**ABSTRACT:** This work reports the effect of the apolipoproteins A-I and A-II (apoA-I and apoA-II) on the release of tumor necrosis factor (TNF)- $\alpha$ , interleukin (IL)-1 $\beta$ , IL-8, and IL-1 receptor antagonist (IL-1Ra) and on the oxidative burst of human neutrophils. By themselves, apoA-I and apoA-II do not affect the basal liberation of these cytokines, whereas apoA-I affects the release of IL-1 $\beta$  from lipopolysaccharide (LPS)-stimulated neutrophils and apoA-II affects IL-8 released from LPS-stimulated neutrophils. ApoA-II also decreases the production of IL-8 released by neutrophils stimulated with the acute phase apolipoprotein serum amyloid A. Both apoA-I and apoA-II exerted ~30% inhibition on the oxidative burst of neutrophils stimulated by opsonized zymosan, as revealed by the luminol-enhanced chemiluminescence assay. These findings give additional support to the idea that the role of human plasma lipoproteins and apolipoproteins goes beyond their function in lipid transport and metabolism. HDL apolipoproteins appear to be a class of mediators that can participate in the regulation of the activity of neutrophils.

Paper no. L9019 in *Lipids* 37, 925–928 (September 2002).

The biological role of human plasma lipoproteins appears to extend well beyond their function in lipid transport and metabolism. For instance, lipoproteins and their apolipoproteins can affect several immunologically relevant processes (1,2). On the other hand, significant modifications in the concentration of plasma lipids and apolipoproteins have been observed during inflammation (3). In addition, HDL suffers intense changes in composition during the acute-phase response (4), when most of the HDL<sub>3</sub> apolipoprotein A-I (apoA-I) is replaced by the acute-phase protein serum amyloid A (SAA) (4,5). The displacement of apoA-I and enrichment in SAA give rise to a new HDL particle, termed acute-phase HDL. Since HDL and its main apolipoprotein apoA-I are involved in the reverse transport of cholesterol (6) and protection against coronary artery disease (7,8), the rise of acute-phase HDL in inflammation has been considered to be a pro-atherogenic condition. In this context, HDL and apoA-I associate with neutrophils (9) and affect their cellular functions (10–12). HDL decreases the production of reactive oxygen species during the oxidative burst (10). ApoA-I was considered to have a role in the inhibition of reactive oxygen species production by HDL, since free apoA-I was shown to decrease degranulation and superoxide production by activated neutrophils (11). In neutrophils, HDL and acute-phase HDL also decrease the basal and lipopolysaccharide (LPS)-stimulated release of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ),

Abbreviations: apoA-I, apolipoproteins A-I; apoA-II, apolipoproteins A-II; IL, interleukin; IL-1Ra, interleukin-1 receptor antagonist; LPS, lipopolysaccharide; RPA, RNase protection assay; SAA, serum amyloid A; TNF, tumor necrosis factor.

interleukin-1 $\beta$  (IL-1 $\beta$ ), and interleukin-8 (IL-8) (12). On the other hand, free SAA acts as a stimulus for the liberation of these proinflammatory cytokines, pointing to a role of SAA in the progression and maintenance of inflammation (12).

In this study, we focused on the effects of apoA-I and apoA-II, the two most abundant HDL proteins in serum, on the release of cytokines from LPS- and SAA-stimulated human blood neutrophils. Since apoA-II is present in the same HDL fraction with which SAA associates, i.e., HDL<sub>3</sub> (4), the effects of HDL on neutrophil functions might be the result of the combined action of these apolipoproteins.

## MATERIALS AND METHODS

Human apoA-I and apoA-II, LPS (*E. coli* 026:B6), zymosan, RPMI-1640-Hepes supplemented with L-glutamine, dextran, Histopaque®, penicillin, and streptomycin from Sigma Chemical Co. (St. Louis, MO); FBS from Gibco (Grand Island, NY); NaCl, Na<sub>2</sub>HPO<sub>4</sub>, KH<sub>2</sub>PO<sub>4</sub>, and KCl from Merck (Darmstadt, Germany); and luminol from Aldrich Chemical Co. (Milwaukee, WI) were used. Recombinant human SAA was from Peprotech Inc. (Rocky Hill, NJ). SAA is essentially endotoxin free as evaluated by the polymixin B assay as described in Morrison and Jacobs (13).

Neutrophils were obtained from blood of healthy volunteers and isolated as previously described (12) using a commercial gradient of Ficoll-Hypaque (Histopaque®). The purity of the cell preparation was higher than 98%.

**Neutrophil culture and cytokine assay.** Neutrophils (2.5  $\times$  10<sup>6</sup> cells/mL) were cultured in RPMI-1640-Hepes supplemented with 0.3 g/L L-glutamine, 2 g/L sodium bicarbonate, 100  $\mu$ g/mL streptomycin, 100 IU/mL penicillin, and 10% FBS. Neutrophils were kept in a CO<sub>2</sub> atmosphere (5%) at 37°C alone or incubated with LPS (0.5 or 5  $\mu$ g/mL), SAA (17, 40, or 100  $\mu$ g/mL), and human apoA-I or apoA-II (40 or 100  $\mu$ g/mL). After 24 h, the supernatants were collected and frozen at  $\leq$ -40°C until the determination of TNF- $\alpha$ , IL-1 $\beta$ , IL-8, and IL-1 receptor antagonist (IL-1Ra) by ELISA (Quantikine; R&D Systems, Minneapolis, MN).

**Total RNA extraction and RNase protection assay (RPA) analysis.** Purified populations of neutrophils (10<sup>7</sup> cells/mL) were cultured with 40  $\mu$ g/mL SAA in the presence or absence of apoA-I or apoA-II (40  $\mu$ g/mL) for 3 and 21 h. Total RNA was then extracted as described (14), and cytokine mRNA levels were assessed by RPA, using the Riboquant Custom Mouse Probe Set containing probes for IL-1 $\beta$ , IL-1Ra, IL-8, and actin (Pharmingen, Franklin Lakes, NJ) according to manufacturer's instructions; 5  $\mu$ g of total RNA was used per each condition.

**Chemiluminescent assay.** The effect of apoA-I or apoA-II (100  $\mu\text{g/mL}$ ) on the neutrophil oxidative burst was evaluated by the luminol chemiluminescence assay. Freshly isolated neutrophils ( $2.5 \times 10^6$  cells/mL) were stimulated with opsonized zymosan ( $1 \times 10^7$  particles/assay) in the presence of luminol (1 mM). The reaction was run at pH 7.4 in phosphate-saline buffer, containing 100 mM  $\text{CaCl}_2$ , 50 mM  $\text{MgCl}_2$ , and 1 mg/mL glucose at  $37^\circ\text{C}$  in a final volume of 0.3 mL. Chemiluminescence was followed in an EG&G Berthold LB96V Microplate Luminometer. At the concentrations used, apoA-I and apoA-II do not scavenge superoxide anion as evaluated by the absence of effect of apoA-I and apoA-II on cytochrome C reduction in the presence of the xanthine/hypoxanthine oxidase system (15).

Statistical analysis was done by two-tailed analysis with a significance level of 95%.

## RESULTS

ApoA-I and apoA-II, by themselves, do not significantly modify the small amounts of  $\text{TNF-}\alpha$ , IL-1 $\beta$ , IL-8, and IL-1Ra recovered from the supernatants of neutrophils cultured for 24 h. In contrast, apoA-I causes a significant decrease ( $\geq 47\%$ ) in IL-1 $\beta$  release, and apoA-II causes a significant decrease ( $\geq 46\%$ ) in IL-8 release from stimulated neutrophils (see Fig. 1).

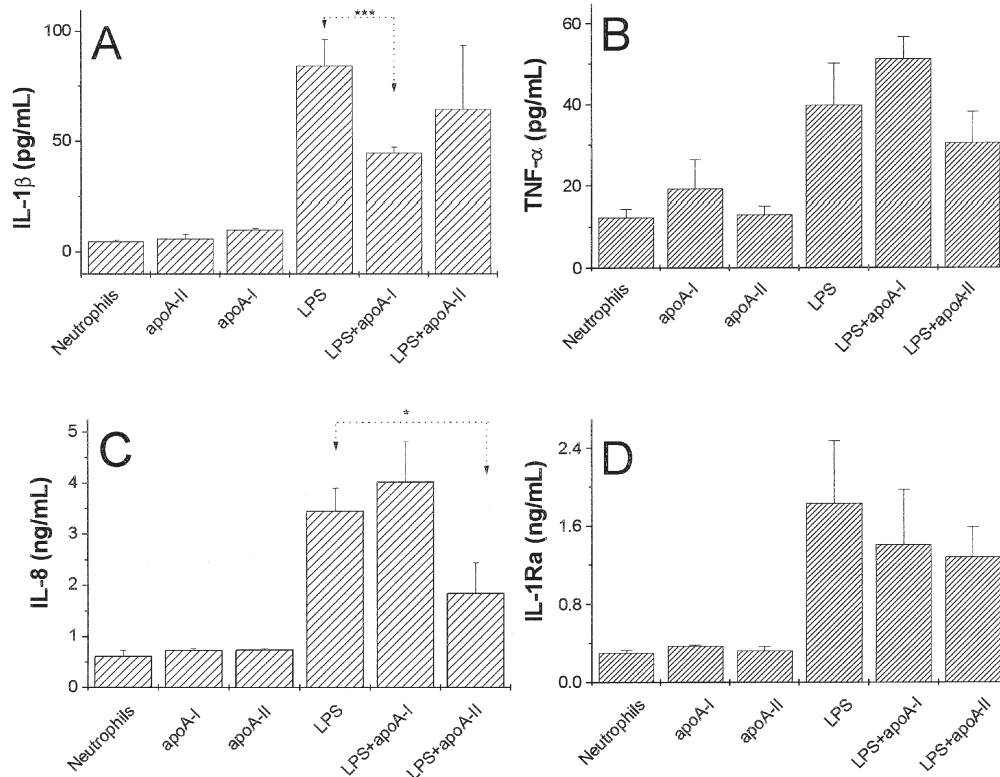

We then examined the effects of apoA-I and apoA-II on the release of IL-8 and IL-1Ra induced by SAA. SAA has previously been shown to trigger the release of neutrophil-derived

proinflammatory cytokines, particularly IL-8 (12). Figure 2 shows that only apoA-II decreases the release of SAA-induced IL-8, by approximately 44%. Neither apoA-I nor apoA-II significantly affected the release of IL-1Ra from SAA-stimulated neutrophils. ApoA-I or apoA-II neither regulate the mRNA transcripts for IL-1 $\beta$ , IL-8, and IL-1Ra nor inhibit the stimulatory effect of SAA on the related genes in 3 h-cultured neutrophils (Fig. 3). The absence of an effect of apoA-I and apoA-II on SAA regulation of mRNA transcripts of IL-1 $\beta$ , IL-1Ra, and IL-8 is also observed at longer incubation times (21 h) (data not shown).

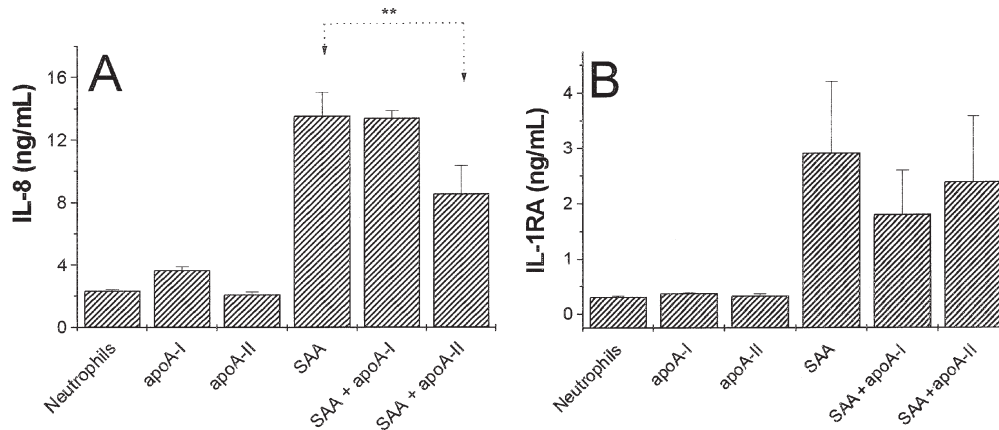

Another function that we studied was the effect of apoA-I and apoA-II on the reactive oxygen species produced by activated neutrophils. The oxidative burst was monitored by the luminol-enhanced chemiluminescence of neutrophils stimulated by opsonized zymosan (Fig. 4). The presence of either apoA-I or apoA-II does not modify the kinetic profile of light emission of opsonized zymosan-stimulated neutrophils but does decrease the integrated chemiluminescence by approximately 30%. The same magnitude of suppression was reported for apoA-I in a previous study where inhibition of superoxide anion formation was followed in neutrophils stimulated by an immunoglobulin G-coated surface (11).

## DISCUSSION

ApoA-I mediates the removal of cholesterol from peripheral tissues and carries it to the liver in a process known as reverse

**FIG. 1.** Effect of lipopolysaccharide (LPS) and the combined action of apolipoprotein A-I (apoA-I) or apolipoprotein A-II (apoA-II) plus LPS on the release of interleukin (IL)-1 $\beta$  (A), tumor necrosis factor (TNF)- $\alpha$  (B), IL-8 (C), and interleukin-1 receptor antagonist (IL-1Ra) (D) by neutrophils ( $2.5 \times 10^6$  cells/mL) after 24 h of cell culture. The concentration of apoA-I and apoA-II was 100  $\mu\text{g/mL}$  and of LPS was 5  $\mu\text{g/mL}$  for the IL-1 $\beta$  and TNF- $\alpha$  assay and 0.5  $\mu\text{g/mL}$  for the IL-8 and IL-1Ra assays. The data represent the average  $\pm$  SD of 4, 6, 5, and 2 experiments for A, B, C, and D, respectively. Significance was \* $P \leq 0.05$  and \*\*\* $P \leq 0.001$  comparing the effect of LPS alone with LPS plus apoA-I or apoA-II.

**FIG. 2.** Effect of apoA-I, apoA-II, or serum amyloid A (SAA) and the combined action of apoA-I or apoA-II plus SAA on the release of IL-8 (A) and IL-1Ra (B) by neutrophils ( $2.5 \times 10^6$  cells/mL) after 24 h of cell culture. The concentration of apoA-I and apoA-II was 100  $\mu\text{g/mL}$  and of SAA was 17  $\mu\text{g/mL}$  for the IL-8 assay and 40  $\mu\text{g/mL}$  for apoA-I, apoA-II, and SAA for the IL-1Ra assay. The data represent the average  $\pm$  SD of seven experiments for IL-8 and two experiments for IL-1Ra. Significance was  $**P \leq 0.005$  comparing the effect of SAA alone with SAA plus apoA-II. For other abbreviations see Figure 1.

cholesterol transport (6). This is considered to be a key process in the protective effect of HDL on coronary artery disease (8). Although the biological role of apoA-I is relatively well known, the functions of the second-most abundant HDL apolipoprotein, apoA-II, are still poorly understood. More recently, with the development of a mouse lineage that overexpresses apoA-II, it has been shown that, in contrast to what happens with apoA-I, HDL enriched with apoA-II lose their ability to protect against LDL oxidation and monocyte transmigration *in vitro* and promote the development of atherosclerosis *in vivo* (16). Apparently, the latter phenomenon is not a direct effect of apoA-II but rather is related to the loss of paraoxonase in the HDL particle (16).

Besides the central function that apoA-I plays in lipid metabolism, apoA-I also affects neutrophil degranulation and oxidative burst (11). From the available information about the possible functions of apoA-I, it was inferred that this apolipoprotein has a general beneficial action, including an anti-inflammatory effect. In this study, we examined the par-

ticipation of both apoA-I and apoA-II in a process unrelated to lipid metabolism. Our results show that apoA-II affects the oxidative burst in a manner similar to apoA-I and that both affect the production of cytokines by neutrophils.

Cytokines are produced during the activation of innate and acquired immunity and serve to initiate the inflammatory response. The cytokine profile that predominates in a specific inflammatory process defines the magnitude and the nature of the immune response. The cytokines assayed in this study included the proinflammatory cytokines IL-1 $\beta$  and TNF- $\alpha$ , the chemokine IL-8, and the immunoregulatory cytokine IL-1Ra. At the concentration used, apoA-I and apoA-II showed inhibitory effects on IL-1 $\beta$  and IL-8 secretion, respectively, supporting the idea that they can act as anti-inflammatory compounds. Our results extend previous ones in which an inhibitory effect of apoA-I on the release of TNF- $\alpha$  and IL-1 $\beta$  from monocytes was described (17) and add an important new role for apoA-II as an inhibitor of IL-8 from neutrophils.

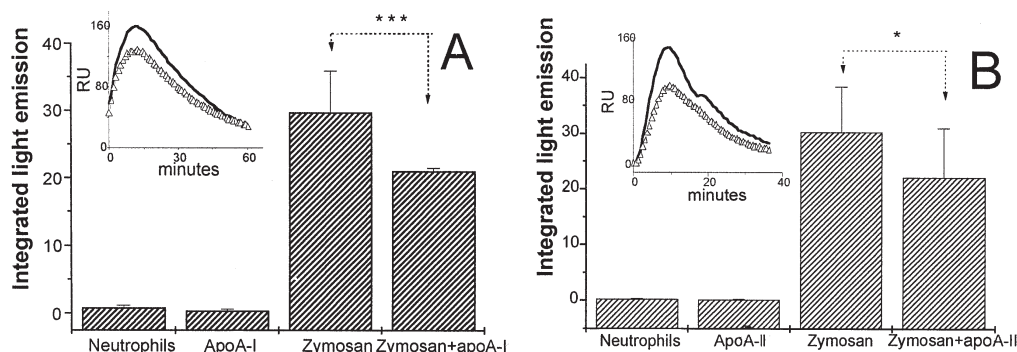

We did not observe any modulation of the various cytokine mRNA levels by either apoA-I or apoA-II in SAA-stimulated neutrophils. The regulation of the mRNA levels and the release of cytokines from neutrophils are complex and not completely understood. For instance, reduction in the mRNA levels of IL-1 $\beta$  and IL-8 in LPS-stimulated neutrophils treated with the inhibitory cytokine IL-10 was observed only at times of incubation beyond the onset of mRNA accumulation (18). Although it is possible that the reduction in the amount of cytokine released from stimulated neutrophils in the presence of apoA-I or apoA-II is due to posttranscriptional or translational effects, an effect of apoA-I and apoA-II on cytokine transcription cannot be completely discarded. This is an open question that merits further study.

Finally, the fact that apoA-I, apoA-II, and apo-SAA are found in the same HDL fraction, HDL<sub>3</sub>, indicates that an active interplay may exist between these apolipoproteins in the lipoprotein particles. Both apo-SAA (2) and apoA-II (19) can displace apoA-I from HDL particles and, although more weakly than for apoA-I, SAA also displaces apoA-II from the HDL (20). The results of the present study provide evidence that apoA-II may be one of the factors responsible for the anti-

**FIG. 3.** IL-1 $\beta$ , IL-8, and IL-1Ra mRNA expression in neutrophils incubated with apoA-I and apoA-II in the absence and presence of SAA for 3 h. The concentration of apoA-I, apoA-II, and SAA was 40  $\mu\text{g/mL}$ . The data are representative of three independent experiments. For abbreviations see Figures 1 and 2.

**FIG. 4.** Effect of apoA-I (A) and apoA-II (B) on the luminol-enhanced chemiluminescence of neutrophils ( $2.5 \times 10^6$  cells/mL) in the absence or presence of zymosan ( $1.0 \times 10^7$  particles/mL). The concentration of apoA-I and apoA-II was 100  $\mu$ g/mL. The data are the average values of the integrated light emission  $\pm$  SD of eight experiments. Significance was  $*P \leq 0.05$  and  $***P \leq 0.001$  for comparison between opsonized zymosan-stimulated neutrophils in the presence and absence of apoA-I or apoA-II. The insets show the kinetics of light emission for a representative experiment. Solid lines represent neutrophils plus zymosan; triangles represent neutrophils plus zymosan plus apoA-I (A) or apoA-II (B). RU, relative units; for other abbreviations see Figure 1.

inflammatory effect of HDL and that, during inflammation, apoA-II may be important in the control of the proinflammatory effects of SAA. Mechanisms that counterregulate neutrophil functions can prevent deleterious effects under inflammatory conditions, and apoA-I and apoA-II may be important in this process.

# Supplementation with a Pine Bark Extract Rich in Polyphenols Increases Plasma Antioxidant Capacity and Alters the Plasma Lipoprotein Profile

Sridevi Devaraj<sup>a</sup>, Sonia Vega-López<sup>a</sup>, Nalini Kaul<sup>a</sup>, Frank Schönlau<sup>b</sup>, Peter Rohdewald<sup>b</sup>, and Ishwarlal Jialal<sup>a,\*</sup>

**ABSTRACT:** Pycnogenol® (PYC), an extract of French maritime pine bark (*Pinus pinaster*), is a potent antioxidant with potential health benefits. Its bioavailability has previously been shown by urinary excretion studies of constituents and metabolites of PYC. The aim of this study was to test the effect of PYC supplementation on measures of oxidative stress and the lipid profile in humans. Twenty-five healthy subjects received PYC (150 mg/d) for 6 wk. Fasting blood was collected at baseline, after 3 and 6 wk of supplementation, and again after a 4-wk washout period. After 6 wk of supplementation with PYC, a significant increase in plasma polyphenol levels was detectable, which was reversed after the 4-wk washout phase. The antioxidant effect of PYC was demonstrated by a significant increase in oxygen radical absorbance capacity (ORAC) in plasma throughout the supplementation period ( $P < 0.05$ ). The ORAC value returned to baseline after the 4-wk washout period. Moreover, in addition to its antioxidant effects, PYC significantly reduced LDL-cholesterol levels and increased HDL-cholesterol levels in plasma of two-thirds of the subjects. While the LDL changes reversed during washout, the HDL increase did not. There was no significant difference in LDL oxidizability or plasma lipid peroxides following PYC supplementation. Hence, following oral supplementation in humans, PYC significantly increases antioxidant capacity of plasma, as determined by ORAC, and exerts favorable effects on the lipid profile.

Paper no. L8982 in *Lipids* 37, 931–934 (October 2002).

Reactive oxygen species (ROS), particularly the highly reactive oxygen radicals, are produced continuously in cells as a by-product of metabolism. They can oxidize biomolecules, with the potential of causing a broad array of degenerative processes. It is now widely accepted that free radical species play an important role in the pathogenesis of various diseases. Atherosclerosis is believed to be initiated by oxidative modification of LDL (1). ROS play a decisive role in the regulation of inflammation by activating transcription factors such as NF- $\kappa$ B, which control expression of adhesion molecules and pro-inflammatory cytokines (2). ROS contribute to the

development of cancer and cardiovascular diseases (3). ROS also play a role in neurodegenerative diseases such as Alzheimer's dementia (4) and in the aging process itself (5).

Dietary micronutrients with antioxidant properties may play an important role in the prevention of atherosclerosis (6). Flavonoids are a large and diverse group of dietary micronutrients found in fruits, vegetables, tea, and wine. Epidemiological studies have shown an inverse association with flavonoid intake and coronary artery disease (CAD) risk and mortality (7,8).

Pycnogenol® (PYC), a bark extract of the French maritime pine (*Pinus pinaster*), is rich in flavonoids and was found to be among the most powerful natural antioxidants (9,10). Chemical composition of PYC has not been completely elucidated. However, it mainly consists of phenolic substances, primarily procyanidins consisting of condensed catechin and epicatechin subunits, forming oligomers up to dodecamers (9). PYC further contains monomeric catechin, taxifolin, and various phenolcarboxylic acids (9,11). PYC has been shown to recycle the ascorbic radical and to protect vitamin E against oxidation (12). In clinical studies PYC was found to counteract increased platelet aggregation in smokers (13), improve microcirculation (14), act as an anti-inflammatory agent [e.g., to inhibit UV-induced erythema (15)], increase capillary integrity in vascular disorders (16,17), and provide various other health benefits (10). These studies all demonstrate that PYC is absorbed by and exerts its action on the human body. This has been corroborated by urinary excretion studies showing that metabolites and constituents of PYC are absorbed (18,19). *In vitro* evidence exists for the potential antioxidant benefits of the flavonoid extract PYC, but dietary supplementation studies in humans are scarce. Here, we have tested the antioxidant effects of supplementation with PYC in normal healthy volunteers.

## METHODS

**Subjects.** The 25 healthy subjects in this study were included without restriction by gender, race, or socioeconomic status. The necessary criteria for participation were age  $< 50$  y, body mass index (BMI)  $< 25$  kg/m<sup>2</sup>, a diet with fewer than five servings of fruit and vegetables per day. Exclusion criteria were alcohol consumption; infection in the past 4 wk; gastrointestinal disorders (e.g., malabsorption); ingestion of vitamins, antioxidants, flavonoid supplements, hypolipidemic drugs, estrogen, thyroxin, or nonsteroidal anti-inflammatory drugs in

Abbreviations: AAPH, 2,2'-azobis(2-amidinopropane)dihydrochloride; BMI, body mass index; CAD, coronary artery disease; CBC, complete blood count; FOX, ferrous oxide-xylene orange; ORAC, oxygen radical absorbance capacity;  $\beta$ -PE,  $\beta$ -phycoerythrin; PYC, Pycnogenol®; ROS, reactive oxygen species; TSH, thyroid-stimulating hormone.

the last month; high consumption of flavonoid-rich foods (e.g., grapes, grape products, dark chocolate, tea, red wine, berries, etc.); abnormal blood count; and abnormal renal or hepatic function. During the period of the study, subjects were advised not to change their usual diet and activity level, and they were instructed to restrict consumption of flavonoid-rich foods (grape products, fruits, fruit juices, dark chocolate, and tea). The subjects received 150 mg PYC per day for 6 wk. The protocol was approved by the Institutional Review Board at the University of Texas Southwestern Medical Center at Dallas. Written informed consent was obtained from all subjects.

**Laboratory tests.** For screening, 15 mL blood samples were collected and used to determine the complete blood count (CBC), plasma lipid and lipoprotein profile, creatinine level, liver function, blood glucose level, and level of thyroid-stimulating hormone (TSH) using standard laboratory assays. Fasting blood (50 mL) was collected in EDTA or heparin from subjects at baseline, after 3 and 6 wk of supplementation with PYC, and again after a 4-wk washout period. Plasma was separated and aliquots were stored at  $-70^{\circ}\text{C}$  for determination of polyphenols, the antioxidant potential of plasma, the lipid profile, and plasma lipid peroxides.

**Plasma total phenols.** Plasma total phenols were measured by the method of Serafini *et al.* (20). Briefly, for total phenols, 500  $\mu\text{L}$  of plasma was acidified and, following extraction of complexed phenols with alcoholic sodium hydroxide, proteins were precipitated using 0.75 M metaphosphoric acid and re-extracted with a mixture of acetone/water (1:1). Phenol content was measured by the Folin–Ciocalteu method using phenol as the standard and was expressed as mg phenol equiv/L.

**Oxygen radical absorbance capacity (ORAC) measurement.** The antioxidant potential of heparinized plasma before and after PYC supplementation was determined following deproteinization of the sample by the ORAC assay based on the procedure described by Cao and Prior (21). The method utilizes  $\beta$ -phycoerythrin ( $\beta$ -PE) as an indicator protein and 2,2'-azobis(2-amidinopropane)dihydrochloride (AAPH) as a peroxyl radical generator. Under appropriate conditions, the loss of PE fluorescence in the presence of reactive species is an index of oxidative damage of the protein. The inhibition by an antioxidant, which is reflected in the protection against the loss of PE fluorescence in the ORAC assay, is a measure of its antioxidant capacity.

**Plasma oxidation.** Plasma oxidation was measured following 4 h of oxidation with AAPH by measuring lipid peroxides using the ferrous oxide-xylene orange (FOX) assay as described previously (22).

**LDL oxidation.** LDL was isolated by sequential ultracentrifugation and the LDL (100  $\mu\text{g}/\text{mL}$ ) was oxidized using 2.5  $\mu\text{M}$  copper for 5 h. The lag phase of conjugated diene formation was assessed by absorbance at 234 nm as described previously (23).

**Plasma ascorbate.** Total ascorbic acid was measured using the ascorbate oxidase method described previously (24).

**Statistics.** Statistical analyses were carried out using Sig-mastat (SPSS Inc., Chicago, IL). Data are presented as mean  $\pm$  SD. A repeated-measures ANOVA followed by a paired *t*-test was used to analyze parametric data. A Wilcoxon signed rank test was used to assess differences relative to the baseline for nonparametric variables. The level of significance was set at  $P < 0.05$ .

## RESULTS

The participants (10 males and 15 females) had a mean age of  $30 \pm 8$  yr and a BMI of  $26 \pm 4$   $\text{kg}/\text{m}^2$ . There were no significant differences in CBC, creatinine levels, liver function tests (aspartate and alanine aminotransferases), and TSH during the study (data not shown). The lipid profile of the subjects at 0, 6, and 10 wk is shown in Table 1. Despite the lack of effect on total cholesterol and TG, PYC supplementation resulted in a significant reduction in LDL-cholesterol (7%,  $P < 0.05$ ) following 6 wk of supplementation, which returned to baseline after the 4-wk washout period. HDL-cholesterol levels were significantly elevated following supplementation and remained elevated following the 4-wk washout period (10.4%,  $P < 0.05$ ). In addition, the reduction in LDL-cholesterol and increase in HDL-cholesterol was consistent among 66% of participants.

To assess compliance and determine whether the phenolic antioxidants of PYC were increased following supplementation, the total phenol level in plasma was measured at baseline and after 3 wk of supplementation. Total phenol levels increased significantly from  $4.6 \pm 1.96$  mg phenol equiv/L at baseline to  $5.67 \pm 4.1$  mg phenol equiv/L after 3 wk of PYC supplementation ( $P < 0.05$ ), demonstrating absorption of PYC in the blood. Plasma ascorbate concentrations did not change with PYC supplementation (baseline vitamin C:  $0.91 \pm 0.46$  mg/dL; 6 wk:  $0.97 \pm 0.37$  mg/dL).

The ORAC of plasma showed that PYC intake indeed significantly increased antioxidant capacity in humans (Fig. 1). Following supplementation with PYC, the ORAC values were significantly increased by about 40% over baseline ( $P < 0.005$ ). During the 4-wk washout period, the ORAC value returned back to baseline.

**TABLE 1**  
Effect of Pycnogenol® Supplementation on Lipid and Lipoprotein Profile

	Week 0	Week 6	Week 10
Total cholesterol (mg/dL)	169.30 $\pm$ 23.15	166.36 $\pm$ 21.69	167.81 $\pm$ 26.74
Total TG (mg/dL)	83.57 $\pm$ 40.08	85.65 $\pm$ 36.12	90.46 $\pm$ 36.74
LDL-cholesterol (mg/dL)	104.38 $\pm$ 17.71	97.11 $\pm$ 26.91*	104.31 $\pm$ 30.98
HDL-cholesterol (mg/dL)	48.07 $\pm$ 10.53	53.15 $\pm$ 12.63*	53.73 $\pm$ 18.01 <sup>a</sup>

<sup>a</sup> $P < 0.05$  compared to week 0.

**FIG. 1.** Oxygen radical absorbance capacity (ORAC) measured in plasma of human subjects at baseline, after daily supplementation with 150 mg Pycnogenol® for 3 and 6 wk, and following a washout period of 4 wk. Presented are mean values and SD; significant differences from baseline ( $P < 0.05$ ) are marked with an asterisk.

Supplementation with PYC did not significantly modify plasma oxidation, as determined by measuring lipid peroxides using the FOX assay (Table 2). Although this method is relatively specific for the measurement of lipid peroxides and has a CV of  $<10\%$ , it is not as sensitive as other direct methods used to determine oxidation, such as quantification of isoprostanes. Similar to plasma oxidation, the decreased susceptibility of LDL to oxidation (i.e., increase in lag phase) observed after supplementation with PYC did not reach significance (Table 2).

## DISCUSSION

PYC is known to be among the most powerful natural antioxidants (9,10). Urinary excretion studies have demonstrated that PYC is absorbed after oral consumption. Metabolites of procyanidins, taxifolin, and ferulic acid appear in the urine already after 2 h (18). Peak excretion of procyanidin metabolites was found after 8–12 h, and excretion was completed after 28–34 h. Another study showed absorption profiles of phenolic acids of PYC using ferulic acid excretion as a marker (19).

Our study demonstrates for the first time that oral consumption of PYC significantly elevates ORAC in the blood, paralleled by a significant increase in plasma concentration of phenolic compounds. During the period of PYC supplementation, the antioxidant capacity was elevated by about 40%. At the end of the 4-wk washout phase, the ORAC value returned almost to the baseline level. This finding demon-

strates that supplementation with PYC considerably improves antioxidant protection in plasma. This effect may be the basis for many of the health benefits discovered with PYC in clinical studies (11,13). A recent study has shown that consumption of PYC decreases UV-induced erythema in humans by inhibiting the redox-sensitive NF- $\kappa$ B-controlled gene expression of inflammatory mediators (15).

ESR studies have shown that PYC is able to reduce the ascorbate radical, leading to regeneration of active vitamin C (12). However, we did not detect significant differences in plasma ascorbate after PYC supplementation.

PYC was previously shown to inhibit LDL oxidation *in vitro* (25). With regard to protection of lipid components of the blood, we did not see a significant decrease in LDL-cholesterol oxidizability or in levels of lipid peroxides in subjects supplemented with PYC. However, the trend in both parameters after supplementation was reversed after the washout phase, which suggests a potentially favorable impact on these parameters. It is probable that the use of more sensitive measures of oxidative stress, such as F2-isoprostanes, may have clearly identified the antioxidant potency of PYC. Furthermore, since PYC is water soluble, it is probable that beneficial effects are not seen on LDL oxidizability, since it may not partition in the LDL particles.

Interestingly, we found that PYC supplementation reduces LDL-cholesterol levels in the blood and increases HDL-cholesterol levels and thus exerts beneficial effects on the lipid profile. Both effects of PYC, i.e., increasing HDL-cholesterol and decreasing LDL-cholesterol, will translate into a net benefit in decreasing cardiovascular events, since both are independent risk factors for CAD (26). Whether this effect is a result of the antioxidant activity of PYC is not clear. In a recent clinical trial investigating PYC to treat venous insufficiency (27), blood parameters were routinely checked. There was a significant reduction of LDL and cholesterol; HDL-cholesterol was not modified in the PYC-treated group (27). In the control group treated with horse chestnut seed extract, the cholesterol and LDL levels remained unaffected. This result points to another interesting function of PYC in influencing lipoprotein levels that is independent of its pronounced antioxidant activity.

Several clinical trials have documented beneficial modifications of the LDL/HDL ratio after intake of flavonoid- and antioxidant-containing food products. Kurowska *et al.* (28) reported that orange juice intake (750 mL/d) increased HDL-cholesterol concentrations by 21%. Fuhrman *et al.* (29) documented that supplementation with licorice root extract (0.1 g/d), which is rich in flavonoids, was associated with a 9% reduction in LDL-cholesterol concentrations in hypercholes-

**TABLE 2**  
Effect of Pycnogenol® Supplementation on Plasma and LDL Oxidizability

	Week 0	Week 3	Week 6	Week 10
Plasma lipid peroxides ( $\mu$ M)	1.8 $\pm$ 1.2	1.6 $\pm$ 1.2	1.8 $\pm$ 1.1	1.9 $\pm$ 1.4
LDL oxidizability—lag time of conjugated dienes (min)	78.5 $\pm$ 24.2	85.5 $\pm$ 36.3	83.6 $\pm$ 35.6	82.1 $\pm$ 33.3

terolemic individuals and suggested that this hypocholesterolemic effect could be secondary to an inhibitory effect on cholesterol biosynthesis. PYC could decrease LDL-cholesterol by upregulating the hepatic LDL receptor and/or enhancing sterol excretion, and it could increase HDL-cholesterol by inhibiting CETP activity. However, the specific mechanism by which PYC beneficially alters plasma lipids is beyond the scope of this study, which tested the effect of PYC on markers of oxidative stress. Future studies will be aimed at addressing these mechanisms.

This study showed that in normal healthy volunteers, PYC results in increased phenols as well as improved ORAC, and potentially also exerts an antioxidant effect. In addition, it has a favorable effect on two risk factors for CAD, i.e., decreasing LDL-cholesterol and increasing HDL-cholesterol. Future trials in larger and more diverse populations will shed light on its efficacy in cardiovascular disease prevention.

**ABSTRACT:** Long-chain n-3 PUFA in fish oil have modulating effects on inflammatory responses. The aim of this open pilot study was to investigate whether duodenal seal oil administration would benefit patients with inflammatory bowel disease (IBD). Seal oil (10 mL) was administered three times a day directly into the distal part of the duodenum *via* a nasoduodenal feeding tube for 10 d in 10 patients, 5 of whom had Crohn's disease and 5 ulcerative colitis. Nine of the 10 patients suffered from IBD-associated joint pain. Various parameters of disease activity and FA incorporation in tissues were analyzed before and after treatment. Following seal oil therapy, joint pain index, disease activity, and serum cholesterol level were significantly decreased, whereas the n-3 to n-6 ratio both in intestinal biopsies and blood was significantly increased. Measures of calprotectin concentration in gut lavage fluid, intestinal permeability, and lipid peroxidation were not significantly changed. The results suggest positive effects of seal oil in patients with IBD, especially on IBD-associated joint pain. Further controlled studies are warranted.

Paper no. L9107 in *Lipids* 37, 935–940 (October 2002).

EPA (20:5n-3) and DHA (22:6n-3) are n-3 PUFA derived from fish or marine mammals. These long-chain PUFA have been found to alter plasma membrane composition and fluidity, ion-channel flux, cell-signaling mechanisms, eicosanoid responses, cytokine release, and immune cell responses. One mechanism by which n-3 FA exert these effects might be that EPA and DHA are incorporated into membrane phospholipids by replacing arachidonic acid (AA, n-6 FA). AA is the substrate for the synthesis of eicosanoids, i.e., leukotriene B<sub>4</sub> (LTB<sub>4</sub>), thromboxane A<sub>2</sub>, and prostaglandin E<sub>2</sub> (PGE<sub>2</sub>), the latter with high inflammatory activity (1). n-3 FA have greater affinity for the cyclo- and lipoxygenase enzymes than n-6 FA. They competitively inhibit the formation of prostaglandins and leukotrienes derived from AA while serving as a substrate for prostaglandins and leukotrienes (PGE<sub>3</sub> and LTB<sub>5</sub>) with less inflammatory activity compared to the AA products (2,3). Hence, increased dietary intake of n-3 FA may shift the balance of the eicosanoid production to a less inflammatory profile.

Abbreviations: AA, arachidonic acid; CD, Crohn's disease; DPA, docosapentaenoic acid; IBD, inflammatory bowel disease; LTB<sub>4</sub>, leukotriene B<sub>4</sub>; LTB<sub>5</sub>, leukotriene B<sub>5</sub>; PGE<sub>2</sub>, prostaglandin E<sub>2</sub>; UC, ulcerative colitis; VAS, visual analog scale.

In the current Western diet, n-6 FA prevail over n-3 FA, and AA is the most abundant C<sub>20</sub> PUFA converted to eicosanoids in the human body. Marine animals are good sources of n-3 FA (EPA and DHA), and the general view is that an increased intake of marine oils will improve the health of the general population.

Seal and fish oils contain approximately the same total amount of n-3 PUFA. However, seal oil contains another PUFA, namely, docosapentaenoic acid (22:5n-3, DPA), which has been shown to interfere with different pathways of eicosanoid formation (4). Seal meat is also an excellent source of minerals, particularly iron and vitamins, including vitamin B<sub>12</sub> (5).

The aims of this study were to evaluate whether administration of seal oil altered the symptoms, inflammatory activity, and FA composition of serum, buffy coat, red blood cells, and rectal mucosal biopsies in patients with inflammatory bowel disease (IBD).

## MATERIALS AND METHODS

**Patients.** Ten patients with IBD were investigated, five with Crohn's disease (CD; female/male = 4:1, age range 27–42 yr) and five with ulcerative colitis (UC; female/male = 2:3, age range 41–57 yr). Disease activity was evaluated by a simple index in CD (6) and a simple clinical colitis activity index in UC (7). Joint pain was graded by the patients on a subjective scale from 0 (no pain) to 10 (very severe pain).

An ileocecal resection had been performed earlier on two of the CD patients, and both were receiving prednisone (5 or 10 mg/d). The other patients were on the following stable medications: four on mesalazine (dose range, 2 to 3 g/d), two on sulfasalazine (3 g/d), and two on both mesalazine (3 g/d) and azathioprin (100 or 150 mg/d).

During the 10 d of the seal oil treatment, all patients lived at home, ate a normal Western diet, and continued taking their usual medications.

Five of the patients (three patients with CD, two with UC; three were receiving mesalazine, one sulfasalazine, and one prednisone) wished to try the treatment a second time. To study the repeatability of results, these five patients were investigated using the same protocol one-half to one year later, but this time with a more extensive clinical evaluation of the rheumatic disease activity, including physicians' global

assessments of joint disease activity using a 100-mm visual analog scale (VAS), duration of morning stiffness (min) and pain throughout the week (VAS), score on the Health Assessment Questionnaire (8), 28 + 2 joint counts of tender and swollen joints (9) (with ankle joints and toes added), and the number of joints with subjective pain.

This study was approved by the ethics committee at Haukeland University Hospital, and all subjects gave informed consent.

**Methods.** Blood samples were drawn from the fasting patients in two vials without anticoagulant and in one with EDTA. One serum sample was sent to the hospital's central laboratory for analysis of cholesterol and TG according to Technicon Chem method no. SA4-0305L90 and Technicon Chem method no. SA4-0324L90, respectively (Technicon Instruments, Tarrytown, NY). TBARS in serum were analyzed at the Institute of Nutrition (10). From the other sample without anticoagulant, red blood cells and buffy coat (white blood cells) were prepared, and plasma was prepared from the EDTA-containing vial.

After an overnight fast, a nasoduodenal feeding tube (Stayput®, Compat Biosystems®; Sandoz Nutrition Corporation, Boston, MA) was positioned with its tip in the distal part of the duodenum by a gastroduodenoscopy or by fluoroscopic control only. Intestinal lavage was performed using a modification of the whole-gut lavage method of Ferguson and colleagues (11,12). Two liters of an isotonic PEG solution (M.W. 3350; Laxabon®; Tika, Lund, Sweden) was administered through the tube over a period of 40 min using a peristaltic pump (505S/RL; Watson-Marlow, Falmouth, United Kingdom). The PEG solution is the same type as that used for bowel cleansing before a barium enema, colonoscopy, or colon surgery. Approximately 50  $\mu$ Ci of  $^{51}\text{Cr}$  EDTA (Amersham International, Amersham, United Kingdom) was added to the solution. Depending on intestinal permeability, trace amounts of this substance are absorbed and excreted in the urine (13). The estimated dose of radiation received during this test was  $<0.1$  mSv (effective dose equiv.), which is within the limits of natural background radiation (14). Urine was collected for 5 h, 20 min (i.e., 4 h, 40 min after finishing the infusion), and the amount of  $^{51}\text{Cr}$  EDTA excreted in the urine was quantified as percentage of the administered dose. When the PEG solution reached the distal colon, bowel movements started. The first clear fluid passed per rectum was collected for analysis of calprotectin (11).

Soon after the lavage procedure, when the patients had emptied their bowels, sigmoidoscopy was performed with a videoendoscope. Five biopsy specimens were taken from the rectum, 20–30 cm above the anus, for analysis of FA composition. These biopsies were collected on ice and stored frozen.

**Seal oil.** Seal oil was obtained from the Norwegian Institute of Fisheries and Aquaculture Inc. (Tromsø, Norway). The seal oil (mainly from harp seal, *Phagophilus groenlandicus*) was produced by A/S Rieber (Tromsø, Norway) and refined by Peter Møller A/S of Orkla A/S (Oslo, Norway). Natural tocopherols 1.5 mg/g (Covi-ox T-70; Henkel, Düsseldorf,

Germany) and DL- $\alpha$ -tocopheryl acetate (1.0 mg/g; Roche A/S, Hvidovre, Denmark) were added to the oil.

After completing the lavage and biopsy procedures, 10 mL seal oil was administered through the nasoduodenal feeding tube three times a day for 10 d. The patients thus received a total amount of 1.8 g of EPA, 1.0 g DPA, and 2.6 g of DHA per day. Seal oil was well tolerated without any noticeable side effects. The blood sample, disease activity, joint pain index, gut lavage, and biopsy procedures were repeated after the 10-d course of treatment (at day 11).

**Lavage fluid processing.** Lavage fluid was filtered through gauze, and 4.5 mL aliquots were added to tubes containing 0.5 mL of a solution with antiseptic and antiproteolytic activity. A stock solution of the latter was prepared by adding 1 mL of 10% sodium azide ( $\text{NaN}_3$ ) to 50 mL of soybean trypsin inhibitor (Sigma, Munich, Germany). The samples were stored frozen at  $-20^\circ\text{C}$  until assayed.

**Analysis of FA.** FA composition was analyzed in plasma, red blood cells, buffy coat, and biopsies. The samples were dissolved in chloroform/methanol (2:1, vol/vol) and a 19:0 FA was added as the internal standard. The samples were filtered, saponified, and methylated using 12%  $\text{BF}_3$  in methanol. FA composition of total lipids was analyzed using methods described by Lie and Lambertsen (15): The methyl esters were separated using a Carlo Erba gas chromatograph (cold on-column injection at a temperature of  $60^\circ\text{C}$ , ramped at  $25^\circ\text{C}/\text{min}$  to 160 and  $190^\circ\text{C}$ , then held at  $220^\circ\text{C}$ ) equipped with a 50-m CP-Sil 88 (Chrompack, Middelburg, The Netherlands) fused-silica capillary column (i.d. 0.32 mm). The FA were identified by retention time using standard mixtures of methyl esters (NuChek-Prep, Elysian, MN), and the FA composition (mol%) was calculated using an integrator (Turbochrom Workstation, Version 6.1.0, PerkinElmer Instruments LLC, Shelton, CT) connected to the gas-liquid chromatograph.

**Analysis of calprotectin.** The gut lavage fluid specimens were thawed and centrifuged at  $1550 \times g$  at  $4^\circ\text{C}$  before diluting the supernatant 1:50 and analyzing the calprotectin concentration by an ELISA method using the Nycotest Phical ELISA kit (Nycomed, Oslo, Norway). Microtiter plates were coated with rabbit anticalprotectin for capture, and immunoaffinity purified rabbit anticalprotectin conjugated with alkaline phosphatase was used for development (16). The ELISA read the absorbance at 405 nm for 96-well plates. The results of the test samples were calculated from the standard curves. Concentrations above 5 mg/L were not diluted further.

