and oils (7–15). High-temperature gas chromatography (GC) with electron impact and chemical ionization mass spectrometry (16–18), high-performance liquid chromatography (HPLC) with chemical ionization mass spectrometry (19), and capillary supercritical fluid chromatography with atmospheric pressure chemical ionization mass spectrometry (20) have been applied to analysis of milk fat TAG that naturally contain short-chain fatty acids. These methods produce sufficient fragmentation for identifying the fatty acid constituents of TAG molecular weight species but no information concerning regiospecific structure of TAG. By fast atom bombardment tandem mass spectrometry, it has been possible to determine also the regiospecific structure of bovine udder TAG containing two short-chain fatty acids (21). However, there are no reports describing the tandem mass spectrometric characterizaton of mixed-acid structured TAG containing medium-chain fatty acids. In the present study, negative ion chemical ionization tandem mass spectrometry utilizing a direct exposure probe in sample introduction was applied to analysis of regioisomeric structures of octanoic acid containing structured TAG.

## MATERIALS AND METHODS

*Preparation of TAG standards.* The MLM- and MLL-type (M, medium-chain fatty acid; L, long-chain fatty acid) (8:0-18:2-8:0 and 8:0-18:2-18:2) TAG standards were prepared by purification of the interesterified products of safflower oil (Róco, Copenhagen, Denmark) and octanoic acid (Sigma Chemical Co., St. Louis, MO). The LML- and MML-type (18:2-8:0-18:2 and 8:0-8:0-18:2) TAG standards were prepared by purification of the interesterified products of trioctanoylglycerol and linoleic acid (both were from Sigma Chemical). In this study 8:0-18:2-18:2 (MLL) is used to denote the mixture of stereoisomers *sn*-8:0-18:2-18:2 + *sn*-18:2-18:2-8:0, and 8:0-8:0-18:2 (MML) denotes *sn*-8:0-8:0-18:2 + *sn*-18:2-8:0-8:0. Both products were synthesized in a small-scale packed-bed reactor using reaction parameters that were

reported previously (3). The required TAG standards were isolated from the interesterified products with preparative HPLC. A Waters Delta Prep 3000 HPLC (Millipore Corporation, Milford, MA) was equipped with a Delta-Pak C18 column (47 × 300 mm, particle size 15 μm and pore size 300 Å, Waters Corporation, Milford, MA). Lambda-Max model 481 LC spectrophotometer (Waters) was used as the detector at 210 nm. The column was maintained at ambient temperature with a flow rate of 60 mL/min (22). A binary solvent system was applied: Solvent A was acetonitrile and solvent B was isopropanol/hexane (2:1, vol/vol). All solvents were of HPLC grade (BDH Laboratory Supplies, Poole, England). The gradient of solvent was changed according to the composition of interesterified products. Two milliliters of the product solution with a concentration of 0.5 g/mL was injected, and the required structured TAG were collected.

To determine the purity of standard TAG, they were methylated to fatty acid methyl esters with 2 M methanolic KOH solution, and the fatty acid methyl esters were analyzed with a gas chromatograph (HP 6890; Hewlett-Packard, Waldbronn, Germany) equipped with a fused-silica capillary column (SP-2380, 60 m × 0.25 mm i.d., $d_f$ 0.2 μm; Supelco Inc., Bellefonte, PA). Oven temperature was programmed from 70 to 160°C at a rate of 15°C/min, then to 180°C at a rate of 1°C/min, further to 185°C at a rate of 0.5°C/min, and finally to 200°C at a rate of 20°C/min and held for 10 min (22). A flame-ionization detector was used at 280°C, and the injector temperature was 250°C. The injector was used in split mode with a ratio 1:20. Carrier gas was helium with a column flow of 2 mL/min. The fatty acid methyl esters were identified by comparing their retention times with authentic standards (Sigma), and the resulting compositions were calculated using the actual response factors for each fatty acid.

*Grignard degradation.* About 10 mg of the purified TAG standards were dissolved in 10 mL diethyl ether. The reaction started after adding 0.3 mL allylmagnesium bromide (1 M in diethyl ether) and lasted for 1 min, and thereafter was stopped by adding acid buffer (0.27 M HCl in 0.4 M boric acid). The organic phase was washed twice with 0.4 M boric acid, dried with anhydrous sodium sulfate, and evaporated under nitrogen. The lipid residues were separated on a thin-layer chromatography plate that was precoated with boric acid, and the 2-monoacylglycerol fraction was scraped off and extracted with diethylether. After methylation with 2 M KOH in methanol, the fatty acid methyl esters were analyzed by GC.

*Mass spectrometry.* Negative ion chemical ionization with ammonia (≥99.998%; Prax Air, Oevel, Belgium) was used to analyze the structured TAG. An aliquot of 0.5 μL of hexane solution (0.5 mg/mL) of TAG was applied on the rhenium wire of a direct exposure probe. After evaporation of the solvent, the probe was introduced into the ion source and the rhenium wire was heated at a rate of 40 mA/s to vaporize the sample. All the mass spectrometric analyses were performed using Finnigan MAT TSQ-700 triple quadrupole mass spectrometer (Finnigan MAT, San Jose, CA) equipped with a combined EI/CI ion source. The pressure of ammonia (8500 mtorr), the ion source temperature (200°C), the electron energy (70 eV), and the filament current (400 μA) were selected based on method optimization that was done earlier in our laboratory (11). Quadrupole 1 of the instrument was used to select the parent ion that was fragmented by colliding it with argon in quadrupole 2, while the fragments formed were monitored with quadrupole 3 by scanning *m/z* values from 100 to 800. To produce appropriate fragmentation, the pressure of argon (≥99.998%; AGA, Lidingö, Sweden) was set to 1.4 mtorr and the collision energy was 15 eV. Scans containing the TAG fragment ions were averaged and displayed. Each sample was analyzed four times, and averaged results with standard deviations are presented.

## RESULTS AND DISCUSSION

Table 1 lists the fatty acid composition of structured TAG standards used to characterize the fragmentation of different regioisomers in the tandem mass spectrometric analysis. The results were obtained by GC and Grignard degradation as described in the Materials and Methods section.

Figure 1 shows the fragmentation pattern of TAG standards (A, 8:0-18:2-8:0; B, 8:0-8:0-18:2; C, 18:2-8:0-18:2; D, 8:0-18:2-18:2) in tandem mass spectrometric analysis. The unfragmented parent TAG $[M - H]^-$ ion (A,B, *m/z* 605; C,D, *m/z* 741) was detected in all cases, as well as $[RCO_2]^-$ ions corresponding to fatty acids 8:0 (*m/z* 143) and 18:2 (*m/z* 279). Diacylglycerol fragment ions $[M - H - RCO_2H]^-$ formed by loss

of either of the fatty acids were also detected in all cases. The loss of 8:0 produced $[M - H - 8:0]^-$ ions (Figs. 1A,B, *m/z* 461; Figs. 1C,D, *m/z* 597) and correspondingly the loss of 18:2 produced $[M - H - 18:2]^-$ ions (Figs. 1A,B, *m/z* 325; Figs. 1C,D, *m/z* 461). In addition, $[M - H - RCO_2H - 56]^-$ and $[M - H - RCO_2H - 100]^-$ ions, the structure of which remained unidentified, were detected in spectra of all standard TAG analyzed. In Figures 1A and 1B $[M - H - 8:0 - 56]^-$ and $[M - H - 8:0 - 100]^-$ fragment ions occur at *m/z* 405 and 361 and $[M - H - 18:2 - 56]^-$ and $[M - H - 18:2 - 100]^-$ ions at *m/z* 269 and 225, respectively. In Figures 1C and 1D, the corresponding fragment ions were detected at *m/z* 541 and 497 as well as at *m/z* 405 and 361.

The fragment ions $[RCO_2]^-$ and $[M - H - RCO_2H - 100]^-$

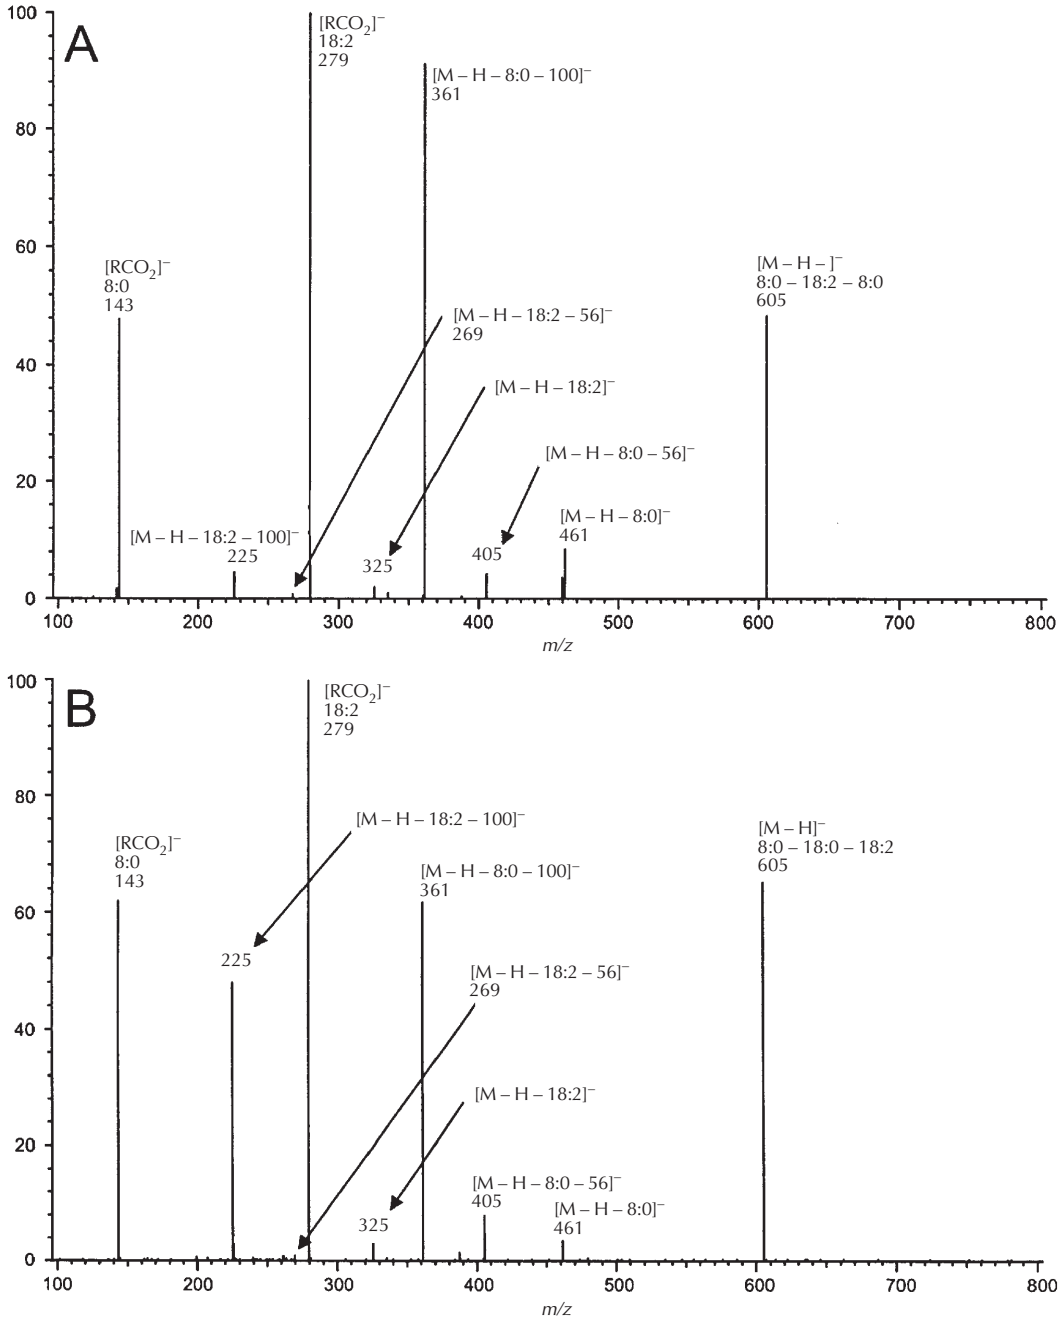

**FIG. 1.** Collision-induced dissociation spectra of MLM/MML (M, medium-chain fatty acid; L, long-chain fatty acid) type triacylglycerol (TAG) isomers 8:0-18:2-8:0 (A) and 8:0-8:0-18:2 (B) and the corresponding LML/MLL type isomers 18:2-8:0-18:2 (C) and 8:0-18:2-18:2 (D). The fragment ions are identified in the figure. In the MLM/MML type TAG $[M - H - 18:2 - 100]^-$ and $[M - H - 8:0 - 100]^-$ ions (*m/z* 225 and 361) are present in both spectra (A,B), but the ratio of the intensities of these ions increases by a factor of 18 when A is compared to B. This increase indicates the easier formation of $[M - H - 8:0 - 100]^-$ fragment ions when 8:0 is located in the primary positions in TAG molecule (A). In the LML/MLL type TAG $[M - H - 8:0 - 100]^-$ and $[M - H - 18:2 - 100]^-$ ions (*m/z* 497 and 361, respectively) are also present in both spectra (C,D). The ratio of intensities of these ions increases by a factor of 5 when C is compared to D. The result indicates that the fragmentation is less regiospecific in the case of LML/MLL type isomers than in the case of MLM/MML type TAG. See the Materials and Methods section for details of mass spectrometric analyses. (Continued)

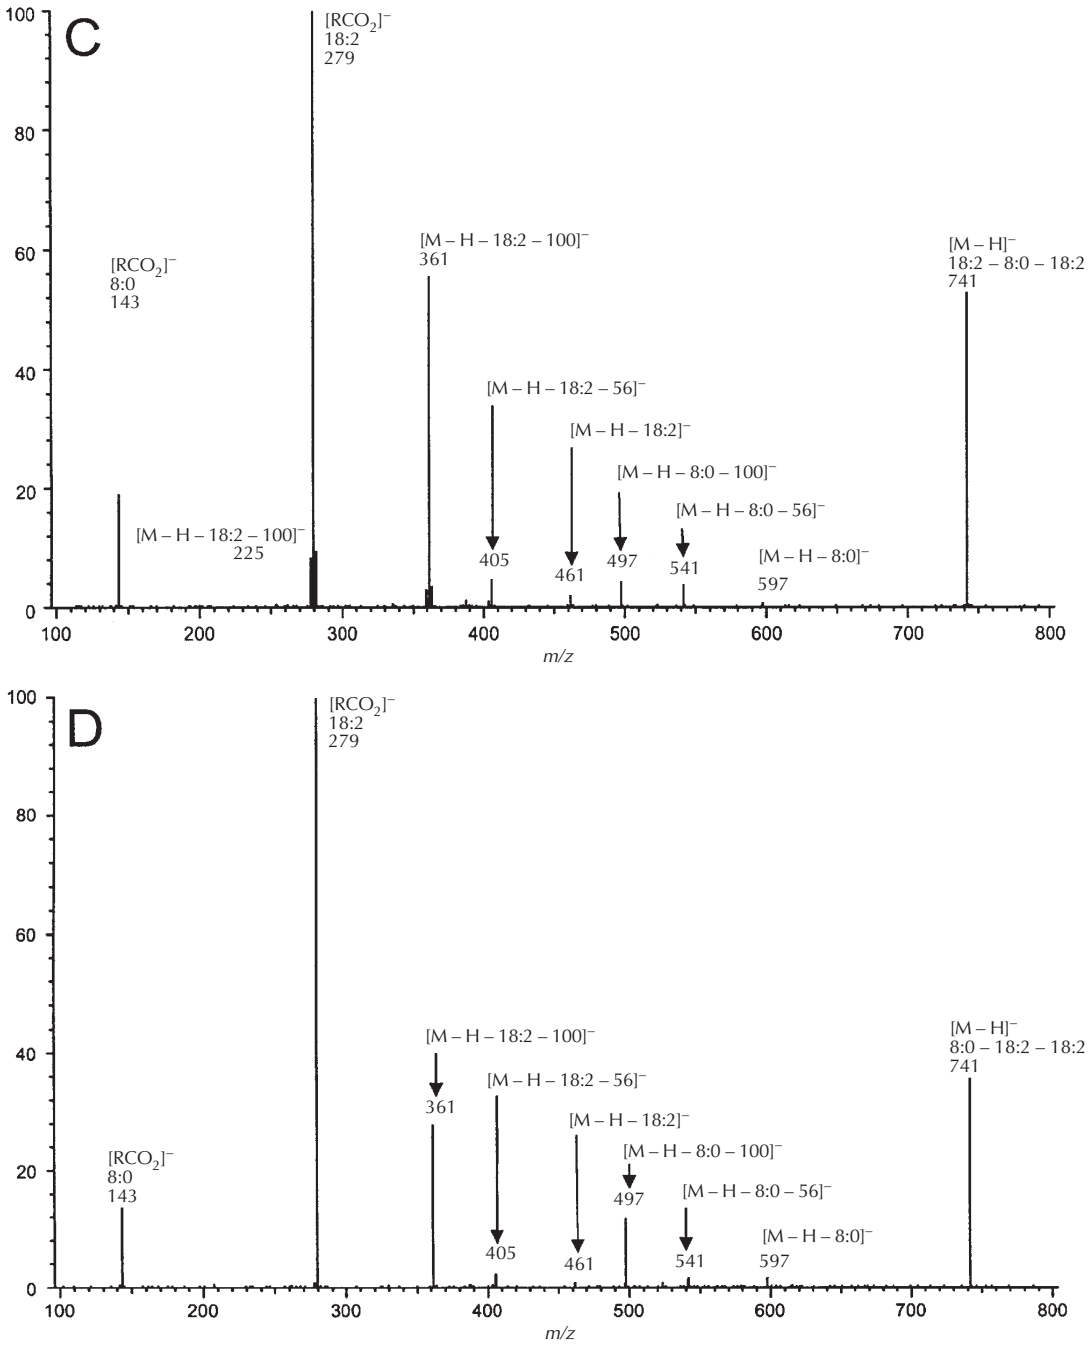

**FIG. 1.** (Continued)

were the most abundant and also gave the most information about the structure of the parent TAG as reported earlier in the case of long-chain fatty acid TAG (8,10). Theoretically, the intensities of $[RCO_2]^-$ ions would be expected to be proportional to the number of corresponding fatty acids in the parent TAG. As an example, in Figure 1A the ratio of $[RCO_2]$ ions of 8:0 (*m/z* 143) and 18:2 (*m/z* 279) would be expected to be 2:1, because there are two octanoic acid molecules and one linoleic acid molecule esterified to parent TAG. In the fragment ion spectrum of 8:0-18:2-8:0, the intensity of $[RCO_2]$ ions of 8:0 is lower than that of 18:2 (Fig. 1A). By analyzing a series of known structured TAG standards, it was calculated that the intensity of $[RCO_2]^-$ ions of 8:0 must be corrected by a factor of 3.0 to obtain the ratio of $[RCO_2]^-$ ions of 8:0 and 18:2 that corresponds to the number of fatty acids in parent TAG. By using this information, together with earlier determined correction factors for different fatty acids (9), it is possible to determine the fatty acid composition of an unknown 8:0-containing TAG molecule.

In the case of MLM- and MML-type structured TAG, the ratio of $[M - H - 18:2 - 100]^-$ and $[M - H - 8:0 - 100]^-$ ions was increased by a factor of 18 when 8:0-18:2-8:0 was compared with 18:2-8:0-8:0 (Figs. 1A,B). The ratio was further investigated by analyzing mixtures containing different molar

proportions of 8:0-18:2-8:0 and 18:2-8:0-8:0 (Fig. 2). The examination of the results showed a linear relationship ($y = 0.11x$, $R^2 = 0.93$) between the ratio of ion intensities and the molar proportion of 18:2-8:0-8:0 in the mixture (Fig. 2). This information enables the quantification of this type of regioisomers in an unknown mixture. When the same investigation of the ratio of $[M - H - 8:0 - 100]^-$ and $[M - H - 18:2 - 100]^-$ ions was performed with LML- and MLL-type structured TAG 18:2-8:0-18:2 and 8:0-18:2-18:2, a different result was obtained. Unexpectedly, the ratio of intensities of these ions increased only by a factor of five when 18:2-8:0-18:2 and 8:0-18:2-18:2 were compared (Figs. 1C,D). This result indicates that the fragmentation is less regiospecific in the case of LML-/MLL-type isomers than in the case of MLM-/MML-type triacylglycerols. The result of investigation of the ratios of $[M - H - 8:0 - 100]^-$ and $[M - H - 18:2 - 100]^-$ ions in mixtures containing different proportions of 18:2-8:0-18:2 and 8:0-18:2-18:2 is presented in Figure 3. The ratio is constant until the proportion of 8:0-18:2-18:2 in the mixture is about 50%, after which the ratio is increased with an increasing proportion of MLL-type isomer. This phenomenon makes the exact quantification of this type of isomers in an unknown mixture impossible. Nevertheless, the predominant isomer is possible to determine, and the proportion of isomers can be estimated providing that the proportion of 8:0-18:2-18:2 exceeds 50%.

The correction factors for the intensities of $[RCO_2]^-$ ions tend to increase with the increasing number of double bonds in the fatty acid and with the decreasing chain length of the fatty acid (9). Relative to 18:2, the correction factor for 8:0 was 3.0 in the present study, which is in accordance with the trend obtained for correction factors for different $[RCO_2]^-$ fragments in earlier studies (8,9). The lower abundance of short chain $[RCO_2]^-$ fragments may be postulated to be caused by the shielding effect of long-chain fatty acids in TAG or the lower probability of collision where the short-chain fatty acid fragment is formed. Instead of the fragmentation process, the lower abundance of unsaturated fatty acid fragments is more likely to be related to the different molecular response in mass spectrometric analysis.

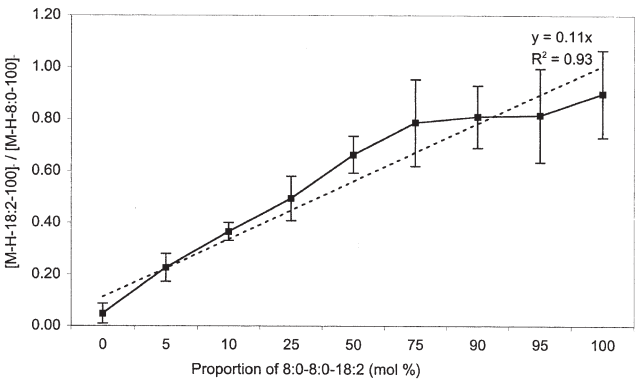

**FIG. 2.** The ratio of $[M - H - 18:2\text{-}100]^-/[M - H - 8:0 - 100]^-$ ions as a function of the molar proportion of 8:0-8:0-18:2 in the mixture of standard triacylglycerol isomers 8:0-8:0-18:2 (MML), and 8:0-18:2-8:0 (MLM) as determined on the basis of collision-induced dissociation spectra. An average and standard deviation of four replicate analyses are presented. The figure shows a linear relationship ($y = 0.11x$, $R^2 = 0.93$) between the ratio of ion intensities and the molar proportions of MLM-/MML-type TAG isomers in the mixture, which enables the quantification of isomers in an unknown mixture. For abbreviations see Figure 1.

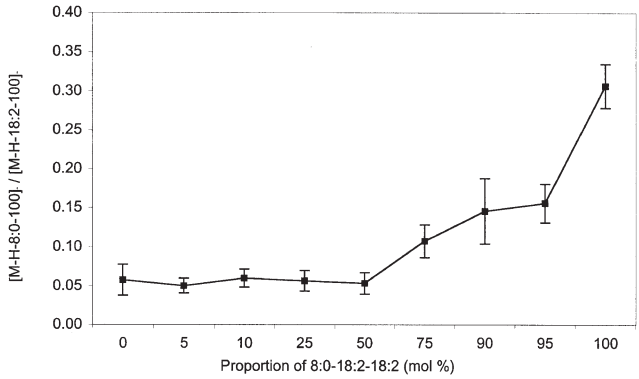

**FIG. 3.** The ratio of $[M - H - 8:0 - 100]^-/[M - H - 18:2 - 100]^-$ ions as a function of the molar proportion of 8:0-18:2-18:2 in the mixture of standard TAG isomers 8:0-18:2-18:2 (MLL) and 18:2-8:0-18:2 (LML) as determined on the basis of collision-induced dissociation spectra. An average and standard deviation of four replicate analyses are presented. The defined relationship between the ratio of ion intensities and proportions of LML-/MLL-type TAG in the mixture could not be found as in Figure 2, making the exact quantification of regioisomers impossible. Nevertheless, the predominant isomer can be determined and the proportions of isomers approximated if the proportion of MLL-type isomer exceeds 50%.

If the fragmentation obtained for medium-chain fatty acid TAG is compared with the fragmentation reported earlier for long-chain fatty acid TAG (7–10,12,13,15), some differences are found. As presented in Figures 2 and 3, the formation of $[M - H - RCO_2H - 100]^-$ ions is different to an extent that the calculation system for interpreting the results (10) cannot be applied if medium-chain fatty acids are present. Formation of $[M - H - RCO_2H - 74]^-$ ions was reported earlier parallel with the formation of $[M - H - RCO_2H - 100]^-$ ions in the case of long-chain fatty acid TAG (8,9). In the fragmentation of medium-chain fatty-acid–containing TAG, the $[M - H - RCO_2H - 56]^-$ ions instead of $[M - H - RCO_2H - 74]^-$ ions were observed as indicated in Figure 1. The formation of diacylglycerol fragment $[M - H - RCO_2H]^-$ ions was observed in both cases.

Previously, electrospray ionization (ESI)-produced $[M + NH_4]^+$ ions have been reported to produce $[M + NH_4 - R_nCOONH_4]^+$, $[R_nCO + 128]^+$, $[R_nCO + 74]^+$, and $R_nCO +$ fragment ions in high-energy collisional activation tandem mass spectrometry, but these fragments did not provide information about the position of acyl groups on the glycerol backbone (24). In the same study ESI- and fast atom bombardment (FAB)–produced $[M + Na]^+$ ions fragmented to eight types of ions, according to which the *sn*-1/3 vs. *sn*-2 position of acyl groups could also be determined. The fragmentation was concluded to proceed through charge-remote and charge-driven pathways, and proposed structures of product ions from $[M + Na]^+$ have been presented (24). A similar type of fragmentation pattern was obtained also when bovine udder TAG containing two short-chain fatty acids were analyzed (21). High-energy collision-induced dissociation of FAB-produced $[M + Na]^+$ ions resulted in

formation of fragment ions that allowed the determination of regiospecific positions of acyl groups according to known reference compounds (21). Negative ionization mass spectrometry has not been applied to analysis of TAG as widely as positive ionization mass spectrometry (25). In-source formation of $[RCO_2]^-$, $[RCO_2 - 18]^-$, and $[RCO_2 - 19]^-$ fragment ions has been reported when high-temperature GC was coupled to negative ion chemical ionization mass spectrometry (26). In the presence of 1% methylene choride in the mobile phase, $[M + Cl]^-$ ions were exclusively formed in HPLC negative ion chemical ionization mass spectrometry (19). The current method produces abundant $[M - H]^-$ ions of TAG under optimized conditions (11), and collision-induced dissociation of these ions produces simple product ion spectra containing informative fragments regarding the regiospecific structure of the parent TAG. Since the structure of the fragment ions $[M - H - RCO_2H - 100]^-$ and $[M - H - RCO_2H - 56]^-$ was not established in the present study, the fragmentation mechanism of $[M - H]^-$ ions produced by negative ion chemical ionization in low-energy collision-induced dissociation needs further investigation.

The method is applicable on regioisomeric structure analysis of simple mixtures of medium-chain fatty acids containing structured TAG provided that appropriate standard compounds are available. In all cases the exact quantification of all fatty acid combinations may not be possible as indicated by the data presented in this paper. Nevertheless, the method offers a considerable choice if a large number of samples need to be characterized because it requires very little sample preparation and is fast to perform, making it possible to analyze 50–100 samples per day.

COMMUNICATION

# Dehydroepiandrosterone Alters Phospholipid Profiles in Zucker Rat Muscle Tissue

**Jude M. Abadie[a,*], Gray T. Malcom[a], Johnny R. Porter[b], and Frank Svec[c]**

Departments of [a]Pathology, [b]Physiology, and [c]Medicine, Louisiana State University Medical Center, New Orleans, Louisiana 70112

**ABSTRACT:** Insulin-resistant muscle tissue contains low proportions of arachidonic acid (AA), and increased proportions of muscle AA correlate with improved insulin sensitivity. Dehydroepiandrosterone (DHEA) and AA, like the thiazolidinedione drugs that decrease insulin resistance (IR), are peroxisome proliferators. Long-chain fatty acids (FA) have been named the "one true" endogenous ligand for activating the peroxisome proliferator-activator receptor (PPAR), and DHEA has been named a "good candidate" as a naturally occurring indirect activator of PPAR. This study was conducted to determine DHEA's effects on lipid profiles of skeletal and cardiac muscle in lean and obese Zucker rats (ZR), a model of IR, type 2 diabetes mellitus, and obesity. We hypothesize that DHEA may alter long-chain FA profiles in muscle tissue of obese rats such that they more closely resemble that of the lean. In our experiments, we employed a DHEA and a pair-fed (PF) group ($n$ = 6) for 12 lean and 12 obese ZR. For 30 d, the diet of the two DHEA groups was supplemented with 0.6% DHEA; PF groups were given the average daily calories consumed by their corresponding treatment group. Hearts and gastrocnemius muscles were assayed for phospholipid (PL), free FA, and triglyceride (TG) FA profiles. The proportion of PL AA was significantly greater in both muscle types of lean compared to obese rats. Hearts from both DHEA groups had greater PL proportions of AA and less oleic (18:1) acid than their PF controls. Likewise, 18:1 proportions were significantly lower in the gastrocnemius; however, AA proportions were not significantly different. Similar phenotypic profile differences were observed in the TG fraction of both muscle types. There were no DHEA-related TG FA profile alterations.

Paper no. L8557 in *Lipids 36,* 1383–1386 (December 2001).

In Zucker rats (ZR), an animal model of youth-onset obesity and type 2 diabetes, dehydroepiandrosterone (DHEA) decreases dietary fat intake, body fat (1–4), adipocyte hyperplasia, and adipocyte hypertrophy (2,5). Recently, we demonstrated that DHEA treatment decreases serum free fatty acid (FFA) levels in lean and obese ZR (6).

DHEA treatment in rodents stimulates a dramatic increase in both the size and number of peroxisomes, inducing those catalyzing fatty acid (FA) β-oxidation (7,8). This may be initiated by activation of the peroxisome proliferator-activated receptors (PPAR-γ) (9–11) within nuclei of myocytes in both skeletal (red and white fibers) and cardiac muscle (12). Synthetic drugs that improve insulin sensitivity, "insulin sensitizers," act as PPAR-γ agonists in muscle and improve glucose utilization without stimulating insulin release.

Studies using ZR demonstrate that PPAR-γ agonists lower circulating triglyceride (TG) and FFA levels (13,14). In humans, these compounds enhance insulin sensitivity and improve glucose homeostasis in insulin-resistant individuals (15). Unfortunately, mechanisms by which PPAR-γ agonists regulate insulin sensitivity remain poorly defined.

DHEA has been termed a "good candidate" as a naturally occurring indirect activator of PPAR-γ (7). Polyunsaturated FA (PUFA) such as arachidonic acid (AA) have been termed "the one true endogenous ligand" for activating several PPAR classes (11,16–18). We have demonstrated that DHEA treatment in the ZR significantly increases hepatic tissue proportions of AA and other PUFA (6). Perhaps a mechanism by which DHEA functions is related to its effects on FA profiles. Because increased PUFA in skeletal muscle phospholipid (PL) have been correlated with an improved insulin sensitivity (19), perhaps FA flux in muscle represents crucial factors that govern the development of insulin resistance (IR).

Our goal in this study is to determine DHEA-related fractional lipid changes in PL, FFA, and TG FA profiles of skeletal and cardiac muscle of lean and obese ZR. Although this study does not measure IR, the identification of DHEA-induced changes in lipid pools may point to a mechanism for a DHEA role in decreasing IR.

## MATERIALS AND METHODS

The IACUS and IRB of the Louisiana State University Health Center approved the methodology of this study. There was a DHEA and a pair-fed (PF) group ($n$ = 6) for 12 lean and 12 obese ZR. For 30 d, the two DHEA groups' diet was supplemented with 0.6% DHEA. PF groups were given the average daily calories consumed by their corresponding treatment group. A specialized macronutrient diet, as described earlier (3), was modified such that the proportions of energy as carbohydrate, protein, and fat were 30, 20, and 50%, respectively. Complete descriptions of the diet, feeding, and ZR are published elsewhere (6).

After 30 d of DHEA treatment or pair-feeding, animals were fasted for 14 h and sacrificed by rapid decapitation.

Abbreviations: AA, arachidonic acid; DHEA, dehydroepiandrosterone; FA, fatty acid; FFA, free fatty acid; IR, insulin resistance; LD, lean DHEA; LPF, lean pair-fed; MUFA, monounsaturated fatty acid; OD, obese DHEA; OPF, obese pair-fed; PF, pair-fed; PL, phospholipid; PPAR, peroxisome proliferator activated receptor; PUFA, polyunsaturated FA; TG, triglyceride; ZR, Zucker rat.

Their left gastrocnemius and hearts were excised, weighed, frozen in liquid nitrogen, and stored at −80°C until assayed for PL, free FA, and TG FA profiles *via* gas–liquid chromatography as previously described (6,20). Insulin levels were determined in duplicate using a rat insulin radioimmunoassay kit (Linco Research, Inc., St. Louis, MO).

*Statistical analysis.* Experimental measurements were examined by one-way analysis of variance on a Power Macintosh 7600/120 Superanova program. Significance for $P \leq 0.05$ was measured using Fisher's Protected Least Squares Difference, giving a *P*-value for each comparison.

**TABLE 1**
**Gastrocnemius and Heart Weights and Serum Insulin Levels at the Time of Sacrifice[a]**

| | OPF | ODHEA | LPF | LDHEA |
|---|---|---|---|---|
| Gastrocnemius (g) | 0.94 ± 0.1 a | 0.93 ± 0.1 a | 1.28 ± 0.2 b | 1.26 ± 0.2 b |
| Heart (g) | 0.89 ± 0.2 a | 0.87 ± 0.2 a | 0.83 ± 0.2 b | 0.84 ± 0.2 a |
| Insulin (ng/mL) | **4.2 ± 0.4 a** | **3.1 ± 0.2 b** | 1.4 ± 0.2 c | 1.2 ± 0.3 c |

[a]Mean ± standard error of the mean (SEM) for each group: obese pair-fed (OPF), obese dehydroepiandrosterone (ODHEA), lean pair-fed (LPF), and lean DHEA (LDHEA). Values in rows that do not share the same letter are significantly different ($P \leq 0.05$). DHEA effects are typed in bold.

## RESULTS

For all tables, values are presented as means ± standard error of the mean. Rows not sharing the same letter are significantly different ($P \leq 0.05$). Values in columns are not statistically compared. Group abbreviations are as follows: obese pair-fed (OPF), obese DHEA (OD), lean pair-fed (LPF), and lean DHEA (LD).

Table 1 presents left gastrocnemius and heart weights at the time of sacrifice and serum insulin levels. Body weights are recorded elsewhere (6) and were not different within phenotype groups; however, by day 14, both lean and obese DHEA groups weighed significantly less than their PF controls. While the lean gastrocnemius weighed significantly more than the obese, there were no DHEA-treatment differences in the weights of either muscle. Obese control insulin levels were significantly greater than lean. Insulin levels were significantly lower in obese but not lean DHEA-treated rats.

Tables 2 and 3 contain FA profiles for the left gastrocnemius and hearts of each group. For each profile, sums are given for saturated FA, monounsaturated fatty acids (MUFA), and PUFA. The sum of all identified FA (values not shown) was never less than 95% of total.

PL FA profiles of the hearts are recorded in Table 2. The proportion of AA was significantly greater in lean compared to obese controls, and the proportion of oleic acid (18:1) was significantly lower in lean than in obese controls. Hearts of both DHEA groups had greater proportions of AA and less oleic acid than their PF controls. These changes resulted in significantly lower proportions of MUFA and higher proportions of PUFA in OD vs. OPF groups.

PL FA profiles for gastrocnemius muscles are recorded in

[a]For abbreviations and other explanations see Tables 1 and 2.

Table 2. AA was proportionally greater in lean compared to obese controls. Proportions of oleic acid were significantly decreased in OD and LD groups when compared to their controls; values for OD and LD controls were not different.

Table 3 presents the TG FA profiles for the hearts. The proportions of palmitic acid (16:0), palmitoleic acid (16:1), saturated FA, and MUFA were significantly lower in lean compared to obese controls. Proportions of linoleic acid (18:2) and PUFA were greater in lean compared to obese controls. DHEA treatment did not alter TG FA profiles in either muscle type.

Table 3 also presents the TG FA profiles for gastrocnemius muscles. The same phenotypic profile differences that are observed in hearts are also seen in the gastrocnemius with an additional significantly greater proportion of AA in the LPF compared to the OPF group. DHEA treatment did not alter TG FA profiles in either muscle type.

## DISCUSSION

In agreement with our results, other investigators have shown that hearts of obese ZR contain significantly lower proportions of AA than lean ZR (21).

Increased proportions of PL FA in skeletal muscle PL has been correlated with improved insulin sensitivity, whereas lower proportions, specifically AA, correlate with IR development (22). Perhaps beneficial effects of DHEA in obese ZR are related to DHEA-specific PL FA profile alterations in skeletal muscle that result in lower serum insulin levels.

Insulin sensitizers, such as the thiazolidinediones, improve skeletal muscle IR *via* a mechanism that involves activation of myocyte PPAR-γ (12). Skeletal muscle PPAR-γ expression is higher in IR patients (23). PPAR-γ levels are initially low in IR tissue but become significantly elevated in muscle during treatment with a peroxisome proliferating agent (24). Because DHEA is also a peroxisome proliferator, it may alter tissue FA *via* a similar mechanism.

This study demonstrates that DHEA treatment alters PL FA profile in ZR muscle tissue. The proportions of muscle PL FA, such as AA, "the one true endogenous ligand" for activating several PPAR classes (11,16–18), may be increased by DHEA, a "good candidate" for a naturally occurring indirect activator of PPAR-γ (7). We therefore hypothesized that DHEA may indirectly decrease IR by altering FA profiles of muscle tissue *via* PPAR activation.

This study demonstrates that the proportion of heart PL AA increases significantly with a corresponding decrease in oleic acid in both lean and obese ZR after 30 d of DHEA treatment. Similar oleic acid changes are seen in the gastrocnemius. AA is proportionally increased in the gastrocnemius; however, these increases did not reach statistical significance as they did in the hearts.

This and other studies show that obese ZR have lower proportions of muscle PUFA than lean ZR. Furthermore, our study implicates the PL fraction as the location of this difference. Increased proportions of muscle PL AA correlates with improved insulin sensitivity, and ZR treated with DHEA for 30 d had increased muscle proportions of PL PUFA. Because both DHEA and PUFA are known PPAR-γ activators, this

study may prove to be an important step to understanding the development of IR in muscle tissue.

LETTER TO THE EDITOR

# Chromatographic Methods for Ceramide Identification

Sir:

In regard to a recent review in *Lipids* about methods for identification and quantification of ceramides (1), we would like to present some additional comments on methods of molecular species analysis of ceramides. The study of chromatographic systems in order to develop tools for ceramide identification is one of the themes of our laboratory. The ceramide class of lipids is highly heterogeneous in structure, i.e., the polar head varies with the nature of the sphingoid base, and two alkyl chains can have a variable number of carbon atoms and varying degrees of unsaturation.

The main idea of our work was to study the retention behavior of these lipids in various chromatographic systems and then model the relationship between their retention and their structure in order to both identify peaks and/or to predict the retention of an unknown structure. This approach was developed because the large number of ceramide structures and the lack of commercially available standards frequently prevent identification by comparison of retention times to those of known standards. Toward this goal, three systems were studied and are briefly discussed here. The development of chromatographic methods was a high priority since these techniques could be applicable in routine analysis for biological samples, and we attempted to construct a simple model of the retention-structure relationship as a linear retention chart diagram (RCD).

First, reversed-phase (RP) liquid chromatography was studied with an octadecyl grafted silica column. The optimized conditions were found in gradient elution from acetonitrile/tetrahydrofuran 95:5 to acetonitrile/tetrahydrofuran/propanol-1 65:35:5 in 30 min (2), where the criteria were the best separation with a high correlation between retention and increased numbers of methylene units. Thereby, a linear model was derived between the retention and the structure, which constitutes our tool for ceramide identification. The basis of this model was knowledge of the retention behavior. In order to accomplish this, structurally well-defined samples were needed. Gas chromatography coupled with mass spectrometric analysis was thus performed in parallel with RP–high-performance liquid chromatography, which allowed direct structural identification (3). Next, a more hydrophobic stationary phase was investigated: Hypercarb® columns (100 × 2.1 mm i.d.; Hypersil, Runcorn, United Kingdom) (4) led to a significantly improved separation with a gradient elution of chloroform/methanol 45:55 to 85:15 in 15 min. This method was also modeled in a linear RCD. Finally, the third linear RCD came from a system with an octadecyl grafted silica stationary phase and a supercritical mobile phase. The optimal condition was 6% of methanol in $CO_2$ at 130 MPa and 31°C (5). Although this chromatographic apparatus is less commonly used, it provided powerful ceramide separation in isocratic conditions with hazardless solvent.

Optimizing the detection was an essential point in our approach, to detect and therefore identify trace amounts of sample. A detection technique suitable for lipid analysis is evaporative light-scattering detection (ELSD), but one of its drawbacks is its low detection limit. We have shown that adding 0.1% vol/vol of triethylamine along with a chemically equivalent amount of formic acid to the mobile phase greatly increased the response of the detector to ceramides (6). Therefore, a limit of detection of 5 ng injected was reached. The response of this detector is, unfortunately, not 1inear, which complicates quantitative analysis. We then studied fluorescence detection without derivatization by adding a molecule in the postcolumn that fluoresces in a hydrophobic environment. The same limit of detection was achieved as with ELSD, and a linear response was obtained between 0 to 1000 ng vs. only two orders of magnitude with ELSD (7).

In conclusion, our different RCD were finally compared and assessed on the basis of their precision and exactitude to provide an identification result. We have concluded that a single model was not sufficient to provide an unambiguous result. The ambiguities, however, can be overcome by combining results from two RCD.

# INTRODUCTION

# Vascular Disease and Nutrition

**S. Endres, Munich, Germany; E. Berg Schmidt, Hjørring, Denmark; S. Dalby Kristensen, Aarhus, Denmark; and R. De Caterina, Pisa, Italy**

Women who eat fish five or more times per week have a markedly reduced probability (relative risk 72% compared with a control cohort) of suffering a cerebral stroke. This is the salient finding in the latest analysis of the Nurses' Health Study, which followed 79,839 nurses in the United States in the years 1980 through 1994 (1). The observation adds another piece to the evidence that nutritional intervention can greatly influence the incidence and natural history of disease.

The influence of nutritional factors on disease, in particular, vascular disease, is the thread that connects a series of five scientific workshops organized by the editors of this supplement during the past decade. The first of these workshops, Fish Oil and Vascular Disease, was held in Pisa, Italy, in 1991 within the framework of the Annual Meeting of the European Society of Clinical Investigation (as were all subsequent workshops); follow-up meetings took place in Heidelberg, Germany, in 1993; in Cambridge, England, in 1995; and in Crakow, Poland, in 1998. The most recent workshop, Prevention and Treatment of Vascular Disease, was held in Aarhus, Denmark, in May 2000.

For three of the previous workshops, the proceedings have been published as books by Springer Academic Publishing, New York: De Caterina *et al.; Fish Oil and Vascular Disease,* 1992; De Caterina *et al., n-3 Fatty Acids and Vascular Disease*, 1993; and Kristensen *et al., n-3 Fatty Acids: Prevention and Treatment in Vascular Disease*, 1995.

Following the tradition of these publications, and in line with the rapid growth and influence of this field of therapy and prevention, the editors are very pleased to present this supplement: *Prevention and Treatment of Vascular Disease—A Nutrition-Based Approach*. The publication brings together leading experts on three aspects of the theme: (i) homocysteinemia, now acknowledged as an independent risk factor for vascular disease; (ii) the large and heterogeneous area of antioxidant therapy; and (iii) the area of n-3 polyunsaturated fatty acids.

In Part I, Falk *et al.* give an overview of the pathophysiology of homocysteine and atherothrombosis; Cattaneo then summarizes the clinical studies that have established hyperhomocysteinemia as an independent risk factor for cardiovascular disease. Malinow *et al.* examine the effect of folic acid supplementation on plasma homocysteine concentrations; and Ueland *et al.* present findings of the Hordaland Homocysteine study, a large (18,043 men and women) epidemiologic study confirming the association of homocysteine with cardiovascular risk factors and identifying a new association with definite complications of pregnancy.

Part II of the supplement, devoted to antioxidants and the Mediterranean diet, is introduced by Iuliano, with a presentation of the oxidant stress hypothesis of atherogenesis. Praticò then describes methods for the *in vivo* measurement of the redox state. Visioli and Galli examine the role of antioxidants in the Mediterranean diet. A negative conclusion, the absence of a relevant clinical effect of vitamin E on the risk of cardiovascular events, was drawn from the results from the antioxidant treatment groups of the GISSI-Prevenzione and the HOPE trials, presented by Marchioli.

The third and largest part of the supplement addresses n-3 polyunsaturated fatty acids, starting with an overview of this lipid class by Schmidt *et al.* De Caterina and Zampolli summarize the evidence for antiatherosclerotic effects. Kristensen *et al.* then review the effects of n-3 fatty acids on coronary thrombosis. Strategies for public health policy based on n-3 fatty acid studies are defined by Simopoulos. Griffin then summarizes findings on the effect of n-3 fatty acids on LDL subfractions. von Schacky *et al.* and Arnesen present intervention studies in patients with coronary artery disease. The topic of n-3 fatty acids and cardiac arrythmias, which has drawn particular attention over the past few years, is addressed by the papers of Leaf, McLennan, and Hagstrup. Finally, the findings of the GISSI-Prevenzione trial, which, in 1999, proved a reduction in coronary events by the long-term intake of 1 g of n-3 fatty acids, are presented by Marchioli, the study's principal investigator. In a concluding roundtable session, summarized by Nordøy, the indication, doses, and preparations of n-3 fatty acids are discussed.

The editors are proud to have brought together clinical and scientific experts on these three pillars of nutrition-based therapy and prevention of cardiovascular disease. The editors are grateful to the individual authors for the diligent and up-to-date papers they provided. Particular thanks are extended to the sponsors who made the workshop and the publication of this supplement possible: Pronova Healthcare, Denmark; Pronova Biocare, Norway; Pharmacia-Upjohn and SPA-Società Prodotti Antibiotici, Italy. Additional support came from Roche Vitamins, Switzerland, and BASF, Germany.

Overall, the field of nutritional intervention for vascular disease has grown over the past two decades from prudent, epidemiology-based hypotheses to *in vitro* mechanistic and animal (*in vivo*) pathophysiologic studies. These were

followed by a number of small, phase II clinical studies that have strengthened some hypotheses and rejected others. Finally, during the past seven years, large phase III intervention studies have identified patient groups that definitely profit from nutritional intervention, in particular that based on n-3 polyunsaturated fatty acids. A recent *in vivo* animal study (2) strikingly illustrates how long in life a transient perinatal n-3 fatty acid deficiency can affect the vascular system.

# Homocysteine and Atherothrombosis

**Erling Falk[a,*], Ji Zhou[a], and Jan Møller[b]**

[a]Departments of Cardiology and [b]Clinical Biochemistry, Aarhus University Hospital (Skejby), Aarhus, Denmark

**ABSTRACT:** Atherosclerosis with or without thrombosis superimposed is the most frequent cause of ischemic heart disease (IHD), peripheral arterial disease, and a main cause of stroke. Conflicting results have been reported in genetic, observational, and experimental studies on the relationship between homocysteine and these atherothrombotic diseases. Although cardiovascular complications are common in homocystinuric patients (severe hyperhomocysteinemia), IHD, the most frequent manifestation of atherothrombosis in the general population, appears to be rare. On the basis of findings in individuals with hyperhomocysteinemia of genetic origin, there is in fact no clear evidence for a causal role of homocysteine in the pathogenesis of atherothrombotic disease, and the positive association between plasma homocysteine and IHD observed in many, but not all epidemiologic studies does not prove causality. To infer causality from observational studies, there should be a temporal, consistent, strong, independent, graded (dose-response effect), and duration-dependent relationship between exposure and outcomes, and a biologically plausible mechanism should exist. The relationship between plasma homocysteine levels and IHD does not fulfill these criteria beyond reasonable doubt. In the general population, plasma homocysteine levels are to a great extent determined by dietary habits, and plasma homocysteine could be a marker, or a consequence, of atherothrombosis and/or risk-associated behavior (e.g., a diet low in fruits and vegetables) rather than a cause of atherothrombosis. Experimentally, hyperhomocysteinemia is not in itself atherogenic in normal animals with relatively low plasma cholesterol levels. The homocysteine theory of atherosclerosis should be tested more thoroughly in hypercholesterolemic animals that develop atherosclerosis spontaneously to determine whether elevated plasma homocysteine levels are harmful under atherogenic conditions. A causal role of homocysteine in atherothrombotic disease remains to be established.

Paper no. L8806 in *Lipids 36*, S3–S11 (2001).

Hyperhomocysteinemia has been proposed as an independent risk factor for ischemic heart disease (IHD), stroke, and peripheral artery disease (1–3). The underlying vascular pathology is usually atherosclerosis, often with thrombosis superimposed. Therefore, if homocysteine plays a causal role in IHD, it probably promotes the development of atherosclerosis or arterial thrombosis, or both. The evidence for a causal role of homocysteine in atherothrombosis will be reviewed in a historical perspective. But first, what is atherothrombosis?

### *IHD vs. Stroke and Cardiovascular Disease*

Atherothrombosis is an occlusive arterial disease that develops over decades and ultimately may lead to luminal narrowing due to a variable mix of atherosclerosis and thrombosis (4). Thrombosis plays no role in the initiation of atherosclerosis and its early development, but thrombosis, superimposed on a ruptured or eroded atherosclerotic plaque, is by far the most frequent precipitating cause of acute coronary syndromes (unstable angina, myocardial infarction, sudden coronary death) and carotid artery–related stroke (5,6). In adults, atherothrombosis is responsible for nearly all cases of IHD but only ~20% of strokes (6). That is, in contrast to IHD, stroke is not a homogenous entity but has many different etiologies besides atherothrombosis; these include cardiogenic embolism (e.g., atrial fibrillation, valve disease, or ventricular thrombi), venous thrombosis (e.g., intracranial embolism through a patent foramen ovale), hypertensive small vessel disease (lacunar stroke), dysplasia and dissection of the arteries of the neck, and cerebral hemorrhage (6,7). Therefore, in the study of potential causal factors in the pathogenesis of atherothrombosis, IHD is a reliable clinical end point; this holds true also for intermittent claudication (peripheral artery disease), but not for stroke. Stable angina pectoris is assumed to reflect the underlying coronary atherosclerosis (chronic luminal narrowing), whereas acute heart attacks, particularly myocardial infarction, reflect superimposed thrombosis (4,5).

From a pathogenetic point of view, even more ambiguous than "stroke" is the term "cardiovascular disease." Cardiovascular disease includes an extremely heterogenous group of diseases of quite different etiologies; for this discussion, it is of particular importance to realize that well-established causal factors in atherosclerosis, arterial thrombosis, and venous thromboembolism differ substantially. Particularly, no single factor has convincingly been shown to promote both arterial and venous thrombosis by a common mechanism.

### *Homocystinuria in Mental Retardation*

In 1962, a new and rare inborn error of methionine-homocysteine metabolism associated with increased urinary excretion of homocystine (homocysteine-homocysteine disulfide) in mentally retarded children was described simultaneously by investigators in Europe and North America (8). Two years later, Mudd and colleagues (9) identified the underlying cause as a defect in the homocysteine-degrading enzyme cystathionine β-synthase (CBS) (Fig. 1); the first description of widespread vascular changes and thrombosis in this syndrome appeared the same year (11).

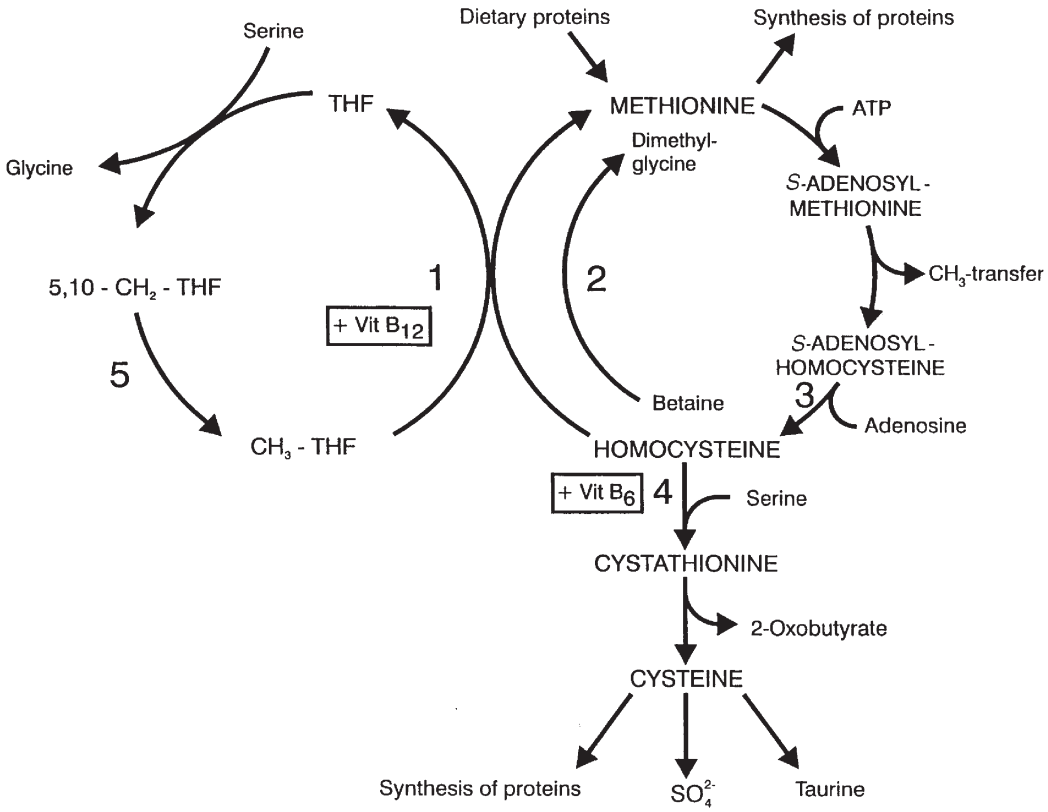

**FIG. 1.** The methionine-homocysteine metabolism. *S*-Adenosylmethionine is the methyl donor in a wide range of transmethylation reactions. The loss of the methyl group results in the formation of *S*-adenosylhomocysteine, which is subsequently converted to homocysteine by *S*-adenosylhomocysteine hydrolase (**3**). 5-Methyltetrahydrofolate: homocysteine methyltransferase (**1**), which uses cobalamin (vitamin $B_{12}$) as a coenzyme, transfers a methyl group from 5-methyltetrahydrofolate ($CH_3$-THF) to homocysteine to form methionine (***remethylation***). 5-Methyltetrahydrofolate is made by reduction of 5,10-methylenetetrahydrofolate (5,10-$CH_2$-THF), the compound of central importance in folate metabolism, by 5,10-methylenetetrahydrofolate reductase (**5**). An alternative pathway for the methylation of homocysteine to methionine is mediated by betaine:homocysteine methyltransferase (**2**) using betaine as methyl donor. In the ***transsulfuration*** pathway, homocysteine is condensed with serine to form cystathionine by the pyridoxal phosphate (vitamin $B_6$)-dependent enzyme cystathionine β-synthase (**4**). (Adapted from Ref. 10 with permission.)

### *McCully's Theory: A Shaky Foundation*

In 1969, Harvard pathologist Kilmer McCully at Massachusetts General Hospital (MGH) in Boston put forward the homocysteine theory of arteriosclerosis, initiated by the findings of widespread arterial changes in a newborn child with hyperhomocysteinemia caused by a vitamin $B_{12}$–dependent remethylation defect (12). The child died at the age of 7.5 wk. At autopsy, no gross lesions or occlusions were found in the cardiovascular system, but microscopic examination of large, medium-sized, and small arteries and arterioles in many organs of the body and the pulmonary artery revealed focal nonspecific changes, including swelling and hyperplasia of endothelial cells, fibrous intimal thickenings, disruption of the internal elastic membrane, and perivascular fibrosis (12). Lipid accumulation (atherosclerosis) was not present, nor was thrombosis or venous disease.