**Analysis of urine.** Urine was analyzed for radioactivity using a gamma counter (1282 Compugamma Counter; Wallac, Oslo, Norway). To calculate the percentage of administered dose of  $^{51}\text{Cr}$  EDTA excreted in urine, we measured the activity of a 5 mL sample of a 1/2000 dilution of the  $^{51}\text{Cr}$  EDTA solution administered and of a 5 mL sample of the pooled urine volume. The percent urinary excretion of the administered dose was calculated as in Equation 1:

$$^{51}\text{Cr EDTA}\% = \frac{(\text{urine cpm} - \text{background cpm}) \cdot \text{urine volume} \cdot 100}{(\text{standard cpm} - \text{background cpm}) \cdot \text{instilled volume}} \quad [1]$$

**Statistical analysis.** Data were analyzed using the GraphPad Prism (GraphPad Software Inc., San Diego, CA) statistical software package. All values were expressed as median with a maximum/minimum range. Differences between groups were evaluated using the Wilcoxon signed rank test.  $P$  values  $< 0.05$  were regarded as significantly different.

## RESULTS

All the patients completed treatment with seal oil without relevant protocol violations. No relevant subjective side effects of the seal oil administration were detected.

Compared with pretreatment levels, the median joint pain index ( $P = 0.002$ ) (Fig. 1), disease activity ( $P = 0.01$ ) (Fig. 2), and serum cholesterol concentration ( $P = 0.002$ ) were significantly decreased after treatment with seal oil. The median serum TG concentration was also decreased but barely reached significance ( $P = 0.05$ ). The calprotectin concentration in gut lavage fluid ( $P = 0.74$ ), intestinal permeability of  $^{51}\text{Cr}$  EDTA ( $P = 0.25$ ), and serum TBARS concentration ( $P = 0.49$ ) were not significantly altered by seal oil treatment (Table 1).

The ratio of n-3 to n-6 FA was significantly increased after treatment compared with that before treatment in serum ( $P = 0.008$ ), buffy coat ( $P = 0.006$ ), red blood cells ( $P = 0.004$ ), and colonic biopsies ( $P = 0.002$ ) (Table 1). Compositions of selected FA in serum, buffy coat, red blood cells, and biopsies from rectal mucosa are presented in Table 2. The total amount of monounsaturated FA was not changed after seal oil treatment in serum, buffy coat, and red blood cells but decreased in biopsies (Table 2).

Vitamins A and E and the FA composition of the seal oil supplied to the IBD patients were also determined (Table 3).

**Retreatment.** After the second study period, seal oil administration in five patients appeared to lower the rheumatic dis-

**FIG. 1.** Joint pain index (0 = no pain, 10 = very severe pain) in inflammatory bowel disease (IBD) patients before and after treatment with seal oil. Individual results are presented in the upper right corner ( $n = 10$ ).  $\circ$ , patients with ulcerative colitis (UC);  $\bullet$ , patients with Crohn's disease (CD).

**FIG. 2.** Individual results of disease activity index in IBD patients before and after treatment with seal oil ( $n = 10$ ).  $\circ$ , patients with UC;  $\bullet$ , patients with CD. For abbreviations see Figure 1.

ease activity but was significant only for the patients' assessment of pain ( $P = 0.04$ ) (Table 4).

## DISCUSSION

This is the first study to look at the effect of seal oil administration in patients with IBD. During the 10-d treatment period, there appeared to be a beneficial effect on joint pain, disease activity, serum cholesterol concentration, and the n-3/n-6 FA ratio in blood and tissue samples.

Fish oil has been reported to be beneficial to UC patients, but results are controversial (17–21). Three studies reported significant clinical improvement after fish oil supplementation (17–19), whereas the clinical benefit in the other two studies was limited, with no histopathological improvement compared with placebo therapy (20,21). Differences between the studies in dose, study design, composition of the supplement, and assessment of clinical improvement may explain the conflicting results (19).

Two studies examined the role of fish oil in preventing relapses in CD patients who had gone into remission with steroids (22,23). In the study by Belluzzi *et al.* (22), 78 Crohn's disease patients with a high risk of relapse were randomly assigned to receive enteric-coated fish oil capsules (total 2.7 g) or placebo (total 1.5 g, containing 60% caprylic acid and 40% capric acid). In the 1-yr follow-up, 59% of patients in the fish oil group remained in remission compared with 26% in the placebo group. In the trial of Lorenz-Meyer *et al.* (23), however, remission rates at the 1-yr follow-up were similar in the fish oil and placebo groups.

Seal oil may have important advantages over fish oil or n-3 preparations, because in seal oil EPA, DPA, or DHA are preferentially located in the *sn*-1 or *sn*-3 positions in the TAG molecule, whereas in fish oil EPA or DHA are mainly in the *sn*-2 position (24). FA in the *sn*-2 position are not easily hydrolyzed in the intestine and are therefore absorbed mainly as MG. However, FA are easily released from the *sn*-1 and *sn*-3 positions and are absorbed directly into the mucosa. Seal oil may therefore generate more FFA within the intestinal lumen than fish oil. Also, postpyloric enteral feeding, as used in the present study, may be advantageous, as higher concentrations

of the active substances could reach the inflamed part of the intestine by this mode of administration compared with the oral liquid or capsules used previously (17–20).

Incorporation of FA from fish and olive oils into colonic mucosal membranes displaces AA, causing less AA to be available for cyclo- and lipoxygenase enzyme systems (25,26). In a comparison of fish and seal oil, Yoshida *et al.* (27) and Ikeda *et al.* (28) found that seal oil was more effective in reducing AA content than fish oil. In the present study administration of seal oil consistently increased the n-3 to n-6 ratio significantly in red and white blood cells as well as in biopsies from rectal mucosa.

Because PUFA are prone to oxidation, administration of PUFA to an inflamed mucosa may theoretically increase lipid peroxidation (29). Concomitant supplementation with antioxidants may counteract this potentially adverse effect of n-3

supplementation. Most research on fish oil supplementation has failed to state the amount of concomitant antioxidants administered. In the present study we used seal oil with added antioxidants, and we found no measurable change in lipid peroxidation as measured by TBARS in blood. Calprotectin levels in stools and intestinal permeability are markers of intestinal inflammation (12,16). The lack of a beneficial effect of seal oil on these inflammatory parameters is disappointing but might be due to the short treatment period (10 d).

The total serum cholesterol concentration was significantly lower after seal oil consumption than before in the IBD patients. Findings in the literature regarding the effect of n-3 PUFA supplements on serum cholesterol are conflicting. Compared to the control group, total cholesterol, TG, and phospholipid concentrations in plasma were significantly decreased when supplements of seal or fish oil were given to patient groups (28). However, Harris observed that levels of both total and LDL cholesterol were unaffected by dietary n-3 FA (30).

For patients with rheumatoid arthritis, n-3 FA supplementation reduced neutrophil LTB<sub>4</sub>, whereas neutrophil LTB<sub>5</sub> levels increased slightly (31). The decrease in LTB<sub>4</sub> production was correlated to a decrease in the number of tender joints (32). Moreover, Volker *et al.* (33) reported that supplementation with fish oil containing 60% n-3 FA for a 15-wk period improved the clinical status of patients with rheumatoid arthritis compared to the control group (i.e., significant differences were found in early morning stiffness, the Health Assessment Questionnaire, and physicians' assessments of arthritis activity).

Peripheral "enteropathic" arthritis is seen in 15–20% of patients with IBD and is more commonly associated with CD than UC (34). In one study the prevalence of Crohn's-associated joint pain was much higher (48%) than that generally reported, possibly due to the inclusion of many patients with arthralgia or more vague rheumatic pains (35).

The weaknesses of this study are the small number of patients, choice of a nonplacebo control, and management of two distinct disease entities with different pathophysiologies and different responses to treatments. However, our 10 patients were specifically recruited because of their joint pain, which is largely independent of inflammatory disease activ-

ity. IBD patients with joint pain represent a group of patients having much suffering and few other treatment alternatives. In the present study, the effect of seal oil on joint pain was marked and appeared after only a few days of treatment. The subsequent routine follow-up indicated that the beneficial effect on the joint symptoms persisted for several months in some of the patients. These encouraging results clearly warrant further controlled studies.

#### ACKNOWLEDGMENT

The authors wish to thank Gro Maria Olderøy, Aud Sissel Hjartholm, and Agnes Nordstrand at the Gastroenterology Laboratory for help and support in conducting the clinical analysis, and Thu Thao Nguyen at the Institute of Nutrition for excellent technical assistance. This study was funded by Rieber Skinn AS, the Norwegian Fishermen Association, and the Ministry of Fisheries.

and <sup>b</sup>Lipid and Diabetes Research Center, Saint Luke's Hospital, Kansas City, Missouri 64111

**ABSTRACT:** The first indication of platelet activation is an increase in mean platelet volume (MPV). n-3 FA are known to inhibit platelet function and to reduce the risk for coronary heart disease. The purpose of this study was to determine the effects of EPA and DHA on MPV. Healthy subjects received olive oil placebo for 4 wk and then were randomly assigned to receive 4 g of ethyl esters of either safflower oil ( $n = 11$ ), EPA ( $n = 10$ ), or DHA ( $n = 12$ ) for 4 wk. At the end of placebo run-in and treatment periods, MPV (fL; mean  $\pm$  SEM) and platelet count (PLT-CT;  $10^3/\mu\text{L}$  blood) were measured in the basal state and after *ex vivo* stimulation with collagen (10  $\mu\text{g}/\text{mL}$ ), cold (4°C), and heat (37°C). Unlike DHA, EPA lowered MPV as compared with safflower oil ( $7.2 \pm 0.1$  vs.  $7.5 \pm 0.1$  fL;  $P < 0.05$ ) and raised PLT-CT ( $211 \pm 18$  vs.  $192 \pm 18$   $10^3/\mu\text{L}$ ;  $P < 0.05$ ) in the fasting state. Collagen and cold significantly increased MPV whereas heat lowered MPV regardless of treatment. All stimuli decreased PLT-CT. EPA significantly increased platelet EPA ( $0.2 \pm 0.1$  vs.  $3.3 \pm 0.4\%$ ) and docosapentaenoic acid (DPA;  $2.2 \pm 0.3$  vs.  $2.9 \pm 0.3\%$ ) concentrations, but not DHA. DHA treatment significantly increased DHA ( $1.4 \pm 0.2$  vs.  $4.1 \pm 0.5\%$ ) and DPA ( $2.0 \pm 0.4$  vs.  $3.0 \pm 0.4\%$ ) concentrations, but not EPA. In conclusion, EPA, but not DHA, reduces platelet activation, an early step in platelet aggregation.

Paper no. L9015 in *Lipids* 37, 941–946 (October 2002).

Mean platelet volume (MPV) is a marker of platelet activation (1). It has been reported that MPV is increased in patients at high risk for acute myocardial infarction (MI) (2–4). Large platelets show a higher degree of adhesion and aggregation than small ones (5). The presence of a greater number of large platelets in such patients is consistent with an elevated risk of thrombus formation. MPV is much easier to measure than agonist stimulated platelet aggregation and thus it may have clinical utility. As platelet activation increases, platelets are likely to form aggregates, leading to a decrease in single platelets in the blood. This is measured by the platelet count. A decrease in count after *ex vivo* stimulation indicates an increase in aggregates.

Interest in fish oil as an antiplatelet agent dates back 20 yr (6), and this mechanism may have played a role in the cardio-protection seen with n-3 fatty acids (FA) use in recent trials. In the GISSI-Prevention study, supplementation with n-3 FA (850 mg) reduced overall mortality in post-MI patients (already taking aspirin) by 20% and risk for sudden cardiac death by 45% (7). The Diet and Reinfarction Trial (8) and the Indian Experiment of Infarct Survival also reported that n-3 FA protected

Abbreviations: ACD, acid/citrate/dextrose; DPA, docosapentaenoic acid; MI, myocardial infarction; MPV, mean platelet volume; PLA<sub>2</sub>, phospholipase A<sub>2</sub>; PLT-CT, platelet count; TxA<sub>2</sub>, thromboxane A<sub>2</sub>.

against coronary artery disease. Clearly, antiplatelet drugs (e.g., aspirin) can reduce the incidence of coronary artery disease (10,11). Several studies have shown that relatively large amounts of n-3 FA can decrease platelet aggregation and prolong bleeding time (12–16); however, the effects of n-3 FA on MPV are not known.

It has been assumed that EPA is more active than DHA in altering platelet function because it is a cyclooxygenase substrate (17). However, DHA appears to decrease thromboxane A<sub>2</sub> (TxA<sub>2</sub>)/prostaglandin H<sub>2</sub> receptor affinity (18). Von Schacky and Weber (19) reported that both EPA and DHA, given for only 6 d, reduced platelet aggregation *in vitro*. Thus, both of these FA have the potential to affect platelet function. The purpose of the present study was to compare the effects of EPA and DHA separately on MPV and on MPV responses to collagen, cold, or heat during the fasting and the fed states. Like collagen, cold exposure is known to cause platelet activation (20,21) whereas heat causes platelets to contract. We tested the hypothesis that treatment with both DHA and EPA would decrease MPV, and increase platelet count (PLT-CT), as compared with safflower oil.

## MATERIALS AND METHODS

**Subjects.** Saint Luke's Hospital Institutional Review Board approved this study and informed written consent was obtained from all participants. The study consisted of three periods (4 wk each): placebo run-in, wash-out, and active treatment. Thirty-three healthy subjects, male ( $n = 17$ ) and female ( $n = 16$ ), were given olive oil capsules (4 g/d) during the placebo run-in period and then were randomized to ethyl esters of either EPA ( $n = 10$ ), DHA ( $n = 12$ ), or safflower oil ( $n = 11$ ; 4 g/d each) during the treatment period. The oils (95% pure) were provided by the Fish Oil Test Material Program of the U.S. Department of Commerce and the National Institutes of Health.

Baseline characteristics are shown in Table 1. Subjects were asked to maintain their usual lifestyle and dietary habits throughout. Intake of drugs known to affect platelet function was restricted 2 wk before blood sampling. Alcohol intake and strenuous physical exercise were also prohibited during the 48 h preceding the blood sampling. At the end of placebo run-in and treatment periods, fasting ( $\geq 12$  h overnight) blood samples were drawn from all subjects. Subjects were then asked to consume a chocolate-flavored test drink made with half-and-half (1 g fat/kg body weight), and blood samples were taken 4 h later (fed state).

**Platelet activation.** Blood samples were drawn into acid/citrate/dextrose (ACD) tube containing 2% Na<sub>2</sub>-EDTA. This

anticoagulant cocktail reportedly prevents platelet activation for 8 h (23). Subjects were sitting during the blood draw, and an 18-gauge needle was used. The first 10 mL of blood was not used for platelet testing. MPV and PLT-CT were measured in whole blood directly from the tube using Coulter Counter MD16 (Beckman, Miami, FL) (5). The instrument was calibrated daily with commercially available controls.

MPV and PLT-CT were measured in eight separate conditions at the end of the placebo and the active treatment periods. The eight conditions were: unstimulated or stimulated with collagen, heat or cold, all in the fasting and the fed states. The effect of eating was examined because platelet activation was expected to be greater in the fed than the fasting state (24,25). Three different *ex vivo* stimuli were included in anticipation that, if EPA or DHA did not activate platelets in the basal state, they might affect platelet response to stimulation.

Within 15 min of the blood draw, a series of measurements of MPV and PLT-CT were initiated as follows (26). Three microfuge tubes were prepared: one was placed on ice, another in a 37°C water bath; to the third was added 10 µL of a 1 µg/µL collagen (type I; Chrono-log Corp., Havertown, PA), and this was kept at room temperature. ACD blood was mixed by gentle inversion seven or eight times before baseline measurements were taken. Unstimulated values were measured four times, twice before (0 and 4 min) and twice after (48 and 52 min) a series of stimulation tests (Fig. 1). Blood (1 mL each) was transferred to the collagen-containing tube, the pre-chilled tube and the pre-warmed tube at 10, 14, and 22 min, respectively, after baseline measurements were taken. MPV and PLT-CT were measured 8 and 11 min after collagen addition, and 18 and 22 min after exposure to cold and heat. Preliminary experiments showed that despite the anticoagulant cocktail, MPV gradually increased in unstimulated blood held at room temperature for 52 min by about 3% (26). Thus, control values for the platelet response to collagen (baseline 1) were defined to be the average MPV and PLT-CT at 0 and 4 min (since these samples were measured closer in time to the peak collagen response). On the other hand, the controls for the platelet responses to heat and cold (baseline 2) were defined as the mean unstimulated measurements at 48 and 52 min since the responses to temperature were assessed closer to the end of the 52 min protocol than to the beginning. All analyses were completed within 67 min from the time of the blood draw.

**Platelet FA composition.** Fasting blood was drawn in ACD tubes and centrifuged at 125 × *g* for 10 min to obtain platelet-rich plasma. Platelet-rich plasma was mixed with Brox washing buffer (63.75 mM Tris, 11.25 mM HCl, and 77 mM

**FIG. 1.** Protocol for measurement of mean platelet volume and platelet count. × indicates the time when blood was added to collagen, or when it was exposed to cold or heat; • indicates the times measurements were made; → indicates which control (baseline 1 or 2) was used for the platelet response to collagen, cold and heat.

EDTA), and the mixture was centrifuged at 500 × *g* for 15 min. After discarding the plasma, the pellet was resuspended with the buffer and centrifuged again. The platelet pellet was resuspended with 1 mL of 2% EDTA and stored at -80°C.

Diheptadecanoyl PC was added as an internal standard to the washed platelets, which were extracted with methanol/methylene chloride (1:2) for total lipids (preliminary experiments showed that >98 % of lipids were phospholipid). Glycerophospholipid FA were methylated with boron trifluoride at 100°C for 10 min (27,28) and then analyzed by GC (GC9A; Shimadzu, Corp., Columbia, MD), using a 30-m SP2330 capillary column (Supelco, Bellefonte, PA). FA were identified by comparison with known standards.

**Statistics.** Data were analyzed by ANOVA or analysis of covariance using Statistical Analysis System (Cary, NC). Differences between means were considered statistically significant at the  $P < 0.05$  level.

## RESULTS

When all data were pooled regardless of treatments (olive oil placebo, safflower oil, EPA, or DHA) or the fasting/fed status, MPV was significantly increased in response to both collagen and cold, whereas it was decreased by heat (Fig. 2). All stimuli significantly decreased PLT-CT regardless of treatments or fed/fasting status, although collagen lowered PLT-CT more than exposure to heat or cold (Fig. 2). There was no significant difference between MPV in the fasting and the fed state. EPA significantly lowered MPV and increased PLT-CT as compared to safflower oil regardless of fed/fasting state or *ex vivo* stimuli, whereas no effect was seen with DHA (Fig. 3).

Platelet responses to *ex vivo* stimuli during the olive oil placebo and the active treatment phases in both the fasting and fed states are shown in Figure 4 (MPV) and Figure 5 (PLT-CT). EPA significantly decreased MPV at baseline 1 during the fed state and at baseline 2 during the fasting state (Fig. 4). EPA significantly increased baseline 1 PLT-CT during the fasting state (Fig. 5).

The effects of treatment on the platelet FA composition (fasting state) is presented in Table 2. EPA significantly in-

creased platelet EPA and docosapentaenoic acid (DPA) levels in an apparent exchange for stearic and arachidonic acids. DHA significantly increased DHA and DPA concentrations at the expense of palmitoleic, oleic, linoleic, and arachidonic acids. There were no significant differences in saturated, monounsaturated, and n-6 PUFA compositions between olive oil and any of the treatment groups, but total n-3 PUFA significantly increased after EPA and DHA supplementation (Table 2).

**DISCUSSION**

Changes in MPV are an early indicator of platelet activation (2,29), thus MPV may be an *in vivo* marker of the potential for platelet aggregation. Smaller platelets have less fibrinogen receptors exposed than larger ones, suggesting a reduced risk of thrombus formation (5); and larger platelets produce more TxB<sub>2</sub> when stimulated with collagen and thrombin (5).

Fish oil supplementation (including EPA and DHA) has been shown (15,16,30,31) to decrease platelet aggregation and to prolong bleeding times (12), but the separate effects of these two FA on platelet function has rarely been examined in the same setting (13–16). In this study, we found that EPA, but not DHA, decreased platelet activation as indicated by a decreased MPV and increased PLT-CT.

Hirai *et al.* (32) reported that 3.6 g of EPA for 24 d significantly inhibited collagen, ADP, and epinephrine-induced platelet aggregation, but the effect of DHA was significant only for collagen. Platelet aggregation was also significantly decreased with 2 g of EPA given for 2 and 4 wk (33,34). Von Schacky and Weber (19) reported that 6 g of EPA and DHA ethyl ester alone for 6 d caused a significant reduction in platelet aggregation with collagen, but the response to ADP was signifi-

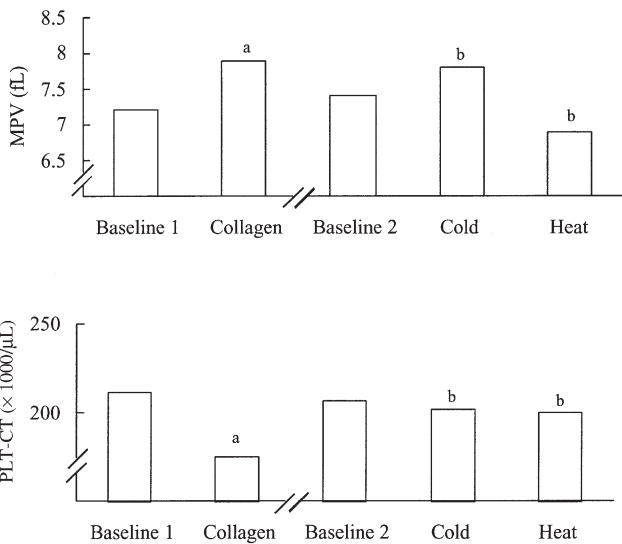

**FIG. 3.** Changes in MPV (fL; top) and PLT-CT (x 1000/μL; bottom) from olive oil to safflower oil (SAF), EPA, or DHA regardless of fed/fasting state or *ex vivo* stimuli. Mean values are presented. *n* = 33. <sup>a</sup>Values differ (*P* < 0.05) between treatments. For other abbreviations see Figure 2.

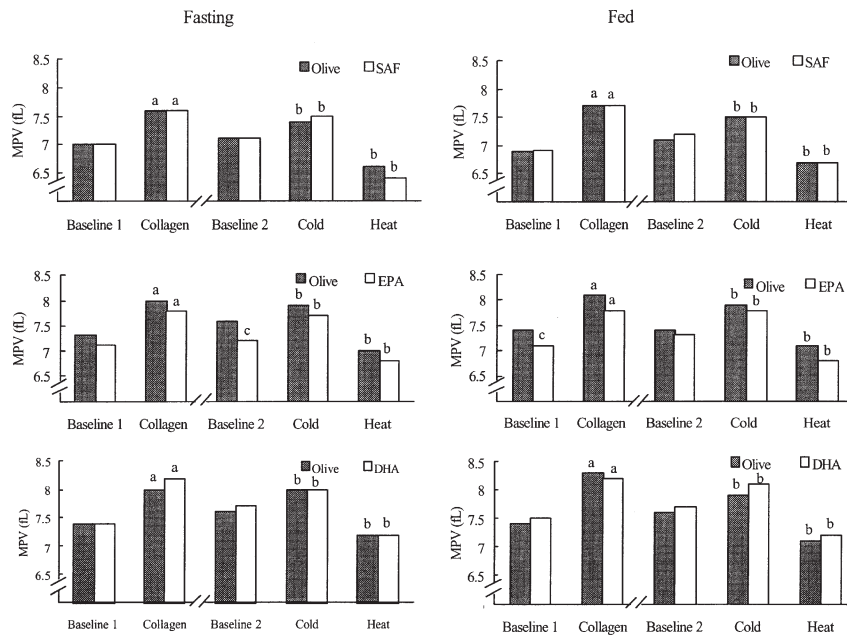

cantly lowered only by DHA. Nelson *et al.* (35) observed that adding 6 g of DHA for 90 d produced no physiological changes in blood coagulation, platelet function, or thrombotic tendencies in six healthy males. In contrast to these high dose studies, Driss *et al.* (36) reported platelet inhibitory effects with 150 mg of EPA, the lowest dose reported to alter platelet function.

Croset *et al.* (37) suggested that EPA and DHA affect platelet function in synergistic ways. EPA competes with endogenous arachidonic acid at the cyclooxygenase level to reduce the amount of TxA<sub>2</sub> formed and to generate the weakly proaggregatory TxA<sub>3</sub> (38). DHA inhibits platelet function by decreasing the affinity of TxA<sub>2</sub> for its receptor (18,39,40). In addition, Shikano *et al.* (17) reported that PE-enriched DHA is a poor substrate for phospholipase A<sub>2</sub> (PLA<sub>2</sub>), the enzyme that mobilizes eicosanoid precursors from cell membranes. What is more, EPA appears to suppress PLA<sub>2</sub> activity, resulting in reduced platelet-activating factor synthesis (41).

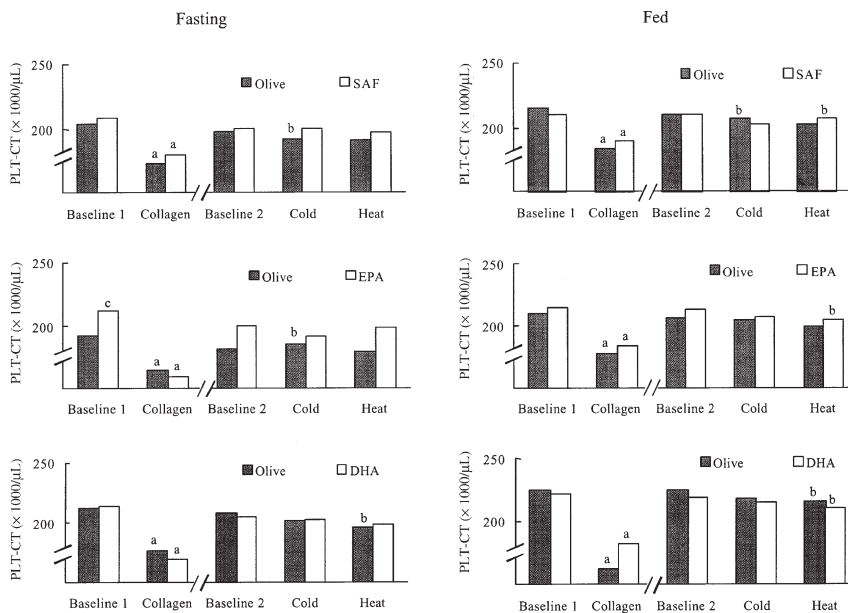

The postprandial state is considered to be more procoagulant than the fasting state. Platelet aggregation induced by ADP (24) and by collagen (25) was significantly increased in normolipemic subjects after fatty meals. Fuhrman *et al.* (24) showed that platelets maintained their hypersensitivity to aggregation 5 h after meals, at a time when plasma TG levels had returned to normal. Chylomicron remnant particles enhanced activation of platelets stimulated with ADP and collagen (42), but native chylomicrons inhibited platelet function (43). These observations imply that, although total plasma TG may not affect platelet activation, certain TG-rich lipoprotein remnants may do so. Broijerssen *et al.* (44) reported that expression of platelet selectin was increased 3 and 6 h postprandially in unstimulated and ADP-stimulated samples. However, Jakubowski *et al.* (45) found no effect of eating on platelet aggregate formation or expression of platelet-specific proaggregatory proteins. We also found that meal consumption did not significantly change MPV or PLT-CT, but PLT-CT tended to be

increased in the fed state. Hansen *et al.* (46) observed that food intake increases PLT-CT, which could be due to a meal-induced release of platelets from the spleen (47).

This study suggests that EPA supplementation reduces platelet activation, an early step in platelet aggregation, whereas DHA does not. These findings constitute further evidence for an antiatherogenic potential for marine n-3 FA. Further studies are warranted to assess the effects of combined treatment with EPA and DHA on MPV, platelet membrane receptor activity, TxA<sub>2</sub> synthesis, and platelet granule constituent release.

## ACKNOWLEDGMENTS

The authors would like to thank Philip Jones for help with the statistical analysis, and Norberta Schoene for her technical advice. Grants from National Heart, Lung, and Blood Institute (HL-47468) and the Heartland Affiliate of the American Heart Association (postdoctoral fellowship for YP) supported this work.

# Effect of Exercise on FA Profiles in n-3 FA-Supplemented and -Nonsupplemented Premenopausal Women

Julie A. Conquer\*, Heather Roelfsema, Julie Zecevic, Terry E. Graham, and Bruce J. Holub

Department of Human Biology and Nutritional Sciences, University of Guelph, Guelph, Ontario, Canada, N1G 2W1

**ABSTRACT:** The purpose of this double-blind study was to investigate the influence of exercise on the FA profile of the non-esterified FA (NEFA) and phospholipid fractions in plasma of sedentary women supplemented with n-3 FA vs. women supplemented with oil containing no n-3 FA. Twenty sedentary, premenopausal women were randomly assigned to receive 12 capsules daily of either fish oil (3.5 g EPA and 2.4 g DHA per day, each as the ethyl ester) or evening primrose oil capsules (no detectable EPA or DHA). Each subject consumed the capsules for one menstrual cycle. At the end of the supplementation period, the sedentary subjects underwent an acute exercise trial [55% maximal oxygen consumption ( $\text{VO}_2$  max), 45 min] on a cycle ergometer. Two subjects in the fish oil group were removed from all calculations owing to noncompliance for reasons not related to side effects. There were no changes in the phospholipid composition of either group of women after exercise. In both control and fish oil-supplemented women, NEFA levels in general rose after exercise. There were no changes in the percentage of any given individual NEFA in either supplementation group. However, absolute levels of certain individual NEFA (16:0, 18:0, 18:1, and 18:3n-3) increased with exercise. Women supplemented with fish oil had increased levels of n-3 NEFA [EPA, DHA, and docosapentaenoic acid (DPA)] prior to exercise. Exercise did not, however, increase the absolute levels of n-3 NEFA in the blood.

Paper no. L8979 in *Lipids* 37, 947–951 (October 2002).

Circulating nonesterified FA (NEFA) are associated with risk for cardiovascular disease (CVD), and there is evidence they play a central role in coronary heart disease development (1). The release of NEFA from intra-abdominal fat cells has been implicated in the unfavorable metabolic profile among Asian Indians (2) and others (1). The mechanism by which elevated NEFA contribute to cardiovascular pathology is not clear; however, exposure to acutely elevated levels of NEFA can be deleterious to myocardial cell activity (3–5).

Although an elevated level of NEFA is associated with CVD risk, there is some evidence to suggest that not all NEFA may

be detrimental. Particular plasma NEFA may exhibit differing effects on thrombosis and myocardial functioning (1). For example, certain saturated NEFA, such as palmitate, have been implicated in both prothrombotic and arrhythmogenic actions (1,6), whereas opposite effects (antiplatelet aggregatory and anti-arrhythmic actions) have been indicated *in vitro* for DHA in its NEFA form (7–9). Furthermore, a decreased ratio of EPA/arachidonic acid (AA) as NEFA may be a coronary risk indicator (10).

Few studies have examined the effect of n-3 supplementation on NEFA levels and composition in humans. Studies have shown that supplementation with DHA, in the absence of EPA, provides a dose-dependent rise in DHA-NEFA concentrations (11) and the maximum DHA-NEFA is formed approximately 6 h after ingestion (12). With n-3 supplementation [including EPA, DHA, and docosapentaenoic acid (DPA)], an increase in EPA, DPA, and DHA was noted in the NEFA fraction (13). Furthermore, there was a decrease in AA- and linoleic acid-NEFA and an increase in the ratio of EPA-NEFA/AA-NEFA and DHA-NEFA/AA-NEFA. n-3 supplementation does not appear to change the levels of total NEFA (11,13). n-3 FA may be incorporated into the NEFA fraction directly (12) or indirectly after release from the adipose stores where it may be stored (14,15).

Exercise has been shown to increase the potential for arrhythmia and sudden cardiac death (16). At intensities of 55% maximal oxygen consumption ( $\text{VO}_2$  max), plasma NEFA are one of the major fuels oxidized by skeletal muscle (17,18). The rate of use depends on various factors including, among other parameters, plasma availability, exercise intensity, and exercise duration. The lipolysis of NEFA from adipose tissue, for use by the skeletal muscle, increases with exercise duration and intensity to about 60%  $\text{VO}_2$  max (19). In addition, there are increases in adipose tissue and muscle blood flow with exercise and decreases in fatty acid re-esterification (20). The relative use of FA from adipose tissue is dependent on the degree of fitness (20). Although there is little evidence to suggest exercise has any effect on the types of individual NEFA released from adipose, one study has suggested that prolonged moderate exercise (60%  $\text{VO}_2$  max) increases the ratio of unsaturated/saturated NEFA in serum (21).

In our study, it was of interest to examine whether acute exercise modifies serum phospholipid (PL) and NEFA compositions in n-3 FA supplemented premenopausal women.

Abbreviations: AA, arachidonic acid; CVD, cardiovascular disease; DPA, docosapentaenoic acid; EPO, evening primrose oil; MI, myocardial infarction; NEFA, nonesterified FA; PL, phospholipid;  $\text{VO}_2$  max, maximal oxygen consumption.

## EXPERIMENTAL PROCEDURES

**Subjects and experimental design.** The subjects were 20 healthy, nonexercising, nonhormone-using, premenopausal women (average menstrual cycle 25–35 d) selected from the Guelph community. Approval for this double-blind study was granted by the Human Ethics Committee of the University of Guelph and written informed consent was obtained from each subject. The 20 subjects (aged  $34.8 \pm 1.8$  yr, mean  $\pm$  SEM) were randomly assigned (10/group) into the two supplementation groups, fish oil-supplemented and control. The encapsulated ethyl ester fish oil concentrate (product #L3020, Ocean Nutrition Canada Ltd., Bedford, Nova Scotia) contained 60% total n-3 FA, including 30% EPA and 20% DHA. The encapsulated evening primrose control oil (EPO; Bioriginal Food & Science Corp., Saskatoon, Saskatchewan) contained 0% EPA and DHA. EPO was chosen as a placebo because of the absence of EPA and DHA, as well as its slight aftertaste. This aftertaste fools many subjects into thinking they are taking fish oil. The experimental group consumed 12 fish oil capsules per day (total 3.5 g EPA/d, 2.4 g DHA/d) with their meals, and the control group consumed 12 EPO placebo capsules per day for one menstrual cycle. To minimize the variations in blood lipids associated with the different phases of the menstrual cycle, each subject began the trial during the early follicular phase (day 3–8) of her menstrual cycle and completed the trial during the same phase of her subsequent menstrual cycle. Thus, the length of the supplementation period ( $29.4 \pm 1.2$  d) varied depending on the length of a given subject's menstrual cycle ( $27.4 \pm 0.8$  d). During the supplementation period, an incremental oxygen consumption test was performed using a cycle ergometer to determine each subject's  $\text{VO}_2$  max. At the end of the supplementation period, both groups took part in an acute exercise session (cycle ergometer; 55%  $\text{VO}_2$  max; 45 min). Subjects were weighed at the beginning and the end of the trial, and height was measured at entry; there were no significant differences in these or other characteristics between the groups at entry (Table 1). Furthermore, FA profiles in the PL and NEFA fractions of subjects at entry did not differ between groups (data not shown). The weight of the subjects in either group was not affected throughout the supplementation period. All dietary records (3 d) were analyzed by the Can West Diet Analysis-Plus program, which includes comparison with the Canadian Recommended Nutrient Intakes (West Publishing Co., St. Paul, MN). The amount of fat consumed in encapsulated form (12 g/d) represented <20% of the dietary fat intake. There were no differences between daily energy intakes (average of all subjects was 8025 kJ/d; data not shown) or intakes of saturated fat, cholesterol, monounsaturated fat, or polyunsaturated fat between the two groups. Compliance was monitored by determining the FA composition of serum PL and FFA at the beginning and end of the trial and from a capsule count at the end of the study. Two subjects in the fish oil-supplemented group were dropped from all further statistics (final  $n = 8$ ) because of noncompliance as determined by blood levels of n-3 FA.

**TABLE 1**  
Subject Characteristics and Estimated Dietary Intake During Placebo or Fish Oil Supplementation<sup>a</sup>

Variable	Placebo	Fish oil
Height (m)	1.7 $\pm$ 0.0	1.6 $\pm$ 0.0
Weight (kg)	75.9 $\pm$ 3.8	67.5 $\pm$ 3.1
BMI (kg/m <sup>2</sup> )	26.7 $\pm$ 1.5	25.8 $\pm$ 1.3
Energy (kJ)	8811.5 $\pm$ 616.6	7258.5 $\pm$ 518.6
Protein (% energy)	14.3 $\pm$ 1.4	15.1 $\pm$ 1.0
Fat (% energy)	33.5 $\pm$ 2.1	31.9 $\pm$ 2.5
Carbohydrate (% energy)	51.5 $\pm$ 2.6	52.2 $\pm$ 3.2
Alcohol (% energy)	0.52 $\pm$ 0.26	0.33 $\pm$ 0.24
Menstrual cycle length (d)	26.5 $\pm$ 1.1	27.6 $\pm$ 1.0

<sup>a</sup>Values are reported as mean  $\pm$  SEM,  $n = 10$  (placebo) and  $n = 8$  (fish oil). No significant differences between the groups were found for the above variables. BMI, body mass index.

**Blood collection.** Blood was collected when the subject was fasted, in the early follicular phase of the menstrual cycle, immediately before and within 5 min of the completion of the exercise session. Blood was collected by antecubital venipuncture, by a registered technologist, into siliconized tubes containing no anticoagulant.

Blood was allowed to coagulate at room temperature (~45 min) and was then centrifuged at  $1250 \times g$  for 15 min to obtain serum. Serum was used for the measurement of total PL and NEFA compositions. Serum was stored at  $-70^\circ\text{C}$  until all samples were collected and thawed just before analyses of lipids.

**Total phospholipid and NEFA analysis.** The composition of total PL and NEFA from serum was determined as follows. Lipid extraction was performed with the addition of a known amount of heptadecaenoic acid (17:0) and PC diheptadecanoyl (17:0 PC) as described by Folch *et al.* (22). The extract was spotted on silica gel G plates and developed in heptane/isopropyl ether/acetic acid (50:50:3). The PL band and NEFA bands, respectively, were removed and methylated with 2.0 mL of boron trichloride in methanol. GLC of the FAME was performed using a Varian 3800 gas chromatograph (Palo Alto, CA) with a 60-m DB-23 capillary column (0.32 mm internal diameter).

**Statistical analysis.** All data are reported as mean  $\pm$  SEM. When observations were missing, least-squared means were calculated so that means could be compared. The general linear models procedure was used in all analyses before examination of specific differences by Fisher's protected least significant differences. Dietary intakes and subject characteristics were compared by *t*-test. Statistical analyses were done using the SAS system (SAS Institute, Inc., Cary, NC). Changes within groups as well as comparisons between groups were considered.

## RESULTS AND DISCUSSION:

Exercise has been shown to increase the potential for arrhythmia and sudden cardiac death risk (16,23). In light of the potential cardioprotective role of n-3 NEFA (6,24) and the rise in n-3 NEFA with n-3 FA supplementation (11,13), this double-blind trial examined the effects of acute exercise on changes in

PL and NEFA composition and status in sedentary premenopausal women supplemented with n-3-containing fish oil or a control oil. To our knowledge, this is the first report examining the effect of acute exercise on NEFA composition of n-3-supplemented female subjects.

The FA compositions of serum total PL (control and fish oil-supplemented) before and after exercise are given in Table 2. The levels of the various FA prior to supplementation were similar between the two groups (data not shown). EPO (control) supplementation resulted in a decrease in 18:1 (−14.7%) and an increase in 20:3n-6 (24.2%) ( $P < 0.05$ ; data not shown). Fish oil supplementation also resulted in a decrease in 18:1 (−15.0%) as well as decreases in 18:2n-6 (−24.4%), 20:3n-6 (−41.4%), AA (−10.2%), 22:4n-6 (−48.7%), and the n-6/n-3 ratio (−68.2%). Also, in the fish oil-supplemented group, increases were noted in EPA (538% overall), DHA (94% overall), and DPA (50% overall) ( $P < 0.05$ ; data not shown). Exercise appeared to have little or no effect on serum PL values.

The FA compositions of serum NEFA (control and fish oil-supplemented) before and after exercise are given in Table 3. The levels of the various FA prior to supplementation were similar between the two groups (data not shown). EPO (control) supplementation resulted in slight but nonsignificant increases in 20:3n-6, 22:4n-6, and the n-6/n-3 ratio (data not shown). Fish oil supplementation resulted in marked increases in EPA (967% overall), DHA (241% overall), and DPA (313% overall) (data not shown). Exercise had no effect on serum NEFA composition in either the fish oil- or placebo-supplemented groups.

The effects of exercise on NEFA levels ( $\mu\text{M}$ ) are given in Table 4. Total NEFA levels did not change with fish oil supplementation or with control supplementation (data not shown). Although there was no effect of supplementation with placebo on individual NEFA levels, fish oil supplementation resulted in

increased NEFA levels of EPA, DPA, and DHA [0.65 (0.20) to 14.6 (8.7)  $\mu\text{M}$ ; 0.59 (0.22) to 2.3 (0.5)  $\mu\text{M}$ ; and 2.0 (0.4) to 11.0 (2.7)  $\mu\text{M}$ , respectively]. Exercise increased levels of total NEFA in both groups. Furthermore, exercise increased absolute levels of 16:0, 18:0, 18:1, 18:2n-6, and 18:3n-3 NEFA. Absolute levels of n-3 NEFA before exercise were higher in the n-3 supplemented women compared with the women supplemented with placebo. Exercise, however, did not increase absolute levels of n-3 NEFA in either group.

Fish oil supplementation (providing 3.6 g EPA and 2.4 g DHA per day for one menstrual cycle) resulted in dramatic increases in the EPA, DHA, and DPA content of the serum NEFA and PL within approximately 28 d. This increase in n-3 NEFA is in agreement with previous studies that have shown fish oils raise the EPA, DHA, and DPA concentration of serum NEFA after supplementation with algal-source DHA (11) or seal oil (13). Exercise has been shown to increase total serum NEFA concentrations and to influence the concentrations of individual NEFA (21). That EPA is the most mobilized FA in fasted rats (25,26) and rabbits (27) has also been shown. Thus, it was hypothesized that exercise would increase the mobilization of EPA and/or DHA from adipocytes in both n-3- and non-n-3-supplemented individuals. Absolute levels of total n-3 NEFA before (41.5  $\mu\text{M}$ ) and after (45.6  $\mu\text{M}$ ) exercise, and DHA-NEFA in particular (12.9 and 12.6  $\mu\text{M}$ , before and after exercise, respectively) in the n-3-supplemented individuals, may offer cardioprotection (8,10). For example DHA-NEFA at these levels has been shown to be antiarrhythmic and antithrombotic (7–9).

The consumption of fish oil containing 3.6 g/d EPA plus 2.4 g/d DHA readily increased the percentage and absolute levels of n-3 FA in serum NEFA and the percentage of n-3 FA in serum total PL in premenopausal women. An acute exercise session (55%  $\text{VO}_2$  max; 45 min) on a cycle ergometer appeared to have little effect on the composition of serum PL. Certain individual

NEFA, mainly saturated and monounsaturated NEFA, increased with exercise. n-3 and n-6 NEFA, in general, however, were not mobilized to a greater extent after exercise in individuals supplemented with fish oil for a period of approximately 4 wk. Future studies could examine the effects of longer exercise durations, the effect of aerobic exercise training, and the effect of a longer duration of fish oil supplementation in order to ascertain the impact of exercise on absolute NEFA levels and composition in n-3 FA-supplemented individuals.

**ABSTRACT:** Long-chain PUFA (LCP) deficiency is a frequent complication in cholestatic infants. We investigated the effects of LCP-supplemented formula on EFA status in infants with cholestasis. Twenty-three infants with cholestasis (biliary atresia after surgery, 8; intrahepatic cholestasis, 15) aged 1.9 to 4.9 mon (median 3.1 mon) were randomized to receive commercial infant formulas either without LCP or with LCP from egg phospholipids for 1 mon. Liver tests, nutrient intakes, and plasma phospholipid FA (%w/w) were determined at baseline and after intervention. At baseline, patients had high serum direct bilirubin levels ( $5.9 \pm 3.0$  mg/dL; mean  $\pm$  SD), they were malnourished (body fat mass:  $40 \pm 13\%$  of normal) and presented with PUFA deficiency [plasma phospholipid PUFA: 28.43%w/w (26.56–30.53) in patients vs. 37.02%w/w (34.53–39.58) in controls; median (1st–3rd quartile)] with elevated Mead acid and palmitoleic acid. LCP-supplemented ( $n = 11$ ) and -nonsupplemented groups ( $n = 12$ ) did not differ in age, indicators of liver function, and EFA status at baseline. After the intervention, LCP-supplemented infants had higher levels of arachidonic acid [7.2 (5.9–8.8) vs. 4.2 (3.0–5.3) %w/w;  $P < 0.001$ ] and DHA [2.8 (2.2–3.2) vs. 1.6 (1.0–2.1) %w/w;  $P < 0.05$ ], accompanied by increased TBARS concentration: 1.9 (1.4–2.2) vs. 1.3 (1.1–1.6) nmol/mL;  $P < 0.05$ ]. We concluded that LCP-supplemented formulae improve LCP status of infants with severe cholestasis but may enhance lipid peroxidation.

Paper no. L9021 in *Lipids* 37, 953–957 (October 2002).

Infants and children with cholestatic liver disease often develop PUFA deficiency (1–3), which is related to both nutritional (1) and metabolic (2) factors. Since PUFA deficiency may develop early in cholestatic infants, dietary intervention may be needed to prevent functional consequences for growth (4,5) and neurodevelopment (6–8). Indeed, cholestatic children usually present with growth failure, malnutrition, and neural disturbances that have been related to deficiencies of various nutrients, including vitamin E (9). An improvement in long-chain PUFA (LCP) status by supplementation with

the precursor PUFA, linoleic acid (LA) and  $\alpha$ -linolenic acid (ALA), may not be sufficient because the conversion EFA to their long-chain derivatives seems to be impaired in cholestasis, presumably owing to hepatocyte injury (2). As an alternative approach, LCP supplementation may be considered in these patients. In this study we assessed the supplementation of infants with cholestasis with arachidonic acid (AA) and DHA in a randomized placebo-controlled trial.

## PATIENTS AND METHODS

We studied 23 infants with cholestasis (8: biliary atresia after surgery; 15: intrahepatic cholestasis, among them two with Progressive Familial Intrahepatic Cholestasis and five with cytomegalovirus infection) aged 1.9 to 4.9 mon (median 3.1 mon) treated at the Children's Memorial Health Institute. We included in the study infants who had not been breast-fed for at least 4 wk before the study started. The patients with biliary atresia were included in the study 2 wk after hepatoportocentrostomy. All children were Caucasians, only eight infants were breast-fed before entering the study (1–6 wk), eight children were born premature; the birth weight was  $2.8 \pm 0.6$  kg ( $n = 23$ ). All children studied were routinely supplemented with a lipid preparation of  $\alpha$ -tocopherol (Vitaminum E, drops; Synteza, Poznań, Poland) in a daily dose of 75 mg  $\alpha$ -tocopherol. As a reference group, we investigated 12 infants in good general health with normal weight and length, aged 1 to 11 mon (median age 5 mon) as previously described (1). The study protocol was approved by the local ethical committee, and parental written informed consent was obtained.