In the files of MGH, McCully found another child who, retrospectively, was assumed to have had hyperhomocysteinemia caused by the genetic CBS deficiency identified by Mudd and colleagues in 1964 (9), i.e., a vitamin $B_6$-dependent transsulfuration defect (12). The child, previously reported as a case record in the *New England Journal of Medicine* already in 1933 (13), was retarded and died of stroke at the age of 8 yr. Autopsy revealed fibrous thickening of the carotid arteries, and the right carotid was almost occluded by an organized thrombus. The designation arteriosclerosis (arterial hardening) was used to characterize the thickened vessel wall; lipid accumulation, atherosclerosis, was not described (12). In addition, widespread focal nonspecific arterial changes as described above were seen by microscopic examination. Venous disease was not found.

These two cases, a neonate who survived <2 mon and an 8-yr-old child, formed the basis for McCully's homocysteine theory of arteriosclerosis. Both had homocystinuria but due to different metabolic defects in methionine-homocysteine metabolism. They shared markedly elevated homocysteine, whereas the concentrations of other metabolites differed (e.g., methionine). This led McCully to conclude that homocysteine (or one of its derivatives) was the common factor responsible

for the arterial damage (12). It should be stressed, however, that McCully used the term arteriosclerosis, not atherosclerosis, in his early landmark article published in 1969 as well as in a recent review on the vascular pathology of hyperhomocysteinemia, in which he summarized that "the vascular pathology of hyperhomocysteinemia caused by deficiency of cystathionine synthase consists of fibrous arteriosclerotic plaques with little lipid deposition, associated with severe narrowing and thrombotic occlusions of aorta, major muscular arteries and arterioles in organs throughout the body" (14).

Recently, Rubba *et al.* (15) updated the existing knowledge on vascular complications of homocystinuria (severe hyperhomocysteinemia), including autopsy findings in 12 cases of premature cardiovascular death. Both arterial and venous thrombosis are frequent and occur at an early age but apparently often without concomitant atherosclerosis, and "heart disease does not represent a prominent feature of this condition. . . . It is unlikely that typical atherosclerotic lesions precede thrombus formation in homocystinuric patients of young age. Pathology studies rarely show typical atherosclerotic lesions in young homocystinuric patients who succumbed to thrombosis" (15). And Wilcken (16), who has been in the forefront of this area for decades, recapitulated in 2000 that ". . . the underlying process as seen in children before the advent of effective therapy was in the nature of a 'non-lipid' model for arteriosclerosis. . . ." Thus, it may indeed be questioned whether these arteriosclerotic and lipid-poor vascular changes seen in homocystinuric patients with severe hyperhomocysteinemia, apparently involving both pulmonary and systemic arteries of all sizes, have anything to do with atherosclerosis or represent a distinct and unique thrombosis-prone disease.

### *Homocysteine and Atherosclerosis: A Misconception*

At the time McCully formulated his homocysteine theory of arteriosclerosis, it fit very well into the contemporary understanding of the response-to-injury hypothesis of atherosclerosis (17–19). Atherosclerosis was believed to evolve through the following sequence of events: focal loss of endothelium (due to "toxic" injury), exposure of subendothelial tissue, and adherence of platelets followed by release of factors (e.g., platelet-derived growth factor) that stimulate intimal smooth muscle cell (smc) proliferation—a fibrous healing response initiated by a denuding endothelial injury and mediated by platelets and smc (17–19). As clearly stated in 1973 in the title of a famous article in the journal *Science* (17), proliferation of smc was believed to be a key event in atherogenesis. Therefore, when it was shown that homocystine infusion in primates caused patchy endothelial desquamation and smc-mediated intimal fibrosis (no or sparse lipid), it was considered strong supportive evidence for McCully's theory (20,21). The response-to-injury hypothesis of atherosclerosis typical of the period was, however, based on a misconception, i.e., de-endothelialization and platelets play no role in atherogenesis until the more advanced stages; early lesion formation occurs under an intact but activated endothelium (4). Today we know that atherosclerosis is a lipid-driven inflammatory disease characterized by endothelial activation, expression of adhesion molecules leading to macrophage recruitment, and lipid accumulation, followed by healing and repair mediated by the vascular smc (22), in which the last-mentioned stabilizes the lesion and is thus beneficial, not detrimental (23,24). Of note, recent observations indicate that plasma homocysteine is unrelated to restenosis after coronary angioplasty, which is an smc-mediated phenomenon (25).

### *Homocysteine and Coronary Thrombosis: Another Misconception*

In 1985, Mudd and co-workers (26) published their classical article on the natural history of homocystinuria due to CBS deficiency, based on a worldwide questionnaire survey of 629 cases. The study confirmed that homocystinuria, i.e., severe hyperhomocysteinemia, is indeed associated with premature vascular diseases but, despite the widely held view, it did not provide evidence for a causal role of hyperhomocysteinemia in the pathogenesis of IHD. Of the 253 thromboembolic events recorded in 158 homocystinuric patients, 51% affected peripheral veins, 32% gave rise to cerebrovascular accidents [probably often of venous origin (27)], 11% involved peripheral arteries, and only 4% ($n$ = 10) led to myocardial infarctions (26). No data on atherosclerosis were provided. Thus, venous thrombosis prevailed, and myocardial infarction was strikingly rare, which is in sharp contrast to atherosclerosis-mediated coronary thrombosis in the general population.

### *Hyperhomocysteinemia and IHD in the General Population*

In 1976, Wilcken and Wilcken (28) studied patients with angiographically proven coronary artery disease without any known metabolic defects such as CBS deficiency and found evidence of a reduced ability to metabolize homocysteine in some of these patients. It was the first study to suggest an association between high plasma homocysteine levels near the average range (after oral methionine) of a population and premature IHD. Subsequently, numerous epidemiologic studies have identified raised plasma homocysteine as an independent risk factor for atherothrombotic disease, including IHD, stroke, and peripheral vascular disease (1–3). A frequently quoted meta-analysis suggests that plasma homocysteine elevation is a graded risk factor; an increment of only 5 μmol/L in plasma homocysteine level is associated with a 60 and 80% increased risk of IHD for men and women, respectively, and homocysteine may account for 10% of the population's IHD risk (1). A strong association between plasma homocysteine and atherothrombotic disease has, however, been observed predominantly in cross-sectional and retrospective case-control studies, in contrast to a weak or absent association in many nested case-control and prospective studies (3). These conflicting results may suggest that plasma homocysteine is a marker or a consequence of atherothrombotic disease rather

than one of its causes (3,27,29). In the case of causality, the epidemiologic data suggest that homocysteine plays a more important role in patients with established disease than in persons without symptoms of vascular disease. That is, mildly elevated homocysteine could promote complications to atherosclerosis (e.g., thrombosis) rather than atherosclerosis itself (30–34), and hyperhomocysteinemia is, in fact, linked to thrombosis of venous origin (31,35). Plasma homocysteine and stable angina pectoris (atherosclerosis-related) did not correlate in the single prospective study that examined the question (36).

### *Homocysteine and IHD: Cause, Consequence, or Marker?*

The mere presence of a positive relation between elevated plasma homocysteine levels and IHD, as seen in many observational studies, does not indicate whether the former is a cause of, related to, or a consequence of the latter. Noticeably, elevated plasma homocysteine levels are associated with many of the well-known conventional risk factors, including old age, male sex, smoking, high blood pressure, elevated cholesterol level, lack of exercise, and a diet low in fruits and vegetables (37). To answer the question about causality and, if present, its strength, studying IHD risk in persons with genetically elevated plasma homocysteine levels (present from birth, precedes the disease, long exposure, and not a consequence of the disease or a marker of something else) provides important information. As mentioned, severe elevation of plasma homocysteine levels caused by homozygous CBS deficiency (>100 μmol/L) is clearly associated with premature venous thromboembolism and possibly with arterial thrombosis with a character of its own, but not with premature atherosclerosis and IHD (15,16,26). Coronary thrombosis appears to be extraordinarily rare (26). Treatment with pharmacologic doses of vitamin $B_6$ appears to reduce the cardiovascular risk dramatically but, strangely enough, not only in biochemically well-controlled patients but also in $B_6$ nonresponders and in responders with persistently high plasma homocysteine levels (~50 μmol/L and higher), i.e., levels that are associated with a markedly increased risk of cardiovascular events in the normal population (38). In a survey among heterozygotes (394 parents of homocystinuric children), no significantly increased risk of heart attack or stroke was identified, although many heterozygotes are known to have abnormally high plasma homocysteine levels after methionine loading (27); it was concluded that the result of this study failed to support McCully's theory (39,40). Heterozygosity for CBS deficiency appears, in fact, to be rare in premature IHD (41), although contrasting results have been reported (42). Similarly, no increased risk of either arterial or venous disease has been documented convincingly with modestly elevated plasma homocysteine levels (e.g., from 15 to 20 μmol/L) caused by milder genetic "defects" such as the TT genotype for the common C677T methylenetetrahydrofolate reductase polymorphism (27). Hyperhomocysteinemia associated with the TT genotype, even in the presence of low folate status, seems to be benign and not related to the risk or severity of cardiovascular disease (27). This mutation did not correlate with IHD in a meta-analysis of >6,000 persons (43). These observations in hyperhomocysteinemia of genetic origin argue against a causal role of homocysteine itself in the pathogenesis of atherothrombotic disease.

It should be remembered that normal (but not necessarily optimal) levels of fasting plasma homocysteine are considered to be <15 μmol/L (37,44), and that epidemiologic observations indicate that a 5-μmol/L increase in plasma homocysteine concentrations is associated with a significant increase in IHD risk (1). Therefore, the question arises concerning why a relatively small life style–mediated increase in plasma homocysteine (~5 μmol/L) appears to be associated with enhanced risk of atherothrombosis, whereas a much larger increase of genetic origin is not. How can these conflicting observations be explained?

It has been suggested that much, if not all of the epidemiologic association between mild hyperhomocysteinemia and atherothrombotic disease could be explained by homocysteine being a consequence of atherosclerosis/IHD or a marker of risk-associated behavior (27). For example, impaired renal function due to hypertension and atherosclerosis (nephrosclerosis) could be an important cause of the elevated plasma homocysteine found in patients with vascular disease, called the reverse causality hypothesis (Fig. 2) (27). Furthermore, several lifestyle factors that lower homocysteine levels are also of proven cardiovascular benefit through other mechanisms (37).

There is, however, a reasonably strong argument for a proatherogenic effect of hyperhomocysteinemia, i.e., it causes endothelial dysfunction (45,46), probably mediated by increased oxidant stress (47), and is seen even with the small physiologic increment in plasma homocysteine (~2 μmol/L) induced by a meal rich in animal protein (46). However, the long-term implications of homocysteine-induced endothelial dysfunction in atherogenesis are not known.

### *Diet, Homocysteine, Vitamins, and IHD*

Foods contain only trace amounts of homocysteine. The primary source of homocysteine in the body is methionine (essential amino acid) in dietary proteins. Although dietary intake of total protein and methionine does not correlate significantly with blood homocysteine (44), meals may transiently affect plasma homocysteine levels (48). Vitamins do not influence the conversion of methionine to homocysteine, but they do determine its fate (Fig. 1) (49). In high-methionine states, homocysteine is degraded predominantly through the transsulfuration pathway, which requires vitamin $B_6$ to function optimally. In low-methionine states, methionine is recirculated *via* homocysteine and the remethylation pathway, which requires folate and vitamin $B_{12}$ to function optimally. Therefore, $B_6$, folate, and $B_{12}$ deficiencies may lead to hyperhomocysteinemia but *via* different mechanisms; the plasma homocysteine level is in fact a very sensitive marker of folate, $B_{12}$, and $B_6$ status (50). Homocysteine levels start to rise as plasma concentrations of

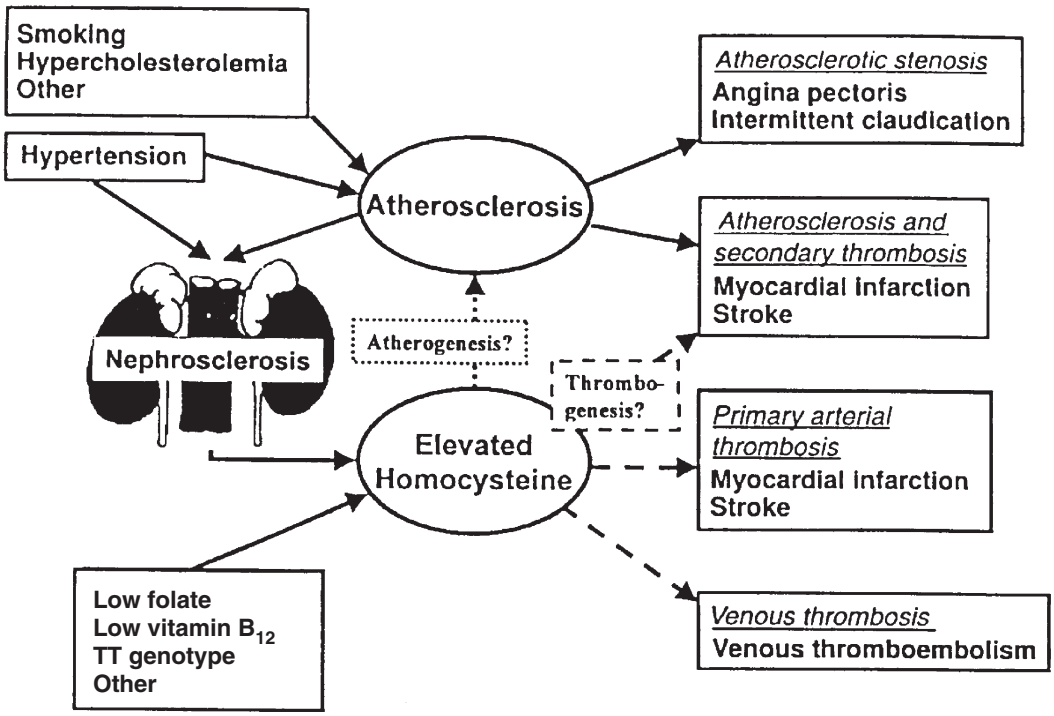

**FIG. 2.** Impaired renal function, poor folate or vitamin $B_{12}$ status, and the TT genotype of the C677T methylenetetrahydrofolate reductase polymorphism are common causes of elevated plasma homocysteine. Hypertension (and age and atherosclerosis?) leads to nephrosclerosis and decline in renal function, which in turn leads to elevated plasma homocysteine. This mechanism may explain much of the association between plasma homocysteine and atherothrombotic disease. Because there is no consistent evidence that elevated homocysteine due to low folate, low vitamin $B_{12}$, or the TT genotype is associated with increased risk of atherosclerotic or thromboembolic disease, the role of a modest elevation in plasma homocysteine in cardiovascular disease remains unclear. (Adapted from Ref. 27 with permission.)

folate or $B_{12}$ fall below the mean value and long before overt vitamin deficiency is present (51). Supplementation with these factors, particularly folate, can reduce homocysteine levels by perhaps 30% in most subjects (51).

One of the most consistent findings in dietary research is that those who consume higher amounts of fruits and vegetables have lower rates of heart disease and stroke as well as cancer (52,53). The precise mechanisms for these apparent protective effects are not clear. A typical cardioprotective diet is low in saturated fat and animal proteins, relatively high in plant proteins (methionine-poor), n-3 fatty acids, and wine, and high in fresh fruits and vegetables, which are major sources of natural antioxidants (vitamins C and E, carotenoids, and polyphenols), minerals (e.g., selenium), dietary fiber, and homocysteine-lowering vitamins (folic acid and $B_6$). One of many consequences of such a cardioprotective diet is a low plasma homocysteine level, and the latter may simply be a marker of the former.

Some observational studies suggest that, to a large extent, the association between hyperhomocysteinemia and vascular disease is explained by a vitamin deficit, especially with regard to vitamin $B_6$ and folate (54–56). Other studies, however, are less consistent, and it has even been suggested that elevation of plasma homocysteine concentrations due to poor folate status is benign with regard to risk or severity of cardiovascular disease (27). Thus, low plasma homocysteine could be a marker of the consumption of a low-risk diet (57), and cardiovascular protection could be mediated by mechanisms independent of the homocysteine-lowering effect. If a reduction in cardiovascular events is seen in ongoing clinical trials of vitamin supplementation, a possible homocysteine-independent vasculoprotective effect of folate will certainly cloud the issue of causality (58–60). For example, randomized trials have shown that periconceptional folic acid supplementation not only reduces the plasma homocysteine levels but also prevents neural tube defects; nevertheless, the mechanism of action remains unclear. Thus, it is still being debated whether this beneficial effect is the result of homocysteine lowering itself or caused by other folate-dependent mechanisms (61).

### *Homocysteine and Atherothrombosis: Experimental Observations*

Experimental models of hyperhomocysteinemia have produced conflicting results regarding the contribution of homocysteine to the development of atherosclerosis. Generally, however, hyperhomocysteinemia is not in itself atherogenic in experimental animals fed a normal low-fat diet, including nonhuman primates (20,21,62,63), rabbits (64), rats (65), pigs

(66), and mice (67). However, all of these animals have relatively low plasma cholesterol levels and none develop atherosclerosis spontaneously to any significant degree. Therefore, the homocysteine theory of atherosclerosis has to be tested more thoroughly in hypercholesterolemic animals to determine whether elevated plasma homocysteine levels are harmful under atherogenic conditions. This possibility is currently under intense investigation.

As long as a causal role of homocysteine in atherothrombotic disease remains to be established, it may be premature to discuss potential pathogenetic mechanisms; however, various mechanisms have been proposed (68). *In vivo*, hyperhomocysteinemia is associated with endothelial dysfunction in animals (69–71) [as in humans (45–47)], and it appears to promote endothelial-dependent neointima formation in rat carotid arteries after balloon injury (72); however, as mentioned, homocysteine itself has not proved to be atherogenic in animal studies (29,73,74). *In vitro*, many potentially proatherothrombotic effects of homocysteine have been reported, including endothelial toxicity (75,76) and stress (77), promotion of smc growth and collagen production (78,79), enhanced low density lipoprotein peroxidation (80), platelet activation (81), downregulation of thrombomodulin on endothelial cells (82), and upregulation of tissue factor activity on both endothelial cells (83) and macrophages (82,84). The culprit, if one exists, has been suggested to be the prooxidant activity of homocysteine (85,86).

Many of these homocysteine-mediated effects, however, have been demonstrated only at very high supraphysiologic concentrations (>1000 μmol/L), and a biological plausible mechanism of action at normal and mildly elevated homocysteine levels (<30 μmol/L) has been more difficult to identify (69,84). It is, in fact, just the opposite of the real world experience in which a small increase (1–2 μmol/L) in plasma homocysteine appears to enhance the risk of atherothrombosis in the general population, whereas no clear-cut effect is seen with the much higher levels in CBS deficiency.

In conclusion, conflicting results have been reported in genetic, observational, and experimental studies on the relation between homocysteine and atherothrombotic disease. McCully's homocysteine theory of arteriosclerosis, evoked by autopsy findings in two homocystinuric children (severe hyperhomocysteinemia), was based on the misconception that arteriosclerosis is equated with atherosclerosis, the disease responsible for IHD in the general population. Another misconception derived from studies of homocystinuric children that continues to prevail is that their high risk of cardiovascular complications includes atherothrombotic disease. Coronary thrombosis, the most frequent manifestation of atherothrombosis in the general population, appears to be rare in homocystinuric patients. On the basis of findings in individuals with hyperhomocysteinemia of genetic origin, there is, in fact, no clear evidence for a causal role of homocysteine in the pathogenesis of atherothrombotic disease, and the positive association between plasma homocysteine and IHD observed in many, but not all epidemiologic studies does not prove causality. For example, considerable epidemiologic evidence exists for a protective role of β-carotene, vitamin E, and hormone replacement therapy in IHD; nevertheless, recent randomized trials failed to prove protection (87–89), and some of these "promising" interventions may, in some cases, even be harmful.

To infer causality from observational studies, there should be a temporal, consistent, strong, independent, graded (dose-response effect), and duration-dependent relation between exposure and outcomes, and a biologically plausible mechanism should exist. The relation between plasma homocysteine levels and IHD does not fulfill these criteria beyond reasonable doubt (90), and particularly troublesome is the lack of consistency among studies. In the general population, plasma homocysteine levels are to a great extent determined by dietary habits, and plasma homocysteine could be a marker, or a consequence of atherothrombosis and/or risk-associated behavior (e.g., a diet low in fruits and vegetables) rather than a cause of atherothrombosis. It is indeed difficult to reconcile the low risk of IHD in severe hyperhomocysteinemia of genetic origin (plasma homocysteine >100 μmol/L) with a strong and graded causal effect of plasma homocysteine in mild hyperhomocysteinemia of dietary origin (<30 μmol/L) in the general population.

Atherosclerosis is a lipid-driven disease and homocysteine cannot in itself initiate the process. It may, however, accelerate the process although we do not know if this is the case. What we do know is that a cardioprotective diet rich in vitamins lowers the plasma homocysteine level and the risk of atherothrombosis, but it remains to be shown whether the beneficial effect is homocysteine mediated. The ongoing clinical trials testing the effect of homocysteine-lowering vitamins on cardiovascular outcomes will probably not answer this question. It has, for example, been documented that folic acid can prevent neural tube defects; nevertheless, the mechanism of action remains unclear. Thus, causality of homocysteine in atherothrombotic disease may be disproved, but never proved, by vitamin supplementation.

# Hyperhomocysteinemia and Thrombosis

**Marco Cattaneo***

Angelo Bianchi Bonomi Hemophilia and Thrombosis Center, Department of Internal Medicine, IRCCS Ospedale Maggiore, University of Milano, Italy

**ABSTRACT:** Homocysteine (Hcy) is a sulfhydryl amino acid derived from the metabolic conversion of methionine, which is dependent on vitamins (folic acid, $B_{12}$, and $B_6$) as cofactors or cosubstrates. In 1969, McCully first reported the presence of severe atherosclerotic lesions in patients with severe hyperhomocysteinemia and hypothesized the existence of a pathogenic link between hyperhomocysteinemia and atherogenesis. Several case-control and cross-sectional studies were consistent with the initial hypothesis of McCully, showing that moderate hyperhomocysteinemia is also associated with heightened risk of occlusive arterial disease. Less consistent results have been reported by prospective cohort studies of subjects who were healthy at the time of their enrollment, whereas prospective cohort studies of patients with overt coronary artery disease or other conditions at risk consistently confirmed the association between moderate hyperhomocysteinemia and cardiovascular morbidity and mortality. More recently, an association between moderate hyperhomocysteinemia and heightened risk of venous thromboembolism has been documented, suggesting that hyperhomocysteinemia might be involved not only in atherogenesis, but also in thrombogenesis. The mechanisms by which hyperhomocysteinemia might contribute to atherogenesis and thrombogenesis are incompletely understood. The mainstay of treatment of hyperhomocysteinemia is folic acid, alone or in combination with vitamin $B_{12}$ and vitamin $B_6$. Although it is quite clear that vitamins effectively reduce the plasma levels of total homocysteine (tHcy), we do not yet know whether they will decrease the risk of vascular disease. The results of ongoing randomized, placebo-controlled, double-blind trials of the effects of vitamins on the thrombotic risk will help in defining whether the relationship between hyperhomocysteinemia and thrombosis is causal, and will potentially have a dramatic effect in the prevention of thromboembolic events.

Paper no. L8812 in *Lipids 36*, S13–S26 (2001).

Homocysteine (Hcy) is a nonprotein sulfhydryl amino acid derived from the metabolic conversion of methionine. It exists in both free and protein-bound forms and is oxidized in plasma to the disulfides homocysteine-homocysteine (homocystine) and homocysteine-cysteine (mixed disulfide). Free and protein-bound Hcy and its disulfides are globally referred to as total homocysteine (tHcy) or homocyst(e)ine. The intracellular metabolism of Hcy occurs through two pathways of remethylation to methionine and one pathway of trans-sulfuration to cysteine. In the remethylation pathway, which is catalyzed by methionine synthase, cobalamin acts as a cofactor and the methyl group is donated by 5-methyltetrahydrofolate, the major form of folate in plasma, which derives from the reduction of 5,10-methylenetetrahydrofolate by methylenetetrahydrofolate reductase (MTHFR). In the other remethylation pathway, which is relatively less important, betaine is the methyl donor and the reaction is catalyzed by betaine-homocysteine methyltransferase. In the trans-sulfuration pathway, homocysteine is transformed by cystathionine-β-synthase (CBS) to cystathionine, with pyridoxal-5′-phosphate, a vitamin $B_6$ derivative, acting as a cofactor. Vitamin $B_6$ is also necessary for transformation of cystathionine to cysteine and α-ketobutyric acid. Under conditions of methionine excess, homocysteine is largely metabolized through the trans-sulfuration pathway; in contrast, under conditions of negative methionine balance, homocysteine is transformed primarily to methionine (1,2).

## CAUSES OF HYPERHOMOCYSTEINEMIA

### *Determinants of Total Homocysteine Levels in Plasma*

The plasma levels of tHcy increase with age, are lower in fertile women than in men, and increase after menopause (3–7). Major determinants of plasma tHcy levels include genetic abnormalities (see below), diet (vitamin $B_{12}$, $B_6$, and folate intake), renal function, cigarette smoking, and coffee consumption (5–11). In a large population study, a lifestyle that included low folate intake, smoking, and heavy coffee consumption was characterized by high median tHcy levels and pronounced skewness toward high tHcy, whereas the contrasting lifestyle profile (high folate intake, no smoking, and low coffee consumption) was associated with low tHcy levels and normal distribution of the tHcy values (11). Two recent reports showed that strict vegetarians tend to have high tHcy levels, probably due to vitamin $B_{12}$ depletion (12,13). Other, less well-established determinants of tHcy are race (14,15), arterial hypertension, hypercholesterolemia, and physical exercise (16).

### *Severe Hyperhomocysteinemia (Homocystinuria)*

The most frequent cause of severe hyperhomocysteinemia (characterized by fasting levels of tHcy in plasma higher than 100 μmol/L) is the homozygous deficiency of CBS, which

Abbreviations: CBS, cystathionine-β-synthase; CI, confidence interval; Hcy, homocysteine; HUVEC, human umbilical vein endothelial cells; MTHFR, methylenetetrahydrofolate reductase; OR, odds ratio; PML, postmethionine loading; RR, relative risk; SLE, systemic lupus erythematosus; tHcy, total homocysteine.

has a prevalence in the general population of ~1 in 335,000, varying between 1:65,000 (Ireland) and 1:900,000 (Japan) (17). Affected individuals develop the classical syndrome of homocystinuria, characterized by ectopic lens, skeletal abnormalities, premature vascular disease, thromboembolism, and mental retardation (18). Approximately 5–10% of cases of severe hyperhomocysteinemia are caused by inherited defects of remethylation (18,19). Homozygous deficiency of MTHFR, which catalyzes the reduction of methylenetetrahydrofolate to methyltetrahydrofolate, is the most common inherited defect of the remethylation pathway and is characterized by neurological dysfunction, psychomotor retardation, seizures, peripheral neuropathy, premature vascular disease, and thromboembolism. Rare cases of homocystinuria have been described in subjects with errors of cobalamin metabolism, resulting in decreased activity of methionine synthase (20).

### *Mild-to-Moderate Forms of Hyperhomocysteinemia*

Mild-to-moderate forms of hyperhomocysteinemia (fasting levels of tHcy between 15 and 100 μM) are encountered in phenotypically normal subjects with genetic defects, acquired conditions, or, more frequently, a combination of both. Genetic defects associated with moderate hyperhomocysteinemia cause approximately a 50% reduction in activities of the corresponding enzymes, such as heterozygosity for CBS or MTHFR deficiency, whose cumulative prevalence in the general population is between 0.4 and 1.5% (21). Another genetic defect that is associated with a 50% reduction of the enzymatic activity is characterized by the presence of a thermolabile mutant of MTHFR (22), which is due to the homozygous C to T substitution at nucleotide 677 of the encoding gene, converting the codon for alanine to that for valine (23). The prevalence of homozygosity for the C677T mutation is between 5 and 20% in subjects of Caucasian descent. Moderate elevations of plasma tHcy levels do not cause a 50% reduction of the corresponding enzyme activities in all subjects with genetic defects, indicating that their phenotypic expression can be influenced by other factors. For instance, homozygotes for the thermolabile form of MTHFR and heterozygotes for CBS deficiency have high homocysteine levels mainly in the presence of low serum concentrations of folic acid (24–26). Another common mutation in the MTHFR gene, A1298C, is not associated with hyperhomocysteinemia, but might interact with the C677T mutation in raising tHcy levels in plasma (27).

Causes of acquired hyperhomocysteinemia include deficiencies of folate, cobalamin, and pyridoxine, which are essential cosubstrates or cofactors for homocysteine metabolism, and chronic renal insufficiency. Vitamin deficiencies are the most frequent cause of hyperhomocysteinemia (7), especially in elderly people (8,28,29). Drugs interfering with the metabolism of folate, such as methotrexate, trimethoprim, and anticonvulsants, of cobalamin, such as nitrous oxide, and of vitamin $B_6$, such as theophylline, can cause moderate hyperhomocysteinemia (21,30–32). The increase in plasma tHcy after therapy with fibrates (33–35) may be related in part to an induced functional reduction in renal function (34,35). Estrogens (36,37), tamoxifen (38,39), penicillamine (40), and acetylcysteine (41) reduce the plasma tHcy levels.

## DIAGNOSIS OF HYPERHOMOCYSTEINEMIA

Of plasma tHcy, ~70% is bound to albumin, 30% is oxidized to disulfides, and only ~1% is present as free homocysteine. For measurement of total homocysteine in plasma, immediate deproteinization of the sample is necessary to avoid its gradual binding to plasma proteins, and very sensitive methods are required. Hence, before the discovery of protein-bound homocysteine, the diagnosis of moderate elevations of plasma homocysteine levels was very cumbersome. For this reason, early epidemiologic studies of the prevalence of moderate hyperhomocysteinemia in health and disease were based on the measurement of plasma homocysteine levels after an oral methionine loading, which temporarily increases the plasma homocysteine levels (see below). Since the introduction of methods that measure tHcy in blood, which imply the treatment of samples with reducing agents, fasting blood levels of homocysteine can be reliably measured to discriminate between normal subjects and patients with mild impairments of its metabolism. Current methods to assay plasma tHcy include gas chromatography–mass spectroscopy and high-performance liquid chromatography with fluorometric or electrochemical detection (reviewed in Ref. 42). Recently, manual or fully automated enzyme immunoassays have become commercially available, which should allow tHcy measurements in nonspecialized clinical laboratories (43,44). Two recent multicenter studies, which compared plasma tHcy measurements in different laboratories, pointed to the need to improve analytical imprecision and to establish an international plasma standard to harmonize tHcy measurement across laboratories (45,46).

### *The Postmethionine Loading (PML) Test*

Measurement of plasma homocysteine 4–8 h after a standardized oral methionine loading (3.8 g/m$^2$ body surface area or 0.1 g/kg body), which was initially developed to detect heterozygosity for CBS deficiency (47,48), improves the ability of distinguishing between normal individuals and subjects with mild abnormalities of homocysteine metabolism (18, 48–52). A shortened 2-h protocol has been validated, and may offer advantages of patient acceptability over the 4- or 8-h protocols (53). However, the equivalence of the 2- and 4-h protocol has been questioned recently (54). It appears that the PML test is most sensitive to the trans-sulfuration pathway of homocysteine (55,56). However, it is also abnormal in individuals who are homozygous for the C677T mutation of the MTHFR gene, who have a selective defect of the remethylation pathway of homocysteine (57).

### *Normal Ranges*

The cutoff point for hyperhomocysteinemia is usually, but arbitrarily, set at the 95th percentile of the homocysteine

distribution in healthy subjects, which, for fasting tHcy levels, corresponds to ~15 μmol/L. Normal ranges vary widely in different populations because they are affected by several lifestyle determinants (see above). When determined in a population with adequate vitamin intake (58,59), the upper limit of the normal range may be as low as 12 μmol/L. Because fasting tHcy levels are affected by gender, different cutoff points should be used for men and women. Reference ranges for the PML increase of tHcy above fasting levels (the PML absolute levels of tHcy should not be considered because they are affected in part by the fasting levels) have been determined less extensively. The effect of gender on PML tHcy increase is controversial (52,60).

## HYPERHOMOCYSTEINEMIA IN ATHEROTHROMBOTIC DISEASE

There are three autosomal recessive inborn errors of homocysteine metabolism associated with very high tHcy levels in plasma and homocystinuria, i.e., deficiency of CBS, deficiency of MTHFR, and errors of cobalamin metabolism resulting in impaired methionine synthase activity (18). All three genetic disorders are characterized by very high risk for early-onset cardiovascular complications of either the arterial or the venous circulation (18). Because high tHcy levels are the only known biochemical abnormality that is common to these conditions, it is likely that Hcy is in some way involved in the pathogenesis of thromboembolic complications in these disorders. In 1969, McCully (61) first reported the presence of severe arteriosclerotic lesions in patients with homocystinuria and hypothesized the existence of a pathogenic link between hyperhomocysteinemia and atherogenesis. Several epidemiologic studies have yielded results consistent with the initial hypothesis of McCully, showing that moderate hyperhomocysteinemia may also be associated with heightened risk of arterial disease (16,62).

### *Case-Control Studies*

In 1976, Wilcken and Wilcken (63) first showed that patients with coronary artery disease have elevated concentrations of plasma cysteine-homocysteine disulfide after an oral methionine load. Increased plasma levels of homocysteine species before and/or after an oral methionine load were subsequently reported by several other groups concerning patients with atherothrombosis (coronary artery disease, cerebrovascular disease, and peripheral arterial occlusive disease) (16,62).

A meta-analysis of 27 studies, most having a case-control design, published before 1994, revealed that the summary odds ratio (OR) as an estimate of the relative risk (RR) in subjects with hyperhomocysteinemia was 1.7 [95% confidence interval (CI) 1.5–1.9] for CAD, 2.5 (2.0–3.0) for cerebrovascular disease, and 6.8 (2.9–15.8) for peripheral arterial disease (64). The results of this meta-analysis were heavily influenced by a high prevalence of case-control studies. For each increase in tHcy concentration of 5 μmol/L, there was an increase of ~40% in the relative risk for CAD. The association of hyperhomocysteinemia with arterial occlusive diseases remained significant after adjustment for known risk factors such as smoking, cholesterol, hypertension, and diabetes. Many other case-control studies have been published since then, most of which confirmed the association of hyperhomocysteinemia with cardiovascular diseases. Among them, a multicenter study of 750 patients with vascular disease and 800 controls confirmed that hyperhomocysteinemia conferred a graded risk of vascular disease, which was similar to and independent of that of other risk factors, such as smoking and hypercholesterolemia (52). In addition, the study demonstrated that, for both sexes combined, high fasting homocysteine levels showed a more than multiplicative effect on risk in smokers and in hypertensive subjects (52). A more recent analysis of the same study revealed that, in addition to plasma homocysteine levels, concentrations of red cell folate below the 10th centile and of vitamin $B_6$ below the 20th centile for control subjects were also associated with increased risk (65). This risk was independent of conventional risk factors and, for folate, it was explained in part by high levels of tHcy. In contrast, the association between vitamin $B_6$ and the risk of vascular disease was independent of tHcy levels both before and after methionine loading (65). These results agree with those of those of other studies, which showed that low pyridoxal-5′-phosphate confers an independent risk for coronary artery disease (66,67).

### *Cross-Sectional Studies*

Two studies reported the correlation between tHcy and carotid arterial wall thickness measured by B-mode ultrasound in subjects without clinically apparent atherosclerosis (29,68). In most of the cases, hyperhomocysteinemia was associated with low concentrations of pyridoxine and folic acid. Low plasma levels of folic acid and pyridoxine were associated with increased risk for carotid artery stenosis (29) also independently of tHcy plasma levels. The association of hyperhomocysteinemia and the risk of atherosclerosis of the carotid and peripheral arteries was later shown in subjects aged 55–74 y, but not in older subjects (69). Other cross-sectional studies demonstrated the existence of a relationship between homocysteine level and the extent of atherosclerosis in the aorta (70), coronary (71,72), and peripheral arteries (73,74).

### *Prospective Studies*

*Prospective studies of healthy subjects.* The results of 13 prospective studies, all with a nested case-control design, of the relationship between tHcy and risk of cardiovascular disease in subjects who were healthy at the time of their enrollment are controversial. Six studies demonstrated that tHcy levels at baseline could predict the risk of future cardiovascular and/or cerebrovascular events, whereas the other seven failed to demonstrate such an association (67–86).

More recently, the results of six prospective studies of elderly healthy subjects, one including postmenopausal women, were published (87–92). All of them showed that high tHcy levels are associated with an increased risk not only for future cardiovascular and cerebrovascular events (87–92) but also for all-cause and cardiovascular mortality (91,92).

*Prospective studies of patients with overt coronary artery disease or other conditions at risk.* The only prospective study of patients with overt coronary artery disease showed a strong, graded, and significant relationship between tHcy levels and overall mortality that was independent of other risk factors (93). When death due to cardiovascular disease was considered as the end point, the relation between tHcy levels and mortality was even stronger. Subgroup analysis revealed that tHcy predicted the risk of death independently of age, gender, serum cholesterol, smoking, blood pressure, and serum creatinine. In a study of 337 patients with systemic lupus erythematosus (SLE), Petri *et al.* (94) found that high tHcy concentrations were significantly associated with stroke (OR, 2.24; 95% CI, 1.22–4.13) and arterial thrombotic events (3.71; 95% CI, 1.96–7.13). The association remained significant after adjustment for established risk factors.

Patients with chronic renal failure have markedly increased plasma levels of tHcy. In addition to case-control and cross-sectional studies (95,96), two prospective studies of maintenance peritoneal dialysis or hemodialysis patients revealed that the adjusted hazard ratios for nonfatal and fatal cardiovascular events were 3.0–4.4 in patients with tHcy levels in the upper quartile, compared with those of patients with tHcy levels in the three lowest quartiles (97) and that the relative risk for cardiovascular events, including death, increased 1% per μM increase in tHcy concentration (RR, 1.01; 95% CI, 1.00–1.01) (98). More recently, hyperhomocysteinemia was shown to be a predictor of mortality in type-2 diabetes (99,100).

In conclusion, in contrast with case-control studies, prospective studies of the association of hyperhomocysteinemia and the risk of arterial disease in otherwise healthy subjects at the time of randomization have given contrasting results. Although the negative results of some prospective studies might weaken causal inference and support the hypothesis of Hcy being a risk marker rather than a causal risk factor, other interpretations could be considered.

The within-person consistency in tHcy levels over time might attenuate the association of a one-time measure with the future vascular events. As a matter of fact, both the Physicians' Health Study (79) and the prospective study by Kark *et al* (92) showed that the association of tHcy levels and incidence of MI or death became weaker after the first 5 yr of follow-up.

In addition, the effects of genetic and/or nutritional differences (101) and of different cardiovascular risk profiles among the populations studied could be considered. In fact, Alfthan *et al.* (102), in an elegant ecological study, showed that mean basal levels of plasma tHcy differ among 11 different countries and are positively correlated with cardiovascular mortality.

The findings that hyperhomocysteinemia consistently proved to be predictive of cardiovascular events in patients affected by pathologies associated with high cardiovascular risk (93–100) suggest that the basal cardiovascular risk profile of the population studied may be relevant. In line with this hypothesis, all of the most recent prospective studies of healthy elderly subjects, who are at higher cardiovascular risk than young individuals, showed consistently that hyperhomocysteinemia is predictive of future cardiovascular and cerebrovascular morbidity and mortality (87–92).

### *Case-Control and Cross-Sectional Studies of Genetic Abnormalities of Hcy Metabolism*

Two studies showed that subjects with heterozygous mutations of the CBS gene are not at increased risk for cardiovascular disease (67,103). The negative data on the association of CBS mutations with cardiovascular disease agree with the findings of an early questionnaire survey on obligate heterozygotes for CBS deficiency, which failed to demonstrate an increased risk for vascular disease (104) and with those of a more recent study of obligate heterozygotes for CBS deficiency (105). However, they are in contrast with the results of other studies, that showed a high prevalence of abnormal methionine loading and decreased CBS activity in cultured fibroblasts of patients with early-onset vascular disease (106,107). It must be noted, however, that the results of decreased CBS activity in thrombotic patients, which were generated by one and the same laboratory for both studies, could not be reproduced when retested in a different laboratory (103).

In contrast to heterozygous CBS deficiency, the homozygous C677T mutation of MTHFR was associated with a threefold increase in cardiovascular risk in the initial study by Kluijtmans *et al.* (103). After this initial report, several additional studies of the frequency of the C677T MTHFR mutation in cardiovascular patients were published. A meta-analysis of eight studies revealed that the homozygous genotype for the C677T mutation was present in 299 of 2476 patients (12.1%) and in 257 of 2481 controls (10.4%), resulting in a significant OR of 1.22 (95% CI, 1.01–1.47) relative to the normal genotype (108). In contrast, a subsequent meta-analysis of 13 studies including a total of 3281 patients with cardiovascular disease and 3218 healthy controls revealed no difference between patients and control subjects in either the allele frequency (33.7 vs. 35.6, respectively) or the frequency of mutant homozygotes (12.2 vs. 13.2, respectively) (109). More recent studies suggest that the C677T mutation of MTHFR may be associated with increased risk for early-onset coronary artery disease (110) or childhood stroke (111).

A common 844ins68 insertion variant in the CBS gene, which was independently described by two groups (112,113), is not associated with hyperhomocysteinemia or with heightened risk of vascular disease (114). In line with similar studies (see above), two recent cross-sectional studies showed that carotid atherosclerosis was associated with high Hcy

levels; however, no such association was found with the C677T mutation (115,116). The lack of associations between genetic determinants of hyperhomocysteinemia and cardiovascular risk or carotid atherosclerosis is in marked contrast with the results of case-control studies of hyperhomocysteinemia in cardiovascular diseases. Although some explanations have been attempted (62), this paradox questions the hypothesis of the existence of a causal relationship between hyperhomocysteinemia and cardiovascular diseases (see below).

## HYPERHOMOCYSTEINEMIA IN VENOUS THROMBOSIS

### *Case-Control Studies*

After the publication of two negative studies of small series of patients (117,118), the association of moderate hyperhomocysteinemia with venous thrombosis was demonstrated by Falcon *et al.* in 1994 (49). They showed a high prevalence of moderate hyperhomocysteinemia in patients with early-onset venous thrombosis, in whom other congenital or acquired causes of thrombophilia had been ruled out (49). In all but one patient, who had low serum levels of folates and vitamin $B_{12}$, acquired causes of hyperhomocysteinemia were excluded and family studies showed that most of the studied probands had at least one first-degree relative with the same abnormality. In this, as well as in subsequent confirmatory studies (50,51), the measurement of tHcy after an oral methionine loading allowed the detection of a greater number of patients with abnormal Hcy metabolism than did measurement of fasting levels alone. In 1995, the association between hyperhomocysteinemia and venous thrombosis was reported in a study of patients with a history of recurrent venous thrombosis (119). This study showed that the prevalence of hyperhomocysteinemia among cases was similar whether it was diagnosed by measuring fasting or PML levels of tHcy. It must be noted, however, that the two measurements were not always concordant, i.e., several patients with abnormal PML tHcy levels had normal fasting levels, and *vice versa*. It is evident, therefore, that in this study the combination of the two tests would also have identified a larger number of patients with impaired homocysteine metabolism than either test alone. Therefore, in laboratory screening of patients at increased risk of thrombosis, plasma tHcy should be measured both before and after an oral methionine loading (51). A high prevalence of hyperhomocysteinemia was later found in patients presenting with first episodes of deep-vein thrombosis of the lower extremities (51,120–122), although results were significant in only two studies (120,121). No association was found between hyperhomocysteinemia and the risk of deep-vein thrombosis of the upper extremities (123). In contrast to arterial thrombosis, the frequency distribution histograms found in a study relating tHcy to the risk for deep-vein thrombosis of the lower extremities indicated the existence of a threshold effect rather than a continuous dose-response relationship (120). Two meta-analyses of published case-control studies of hyperhomocysteinemia in venous thrombosis have been published. Both showed that both fasting and PML hyperhomocysteinemia are associated with a two- to threefold relative risk of venous thrombosis (124,125).

Whether hyperhomocysteinemia is associated with increased risk for venous thrombosis by itself or only when combined with other congenital risk factors has been a matter of debate, although the bulk of evidence now suggests that the thrombotic risk associated with hyperhomocysteinemia is independent of the coexistence of abnormalities of the natural anticoagulant system. Two studies of patients with homocystinuria gave conflicting results, i.e., in one, factor V Leiden did not prove to be a major determinant of thrombosis in patients with homocystinuria due to CBS deficiency (126), whereas the other study observed thrombotic complications only in those homocystinuria patients with concomitant heterozygous or homozygous factor V Leiden (127). Three reports showed that the association of mild-to-moderate hyperhomocysteinemia and venous thrombosis persisted after exclusion of patients with known congenital risk factors, such as deficiencies of natural inhibitors of coagulation and/or resistance to activated protein C due to factor V Leiden (49,120,121).

### *Prospective Studies*

*First episodes of venous thromboembolism.* Three prospective studies of tHcy as predictor of the risk for first episodes of venous thromboembolism gave essentially negative results (94,128,129). There was no association of hyperhomocysteinemia and the risk of venous thromboembolism in SLE patients (94), or in patients who underwent elective hip replacement surgery and were screened for postoperative deep-vein thrombosis with bilateral phlebography (129). Ridker *et al.* (128), in their nested case-control study of a subset of 22,071 male physicians participating in the Physicians' Health Study, did find an association between hyperhomocysteinemia and an increased risk of developing future episodes of idiopathic venous thrombosis, but only when hyperhomocysteinemia was associated with factor V Leiden, an established risk factor for venous thromboembolism. The association of hyperhomocysteinemia with idiopathic venous thrombosis in the absence of factor V Leiden tended to be significant ($P = 0.06$). The inclusion of men only and of patients with cancer in this prospective study are among the possible reasons accounting for the differences with case-control studies, which demonstrated an association between hyperhomocysteinemia and venous thrombosis that was independent of the coexistence of resistance to activated protein C or factor V Leiden (Table 3 in Ref. 130).

*Recurrent episodes of thromboembolism.* In a prospective, multicenter study of 264 patients with an objectively documented single episode of idiopathic venous thromboembolism, Eichinger *et al.* (131) recently showed that the risk of recurrent venous thromboemblism is higher (RR, 2.7; 95% CI, 1.3–5.8) in patients with hyperhomocysteinemia than in patients with normal tHcy levels.

### *Case-Control Studies of Genetic Abnormalities of Hcy Metabolism*

Studies of the prevalence of mutant C677T MTHFR in patients with venous thrombosis gave conflicting results (57,132–138). In three studies, C677T was shown to be a risk factor for venous thrombosis (132,136,137). The other studies failed to demonstrate an increased prevalence of C677T MTHFR among patients compared with controls. The coexistence of factor V Leiden or the G20210A mutation of the gene encoding for factor II and mutant C677T MTHFR conferred a particularly high risk for venous thrombosis in some studies (57,136,139) but not in others (133,134,140).

## IS HYPERHOMOCYSTEINEMIA A CAUSAL RISK FACTOR FOR ARTERIAL AND VENOUS THROMBOSIS?

The demonstration of an association between hyperhomocysteinemia and thrombosis has relied mainly on case-control and cross-sectional studies, which consistently showed that patients with previous episodes of arterial or venous occlusive diseases have higher tHcy plasma levels than healthy controls. However, prospective studies of individuals who were healthy at the time of their enrollment gave conflicting results. In addition, the lack of association of genetic abnormalities responsible for moderate hyperhomocysteinemia with an increased risk for thrombosis does not support the concept that hyperhomocysteinemia is causally related to the development of thrombotic events. Intervention studies with agents that lower the tHcy plasma levels and further prospective cohort studies on healthy individuals are necessary to shed more light on the problem of hyperhomocysteinemia as an independent and causal risk factor for arterial and venous thrombotic diseases. Screening for plasma tHcy levels is probably not yet justified in healthy individuals at low cardiovascular risk but may be advisable in individuals at high risk (141,142).

## HYPERHOMOCYSTEINEMIA IN OTHER PATHOLOGIC CONDITIONS

In addition to renal failure and cobalamin and folate deficiencies, hyperhomocysteinemia can be found in other pathologic conditions, such as hypothyroidism (143), inflammatory bowel disease (144), and rheumatoid arthritis (145), suggesting a potential mechanism for the high incidence of thrombotic complications in these patients. Hyperhomocysteinemia was also found in patients with renal or heart transplantation (reviewed in 146) with lymphoproliferative disorders (147) but not in patients with polycythemia (148). It is common in insulin-dependent diabetes mellitus if it is complicated by nephropathy and may contribute to increased mortality from cardiovascular disease in these patients (149); in addition, it is a very strong risk factor for cardiovascular complications in patients with noninsulin-dependent diabetes mellitus (150).

## MECHANISMS BY WHICH HYPERHOMOCYSTEINEMIA MIGHT PREDISPOSE TO ATHEROSCLEROSIS AND THROMBOSIS

The mechanism(s) by which hyperhomocysteinemia might contribute to atherogenesis and thrombogenesis are incompletely understood. *In vivo* studies in baboons showed that homocysteine causes endothelial cell desquamation, smooth muscle cell proliferation, and intimal thickening (151). *In vitro* studies showed that homocysteine-induced endothelial injury requires copper and oxygen and is prevented by catalase but not superoxide dismutase, suggesting that production of hydrogen peroxide is responsible for the toxic effect on endothelial cells (152). Other *in vitro* effects of homocysteine include the following: activation of factor V (153) and interference with protein C activation and thrombomodulin expression (154–156); inhibition of tissue plasminogen activator binding (157) and modulation of tissue plasminogen activator binding to annexin II tail domain (158); impaired generation and decreased bioavalability of endothelium-derived relaxing factor/nitric oxide (157–160) and prostacyclin (162), which are potent antiaggregating agents and vasodilators; induction of tissue factor activity (163); suppression of the expression on the vessel wall of the anticoagulant substance heparan sulfate (164); inhibition of ecto-ADPase (165); increase of DNA synthesis in aortic smooth muscle cells and inhibition of DNA synthesis in human umbilical vein endothelial cells (HUVEC) (166); enhanced collagen production and accumulation by smooth muscle cells (167); endoplasmic reticulum stress and growth arrest in HUVEC (168); and acceleration of endothelial cell senescence (169). It must be noted, however, that most *in vitro* effects of homocysteine on endothelial cells have been demonstrated for very high homocysteine concentrations, usually at least one order of magnitude higher than the plasma concentrations of homocysteine that can be found in patients with homozygous homocystinuria. The lack of control samples in which the effects of other thiols, such as cysteine, were studied casts doubt on the specificity of the observed effects. Therefore, the pathophysiologic relevance of most *in vitro* studies awaits confirmation from *in vivo* and *ex vivo* experiments.

The data of an *in vivo* study of the effects of diet-induced hyperhomocysteinemia on vascular functions in monkeys showed that Hcy decreases vascular relaxation in response to various stimuli and inhibits thrombomodulin-dependent protein C activation in aortic endothelial cells (170). These findings are consistent with the observation that *in vitro* exposure of endothelial cells to Hcy decreases the activity of nitric oxide and the activation of protein C. However, the finding that circulating plasma levels of activated protein C are not decreased in subjects with hyperhomocysteinemia and are increased in hyperhomocysteinemic patients with previous deep-vein thrombosis, questions the pathogenic role of the thrombomodulin-protein C pathway in Hcy-induced thrombosis (171). In agreement with these data, another *ex vivo* study showed that patients with homocystinuria due to CBS deficiency have high plasma levels of activated protein C

(172). These patients also had high plasma levels of markers of thrombin generation, and abnormally high *in vivo* biosynthesis of thromboxane $A_2$, as reflected by increased urinary excretion of its metabolite 11-dehydro-thromboxane $B_2$ (172,173).

Compelling evidence indicates that both chronic (174,175) and acute (induced by an oral methionine loading) (176–181) hyperhomocysteinemia impair the endothelium-dependent flow-mediated dilation of the brachial artery. The inhibitory effects of homocysteine were inhibited by antioxidant vitamins (178–180), suggesting that the adverse effects of homocysteine on vascular endothelial cells are mediated through oxidative stress mechanisms. However, this hypothesis has recently been questioned (181).

## TREATMENT OF HYPERHOMOCYSTEINEMIA

Estrogens reduce the mean plasma tHcy levels in postmenopausal women (36). The estrogen agonist/antagonist tamoxifen, which is the standard endocrine treatment for breast cancer, reduces tHcy levels not only in patients with advanced breast cancer (38), but also in healthy women (39), indicating that its lowering effect is due not only to its antitumoral activity, but also to its direct effect on estrogen-regulated targets. This finding may explain the observed reduction in coronary artery disease associated with tamoxifen treatment (182) and bears potentially important implications for the outcome of the ongoing trials of breast cancer prevention.

L-Thyroxine administration normalizes the high tHcy levels in patients with hypothyroidism (183).

The mainstay of treatment of hyperhomocysteinemia is folic acid, alone or in combination with cobalamin and vitamin $B_6$ (184). Although the three vitamins are often administered in combination, it appears that folic acid is the most effective agent because it also dramatically reduces the plasma tHcy fasting levels when given alone (185,186). A meta-analysis of 12 trials of reduction of tHcy by dietary supplementation with folic acid alone or in combination with vitamin $B_6$, vitamin $B_{12}$, or both, including 1114 individuals, was recently published (187). It showed that the proportional and absolute reductions in blood fasting tHcy produced by folic acid supplements were greater at higher pretreatment blood tHcy concentrations and lower pretreatment serum folic acid levels. After standardization to pretreatment tHcy levels of 12 μM and of folate of 12 nM, folic acid, at doses ranging between 0.5 and 5 mg/d, significantly reduced plasma tHcy levels by 25% (95% CI, 23–28%) (187). A lower dose of folic acid (0.5 mg every second day) decreased the tHcy levels by only 11% in 50 healthy women (188). Higher doses of folic acid (2.4 mg) may be necessary to treat hyperhomocysteinemia in renal transplant recipients (189,190). Vitamin $B_{12}$ (mean 0.5 mg/d) caused an additional reduction of 7% (3–10%), whereas vitamin $B_6$ (mean 16.5 mg/d) did not have a significant additional effect (187). However, vitamin $B_6$ should be added to folic acid and vitamin $B_{12}$ because it effectively reduces the PML tHcy levels (189). This finding corroborates the hypothesis that the PML test is most sensitive to the trans-sulfuration pathway of Hcy metabolism, in which vitamin $B_6$ acts as a cofactor (32,55,56).

Although it is quite clear that vitamins effectively reduce the plasma levels of tHcy, we do not yet know whether they will decrease the risk of vascular disease. On the basis of the graded effect of Hcy on coronary risk, a meta-analysis of 11 studies of the effects of increasing folic acid intake calculated that 13,500–50,000 deaths due to coronary artery disease could be avoided annually in the United States by fortification of food with folic acid (64). Cereal-grain products in the U.S. food supply are being fortified with folic acid to prevent neural tube defects. Cereals providing 127 μg of folic acid daily, which approximates the levels of folic acid fortification recommended by the Food and Drug Administration (140 μg/100 g cereal grain products), decreased plasma tHcy levels by only 3.7% in a recent controlled trial, which is probably insufficient to prevent cardiovascular disease (191). A subsequent trial showed that a meal providing mean folate intakes of 601 ± 143 μg/d decreased the serum tHcy concentration from 10.8 ± 5.8 to 9.3 ± 4.9 μM, whereas the normal diet, providing mean folate intakes of 270 ± 107 μg/d had no effects on tHcy levels (192). The first published study of the effects of folic acid fortification in the United States was done within the frame of the Framingham Offspring Study (193). It showed that folic acid fortification decreased the mean tHcy levels from 10.1 to 9.4 μM and the prevalence of high tHcy concentrations (>13 μM) from 18.7 to 9.8%. The most marked effect of folic acid fortification on tHcy levels was seen in subjects with hyperhomocysteinemia at baseline, whose mean levels decreased from 18.7 to 9.8 μM (193).

Recently, some interesting data from the Nurses' Health Study, including 80,082 women followed up for 14 yr, were published (194). All participants completed a detailed food-frequency questionnaire when they were enrolled in the study in 1980. From these data the usual intake of folate and vitamin $B_6$ was derived. After controlling for other cardiovascular risk factors, the RR of coronary heart disease between the extreme quintiles of total energy-adjusted daily intakes were 0.69 (95% CI, 0.53–0.87) for folate (median intake 696 vs. 158 μg/d), and 0.67 (0.53–0.85) for vitamin $B_6$ (median intake 4.6 vs. 1.1 mg/d). The risk of coronary heart disease was reduced among women who regularly used multiple vitamins (RR = 0.76, 0.65–0.9). These data strongly suggest that intake of folate and vitamin $B_6$ may be important in the primary prevention of cardiovascular disease.