Cholestatic infants were randomized to receive commercial infant formulas either without LCP (Aptamil; Milupa, Friedrichsdorf, Germany) or with LCP from fractionated egg phospholipids (Aptamil with Milupan) for 1 mon. The PUFA contents of the formulas were as follows: Aptamil 1—LA 13.5%, ALA 0.55%; Aptamil with Milupan—LA 10.2–12.5%, ALA 1.2–1.5%, AA 0.3–0.4%, DHA 0.04%. Since body weight is not a reliable indicator of nutritional status in liver disease (10), we based clinical assessment of nutritional status on midarm skinfold thickness measurements with a standard caliper (Holtain Tonner/Cohirehouse caliper, A. Winter Machinery Ltd., Rapperswill, Switzerland) and arm circumference

Abbreviations: AA, arachidonic acid; ALA,  $\alpha$ -linolenic acid; ALAT, alanine aminotransferase; FBM, fat body mass;  $\gamma$ -GT,  $\gamma$ -glutamyl transpeptidase; LA, linoleic acid; LBM, lean body mass; LCP, long-chain PUFA; PL, phospholipids.

at baseline. Based on these parameters, we calculated lean body mass (LBM) and fat body mass (FBM) according to the following formulae (11):

$$\text{LBM (\%)} = \frac{[10 \times (\text{arm circumference}) - \pi \times (\text{skinfold thickness})]^2}{4 \times \pi} \quad [1]$$

$$\text{FBM (\%)} = \frac{[10 \times (\text{arm circumference})]^2}{4 \times \pi - (\text{LBM})} \quad [2]$$

Both LBM and FBM were expressed as a percentage of the mean normal value for age (12). At baseline and after 1 mon of treatment, we assessed nutrient intakes and liver function as well as FA composition of plasma phospholipids (PL). Intakes of energy, lipids, carbohydrates, proteins, and LA were calculated from 24-h recall protocols supplemented with a checklist of foods usually consumed at this age. The calculation was done with the Polish nutritional value database "Food 2" (Food and Nutrition Institute 1998, Warszawa, Poland). Venous blood was obtained at baseline and after a month from fasted liver patients. Serum was obtained for the measurement of total and direct bilirubin; activities of alanine aminotransferase (ALAT) and  $\gamma$ -glutamyl transpeptidase ( $\gamma$ -GT); prothrombin time; total serum bile acids, serum TG, cholesterol, and PL concentrations. Serum concentrations of retinol and  $\alpha$ -tocopherol were measured by HPLC (13).

Venous plasma was obtained with sodium EDTA (1 mg/mL) as anticoagulant and stored at  $-20^\circ\text{C}$  until analysis of the FA composition of plasma PL. Lipids were extracted from 0.5 mL plasma with chloroform/methanol, and lipid classes were separated by TLC as previously described (14). FA were transesterified with methanol and hydrochloric acid and analyzed by high-resolution capillary GLC using a Hewlett-Packard Series II 5890 gas chromatograph with split/splitless injection and FID (SGE column 60QC3/BPX70, Melbourne, Australia; column diameter 0.32 mm; column head pressure 1.5 bar; oven temperature initially  $150^\circ\text{C}$ , temperature rise by  $3^\circ\text{C}/\text{min}$  up to  $180^\circ\text{C}$ , then temperature rise by  $4^\circ\text{C}/\text{min}$  up to  $200^\circ\text{C}$ , rise by  $1^\circ\text{C}/\text{min}$  up to  $210^\circ\text{C}$ , isothermal period for 20 min). Peak identification was

verified by comparison with authentic standards (Nu-Chek-Prep. Inc., Elysian, MN; Sigma, Deisenhofen, Germany). Results are expressed as percentage (%w/w) of all FA detected having a chain length between 12 and 24 carbon atoms (15). Plasma lipid peroxides were determined with the spectrofluorometric method of Yagi (16,17) and expressed as TBARS (nmol/mL) in cholestatic patients and in 12 age-matched controls.

Results were evaluated with Statistica for Windows release 5.0 (Statsoft, Inc., Tulsa, OK). We present the data as medians with lower and upper quartiles (1st–3rd). For comparison of FA profiles, biochemical tests, and nutrient intakes in different groups, Mann-Whitney's two-sided rank test was used. The treatment effects in the same group of patients were evaluated with the Wilcoxon matched-pairs test. Differences were regarded as statistically significant at  $P < 0.05$ .

## RESULTS

At the entry to the study, the 23 patients presented with markedly elevated bilirubin levels and serum bile acids, reflecting severe cholestasis (Table 1). Severe malnutrition with an extremely low FBM was found in spite of a relatively high intake of energy, protein, and fat (Table 2). TBARS as indicators of lipid peroxidation were significantly increased relative to levels in healthy age-matched controls [1.9 (1.6–2.5) vs. 0.9 (0.7–1.0) nmol/mL]. The cholestatic patients presented with a poor PUFA status, which was mainly due to the low plasma PL levels of the precursor EFA LA (18:2n-6) and its metabolite AA (20:4n-6) (Table 3). The supplemented and placebo groups did not differ at baseline in biochemical tests (Table 1), nutritional status (Table 2), FA status (Fig. 1), and nutrient intakes except for a lower fat intake in the LCP-supplemented group (Table 2).

After the intervention, nutrient intakes of nutrients were also similar in both groups (Table 2). Bilirubin and bile acid levels decreased during the course of the study. After 1 mon, the LCP-supplemented children had significantly higher levels of LA, its metabolite AA, and DHA than the placebo

**TABLE 1**  
Clinical Chemistry in Children Supplemented with LCP and in the Placebo Group at Baseline and After 1 mon of Treatment

Parameter	At baseline		After 1 mon		Reference values

<sup>a</sup> $P < 0.05$ , LCP-supplemented group vs. placebo group (at baseline and after 1 mon of treatment). Data represent medians with lower and upper quartiles (1st–3rd). For abbreviation see Table 1.

group (Fig. 1). Total PUFA, AA, DHA, and total LCP increased significantly ( $P < 0.05$  for all parameters) in the LCP-supplemented group with the intervention, whereas LA and ALA remained unchanged. In contrast, there was no change of PUFA levels in the placebo group over time. After 1 mon of intervention, the LCP-supplemented group still had lower LA values than healthy controls ( $P < 0.001$ ), but AA and

DHA values had reached the levels of healthy infants. At the end of the study the placebo and LCP-supplemented groups did not differ in biochemical indicators of liver function, except for a higher  $\gamma$ -GT in LCP-supplemented infants. TBARS concentrations were higher in the LCP-supplemented group than in the placebo group (Table 1).

## DISCUSSION

The results presented here confirm a high risk of PUFA deficiency in young infants with cholestatic liver disease (1). Increased values of palmitoleic and Mead acids indicate the presence of PUFA deficiency in this patient population (18). The triene/tetraene ratio was not analyzed, as it is not a good indicator of PUFA deficiency in cholestasis where the decline in desaturase/elongase activity affects synthesis of both AA and Mead acid (2). The most prominent deficiencies we found were in LA and AA, whereas DHA only tended to be lower in cholestatic children. This supports the concept that both AA and DHA should be supplemented in cholestasis.

The dietary supply of PUFA, energy, and presumably of other substrates may affect PUFA status. The patients studied here showed relatively high intakes of energy and macronutrients compared to the usual consumption of healthy infants. The macronutrient intake did not change significantly over time (Table 2). However, the achieved mean caloric intake appears not to have met the high energy requirements in cholestasis of infancy, which may be well above 150 kcal/kg/d (19,20). A negative energy balance may result in enhanced oxidation of PUFA to provide energy and thus contribute to the development of PUFA deficiency. The patients presented with malnutrition, as expressed especially by low FBM, which points to short-term malnutrition. Body weight can be affected by edema, ascites, and hepatosplenomegaly. Height is more reliable, but it indicates chronic malnutrition. Skinfold thickness and arm circumference are considered to be more accurate measurements (10). A poor nutritional status may well be accompanied by a preferential utilization of nutrients as an energy source. Moreover, poor availability of antioxidants such as vitamin E may induce enhanced PUFA peroxidation and thereby also contribute to PUFA depletion (1–3). Even if the children had been treated with  $\alpha$ -tocopherol, the concentrations of vitamin E in serum tended to be low from the beginning to the end of the study. However, in a previous intervention study in another population of children with chronic cholestasis we did not find any effect of improving vitamin E status on lipid peroxidation *in vivo* and on PUFA levels (3).

At baseline, the supplemented and the placebo groups did not differ in FA status, liver parameters, nutritional status, and nutrient intakes except for a lower fat intake in the LCP-supplemented children. AA and DHA levels in the LCP-supplemented group at study's end were similar to those in healthy controls and indicated a good metabolic efficacy of the LCP-supplemented formula in the cholestatic infants. An early dietary intervention to normalize the EFA status may be very important in view of the rapid brain growth and development in early life. A number of studies performed in healthy term infants found LCP depletion with feeding of conventional infant formula without preformed LCP relative to breast-feeding or feeding LCP-supplemented formula (6–8). Some studies have related the dietary supply of preformed LCP, either with human milk or with LCP-containing formula, to im-

proved results for measures of visual acuity and neural development in healthy preterm and term infants (6–8,21–23), indicating that LCP may be conditionally essential substrates in early infancy. Cholestatic infants are at risk for neurological handicaps (9,23), which have been related in part to vitamin E deficiency (23). It is conceivable that poor availability of PUFA also could contribute to the poor growth and neurological development of cholestatic infants.

LCP are prone to lipid peroxidation owing to free radical injury. Indeed, LCP-supplemented children showed higher plasma concentrations of TBARS, indicating enhanced lipid peroxidation, than controls. The similar effect of LCP supplementation was demonstrated in healthy individuals (24), and children with cholestasis seem to be extremely vulnerable to free radical damage. Increased lipid peroxidation in children with cholestasis was shown in several studies (1–3,25), but the clinical significance of this finding remains unknown. Adequate supplementation of vitamin E and potentially other antioxidants also should be tested in children with cholestasis receiving an extra LCP supply. Moreover, the potential clinical benefits of LCP supplementation in this critical patient population need to be investigated further. We can expect that disturbances of visual function may occur in cholestatic infants although one study did not confirm this (26).

Results of the liver tests improved during the study, which reflect transient cholestasis in some subjects and improvement of bile flow in the others (e.g., biliary atresia after hepatoportoenterostomy). Still, the main factor that influenced FA status was LCP supplementation, which is indicated by higher LCP levels in the supplemented group in this randomized study. Regarding the critical period of central nervous system development in early life, LCP supplements should be considered in early infancy even if the diagnosis of cholestasis is not well established. The positive finding of our study was the relatively good absorption of LCP supplements as indicated by rising AA and DHA levels. Still, we can regard PUFA absorption in cholestatic children to be less effective than in healthy infants.

## ACKNOWLEDGMENTS

The study was supported by the Milupa company. We would like to thank Ewa Skorupa for her essential support in the laboratory work.

**ABSTRACT:** Long-chain PUFA play an important role in early human neurodevelopment. Significant inverse correlations were reported between values of *trans* isomeric and long-chain PUFA in plasma lipids of preterm infants and children aged 1–15 yr as well as in venous cord blood lipids of full-term infants. Here we report FA compositional data of cord blood vessel wall lipids in 308 healthy, full-term infants (gestational age: 39.7 ± 1.2 wk, birth weight: 3528 ± 429 g, mean ± SD). The median (interquartile range) of the sum of 18-carbon *trans* FA was 0.22 (0.13) % w/w in umbilical artery and 0.16 (0.10) % w/w in umbilical vein lipids. Nonparametric correlation analysis showed significant inverse correlations between the sum of 18-carbon *trans* FA and both arachidonic acid and DHA in artery ( $r = -0.38$ ,  $P < 0.01$ , and  $r = -0.20$ ,  $P < 0.01$ ) and vein ( $r = -0.36$ ,  $P < 0.01$ , and  $-0.17$ ,  $P < 0.01$ ) wall lipids. In addition, the sum of 18-carbon *trans* FA was significantly positively correlated to Mead acid, a general indicator of EFA deficiency, in both artery ( $r = +0.35$ ,  $P < 0.01$ ) and vein ( $r = +0.31$ ,  $P < 0.01$ ) wall lipids. The present results obtained in a large group of full-term infants suggest that maternal *trans* FA intake is inversely associated with long-chain PUFA status of the infant at birth.

Paper no. L9040 in *Lipids* 37, 959–965 (October 2002).

The long-chain PUFA, arachidonic acid (all-*cis*-5,8,11,14-arachidonic acid; 20:4n-6) and DHA (all-*cis*-4,7,10,13,16,19-DHA; 22:6n-3) play an important role in early human development (1–4). They are synthesized from the parent EFA, linoleic acid (all-*cis*-9,12-linoleic acid; 18:2n-6) and  $\alpha$ -linolenic acid (all-*cis*-9,12,15- $\alpha$ -linolenic acid; 18:3n-3), *via* a complex pathway consisting of several desaturations, chain elongations, and

peroxisomal  $\beta$ -oxidation (for biochemical details see Ref. 4), and/or consumed preformed in the diet. Oleic acid (*cis*-9-oleic acid; 18:1n-9) also may be converted *via* the same pathway into its longer-chain metabolites including Mead acid (20:3n-9). Because the affinity of 18:1n-9 for the enzymes of the pathway is considerably lower than that of 18:2n-6 and 18:3n-3, accumulation of 20:3n-9 indicates EFA deficiency.

The effect of modification of the 22:6n-3 and 20:4n-6 supply in infancy on visual and cognitive functions currently is being investigated (5–9). However, recent observations suggest that for 20:4n-6 and 22:6n-3, status at birth is one of the important determinants of postnatal changes in these FA (10). EFA status of the mother before and during pregnancy is the principal determinant of the EFA status of the infant at birth (11). Accumulating evidence indicates that factors other than maternal EFA intake may adversely affect the availability of 20:4n-6 and 22:6n-3 for the fetus.

At least four peer-reviewed publications indicated the potential interference of *trans* FA with long-chain PUFA availability in humans. First, significant inverse correlations were described between *trans*-octadecenoic acid (*t*-18:1) values and both 20:4n-6 and 22:6n-3 in plasma cholesterol esters and TAG in 29 premature infants on day 4 of life (12). Second, a significant inverse correlation was reported between *t*-18:1 and 20:4n-6 in plasma phospholipids in 53 healthy children aged 1 to 15 yr (13). Third, significant inverse correlations were seen between concentrations of *trans* FA, on the one hand and those of 22:6n-3 and 20:4n-6 on the other hand in venous cord blood plasma TAG and cholesteryl esters, respectively, in 70 healthy, full-term infants (14). Finally, significant inverse associations were described between the sum of *trans* FA and 20:4n-6 and 22:6n-3 in venous cord blood plasma phospholipids, cholesterol esters, and nonesterified FA of 42 full-term infants with an atopic trait (15).

The above-mentioned data obtained immediately or shortly after birth (12,14,15) suggest that maternal exposure to *trans* isomeric FA may be inversely related to the availability of long-chain PUFA to the fetus around birth. Shortcomings of these publications were the relatively small numbers of infants

Abbreviations: *Cis* unsaturated FA: 18:1n-9, *cis*-9-oleic acid; 18:2n-6, all-*cis*-9,12-linoleic acid; 18:3n-3, all-*cis*-9,12,15- $\alpha$ -linolenic acid; 20:3n-9, all-*cis*-5,8,11-eicosatrienoic acid; 20:4n-6, all-*cis*-5,8,11,14-arachidonic acid; 22:6n-3, all-*cis*-4,7,10,13,16,19-docosahexaenoic acid. *Trans* isomeric FA: *t*-16:1, *trans*-7-hexadecenoic acid; *t*-18:1, *trans*-9/11-octadecenoic acid; *tt*-18:2, all-*trans*-9,12-octadecadienoic acid; *tc*-18:2, *trans*-9,*cis*-12-octadecadienoic acid; *ct*-18:2, *cis*-9,*trans*-12-octadecadienoic acid.

who were selected for study. Furthermore, only plasma lipids, reflecting FA status for a relatively short time, were investigated.

To avoid these shortcomings, we studied the association between five different *trans* isomeric FA and long-chain PUFA in cord blood vessel wall lipids in a large group of apparently healthy, full-term infants, all of whom were born after a normal pregnancy. In addition, a comparison was made between the FA composition of the wall of the efferent (umbilical arteries) and the afferent (umbilical vein) blood vessels of the umbilical cord.

## SUBJECTS AND METHODS

This study was part of a prospective cohort study investigating the effect of pre- and postnatal exposure to long-chain PUFA on growth and neurological development up to 18 mon of age. Apparently healthy pregnant women were informed between weeks 30 and 34 of their pregnancy about the study goal and design either by gynecologists of the University Hospital Groningen and the Martini Hospital (Groningen, The Netherlands) or by midwives in the city of Groningen. After the pregnant women gave their permission, they were called by one of the investigators who gave more detailed information. Exclusion criteria were as follows: multiple pregnancy, congenital abnormalities, and neonatal morbidity requiring intensive care. Mothers with type 1 diabetes, gestational diabetes, hypertension, and heart disease were not excluded from the study if the condition was well controlled. Written informed consent was obtained from all participants. The local medical ethical committee approved the study protocol.

We studied 308 apparently healthy, full-term infants [136 boys and 172 girls, 129 (42%) from primiparous and 179 (58%) from multiparous women]. Median maternal age was 30 yr (ranges: 18–47 yr); 24.8% of the mothers smoked during pregnancy. The mean  $\pm$  SD gestational age of the infants was  $39.7 \pm 1.2$  wk. Mean birth weight was  $3528 \pm 429$  g, and mean length at birth  $52.1 \pm 2.3$  cm.

Immediately after delivery, an approximately 7-cm sample of the umbilical cord located at the most proximal site of the placenta was removed. The sample was immediately placed in an ice-cold 0.9% NaCl solution until further processing. The two umbilical arteries and the umbilical vein were subsequently dissected from the surrounding tissue, thoroughly washed with an ice-cold 0.9% NaCl solution, and dried on paper tissue. No attempt was made to differentiate tissue layers within the blood vessel walls. Umbilical arteries and veins were weighed and subsequently transmethylated by incubating with 2 mL methanol/HCl (5:1 vol/vol; 6 mol HCl/L), which contained 5 mg BHT, at 90°C for 4 h. It was previously demonstrated in our laboratory that direct transmethylation is a suitable method in the determination of the FA composition of biological fluids and blood cells (16). All samples were stored at  $-20^\circ\text{C}$  until transported on dry ice to the Laboratory of the Department of Paediatrics, University of Pécs.

FAME were determined by high-resolution capillary GLC

with a Finnigan 9001 chromatograph (Finnigan/Tremetrics Inc., Austin, TX) with split injection (ratio: 1 to 15) and a FID. Two 30-m fused cyanopropyl columns (BPX70; SGE, Melbourne, Australia) were coupled and used for the analysis. The temperature program was as follows: an initial temperature of the injector of 80°C for 0.1 min, followed by a temperature increase of 180°C  $\text{min}^{-1}$  up to 280°C; temperature of the detector 280°C; an initial temperature of the column area of 60°C for 0.2 min, followed by a temperature increase of 20°C  $\text{min}^{-1}$  up to 160°C, followed by a 5-min isothermal period, followed by a temperature increase of 1°C  $\text{min}^{-1}$  up to 183°C, followed by a temperature increase of 5°C  $\text{min}^{-1}$  up to 200°C, followed by a 5-min isothermal period, followed by a temperature increase of 40°C  $\text{min}^{-1}$  up to 230°C, followed by a 10.65-min isothermal period. The ramped pressure program was as follows: an initial pressure of 30 psi for 0.2 min, followed by a pressure increase of 5 psi  $\text{min}^{-1}$  up to 35 psi, followed by a 9-min isobaric period, followed by a pressure increase of 5 psi  $\text{min}^{-1}$  up to 37 psi, followed by a 31.4-min isobaric period, followed by a pressure increase of 5 psi  $\text{min}^{-1}$  up to 45 psi, followed by a 9.4-min isobaric period. A typical chromatogram illustrating *trans* FA has been recently published from our laboratory (15). Identification of FA was confirmed by comparison with authentic standards (Nu-Chek-Prep, Elysian, MN). FA results were expressed as %w/w of the FA detected with a chain length between 14 and 24 carbon atoms.

We used SPSS for Windows, Release 7.5 (SPSS Inc., Chicago, IL) for the statistical analysis. The FA data are presented as median and range from the first to the third quartile values, because skewed distributions were found especially in FA present at lower concentrations. Nonparametric detection of correlation was carried out by calculating Spearman's  $\rho$  correlation coefficients. Because many ( $n = 57$ ) of the correlation analyses yielded significant results, in spite of the relatively high number of calculations ( $n = 82$ ), no attempt was made to correct for multiple testing. Results were regarded as statistically significant at  $P < 0.05$ .

## RESULTS

Percentage contributions of FA to the FA composition of umbilical cord blood vessel wall lipids are shown in Table 1. Values of *trans* FA were nearly similar in artery and vein wall lipids. In both artery and vein lipids, *trans*-7-hexadecenoic acid (*t*-16:1) was the major *trans* isomeric FA, whereas 18-carbon *trans* FA constituted about one-third of the total *trans* FA contents. Values of 20:3n-9 were about sevenfold higher in artery than in vein wall lipids.

In the wall of umbilical arteries, the sum of 18-carbon *trans* FA was positively related to 18:1n-9, 20:3n-9, and 18:3n-3, whereas it was inversely related to 20:4n-6 and 22:6n-3 (Table 2). The correlation of the sum of 18-carbon *trans* FA vs. 20:3n-9, 20:4n-6, and 22:6n-3 in umbilical artery lipids are graphically represented in Figure 1. Total *trans* FA values were positively related to 20:3n-9, 18:2n-6 and 18:3n-3, whereas they were inversely related to 20:4n-6.

<sup>a</sup>Values are %w/w expressed as median (interquartile range).

In the wall of umbilical vein, the sum of 18-carbon *trans* FA was positively related to 18:1n-9, 20:3n-9, and 18:3n-3, whereas it was inversely related to 20:4n-6 and 22:6n-3 (Table 3). The correlation of the sum of 18-carbon *trans* FA with 20:3n-9, 20:4n-6, and 22:6n-3 in umbilical vein lipids is graphically represented in Figure 2. Total *trans* FA values were positively related to 20:3n-9, 18:2n-6, and 18:3n-3, whereas they were inversely related to 20:4n-6.

## DISCUSSION

The most notable findings of the present study are the significant inverse associations between 18-carbon *trans* isomeric FA and the most important long-chain PUFA, 20:4n-6 and 22:6n-3, in fetal tissue lipids at the end of apparently normal human pregnancies. FA compositions of fetal tissues are influenced by maternal FA supply to the fetus (11). For instance, significant positive correlations were found for almost all n-6 and n-3 FA between maternal plasma investigated during pregnancy and umbilical plasma levels (17). Parallel investigations on FA composition of the wall of umbilical cord veins and arteries allow researchers, to at least some extent, to assess maternal supply (vein) and fetal return (artery) separately.

Humans do not synthesize *trans* FA, although the human metabolism is able to elongate and desaturate ingested *trans* FA into longer-chain and more unsaturated metabolites (18). Anyhow, the *trans* FA detected in fetal tissues must have their origin in the maternal diet. In the human diet *trans* FA originate partly from the meat and milk of ruminant animals, but the major part of human *trans* FA exposure is the consequence of the production of by-products during industrial food processing, i.e., partial hydrogenation and heat-deodorization of various fats (e.g., Ref. 19). *trans* FA constitute a sizable portion of FA intake in Western-type diets. The average *trans* FA consumption was reported to be 7–12 g/d in the United States (20, 21) and 4–6 g/d in the United Kingdom (22). In pregnant and breast-feeding women, average *trans* FA intakes were estimated to be 6.4 g/d in the United States (23) and 6.9 g/d in Canada (24).

However, dietary *trans* FA intakes in The Netherlands appear to be considerably lower than those in North America. A

recent report of the Dutch Health Council estimates the mean *trans* FA intake of the Dutch population to be 1.2 g/d (25). Despite this relatively low intake, it is important to note that an inverse association between *trans* isomeric and long-chain PUFA in umbilical cord blood vessel wall lipids was recorded in the present study. It may reasonably be assumed that similar or even stronger associations may be observed in populations with *trans* FA intakes exceeding the Dutch values.

The most prevalent *trans* FA in the human diet is *t*-18:1 (26,27). FA composition of blood lipids usually reflects the FA composition of the diet; for example, one of us previously investigated the contribution of *trans* FA to the FA composition of plasma lipid classes in seven age groups from birth to young adulthood and found *t*-18:1 to be the major plasma *trans* FA in all sample categories including venous cord blood (28). We are not aware of published data on the contribution of individual *trans* FA to the FA composition of cord blood vessel wall lipids.

Experimental evidence obtained in *in vitro* investigations and animal studies indicates that *trans* FA may impair the synthesis of long-chain PUFA from 18:2n-6 and 18:3n-3. Investigations both on rodent tissues (29) and on human fibroblast cultures (30) clearly demonstrated that various *trans* FA inhibit the desaturation and chain-elongation of 18:2n-6 and 18:3n-3 to their longer-chain metabolites. *In vivo* investigations in rats also showed an impairment of 18:2n-6 and 18:3n-3 metabolism with exposure to various *trans* FA (31–35). In pregnant rats, high dietary intakes of *trans* FA were associated with diminished  $\Delta 6$ -FA desaturase activity in liver microsomes and decreased contribution of longer-chain 18:3n-3 metabolites to fetal plasma lipids in the offspring (36). In an *in vitro* system of isolated human placental membranes, the presence of *t*-18:1 in the incubation medium reduced to 68–70% of binding of radio-labeled FA, whereas the inhibition of binding of 18:2n-6 and 18:3n-3 by 18:1n-9 was only around 45% (37). These data suggest that *trans* FA may effectively compete with EFA and their longer-chain metabolites for FA-binding sites in human placental membranes, thereby inhibiting the transport of these FA to the placenta (38).

In the present study it was surprising that 18-carbon *trans* FA were negatively associated with long-chain PUFA, whereas 16-carbon *trans*-FA and PUFA were positively and signifi-

cantly correlated. Industrially processed oils are usually enriched with EFA; therefore, it is reasonable to assume a positive correlation between the dietary intakes and the tissue accumulations of *trans* isomeric and EFA. However, the putative inhibitory interaction of 18-carbon *trans* FA with the metabolism of EFA may substantially influence accumulation in fetal tissues.

The significant positive correlation observed in the present study between 18-carbon *trans* FA and 20:3n-9 (Mead acid), a general indicator of EFA deficiency, may either support further the concept that high maternal intake of 18-carbon *trans* FA may impair fetal supply of long-chain PUFA, or may suggest a dietary deficiency of long-chain PUFA. Mead acid is synthesized from 18:1n-9 via  $\Delta 6$ -FA desaturation, chain elongation, and  $\Delta 5$ -FA desaturation. In classical EFA deficiency, Mead acid accumulates because of the low availability of the alternative substrates, 18:2n-6 and 18:3n-3, for  $\Delta 6$ -FA desaturation (39). However, because long-chain PUFA inhibit Mead acid synthesis, therefore, enhanced amounts of Mead acid may also indicate long-chain PUFA deficiency even if the availability of 18:2n-6 and 18:3n-3 is normal (11). The several-fold higher contribution of 20:3n-9 to cord artery than to cord vein wall lipids has been described previously by others (40) as well as by one of us (41) and is considered to represent a higher rate of substitution of 20:3n-9 for 20:4n-6 and 22:6n-3 at the efferent than at the afferent end of materno-fetal circulation.

In summary, we report a negative association between values of 18-carbon *trans* FA and that of long-chain PUFA in cord blood vessel wall lipids in a large group of apparently healthy, full-term infants. We think that the data reported here bear two immediate messages for research on PUFA. First, supply of 18-carbon *trans* isomeric FA should be taken into account as a potential independent variable in any study aimed at modifying FA supply during pregnancy. Second, individual *trans* isomeric FA rather than the parameter "sum of all *trans* fatty acids" alone should be considered as separate variable(s) in studies on the effects of *trans* FA on human health.

**ABSTRACT:** Recent studies have demonstrated that the incidence of cardiovascular events occurring with renal transplantation is higher than that in the general population. Renal transplantation modifies the characteristic dyslipidemia of chronic renal failure. In this study the change in lipoprotein and lipid values of 103 transplant recipients after transplantation was investigated. The aim of our work was to examine the short-term and long-term variations in lipid metabolism. The major lipoprotein fractions (VLDL, LDL, HDL) were separated by preparative ultracentrifugation, and TG and cholesterol concentrations were determined in plasma and lipoprotein fractions. Whole plasma apolipoproteins were determined by a rate immunonephelometric technique. In the pretransplant period the patients displayed the typical picture of uremics. After transplantation the most evident alterations in the lipoprotein profile occurred in our case series after 3 mon. The major finding was a 35% reduction in plasma TG. The modifications in the TG-rich lipoproteins of our transplant recipients persisted throughout the observation period. In the initial 3-mon period, total cholesterol remained steady, whereas LDL-cholesterol and total apolipoprotein B showed a significant increase. No significant changes were found in total and transported TG and cholesterol between the 3-mon and the 6-yr values. The substantial stability of cholesterol levels after transplantation and in subsequent reports, as well as a higher incidence of cardiovascular complications, may suggest that the mechanisms responsible for vessel damage must be sought mainly in the structural and physicochemical alterations of the individual lipoprotein fractions or in other risk factors.

Paper no. L9073 in *Lipids* 37, 967–974 (October 2002).

Cardiovascular complications are the main cause of death in chronic renal failure and renal transplant patients. Their incidence is much higher than in the general population (1). Atherosclerosis is the prime cause of these complications. Some of its risk factors are shared with the general population; others are typical of transplant patients (2,3). Particular attention has been directed to the effects of immunosuppressive management, the type of dialysis, and the pre- and posttransplant alterations in lipid metabolism (4–6).

Abbreviations: apo, apolipoprotein; BMI, body mass index; Chol, cholesterol; CVD, cardiovascular disease; HD, hemodialysis; LPL, lipoprotein lipase; NDDG, National Diabetes Data Group; TRL, triglyceride-rich lipoproteins.

Both in the general population and in transplant recipients, lipid metabolism is of prime importance, particularly because of its presumed role in chronic organ rejection (7). The post-transplant persistence or aggravation of lipoprotein alterations has been observed for at least 20 yr and has been the subject of several studies (3,6,8,9).

At least 60% of transplant recipients display an increase in total cholesterol (Chol) and LDL-transported cholesterol (LDL-Chol), as well as an inconstant increase in plasma TG and normal HDL-Chol levels.

Various factors predisposing the patient to pretransplant dyslipidemia and its posttransplant modification have been identified: age (10), diet, posttransplant weight increases (11), pretransplant lipoprotein levels (12), renal function (7), hyperglycemia and/or hyperinsulinism (13), and immunosuppressive management (5). A genetic predisposition is also thought to play a preponderant role (14). Several studies (15,16) have shown that steroids and cyclosporine, both singly and synergistically, induce dyslipidemia, whereas cyclosporine, which has an affinity to lipoproteins, results in the direct alteration of their metabolism.

Longitudinal studies have assessed lipid profile changes following transplantation. Their evaluation over the years, however, has been confined to total Chol, HDL-Chol, and TG. This paper describes the long-term monitoring of the lipoprotein and apolipoprotein (apo) profiles of 103 nondiabetic renal transplant recipients immunosuppressed with cyclosporine plus prednisone.

## MATERIALS AND METHODS

**Patients.** Nondiabetic patients ( $n = 103$ ) were recruited at the Nephrology and Dialysis Division of San Giovanni Battista Hospital, Turin (Italy) from July 1988 to March 1992. The study was terminated in July 1998.

Thirty-eight women and 65 men (aged  $41 \pm 11.3$  yr) had been on hemodialysis (HD) for  $4.5 \pm 2.6$  yr (mean  $\pm$  SD) prior to transplantation and were not diabetic according to National Diabetes Data Group (NDDG) criteria (17). The underlying diseases leading to renal failure were chronic glomerulonephritis (52%), chronic pyelonephritis (22%), vascular nephropathy (4%), systemic lupus erythematosus (2%), blood disease (4%), toxic nephropathy (5%), cystic renal disease (5%), and interstitial nephritis (5%). Their proteinuria was  $<3.5$  g/24 h, and they

were free of thyroid and liver disease. Blood creatinine 3 mon after transplantation was  $1.6 \pm 0.4$  mg/dL.

Thirty-one hypertensive subjects were placed on loop diuretics (generally furosemide) and 14 on  $\beta$ -adrenergic blocking agents. None of the patients was in treatment with lipid-lowering agents.

All patients received cyclosporine as the immunosuppressive drug associated with prednisone. Its dose was adjusted to keep plasma levels within 150–200 ng/mL, with an average dose of  $3.75 \pm 0.15$  mg/kg/d. Acute rejection episodes were treated with 1 g i.v. methylprednisolone boluses. The mean dose of prednisone in the first year was  $4.90 \pm 1.0$  g per os and  $1.25 \pm 0.62$  g i.v., and 10 mg/d in the second. In subsequent years, it was reduced, irrespective of acute rejection episodes, to reach a mean of  $5.51 \pm 1.70$  mg/d at the end of the observation period.

The posttransplantation diet provided 25–30 kcal/kg ideal body weight/d, 35% of lipids as total calories, with a polyunsaturated/saturated ratio of 2:1 and a daily cholesterol intake less than 250 mg, about 40 g/d dietetic fibers, and elimination of simple sugar.

One hundred age-matched healthy subjects (49 male and 51 female), with a mean age of  $52 \pm 6$  yr,  $\pm 10\%$  of ideal body weight, and a negative family history of diabetes and blood lipid disorders, were randomly selected from blood donors as controls for pretransplant lipid parameters.

**Lipid and lipoprotein analysis.** All lipid and lipoprotein sample preparations and analyses were performed in a single laboratory. Blood was collected into 5% EDTA- $\text{Na}_2$  in the morning after an overnight fast, and plasma was immediately centrifuged for 30 min at  $3000 \times g$  at  $4^\circ\text{C}$  in a Beckman J6B centrifuge and separated. The blood samples were drawn at least 36 h from the last HD treatment.

Blood samples were also obtained, after an overnight fast, at 3, 6, 12, 24, 36, 48, 60, and 72 mon after transplantation.

The major lipoprotein fractions (VLDL, LDL, HDL) were separated by preparative ultracentrifugation (Beckman model L8-55M ultracentrifuge with a 50.4 Ti rotor) (18).

Concentration of TG and Chol were then determined enzymatically in plasma and lipoprotein fractions by automated methods with a Shimadzu CL-7000 enzymatic photometer (Shimadzu Instruments, Kyoto, Japan). HDL-Chol was determined after precipitation of apoB-containing lipoproteins with heparin and manganese chloride (19). HDL2-Chol was determined on whole plasma by  $\text{Mn}^{2+}$ /heparin/dextran fractionated separation (20). Whole plasma apo were determined by a rate immunonephelometric technique (Alfa-Wassermann, Milan, Italy). The coefficients of variation for apoAI, -B, -CII, and -CIII were 3.80, 4.90, 2.80, and 2.10%.

Body mass index (BMI) was calculated as weight (kg) divided by height squared ( $\text{m}^2$ ).

**Statistical analysis.** Baseline values for patients and controls were compared by unpaired *t*-tests. Short-term effects of transplantation on serum lipid values were calculated as the values measured 3 mon after transplant minus pretransplant values. Long-term effects were calculated as the mean of values measured at 3, 6, and 6+ yr after transplant minus pre-

transplant values. In order to assess the persistence of effects, we also calculated the difference between long-term (6 yr and over) and posttransplant values.

All variations were also computed as percentage differences over reference values. The significance of short- and long-term variations was assessed by paired-samples *t*-tests, and the Bonferroni correction was applied to account for the large number of tests.

Patient and graft survival and a cardiovascular disease (CVD) event rate analysis were performed by the Kaplan-Meier method, and the effect of lipid, clinical, and pharmacological variables was assessed by the log-rank test. A multivariate survival analysis was performed by the Cox proportional hazard regression method, adjusting for gender and age.

## RESULTS

**Baseline.** Baseline clinical characteristics of transplant recipients are reported in Table 1. Comparisons of the baseline lipid parameters of patients and normal subjects are reported in Table 2. A highly significant difference was observed in both men and women for total TG; VLDL-TG; LDL-TG; VLDL-Chol; HDL2-Chol; and apoAI, -AII, -CII, and -CIII. There were no differences in total Chol, LDL-Chol, and apoB levels. HDL-Chol differed significantly between male patients and controls only.

**Follow-up.** A total of 103 patients (65 male, 38 female) were enrolled and received transplants. Of this number, 93 were examined 3 mon after transplantation. By the end of the study, 25 patients had died (10 from CVD, 2 from carcinoma, 2 from liver disease, and 11 from unknown causes) and 46 had undergone explantation and were considered dropouts from the study. Forty-five patients were followed for 6 yr or longer; the median duration of follow-up was 68.4 mon (range 3–131 mon).

Clinical and lipid profiles were checked every 3 mon for the first year and annually thereafter. The statistics in Table 3 were elaborated using the findings after the first 3-mon examination, since the most significant variations from the pretransplant values occurred early. The plasma values of total TG, VLDL-TG, and apoAI in particular fell rapidly.

The average BMI was  $21.1 \pm 2.7$  before transplant, and it

rose to 22.1 ± 2.5 after 6 and 12 mon, respectively. Thereafter, it remained essentially stable, with a moderate increase (23.4 ± 3.2) for the 46 subjects after at least 96 mon of follow-up.

Average basal blood glucose remained fairly stable throughout the entire follow-up period, ranging from 86.3 ± 11.0 mg/dL at baseline to 92.0 ± 20 mg/dL at 36 mon.

*Lipid profile.* Table 3 shows the lipid parameter values be-

fore transplantation and at follow-up after 3 mon, 3 yr, and 6 yr. The absolute and percentage short-term (3 mon vs. pretransplant) and long-term (mean at 3 and 6 yr vs. pretransplant) differences also are included. The posttransplant pattern was determined from the differences between the 3-mon and the 6-yr values.

Column 5 illustrates a significant reduction in total plasma

<sup>a</sup>All differences are also reported as percentages over the reference values. The second column reports values obtained 3 mon after transplantation. The fourth column reports the means of all available values after 5 yr for subjects with at least 6 yr of follow-up. Column 5 reports the differences between values in column 2 and in column 1 for 91 subjects with at least 3 mon of follow-up. Column 7 reports the difference between column 4 and column 2 for 45 subjects with at least 6 yr of follow-up. Column 8 reports the difference between column 4 and column 1 for 45 subjects with at least 6 yr of follow-up. Within-patient differences were assessed with a paired-samples *t*-test. To account for multiple testing, according to the Bonferroni correction only *P*-values below 0.002 should be considered as significant. For abbreviations see Table 2.

<sup>a</sup>None of the parameters was significantly different in the three groups after the Bonferroni correction. CVD, cardiovascular disease.

TG and all the VLDL-transported components. The protein component (especially apoCII and -CIII) was also reduced; there was thus an increase in HDL-Chol and both its fractions, especially HDL2, whose Chol load rose by 90%. The apo component of HDL increased significantly for apoAI (a 21% rise in plasma levels). In the initial 3-mon period, total Chol remained steady, whereas LDL-Chol and total apoB showed a significant increase. Column 8 shows the mean differences between the 6-yr and the 3-mon values and hence the behavior of the lipid parameters in relation to the new metabolic setting induced by the transplant. As can be seen, there were no significant changes in total and transported TG and Chol. There were slight alterations in apoAI and -B, together with a nonsignificant reduction in the apoB/LDL-Chol ratio.

Column 7 gives the long-term variations vs. the pretransplant situation. Most of the significant changes induced after 3 mon were maintained after 6 yr. The main exceptions were the continued decrease in apoCIII and the apoB/LDL-Chol ratio.

**Mortality, rejections, and cardiovascular events.** A total of 25 deaths (25%) occurred over the follow-up period. No lipid or pharmacological parameters were significantly associated with overall mortality. Of these, 15 major cardiovascular events (fatal and nonfatal acute myocardial infarction and stroke). Baseline and posttransplant lipid levels are reported in Table 4 according to the occurrence of cardiovascular events or rejections. None of the parameters was significantly different in the three groups after the Bonferroni correction.

A Kaplan–Meier analysis of the 15 major cardiovascular events indicated that the apoAI level at the time of transplant was significantly associated with earlier events (log-rank test:

$P = 0.005$ ) (Fig. 1). A multivariate analysis with the Cox model showed that this significance was present after adjusting for age and gender ( $P = 0.006$ ). None of the other lipoprotein parameters was strongly associated with the risk of cardiovascular events, although a weak association was found for baseline LDL-Chol ( $P = 0.02$ ) and for apoB ( $P = 0.08$ ).

During follow-up, 46 rejections (estimated median organ

**FIG. 1.** Kaplan–Meier estimate of cardiovascular disease (CVD)-free survival stratified by baseline apoAI below or over the median value (103 mg/dL).

survival: 126 mon; 95% confidence interval, 87–131) occurred. Apart from the baseline apoAI ( $P = 0.048$ ), none of the biological and pharmacological parameters was associated with overall organ survival.

## DISCUSSION

Cardiovascular complications have long been regarded as one of the factors that determine the mortality of renal transplant recipients (1–3). Corroboration of this view can be found in the 1998 Annual Report of the United States Renal Data System (21), which shows that cardiac ischemia and cerebral and peripheral vasculopathies are the main cause of posttransplantation death.

Recent studies (22) also have demonstrated that the incidence of cardiovascular events in transplant recipients is higher than in the general population, with an odds ratio that rises to more than 12 in males ages 40–49.

These findings inevitably draw attention to the cardiovascular risk factors in transplant recipients—some shared with the general population, others typical of these patients—that are associated with cardiovascular events and whose correction can reduce the overall risk during the posttransplantation period (22).

All the studies directed at identifying the causes of the metabolic alterations observed in transplant recipients have illustrated the concurrence of several factors: the clinical and metabolic condition of the patient prior to transplantation, the type of dialysis, and immunosuppressive management and drug treatment (4,5,12).

A frequent finding in the literature is also the difference in the lipoprotein profile, and hence in the incidence of cardiovascular complications, of transplant recipients from different geographical areas (23–25), as in the normal population.

The pretransplant Chol and total TG values of our Caucasian subjects were similar to those described in other studies. As shown in Table 2, they displayed the typical profile of uremics prior to transplantation: elevated TG, elevated VLDL-Chol, reduced HDL-Chol in males, and a marked reduction of HDL2-Chol in both sexes with an increase in the content of TG in the LDL compared to that of a normal control population.

Our data, however, are somewhat different from those in a similar study (9), especially with regard to our higher HDL-Chol and lower LDL-Chol values. Higher HDL2-Chol levels were also observed, whereas the HDL3-Chol values were much the same in both studies. One can deduce that the profile is substantially better in our patients owing to factors that could be linked to their different characteristics, including their eating habits and possibly the dialytic management, since HDL2-Chol levels are also a reflection of the peripheral clearance of TG-rich lipoproteins (TRL) (26).

In our patients, we have taken into consideration the greatest number of lipid parameters, lipoprotein fractions, and apo levels. We hoped to characterize the profile of the patient in chronic renal failure in a precise manner as a candidate for a

renal transplant and to evaluate variations in this profile in the years following transplantation. The most evident alterations in the lipoprotein profile occur in our case series 3 mon after transplantation, a finding not always present in the literature. The first finding that emerges is the 35% reduction of plasma TG, a reduction that embraces all the lipoprotein fractions, principally the portion transported by the VLDL (–43%). The reduction in the lipid component of the VLDL involves not only the TG but also Chol (–52%). This finding indicates that the transplant has significantly modified the metabolism of the TRL. The observations of other workers (27,28) corroborate this finding in that the activity of the two enzymes involved in the clearance of these lipoproteins [hepatic TG lipase and lipoprotein lipase (LPL)] improves after transplantation. In this connection, it also becomes important to consider the circulating levels of the LPL effectors apoCII and -CIII, which in our study were measured on whole plasma and not on the isolated lipoprotein fractions. Even though this finding is indirect, their simultaneous reduction could indicate a reduction in the dimension of the particles, an expression of their better metabolism. In this connection, evaluation of the size of the VLDL before and after transplantation could provide important data.

The modifications in the TRL of our transplant recipients persisted throughout the observation period (Table 3, column 8). The substantial stability of the VLDL-transported lipid components, together with the reduction in the apoCIII levels after transplantation and during the next 6 yr, while not significant, suggest that the metabolic profile before transplantation was substantially changed. Lasting stabilization of the HDL-Chol levels after transplantation, too, can be seen as a consequence of improved TRL metabolism. The changes in the protein component of the lipoproteins follow those of the lipid component, even though the determinations were performed on whole plasma and not on the individual lipoprotein fractions. ApoCIII, an inhibitor of the enzymatic activity of LPL, fell by 10% in the 3 mon after transplantation and continued to fall throughout the 6 yr.

Chol metabolism, on the other hand, differed and is more difficult to interpret. Changes in total and transported Chol reflect both the alterations in the lipoproteins that transport the TG and quantitative changes in the LDL particles, the main plasma Chol carriers. If, in fact, an alteration in TRL metabolism (i.e., reduced clearance) changes quantitatively and qualitatively after transplantation, the result is a reduction mainly in TG, but also in the Chol transported by some lipoprotein fractions. VLDL-Chol, indeed, fell by 52% after 6 yr.

The increase in the Chol transported by the LDL and HDL, like that of the apo that characterize them (apoB and apoAI), is a very complex event. The increase in LDL-Chol can be viewed as the result of better TRL clearance, and hence better transformation into intermediate density lipoproteins and then LDL, and also as the expression of alterations in the lipoprotein structure (glycosylations, oxidations, lipoperoxidations) that significantly decrease their receptorial catabo-

lism (29,30). Moreover, the possibility cannot be ruled out that a greater flow of substrates to the liver may help to augment the circulating LDL pool.

An important role is also played by immunosuppressive management. Considerable evidence supports the pathogenic role of drugs, steroids, and cyclosporine in particular on dyslipidemia in renal transplant recipients, but the mechanism by which this is accomplished is not yet fully elucidated. *In vitro* and *in vivo* reports have shown that cyclosporine increases LDL-Chol (5,8,15,16,31) and reduces hepatic secretion of apoB and hence the production of VLDL (32). It can directly reduce the expression of the mRNA of the LDL receptor by 40% (33).

The corticosteroids, whose effect is predominantly on VLDL, are also able to reduce the expression of mRNA of the LDL receptor *in vitro* in a dose-dependent manner (34). Furthermore, data obtained *in vitro* show that the inhibitory effect on the uptake of the LDL by the two immunosuppressors is annulled with the use of the HMG-CoA reductase inhibitors (35).

On the other side, clinical reports have positively correlated the presence of dyslipidemia to the use of cyclosporine in kidney- or liver-transplant patients (15,16,36,37), whereas others found no correlation (38). The association of dyslipidemia with different immunosuppressors, such as prednisone and cyclosporine, brings an additional confusing element into its development caused by grafting. As a matter of fact, if cyclosporine or prednisone has well-characterized effects when taken alone, the combined use in patients with a preexisting altered metabolism makes interpreting their metabolic parameters much more difficult. Our work, which has followed some patients for 6 yr from transplantation with the same immunosuppressive therapy (cyclosporine and prednisone), does not clearly highlight single drug effects, nor does it allow evaluation of a direct effect of the immunosuppressive therapy on lipoprotein metabolism.

A therapeutic approach appears necessary since dyslipidemia contributes to both cardiovascular disease and mortality. It also influences the development of chronic vascular rejection in the transplant, thus having an influence on graft outcome. Drugs such as HMG-CoA reductase inhibitors (statins) are available for reducing LDL-Chol and TG efficiently (39,40). Statins also reduce the level of oxidized LDL, and they have direct effects on smooth muscle cells and the intima of the arteries (41). The statins represent the most effective Chol-lowering agents available, and side effects, myopathy in particular, are controlled with appropriate daily dosages.

Therapeutic options for treating dyslipidemia in cyclosporine-treated renal transplant recipients were limited when our study was performed. Although the use of the statins in transplant patients had begun in the early 1990s, the efficacy and tolerability of the drug were tested later in several prospective trials, as shown in a recent review (42). Hence, our patients were not given the drug since they were nearly at the end of the follow-up when statins were routinely introduced.

We should also consider the atherogenic lipid profile of our patients: We observed the simultaneous presence of improved metabolism (reduced VLDL-Chol and increased HDL-Chol) on the one hand and the occurrence of adverse events, such as the increase in LDL-Chol and structural LDL particle changes on the other. The substantial stability of Chol levels after transplantation and in subsequent reports, together with a higher incidence of cardiovascular complications, would lead one to believe that the mechanisms responsible for vessel damage must be sought mainly in the structural and physicochemical alterations of the individual lipoprotein fractions or in other risk factors. In this regard, LDL from transplant subjects undergoes not only oxidative processes but also peroxidation, glycation, and carbamoylation, making lipoprotein particles more atherogenic (43). The damage to lipid metabolism may be more consistent than it appears from the quantitative observation of the lipoprotein fractions, given that the increases in HDL-Chol and HDL2-Chol also could be related to the better exchange of lipid components between the lipoprotein classes, as mediated by the CETP following the modification of TG metabolism (44). This improvement occurred in the first 3 mon after transplantation and persisted throughout the observation period.

Last, the association between major cardiovascular events and the circulating apoAI level at the time of transplantation is a useful finding. Although the small number of events suggests that caution is necessary when interpreting this result, it is in agreement with the already known but controversial role of the apo as more sensitive markers of cardiovascular risk than such classical parameters as LDL or HDL (45).

Additional research is needed to better define the relationship between lipid abnormalities and both CVD and renal disease progression. In particular, the role of increased TG, low HDL, and associated lipoprotein compositional abnormalities in CVD should be studied. Large, multicenter trials to study the effects of lipid-lowering therapy on the rate of renal disease progression should be conducted.

# Dietary Long-Chain PUFA in the Form of TAG or Phospholipids Influence Lymph Lipoprotein Size and Composition in Piglets

Laura Amate<sup>a,b,\*</sup>, Angel Gil<sup>b</sup>, and María Ramírez<sup>a</sup>

<sup>a</sup>Research and Development Department, Abbott Laboratories, 18004 Granada, Spain, and <sup>b</sup>Department of Biochemistry and Molecular Biology, University of Granada, 18071 Granada, Spain

**ABSTRACT:** Several sources of long-chain PUFA (LCP) are currently available for infant formula supplementation. These oils differ in their FA composition, the chemical form of the FA esters [TAG or phospholipids (PL)], and presence of other lipid components. These differences may affect LCP absorption, distribution, and metabolic fate after ingestion. The purpose of this study was to evaluate the influence of different chemical forms of dietary LCP on the composition of lymph lipoproteins. Eighteen pigs (5 d old) were bottle-fed different diets for 2 wk: a control diet (C), a diet containing LCP as TAG from tuna and fungal oils (TF-TAG), or a diet containing LCP as PL from egg yolk (E-PL). We measured lipid and FA composition of lymph, main lymph fractions (TAG or PL), and the particle size of lymph lipoproteins. The average diameter of lymph lipoproteins was significantly lower in the E-PL group compared with the control and TF-TAG groups (C:  $3902 \pm 384$  Å; TF-TAG:  $3773 \pm 384$  Å; E-PL:  $2370 \pm 185$  Å). Arachidonic acid and DHA contents in lymph and lymph-TAG were significantly higher in the TF-TAG group compared to the E-PL group ( $0.50 \pm 0.03$  and  $0.24 \pm 0.03$  g/100 g vs.  $0.29 \pm 0.04$  and  $0.12 \pm 0.03$  g/100 g, respectively). The addition to the diet of LCP in the form of TAG or PL affected the size of intestinal lipoproteins and also led to a different distribution of these FA in lymph lipoproteins.

Paper no. L9004 in *Lipids* 37, 975–980 (October 2002).

The presence of DHA and arachidonic acid (AA) in human milk, together with some reports indicating that long-chain PUFA (LCP) status is improved in infants fed breast milk or LCP-containing formulas (1,2), has prompted international committees to propose the use of formulas containing balanced quantities of n-3 and n-6 LCP, similar to those found in human milk (3–6). In addition, several clinical trials have been designed to evaluate whether LCP enrichment of infant formulas has beneficial effects on the maturation of the visual system and cognitive development (7–14). These trials have shown significant functional advantages of LCP supplementation for both preterm (7–11) and term infants (12–14).

Several sources of LCP, such as fish oils, oils from unicellular organisms, or from eggs, could be used to supplement infant formulas and attain such recommendations. Fish and unicellular

oils are composed mainly of TAG, and oil fractions from commercial egg preparations are rich in phospholipids (PL). Furthermore, these lipid sources differ in the FA composition, presence of other lipid components, and the molecular structure of their TAG and PL. Because lipid digestion is a complex process involving enzymes, it is likely that these differences may affect LCP absorption, distribution, and metabolic fate.

A number of studies have focused on TAG absorption and metabolism, mainly on the importance of the *sn*-2 position (15–17). Less attention has been paid to dietary PL, but there is evidence showing TAG absorption is impaired when the supply of exogenous PL is insufficient for micelle formation during fat digestion and absorption (18–21). Moreover, clinical trials with premature infants found that DHA from egg PL was absorbed better than DHA from breast milk and DHA TAG from single-cell oils (22). Other studies have shown a positive effect of LCP-PL supplementation on fat absorption (23). PL are also essential for intestinal lipoprotein formation and for fat distribution outside the enterocytes. Data from animal studies suggest that intraduodenal infusion of triolein results in the formation of chylomicrons (CM), whereas the infusion of egg PC favors the formation of intestinal VLDL-size particles (24).

In addition, we have studied the effect of the chemical form of LCP on fasting plasma lipoprotein composition and found a different distribution of these FA in lipoprotein fractions depending on whether they were added as TAG or PL (25). In that study, the authors hypothesized that their results were due to the way LCP were packaged on lymph particles. In line with those findings, the goal of this study was to evaluate the influence of the chemical structure of the LCP added to the diet on lymph lipoprotein composition and size during active lipid absorption.

## MATERIALS AND METHODS

**Animals and diets.** Eighteen 5-d-old Yorkshire piglets at term gestation [mean body weights  $2241 \pm 67.5$  g (SD)] were obtained from Ntra. Sra. de las Mercedes Farm (La Guardia, Jaen, Spain) and were randomly assigned to one of three dietary groups. Each group of piglets was housed together and freely fed by bottle three times a day for 2 wk. Heating was provided with spot heat lamps attached above each cage. The study was approved by the Animal Care Committee at the University of Granada and conformed to the European Union Regulation of Animal Care for care and use of animals for research.

Abbreviations: AA, arachidonic acid; CM, chylomicrons; E-PL diet, diet supplemented with egg yolk phospholipid; LCP, long-chain PUFA; PL, phospholipids; TF-TAG diet, diet supplemented with tuna oil or fungal oil as a source of LCP.

Three powder formulas, identical in all ingredients except for fat composition, were designed to meet the nutrient requirement of growing piglets (26). The formulas were dissolved in warm water at a concentration of 188 g/L. The general composition of the control formula has been reported (27). Control fat was composed of a blend of olive, soy, and coconut oils and milk fat. LCP were added by supplementing with tuna oil and fungal oil (TF-TAG diet) or egg yolk-PL (E-PL diet). The final FA composition of the diets is given in Table 1. Tuna oil with a low ratio 20:5n-3/22:6n-3 was supplied by Mochida (Tokyo, Japan) and fungal oil by Suntory (Tokyo, Japan). Part of the vegetable fat blend in the control formula (2.7 g/100 g) was replaced by tuna and fungal oils to achieve an amount similar to that found in swine milk: 0.6 and 0.3 g/100 g of AA and DHA, respectively. E-PL (Ovothin 160) were supplied by Lucas Meyer (Hamburg, Germany). For this diet, 13.2 g/100 g of the fat blend in the control formula was replaced by this source of PL to reach the same concentration of AA and DHA as in the TF-TAG diet.

Because the E-PL source contained a certain amount of cholesterol, the control and the TF-TAG diets were supplemented with cholesterol to produce a final concentration of 0.33 g/100 g diet. In this fashion, dietary cholesterol effects on lipoprotein metabolism were avoided, and it was ensured that any difference found between LCP-supplemented groups was due to the particular forms of LCP in the diets.

**Experimental protocol.** One and a half hours after the intake of 120 mL of each formula, piglets were operated on under intramuscular ketamine anesthesia (15–20 mg/kg body weight). An abdominal incision was made, and the intestines were placed on the right side of the animal, keeping them at 37°C with warm saline solution. The cistern chyli was identified just distal to the right renal vein, and a small incision was made. Samples of lymph were collected with the help of a Pasteur pipet into ice-cooled tubes containing 5 µg of leupeptin to avoid protein degradation, and 40 µL of a preservative solution (25 mM EDTA, 2.5 mg/mL gentamicin sulfate,

1.25 mg/mL chloramphenicol, and 5 mg/mL sodium azide). An aliquot of lymph was separated for the electron microscopy analysis, and the rest was frozen in liquid nitrogen and stored at –80°C until analyzed (24). Since lymph was collected at 1.5 h during the digestion period, the major component of lymph was CM; therefore, sizing was performed directly on the lymph samples.

**Analytical methods.** Freshly isolated lymph samples were photographed using negative staining with electron microscopy. Samples were prepared as follows: a copper-coated grid was floated on a drop of lymph and incubated at room temperature for 4 min. Then the grid was washed twice with double-distilled water and floated on a drop of 2% uranyl acetate for 1 min. Finally, the grid was dried in a stove until it was examined. The negatively stained samples were examined with a Zeiss 10 CR electron microscope (Carl Zeiss, Thornwood, NY) at 100 kV and 50,000× magnification. To measure the particle size distribution, 300–600 particles were measured on the electron micrographs as the average length of diameters measured at 5° intervals around the centroid of each object by the image analysis software Microimage (Olympus Optical, Hamburg, Germany). The mean diameter for each group was calculated from these measurements (24).

An aliquot of lymph was extracted using hexane/isopropanol (3:2) according to Kolarovic and Fournier (28) and dried under nitrogen. The main lipid fractions from lymph extracts (TAG and PL) were separated by TLC on Silica Gel 60 plates (0.5 mm; Merck, Darmstadt, Germany) using hexane/isopropyl ether/acetic acid (75:25:1.5, by vol) according to the method previously described by Skipski and Barclay (29).

Aliquots of lymph and lymph lipid fractions were converted to FAME by transmethylation as previously described by Lepage and Roy (30). FAME were separated and quantified by GLC, using a Hewlett-Packard 5890 gas chromatograph equipped with a FID and a 60 m × 0.32 mm i.d. SP-2330 capillary column (Supelco, Bellefonte, PA) as previously described (31). A mixture of FA standards (Sigma, St. Louis, MO) was used to identify the FA peaks of the different samples.

Cholesterol and TAG in lymph were measured using commercial kits (Roche Diagnostic GmbH, Mannheim, Germany) adapted for a microplate assay. PL were measured in lipid extracts by Ziversmit's method (32). Protein content was measured by Bradford's method (33).

**Statistical analysis.** Diet group differences were investigated by one-way ANOVA using the 7D program of BMDP Statistical Software PC 90 version (Los Angeles, CA) (34). The homogeneity of variances was analyzed by Levene's test. If variances were not homogeneous, Welch's test was used to study group differences. When a significant difference was found ( $P < 0.05$ ), Bonferroni's test was used to examine individual comparisons.

## RESULTS

**Lymph lipoprotein size.** The average diameter of lymph lipoproteins was significantly lower in the E-PL group com-

pared to the control and the TF-TAG groups (mean  $\pm$  SEM) (C:  $3902 \pm 186$  Å; TF-TAG:  $3773 \pm 384$  Å; E-PL:  $2370 \pm 185$  Å;  $P < 0.05$ ) as illustrated in Figure 1. When lymph lipoprotein size was represented in ranges, a different distribution was observed for the study groups (Fig. 2). Most of the lipoproteins in the control and TF-group were between 2500 and 5000 Å, whereas they were within the lower range (<2500 Å) in the E-PL group.

**Lipid and FA composition of lymph.** The content of lipids and proteins in lymph samples from piglets fed the study diets is shown in Table 2. There were no significant differences in the content of cholesterol, TAG, PL, and proteins of lymph among the control, the E-PL, and the TF-TAG groups.

The FA composition of total lymph and of lymph TAG and PL is shown in Table 3. The proportion of 16:0 and 16:1n-7

**FIG. 1.** Electron micrographs of intestinal lymph lipoproteins negatively stained with uranyl acetate 2% and examined with a Zeiss 10 CR electron microscope. Magnification of micrographs is 50,000 $\times$ . (A) Intestinal lymph lipoproteins from piglets fed control diet (average diameter  $\pm$  SEM:  $3902 \pm 384$  Å); (B) intestinal lymph lipoproteins from piglets fed adapted milk formula supplemented with long-chain PUFA (LCP) from fungal and tuna oils ( $3773 \pm 384$  Å); (C) intestinal lymph lipoproteins from piglets fed adapted milk formula supplemented with LCP from egg yolk phospholipids ( $2370 \pm 185$  Å).

**FIG. 2.** Distribution of sizes (Å) of lymph lipoproteins from piglets fed diets supplemented with LCP in the form of TAG or phospholipids (PL). Values are means  $\pm$  SEM,  $n = 6$ . Control: group fed adapted milk formula for piglets. TF-TAG: group fed adapted milk formula for piglets supplemented with LCP from fungal and tuna oils. E-PL: group fed adapted milk formula for piglets supplemented with LCP from egg yolk phospholipids. For abbreviation see Figure 1.

was higher and that of 18:1n-9 lower in the E-PL group than in the TF-TAG and C groups in total lymph and lymph TAG. The proportion of 18:2n-6 in lymph PL was lower in the TF-TAG group than in the E-PL and C groups. Regarding LCP, both groups of animals fed with LCP-supplemented diets had higher proportions of AA and DHA in lymph lipids. The TF-TAG group had significantly higher proportions of AA and DHA in total lymph and lymph TAG than the E-PL group. No significant differences were found in lymph PL for the FA mentioned above.

## DISCUSSION

There is some evidence that LCP added in the form of PL or TAG may not be equally digested, absorbed, or distributed. First, TAG and PL are hydrolyzed by different enzymes, yielding different products in the intestine. Pancreatic lipase cleaves the *sn*-1 and *sn*-2 position of TAG and releases 2-MAG and FFA (35). Activated pancreatic phospholipase A<sub>2</sub> releases 1-lysophospholipids and FFA from PL (24). In addition, some studies in newborn infants have indicated that dietary PL may be better absorbed than TAG. Morgan *et al.* (23) found that fat

absorption was higher in term infants fed a formula containing LCP from egg yolk-PL than in those fed a standard formula without LCP. Carnielli *et al.* (36) studied a group of infants fed a formula with LCP from egg yolk-PL and a group fed a formula with LCP in the form of TAG from unicellular microorganisms. The absorption of DHA was higher in infants receiving the PL-LCP formula than in infants fed breast milk or the TAG-LCP formula. However, in the Morgan *et al.* study, no group was fed LCP in the form of TAG, and in the Carnielli *et al.* study, the quantities of LCP were not balanced in the LCP-supplemented diets; hence, the apparent absorption of DHA may simply reflect the usual greater percentage of absorption of lower intakes (37). Our own work in weanling rats supported differences in absorption between LCP sources, although these differences were related to other characteristics of the LCP source (other lipid components and FA positional distribution) rather than chemical structure (38).

On the other hand, PL are needed for intestinal lipoprotein formation and for fat distribution outside the enterocyte (18). PL may also affect the composition and metabolism of lipoproteins (24). Our result did not support differences in lipid lymph composition as inferred from the absence of significant differences in Table 2. However, this study showed evidence that dietary PL affects CM size. In fact, lymph lipoproteins from pigs fed the diet containing LCP in the form of PL were smaller than those from pigs fed the control or the LCP-TAG diet, and their size distribution was different. Another study in rats demonstrated that the intraduodenal infusion of triolein results in the formation of CM, whereas the infusion of egg PC favors the formation of intestinal VLDL-size particles (24). Unlike this previous study in which pure lipids were infused intraduodenally to rats, our study was done in piglets fed standard diets containing a mixture of vegetable oils added with LCP-PL or LCP-TAG to reach the same concentration of AA and DHA in both supplemented

diets and closer to the LCP of sow's milk. As described in the Materials and Methods section, the E-PL diet contained 13.6% of total fat as PL; this low amount (in comparison to Ref. 24) was able to produce an effect in lymph lipoproteins similar to that found using pure PL. However, in our study, lymph lipoproteins from the group fed the E-PL diet could not be considered VLDL-like particles: The majority were small CM, and a subpopulation was within the range of VLDL size (300–800 Å). The physiological implications of a different CM size in the experimental model studied may be a modification of absorption rate and/or in plasma metabolism of these lipoproteins. It has been shown that the number of particles synthesized and secreted by the small intestine remains relatively constant during fasting and active lipid absorption; and instead of increasing the number of CM, the enterocytes expand the size of the CM particles to secrete the large amounts of absorbed lipids from the intestinal mucosa (39). In considering this, the rate of absorption of dietary lipid in the E-PL group would be lower than that of the TF-TAG group, although the net absorption of both groups has not been proven to be different in our fat balance study in rats (38). Moreover, our results for lymph lipid composition (Table 2) did not support this hypothesis because there were no significant differences in PL, cholesterol, and TAG of lymph between the E-PL and TF-TAG groups and between these two groups and the control group. The amount of lymph lipids in the TF-TAG group was even lower than that of the other study groups, although not significantly different. On the other hand, it has been reported that large CM are metabolized faster than small ones (40), which means that CM from the TF-TAG would last for a shorter time in the blood stream. Therefore, LCP esterified to TF-TAG would reach target organs before LCP in the form of E-PL.

Mathews *et al.* (40) have recently reported the measurement of higher concentrations of DHA in piglets fed a diet

containing LCP-TAG from single-cell oils in comparison to piglets fed a diet containing LCP from E-PL. They also found no differences between the control group and the E-PL group in spite of the 0.3% FA as DHA in the diet. Our results showed changes in CM size and lipid fraction FA composition of lymph from piglets fed the E-PL diet. These differences may indicate, as explained above, a different absorption rate, but they do not imply a lower net absorption. In fact, in our previous experiments with fasting piglets, E-PL and the TF-TAG groups had higher plasma percentages of AA and DHA than controls, with no significant differences between both LCP-supplemented groups. In the same previous experiment, we reported an effect of LCP in the form of TAG or PL on the distribution of AA and DHA between lipoprotein fractions (22). HDL-PL contained a higher proportion of LCP when those FA were given in the diet as PL. Opposite results were found in LDL-PL, which contained a higher proportion of LCP when those FA were given in the diet as TAG. We hypothesized that this different distribution of LCP in lipoprotein PL may be explained as follows: After digestion and absorption, LCP are reesterified to the same chemical structure in which they were added to the diet (as PL or TAG) and are assembled mainly as PL on the CM surface in case of the E-PL group and mainly as TAG in the CM core in case of the TF-TAG group. Plasma CM exchange PL with HDL during intravascular catabolism (35); therefore, HDL from piglets fed an E-PL diet would contain a higher proportion of AA and DHA in HDL-PL. The results of the present study are consistent with this hypothesis: Lymph TAG from piglets fed the LCP-TAG diet contained a higher proportion of AA and DHA than lymph TAG from piglets fed the diet containing LCP in the form of PL. Opposite results were expected in lymph PL, but they were not statistically significant. However, because the data showed higher values of LCP in the lymph PL of the PL-supplemented group, the lack of significance may be due to the difficulty of analyzing the contribution of a low amount of dietary FA (less than 1% of total FA in the diet) to the PL fraction, which is the less abundant fraction of lymph lipids.

The addition to the diet of LCP in the form of TAG or PL resulted in a different distribution of these FA in lymph CM. On the other hand, LCP in the form of PL affect the packaging and secretion of intestinal lipoproteins resulting in a decrease of the lymph CM size. These results do not support an advantage of any of the LCP sources studied for infant feeding. However, the TAG source shows a lipoprotein distribution similar to the control group. Further studies would be necessary to find out whether the differences found in PL source are beneficial.

## ACKNOWLEDGMENTS

The authors thank Maria Luisa Jimenez for her help in care of animals and for her technical assistance. We also thank the Animal Nutrition Department of CSIC, especially D. José Aguilera for providing animal facilities and advice in raising piglets. This work was partly supported by a fellowship from the Spanish Ministry of Education.

**ABSTRACT:** In this study is presented the effect of fenofibrate, a prototypical peroxisome proliferator of the fibrate class, on wild-type and peroxisome proliferator-activated receptor  $\alpha$  (PPAR $\alpha$ )-/- mouse liver FA profile, desaturase mRNA levels, and activities. We established that, following peroxisome proliferator exposure, the hepatic FA profile was greatly modified. These modifications in hepatic FA content required the expression of PPAR $\alpha$ , as they are suppressed in transgenic mice deficient in this nuclear receptor. Following peroxisome proliferator exposure,  $\Delta 6$ - and  $\Delta 5$ -desaturase mRNA levels and activities were increased in wild-type but not in PPAR $\alpha$ -deficient mouse liver. These results suggest the involvement of PPAR $\alpha$  in the control of hepatic  $\Delta 6$ - and  $\Delta 5$ -desaturases in mice. Their roles in minimizing long-chain PUFA depletion in the liver during peroxisome proliferator exposure are discussed.

Paper no. L9100 in *Lipids* 37, 981–989 (October 2002).

Synthetic compounds of the therapeutic class of fibrates are commonly referred to as peroxisome proliferators (PP). They have been beneficially prescribed for decades in the treatment of human hyperlipidemia and hypercholesterolemia. PP decrease circulating lipids when administered to mice, rats, and also humans (1). The molecular mode of action of these hypolipidemic drugs has been extensively studied in laboratory rodent models. The transcription of many critical genes involved in several aspects of the metabolism is altered by PP administration (2). Virtually all these effects are abolished in mice deficient in the  $\alpha$  isoform of the peroxisome proliferator-activated receptor (PPAR $\alpha$ ) (3), a member of the class 2 of the nuclear receptor family (4). PPAR $\alpha$  is a transcription factor shown to be preferentially expressed in the liver and kidney in rodent species (5). Upon ligand activation by fibrates, PUFA, or eicosanoids, it binds to the retinoid X receptor (6), and the resulting heterodimeric complex interacts with target DNA sequences to modulate gene expression levels (7). PPAR $\alpha$  target genes include a relatively homogeneous group

of genes that mainly contribute to increasing FA catabolism (3,8). Conversely, FA desaturases that catalyze the biosynthesis of unsaturated FA are thought to be increased in rodent liver following exposure to fibrates (9,10). The desaturases catalyze the introduction of double bonds at singular locations along carbon fatty acyl chains (11). In animals, three distinct desaturase enzymes introduce double bonds at the  $\Delta 9$ ,  $\Delta 6$ , and  $\Delta 5$  positions.

$\Delta 9$ -Desaturase, also called stearoyl-CoA desaturase (SCD), displays a marked substrate specificity for palmitoyl-CoA and stearoyl-CoA, which are converted by  $\Delta 9$ -desaturation to palmitoleyl-CoA and oleyl-CoA, respectively (12). The hepatic regulation of  $\Delta 9$ -desaturase activity has been extensively studied in rats and mice (12). Whereas both PUFA and fibrates are considered as PPAR $\alpha$  activators, PUFA and fibrates display opposite effects on  $\Delta 9$ -desaturase. Dietary PUFA show an inhibitory effect on  $\Delta 9$ -desaturase activity that correlates with a decreased SCD1 transcript level (13). By contrast,  $\Delta 9$ -desaturase activity is enhanced by fibrates in rodent liver (9) and in human HepG2 cells (14). In mice, this induction occurs through an increased SCD1 transcription that involves a functional peroxisome proliferator responsive element (PPRE) localized in the SCD1 promoter (15).

The  $\Delta 6$ - and  $\Delta 5$ -desaturases govern the rate-limiting steps for the biosynthesis of very long chain PUFA, which play pivotal roles in numerous biological functions. Little information is available on  $\Delta 6$ - and  $\Delta 5$ -desaturase mechanisms of regulation by PUFA and fibrates. Several groups have reported the cloning of  $\Delta 6$ - and  $\Delta 5$ -desaturases in different species (16–20). Evidence for a down-regulation of  $\Delta 6$ - and  $\Delta 5$ -desaturase gene expression by dietary PUFA (16,17) has been presented. Conversely, the hepatic expression of  $\Delta 6$ - and  $\Delta 5$ -desaturases is highly activated in transgenic mice overexpressing nuclear sterol regulatory element binding protein-1 (20), a key transcription factor in lipogenesis. Regarding the effect of fibrates, they enhance linoleic acid (18:2n-6) metabolism in rats (10) and  $\Delta 6$ - and  $\Delta 5$ -desaturase mRNA levels in mice (20). These observations suggest that, as reported for  $\Delta 9$ -desaturase (15),  $\Delta 6$ - and  $\Delta 5$ -desaturase gene expressions could be down-regulated by PUFA and stimulated by fibrate drugs.

The current study was undertaken to further investigate the

Abbreviations: AOX, peroxisomal acyl-CoA oxidase; CYP4A10, cytochrome P450 4A10; PP, peroxisome proliferator; PPAR $\alpha$ , peroxisome proliferator-activated receptor  $\alpha$ ; PPRE, peroxisome proliferator responsive element; SCD, stearoyl-CoA desaturase; TBS, Tris-buffered saline; W-T, wild-type.

*in vivo* influence of PPAR $\alpha$  on FA metabolism with particular emphasis on desaturases. This study provides evidence that PP exposure results in numerous changes of the hepatic FA profile that are dependent on the expression of PPAR $\alpha$ . We also demonstrate that fenofibrate enhances  $\Delta 6$ - and  $\Delta 5$ -desaturase mRNA levels and activities in mice. By using the PPAR $\alpha$ -null mice, we further suggest that PPAR $\alpha$  may be involved in the regulation of  $\Delta 6$ - and  $\Delta 5$ -desaturase by fenofibrate in this species. Our results strongly support the role played by hepatic  $\Delta 6$ - and  $\Delta 5$ -desaturases in counteracting exacerbated PUFA catabolism that occurs during PP exposure.

## MATERIALS AND METHODS

**Chemicals.** The Trizol solution was from Life Technologies (Paris, France). Gene Screen Plus Nylon membrane, [1-<sup>14</sup>C]-stearic acid, [1-<sup>14</sup>C] $\alpha$ -linolenic acid, and [1-<sup>14</sup>C]eicosatrienoic acid were purchased from NEN Life Science Products (Paris, France). Radiolabeled nucleotides, random priming kit (Ready Prime II), ECL Plus reagent, Phosphorcreens, Storm 840 imager, and Storm Image Analysis System were purchased from Amersham Pharmacia Biotech (Les Ulis, France). Nitrocellulose membrane was from Schleicher & Schuell (Dassel, Germany). Solvents and other chemicals were obtained from Prolabo (Paris, France) or Merck (Darmstadt, Germany), except high-purity reagents for HPLC application, which were from Fisher (Elancourt, France). Fenofibrate and standards for FA analyses were from Sigma Chemical (Saint-Quentin Fallavier, France).

**Animal housing and treatment.** Care of mice was in compliance with European Union guidelines for animal care and use. PPAR $\alpha$  homozygous-deficient mice (PPAR $\alpha$ -/-), generated initially from homologous recombinant 129Sv-ES cells (3), were interbred on a C57BL/6J genetic background (21). Age-matched wild-type (W-T) C57BL/6J male mice were obtained from Charles River (Les Oncins, France) and acclimated to local animal facility conditions for 2 wk prior to treatment. Nine-week-old mice were fed *ad libitum* on a standard chow diet (Harlan #9607, Gannat, France) with free access to water. The FA composition of the standard diet is: palmitic acid (16:0), 12.9% of total FA; stearic acid, 3.3%; oleic acid (18:1n-9), 22.8%; linoleic acid (18:2n-6), 56.1%;  $\alpha$ -linolenic acid (18:3n-3), 4.9%; total fat content (g oil/100 g diet), 4.3%. Mice were housed in groups of five in plastic cages at a temperature of 21  $\pm$  2°C with a 12 h/12 h light/dark cycle. Five W-T mice and five PPAR $\alpha$ -/- mice (9 wk old) received fenofibrate (100 mg/kg of body weight per day, suspended in a 3% aqueous sterile solution of gum arabic) by daily gavage for 14 d at 9 A.M. Five controls each of both genotypes received the vehicle alone. After 2 wk of treatment, animals were euthanized by neck dislocation. The livers were promptly removed, weighed, snap-frozen in liquid nitrogen, and stored at -80°C for later RNA extraction. About 200 mg of each fresh liver was rapidly minced for postmitochondrial supernatant preparation.

A time-course study was also performed to determine the short-term effect of fenofibrate on desaturase expression. Ten W-T mice and 10 PPAR $\alpha$ -/- mice (12 wk old) received a single dose of fenofibrate (100 mg/kg of body weight) by gavage. Two W-T and 2 PPAR $\alpha$ -/- mice were euthanized at various times after treatment (2, 4, 8, 16, and 24 h).

**Enzyme assays.** Fresh liver samples were minced in 2 mL of 50 mmol/L phosphate buffer (pH 7.4) containing 0.25 mol/L sucrose. The samples were centrifuged twice at 10,000  $\times g$  for 30 min. The resulting postmitochondrial supernatant was diluted five times and used for  $\Delta 9$ -,  $\Delta 6$ -, and  $\Delta 5$ -desaturase assays. Aliquots were stored at -20°C for subsequent protein measurements. Enzymatic activities were determined using a 1-mL assay mixture containing 100  $\mu$ L of supernatant (400 to 500  $\mu$ g protein), 150 mmol/L phosphate buffer (pH 7.16), 6 mmol/L MgCl<sub>2</sub>, 7.2 mmol/L ATP, 0.54 mmol/L CoA, and 0.8 mmol/L NADH. The reaction was started with the addition of 30 nmol of [1-<sup>14</sup>C]stearic acid (740 MBq/mmol) for  $\Delta 9$ -desaturase assay and 60 nmol of [1-<sup>14</sup>C] $\alpha$ -linolenic acid or [1-<sup>14</sup>C]eicosatrienoic acid (740 MBq/mmol) for  $\Delta 6$ - or  $\Delta 5$ -desaturase assays, respectively. The incubations were carried out in a shaking water bath at 37°C for 30 min. The reactions were stopped by adding 1 mL of 0.5 mol/L KOH in ethanol. Control assays were performed by adding KOH in ethanol before adding the substrate. FA saponification was carried out at 70°C for 30 min. After acidification, FA were extracted with diethyl ether and dried. They were converted to FA naphthacyl esters (22) and separated on HPLC (Alliance Integrated System; Waters, St. Quentin en Yvelines, France) using a Nova-Pak C18 column (4.6  $\times$  250 mm, Waters) and a guard column (Nova-Pak C18, 3.9  $\times$  20 mm). Radiolabeled substrates and products of each desaturase assay were collected and subjected to liquid scintillation counting (Packard Tri-Carb 1600 TR; Meriden, CT). Preliminary identification of FA naphthacyl esters was based on retention times obtained for naphthacyl esters prepared from radiolabeled and nonradiolabeled FA standards (23). From the amount of radioactivity found in the product compared to the radioactivity incubated, the enzyme activity could be determined and expressed as pmol substrate converted to product per min per mg of protein. The protein content in the supernatant used for enzyme assays was determined by a modified Lowry procedure (24).

**Western blotting.** The anti-rat  $\Delta 6$ -desaturase sera, named S1 and S2, were generated by immunizing two rabbits with recombinant peptides corresponding to the 108 carboxyl-terminal amino acids and the 131 amino-terminal amino acids of the  $\Delta 6$ -desaturase, respectively (25). For Western blotting analyses, 80  $\mu$ g of protein from the postmitochondrial supernatants used for the enzyme assays were diluted in Laemmli sample buffer, separated by SDS-PAGE (11% acrylamide), and blotted onto a nitrocellulose membrane. The membrane was probed with a mixture of S1 and S2 sera, both at 1:2000 dilution. The secondary antibody was a horseradish-peroxidase-conjugated sheep antirabbit immunoglobulin (IgG) (Sigma). Incubation with antibodies was carried out for 90

min in Tris-buffered saline (TBS) (20 mM Tris-HCl, 150 mM NaCl, pH 7.4) containing 0.05% Tween-20 and 10% nonfat dry milk. Washes were performed in TBS containing 0.05% Tween-20. Peroxidase activity was revealed using ECL Plus reagent according to the manufacturer's instructions and scanned with a Storm 840 Imager.

**RNA isolation and Northern blot analysis.** Hepatic mRNA levels of mouse  $\Delta 6$ -desaturase,  $\Delta 5$ -desaturase,  $\Delta 9$ -desaturase (SCD1), peroxisomal acyl-CoA oxidase (AOX), cytochrome P450 4a10 (CYP4A10), and  $\beta$ -actin were detected by Northern blotting. Total RNA was prepared from 100-mg fragments of the large lobe of the liver homogenized in 1 mL of Trizol solution using a tissue homogenizer (Ika, Jena, Germany). RNA samples were fractionated on a 1% agarose gel containing 2.2 M formaldehyde and transferred to a nylon membrane. Probes were polymerase chain reaction (PCR)-amplified from hepatic mouse or rat cDNA using the primers described in Table 1. All probes were labeled with [ $\alpha$ - $^{32}$ P]dCTP by random priming. The membranes were hybridized with each radiolabeled probe at 65°C overnight in the hybridization buffer (900 mM NaCl, 90 mM sodium citrate, pH 7.0, Denhardt's reagent, 0.5% SDS, and 20  $\mu$ g/mL salmon sperm DNA). After hybridization, the membranes were washed in 0.1  $\times$  SSC (saline-sodium citrate buffer), 0.1% SDS at 65°C. Hybridizing bands were visualized with a Storm Imager and analyzed using ImageQuant Software (Amersham Pharmacia Biosciences).

**Hepatic FA composition.** Total lipids were extracted from 100-mg liver samples homogenized in a mixture of dimethoxymethane/methanol (4:1, vol/vol) and incubated for 30 min on ice before extraction. Total hepatic lipids were

saponified for 30 min at 70°C by 1 mL of 0.5 mol/L NaOH in methanol and methylated with 1 mL BF $_3$  (14% in methanol) at 70°C for 10 min. FAME were extracted with pentane and analyzed by GC using a GIRA 1600 chromatograph (GIRA, Morlaas, France) with a split injector (1:10) at 240°C, a bonded-silica capillary column (30 m  $\times$  0.25 mm i.d., BPX 70; SGE, Villeneuve-St-Georges, France) with a stationary phase of 70% cyanopropylpolysilphenylene-siloxane (0.25  $\mu$ m film thickness). Helium was used as gas vector (1 bar). The column temperature program started at 150°C, ramping at 2°C/min to 220°C. The FID temperature was 260°C. Identification of FAME peaks was based on retention times obtained for methyl esters prepared from FA standards. The quantification of total hepatic FA was performed using heptadecanoic acid as internal standard.

**Results and statistical analysis.** All measurements were performed on samples from individual animals, and the results are expressed as mean of five animals. Statistical significance of differences was calculated by a two-tailed Student's *t*-test. A value of *P* < 0.05 was considered to be statistically significant.

## RESULTS

**Effect of a 14-d fenofibrate treatment on body and liver weight.** Fenofibrate is a prototypical PP. We investigated the effects of a 14-d fenofibrate treatment on hepatic lipids, in W-T C57Bl/6J and PPAR $\alpha$ -deficient male mice, with particular focus on FA. In W-T mice but not in PPAR $\alpha$ -deficient mice, fenofibrate administration promoted a significant liver enlargement without affecting body weight (Table 2).

<sup>c</sup>Significant difference due to genotype (W-T vs. PPAR $\alpha$ -/-; *P* < 0.05). W-T, wild-type; PPAR $\alpha$ , peroxisome proliferator-activated receptor  $\alpha$ .

*Effect of a 14-d fenofibrate treatment on total lipid FA profile in the liver.* In W-T mice, PP-induced hepatomegaly was associated with an increase in hepatic FA content (Table 2). Moreover, our data emphasize a major difference in hepatic FA content between W-T and PPAR $\alpha$ -/- mice. Independently of the fenofibrate administration, the PPAR $\alpha$ -/- male mice had a higher FA content when compared to W-T mice (Table 2).

The consequences of fenofibrate treatment on liver FA composition were measured by analysis of FA from total hepatic lipids (Table 3). In our experiments, W-T mice treated with fenofibrate showed a significant increase in 16:0, 16:1n-7, 18:1n-9, and 20:3n-6, and 18:0, 18:2n-6, 20:4n-6, and 22:6n-3 contents significantly decreased (Table 3). Conversely, no significant change was detected in the total FA profile of fenofibrate-treated PPAR $\alpha$ -/- mice when compared to untreated PPAR $\alpha$ -/- mice (Table 3). Concerning monoenes, fenofibrate induced a marked increase in the 16:1n-7 and 18:1n-9 content in the W-T mice, but not in the PPAR $\alpha$ -null mice, suggesting a PPAR $\alpha$ -dependent activation of  $\Delta$ 9-desaturase. Whatever the treatment, a major difference due to genotype was observed in the relative abundance of hepatic FA: The 18:2n-6 content is much higher in the PPAR $\alpha$ -deficient mouse liver than in the W-T mouse liver (untreated  $23.68 \pm 1.21\%$ , treated  $15.77 \pm 1.51\%$ ; PPAR $\alpha$ -/-: untreated  $36.56 \pm 1.85\%$ , treated  $32.60 \pm 2.26\%$ ).

*Effect of a 14-d fenofibrate treatment on desaturase activities.* To gain further insight into the mechanisms leading to these marked changes in hepatic FA profile, we investigated the *in vivo* involvement of the  $\Delta$ 9-,  $\Delta$ 6-, and  $\Delta$ 5-desaturases in the PPAR $\alpha$ -dependent regulatory network. We first tested whether fenofibrate-induced changes in hepatic FA profile could be associated with changes in desaturase activities. On the animal livers used for FA profile analyses, desaturase activity assays were carried out.

Whatever the desaturase, the activity was significantly enhanced in W-T mice by the 14-d fenofibrate treatment:  $\Delta$ 9-,  $\Delta$ 6-, and  $\Delta$ 5-desaturase activities were induced 8-, 2-, and 2.5-fold, respectively (Fig. 1). Following 14 d of fenofibrate exposure,  $\Delta$ 6- and  $\Delta$ 5-desaturase activities were slightly increased in the liver of PPAR $\alpha$ -deficient mice; these changes were far from the range of induction observed in W-T animals (Fig. 1). Although the induction of desaturase activities after fenofibrate exposure seems to depend on PPAR $\alpha$  expression, the invalidation of PPAR $\alpha$  does not abolish desaturase activities since PPAR $\alpha$ -/- mice displayed basal desaturase activities similar to untreated W-T mice (Fig. 1).

*Effect of a 14-d fenofibrate treatment on hepatic desaturase mRNA levels.* We investigated by Northern blot whether fenofibrate could influence mouse hepatic  $\Delta$ 9- (SCD1),  $\Delta$ 6-, and  $\Delta$ 5-desaturase gene expression (Fig. 2). Since AOX and CYP4A10 are characteristic PPAR $\alpha$  target genes (3), their mRNA levels were also estimated (Fig. 2) as positive controls of transcriptional induction by fenofibrate treatment.

Following a 14-d treatment of W-T mice, fenofibrate enhanced hepatic SCD1,  $\Delta$ 6-, and  $\Delta$ 5-desaturase mRNA levels (Fig. 2). Both  $\Delta$ 9- and  $\Delta$ 6-desaturase mRNA levels were greatly increased, while the  $\Delta$ 5-desaturase mRNA level increase was weaker (Fig. 2). Conversely, fenofibrate exposure of PPAR $\alpha$ -deficient mice did not modify any desaturase mRNA levels. PPAR $\alpha$  target genes such as AOX and CYP4A10 were used as positive controls and were shown to be highly induced in W-T but not in PPAR $\alpha$ -/- mice (Fig. 2). Noticeably, all the different hepatic desaturase mRNA were detected in PPAR $\alpha$ -deficient mouse liver, suggesting that PPAR $\alpha$  is not required to sustain the constitutive level of expression of these transcripts. However, in untreated PPAR $\alpha$ -/- mice, the mRNA levels measured for SCD1 and  $\Delta$ 6-desaturase were significantly lower than in untreated W-T mice (Fig. 2).

<sup>a</sup>Plus and minus indicate the presence or absence of a 14-d fenofibrate administration. Values are mean ratios (% weight) of each FA relative to the total FA content  $\pm$  SD ( $n = 5$ ).

<sup>b</sup>Significant difference due to treatment (- vs. +;  $P < 0.05$ ).

<sup>c</sup>Significant difference due to genotype (W-T vs. PPAR $\alpha$ -/-;  $P < 0.05$ ). SFA, saturated FA; MFA, monounsaturated FA. For other abbreviations see Table 2.

**FIG. 1.** Effect of a 14-d fenofibrate treatment on desaturase activities in wild-type (W-T) and peroxisome proliferator-activated receptor  $\alpha$  (PPAR $\alpha$ )-/- mouse liver.  $\Delta$ 9-,  $\Delta$ 6- and  $\Delta$ 5-Desaturase activities were measured on postmitochondrial liver fractions of four experimental groups: W-T mice untreated (W-T, -), W-T mice treated for 14 d with fenofibrate (W-T, +), PPAR $\alpha$ -deficient mice untreated (PPAR $\alpha$  -/-, -), and PPAR $\alpha$ -deficient mice treated for 14 d with fenofibrate (PPAR $\alpha$  -/-, +). The  $\Delta$ 9-,  $\Delta$ 6-, and  $\Delta$ 5-desaturase activities were calculated as described in the Materials and Methods section. Activities are presented as means  $\pm$  SEM of five individual assays for each group. Each assay was carried out in triplicate. <sup>a</sup>Indicates a significant difference due to fenofibrate treatment (- vs. +;  $P < 0.05$ ). <sup>b</sup>Indicates a significant difference due to genotype (W-T vs. PPAR $\alpha$  -/-;  $P < 0.05$ ).

*Effect of a 14-d fenofibrate treatment on hepatic  $\Delta$ 6-desaturase protein level.* To determine whether the fenofibrate-induced increase in  $\Delta$ 6-desaturase mRNA level was correlated with an elevated  $\Delta$ 6-desaturase protein expression, Western blot analyses were performed on hepatic postmitochondrial fractions. Rabbit sera anti-rat  $\Delta$ 6-desaturase obtained in our laboratory (25) were used (Fig. 3). Under our experimental conditions,  $\Delta$ 6-desaturase was not detected in PPAR $\alpha$ -/- mice or in untreated W-T mice (Fig. 3). Conversely, after a 14-d fenofibrate treatment, the  $\Delta$ 6-desaturase protein level strongly increased in W-T mice but not in PPAR $\alpha$ -deficient mice (Fig. 3).

*Short-term effect of fenofibrate on desaturase mRNA levels.* Desaturase mRNA levels were also analyzed 2, 4, 8, 16, and 24 h after a single intragastric administration of fenofibrate in W-T and PPAR $\alpha$ -/- mice. The results of Northern blot analyses were quantified and plotted on four separate graphics (Figs. 4A–D). A calculated model curve is represented on the figures (based on polynomial regression). We used CYP4A10, a well-documented PPAR $\alpha$  target gene, as a reference of early PPAR $\alpha$ -dependent transcriptional induction. As shown in Figure 4A, the CYP4A10 mRNA level was rapidly and strongly increased by fenofibrate in W-T animals, but it was not detected in PPAR $\alpha$ -deficient mice under the stringent washing conditions required for the W-T samples blotted on the same membrane.

As previously observed (Fig. 1), SCD1 mRNA level was markedly higher in W-T mice than in PPAR $\alpha$ -/- mice, whatever the time after treatment (Fig. 4B). A maximal difference was measured 24 h after fenofibrate exposure (Fig. 4B). We observed that  $\Delta$ 6-desaturase mRNA levels were also induced in W-T mice, but not in PPAR $\alpha$ -/- mice 16 h after treatment (Fig. 4C).  $\Delta$ 5-Desaturase mRNA level in PPAR $\alpha$ -/- mice was comparable to  $\Delta$ 5-desaturase mRNA level in W-T mice until 24 h after PP exposure (Fig. 4D). However, at 24 h after treatment, the  $\Delta$ 5-desaturase transcript level was higher in W-T animals than in PPAR $\alpha$ -/-.