In an uncontrolled study, the supplementation of vitamins (folic acid 2.5 mg/d, pyridoxine 25 mg/d, and cyanocobalamin 250 μg/d) to 50 patients with vascular disease and hyperhomocysteinemia for ~2 yr decreased the rate of progression of carotid plaque (measured by two-dimensional B-mode ultrasound) from 0.21 ± 0.41 $cm^2$/y to –0.049 ± 0.24 $cm^2$/yr (193). A lesser effect of the same vitamin regimen was also seen in 51 vascular disease patients with normal tHcy concentrations (195).

The recommended treatment of hyperhomocysteinemia today should include folic acid (at least 0.5 mg/d) and vitamin

$B_6$, with the addition of vitamin $B_{12}$ to secure full folic acid responsiveness and to avoid the risk of deteriorating cobalamin neuropathy in deficient patients, due to masking of hematologic changes by folic acid (196). The doses of vitamin $B_6$ and $B_{12}$ to be added in addition to folic acid have not yet been clearly defined (62). Ongoing prospective, placebo-controlled clinical trials will tell us whether the hypothetical preventive effect of vitamin supplementation on thrombotic diseases is real.

In conclusion, case-control and cross-sectional studies clearly indicated that mild-to-moderate hyperhomocysteinemia is associated with heightened risk of both arterial and venous thrombosis. On the other hand, additional studies are required to define unequivocally whether hyperhomocysteinemia is a causal risk factor for thrombosis, especially of the venous circulation. Among these, prospective cohort studies will clarify better the temporal relationship between high homocysteine levels and the thrombotic event. Most important, however, randomized, placebo-controlled, double-blind trials of the effects of vitamins on the thrombotic risk are urgently needed. They will help to define whether the relationship between hyperhomocysteinemia and thrombosis is causal (197).

# Short-Term Folic Acid Supplementation Induces Variable and Paradoxical Changes in Plasma Homocyst(e)ine Concentrations

**ABSTRACT:** Folic acid is presently the mainstay of treatment for most subjects with elevated plasma homocyst(e)ine concentrations [Plasma or serum homocyst(e)ine, or total homocysteine, refers to the sum of the sulfhydryl amino acid homocysteine and the homocysteinyl moieties of the disulfides homocystine and homocystein-cysteine, whether free or bound to plasma proteins.] Changes in homocyst(e)ine in response to folic acid supplementation are characterized by considerable interindividual variation. The purpose of this study was to identify factors that contribute to heterogeneity in short-term responses to folic acid supplementation. The effects of folic acid supplementation (1 or 2 mg per day) for 3 wk on plasma homocyst(e)ine concentrations were assessed in 304 men and women. Overall, folic acid supplementation increased mean plasma folate 31.5 ± 98.0 nmol/L and decreased mean plasma homocyst(e)ine concentrations 1.2 ± 2.4 μmol/L. There was evidence of substantial interindividual variation in the homocyst(e)ine response from –18.5 to +7.1 μmol/L, including an increase in homocyst(e)ine in 20% of subjects (mean increase 1.5 ± 1.4 μmol/L). Basal homocyst(e)ine, age, male gender, cigarette smoking, use of multivitamins, methylene tetrahydrofolate reductase, and cystathionine β-synthase polymorphisms accounted for 47.6% of the interindividual variability in the change in homocyst(e)ine after folic acid supplementation, but about 50% of variability in response to folic acid was not explained by the variables we studied.

Paper no. L8807 in *Lipids 36*, S27–S32 (December 2001).

Biochemical and pathological studies in homocystinuric children led McCully to propose that moderately elevated blood levels of homocyst(e)ine may cause arteriosclerosis in adults who lack other characteristics of homocystinuria (1). The association of moderately high levels of homocyst(e)ine [plasma or serum homocyst(e)ine, or total homocysteine, refers to the sum of the sulfhydryl amino acid homocysteine and the homocysteinyl moieties of the disulfides homocystine and homocysteine-cysteine, whether free or bound to plasma proteins] and vascular disease has been confirmed in numerous studies (2). A recent review of about 80 clinical and epidemiological studies suggested that a moderately elevated level of homocyst(e)ine is a common risk factor for atherosclerosis and venous thromboembolism (3).

It could be questioned whether it is necessary or appropriate to treat moderately elevated levels of homocyst(e)ine before the results of ongoing clinical trials are available (4). However, the overwhelming positive association of high homocyst(e)ine levels and cardiovascular diseases (3), together with the accepted clinical practice of treating modifiable, established risk factors, makes us believe it is indeed justifiable to attempt to lower homocyst(e)ine levels with an inexpensive and generally innocuous vitamin therapy prior to the availability of supporting data from clinical trials.

Since the pioneering observation of Kang and colleagues (5) of the association between high blood levels of homocyst(e)ine and low blood folate, supplemental folic acid has been considered to be the mainstay of the treatment for an elevated level of homocyst(e)ine, with the addition of vitamins B-6 and B-12 as needed (6–8).

A metaanalysis of 12 studies showed that group averages of plasma homocyst(e)ine concentrations could be comparably reduced by folic acid supplementation at mean doses ranging from 0.5 to 5.7 mg per day (8). Although group mean plasma homocyst(e)ine levels are consistently decreased by folic acid supplementation (6–8), individual responses vary substantially. For example, Santhosh-Kumar *et al.* (9) reported "unpredictable inter-individual variation" in the response of homocyst(e)ine to folic acid supplementation. In one "unusual case," homocyst(e)ine increased when folate intake was raised from 286 to 516 μg/day (10), and a limited number of patients showed a small increase in the homocyst(e)ine concentration, following a 5-wk period ingesting folic acid-fortified breakfast cereal (11). Furthermore, Worley and Turi (12) reported that 30 to 50% of patients with homocyst(e)ine levels >10.5 μmol/L or post-methionine load levels >28 μmol/L failed to respond to pharmacological doses of folic acid, pyridoxine, and vitamin

B-12. In view of these observations, the present study was conducted to identify factors that contribute to interindividual heterogeneity in the effects of folic acid supplementation on levels of plasma homocyst(e)ine.

## SUBJECTS AND METHODS

The study population of 304 men and women included 242 subjects previously treated with folic acid (13) and a subset of 22 subjects who were retested 3 yr later, when all subjects in the upper and lower quintiles of plasma homocyst(e)ine changes following the folic acid supplementation were invited for a continuation of the study. Twenty-two subjects agreed to participate and received identical folic acid supplements as in the initial test. The present study population included new data on methylene tetrahydrofolate reductase (MTHFR) and cystathionine β-synthase (CBS) gene polymorphisms and excluded subjects receiving nicotinic acid. Subjects were recruited from internists or family physicians associated with Providence St. Vincent Hospital (Portland, OR), from a cohort of patients discharged with the diagnosis of ischemic heart disease (ICD 9 code 410-414), or were self-referred in response to advertisements. The study subjects were men and women 45–85 yr of age at the time of the initial interview. Subjects were excluded if they received medication(s) that might affect homocyst(e)ine levels (i.e., methotrexate, tamoxifen, anticonvulsants, niacin, bile acid sequestrants, or recent exposure to nitrous oxide anesthesia). Other exclusion criteria were missed lab appointments, ingesting ≥0.8 mg folic acid daily, or basal plasma creatinine levels ≥1.7 mg/dL. All subjects were advised to continue with their usual medications, including multivitamins, throughout the intervention. The study was approved by the Institutional Review Boards of Providence St. Vincent Hospital and Oregon Regional Primate Research Center (ORPRC).

Case subjects were diagnosed more than 3 mon previously with a history of acute myocardial infarction, angina pectoris documented by a cardiologist, percutaneous transarterial coronary angioplasty, or coronary bypass graft surgery. Control subjects had no self-reported or documented history of coronary heart disease. Case and control subjects reported having no history of stroke, intermittent claudication, or peripheral arterial revascularization. All subjects completed a medical history form, signed an informed consent form, and were then randomized to receive either 1 or 2 mg folic acid orally per day for 3 wk. The amount of folic acid selected accords with the data in the metaanalysis of the Trialists' Collaboration (8). The length of folic acid supplementation was sufficient to observe an effect on plasma homocyst(e)ine. Lowering in plasma homocyst(e)ine concentrations was reported after only 2 wk of supplementation with smaller doses than 1 or 2 mg per day by Seltzer *et al.* (14) and Brouwer *et al.* (15) as well as with larger doses by Brattstrom *et al.* (6). The need for a placebo group may be obviated by previous studies that demonstrated stability of homocyst(e)ine plasma levels during a 4-wk interval by Garg *et al.* (16) and Brouwer *et al.* (15). Subjects were instructed to arrive for laboratory appointments from 7:00 to 10:30 A.M., Monday through Friday, in the fasting state (i.e., no food after midnight) and were instructed not to take any vitamins on the morning of phlebotomy. During the first appointment, 1-mg folic acid tablets were given to the subjects, with appropriate instructions (1 or 2 tablets daily). During the second visit, subjects returned their remaining folic acid tablets for assessment of compliance.

Within 30 min of venous blood drawing, plasma was separated in a refrigerated centrifuge at 4°C for clinical chemistry; then plasma was frozen and stored at –20°C for duplicate analyses of homocyst(e)ine by high-pressure liquid chromatography and electrochemical detection as described (17,18) (performed at ORPRC by M.R. Malinow). Plasma aliquots were protected from light, frozen, and stored at –20°C for single radioassays of folic acid and vitamin B-12 (Bio-Rad Quantaphase II; Bio-Rad Diagnostics, Hercules, CA) (performed at ORPRC by D.L. Hess). The blood buffy-coat layer was separated, mixed with three drops of dimethylsulfoxide, and the blood cell pellets were frozen and stored at –20°C for genotype analyses (performed at Fox Chase Cancer Institute, Philadelphia, PA, by W.D. Kruger). The inter-run coefficients of variation for plasma samples were 6% for homocyst(e)ine, 13.5% for plasma folate, and 14.9% for plasma vitamin B-12.

*Statistical analysis.* The frequency distributions of participants' characteristics were examined. Comparisons of categorical variables were made using chi-square or Fisher's exact tests. Unadjusted mean differences in continuous variables such as body mass index (BMI) and levels of homocyst(e)ine, folate and vitamin B-12 were assessed using the Student's *t*-test statistic. The absolute change in homocyst(e)ine was calculated as the difference between the homocyst(e)ine level of post- minus pre-folic acid supplementation [Δ homocyst(e)ine in μmol/L]. Because we had previously demonstrated that 1 or 2 mg of folic acid supplementation has similar effects on plasma homocyst(e)ine (13), in agreement with the Trialist metaanalysis mentioned above (8), results from subjects receiving 1 or 2 mg folic acid supplementation were combined in our statistical analyses.

A least-squares multiple linear regression analysis was used to evaluate the relationships among the dependent variable, Δ homocyst(e)ine, and independent variables (Table 1). A modified stepwise selection algorithm was used for development of the final model. The level of statistical significance was fixed at $\alpha = 0.05$. Variables of *a priori* interest, but which did not reach statistical significance (e.g., multivitamin use, current cigarette smoking status, and MTHFR genotype) were forced in the final model. The adjusted $R^2$ values from the final models are reported and used as a measure of the total variation in Δ homocyst(e)ine that is explained by the final multivariate model.

Logistic regression analyses were conducted to identify characteristics that predict Δ homocyst(e)ine after folic acid supplementation. The study population for this analysis included subjects in the top [increased homocyst(e)ine] and bottom [decreased homocyst(e)ine] quintiles of the distribution of Δ homocyst(e)ine, thus containing only the extreme

**TABLE 1**
**Association in a Multivariate Linear Regression Model Between Several Characteristics and the Change in Homocyst(e)ine After Folic Acid Supplementation in 247 Subjects[a]**

| Covariate | Parameter estimate ± SE | *P* value |
|---|---|---|
| Intercept | –0.551 ± 2.16 | 0.799 |
| Age (yr) | 0.035 ± 0.012 | 0.003 |
| Male gender | 0.721 ± 0.230 | 0.002 |
| Current smoker | 0.837 ± 0.472 | 0.078 |
| Basal homocyst(e)ine | –0.478 ± 0.036 | 0.0001 |
| CBS (699 T/T or C/T and 1080 C/C) | 0.681 ± 0.244 | 0.006 |
| Multivitamins | –0.043 ± 0.230 | 0.853 |
| MTHFR 677 C/T | –0.243 ± 0.229 | 0.288 |
| MTHFR 677 T/T | –0.602 ± 0.359 | 0.096 |

[a]Negative sign indicates variable is associated with lower postsupplementation homocyst(e)ine level. Adjusted *R*-squared = 47.6%. 47.6% of the total variation in homocyst(e)ine change after supplementation is explained by these variables. CBS, cystathionine β-synthase; MTHFR, methylene tetrahydrofolate reductase. T/T, C/T, and C/C refer to genetic polymorphism.

responses (data not shown in tables). The odds ratio (OR) was used as a measure of association between extreme responses to folic acid supplementation and various participants' characteristics. Logistic regression procedures were used to calculate maximum likelihood estimates for the coefficient; their standard errors were used to calculate OR and 95% confidence intervals (CI) adjusted for confounding factors. Confounding was assessed by comparing the adjusted and unadjusted OR, after entering variables into a logistic regression model one at a time (19). Other statistical analyses were performed with Microsoft Excel 7.0 (Redmond, WA), PRISM GraphPad 2.0 Software, Inc. (San Diego, CA), and SAS Statistical Software (Cary, NC).

## RESULTS

Table 2 shows the characteristics of the 304 subjects. Consumption of folic acid tablets administered during the intervention (estimated from returned pill counts) was 99.7% (13). The substantial heterogeneity in the change in homocyst(e)ine after folic acid supplementation in the 304 subjects is evident in Figure 1.

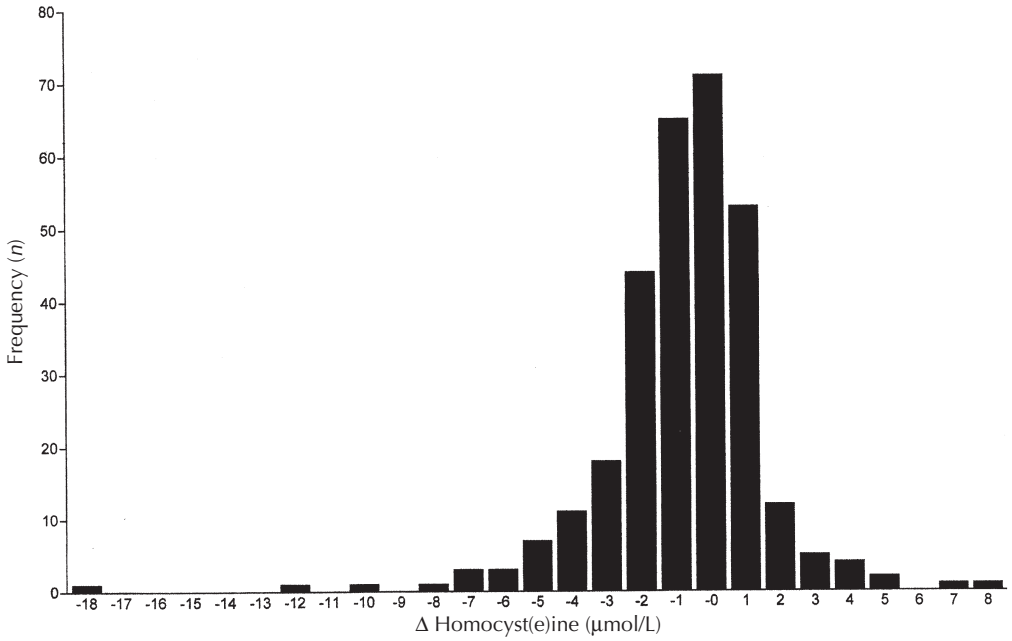

**FIG. 1.** Frequency distribution of changes in plasma homocyst(e)ine after folic acid supplementation for 3 wk in 304 subjects. Values vary between decreases of 19 μmol/L to increases of 8 μmol/L.

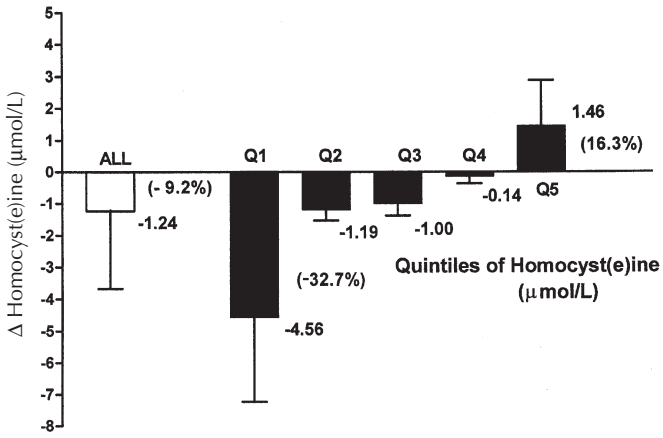

**FIG. 2.** The data of Figure 1 categorized by quintiles of change in plasma homocyst(e)ine in μmol/L. Although the overall effect was a decrease in homocyst(e)ine, an increase was observed in 20% of the subjects, whereas in the fourth quintile, only minor differences were observed that could be explained by the coefficient of variation of the method. Selected percentages indicate relative change in homocyst(e)ine. Quintiles were formed as follows: [Q1 < –2.5; Q2 = –2.49 to –1.38; Q3 = –1.37 to –0.48; Q4 = –0.47 to 0.29; Q5 > 0.30 to 7.3 (units are Δ homocyst(e)ine in μmol/L)].

There was a –1.24 ± 2.43 μmol/L mean decrease in homocyst(e)ine. The unadjusted data of Figure 1 were categorized by quintiles of changes in homocyst(e)ine to allow further analysis (Fig. 2). However, the change in homocyst(e)ine ranged from a mean of –4.56 μmol/L in the bottom quintile [decreased homocyst(e)ine] to a mean increase of 1.46 (μmol/L in the top quintile [increased homocyst(e)ine].

Males had a mean decrease of homocyst(e)ine after intervention of 0.98 μmol/L (± 1.74), whereas for women the decrease was 1.16 μmol/L (± 2.51). This difference was statistically insignificant in univariate analysis, but the result was confounded by the significantly different baseline homocyst(e)ine measurements in males and females (10.54 ± 3.14 vs. 8.53 ± 2.66, respectively; $P = 0.0001$). After adjustment for baseline homocyst(e)ine and the other factors in the model (Table 1), the difference in Δ homocyst(e)ine between males and females was 0.72 μmol/L ($P = 0.002$), with males having a smaller Δ homocyst(e)ine. As indicated in Table 1, the final regression model explained 47.6% of the total variation in homocyst(e)ine response.

Among users and nonusers of multivitamins, the mean decreases in homocyst(e)ine in the present study were –0.4 ± 1.67 μmol/L and –1.7 ± 2.74 μmol/L, respectively ($P < 0.0001$) (data not shown in tables). Because the univariate analyses suggested that the homocyst(e)ine response differs for users and nonusers of multivitamins (13), all least-square regression modeling was done for both groups separately. Results showed that although statistical significance was less frequently achieved, the β-coefficient for most of the independent variables was slightly greater for nonusers of multivitamins as compared with users of multivitamins (data not shown in tables).

Genetic polymorphisms in genes encoding two different enzymes involved in homocyst(e)ine metabolism were included in the model. These polymorphisms included the C 677T alteration in MTHFR, and the C699T and C1080T polymorphisms in CBS. Since the two polymorphisms in CBS are in strong linkage disequilibrium with each other, as shown by Kruger *et al.* (20), we decided to treat these two polymorphisms as a single variable. Therefore, individuals were grouped according to their combined genotype, i.e., individuals homozygous for C1080 and containing at least one 699T allele in one group, and all other genotypes in the other group. The MTHFR genotype was also divided into three groups, C/C vs. C/T and vs. T/T for MTHFR. When all other factors in the model were controlled for, subjects with the MTHFR genotype T/T experienced a mean 0.602 μmol/L (±0.359) greater reduction in homocyst(e)ine compared to those with the wild-type C/C genotype. Those with the MTHFR C/T genotype had a mean 0.243 μmol/L (±0.229) greater reduction.

Results from logistic regression analyses for Δ homocyst(e)ine, restricted to subjects in the top [increased homocyst(e)ine] and bottom quintiles [decreased homocyst(e)ine], were generally consistent with those from least-squares multiple linear regression analyses, although the analysis was hindered by the relatively small sample size. After adjusting for age, hypertension, gender, BMI, and cigarette smoking status, there was a very strong inverse relation between basal homocyst(e)ine and risk of increased homocyst(e)ine concentration after folic acid supplementation. For each unit increase in basal homocyst(e)ine, there was a 54% reduction in the likelihood of an increase in homocyst(e)ine after folic acid supplementation (OR = 0.46; 95% CI 0.35–0.62). Compared to females, males were 3.82 times more likely to experience an increase in homocyst(e)ine after folic acid supplementation (95% CI 1.14–12.85). Subjects above age 69 yr (OR = 1.92; 95% CI 0.60–6.15), with a history of chronic hypertension (OR = 1.57; 95% CI 0.50–4.88), or who reported cigarette smoking (OR = 4.41; 95% CI 0.82–23.51) also were more likely to experience an increase in homocyst(e)ine in response to folic acid supplementation (data not shown in tables).

A subgroup of 22 subjects was studied initially in 1995 and restudied in 1998. The basal homocyst(e)ine and folate levels in 1995 and 1998 were 9.6 ± 3.6 and 9.0 ± 2.7 μM ($P = 0.290$) and 18.1 ± 9.4 and 30.2 ± 11.8 μM ($P = 0.001$), respectively. The differences in basal folate may be related to the mandatory fortification of grain products with folic acid in the United States. since 1998 (26). Figure 3 shows the homocyst(e)ine responses in the 22 subjects studied in 1995 and 1998. Results document the marked intrasubject variability in responses.

## DISCUSSION

Following the demonstration of the inverse correlation between plasma homocyst(e)ine and folate levels (5), numerous authors have documented that folic acid supplementation in doses between 0.2 and 15 mg/d can lower plasma homocyst(e)ine concentration without apparent toxicity (4,21,22)

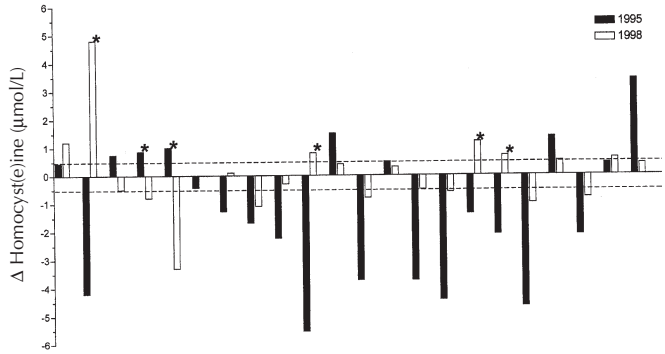

**FIG. 3.** Individual changes in homocyst(e)ine in 22 subjects studied in 1995 and 1998. Each pair of bars depicts data for a single subject in 1995 (■) and 1998 (□). Opposite responses of homocyst(e)ine in retesting, beyond the coefficient of variation of the method (indicated by dotted lines), were observed in six subjects (*).

and might beneficially modify a potentially important risk factor for vascular disease. Boushey *et al.* (23) estimated that an increased intake of folic acid ~400 μg/day would potentially prevent 50,000 deaths from vascular causes per year as a consequence of homocyst(e)ine lowering. A metaanalysis of 12 clinical studies, which included results from 1,114 patients, reported that supplementation with a mean dosage of 0.5 to 5.7 mg of folic acid per day reduced homocyst(e)ine levels by a mean of 25% (8). The smaller reduction of homocyst(e)ine (9.1%) following supplementation of 1 or 2 mg of folic acid/day in our study may be partly due to the use of multivitamins in 39.6% of the population (13). We previously have shown that the homocyst(e)ine-lowering effects of 1 or 2 mg of folic acid are similar, and that the effects of additional folic acid supplementation in users of multivitamins are minimal in most individuals (13).

In spite of the overwhelming evidence that folic acid supplementation lowers mean homocyst(e)ine levels in groups of subjects, there are occasional references of "unpredictable interindividual variation" in the response of homocyst(e)ine to folic acid supplementation (9,11). Moreover, Worley and Turi (12) demonstrated that a combination of pharmacological doses of folic acid and vitamins B-6 and B-12 failed to normalize homocyst(e)ine levels in 30 to 50% of patients with fasting homocyst(e)ine >10.5 (μmol/L, or post-methionine load homocyst(e)ine >28 μmol/L.

An apparent increase in homocyst(e)ine levels in response to folic acid fortification of grain products was also observed in recent reports of Framingham cohorts. Subjects studied before and after fortification of grain products experienced "a slight upward shift in homocyst(e)ine concentrations between examinations among those who used supplements" (24). Rader *et al.* (25) analyzed the folate content of folic acid–fortified foods and found that the measured amounts frequently exceeded the concentration recommended by the FDA (26). Their data suggest that grain products fortified with folic acid can easily provide ≥1 mg of folic acid per day in some individuals.

The results from our study demonstrated that basal homocyst(e)ine concentration, gender, CBS genotypes, and cigarette smoking influenced the response of homocyst(e)ine to folic acid supplementation. Male subjects with the lowest baseline homocyst(e)ine levels had the greatest risk of increasing their homocyst(e)ine level after treatment with folic acid. Previous univariate analyses of the response of the MTHFR genotype demonstrated a strong influence of the MTHFR T/T homozygote mutant, as well as the intake of multivitamin supplementation, on the responses of plasma homocyst(e)ine to folic acid supplementation (13). However, these effects did not attain statistical significance in the present multivariate model. Further research is needed to identify mechanisms responsible for the association between these factors and heterogeneity in responses of homocyst(e)ine to folic acid supplementation.

It is unknown whether pharmacological doses of B vitamins (including folic acid) will affect the course of atherosclerotic disease. Data from current clinical trials will probably provide an answer to this important question. Additional data are required to delineate the differential effects on atherosclerosis of changes in homocyst(e)ine levels after folic acid supplementation vs. those possibly independent, direct effects of B vitamins on atherothrombosis, or other aspects of atherosclerosis.

If the paradoxical finding of increased homocyst(e)ine in response to folic acid supplementation is confirmed, it may also have implications for the health and well-being of pregnant women and their fetuses. For example, pregnant women commonly have low homocyst(e)ine levels (i.e., <5.0 μmol/L) (27), but slightly elevated homocyst(e)ine levels (i.e., 8.7 μmol/L) may be associated with abnormal pregnancy outcomes (27). Increases in homocyst(e)ine after folic acid supplementation were observed in our study, especially when initial plasma homocyst(e)ine levels were low. If pregnant women respond similarly to routine administration of folic acid as nonpregnant women in our study, folic acid supplementation may cause mild increases in homocyst(e)ine in some individuals. If elevated levels of homocyst(e)ine are confirmed to contribute to the pathogenesis of abnormal pregnancy outcomes, an increase in homocyst(e)ine secondary to folic acid supplementation and/or fortification might have detrimental effects. Further studies are needed to evaluate this possibility.

Although folic acid supplementation lowered the mean homocyst(e)ine concentration in the present cohort, our data suggest there is considerable heterogeneity in responses to folic acid supplementation, as measured by absolute changes in homocyst(e)ine. In addition, 20% of the subjects responded to folic acid supplementation by increasing their mean homocyst(e)ine level 1.4 μmol/L. The homocyst(e)ine responses were not reproducible when subjects were retested 3 yr later. Thus, our observations suggest that repeat testing may be required to verify responsiveness of homocyst(e)ine to folic acid. The factors we studied accounted for 47.6% of the variation in the change in homocyst(e)ine after folic acid supplementation, yet about 50% of the response was unexplained by the factors studied here. Further follow-up studies are needed to (i) identify determinants of homocyst(e)ine responses to folic acid,

including the mechanism(s) responsible for a paradoxical increase in homocyst(e)ine concentration, and (ii) determine whether sustained increases in homocyst(e)ine after folic acid supplementation are associated with adverse effects on health.

## ACKNOWLEDGMENTS

We are supported in part by grants from the National Institutes of Health (RR00163) and from the American Heart Association (HDR0132562); a grant from Bio-Rad Laboratories from the Diagnostics Group in Hercules, CA; and by a Bugher Foundation and USPHS grant (HL57299).

LOCUS for Homocysteine and Related Vitamins, Armauer Hansens hus, University of Bergen, 5021 Bergen, Norway

**ABSTRACT:** The Hordaland Homocysteine Study is a population-based screening of total plasma homocysteine (tHcy) in ~18,000 men and women aged 40–67 yr that took place in 1992–1993 in the county of Hordaland in Western Norway. In this cohort, tHcy was associated with several physiologic and life-style factors, including age and gender, blood pressure, serum cholesterol, smoking, alcohol and coffee consumption, physical activity, diet, and vitamin status. All associations with established cardiovascular risk factors were in the direction expected to confer increased risk. In a subset of 5,883 women aged 40–42 yr, tHcy was associated with previous pregnancy outcomes, including preeclampsia, placental abruption, and neural tube defects. This article reviews the published results from the Hordaland Homocysteine Study in the light of relevant literature. The Hordaland Homocysteine cohort will be used for future investigations of the stability of tHcy and vitamin status over time, and to investigate associations with mortality and morbidity including cancer incidence.

Paper no. L8810 in *Lipids 36*, S33–S39 (2001).

The Hordaland Homocysteine Study is an investigation of 18,043 men and women, aged 40–67 y, living in Hordaland County in Western Norway (Fig. 1). The study was a collaboration between the University of Bergen and the National Health Screening Service. Eligible subjects were selected from the National Population Register, identified by site of residence and age on December 31, 1992, and plasma total homocysteine (tHcy) was determined in all subjects in 1992–1993. The aim of the study was to obtain cross-sectional data on the relationship between tHcy and life style and risk factors related to chronic diseases, in particular, cardiovascular disease (CVD). Furthermore, the long-term prospect of this study was to relate the tHcy concentration to future all-cause and cardiovascular mortality and morbidity. Finally, we used the collected data to assess relationships between tHcy level in 1992–1993 and previous pregnancy outcomes in the female participants of the Hordaland Study.

### *Recruitment and Data Collection*

A total of 24,815 subjects from three different age groups were invited to participate; the overall acceptance rate was 72.7%. The younger and the largest group ($n$ = 12,594) included all subjects in the county aged 40–42 yr. The older group ($n$ = 4,766) covered all subjects aged 65–67 yr in the city of Bergen. A third group ($n$ = 683), aged 43–64 yr, was a 2% random sample of residents in Bergen. Men and women in the younger and older age group represent the four main groups.

Data on type of work, physical activity, smoking habits, medical history of CVD, hypertension, diabetes mellitus, and food and vitamin intake were obtained by questionnaire. Blood samples from nonfasting subjects were collected into evacuated EDTA tubes and placed in a refrigerator (4–5°C) for 15–30 min; the plasma fraction was isolated within 1–3 h and stored at –20°C until analysis. tHcy was determined in plasma with high-performance liquid chromatography (HPLC) and fluorescence detection (1).

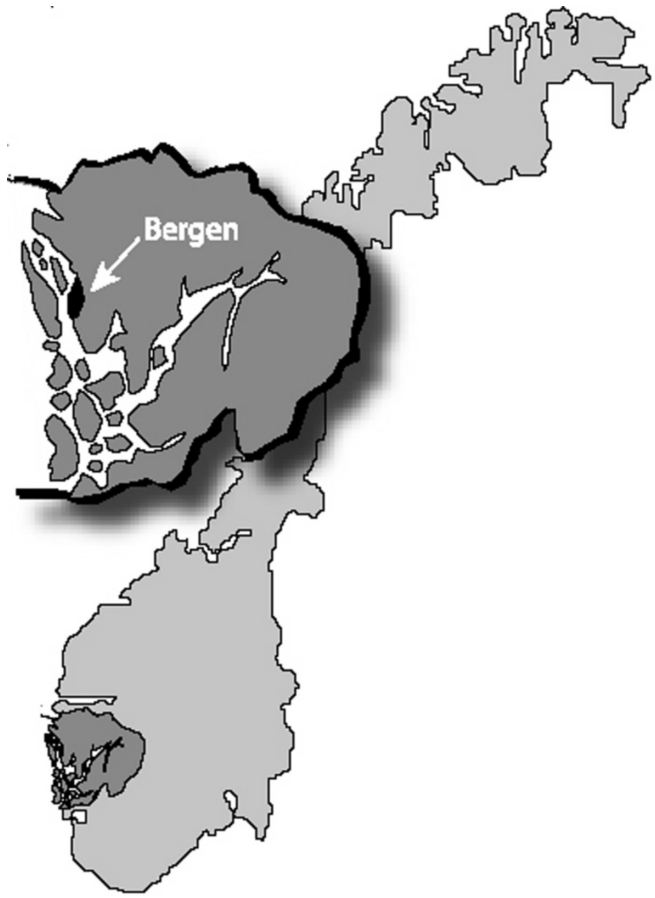

**FIG. 1.** The county of Hordaland is located on the western coast of Norway.

Abbreviations: CVD, cardiovascular disease; HPLC, high-performance liquid chromatography; MTHFR, methylenetetrahydrofolate reductase; tCys, total cysteine; tHcy, total homocysteine.

### *Age, Gender, Blood Pressure and Cholesterol*

Plasma tHcy showed a skew distribution, with a tail toward higher levels in all four main age and sex groups investigated. The arithmetic means were 11.4 μM in 5,918 healthy men and 9.6 μM in 6,348 women aged 40–42 yr, demonstrating that tHcy is ~2 μM higher in men than in women. In the oldest age group (65–67 yr), the corresponding values were 13.0 and 11.6 μM. Thus, there was an increase in tHcy by age, which was more pronounced in women than in men (2).

There are consistent data based on large populations (3,4), demonstrating age- and sex-related differences in tHcy. Higher tHcy in men than in women has been explained by difference in muscle mass and hormonal effects, whereas the age-related increase is probably due to deterioration of renal function and impaired vitamin status with age (4,5).

The Hordaland study demonstrates a positive relation between tHcy and diastolic and systolic blood pressure. tHcy also showed a positive relation to serum cholesterol. These relations were essentially confined to the younger age group, and the difference in tHcy between the extreme groups was <1 μM after multivariate adjustments (2). A weak relation between tHcy and serum cholesterol has been demonstrated in some studies (6–8). Conceivably, thyroid status is a strong determinant of both tHcy and serum cholesterol (9), and may explain the correlation between these indices. The weak association between tHcy and blood pressure is not a consistent finding (10–12).

### *Life-Style Factors*

*Smoking and alcohol.* The first large study to address these issues was the Hordaland Homocysteine Study (13). There was a strong graded relationship between the number of cigarettes and tHcy levels, independent of age and sex (2), and folate intake (14). Notably, smoking was associated with an increased mean tHcy and a shift of the whole tHcy distribution curve to higher levels, similar to that observed in populations with low folate intake (14). The effect from smoking was more pronounced in women than in men. In women aged 40–42 yr, the estimated tHcy increase corresponded to 2% per cigarette/d. Comparing never smokers with heavy smokers (≥20/d), plasma tHcy levels were 8.7 and 10.7 μM in 40- to 42-yr-old women, and 10.5 and 11.7 μM in 40- to 42-yr-old men. There was no significant difference in tHcy between former smokers and subjects who had never smoked. Among smokers, the increase in tHcy was independent of the number of years of smoking (14).

A positive relation between smoking and tHcy has been demonstrated in most (12,15–17) but not all (18) smaller studies. Smokers in general consume a less healthy diet than nonsmokers, and elevated tHcy may be related to the effect of smoking on homeostasis of B-vitamins involved in homocysteine metabolism, including folate, vitamin $B_6$, and vitamin $B_{12}$ (5).

In the Hordaland cohort, alcohol consumption showed a weak U-shaped relation to tHcy with a negative association with consumption up to 14 units per week. This effect was markedly stronger in smokers (19).

The first studies on alcohol effect on tHcy were done in abusers and chronic alcoholics, and in these subjects, a marked increase in tHcy was observed (13). A positive relation between tHcy and blood alcohol concentration in alcohol abusers has recently been reported (20). The effect of moderate alcohol consumption was investigated in the large population-based Caerphilly cohort (21), and in this study, alcohol intake was negatively associated with tHcy and showed a positive relation to folate intake. The authors suggest that the tHcy reduction is mediated by folate (21). Smaller studies have demonstrated increased tHcy or no effect from moderate alcohol consumption (13). A recent intervention trial demonstrated that consumption of liquor and red wine, but not beer, increases the tHcy level (22). The beverage specificity may be related to the large amount of folate and vitamin $B_6$ in beer and negligible amounts in red wine and spirits (22).

*Physical activity.* There was a negative relation between physical activity in leisure time and plasma tHcy in the Hordaland cohort. After multivariate adjustment, individuals reporting heavy exercise had tHcy ~0.5 μM lower than individuals who characterized themselves as sedentary (2). Other observational studies noted no (11,23) or only a minor (12) effect from physical activity. One experimental study demonstrated a moderate increase in tHcy after acute exercise, which paralleled hemoconcentration (24), whereas another study demonstrated no tHcy response (25).

*Coffee.* Daily coffee consumption was registered for 89% of the Hordaland study participants, and among these, 95% used filtered coffee. There was an unexpected and strong positive association between plasma tHcy and consumption of various types of coffee, except decaffeinated coffee. This relation was almost as strong as that observed between tHcy and smoking, and was also found in nonsmokers and at both high and low folate intake. Heavy coffee consumption increases mean tHcy by decreasing the proportion with low and intermediate tHcy (<17 μM), and in this respect can be distinguished from folate deficiency and cigarette smoking (26).

The strong effect of heavy coffee consumption on plasma tHcy has been confirmed in several recent studies (27,28). Moderate coffee consumption in the Atherosclerosis Risk In Communities (ARIC) cohort was not associated with elevated tHcy (29), but recent intervention trials demonstrated that 1 L/d of unfiltered (30) as well as filtered coffee (31) increased tHcy by ~1.5 M. The coffee effect was observed within 2 wk and was reversible (31). Serum levels of folate, vitamin $B_6$, or vitamin $B_{12}$ did not change during the coffee consumption period (31). In the Framingham offspring cohort, the tHcy rising effect was observed from coffee and other caffeine-containing beverages (e.g., cola) but not from decaffeinated coffee (28). The elevation of tHcy by coffee is probably mediated by caffeine, which may influence the cardiovascular system or kidney function, or possibly interfere with vitamin $B_6$ function (5).

*Diet and vitamins.* In the Hordaland study, we constructed and verified folate and cobalamin intake scores, based on con-

sumption of various dietary items and vitamin supplements (14). Folate derived from food showed a weaker negative relation to plasma tHcy than folate taken as supplements. We could distinguish between the reduction of high tHcy to normal levels, which is usually conferred by folate derived from food, and the reduction from normal to subnormal levels, which is attributable to intake of folic acid supplements (14).

A large and consistent literature describes the effect of B-vitamins involved in homocysteine metabolism on plasma concentration of tHcy. In folate- or cobalamin-deficient subjects, tHcy is markedly reduced by treatment with the deficient vitamin (32). In subjects with no overt vitamin B deficiency, folate supplementation induces an average reduction of tHcy by ~25% (33), and there is essentially no additional effect from vitamin $B_6$ or cobalamin (33,34). Vitamin $B_6$ supplementation alone has no or only a modest effect on fasting tHcy (35). In several large population-based studies, tHcy shows a strong, inverse relation with serum folate concentration or folate intake, a weaker relation to serum cobalamin concentration, and often no relation to estimated intake of cobalamin. Both serum level and intake of vitamin $B_6$ show a significant relation to tHcy (13,28,36). Thus, folate status in particular but also cobalamin status are established determinants of fasting tHcy, whereas the observed vitamin $B_6$ effect may represent confounding from folate, and vitamin $B_6$ seems important to control postmethionine load tHcy.

*Combined effects and tail effects.* A life-style profile that reflects the combined effect of three major modifiable tHcy determinants, i.e., folate intake, smoking, and coffee consumption, is strongly correlated with tHcy (14). Subjects with a contrasting lifestyle with respect to these factors have a difference of 3–5 μM in tHcy, a difference that is larger than the effect attributable to each factor alone. This supports the notion of different mechanisms underlying the tHcy elevating effects of smoking, low folate intake, and heavy coffee consumption. Furthermore, tHcy is essentially normally distributed in a population characterized by a high folate intake, low coffee consumption, and nonsmoking (14).

The major tHcy determinants (age, gender, coffee consumption, smoking, and no intake of vitamin supplements) show different relationships with the extremes of the tHcy distribution curve (13). Male gender, old age, and heavy coffee consumption decreased the likelihood of having low tHcy (<7 μM), but had essentially no effect on the likelihood of having moderately (15–30 μM) or markedly elevated (30–100 μM) tHcy. Thus, these factors had their main effect on the lower part of the tHcy distribution curve. In contrast, smoking and no intake of vitamin supplements decreased the likelihood of low tHcy and increased the likelihood of moderately and markedly elevated tHcy, and thereby were associated with a displacement/shift of the whole tHcy distribution curve to a higher level (Fig. 2). These distribution effects suggest different mechanisms whereby age, gender, coffee consumption, smoking, and no intake of vitamin supplements affect the tHcy concentration, but also raise the possibility that the tHcy elevation related to coffee consumption and increasing age has less adverse effects than the high levels associated with smoking and impaired vitamin status (13).

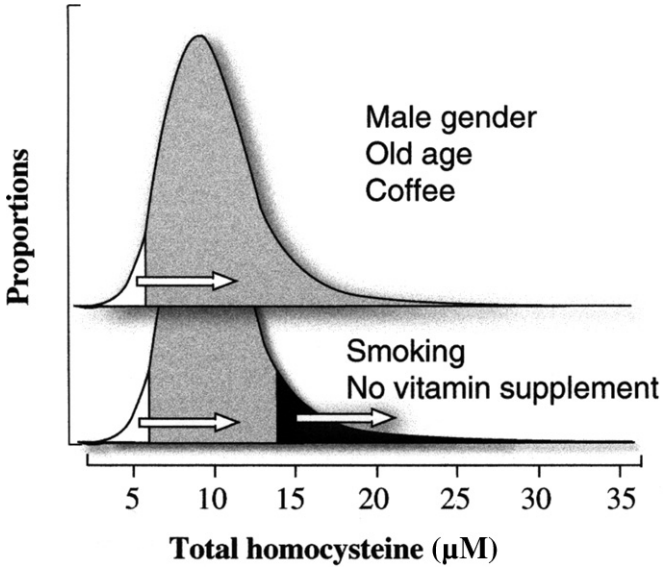

**FIG. 2.** Scheme of tail effects of total homocysteine (tHcy) determinants. The determinants gender, age, and coffee consumption, presented in the upper panel, have a selective effect on the lower part of the tHcy distribution curve. Smoking and no use of vitamin supplements (lower panel) cause a shift of the whole distribution curve to higher levels.

### *Intermediate Hyperhomocysteinemia and the 677C→T Methylenetetrahydrofolate Polymorphism*

Among the 18,043 subjects investigated in the Hordaland Homocysteine Study, 67 (0.4%) had tHcy ≥40 μM (37). Compared with controls, these subjects had lower plasma folate and cobalamin levels, lower intake of vitamin supplements, consumed more coffee, and were more frequently (60%) smokers. When seven subjects with cobalamin deficiency were excluded, 92% of these hyperhomocysteinemic subjects (compared with 10.4% of controls) were homozygous for the 677C→T methylenetetrahydrofolate reductase (MTHFR) polymorphism. These findings demonstrate a strong positive interaction between MTHFR genotype and life-style determinants of tHcy (37).

The 677C→T MTHFR polymorphism has been studied extensively during the last 5 yr because it is a genetic determinant of tHcy. MTHFR catalyzes the irreversible formation of 5-methyletrahydrofolate which serves as a methyl donor in the remethylation of Hcy to methionine (38). The T-allele codes for a thermolabile enzyme variant with low catalytic activity and reduced affinity for 5-methyltetrahydrofolate and the MTHFR co-factor, FAD. This explains the finding of elevated tHcy in subjects with the combination of the TT genotype and impaired folate status, and also the recent observation that low plasma riboflavin (vitamin $B_2$) increases tHcy in subjects with the T-allele (39). However, there is effect modification by the MTHFR polymorphism of several factors predisposing to hyperhomocysteinemia, which cannot readily be

explained by the enzymic properties of the thermolabile MTHFR variant. Thus, low serum cobalamin, renal failure, and drugs such as L-dopa and antifolate agents cause higher tHcy in subjects with the TT-genotype than those with the CC genotype (38). It therefore seems that the T-allele is associated with increased propensity toward hyperhomocysteinemia, which is in accordance with the high prevalence of the TT genotype and negative life-style factors in hyperhomocysteinemic subjects in the Hordaland cohort.

### *Total Cysteine vs. the Cardiovascular Risk Profile*

The relationship between the cardiovascular risk profile (which included life-style factors, age, gender, blood pressure, and cholesterol) and total concentration of another plasma aminothiol, cysteine, was investigated in the Hordaland cohort (40). Total cysteine (tCys) and tHcy showed a distinct and differential relation to components of the risk profile. Age, cholesterol, diastolic blood pressure, and coffee were positively related to both tCys and tHcy; body mass index showed a strong positive relation only to tCys, whereas smoking, folate and vitamin intake, heart rate, and physical activity (which were associated with tHcy) showed no relation to tCys (40).

There are a few studies (17,41–43) demonstrating significantly higher levels of plasma tCys in vascular patients than in healthy controls, suggesting that tCys is associated with cardiovascular risk. Furthermore, cysteine and homocysteine are interactive components of the plasma redox thiol status (44). Therefore, knowledge of tCys determinants is important to understand the possible pathogenic role of cysteine and to assess confounding of the observed disease-tCys relationships.

### *Pregnancy Outcomes*

Adverse pregnancy outcomes were investigated in 5,883 women from the age group 40–42 yr in the Hordaland cohort (45). Records of 14,492 pregnancies in the period from 1967 to 1996 were retrieved from the Medical Birth Registry of Norway, and outcomes were related to the tHcy level measured in 1992–1993.

The levels of tHcy in 1992–1993 showed a strong, concentration-dependent association with preeclampsia, prematurity, and low birth weight, whereas a moderate association was observed with stillbirth. An increased frequency of placental abruption was observed at tHcy > 15 μM. Plasma tHcy was also related to malformations such as neural tube defects and clubfoot, but not to orofacial cleft (45).

Of the pregnancies investigated, ~80% occurred more than 10 yr before the tHcy measurements. The associations with preeclampsia, prematurity, low birth weight, and stillbirth were strongest in the time interval closest to the tHcy determinations. Thus, the long time interval weakens the association between plasma tHcy and pregnancy outcomes.

The relationship among folate status, plasma tHcy, and pregnancy outcome has been investigated in several smaller studies (46–48). Most have a case-control design and demonstrate that hyperhomocysteinemia is associated with habitual miscarriage, preeclampsia, placenta abruption, thromboembolic events, neural tube defects, and perhaps with fetal death *in utero* and intrauterine growth retardation (46–48).

### *Prospective Analysis of Mortality*

The ability of tHcy to predict mortality was investigated in a population of 587 patients with angiographically verified coronary artery disease recruited from the Haukeland University hospital. The median follow-up time was 4.6 yr. There was a strong, graded relation between tHcy and both cardiovascular and overall mortality. After 4 yr, 3.8% of the patients with tHcy < 9 μM had died, compared with 24.7% of those with tHcy ≥ 15 μM (49). Notably, mortality rate was highest in patients with other established CVD risk factors, in particular diabetes mellitus, low ejection fraction, and elevated fibrinogen (Fig. 3). These data have inspired investigations of the association between tHcy and future CVD events and overall mortality and morbidity in the Hordaland cohort, and two Norwegian ongoing secondary intervention studies with tHcy-lowering B-vitamins in coronary patients

By the end of year 2000, there were ~35 prospective studies on the association between tHcy and CVD (50–61). About half (9 of 18) of the population-based studies and most (14 of 17) studies in clinical cohorts or in elderly demonstrated a significant positive relation. Thus, tHcy seems to be a particularly strong predictor of cardiovascular events or death in subjects with a preexisting illness, such as coronary heart disease, diabetes, or renal failure (62).

### *Conclusion and Perspectives*

The first part of the Hordaland Homocysteine Study provided cross-sectional data on the relation between plasma tHcy and several established cardiovascular risk factors and life style in a large general population ($n$ = 18,043) of men and women. The study demonstrated for the first time a positive relation between tHcy and coffee consumption, and affirmed the as-

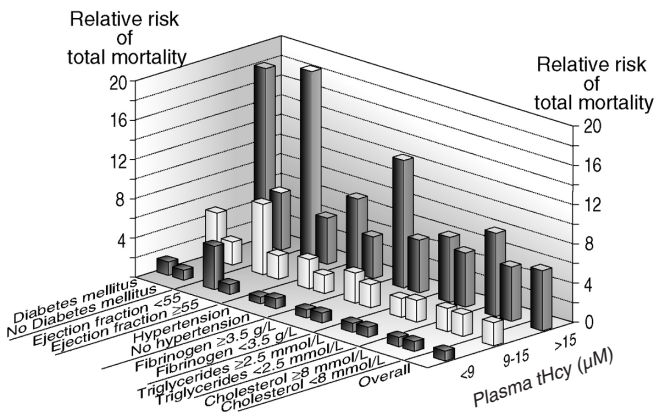

**FIG. 3.** Total mortality according to plasma total homocysteine (tHcy) and other established risk factors for cardiovascular disease. Data from Reference 49.

sociations between tHcy and age, sex, smoking, and blood pressure. The magnitude of this cohort allows the investigation of a diversity of clinical conditions related to tHcy in the same population, as demonstrated by the study on pregnancy outcomes. Ongoing and future investigations include studying the relationship between baseline tHcy and all-cause and cause-specific mortality, cardiovascular morbidity, and cancer incidence. Finally, on-going reinvestigation in 1998–1999 of ~6000 subjects from the age groups 40–42 and 65–67 yr in 1992–1993 allows assessment of the stability of tHcy and folate status over time, the relation to single nucleotide polymorphisms, and the association of two measurements with mortality and morbidity due to common diseases.

# The Oxidant Stress Hypothesis of Atherogenesis

**Luigi Iuliano***

Department of Internal Medicine, Institute of Clinical Medicine I, University La Sapienza, 00185 Rome, Italy

**ABSTRACT:** Atherosclerosis is the commonest lesion of blood vessels and is responsible for life-threatening events such as myocardial infarction and stroke. In the last two decades a series of excellent studies unraveled biochemical mechanisms that provided the background for a theory of atherogenesis. This theory is centered on foam cells and on free radical–mediated modification of low density lipoprotein (LDL). Foam cells are the main cell type of atherosclerotic lesions and originate from monocytes migrated from blood and from smooth muscle cells of the arterial wall. Foam cells are engulfed of lipids taken from LDL. Paradoxically, accumulation of LDL in developing foam cells does not occur *via* the classic LDL receptor. Incubation of macrophages with even very high concentrations of LDL does not appreciably increase cholesterol content. Chemically modified LDL easily enter the cells of atherosclerotic plaque *via* an unregulated receptor, the scavenger receptor. The most studied chemical modification of LDL is that induced by free radicals.

Paper no. L8811 in *Lipids 36,* S41–S44 (2001).

Half of the mortality in the Western population is due to disease of the cardiovascular system in which the main pathophysiologic factor is atherosclerosis. This process occurs at a young age in the arteries as accumulation of lipids in the subintimal area, known as fatty streaks (1). After years in localized areas of the arterial tree, the fatty streak undergoes changes to form an atherosclerotic plaque, which causes progressive narrowing of the lumen and eventually ischemia. The atherosclerotic plaque is composed of lipids in the extracellular space and within cells, cells, fibrosis and calcium deposits as the result of complex events of cell migration, cell growth, and apoptosis mediated by multiple cytokines and growth factors (2). Acute events associated with plaque rupture are local thrombosis and embolization, which are responsible for life-threatening events, i.e., myocardial infarction and stroke (3).

For a long time, only the manifestations of the disease and its consequences were known; the proposed biochemical mechanism of atherogenesis remained largely speculation. A central role in the atherogenic process is played by two components, i.e., cholesterol and macrophages, the cells that accumulate cholesterol in the plaque.

It has been known for many years that high levels of blood cholesterol are associated with premature death. The role of cholesterol was initially elucidated by studying familial hypercholesterolemia (FH), a clear-cut human model of premature atherosclerosis (4). FH is an inborn error of metabolism that causes very high blood cholesterol levels and heart attack in young people. Heterozygotes are frequent in the general population, accounting for 1:500 persons. They have twofold the normal cholesterol levels of low density lipoprotein (LDL)-cholesterol even before they are born, develop premature atherosclerosis, and frequently suffer heart attacks by the age of 35 yr. Homozygous individuals (1:100,000) can develop myocardial infarction even in the first 5 yr of life, and by the age of 20 yr, myocardial infarction is practically inevitable. However, there is considerable variation in the atherosclerotic disease at any given level of cholesterolemia, even in FH patients (5). On the other hand, atherosclerosis may also be present in persons with cholesterol levels <200 mg/dL; some patients with heterozygous FH and high cholesterol levels can survive until they are ≥70 yr old without signs of coronary heart disease (CHD).

Why and how cholesterol accumulates in the arteries remain largely unknown. Cholesterol is carried in plasma mainly in the LDL fraction, composed of a protein moiety, the apolipoprotein (apo) B100, an outer layer of phospholipids and free cholesterol, and a core composed of triglycerides and esterified cholesterol (6).

In 1974, Brown *et al.* (4) elucidated the receptor pathway of cholesterol influx into cells. Apo B100 binds to a specific cell membrane receptor, the complex is internalized, the protein component is degraded in lysosomes, and cholesterol is shifted into the cell cholesterol pool. Cells have fine-tuned mechanisms for cholesterol homeostasis. Intracellular cholesterol levels inhibit the activity of β-hydroxyl-β-methyl glutarate CoA reductase, with consequent inhibition of cholesterol synthesis, activate the acyl-CoA:cholesterol transferase enzyme to maintain low free cholesterol levels, and suppress the synthesis of the LDL receptor. The receptor has been shown to function in several cell types and is not present in an active form in skin fibroblasts from homozygous FH. Thus, understanding the LDL receptor pathway led to the explanation that the high plasma cholesterol of these patients was due to a reduction of LDL clearance. However, this discovery did not explain how these patients accumulated cholesterol in foam cells in the plaque. In other words, why did these patients with no B100 receptors have foam cells in plaque?

Goldstein *et al.* (7) demonstrated the absence of B100 receptor activity in macrophages that do not accumulate cholesterol

Abbreviations: apo, apolipoprotein; CHD, coronary heart disease; FH, familial hypercholesterolemia; IP, isoprostane; LDL, low density lipoprotein; MDA, malondialdehyde.

if incubated with LDL. In contrast, it was shown that macrophages accumulated large amounts of cholesterol if incubated with LDL previously modified by acetylation. Thus, it was demonstrated that a second pathway of cholesterol influx can operate in macrophages *in vitro*, and is not present in fibroblasts. This receptor, the scavenger receptor, recognizes modified LDL and is not downregulated by cholesterol influx so that the macrophage continues to take up modified LDL until it is engulfed with lipids and becomes a foam cell (8). However, acetylation does not occur *in vivo*, and the physiologic importance of this receptor remained initially unknown until Fogelman and colleagues (9) reported on the LDL modification by malondialdehyde (MDA), which derivatizes lysines as occurs with acetylation. MDA-modified LDL induced cholesterol accumulation in human monocyte/macrophages *via* the scavenger receptor. The physiologic plausibility of the MDA-modification of LDL was suggested by generating MDA-LDL after incubation of LDL with platelets (9). In fact, MDA is formed during the arachidonic acid metabolism in platelets in nearly equimolar amounts with thromboxane $A_2$. Furthermore, Henriksen *et al.* (10) showed that LDL incubated with endothelial cells could be modified to bind to the scavenger receptor, in association with the peroxidation of LDL lipids (11,12).

In the last two decades, the discovery of the scavenger receptor pathway of cholesterol accumulation in monocyte/macrophages has stimulated an extensive investigation into the mechanism of LDL oxidation and its effect on atherosclerosis. In brief, peroxidation is initiated by free radicals that attack the very highly oxidizable polyunsaturated fatty acids, cholesterol, and other LDL lipids. The source of free radicals can be cells (endothelial cells, smooth muscle cells, activated monocytes, macrophages, and neutrophils), hemoglobin, and other metalloenzymes (6). The oxidation of LDL lipids induces formation of intermediates such as MDA and other aldehydes capable of derivatizing apo B100. The final result is modification of LDL into an analog with alterations of both the protein and lipid moiety that is recognized by the scavenger receptor; it is called oxidized LDL. The lipid peroxidation of LDL is important not only for protein modification and consequent scavenger receptor binding but also because lipid peroxidation intermediates have a broad range of biological activities, i.e., the induction of endothelial dysfunction, activation of endothelial adhesiveness, monocyte differentiation, cytotoxicity, monocyte chemotactic activity, and inhibition of macrophage migration with consequent sequestration of these cells in the atherosclerotic lesion (13,14). The importance of LDL-oxidation has also been suggested by studies with antioxidants. It was shown that vitamin E and butylated hydroxytoluene totally inhibited the LDL modification by cells (11,12). Native LDL carry several antioxidants with an important protective effect toward free radical attack (6).

On the basis of these findings, a new hypothesis was constructed on the mechanism of atherogenesis based on the oxidative modification of LDL (13,15,16). This hypothesis has been supported by much experimental evidence accumulated in the last two decades, which can be summarized as follows: (i) the scavenger receptor is the pathway of cholesterol influx in macrophages, the main cell type of the atherosclerotic lesion; (ii) the scavenger receptor recognizes only oxidized LDL and not native LDL; (iii) the scavenger receptor is not downregulated by the intracellular cholesterol content, and macrophages take up oxidized LDL until engorged with lipids; (iv) LDL oxidation has been produced *in vitro* by physiologically plausible mechanisms in both cell-free and cell systems. Importantly, the cell-mediated LDL oxidation has been obtained with monocyte/macrophages, endothelial cells, and smooth muscle cells, all of major importance in the development of atherosclerotic lesions; (v) by-products of peroxidation of LDL lipids have proatherogenic activity toward all of the cells involved in the atherosclerotic process (14); and (vi) antioxidants inhibit LDL oxidation and accumulation of cholesterol in macrophages (13,15–18). Several studies have shown inhibition of experimental atherosclerosis in animal models by natural and synthetic antioxidants. These studies included cholesterol-fed rabbits, LDL receptor–deficient rabbits, cholesterol-fed nonhuman primates, cholesterol-fed hamsters, and transgenic mice (16,19).

However, what is the importance of these findings in humans? Do we have additional information on the occurrence of oxidatively modified LDL? A first body of evidence comes from the immunohistochemical studies. A series of polyclonal and monoclonal antibodies to various forms of oxidized-LDL and aldehyde-modified LDL, used in Watanabe heritable hyperlipidemic (WHHL) rabbits, stained macrophages present in fatty streak areas (20–22). A monoclonal antibody raised against 8-epi-prostaglandin $F_{2\alpha}$, a specific free radical–generated oxidation product of arachidonic acid, stained macrophages of atherosclerotic plaque of patients undergoing carotid surgery (23). In addition, autoantibodies against epitopes of oxidized LDL have been demonstrated in the serum of both animals and humans (20).

Further evidence comes from isolation of specific markers of lipid peroxidation from the atherosclerotic lesion. As early as 1952, it was reported that chloroform extracts from human atherosclerotic lesions obtained *post mortem* contained lipid peroxide and correlated positively with the extension of lesions (24). In several studies, LDL extracted from human atherosclerotic plaque resulted in LDL similar to that oxidized *in vitro*, i.e., having increased electrophoretic mobility, increased lipid oxidation products, and being taken up by the macrophage receptor (25–28). Most of these studies used methodologies (the thiobarbituric acid and iodometric assays) whose specificity and sensitivity have been questioned. In addition, lipids both of isolated LDL and plaque are intrinsically unstable and represent potential sources of artifacts during handling. The main criticism was whether these altered LDL and lipid peroxidation products were actually present in the plasma/plaque or whether they were derived from spurious oxidation *in vitro* during processing.

Evidence for the presence of lipid peroxidation products in atheroma comes from studies that analyzed markers of lipid per-

oxidation by specific and sensitive methods based on gas chromatography coupled with mass spectrometry or mass spectrometry–negative ion chemical ionization. Chisolm *et al.* (29) found 7-α-OOH-cholesterol, a product of free radical–mediated cholesterol oxidation, and Praticò *et al.* (19) found two isoprostane (IP) isomers derived from free radical–mediated arachidonic acid oxidation in freshly excised human atherosclerotic lesions obtained at carotid endoarterectomy (23). Importantly, all of these lipid peroxidation products possess biological activity (19,29). In these studies, artifactual generation of 7-α-OOH-cholesterol, and $IPF_{2\alpha}$-III and $IPF_{2\alpha}$-VI, during sample processing was taken into account. These authors injected appropriate internal standards, [$^{14}$C]-cholesterol and [$^{2}H_{8}$]-arachidonic acid, into the lesion at the time of acquisition and no formation of labeled isomers was detected.

Recently, a study from this laboratory (30) provided strong support for the theory of LDL oxidation and scavenger pathway uptake *in vivo* by injecting radiolabeled native LDL in patients undergoing endoarterectomy for critical carotid stenosis (>70%). In the same clinical model, previous studies showed that both native and oxidized LDL labeled with $^{99m}$Tc can be detected at the level of carotid plaque by noninvasive gamma camera imaging (31). This study did not reveal the site of the plaque responsible for the uptake of radiolabeled LDL, but showed the uptake of native LDL at the site of atherosclerotic plaque, suggesting the occurrence of oxidation *in vivo*. Thus, a study was planned to specifically investigate the plaque uptake of native LDL by autoradiography in the clinical setting of carotid atherosclerosis (30). This human clinical model is relevant in the field of experimental atherosclerosis because patients with carotid stenosis >70% are eligible for surgery, and the plaque obtained by endoarterectomy can be used for analytical purposes. LDL separated from patients were labeled with $^{125}$I, the tracer currently used to measure the cellular uptake of LDL *in vitro*, and several tests were used to check for spurious oxidation during handling. On the basis of these postlabeling tests (thiobarbituric acid–reactive substances, lipid peroxides, electrophoresis, dienes, and protein fluorescence), radiolabeled LDL were comparable to prelabeled native LDL. Thus, native-$^{125}$I-LDL were injected 24–72 h before surgery in patients with carotid stenosis. Carotid specimens obtained at endoarterectomy were analyzed by autoradiography and immunohistochemistry.

Autoradiography revealed intense deposition of LDL primarily in the foam cells of atherosclerotic plaque and no accumulation in the lipid core. Immunohistochemistry revealed that foam cells that had accumulated radiolabeled LDL were mostly CD68 positive, and a small number were β-actin positive. This demonstrates that LDL uptake is specific; this was further supported by injecting radiolabeled human albumin that was not followed by specific accumulation of radioactivity in the plaque.

Thus, it seems logical that accumulation of LDL within the foam cells may be explained by assuming oxidative changes of LDL. In agreement, we observed that uptake of radiolabeled LDL by plaque-resident macrophages was almost completely suppressed in a group of patients under treatment with vitamin E, 900 mg/d, in the 4 wk preceding surgery (30). Taken together, these data indicate that oxidation of LDL is important also in advanced lesions and should be taken into account in the "vitamin E controversy" at the clinical level (32,33). Thus, in selected types of patients with atherosclerosis, new clinical trials with high-dose vitamin E may be warranted.

In conclusion, the last two decades have provided a wide experimental base for understanding the biochemical mechanisms of atherogenesis. LDL oxidation by free radicals and its consequences at the cellular and vascular levels have been thoroughly investigated with the result that it is now the main and most detailed mechanism in the network of the atherogenic process.

# *In Vivo* Measurement of the Redox State

**Domenico Praticò***

Center for Experimental Therapeutics, Department of Pharmacology, University of Pennsylvania, Philadelphia, Pennsylvania 19104

**ABSTRACT:** As part of an aerobic life, we oxidize a large pool of biomolecules to obtain chemical energy. During this process, several intermediates are formed; some are chemically unstable and are referred to as free radicals (FR). FR tend to react quickly with their surrounding biological environment; depending on the nature of the molecule attacked, different reactions can occur, i.e., lipid peroxidation, protein oxidation, or DNA oxidation products. As aerobic life has evolved, antioxidant defense systems against FR have developed. When an imbalance between production of FR (oxidants) and defense systems against them (antioxidants) happens, a situation of oxidative stress occurs. This can lead to irreversible biochemical changes, with subsequent tissue damage and disease. Establishing the involvement of FR in the pathogenesis of a disease has been difficult because of the lack of sensitive and specific methodology to detect them. No ideal biomarkers for *in vivo* FR-induced damage are available as yet. However, some reliable indices of FR formation are now available, and in some pathologic conditions, evidence is accumulating to show that FR damage might play a functional role. The task for the near future will be to try to simplify the analytical methodology and elucidate the molecular mechanisms underlying the formation, disposition, and kinetics of FR marker molecules.

Paper no. L8817 in *Lipids 36*, S45–S47 (2001).

During the last decade it has become more and more difficult to read any medical journal without having some report on the involvement of "free radicals" or "reactive oxygen species" in most human diseases. There are several definitions of free radicals (FR), but they are generally defined as *"any chemical species containing one or more unpaired electrons."* As part of aerobic life, we utilize (oxidize) a large pool of biomolecules to obtain chemical energy. This means that when we oxidize these substrates, oxygen itself can become reduced and originate intermediates (including FR), which we generally call reactive oxygen species (ROS). This is a collective name that includes not only the oxygen-centered ($O2^{\bullet -}$) and hydroxyl ($OH^{\bullet}$) radicals but also some nonradical species of oxygen such as hydrogen peroxide ($H_2O_2$). Nowadays, it is well accepted that FR are continuously produced *in vivo*, some accidentally (e.g., by autoxidation reactions), some deliberately (e.g., for phagocyte killing mechanisms and intra- or intercellular signaling). Once formed, they react with their surrounding in the following two main ways: (i) with another radical to join their impaired electrons and make a covalent bond; or (ii) with a nonradical. The latter is probably the more frequent type of reaction because the majority of the molecules *in vivo* are nonradicals and contain paired electrons. Depending on the nature of the nonradical attacked, different reactions can originate, e.g., lipid peroxidation, protein oxidation, or DNA oxidation (1).

As aerobic life forms, we have evolved and developed antioxidant defense systems to protect ourselves against FR. Cells have excellent defense mechanisms against oxidative damage. Enzymes such as superoxide dismutases, catalase, and glutathione peroxidase are highly active and expressed in most mammalian cells. Cell membranes have different molecules within their hydrophobic lipid layer that can act as antioxidants in this milieu, e.g., vitamin E and β-carotene. Finally, body extracellular fluids contain a long list of proteins and low-molecular-mass molecules that can act as antioxidants. These include transferrin, haptoglobin, albumin, ceruloplasmin, bilirubin, urate, and ascorbic acid (2). When an imbalance between production of FR (oxidants) and defense systems against them (antioxidants) occurs, a situation of oxidative stress arises. This can lead to irreversible biochemical changes and subsequent tissue damage. A growing list of diseases and syndromes, ranging from atherosclerosis to cancer, have been putatively linked to oxidative stress.

What is the exact role played by FR in human disease? It is important to emphasize that oxidative stress could be as much a cause of tissue damage as a consequence of it. Establishing the involvement of FR in the pathogenesis of a disease has been very difficult in the past for two major reasons, i.e., the evanescent nature of these chemical species and the lack of sensitive and specific technology to detect them in complex biological systems (3). In the next part of this article, I will review some of the most common techniques used to measure markers of oxidative stress *in vivo*.

## *Lipid Peroxidation (LP)*

Oxidation of lipids has been recognized since antiquity as a problem in the storage of fats and oils, but only in the 1950s was it considered to be relevant to biology and medicine. Many techniques are available to measure LP when such methods are applied in *in vitro* systems (liposomes, microsomes), but concerns arise when they are applied to more

Abbreviations: FR, free radical; GC, gas chromatography; HNE, 4-hydroxynonenal; HPLC, high- performance liquid chromatography; iP, isoprostanes; LP, lipid peroxidation; MDA, malondialdehyde; MS, mass spectrometry; 8-OHdG, 8-hydroxy-2-deoxy-guanosine; 8-OHG, 8-hydroxyguanine; PG, prostaglandins; ROS, reactive oxygen species; TBARS, thiobarbituric acid reacting substances.

complex biological systems. As a general rule, it is always better to separate the product of interest before assaying the sample, in particular when complex mixtures are being studied. This can be done by high pressure liquid chromatography (HPLC) or by converting the analyte into a volatile derivative by gas chromatography (GC) and then unambiguously identifying it by mass spectrometry (MS). Although these more sophisticated analytical techniques require the most sample preparation and care, they should be the choice for investigations of LP in biological fluids (4).

### *Thiobarbituric Acid (TBA) Test and Conjugated Dienes*

Historically, these are the most commonly used tests to assess LP. They are both easy and inexpensive to perform. In the thiobarbituric acid reactive substances (TBARS) test, the material is heated with TBA at low pH and the formation of a pink chromogen is measured. The chromogen is formed by reaction of one molecule of malondialdehyde (MDA) with two of TBA. If applied to simple *in vitro* systems, this test can provide useful information, but problems emerge when it is used to assess LP in biological fluids. The specificity of the assay is improved by measurement of the TBA–MDA adducts after HPLC and GC/MS (5). Peroxidation of polyunsaturated fatty acids (PUFA) is accompanied by formation of conjugated diene structures (two double bonds separated by a single bond), which can be detected spectrophotometrically. However, many other compounds can have similar absorbance. The primary use of this test is in monitoring changes in absorbance in dynamic *in vitro* experiments of LP.

### *4-Hydroxynonenal (HNE)*

As breakdown products during LP, many aldehydes other than MDA are formed. Among them, the unsaturated aldehyde HNE has gained acceptance as an index of LP. It is volatile, very unstable, and tends to form adducts on lysine residues and the imidazole group on histidine residues of protein. It possesses several biological activities and can also be cytotoxic *in vitro*. It is generally assayed by HPLC or GC/MS (6).

### *Isoprostanes (iP)*

iP are members of a complex family of lipids, isomers of the conventional enzyme-derived prostaglandins (PG); they are produced primarily, if not exclusively, *in vivo* by a FR-catalyzed peroxidation of PUFA. Most of the work here has focused on a group of isomers of prostaglandin $F_{2\alpha}$, called $F_2$-isoprostanes ($F_2$-iP). Because of their mechanism of formation and chemical stability, they have potential as reliable, noninvasive indices of LP *in vivo*. Their analysis has been based for a long time on the highly sensitive GC/MS technique. A variation of this assay, based on an initial immunoaffinity column extraction, derivatization, and then analysis has been also described. More recently, enzyme-immunoassays have been developed for measuring a particular $F_2$-iP, 8-iso-$PGF_{2\alpha}$, now known as $iPF_{2\alpha}$-III. However, concerns have been expressed that the degree of cross-reactivity among $F_2$-iP may be high because they share the same basic ring structure (7).

### *DNA Oxidation*

FR can attack almost any cellular structure or molecule. Thus, they can cause DNA-protein cross-links; attack deoxyribose-phosphate backbone, causing base release and strand breaks; and finally, modify directly purine and pyridine bases, resulting in DNA mutations. Traditionally, direct damage to DNA by FR has been thought to contribute to aging and the development of cancer.

### *Oxidized Bases*

Oxidized bases represent one of the major classes of DNA lesions induced by FR. In the last decade, major efforts have been made to develop various assays aimed at measuring altered DNA bases. However, most of the available methods require an initial extraction from cells or tissues, followed by either chemical hydrolysis or enzymatic digestion before analysis. All of these steps could give artifactual oxidation of the normal purines and pyrimidines present in the specimen. In addition, acid hydrolysis may promote the decomposition of unstable compounds. Two major techniques have been widely applied to date, i.e., HPLC with electrochemical detection, restricted to a few electroactive oxidized bases and nucleosides, and GC/MS, which requires a HPLC prepurification step aimed at measuring a wide range of modified bases. There is also a more recent and promising HPLC–MS/MS technique (8).

In recent years, measurement of DNA hydroxylation base products has been widely used to obtain markers of *in vivo* DNA oxidation. Among these, the most popular base assayed is hydroxylated guanine, measured as the base 8-hydroxyguanine (8-OHG) or as the nucleoside 8-hydroxy-2-deoxyguanosine (8-OHdG). Urinary excretion of 8-OHdG is considered a measure of "whole-body" DNA oxidative damage. The applicability of 8-OHdG as a biomarker of DNA oxidative FR damage has been investigated in several *in vivo* studies. High levels have been described in patients subjected to whole-body irradiation, chemotherapy, or smoking. Diet can influence its levels and it may arise not only from the DNA base but also from DNA base precursors. In summary, analysis of a wide range of DNA base damage products is preferable to the analysis of a single base (9).

### *Protein Oxidation*

FR-mediated attack of protein has been studied since the beginning of the century, although the use of the products of these reactions as specific markers of oxidative damage *in vivo* has been developed only in the last few years. FR can react with proteins and modify (oxidize) both the backbone or their side chains (10).

### *Protein Backbone*

A number of mechanisms that give rise to cleavage of the protein backbone have been elucidated; it can be examined readily with isolated proteins (e.g.,SDS-PAGE or HPLC). However, its use as a marker of protein oxidation *in vivo* is very limited because of the quantity of other proteins present and the potential role of proteases. Thus, backbone fragmentation is rarely used to quantify protein oxidation in complex systems.

### *Protein Side Chains*

The reaction of FR with side-chain residues gives rise to a multitude of products that can, for example, attack amino acid residue side chains (particularly histidine, arginine, and lysine) to produce carbonyl functions (>C=O), which by reacting with 2,4-dinitrophenylhydralazine form a chromogen that can be measured spectrophotometrically. This is the base for the "carbonyl assay," which has been developed as a general method for measuring protein oxidation especially for *in vitro* systems. It has become widely used, but its use *in vivo* is problematic due to potential interference with aldehyde/ketones generated from sugar or lipids bound in the system when biological fluids are investigated (11).

In summary, three major methods have been developed for the measurement of specific amino acid side-chain oxidation products: a qualitative method based on specific antibodies that recognize episodes on tissue or isolated protein (e.g., 3-nitrotyrosine), and two quantitative methods based on GC/MS and HPLC with different detectors (fluorescence or electrochemical) depending on the oxidized molecules of interest. Both require isolation, purification, and hydrolysis of the protein under investigation before analysis of any particular oxidized amino acid side chain. Artifactual formation of oxidized amino acid during those procedures for sample preparation could be potentially serious; it is necessary to control for this using complementary approaches such as adding free parent amino acids to the sample before hydrolysis and determining their conversion in oxidized forms, or adding antioxidants to the specimen at the very beginning of the process. Much remains to be determined about the validity of such measurements, which markers most accurately reflect *in vivo* protein oxidation, and which ones are the least affected by metabolic or clearance pathways under different *in vivo* conditions.

## SUMMARY

In conclusion, from the data presented in this review, it is evident that no ideal biomarkers for *in vivo* FR damage are available to date. All of the biomarkers used so far have specific advantages and disadvantages. However, the major problem for most is that analytical methods are still quite laborious and expensive. At the same time, some reliable indices of FR-induced damage to specific cellular components are becoming available, and in some pathologic conditions, evidence is accumulating to show that FR damage might play a functional role. The task for the future will be to simplify the analytical methodology and elucidate the molecular mechanisms underlying the formation, disposition, and kinetics of marker molecules. Another important point will be the simultaneous measurement of markers representing damage to different cellular components (lipids, DNA, proteins) to evaluate any relationship among them. All of these considerations together will allow us to establish a causal relationship between the biomarker and the disease of interest.

# The Role of Antioxidants in the Mediterranean Diet

**Francesco Visioli* and Claudio Galli**

University of Milan, Department of Pharmacological Sciences, 20133 Milan, Italy

**ABSTRACT:** Traditional Mediterranean diets, as opposed to North European and American diets, include a significantly large amount of plant foods; this notable difference between the two eating styles, despite the similarities among other classic risk factors for coronary heart disease (CHD) such as high plasma cholesterol levels, has been associated with a lower risk of developing the CHD and certain cancers. The involvement of excessive free radical production and the great number of epidemiologic studies linking antioxidant intake with a reduced incidence of the above-mentioned diseases indicate that dietary antioxidants likely play a protective role. Because diets in the Mediterranean are (or better yet, were) characterized by abundant plant foods (fruits, vegetables, breads, nuts, seeds; wine and olive oil), this article includes a review of the potential activities of dietary antioxidants, which are plentiful in Mediterranean diets, and wine as related to human disease.

Paper no. L8819 in *Lipids 36*, S49–S52 (2001).

Dietary intake of fruits and vegetables has a strong and inverse association with the risk of developing coronary heart disease (CHD) and cancer (1); low amounts of plant foods in the diet double the risk of most cancers and significantly increase the risk for developing CHD (2). Traditional Mediterranean diets, as opposed to North European and American diets, include a significantly large amount of plant foods; this notable difference between the two eating styles, despite the similarities among other classic risk factors for CHD such as high plasma cholesterol levels, has been associated with a lower risk of developing the above-mentioned diseases (3). The involvement of excessive free radical production and the great number of epidemiological studies linking antioxidant intake with a reduced incidence of the above-mentioned diseases indicate that dietary antioxidants likely play a protective role (4).

Because diets in the Mediterranean are (or better yet, were) characterized by abundant plant foods (fruits, vegetables, breads, nuts, seeds; wine and olive oil), this article will include a review of the potential activities of dietary antioxidants, which are plentiful in Mediterranean diets, and wine as related to human disease.

Abbreviations: CHD, coronary heart disease; iNOS, nitric oxide synthase; LDL, low density lipoprotein; ROS, reactive oxygen species.

### *Reactive Oxygen Species (ROS) and Their Connection with Human Health*

The participation of excessive ROS production in the origination of several diseases is now supported by a wealth of experimental data. An illustrative example is the formation of oxidatively modified human low density lipoprotein (LDL), which renders these particles highly atherogenic (5). *In vivo* evidence of the formation of oxidized LDL includes their presence in human atherosclerotic plaques and in the bloodstream; further, their circulating levels have been positively correlated with the progression of carotid lesions (6). Moreover, many epidemiologic studies have correlated a high dietary intake of antioxidants (e.g., tocopherols, carotenoids, flavonoids, and polyphenols) with a lower incidence of cardiovascular disease (7,8). The features setting the Mediterranean diets apart from other diets are illustrated in various articles, but the abundance of fresh fruits and vegetables and the use of olive oil instead of hard fat are key factors for which the Mediterranean diets are renowned (9). Fruits, vegetables, wine, and olive oil (see below) are rich in antioxidants, which may therefore contribute to the observed protection from CHD.

Nevertheless, intervention studies performed with supplements have yielded mixed results. Descriptive, case-controlled, and prospective studies have shown a protection vs. cardiovascular events, whereas randomized trials have failed to confirm these results (10). Other trials are underway and may shed light on the contribution of antioxidant vitamins to a lower incidence of CHD.

## ANTIOXIDANTS IN THE MEDITERRANEAN DIET

Fruits and vegetables, in which the Mediterranean diet is very rich, represent the major source of antioxidants; they are rich in vitamins, minerals, and phytochemicals (mainly polyphenols). The relative contribution of individual compounds to human health remains unclear because of the concomitant presence of other beneficial components such as fiber and nonantioxidant molecules, which may mask or render extremely difficult the determination of the exact role of each compound. What follows is a brief overview of the biochemical aspects of each subclass.

### *Antioxidant Vitamins*

*Tocopherols.* The main dietary sources of tocopherols (notably α- and γ-tocopherols) include the following: nuts, wheat

germ, vegetable oils (i.e., seed oils), margarine, mayonnaise, butter, and eggs. It is noteworthy that although epidemiologic studies have clearly shown a correlation between tocopherol intake and protection from CHD and cancer, clinical trials have not confirmed such results (10).

*Carotenoids.* Carotenoids, the precursors of vitamin A, are found in heavily pigmented fruits and vegetables such as carrots, broccoli, tomatoes, red peppers, and pumpkins, all widely used components of a Mediterranean meal. Epidemiologic studies have found that plasma levels of carotenoids—lycopene in particular—are positively correlated with a lower incidence of CHD and lung cancer. Surprisingly, two large clinical trials (11,12) have reported a deleterious effect of β-carotene supplementation, indicating that the *in vivo* antioxidant actions of carotenoids are yet to be established. Indeed, one interpretation of the discrepancy between epidemiologic observations and clinical trials is that high circulating levels of carotenoids may simply reflect a diet rich in fruits and vegetables, which contain healthful components other than β-carotene that are responsible for the observed protective effects (13).

*Vitamin C.* Ascorbic acid in the Mediterranean area is provided by citrus fruits (orange, tangerine, grapefruit, lemon) and leafy vegetables. Vitamin C is the principal antioxidant of human plasma, and several reports add weight to the hypothesis that ascorbic acid plays a protective role toward development of CHD. For instance, Vitamin C has been shown to restore endothelial function (by plaque stabilization and enhanced vasorelaxation); thus, it may act directly on the arterial wall rather than exerting a direct action on the progression of atherosclerosis (14,15). It is noteworthy that most of the oxidative modifications of LDL take place in the aqueous phase and it is thus conceivable that water-soluble antioxidants such as ascorbate are more effective than those that are lipid-soluble. As for protection from cancer, it is conceivable that the protective role of vitamin C is due to removal, or neutralization, of exogenous noxious substances such as nitric dioxide and ozone.

*Nonvitamin antioxidants (phytochemicals).* Phytochemicals such as polyphenols are particularly abundant in the Mediterranean diet owing to its high proportion of fruits and vegetables and to the consumption of red wine and olive oil. Ubiquitous in plant foods, polyphenols include several classes of phenolic compounds such as simple phenols, phenolic acids, benzoquinones, hydroxycinnamates, and flavonoids (16). In the Mediterranean basin, because of the warm climate and the prolonged exposure of crops to sunlight radiation, some plant species such as olives and grapes are particularly abundant in polyphenolic compounds, which are synthesized by the plant in response to environmental stress. The presence of such secondary plant metabolites in the diet (the daily intake of polyphenols in the Mediterranean area is on the order of several hundreds of milligrams) has stimulated research on their "pharmacological" properties, including the possibility that the strong antioxidant activity exhibited *in vitro* by several polyphenols could explain in part the lower incidence of the diseases mentioned above.

*Wine.* The "alimentary" use of wine, i.e., wine in moderation as food, as in the case of the Mediterranean diets, very likely provides protection from coronary heart disease. In addition to the role played by ethanol itself, the protective effects of moderate wine consumption are possibly due to the healthful effects of the minor wine components, i.e., polyphenols (Table 1). For instance, the inhibition of platelet aggregation and therefore blood clotting by wine polyphenols, along with inhibition of LDL-oxidation, is likely to play an important role in CHD prevention (17). The most significant phenol in red wine, *trans*-resveratrol, has been experimentally demonstrated in mice to exert tumor-inhibiting properties (18). To date, it is difficult to distinguish between the protective effects of ethanol alone, which would imply that even beer and spirits are protective regardless of their composition, and those of minor wine components (19).

*Olive oil.* Peculiar to the Mediterranean area is the use of olive oil as the principal source of fat. As opposed to other vegetable oils, extra virgin olive oil (but not plain olive oil) contains phenolic compounds (50–800 mg/kg, depending on several factors such as the cultivar, soil, degree of drupe ripeness, and the manner in which the oil is produced and stored) that provide its unique aroma and taste. This is due to the fact that although most vegetable oils are extracted from seeds by organic solvents, olive oil is obtained from the whole fruit (drupe) by means of physical pressure, without the use of chemicals. From a nutritional point of view, it is noteworthy that the flavor of extra-virgin olive oil favors the consumption of raw vegetables, which are generally dressed with olive oil and vinegar (the latter ingredients also contain antioxidants); thus, the use of good quality olive oil likely provides indirect benefits such as an increased consumption of healthful foods.

The polyphenolic fraction amounts to 50–800 mg/kg, depending on several key factors such as the cultivar, the soil, the degree of ripeness of the drupes, and the way the oil is produced and stored. Many phenolic components have been identified and can be conveniently classified into two major subclasses, i.e., simple and complex (hydrolyzable). The former includes hydroxytyrosol [2(3,4-dihydroxyphenylethanol)], tyrosol, and phenolic acids such as vanillic and caffeic (20). The latter (complex) subclass comprises tyrosol and hydroxytyrosol esters, oleuropein and its aglycone, and several other molecules yet to be identified. Oleuropein is responsible for the bitter taste of olives and for the browning of the olive skin. Its levels slowly taper off during the late days of the ripening season, yielding

- Vasorelaxation
- Inhibition of platelet aggregation
- Inhibition of cycloxygenase-2
- Inhibition of human polymorphonuclear leukocytes

several simpler molecules that build up the full, fruity taste of the oil.

Both hydroxytyrosol and oleuropein potently inhibit oxidation of LDL in a dose-dependent manner, when incubated from $10^{-6}$ to $10^{-4}$ M (21). Also, hydroxytyrosol was shown *in vitro* to inhibit platelets, the accumulation of the proaggregant agent thromboxane in human serum, the production of the proinflammatory leukotriene molecules by activated human leukocytes; and to inhibit arachidonate lipoxygenase (22,23). The potent (50% effective concentrations in the $10^{-5}$ M range) inhibitory effect of hydroxytyrosol toward all of these parameters discloses biological activities of olive oil phenolics that go beyond their antioxidant properties (Table 2).

Finally, when added to murine macrophages challenged with bacterial lipopolysaccharide, oleuropein increases the functional activity of these immune-competent cells, as evaluated by a significant increase (+58.7 ± 4.6% at a concentration of $10^{-4}$ M) in the production of the bactericidal and cytostatic factor nitric oxide. This effect is due to a direct effect of oleuropein on both the activity and expression of the inducible form of the enzyme nitric oxide synthase (iNOS), as demonstrated by Western blot analysis of cell homogenates and by the use of the iNOS inhibitor l-nitromethylarginine methylester (24).

The adoption of phenol-rich olive oil as the fat of choice, as a substitute for animal fat, contributes to the dietary intake of biologically active compounds in estimated quantities that have been correlated with a reduced risk of developing CHD (8).

### *Bioavailability of Phenolic Antioxidants*

The lack of a reliable method for measuring the polyphenolic content of foods (25), including olive oil and wine, renders the accurate estimation of the daily intake of such compounds difficult. Nevertheless, the calculated values of daily polyphenolic consumption in the Mediterranean area fluctuate from a few hundred milligrams up to 1.5 g (7,26).

One of the major issues in the antioxidant field today concerns the bioavailability of polyphenolic compounds, and several studies are under way to investigate the absorption and metabolism of these molecules. Depending on their structure, some classes of phenolics are absorbed as they are, others are metabolized in the gastrointestinal tract, and some polyphenols (i.e., the nonextractable phenolics) are not bioavailable. Recently, Visioli *et al.* (27) demonstrated that olive oil phenolics are absorbed in humans in a dose-dependent manner, and are excreted in the urine as glucuronide conjugates (Fig. 1). Interestingly, the increased availability of phenolic substrates increases their rate of conjugation with glucuronide.

Future development of an appropriate methodology, e.g., mass spectrometry, to determine quantitatively low levels of individual compounds in foods, human plasma, and urine, along with the availability of pure and even radiolabeled standards, will help to clarify this issue.

Finally, it should be noted that, in spite of the general consensus that calls for a protective role of polyphenols, two epidemiologic studies (28,29) failed to link a higher flavonoid intake with a lower mortality due to CHD, possibly due to imperfectly accounted for confounders, such as unhealthy lifestyles (e.g., tea consumption in the United Kingdom is currently predominant among blue-collar workers and is declining in the affluent class) or preexisting unidentified coronary risk factors. Also, *ex vivo* studies on the effects of tea and red wine on LDL oxidizability have again yielded controversial results (30). A plausible explanation for this apparent contradiction between epidemiologic observations and *ex vivo* studies is that strong antioxidant flavonoids such as flavanols and catechins probably do not accumulate in LDL or they are lost during LDL isolation; indeed, in humans, LDL oxidation is likely to take place in the aqueous phase of the subendothelial space.

In conclusion, antioxidant therapy, by means of supplementation of pure compounds such as vitamins, has yet to be proved beneficial. By contrast, a plethora of epidemiologic studies continue to link certain dietary habits, such as those in use in the Mediterranean area during the mid-1940s, with a lower incidence of cardiovascular events and certain cancers. Apparently, the key factor that affords protection from such pathologies might be the intake and the interaction of several "micronutrients" provided by a healthful diet, in which the

**TABLE 2**
**Biological Activities of Olive Oil Phenolics**

- Inhibition of low density lipoprotein oxidation, both *in vitro* and *ex vivo*
- Inhibition of apoprotein derivatization
- Inhibition of platelet aggregation
- Reduced thromboxane $B_2$ and leukotriene $B_4$ production by activated human leukocytes
- Scavenging of superoxide and other reactive oxygen species
- Inhibition of peroxynitrite-induced DNA damage
- Inhibition of peroxynitrite-induced tyrosine nitration
- Scavenging of hypochlorous acid
- Increased nitric oxide production by lipopolysaccharide-challenged macrophages
- Inhibition of neutrophil respiratory burst
- Inhibition of bacterial growth and activity
- Cytostasis
- Hypotensive action

# Antioxidant Vitamins and Prevention of Cardiovascular Disease: Epidemiological and Clinical Trial Data

**Roberto Marchioli[a,*], Carlo Schweiger[b], Giacomo Levantesi[c], Luigi Tavazzi[d], and Franco Valagussa[e]**

[a]Laboratory of Clinical Epidemiology of Cardiovascular Disease, Istituto di Ricerche Farmacologiche Mario Negri, Consorzio Mario Negri Sud, Santa Maria Imbaro (Chieti), Italy, [b]Ospedale di Passirana di Rho, Milano, Italy, [c]Ospedale di Vasto, Chieti, Italy, [d]Policlinico San Matteo, Pavia, Italy, and [e]Ospedale di Monza, Italy

**ABSTRACT:** Naturally occurring antioxidants such as vitamin E, β-carotene, and vitamin C can inhibit the oxidative modification of low density lipoproteins. This action could positively influence the atherosclerotic process and, as a consequence, the progression of coronary heart disease. A wealth of experimental studies provide a sound biological rationale for the mechanisms of action of antioxidants, whereas epidemiologic studies strongly sustain the "antioxidant hypothesis." To date, however, clinical trials with β-carotene supplements have been disappointing, and their use as a preventive intervention for cancer and coronary heart disease should be discouraged. Only scanty data from clinical trials are available for vitamin C. As to vitamin E, discrepant results have been obtained by the Alpha-Tocopherol, Beta Carotene Cancer Prevention Study with a low-dose vitamin E supplementation (50 mg/d ) and the Cambridge Heart Antioxidant Study (400–800 mg/d). The results of the GISSI-Prevenzione (300 mg/d) and HOPE (400 mg/d) trials suggest the absence of relevant clinical effects of vitamin E on the risk of cardiovascular events. Currently ongoing are several large-scale clinical trials that will help in clarifying the role of vitamin E in association with other antioxidants in the prevention of atherosclerotic coronary disease.

Paper no. L8808 in *Lipids 36*, S53–S63 (2001).

In the past few years, substantial interest has successfully focused on therapeutic strategies aimed at the treatment of acute coronary events. Availability of effective drugs [e.g., thrombolytics, aspirin, β-blockers, angiotensin-converting enzyme (ACE)-inhibitors, IIb/IIIa-glycoprotein antagonists as well as of emergency coronary revascularization procedures] has led to a clear reduction of intrahospital mortality rates (1). Out-of-hospital coronary heart disease (CHD) mortality, however, remains the major component of total cardiovascular disease (CVD) mortality (2,3). This figure clearly highlights the need of effective preventive strategies for at least two main issues: (i) lowering the risk of CHD events, and (ii) reducing the lag time between the onset of coronary symptoms and the admission to hospital to allow a prompt start of acute treatments.

Although the latter is mainly a public health issue concerning the degree of knowledge people have about CHD and the organization of health systems, the former is characterized by several questions that require more research. In this sense, further research on the use of antioxidants, particularly naturally occurring antioxidant vitamins such as vitamins E and C and β-carotene, seems to be a very promising field of investigation for the prevention of myocardial infarction (MI), progression of CHD, or stroke (4–12).

Several large observational epidemiologic studies done in the 1980s and 1990s suggested that persons with a high dietary intake of fruits and vegetables have a lower incidence of ischemic heart disease (IHD) events and strokes compared with those having a low intake of these nutrients. Higher intakes of β-carotene, vitamin C, and vitamin E have been implicated in this cardiovascular protective effect. These findings are supported by experimental data showing attenuation in the development and progression of atherosclerosis in animals, by higher resistance to radical-initiated oxidation in low density lipoprotein (LDL) isolated from vitamin-supplemented individuals, and by the observation of a lower event rates among persons with dietary intake or supplementation of these vitamins (13–23). The potential benefits of these vitamins are attributed mainly to their antioxidant activities on the oxidation of LDL, which is considered to be an important step in the development and progression of atherosclerosis (24–69). This article briefly summarizes epidemiologic studies as well as randomized clinical trials with regard to the potential role of antioxidant vitamin therapy in CVD prevention.

## MATERIALS AND METHODS

*Data sources.* A MEDLINE search of scientific literature was carried out to retrieve all relevant epidemiologic studies and randomized clinical trials of antioxidants (vitamin E, vitamin C, and β-carotene) in cardiovascular disease. To enhance the completeness of the literature search, we also examined bibliographies of review articles and original articles.

*Study selection.* Only studies specifically defining the type of intake or of supplements of antioxidants were included. To have a more reliable estimate, more stringent inclusion criteria

*Address correspondence at Laboratory of Clinical Epidemiology of Cardiovascular Disease, Istituto di Ricerche Farmacologiche Mario Negri, Consorzio Mario Negri Sud, Via Nazionale, 66030 Santa Maria Imbaro (Chieti), Italy. E-mail: marchioli@cmns.mnegri.it

Abbreviations: ATBC trial, Alpha-Tocopherol, Beta Carotene trial; CARET, β-Carotene and Retinol Efficacy cancer prevention Trial; CHAOS, Cambridge Heart Antioxidant Study; CHD, coronary heart disease; CI, confidence interval; CVD, cardiovascular disease; GISSI, Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardio; HOPE, Heart Outcomes Prevention Evaluation; IHD, ischemic heart disease; LDL, low density lipoprotein; MI, myocardial infarction; OR, odds ratio; PHS, Physicians' Health Study.

were used for clinical trials, i.e., patients had to be randomly assigned to experimental treatments, >100 patients had to have been included, and treatment duration had to be >1 yr.

*Statistical analysis.* The meta-analytic tool was used to depict more clearly the amount and quality of evidence furnished by epidemiologic studies. In this sense, the use of the meta-analytic technique should be viewed as exploratory and broadly indicating the existence of an association between antioxidant nutrients and CHD. For randomized clinical trials, meta-analysis can give a more reliable estimate of the benefit (if any) associated with the administration of vitamin supplements. Such estimates, however, should be carefully evaluated according to their quality as well as the amount of information currently available, i.e., the total number of patients included in each overview.

Data from different studies were combined by using the general variance-based method (70). This method requires only information on the odds ratio (OR) estimate and its confidence interval (95% CI) for each study (71). The 95% CI were used to assess the variance of each study effect measure. Adjusted OR and their CI, when these were provided by authors, were preferred. Crude OR and their 95% CI were used when an adjusted estimate was not provided. These estimates were used to carry out the overview for all studies as well as for the aforementioned subgroups.

## EPIDEMIOLOGIC STUDIES AND CLINICAL TRIALS OF ANTIOXIDANT VITAMINS AND CARDIOVASCULAR DISEASE

### *β-Carotene*

Figure 1 shows the results of main epidemiologic studies and clinical trials of β-carotene in cardiovascular disease (72–88).

*Epidemiologic studies.* Patients ($n$ = 84,331) were enrolled in observational, prospective studies. Overall, prospective studies had positive results, thus suggesting a relevant role of β-carotene as a cardioprotective nutrient (OR, 0.66; 95% CI, 0.57–0.78). Discrepant results, however, were obtained in the three main prospective studies. The Health Professional Study (which included >39,000 men, 40–75 yr old, free of CHD, and followed for an average of 4 yr) showed a 29% reduction (95% CI, –14 to –47%) of CHD events in the highest quintile of intake compared with the lowest (72). Conversely, no association was found between β-carotene intake and CVD risk in the Nurses' Health Study (which included 87,000 women followed for an average of 8 yr) once intake of vitamin E and C was accounted for (73). Similarly, no benefit as to CHD death was evident in the study of Kushi *et al.* (35,000 postmenopausal women followed for an average of 8 yr) (74). The Finnish study on 2,748 men and 2,385 women showed a reduction in the risk of CHD death (75). A smaller study of 1,299 nursing home residents suggested a ben-

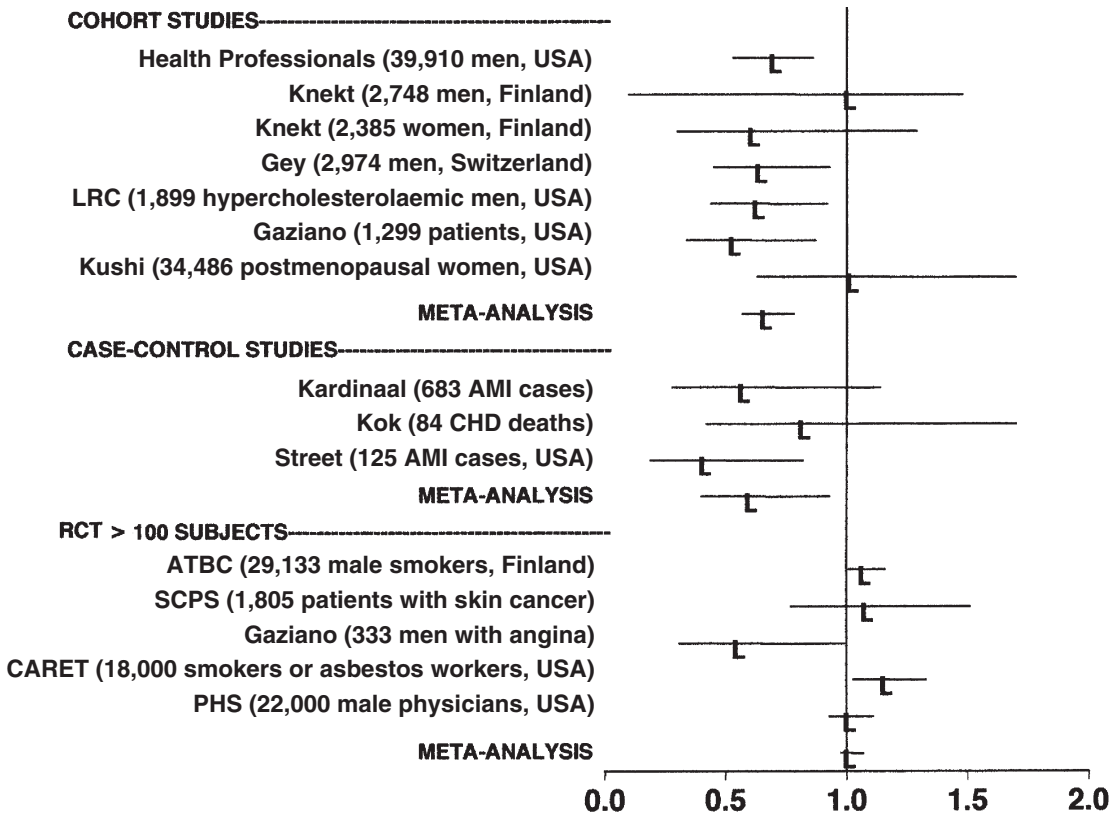

**FIG. 1.** Results of the main epidemiologic studies and clinical trials of β-carotene in cardiovascular disease. Abbreviations: LRC, Lipid Research Clinics; AMI, acute myocardial infarction; CHD, coronary heart disease; RCT, randomized clinical trials; ATBC, Alpha-Tocopherol, Beta Carotene trial; SCPS, Skin Cancer Prevention Study; CARET, β-Carotene and Retinol Efficacy cancer prevention Trial; PHS, Physicians' Health Study.

efit from high dietary intake of β-carotene (76). Various small prospective studies also found a protective effect associated with high intake of dietary β-carotene (77,78). In the case-control studies, two of three showed a significant association between high dietary intake of β-carotene and risk of CVD events (OR, 61; 95% CI, 0.40–0.93) (79–82).

*Clinical trials.* More than 71,000 subjects were included in randomized clinical trials with β-carotene. The results of trials of β-carotene have uniformly failed to show benefit in the prevention of CHD (OR, 1.02; 95% CI, 1.07) as well as of cancer. In addition, a significant increased risk of malignancy was apparent in individual studies and in the meta-analysis of their results. The Alpha-Tocopherol, Beta Carotene (ATBC) trial for the prevention of lung cancer in >29,000 Finnish male smokers tested the efficacy of 50 mg of α-tocopherol and 20 mg daily of β-carotene with a $2 \times 2$ factorial design (83). After 3 yr of study, serum levels of α-tocopherol were only modestly increased, whereas there was a 15-fold increase in the serum levels of β-carotene in subjects randomized to β-tocopherol and β-carotene, respectively. β-Carotene supplementation led to a significant increase in total mortality (+9%; 95% CI, +2 to +17%) and lung cancer (+18%; 95% CI, +3 to +36%), and a nonsignificant increase in mortality from CVD (+11%; –1 to +23%) after 6.5 yr of follow-up. The β-Carotene and Retinol Efficacy cancer prevention Trial (CARET) randomized 18,134 smokers, former smokers, and workers exposed to asbestos to supplements of 30 mg of β-carotene plus 25,000 IU of retinol or placebo (84). The CARET trial was stopped after 4 yr of followup (i.e., earlier than planned) due to a significant increase in lung cancer incidence in subjects randomized to active treatment (total mortality: +17%; 95% CI, +3 to +33%; lung cancer mortality: +28%; 95% CI, +4 to +57%; CVD mortality: +9%; 95% CI, –7 to +27%). The Physicians' Health Study (PHS) randomized 22,071 adult U.S. male physicians to receive 50 mg β-carotene on alternate days or placebo (85). No change of total mortality, cancer mortality, or CVD mortality was apparent after an average follow-up of 12 yr. Three additional smaller studies showed unclear benefit attributable to β-carotene supplementation (86–88). Interestingly, discrepant results between epidemiologic and experimental analyses became apparent in the ATBC trial as well as in the study by Greenberg and co-workers (88). In fact, the lack of association with or even the significant excess of deaths in patients allocated to β-carotene treatment was not paralleled by a similar association between plasmatic concentration of β-carotene and incidence of events in these two studies. On the contrary, a significant inverse association between increasing concentration of plasma levels of β-carotene and risk of death was apparent.

### *Vitamin C*

Figure 2 shows the results of main epidemiologic studies and clinical trials of vitamin C in cardiovascular disease (72–74, 89–94).

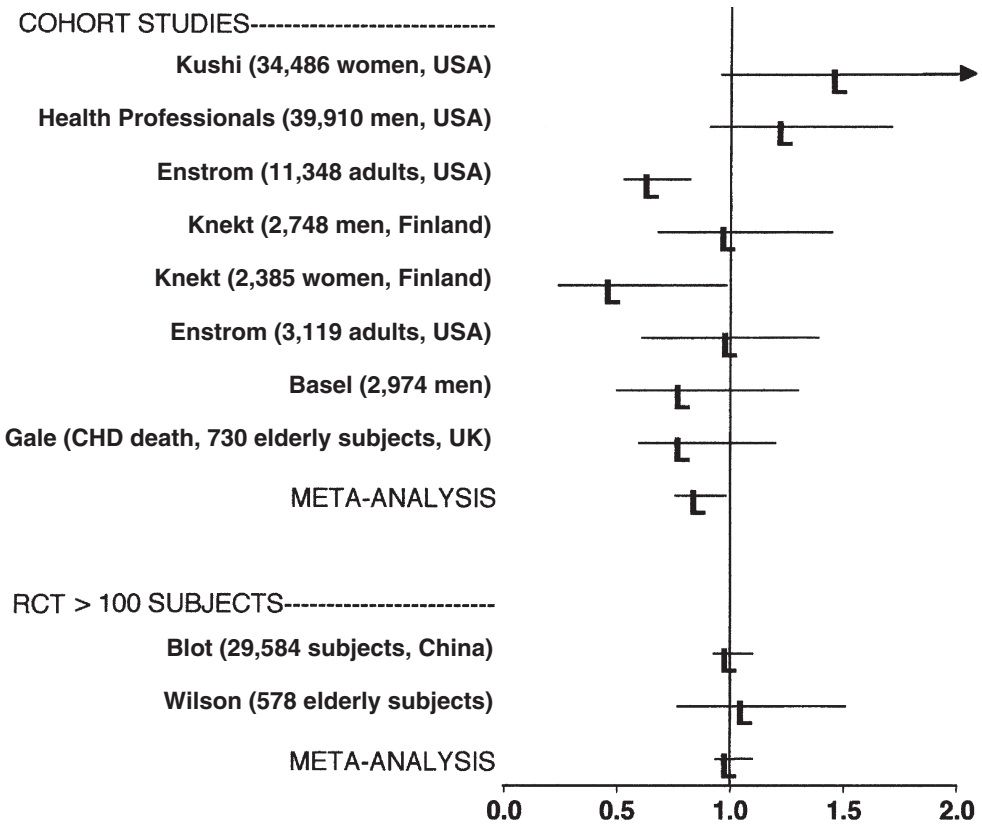

**FIG. 2.** Results of the main epidemiologic studies and clinical trials of vitamin C in cardiovascular disease. For abbreviations see Figure 1.

*Epidemiologic studies.* A number of epidemiologic studies conducted in England, Scotland, and the United States have suggested an inverse association between dietary intake of fresh fruit and vegetables, which are generally rich in antioxidant substances, and CVD mortality. Subjects ($n$ = 110,483) were enrolled in prospective studies on vitamin C; however, these had discordant results (OR, 0.93; 95% CI, 0.84–1.02). The three largest cohort studies (Kushi and co-workers, 73; Nurses' Health Study, 73; American Health Professional Health Study, 72), evaluating together more than 150,000 subjects, failed to find any association between vitamin C intake and CVD mortality. At variance with these results, the National Health and Nutrition Examination Survey, a large prospective, population-based study conducted in the United States among 11,348 adults followed for 10 yr found a 34% lower standardized mortality ratio (95% CI, –18.1 to –47.1%) among subjects consuming at least 50 mg of vitamin C per day by diet or supplements compared with those with lower intake (89). A number of epidemiologic studies found varied associations (in degree and direction) between vitamin C intake and CVD mortality and morbidity (74,75,89–92).

*Clinical trials.* Few randomized clinical trials of vitamin C (30,162 subjects recruited) have been conducted to date (OR, 1.01; 95% CI, 0.94–1.10). The Chinese Cancer Prevention trial was a large-scale randomized study of an undernourished population in Linxian County, China, designed to test the efficacy of various combinations of 10 antioxidant substances with a partial $2 \times 4$ factorial design in 29,854 subjects followed for 5 yr (94). In this study, supplementation of diet with vitamin C plus molybdenum was not associated with changes in CVD mortality. However, encouraging results were found for esophageal, gastric, and total cancer mortality. Supplementation of diet with 200 mg of vitamin C daily did not reduce mortality at 6 mon in a small trial of 578 geriatric patients (95).

### *Vitamin E*

Figure 3 shows the results of the main epidemiologic studies and clinical trials of vitamin E in cardiovascular disease (72–75, 94,96–103).

*Epidemiologic studies.* A number of large prospective epidemiologic studies have found a significant inverse correlation between vitamin E intake and risk of CVD. Overall, 166,774 subjects were studied, and there was a statistically significant reduction of deaths (OR, 0.64; 95% CI, 0.56–0.73). In the Nurses' Health Study, 87,000 women were followed for an average of 8 yr. Investigators compared the risk of heart disease among those in the highest intake category for vitamin E with those in the lowest (73). In the highest quintile of vitamin E intake group, there was a 34% reduction in risk of CHD events compared with women in the lowest quintile after adjustment for a number of potential confounding factors (including β-carotene and vitamin C). Reduced risk was seen only with vitamin E supplements (at least 100 IU daily) and not with multivitamin use. Presumably because of the low number of women with a long-term intake of vitamin E supplements, increasing duration of use did not show a dose-

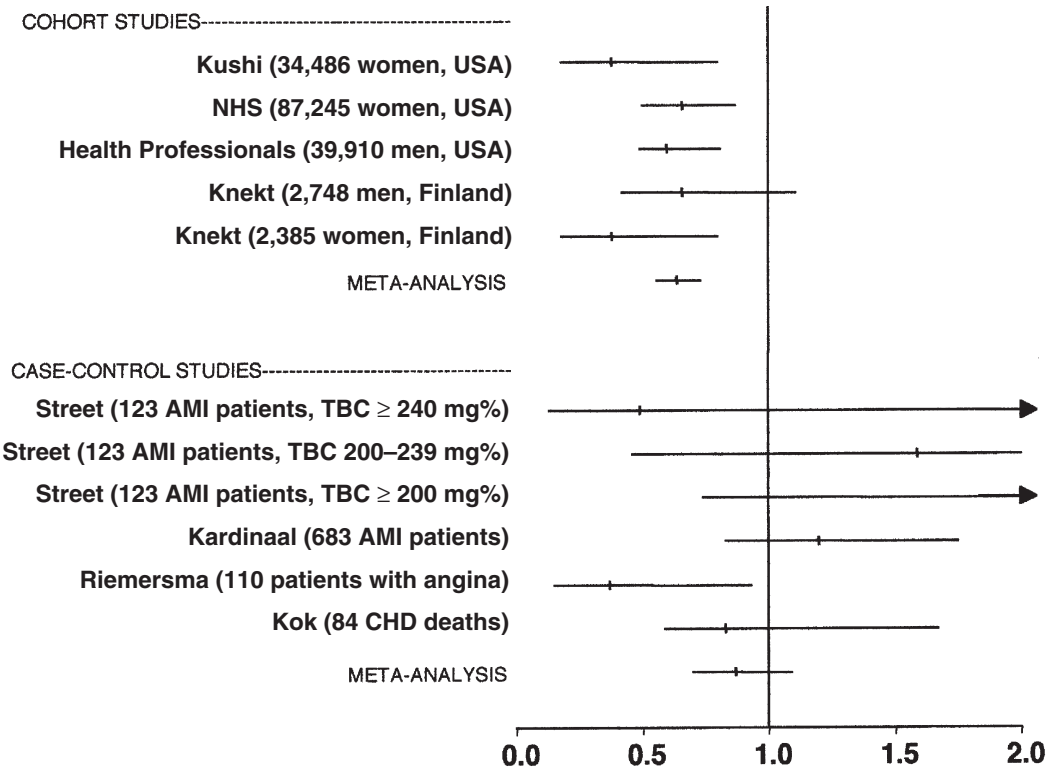

**FIG. 3.** Results of the main epidemiologic studies and clinical trials of vitamin E in cardiovascular disease. Abbreviations: NHS, Nurses' Health Study; AMI, acute myocardial infarction; for other abbreviation see Figure 1.

response relationship with the incidence of CHD events. Only use of vitamin E beyond 2 yr was significantly associated with better prognosis.

The Health Professionals' Study is a cohort of ~40,000 adult men who provided similar dietary data from a food-frequency questionnaire and were followed for an average of 4 yr (72). The Health Professionals' Study results were remarkably similar to those of the Nurses' Health Study. After controlling for age and several risk factors, there was a 39% reduction in risk of major coronary events in the highest intake category for vitamin E compared with the lowest. Short-term use of vitamin E supplements (≤2 yr) was not associated with a reduced risk for cardiovascular events. At variance with the results of the two aforementioned studies, a large epidemiologic study of ~35,000 postmenopausal women followed for an average of 7 yr found a 62% reduction (95%, CI, –0.18 to –0.80) in CVD deaths in those with higher vitamin E intake from food (74). No significant association was apparent when the intake of vitamin E from supplements as well as from supplements plus dietary sources was evaluated. In a Finnish epidemiologic prospective study, 2748 men and 2385 women were followed for an average of 14 yr. Investigators compared the risk of heart disease among those in the highest tertile of intake for vitamin E with those in the lowest (75). Men in the highest category of intake had a nonsignificant, although remarkable 34% reduction of risk of CHD death (95% CI, –58 to +11%). On the contrary, women in the highest category of intake had a significant 65% reduction of risk of CHD death (95% CI, –86 to –12%).

At least six case-control studies on vitamin E and CVD risk were published (79,81,82,96–99). They were small in size ($n$ = 1,846) and their results did not agree (OR, 0.88; 95% CI, 0.70 to 1.09). Such results are not surprising because these studies have major potential sources of error and short-term and long-term intake cannot be separated.