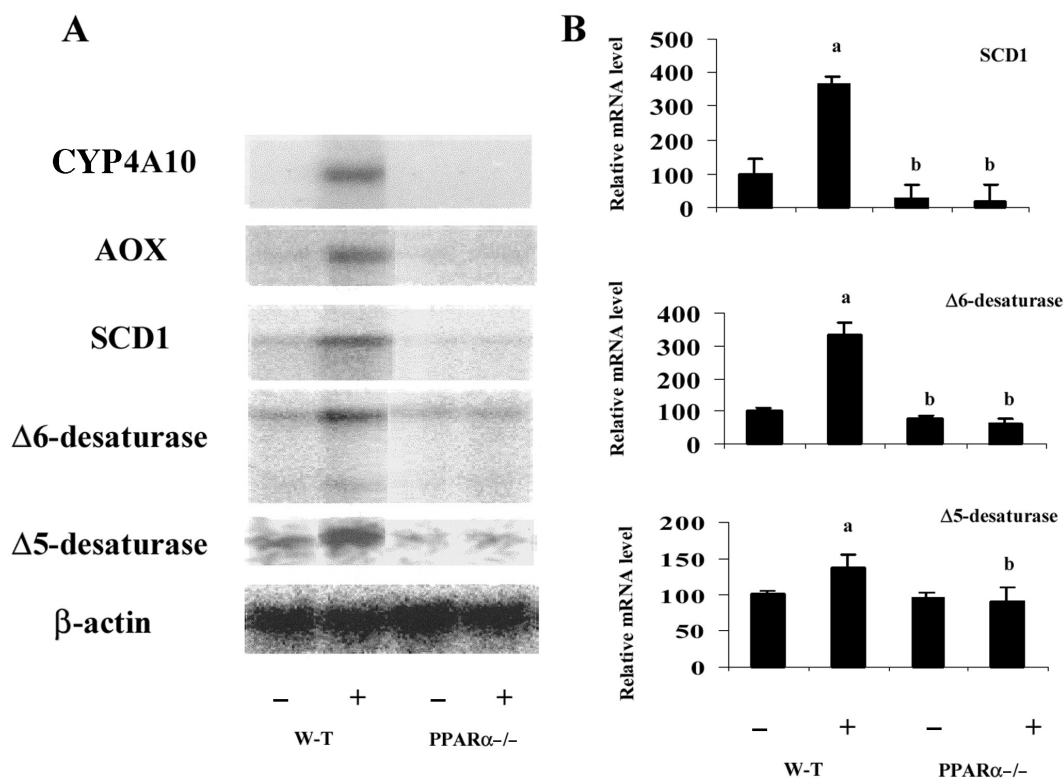

The short-term differences observed between mice from both genotypes concerning their  $\Delta$ 9-,  $\Delta$ 6-, and  $\Delta$ 5-mRNA levels are consistent with the differences reported after 2 wk of daily treatment (Fig. 1). Although SCD1 and  $\Delta$ 6-desaturase mRNA levels are rapidly and markedly increased in a PPAR $\alpha$ -dependent manner, the differential effect of PP on  $\Delta$ 5-desaturase mRNA levels between mice of both genotypes is not observed until 24 h after treatment.

## DISCUSSION

PPAR $\alpha$ -/- mice were initially investigated in pharmacological studies. This animal model led to major advances in the identification and characterization of main PPAR $\alpha$  target genes (3). Moreover, the use of PPAR $\alpha$ -deficient mice permitted a better understanding of PPAR $\alpha$  implications in metabolic adaptations (26,27) and a greater understanding of PPAR $\alpha$ -independent effects of dietary PUFA (28). The aim of our work was to document, *in vivo*, the PPAR $\alpha$ -dependent changes in hepatic FA profile and the involvement of SCD1,  $\Delta$ 6-desaturase, and  $\Delta$ 5-desaturase in the hepatic regulatory network controlled by PPAR $\alpha$  in rodents.

Our results confirm the previously mentioned PPAR $\alpha$ -deficient mice hepatic steatosis (3,21,29), for the 11-wk-old male transgenic mice had a much higher level of hepatic FA than age-matched W-T (Table 2). As has been previously reported for the liver of rats treated with PP (30), PP administration induced numerous changes in mouse hepatic FA composition (Table 3). None of the significant changes promoted in W-T mouse liver by treatment with PP occurred in the livers of PPAR $\alpha$ -deficient mice that received a similar treatment.

**FIG. 2.** Effect of a 14-d fenofibrate treatment on desaturase mRNA levels in W-T and PPAR $\alpha$ -/- mouse liver. (A) Total RNA was extracted from four mouse livers of the four experimental groups: W-T mice untreated (W-T, -), W-T mice treated for 14 d with fenofibrate (W-T, +), PPAR $\alpha$ -deficient mice untreated (PPAR $\alpha$ -/-, -), PPAR $\alpha$ -deficient mice treated for 14 d with fenofibrate (PPAR $\alpha$ -/-, +). Twenty micrograms of total RNA was run on a 1% formaldehyde-agarose gel, blotted onto a nylon membrane, and probed with six different random-primed  $^{32}$ P-labeled cDNA probes. cDNA probes AOX, CYP4A10, and  $\beta$ -actin were from a murine origin, whereas SCD1,  $\Delta$ 6 ( $\Delta$ 6-desaturase), and  $\Delta$ 5 ( $\Delta$ 5-desaturase) were from rat. Phosphorscreens were exposed for 24 h. (B) mRNA levels corresponding to SCD1,  $\Delta$ 6-, and  $\Delta$ 5-desaturase were analyzed for four animals of each genotype (W-T and PPAR $\alpha$ -/-) and each treatment (-: untreated, +: treated with fenofibrate) by densitometry using  $\beta$ -actin as loading control. Results are presented as means  $\pm$  SD of four individual analyses for each group. <sup>a</sup>Indicates a significant difference due to fenofibrate treatment (- vs. +;  $P < 0.05$ ). <sup>b</sup>Indicates a significant difference due to genotype (W-T vs. PPAR $\alpha$ -/-;  $P < 0.05$ ). CYP4A10, cytochrome P450; AOX, peroxisomal acyl-CoA oxidase; SCD1, stearoyl-CoA desaturase; for other abbreviations see Figure 1.

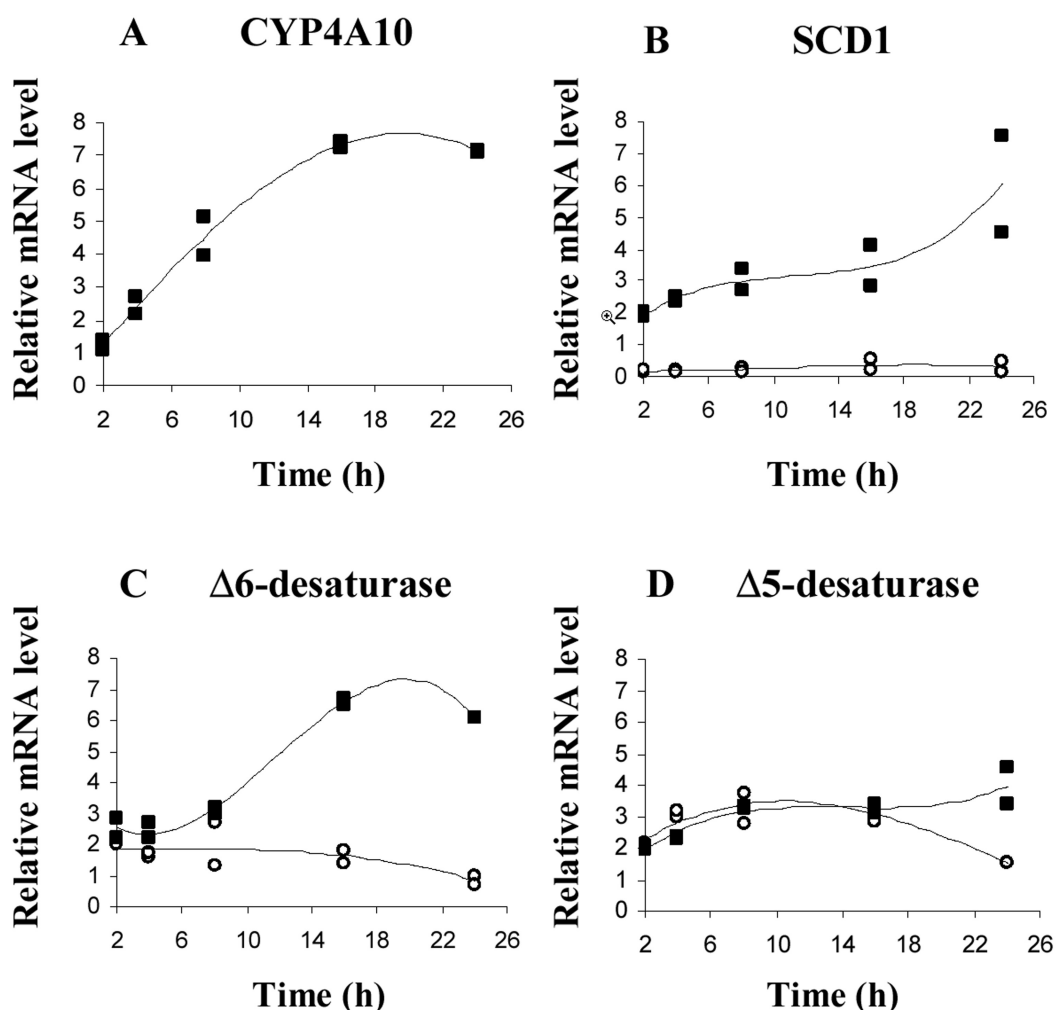

This result illustrates the major role of PPAR $\alpha$  in the regulation of FA-metabolizing enzymes.

Concerning desaturases, our data indicate that PPAR $\alpha$  is not required for their constitutive expression, as their mRNA were detected in PPAR $\alpha$ -/- mice (Fig. 2). However, SCD1 and  $\Delta$ 6-desaturase mRNA levels in untreated PPAR $\alpha$ -/- mice were significantly lower than in untreated W-T mice. Like other FA-metabolizing enzymes (31), SCD1 and  $\Delta$ 6-desaturase expression may be altered in mice lacking PPAR $\alpha$ . By contrast, the physiological consequences of PPAR $\alpha$  inactivation do not significantly alter  $\Delta$ 9- and  $\Delta$ 6-desaturase activities in 11-wk-old male mice. Therefore, the major difference in 18:2n-6 hepatic content between mice from either genotype is not correlated to a significant change in  $\Delta$ 6-desaturase activity between mice from both genotypes. We hypothesize that, as linoleic acid is by far the major FA provided by the diet, it may be less oxidized and subsequently accumulated in the liver of PPAR $\alpha$ -deficient mice.

In the liver of W-T mice treated with fenofibrate, extensive modifications in both PUFA and monoenoic FA contents were observed (Table 3). The PP-induced decrease in PUFA is consistent with the well-known induction of enzymes involved in peroxisomal  $\beta$ -oxidation, which preferentially

**FIG. 3.** Effect of a 14-d fenofibrate treatment on  $\Delta$ 6-desaturase protein level in W-T and PPAR $\alpha$ -/- mouse liver. Eighty micrograms of proteins from hepatic postmitochondrial supernatants of the four experimental groups were run on SDS-PAGE and transferred onto a nitrocellulose membrane. Rabbit polyclonal anti-rat  $\Delta$ 6-desaturase antibodies were used for the detection. For abbreviations see Figure 1.

**FIG. 4.** Short-term effect of fenofibrate treatment on desaturase mRNA levels in W-T and PPAR $\alpha$ -/- mouse liver. Total RNA was extracted from two mouse livers of the two experimental groups: W-T mice 2, 4, 8, 16, and 24 h after treatment with fenofibrate (W-T, +; ■), PPAR $\alpha$ -deficient mice 2, 4, 8, 16, and 24 h after treatment with fenofibrate (PPAR $\alpha$ -/-, +; ○). Twenty micrograms of total RNA was run on a 1% formaldehyde-agarose gel, blotted onto a nylon membrane, and probed with five different random-primed  $^{32}$ P-labeled cDNA probes. cDNA probes CYP4A10 and  $\beta$ -actin were from a murine origin, whereas SCD1,  $\Delta$ 6 ( $\Delta$ 6-desaturase), and  $\Delta$ 5 ( $\Delta$ 5-desaturase) were from rat. Phosphorscreens were exposed for 24 h CYP4A10 (A), SCD1 (B),  $\Delta$ 6-desaturase (C), and  $\Delta$ 5-desaturase (D) mRNA levels were analyzed for two animals of both genotypes at 2, 4, 8, 16, and 24 h after treatment. The results of Northern blotting were quantified and plotted on each graph as ratios relative to  $\beta$ -actin. Calculated model curves obtained by polynomial regression are represented on each graphic. For abbreviations see Figures 1 and 2.

break down PUFA (32). The increase in monoenoic FA is also consistent with a previous study that established that hepatic  $\Delta$ 9-desaturase activity was increased by a number of pharmaceutical molecules of the fibrate class (9). The mechanism underlying this phenomenon was shown to involve a transcriptional increase of SCD1 mRNA level, due to a functional PPRE in mouse SCD1 promoter (15). Consistent with these studies, we demonstrated that fenofibrate, like other PP, enhances  $\Delta$ 9-desaturase activity (Fig. 2) and SCD1 mRNA level (Fig. 3) *in vivo*. Since this induction did not occur in PPAR $\alpha$ -deficient mice, we presented evidence for a PPAR $\alpha$  requirement in this pretranslational mechanism.

Numerous studies have shown that dietary PUFA (16,17) and cholesterol (33), hormones (34,35), or lipid-lowering drugs such as fibrates (10) may regulate  $\Delta$ 6- and  $\Delta$ 5-desat-

urase activities in rodent liver. Here, we report an increase in the  $\Delta$ 6-desaturase activity (Fig. 1), mRNA level (Fig. 2), and protein level (Fig. 3) in the liver of W-T mice treated for 14 d with fenofibrate but not in PPAR $\alpha$ -/- mice. Similarly,  $\Delta$ 5-desaturase activity (Fig. 1) and mRNA level (Fig. 2) were enhanced in the liver of W-T but not PPAR $\alpha$ -/- mice after 14 d of treatment with fenofibrate. Moreover, a short-term time-course study showed that the significant effect of fenofibrate on  $\Delta$ 6- and  $\Delta$ 5-desaturase mRNA levels reported after 2 wk of daily treatment (Fig. 2) was already detectable, respectively, at 16 and 24 h after treatment (Fig. 4). Therefore, our result supports the involvement of PPAR $\alpha$  in the early control of not only  $\Delta$ 9-desaturase but also  $\Delta$ 6-desaturase and, to a lesser extent,  $\Delta$ 5-desaturase in mouse liver.

The 14-d fenofibrate treatment induced a significant

decrease in main hepatic PUFA (18:2n-6, 20:4n-6, 22:6n-3) through a PPAR $\alpha$ -mediated process (Table 3). This may have considerable physiological consequences, as PUFA perform numerous vital functions (36). Changes in the cellular availability of long-chain PUFA may indirectly contribute to delayed effects of PPAR $\alpha$  pharmacological ligands. Indeed, long-chain PUFA and certain of their derivatives, i.e., eicosanoids, are endogenous ligands for PPAR $\alpha$  itself and other nuclear receptors (37). Moreover, PUFA are known to inhibit the expression of certain lipogenic enzymes (37). Apart from these observations, it appears that changes in the activity of  $\Delta$ 6- and  $\Delta$ 5-desaturases are likely to limit the PUFA decrease in liver of mice treated by PP. Thus,  $\Delta$ 6- and  $\Delta$ 5-desaturase activities may restore secondary regulations by sustaining long-chain PUFA availability and counterbalancing their excessive degradation through peroxisomal  $\beta$ -oxidation.

Our current study shows that hepatic  $\Delta$ 6- and  $\Delta$ 5-desaturases are up-regulated by fenofibrate in W-T mice but not in PPAR $\alpha$ -/- mice after a long-term treatment. In a recent study, Cherkaoui-Malki *et al.* (38) proposed that long-term administration of PPAR $\alpha$  pharmacological ligands may result in delayed changes in gene expression occurring secondary to PPAR $\alpha$  activation and alterations in lipid metabolism. The short-term effect of fenofibrate on  $\Delta$ 6-desaturase mRNA level reported here (Fig. 4) suggests that  $\Delta$ 6-desaturase may be directly regulated by PPAR $\alpha$ . Regarding  $\Delta$ 5-desaturase, the short-term effect of fenofibrate exposure on mRNA level is less suggestive of a direct PPAR $\alpha$ -dependent control of gene expression. A molecular and functional analysis of the regulatory regions of  $\Delta$ 6- and  $\Delta$ 5-desaturase genes and the search for PPRE would further address this problem.

Dietary PUFA induce the transcription of numerous genes encoding proteins involved in FA oxidation through activation of PPAR $\alpha$ . PUFA are also known to inhibit hepatic  $\Delta$ 6- and  $\Delta$ 5-desaturase gene expression (16,17). Thus, our results document a discrepancy between fibrates and PUFA, both commonly considered as members of PPAR $\alpha$  activators, which induce opposite effects on desaturase expressions. The search for the responsive element to both PPAR $\alpha$  and other PUFA-sensitive transcription factors in the regulatory regions of  $\Delta$ 6- and  $\Delta$ 5-desaturases would contribute to elucidating this paradox.

## ACKNOWLEDGMENTS

PPAR $\alpha$ -deficient mice were a gift from Dr. Frank J. Gonzalez. We thank Dr. Christian Diot for the rat SCD1 probe and for helpful discussion. We thank Colette Bétoulière, Pablo Olivera, Anne Leborgne, and Kim L. Cung for animal care and able technical assistance. This work was supported by grants from the Région Midi Pyrénées (no. 9600469), from the Association pour la Recherche sur le Cancer (no. 1386), and from Arilait Recherches.

USDA, ARS, Western Regional Research Center, Albany, California 94710

**ABSTRACT:** As part of a program to elucidate castor oil biosynthesis, we have identified 36 molecular species of PC and 35 molecular species of PE isolated from castor microsomes after incubations with [ $^{14}\text{C}$ ]-labeled FA. The six [ $^{14}\text{C}$ ]FA studied were ricinoleate, stearate, oleate, linoleate, linolenate, and palmitate, which were the only FA identified in castor microsomal incubations. The incorporation of each of the six FA into PC was better than that into PE. The [ $^{14}\text{C}$ ]FA were incorporated almost exclusively into the *sn*-2 position of both PC and PE. The incorporation of [ $^{14}\text{C}$ ]stearate and [ $^{14}\text{C}$ ]palmitate into 2-acyl-PC was slower compared to the other four [ $^{14}\text{C}$ ]FA. The incorporation does not show any selectivity for the various *lyso*PC molecular species. The level of incorporation of [ $^{14}\text{C}$ ]FA in PC was in the order of: oleate > linolenate > palmitate > linoleate > stearate > ricinoleate, and in PE: linoleate > linolenate > oleate > palmitate > stearate > ricinoleate. In general, at the *sn*-1 position of both PC and PE, linoleate was the most abundant FA, palmitate was the next, and oleate, linolenate, stearate, and ricinoleate were minor FA. The activities of oleoyl-12-hydroxylase, oleoyl-12-desaturase seem unaffected by the FA at the *sn*-1 position of 2-oleoyl-PC. The FA in the *sn*-1 position of PC does not significantly affect the activity of phospholipase  $A_2$ , whereas ricinoleate is preferentially removed from the *sn*-2 position of PC. The results show that (i) [ $^{14}\text{C}$ ]oleate is most actively incorporated to form 2-oleoyl-PC, the immediate substrate of oleoyl-12-hydroxylase; (ii) 2-ricinoleoyl-PC is formed mostly by the hydroxylation of 2-oleoyl-PC, not from the incorporation of ricinoleate into 2-ricinoleoyl-PC; and (iii) 2-oleoyl-PE is less actively formed than 2-oleoyl-PC.

Paper no. L9031 in *Lipids* 37, 991–995 (October 2002).

Ricinoleate has many industrial uses. Its only commercial source is castor oil, in which ricinoleate constitutes 90% of the FA (1). Since castor bean contains the toxin ricin as well as potent allergens, it is hazardous to grow, harvest, and process. It would be desirable to produce ricinoleate instead in a transgenic oilseed lacking these toxic components. To develop a transgenic plant capable of producing a high level of ricinoleate in its seed oil, one must understand the biosynthesis of castor oil. The identified enzymatic steps on the path-

way regulating the production of ricinoleate-rich castor oil can be used to identify the corresponding genes to be cloned and expressed in other oilseed plants.

We have previously reported on the biosynthesis of castor oil and identified the key enzymatic steps on the pathway that drive the ricinoleate into castor oil (2,3). The main pathway is: 2-oleoyl-PC (1-acyl-2-oleoyl-*sn*-glycero-3-phosphocholine)  $\Rightarrow$  2-ricinoleoyl-PC (1-acyl-2-ricinoleoyl-*sn*-glycero-3-phosphocholine)  $\Rightarrow$  ricinoleate  $\rightarrow$  ricinoleoyl-CoA  $\rightarrow$  ricinoleoyl-*lyso*PA  $\rightarrow$  diricinoleoyl-PA  $\rightarrow$  1,2-diricinoleoyl-*sn*-glycerol  $\Rightarrow$  triricinolein. The heavy arrows ( $\Rightarrow$ ) indicate the key enzymatic steps. In castor microsomal incubation, oleoyl-CoA is rapidly incorporated into 2-oleoyl-PC by acyl-CoA:*lyso*PC acyltransferase (EC 2.3.1.23) (4,5). The 2-oleoyl-PC formed is then hydroxylated to 2-ricinoleoyl-PC by oleoyl-12-hydroxylase and desaturated to 2-linoleoyl-PC by oleoyl-12-desaturase (EC 1.3.1.35) (2). 2-Ricinoleoyl-PC is then hydrolyzed by phospholipase  $A_2$  (EC 3.1.1.4) to release ricinoleate for the biosynthesis of TAG containing ricinoleate (2). 2-Oleoyl-PE (1-acyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine) cannot be hydroxylated to 2-ricinoleoyl-PE, but can first be converted to 2-oleoyl-PC and then hydroxylated (3). The key enzyme, oleoyl-12-hydroxylase, has been characterized (5,6). We would like to extend the understanding of this pathway to the molecular species of lipid classes.

We have recently reported the molecular species of acyl-glycerols produced in microsomal incubations after incorporating six [ $^{14}\text{C}$ ] FA in castor microsomal incubations (7). The incorporations of these FA into TAG are in the order of: ricinoleate > oleate > linoleate > linolenate > stearate > palmitate. In this work, we also describe the incorporation of six [ $^{14}\text{C}$ ]FA, representing the endogenous FA, into the molecular species of PC and PE, intermediates in the biosynthesis of castor oil.

## EXPERIMENTAL PROCEDURES

**Microsomal incubation.** Microsomes from castor bean were prepared as described previously (2). To obtain suitable amounts of label incorporation for analysis, the incubation mixture was scaled up 20-fold in a total volume of 20 mL: sodium phosphate buffer (0.1 M, pH 6.3), CoA-SH (10  $\mu\text{mol}$ ), NADH (10  $\mu\text{mol}$ ), ATP (10  $\mu\text{mol}$ ),  $\text{MgCl}_2$  (10  $\mu\text{mol}$ ), catalase (20,000 units), and microsomal fraction from

Abbreviations: 2-oleoyl-PC, 1-acyl-2-oleoyl-*sn*-glycero-3-phosphocholine; 2-oleoyl-PE, 1-acyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine; 2-ricinoleoyl-PC, 1-acyl-2-ricinoleoyl-*sn*-glycero-3-phosphocholine; RT, retention time.

endosperm of immature castor bean (300  $\mu$ L, 2.76 mg of protein). The [ $^{14}$ C]FA, ricinoleate (55 Ci/mol; American Radiolabeled Chemicals, Inc., St. Louis, MO), stearate (44 Ci/mol; NEN Life Science Products, Boston, MA), oleate (52 Ci/mol; NEN), linoleate (51 Ci/mol; NEN), linolenate (52 Ci/mol; NEN), and palmitate (56 Ci/mol; NEN) were incubated individually. The [ $^{14}$ C]FA (5.0  $\mu$ Ci) in 400  $\mu$ L ethanol was added last into a screw-capped bottle containing incubation mixture and then immediately mixed.

The mixture was then incubated in a shaking water bath for 60 min at 22°C. The incubation was stopped by suspension in 75 mL of chloroform/methanol (1:2, vol/vol). The mixture was again mixed with 12.5 mL of chloroform and 12.5 mL of water. The lower chloroform layer, containing the lipid extract, was dried and fractionated by silica HPLC to separate lipid classes as described below. For time-course studies,  $\frac{1}{2}$  of the incubation components and extraction solvents, and [ $^{14}$ C]FA (0.5  $\mu$ Ci) were used. Duplicate incubations were done at various times and the averages of incorporations were used.

**Determination of the sn-1,2 positions of [ $^{14}$ C]FA on PC and PE.** The [ $^{14}$ C]PC and [ $^{14}$ C]PE obtained from the castor microsomal incubations were hydrolyzed with 0.2 mg phospholipase A<sub>2</sub> (*Naja mossambica mossambica*, P4034; Sigma) dissolved in incubation buffer, in a total of 1 mL buffer (0.1 M Tris, pH 8.9). The PC or PE was dissolved in 20  $\mu$ L of ethanol and added to start the reaction, followed by immediate mixing. The mixture was incubated in a shaking water bath at 25°C overnight and then neutralized with HCl (0.1 M). The total lipid was extracted as described above for the castor microsomal incubation. The free FA and *lyso*PC (*lyso*PE) formed were separated by silica HPLC and counted by a flow scintillation analyzer as described below. Under these conditions, the esters at sn-2 of both PC and PE were completely hydrolyzed by phospholipase A<sub>2</sub>.

**HPLC.** HPLC was carried out on a liquid chromatograph (Waters Associates, Milford, MA), using a UV detector (Waters 2487) at 205 nm and a flow scintillation analyzer (150TR; Packard Instrument Co., Downers Grove, IL) to detect [ $^{14}$ C]-labeled compounds. Labeled lipids were separated by HPLC and where possible identified by co-chromatography with lipid standards and matching the retention times (RT) on the UV chromatogram and radiochromatogram. The PC and PE standards were purchased from Avanti Polar Lipids, Inc. (Alabaster, AL) and Sigma. The flow rate of HPLC eluents was 1 mL/min. The flow rate of liquid scintillation fluid (Ultima Flo M; Packard Instrument Co.) in the flow scintillation analyzer was 3 mL/min. The maximum scaling value of the graph from the flow scintillation analyzer was set at 10000.

(i) **Separation of lipid classes.** Lipid classes were separated according to Singleton and Stikeleather (8) on a silica column (25  $\times$  0.46 cm, 5  $\mu$ m, Luna, silica(2); Phenomenex, Torrance, CA) with a linear gradient of 2-propanol/hexane (4:3, vol/vol) to 2-propanol/hexane/water (4:3:0.75, by vol) in 20 min, then isocratically for 20 min. A prepacked silica saturator column (3  $\times$  0.46 cm, 15–25  $\mu$ m; Phenomenex) was installed between

the pump and injector to saturate the mobile phase with silica before it reached the column. To elute *lyso*PC more rapidly after phospholipase A<sub>2</sub> hydrolysis of PC, a linear gradient of 2-propanol/hexane (4:3, vol/vol) to 2-propanol/hexane/water (4:3:0.85, by vol) in 20 min, then isocratic for 30 min, was used. Eluent B is near saturation with water. In this HPLC system, RT were: 40.0 min, *lyso*PC (1-oleoyl-*lyso*PC); 30.6 min, PC (1-palmitoyl-2-oleoyl-PC); and about 3.5 min, FFA. For the separation of *lyso*PE, the former silica HPLC system (2-propanol/hexane/water, 4:3:0.75 by vol) was used, and the RT were: 22.6 min, *lyso*PE (1-oleoyl-*lyso*PE); 17.7 min, PE (1-palmitoyl-2-oleoyl-PE); and about 3.5 min, FFA.

(ii) **Separation of molecular species of PC.** Molecular species of PC were separated in 40 min as previously reported (9), using a C<sub>8</sub> column (25  $\times$  0.46 cm, 5  $\mu$ m, Luna C8; Phenomenex) with a linear gradient of 90% aqueous methanol to 100% methanol, both containing 0.1% of concentrated NH<sub>4</sub>OH. NH<sub>4</sub>OH was used as silanol-suppressing agent.

(iii) **Separation of molecular species of PE.** Molecular species of PE were separated as previously reported (10), using a C<sub>8</sub> column (Luna C8; Phenomenex) with a linear gradient of 88% aqueous methanol to 100% methanol containing 0.1% of concentrated NH<sub>4</sub>OH in 40 min.

## RESULTS AND DISCUSSION

**Separation of lipid classes.** The total lipids obtained from the incubation of each [ $^{14}$ C]FA were separated into lipid classes by silica HPLC as shown earlier (Fig. 1; Ref. 7). The lipid classes separated were AG (and FFA), PE, PC (without ricinoleoyl chain), and ricinoleoyl-PC in the order of elution. All of the six [ $^{14}$ C]FA used were incorporated into PC and PE. The levels of [ $^{14}$ C]PC were higher than those of [ $^{14}$ C]PE and [ $^{14}$ C]AG (7).

Time course studies, of up to 120 min, of microsomal incubations of the six [ $^{14}$ C]FA individually showed that in general the level incorporated by PE, PC (without ricinoleoyl chain), and ricinoleoyl-PC increased initially and then equilibrated at 45 to 60 min when the rate of incorporation from FA became equal to the rate of hydrolysis. Since ricinoleate is actively removed from the mixture of 2-acyl-PC containing different FA at sn-2 (2), the radioactivity levels at 15 min (initial rate) were used to compare the rates of incorporation. The incorporation of [ $^{14}$ C]stearate and [ $^{14}$ C]palmitate into 2-acyl-PC was slower than of the other four [ $^{14}$ C]FA. Usually these two FA are strongly excluded from the sn-2 position of phospholipids. In comparing the amount of label incorporated at the equilibrium stages, PC and PE incorporating [ $^{14}$ C]-labeled oleate, linoleate, and linolenate were at higher levels than those with ricinoleate, stearate, and palmitate. The low incorporation of label by 2-ricinoleoyl-PC at equilibrium stage may be attributed to a futile cycle of incorporation and hydrolysis. With the exception of ricinoleate, which was most actively incorporated into TAG (7), the incorporation of FA (FA preference) is similar to that observed for the incorporations of the six [ $^{14}$ C]FA into TAG. This is also consistent with

earlier studies in which [ $^{14}\text{C}$ ]oleoyl-CoA and [ $^{14}\text{C}$ ]ricinoleoyl-CoA were incorporated into [ $^{14}\text{C}$ ]PC in castor microsomal incubation (4) and when [ $^{14}\text{C}$ ]oleoyl-CoA, [ $^{14}\text{C}$ ]linoleoyl-CoA, and [ $^{14}\text{C}$ ]palmitoyl-CoA were incorporated into [ $^{14}\text{C}$ ]PC in soybean microsomal incubation (11). The incorporation of label from [ $^{14}\text{C}$ ]oleate, [ $^{14}\text{C}$ ]linoleate, and [ $^{14}\text{C}$ ]linolenate into PE was higher than that from [ $^{14}\text{C}$ ]ricinoleate, [ $^{14}\text{C}$ ]stearate, and [ $^{14}\text{C}$ ]palmitate. PE had not been previously reported in microsomal incubations of [ $^{14}\text{C}$ ]FA and [ $^{14}\text{C}$ ]acyl-CoA.

**Determination of the ratio of [ $^{14}\text{C}$ ]FA on sn-1,2 positions of [ $^{14}\text{C}$ ]PC and [ $^{14}\text{C}$ ]PE.** The [ $^{14}\text{C}$ ]PC and [ $^{14}\text{C}$ ]PE fractions collected after silica HPLC from the 60-min incubations were subjected to phospholipase A<sub>2</sub> hydrolysis to determine the ratio of [ $^{14}\text{C}$ ]FA on the sn-1 and -2 positions. The percentage of label at sn-1 in the total [ $^{14}\text{C}$ ]PC (sn-1 and -2 combined) from each [ $^{14}\text{C}$ ]FA were: 0.3% (1-[ $^{14}\text{C}$ ]ricinoleoyl-*lyso*PC, RT 47.7 min), 3.5% (1-[ $^{14}\text{C}$ ]stearoyl-*lyso*PC, 38.7 min), 2.3% (1-[ $^{14}\text{C}$ ]oleoyl-*lyso*PC, 40.0 min), 0.6% (1-[ $^{14}\text{C}$ ]linoleoyl-*lyso*PC, 40.8 min), 0.3% (1-[ $^{14}\text{C}$ ]linolenoyl-*lyso*PC, 41.2 min), and 7.3% (1-[ $^{14}\text{C}$ ]palmitoyl-*lyso*PC, 40.3 min). In earlier studies, in a soybean microsomal incubation, 95% of the [ $^{14}\text{C}$ ]PC incorporating [ $^{14}\text{C}$ ]oleoyl-CoA was labeled at the sn-2 position (11), and in a castor microsomal incubation of [ $^{14}\text{C}$ ]oleoyl-CoA, 84.4% of the [ $^{14}\text{C}$ ]PC incorporated label at the sn-2 position (4). The percentage of the label at sn-1 in the total [ $^{14}\text{C}$ ]PE (sn-1 and -2 combined) from each [ $^{14}\text{C}$ ]FA were: 2% (1-[ $^{14}\text{C}$ ]stearoyl-*lyso*PE, RT 22.3 min) and 1.8% (1-[ $^{14}\text{C}$ ]linoleoyl-*lyso*PE, 22.7 min). The levels of 1-[ $^{14}\text{C}$ ]ricinoleoyl-*lyso*PE, 1-[ $^{14}\text{C}$ ]oleoyl-*lyso*PE (22.6 min), 1-[ $^{14}\text{C}$ ]linolenoyl-*lyso*PC and 1-[ $^{14}\text{C}$ ]palmitoyl-*lyso*PC were not detectable. For both PC and PE, the [ $^{14}\text{C}$ ]FA are incorporated predominantly at the sn-2 position.

**Identification of the molecular species of [ $^{14}\text{C}$ ]PC.** The radiochromatogram separating molecular species of PC from the incubation of [ $^{14}\text{C}$ ]oleate on a C<sub>8</sub> column (9) is shown as Figure 1. Peaks #4, 5, and 6 were identified by co-chromatography with the standards 1-palmitoyl-2-oleoyl-PC, 1,2-dioleoyl-PC, and 1-stearoyl-2-oleoyl-PC. Since the standards for peaks #1, 2, and 3 were not available, they were designated as 1-ricinoleoyl-2-oleoyl-PC, 1-linolenoyl-2-oleoyl-PC, and 1-linoleoyl-2-oleoyl-PC, based on relative RT and elution characteristics of the molecular species of PC (9).

We have calculated the relative RT of the molecular species of PC from the six [ $^{14}\text{C}$ ]FA incubations based on the RT (32.15 min) of 1-palmitoyl-2-oleoyl-PC in our previous report (9) by co-chromatography with this PC standard (Lin, J.T., and McKeon, T.A., unpublished data). The calculated RT of the six 2-ricinoleoyl-PC in Figure 1 from the [ $^{14}\text{C}$ ]ricinoleate incubation are 9.4 min (1,2-ricinoleoyl-PC), 14.6 min (1-linolenoyl-2-ricinoleoyl-PC), 16.9 min (1-linoleoyl-2-ricinoleoyl-PC), 18.5 min (1-palmitoyl-2-ricinoleoyl-PC), 19.6 min (1-oleoyl-2-ricinoleoyl-PC), and 22.7 min (1-stearoyl-2-ricinoleoyl-PC). 1,2-Diricinoleoyl-PC (9.4 min) was not detected. It was probably hydrolyzed by phospholipases immediately after formation. The RT of peaks #7–10

**FIG. 1.** The C<sub>8</sub> HPLC radiochromatogram separating the molecular species of PC incorporated from [ $^{14}\text{C}$ ]oleate in castor microsomal incubation. (1) 1-Ricinoleoyl-2-oleoyl-PC; (2) 1-linolenoyl-2-oleoyl-PC; (3) 1-linoleoyl-2-oleoyl-PC; (4) 1-palmitoyl-2-oleoyl-PC; (5) 1,2-dioleoyl-PC; (6) 1-stearoyl-2-oleoyl-PC; (7) 1-linolenoyl-2-ricinoleoyl-PC; (8) 1-linoleoyl-2-ricinoleoyl-PC; (9) 1-palmitoyl-2-ricinoleoyl-PC; (10) 1-stearoyl-2-ricinoleoyl-PC; (11) 1-linolenoyl-2-linoleoyl-PC; (12) 1-palmitoyl-2-linoleoyl-PC.

are the same as the calculated RT. Labeled 1-oleoyl-2-ricinoleoyl-PC is a minor component in peak #1 (19.7 min, mostly 1-ricinoleoyl-2-oleoyl-PC), because the levels of label in 2-ricinoleoyl-PC were lower than those of 2-oleoyl-PC and the ratio of the six labeled 2-ricinoleoyl-PC to each other were similar to those of the six 2-oleoyl-PC. Similarly, the calculated RT of 2-linoleoyl-PC in Figure 1 from the incubation with [ $^{14}\text{C}$ ]linoleate were used to designate the peaks #11 (1-linolenoyl-2-linoleoyl-PC) and #12 (1-palmitoyl-2-linoleoyl-PC). The other four 2-linoleoyl-PC co-eluted with other [ $^{14}\text{C}$ ]PC as minor components. The label incorporated in 2-linoleoyl-PC was lower than in 2-ricinoleoyl-PC. The molecular species of PC incorporating the other five [ $^{14}\text{C}$ ]FA were identified and designated the same as those from [ $^{14}\text{C}$ ]oleate, except the [ $^{14}\text{C}$ ]FA were unchanged in the incubations.

The incorporations of [ $^{14}\text{C}$ ]oleoyl-CoA, [ $^{14}\text{C}$ ]oleate, and [ $^{14}\text{C}$ ]linoleate into the molecular species of PC in the microsomes prepared from soybean (11), potato tuber (12), pea leaf (13), and developing sunflower seeds (14) have been reported. The labeled PC in these systems contained two of the labeled and unlabeled oleate, linoleate, linolenate, stearate, and palmitate (no ricinoleate) at both sn-1 and sn-2 positions.

**Radioactivity levels of the molecular species of [ $^{14}\text{C}$ ]PC.** Table 1 shows the level of [ $^{14}\text{C}$ ]label in the molecular species of [ $^{14}\text{C}$ ]PC incorporating each [ $^{14}\text{C}$ ]FA during a 60-min castor microsomal incubation. The [ $^{14}\text{C}$ ]PC are primarily derived from the action of acyl-CoA:lysoPC acyltransferase with endogenous lysoPC as acyl acceptor. The lysoPC are endogenous to the microsomes and contain any of the six different FA in the sn-1 position, and the [ $^{14}\text{C}$ ]FA at sn-2 are from [ $^{14}\text{C}$ ]acyl-CoA. In general, the levels of label of [ $^{14}\text{C}$ ]PC with the FA at the sn-1 position were in the order of linoleate > palmitate > oleate > linolenate, stearate, and ricinoleate, with linoleate and palmitate as the major sn-1 component of PC.

Palmitate (89)	3.6	2.4	14.6	9.5	3.5	1.8	35.4

<sup>a</sup>For each FA incubation 5.0 μCi was used. The amounts (nmol) of FA used are different because the specific radioactivities of FA are different.

<sup>b</sup>Fa is the FA shown in the FA column on the Table at the *sn*-2 position of PC.

<sup>c</sup>2-Ricinoleoyl-PC and 2-linoleoyl-PC in the incubation of [<sup>14</sup>C]-oleate.

<sup>d</sup>Estimated from the ratio of the levels of molecular species of 2-oleoyl-PC. ND, not detected; R, ricinoleate; Ln, linolenate; L, linoleate; P, palmitate; O, oleate, S, stearate.

For example, in the incorporation of [<sup>14</sup>C]ricinoleate into PC as shown in Table 1, the levels of label were 1-linoleoyl-2-ricinoleoyl-PC (7.6) > 1-palmitoyl-2-ricinoleoyl-PC (5.3) > 1-oleoyl-2-ricinoleoyl-PC (2.2). This order, reflects the relative levels of the six molecular species of *lyso*PC in castor microsomes. In previous reports of microsomal incubations of [<sup>14</sup>C]oleoyl-CoA from soybean (11), potato tuber (12), and pea leaf (13), the major PC molecular species also contained linoleate and palmitate at the *sn*-1 position. The ratios of the six PC incorporating each of the six [<sup>14</sup>C]FA were similar and thus the activity of the enzyme seems unaffected by the difference of FA at *sn*-1 position on *lyso*PC. The total [<sup>14</sup>C]-label (Table 1) from each [<sup>14</sup>C]FA was incorporated in the order: oleate > linolenate > palmitate > linoleate > stearate > ricinoleate. The acyl-CoA:*lyso*PC acyltransferase activity also may be affected by which FA more readily forms acyl-CoA, since acyl-CoA synthetase may be specific for certain FA. In soybean microsomes, acyl-CoA:*lyso*PC acyltransferase was highly specific for oleoyl-CoA and linoleoyl-CoA over palmitoyl-CoA and did not show any selectivity for the various *lyso*PC molecular species (11). In the incubation of [<sup>14</sup>C]oleate (Table 1), the proportion of label incorporated into the six 2-[<sup>14</sup>C]oleoyl-PC with different FA at *sn*-1 was similar to the proportion of the six 2-[<sup>14</sup>C]ricinoleoyl-PC and that of 2-

[<sup>14</sup>C]linoleoyl-PC from the 2-[<sup>14</sup>C]oleoyl-PC. Thus, the activities of both oleoyl-12-hydroxylase and oleoyl-12-desaturase seem not to be affected by the different FA at *sn*-1 of 2-oleoyl-PC, the immediate substrate of these two enzymes. The same conclusion was also drawn for the activity of oleoyl-12-desaturase in the microsomes of potato tuber (12) and pea leaf (13). However, the effect on oleoyl-12-hydroxylase activity has not previously been reported. Oleoyl-12-hydroxylase from *Ricinus communis* L. is an oleoyl-12-desaturase homolog (15).

*Time course for production of the molecular species of [<sup>14</sup>C]PC.* The levels of labeled molecular species of PC at various incubation times were also determined. The ratios of the levels of six molecular species of PC containing the same *sn*-2 FA from the incubations of the six [<sup>14</sup>C]FA at various times were similar to the ratio in Table 1. It seems that the activity of phospholipase A<sub>2</sub> in castor microsomes, one of the key enzymes in castor oil biosynthesis, is not significantly affected by the difference of these FA at the *sn*-1 position of PC. However, ricinoleate is preferentially removed from the *sn*-2 position of PC by phospholipase A<sub>2</sub> (2).

*Identification of the molecular species of [<sup>14</sup>C]PE.* Molecular species of PE were identified and designated as those of PC. The RT of minor [<sup>14</sup>C]PE from [<sup>14</sup>C]oleate incubation cannot be matched with our calculated RT of 2-ricinoleoyl-PE

<sup>b</sup>Fa is the FA shown in the FA column on the Table at the *sn*-2 position of PE. For abbreviations see Table 1.

and 2-linoleoyl-PE. They may be the molecular species of other lipid classes, which elute near PE on the silica HPLC including PI, PA, and PS (see Fig. 1, Ref. 2). That 2-[<sup>14</sup>C]ricinoleoyl-PE and 2-[<sup>14</sup>C]linoleoyl-PE were not detected agrees with our earlier conclusion (3) that 2-oleoyl-PE is not a substrate for oleoyl-12-hydroxylase and oleoyl-12-desaturase. Although 2-oleoyl-PE is not a substrate under these isolated conditions, we cannot yet rule it out as a substrate *in vivo*.

**Incorporation of label into molecular species of [<sup>14</sup>C]PE.** The radiolabeling of molecular species of PE incorporating the six [<sup>14</sup>C]FA in castor microsomal incubations (60 min) was lower than those of PC as shown in Table 2. Except for the PE products incorporating [<sup>14</sup>C]stearate and [<sup>14</sup>C]palmitate, PE with linoleate and palmitate at *sn*-1 position were the major PE, as for PC. Unlike PC, the levels of molecular species of PE incorporating [<sup>14</sup>C]ricinoleate were much lower than the other five [<sup>14</sup>C]FA. The labeling of PE containing only saturated FA was also very low. The total incorporation of label was in the order: linoleate > oleate > linolenate > palmitate > stearate > ricinoleate. 2-Oleoyl-PE seems less important than 2-oleoyl-PC as an intermediate in the biosynthesis of castor oil, not only because it has a lower radioactivity level but also because it cannot be hydroxylated to 2-ricinoleoyl-PE (3). Both 2-ricinoleoyl-PC and 2-ricinoleoyl-PE can be used as the substrates of phospholipid:DAG acyltransferase for the biosynthesis of triricinolein (16).

In conclusion, we have identified and quantified 36 molecular species of PC and 35 molecular species of PE in castor microsomal incubations of six [<sup>14</sup>C]FA individually. Both PC and PE are intermediates in the biosynthetic pathway of castor oil (3). The schematic overview of the plant lipid biosynthetic pathway and its compartmentation have been reported (17). The results here show that (i) 2-oleoyl-PC is actively formed as the immediate substrate of oleoyl-12-hydroxylase, comparing the six endogenous FA; (ii) 2-ricinoleoyl-PC is mostly formed by the hydroxylation of 2-oleoyl-PC, not from the incorporation of ricinoleate into 2-ricinoleoyl-PC; and (iii) 2-oleoyl-PE is not actively formed for the biosynthesis of castor oil.

# Lipase-Catalyzed Hydrolysis of TG Containing Acetylenic FA

Marcel S.F. Lie Ken Jie<sup>a,\*</sup>, Xun Fu<sup>a</sup>, Maureen M.L. Lau<sup>a</sup>, and M.L. Chye<sup>b</sup>

Departments of <sup>a</sup>Chemistry and <sup>b</sup>Botany, The University of Hong Kong, Hong Kong, SAR, P.R. China

**ABSTRACT:** Hydrolysis of symmetrical acetylenic TG of type AAA [viz., glycerol tri-(4-decynoate), glycerol tri-(6-octadecynoate), glycerol tri-(9-octadecynoate), glycerol tri-(10-undecynoate), and glycerol tri-(13-docosynoate)] in the presence of eight microbial lipases was studied. Novozyme 435 (*Candida antarctica*), an efficient enzyme for esterification, showed a significant resistance in the hydrolysis of glycerol tri-(9-octadecynoate) and glycerol tri-(13-docosynoate). Hydrolysis of acetylenic TG with Lipolase 100T (*Humicola lanuginosa*) was rapidly accomplished. Lipase PS-D (*Pseudomonas cepacia*) showed a fair resistance toward the hydrolysis of glycerol tri-(6-octadecynoate) only, which reflected its ability to recognize the  $\Delta^6$  positional isomer of 18:1. Lipase CCL (*Candida cylindracea*, syn. *C. rugosa*) and AY-30 (*C. rugosa*) were able to catalyze the release of 10-undecynoic acid and 9-octadecynoic acid from the corresponding TG, but less readily the 13-docosynoic acid in the case of glycerol tri-(13-docosynoate). The two lipases CCL and AY-30 were able to distinguish the small difference in structure of fatty acyl moieties in the TG substrate. To confirm this trend, three regioisomers of mixed acetylenic TG of type ABC (containing one each of  $\Delta^6$ ,  $\Delta^9$ , and  $\Delta^{13}$  acetylenic FA in various positions) were prepared and hydrolyzed with CCL and AY-40. The results reconfirmed the observation that AY-30 and CCL were able to distinguish the slight differences in the molecular structure (position of the acetylenic bond and chain length) of the acyl groups in the TG during the hydrolysis of such TG substrates.

Paper no. L9066 in *Lipids* 37, 997–1006 (October 2002).

Lipases are key enzymes in catalyzing the breakdown of fats and oils to FFA, DAG, MAG, and glycerol. They are important to an organism in the digestion, mobilization, and deposition of lipid molecules. By understanding the activities of various lipases as biocatalysts in the hydrolysis of TG and in the esterification of FA to glycerol, scientists have successfully utilized these properties to isolate FFA and have prepared structured TG (1–5).

For example, pancreatic lipase hydrolyzes TG to 2-MG (5,6). Lipases also show specific activities toward the hydroly-

ysis of phospholipids and PC (components of cell or neuronal membranes) (7,8).