*Clinical trials.* Starting from the early 1950s, a number of small clinical trials in angina pectoris or intermittent claudication have been conducted (20). However, their size, the lack of a clear randomization procedure, and the use of surrogate end points (e.g., the use of nitrates, walking distance, or chest pain) hamper their usefulness. More recently, the results of two small- and five large-scale trials have been made available for a total of 80,000 subjects (83,94,100–103). Among the large-scale trials, the ATBC trial and the Chinese study were adequately sized, enrolling almost 30,000 patients each. In the ATBC trial, 50 IU/d of vitamin E showed a modest association with a lower risk of onset of angina, no reduction at all in CVD death, and slight, nonsignificant excess in intracerebral hemorrhages. In the substudy in men with previous MI, vitamin E was associated with a significant reduction of 38% in nonfatal MI but a nonsignificant increase in fatal MI (104). The Linxian trial was conducted in an unusual way in a malnourished population of China. The combination of β-carotene, selenium, and vitamin E (30 mg daily) had a marginally significant reduction in total mortality (–70%; 95% CI, –0 to –70%), which was due mainly to a reduced number of stomach cancers. A trend toward a reduction of CVD mortality, however, was also observed (–9%; 95% CI, –24 to +8%). The low vitamin E dose, the unusual population, and the complexity in study design, however, limit the transferability of this trial to other settings. The Cambridge Heart Antioxidant Study (CHAOS) is a relatively small trial in secondary prevention (101). It is a double-blind, placebo-controlled, randomized trial of 2002 patients with angiographically proven CHD. Patients allocated to the experimental arm received 400 or 800 IU of vitamin E daily and were followed for an average of 18 mon. Incidence of nonfatal MI was impressively reduced by 77% (95% CI, –53 to –9%). The combined end point of any major cardiovascular event was also significantly reduced in vitamin E recipients (–53%; 95% CI, –17 to –66%). Total and cardiovascular mortality, however, were increased in the experimental arm (total mortality +29%; 95% CI, –24 to +119%; CVD mortality, –10%; 95% CI, –39 to +96%). The short duration of the trial, the unbalanced nature of the randomized group at baseline, the unclear demonstration of follow-up completeness, the exceedingly high effect of vitamin E supplements, and the low number of events recorded in the study (i.e., 14 vs. 41 nonfatal myocardial infarctions) all suggest the need to wait for the publication of well-conducted, large-scale clinical trials before considering such promising evidence as the proof of the efficacy of vitamin E administration in patients at high CHD risk.

The Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardio (GISSI)-Prevenzione trial enrolled 11,323 men and women with a recent MI, who were allocated to vitamin E (300 mg/d) or no treatment in a four-arm trial over a 3.5-yr period (102). In the four-way analysis, the main study end points were not significantly reduced, although a significant reduction of fatal cardiovascular events was observed. In an additional analysis carried out according to the administration of vitamin E as a whole (two-way analysis), vitamin E intake was not associated with a reduction in cardiovascular events, although a nonsignificant trend toward lower fatal but not nonfatal cardiovascular events was observed.

Finally, the Heart Outcomes Prevention Evaluation (HOPE) trial randomized 9,541 high risk men and women according to their previous vascular event or diabetes associated with one risk factor (103). Vitamin E (400 IU) had no effect on death from CVD or IHD, nonfatal MI or stroke events. Tables 1–3 summarize the main findings in the four trials done in Europe and America on the effects of vitamin E on death from CVD and IHD and nonfatal MI.

*Comments on studies on vitamin E.* Large observational studies done in men and women mostly without CVD showed a significant lower rate of IHD events associated with vitamin E supplement or dietary intake. The different randomized trials on vitamin E can be divided according to the participants with and without CVD such as previous MI, defined coronary artery disease, stroke or peripheral artery disease. In the nearly 60,000 participants without CVD, vitamin E did not have a significant effect on IHD, total stroke events, or

peripheral artery disease. These results were consistent across a range of low or high doses of vitamin E used with other nutrients as in the Chinese Study (30 mg, β-carotene with selenium) and ATBC (50 mg alone or with β-carotene), and vitamin E alone in the participants with diabetes without CVD in the HOPE study (400 IU). In these studies, the vitamin was administered for a mean duration of 4.5–6.1 yr.

In the participants with CVD, vitamin E alone appeared to reduce the occurrence of nonfatal MI in the 1,035 patients with coronary disease in the CHAOS study (400 or 800 IU) and in the 466 patients with previous MI (50 mg) in the ATBC subgroup study (101,104). In the CHAOS study, the benefit of a 77% risk reduction in nonfatal MI within a relatively short period (1.4 yr) with no effect on fatal cardiovascular event is surprising. It is possible that the findings in this trial may be attributed at least in part to important imbalances in the baseline characteristics between the participants allocated to vitamin E and those to placebo, or to a type 1 error due to chance. The evidence for a benefit from the CHAOS study is not persuasive. In the subgroup analysis from the ATBC involving male smokers with a previous MI, there were only 40 nonfatal MI in the vitamin E group. In this subgroup, there was a nonsignificant increase in fatal IHD, and when associated with β-carotene, the decrease in nonfatal MI was no longer significant (101). Furthermore, these observations were not supported by larger trials such as the GISSI (300 mg) and the HOPE participants (400 IU) with CVD (102,103). Thus, in patients with a previous reported CVD, the overall evidence indicates that vitamin E administered for 3–6 yr does not improve prognosis in low- or high-risk persons. The latter large-scale clinical trials, however, were designed and powered to catch a 20% relative difference in risk of events, which was considered to be clinically relevant and worth pursuing with medical interventions. This means that a lower protective effect of vitamin E in the long term cannot be excluded.

In 1995, Steinberg (105) made the point that assessing the effect of antioxidants such as vitamin E over a 4- to 6-yr period of time, similar in duration to other intervention trials on lipid lowering or antiplatelets, was most likely not long enough. Vitamin E is hypothesized to reduce new plaque formation and early lesion progression in rabbits and nonhuman primates, instead of having an effect on reduction of the atherosclerotic lesions or on the stability of the plaque (14,106). For this reason in part, the HOPE trial is continuing the followup with the vitamin E arm for another 3 yr. However, it should be noted that trials such as the PHS conducted over a 12-yr period involving β-carotene failed to show any effect (85). Nevertheless, longer trials with vitamin E are warranted. A second issue is whether the current trials enroll the best population with which to assess the effects of vitamin E. It is possible that the participants in most of these randomized trials already had well-established atherosclerosis, which may require a longer duration of observation to detect the effect of vitamin E, if it is attenuating only the development of new lesions but not the progression of established lesions.

In the different randomized trials, the doses of vitamin E used were different. However, in all trials, the plasma levels of vitamin E were significantly increased from the baseline; however, despite the various doses, the levels were not markedly different. The possibility that use of a high dose of vitamin E for a long period of time may induce some prooxidant effects as demonstrated *in vitro* cannot be excluded. It is also possible that in the presence of other antioxidants such as vitamin C and ubiquinol, vitamin E may not have a prooxidant function (107). As discussed for β-carotene, it is possible that vitamin E requires some co-factor(s) or other vitamin(s) (e.g., vitamin C) to have a prolonged antioxidant effect. Trials currently in progress are assessing such associations (108,109).

## DISCUSSION

According to randomized clinical trials, which have taken place mostly in men, β-carotene does not reduce cardiovas-

cular events. In fact, in men who smoke or had smoked or had been exposed to asbestos, β-carotene increased the risk of mortality and, in those who had a previous MI, the risk of death from IHD. Furthermore, in male smokers, β-carotene may increase the risk of intracerebral hemorrhage. In women, most large observational studies did not show any cardiovascular effect. Thus, there is no evidence to recommend β-carotene to adults to prevent IHD or stroke. According to the results of trials in subjects at high risk of lung cancer, it is likely that the use of β-carotene supplements in such subjects could cause real harm, i.e., produce at least 1 excess lung cancer per 1000 high-risk subjects treated per 1 yr. To explain such unexpected results, it has been suggested that high-dose supplements of β-carotene could have prooxidant effects *in vivo*; for instance, it is now known that reactive epoxides and other oxidation products of carotenoids can be formed *in vivo*. Such substances could in turn exert negative biologic effects [e.g., oxidized β-carotene could increase the formation of benzo(α)pyrene-DNA adducts]. The discrepant results of epidemiologic studies and clinical trials with β-carotene are disappointing and highlight the need for basing firm conclusions on the efficacy of antioxidant supplements only on the results of large-scale, well-designed, randomized clinical trials because observational studies are flawed by several limitations. Differences in study design, characteristics of populations, assessment of intake of antioxidants, end points, and length of followup hamper a precise estimate of the magnitude of the association between antioxidant levels (measured as dietary intake or blood levels) and the risk of CVD (Table 4).

The observational studies and randomized trials on vitamin C and cardiovascular events are limited. Nevertheless, there is no evidence now to recommend the administration of this vitamin to reduce cardiovascular events.

Vitamin E administered in persons without or with IHD during a period of 4 yr does not reduce the risk of IHD and all stroke events, and does not have a significant deleterious effect. In male smokers, vitamin E has no beneficial effect on the incidence or progression of intermittent claudication. There is no justification to prescribe this vitamin to prevent CVD until the results of the current trials in progress are known. It is possible that vitamin E associated with a co-factor or another vitamin such as vitamin C may reduce cardiovascular events. However, such recommendations must be confirmed by randomized trials before any recommendation is made. Major discrepancies exist between the findings of observational studies and randomized trials. Perhaps, in randomized trials, the limited (5–6 yr) allocation of vitamin E or the absence of administration of other cofactors found in fruits and vegetables with the vitamins may explain the discrepancies. Randomized trials in progress are addressing some of these issues.

The efficacy of antioxidants is a major issue for CVD prevention. The great improvement in the treatment of acute coronary events has impressively reduced in-hospital mortality (1). Recent estimates of international CHD mortality trends suggest that out-of-hospital mortality is the major component of CHD death rates (almost two-thirds), and it is apparent that only thoughtful preventive strategies can lower such a burden (3).

On the other hand, nutrition is a very complex research topic in CVD, and only recently has the interest of researchers shifted from the evaluation of the effects of diet on blood lipids to other components of diet. Various epidemiologic studies suggest an inverse association between dietary intake of fruit and vegetables and CVD (110,111). However, it is not clear whether an individual component of the diet (antioxidant vitamins, low intake of saturated fatty acids, high intake of unsaturated fatty acids) or a particular combination of nutrients or dietary habits might exert full cardioprotective effects (20,23,24,112–117).

It is important to underline that CHD risk could be lowered either by reducing the level of selected risk factors (e.g.,

**TABLE 4**
**Limitations of Epidemiologic Studies**

| Case-control studies |
|---|
| 1. Sample size, quality of information on exposures, biases in cases and control selection, differential misclassification, and recall bias. |
| 2. Blood levels of vitamins assessed with a single measurement some time after the index event, thus not allowing a distinction between short- and long-term exposures to usual blood levels. |
| 3. Time from blood collection to laboratory dosages, i.e., long-term storage of blood samples tends to decrease vitamin levels. |
| **Cohort studies** |
| 1. Existence of various confounders that could lead to underestimation as well as overestimation of results (the discrepant results of cohort studies and randomized clinical trials on carotene are paradigmatic). |
| 2. Existence of confounding factors that were either not measured or controlled for in multivariate analyses. |
| 3. Subjects taking vitamin supplements may have been more health conscious than nonusers. As such, they had more regular physical activity, did not smoke or were light smokers, had healthier dietary habits, and were more often users of acetylsalicylic acid or estrogen replacement therapy. |
| 4. The precision and reliability of nutrient intake ascertained by means of food-frequency questionnaires is questionable. |
| 5. The intake of antioxidant vitamins as dietary supplements could be viewed as an indicator of other protective health or life style habits. Statistical adjustment in multivariate models cannot eliminate the effects of such confounders if they were poorly measured or not measured. |
| 6. Intake of vitamin supplements could be only a piece of a more complex pattern of healthy habits of life that cannot be separated into their individual component parts. |
| **Randomized clinical trials** |
| 1. Supplementation of diet with individual antioxidants could not exert its optimal effects because of the concerted mechanism action of the antioxidant system, which could require the availability of "harmonized" levels of various antioxidants. |
| 2. Choice of the right antioxidant, i.e., the intake of vitamin E, C, and β-carotene could be a marker for the intake of another not yet identified or measured antioxidant substance, which is in turn responsible for the protective effect attributed to the aforementioned vitamins (e.g., intake of other carotenods such as lutein and zeaxanthin contained in dark green, leafy vegetables, flavonoids such as quercetin, phytoestrogens, and phenol-derived substances). |

blood lipids) or by increasing the level of "protective" factors, such as antioxidants or unsaturated fatty acids (118). In addition, the efficacy of dietary interventions aimed at reducing the level of blood lipids is somewhat unclear. A meta-analysis of metabolic ward studies on the cholesterol-lowering effects of replacing 5% of energy as dietary saturated fatty acids with polyunsaturated or monounsaturated fatty acids suggests that total blood cholesterol can be reduced up to 39 and 24%, respectively. Similarly the reduction of dietary cholesterol intake by 200 mg can lower total blood cholesterol by 13%. All of the aforementioned changes could lower total blood cholesterol up to 76% (119).

However, the results of multifactorial studies aimed at improving life style habits and reducing risk factor levels in the population at large suggest that in free-living subjects, total blood cholesterol can be reduced by 0.14 mM (5 mg/dL), smoking prevalence by 4.2%, and systolic and diastolic blood pressure by 4.2 and 2.7 mm Hg, respectively (120). Studies evaluating the cholesterol-lowering efficacy of low-fat diets, such as the American Heart Association Step 1 and 2 diets, can decrease total blood cholesterol by 3.0 and 5.8%, respectively. Dietary intervention studies aimed at increasing the polyunsaturated/ saturated fatty acids showed better results, with decreases of total blood cholesterol up to 7.6%. Even though these results suggest a limited efficacy of cholesterol-lowering diets in free-living subjects, the potential protective effect of correct dietary habits cannot be discarded. The decrease of saturated fatty acids, in fact, is accompanied by an increase in the intake of unsaturated fatty acids as well as of antioxidant substances, i.e., nutrients that could have cardioprotective effects by themselves. An exploratory analysis conducted in the Nurses' Health Study database, for example, suggests that the substitution of mono- or polyunsaturated fatty acids for saturated fatty acids or *trans* fatty acids (equivalent to 5% of the total energy intake) could be associated with a 30–50% reduction in the risk of CHD events (120).

Finally, it should also considered that not only the quality of diet but also the quantity of food can be associated with different quality and duration of life. For instance, experimental studies in animals suggest that the amount of food eaten lifelong could be associated with a prolonged life, i.e., thinner animals live longer than fatter ones (121). In this sense, the ever-increasing prevalence of obesity in Western countries is disturbing.

In conclusion, no positive suggestion can be given at present concerning the use of vitamin supplements. The best possible advice is extremely close to common sense derived from clinical experience, i.e., eat less; increase the intake of fruit and vegetables, vegetable oils, and unsaturated fats; and lower the intake of animal fats. Better life style habits, including regular physical exercise and avoidance of cigarette smoke, could significantly reduce the burden of CVD. It would be advisable that agricultural and food industries, with the help of government agencies, agree to make healthy foods available at reasonable prices.

# Marine n-3 Fatty Acids: Basic Features and Background

**Erik Berg Schmidt[a,c,*], Jeppe Hagstrup Christensen[b], Inge Aardestrup[c], Trine Madsen[a], Sam Riahi[b], Vibeke Ellegaard Hansen[a], and Helle Aarup Skou[a]**

[a]Department of Medicine Hjorring/Bronderslev Sygehus, [b]Departments of Nephrology and [c]Clinical Biochemistry, Aalborg Hospital, Denmark

**ABSTRACT:** There is some evidence from epidemiology that intake of n-3 polyunsaturated fatty acids (PUFA) from seafood may protect against coronary artery disease (CAD). This hypothesis is further supported from animal data showing a beneficial effect of n-3 PUFA on thrombosis and atherosclerosis in animals fed fish oils in most, but not all, studies. There are several mechanisms by which an increased intake of marine n-3 PUFA may protect against CAD; the most universal finding is a reduction of plasma triglycerides. It is puzzling, however, that a very low amount of n-3 PUFA, with no known beneficial biochemical effects, seems to be cardioprotective. It has therefore been of paramount interest to perform clinical trials. Such evidence and trials are discussed in later chapters, and the results have been very encouraging.

Paper no. L8803 in *Lipids 36*, S65–S68 (2001).

This article will first review basic features about the composition of different types of fatty acids. We will primarily deal with n-3 polyunsaturated fatty acids (PUFA) derived from seafood and their content in various types of seafood. We will then address the background for the interest in n-3 PUFA as a way to reduce coronary artery disease (CAD) and comment on their potential beneficial and detrimental biochemical effects in relation to CAD. Other chapters will deal specifically with the effect of n-3 PUFA in atherogenesis, thrombogenesis, and in particular, their effect in clinical trials with hard endpoints—the cornerstone of evidence-based medicine.

### *n-3 PUFA—An Introduction*

Fatty acids are separated into saturated (no double bonds), monounsaturated (one double bond), and PUFA (more than one double bond) with important examples of PUFA shown in Figure 1.

The n-3 PUFA are members of an essential fatty acid family characterized by having their first double bond at carbon atom number 3, as opposed to the other essential fatty acid family, n-6 PUFA, whose members have their first double bond at carbon atom number 6, counted from the methyl end of the carbon chain constituting the backbone of fatty acids (1).

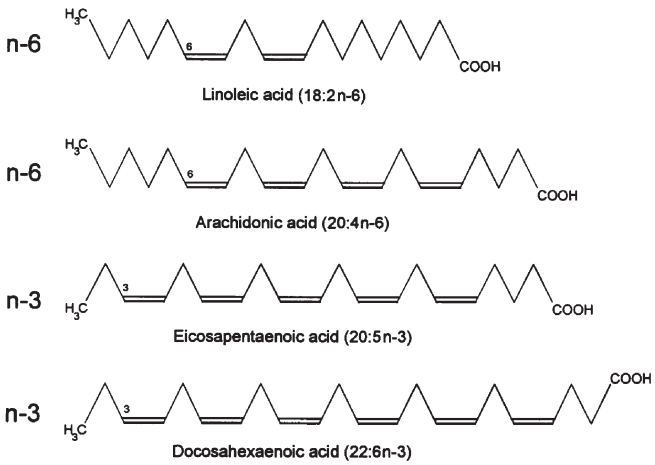

**FIG. 1.** Major n-3 and n-6 PUFA. The number of carbon atoms is given before and the number of double bonds after the colon. The position of the first double bond counted from the methyl end of the fatty acid separates PUFA into n-3 or n-6 PUFA.

There are two subgroups of n-3 PUFA. One is α-linolenic acid derived from plant oils (canola oil, rapeseed oil, and linseed oil) composed of 18 carbon atoms and 3 double bonds (nomenclature 18:3n-3). The daily intake of this fatty acid in Denmark is ~2 g/d. The other group of n-3 PUFA is derived from seafood; the major marine n-3 PUFA are eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3). Because of their larger number of carbon atoms (20 and 22, respectively), these are also sometimes called long-chain n-3 PUFA. α-Linolenic acid can to some (disputed) degree be elongated and desaturated in humans to EPA and DHA; otherwise, EPA and DHA are acquired only from seafood.

The content of n-3 PUFA varies among fish species. It is high in fatty fish such as mackerel, herring, and salmon and low in lean fish such as flounder and cod (Table 1, adapted from Ref. 2). It is worth noting that the content of n-3 PUFA in seafood varies considerably in relation to the location and the time of year of capture (2,3). Furthermore, the way the fish is prepared is also important. It is therefore very difficult to estimate the amount of n-3 PUFA ingested in populations and also in (long-term) clinical trials with fish as the source of n-3 PUFA.

The intake of long-chain marine n-3 PUFA varies considerably among populations; intake is very high in traditionally living Greenland Eskimos (10-14 g/d), low in Western populations (<0.5 g/d), and intermediate in countries such as Japan

**TABLE 1**
**The Approximate Content of n-3 Polyunsaturated Fatty Acids (PUFA) in Seafood[a]**

| Seafood | g n-3 PUFA/100 g |
|---|---|
| Mackerel | 1.8–5.3 |
| Herring | 1.2–3.1 |
| Salmon | 1.0–2.0 |
| Trout | 0.5–1.6 |
| Tuna | 0.5–1.6 |
| Halibut | 0.5–1.0 |
| Shrimp | 0.2–0.4 |
| Cod, plaice, flounder | ~0.2 |

[a]Depends on variables such as season and place of capture.

and Norway (1-3 g/d). The content of n-3 PUFA in cod liver oil is ~20%, and can be up to 90% (30–60% in many preparations) in fish oil capsules.

## *Epidemiology*

There is some evidence from epidemiologic data that populations with a high intake of marine n-3 PUFA have a low risk of CAD. This has been shown most clearly in Greenland Eskimos (4), but a low occurrence of CAD has also been reported in Alaskan Eskimos (5). In studies from Japan, the incidence of CAD was also lower in fishing villages compared with farming villages with a lower intake of fish (6). The possible association between consumption of seafood and CAD has also been studied in Western populations with an average intake of n-3 PUFA <0.5 g/d. In Zutphen, a Dutch area included in the Seven Countries Study, an inverse correlation between fish consumption and CAD was reported in middle-aged men during 20 yr of follow-up (7). A similar inverse correlation between heart disease and fish consumption in Caucasian populations was reported by some, but not by all investigators (for review see Refs. 1 and 8). Importantly, only in the study from Finland (9) was there a positive correlation between fish consumption and CAD, which the authors attributed to a high content of mercury in the fish consumed. In the Health Professionals Study, there was no correlation between fish consumption and CAD, but an inverse correlation between dietary α-linolenic acid intake and CAD was noted (10). In a recent review of the literature, Marckmann and Grønbœk (8) concluded that fish consumption at 40–60 g daily markedly reduced CAD mortality in populations at high, but not low risk for CAD.

Finally, it is of interest that fish consumption in the Physicians Health Study had no protective effect against cardiovascular mortality, but total mortality and the risk of sudden cardiac death were indeed reduced in those who ate fish (11).

It is puzzling why an intake of fish (and n-3 PUFA) of this order of magnitude seems to offer protection against CAD, because the beneficial biochemical effects of n-3 PUFA (see below) have not been shown at this low dosage (1). The possibility that components in fish other than n-3 PUFA might contribute to this effect therefore must be kept in mind, and it may be that fish consumption is associated with a healthier lifestyle including more prudent dietary habits.

## *Marine n-3 PUFA and Risk Factors for CAD*

The risk of CAD is determined in part by inherited genetic traits, age, and gender, all risk factors that cannot be modified. Known modifiable risk factors for CAD include smoking, hypertension, adiposity, high plasma levels of low density lipoprotein (LDL) cholesterol, and low levels of high density lipoprotein (HDL) cholesterol; the effect of hypertriglyceridemia on cardiac risk remains controversial (12,13). High levels of plasma homocysteine, fibrinogen, and coagulation factor VII as well as impaired fibrinolysis are also associated with an increased risk of CAD (12,13). Several other risk factors for CAD have been proposed and the list of risk factors grows steadily with new research (14).

The effect of n-3 PUFA on risk factors for CAD has been investigated in many studies (1). Although dietary n-3 PUFA in practical doses (in contrast to common public belief) have no effect on LDL cholesterol levels, they slightly increase the antiatherogenic $HDL_2$ cholesterol, and substantially decrease plasma triglycerides (15,16). n-3 PUFA may also decrease blood pressure by 2–5 mm Hg, in particular in patients with high blood pressure (1,17). Most studies have shown no effect of n-3 PUFA on plasma fibrinogen and coagulant factor VII levels (1), but n-3 PUFA do slightly reduce platelet reactivity and may impair fibrinolysis (1). Other potential effects of n-3 PUFA with respect to preventing atherosclerosis and thrombosis by modifying risk factors for CAD include a reduction in leukocyte reactivity, an improvement of vessel wall function, and a beneficial effect on blood rheology (1,18). The biochemical effects of n-3 PUFA are commonly seen after daily doses between 2 and 5 g and are dose dependent; the most favorable effects are achieved with the higher doses of n-3 PUFA (1).

The concept of assessing the individual risk of CAD as the sum of risk factors, instead of focusing on single risk factors, e.g., high plasma cholesterol, is very important as stressed in the recently published guidelines on prevention of CAD (12,13). n-3 PUFA induce several beneficial changes in risk factors (Table 2), which in our view make them very attractive in the prophylaxis and treatment of the multifactorial disease, CAD (19).

**TABLE 2**
**Suggested Beneficial Effects of n-3 Polyunsaturated Fatty Acids (PUFA) in Coronary Artery Disease (CAD)[a]**

| Monocyte reactivity ↓ |
| Neutrophil reactivity ↓ |
| Blood pressure ↓ |
| Improvement of vasoreactivity |
| Antiarrhythmic properties |

[a]↑ represents an increase; ↓ represents a decrease.

### *n-3 PUFA: Types and Safety*

Lean fish provide low amounts of n-3 PUFA but contain little saturated fat and cholesterol and can be recommended for reducing the risk of CAD. Fatty fish have a lower content of saturated fat than most meat servings and may for this reason, independent of likely beneficial effects of n-3 PUFA, be a better food source.

The concept of substituting fish for other food sources and not supplementing fish oils to the habitual diet must be emphasized. However, if fish oils are considered, products of high quality with declared amounts of EPA and DHA, and with antioxidants added, should be chosen.

Concern has been expressed about increased consumption of fish due to intake of heavy metals and pesticides from contaminated fish (9). The risk is low but must not be neglected, and pollution of the sea and its fish should be monitored by international organizations. During industrial processing, it is possible to remove toxic substances from fish oil concentrates.

PUFA (including n-3 PUFA) are susceptible to oxidation due to their high number of double bonds. This may be of importance because of the suggested pivotal role of oxidation of LDL in atherogenesis (20). However, epidemiologic data do not suggest increased atherosclerosis in fish consumers. Whether increased intake of n-3 PUFA leads to clinically relevant enhanced *in vivo* oxidation of LDL continues to be debated (21). Nevertheless, oxidation of n-3 PUFA in fish oil concentrates should be minimized before their intake, which can be achieved by the addition of antioxidants (vitamin E), proper storage, and encapsulation.

There has been concern about an increased risk of bleeding, especially after consumption of larger doses of fish oil concentrates, but there is very little clinical evidence in support of this (22). Furthermore, there is no indication that n-3 PUFA are contraindicated in patients treated with aspirin or anticoagulation, but this has been studied only to a very limited extent (1).

It has been claimed, on the basis of limited data, that n-3 PUFA are detrimental to glycemic control in patients with overt diabetes or impaired glucose intolerance, but recent data have discarded this hypothesis (17,23,24). Although immune responses may be reduced by n-3 PUFA, there is no evidence that intake of n-3 PUFA is associated with an increased risk of cancer or serious infections (1,22). Overall, we conclude that dietary fish and n-3 PUFA are unlikely to promote health problems (25).

In summary, there is some evidence from epidemiology that intake of n-3 PUFA from seafood may protect against CAD. There are several mechanisms by which an increased intake of marine n-3 PUFA may protect against CAD. It is puzzling, however, that a very low amount of n-3 PUFA, with no known beneficial biochemical effects, seems to be cardioprotective. On the other hand, it is reassuring that there is little indication that increased consumption of fish is harmful.

On the bases of epidemiology and the biochemical effects reported, it has therefore been of paramount interest to perform clinical trials, because properly conducted clinical trials remain the cornerstone for a decision to increase the intake of marine n-3 PUFA in the prevention and treatment of CAD. Such evidence and trials are discussed in later chapters, and it should be noted here that the results have indeed been encouraging.

# n-3 Fatty Acids: Antiatherosclerotic Effects

**Raffaele De Caterina[a,*] and Antonella Zampolli[b]**

[a]Department of Cardiology, G. d'Annunzio University, Chieti, and [b]CNR Institute of Clinical Physiology, Pisa, Italy

**ABSTRACT:** The low incidence of cardiovascular disease associated epidemiologically with high consumption of food rich in n-3 fatty acids suggests the possibility that part of the beneficial cardiovascular effects of these natural substances may be due to a reduction of atherosclerosis. This has been recently confirmed in autoptic data and in at least one prospective trial evaluating the progression of coronary atherosclerosis in humans. This paper reviews published literature on n-3 fatty acids and atherosclerosis in animal models and in humans and *in vitro* experimental data yielding suport to the hypothesis of antiatherosclerotic effects of these substances.

Paper no. L8805 in *Lipids 36*, S69–S78 (2001).

The n-3 (omega-3), polyunsaturated fatty acids, particularly eicosapentaenoic (EPA) and docosahexaenoic acids (DHA), are thought to display a variety of beneficial effects in areas ranging from fetal development to cancer prevention (1). The occurrence of apparently protective effects on cardiovascular disease provided the stimulus for the early biomedical interest in such compounds and is well documented. Historically, the epidemiologic association between dietary consumption of n-3 fatty acids and cardiovascular protection was first suggested by Bang and Dyerberg (2,3). These authors identified the high consumption of fish, whale, and seal, and thus of n-3 fatty acids, as the likely explanation for the strikingly low rate of coronary heart disease events reported in the Inuit population (2,3). Since their initial reports, research has proceeded along several lines to provide further evidence for this cardioprotection and to understand its underlying mechanisms. Decreased atherogenesis is currently thought to be a part of the cardiovascular protection by n-3 fatty acids. This chapter summarizes the evidence for such a claim and mechanisms putatively involved.

## *Evidence for Antiatherogenic Effects of n-3 Fatty Acids*

*Effects of n-3 fatty acid in animal models of atherosclerosis.* In animal models, the hypotriglyceridemic action of n-3 fatty acids, which is well documented in humans, is not observed consistently, whereas a reduction in high density lipoprotein (HDL)-cholesterol has been reported consistently (4). Putative antiatherogenic effects of n-3 fatty acids are therefore not attributable to the favorable effects on serum lipids that occur in humans (see below). The n-3 fatty acids have been reported to lessen the development of atherosclerotic lesions in several animal models. However, results have not been unequivocal, due to species differences and variations in study design. The n-3 fatty acids were usually supplemented as fish oils. Studies aimed at determining their effect on atherogenesis or on lesion regression have been carried out in nonhuman primates, pigs, rabbits, and mice. The design of most such studies has been criticized for a variety of reasons including the extremely high levels of supplementation with fish oils, i.e., between 10 and 40% of total energy intake as n-3 fatty acids in most studies, whereas "realistic" dietary values for these species should be 1–2% (4). Another reason is the frequent lack of an appropriate control. In some cases, fish oils were simply substituted for saturated fats; in others, the control oil had a different polyunsaturated/saturated (P/S) ratio, a variable that might *per se* have an influence on lesion development (5,6). Also, the choice of the end point parameters and relative methods in the evaluation of atherosclerosis have been quite variable. The choice of the experimental model is also relevant to explain the different outcome, i.e., in some cases atherogenesis has been induced by drastic dietary changes, quite different from the pathophysiologic conditions occurring in humans. Ideally, animal models showing similarities with the inception and progression of human atherosclerosis should be used, and the control oil should be carefully chosen (4). The majority of experimental studies available in the literature do not meet these criteria.

*Studies in nonhuman primates.* Monkeys have been used to determine the effects of n-3 fatty acid on lipoprotein cholesterol and triglyceride plasma levels (7–10) and on atherosclerosis development (11–13). Such studies are difficult to compare to one another due to metabolic differences among species and to different study designs. Usually n-3 fatty acids were substituted for fat in high amounts, so that the experimental results can be either attributed to n-3 fatty acids or to the removal of hyperlipidemic (saturated) fatty acids. A consistent finding in monkey studies has been the decrease of plasma HDL-cholesterol, an effect often observed in other

species (4). The development of atherosclerosis in general appears to be retarded or diminished (11,12). These results were obtained with the concomitant removal of saturated fats from the diet; these were replaced by high amounts of fish oil without balancing the saturated/unsaturated ratio. Studies aimed at demonstrating the effect of α-linolenic acid (ALA) on atherogenesis support a protective effect also for this specific n-3 fatty acid (14,15). In one regression study, dietary supplementation with a relatively low dose of fish oil (2.5% of total energy intake) added to both an atherogenic and a therapeutic diet with sunflower oil as a control for both, caused an increase in cholesterol and phospholipid content in the aortic intima and no changes in atherosclerosis (13). In an *in vivo* baboon model, high doses of fish oil (vs. an olive oil control) prevented platelet deposition on a plastic vascular shunt and vascular lesion formation in response to mechanical vascular injury in endarterectomized carotids as well as in uninjured aortae (16). Recently, in a different macaque model, the effect of fish oil on the long-term occlusive tendency of aorto-coronary vein bypass grafts was evaluated and found no more effective than olive oil (17).

*Studies in swine.* Pigs have been widely used in studies of lipoprotein metabolism, which appears to be similar to that of humans, and for the study of effects on atherosclerosis, because spontaneous atherogenesis occurs in this species with an early spontaneous beginning. However, native lesion development in pigs is slow and has to be accelerated by high-fat diet, cholesterol, and bile acid supplementation. Fish oils have usually decreased triglycerides and HDL-cholesterol (4). The effects on atherosclerosis are, again, conflicting. A significant dose-dependent reduction in the extent of aortic and coronary luminal enchroachment has sometimes been observed when the vessel is mechanically abraded, whereas atherosclerosis progression is prevented in nonabraded arteries (18–21). The aortic lesion area was, however, not reduced in one set of studies (18–21). The question of lesion regression was also addressed specifically. A favorable effect of fish oil supplementation after a period of atherosclerosis induction by an atherogenic diet was observed in one set of experiments, and regression appeared to be more evident with low levels of plasma cholesterol. In these studies, however, there was no control oil or a control oil was used with a P/S ratio different from that of fish oil (22,23). When a control oil with a matching polyunsaturated/saturated fatty acid ratio was used in one lesion regression study, fish oil had no effect on lesion regression (24). This was accompanied by an unfavorable increase in low density lipoproteins (LDL), a decrease in HDL, and increased susceptibility of LDL to oxidation (25).

*Studies in rabbits.* Rabbits provide a convenient model for atherosclerosis because atherosclerosis can be easily and quickly induced in this species. This is usually obtained by feeding either a cholesterol-rich or a casein-based, fat-free diet. Also, Watanabe heritable hyperlipidemic rabbits (WHHL), lacking functional native LDL receptors and thereby promoting atherosclerosis due to a very high increase in circulating atherogenic lipoproteins, are a well-established model for atherosclerosis, resembling one type of human inheritable type of atherosclerosis. Lipoprotein metabolism, however, is different in rabbits and humans. In rabbits, an increase in dietary cholesterol does not result in LDL but in β-very low density lipoprotein (β-VLDL) elevation, so that any change in lipoprotein levels is not necessarily pertinent to most situations occurring in humans. Studies aimed at verifying the effect of n-3 fatty acids in the rabbit atherosclerosis model are inconsistent with regard to both lipoprotein and triglyceride/cholesterol concentrations (4). In addition, results of n-3 fatty acid supplementation on atherosclerosis are conflicting in this species, and most studies lack an adequate control. Fish oils were reported to inhibit atherosclerosis development in cholesterol-fed rabbits (26–28), to enhance lesion formation (29,30), or to have no effect (31,32). Fish oils, however, reduced intimal proliferation in arteries after balloon injury (33,34). This effect was inversely related to serum cholesterol values, in agreement with data obtained in porcine models (22,35). Also, the efficacy of fish oil was apparently enhanced by vitamin E supplementation (28). In WHHL rabbits, n-3 fatty acids were initially reported to have either no effect on plasma lipids and aortic lesion size (36), or to lower triglycerides, total lipoproteins, and cholesterol in female rabbits, but to be ineffective on lesion size of treated vs. untreated controls (37). With a similar experimental protocol, but with different criteria for lesion evaluation, fish oil reduced triglyceride and cholesterol levels and aortic lesions (38). Recently, a direct comparison of fish oil against olive oil treatment confirmed the occurrence of a hypolipidemic effect of fish oil in this species, and these findings were associated with a retardation of atherosclerosis development in young WHHL rabbits (39).

*Studies in mouse models.* Studies in mouse models have been scarce. Reiner *et al.* evaluated the effect of n-3 fatty acid on the development of atherosclerosis and on the secretory activity of peritoneal macrophages in the atherosclerosis-susceptible strain C57BL/6J (40). These authors compared a saturated fatty acid and a fish oil–supplemented diet. Lesion size was diminished by fish oils. Macrophages displayed a decreased ability to produce basal tumor necrosis factor (TNF)-α and lipopolysaccharide (LPS)-elicited TNF-α and interleukin (IL)-1β production, reduced lipoprotein lipase expression, and an enhanced nitrate synthesis (used as an index of nitric oxide production). In a recent study on murine macrophages, fish oil reduced the expression of intercellular adhesion molecule (ICAM)-1 and of scavenger receptor A type I and II (41). These findings suggest an effect of n-3 fatty acid on macrophage phenotype and on their role in lesion formation.

Recently, transgenic mouse models of atherosclerosis have been introduced (42). The LDL receptor-deficient (LDLR–/–) mouse develops atherosclerosis when fed a Western-type, high-fat diet (43). In this model, LDL are not efficiently cleared from plasma, and hypercholesterolemia and atherogenesis proceed with a pattern similar to the human situation. The apolipoprotein (apo)E-deficient mouse is another model of atherogenesis (44,45). In this model there is no need to

modify the diet because atherosclerosis proceeds spontaneously and very rapidly. The serum lipid profile is quite different from the human condition, however, because apoE is a constituent of all lipoproteins except LDL, and serves as a ligand for receptors involved in the clearance of chylomicrons and VLDL remnants. The only human counterpart for this situation is the genetic defect of apoE, a rare clinical condition that leads to severe atherosclerosis. In both models, atherosclerotic lesions start to spread from the abdominal aorta to the whole aorta and to its main branches, predominantly at bifurcation sites. The pattern of lesion formation has been characterized and found to be similar in both of the above models (46). The influence of gender is controversial, nonetheless the presence of an active production of estrogens seems to be protective.

Although the effect of n-3 fatty acid in the LDLR–/– model has not yet been the object of any published work, studies of n-3 fatty acid in the apoE–/– mice have been done. In the work of Calleja *et al.* (47), apoE–/– mice were fed diets enriched with different oils commonly used in human nutrition, without cholesterol addition. In this model, after the evaluation of lesion area, male mice appeared to respond to sunflower oil, whereas females responded to palm oil and elevated amounts of dietary olive oil. This model therefore seems suitable for the evaluation of dietary oil supplementation. In the recent work of Adan *et al.* (48), 7-wk-old apoE-deficient mice were fed an atherogenic diet in the presence or absence of DHA supplementation (1% final concentration) for 8 wk. No effect of DHA on atherosclerosis was reported, i.e., the size and extent of lesions in the aortic arch, and the thoracic and abdominal aorta did not differ in the two experimental groups. These results might have been influenced by the use of cholesterol and cholate in the diet.

In summary, animal experimental studies with n-3 fatty acid are pointing mainly to the existence of an antiatherogenic effect, but are hampered by differences in study design and species. No definite claim on the existence of true antiatherogenic effects of n-3 fatty acid can be made to date on this basis.

*Studies in humans.* Nutritional intake of n-3 fatty acids is highly likely to lead to cardioprotection. This was confirmed recently by a 30-yr follow-up in men who were free of overt cardiovascular disease at baseline and who consumed up to 35 g of fish per day (49). However, because of the multifactorial nature of ischemic heart disease, in which atherosclerosis is one important component, but not the only one, evidence about the occurrence of a true antiatherogenic effect of n-3 fatty acid in humans is not easy to gather. Autopsy studies in Alaskan natives (consuming high amounts of fish-derived products) and nonnatives consuming mainly Western-type diets provide circumstantial evidence about a lesser extent of atherosclerosis in populations exposed to high nutritional intake of n-3 fatty acids. Newman and co-workers (50) reported a decreased percentage of intima covering with fatty streaks and raised lesion in Alaskan natives, with a high n-3 fatty acid dietary intake (51), vs. nonnatives. In their study, the magnitude of difference in fatty streak development appears larger in younger age groups (Fig. 1), suggesting an effect of diet mainly in the early events leading to fully developed atherosclerotic lesions. Prospective studies in humans are few, but point mainly to the true occurrence of such effects. A study of high-dose n-3 fatty acid supplementation on coronary artery disease regression, evaluated by angiography, was negative (52), but a subsequent well-controlled study [the Study on prevention of Coronary atherosclerosis by Intervention with Marine Omega-3 fatty acids (SCIMO)] showed a slower progression in subjects supplemented with lower doses (1.65 g/d EPA + DHA) (53). Interestingly, the same authors have recently reported no effect of the treatment on carotid intima-media thickness evaluated by carotid ultrasound in the very same subjects [see von Schacky *et al.*, pp. S99–S102 of this volume], indicating some regiospecificity for the fish oil effect. It has been speculated that 0.5–2.0 g of n-3 fatty acids per day is effective in reducing clinical end points (54). By contrast, higher doses have been suggested to yield no effect (52). This contention is based, however, on very few studies examining the effects of these substances on true atherogenesis and not on a mixed end point. One study conducted after coronary by-pass surgery indicates that n-3 fatty acids significantly reduce vein graft stenosis (55), a process that may be regarded as an accelerated form of atherosclerosis. Studies on restenosis after percutaneous coronary angioplasty have been contradictory and, in the end, largely negative when studies of sufficient size and power were performed (56,67). Issues of study design still leave open the door in the minds of some investigators to the possibility that n-3 fatty acids can have some efficacy on restenosis (68). Restenosis after percutaneous interventions, however, is the result of a mechanical injury to an already diseased vessel wall, and its relevance to native atherosclerosis is very questionable.

In summary, evidence for an antiatherogenic effect of n-3 fatty acids is perhaps more persuasive in human than in animal studies because it is now based on at least one placebo-

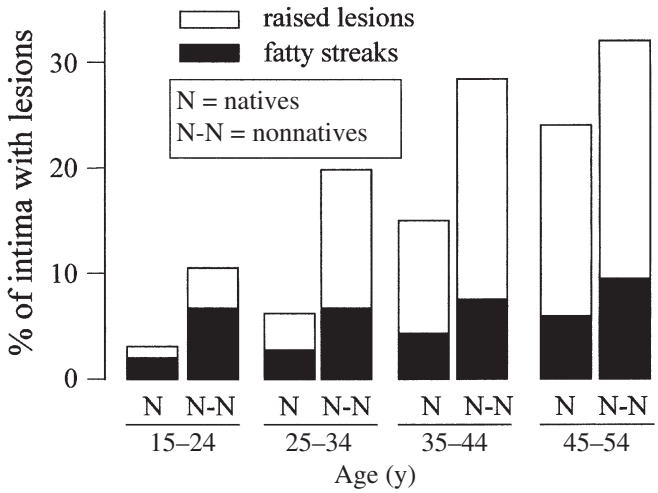

**FIG. 1.** The percentage of coverage of the aorta with fatty streaks (solid areas) and raised plaques (open areas) in Alaskan natives (N) vs. nonnatives (NN), according to age. Notice the larger difference, attributable to the prevalence of fatty streaks, in the younger age groups. Redrawn, with modifications, from Reference 51.

controlled prospective study in native atherosclerosis in the coronary arteries and a placebo-controlled prospective study in coronary bypass surgery grafts. These studies indicate a reduced atherogenesis in the coronary arteries and probably the aorta.

### *Putative Mechanisms by Which n-3 Fatty Acids Interfere with Atherogenesis*

*Molecular mechanisms in atherogenesis.* The initial event in the development of atherosclerosis is a condition of endothelial dysfunction, which precedes any morphologic evidence of endothelial damage (69). Endothelial dysfunction can be triggered by a number of different stimuli (e.g., toxins, shear stress, cigarette smoking, or high cholesterol levels). One type of endothelial dysfunction is termed endothelial "activation" in which the endothelium modifies its phenotype in a proadhesive direction, triggering an increased adhesion of circulating monocytes. Their subsequent infiltration into the arterial intima is one of the first visible findings in atherosclerosis. In the intima, monocytes become activated and begin to incorporate circulating LDL that have become oxidized through the exposure to reactive oxygen species of both endothelial and macrophagic origin, thus initiating the formation of the fatty streak (70) (Fig. 2).

Atherosclerosis and inflammation share similar basic mechanisms, involving the adhesion of leukocytes to the vascular endothelium in their early phases. Multiple protein families, each with a distinct function, provide "traffic signals" for leukocytes. These include the following: (i) the "selectin" family of adhesion molecules; (ii) the chemoattractants, some of which ("classical" chemoattractants, such as *N*-formyl peptides, complement components, leukotriene $B_4$, and platelet-activating factor), act broadly on neutrophils, eosinophils, basophils, and monocytes, whereas more recently described "chemokines," such as monocyte chemoattractant protein-1 (MCP-1) and IL-8, have selectivity for leukocyte subsets; and (iii) the immunoglobulin superfamily members on the endothelium ICAM-1, ICAM-2, ICAM-3, and vascular cell adhesion molecule (VCAM)-1, recognizing "integrin" ligands on the leukocyte surface. For neutrophil (and likely lymphocyte) adhesion, selectins mediate initial tethering of the circulating leukocyte over the endothelium, allowing it to roll over the endothelium, considerably slowing down its speed, and allowing leukocytes to "sense" the presence of chemotactic gradients. Final firm attachment of leukocytes to the endothelium requires the interaction of integrin ligands on the leukocyte surface with immunoglobulin superfamily members, expressed on the endothelium, such as ICAM-1, ICAM-2, and VCAM-1. The multiple molecular choices available for each of these ligand–ligand interactions provide great combinatorial diversity in signals, allowing the selective responses of different leukocyte classes to inflammatory agents, the preferential recirculation patterns of lymphocyte subpopulations, or the selective binding of monocytes to arterial endothelium during early phases of atherogenesis.

Monocyte recruitment into the intima of large arteries is specific for atherosclerosis compared with other forms of leukocyte-endothelial interactions. It was therefore hypothesized that these localized monocyte-endothelium interactions reflect specific molecular changes in the adhesive properties of the endothelial surface, leading to surface expression of

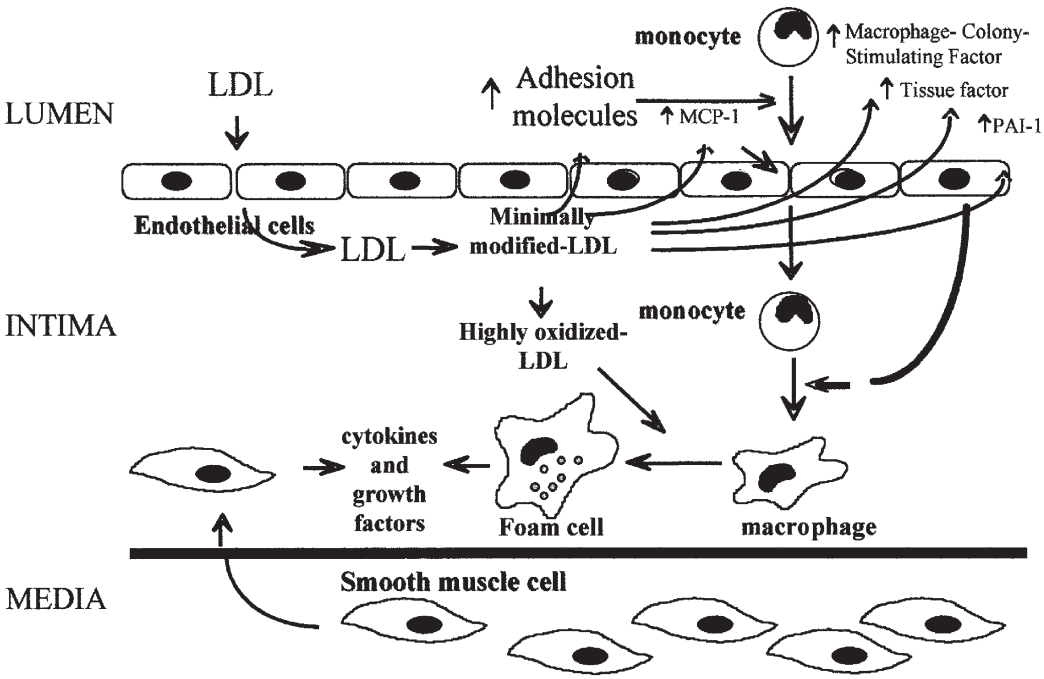

**FIG. 2.** A scheme of the modifications of the arterial intima occurring in early atherogenesis. Abbreviations: MCP-1, macrophage chemoattractant protein-1; PAI-1, plasminogen activator inhibitor-1; LDL, low density lipoprotein. From Reference 90, with permission.

"athero-ELAM," i.e., endothelium-leukocyte adhesion molecules (ELAM) expressed in the early phases of atherosclerosis. The first such protein, originally identified in the rabbit hypercholesterolemic model, is VCAM-1, a member of the immunoglobulin superfamily, expressed on human vascular endothelium in at least two molecular forms. Both forms are able to bind a heterodimeric integrin receptor, very late antigen (VLA)-4, whose leukocyte selectivity of expression, on monocytes and lymphocytes, but not on neutrophils, can explain the selectivity of monocyte recruitment in early atherogenesis (71). Endothelial cells express VCAM-1 early during cholesterol feeding in rabbits, before the appearance of macrophages/foam cells in the intima of developing fatty streak, in a temporal pattern consistent with its pathogenetic role in lesion development. Pathophysiologically relevant stimuli for VCAM-1 expression in atherogenesis could include minimally oxidized LDL or β-VLDL, the advanced glycosylation end-products (AGE) associated with diabetes, lipoprotein (a), or perhaps homocysteine, elevated in homocysteinuria and in subtler forms of congenital or acquired enzyme defects in its biosynthetic pathway. In addition to these humoral stimuli, VCAM-1 endothelial gene expression also responds to hemodynamic forces, thus potentially explaining the localization of atherosclerosis in particular points of the arterial vasculature. For a general review on these issues, see Reference 71.

The progression from fatty streak to atheroma is driven by the production of cytokines and chemoattractants that determine the intimal accumulation of leukocytes, smooth muscle cells, and fibroblasts, as well as platelet adhesion. The thin-capped, lipid-rich atheromatous plaques have a strong tendency to rupture and are at risk of complicating with thrombosis, which is usually the ultimate event leading to unstable angina and myocardial infarction (72).There are, therefore, multiple potential points of action of n-3 fatty acids on atherogenesis. The best-characterized ones are reviewed briefly.

*Effects of n-3 fatty acids on plasma lipids.* In humans, n-3 fatty acids decrease serum triglycerides, an effect that is pronounced in marked hypertriglyceridemia. VLDL-cholesterol is reduced, whereas LDL-cholesterol tends to be either elevated or unchanged (73,74). In fact, in patients with mixed hyperlipidemia and in marked hypertriglyceridemia, n-3 fatty acids are a highly effective means for reducing both triglyceride and VLDL. Thus, n-3 fatty acids appear to reduce one of the atherogenic triggers.

*Effects of n-3 fatty acids on cellular responses to atherogenic triggers.* Dietary intake of n-3 fatty acids, such as EPA and DHA, allows their incorporation into the phospholipids of cell membranes, replacing arachidonic acid (AA). Originally, the beneficial effects of n-3 fatty acids on the cardiovascular system were attributed to their substitution of AA. Metabolites that are enzymatically derived from n-3 fatty acids (through cyclooxygenase, lipoxygenase and cytochrome P-450 monoxygenase) are less prothrombotic and vasoconstrictive than the corresponding AA derivatives. Many vascular effects of n-3 fatty acids are equally shared by DHA and EPA, or possibly even more prominently shown by DHA than EPA. Because DHA, at variance with EPA, is a poor substrate for metabolization into eicosanoids, effects of n-3 fatty acids other than generation of eicosanoids are likely to play a greater role in preventing atherogenesis. In recent years, direct effects of n-3 PUFA on endothelial activation have been demonstrated. These include the following: (i) reduced production of cytokines such as IL-1 and TNF in LPS-stimulated monocytes (75); reduced production of the mitogen and smooth muscle cell attractant platelet-derived growth factor (PDGF A and B protein and mRNA) (76,77); reduced expression of tissue factor by monocytes (78); increased endothelial nitric oxide bioavailability (79); the specific downregulation of gene expression for MCP-1 (80); and reduced expression of endothelial adhesion molecules, essential for monocyte adhesion to sites of inflammation and dysfunctional endothelium (81). Research on this last aspect will be now highlighted in greater detail because it provides a potentially comprehensive explanation of the behavior of these agents as modulators of gene expression.

*Modulation of endothelial-leukocyte interactions by n-3 fatty acids.* We used human adult saphenous vein endothelial cells activated by cytokines, as an *in vitro* model of these early steps in atherogenesis, first assessing the effects of various fatty acids on the surface expression of endothelial leukocyte adhesion molecules, and subsequently characterizing mechanisms and functional relevance of such effects. One n-3 fatty acid, DHA, when added to cultured endothelial cells hours to days before the stimulation with cytokines, early enough to allow a significant incorporation of this fatty acid in cell membrane phospholipids, significantly inhibited events connected with endothelial activation. These included the expression of adhesion molecules such as VCAM-1, E-selectin and, to a lesser extent, ICAM-1, after stimulation with virtually any stimulus able to elicit the coordinated expression of such genes (81,82). Thus, this inhibition could be demonstrated with IL-1α and IL-1β, TNF-α, IL-4, and LPS (Fig. 3). Inhibition of adhesion molecule expression occurred in a range of DHA concentrations compatible with nutritional

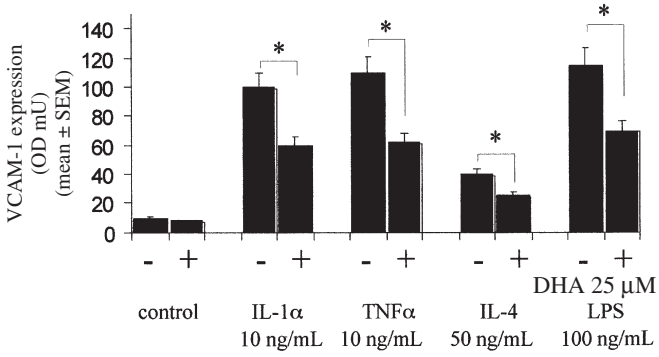

**FIG. 3.** The inhibition of vascular cell adhesion molecule (VCAM) expression by docosahexaenoic acid (DHA), occurring with diverse stimuli, including interleukin (IL)-1α and IL-1β, tumor necrosis factor (TNF)-α, IL-4 and lipopolysaccharide (LPS). Asterisks denote significant differences, $P < 0.01$. From De Caterina, R., unpublished data.

supplementation of this fatty acid to normal Western diets. Also, this inhibition occurred at any time point after the appearance of the cytokine effects, modifying the specific kinetics of surface expression of adhesion molecules, and was strictly related in its magnitude to the extent of incorporation into total cell lipids. Indeed, the extent of VCAM-1 inhibitory effect paralleled the incorporation of DHA and the overall increase in incorporation of n-3 fatty acids, and was inversely related to the content of n-6 fatty acids. Following the fate of $^{14}$C-labeled DHA into cell phospholipids, we could show a significant incorporation of DHA into the phosphatidylethanolamine pool. This is a specific and second most abundant phospholipid pool, with the majority of molecules in the inner plasma membrane, and therefore possibly in a strategic position to alter intracellular signal transduction pathways. This effect was not limited to the expression of transmembrane molecules involved in leukocyte recruitment. It also appeared to occur for other cytokine-activated products, such as the soluble proteins IL-6 and IL-8, involved in either the amplification of the inflammatory response (IL-6) or in the specific chemoattraction for granulocytes (IL-8). The effect was also accompanied by a functional counterpart, i.e., a reduced monocyte or monocytoid cell adhesion to cytokine-activated endothelium. Compared with DHA, EPA was a weaker inhibitor of the expression of these molecules and of monocyte adhesion, although still more potent than other fatty acids. We also showed that the effects of DHA on VCAM-1 expression are accompanied by parallel reductions in VCAM-1 mRNA steady-state levels, as assessed by Northern analysis (81,82). Similar results, in experiments with remarkably similar design, were later reported by Weber *et al.* (83). These authors also carried these investigations one step further, demonstrating an inhibition by DHA of the activation of the nuclear factor (NF)-κB system of transcription factors (83), which controls the coordinated expression of adhesion molecules and of leukocyte-specific chemoattractants upon cytokine stimulation (84,85).

We further analyzed endothelial effects of various fatty acids differing in chain length, number, position (n-3 vs. n-6 vs. n-9), and *cis/trans* configuration of the double bonds. Using VCAM-1 surface expression as a marker, we concluded the following marker: (i) saturated fatty acids are inactive; (ii) the potency of polyunsaturated fatty acids increases with the number of unsaturations; (iii) potency does not depend on chain length; (iv) the single double bond present in the monounsaturated fatty acid oleic acid is indeed sufficient to produce all of the effects obtainable with higher unsaturated fatty acids, albeit at higher concentrations; and (v) for such an effect to occur, even the configuration (*cis* vs. *trans*) of the double bond does not really matter because oleic acid (19:1n-9 *cis*) and its *trans* stereoisomer elaidic acid are of equal potency (86). Indeed, inhibition of NF-κB activation could also be reproduced upon incubation of endothelial cells with oleic acid (87).