The discovery of the nutritional importance of n-3 PUFA (viz.,  $\alpha$ -linolenic acid, EPA, and DHA) initiated an intense effort to determine the action of lipases on such PUFA (9–11).

Apart from hydrolytic activities, lipases are also efficient in reactions such as esterification, transesterification, and aminolysis. These activities have led to the development and application of various immobilized lipases for oleochemical industries (12–14).

A large amount of work has been done on the hydrolysis of saturated and polyolefinic TG (15,16), but little has been conducted on TG containing acetylenic FA, found as minor components in some seed oils (17–20).

The role of acetylenic FA is not clear, but compounds such as stearolic acid [9-octadecynoic acid; abbreviated as 18:1(9a)] act as strong DNA-binding agents (21). Acetylenic alcohols also can inactivate oxidases (22) or lipoxygenase (23,24). In view of the biological importance of acetylenic FA, this paper reports the lipase-catalyzed hydrolysis of some symmetrical structured acetylenic TG of the type AAA and unsymmetrical structured acetylenic TG of the type ABC, where the acyl groups are different positional acetylenic FA isomers or homologs. The aim of this work was to investigate the effects of the acetylenic bond located at different positions in the acyl chains on the rate of hydrolysis of acetylenic TG substrates in the presence of different lipases as biocatalysts.

## MATERIALS AND METHODS

Immobilized lipases from *Rhizomucor miehei* (Lipozyme IM 20; activity 5.8 unit/mg), *Humicola lanuginosa* (Lipolase 100T; 20.8 unit/mg), and *Candida antarctica* (Novozyme 435; 7.8 unit/mg) were gifts from Novo Nordisk A/S (Hong Kong). Lipases from *C. cylindracea*, syn. *C. rugosa* (CCL, type VII; 8.4 unit/mg) and porcine pancreatic lipase (PPL, type II; 13.4 unit/mg) were purchased from Sigma Chemical Co. (St. Louis, MO). Immobilized lipases from *Pseudomonas cepacia* (PS-D, type I; 10.5 unit/mg), *Aspergillus niger* (Lipase A-12; 2.3 unit/mg), and *C. rugosa* (Lipase AY-30; 11.4 unit/mg) were gifts from Amano Pharmaceutical Co. Ltd. (Nagoya, Japan). Lipase activity in this study was measured as the liberation of 1  $\mu$ mol of butyric acid from tributyrin per minute at 37°C. One micromole of NaOH consumed (titra-

Abbreviations: 18:1(6a), 6-octadecynoate; 18:1(9a), 9-octadecynoate; 22:1(13a), 13-docosynoate; CCL, lipase from *Candida cylindracea*, syn. *C. rugosa*; PPL, porcine pancreatic lipase; PS-D, immobilized lipase from *Pseudomonas cepacia*; triolein, glycerol tri-(9Z-octadecenoate), or [18:1(9c)]<sub>3</sub>.

tion with 0.1 M NaOH) per minute corresponds to 1 unit of lipase activity.

Glycerol tri-(9Z-octadecenoate) [triolein], 10-undecenoic acid, and glycerol (99+%) were purchased from Aldrich Chemical Co. (Milwaukee, WI). Carrot seeds and high-erucic acid rapeseed oil were obtained from local sources. Preparation of acetylenic FA from the corresponding olefinic FA or seed oils by bromination and dehydrobromination was performed by the method described elsewhere (25). 4-Decynoic acid was obtained by condensing 4-pentynoic acid with *n*-bromopentane under *n*-butyllithium as described by Gilman and Holland (26).

$^1\text{H}$  and  $^{13}\text{C}$  NMR spectra were obtained using a Bruker Avance DPX<sub>300</sub> NMR spectrometer with the sample dissolved in deuteriochloroform and with tetramethylsilane as internal reference standard. TLC analysis was done on TLC plates coated with silica gel 60 GF<sub>254</sub> (art. 7730, 70–230 mesh), and column chromatographic separation was performed on silica gel 60 (art. 9385, 230–400 mesh; Merck, Darmstadt, Germany). GC was performed on a Hewlett-Packard gas chromatograph model 5890, equipped with an FID and a Hewlett-Packard model HP3394A electronic integrator. The GC columns used were fused-silica capillary columns with Nukol<sup>TM</sup> (Supelco Inc., Bellefonte, PA) as stationary phase (15 m × 0.53 mm, 0.50 μm film thickness) and Omegawax<sup>TM</sup> (Supelco Inc.) as stationary phase (30 m × 0.32 mm, 0.25 μm film thickness), for analyzing acetylenic acid and methyl ester, respectively. The temperatures of the column oven, injection port, and detector were maintained at 200, 250, and 250°C, respectively.

*General method for the preparation of TG of type AAA by enzymatic esterification in the presence of Novozyme as exemplified by the reaction of 10-undecynoic acid with glycerol.* A mixture of glycerol (400 mg, 4.35 mmol), 10-undecynoic acid (2.40 g, 13.0 mmol), Novozyme (160 mg), molecular sieve (4 Å, 1.0 g), and *n*-hexane (24 mL) was stirred vigorously in a 50-mL round-bottomed flask at 55°C for 24 h. The mixture was centrifuged, and the supernatant liquid was loaded on a silica gel column (100 g, 3.2 mm internal diameter). The column was then eluted with a mixture of *n*-hexane/diethyl ether (9:1, vol/vol, 500 mL). The eluent was evaporated to give glycerol tri-(10-undecynoate) (1.62 g, 63%). Similar reactions were carried out for the preparation of other TG of type AAA: namely, glycerol tri-(4-decynoate) (73%), glycerol tri-(6-octadecynoate) (70%), glycerol tri-(9-octadecynoate) (62%), and glycerol tri-(13-docosynoate) (61%).

*General method for the enzymatic hydrolysis of acetylenic TG as exemplified by the hydrolysis of glycerol tri-(9-octadecynoate) in the presence of PPL.* A mixture of glycerol tri-(9-octadecynoate) (53 mg, 0.06 mmol), 0.1 M NaH<sub>2</sub>PO<sub>4</sub>–Na<sub>2</sub>HPO<sub>4</sub> buffer solution (1.2 mL, pH 7), and lipase (PPL) (22 mg) was stirred at 40°C in a glass culture tube for definite periods. The reaction mixture was then extracted with diethyl ether (3 × 2 mL) and centrifuged to remove the lipase. The ethereal layer was concentrated and loaded on a silica gel (7.0 g) column. A mixture of *n*-hexane/diethyl ether (9:1, vol/vol, 90 mL)

was used to elute unhydrolyzed TG, and a mixture of *n*-hexane/diethyl ether/acetic acid (90:10:1, by vol; 100 mL) was used to elute the free 9-octadecynoic acid. The remaining components on the column were eluted with *n*-hexane/diethyl ether (3:2, vol/vol; 100 mL) and *n*-hexane/diethyl ether (1:1, vol/vol; 100 mL) to remove DG and MG, respectively. The solvent of each fraction was evaporated under reduced pressure, and the weights of TG, FAA, DG, and MG were determined.

For the remaining hydrolysis reactions, 0.06 mmol of TG substrates was used. The amount of lipases employed for each reaction was about 300 units [Lipase A-12 (125 mg), Lipase AY-30 (25 mg), PPL (22 mg), CCL (35 mg), PS-D (28 mg), Lipolase (15 mg), Lipozyme (50 mg), and Novozyme (35 mg)].

*General method for the preparation of mixed structured TG of type ABC by enzymatic esterification as exemplified by the preparation of glycerol 1-(3)-(9-octadecynoate)/6-octadecynoate)-2-(13-docosynoate) (1).* Glycerol 1-(3)-(9-octadecynoate) was produced by esterification of glycerol (250 mg, 2.7 mmol) with 9-octadecynoic acid (1.5 g, 5.4 mmol) in *n*-hexane (10 mL) and catalyzed by Lipozyme (150 mg) at 45°C for 12 h. The yield of MG, glycerol 1-(3)-(9-octadecynoate), was 27% after column chromatographic purification. A mixture of glycerol 1-(3)-(9-octadecynoate) (780 mg, 2.2 mmol), 13-docosynoic acid (780 mg, 2.32 mmol), Novozyme (90 mg), and *n*-hexane (10 mL) was stirred at 60°C for 8 h. Glycerol 1-(3)-(9-octadecynoate)-2-(13-docosynoate) (340 mg, 23%) was isolated by column chromatography. The DG obtained (280 mg, 0.42 mmol) was further esterified with 6-octadecynoic acid (120 mg, 0.43 mmol) in *n*-hexane (3.0 mL), in the presence of Novozyme (25 mg) at 60°C for 12 h. Compound **1** (246 mg, 63.3%) was obtained after column chromatographic separation. By a similar procedure, glycerol 1-(3)-(9-octadecynoate)/13-docosynoate)-2-(6-octadecynoate) [18:1(9a)/18:1(6a)/22:1(13a)] (compound **2**) and glycerol 1-(3)-(6-octadecynoate)/13-docosynoate)-2-(9-octadecynoate) [18:1(6a)/18:1(9a)/22:1(13a)] (compound **3**) were prepared in yields of 61.0 and 61.9%, respectively, for the last esterification step.

The position ( $\alpha$  or  $\beta$ ) of the various acyl chains in compounds **1–3** was confirmed by referring to the carbon chemical shifts of the C-1, C-2, and the carbon shifts of the acetylenic carbon nuclei published by Lie Ken Jie and Lam (27). The characteristic carbon shifts were identified as follows: 173.190/172.839/172.940 (C-1 for compound **1**), 34.000/34.202/33.527 (C-2 for compound **1**), 80.020/80.320/80.194/80.223/79.245/80.800 ( $\Delta^9/\Delta^{13}/\Delta^6$  for compound **1**); 173.214/172.550/172.259 (C-1 for compound **2**), 33.993/33.694/34.040 (C-2 for compound **2**), 80.031/80.329/79.245/80.806/80.207/80.231 ( $\Delta^9/\Delta^6/\Delta^{13}$  for compound **2**); 172.945/172.798/173.246 (C-1 for compound **3**), 33.529/34.160/34.044 (C-2 for compound **3**), 79.249/80.806/80.007/80.326/80.198/80.228 ( $\Delta^6/\Delta^9/\Delta^{13}$  for compound **3**).

*General method for the hydrolysis of structured acetylenic TG catalyzed by Lipase AY-30 or CCL as exemplified by the hydrolysis of compound 1 in the presence of CCL.* A mixture

of compound **1** (500 mg, 0.54 mmol), 0.1 M  $\text{NaH}_2\text{PO}_4$ – $\text{Na}_2\text{HPO}_4$  buffer solution (10 mL, pH 7), and lipase (CCL, 200 mg) was stirred at 40°C for 5 h. [Note: In the case of compounds **2** (500 mg) and **3** (500 mg), the amount of biocatalyst used was 200 mg of CCL or 150 mg of lipase AY-30.] The reaction products were extracted with diethyl ether and fractionated by column chromatography as described above. The relative amounts of the different FFA (183 mg) were determined from the intensities of the C-1 signals in the  $^{13}\text{C}$  NMR spectrum (180.32/180.59/180.65 for  $\Delta^6/\Delta^9/\Delta^{13}$ , respectively) as 6:7:4 for 18:1(6a):18:1(9a):22:1(13a), respectively. The mixed acetylenic FA (30 mg) were esterified with 15%  $\text{BF}_3$ /methanol (5 mL) for 15 min at 70°C. GC analysis indicated that the ratio of the methyl esters of 18:1(9a) and 18:1(6a) (overlapped) to 22:1(13a) was 7:2.

The isolated mixture of DG (164 mg) was stirred with potassium hydroxide (100 mg) in 95% ethanol solution (20 mL) at 80°C for 2 h. The reaction mixture was diluted with water (50 mL), acidified with HCl (4 M, 8 mL), and extracted with diethyl ether (3 × 20 mL). The solvent was evaporated and the residue was separated by column chromatography to give a mixture of free acetylenic FA. The components and ratio of acetylenic FA positional isomers in the DG fraction were determined by  $^{13}\text{C}$ -NMR from the intensities of the C-1 signals (180.32/180.59/180.65 for  $\Delta^6/\Delta^9/\Delta^{13}$ , respectively) as 9:8:12.

The time courses of lipase-catalyzed hydrolysis of TG are graphically presented in Figures 1–4. The graphs in Figures 1A–H show the amount (based on the weight of products isolated by silica column chromatographic separation) of unhydrolyzed (recovered) acetylenic TG left at the end of the indicated hydrolysis period (maximum of 45 h). Figures 2A–H give the amount of FFA, Figures 3A–H shows the amount of DG, and Figures 4A–H gives the amount of MG isolated by silica gel column chromatography. The results are the averages of three experiments conducted for each TG under investigation with a deviation  $\leq 5\%$ .

## RESULTS AND DISCUSSION

A total of eight lipase preparations [Lipozyme (*R. miehei*), Lipolase (*H. lanuginosa*), Novozyme (*C. antarctica*), CCL (*C. cylindracea*), PPL (porcine pancreatic lipase), PS-D (*P. cepacia*), A-12 (*A. niger*), and AY-30 (*C. rugosa*)] were used as biocatalysts to study the hydrolysis of five symmetrical acetylenic TG of type AAA {viz., [10:1(4a)]<sub>3</sub>\*, [18:1(6a)]<sub>3</sub>, [18:1(9a)]<sub>3</sub>, [11:1(10a)]<sub>3</sub>, and [22:1(13a)]<sub>3</sub>} along with triolein [18:1(9c)]<sub>3</sub>. [Note: The first number denotes the chain length of the FA. The number after the colon denotes the number of unsaturation and the number within the brackets indicates the position of the unsaturation; the letter “a” stands for acetylene, “c” stands for *cis* ethylene. The number 3 outside of the square bracket means that three FA moieties are acylated to the backbone of glycerol to form a TG.]

All eight of the lipases used in our hydrolysis reactions were effective biocatalysts. Even lipases A-12 and AY-30, which were poor performers in the esterification of acetylenic

acids with *n*-butanol (28), displayed good hydrolytic activities. In most cases, less than 20% of the acetylenic TG was left unreacted after 45 h. All lipases used were able to catalyze the hydrolysis of triolein efficiently (complete hydrolysis after 45 h). Novozyme distinguished fatty acyl chains in which the triple bond was located at the 9-position {as in [18:1(9a)]<sub>3</sub>} or the 13-position {as in [22:1(13a)]<sub>3</sub>}. It was interesting to realize that Novozyme, which is a nonregiospecific but an efficient lipase for esterification, was not as efficient in the hydrolysis of these TG as many of the other lipases used here.

None of the acetylenic TG was completely resistant to hydrolysis. However, Lipase A-12 was able to show a degree of differentiation in the case of [18:1(9a)]<sub>3</sub> and [22:1(13a)]<sub>3</sub>, as the hydrolysis process appeared rather slow during the first 25 h of reaction for these substrates. Lipases CCL and AY-30 showed a significant degree of resistance to the hydrolysis of [22:1(13a)]<sub>3</sub>, and about 30% of this symmetrical TG was recovered after stirring the reaction for 25 h.

The results for FFA isolated from these experiments also showed that the release of 18:1(6a) was comparatively slow when PS-D and Lipozyme were used as biocatalysts (Fig. 2). This result could be interpreted as follows: During the hydrolysis of [18:1(6a)]<sub>3</sub> to the FFA, these two lipases were significantly affected by the acetylenic bond at the 6-position of the acyl chain at either the intermediate DG or MG stage. Hence, the release of further FFA was relatively slow.

The results of FFA in Figures 2A–H reflected quite accurately the expected amounts of FFA liberated during the hydrolysis process. Where the amount of isolated TG was high (refer to Figs. 1A–H), the amount of the corresponding FFA tended to be low. For example, in the case of AY-30 and CCL, the amount of 22:1(13a) liberated was markedly lower than those of other positional acetylenic fatty isomers or homologs. Interestingly, in the presence of AY-30 and CCL, all TG showed a quick release of FFA (>70% within the first hour of reaction) except, of course, that of [22:1(13a)]<sub>3</sub>.

The total amount of DG for each reaction was also determined, and the results are shown in Figures 3A–H. The amount of DG isolated in all cases was less than 30% yield after 45 h. Lipases CCL, Lipolase, and Novozyme showed the lowest levels of DG (<10% after 5 h of contact time with the lipases), whereas PPL showed the highest level (>15% within 25 h). The amount of DG containing 18:1(9a) was comparatively high when [18:1(9a)]<sub>3</sub> was hydrolyzed in the presence of lipases A-12 and PPL.

In the case of PS-D, the amount of DG containing 18:1(6a) was significantly high. This result could be predicted from the low amount of FFA, 18:1(6a), isolated, as discussed above (see Fig. 2E). It could therefore be concluded that PS-D had experienced difficulty in hydrolyzing the DG intermediate containing 18:1(6a) acyl groups.

Figures 4A–H shows the amounts of MG isolated from these reactions. Reactions with Lipase A-12 and PPL showed relatively high amounts of MG (1.5–7%) after 25 h of reaction time. In the case of PS-D and Lipozyme, the 18:1(6a)

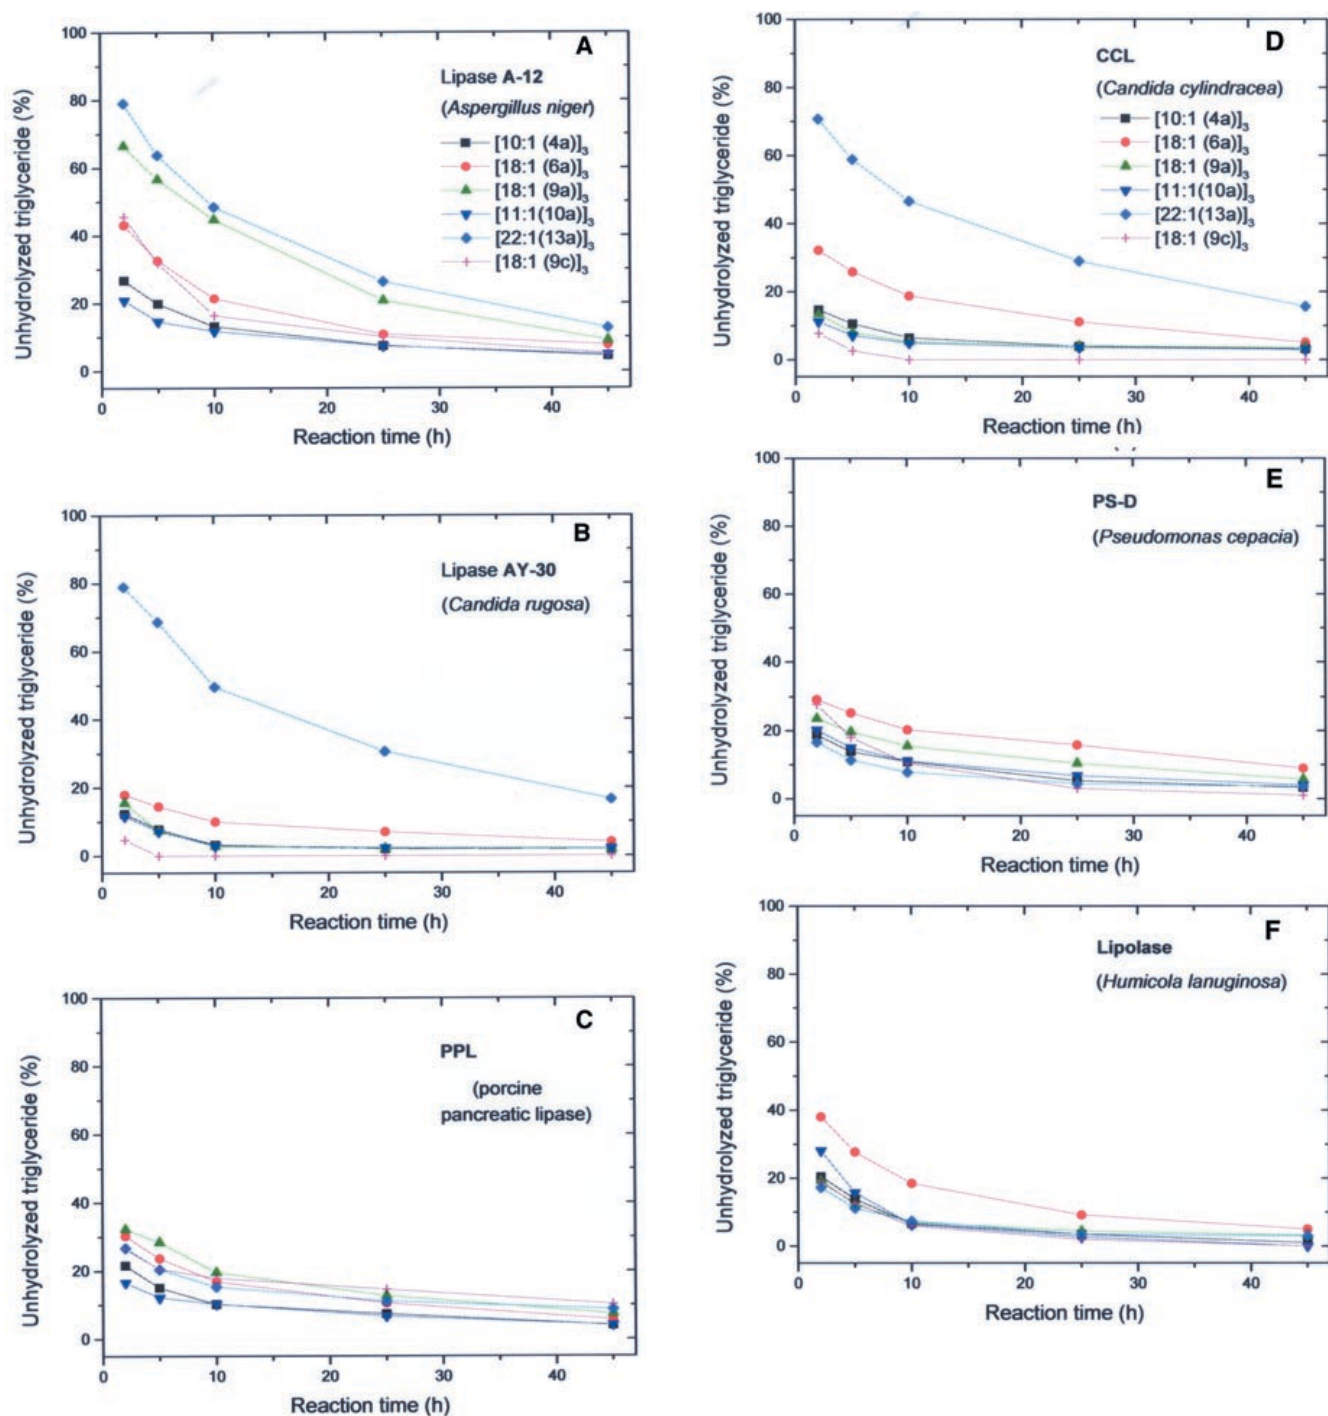

FIG. 1. Amount of unhydrolyzed TG in the hydrolysis of acetylenic TG.

MG was the highest (about 4%). The lowest amount of MG was found in the case of CCL and AY-30.

In the study of these symmetrical acetylenic TG of type AAA, lipase A-12, AY-30, and CCL were the least effective biocatalysts in the hydrolysis of  $[22:1(13a)]_3$ . Also, these three lipases exhibited different rates of hydrolysis between  $[18:1(6a)]_3$  and  $[18:1(9a)]_3$ , which are substrates containing positional isomers of  $C_{18}$  acetylenic FA. To reconfirm these observations, it was decided to prepare three regioisomeric

mixed acetylenic TG of type ABC, namely, compounds **1**, **2**, and **3**, by stepwise esterification of each acetylenic acid to glycerol. Lipase AY-30 and CCL were then used to study the hydrolysis of these three mixed acetylenic TG of type ABC.

When the mixed acetylenic TG **1**  $[18:1(9a)/22:1(13a)/18:1(6a)]$  was subjected to hydrolysis with either CCL or AY-30 for 5 h, the FFA produced from the reaction in the presence of CCL were isolated, methylated, and analyzed by GC. When CCL was used as the biocatalyst, GC analysis

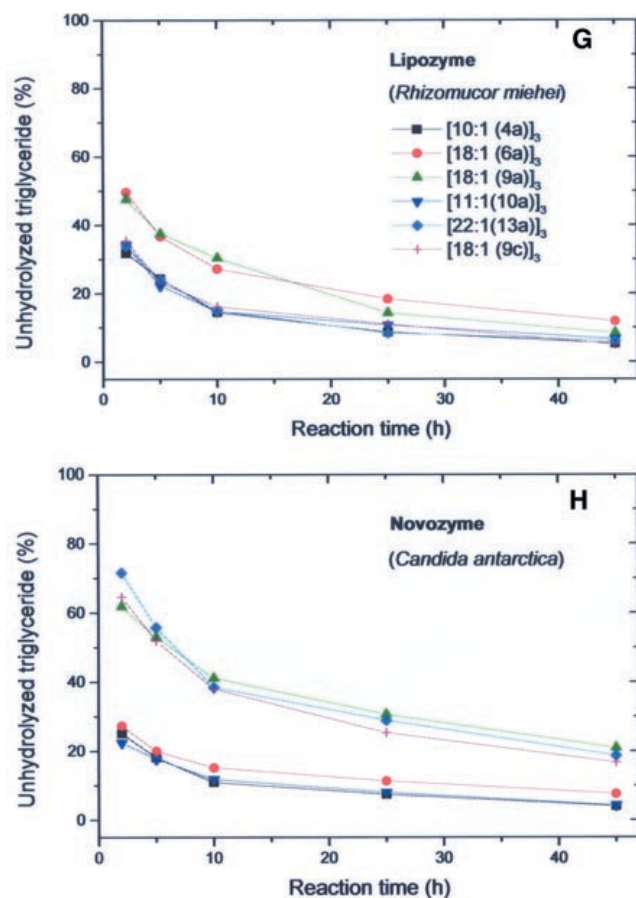

FIG. 1. Continued

showed a ratio of the combined amount of methyl esters of 18:1(9a) and 18:1(6a) (the peaks of these two component overlapped) to 22:1(13a) as 7:2. In the case where AY-30 was used as the biocatalyst, the ratio of the combined amount of methyl esters of 18:1(9a) and 18:1(6a) (GC peaks overlapped) to 22:1(13a) was 4:1. The ratios of these FFA were supported by  $^{13}\text{C}$  NMR spectroscopic analysis. The ratio of  $\Delta^6/\Delta^9/\Delta^{13}$  free acetylenic acids was 6:7:4 when CCL was used as the biocatalyst, and 3:4:2 with AY-30. This was found by comparing the intensities of C-1 signals of the corresponding acids (180.32/180.60/180.65,  $\Delta^6/\Delta^9/\Delta^{13}$ , respectively) in the  $^{13}\text{C}$  NMR spectra (27).

Thus, with the 22:1(13a) acylated to the  $\beta$ -position of the TG, the amount of free 22:1(13a) acid released was about onefold lower than either of the other two acetylenic FA. It was also found that the DG intermediates contained a comparatively larger amount (50%) of 22:1(13a) acid than that of 18:1(6a) and 18:1(9a) acid isomers combined. These results indicated that a comparatively large amount of 22:1(13a) remained unhydrolyzed on the glycerol backbone after 5 h.

When similar hydrolysis experiments were conducted on 18:1(9a)/18:1(6a)/22:1(13a) (**2**) in the presence of AY-30 and CCL, the relative ratio of FFA isolated for 18:1(6a)/18:1(9a)/22:1(13a) was 4:5:3 with CCL and 7:9:5 with AY-30. This result again showed that even though 22:1(13a) was acylated to the  $\alpha$ -position of the glycerol backbone, the amount of free

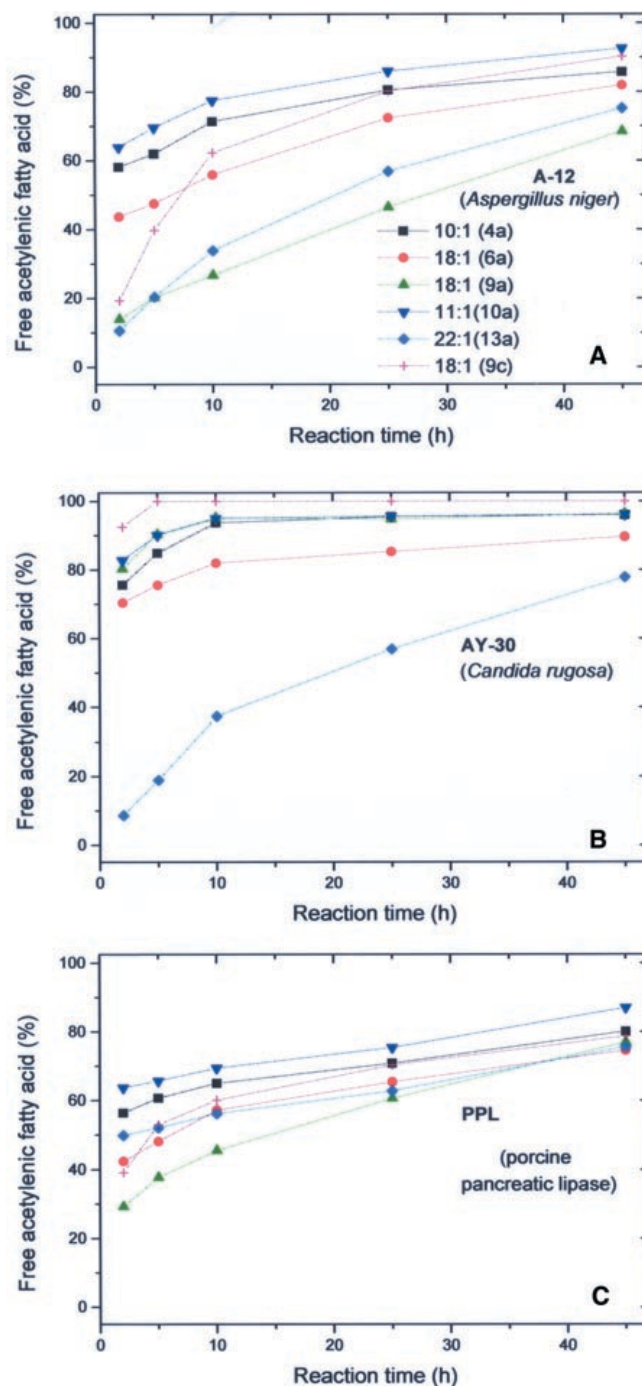

FIG. 2. Yield of released FFA in the hydrolysis of acetylenic TG.

22:1(13a) acid released was 0.3–0.8-fold lower than either one of the other two acetylenic FA [i.e., 18:1(6a) or 18:1(9a)]. The results of the hydrolysis of compound **2** [18:1(9a)/18:1(6a)/22:1(13a)] again demonstrated that lipases AY-30 and CCL were able to distinguish the 22:1(13a) acyl group. Similar observation was found in the case of the hydrolysis of 18:1(6a)/18:1(9a)/22:1(13a) (**3**). In the presence of CCL and AY-30, the relative ratio of FFA isolated from 18:1(6a)/18:1(9a)/22:1(13a) was 5:7:4 with CCL and 3:4:2 with AY-30 as the biocatalyst. Therefore, TG containing a 22:1(13a)

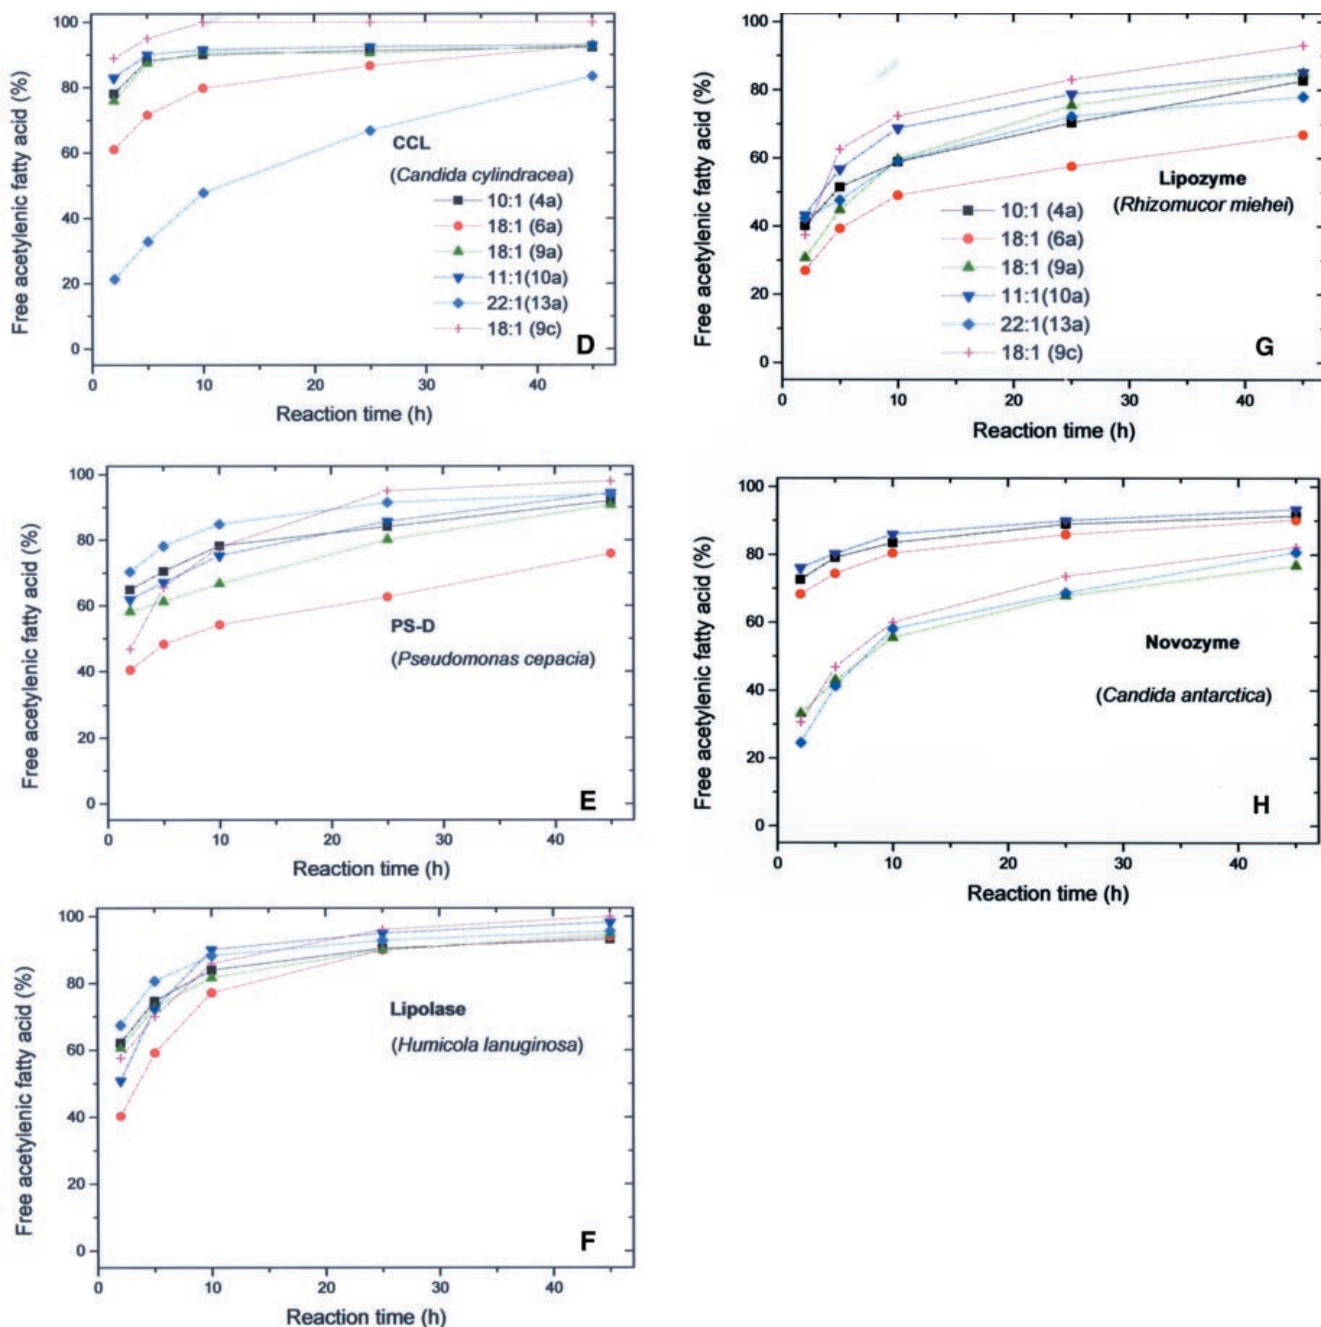

FIG. 2. Continued

acid inhibit the hydrolytic activities of CCL (*C. cylindracea*) and AY-30 (*C. rugosa*). McNeill and Sonnet (29) also reported the discrimination toward 22:1(13c) (erucic acid) in rapeseed oil by *C. rugosa* lipase (AY-30).

From these experiments it was found that some of these lipases could to some degree recognize the acyl groups of the acetylenic TG according to the position of the acetylenic bond in the acyl chains. Lipase A-12 was slow in hydrolyzing the [22:1(13a)]<sub>3</sub> and [18:1(9a)]<sub>3</sub> substrates, as compared to other symmetric TG in this study. Lipase AY-30 and CCL showed a significant resistance toward [22:1(13a)]<sub>3</sub>. The catalytic activities of PS-D and Lipozyme were also decreased in the hydrolysis of [18:1(6a)]<sub>3</sub>.

Novozyme was an efficient enzyme for esterification, but was not so efficient as many of the other lipases used in the hydrolysis of TG. Of the eight lipases studied, Lipolase appeared to be the most efficient lipase for hydrolysis. The application of this work can lead to the production of a vast range of lipid intermediates (MG, DG, and FFA) for the cosmetic, therapeutic, and nutrition industries.

# Ozonation of PC in Ethanol: Separation and Identification of a Novel Ethoxyhydroperoxide

Misako Tagiri-Endo, Kaori Ono, Kiyotaka Nakagawa,  
Mari Yotsu-Yamashita, and Teruo Miyazawa\*

Food & Biodynamic Chemistry Laboratory, Graduate School of Life Science and Agriculture, Tohoku University, Sendai, Japan

**ABSTRACT:** The product of the ozonolysis of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine in ethanol-containing solvent was analyzed by chemiluminescence detection–HPLC with on-line electrospray MS, and characterized on the basis of NMR spectroscopy and MS in high-resolution fast atom bombardment mode. The reaction yielded a large amount of a novel ethoxyhydroperoxide compound [1-palmitoyl-2-(9-ethoxy-9-hydroperoxynonyl)-*sn*-glycero-3-phosphocholine]. In addition to a structural analysis, we speculate on the reaction pathway and discuss the possibility of ethoxyhydroperoxide as a potentially reactive ozonized lipid in food and biological materials.

Paper no. L9108 in *Lipids* 37, 1007–1012 (October 2002).

Ozone, one of the most powerful oxidants in polluted air, reacts with most organic compounds (1). Exposure of animals and humans to ozone causes lung injury, including increased epithelial macromolecular permeability and neutrophil infiltration (2,3). In addition, cell leakage and lysis are observed in bacteria such as *Escherichia coli* after ozone exposure (4). Owing to its high oxidative power, it is frequently applied to the disinfection, deodorization, and bleaching of foods, water, and air (5).

Since unsaturated lipids (i.e., phospholipid and cholesterol) are expected to be important targets of ozone in lung lining fluids, cell membranes, and foods, the reaction of ozone with lipids has been studied in detail (6–11). In the case of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), the ozonation of unsaturated FA (oleoyl moiety) of POPC gives an unstable 1,2,3-trioxolane (Fig. 1). The compound rapidly decomposes to give both carbonyl oxide and aldehyde (12,13). These two species (carbonyl oxide and aldehyde) recombine to give the Criegee ozonide in nonparticipating organic solvents (12). In the presence of H<sub>2</sub>O, however, the

H<sub>2</sub>O can readily react with carbonyl oxide to form an unstable hydroxyhydroperoxide. Elimination of H<sub>2</sub>O<sub>2</sub> from the hydroxyhydroperoxide yields an aldehyde-containing PC. Oxidation of the aldehyde by ozone gives a carboxylic acid-containing PC as a final product (13) (Fig. 1). Therefore, the selection of solvent might have a significant impact on the mechanism of the reaction of ozone with POPC.

According to an early study (14), Heath and Tappel studied the reaction of ozone with linoleic acid in the presence of ethanol. They found that ozone reacts with linoleic acid to give an “organic hydroperoxide” in ethanol. This compound is presumably the ethanol adduct of the carbonyl oxide; that is, the ethoxyhydroperoxide molecule [HOO–CH(OC<sub>2</sub>H<sub>5</sub>)–(CH<sub>2</sub>)<sub>7</sub>–COOH]. However, the ozonation products from POPC in the presence of alcohol have never been investigated. It seemed logical to anticipate that POPC could react with ozone in the presence of ethanol to yield the ethoxyhydroperoxide-containing PC. The compound might be a new toxic molecule arising during ozone exposure because it possesses a reactive hydroperoxide group.

Previously, we developed a chemiluminescence (CL) detection–HPLC method for sensitive and selective determination of organic hydroperoxides present in food models and biological samples (15,16). Using this method, hydroperoxidation of various kinds of molecules, such as phospholipids (15,16), TAG (17),  $\alpha$ -tocopherol (18), squalene (19), and cholesterol (20), has been demonstrated. The application of an effective CL–HPLC assay would help to understand lipid ozonation reactions in foods and biological tissues. Hence, in the present study, we investigated the structures of the ozonation products of POPC, focusing especially on ethoxyhydroperoxide-containing PC formation in the presence of ethanol using our CL–HPLC with on-line MS.

## EXPERIMENTAL PROCEDURES

**Materials.** POPC and soybean phosphatidylcholine (soyPC) were purchased from Funakoshi (Tokyo, Japan). Other reagents and solvents were of the highest grade available.

**Ozone exposure.** POPC (5  $\mu$ mol) was dissolved in 3 mL of ethanol/hexane (1:9, vol/vol). An EO-301 Okano Works ozonator was used for generating a 1.3% ozone-in-oxygen stream. POPC solution was bubbled at a flow rate of 100 mL/min for 3 min under ice-cold conditions (12,13). After ozonation, the reaction mixture was dried and redissolved in

**FIG. 1.** Chemical reaction of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) with ozone. PC-ald, 1-palmitoyl-2-(9-oxononanoyl)-*sn*-glycero-3-phosphocholine; PC-acid, 1-palmitoyl-2-(9-carboxynonanoyl)-*sn*-glycero-3-phosphocholine.

300  $\mu$ L of methanol. An aliquot portion (10  $\mu$ L) was subjected to CL-HPLC with on-line MS (HPLC-CL-MS). The principal ozonation products (retention times of 25 and 27 min in HPLC-CL-MS) were isolated and their chemical structures determined as described below.

In studies aimed at assigning the mechanism of product formation, the following procedure was adopted: POPC or soyPC (5  $\mu$ mol each) was dissolved in hexane containing different amounts of ethanol (0–60%, vol/vol), and treated with ozone gas for various lengths of time (0–10 min). Following the reactions, the yields of ozonized lipids were determined by HPLC-CL-MS.

**HPLC analysis.** For the HPLC-CL-MS system, an ODS column (TSKgel ODS-80Ts, 4.6  $\times$  250 mm; Tosoh, Tokyo, Japan) was used. The column was eluted using a binary gradient consisting of the following HPLC solvents: A,

methanol/water (1:1), and B, methanol. The gradient profile was as follows: 0–15 min, 70% B; 15–25 min, 70–98% B linear; 25–28 min, 98–100% B linear; 28–40 min, 100% B. The flow rate was adjusted to 1 mL/min and the column temperature was maintained at 36°C. At the column exit, the eluant was split. One of the split eluants (flow rate, 0.9 mL/min) was subsequently mixed with a hydroperoxide-specific CL cocktail (a mixture of luminol and cytochrome C in 50 mM borate buffer; pH 10) (15,16) and sent to a JASCO 825CL detector (Japan Spectroscopic Co., Tokyo, Japan). The flow rate of the CL cocktail was 1 mL/min. The other split column eluant (flow rate, 0.1 mL/min) was sent to a Mariner electrospray ionization time-of-flight mass spectrometer (PerSeptive Biosystems, Framingham, MA). MS was carried out in the positive ion measurement mode with a spray voltage of 1900 V, a nozzle potential of 150 V, and a nozzle temperature of 150°C. The flow rate

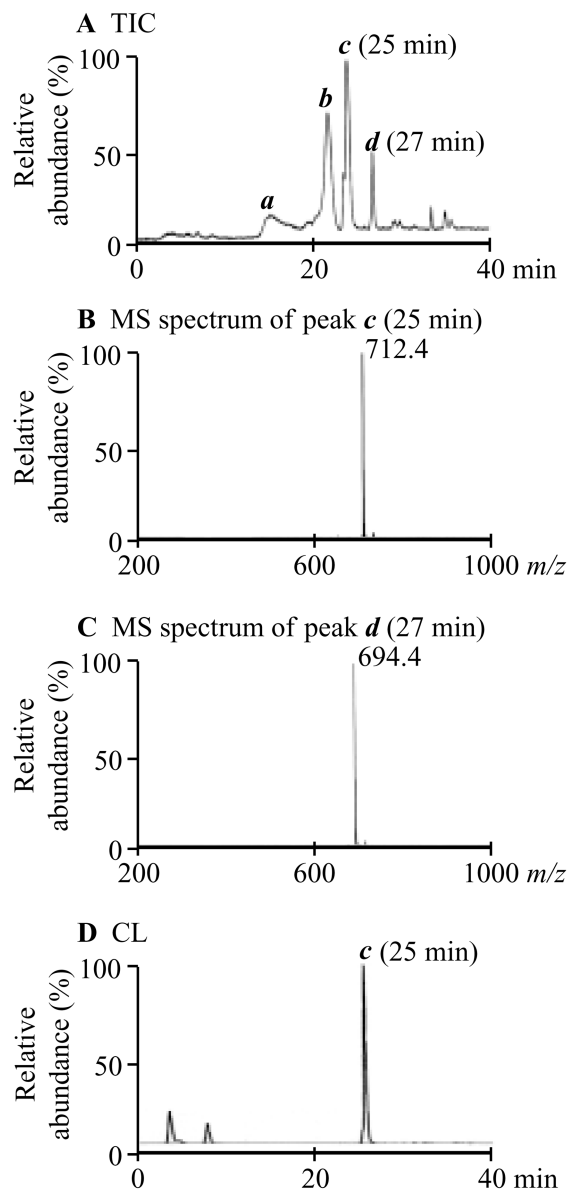

of nebulizer gas was 0.3 mL/min. Full-scan spectra were obtained by scanning masses between  $m/z$  range 200–1000.