*Possible molecular mechanisms by which unsaturated fatty acids inhibit endothelial activation.* To ascertain mechanisms for these effects, we demonstrated inhibition of NF-κB activation by DHA (the most potent fatty acid inhibitor of endothelial activation) in parallel with measurements of production of hydrogen peroxide by cultured endothelial cells. This reactive oxygen species (or one or more of its downstream unstable products) appears to be a critical mediator of NF-κB activation (Fig. 4). Indeed, we had previously shown that treatment of endothelial cells with polyethylene glycol (PEG)-complexed superoxide dismutase (a cell membrane–permeable form of this enzyme, which catalyzes the conversion of superoxide anion to hydrogen peroxide) does not greatly affect VCAM-1 mRNA production. On the contrary, a treatment with PEG-catalase, which acts by accelerating the degradation of hydrogen peroxide, quenches endothelial activation (88). This suggests that hydrogen peroxide (or some of its downstream products) is more relevant than upstream products (i.e., superoxide anion) in the activation of NF-κB. We also assessed the production of intracellular hydrogen peroxide (and/or its downstream products) by dichlorofluorescein before or after stimulation with IL-1 or TNF-α. In both these experimental systems, we could document (De Catarina, R., preliminary results) a decrease in baseline production of reactive oxygen species after cell membrane enrichment with DHA, and an even more pronounced dampen-

ing of the increase produced by stimulation with cytokines. Saturated fatty acids served as a negative control in these experiments. Therefore, our current understanding of these phenomena is that a property related to fatty acid peroxidability (the presence of multiple double bonds), usually regarded as a detrimental consequence of polyunsaturated fatty acid enrichment of cell membranes, is indeed also directly related to this putatively favorable outcome (Fig. 5).

These results have led to a reappraisal of how fatty acids may act on endothelial cells in modulating general phenomena such as atherogenesis (investigated mainly by our experimental systems), but also, potentially, inflammation or some immune responses. Because all of these effects could be confirmed to occur even in the presence of inhibitors of metabolic conversion of fatty acids to eicosanoids, they provide a novel explanation for the modulating effect of n-3 fatty acids in atherogenesis, distinct from the original hypothesis of substrate substitution (89). The results with oleic acid might also be an explanation for at least some of the beneficial effects of olive oil–rich ("Mediterranean") diets on atherogenesis. It is noteworthy in this regard that oleic acid appeared to be incorporated mainly at the expense of saturated fatty acids, thus disclosing the possibility of additive effects with n-3 fatty acids, which substitute mainly less unsaturated fatty acids in the membrane phospholipid pools. If extended to cell types different from endothelial cells, such as the monocyte-macrophage, also undergoing "activation" phenomena upon cytokine or LPS stimulation, our results may provide a coherent explanation for a number of previous observations such as the inhibition of cytokine formation from LPS-activated macrophages (75). As to the mechanism(s) involved, these effects might be closely linked to polyunsaturated fatty acid peroxidability.

Future research will have to further elucidate the molecular basis for these phenomena as well as expanding the scope of this research line into explaining many biological effects of unsaturated fatty acids as modulators of the biological responses to cytokines.

# n-3 Polyunsaturated Fatty Acids and Coronary Thrombosis

**S.D. Kristensen[a,*], A.M. Bach Iversen[a], and E.B. Schmidt[b]**

[a]Department of Cardiology, Skejby Hospital, Aarhus University Hospital, Brendstrupgaardsvej, DK-8200 Aarhus N, Denmark and [b]Department of Internal Medicine, Hjoerring Hospital, 9800 Hjoerring, Denmark

**ABSTRACT:** Studies of Greenland Eskimos showed that a very high intake of marine n-3 fatty acids markedly inhibited platelet reactivity and suggested that intake of these fatty acids might prevent coronary thrombosis. Later studies with lower, more practical doses of n-3 fatty acids also have shown a platelet inhibitory effect of n-3 fatty acids, albeit fairly marginal. Furthermore, n-3 fatty acids have little effect on measures of blood coagulability and may slightly decrease fibrinolysis. In animal models, n-3 fatty acids often have been shown to inhibit thrombosis, but again the doses have tended to be very high. Finally, there has been little effect of (low-dose) n-3 fatty acids in clinical trials in humans on the incidence of myocardial infarction. Overall, there is little evidence for a major antithrombotic effect of practical doses of n-3 fatty acids on coronary thrombosis. This does not exclude a beneficial effect of n-3 fatty acids on coronary heart disease as suggested from clinical trials, but the major effect may be antiarrhythmic rather than antithrombotic.

Paper no. L8813 in *Lipids 36*, S79–S82 (2001).

Dyerberg and Bang suggested that the low incidence of acute myocardial infarction (MI) observed in Greenland Eskimos could be due to their high intake of n-3 polyunsaturated fatty acids (PUFA). Their hypothesis, published in *The Lancet* in 1978 and 1979, was that the major effect of n-3 PUFA was a shift in the balance between pro- and antiaggregatory eicosanoids changing the platelet–vessel wall interaction in an antithrombotic direction (1,2). We shall briefly review the evidence of an antithrombotic effect of n-3 PUFA and discuss whether such an effect might be of clinical importance in patients with ischemic heart disease (IHD).

## *Epidemiology*

Epidemiologic studies to some extent support the notion that intake of n-3 PUFA is associated with a low incidence of acute MI and mortality from cardiovascular disease. Kromann and Green (3) studied the disease pattern from 1950 to 1974 from files at the Upernavik Hospital, Greenland, and found only three cases of MI when 40 were expected according to Danish data. In the period from 1979 to 1983, when 92% of deaths were registered by death certificates, the age-standardized incidence of deaths from IHD in Greenland was approximately half that in Denmark (4,5). The incidence of atherosclerosis and IHD has also been reported to be low in Alaskan Eskimos (6,7), and the incidence of IHD in Japan was reduced in fishing villages with a high consumption of fish compared with farming villages with a lower fish intake (8–10). In the Zutphen study, a negative correlation between IHD and fish intake was reported (11). Although the results from Western countries are not entirely consistent, most studies have shown a beneficial effect of fish consumption on IHD, in particular, in high-risk populations (for review see Ref. 12). In a recent review it was concluded that fish consumption of 40–60 g/d was associated with a markedly reduced risk of IHD in high-risk, but not in low-risk, populations (12).

## *Experimental Studies*

Hornstra (13) investigated the effect of PUFA on experimental arterial thrombosis in rats and showed that n-3 PUFA in combination with a low intake of saturated fat reduces thrombosis. In an extensive study in baboons, a very high dose of fish oil markedly reduced thrombus formation in arteriovenous shunts and segments of endarterectomized aortae, impaired smooth muscle cell proliferation, and virtually abolished vascular lesion formation at sites of carotid endarterectomy (14).

Microvascular perfusion after ischemia and reperfusion were improved in hamsters given fish oil, probably because leukocyte adhesion and obstruction of capillaries were inhibited by n-3 PUFA (15). Dietary fish oil improved the microcirculation secondary to an ischemic insult in an experimental rat model (16). We recently reported that n-3 PUFA decreased microvascular thrombosis after ischemia–reperfusion injury in a porcine experimental model (17). Finally, cod liver oil has been shown to reduce platelet deposition and injury-related vasoconstriction in pigs (18).

In conclusion, there is evidence from different animal models that n-3 PUFA may have beneficial effects on arterial thrombosis and may improve the microcirculation. However, the dose of n-3 PUFA in most of these experiments was considerably higher than what can be consumed by humans.

Abbreviations: AA, arachidonic acid; DART, diet and reinfarction trial; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; IHD, ischemic heart disease; MI, myocardial infarction; PG, prostaglandin; PUFA, polyunsaturated fatty acids; TX, thromboxane.

### *n-3 PUFA and Platelet Reactivity*

Platelets enriched with n-3 PUFA generate thromboxane (TX) $A_3$, and often less arachidonic acid (AA) is available for the formation of $TXA_2$. Competition between AA and eicosapentaenoic acid (EPA) for the cyclooxygenase enzyme and, possibly, an inhibitory effect of docosahexaenoic acid (DHA) on cyclooxygenase may further reduce platelet formation of $TXA_2$ (13). Furthermore, both EPA and DHA may antagonize AA and $TXA_2$ at receptor levels (19,20) and may be metabolized *via* lipoxygenase pathways in platelets to products that have been suggested to inhibit platelet reactivity (21,22).

The effect of n-3 PUFA on human platelet function has been studied extensively (see Refs. 23 and 24 for reviews). In summary, n-3 PUFA inhibit $TXB_2$ production, platelet aggregation, and platelet adhesion and cause a minor prolongation of the bleeding time. However, these effects are probably marginal, and the inhibitory effect of n-3 PUFA on the production of proaggregatory thromboxanes is well below that obtained after intake of a low dose of aspirin (25). Some studies have shown that n-3 PUFA and aspirin have synergistic inhibitory effects on measures of platelet reactivity (26,27). Clearly, such an effect would be of importance in patients with IHD for whom aspirin treatment is now mandatory.

### *n-3 PUFA and the Vessel Wall*

Dietary n-3 PUFA lead to endothelial formation of prostaglandin $I_3$ $PGI_3$ with effects believed to be similar to those of $PGI_2$ (13); the sum of $PGI_2$ and $PGI_3$ increases rather than decreases after intake of n-3 PUFA (28,29), whereas n-3 PUFA may augment the release and effects of NO (30–33). Interestingly, dietary n-3 PUFA have been reported to reduce vasoconstriction and improve vasodilatory responses in healthy humans (32). In conclusion, n-3 PUFA have effects on endothelial cells and vessel wall function likely to be beneficial in the prevention of IHD.

### *n-3 PUFA and Coagulation*

Numerous studies have evaluated the effect of n-3 PUFA on various coagulation factors (reviewed in Ref. 24). Early uncontrolled studies tended to indicate that n-3 PUFA lowered plasma fibrinogen, a well-described risk factor for IHD, but recent studies have not been able to confirm this. Data are also conflicting for other measures of coagulability but overall coagulability is probably not substantially altered by n-3 PUFA.

### *n-3 PUFA and Fibrinolysis*

Impaired fibrinolysis is linked to an increased risk of IHD (34). Initially, intake of n-3 PUFA was reported to enhance fibrinolysis (35), but a number of studies investigating this issue were unable to confirm this finding. In fact, several studies have reported that plasminogen activator inhibitor may increase after dietary n-3 PUFA, suggesting that n-3 PUFA may depress fibrinolysis (24). Again, results are conflicting, but n-3 PUFA likely have little effect on fibrinolysis.

### *Clinical Studies*

What is the evidence that n-3 PUFA prevent coronary thrombosis in humans? There are no data from healthy persons, but two large and one small secondary prevention, randomized studies in patients surviving an acute MI have been published.

The Diet And Reinfarction Trial (DART) study (36) included 2,033 men surviving a recent MI. The patients were randomized to different kinds of dietary advice, i.e., reduction in fat intake, increase in dietary fiber, or increase in fish consumption. The patients given fish advice were asked to eat at least two meals of fatty fish per week [or in case this was not possible, to take fish oil capsules containing ~1 g n-3 PUFA (taken by 22% of the patients)]. The groups were followed for 2 yr. The patients receiving fish advice had a significant (29%) reduction in total death and a significant (33%) reduction in cardiovascular death. However, the number of total coronary events was not significantly reduced because the number of nonfatal MI was higher in the fish advice group. The results from DART therefore do not support an antithrombotic effect of dietary n-3 PUFA.

These results were confirmed in the Gruppo Italiano per lo Studio della Sopravivenza nell'Infarto Miocardio (GISSI)-Prevenzione trial (37). In this large-scale, Italian multicenter trial, 11,324 patients with recent (<3 mon) MI were randomized to four treatment groups as follows: n-3 PUFA (0.85 g), vitamin E (300 mg), the combination of n-3 PUFA (0.85 g) and vitamin E (300 mg), or no supplement. Most patients received recommended preventive treatments (including aspirin, 92%). n-3 PUFA supplementation reduced long-term complications of MI to a clinically important extent. The combined primary end point of death, nonfatal MI, and nonfatal stroke was significantly reduced by n-3 PUFA supplementation; relative risk reduction was 15%. All of the benefit seen in the combined end point was due to the reduction in total mortality (relative risk reduction, 20%); the rate of nonfatal cardiovascular events (MI and stroke) was unchanged. n-3 PUFA significantly reduced the risk of cardiovascular death, coronary death, and sudden death. Again, there was no decrease in MI in the group receiving n-3 PUFA, arguing against a significant antithrombotic effect of n-3 PUFA in this trial.

In a study from India (38), 360 patients with suspected MI were randomized to treatment with 1.9 g of EPA + DHA, 2.9 g of α-linolenic acid, or placebo. After 1 yr, there was a significant reduction in cardiac death, nonfatal MI, and total cardiac events in patients randomized to EPA + DHA. This may indicate an antithrombotic effect of n-3 PUFA. This is supported by the recent finding from a Finnish epidemiologic study (39). In that trial, there was a negative association between the serum level of DHA + docosapentaenoic acid and the risk of acute coronary events, often thrombotic in origin, over 10 yr and follow-up.

Experimental studies suggest that intake of n-3 PUFA inhibits thrombus formation and has beneficial effects on microcirculation, especially after ischemia–reperfusion injury.

Intake of n-3 PUFA inhibits human platelet reactivity and has beneficial effects on the arterial wall. Changes in fibrinolysis after intake of n-3 PUFA have not been established, whereas routine clinical indices of coagulation are definitely unchanged. In large-scale clinical trials, intake of n-3 PUFA has been shown to improve survival in patients with recent MI. However, n-3 PUFA intake did not significantly protect against reinfarction in these trials; therefore, it is unlikely that n-3 PUFA exert a major antithrombotic effect in patients with recent MI.

## ACKNOWLEDGMENT

We thank Pia Hansen for excellent preparation of the manuscript.

# n-3 Fatty Acids and Human Health: Defining Strategies for Public Policy

**Artemis P. Simopoulos***

The Center for Genetics, Nutrition and Health, Washington, DC 20009

**ABSTRACT:** The last quarter of the 20th century was characterized by an increase in the consumer's interest in the nutritional aspects of health. As a result, governments began to develop dietary guidelines in addition to the traditional recommended dietary allowances, which have been superseded now by dietary reference intakes. In addition to governments, various scientific societies and nongovernmental organizations have issued their dietary advice to combat chronic diseases and obesity. Human beings evolved on a diet that was balanced in n-6 and n-3 essential fatty acid intake, whereas Western diets have a ratio of n-6/n-3 of 16.74. The scientific evidence is strong for decreasing the n-6 and increasing the n-3 intake to improve health throughout the life cycle. This paper discusses the reasons for this change and recommends the establishment of a *Nutrition and Food Policy*, instead of a *Food and Nutrition Policy*, because the latter subordinates the nutritional aspects to the food policy aspects. Nutrition and food planning comprise a tool of nutrition and food policy, whose objectives are the achievement of the adequate nutrition of the population as defined by nutritional science. The scientific basis for the development of a public policy to develop dietary recommendations for essential fatty acids, including a balanced n-6/n-3 ratio is robust. What is needed is a scientific consensus, education of professionals and the public, the establishment of an agency on nutrition and food policy at the national level, and willingness of governments to institute changes. Education of the public is essential to demand changes in the food supply.

Paper no. L8818 in *Lipids 36*, S83–S89 (2001).

The last quarter of the 20th century was characterized by an increase in the consumer's interest in the nutritional aspects of health (1). As a result, governments began to develop dietary guidelines in addition to the traditional recommended dietary allowances (RDA), which have been superseded by dietary reference intakes (DRI) (Table 1) (1,2). In addition to governments, various scientific societies and nongovernmental organizations have issued their dietary advice to combat chronic diseases and obesity (3–5).

Obesity has increased exponentially over the past 20 yr. In industrialized societies, a number of factors have contributed to a large proportion of the population being overweight and obese. Among them, an increase in energy intake owing to a palatable food supply and a decrease in energy expenditure, the latter due to sedentary lifestyle, are most important. The advent of the automobile and mechanical devices doing the work previously accomplished by walking and muscular work have compounded the problem. In the beginning of the 20th century, 30% of energy came from muscular work, whereas now it is only 1% (6). Therefore, recommendations on the type and amount of physical activity must be included in addition to dietary recommendations to overcome the enormous increases in obesity in both developed and developing countries (5,7–11).

**TABLE 1**
**Dietary Reference Intakes (DRI)[a,b]**

| |
|---|
| EAR (Estimated Average Requirement): the intake that meets the estimated nutrient need of 50% of the individuals in that group. |
| RDA (Recommended Dietary Allowance): the intake that meets the nutrient need of almost all (97–98%) individuals in that group. |
| AI (Adequate Intake): average observed or experimentally derived intake by a defined population or subgroup that appears to sustain a defined nutritional state, such as normal circulating nutrient values, growth, or other functional indicators of health. |
| UL (Tolerable Upper Intake Level): the maximum intake by an individual that is unlikely to pose risks of adverse health effects in almost all (97–98%) individuals. |

[a]Refers to daily intakes, averaged over time.

Consumer interest in the nutritional aspects of health has led to the development of health messages by governments for some food components, i.e., fiber, calcium, sodium, and to the use of new terminology—nutraceuticals, functional or designer foods—despite the fact that these particular foods have been part of the diet of humans for thousands of years. But what is the situation with the nutrients of interest to us, essential fatty acids and particularly n-3 fatty acids?

Although essential fatty acids (EFA) were recognized as such by Burr and Burr in 1929 and 1930 (12,13), major interest in n-3 fatty acids followed the work of Bang and Dyerberg in the 1970s (14–18). Since then, there has been major expansion in our knowledge on the role of the various n-3 fatty acids in growth and development and in health and disease (19–26), particularly cardiovascular disease (27–34). Studies on the composition of the diet at various periods of time reveal a continuous decrease of n-3 fatty acids in the food supply, but an enormous increase in n-6 fatty acids (35,36). Evidence on

Abbreviations: AA, arachidonic acid; ALA, α-linolenic acid; DRI, dietary reference intakes; EFA, essential fatty acids; LA, linoleic acid; RDA, recommended dietary allowances.

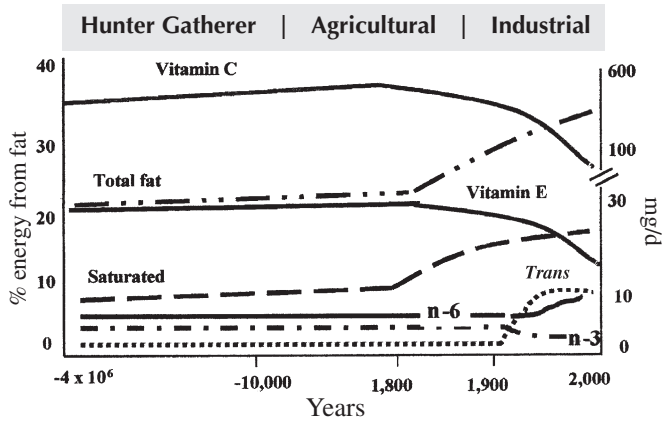

**FIG. 1.** Hypothetical scheme of fat, fatty acid (n-6, n-3, *trans,* and total) intake (as a percentage of energy from fat) and intake of vitamins E and C (mg/d). Data were extrapolated from cross-sectional analyses of contemporary hunter-gatherer populations and from longitudinal observations and their putative changes during the preceding 100 yr. *Source:* Reference 39.

the composition of the diet from the Paleolithic period ~40,000–15,000 yr ago suggests that the Paleolithic diet was characterized by a lower fat and lower saturated fat intake than Western diets, a balanced intake of n-6 and n-3 EFA, small amounts of *trans* fatty acids, contributing <2% of dietary energy, large amounts of green leafy vegetables and fruits providing higher levels of vitamin E and vitamin C and other antioxidants than today's diet, and higher amounts of calcium and potassium but lower sodium intake (36–39) (Fig. 1). Grains were not part of the Paleolithic diet. In terms of their entry into the diet 10,000 yr ago during the agricultural revolution, grains are in essence "newcomers" (40). It is estimated that during the late Paleolithic period, 35% of energy came from animal sources and 65% from vegetable sources (38). Although major changes have taken place in our diet over the past 10,000 yr since the beginning of the agricultural revolution, our genes have not changed. Information from archeological findings and studies from modern day hunter-gatherers suggest that the Paleolithic diet is the diet on which we evolved, and for which our genetic profile was programmed. The spontaneous mutation rate for nuclear DNA is estimated at 0.5% per million years. Therefore, over the past 10,000 yr, there has been time for very little change in our genes, perhaps 0.005%, but major changes in our food supply have occurred, particularly during the last 150 yr.

### *The Status of n-3 Fatty Acids in the Food Supply*

Today, the ratio of n-6/n-3 is between 15:1 and 20:1 in Western Europe and the United States, whereas during our evolution it was 1:1 or even less (Tables 2–4) (19,35–39). The change in the EFA balance came about because of the recommendation in the 1960s to substitute vegetable oils, i.e., corn oil, safflower, sunflower, and cottonseed oils, for saturated fat. These vegetable oils are very high in n-6 fatty acids and very low in n-3 fatty acids. Corn oil has a ratio of n-6/n-3 of 60:1 and safflower oil 77:1 (Table 5). In addition, because farm animals are grain-fed, their carcasses contain small amounts of n-3 fatty acids, but high amounts of saturated fat and n-6 fatty acids, unlike the composition of meat from animals in the wild (41). Similarly, eggs and poultry (42,43), fish from aquaculture (44), and cultivated plants (45,46) contain lower amounts of n-3 fatty acids than eggs and meat from free-ranging chickens, fish in the wild, and uncultivated plants (42–48).

Table 6 shows the ratio of n-6/n-3 in various countries (35,36,49,50). Only the traditional diet of Greece has a ratio similar to that of the Paleolithic diet. The Greek diet, as exemplified by the diet of Crete, is associated with the longest life expectancy and lowest rate of cardiovascular disease (51,52). A modified diet of Crete was used in the Lyon Heart study, which

showed a 70% decrease in mortality in 2 yr (27). The Lyon Heart study (27–29), the Singh study (31,32), and Gruppo Italiano per lo Studio della Sopravivenza nell'Infarto Miocardico (GISSI)-Prevenzione trial (34) were characterized by a dietary pattern similar to that of Crete with the following differences: (i) the addition of 850–882 g of n-3 fatty acids on top of a Mediterranean diet in the GISSI trial; (ii) an increase in fish or mustard oil along with fruits and vegetables in the Singh study; and (iii) the addition of canola oil as a source of α-linolenic acid (ALA) in the Lyon Heart study. Similarly, the addition of canola oil along with other changes—lower saturated fat intake, more fruits and vegetables—brought about a desirable decrease in the death rate from cardiovascular disease in Finland (53).

### *EFA: Dietary Recommendations*

A number of organizations have already made dietary recommendations (54–56). In April 1999, an international group consisting of scientists from academia, government, and industry held a Workshop on the Essentiality of and Recommended Dietary Intakes (RDI) for Omega-6 and Omega-3 Fatty Acids. The group's recommendations are shown in Tables 7 and 8 (57). The scientific evidence is indeed sufficiently robust to permit a definition of an Adequate Intake (AI) for n-6 and n-3 fatty acids.

In addition to these recommendations, industry has already begun to return n-3 fatty acids to the food supply (58–59) (Table 9), which has also raised a number of issues (Table 10) that must be considered carefully. It is desirable that nutrition science drive food science and production, particularly in the development of novel foods.

It is now necessary to continue discussions on these issues with government officials at the level of the scientific community and with consumer organizations to return n-3 fatty acids to the food supply, decrease n-6 intake, and balance the n-6/n-3 fatty acid ratio. Because the reformulation of products is expensive, one could first begin to change the cooking and salad oils. Corn, safflower, sunflower, and cottonseed oils have high concentrations of n-6 fatty acids (Table 5). These oils have been part of the food supply only for the last 150 yr, i.e., since the advent of the oil press (19). Never before in the history of human beings has there been such a mass dietary change. Even soybean oil and canola oil, because they are hydrogenated, are lower in ALA than in their natural state. In the Lyon Heart study the ratio of linoleic acid (LA)/ALA was 4:1 and AA/eicosapentaenoic acid (EPA) was 1:1. We should aim for a ratio of LA/ALA of 4:1 or less (60), a goal already achieved in Japan (49) (Table 6).

### *Defining Strategies for Public Policy: A Nutrition and Food Sciences Agency Is Needed*

The League of Nations proposed that it was a collective duty of society to assume responsibility for a Nutrition and Food Policy. Until 1950, the main challenges for the policy makers were to provide enough food for all of the people. After the

[b]Assuming an energy intake of 35:65 of animal/plant sources.

1950s, the dietary problems changed. The economy improved markedly, and the variety of foods within markets proliferated. With energy-rich foods in abundance, people could now eat according to the longstanding recommendation to avoid malnutrition (undernutrition). No one foresaw that this could create health problems, and soon the effects of overnutrition and a diet unbalanced in EFA revealed a substantial increase in mortality from coronary heart disease, an increase that was associated with changes in food habits and lifestyle.

**TABLE 7**
**Adequate Intakes (AI) for Adults[a,b]**

| Fatty acid | Amount (2000 kcal diet) (g/d) | % Energy |
|---|---|---|
| LA | 4.44 | 2.0 |
| Upper limit[1] | 6.67 | 3.0 |
| ALA | 2.22 | 1.0 |
| DHA + EPA | 0.65 | 0.3 |
| DHA to be at least[2] | 0.22 | 0.1 |
| EPA to be at least | 0.22 | 0.1 |
| *Trans*-FA | | |
| Upper limit[3] | 2.00 | 1.0 |
| SAT | | |
| Upper limit[4] | — | <8.0 |
| MUFA[5] | — | — |

1. Although the recommendation is for AI, the Working Group felt that there was enough scientific evidence also to state an upper limit (UL) for LA of 6.67 g/d based on a 2000 kcal diet (3.0% of energy).
2. For pregnant and lactating women, ensure 300 mg/d of DHA.
3. Except for dairy products, other foods under natural conditions do not contain *trans*-FA. Therefore, the Working Group does not recommend *trans*-FA to be in the food supply as a result of hydrogenation of unsaturated fatty acids or high-temperature cooking (reused frying oils).
4. Saturated fats should not comprise >8% of energy.
5. The Working Group recommended that the majority of fatty acids be obtained from monounsaturates. The total amount of fat in the diet is determined by the culture and dietary habits of people around the world (total fat ranges from 15 to 40% of energy) but with special attention to the importance of weight control and reduction of obesity.

[a]If sufficient scientific evidence is not available to calculate an Estimated Average Requirement, a reference intake called an Adequate Intake is used instead of a Recommended Dietary Allowance. The AI is a value based on experimentally derived intake levels or approximations of observed mean nutrient intakes by a group (or groups) of healthy people. The AI for children and adults is expected to meet or exceed the amount needed to maintain a defined nutritional state or criterion of adequacy in essentially all members of a specific healthy population.
[b]Abbreviations: *trans*-FA, *trans* fatty acids; SAT, saturated fatty acids; MUFA, monounsaturated fatty acids. For other abbreviations see Table 2.

**TABLE 8**
**AI for Infant Formula/Diet[a]**

| Fatty acid | (%) |
|---|---|
| LA[1] | 10.00 |
| ALA | 1.50 |
| AA[2] | 0.50 |
| DHA | 0.35 |
| EPA[3] | |
| Upper limit | <0.10 |

1. The Working Group recognizes that in countries such as Japan, the breast milk content of LA is 6–10% of fatty acids and the DHA is higher, ~0.6%. The formula/diet composition described here is patterned on infant formula studies in Western countries.
2. The Working Group endorsed the addition of the principal long-chain polyunsaturates, AA and DHA, to all infant formulas.
3. EPA is a natural constituent of breast milk, but in amounts >0.1% in infant formula, it may antagonize AA and interfere with infant growth.

[a]See Table 7 for explanation of AI and abbreviations.

**TABLE 9**
**New Products on the Market Enriched with n-3 Fatty Acids[a]**

| Product | Description |
|---|---|
| Oils | Oils rich in ALA, such as canola, flaxseed, perilla, and soybean. In addition, avoidance of vegetable oils rich in n-6 and the use of oils lower in LA such as olive oil, canola oil, and new vegetable oils rich in monounsaturated oils help bring about an improvement in the LA/ALA ratio. |
| Bakery products | Flaxseed flour and encapsulated fish oils are used in bakery products, including breads. |
| Eggs | Changes in chicken feeds lead to enrichment of n-3 fatty acids in eggs; n-3–enriched eggs are found in many markets around the world. Chicken feeds are enriched with fish-meal, flaxseed, or DHA from algae. These eggs have a lower n-6/n-3 ratio and contain significant amounts of AA and DHA and are modeled after the "natural egg" (i.e., the egg from the Ampelistra farm in Greece), which is the egg obtained under completely natural conditions. |
| Infant formula | Human milk contains AA, DHA, and EPA, whereas infant formula based on cow's milk does not. In Europe and the Far East, infant formula is now enriched with AA and DHA from various sources. However, in the United States, infant formula does not yet contain AA and DHA. |
| Milk | Research shows promising results in increasing DHA in cow's milk. |
| Mayonnaises, margarines, and salad dressings | Hydrogenated fish oils and canola oil are used in the preparation of these products. |
| Meat/poultry | Research on how best to titrate the amount of fish oils and other sources of n-3 fatty acids (i.e., flax, DHA from algae) in animal feeds without affecting the stability and organoleptic properties is advancing in many parts of the world. Poultry, cattle, and pigs are being studied, and the consumption of n-3–enriched meats is not far into the future. |
| Farmed fish | There is a need to further improve the fatty acid composition in aquaculture. |

[a]See Table 2 for fatty acid abbreviations.

**TABLE 10**
**Issues Related to the Return of n-3 Fatty Acids to the Food Supply[a]**

→How much n-3 fatty acids should be in each serving?
→How much ALA, EPA, DPA, and DHA?
→What should be the ratio of total n-6/n-3?
→What should be the ratio of LA/ALA and (AA + DTA)/(EPA + DPA + DHA)?
→What should be the proportions of EPA, DPA, and DHA?
→What are the best models, i.e.,
land animals in the wild?
fish in the wild?
mother's milk from women consuming a Paleolithic diet?
mother's milk from women consuming a Greek/Mediterranean diet?
other?
→What can we learn from the composition of edible wild plants?
→Should we incorporate n-3 fatty acids into foods rather than supplement?

[a]See Table 2 for fatty acid abbreviations

In 1974, the FAO/WHO World Conference in Rome proposed that each nation should have a Nutrition and Food Policy. It is important to use the term "Nutrition and Food Policy" because the term "Food and Nutrition Policy" subordinates the nutritional aspects to the food policy aspects. Nutrition and food planning is a tool of a Nutrition and Food Policy. The goal of a Nutrition and Food Policy is the satisfaction of nutritional needs of the population as defined by nutritional science. The primary Nutrition and Food Policy objective is "The achievement of the adequate nutrition of the population." Adequate nutrition is also determined by physiologic requirements, and levels can be stated within a certain range. It is therefore necessary to define the nutritional requirements for the EFA. The prerequisites for a Nutrition and Food Policy are based on the following:

1. Nutritional needs become the central element, and are expressed as dietary allowances.
2. Establishment of a Department or Agency relating to the nutrition of the population.
3. Nutrition education for the public.
4. Nutrition education for professionals.

Public policy should be based on scientific evidence. Education of the public is essential to induce changes in the food supply. In many Western countries, including the United States and the United Kingdom, nutrition research, food inspection, and regulation is either shared by the Departments of Health and Agriculture (USA) or is carried out by the Department of Agriculture (UK). Neither of these situations is satisfactory, and having the Department of Agriculture in charge represents a conflict of interest as shown by the problems in "mad cow" disease. The solution to "mad cow" disease included among other things the recommendation for the establishment of a new food standards agency (61). The health department would assume responsibility for food policy in Britain (62) and would create an independent agency to protect consumers' interests in every aspect of food safety as well as nutrition. The loss of public confidence in meat after the experience of bovine spongiform encephalopathy and *Escherichia coli* contributed to this action. In the 1980s, the United States and other countries began to develop dietary recommendations (1). In 1989, I wrote a paper giving the reasons for the establishment of a Nutrition and Food Sciences Agency in the United States, separate and independent of the Departments of both Health and Agriculture (63). As we begin the new century, scientists and particularly physicians must work together with consumer organizations, industry, and governments to establish a Nutrition and Food Sciences Agency in every country.

Because scientific change is more rapid than changes in the law, continuing education of professionals and the public will be an essential part of progress in bringing about change and improving the health and well-being of people worldwide. The development of a Dietary Reference Intake (DRI) for essential fatty acids is urgently needed (Table 1). The science is strong; what is needed is collaboration among government, scientists, regulators, and industry. Finally, there is a need for the establishment of one agency in the European Community that will take responsibility for advancing the following:

- Nutrition research
- Food sciences research
- Education for professionals
- Education for the public
- Development of dietary guidelines for health
- Food regulation (implementation of nutrition and food policy)

Nutrition and genetics have a strong influence on health and disease. Early in 2001, sequencing of the human genome was complete in rough draft form. Eventually the function of all genes will be known, and diets will be targeted to individuals for the prevention and management of chronic diseases. For the prevention and treatment of chronic diseases, universal recommendations are inappropriate because of genetic variation and the differences in frequency of polymorphisms in various parts of the world. Therefore, nations cannot adopt each other's dietary recommendations. Furthermore, traditional diets must be studied carefully and serve as a model for foods to be developed. Physicians must take an active part because they are the only profession responsible for the diagnosis and treatment of the chronically ill. An academic consensus is considered vital when developing goals and proposing strategies for implementing a nutrition policy. Once the nutrition policy is established, an effective administrative body is required to supervise, on a daily basis, a nutrition policy and its implementation. Nongovernment organizations and other consumer groups should be linked in a cooperative process.

In summary, the scientific basis for the development of a public policy to develop dietary recommendations for EFA, including an n-6/n-3 ratio, exists. Necessary conditions include a scientific consensus, education of professionals and the public, the establishment of an agency on nutrition and food policy at the national level, and willingness of governments to institute changes. In fact, I would suggest that in bringing about a decrease in dietary n-6 fatty acid intake and

an increase the n-3 fatty acids, government should require proof from the opponents (to a change in policy) that such changes will do harm and proof that continuation of existing dietary patterns do not.

# The Effect of n-3 Fatty Acids on Low Density Lipoprotein Subfractions

**Bruce A. Griffin***

Centre for Nutrition & Food Safety, School of Biomedical & Life Sciences, University of Surrey, Guildford, Surrey GU2 7XH, United Kingdom

**ABSTRACT:** A predominance of small, dense low density lipoprotein (LDL) represents a significant source of increased risk for the development of coronary heart disease in Westernized countries. Dietary long-chain n-3 polyunsaturated fatty acids exert a potent triglyceride-lowering effect that redistributes LDL subfractions toward larger and lighter particles. These dietary fatty acids thus have a key role to play in providing protection against this particularly atherogenic type of LDL.

Paper no. L8802 in *Lipids 36*, S91–S97 (2001).

Conclusive evidence now exists to support the benefits of dietary long-chain n-3 fatty acids in fish oil in individuals with existing coronary heart disease (CHD) (1). Although this quality of evidence is still lacking in normal, healthy populations, we can now identify with confidence individuals who are predisposed to increased coronary disease by a collection of risk factors that are responsive to these dietary fatty acids. These susceptible individuals stand to gain the greatest benefit from increased consumption of n-3 polyunsaturated fatty acids (PUFA) and are thus the most appropriate population to target and treat.

## *Plasma Triacylglycerols (TAG) and Cardiovascular Risk*

Interest in the cardioprotective effects of dietary n-3 PUFA stems from early observations of the native Eskimo who, in spite of a high-fat diet, suffer low rates of cardiovascular disease as a consequence of a high intake of fish (2). Sadly, the subsequent application of this knowledge in the primary and secondary prevention of CHD was hindered, largely because fish oil exerted minimal effects on serum cholesterol, and in patients with raised serum triacylglycerols (TAG), actually increased low density lipoprotein (LDL). Large epidemiologic studies in the 1970s such as MRFIT (3) helped to establish the "absolute" coronary risk associated with increased serum cholesterol and the cholesterol hypothesis, which has since been tested and impressively confirmed in cholesterol-lowering drug trials (4,5). However, for free-living individuals within populations, serum cholesterol is actually a poor discriminator of disease status (6) and provides an inadequate basis by which to explain the relationship between diet and CHD. There are other more important risk factors that confer significantly greater "attributable" risk within populations and that are more amenable to dietary modification. One such factor is raised serum TAG. Despite its early exclusion as a coronary risk factor on statistical grounds, there has been a resurgence of interest in the role of serum TAG in relation to CHD. A meta-analysis of existing clinical studies (7) and intensive study of the mechanisms by which TAG-rich lipoproteins influence the disease process (8) have together provided incontrovertible evidence to implicate raised TAG in the development of atherosclerosis and also in the more acute manifestations of heart disease such as coronary thrombosis.

There is now convincing evidence to show that even moderately raised plasma TAG confers increased cardiovascular risk in otherwise normal, healthy individuals. Moderately raised plasma TAG (>1.5 mM) has a predicted frequency of between 25 and 30% in middle-aged men and postmenopausal women. It is a major progenitor of abnormalities in high and low density lipoprotein subfractions, which are collectively known as an atherogenic lipoprotein phenotype (ALP) (9). In its most frequent form of presentation, an ALP represents a subclinical dyslipidemia and thus silent risk factor for CHD. Its metabolic origins lie in insulin resistance and, as such, it is likely to represent the most common source of lipid-mediated CHD risk in free-living populations (8).

## *Small, Dense "Atherogenic" LDL-3*

LDL shows structural heterogeneity and exists in the plasma of all humans as a small number of discrete subfractions (8) (Fig. 1). These subfractions express variable metabolic properties and a gradient of atherogenic potential. In clinical studies, LDL subfractions have been traditionally grouped into two patterns or phenotypes, i.e., a normal pattern "A" consisting of predominantly large and less dense LDL particles, and an abnormal pattern "B" of high risk in which small, dense LDL particles predominate. The latter pattern is strongly associated with low high density lipoprotein (HDL; <1 mM) and increased plasma TAG. Moreover, a concentration for plasma TAG in excess of 1.5 mM has been identified as a critical threshold for the development of small, dense

*E-mail: B.Griffin@surrey.ac.uk

Abbreviations: ALP, atherogenic lipoprotein phenotype; apo, apolipoprotein; AUC, area under the curve; C, cholesterol; CETP, cholesteryl ester transfer protein; CHD, coronary heart disease; CM, chylomicrons; CMR, chylomicron remnant; HDL, high density lipoprotein; HTG, hypertriglyceridemia: IAUC, incremental area under the curve; LDL, low density lipoprotein; LPL, lipoprotein lipase; NEFA, nonesterified fatty acids; PUFA, polyunsaturated fatty acids; TAG, triacylglycerols; VLDL, very low density lipoprotein.

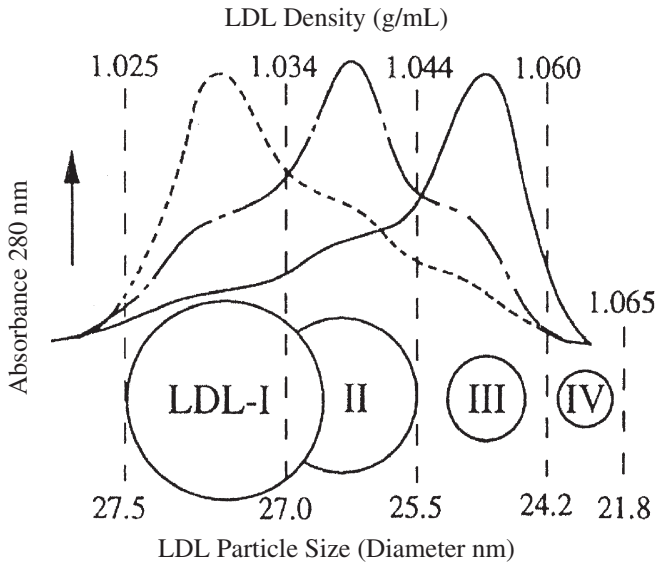

**FIG. 1.** Plasma low density lipoprotein (LDL) shows structural heterogeneity. LDL subclass profiles from three different individuals as measured by density gradient centrifugation are shown. Predominance of large LDL-I (1) e.g., normal, healthy premenopausal female (--------); predominance of intermediate LDL-II (2) e.g., normal, healthy male (— - —); predominance of small, dense LDL-III (3) e.g., pattern found in an atherogenic lipoprotein phenotype (———).

LDL-3 (Fig. 2) (10). Case-control studies have shown that small dense LDL carries at least a threefold increase in risk of myocardial infarction (11), whereas prospective trials have shown small LDL size to be predictive of future coronary events, with relative risk comparable to that of smoking or hypertension (12,13). The properties that render small, dense LDL-3 more atherogenic include rapid penetration of the endothelial barrier lining the arterial wall by virtue of its small size (14), its selective binding to arterial proteoglycans in the subintimal space (15), and its relatively greater susceptibility to oxidative modification compared with its larger and lighter counterparts (16).

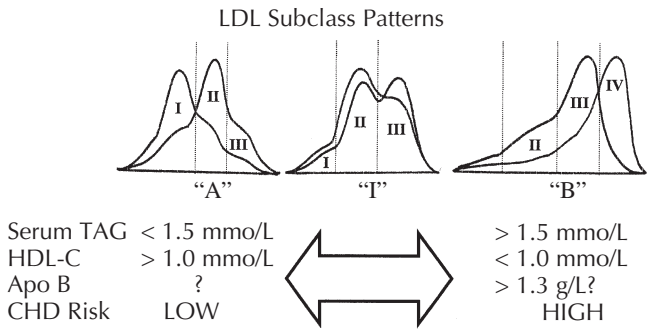

**FIG. 2.** LDL subclass patterns or phenotypes. Pattern "A" represents the normal pattern of low coronary heart disease (CHD) risk and is associated with low serum triacylglycerols (TAG; <1.5 mM) and raised high density lipoprotein cholesterol (HDL-C) (>1 mM). Pattern "B"represents the abnormal pattern of high CHD risk and is associated with moderately raised serum TAG (>1.5 mM) and low HDL (<1 mM). Pattern "I" is intermediate between "A" and "B." Apo B, apolipoprotein B. For abbreviation see Figure 1.

### *Small, Dense LDL-3: Relevance of Relative Abundance (%) (Pattern "B") vs. Increased Particle Number (Hyperapo B)*

Because each LDL particle carries a single molecule of apolipoprotein B (apoB), the measurement of apo B in LDL provides a surrogate marker for LDL particle number. It has been known for many years that an increased number of LDL particles as measured by apo B (hyperapo B) represents a major source of CHD risk (17). Hyperapo B is always associated with a predominance of small, dense LDL but, conversely, a predominance of small, dense LDL-3, as found in an ALP, is not always associated with hyperapo B (18). This raises the following question: Are individuals with a predominance of small, dense LDL-3 but without a raised particle number still at increased risk? This issue is of relevance because dietary n-3 PUFA may positively influence the distribution of LDL subfractions without altering the number of particles and consequently have minimal effect on CHD risk.

The mechanisms by which moderately raised TAG generate small, dense LDL are complex but relevant in the present context because dietary long-chain n-3 PUFA are thought to specifically target and correct the metabolic aberrations that underlie this condition. They almost certainly involve the overproduction of TAG in the liver which, through the production of TAG-enriched very low density lipoproteins (VLDL), perturbs the clearance of TAG-rich lipoproteins in the postprandial period (19).

It is over 30 yr since Zilversmit (20) linked enhanced postprandial lipemia with CHD and proposed atherosclerosis to be a postprandial phenomenon (Fig. 3). In the intervening period, postprandial TAG-rich lipoproteins, which, in addition to the chylomicrons (CM) and chylomicron remnants (CMR) carrying dietary fat, will include substantial quantities of VLDL, have been ascribed direct and indirect atherogenic potential (21,22). Although CMR have been shown to be the only native (nonoxidized) lipoproteins capable of inducing foam cell formation in arterial lesions, it is the indirect effects of these postprandial lipoproteins in modulating the structure and function of LDL and HDL that may be of even greater relevance to the atherogenic process.

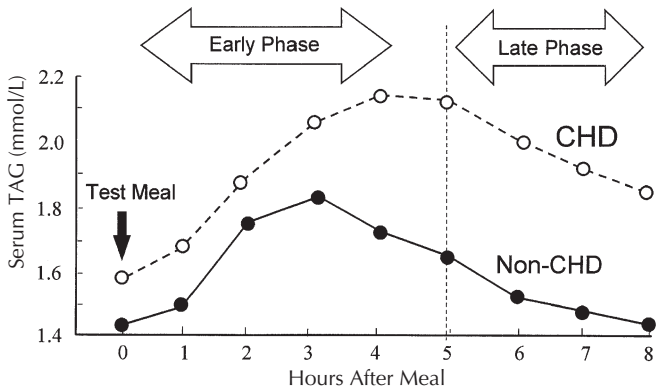

**FIG. 3.** Typical postprandial responses to fat-containing meal in subjects with and without CHD. Patient with CHD shows enhanced postprandial lipemia and an increase in the duration and magnitude of serum TAG concentration. For abbreviations see Figure 2.

Postabsorptive (fasting) serum TAG is a major determinant of variation in the distribution of LDL subfractions, accounting for ~40% of variation in small, dense LDL-3 in nearly all studies. However, because most people spend most of the day in a postprandial state, it could be argued that the fasting state is unphysiologic in this situation and that greater emphasis should be placed on repeated bouts of lipemia throughout the day. The latter would be responsible for maintaining plasma TAG levels above the critical threshold value for the development of small, dense LDL-3 of 1.5 mM. This is again relevant to the effects of long-chain n-3 PUFA, which have been shown to reduce the magnitude and duration of these lipemic bouts.

The explanation for the existence of a threshold for plasma TAG lies in the complex transfer and exchange of neutral lipids between circulating TAG-rich lipoproteins and cholesterol-rich lipoproteins (LDL and HDL). At subthreshold TAG levels, TAG-rich lipoproteins donate TAG to LDL and HDL in equimolar exchange for cholesteryl esters (CE), a process facilitated by cholesteryl ester transfer protein (CETP) (19). For HDL, this process forms an essential part of the centripetal transport of cholesterol from the peripheral tissues, including arterial lesions, back to the liver for excretion. As plasma TAG increases, a point is reached at 1.5–1.6 mM at which this equimolar exchange is replaced by a net transfer of TAG into LDL; the particle becomes transiently TAG rich and a favored substrate for hepatic lipase. The result is the generation of smaller and denser LDL particles (Fig. 4).

The concentration of TAG in plasma at any given time is a variable function of the rate of production and clearance of TAG-rich lipoproteins. The rate of production and secretion of VLDL from the liver is controlled to a major extent by the supply of substrates for the synthesis of TAG [remnant lipoproteins and nonesterified fatty acids (NEFA) chiefly], whereas CM production is determined mainly by the size and fat content of each meal (21). Both of these lipoproteins share a common saturable pathway for the hydrolysis of their TAG in the circulation *via* the endothelial lipase lipoprotein lipase (LPL) (23). The overproduction of TAG and large, TAG-rich VLDL in the liver has been implicated in the generation of small, dense LDL-3 in insulin-resistant states such as obesity, type II diabetes, and combined hyperlipidemia (24). Nevertheless, TAG clearance is also frequently impaired in these conditions (25,26), implicating the failure of LPL as an additional contributory factor. It is important to appreciate that raised VLDL levels make a significant contribution to enhanced postprandial lipemia by competing, relatively ineffectively, with CM for LPL-mediated clearance (27). VLDL particles are also in greater abundance than CM throughout the postprandial period (28). Competition will be more pronounced when the VLDL particle is larger and is heavily enriched with TAG as in the insulin-resistant states described above. In summary, factors that influence the production and clearance TAG-rich lipoproteins are of key importance in conferring protection against the development of small, dense LDL-3.

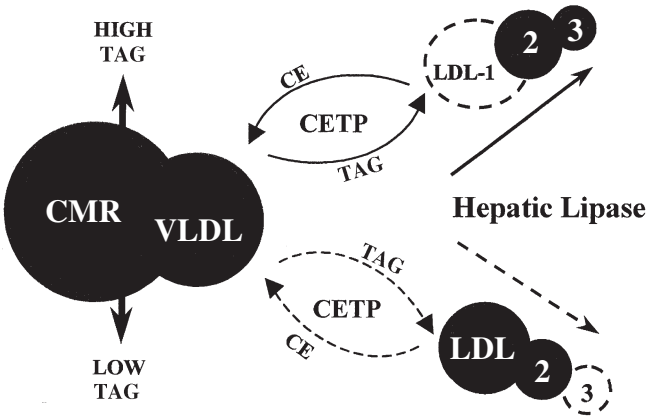

**FIG. 4.** Neutral lipid exchange. Relationship between serum TAG is explained in part by a mechanism of exchange and transfer of neutral lipids. At low concentrations of serum TAG, there is an equimolar exchange of cholesteryl esters (CE) from LDL to TAG-rich lipoproteins and TAG from TAG-rich lipoproteins back to LDL. In contrast, at high concentrations of serum TAG, there is a net transfer of TAG into LDL. This latter process produces a transient enrichment of LDL with TAG, which is rapidly hydrolyzed in the liver by hepatic lipase producing smaller and denser LDL particles (LDL-3). CETP, cholesteryl ester transfer protein; CMR, chylomicron remnant; VLDL, very low density lipoprotein; for other abbreviations see Figures 1 and 2.

### *Effects of n-3 Fatty Acids on Plasma TAG, Lipoproteins and LDL Subfractions*

Review of the influence of fish oils on plasma cholesterol and lipoproteins reveals their effects to be highly dependent on the initial lipid phenotype (29); in all cases, however, they significantly decrease plasma TAG in the fasting state and, when introduced into the habitual diet, produce a marked attenuation of enhanced postprandial lipemia (Fig. 5) (30). In view of the central role of TAG in regulating LDL subfractions, it is predictable that fish oils will redistribute LDL particle size toward larger and less dense particles. Baumstark *et al.* (31) were among the first to demonstrate this effect on both LDL and HDL subfractions.

A well-accepted explanation for this TAG-lowering action lies in the capacity of long-chain n-3 PUFA to suppress the production of TAG in the liver (32) by inhibiting the activity

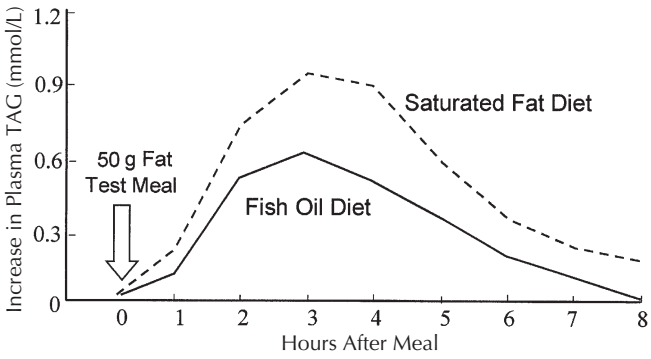

**FIG. 5.** A fish oil diet rich in long-chain n-3 polyunsaturated fatty acids (PUFA) will attenuate the postprandial response to dietary fat relative to a diet. For other abbreviation see Figure 2.

of lipogenic enzymes responsible for the synthesis of TAG, most notably diacylglycerol acyltransferase (33). This limits the amount of TAG available for packaging into VLDL, which results in the liver producing a smaller VLDL particle that contains relatively less TAG. There may well be additional contributory factors for the TAG-lowering effects on n-3 PUFA; these include limiting the supply of lipid substrates for TAG synthesis, essentially circulating NEFA and lipoprotein remnants circulating in the postprandial period. Failure to suppress the release of NEFA from adipose tissue and catabolize TAG-rich lipoproteins results from dysregulation of the insulin-sensitive enzyme's hormone-sensitive lipase and LPL, respectively (34). There is evidence to suggest that dietary long-chain n-3 PUFA can increase the sensitivity of certain tissues to the action of insulin (35); by doing so, they may upregulate the expression of these enzymes at pre- and post-transcriptional levels of control.

Whatever the underlying metabolic mechanisms, fish oil–induced changes in the structure and composition of VLDL will have major consequences for the production of LDL and remodeling LDL subfractions. It reduces the net exchange of neutral lipids between VLDL and LDL, which will counteract the production of small, dense LDL. Small VLDL is a weaker competitor for LPL in the postprandial phase and will contribute to the attenuation of postprandial lipemia. Furthermore, trace-labeling studies have shown that small VLDL is more likely to be converted into LDL, which implicates the former in the increases in LDL cholesterol (LDL-C) that frequently accompany reductions in plasma TAG in patients with hypertriacylglycerolemia (HTG). There are alternative explanations for this effect on LDL-C involving LDL subfractions and a common polymorphism in the apo E gene as discussed below.

### *Intervention with Dietary Long-Chain n-3 PUFA in ALP Subjects*

A study was designed in collaboration with the Department of Food Biosciences at the University of Reading, to examine the influence of n-3 PUFA on LDL subfractions in subjects expressing an ALP, and to elucidate the molecular basis by which these dietary fatty acids reverse this high-risk lipoprotein phenotype (36). The study was unique in screening potential volunteers from the free-living population for the presence of an ALP and selecting these individuals as the most responsive and therefore most appropriate target group for this form of intervention. Initial selection of subjects was based on existing data to show a fasting plasma TAG in excess of 1.5 mM and HDL-C < 1.1 mM. Those with acceptable lipid values were screened for the predominance of small, dense LDL-3 (>50% or LDL subclass pattern B). With this method of recruitment, 60% of those screened were shown to express all three features of the dyslipidemia known as an ALP and were selected for the intervention trial (18). The trial consisted of a double-blind crossover design with two 6-wk intervention periods with consumption of either a long-chain n-3 PUFA supplement (6 g/d 50% fish oil concentrate, equivalent to 3 g eicosapentaenoic acid and docosahexaenoic acid; 'Pikasol,' EPAX 5500 TG, Pronova, Norway) or a placebo of olive oil separated by a 12-wk washout period. Both supplements were superimposed on the subjects' habitual diets. At the end of each intervention period, subjects were given two standard test meals, a relatively high-fat breakfast (49 g fat) at baseline (0 min), and a lower-fat lunch (30 g fat) after 330 min. Blood samples for the analysis of LDL subfractions were taken at the beginning and end of each intervention period.

### *Effects on Lipids, Lipoproteins and LDL Subfractions*

Supplementation with dietary long-chain n-3 PUFA produced marked decreases in fasting plasma TAG ($P < 0.05$) and attenuation of postprandial lipemia; the latter was measured by the area under the curve (AUC; $P < 0.05$) and the incremental area under the curve (IAUC = TAG values – baseline TAG; $P < 0.05$) (Fig. 6). The decrease in plasma TAG in both fasting and postprandial plasma was inversely associated with the initial plasma TAG values. The group as a whole showed no significant changes in total plasma cholesterol or HDL-C but a small, nonsignificant increase in LDL-C (+7%) (36). There was no change in LDL apo B but a highly significant decrease in both the relative abundance (%) and particle number (apo B) of small, dense LDL-3 (–26%, $P < 0.01$), as measured by quantitative density gradient centrifugation (37). Of the group ($n = 12$), 25% showed a change in LDL subfraction phenotype from pattern "B" to pattern "A" (Fig. 7). Of the remaining 75%, 50% ($n = 24$) showed decreases in LDL-3, whereas 25% showed either no response or a slight increase in this LDL subfraction.

### *Determinants of Change in LDL Subfractions*

The change in the distribution of LDL subfractions was highly correlated with fasting TAG, which explained ~40% of the variation in small, dense LDL-3 as seen previously. The TAG AUC

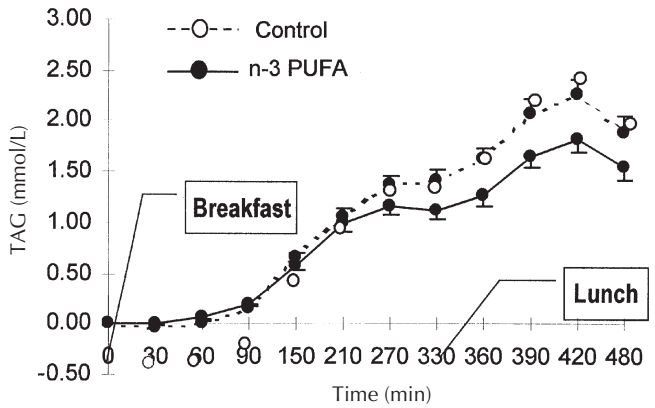

**FIG. 6.** Supplementation with long-chain n-3 PUFA (3 g/d for 6 wk) attenuates the postprandial response to fat-containing meals in subjects with an atherogenic lipoprotein phenotype. Graph shows the incremental postprandial TAG responses (serum TAG – baseline TAG) (36). Data represent mean ± SEM. For abbreviations see Figures 2 and 5.