**Identification procedures.** The accurate mass for the isolated ozonation product was determined by a JEOL-JMS-700 mass station (JEOL, Tokyo, Japan) in high-resolution fast atom bombardment mode (HRFAB). HRFAB-MS measurements were performed in the positive mode with glycerol as matrix.  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra were measured on a Varian Unity 600 spectrometer at 600 MHz for  $^1\text{H}$  NMR and at 150 MHz for  $^{13}\text{C}$  NMR, respectively, using  $\text{CDCl}_3$  as the solvent.

## RESULTS AND DISCUSSION

Figure 2A shows the typical total ion current (TIC) chromatogram when ozone gas-exposed POPC in ethanol/hexane (1:9) was subjected to HPLC-CL-MS. After only 3 min of ozonation, POPC itself was completely decomposed, and the peak components *a-d* ascribed to ozonation products appeared in the TIC chromatogram (Fig. 2A). Of these peaks, peaks *a* (retention time = 16 min) and *b* (22 min) gave molecular ions  $[\text{M} + \text{H}]^+$  at  $m/z$  666.5 and 650.5, which were identical to the well-known ozonolysis products PC-acid [1-palmitoyl-2-(9-carboxynonanoyl)-*sn*-glycero-3-phosphocholine] and PC-ald [1-palmitoyl-2-(9-oxononanoyl)-*sn*-glycero-3-phosphocholine], respectively (Fig. 1) (13). Of the other known products of ozonized POPC, the Criegee ozonide (12,21) was at trace level and the hydroxyhydroperoxide (13) could not be detected under the present experimental conditions. On the other hand, the peak components *c* (25 min) and *d* (27 min) showed molecular ions at  $m/z$  712.4 and 694.4 (Figs. 2B and C), respectively, although these components have not yet been characterized. Component *c* gave an intense CL peak (25 min) in the CL chromatogram (Fig. 2D), whereas peak *d* did not react with the CL cocktail (data not shown). The MS spectra (Figs. 2B and C) and CL properties (Fig. 2D) of peak *c* suggest that it might possess a hydroperoxy group in the molecule.

Next, to determine the chemical structures of peaks *c* and *d*, these components were isolated by HPLC (see the Experimental Procedures section), and their structures were determined by spectroscopic procedures. Peak *c*: HRFAB-MS (glycerol)  $[\text{M} + \text{H}]^+$   $m/z$  712.4767 (calcd. for  $[\text{C}_{35}\text{H}_{71}\text{N}_1\text{O}_{11}\text{P}_1]^+$   $m/z$  712.4686). Further NMR measurements, i.e., COSY, heteronuclear single-quantum coherence (HSQC) and heteronuclear multiple bond correlation (HMBC) ( $J = 8$  Hz), enabled us to identify component *c* as 1-palmitoyl-2-(9-ethoxy-9-hydroperoxynonanoyl)-*sn*-glycero-3-phosphocholine (PC-EHP, Fig. 3A). The presence of the  $\text{CH}(\text{OOH})\text{OCH}_2\text{CH}_3$  fragment in this molecule is supported by the HMBC between  $\text{H}_a$  and  $\text{C}_{e1}$ . NMR data are listed below:  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ): 0.85 (*t*, 3H,  $\text{H}_w$ ), 1.18 (*t*, 3H,  $\text{H}_{e2}$ ), 1.25–1.30 (*m*, 32H,  $\text{H}_v$ ), 1.48–1.60 (*m*, 6H,  $\text{H}_\alpha$ ,  $\text{H}_\beta$ ), 2.20–2.30 (*m*, 4H,  $\text{H}_\alpha$ ), 3.35 (*s*, 9H,  $\text{H}_m$ ), 3.55 (*m*, 1H,  $\text{H}_{e1}$ ), 3.87 (*m*, 1H,  $\text{H}_{e1}$ ), 3.90 (*m*, 2H,  $\text{H}_{c1}$ ), 4.00 (*m*, 2H,  $\text{H}_{g3}$ ), 4.08 (*m*, 1H,  $\text{H}_{g1}$ ), 4.28 (*m*, 1H,  $\text{H}_{g1}$ ), 4.37 (*m*, 2H,  $\text{H}_{c2}$ ), 4.75 (*m*, 1H,  $\text{H}_a$ ), 5.18 (*m*, 1H,  $\text{H}_{g2}$ ) ppm.  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ): 13.5 ( $\text{C}_w$ ), 14.1 ( $\text{C}_{e2}$ ), 24.3 ( $\text{C}_\alpha$ ,  $\text{C}_\beta$ ), 28.4–29.1 ( $\text{C}_v$ ), 33.5 ( $\text{C}_\alpha$ ), 54.2 ( $\text{C}_m$ ), 60.0 ( $\text{C}_{c2}$ ), 62.2 ( $\text{C}_{g1}$ ), 64.1 ( $\text{C}_{g3}$ ), 64.8 ( $\text{C}_{e1}$ ), 65.7 ( $\text{C}_{c1}$ ), 69.8 ( $\text{C}_{g2}$ ), 107.5 ( $\text{C}_a$ ) ppm.

**FIG. 2.** Ozonation products of POPC in ethanol. POPC (5  $\mu\text{mol}$ ) in ethanol/hexane (1:9) was exposed to ozone gas for 3 min and analyzed by HPLC-chemiluminescence (CL)-MS. A, total ion current (TIC) chromatogram; B, mass spectrum of the peak *c* component (25 min) in chromatogram A; C, mass spectrum of the peak *d* component (27 min) in chromatogram A; D, CL chromatogram. For other abbreviation see Figure 1.

The chemical shifts of  $^{13}\text{C}$  signals were determined by the cross-peaks in HSQC and HMBC spectra. This isolated PC-EHP was used as a reference standard in later experiments. On the other hand, peak *d* was tentatively determined as 1-palmitoyl-2-(9-carbethoxynonanoyl)-*sn*-glycero-3-phosphocholine (PC-CE, Fig. 3B) based on MS data; HRFAB-MS,  $[\text{M} + \text{H}]^+$   $m/z$  694.4662 (calcd. for  $[\text{C}_{35}\text{H}_{69}\text{N}_1\text{O}_{10}\text{P}_1]^+$   $m/z$  694.4581). NMR measurement of PC-CE could not be carried out in the present study owing to the insufficient amount of isolated PC-CE.

To help assign pathways for PC-EHP and PC-CE formation in ethanol, POPC was dissolved in hexane containing different amounts of ethanol (0–60%) and then treated with

**FIG. 3.** A, Chemical structure of peak **c**: 1-palmitoyl-2-(9-ethoxy-9-hydroperoxynonyl)-*sn*-glycero-3-phosphocholine (PC-EHP). The arrow shows the heteronuclear multiple bond correlation (HMBC) between  $H_a$  and  $C_{e1}$ . The other HMBC are not shown. B, proposed structure of peak **d**: 1-palmitoyl-2-(9-carbethoxynonyl)-*sn*-glycero-3-phosphocholine (PC-CE).

ozone for 3 min. Neither PC-EHP nor PC-CE was formed in the absence of ethanol (Fig. 4). Hence, these components would appear to be principal products during ozonation in the presence of alcohol. The PC-EHP yield showed a maximum when POPC in ethanol/hexane (6:4) was treated with ozone. In contrast, the yield of PC-CE was at a maximum when exposing POPC in ethanol/hexane (1:9) to ozone gas (Fig. 4). When isolated PC-EHP was incubated in ethanol-free solvent (i.e., chloroform, hexane, and methanol), PC-EHP did not decompose (data not shown). This implied that PC-EHP is a stable compound and that PC-CE could not be formed *via* PC-EHP. Based on these findings, two possible pathways for POPC ozonation in ethanol can be envisaged (Figs. 5A and B). In the first, ethanol reacts with the carbonyl oxide to form PC-EHP (Fig. 5A). In the second, the Criegee ozonide and/or 1,2,3-trioxolane reacts with ethanol to form PC-EHP, PC-ald, the short-chain aldehyde [ $\text{CH}_3-(\text{CH}_2)_7-\text{CHO}$ ], and an ethoxyhydroperoxide molecule [ $\text{HOO}-\text{CH}(\text{OC}_2\text{H}_5)-(\text{CH}_2)_7-\text{CH}_3$ ] (Fig. 5B). PC-ald in the presence of ethanol may be in equilibrium with its ethyl hemiacetal. This compound can be transformed into PC-CE by a simple oxidation step (Fig. 5B).

Figure 6 shows the time course of changes in the yields of ozonation products when POPC in ethanol/hexane (1:9) was exposed to ozone for 0–10 min. Interestingly, POPC itself was rapidly degraded during ozonation, but considerable amounts of PC-ald, PC-EHP, and PC-CE were formed and remained in the reaction mixture even after 10 min of ozone exposure. Hence, these products (PC-ald, PC-EHP, and PC-CE) might be useful marker molecules for ozone exposure.

For food sterilization, the use of a combination of different disinfection procedures (i.e., treatment of ozone together with alcohol or UV light) was recently recommended to enhance

the bactericidal effect (22,23). If one is applying the  $\text{O}_3$ /ethanol treatment for food disinfection, PC-EHP may be formed from food phospholipids, influencing the quality, taste, and flavor of food. To assess such a possibility, we tested the frequently used food extender soyPC. Figure 7 shows a typical CL chromatogram when soyPC (5  $\mu\text{mol}$ ) in 3 mL of ethanol/hexane (1:9) was exposed to ozone gas for 3 min. Molecular species of PC-EHP, having palmitoyl (16:0-PC-EHP) or oleoyl (18:0-PC-EHP) residues at the *sn*-1 position of the glyce-

**FIG. 4.** The yields of PC-EHP and PC-CE during ozonation of POPC in ethanol. POPC was dissolved in hexane containing different amounts of ethanol (0–60%) and then treated with ozone for 3 min. After the reaction, the samples were analyzed by HPLC–CL–MS. Values are mean  $\pm$  SD ( $n = 4$ ). For other abbreviations see Figures 2 and 3.

**FIG. 5.** Proposed pathway for the formation of PC-EHP and PC-CE during ozonation of POPC in ethanol. For abbreviations see Figures 1–3.

erol moiety, were detected in the CL chromatogram. Ethoxyhydroperoxide concentrations were determined as 0.21  $\mu\text{mol}$  for 16:0-PC-EHP and 0.11  $\mu\text{mol}$  18:0-PC-EHP/3 mL of total reaction mixture using a calibration curve generated from standard PC-EHP. This means that 6.4 mol% of soyPC is converted to the ethoxyhydroperoxide products during only 3 min of ozonation. Such high hydroperoxidation values will impair the nutritive value of soy products.

When POPC was exposed to ozone gas in the presence of ethanol, the formation of an ethoxyhydroperoxide derivative (PC-EHP) could be confirmed. The present HPLC–CL–MS system is an effective method for the structural elucidation of ozonized phospholipids. In addition, CL measurement allows

the selective and sensitive determination of PC-EHP. Applying the present method to the ozonation of soyPC in ethanol, we succeeded in detecting a large amount of PC-EHP. We anticipate that the compound may be useful as a new specific marker molecule for detecting exposure of food lipids to ozone.

**ABSTRACT:** Racemic 1,4-dihydroxynonane mercapturic acid (DHN-MA) and 9,9,9-trideutero-1,4-dihydroxynonane mercapturic acid ( $d_3$ -DHN-MA) are synthesized on a 400-mg scale (overall yield ~40%) by a two-step sequence involving Michael addition of *N*-acetyl-L-cysteine to methyl 4-hydroxynon-2(*E*)-enoate or methyl 9,9,9-trideutero-4-hydroxynon-2(*E*)-enoate, followed by reduction of the intermediate adducts with lithium borohydride. The requisite starting methyl esters are obtained, respectively, from heptanal or 7,7,7-trideuteroheptanal and methyl 4-chlorophenylsulfanylacetate *via* a sulfoxide piperidine and carbonyl reaction described in the literature. The 7,7,7-trideuteroheptanal is easily prepared by classical methods in four steps from 6-bromo-1-hexanol. <sup>13</sup>C NMR data indicate that DHN-MA as well as  $d_3$ -DHN-MA are obtained as mixtures of four diastereomers. Preliminary results show that  $d_3$ -DHN-MA could be used as an internal standard for mass spectrometric quantification of DHN-MA in human urine.

Paper no. L9123 in *Lipids* 37, 1013–1018 (October 2002).

Despite much investigation, the quantitative evaluation of oxidative stress remains a difficult task for biologists. Lipoperoxidation, one of the main consequences of oxidative stress, yields numerous cytotoxic and mutagenic aldehydes, of which malondialdehyde and 4-hydroxy-2(*E*)-nonenal (4-HNE) have been the most extensively studied (1–3). Lipoperoxidation is often estimated by the TBARS method, which is rather unspecific (4). Recently, the cell-detoxifying process of 4-HNE was discovered to result from at least three different routes. From a quantitative viewpoint, in rats and humans, its conjugation to glutathione seems the most important, and its main final product is urinary dihydroxynonane-mercapturic acid (DHN-MA) (5–8). Thus, DHN-MA may be a good candidate as a noninvasive biomarker of oxidative stress. Therefore, the preparation of a deuterium-labeled DHN-MA derivative that can be used as an internal standard for mass spectrometric quantification of DHN-MA in urine is needed. The objective of the present note is to report an improved synthesis of DHN-MA, its application to the preparation of stable 9,9,9-trideutero-1,4-dihydroxynonane mercapturic acid ( $d_3$ -DHN-MA), and preliminary re-

sults on the utilization of this trideuterated compound to quantify DHN-MA in human urine.

## EXPERIMENTAL PROCEDURES

**Materials and methods.** All reagents of analytical reagent grade were purchased from Sigma Aldrich (L'Isle d'Abeau, France) and used without further purification. Methyl 4-chlorophenylsulfanylacetate was prepared from 4-chlorothiophenol and methyl chloroacetate following a described procedure (9). THF was distilled from sodium/benzophenone ketyl and dichloromethane from phosphorus pentoxide immediately before use. Flash chromatographies were performed using Merck Silica Gel 60 (40–63  $\mu$ m), and TLC separations were carried out using Merck Kieselgel 60 F254 plates (Merck S.A., Chelles, France). IR spectra were recorded on a PerkinElmer 1310 IR spectrophotometer; the abbreviation for shoulder is sh. NMR spectra were recorded on a Bruker AC200 instrument (200/50 MHz) and for specified cases on a Bruker DRX-500 (500/125 MHz). Splitting pattern abbreviations are *s*, singlet; *d*, doublet; *t*, triplet; *p*, pentuplet; *m*, multiplet; and *app*, apparent. Multiplicity (<sup>13</sup>C NMR) was determined by distortionless enhancement by polarization transfer sequences. High-resolution negative ion fast atom bombardment MS (HR-NI-FABMS) was performed by Centre de Spectrométrie de Masse (Université Claude Bernard-Lyon 1, Villeurbanne, France).

**Synthetic procedures.** (i) *Methyl 4-hydroxynon-2(E)-enoate (2a) and methyl 9,9,9-trideutero-4-hydroxynon-2(E)-enoate (2b).* To a solution of 4 g (17.2 mmol) of methyl 4-chlorophenylsulfanylacetate (9) in 40 mL of acetonitrile was added 2.4 mL (24 mmol) of piperidine followed by dropwise addition of 2.5 g of heptanal **1a** (21.9 mmol) or 7,7,7-trideuteroheptanal **1b** (21.3 mmol). The reaction mixture was stirred overnight at room temperature and then evaporated *in vacuo*. The residue was purified by flash chromatography on silica gel (150 g; dichloromethane/diethyl ether, 90:10 vol/vol) to afford the ester **2a** or **2b** contaminated with residual methyl 4-chlorophenylsulfanylacetate. A second flash chromatography on silica gel (150 g; diethyl ether) afforded 2.16 g (67%) of pure ester **2a** or 2.32 g (71%) of pure ester **2b** as yellowish oils. **Ester 2a:** The NMR spectra were in accordance with literature data (9). **Ester 2b:** IR: (neat)  $\nu$  (cm<sup>-1</sup>): 3450 (OH); 2220, 2115, 2080 (CD); 1730, 1715 sh (CO); 1615 (C=C). <sup>1</sup>H NMR:

Abbreviations: DHN-MA, 1,4-dihydroxynonane mercapturic acid; 4-HNE, 4-hydroxy-2(*E*)-nonenal; HR, high-resolution; NI-FABMS, negative ion fast atom bombardment MS; PCC, pyridinium chlorochromate.

(CDCl<sub>3</sub>)  $\delta$ : 1.15–1.50 (6H, *m*); 1.50–1.80 (2H, *m*); 2.17 (1H, *d*,  $J = 3$  Hz); 3.73 (3H, *s*); 4.29 (1H, *m*); 6.02 (1H, *dd*,  $J = 15.7$ ,  $J = 1.6$  Hz); 6.95 (1H, *dd*,  $J = 15.7$ ,  $J = 4.9$  Hz). <sup>13</sup>C NMR: (CDCl<sub>3</sub>)  $\delta$ : 13.12 (app. *p*, C-9, <sup>1</sup> $J_{CD} = 18.8$  Hz); 22.30 (C-8); 24.95 (C-6); 31.62 (C-7); 36.64 (C-5); 51.64 (C-10); 71.06 (C-4); 119.58 (C-2); 150.92 (C-3); 167.21 (C-1).

(ii) *Michael addition of N-acetyl-L-cysteine to esters 2a,b*. To a solution of 0.85 g of ester **2a** (4.56 mmol) or ester **2b** (4.49 mmol) in methanol (20 mL) were added 665 mg (4 mmol) of *N*-acetyl-L-cysteine and 1.26 mL (9 mmol) of triethylamine. The reaction mixture was stirred under a nitrogen atmosphere at room temperature for 3 d. The solvent was evaporated *in vacuo* and the crude product was purified by flash chromatography on silica gel (170 g; chloroform/methanol/acetic acid, 10:3:0.5 by vol) to afford a mixture of diastereomeric ester **3** and diastereomeric lactone **4** as a sticky oil contaminated with residual acetic acid. A second flash chromatography on silica gel (140 g; chloroform/methanol/ether, 10:6:1 by vol) gave 1.33 g (~73%) of a **3a/4a** mixture or 1.20 g (~83%) of a **3b/4b** mixture as white solid foams. The **3a/4a** or **3b/4b** ratios were determined to be about 1:2 by <sup>1</sup>H NMR (see Results and Discussion section below). **3a/4a** mixture: IR (CHCl<sub>3</sub>)  $\nu$  (cm<sup>-1</sup>): 3600–2400 (OH, NH); 1770 (CO lactone); 1715 (CO ester and acid); 1660 (CO amide). <sup>1</sup>H NMR (500 MHz, CD<sub>3</sub>OD)  $\delta$ : 0.90 (3H, *t*); 1.10–1.90 (8H, *m*); 2.10 and 2.15 (3H, 2*s*); 2.45–2.80 (1H, *m*); 2.80–3.50 (3H, *m*); 3.60–3.90 (1H, *m* with a singlet at 3.73 ppm for the methyl ester resonance of **3a**); 4.10–5.00 (2H, *m*). **3b/4b** mixture: IR (CHCl<sub>3</sub>)  $\nu$  (cm<sup>-1</sup>): 3600–2400 (OH, NH), 2220, 2115, 2080 (CD); 1775 (CO lactone); 1720 (CO ester and acid); 1660 (CO amide). <sup>1</sup>H NMR (500 MHz, CD<sub>3</sub>OD)  $\delta$ : 1.25–1.90 (8H, *m*); 2.01 and 2.06 (3H, 2*s*); 2.45–2.75 (1H, *m*); 2.75–3.50 (3H, *m*); 3.65–3.90 (1H, *m* with a singlet at 3.73 ppm for the methyl ester resonance of **3b**); 4.25–4.75 (2H, *m*).

(iii) *DHN-MA (5a) and d<sub>3</sub>-DHN-MA (5b)*. To a stirred solution of 900 mg (~2.5 mmol) of **3a/4a** or **3b/4b** mixture in anhydrous THF (20 mL) under a nitrogen atmosphere at 0°C was added lithium borohydride (150 mg, 6.89 mmol) in one portion. After 10 min at 0°C, the cooling bath was removed and the reaction mixture was stirred for 24 h at room temperature. The reaction mixture was cooled in a water-ice bath, quenched with acetic acid (~1 mL), and concentrated *in vacuo*. The residue was purified by flash chromatography on silica gel (140 g; chloroform/methanol/acetic acid, 10:3:0.5 by vol) to afford 520 mg of **5a** or 500 mg of **5b** contaminated with residual acetic acid. A second flash chromatography on silica gel (80 g; chloroform/methanol/ether, 5:4:1 by vol) gave 432 mg (~54%) of **5a** or 418 mg (~51%) of **5b** as white solid foams that slowly decomposed at about 120°C. *DHN-MA 5a*: <sup>1</sup>H NMR (500 MHz, CD<sub>3</sub>OD)  $\delta$ : 0.92 (*t*, 3H,  $J = 6.85$  Hz); 1.25–1.40 (5H, *m*); 1.40–1.70 (4H, *m*); 1.82–1.92 (1H, *m*); 2.02 (3H, *s*; three peaks were observed by enlargement of this signal); 2.82–3.32 (3H, *m*); 3.62–3.85 (3H, *m*); 4.35–4.50 (1H, *m*). <sup>13</sup>C NMR (125 MHz, CD<sub>3</sub>OD; pertinent signals)  $\delta$ : 13.58 (C-9); 21.98 (C-5'); 49.31, 49.70, 50.63 (C-3); 55.21, 55.27 (C-2'); 59.50, 59.71 (C-1); 74.16, 74.27, 74.35, 74.50 (C-4); 172.09, 172.17 (C-4');

176.58–176.70 (C-1'). HR-NI-FABMS: (M – H)<sup>-</sup>: Calculated for C<sub>14</sub>H<sub>23</sub>D<sub>3</sub>NO<sub>5</sub>S, 323.1715; found, 323.1720.

(iv) *6-Tetrahydropyran-1-bromohexane (7)*. To a stirred solution of 10 g (55 mmol) of 6-bromo-1-hexanol (**6**) in 120 mL of dichloromethane was added 6.5 mL (67 mmol) of dihydropyran in one portion, followed by 2.8 g (11 mmol) of pyridinium *p*-toluenesulfonate. After being stirred for 24 h at room temperature, the reaction mixture was washed successively with saturated aqueous sodium hydrogencarbonate (40 mL) and brine (40 mL), dried over sodium sulfate, and concentrated *in vacuo*. The residue was purified by flash chromatography on 150 g of silica gel (pentane/ethyl acetate, 95:5 vol/vol) to afford 12 g (82%) of bromide **7** as a colorless liquid (10).

(v) *7,7,7-Trideutero-1-tetrahydropyran-1-ol (8)*. To a stirred solution of 6 g (22.6 mmol) of bromide **7** in 100 mL of anhydrous THF, under a nitrogen atmosphere, was added 7 mL of a 0.1 M solution of Li<sub>2</sub>CuCl<sub>4</sub> in THF. The resulting solution was cooled in an ice-sodium chloride bath, and 25 mL of a 1 M solution of CD<sub>3</sub>MgI in diethyl ether was added dropwise. After stirring for 24 h at room temperature, the reaction mixture was quenched with saturated aqueous ammonium chloride (100 mL) and extracted with diethyl ether (3 × 40 mL). The combined extracts were washed with brine (40 mL), dried over sodium sulfate, and concentrated *in vacuo*. The residue was purified by flash chromatography on silica gel (120 g; pentane/diethyl ether, 95:5 by vol) to afford 4.1 g (89%) of **8** as a colorless liquid. IR (neat)  $\nu$  (cm<sup>-1</sup>): 2200, 2130, 2080 (CD). <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 1.20–1.45 (8H, *m*); 1.45–2.00 (8H, *m*); 3.30–3.60 (2H, *m*); 3.65–3.95 (2H, *m*); 4.85 (1H, *m*).

(vi) *7,7,7-Trideuteroheptan-1-ol (9)*. A solution of **8** (7 g, 34.4 mmol) and *p*-toluenesulfonic acid monohydrate (1 g, 5.26 mmol) in methanol (60 mL) was stirred for 36 h at room temperature. The solution was then neutralized by addition of solid sodium hydrogencarbonate (1.5 g). After evaporation of the solvent, 20 mL of dichloromethane was added and the solution was filtered and evaporated *in vacuo*. The residue was purified by flash chromatography on silica gel (120 g; pentane/diethyl ether, 80:20 by vol) to afford 3.55 g (86%) of trideuteroheptanol **9** as a colorless liquid. IR (neat)  $\nu$  (cm<sup>-1</sup>): 3340 (OH); 2220, 2130, 2080 (CD). <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 1.20–1.45 (8H, *m*); 1.45–1.65 (2H, *m*); 1.69 (1H, *s*); 3.62 (2H, *t*,  $J = 6.5$  Hz).

(vii) *7,7,7-Trideuteroheptanal (1b)*. To a stirred suspension

of pyridinium chlorochromate (PCC) (10 g, 46.4 mmol) and anhydrous sodium acetate (0.6 g, 7.3 mmol) in dichloromethane (50 mL) cooled in a water-ice bath was added 3.5 g (30.1 mmol) of alcohol **9** in one portion. The reaction mixture was stirred for 5 min at 0°C and then for 1 h at room temperature. After addition of 100 mL of diethyl ether, the resulting suspension was filtered through silica gel (60 g). The silica gel was washed with four 50-mL portions of diethyl ether. The combined organic eluates were concentrated *in vacuo*, and the residue was purified by flash chromatography on silica gel (50 g; dichloromethane) to afford 2.68 g (78%) of trideuteroheptanal **1b** as a colorless liquid. IR (neat)  $\nu$  ( $\text{cm}^{-1}$ ): 2220, 2130, 2080 (CD); 1725 (CO).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$ : 1.20–1.40 (6H, *m*); 1.55–1.75 (2H, *m*); 2.42 (2H, *td*,  $J = 7.20$ ,  $J = 1.85$  Hz); 9.77 (1H, *t*,  $J = 1.85$  Hz).

**HPLC analysis of DHN-MA 5a.** Analytical HPLC separation was performed with a Thermo Finnigan liquid chromatograph (pump P4000, injector AS 3000, and a UV/vis diode-array detector UV 6000 LP) on a  $150 \times 2$  mm Uptisphere ODB C18 cartridge (3  $\mu\text{m}$  particle size) (Interchim, Montluçon, France). The flow rate was 200  $\mu\text{L}/\text{min}$  with the cartridge kept

at 37°C and the detector set at 215 nm. The mobile phase was 10 mM ammonium acetate (final concentration) adjusted to pH 3.5 with formic acid, and 20% (vol/vol) of acetonitrile. DHN-MA (600  $\mu\text{mol}/\text{L}$ ) (10  $\mu\text{L}$  injected) was detected as a double peak at 6.6 and 6.9 min in a pattern similar to that described by Alary *et al.* (6).

**DHN-MA analysis in human urine.** Urine (100  $\mu\text{L}$ ), acidified with 10  $\mu\text{L}$  HCl (1 M) and spiked with  $d_3$ -DHN-MA, was prepared by solid-phase extraction on Oasis HLB (60 mg, Waters®) according to the manufacturer's instructions. After optimization of the washing step by using methanol/water 20:80 (vol/vol;  $2 \times 500$   $\mu\text{L}$ ), the sample was eluted with methanol, dried under vacuum, and reconstituted with 100  $\mu\text{L}$  of the mobile phase (10 mM ammonium acetate adjusted to pH 2.5 with formic acid and containing 35% vol/vol methanol). The HPLC analysis was carried out with the same device as described for HPLC analysis of DHN-MA **5a**. The sample (10  $\mu\text{L}$ ) was injected onto an Alltech (Deerfield, IL) Adsorbosphere HS C18 (150  $\times$  2 mm, 3  $\mu\text{m}$  particle size) held at 45°C, with a 200  $\mu\text{L}/\text{min}$  flow rate. Detection was with a single quadrupole mass spectrometer (Navigator Aqua, Thermo Finnigan) in electron

**FIG. 1.** Typical LC/MS chromatograms ( $[M + H]^+$ , single ion monitoring mode) of: (A, B) a human urine of a burnt patient, prepared and analyzed as described in the text, with authentic DHN-MA eluted at the retention time (RT) = 5.93 min and  $m/z = 322$  (A) and its internal  $d_3$ -DHN-MA standard recorded at RT = 5.88 min and  $m/z = 325$  (B). (C) A DHN-MA standard (140 nM) at RT = 5.96 min and  $m/z = 322$ . (D) The  $d_3$ -DHN-MA prepared like a sample and injected alone (RT = 5.94 min at  $m/z = 325$ ) to calculate the recovery for the urine sample shown in (A) and (B), i.e., around 71%. From these chromatograms it appeared that DHN-MA was present at about 102 nM in the analyzed urine sample. DHN-MA, 1,4-dihydroxynonane mercapturic acid.

spray ionization positive mode. The probe was set at 225°C and 2.5 kV with an entrance cone voltage at 10 V. Typical chromatograms recorded in single-ion monitoring mode ( $M + H$ )<sup>+</sup> at  $m/z = 322$  and  $325$  are shown in Figure 1.

## RESULTS AND DISCUSSION

DHN-MA was first synthesized by Alary *et al.* (6) on a 5-mg scale for identification purposes. Starting from 3,3-diethoxy-1-propyne and hexanal, racemic 4-HNE diethyl acetal was prepared in two steps (11,12). Hydrolysis of 4-HNE diethyl acetal to 4-HNE was followed by Michael addition of *N*-acetyl-L-cysteine and reduction of the intermediate aldehyde to DHN-MA. Alary's synthesis could be applied to the preparation of *d*<sub>3</sub>-DHN-MA starting from 9,9,9-trideutero-4-HNE since this compound has been synthesized in five steps with a total yield of about 20% (13). However, the yield of the Michael addition–reduction steps in Alary's sequence was rather low (about 15%), presumably because the reactive intermediate saturated aldehyde, formed from 4-HNE in the Michael addition reaction, could give rise to side reactions. In an attempt to improve the yield and ease of synthesis of DHN-MA, we turned our attention to methyl 4-hydroxynon-2(*E*)-enoate as the starting material, in place of 4-HNE, for the following reasons. A facile synthesis of racemic methyl 4-hydroxynon-2(*E*)-enoate **2a**, starting from heptanal **1a** and methyl 4-chlorophenylsulfanylacetate (Scheme 1) *via* a sulfoxide piperidine and carbonyl reaction, has been described by Tanikaga *et al.* (9). The utilization of an ester should minimize the side reactions in the Michael addition step. If successful, the procedure could be easily transposed to the preparation of *d*<sub>3</sub>-DHN-MA starting from 9,9,9-trideutero-4-hydroxynon-2(*E*)-enoate **2b**.

Michael addition of *N*-acetyl-L-cysteine to racemic unsaturated ester **2a** was conducted in methanol in the presence of triethylamine for 3 d and afforded an inseparable mixture of diastereomeric ester **3a** and diastereomeric lactone **4a**. The formation of **4a** was evidenced by a deficit in the integration of the methyl ester resonance in the <sup>1</sup>H NMR together with a strong absorption at 1770 cm<sup>-1</sup> in the IR spectrum. The **3a/4a** ratio was estimated to be 1:2 by <sup>1</sup>H NMR from the integrations of the methyl ester resonances centered at 3.73 ppm for **3a** and acetamido resonances between 2.10 and 2.15 ppm for (**3a** + **4a**). The **3a/4a** ratio should presumably reflect an equilibrium between ester **3a** and lactone **4a** because the Michael addition is a slow process and **4a** can reopen to **3a** by reaction with methanol. Alary *et al.* (5) also have observed the formation of lactone **4a** in the Michael addition of *N*-acetyl-L-cysteine to 4-hydroxynon-2(*E*)-enoic acid (5). Subsequent simultaneous reduction by lithium borohydride in THF (14) of the ester and lactone functionalities in the **3a/4a** mixture gave rise to DHN-MA **5a**. This sequence allowed us to prepare DHN-MA on a 400-mg scale, with a 39% yield from ester **2a** after chromatographic purification.

The procedure was then applied to the synthesis of *d*<sub>3</sub>-DHN-MA **5b** through the key trideuterated ester **2b**, which was prepared from the 7,7,7-trideuteroheptanal **1b** (Scheme 1). This aldehyde was readily obtained from 6-bromo-1-hexanol **6** (Scheme 2) by classical methods [alcohol protection as a tetrahydropyranloxy derivative (10), reaction with trideuteroethylmagnesium iodide in the presence of lithium tetrachlorocuprate (15), deprotection, and PCC oxidation (15)] in a 49% overall yield. The spectroscopic data were in full agreement with the structure of **1b**, in particular a triplet resonance at 9.77 ppm with a <sup>3</sup>*J* coupling of 1.85 Hz, which was observed

SCHEME 2

for the aldehydic proton in the  $^1\text{H}$  NMR spectrum, and absorption bands in the IR spectrum at  $2080\text{--}2220\text{ cm}^{-1}$  for the C–D bonds. The aldehyde **1b** was transformed into the key ester **2b** by following the procedure of Tanikaga *et al.* (9). The structure of **2b** was fully consistent with the IR,  $^1\text{H}$  NMR, and  $^{13}\text{C}$  NMR data. The presence of the hydroxyl group was confirmed by the band at  $3450\text{ cm}^{-1}$  in the IR spectrum together with the doublet at 2.17 ppm due to the  $^3J$  coupling between the OH and C4-*H* protons in the  $^1\text{H}$  NMR spectrum. The double bond was evidenced by the resonances at 6.02 ppm (C2-*H*) and 6.95 ppm (C3-*H*), occurring as doublets of doublets, in the  $^1\text{H}$  NMR spectrum and at 150.92 (C2) and 119.58 ppm (C3) in the  $^{13}\text{C}$  NMR spectrum. The presence of the  $\text{CD}_3$  group was indicated by the CD bands at  $2080\text{--}2220\text{ cm}^{-1}$  in the IR spectrum and a resonance at 13.12 ppm in the  $^{13}\text{C}$  NMR spectrum; this resonance was observed as a pentuplet, with a  $^1J_{\text{CD}}$  coupling of 18.8 Hz, in place of the expected septuplet, because the two smallest peaks were lost in the spectral noise. Michael addition of *N*-acetyl-L-cysteine to unsaturated ester **2b** afforded an inseparable mixture of diastereomeric ester **3b** and diastereomeric lactone **4b**. The **3b/4b** ratio was estimated to be 1:2 by  $^1\text{H}$  NMR in a similar manner as for the **3a/4a** mixture. Reduction of the **3b/4b** mixture, in a similar way as for the **3a/4a** mixture, afforded  $d_3$ -DHN-MA **5b**, on a 400-mg scale, with a 42% yield from **2b** after chromatographic purification.

Four diastereomers of DHN-MA **5a** and  $d_3$ -DHN-MA **5b** could be expected since three asymmetric carbons are present in these molecules. HPLC analysis of synthetic DHN-MA **5a** showed the presence of two partially resolved peaks in a pattern similar to that observed by Alary *et al.* (6) and consistent with the presence of at least two diastereomers. Examination of the complex NMR spectra of both **5a** and **5b** gave further insight into the diastereomeric composition. The  $^1\text{H}$  NMR spectrum of **5a** was in agreement with the data of Alary *et al.* (6). The  $^1\text{H}$  NMR spectra of **5a** and **5b** were impossible to analyze fully, but the presence of three diastereomers could be deduced from these spectra since three peaks were observed by enlargement of the acetyl group at about 2 ppm. A careful

examination of the  $^{13}\text{C}$  NMR spectra of **5a** and of **5b** showed that two peaks were observed for carbons C-1, C-1', or C-2', three peaks for carbon C-3, and four peaks for carbon C-4. The chemical shifts of these carbons (see Experimental Procedures section) are consistent with literature data for similar carbons, observed in 3-mercapto-2-butanol (for C-3 and C-4) and *N*-acetyl-L-cysteine (for C-1' and C-2') (16). In particular, the four C-4 resonances appeared at 74.16, 74.27, 74.35, and 74.50 ppm for **5a** and 74.15, 74.26, 74.39, and 74.52 ppm for **5b**. On this basis we concluded that DHN-MA **5a** and  $d_3$ -DHN-MA **5b** were obtained as mixtures of four diastereomers.

The structures of **5a** and **5b** were confirmed by NI-FABMS.  $(\text{M} - \text{H})^-$  base peaks appeared at  $m/z$  320 for **5a** and  $m/z$  323 for **5b**. Two other significant ions resulting from  $\text{C}_3$ -S and  $\text{C}_3$ -S bond cleavages were observed at  $m/z$  162 ( $\text{C}_5\text{H}_8\text{NO}_3\text{S}^-$ ) and 191 ( $\text{C}_9\text{H}_{19}\text{O}_2\text{S}^-$ ) for **5a** or at  $m/z$  162 ( $\text{C}_5\text{H}_8\text{NO}_3\text{S}^-$ ) and 194 ( $\text{C}_9\text{H}_{16}\text{D}_3\text{O}_2\text{S}^-$ ) for **5b**. Exact mass measurements of the  $(\text{M} - \text{H})^-$  ion by HR-NI-FABMS for both compounds were in perfect accordance with the expected values.

Preliminary analyses of human urine for DHN-MA were done on samples of burnt patients that were expected to have a high DHN-MA content. They are illustrated by the chromatograms recorded in single-ion monitoring mode  $(\text{M} + \text{H})^+$  at  $m/z = 322$  and  $325$  shown in Figure 1. Authentic urine DHN-MA is eluted at the same retention time as  $d_3$ -DHN-MA (chromatograms A, B), and this elution time is similar for synthetic DHN-MA standard (chromatogram C) or  $d_3$ -DHN-MA alone (chromatogram D). Our preliminary results allowed us to determine DHN-MA urine concentrations at a 100 nM level. Further refinements are needed to obtain an improved sensitivity for analyzing normal samples.

# Clinical Trial Results Support a Preference for Using CLA Preparations Enriched with Two Isomers Rather Than Four Isomers in Human Studies

Jean-Michel Gaullier\*, Grethe Berven, Henrietta Blankson, and Ola Gudmundsen

Scandinavian Clinical Research, 2027 Kjeller, Norway

**ABSTRACT:** CLA mixtures are now commercially available. They differ from each other with respect to their content of CLA isomers and their degree of purification. As a group of natural FA, CLA have been widely assumed to be safe. However, the suspected presence of both impurities and particular isomers might induce undesirable side effects. Despite this potential health risk, only a few CLA preparations have been tested under rigorous conditions for clinical efficacy and safety. Based on the limited results available, it is possible to suggest that preparations enriched in *c9,t11* and *t10,c12* isomers are preferable for human consumption compared to preparations containing four isomers, in terms both of safety and efficacy.

Paper no. L9016 in *Lipids* 37, 1019–1025 (November 2002).

The interest in CLA has developed since the 1980s when CLA was identified as a component present in fried ground beef, which exhibited anticarcinogenic properties against chemically-induced tumor formation in animal models (1). Progressively, *in vitro* and animal research have confirmed the anticarcinogenic properties of CLA in such models (2–4), and shown that CLA could be an antiatherosclerotic agent (5,6), stimulator of the immune functions (7,8), growth factor (9), and modulator of body composition in animals (10–15).

CLA refers to a mixture of linoleic acid isomers (18:2) with conjugated double bonds and not simply to a single FA. All CLA isomers are described according to the *cis* or *trans* configuration of both double bonds at any position of the carbon chain, and may be purified by silver ion-HPLC or GC with capillary columns (16). The synthesis of CLA occurs *in vivo* during the biohydrogenation of linoleic acid by rumen bacteria such as *Butyrivibrio fibrisolvens*. Incorporation of CLA into several bovine tissues renders dairy products (e.g., milk and cheese) and beef suitable as the main dietary sources of CLA for humans (17).

However, the CLA content of the human diet is far below the dose that is known to exert effects on animals. Depending on gender and diet, the average daily intake of CLA by human adults is estimated to range from 15 to 430 mg/d (18), whereas the lowest dose of CLA to obtain effects in animal

models is about 10 times higher. To provide a higher CLA intake, a number of commercial preparations containing highly purified CLA have appeared on the market. In 1997, only two companies (Natural ASA, Hovdebygda, Norway; PharmaNutrients Inc., Lake Bluff, IL) marketed CLA as a dietary supplement. Today, numerous companies are marketing CLA, claiming a variety of health benefits. The discrepancies among these preparations are huge, and all preparations may not be appropriate for human use. The marked heterogeneity and variable purity of commercial CLA preparations has already been well documented, based on state-of-the-art chemical analyses of several commercial preparations (19).

The present review will discuss the isomer content in commercial CLA products in terms of the safety and physiological effects shown in clinical studies.

*CLA preparations for humans.* Alkaline isomerization of linoleic acid (LA, *c9,c12*-18:2) is a common method used in the synthesis of mixtures of CLA isomers. The CLA concentration in the final product depends on the level of LA in the starting material. Commercial CLA preparations are usually made from sunflower oil (app. 60–70% LA) or safflower oil (70–80% LA) (20). By chemical treatment, the linoleic acid is progressively converted to CLA without affecting the saturated and monounsaturated acids present in the oil (21,22).

Whatever the chemical procedure used or the nature of the oil, the double bonds migrate to form more isomers than in the product of the initial conjugation step. As a result, the purification provides mainly four isomers: *t8,c10*; *c9,t11*; *t10,c12*; and *c11,t13* (19,23,24). The preparations are mainly in the form of gelatin capsules with CLA FFA or CLA TG.

Lately, some manufacturers have given priority to the production of CLA preparations containing a limited number of isomers, based on recent research showing that the diverse putative benefits of CLA might be due to distinct isomers.

Isomer *c9,t11*, the main isomer found in the diet, has been claimed to modulate growth (25), whereas the isomer *t10,c12* has been claimed to positively modulate body composition and diabetes in mice (11). However, the isomer *t10,c12* also has been found to increase insulin resistance in some humans with metabolic syndrome (26). Both CLA isomers could reduce the appearance or progression of some tumors in humans if their anticarcinogenic effects were similar to those found against chemically-induced tumors in rat models (27,28).

E-mail: j-m@scr.no

Abbreviations: *c*, *cis* configuration; LA, linoleic acid; *t*, *trans* configuration.

CLA may also have useful antiatherogenic effects on lipid metabolism in humans (29). In contrast, the isomer *c11,t13* has been shown to accumulate in the liver and in the heart muscle of pigs (30). The pigs were not shown to suffer from any growth or pathological abnormalities (15). However, incorporation and accumulation of this isomer into mitochondrial phospholipids may affect enzymes embedded in the membrane and thus lead to disorders in the long term (30). Because of this, some producers are now trying to eliminate the *c11,t13* isomer from their preparations (Table 1).

The first CLA preparations to appear on the market in 1996 were produced from sunflower oil and generally contained four isomers of CLA. In this article, such products will be referred to as "four-isomer" preparations; these contain approximately 60% CLA (Table 1). More recently, producers have purified CLA (by manipulation of temperature and time reactions) in order to obtain mainly the two apparently active isomers, *c9,t11* and *t10,c12*, and their total CLA content can reach 80%. By analogy, they will be referred to as "two-isomer" preparations (Table 1). However, one must exert caution in making assumptions about the composition of the CLA preparations since they refer to analyses by producers who might be less reliable than claimed.

Owing to the presence of catalysts as well as to trace elements and residual solvents, the conjugation of CLA may also result in the production of *cis,cis* and especially *trans,trans* isomers that can accumulate progressively with time (21). The four-isomer preparations contain between 7.3 up to 22.43% *trans,trans* and *cis,cis* isomers, whereas the two-isomer preparations contain only trace amounts of isomers other than the two main one, and less than 5% of *trans,trans* and *cis,cis* isomers.

**Clinical trials.** Based on the very promising benefits observed in animals fed CLA, 16 clinical trials were published or reported within the last five years (Table 2). Most of them can be considered early phase studies, as they include a relatively small number of subjects.

(i) **Safety.** CLA is a natural substance detected in several food products as well as in the tissues and body fluids in humans (31,32), and has generally been considered nontoxic. Nevertheless, since the recommended doses of CLA supplementation are approximately 10–200 times higher than the normal dietary intake, efforts have been made to evaluate the toxicological features and the tolerability of some of the CLA preparations whose composition is available (Table 2).