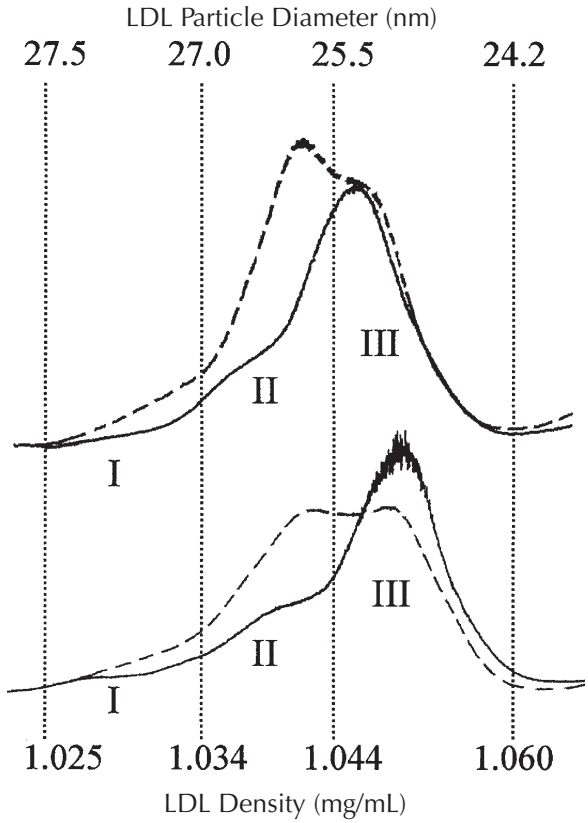

**FIG. 7.** Effect of dietary long-chain n-3 PUFA on LDL subclass profile. n-3 PUFA induce a redistribution of LDL subclasses toward larger and less-dense particles (LDL-1,-2). For abbreviations see Figures 1 and 5.

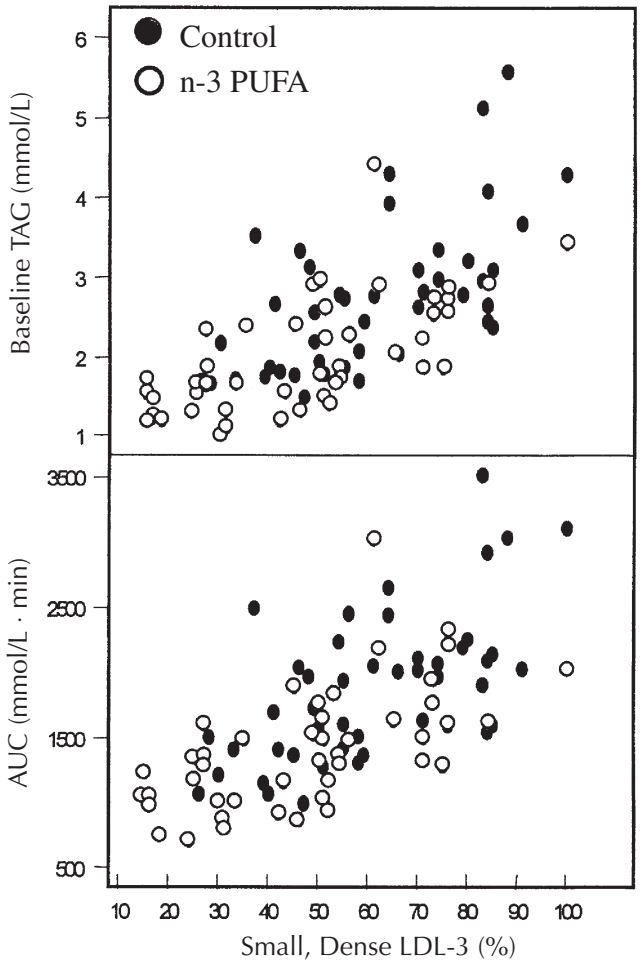

**FIG. 8.** Relationship between small, dense LDL-3 and postabsorptive and postprandial TAG levels. LDL-3 shows significant association with postabsorptive TAG levels in control subjects, $r = 0.62$, $P < 0.001$) and subjects supplemented with n-3 PUFA, $r = 0.66$, $P < 0.001$); and postprandial TAG as measured by area under the curve (AUC) (control $r = 0.61$, $P < 0.001$; n-3 PUFA $r = 0.63$, $P < 0.001$) but not with postprandial TAG as measured by the incremental AUC. For abbreviations see Figures 1, 2, and 5.

was again highly correlated with LDL-3 but provided no additional information (Fig. 8). In contrast, the IAUC showed no relationship with these changes in LDL subfractions. Because the IAUC reflects postprandial clearance of TAG-rich lipoproteins and particularly CM from the influx of dietary fat from the second meal, this finding suggests that fish oil–induced decreases in VLDL are of greater importance to the observed changes in LDL subfractions than effects on CM clearance. Note that reduced VLDL levels would be expected to contribute to the attenuation of postprandial lipemia by allowing CM greater access to LPL, i.e., through reduced competition between these TAG-rich lipoproteins. Of the 25% of subjects who demonstrated a change in LDL phenotype, all achieved reductions in plasma TAG of between 25 and 45%, with 6 of 12 subjects achieving subthreshold values for post–fish oil plasma TAG (<1.5 mM). There were subjects who achieved greater absolute and subthreshold reductions in plasma TAG who showed decreases in LDL-3 but no change in overall phenotype. These subjects generally were more extreme in their phenotypic expression with higher levels of small, dense LDL-3 at baseline.

### *Effects on LDL Cholesterol Explained by Shift in LDL Subfractions*

Dietary long-chain n-3 PUFA in fish oil have frequently been associated with increases in LDL-C, most notably in patients with HTG. One explanation for this effect is that n-3 PUFA generate smaller VLDL particles, which are a favored precursor of LDL. From our data, it was apparent that LDL-C increased in subjects who showed greater reductions in small, dense LDL-3. (This is also likely to be the case in subjects with HTG because of the strong metabolic links between initial plasma TAG, change in plasma TAG, and a decrease in small, dense LDL-3.) Because larger LDL-2 particles contain more molecules of cholesterol ester per LDL particle, both in normal and HTG subjects (38) (Fig. 9), an increase in LDL particle size will almost certainly be accompanied by an increase in LDL-C. The intermediate LDL-2 subfraction has also been shown to have a greater binding affinity to the LDL receptor than its larger (LDL-1) and smaller (LDL-3) relatives (39). Furthermore, there is evidence to show that LDL-1 and LDL-3 are converted into LDL-2 as a means of facilitating the removal of LDL-C from the circulation. Thus, n-3 PUFA–induced increases in LDL-C may reflect changes in

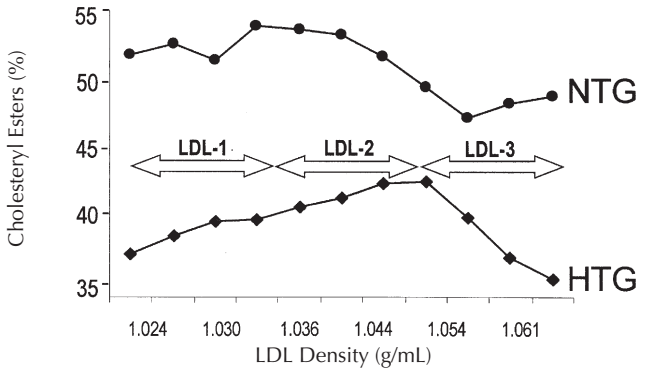

**FIG. 9.** Cholesteryl ester content in LDL subfractions in normolipidemic (NTG) and hypertriacylglycerolemic (HTG) subjects. Data for plots taken from Reference 38. For abbreviation see Figure 1.

LDL composition that, in the presence of an efficient removal of LDL-C, makes physiologic sense and should not necessarily be viewed as an adverse effect of n-3 PUFA. Interestingly, the increases in LDL-C were confined mainly to carriers of a common polymorphism in the gene for apolipoprotein E, apo E4.

### *Effects of Apo E Polymorphism on Responsiveness to n-3 PUFA*

A common genetic polymorphism in the apo E gene gives rise to three structural variants in apo E (apo E2, E3, and E4). These different isoforms of apo E have a profound influence on the metabolism of TAG-rich lipoproteins and LDL and consequently on cholesterol levels and the postprandial response to dietary fat. Their effect on metabolism arises from their variable affinities for the LDL (B/E receptor) and remnant receptor (E receptor) in the order of apo E2 > apo E3 > apo E4. As a result of this difference, carriers of the E2 allele tend to have lower serum cholesterol levels and carriers of E4 higher serum cholesterol through the classic feedback mechanism whereby increasing intracellular cholesterol suppresses the production and thus activity of LDL receptor activity (40). The latter group suffers from a higher risk of CHD and also shows greater responsiveness to low-fat, high-carbohydrate diets in terms of LDL-C lowering (41), largely because of dramatic decreases in LDL particle size, the exact opposite effect to that of dietary n-3 PUFA. The frequency of the E4 allele in Northern Europeans is ~15–20%, whereas in our ALP, 40% were carriers. These subjects showed the greatest decreases in fasting plasma TAG and small, dense LDL-3, and small increases in LDL-C. Because the E4 isoform associates preferentially with VLDL particles, its greater binding affinity for the LDL (B/E) receptor may accelerate the direct clearance of large, TAG-rich VLDL and in turn limit the net transfer of TAG into LDL and thus LDL-3 production. Although this would help to explain the accentuated fall in fasting plasma TAG and LDL-3 in E4 carriers, the down-regulation of LDL receptor activity in this group will almost certainly contribute to the increase in LDL-C.

In summary, dietary long-chain n-3 PUFA exert powerful effects on LDL subfractions by decreasing the concentration of small, dense LDL-3 and, in certain cases, totally correct the abnormal and high-risk LDL pattern "B." This effect is mediated through significant reductions in plasma TAG, chiefly VLDL, and is more pronounced in carriers of the apo E4 polymorphism. Synthetic events in liver seem to be central to the effects of n-3 PUFA on VLDL. However, changes in VLDL will almost certainly impinge on the capacity to clear TAG-rich lipoproteins from the circulation in the postprandial period. As such, factors that determine the rate of TAG removal such as LPL may be equally important in this equation.

## ACKNOWLEDGMENTS

The intervention study was undertaken in collaboration with Professor Christine M. Williams at the Department of Food Biosciences at the University of Reading, UK. The apo E genotyping was performed in collaboration with Dr. Philipa Talmud at the Department of Cardiovascular Genetics, University College London, UK. We gratefully acknowledge support from the Biotechnology and Biological Sciences Research Council.

# The Effect of n-3 Fatty Acids on Coronary Atherosclerosis: Results from SCIMO, an Angiographic Study, Background and Implications

**C. von Schacky*, K. Baumann, and P. Angerer**

Medizinische Klinik Innenstadt, Klinikum der Universität München, Germany

**ABSTRACT:** According to the model of "response to injury," the arterial endothelium is occasionally injured in hyperlipidemia, hypertension, diabetes mellitus and in other states known as risk factors. The ensuing inflammatory response is modulated by cytokines and growth factors, among them platelet-derived growth factor (PDGF), and monocyte chemoattractant protein-1 (MCP-1). In two independent studies, we demonstrated that mRNA levels for PDGF-A and -B and for MCP-1 are reduced after ingestion of n-3 fatty acids by human volunteers. This reduction persists after monocyte stimulation/differentiation by adherence. Moreover, the reduction is brought about only by dietary n-3 fatty acids and not by other classes of unsaturated fatty acids (n-6 or n-9). This appears to be one major mechanism of action of reduced progression/increased regression of established coronary artery disease by ingestion of 1.5 g/d n-3 fatty acids, as assessed by coronary angiography in a randomized placebo-controlled double-blind intervention study in 223 patients. The study was conducted according to "Good Clinical Practice," comprehensive rules regulating investigations with pharmaceutical compounds. Together, our investigations lend support to the importance of PDGF-A, PDGF-B, and MCP-1 in the pathogenesis of atherosclerosis, and the beneficial role of n-3 fatty acids therein.

Paper no. in L8801 in *Lipids 36*, S99–S102 (2001).

Atherosclerosis can be divided into two parts, the slow part of arterial lumen encroachment and the rapid part of lumen obstruction with sometimes catastrophic consequences. This review deals with the slow part, and the effect that is being exerted upon it by the two marine n-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in humans.

According to the model of "response to injury" (1,2), the arterial endothelium is occasionally injured in hyperlipidemia, hypertension, diabetes mellitus, and in other states known as risk factors (1,3). Injured endothelial cells secrete less antithrombotic and more prothrombotic factors (2,4,5). Injured and activated endothelial cells also secrete cytokines and growth factors, leading to chemoattraction of mononuclear cells and immigration of monocytes/macrophages into the subendothelial layer (2,4). Macrophages in the intima then become lipid-rich foam cells and T-lymphocytes immigrate; together with other changes, a "fatty streak "develops (5). Proliferation of smooth muscle cells is then initiated, and a "fibrofatty lesion " results (6). "Advanced lesions " or atherosclerotic plaques are characterized by collagen, smooth muscle cells, immigrated mononuclear cells, and necrotic material (6–8). As a whole, this can be considered a chronic inflammatory process (2,7).

The cells involved in the formation of an atherosclerotic lesion (endothelial cells, smooth muscle cells, and mononuclear cells) communicate through a multitude of cytokines and growth factors (7,8), thus modulating the development of atherosclerosis. A central role is ascribed to platelet-derived growth factors-A and -B (PDGF-A and PDGF-B), and monocyte chemoattractant protein-1 (MCP-1) (2,4,7,8). PDGF induces expression of MCP-1 (9). Other activators of endothelial cells and mononuclear cells also regulate expression of PDGF and MCP-1 (8).

Epidemiology, mechanisms of action, and a number of studies in animal models have demonstrated an antiatherosclerotic potential of dietary n-3 fatty acids in terms of less arterial lumen encroachment (10–12). Previously, we demonstrated that dietary n-3 fatty acids reduced PDGF-A and -B mRNA steady state levels in unstimulated human mononuclear cells of volunteers (13). Against this background, we conducted the following two studies: (i) The first took place among healthy volunteers to test whether the reduction in PDGF-A and -B mRNA steady-state levels seen earlier (13) is limited to PDGF, is brought about only by n-3 fatty acids, or also by n-6 or n-9 fatty acids, and whether it persists after mild monocyte stimulation by adherence *ex vivo* (8). Other growth factors and cytokines investigated were MCP-1, heparin-bound epidermal growth factor (HB-EGF), and interleukin (IL)-10 (14). (ii) The second study took place in patients with coronary artery disease and examined the progression/regression of lesions found at coronary angiography (SCIMO, 15), an established intermediate end point for investigations in coronary atherosclerosis.

Abbreviations: DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; HB-EGF, heparin-bound epidermal growth factor; 12-HETE, 12-hydroxyeicosatetraenoic acid; IL, interleukin; LDL, low density lipoprotein; MCP-1, monocyte chemoattractant protein-1; 3n-PCR, nested, nonoverlapping nonradioactive reverse transcriptase (RT)-polymerase chain reaction; PDGF-A and PDGF-B, platelet-derived growth factors -A and -B.

## MATERIALS AND METHODS

*Volunteer study.* Volunteers ($n$ = 28) were evenly randomized to receive 7 g/d of n-3, n-6, or n-9 fatty acids (Biomedical Test Materials Program, Rockville, MD) or to serve as controls for 4 wk (14). For the quantitative analysis of mRNA levels in human peripheral blood cells, 3n-PCR, a nested, nonoverlapping nonradioactive reverse transcriptase-polymerase chain reaction (RT-PCR) was used (13,16). Experiments were performed in platelet-free preparations of human granulocytes or mononuclear cells, as assessed by light microscopy, the absence of the platelet 12-lipoxygenase product 12-hydroxyeicosatetraenoic acid (12-HETE) by HPLC, and the absence of EGF mRNA, a specific platelet marker (16). Quiescence of cells analyzed was confirmed by measurement of IL 1β (13,14). After suspension in a standard buffer supplemented with 5% serum from the respective donor at the respective time point, mononuclear cells were stimulated by 4 and 20 h adherence to polysterene (14). Personnel involved in analyses and data handling were unaware of the treatment allocation, i.e., "blinded" (14).

*Angiographic study (SCIMO, 15).* This was a randomized, double-blind, placebo-controlled, stratified, clinically controlled 2-yr trial, which was conducted according to the Guidelines for "Good Clinical Practice," a standard design for intervention trials investigating pharmaceutical compounds. Patients ($n$ = 223) with lesions detected at a coronary angiography and without a short number of exclusion criteria (tailored with the aim of losing few patients during the study) were recruited. Intervention consisted of six 1-g capsules/d for 3 mon followed by three for the subsequent 21 mon, containing either a placebo reflecting the fatty acid composition of the average European diet (17) or a 55% marine n-3 fatty acid concentrate. Patients were seen as outpatients during the study at 6-mon intervals. During a short hospital stay, angiograms were taken at the beginning and after 24 mon in a standardized manner. Films of angiograms were evaluated by an expert panel of three experienced cardiologists and rated according to a score system (18). Technically suitable angiograms with lesions considered to have changes were also evaluated using a computer-assisted quantitative angiography system, equivalent to other second-generation systems (secondary end point, ARRI, 19). Secondary end points were predefined cardiovascular events, e.g., sudden death, fatal or nonfatal myocardial infarction, congestive heart failure, and cerebrovascular events. Compliance was assessed by interrogation, capsule count, and by analysis of red cell phospholipid fatty acid composition.

## RESULTS

*Volunteer study.* Ingestion of n-6 or n-9 fatty acids left all variables investigated unaltered (except fatty acid compositions), as was the case in control volunteers. In quiescent mononuclear cells, dietary n-3 fatty acids downregulated mRNA steady-state levels of PDGF-A by 25 ± 10%, of PDGF-B by 31 ± 13%, and of MCP-1 by 40 ± 14%. HB-EGF of IL-10 mRNA steady-state levels were left unaltered by dietary n-3 fatty acids. The reductions in PDGF-A, PDGF-B, and MCP-1 mRNA steady-state levels persisted after stimulation by adherence for 4 or 20 h in a quantitatively similar way (14). We concluded that human gene expression for PDGF-A, -B, and MCP-1, factors thought relevant to atherosclerosis, is constitutive, is constant, and can be reduced only by dietary n-3 fatty acids in unstimulated and adherence-activated monocytes (14).

*SCIMO.* Among the patients, 112 were randomized to placebo, 111 to fish oil. A large number of baseline characteristics were evenly distributed. Meeting predefined noncardiovascular end points, and complaints about study medications, both resulting in early termination of the study, were evenly distributed in both patient groups. Among patients, 80 in the placebo group and 82 in the fish oil group underwent both angiograms, and the resulting pairs of films were evaluated for the primary endpoint. Analyses according to "intention to treat" were as follows. Of 80 pairs in the placebo group, 35 were considered changed in global score; of 82 in the fish oil group, 35 were considered changed in global score, slightly favoring the fish oil group ($P$ for changes in global score = 0.152). One pair in each group was considered unchanged in global score, because progression and regression were balanced. Coronary segments in the fish oil group showed less progression and more regression than did coronary segments in the placebo group. Of 48 segments with angiographic changes in the placebo group, 36 showed mild progression, 5 showed moderate progression, and 7 showed mild regression. Of 55 segments with angiographic changes in the fish oil group, 35 showed mild progression, 4 showed moderate progression, 14 showed mild regression, and 2 showed moderate regression ($P$ = 0.041). Analyses according to "clinical efficacy" and a number of other analyses by the expert panel underline the angiographic difference between placebo and fish oil, in favor of fish oil. Quantitative coronary angiography was possible on 29 pairs of films in the placebo group and 29 pairs of films in the fish oil group. In both groups, a loss in minimal luminal diameter occurred, which was slightly, but nonsignificantly larger in the placebo group. Cardiovascular events occurred in seven patients in the placebo group and in two in the fish oil group ($P$ = 0.10); other clinical parameters were not different. Interestingly, low density lipoprotein (LDL)-cholesterol levels tended to be higher in the fish oil group, at certain time points significantly so, whereas triglyceride levels were significantly lower during fish oil at most time points. The study medication was safe. Blinding of patients and investigators was maintained successfully. Noncompliance occurred in six placebo patients and in nine fish oil recipients. In contrast to our expectations, as assessed by ultrasound, no effect of dietary n-3 fatty acids was seen in the carotid arteries of the SCIMO patients (20). We concluded that dietary intake of n-3 fatty acids modestly mitigated the course of coronary atherosclerosis in humans.

## DISCUSSION

To our knowledge, investigations on the effects of diet or dietary fatty acids on gene expression *ex vivo* are few, whereas

a number of *in vitro* studies have been reported (21–24). Therefore, the precise mechanism(s) behind the reduced gene expression of PDGF-A and -B, and MCP-1 remain to be elucidated. Interestingly, reduction of mRNA levels by dietary n-3 fatty acids in quiescent cells translated into reduced mRNA levels after adherence in a quantitatively similar fashion. This limits slightly the area of research for mechanisms. However, mechanisms discernible *in vitro* are not necessarily operative (or important) *in* or *ex vivo*. Thus, elucidating and defining the underlying mechanism(s) will call for cumbersome volunteer studies.

SCIMO demonstrated a magnitude of effect of dietary n-3 fatty acids on the course of coronary atherosclerosis that is similar to the magnitude of effect seen in studies with a similar design, using other approaches such as cholesterol-lowering, lifestyle changes, or vigorous exercise (25). A smaller study with a less homogeneous patient population, using a different placebo, showed no effect of dietary n-3 fatty acids (26).

Based on "intention to treat," in only one of the two primary end points was statistical significance achieved. However, "clinical efficacy" and other analyses by the expert panel corroborate the conclusion that dietary n-3 fatty acids modestly mitigate the course of coronary atherosclerosis, as assessed by the coronary angiogram. Interestingly, the effect occurred in spite of increased LDL-cholesterol levels, essentially ruling out a dependence on conventional parameters of cholesterol metabolism, and at the same time, making it likely that the effect of n-3 fatty acids occurs at a broad range of LDL-cholesterol levels.

Clearly, the dose of n-3 fatty acids effective in the volunteer study (7 g/d) and the dose effective in SCIMO (1.5 g/d) are different. Therefore, a firm conclusion that reduced growth factor and gene expression are mechanisms of action responsible for the effect seen in SCIMO cannot be drawn. A study using the dose of SCIMO and an approach similar to the volunteer study seems necessary and is being conducted presently in our laboratory. Moreover, the importance of growth factors and cytokines other than PDGF-A and -B and MCP-1, believed to be involved in the pathogenesis of atherosclerosis, remains to be defined in specifically tailored *ex* and *in vivo* studies. All of this is complicated by the observation that in the same patients, n-3 fatty acids were effective in the coronary but not carotid arteries. Thus, the pathogenesis of atherosclerosis might differ in different vascular beds.

In summary, 7 g/d of dietary n-3, but not n-6 or n-9 fatty acids for 4 wk downregulated PDGF-A, PDGF-B, and MCP-1 mRNA levels measured *ex vivo* in mononuclear cells. After stimulation/differentiation of these cells by adherence, this downregulation persisted to a quantitatively similar degree. It is specific and selective for PDGF-A, PDGF-B, and MCP-1, which are thought to promote atherogenesis, but not for HB-EGF or IL1β. In a 2-yr randomized double-blind, placebo-controlled, clinically controlled coronary angiography study in 223 patients, 1.5 g/d dietary n-3 fatty acids reduced progression/increased regression of coronary lesions, as assessed by an expert panel of cardiologists. The two studies combined lend support to the importance of PDGF-A, PDGF-B, and MCP-1 in the pathogenesis of atherosclerosis, and the beneficial role of n-3 fatty acids therein. We hope that future work will more closely define a large number of aspects that remain unclear.

## ACKNOWLEGDMENTS

The original work was supported by Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie, Deutsche Forschungsgemeinschaft, Wilhelm-Sander Stiftung, Fundacion Federico. Pronova AS, Lysaker, Norway supplied capsules for SCIMO and funds for monitoring SCIMO. The contributions of Dr. Wolfgang E. Kaminski, Dr. Ellen Jendraschak, Dr. Wolfgang Kothny, Dr. Stefan Störk and Rosemary Kiefl are appreciated.

# n-3 Fatty Acids and Revascularization Procedures

**Harald Arnesen***

Ullevål University Hospital, Oslo, Norway

**ABSTRACT:** Largely initiated by studies among Greenland Eskimos in the early 1970s, great attention has been given to the possible effects of the very long chain n-3 polyunsaturated fatty acids (PUFA) in a variety of cardiovascular disease states. A series of possibly positive effects on pathogenetic mechanisms in cardiovascular disease has evolved from laboratory studies in cell cultures and animals as well as in humans, focusing mainly on eicosanoid metabolism with reduced activities of platelets and leucocytes, reduced plasma triglycerides and, antiarrhythmic effects in the myocardium. A rationale for a positive effect of very long chain n-3 PUFA in the secondary prophylaxis after revascularization procedures obviously also exists. The positive clinical effects based on prospectively randomized trials are summarized as follows. After coronary artery bypass grafting (CABG), the SHOT study showed statistically significant reduction in angiographic vein graft occlusion in 610 patients after 1 yr with supplementation of 3.4 g/d of highly concentrated very long chain n-3 PUFA. The reduction in occlusion rates was significantly related to the change in the n-3 PUFA concentration in serum phospholipids during the study period with the occlusion rate in the upper quartile of such changes at only ~50% of that in the lower quartile. These results were also clearly related to the presence of angina pectoris and occurrence of myocardial infarction after 1 yr. Several studies were conducted in patients after percutaneous transluminal coronary angioplasty (PTCA). By 1993, two meta-analyses indicated a positive effect on the restenosis rate, a significant problem after otherwise successful PTCA. During the late 1990s, three large prospective randomized placebo-controlled angiographic studies were conducted with very long n-3 PUFA 5.1–8.0 g/d, all with completely negative results. Today, therefore, very long chain n-3 PUFA supplementation cannot be recommended to reduce the incidence of restenosis after PTCA. All studies were performed without stenting of the coronary lesion. In the very special revascularization procedure of heart transplantation, evolving hypertension and accelerated atherosclerosis have been major clinical problems. In other studies, positive effects by supplementation with very long chain n-3 PUFA (3.4–5.7 g/d) were obtained on the surrogate end points coronary vasoreactivity to acetylcholine and hypertension, respectively. On the basis of the presently available literature from clinical studies, recommendations for supplementation with very long chain n-3 PUFA can be given to patients after venous CABG (up to 3.4 g/d), and after heart transplantation (3.4–5.7 g/d) but not to patients after traditional PTCA. In fact, data from substudies suggested the possibility that large doses (5.1 g/d) of very long chain n-3 PUFA might be contraindicated because they induce a proinflammatory state in patients under oxidative stress.

Paper no. L8804 in *Lipids 36*, S103–S106 (2001).

Largely initiated by the reports of Bang, Dyerberg, and coworkers in the 1970s that a low prevalence of coronary artery disease among Greenland Eskimos possibly was associated with their special diet rich in n-3 polyunsaturated fatty acids (PUFA) (1,2), great attention has been given to the influence of these very long chain PUFA on a variety of cardiovascular disease states.

In addition, a large number of laboratory studies in cell culture and animal models have pointed out a series of possible beneficial effects of very long chain n-3 PUFA on the pathogenetic mechanisms of cardiovascular disease, focusing mainly on eicosanoid metabolism with reduced activities of platelets and leucocytes, lowering of plasma triglycerides, and also antiarrhythmic effects in the myocardium.

The possibility of a rationale for positive effects in relation to various revascularization procedures is obviously present, and I will try to summarize the evidence that positive clinical effects of supplementation with very long chain n-3 PUFA can be expected.

Today the primary vascularization procedures include coronary artery bypass grafting (CABG) and percutaneous transluminal coronary angioplasty (PTCA) for coronary heart disease; I will focus mainly on these therapeutic approaches. In addition, I will include some interesting data obtained in the very special revascularization procedure of heart transplantation.

Starting with the last-mentioned data, Fleischhauer and coworkers in 1993 (3) elegantly demonstrated in a randomized study of heart transplant patients that supplementation of 5.7 g/d of very long chain n-3 PUFA normalized the pathologic reactivity of their coronary arteries to intracoronary injection of acetylcholine. Thus, endothelial-dependent vasodilatation was reestablished.

It is well known that heart transplant patients as a group become hypertensive (related to their cyclosporin therapy) and experience accelerated coronary atherosclerosis. In this connection, Andreassen and coworkers (4) in 1997 published their results from a randomized study of 28 heart transplant patients in which supplementation with 4 g/d of n-3 fatty acids significantly reduced the blood pressure compared with a group given corn oil. In fact, after 6 mon the systolic blood

Abbreviations: CABG, coronary artery bypass grafting; CI, confidence interval; OR, odds ratio; PDGF, platelet-derived growth factor; PTCA, percutaneous transluminal coronary angioplasty; PUFA, polyunsaturated fatty acids.

pressure was lower than preoperatively in the n-3 fatty acid group compared with an increase of 17 mm Hg in the corn oil group. In the same period, the diastolic blood pressure had increased by 21 mm Hg in the corn oil group compared with only 10 mm Hg in the n-3 fatty acid group. Of course the data mentioned relate to surrogate end points, but might give a good indication of possible clinical effects for patients in this special group.

For the revascularization procedure of CABG, it is well recognized that up to 50% of patients experience occlusion of venous aortocoronary grafts by angiographic examination after 1 yr. The figures for occlusion of arterial grafting with the internal mammary artery are significantly lower, approaching ~15% after 5 yr.

The vein graft disease, with a high frequency of occlusion after 1 yr, is thought to be caused initially by thrombotic occlusion during the first weeks, and thereafter by a specialized intimal hyperplasia with possible secondary thrombotic occlusion. More traditional atherosclerotic lesions may be seen in vein grafts within the first postoperative year, but generally a period of >1 yr seems to be required for their development. Thus, processes of thrombosis, intimal hyperplasia, and traditional atherosclerosis seem to be involved in the pathophysiology of vein graft occlusion. Related to possible antiatherosclerotic effects of n-3 PUFA, both antithrombotic and antimitogenic mechanisms might be operative.

To date, only one large prospective randomized study on the effect of n-3 PUFA on the incidence of graft occlusion rates has been published. This is the so-called SHOT study by Eritsland and coworkers from our research group (5). In this study, 610 patients undergoing coronary artery bypass grafting were assigned randomly to either supplementation with 4 g/d of highly concentrated n-3 PUFA or a control group. Simultaneously, all patients by stratification received antithrombotic treatment with aspirin or warfarin. Both diet and serum phospholipid fatty acid profiles were monitored and the primary end point was 1-yr graft patency assessed by repeat angiography. The latter procedure was completed in 95% of the patients, and data on the serum phospholipid fatty acids indicated very good compliance with the study medication.

Vein graft occlusion rates per distal anastomoses were 27% in the n-3 PUFA group and 33% in the control group. That gives an odds ratio (OR) of 0.77 with a 95% confidence interval (CI) of 0.6–0.99 and a *P*-value of 0.034. When calculated on a patient basis, 43% in the n-3 PUFA group had one or more occluded vein grafts compared with 51% in the control group. That gives an OR of 0.72 with a 95% CI of 0.51–1.01 and a *P*-value of 0.05.

Interestingly, there was a significant trend to fewer patients with vein graft occlusions with increasing relative change in serum-phospholipid n-3 fatty acids during the study period (*P* for linear trend = 0.0037) (Fig. 1). No effect on a much lower occlusion rate (13.5%) was found for supplementation with n-3 PUFA for the internal mammary artery grafts.

From this study one could conclude that dietary supplementation with 4 g/d of highly concentrated n-3 PUFA

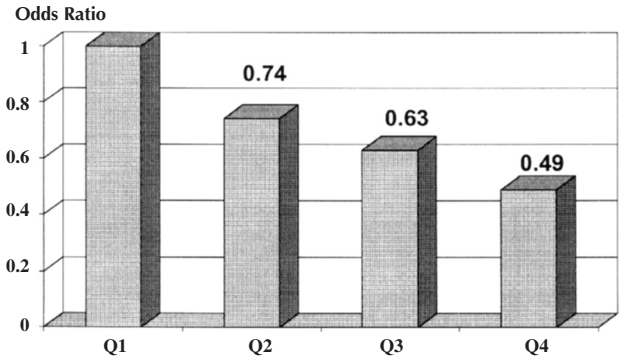

**FIG. 1.** Patients with vein graft occlusion in quartiles of the relative change in polyunsaturated n-3 fatty acids; $n = 524$ patients with vein shunts. *P* for trend = 0.0037 (5).

reduced the incidence of vein graft occlusion after 1 yr and that an inverse relation between relative change in serum phospholipid n-3 fatty acids and vein graft occlusions was observed.

Again, vein graft occlusion is a surrogate end point and the question arises about the clinical relevance of these data. The SHOT study was not designed to evaluate the clinical effects. However, evaluation of the clinical results showed that postoperative angina pectoris was significantly more often related to one or more vein graft occlusions which were present in 67.6% of patients with angina pectoris compared with 40.1% in patients with no postoperative angina ($P < 0.0001$) (6).

In larger prospective studies on CABG patients, there is also a clear correlation between long-term patency of venous aortocoronary grafts and morbidity and mortality after aortocoronary bypass grafting. Finally, it should be mentioned that in the SHOT study no differences in the prevalence of shunt occlusions were observed in the two stratified subgroups of antithrombotic treatment. Thus, it seems reasonable to advocate the supplementation of n-3 PUFA to patients after aortocoronary bypass grafting. According to the limited literature available, supplementation with 3–4 g/d n-3 PUFA concentrates seems reasonable.

The third procedure of revascularization that I will discuss is the potential effect of n-3 PUFA on the phenomenon of restenois after PTCA. This procedure was introduced by Gruentzig in 1977; in most cardiological centers, more patients with coronary heart disease are now being treated with PTCA than with aortocoronary bypass surgery for myocardial revascularization. Although the initial success rate with PTCA is high (~90%), restenosis occurs in up to 50% of the patients after 3–6 mon and obviously represents a large methodological problem and a therapeutic challenge today. The use of intracoronary stenting in parallel with PTCA has reduced the tendency to clinically important restenosis to ~50%. But restenosis remains an important threat to a lasting successful PTCA.

The process of restenosis should be looked on as a response to intimal damage brought about by repeated balloon pressures of ~10 atm. The restenosis process is composed of passive elastic vascular recoil, thrombus formation, and

mainly intimal smooth muscle cell proliferation, extracellular matrix formation, and vessel remodeling. The process includes the active participation of thrombogenic, mitogenic, and vasoactive factors, in which platelet aggregation, inflammation, and cell proliferation are major components. Special attention has been given to platelet-derived growth factor (PDGF) as an important factor for smooth muscle cell chemotaxis. Because n-3 PUFA are known to reduce platelet activation, downregulate leucocytic inflammatory activity, and reduce synthesis of PDGF, a solid rationale for a possible inhibitory effect on the process of restenosis is present.

From 1987 to 1992, seven clinical trials with n-3 PUFA were undertaken to evaluate the possible effect on restenosis after PTCA. The studies varied with respect to type and dosage of n-3 PUFA, time point of starting the supplementation, and diagnostic preciseness toward restenosis. In 1992 and 1993, two meta-analyses were published, the first by O'Connor and coworkers (7), the second by Gapinski and coworkers (8). On the basis of these trials, they concluded that there was a beneficial effect of n-3 PUFA on restenosis, with an OR of 0.71 (95% CI 0.54–0.94, $P = 0.016$) (7). In addition, Gapinski and coworkers (8) pointed out a possible dose-response effect based mainly on the studies with angiographic end-point evaluation. Both studies recommended larger prospective randomized studies to further establish the possible effect.

In the years from 1994 to 1999, three large, prospective placebo-controlled trials of n-3 PUFA in patients undergoing PTCA were published, i.e., Leaf *et al.* in *Circulation* in 1994 (9), Cairns *et al.* in *Circulation* in 1996 (10), and Johansen *et al.* in the *Journal of the American College of Cardiology* in 1999 (11). The studies were of equal size with patient numbers from 500 to 653; the dosage of n-3 PUFA was from 5.1 to 8.0 g/d; and all studies used corn oil as placebo. The n-3 PUFA supplementation was started from 7 to 14 d before the PTCA, and the presence of restenosis was evaluated by quantitative coronary angiography after 18 wk to 6 mon. There were no significant differences between the n-3 PUFA group and the placebo group with respect to restenosis.

In the study of Leaf and coworkers (9), 551 patients were randomized to receive 8.0 g/d of an ethyl ester formulation of n-3 PUFA or corn oil as placebo, starting 12–14 d before elective PTCA. At coronary angiography after 6 mon, 46% of the patients receiving corn oil met the criteria for restenosis (<50% final luminal diameter and >30% increase in narrowing at the stenosis site), compared with 52% in the n-3 PUFA group ($P = 0.37$). Thus, the restenosis rate was actually somewhat higher in the n-3 PUFA group, although this difference was not significant. In this study, two-thirds of the patients additionally received 200 mg α-tocopherol as antioxidant. The incidence of restenosis and the difference between the groups did not differ among patients receiving α-tocopherol and those who did not. They concluded that the supplement of 8 g/d of n-3 fatty acids failed to prevent the usual high rate of restenosis after PTCA.

In the EMPAR study by Cairns and coworkers from Canada (10), 653 patients were randomized to receive 5.4 g/d of n-3 PUFA in a triglyceride formulation or corn oil as placebo with a median start 6 d before elective PTCA and continued until angiography after 18 wk. Again, coronary angiography revealed equal frequency of restenosis defined as loss of >50% of the gain of luminal diameter achieved by PTCA. Thus, in the n-3 PUFA group, 46.5% of the patients fulfilled the criteria for restenosis compared with 44.7% in the placebo group. In this study, low-molecular-weight heparin was also tried in a $2 \times 2$ factorial design. The simultaneous testing of low-molecular-weight heparin did not influence these results. They concluded that there was no evidence for a clinically important reduction of restenosis by n-3 PUFA after PTCA in this trial.

Finally, in the CART study by Johansen and coworkers from our research group (11), 500 patients were randomly allocated to supplementation with 5.1 g/d of highly concentrated n-3 PUFA in an ethyl ester formulation or corn oil as placebo starting at least 2 wk before elective PTCA. Restenosis on quantitative coronary angiography after 6 mon was defined as >50% luminal stenosis or a late loss of at least 20% of diameter or an increase in stenosis of at least 0.7 mm. In this study, restenosis occurred in 45.9% of the patients in the n-3 PUFA group compared with 44.8% in the placebo group. That gives an OR of 1.05, a 95% CI of 0.69–1.59, and a *P*-value of 0.82. On the basis of treated stenoses, the restenosis rate was 40.6% in the n-3 PUFA group compared with 35.4% in the placebo group (OR 1.25, 95% CI 0.87–1.80, $P = 0.21$). In this study, we concluded that supplementation with 5.1 g/d n-3 PUFA for 6 mon initiated at least 2 wk before coronary angioplasty did not reduce the incidence of restenosis.

Given the results of these three large prospective randomized trials, the issue of n-3 PUFA supplementation to counteract restenosis after PTCA has come to a final result: It is not effective and should not be advocated for such use. It should be added that these trials were conducted before stenting became common in connection with PTCA. Today, most PTCA procedures are accompanied by stenting. The latter procedure has reduced the frequency of restenosis to about half that of PTCA alone, but the process of restenosis seems to be the same whether stenting is performed or not.

Finally, I would like to comment on the possibility of negative effects on patients with coronary artery disease with these high doses of highly concentrated n-3 PUFA. Thus, in the CART study, the clinical results, although not the primary aim of the study, seemed to be somewhat poorer in the n-3 PUFA group than in the placebo group. Thus, when angina pectoris was classified in the New York Heart Association classes after 6 mon, significantly more patients were in class 3 and 4 in the n-3 PUFA group than in the placebo group (22 vs. 13%, $P = 0.032$). In line with this observation, the use of betablockers and nitrates was more frequent in the n-3 PUFA group than in the placebo group (39 vs. 30% and 28 vs. 18%, respectively). Whether these observations are relevant to the recently described increase in soluble markers of inflammation after supplementation with high doses of highly concentrated n-3 PUFA (12) remains hypothetical, but obviously the possibility exists.

In summary, on the basis of the literature the following conclusions seem warranted: (i) supplementation with 3.4–5.7 g/d n-3 PUFA concentrate counteracts hypertension and normalizes coronary vasoreactivity to acetylcholine in heart transplantation patients; (ii) supplementation with 3.4 g/d n-3 PUFA concentrate counteracts occlusion of venous aortocoronary grafts 1 yr after by-pass operation; and (iii) supplementation with up to 8.0 g/d n-3 PUFA concentrate does not counteract restenosis 6 mon after PTCA.

# The Electrophysiologic Basis for the Antiarrhythmic and Anticonvulsant Effects of n-3 Polyunsaturated Fatty Acids: Heart and Brain

**Alexander Leaf***

Departments of Medicine, Massachusetts General Hospital and the Harvard Medical School, Boston, Massachusetts

**ABSTRACT:** The n-3 polyunsaturated fatty acids (PUFA) have been shown to be antiarrhythmic in animals and probably in humans. PUFA stabilize the electrical activity of isolated cardiac myocytes by modulating sarcolemmal ion channels, so that a stronger electrical stimulus is required to elicit an action potential and the refractory period is markedly prolonged. Inhibition of voltage-dependent sodium currents, which initiate action potentials in excitable tissues, and of the L-type calcium currents, which initiate release of sarcoplasmic calcium stores, thus increasing cytosolic free calcium concentrations and activating the contractile proteins in myocytes, appears at present to be the probable major antiarrhythmic mechanisms of PUFA. Because the ion channels in neurons have channel proteins essentially homologous to those in the heart, the n-3 fatty acids would appear to be likely to affect the electrical activity in the brain in a manner similar to their effects in the heart, and accumulating evidence supports this notion. Evidence of important beneficial neurological effects of dietary n-3 PUFA are emerging with more likely to be discovered.

Paper no. L8814 in *Lipids 36*, S107–S110 (2001).

After confirming earlier reports by McLennan *et al.* (1) that polyunsaturated fatty acids (PUFA), particularly of the n-3 class, prevent ischemia-induced malignant ventricular arrhythmias (2), we sought to learn the mechanism of their antiarrhythmic action. Working with Dr. Jing X. Kang, we adopted the cultured neonatal rat cardiac myocyte preparation for our studies because we could observe and record the contractile function of the isolated myocytes and the effects on their function of adding agents of interest to the medium bathing the myocytes. The beauty of this preparation is that the enzymatically separated neonatal myocytes can be cultured directly on microscope cover slips to which they adhere. By day 2 in culture, clumps of varying numbers of myocytes can be seen, and each syncytial cluster is beating spontaneously, rhythmically, and synchronously. With an inverted microscope, video camera with monitor, an edge monitor, and tracing recorder, we could observe and record the rate and amplitude of spontaneous contractions (3). We found that a variety of agents that can cause fatal arrhythmias in humans will cause an acceleration of the beating rate of the myocytes and then produce fibrillatory, asynchronous contractions mimicking fibrillation in the whole heart (4). Elevated perfusate ($Ca^{2+}$), the cardiac glycoside ouabain (3), catecholamines (5), thromboxane (4), lysophosphatidylcholine or acylcarnitine, and even the calcium ionophore A23187 (6) all caused the cultured myocytes to fibrillate. However, if low micromolar concentrations of the fish oil fatty acids eicosapentaenoic acid (20:5n-3, EPA) or docosahexaenoic acid (22:6n-3, DHA) were first added to the bathing medium of the myocyte, their beating rate would slow. But when the arrhythmogenic agent was added to the superfusate, no arrhythmias occurred. If the arrhythmic agent was added first and an arrhythmia was induced, then addition of the EPA or DHA to the superfusate within a few minutes stopped the arrhythmia in the continued presence of the cardiac toxin. Finally, addition of delipidated serum albumin, which has high-affinity binding sites for fatty acids will extract the free fatty acids from the cells and the fibrillation resumes (3).

These simple observations taught us two important things (3). First, they showed that the antiarrhythmic action of the n-3 PUFA required the fatty acids simply to partition (dissolve) into the lipophilic phospholipid acyl chains of the plasma membrane without covalent bonding to any constituent of the cell. Otherwise, the PUFA could not be extracted from the myocytes by the serum albumin. We had expected the PUFA to be incorporated rapidly into membrane phospholipids, but we have shown that once they are so incorporated they are no longer antiarrhythmic (7). Second, we found that only the free fatty acid is promptly arrhythmic. Administration of esterified PUFA, such as their ethyl esters or triglycerides, does not produce acute antiarrhythmic actions. In fact, the structure–function requirement for a molecule to be antiarrhythmic in the manner of these PUFA is simply a hydrophobic molecule with a free carboxyl group at one end of a long acyl chain or hydrocarbon and with two or more C=C unsaturated bonds (8).

By this time, we realized that the n-3 fatty acids must be affecting the basic automaticity/excitability of cardiac myocytes. Therefore, with Dr. Yong-Fu Xiao, we tested their effects on the electrophysiology of the cardiac myocytes. Two important effects were found (9). First, in the presence of these fatty acids (5–10 μM), a stronger electrical depolariz-

Abbreviations: CNS, central nervous system; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; HEK, human embryonic kidney; $IC_{50}$, 50% inhibitory concentration; PUFA, polyunsaturated fatty acids.

ing stimulus of 40–50% was required simply to elicit an action potential. This was because the presence of these PUFA caused a slight hyperpolarization of the resting or diastolic membrane potential, while at the same time moving the potential for the gating of the voltage-dependent $Na^+$ current to more positive values. Second, these fatty acids markedly prolonged the refractory period of the myocytes without any prolongation of duration of the action potential. These two electrophysiologic effects are important for the antiarrhythmic effects of PUFA.

To demonstrate that these fatty acids stabilize the cardiac myocytes electrically, a simple experiment was designed (6). While a continuous tracing of the regular spontaneous beating rate of the cultured neonatal rat cardiomyocytes was under way, the myocytes could be stimulated with an external voltage source at 15 V *via* two platinum electrodes immersed in the perfusion fluid at the two ends of the perfusion chamber. With this setup, it was easy to double the beating rate of the myocytes. When the external electrical stimulator was turned off, the contractions of the myocytes returned to their control beating rate. Adding the n-3 PUFA to the perfusate slowed the beating rate of the myocyte, but when the external electrical stimulus was again turned on at 15 V, the myocytes showed no response to the stimuli. At 20 V, the myocytes still did not respond; at 25 V, they did respond, but only to every other electrical stimulus. Now, after the addition of delipidated bovine serum albumin to the perfusing fluid and extraction of the free fatty acids from the myocytes, the beating rate again returned to its control rate. When the external electrical stimulator was again turned on at 15 V, the myocytes doubled their beating rate, just as they had before exposure to the n-3 PUFA. This experiment was done on isolated cardiac myocytes in the absence of humoral or neural regulation. When one considers that this is a direct action of the free n-3 fatty acids on every individual myocyte in the heart, one can appreciate what a potentially effective antiarrhythmic agent they are.

Because all electrical activity of excitable tissues results from the flow of charged ions through specific protein ion channels embedded in the plasma membranes of cells, we turned to an examination of the effects of PUFA on specific membrane ion currents. Dr. Xiao began his study with the effects of the fatty acids on the voltage-dependent $Na^+$ current, $I_{Na}$. PUFA inhibited the $I_{Na}$ in a concentration-dependent manner, with a 50% inhibitory concentration ($IC_{50}$) of 4.8 μM in neonatal rat cardiomyocytes (10), but only 0.51 ± 0.06 M in a human embryonic kidney (HEK) cell line, HEK293t, transiently expressing human myocardial sodium α-subunits, $hH1_\alpha$ (11). Inhibition occurred within seconds of application of the PUFA to the myocytes and was reversed as rapidly by the addition of delipidated bovine serum albumin to the perfusate. It was voltage dependent, but not use dependent, consistent with the lipophilic nature of PUFA (12). In both preparations, $I_{Na\alpha}$ in the rat cardiomyocyte and $I_{Na\alpha}$ in the human myocardial α-subunit (hH1) transiently expressed in HEK293t cells, PUFA caused a large voltage-dependent shift of the steady-state inactivation potential to more hyperpolarized values; the shift at $V_{1/2} = –19$ mV with 10 μM EPA in the neonatal rat cardiomyocyte and a further –27.8 mV with 5 μM EPA in the $hH1_\alpha$. There was no effect of PUFA on the activation of the $Na^+$ channels, only on the inactivated channel. PUFA prolonged the inactivated state of the $hH1_\alpha$ channels by speeding the transition from the activated to the inactivated state and retarding the slow inactivation phase of the channel. In more recent studies (13), the β1-subunit has been transiently coexpressed with the α-subunit in HEK293t cells to produce the $hH1_{\alpha\beta}$, and this shifted the steady-state inactivation potential to the right (to more depolarized potentials), returning the electrophysiology of the $hH1_\alpha$ channels back almost to identity with what we had observed for the neonatal rat cardiomyocytes. EPA was found to have no effect on the activation but only on the inactivation of the $Na^+$ currents, i.e., $I_{Na\alpha\beta}$, $I_{Na\alpha}$, and $I_{Na,rat}$. Consistent with the effects of these fatty acids solely on the inactivated state of the $hH1_{\alpha\beta}$ $Na^+$ channel is the finding that the binding or interaction of EPA to the inactivated state of the $Na^+$ channels displayed a 265-fold higher affinity for EPA than channels in the resting state of $hH1_{\alpha\beta}$ (13).

### *Current Hypothesis*

These effects of the n-3 PUFA (and DHA and α-linolenic acid do the same as EPA), we think, are pertinent to the antiarrhythmic actions of these fatty acids. Our current hypothesis (13) is that this voltage-dependent shift of the steady-state inactivation potential to more negative, hyperpolarizing voltages is important to the demonstrated antiarrythmic action of PUFA in ischemia-induced fatal arrhythmias. With a coronary thrombosis, there occurs a gradient of depolarizations of cardiomyocytes within the ischemic tissue. Cells in the central core of the ischemic tissue quickly depolarize and die due to lack of oxygen and metabolic substrates. Depolarization results from the dysfunctional state of Na,K-ATPase and the rise of interstitial $K^+$ concentrations in the ischemic tissue. But at the periphery of the ischemic zone, myocytes may be only partially depolarized. They become hyperexcitable because their resting membrane potentials become more positive, approaching the threshold for the gating of the fast $Na^+$ channel. Thus, any further small depolarizing stimulus (e.g., currents of injury) may elicit an action potential that may initiate an arrhythmia if it occurs out of phase with the electrical cycle of the heart. In the presence of the n-3 PUFA, however, a voltage-dependent shift of the steady-state inactivation potential to more hyperpolarized resting potentials occurs. The consequence of this voltage-dependent, hyperpolarizing shift is that the negative potential necessary to return these $Na^+$ channels from an inactive state to a closed resting, but activatable state, requires a physiologically unobtainable hyperpolarized resting membrane potential. Also these partially depolarized cardiomyocytes have $Na^+$ channels that can slip into "resting inactivation" from the closed resting state within milliseconds without eliciting an action potential (11). The

result of these two effects of the n-3 PUFA is that these partially depolarized myocytes are quickly eliminated from functioning, and their potential arrhythmic mischief is aborted. By contrast, myocytes in the nonischemic myocardium, with normal resting membrane potential, will not be so drastically affected by this voltage-dependent action of PUFA and will continue to function normally (13).

Disturbed regulation of cytosolic free calcium concentrations is another cause of malignant arrhythmias occurring in ischemia or resulting from a variety of cardiac toxins. Elevations of cytosolic calcium concentrations can result in tachyarrhythmias. The arrhythmias induced by some cardiac toxins mentioned (e.g., elevated extracellular $Ca^{2+}$, ouabain, or catecholamines) are examples of arrhythmias induced by excessive cytosolic $Ca^{2+}$ fluctuations. Such excessive cytosolic free $Ca^{2+}$ fluctuations can induce delayed after-potentials *in vivo*, which may trigger fatal arrhythmias if the after-potential occurs at a vulnerable moment in the electrical cycle of the heart. Because both current through the L-Ca gate ($I_{Ca,L}$) and sarcoplasmic reticulum release of $Ca^{2+}$ underlie many cardiac arrhythmias, together with Drs. A.M. Gomez and W.J. Lederer, the effects of PUFA on $I_{Ca,L}$ and $Ca^{2+}$ sparks were examined (14). Whole-cell voltage clamp techniques and confocal $Ca^{2+}$ imaging were used to determine the effects of PUFA on the voltage-gated L-type $Ca^{2+}$ current ($I_{Ca,L}$), elementary sarcoplasmic reticulum $Ca^{2+}$-release events ($Ca^{2+}$-sparks), and $[Ca^{2+}]_i$ transients in isolated adult rat ventricular myocytes. Extracellular application of EPA and the other antiarrhythmic PUFA, but not saturated or monounsaturated fatty acids produced a prompt and reversible concentration-dependent inhibition of $I_{Ca,L}$. The $IC_{50}$ of EPA was 0.8 μM for $I_{Ca,L}$ in neonatal rat heart cells and 2.1 μM in adult rat ventricular myocytes. Although the EPA-induced suppression of $I_{Ca,L}$ did not significantly alter the shape of the current-voltage relation, it did produce a small but significant negative shift of the steady-state inactivation curve ($\Delta V_{1/2}$ = –3 to –5 mV). The suppression of the $I_{Ca,L}$ by PUFA was voltage and time dependent but not use dependent. The effects of PUFA on $I_{Ca,L}$ resemble their effects on $I_{Na}$, except that the steady-state inactivation potentials for $I_{Ca,L}$ were shifted to the left to a much lesser degree.

When heart cells become "overloaded" with $Ca^{2+}$, they become arrhythmogenic and produce arrhythmogenic $I_{TI}$ currents and waves of elevated $[Ca^{2+}]_i$ that propagate within the heart cells. During the $Ca^{2+}$ overload, the ryanodine receptors (RyRs) also become more sensitive to the triggering process, producing an increased number of spontaneous $Ca^{2+}$ sparks and propagating waves of elevated $Ca^{2+}$, all of which can be viewed with the confocal microscope while measuring membrane current. Thus, it seems that our findings that the n-3 PUFA are potent inhibitors of $I_{Ca,L}$ and that this prevents the cytosolic $Ca^{2+}$ overload (14) appear to be the major mechanism by which the causes of these triggered arrhythmias evoked by ischemia or cardiac toxins are prevented by PUFA. Both repolarizing potassium currents, the initial fast outward current, $I_{to}$, and the slow, delayed rectifier current, $I_{ks}$, were also inhibited but less potently with $IC_{50}$ of 7.5 and 20 μM of DHA, respectively. The inward rectifier potassium current, $I_{k1}$, by contrast, was not affected by PUFA (Xiao, Y.-F. and Morgan, A.L., unpublished results). The net effect of inhibiting the two main repolarizing $K^+$ currents should result in prolongation of the action potential duration; however, the action potential was slightly but significantly shortened by PUFA. This action, together with the higher concentrations of PUFA required to inhibit these currents, makes us think that the effects of PUFA on $K^+$ currents do not play a significant role in their antiarrhythmic effects.

### *Effects of PUFA on the Brain*

Once we had found that the fatty acids affected the ion channels in the heart, the possibility that they likely affect the other excitable tissues, namely, skeletal muscles and the nervous system, was apparent. All excitable tissues utilize the same electrical signaling system generated by ionic currents through specific membrane ion channels, and these are highly conserved in voltage-dependent ion channels. It was the central nervous system (CNS) that interested us primarily. I turned to colleagues at the Epilepsy Institute at the University of Amsterdam, and Dr. Vreugdenhil and associates (15) performed whole-cell voltage-clamp experiments on isolated rat hippocampal CA1 neurons. They found the sodium and calcium channels in these neurons to be modulated by PUFA in a very similar way to what we had found in the heart but with the major effect being to prolong the inactivated state of these channels (15). A functional consequence of these electrophysiologic effects of PUFA in the CNS was then shown by Dr. R.A. Voskuyl *et al.* (16) at the University of Leiden in their rat model. They reported that the electrical threshold for generalized seizure activity was raised after the intravenous infusion of n-3 PUFA. Thus, an anticonvulsant action of PUFA occurs in the CNS. Once the modulation of the functions of cells of the nervous system has been demonstrated, we may expect other studies to report the effects of these fatty acids to modulate other important aspects of the nervous system and of behavior, for which we have mainly only descriptive explanations at present. As with the very rapid effects of the fatty acids on the heart, in the brain they also rapidly cross the blood–brain barrier and should reach all cells promptly (16).

### *Antiarrhythmic Clinical Benefits of n-3 PUFA*

Clinical evidence has been accumulating gradually, suggesting that the n-3 PUFA have antiarrhythmic effects in humans. There have been three encouraging secondary prevention trials that found suppression of sudden cardiac death in the experimental subjects ingesting n-3 fatty acids in their diet (17–19) and also one cohort-control study (20). Further work on the nervous system effects of these antiarrhythmic fatty acids may support our findings in the heart and, we hope, will be pursued by others.

In conclusion, it is apparent that there exists an influence on cardiac and other excitable tissues by common dietary fatty acids that has been largely overlooked. With ~250,000 sudden cardiac deaths annually in the United States, largely due to ventricular fibrillation, and millions more worldwide, there may be an enormous public health benefit from the practical application of this recent understanding. Initial reports suggest that n-3 PUFA are producing beneficial effects in the treatment of depression (21), bipolar, and other behavioral diseases (22). The knowledge that these fatty acids have direct physical effects on a fundamental property of the nervous system, namely, its electrical activity, should encourage further exploration of potential beneficial effects on brain functions both normal and pathologic. It seems likely that we are just scratching the surface of the potential health effects of these interesting dietary PUFA.

# Myocardial Membrane Fatty Acids and the Antiarrhythmic Actions of Dietary Fish Oil in Animal Models

**P.L. McLennan***

Smart Foods Centre, Department of Biomedical Science, University of Wollongong, NSW 2522, Australia

**ABSTRACT:** Epidemiologic studies, animal studies, and more recently, clinical intervention trials all suggest a role for regular intake of dietary fish oil in reducing cardiovascular morbidity and mortality. Prevention of cardiac arrhythmias and sudden death is demonstrable at fish or fish oil intakes that have little or no effect on blood pressure or plasma lipids. In animals, dietary intake of fish oil [containing both eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3)] selectively increases myocardial membrane phospholipid content of DHA, whereas low dose consumption of purified fatty acids shows antiarrhythmic effects of DHA but not EPA. Ventricular fibrillation induced under many conditions, including ischemia, reperfusion, and electrical stimulation, and even arrhythmias induced *in vitro* with no circulating fatty acids are prevented by prior dietary consumption of fish oil. The preferential accumulation of DHA in myocardial cell membranes, its association with arrhythmia prevention, and the selective ability of pure DHA to prevent ventricular fibrillation all point to DHA as the active component of fish oil. The antiarrhythmic effect of dietary fish oil appears to depend on the accumulation of DHA in myocardial cell membranes.

Paper no. L8815 in *Lipids 36*, S111–S114 (2001).

Epidemiologic studies suggest that regular fish consumption may have a role to play in reducing cardiovascular disease morbidity and mortality. It is widely regarded that the long-chain n-3 fatty acids in fish oil are the active nutrients. A variety of cardiovascular effects attributable to fish oils and n-3 fatty acids could contribute, including reduction of blood pressure, antiplatelet actions, and lowering of circulating triglyceride concentrations. However, regular fish or fish oil consumption by patients who have survived a myocardial infarction was shown in 1989 to reduce mortality without attenuating blood pressure, plasma lipids, or new cardiac events (1). Reducing dietary fat or increasing fiber intake was ineffective, suggesting a specific role of the n-3 polyunsaturated fatty acids (PUFA). Postinfarction patients represent a cardiovascular disease population considered to be at very high risk of sudden cardiac death. The findings of the Diet and Reinfarction Trial (DART) (1), when considered in the light of contemporary animal studies (2), suggested a novel alternative mechanism for fish oil in reducing cardiovascular disease mortality, i.e., preventing fatal cardiac arrhythmias.

Publication of the DART results coincided with or preceded a series of clinical trials of class I antiarrhythmic drugs in similar, high-risk, postinfarction patients (3,4). Unlike fish oil, the antiarrhythmic drugs not only failed to prevent fatal arrhythmias, but the trials were halted early because of an increased incidence of sudden cardiac death in the treated groups compared with the placebo groups. More recently, the Gruppo Italiano per lo Studio della Sopravivenza nell'Infarto Miocardico (GISSI) Prevenzione trial, a randomized controlled trial of >11,000 postinfarction patients, found a reduced incidence of sudden death after low-dose fish oil supplementation, thus confirming the earlier DART results and providing further support for a possible antiarrhythmic effect of fish oil (5). Sudden cardiac death from ventricular fibrillation remains a serious problem in medicine. This report reviews the data from animal studies that may provide evidence for or against an antiarrhythmic effect of regular fish oil consumption.

## *Fish Oil and Cardiac Arrhythmia*

Numerous studies demonstrate that dietary lipids can both influence the phospholipid fatty acid composition of myocardial cells and modulate cardiac arrhythmia vulnerability. Diets rich in PUFA of plant (n-6) or marine (n-3) origin reduce the incidence of fatal cardiac arrhythmias generated by acute regional myocardial ischemia in rats (6–9), by electrical stimulation and myocardial ischemia in the marmoset monkey (10), and by calcium or isoprenaline in isolated myocardial tissue (11,12). However, a comparison of the effects of fish oils and dietary vegetable oils indicates an enhanced antiarrhythmic effect of dietary fish oils beyond that attributable to their PUFA content alone (Fig. 1) (13). Fish oils typically contain 30–40% PUFA, mainly as eicosapentaenoic acid (EPA, 20:5n-3) or docosahexaenoic acid (DHA, 22:6n-3); yet without exception, they provide equal or greater antiarrhythmic protection than do equivalent dietary intakes of polyunsaturated vegetable oil, typically containing in excess of 60% PUFA as linoleic acid (18:2n-6) (2,13,14). The difference between the two fatty acid families is more decisively demonstrated in studies in which animals consumed different levels

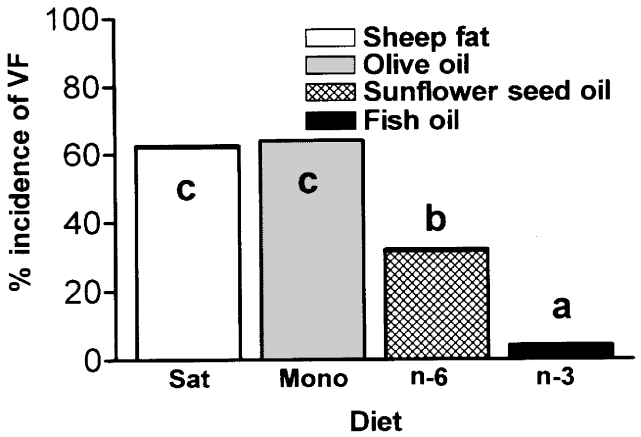

**FIG. 1.** Incidence of ventricular fibrillation (VF) during either 15 min of myocardial ischemia and subsequent reperfusion or during reperfusion after 5 min ischemia in rats after 6 wk of consuming a diet containing 10% sheep perirenal fat (open column, sat), olive oil (grey column, mono), sunflower seed oil (hatched column, n-6), or fish oil (closed column, n-3). Columns not sharing a common letter are significantly different ($\chi^2$, $P < 0.05$, $n = 24–25$).

of n-3 and n-6 PUFA within diets of equal total PUFA content. Marmoset monkeys consuming a diet containing n-3 PUFA required significantly higher threshold stimulation current in comparison to those consuming an n-6 diet to induce ventricular fibrillation electrically under both control and ischemic conditions or when vulnerability was further enhanced by β-adrenergic stimulation (15). In rats subjected to a similar dietary regimen, the antiarrhythmic effect of fish oil was maintained after the n-3 content was diluted by blending with a highly saturated animal fat; the antiarrhythmic effect of n-6 PUFA-rich vegetable oil was lost, however, after blending with the animal fat (16). Dietary fish oil, but not corn oil, also protects against fatal ventricular fibrillation induced by acute administration of a high dose of catecholamines in rats (17). Therefore, a specific antiarrhythmic effect of n-3 fatty acids is proposed, which can be demonstrated in a nonhuman primate, the marmoset monkey, as well as in the commonly used rat models of arrhythmia.

### *Fish Oil and Membrane Fatty Acids*

Modulation of dietary fat intake has marked effects on the fatty acid composition of myocardial cell membranes (18). The phospholipids that make up the myocardial cell membranes are highly responsive to the presence or absence of PUFA of the n-6 and n-3 families. Fish oils used in dietary studies vary considerably in their composition, both in respect to the total n-3 fatty acid content and in the relative concentrations of EPA and DHA (2,13–17,19–23). Studies consistently show that regardless of the type of fish oil used, whether it is high EPA or high DHA fish oil, DHA is the fatty acid that accumulates in myocardial phospholipids after fish oil consumption with very little change in EPA. It accumulates in exchange for monounsaturated oleic acid (18:1n-9) as well as the n-6 PUFA, linoleic acid (18:2n-6) and arachidonic acid (20:4 n-6) (Table 1).

The fatty acid profile of the cell membrane, although directly influenced by the fatty acid composition of the diet, is subject to some regulatory action. Thus, after 6 wk of consumption of a fish oil diet the plasma fatty acids varied from those in the diet, and the profile of heart phospholipid fatty acids differed markedly from those of both the plasma and the diet (Fig. 2). A diet containing 28% of the fat as EPA and 12% as DHA produces rat myocardial membranes containing <5% EPA and >20% DHA. A fish oil containing 12% EPA and 28% DHA can produce myocardial EPA levels of <1% and DHA levels >30%, whereas consumption of a fish oil–free diet will result in undetectable EPA levels and <10% DHA. Thus, the heart, like the brain, has the capacity to accumulate and retain high levels of DHA (21).

Although early studies often fed animals for 12 mon or more, the age of the animal is an important consideration because young control animals are less prone to fatal arrhythmias than are older animals (24). In adult rats, significant alterations in membrane composition occur within 2 d of fish oil feeding; in contrast, it takes 7–14 d of feeding to achieve maximal incorporation of EPA or DHA into the myocardial membrane of adult rats, whereas significant antiarrhythmic effects are achieved only after 7 d or more of feeding (Table

1). Direct comparison of DHA and EPA shows that when rats are fed pure n-3 fatty acids at levels of <0.5% of the diet by weight, DHA is potently antiarrhythmic, whereas EPA is not (25). Under these conditions, consumption of pure EPA is associated with only a small elevation in myocardial DHA levels and an even smaller increase in myocardial EPA. Combining the data from many studies, there is an apparent linear relationship between the dietary intake of DHA and its accumulation in the myocardium (Fig. 3). Studies to date suggest that in rats, a myocardial membrane DHA composition >18% is required for antiarrhythmic effects during myocardial ischemia, whereas <16% is not protective.

In conclusion, in view of the wide variety of both fish oil diets and animal models used in published studies, the results permit unequivocal interpretation that dietary fish oil fatty acids are antiarrhythmic and in particular prevent ventricular

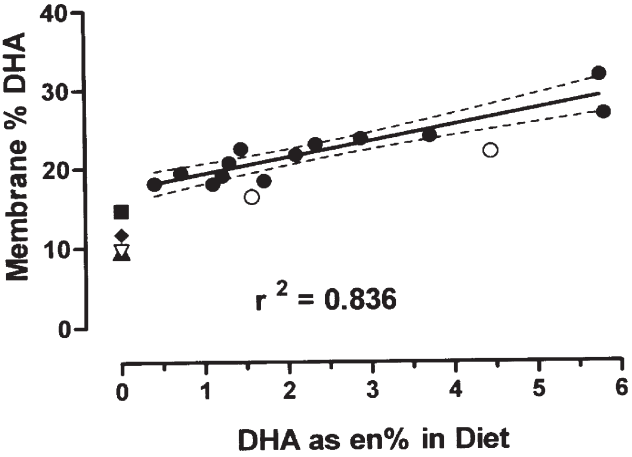

**FIG. 3.** Relationship between dietary intake of docosahexaenoic acid (DHA) as percentage of energy (en%) in the diet and myocardial phospholipid fatty acid composition of rats (closed symbols) or marmoset monkeys (open symbols) fed fish oil or pure DHA- (circles), eicosapentaenoic acid (EPA)- (square), or canola oil– (diamond) supplemented diets or control diets (triangles). fibrillation believed to be so often responsible for sudden cardiac death in humans. The preferential accumulation of DHA in myocardial cell membranes, the association of its accumulation with arrhythmia prevention, and the selective ability of pure DHA to prevent ventricular fibrillation all point to DHA as the active component of dietary fish oil. The antiarrhythmic effect of dietary fish oil observed *in vivo* appears to depend on the myocardial membrane accumulation of DHA.

# n-3 Fatty Acids, Heart Rate Variability, and Sudden Cardiac Death

**Jeppe Hagstrup Christensen[a,*] and Erik Berg Schmidt[b]**

[a]Department of Nephrology, Aalborg Hospital, 9100 Aalborg, Denmark and [b]Department of Medicine, Hjørring/Brønderslev Hospital, 9800 Hjørring, Denmark

**ABSTRACT:** Sudden cardiac death (SCD) is a major cause of mortality in Western countries. Furthermore, SCD is often the first manifestation of coronary artery disease, making it difficult to prevent. Heart rate variability (HRV), which can be determined by extended recording of the heart rate by 24-h Holter monitoring, has been shown to be one of the best predictors of the risk of SCD. There is increasing evidence from animal experiments and clinical trials in humans that n-3 fatty acids reduce the risk of SCD. We have studied the effect of n-3 fatty acids on HRV and present data clearly showing that n-3 fatty acids increase HRV. This adds further to the hypothesis that an increased intake of n-3 fatty acids may reduce the risk of SCD.

Paper no. L8830 in *Lipids 36*, S115–S118 (2001).

This chapter describes the possible protective effect of marine n-3 polyunsaturated fatty acids (PUFA) against sudden cardiac death (SCD) in humans. First, some facts are given regarding SCD, stressing the serious effect of this major problem. Then predictors of SCD will be addressed with emphasis on heart rate variability (HRV). Finally, human studies showing a beneficial effect of n-3 PUFA on HRV will be introduced together with a brief review of studies showing a reduced risk of SCD in humans with a modest intake of n-3 PUFA.

## *Sudden Cardiac Death*

SCD accounts for >300,000 deaths annually in the United States (1). If the definition of SCD is restricted to death within 2 h from onset of symptoms, 12% of all natural deaths have been classified as sudden and >80% of these death are due to cardiac disease (2). Thus, diffuse coronary atherosclerosis constitutes the most common underlying substrate for SCD.

Despite this significant reduction in cardiovascular mortality rate during the past decades, the proportion of patients suffering from SCD has remained constant. Because SCD is responsible for ~50% of the mortality from cardiovascular disease in Western countries (3), attention has been paid to identify persons at risk. However, such identification is flawed by the fact that SCD is often the first manifestation of coronary heart disease (CHD). In other words, although it may be possible to identify high-risk patients and implant cardiodefibrillators, these patients constitute only a very small percentage of the total number at risk for SCD. Therefore, a substantial further reduction in death from acute coronary events can be achieved only from measures preventing death before arrival at the hospital or by reducing the incidence of CHD.

## *Risk Factors for SCD with Emphasis on HRV*

Gender is a major risk factor for SCD because 75% of SCD occur in men. Other traditional risk factors are age, hypertension and left ventricular hypertrophy, hypercholesterolemia, glucose intolerance and diabetes, decreased vital capacity, smoking, and heart rate. Many of these factors have been identified from the Framingham Study (4).

A major independent predictor of SCD is left ventricular dysfunction (5). Also, the presence of ventricular arrhythmias such as premature ventricular depolarizations (PVD) predicts SCD in patients with CHD especially if PVD exceed 10/h in 24-h Holter recordings (6). Other electrocardiogram (ECG) analyses used in predicting SCD are QT prolongation, QT dispersion (7), signal-averaged ECG, and heart rate turbulence (8).

A decreased 24-h HRV is one of the strongest independent predictors for SCD and arrhythmic events (9–11), and HRV is likely the ideal parameter with which to assess intervention therapies because it is stable and free of any placebo effects (11). HRV is considered to represent a noninvasive tool with which to assess cardiac autonomic tone at the level of the sinus node and, thus, indices of HRV provide a window onto autonomic modulation of the heart. Increased HRV normally reflects increased parasympathetic tone, whereas a decreased HRV may reflect a sympathetic predominance.

In population studies, decreased HRV has had predictive value for mortality among healthy adults. It is a well-established risk factor for arrhythmic events and mortality among postmyocardial infarction (MI) patients, and many interventions with drugs leading to increased HRV are also associated with better survival rates (12).

There are many mechanisms precipitating SCD. However, activation of the sympathetic nervous system is essential, leading to a decreased HRV, an increase in sympathetic tone,

Abbreviations: CHD, coronary heart disease; CRF, chronic renal failure; DART, Diet and Reinfarction Trial; ECG, electrocardiogram; HRV, heart rate variability; MI, myocardial infarction; PUFA, polyunsaturated fatty acids; PVD, premature ventricular depolarizations; SCD, sudden cardiac death; SDNN, standard deviation of all normal RR intervals during 24 h.

increasing blood pressure, shear forces, heart rate, platelet aggregation, blood viscosity, and lowering of the ventricular fibrillation threshold. Such changes increase the likelihood of plaque rupture or erosion and platelet aggregation, resulting in ischemic or electrical SCD (13). Increasing evidence suggests that sympathetic hyperactivity during the abrupt rupture of a vulnerable plaque resulting in thrombotic occlusion of a coronary artery favors the genesis of life-threatening ventricular tachyarrhythmias, whereas vagal activation exerts an antiarrhythmic effect (14). The importance of a decreased HRV in post-MI patients has been further substantiated in the recent ATRAMI trial, which included >1200 post-MI patients. HRV was found to carry significant independent information regarding prediction of death (10). Furthermore, apparently healthy subjects subsequently suffering SCD have a decreased HRV (15).

### *Effects of n-3 PUFA on the Risk of SCD in Humans*

The Diet and Reinfarction Trial (DART) was the first study with death as an end point, which suggested an antiarrhythmic effect of n-3 PUFA and thereby a protection against SCD (16). In this trial men with a previous MI who were advised to eat fatty fish at least twice a week had a 29% reduction in mortality after 2 yr compared with patients not given this dietary advice. The survival curves for the two groups separated quite early during the followup, which argued against an antiatherosclerotic effect of n-3 PUFA, and the increased incidence of nonfatal MI in the group given fish advice argued against an antithrombotic effect. On the basis of the emerging evidence for an antiarrhythmic effect of n-3 PUFA in animals, such an effect was suggested as an explanation of the DART results.

A population-based case-control study with 334 cases of primary cardiac arrest and 493 controls found that dietary intake of n-3 PUFA from seafood equal to one fatty fish meal per week was associated with a 50% reduction in the risk of primary cardiac arrest compared with no intake of n-3 PUFA (17). Furthermore, in a subgroup of patients, the levels of n-3 PUFA in red blood cells were measured and the authors divided the subjects into quartiles according to the content of n-3 PUFA in the cell membranes. In comparing the subjects from the lowest quartile with those from the highest quartile, a 70% reduction in the risk of SCD was observed. Thus, there was clearly a decrease in the risk of SCD with increasing cellular levels of n-3 PUFA.

In line with this, the results from the U.S. Physicians' Health Study in which 20,551 male physicians were followed for up to 11 yr showed that consumption of fish once a week was associated with a 52% reduction in the risk of SCD compared with men who consumed fish less than monthly (18). A more frequent intake of fish did not reduce the risk of SCD further.

In a trial from India, 360 patients with suspected MI were randomized to daily supplementation with ~1.1 g of n-3 PUFA, 2.9 g of α-linolenic acid, or placebo (19). Cardiac events were significantly reduced after 1 yr with both active treatments compared with placebo, but cardiac deaths were reduced only in the fish oil group. These patients were not entirely comparable to post-MI patients in Western countries with respect to standard medical treatment because only a very small fraction of these Indian patients received thrombolytic therapy, and the randomization failed to balance the proportion of diabetics and the extent of coronary disease among groups.

Recently, the large GISSI Prevenzione trial including more than 11,000 post-MI patients was published (20). Nearly 3,000 of these patients were given one fish oil capsule daily (0.85 g of n-3 PUFA) for 3.5 yr and compared with a control group of equal size. n-3 PUFA significantly reduced overall mortality and cardiovascular mortality. Moreover, n-3 PUFA supplementation resulted in a striking 45% reduction in the incidence of SCD compared with controls. As in the DART trial, the survival curves in the GISSI Prevenzione trial concerning the n-3 PUFA group controls separated quite early and the difference became significant after only 90 d (Marchioli, R., personal communication). This argues for an antiarrhythmic effect of n-3 PUFA caused by the incorporation of n-3 PUFA into cardiac cell membranes.

Overall, these studies demonstrate that dietary intake of n-3 PUFA clearly is associated with a reduction in SCD. This again points to an antiarrhythmic effect of n-3 PUFA in humans, although such an effect is not addressed directly in these studies with hard end points.

### *n-3 PUFA and the Risk of SCD Assessed by HRV*

In a series of human studies, the potential antiarrhythmic effect of n-3 PUFA has been addressed by means of 24-h HRV. High-risk patients ($n = 55$) with a previous MI and left ventricular dysfunction (ventricular ejection fraction <40%) were randomized to either 5.2 g of PUFA daily or control for 12 wk (21). At baseline, a positive significant correlation ($r = 0.30$, $P < 0.05$) was found between levels of n-3 fatty acids in cell membranes (platelets) and HRV (22). Furthermore, patients who had at least one fish meal per week tended to have a higher HRV than patients not eating fish. After dietary intervention with n-3 PUFA, the important HRV parameter SDNN [standard deviation of all normal RR intervals during 24 h] increased significantly from 115 ms at baseline to 124 ms ($P = 0.01$) after n-3 PUFA supplementation, strongly indicating an antiarrhythmic effect of n-3 PUFA (21). Post-MI patients with the lowest HRV were at the highest risk of SCD, and if the patients with a baseline SDNN < 100 ms were analyzed separately, SDNN increased from 85 ± 16 to 102 ± 21 ms after supplementation with n-3 PUFA ($P = 0.006$). Thus, in this high-risk subgroup, the effect of n-3 PUFA on SDNN was most pronounced.

Patients with chronic renal failure (CRF) are also at high risk of malignant ventricular arrhythmias. In 29 CRF patients, a strong positive association between granulocyte levels of n-3 PUFA and HRV was found, indicating a possible antiarrhythmic effect of n-3 PUFA also in these patients (23).

The relationship between the dose of n-3 PUFA and effect on HRV in healthy subjects has also been investigated (24). Healthy volunteers ($n$ = 60) were allocated to 2.0 g of n-3 PUFA, 6.6 g of n-3 PUFA acids daily, or control. The dietary supplementation was given for 12 wk. At baseline, there was a highly significant positive correlation between marine n-3 fatty acid levels in cell membranes and HRV in men, whereas this association was absent among women. Figure 1 shows the correlation between the docosahexaenoic acid content in platelets and SDNN in men. After dietary intervention, a significant dose-dependent increase in HRV was observed among the men and no effect on HRV was seen in women. The increase in HRV was most pronounced for healthy men with a low baseline HRV. In Table 1, HRV indices are given before and after dietary supplementation with n-3 PUFA for those men belonging to the lowest tertile with respect to SDNN at baseline. Thus, this study showed that even in healthy men, it is possible to increase HRV. This may be of importance because an attenuated HRV in healthy subjects increases the risk of SCD later in life (15).

Recently, HRV was examined in 295 patients referred for coronary angiography (25). HRV was positively associated with the content of n-3 PUFA in both cell membranes and adipose tissue. Furthermore, multiple regression analysis revealed that n-3 PUFA–related factors independently correlated with HRV. An accompanying Editorial stated that, given the safety and low cost of implementing a recommendation for a modest amount of fish in the diet, adequate dietary fish intake has a significant role to play in the primary and secondary prevention of out-of-hospital SCD (26).

Also, in patients with type 1 diabetes mellitus, a significant positive correlation between HRV and n-3 PUFA in cell membranes was observed (27), suggesting that n-3 PUFA supplementation might be beneficial in these patients at high risk of SCD.

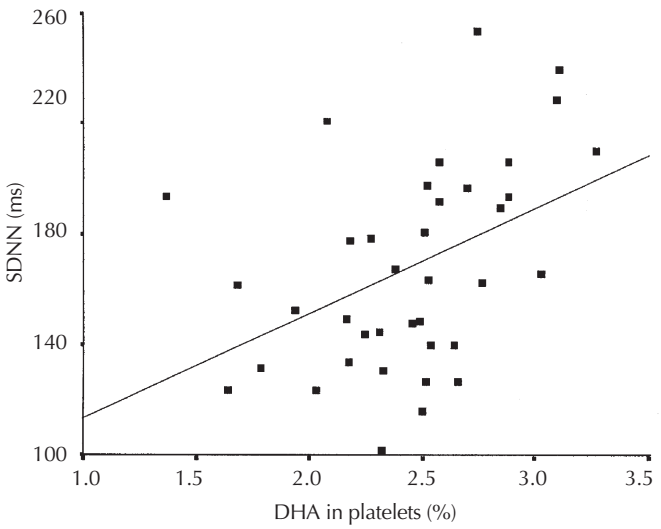

**FIG. 1.** The relation between the level of docosahexaenoic acid (DHA) in platelets and the heart rate variability parameter SDNN (standard deviation of all normal RR intervals during the 24-h recording) in healthy men; $r = 0.48$, $P < 0.01$.

**TABLE 1**
**Heart Rate Variability Indices Before and After 12 wk of Dietary Supplementation with n-3 PUFA (2.0 or 6.6 g) in Healthy Men with a Low Baseline SDNN[a,b]**

| | Before n-3 PUFA | After n-3 PUFA | P-value |
|---|---|---|---|
| RR (ms) | 751 (67) | 796 (93) | 0.03 |
| SDNN (ms) | 130 (9) | 142 (20) | 0.03 |
| SDANNindex (ms) | 120 (18) | 134 (27) | 0.04 |
| RMSSD (ms) | 26 (7) | 32 (9) | 0.01 |
| PNN50 (%) | 6 (5) | 10 (6) | 0.03 |

[a]Values are means (SD).
[b]Abbreviations: RR, mean of all normal RR intervals during the 24-h recording; SDNN, standard deviation of all normal RR intervals in the entire 24-h recording; SDANNindex, the standard deviation of the mean RR intervals measured in successive 5-min periods; RMSSD, the square root of the mean of the sum of the squares of differences between adjacent intervals; pNN50, the percentage of successive RR interval differences ≥50 ms.

In conclusion, the close association between cellular levels of n-3 PUFA and HRV in humans and the fact that dietary supplementation with n-3 PUFA increases HRV support an antiarrhythmic effect of n-3 PUFA in humans, and may explain in part the ability of dietary n-3 PUFA to reduce the risk of SCD. Further intervention studies are warranted in patients with ischemic heart disease as well as in other high-risk groups such as patients with diabetes mellitus.

# Efficacy of n-3 Polyunsaturated Fatty Acids After Myocardial Infarction: Results of GISSI-Prevenzione Trial

**Roberto Marchioli*[,a], Carlo Schweiger[b], Luigi Tavazzi[c], and Franco Valagussa[d]**

[a]Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico, Associazione Nazionale Medici Cardiologi Ospedalieri (ANMCO), Italy, and Istituto di Ricerche Farmacologiche Mario Negri, Consorzio Mario Negri Sud, Santa Maria Imbaro (Chieti), Italy, [b]Ospedale di Passirana di Rho, Milano, Italy, [c]Policlinico San Matteo, Pavia, Italy, and [d]Ospedale di Monza, Italy,

**ABSTRACT:** Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardio (GISSI)-Prevenzione was conceived as a population, pragmatic trial on patients with recent myocardial infarctions conducted in the framework of the Italian public health system. In GISSI-Prevenzione, patients were invited to follow Mediterranean dietary habits, and were treated with up-to-date preventive pharmacological interventions. Long-term n-3 PUFA (1 g daily) but not vitamin E (300 mg daily,) was beneficial for death and for combined death, nonfatal myocardial infarction, and stroke. All the benefit, however, was attributable to the decrease in risk for overall, cardiovascular, cardiac, coronary, and sudden death.

At variance with the orientation of a scientific scenario largely dominated by the "cholesterol–heart hypothesis," GISSI-Prevenzione results indicate n-3 PUFA (virtually devoid of any cholesterol-lowering effect) as a relevant pharmacological treatment for secondary prevention after myocardial infarction.

As to the relevance and comparability of GISSI-Prevenzione results, up to 5.7 lives could be saved every 1000 patients with previous myocardial infarction treated with n-3 PUFA (1 g daily) per year. Such a result is comparable to that observed in the Long-Term Intervention with Pravastatin in Ischaemic Disease (LIPID) trial, where 5.2 lives could be saved per 1000 hypercholesterolemic, coronary heart disease patients treated with pravastatin for 1 yr.

The choice of a relatively low-dose regimen (1-g capsule daily) more acceptable for long-term treatment in a population of patients following Mediterranean dietary habits, and the pattern of effects seen in GISSI-Prevenzione (namely, reduction of overall mortality with no decrease in the rate of nonfatal myocardial infarction) all strongly suggest that n-3 PUFA treatment should be considered a recommended new component of secondary prevention. The importance of this combined/additive effect is further suggested by the analyses of the interplay between diet and n-3 PUFA: There is an interesting direct correlation between size of the effect and "correctness" of background diets. It can be anticipated that a conceptual barrier must be overcome: A "dietary drug" should be added to "dietary advice," which remains fundamental to allow this statement to become true in clinical practice.

Paper no. L8816 in *Lipids 36*, S119–S126 (2001).

The importance of n-3 polyunsaturated fatty acids (PUFA) in human health was noted 20 years ago by Bang and co-workers (1) who suggested that it was the high n-3 fatty acid content in Eskimo's diets that accounted for the low rate of ischemic heart disease. Some years later, Kromann and Green (2) reported on the low mortality of Greenland Inuit from ischemic heart disease and other chronic diseases. Since then, many studies have been carried out on the role on n-3 PUFA in health and disease and in growth and development; most of the studies however, have focused on the prevention and management of cardiovascular disease (3–17).

From the wealth of information made available by studies that explored and supported the antiatherogenic and antithrombotic effects of n-3 PUFA, it now appears that these fatty acids are able to stabilize myocardial membranes electrically, reducing susceptibility to ventricular dysrhythmias and consequently the risk of sudden death (18–31). The Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI)-Prevenzione trial (32–34) was conceived at the beginning of the last decade as a large-scale, population-based clinical trial of patients with recent myocardial infarction, aimed at testing the effectiveness of the administration of the following: (i) n-3 PUFA, which are virtually devoid of any cholesterol-lowering effect, and have also been suspected of increasing the susceptibility of low density lipoprotein particles to oxidative phenomena (35); and (ii) vitamin E, a promising antioxidant substance, sustained by a wealth of experimental and epidemiologic data (36–55). The purpose of this paper was to provide updated data on the GISSI-Prevenzione trial and help clarify some methodological issues raised by the study.

## PATIENTS AND METHODS

### *Study Design*

The study design has been described previously (33,34). Briefly, patients with recent (3 mon) myocardial infarction were enrolled. Eligible patients had no known contraindica-

Abbreviations: ACE, angiotensin-converting enzyme; CHD, coronary heart disease; CI, confidence interval; DART, Diet and Reinfarction Trial; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; GISSI, Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico; PUFA, polyunsaturated fatty acids.

tions to the dietary supplements, were able to provide informed written consent, and had no unfavorable short-term outlook (e.g., overt congestive heart failure or cancer). Age limits were not defined; the clinicians' decision to include elderly subjects in the study depended merely on the expectation of potential benefits in the light of the patient's clinical condition.

A multicenter, open-label design, in which patients were randomly allocated to four treatment groups was adopted. In the absence of evidence for preferred doses of treatments, we decided on daily doses of n-3 PUFA as one gelatine capsule containing 850–882 mg eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) as ethyl esters, and 300 mg vitamin E, given as one capsule of synthetic α-tocopherol; these doses used existing available formulations to help maintain compliance in patients already receiving many other long-term treatments. Patients were randomly assigned n-3 PUFA alone ($n$ = 2835), vitamin E alone ($n$ = 2830), n-3 PUFA and vitamin E combined ($n$ = 2830), or no supplement (control, $n$ = 2828). Patients were asked to adhere to recommended preventive treatments, i.e., aspirin, β-blockers, and inhibitors of angiotensin-converting enzyme (ACE) (statins were not supported by definitive data on efficacy when the trial was started). The treatment assigned had to be continued until the end of follow-up. As an "open" study, it was recommended that participating cardiologists provide the same care and treatment attitude for all patients, regardless of their allocation.

Trial procedures were planned to mimic as closely as possible the routine care after a myocardial infarction. Follow-up visits were scheduled at 6, 12, 18, 30, and 42 mon; these included clinical assessment and the administration of a food-frequency questionnaire. The primary combined efficacy end points were the following: the cumulative rate of all-cause death, nonfatal myocardial infarction, and nonfatal stroke; and the cumulative rate of cardiovascular death, nonfatal myocardial infarction, and nonfatal stroke. We did secondary analyses for each component of the primary end points and for the main causes of death. Subgroup analyses for women and patients aged >70 yr were prespecified in the protocol. The validation of the clinical events included in the primary end points was assured by an *ad hoc* committee of expert cardiologists and neurologists who were not aware of patients' treatment assignment.

*Revision of the database.* After the main results of GISSI-Prevenzione were published (34), more updated information was retrieved through the investigators, census offices, and hospital records. The availability of more information on clinical events allowed further completion of the validation of events included in the main end point. In particular, various unknown causes of death, previously included in the item "other deaths," could be correctly attributed and validated, whereas some nonfatal major cardiovascular events were rejected. Finally, a careful check of the database was performed and at the end of the revision, a patient erroneously randomized twice by a center was identified and eliminated from the analysis.

*Statistical methods.* According to the protocol, follow-up data were right-censored at 42 mon, when follow-up information on the vital status of patients was available for 99.9% of the population through clinical visits or census offices. The analysis was done by intention to treat and according to the main strategy defined in the protocol, i.e., a four-way analysis of efficacy of n-3 PUFA supplements, vitamin E supplements, and the combined treatments compared with controls, as well as the efficacy of the combined treatment compared with individual interventions. According to the possibility of

conducting a two-way factorial analysis as well as of exploring interaction between treatments, we fit multivariate models including the two experimental treatments and the interaction term. If significant, the latter indicates effect modification when the two treatments are given together (56–58). All $P$-values are from two-sided tests for significance.

## RESULTS

The characteristics of GISSI-Prevenzione patients are shown in Tables 1 and 2. Subjects in GISSI Prevenzione appeared to be a relatively low-risk population of acute myocardial infarction survivors recruited early after the index event, i.e., 50% of subjects were recruited within 16 d after myocardial infarction, mean age (± SD) was 59 ± 11 yr; 16% were >70 yr old; 15% were women; and 14% had an ejection fraction ≤40%. Total blood cholesterol levels were almost normally distributed at recruitment with a mean of 211 ± 42 mg/100 mL. Arterial hypertension, diabetes mellitus, and claudication were present in 36, 15, and 4% of patients, respectively; 43% of patients smoked before the index events and only one third of them were still smoking thereafter.

Patients recruited into the study received life style recommendations, and up to date preventive interventions. At the end of the study, in addition to the drugs tested in the trial, antiplatelet drugs, β-blockers, ACE-inhibitors, and lipid-lowering drugs were prescribed to 83, 38, 39, and 46% of patients, respectively. Finally, 5% of patients had coronary artery bypass graft or angioplasty procedures before recruitment and a total of 24% of patients had been revascularized at the end of the study.

### *The Four-Way Analysis*

The full profile of the effects of n-3 PUFA is summarized in Table 3. In the four-way analysis, the 15% relative decrease in risk for the combined primary end point of death, nonfatal myocardial infarction, and nonfatal stroke [95% confidence interval (CI), 2–6, $P$ = 0.022] and the decrease in risk for the other combined end point of cardiovascular death, nonfatal myocardial infarction, and nonfatal stroke (20%, 95% CI, 6–32, $P$ = 0.006) were significant. Analyses of the individual components of the main end point showed that the decrease in mortality (20% of total deaths, 30% of cardiovascular deaths, and 44% of sudden deaths) obtained with n-3 PUFA accounted for all of the benefit seen in the combined end point. There was no difference across the treatment groups for nonfatal cardiovascular events. The results for the combined treatment compared with controls on the primary combined end point and on total mortality were consistent with those obtained with n-3 PUFA alone. No increased benefit was apparent when the rate of the combined end point of death, nonfatal myocardial infarction, and nonfatal stroke among patients receiving n-3 PUFA plus vitamin E was compared with that of the group receiving n-3 PUFA alone or with that of patients treated with vitamin E alone.

Treatment with n-3 PUFA alone significantly lowered the risk of total coronary heart disease (CHD) events (0.78 [0.65–0.94], $P$ = 0.008), whereas the risk reduction observed either with vitamin E alone or with the combined treatment was not significant. No change in fatal plus nonfatal stroke was found for any tested treatment. No change in the patients' risk of undergoing coronary artery bypass surgery or angioplasty was observed for n-3 PUFA or for vitamin E treatment. Patients receiving vitamin E and controls did not differ significantly when data were analyzed for the combined end point and for total mortality.

*$P < 0.10$; **$P < 0.05$ for the interaction term exploring the effects of the two treatment combined.

### *The Two-Way Analysis*

As stated in the protocol, GISSI-Prevenzione was originally conceived and designed as a four-arm clinical trial aimed at recruiting 12,000 patients to allow the comparison of four groups (i.e., n-3 PUFA, vitamin E, and their combination, vs. a control group with standard treatment only) of 3000 patients each over a 3-yr follow-up. The GISSI-Prevenzione design also allowed analyses to be conducted according to the factorial approach (two-way) with or without adjustment for potential interaction between tested interventions. We decided to formally present both analyses (four- and two-way), to allow readers to compare them and judge for themselves the reliability of a statistical analysis of a factorial design when complete independence of either treatment effects or outcomes is not assured.

The two-way analysis adjusted for interaction gave exactly the same results as the four-way analysis and clearly modified all of the point estimates of n-3 PUFA effects on the various study outcomes that were observed in the two-way analysis without adjustment for interaction. The difference between the two-way analyses including or excluding the interaction term reflects the effect modification due to patients receiving both experimental treatments. The interaction term almost reached significance for cardiovascular mortality plus nonfatal myocardial infarction and stroke, and reached the formal level of significance for cardiovascular, cardiac, and sudden death. Such results clearly indicate the need of appropriately allowing for interaction and confounding in the analyses as well as the correctness of the four-way analysis on the basis of both the *a priori* expectations and *post hoc* facts.

## DISCUSSION

GISSI-Prevenzione was a secondary prevention, pragmatic, population trial aimed at assessing the effect of promising treatments on top of accepted preventive interventions such as modification of lifestyle and dietary habits, and pharmacologic therapy (antiplatelets, β-blockers, ACE-inhibitors), in the framework of the clinical practice of a country-wide network of hospitals within the Italian national public health service. The size of the network (about half of the Italian cardiology departments) and of the recruited population, the pragmatism of

the study design aimed at not interfering with clinical practice, and the widespread use of effective preventive interventions assure the transferability of its results to patients with myocardial infarction. In addition to the results of the Diet and Reinfarction Trial (DART), several epidemiologic studies [e.g., Multiple Risk Factor Intervention Trial (MRFIT), Western Electric Study, Zutphen study] suggested that even a low dietary fish intake was associated with a clear reduction of cardiovascular risk in non-Mediterranean countries compared with no intake. GISSI-Prevenzione further extended this finding, i.e., n-3 PUFA, administered as a drug in a population exposed to recommended and Mediterranean dietary habits (also including fish) and to preventive pharmacologic interventions, were able to lower the risk of death in patients with recent myocardial infarction. It is worth noting, in addition, that the results of preliminary subgroup analyses suggest no interaction among correctness of diet, n-3 PUFA administration, and risk of death (data not shown). If any, a somewhat greater, nonsignificant effect was observed in n-3 PUFA–treated subjects with better dietary habits or higher fish intake.

In terms of the number of subjects needed to be treated to save a life, this lower risk of death corresponds to 46.7 (95% CI, 27.2–162.4) subjects to be treated for 3.5 yr or to 163.4 (95% CI, 95.4–568.3) subjects to be treated per year. The latter estimates compare favorably with the results of recent clinical trials, if the correct benefit per year is calculated. For instance, the benefit of pravastatin in the Long-term Intervention with Provastatin in Ischaemic Disease (LIPID) trial was 32.3 (95% CI, 22.4–57.7) subjects to be treated for 6.1 y or 197.0 (95% CI, 136.6–353.0) subjects to be treated per year (59). Such estimates underline the need to consider the duration of follow-up in comparing absolute measures of benefit of different trials. At variance with relative measures of effect, absolute measures of effect are greatly influenced by both the duration of follow-up and the background absolute risk of recruited populations (the latter can be estimated correctly from the rate of events per year in the control group).

GISSI-Prevenzione results were consistent with existing scientific evidence. Several prospective cohort studies found an inverse relationship between n-3 PUFA from fish intake and CHD death. The Zutphen study found that men with low or no fish intake had a higher rate of CHD compared with men who consumed fish one or more times per week (7). The 30-y follow-up in the Western Electric Study, in the Multiple Risk Factor Interventional trial and in the Honolulu Heart Program confirmed this finding (8–10). According to the per-protocol four-way analysis of GISSI-Prevenzione, both primary combined end points were significantly lowered (two-tailed $P < 0.0179$ and $< 0.006$) with n-3 PUFA treatment (by 16 and 20%, respectively). In addition, total mortality (i.e., the most important end point) was 21% lower in patients receiving n-3 PUFA treatment (two-tailed $P = 0.0064$). It is worth underlining that mortality can hardly be considered a "secondary" outcome in any clinical trial. Finally, cardiovascular, cardiac, coronary, and sudden death were significantly decreased by n-3 PUFA treatment.

The results obtained with n-3 PUFA are consistent with those of the DART trial (14). They found a 29% decrease over 2 y in overall mortality in men who ate fatty fish twice a week, with no decrease in the rate of nonfatal myocardial infarction. In addition to the results of the DART trial, the Lyon Diet Heart study (11,15) and the Indian trial by Singh and colleagues (12,13) strongly suggest a protective effect of n-3 PUFA. In the 20,551 male patients of the U.S. Physicians' Health Study, regular fish consumption (≥1 fish meal/wk) conferred a 52% risk-adjusted reduction in sudden deaths compared with fish intake <1 time/mo (6). As in GISSI-Prevenzione, a significant reduction of total mortality paralleled by no modification of nonfatal myocardial infarction was observed. In the U.S. Health Professionals Study a nonsignificant reduction of non-fatal myocardial infarction and CHD death was observed (5). Siscovick *et al.* (25) reported that little or no fish intake (or low n-3 PUFA blood levels) was associated with an increased risk of sudden cardiac death compared with regular fish consumption. However, not all epidemiologic studies have documented benefits from fish intake. In the Alpha-Tocopherol, Beta Carotene cancer study, a nonsignificant excess of risk-adjusted CHD was found in the highest quintile of intake of n-3 PUFA (2.5 g/d) compared with the lowest (0.9 g/d). This is not the only puzzling result of this study, however; the saturated fatty acid intake was also associated with a significantly lower risk of CHD death (60). A recent European study was unable to show that increased levels of adipose tissue DHA were cardioprotective (61). In contrast, Seidelin *et al.* (62) showed an inverse association between adipose tissue DHA levels and coronary artery stenosis.

At the inception of the GISSI-Prevenzione study, information on the antiarrhythmic effects of n-3 PUFA was available, albeit limited to some animal experiments. n-3 PUFA treatment was supposed to act through a modification of the mechanisms related to thrombosis, inflammation, endothelial dysfunction, and atherosclerosis, with the true mechanism of action not known. The triglyceride-lowering effect was not considered important at the dose of n-3 PUFA used in the study and in a mixed population comprised mainly of normolipidemic subjects. During the course of the study, however, new information became available strongly supporting an antidysrhythmic effects of n-3 PUFA, especially for preventing fatal ischemia-induced malignant ventricular rhythms (20). Consistent with the results of the DART trial and with the wealth of epidemiologic and experimental evidence on the antiarrhythmic effects of n-3 PUFA, the nonsignificant results of GISSI-Prevenzione on nonfatal myocardial infarctions along with the significant results on total mortality and sudden death, all strongly suggest an effect of n-3 PUFA on electrical stability of cell membranes.

As to the study design, several recent clinical trials were designed as factorial trials and therefore analyzed according to the two-way approach (63–65). The Physicians' Health Study, for instance, was a correctly designed factorial trial, i.e., aspirin was supposed to act through its antiplatelet activ-

ity on the risk of thrombotic events, whereas β-carotene was supposed to act as an antioxidant to lower the risk of cancer (56,57). Therefore both the outcome measures and the hypothetical biological effects of the treatments were completely independent in this trial. A factorial design allows a clinical trial to include substantially fewer patients than would be required to test two hypotheses separately. Such optimization, however, has a price. The price is to forgo testing the efficacy of the two combined treatments and to aim only at assessing the independent effect of the two treatments. The latter issue, however, is particularly important. In fact, the following two statistical requirements must be fulfilled to test two treatments with a factorial design: (i) the two treatments must have independent effects (i.e., their mechanisms of action should be different and independent of each other); and (ii) the outcome measures (i.e., end points) should be different and independent. If both requirements were fulfilled in GISSI-Prevenzione, then a total of 6900 patients would have been required according to pretrial expectations to carry out a $2 \times 2$ factorial clinical trial with the same power ($1\text{-}\beta = 98\%$ and $= 0.05$). The independence of the outcomes, however, was not fulfilled in GISSI-Prevenzione, whereas the independence of pharmacologic mechanisms of actions known when the study was started (see below) was at least questionable.

Because the main outcome measure of GISSI-Prevenzione (total mortality plus nonfatal myocardial infarction and nonfatal stroke) was significantly lowered according to both statistical approaches, the difference between the 4- and 2-way analyses is only a quantitative issue with respect to the size of effect observed. The size of the benefit, in fact, was greater in the four-way than in the two-way analysis. The four-way analysis, which avoids the possible interference of the interaction of effects between treatments, should be seen as the per-protocol approach showing the "true" results.

In conclusion, GISSI-Prevenzione was conceived as a population-based, pragmatic trial on patients with recent myocardial infarction conducted in the framework of the Italian public health system. Long-term n-3 PUFA (1 g/d), but not vitamin E (300 mg/d), was beneficial for death and for combined death, nonfatal myocardial infarction, and stroke. All of the benefit, however, was attributable to the decrease in risk for overall, cardiovascular, cardiac, coronary, and sudden death. Up to 5.7 lives could be saved every 1000 patients with previous myocardial infarction treated with n-3 PUFA (1 g/d) each year. It is worth noting that n-3 PUFA therapy was given to patients following Mediterranean dietary habits, which are characterized by a high intake of fruit, vegetables, olive oil, and with almost 90 and 55% of subjects consuming fish at least 1 and 2 times/wk, respectively. This issue is particularly important, because dietary recommendations given to GISSI-Prevenzione patients were remarkably similar to the dietary guidelines recently proposed by the American Heart Association for reducing the risk of cardiovascular disease (66). At variance from the orientation of a scientific scenario largely dominated by the "cholesterol-heart hypothesis," GISSI-Prevenzione results indicate that n-3 PUFA (virtually devoid of any cholesterol-lowering effect) represent a relevant pharmacologic treatment for secondary prevention after myocardial infarction. Treatment with n-3 PUFA should be considered a recommended new component of secondary prevention. It can be anticipated that a conceptual barrier must be overcome, i.e., a "dietary drug" should be added to "dietary advice," which remains fundamental to allow this statement to become true in clinical practice (67).

## ACKNOWLEDGMENTS

GISSI is endorsed by Associazione Nazionale Medici Cardiologi Ospedalieri (ANMCO), Firenze, Italy and by Istituto di Ricerche Farmacologiche Mario Negri-Consorzio Mario Negri Sud, Santa Maria Imbaro, Italy. This study was supported by grants from Bristol-Myers Squibb, Pharmacia-Upjohn, Società Prodotti Antibiotici, and Pfizer. Pharmacia-Upjohn and Società Prodotti Antibiotici supplied marketed capsules containing 850–882 mg EPA/DHA ethyl esters. Vitamin E (acetyl *d,l*-α-tocopherol) was supplied by Bracco. We thank Miss Carla Pera, Miss Barbara Ferri, Mrs. Anna Flamminio, and Mrs. Anna Polidoro for secretarial help.

# n-3 Polyunsaturated Fatty Acids and Cardiovascular Diseases: To Whom, How Much, Preparations

**Arne Nordøy[a,*], Roberto Marchioli[b], Harald Arnesen[c], and Jørgen Videbæk[d]**

[a]Department of Medicine, University of Tromsø, Norway, [b]Consorzio Mario Negri Sud, Department of Clinical Pharmacology and Epidemiology, 66030 Santa Maria Imbaro, Italy, [c]Department of Cardiology, Ullevål University Hospital, Oslo, Norway, [d]Research Department, The Heart Association, Copenhagen K, Denmark

**ABSTRACT:** An expert round table discussion on the relationship between intake of n-3 polyunsaturated fatty acids (PUFA) mainly of marine sources and coronary heart disease at the 34th Annual Scientific Meeting of European Society for Clinical Investigation came to the following conclusions:

1. Consumption of 1–2 fish meals/wk is associated with reduced coronary heart disease (CHD) mortality.
2. Patients who have experienced myocardial infarction have decreased risk of total, cardiovascular, coronary, and sudden death by drug treatment with 1 g/d of ethylesters of n-3 PUFA, mainly as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). The effect is present irrespective of high or low traditional fish intake or simultaneous intake of other drugs for secondary CHD prevention. n-3 PUFA may also be given as fatty fish or triglyceride concentrates.
3. Patients who have experienced coronary artery bypass surgery with venous grafts may reduce graft occlusion rates by administration of 4 g/d of n-3 PUFA.
4. Patients with moderate hypertension may reduce blood pressure by administration of 4 g/d of n-3 PUFA.
5. After heart transplantation, 4 g/d of n-3 PUFA may protect against development of hypertension.
6. Patients with dyslipidemia and or postprandial hyperlipemia may reduce their coronary risk profile by administration of 1–4 g/d of marine n-3 PUFA. The combination with statins seems to be a potent alternative in these patients.
7. There is growing evidence that daily intake of up to 1 energy% of nutrients from plant n-3 PUFA (α-linolenic acid) may decrease the risk for myocardial infarction and death in patients with CHD. This paper summarizes the conclusions of an expert panel on the relationship between n-3 PUFA and CHD. The objectives for the experts were to formulate scientifically sound conclusions on the effects of fish in the diet and the administration of marine n-3 PUFA, mainly eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3), and eventually of plant n-3 PUFA, α-linolenic acid (ALA, 18:3n-3), on primary and secondary prevention of CHD. Fish in the diet should be considered as part of a healthy diet low in saturated fats for everybody, whereas additional administration of n-3 PUFA concentrates could be given to specific groups of patients. This workshop was organized on the basis of questions sent to the participants beforehand, on brief introductions by the participants, and finally on discussion and analysis by a group of ~40 international scientists in the fields of nutrition, cardiology, epidemiology, lipidology, and thrombosis.

Paper no. L8809 in *Lipids 36*, S127–S129 (2001).

### *Fish and Coronary Heart Disease*

To highlight the benefit of fish intake in low- as well as high-risk populations, cross-sectional studies on Inuits and Danes and later different Japanese populations have suggested that fish consumption is protective against coronary heart disease (CHD) (1,2). In a recent review of all prospective cohort studies examining the relationship between fish intake and CHD mortality and including >115,000 individuals, the authors concluded that fish consumption is not associated with a lower rate of CHD mortality in low-risk populations, whereas fish consumption at 40–60 g daily is associated with markedly reduced CHD mortality in high-risk populations (3). The most striking observation was the high CHD mortality in people not eating fish at all and the significant reduction in those with an average fish intake of 1–2 meals per week. The mechanisms related to this effect of fish consumption are not clear; however, epidemiologic and clinical studies suggest that antiarrhythmic effects from the consumption of fish and marine n-3 polyunsaturated fatty acids (PUFA) may be of significance (4,5). No inverse association between fish intake and fatal CHD was found in other prospective studies (3). This may have been related to a higher overall fish intake by subjects in these studies. However, confounding factors related to nutritional and genetic variables may be involved.

Clinical, secondary prevention trials including dietary supplementation of n-3 PUFA from marine sources *via* two meals of fatty fish per week or a Mediterranean, α-linolenic acid–rich diet showed a decrease in the risk of myocardial infarction and death (6,7). The Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI) Prevenzione Trial, including >11,000 patients with recent myocardial infarction (MI), showed a preventive effect both on total and cardiovascular, coronary, and sudden death, with n-3 PUFA treatment (1 g/d) given on top of Mediterranean dietary habits and currently recommended secondary prevention treatments (8). Special attention should be given to patients after coro-

Abbreviations used: CHD, coronary heart disease; DHA, docosahexaenoic acid; EPA. eicosapentaenoic acid; GISSI, Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico; MI, myocardial infarction; PUFA, polyunsaturated fatty acids.

nary artery bypass (CAB) surgery. Graft occlusion is a common complication, and there are indications that vein graft occlusion frequency may be reduced by n-3 PUFA (9).

### *n-3 PUFA and Cardiovascular Risk Factors*

In a series of intervention studies, it has been well documented that administration of n-3 fatty acids has beneficial effects on patients with moderate hypertension, on patients with hypertension developing after heart transplantation, and on patients with dyslipidemia and severe postprandial hyperlipemia, all independent risk factors for developing CHD (10–12). The effects on these risk factors, as well as effects on platelet endothelial cell interaction and myocardial cells (14,15), may explain the clinical effects of n-3 PUFA and may also point out subgroups of the population for whom supplementation of n-3 PUFA on a regular basis should be considered.

### *To Whom?*

On the basis of present knowledge we recommend the following as candidates for administration of long-chain n-3 PUFA: (i) patients with myocardial infarction; (ii) patients with hypertriglyceridemia; (iii) and patients with CAB vein grafts, moderate hypertension, decreased heart rate variability, increased platelet reactivity, and after heart transplantation should also be considered for treatment.

### *How Much Should Be Given?*

The initial studies suggesting a relationship between n-3 PUFA and a low incidence of CHD were performed in population groups with diets that contained very high amounts of n-3 PUFA and were also low in saturated and high in monounsaturated fatty acids. In addition, the diets were usually low in n-6 PUFA. The prospective cohort studies have documented that in the Western world with a "traditional" Western diet, the most striking effects have been observed in high-risk populations with an intake of fish equal to 1–2 meals of fatty fish per week (~0.6 g/d).

Both prospective, randomized secondary prevention studies based on increased intake of fatty fish in addition to other healthy dietary habits, or supplementation of the diet with n-3 PUFA, seem to indicate that ~1 g/d of these fatty acids is beneficial (6,8). However, no larger secondary prevention studies using higher dosages have been performed. Subgroup analysis of the GISSI Prevenzione Study (8) showed that the effect of n-3 PUFA supplementation is present irrespective of currently prescribed pharmacologic treatments for secondary prevention after MI. Similarly, the effect was present in subjects eating no fish and in those consuming ≥2 fish meals/wk (R.M.).

With regard to α-linolenic acid, the Lyon Heart Study (7) included 0.61 energy% of this acid in the diet. Supplementation of both plant and marine n-3 PUFA may be required due to their different physiologic effects (for review see Ref. 15). On the basis of nutritional studies, a recommendation for α-linolenic acid of 1 energy% has been suggested. However, more studies are required to evaluate the optimal daily intake with regard to cardiopreventive effects.

Most studies that have evaluated the effect of marine n-3 PUFA on cardiovascular risk factors such as hypertension, dyslipidemia, and postprandial hyperlipemia have shown effects of a daily administration of 3–4 g PUFA (EPA 49%, DHA 35%).

### *Which Preparations?*

There was general agreement in the group that fish should be the first choice as a source for marine n-3 PUFA, including at least two fish meals per week for everyone as part of normal, healthy dietary habits. Administration of n-3 PUFA preparations given at a daily dosage of 1–4 g should be considered in patients post-MI and to other patient groups for whom the use of n-3 PUFA is indicated, especially if the patient is not able to eat rich fish meals.

Because consumption of n-3 PUFA has been associated with a higher susceptibility to oxidation of low density lipoproteins, it is likely that use of concentrated n-3 PUFA products should be accompanied by adequate amounts of antioxidants such as α-tocopherol (16).

In conclusion, in population groups with a high risk for CHD, there is good scientific evidence to recommend intake of n-3 PUFA both from plant and marine sources as part of otherwise healthy dietary habits. One–two fatty fish meals per week is recommended. In patients with coronary heart disease or a risk profile that includes hypertension or hypertriglyceridemia for CHD, higher dosages up to ~4 g/d of marine n-3 PUFA should be used. Of total energy, 1 energy% should come from α-linolenic acid.