However, records and reports of side effects (based on adverse events and blood sample analyses) from clinical studies, as well as from postmarketing surveillance, have been limited. Even though adverse events have been properly reported in some CLA studies involving two-isomer preparations (33,34), adverse events have been poorly documented in the studies using four-isomer ones (35–41). The most frequent side effects reported from the studies on two-isomer preparations are gastrointestinal disturbances such as diarrhea, constipation, and flatulence; however, these adverse events have been reported as only mildly to moderately severe (33,34,42). No difference in the frequency of adverse events was found between the CLA- and placebo-treated groups (who received olive oil in the studies mentioned above). The side effects may thus be caused either by the oil ingested or by the capsule material itself. For instance, constipation can be caused by iron oxide used as a dye agent in some capsules. Nevertheless, the withdrawal rate in these studies was very low, indicating that the majority of the subjects did not experience any discomfort when taking CLA. Importantly, no acute toxic reaction has been reported in any of the clinical trials performed to date. The safety of the CLA preparations in humans can also be evaluated based on the analysis of blood parameters such as liver transferases and other serum biochemical markers. Thus far, all data obtained with the two-isomer preparations indicate that these isomers lack any observed detrimental effect on blood lipids or liver enzymes (33,34,43). Neither Berven *et al.* (33) nor Blankson *et al.* (34) reported any clinically important changes in the

**Clinical Trials with CLA<sup>a</sup>**

Studies (code number and reference)	Subjects	CLA preparation	Dose g/d (duration)	Results
# 001 Atkinson (49)	80 overweight	Two isomers	2.7 (26 wk)	<i>Slight decrease:</i> BW, BFM <i>Slight increase:</i> LBM <i>Safety:</i> One patient with edema that resolved when CLA was discontinued. CLA started again without problems for the last 3 mon.
# 002 Basu <i>et al.</i> (46) Riserus <i>et al.</i> (26)	24 overweight	Two isomers	4.2 (4 wk)	<i>Decrease:</i> Sagittal abdominal diameter <i>Stable:</i> BW and BMI <i>Increase:</i> 8-iso-PGF <sub>2α</sub> and 15-oxo-dihydro-PGF <sub>2α</sub> <i>Safety:</i> No reported AE
# 003 Basu <i>et al.</i> (48) Smedman and Vessby (42)	53 healthy	Two isomers	4.2 (12 wk)	<i>Decrease:</i> BFM <i>Stable:</i> BW, BMI, and sagittal abdominal diameter <i>Increase:</i> 8-iso-PGF <sub>2α</sub> and 15-oxo-dihydro-PGF <sub>2α</sub> <i>Safety:</i> Few gastrointestinal disturbances (diarrhea)
# 004 Basu <i>et al.</i> (47)	60 healthy	Two isomers or one isomer r10,c12	3 (4 wk after 2 wk with vitamin E or COX2 inhibitor)	<i>Increase:</i> Isomer r10,c12 increases both 8-iso-PGF <sub>2α</sub> and 15-oxo-dihydro-PGF <sub>2α</sub> <i>Decrease:</i> COX2 inhibitor reduces 15-oxo-dihydro-PGF <sub>2α</sub>
# 005 Belury (53)	Diabetics type 2	Two isomers	6 (8 wk)	<i>Stable:</i> Insulin, TG, cholesterol, HDL <i>Decrease:</i> Blood glucose, leptins, BMI, and BW
# 006 Benito <i>et al.</i> (35,36) Kelley <i>et al.</i> (54,55) Medina <i>et al.</i> (37) Zambell <i>et al.</i> (39,40)	17 healthy	Four isomers	3.9 <sup>b</sup> (9 wk)	<i>Decrease:</i> Leptins <i>Increase:</i> For skinfold corrected armgirth, body mass, and leg press <i>Stable:</i> BW, BFM, and LBM; blood coagulation and platelet function; immune status (in response to influenza virus); insulin, glucose, lactate, and appetite <i>Safety:</i> No change in plasma cholesterol LDL, HDL, and TG; no reported AE; no difference in tympanic temperature or blood parameters
# 007 Berven <i>et al.</i> (33)	60 overweight	Two isomers	3.4 (12 wk)	<i>Decrease:</i> BW and BMI <i>Safety:</i> Gastrointestinal disturbances; no change in blood parameters and vital signs
# 008 Blankson <i>et al.</i> (34)	60 overweight	Two isomers	1.7, 3.4, 5.1, or 6.8 (12 wk)	<i>Decrease:</i> BFM <i>Increase:</i> LBM <i>Stable:</i> BW and BMI <i>Safety:</i> Gastrointestinal disturbances; no change in vital signs and a decrease in total cholesterol in blood
# 009 Jahreis and Loeffelholz (41)	21 bodybuilders	Four isomers	7 <sup>c</sup> (26 wk)	<i>Increase:</i> LBM <i>Decrease:</i> BFM in both groups <i>Stable:</i> Leptins <i>Safety:</i> Increase in total cholesterol and LDL in beginners but not in advanced athletes
# 10 Kreider <i>et al.</i> (56)	24 bodybuilders	Two isomers	6 (4 wk)	<i>Stable:</i> BMI, BFM, and strength <i>Safety:</i> Not recorded; no change in creatinine levels
# 11 Lowery <i>et al.</i> (43)	24 bodybuilders	Two isomers	7.2 (6 wk)	<i>Increase:</i> For skinfold corrected armgirth, body mass, and leg press <i>Stable:</i> BFM <i>Safety:</i> No difference in tympanic temperature and blood parameters (glucose, lipids, creatinine, enzymes)
# 012 Mohede <i>et al.</i> (44)	50 healthy	Two isomers	1.7 <sup>c</sup> (12 wk)	<i>Increase:</i> Seroprotection rate (in response to hepatitis B vaccination) <i>Safety:</i> Decrease of HDL; no AE recorded

**TABLE 2**  
(Cont.) Clinical Trials with CLA

Studies (code number and reference)	Subjects	CLA preparation	Dose g/d (duration)	Results
# 013 Mougios <i>et al.</i> (45)	22 healthy	Two isomers	0.7 and 1.4 (4 wk and 4 wk)	<i>Decrease:</i> Sum of skinfolds, percentage body fat, and fat mass (second period) <i>Safety:</i> No AE related to CLA supplementation; decrease in HDL
# 014 Noone <i>et al.</i> (29)	51 healthy	Two isomers (50:50 or 80:20)	3 (8 wk)	<i>Stable:</i> BW <i>Safety:</i> Decrease in TAG with the 50:50 preparation; decrease in VLDL-cholesterol with the 80:20 preparation; no effect on HDL, LDL, insulin, or glucose
# 015 Riserus <i>et al.</i> (50)	60 overweight/ obese with metabolic syndrome	Two isomers or one isomer <i>t</i> 10, <i>c</i> 1	3.4 (12 wk)	<i>Stable:</i> BW <i>No difference between groups:</i> BFW, LBM <i>Safety:</i> Decrease of HDL; <i>t</i> 10, <i>c</i> 12, increase insulin resistance and glycemia, but not the two-isomer preparation
# 016 Thom <i>et al.</i> (38)	20 healthy exercising	Four isomers	1.8 (12 wk)	<i>Decrease:</i> BFM <i>Safety:</i> One case of gastrointestinal distress

<sup>a</sup>BW, body weight; BFM, body fat mass; LBM, lean body mass; BMI, body mass index; PC<sub>F<sub>2α</sub></sub>, prostaglandin F<sub>2α</sub>; COX2, cyclooxygenase 2; AE, adverse event(s).

<sup>b</sup>According to the authors, the right dose of CLA given per day was 3.9 g (and not 3 g as mentioned in the article) out of 6 g oil in the capsules.

<sup>c</sup>CLA given as TG.

blood levels of liver enzymes during the 12-wk treatment with CLA. This is in agreement with Lowery *et al.* (43), who also found no effect of the CLA mixture on the liver enzyme transferases in novice body builders supplemented with a two-isomer preparation (3.9 g/d) for 6 wk. In Blankson *et al.* (34), the cholesterol level (total cholesterol, LDL, and HDL) was significantly reduced in all groups treated with the two-isomer preparation. A decrease in HDL was also reported after 12 wk (44) or 8 wk (45) of supplementation with a two-isomer preparation, whereas a recent study found no significant effect of both two-isomer preparations (see Table 2) on either HDL or LDL (29). The last study, however, showed a significant decrease in plasma TAG concentrations with the 50:50 blend mixture of the two-isomer preparation and a significant reduction in the VLDL-cholesterol with the 80:20 preparation enriched with the *c*9,*t*11 isomer (29). On the other hand, a four-isomer preparation containing a high percentage of *trans,trans* isomers was found to increase blood lipids (total cholesterol and LDL) (41). Interestingly, another four-isomer preparation that contained a much lower amount of *trans,trans* isomers but a substantial amount of *c*11,*t*13 (35), an isomer that is found to accumulate in cardiac lipid fractions in pigs, had no effect on blood lipid levels in humans (36).

Intriguingly, an increased level of urinary isoprostanes was observed as a possible lipid peroxidation product *in vivo* after 3 mon of supplementation with a two-isomer preparation (46–48). However, no adverse events were reported from these studies.

(ii) *Efficacy.* One of the most widely reported effects of two-isomer preparations is its influence on body composition

(26,33,34,42,43,49,50,53). Body fat mass is decreased concomitantly with an increase in or maintenance of lean body mass (also described as the fat-free mass, which includes water, bones, and musculature). However, despite 6 mon of supplementation with one two-isomer preparation, Atkinson reported only nonsignificant changes in adult humans (49). This might be due to the low dose of CLA (2.7 g/d) given to the subjects in this trial, since the only dose–response study performed to date shows that the lowest dose required to obtain changes in body composition is 3.4 g CLA/d (34).

The effect of CLA on body composition is supported by recent studies performed *in vitro* and in animals that describe the *t*10,*c*12 isomer to be responsible for the effects on body composition and diabetes (11,25,51,52). The mechanisms by which one or both isomers would exert their effects remain to be documented. One proposed mechanism implicates the hormone leptin, whose level was noted to decrease after supplementation with two-isomer preparations in diabetic (53) and healthy subjects (37).

In addition to the effects on body composition, a two-isomer preparation has been suggested to stimulate the immune response after vaccination against the hepatitis B virus (44). The results reported with four-isomer preparations have varied. Thus far, one study performed with a four-isomer preparation has shown an effect on body composition (38). Other investigations have strongly pointed out a lack of effect on several physiological parameters (35–37,39–41,54–56). For example, the four-isomer preparations have not been found to affect blood coagulation and platelet functions (35) or to increase immune stimulation in response to the influenza virus (54,55).

None of the two- and four-isomer preparations seem to alter either the glucose level (37,42,43) or the glycosylated hemoglobin level in healthy subjects (33,34). On the contrary, the two-isomer products may modulate insulin levels (26). According to a preliminary report by Belury (53), the two-isomer products could provide health benefits if the effect of reducing fasting blood glucose levels of type 2 diabetics could be confirmed. Conversely, another report found that purified *t10,c12* alone increased the insulin resistance of obese patients with metabolic syndrome, although the combination of both *c9,t11* and *t10,c12* did not (50).

## DISCUSSION

*What CLA product should be preferred in the future?* The numerous choices of commercial CLA preparations available as food supplements may be a matter of concern, since the formulations differ greatly in the content of isomers that might jeopardize health. First, *cis,cis* and *trans,trans* isomers may increase with reaction time owing to the presence of catalysts but also to other trace elements and residual solvents (21). Their presence, and especially that of *trans,trans* isomers, therefore mirrors the impurity level of the synthetic preparations. Considering that some of these impurities might be toxic, preparations with as low *trans,trans* isomer content as possible are preferable for human use. As mentioned in the previous section, this potential risk to human health is illustrated by the increase in LDL reported with a four-isomer preparation rich in *trans,trans* isomers (41). There is a consensus that a higher HDL/LDL ratio is associated with a lower risk of cardiac disease. Thus, if LDL increases due to the presence of the *trans,trans* isomers, their removal from CLA preparations would be important. In addition, even if the presence of the isomer *c11,t13* does not influence the serum lipid composition (35,36), other potential problems with this isomer in some of these formulations should not be underestimated. An accumulation of *c11,t13* in the inner membrane of the mitochondria (30) may affect energy metabolism and thus represent a danger. Consequently, preparations with a high content of *trans,trans* isomers and of *c11,t13* would best be avoided. Interestingly, the two-isomer preparations contain on average about 1/20th as much of these isomers as do some of the four-isomer preparations.

At the same time, some studies performed with two-isomer preparations have found a significant decrease in HDL that might be undesirable (44,45,50), but other studies performed with two-isomer preparations have shown no effect on HDL (29,33,34) and a significant reduction in the potentially atherogenic VLDL-cholesterol concentrations (29).

On the other hand, markers of possible lipid peroxidation *in vivo* (isoprostanes) have been found in the urine of subjects after supplementation with one two-isomer preparation (46,48).

The mechanisms behind this peroxidation are unclear (47), and we do not know whether this lipid peroxidation may be harmful to humans. Since this test has not been conducted

using the urine of subjects taking any of the four-isomer preparations, whether a four-isomer CLA preparation would lead to the same urinary findings is unknown.

Based on the limited preliminary findings on body composition, diabetes, and immune stimulation in humans, it would seem that the CLA formulations most likely to have benefits and least likely to exert adverse effects for human would be those containing high amounts of the two presumably active isomers, *c9,t11* and *t10,c12*. The notable differences in effects between the two-isomer and four-isomer preparations could be due either to a negative effect of the extra isomers (and/or contaminants) that would counterbalance the positive effects of both *c9,t11* and *t10,c12*, or to the lower dose of both *c9,t11* and *t10,c12* in the four-isomer preparations compared to those in the two-isomer ones. As Table 1 shows, the average percentage of both active isomers in the two-isomer preparation reaches 80%, whereas their average percentage in the four-isomer preparations never exceeds 30–40%. Therefore, to reach the same effective dosage as the two-isomer preparations, the four-isomer ones should be taken in higher doses, yet doing so might subsequently increase the risk of side effects.

There are indications that the *t10,c12* CLA isomer affects body composition, whereas the *c9,t11* isomer is responsible for growth modulation (11). This knowledge might lead to production of highly purified preparations containing only one of the isomers. Nevertheless, as illustrated by the study of Riserus *et al.* (50) showing that the isomer *t10,c12* might increase the insulin resistance of diabetics, it will be necessary to test (i) whether either isomer is efficacious in producing specific biological effects in humans with an acceptable safety profile, and (ii) whether there might be any advantage or disadvantage of giving both isomers together.

Taken together, the limited human safety and efficacy data available indicate that two-isomer preparations are preferable to four-isomer preparations for human supplementation studies. However, particular caution should be given to all preparations found on the market that have not been tested clinically (some soluble preparations may not contain any CLA at all; Ref. 19), and thus should not be advised for human consumption.

Finally, long-term effects (safety and efficacy) of CLA supplementation in humans need to be documented, since only supplementation periods up to 6 mon with low daily doses or up to 3 mon with higher doses have been reported thus far. Data from studies lasting one year or more should be part of the postcommercial surveillance that should be provided by the manufacturers of every CLA preparation marketed for human use.

## ACKNOWLEDGMENT

The authors' research was supported by a grant from Natural ASA.

# Purification of Lipoxygenase from *Chlorella*: Production of 9- and 13-Hydroperoxide Derivatives of Linoleic Acid

Alberto Nuñez\*, Brett J. Savary, Thomas A. Foglia, and George J. Piazza

USDA, ARS, ERRC, Wyndmoor, Pennsylvania 19038

**ABSTRACT:** Oxygenation of linoleic acid by the enzyme lipoxygenase (LOX) that is present in the microalga *Chlorella pyrenoidosa* is known to produce the corresponding 9- and 13-hydroperoxide derivatives of linoleic acid (9- and 13-HPOD, respectively). Previous work with this microalga indicated that partially purified LOX, present in the 30–45 and 45–80% saturated  $(\text{NH}_4)_2\text{SO}_4$  precipitate fractions, produced both HPOD isomers but in different ratios. It was not clear, however, if the observed activity in the two isolates represented the presence of one or more isozymes. In the present work, LOX isolated from the intracellular fraction of *Chlorella* by  $(\text{NH}_4)_2\text{SO}_4$  precipitation (35–80% saturated) was purified by ion exchange and hydrophobic interaction chromatography to apparent homogeneity. Analysis of the purified protein by SDS-PAGE and subsequent native size exclusion chromatography demonstrated that LOX in *Chlorella* is a single monomeric protein with a molecular mass of approximately 47 kDa. The purified LOX produced both the 9-HPOD and 13-HPOD isomers from linoleic acid in equal amounts, and the isomer ratio was not altered over the pH range of 6 to 9. Optimal activity of LOX was at pH 7.5.

Paper no. L9022 in *Lipids* 37, 1027–1032 (November 2002).

Lipoxygenase (LOX; EC 1.13.11.12) catalyzes the addition of molecular oxygen to PUFA to form hydroperoxide derivatives. This enzyme promotes the regio- and stereoselective dioxygenation of PUFA containing one or more 1(Z),4(Z)-pentadiene bond systems to produce (Z,E)-conjugated monohydroperoxy FA (1,2). LOX is widely distributed throughout the plant and animal kingdom and can be classified according to its specificity. In higher plants, LOX is classified according to its specificity on linoleic acid (LA) or linolenic acids. The enzyme is characterized as 9-LOX when the main product formed is 9-hydroperoxy-10(E),12(Z)-octadecadienoic acid (9-HPOD) or 13-LOX when 13-hydroperoxy-9(Z),11(E)-octadecadienoic acid isomer (13-HPOD) is the product (1,3). However, other minor amounts of positional isomers also can be formed. For example, soybean LOX, which produces 13-HPOD as the main product, also produces small amounts of

9-HPOD (1). In higher plants, additional forms of the enzyme produce a mixture of HPOD isomers (1–3).

LOX activity also is found in microorganisms such as fungi (4) and microalgae (5–7). Zimmerman and Vick reported LOX activity in the single-cell microalga *Chlorella pyrenoidosa* that produced 13-HPOD as the predominant oxidation product of LA. This activity was present in the fraction from the crude intracellular extract that precipitated from 0–42% saturated  $(\text{NH}_4)_2\text{SO}_4$ . This LOX was reported to have a maximum activity at pH 7.5 (5) and an apparent M.W. of 182 kDa (8). Bisakowski and Kermasha later reported that *C. pyrenoidosa* also contained a LOX activity in the fraction precipitated from 40–80%  $(\text{NH}_4)_2\text{SO}_4$  (7). They reported that this LOX showed optimal activity at pH 4.5. Nondenaturing gel electrophoresis of this LOX-containing fraction indicated a M.W. range between 67 and 140 kDa, but product specificity was not reported. Subsequent work reported the 9-, 10-, and 13-HPOD isomers were formed from LA using a LOX fraction precipitated from 40–80%  $(\text{NH}_4)_2\text{SO}_4$  at pH 7.0 (9). These studies, however, did not establish whether the reported LOX activities were the result of one or more isozymes.

Recently we reported that in addition to its peroxidation activity, LOX present in *C. pyrenoidosa* also cleaved 13-HPOD to a  $\text{C}_5$  fragment and a  $\text{C}_{13}$  oxo-FA under anaerobic conditions (10). The LOX fraction precipitated from 40–80%  $(\text{NH}_4)_2\text{SO}_4$  was further purified by size exclusion chromatography (SEC) and hydrophobic interaction chromatography (HIC). LOX peroxidation and the anaerobic cleavage activity eluted coincidentally with these chromatographic purification techniques, as similarly reported for soybean LOX (11,12), but the LOX peroxidation products were not characterized (10).

In a following study, we reported an HPLC method with EI-MS detection (LC/EI-MS) that allowed the analysis of the methylated HPOD products formed by LOX. This method does not require derivatization of the hydroperoxy group as required by GC with mass detection (GC-MS) (13). Using the LC/EI-MS method, we analyzed the products formed by LOX present in the *C. pyrenoidosa*-derived fraction precipitated from 30–45 and 45–80%  $(\text{NH}_4)_2\text{SO}_4$ . The 30–45%  $(\text{NH}_4)_2\text{SO}_4$  fraction gave an HPOD product distribution that was dominated by the 13-HPOD isomer, consistent with the results reported by Zimmerman and Vick (5). The 45–80% fraction, however, contained primarily the 9-HPOD isomer, and the 10-HPOD isomer (10-hydroperoxy-8(E),12(Z)-octadecadienoic acid) reported by Bisakowski *et al.* (9) was

not found. These results suggested the presence of two LOX isozymes.

In this study, the LOX activity present in the microalga *Chlorella* was purified to apparent electrophoretic homogeneity. The HPOD products formed from LA using this purified LOX were analyzed by LC/EI-MS to clarify previous reports that suggested the presence of LOX isozymes.

## MATERIALS AND METHODS

**Materials.** LA was purchased from Sigma Chemical (St. Louis, MO). All other reagents used were of the highest purity available. Products were methylated with diazomethane before LC/EI-MS analysis (13).

**Algae growth and protein extraction.** *Chlorella pyrenoidosa* from American Type Culture Collection (no. 11469; Manassas, VA) or its equivalent, *C. fusca*, from the Cultural Collection at UTEX (no. 251; Austin, TX) was grown, harvested, and processed for protein extraction as described previously (14). Soluble proteins from the crude extract were partially purified by  $(\text{NH}_4)_2\text{SO}_4$  precipitation at 0°C. The 0–35% fraction, containing most of the chlorophyll pigments and negligible LOX activity, was discarded and the 35–80% fraction used for further purification. Procedures for these steps as well as protein concentration assay were reported (13).

**Chromatographic protein purification.** Proteins present in the fraction precipitated from 35–80% saturated  $(\text{NH}_4)_2\text{SO}_4$  were dissolved in 5 mL of Tris buffer (10 mM, pH 8.0) and dialyzed with a 14,000 M.W. cutoff (MWCO) Spectra/Por membrane (Spectrum Laboratories, Rancho Dominguez, CA) against 4 L of buffer. Chromatography was performed on a BioCAD 700E system with Poros perfusion media (PerSeptive Biosystem, Inc., Framingham, MA). LOX activity was first separated on a Poros-HQ20 anion-exchange chromatography column (10 mm diameter  $\times$  100 mm length, column volume 7.9 mL) using Tris buffer (10 mM, pH 8.0) at 5 column vol/min with a linear gradient of 30 column vol (about 240 mL) to a final concentration 0.20 M NaCl, in the same buffer. Fractions of 0.5 column vol (ca. 4.0 mL) were collected and assayed for LOX activity. The active fractions were pooled and concentrated with a Centricon-10 membrane filter (Amicon, Beverly, MA); then  $(\text{NH}_4)_2\text{SO}_4$  was added to a final 2.0 M. The sample was then loaded onto a Poros-PE20 hydrophobic interaction chromatography column (100  $\times$  4.6 mm, column vol. 1.7 mL). The column was equilibrated with 2.0 M ammonium sulfate in Tris buffer, then developed with a linear gradient of 25 column vol (42 mL) to 0.0 M ammonium sulfate (100% 10 mM Tris buffer, pH 8.0) at a flow rate of ca. 5 mL/min. Fractions of 0.5 column vol were collected and assayed for LOX activity. The active fractions were pooled and concentrated for electrophoretic analysis and incubated with LA to determine product specificity.

Native determination of LOX M.W. involved treating the  $(\text{NH}_4)_2\text{SO}_4$ -treated *Chlorella* extract by dialysis using Spectrum CE DispoDialyzer (Spectrum Laboratories) 50,000

MWCO dialysis tubes with Tris buffer (10 mM, pH 8.0). The dialyzed fraction was passed (five times) through a DE Septra-Sorb 10-mL cartridge (Sepragen Corporation, Hayward, CA) that had previously been equilibrated with Tris buffer (10 mM, pH 8.0) containing NaCl (0.1 M). The unbound proteins containing the LOX activity (final volume of 10 mL) were concentrated and further resolved by SEC with a High Prep 26/60 Sephacryl S-200 column (Pharmacia Biototech Inc., Alameda, CA). Fractions of 5.6 mL were collected and assayed for LOX activity. The active fractions were combined, concentrated, and incubated with LA for product analysis by LC/EI-MS. Final M.W. estimation of the LOX activity eluted from the Sephacryl S-200 column was performed with a Bio-Silect SEC 125-5 column (Bio-Rad, Hercules, CA). The column was run with potassium phosphate (200 mM, pH 8.0) at 1 mL/min using a Waters Separation Module 2690 (Waters Co., Milford, MA); fractions were collected and assayed for LOX activity. The Sephacryl-S200 and the Bio-Silect SEC columns were calibrated using the following M.W. standards: glucose-oxidase (120,000), BSA (67,000), chymotrypsinogen A (25,000), and ribonuclease A (13,700).

**Electrophoresis.** Proteins were resolved by SDS-PAGE using a 12% gel in a Mini-Protein electrophoresis cell following the manufacturer's instructions (Bio-Rad). Samples were reduced using 25 mM DTT. Molecular sizes were calculated with Bio-Rad broad range M.W. marker proteins (200,000, 116,000, 97,400, 66,200, 45,000, 31,000, 21,500, 14,400, and 6,500). About 5 to 15  $\mu\text{g}$  total protein was loaded per lane, and gels were stained with Coomassie brilliant-blue R-250.

**LOX activity assay and product characterization.** Enzymatic activity was assayed by adding 5–20  $\mu\text{L}$  of the enzyme concentrate to a solution of 900  $\mu\text{L}$  LA (1 mM) in potassium phosphate (100 mM, pH 8.0) and Tween 20 (1%) to final volume of 1 mL and by monitoring the initial rate of increase in absorbance at 234 nm.

For product characterization, active LOX fractions were incubated with 50 mL of the LA solution under oxygen, and the progress of the reaction was followed spectrophotometrically at 234 nm. At the end of the reaction the products were extracted with ether, methylated, and analyzed by LC/EI-MS. LC was performed with a Waters HPLC 2690 Separation Module connected in series to a Waters 996 Photodiode Array Detector and a Waters Thermabeam Mass Detector (Integrity System). The LC portion used a Valco LiChrosorb Diol 5  $\mu\text{m}$  column (2  $\times$  250 mm) (Varian/Chrompack, Raritan, NJ) using the method reported previously (13).

## RESULTS AND DISCUSSION

**Purification of LOX activity.** Previously we reported that the fractions obtained from the protein extract of *C. pyrenoidosa* and precipitated from 45 and 80% saturated  $(\text{NH}_4)_2\text{SO}_4$  had LOX activity that produced the 9- and 13-HPOD isomers, but in different ratios (13). These results suggested the presence of two LOX isozymes, which was consistent with other reports on LOX activity in the microalga (5,9). In this study the

microalga *C. fusca* was used as an alternative source of *C. pyrenoidosa*, since it was found before that these two strains have the same enzymatic activity associated with LOX (10,14,15). Product characterization of LOX for both strains in the 30–45 and 45–80% fractions showed similar product distributions (see below). In addition, the *C. fusca* is offered as equivalent to *C. pyrenoidosa* by UTEX.

To determine the presence of one or more isozymes in

*Chlorella*, LOX activity expressed in the fraction precipitated from 35–80%  $(\text{NH}_4)_2\text{SO}_4$  was sequentially purified by ion exchange chromatography (IEC) and HIC. Figure 1A shows the separation of the dialyzed  $(\text{NH}_4)_2\text{SO}_4$  fraction using a Poros-HQ20 anion exchange column with protein detection at 280 nm. LOX activity eluted under the well-defined peak noted in Figure 1A, indicating the weak binding of this protein to this column in relation to the other proteins present in the 35–80% fraction. Since in a previous report the LOX activity precipitated at different percentages of  $(\text{NH}_4)_2\text{SO}_4$  seemed to determine the ratio of the HPOD isomers formed (10), the active fractions from this anion exchange column were concentrated and treated with 2 M  $(\text{NH}_4)_2\text{SO}_4$  and further resolved using HIC with a Poros-PE20 column. Figure 1B shows the HIC chromatogram with detection at 280 nm, where a single LOX activity eluted under the later peak as indicated. Table 1 summarizes the purification steps, indicating a 1.2-fold increase in the specific activity after  $(\text{NH}_4)_2\text{SO}_4$  precipitation and a 270-fold increase after IEC. Despite the removal of other proteins by HIC, however, specific activity decreased about 50% (Table 1). This significant total activity loss was associated with the concentration step of the IEC fraction after ultrafiltration at 10,000 MWCO. The reason for this loss in LOX activity is not clear and needs to be further studied. On the other hand, the elution of the LOX activity from the Poros-PE20 column was consistent with our early report of LOX activity in *C. pyrenoidosa*, in which the peroxidation and anaerobic cleavage activity eluted under the same conditions (10).

Figure 2A shows the SDS-PAGE of the purified LOX fractions after the two-mode adsorption chromatography sequence. The electrophoretic pattern indicated two major proteins in an approximate 1:1 ratio, each with an estimated M.W. of 34 and 47 kDa, respectively, but did not provide direct information on the native size of the LOX activity.

**Size exclusion purification.** SEC was used to determine the native size of LOX. The 35–80%  $(\text{NH}_4)_2\text{SO}_4$  fraction was dialyzed against a 50,000 MWCO membrane and then passed through a DEAE ion-exchange cartridge using conditions where the protein having LOX activity did not bind to the ion-exchange support (see the Materials and Methods section). The protein with LOX activity was purified further by SEC on a Sephacryl 200 column. The SEC protein fractions eluting from the column were assayed for LOX activity. The results are plotted in Figure 3A, which shows that the enzymatic

presence of an intense band at 47 kDa, as shown in Figure 2B. The active pooled fractions from the Sephacryl column were resolved using a high-resolution Bio-Silect SEC 125-5 column. Fractions from this column were collected and assayed for LOX activity, and the results are shown in Figure 3B, thus confirming that LOX activity corresponded to a protein with a M.W. of approximately 47 kDa. These results show that LOX activity in *Chlorella* is due to a monomeric enzyme of 47 kDa size, and that the smaller 34 kDa protein (Fig. 2A), which is isolated in the adsorption chromatography steps, does not have LOX activity. The native size determined for LOX, however, is not consistent with the previously reported M.W. of 182 and 120 kDa in *C. pyrenoidosa* (8,10). We have in fact observed a minor LOX activity in the  $(\text{NH}_4)_2\text{SO}_4$  fraction eluted from the Sephacryl 200 column at the previously reported size of 120 kDa, Figure 3A (10), but its activity was lost in the subsequent purification process. Analysis of the products formed by the 120 kDa LOX from the Sephacryl column were not different from the products formed by the 47 kDa LOX, suggesting the possible aggregation of LOX protein in the early purification steps.

Although most LOX enzymes reported in higher plants, animals, and fungi are in the size range of 80–120 kDa, smaller proteins with LOX activity also have been reported. In potato tubers two LOX isozymes of 35 and 85 kDa size have been reported by Reddanna *et al.* (16). The alga *Ulva lactuca* also was reported to have two LOX isozymes with the major activity corresponding to a LOX protein of 41 kDa size and a minor protein with LOX activity of 116 kDa size (17). This later report is quite consistent with the size determined for the LOX isolated from *Chlorella* in this work.

Anaerobic cleavage of the 13-HPOD by the LOX enzyme also was associated with the purified 47 kDa enzyme, as determined by GC-MS analysis of the headspace volatiles, in accordance with our previous finding of anaerobic activity associated with LOX in *Chlorella* (10).

**Characterization of purified LOX products.** Recently we reported an LC/EI-MS method that allowed for separation and identification of the methyl esters of HPOD isomers from LA (13). Characteristic ion fragments for the HPOD isomers allowed the positional assignment of the hydroperoxide group in the HPOD isomers. In general, EI-MS of HPOD isomers does not yield a molecular ion but produces characteristic ions at  $m/z$  310 [M – oxygen], 308 [M – H<sub>2</sub>O], and 293 [M – O<sub>2</sub>H]. An ion fragment at  $m/z$  185 was observed exclusively for the 9-HPOD isomer, while 13-HPOD has a characteristic ion at  $m/z$  99. Also, the 10-HPOD and 12-HPOD [12-hydroperoxy-9(Z),13(E)-octadecadienoic acid] isomers can be identified from fragment ions that are distinctive for these HPOD isomers. EI-MS analysis does not distinguish between the Z,E and E,E conjugated forms of the isomers; UV, however, provides evidence for these geometrical isomers since the Z,E and the E,E isomers have maximal absorptions at 233 and 228 nm, respectively (18).

The purified and concentrated active LOX fractions obtained by sequential adsorption chromatography were incu-

bated with LA under oxygen, and the reaction products were analyzed by LC/EI-MS after extraction and methylation. Figure 4A, the 232 nm UV chromatogram for these products, shows three peaks, which is consistent with three products having conjugated double bonds. The total ion current chromatogram (TIC) in Figure 4B shows the corresponding number of peaks. The EI spectra of the peaks gave characteristic ions for HPOD at  $m/z$  310, 308, and 293. The peaks eluting at approximately 46 and 49 min (labeled I and II in Fig. 4B) were identified as the 9(*Z*),11(*E*)- and 9(*E*),11(*E*)-13-HPOD isomers from the characteristic ion at  $m/z$  99 and UV absorptions at 232 and 228 nm, respectively (13). The peak eluting at approximately 51 min (labeled III in Fig. 4B) had an ion at  $m/z$  185 and UV absorption at 232 nm, characteristic of the 10(*E*),12(*Z*)-9-HPOD isomer. The small companion peak at 54 min (labeled IV in Fig. 4B) was identified as the 10(*E*),12(*E*)-9-HPOD. The product ratio for the 9- and 13-HPOD isomers was 49 and 51%, respectively. This product ratio also was obtained with the 35–80%  $(\text{NH}_4)_2\text{SO}_4$  fractions (see below), indicating that the LOX activity recovered after absorption chromatography retained its initial activity.

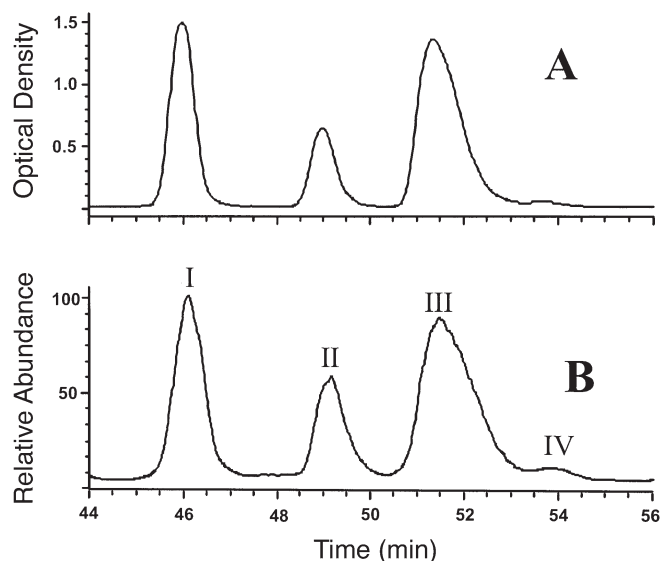

Most LOX enzymes catalyze the formation of one particular regiospecific isomer with a stereospecific configuration *S* (1,2). The stereospecificity of the *Chlorella* products has not been reported, but the product distribution found in this study is similar to the product ratio produced from LA by LOX present in the blue-green microalga *Oscillatoria* sp. (6), where the LOX products from the microalga were concluded to be 13-(*S*)-HPOD and 9-(*S*)-HPOD in a ratio of 52:48.

**pH effect on product formation.** The ratio between the 9- and 13-HPOD isomers can be affected by reaction pH. For

example, soybean LOX produces 13-HPOD almost exclusively at pH values above 8.5, whereas the 9-HPOD isomer is 25% of the total HPOD product at pH 6 (19). This pH dependency on product distribution is thought to be related to the orientation of the LA substrate at the active site. At the lowest pH, the protonated carboxylic acid group of LA can orient head-to-tail or tail-to-head at the active site, whereas at the higher pH the carboxylate anion can only be oriented one way (1,19). Since LOX from *Chlorella* produces both the 9- and 13-HPOD isomers, a pH dependency could be associated with HPOD product distribution. To investigate this aspect, the products isolated from the oxidation of LA by LOX present in the 35–80%  $(\text{NH}_4)_2\text{SO}_4$  fraction of *Chlorella* extracts at pH 6, 7, 8, and 9 were characterized by LC/EI-MS. This analysis showed that the ratio between the 9- and 13-HPOD isomers is not significantly altered, remaining in a ratio close to 50:50, indicating that pH did not alter the product ratio.

In further pH studies, activity of the purified fractions from *Chlorella* showed that the LOX activity producing the 9- and 13-HPOD isomers is maximal at pH 7.5, which is consistent with the pH for optimal activity reported by Zimmerman and Vick (5).

In this study, we purified the LOX activity in *Chlorella* producing the 9- and 13-HPOD isomers. The LOX activity was derived from a monomeric enzyme with a molecular weight of 47 kDa, as determined by SDS-PAGE after sequential adsorption chromatography and native size determination by SEC. The product distribution ratio was not dependent on pH, and the 9- and 13-HPOD isomers were formed in an equal ratio by this LOX, which has optimal activity at pH 7.5.

**FIG. 4.** LC/EI-MS analysis with a Diol column of the hydroperoxy-octadecadienoic acid products obtained by incubation of the chromatographically purified LOX activity with linoleic acid under oxygen. (A) UV chromatogram at 234 nm; (B) MS total ion chromatogram. Peak number, HPOD isomer: I, 9(*Z*),11(*E*)-13-HPOD; II, 9(*E*),11(*E*)-13-HPOD; III, 10(*E*),12(*Z*)-9-HPOD; and IV, 10(*E*),12(*E*)-9-HPOD.

# Total Synthesis of 2-Methoxy-14-methylpentadecanoic Acid and the Novel 2-Methoxy-14-methylhexadecanoic Acid Identified in the Sponge *Agelas dispar*

Néstor M. Carballeira\*, Heidyleen Cruz, and Norma L. Ayala

Department of Chemistry, University of Puerto Rico, San Juan, Puerto Rico 00931-3346

**ABSTRACT:** The phospholipid FA composition of the Caribbean sponge *Agelas dispar* was revisited and 40 different FA were identified. Among these a novel 2-methoxylated FA, namely, the anteiso methyl-branched 2-methoxy-14-methylhexadecanoic acid, was identified together with the recently discovered iso methyl-branched 2-methoxy-14-methylpentadecanoic acid and the normal-chain 2-methoxytetradecanoic acid. The structures of the iso and anteiso methyl-branched 2-methoxylated FA were confirmed by total syntheses, which were accomplished in seven steps and in 45–48% overall yields. Other phospholipid FA identified in *A. dispar* include the unusual methyl-branched 10,13-dimethyltetradecanoic acid, 3,7,11,15-tetramethylhexadecanoic (phytanic) acid, and the 11-methyloctadecanoic acid. In addition, the  $\Delta^{5,9}$  FA (5Z,9Z)-15-methyl-5,9-hexadecadienoic acid and (5Z,9Z)-5,9-octadecadienoic acid were characterized. These findings establish alternative FA biosynthetic possibilities for these marine organisms.

Paper no. L9120 in *Lipids* 37, 1033–1037 (November 2002).

The only known 2-methoxylated FA to date have arisen from the phospholipids of sponges despite the fact that 1-*O*-(2-methoxyalkyl)glycerols have been known for some time since their initial discovery by Hallgren *et al.* in shark liver oil (1,2). These 2-methoxylated FA are of interest because the shortest member of the series, namely, the 2-methoxytetradecanoic acid, is cytotoxic against the T-cell human acute lymphocytic leukemia (CEM-SS) cell line with an average 50% toxic concentration (TC<sub>50</sub>) value of 66  $\mu$ M and against human chronic myelogenous leukemia K-562 (ATCC CCL-243) with a 50% inhibitory concentration (IC<sub>50</sub>) of 670  $\mu$ M (Carballeira, N.M., unpublished results). Therefore, the search for other types of methoxylated FA, with better antileukemic activity, is warranted. Among these 2-methoxylated FA, a series of C<sub>15</sub>–C<sub>16</sub> iso and anteiso FA were recently discovered in the phospholipids of the marine sponge *Amphimedon complanata*, most likely arising from microorganisms coexisting with the sponge (3). These unprecedented FA were characterized by GC retention times and characteristic

mass spectral fragmentations (3). However, there is a high probability that other sponges contain additional iso and anteiso 2-methoxylated FA in their phospholipids. With this hypothesis we re-examined the phospholipid FA composition of the demosponge *Agelas dispar* (family Agelasidae) and discovered a series of iso and anteiso 2-methoxylated FA including 2-methoxy-14-methylpentadecanoic acid (**1**) and the unprecedented 2-methoxy-14-methylhexadecanoic acid (**2**). In addition, we have synthesized **1** and **2** for the first time, which permitted the confirmation of the iso and anteiso methyl branching in these natural FA.

The chemical composition of *A. dispar* has been partially explored before. For example, *A. dispar* possesses an unusual phospholipid FA composition inasmuch as preliminary studies with this demosponge revealed considerable amounts of methyl-branched FA, in particular phytanic acid (3,7,11,15-tetramethylhexadecanoic acid) (4). In addition, *A. dispar* biosynthesizes a series of brominated alkaloids with diverse biological activities such as inhibitors of serotonergic receptors, noncompetitive antihistaminic agents and antifungal compounds (5,6). Moreover, immunostimulating  $\alpha$ -glycosphingolipids also have been isolated from *A. dispar* (7).

## MATERIALS AND METHODS

**Sponge collection.** *Agelas dispar* Duchassaing and Michelotti, 1860 (class Demospongiae, order Agelasida, family Agelasidae) was collected from Mona Island, Puerto Rico, during August 1992, at 20 m depth by scuba. The sponge was freeze-dried and stored at  $-20^{\circ}\text{C}$  until extraction. A voucher specimen is stored at the Chemistry Department of the University of Puerto Rico, Río Piedras campus.

**Instrumentation.** FAME were analyzed by direct ionization using a GC–MS (Hewlett-Packard 5972A MS ChemStation) at 70 eV equipped with a 30 m  $\times$  0.25 mm special performance capillary column (HP-5MS) of polymethylsiloxane cross-linked with 5% phenyl methylpolysiloxane. The temperature program was as follows: 130 $^{\circ}\text{C}$  for 1 min, then increased at a rate of 3 $^{\circ}\text{C}/\text{min}$  to 270 $^{\circ}\text{C}$  and maintained for 30 min at 270 $^{\circ}\text{C}$ . <sup>1</sup>H NMR and <sup>13</sup>C NMR were recorded on either a Bruker DPX-300 or a Bruker DRX-500 spectrometer. <sup>1</sup>H NMR chemical shifts are reported with respect to internal (CH<sub>3</sub>)<sub>4</sub>Si, and <sup>13</sup>C NMR chemical shifts are reported in parts per million relative to CDCl<sub>3</sub> (77.0 ppm).

Abbreviations: DME, dimethoxyethane; DMDS, dimethyl disulfide; phytanic acid, 3,7,11,15-tetramethylhexadecanoic acid.

**Extraction and isolation of phospholipids.** The sponge (25 g) was carefully cleaned and cut into small pieces. Immediate extraction after collection with  $3 \times 300$  mL of  $\text{CHCl}_3/\text{MeOH}$  (1:1) yielded the total lipids (2 g). The neutral lipids (0.06 g), glycolipids (0.5 g), and phospholipids (0.6 g) were separated by column chromatography on silica gel (60–200 mesh) from the 1.5 g of total lipids that were used in the procedure of Privett *et al.* (8).

**Derivatives.** The fatty acyl components of the phospholipids were obtained as their methyl esters (0.06 g) by reaction of the phospholipids (0.50 g) with methanolic HCl followed by column chromatography. They were stored at  $-20^\circ\text{C}$  in hexane with 2,6-di-*tert*-butyl-4-methylphenol (BHT) as antioxidant and under nitrogen until analyzed in 1992. The double-bond positions in these compounds were determined by dimethyldisulfide (DMDS) derivatization following a previously described procedure (9). *N*-Acylpyrrolidide derivatives were prepared by direct treatment of the methyl esters with pyrrolidine/HOAc (10:1) in a capped vial (24 h at  $100^\circ\text{C}$ ). The methyl esters were hydrogenated in 10 mL absolute methanol in the presence of catalytic amounts of platinum oxide ( $\text{PtO}_2$ ).

**Lithium aluminum hydride reductions.** To a stirred solution of lithium aluminum hydride in dry diethyl ether (5 mL) at  $0^\circ\text{C}$  was added a solution of either 0.024 g (0.09 mmol) of the anteiso methyl ester or 0.021 g (0.09 mmol) of the iso acid dissolved in diethyl ether (5 mL). The resulting gray mixture was stirred for 2 h and then carefully quenched with a saturated aqueous ammonium chloride solution (8 mL). Diethyl ether (10 mL) was then added, and the organic layer was separated and dried over  $\text{Na}_2\text{SO}_4$ , filtered, and concentrated *in vacuo*, affording either the anteiso or iso alcohols, 0.018–0.019 g (0.08 mmol) in 99% GC yields with spectral data identical to that reported in the literature (10,11).

**Pyridinium chlorochromate oxidations.** To a stirred solution of 0.19 g (0.87 mmol) pyridinium chlorochromate in 15 mL of  $\text{CH}_2\text{Cl}_2$  was added dropwise either the anteiso or iso alcohols, 0.02–0.13 g (0.08–0.58 mmol) in 1 mL of  $\text{CH}_2\text{Cl}_2$  at room temperature. After 24 h the reaction mixture was filtered through Florisil and washed with diethyl ether (20 mL). Evaporation of the solvent afforded either the anteiso or iso aldehydes, 0.02–0.13 g (0.08–0.58 mmol) for a 99% GC yield with spectral data identical to that reported in the literature (12–14).

**Trimethylsilyl cyanide additions.** To either the iso or anteiso aldehydes, 0.04–0.13 g (0.20–0.58 mmol), in 10 mL of anhydrous  $\text{CH}_2\text{Cl}_2$ , were added dropwise 0.02–0.06 g (0.20–0.58 mmol) trimethylsilyl cyanide and catalytic amounts of  $\text{Et}_3\text{N}$  (10%) at  $0^\circ\text{C}$ . The reaction mixture was stirred for 2 h at  $0^\circ\text{C}$ . Then the solvent was removed *in vacuo*, affording 0.06–0.18 g (0.19–0.54 mmol) of either the anteiso or iso adducts for a 93% isolated yield. Spectral data for the trimethylsilyloxynitriles are presented below.

(i) *2-Trimethylsilyloxy-14-methylpentadecanonitrile.*  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 500.1 MHz)  $\delta$  4.38 (1H, *t*,  $J = 6.5$  Hz, H-2), 1.77 (2H, *m*, H-3), 1.52 (1H, *m*, H-14), 1.44 (2H, *m*, H-4), 1.29–1.25 (16H, *brs*,  $\text{CH}_2$ ), 1.14 (2H, *m*,  $\text{CH}_2$ ), 0.85 [6H, *d*,  $J = 6.6$  Hz,  $\text{CH}(\text{CH}_3)_2$ ], 0.20 [9H, *s*,  $\text{Si}(\text{CH}_3)_3$ ];  $^{13}\text{C}$  NMR

( $\text{CDCl}_3$ , 125.8 MHz)  $\delta$  120.1 (*s*, C-1), 61.5 (*d*, C-2), 39.0 (*t*, C-13), 36.2 (*t*, C-3), 29.9 (*t*), 29.7 (*t*), 29.60 (*t*), 29.56 (*t*), 29.4 (*t*), 29.3 (*t*), 28.9 (*t*), 27.9 (*d*), 27.4 (*t*), 24.5 (*t*), 22.6 [*q*,  $\text{CH}(\text{CH}_3)_2$ ],  $-0.4$  [*q*,  $\text{Si}(\text{CH}_3)_3$ ]; GC–MS *m/z* (relative intensity)  $\text{M}^+$  325 (2), 311 (24), 310 (100), 298 (26), 284 (13), 283 (56), 255 (3), 241 (2), 227 (3), 225 (3), 208 (7), 199 (4), 185 (11), 171 (23), 157 (5), 143 (12), 140 (9), 130 (6), 129 (49), 123 (5), 115 (13), 114 (14), 109 (11), 101 (19), 97 (20), 96 (13), 91 (28), 84 (21), 83 (25), 82 (20), 75 (75), 73 (74), 69 (31), 59 (10), 57 (28), 55 (35).

(ii) *2-Trimethylsilyloxy-14-methylhexadecanonitrile.*  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 500.1 MHz)  $\delta$  4.38 (1H, *t*,  $J = 6.6$  Hz, H-2), 1.68 (2H, *m*, H-3), 1.65 (1H, *m*, H-14), 1.34–1.26 (22H, *brs*,  $\text{CH}_2$ ), 0.85 (3H, *t*,  $J = 7.1$  Hz,  $-\text{CH}_2\text{CH}_3$ ), 0.83 (3H, *d*,  $J = 6.3$  Hz,  $-\text{CHCH}_3$ ), 0.20 [9H, *s*,  $\text{Si}(\text{CH}_3)_3$ ];  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ , 125.8 MHz)  $\delta$  120.1 (*s*, C-1), 61.5 (*d*, C-2), 38.7 (*t*), 36.6 (*t*), 34.4 (*d*), 30.0 (*t*), 29.7 (*t*), 29.6 (*t*), 29.5 (*t*), 29.46 (*t*), 29.43 (*t*), 29.3 (*t*), 28.9 (*t*), 27.1 (*t*), 24.5 (*t*), 19.2 (*q*, C-17), 10.9 (*q*, C-16),  $-0.4$  [*q*,  $\text{Si}(\text{CH}_3)_3$ ]; GC–MS *m/z* (relative intensity)  $\text{M}^+$  339 (2), 325 (27), 324 (100), 312 (36), 298 (15), 297 (56), 283 (12), 269 (3), 255 (2), 241 (3), 222 (9), 213 (3), 199 (4), 185 (11), 171 (21), 157 (5), 155 (3), 143 (10), 140 (10), 129 (50), 123 (7), 115 (14), 114 (13), 101 (19), 100 (12), 97 (22), 95 (24), 91 (35), 84 (24), 83 (26), 82 (22), 75 (74), 73 (81), 57 (60), 55 (44).

**Hydrolysis of the trimethylsilyloxy nitriles.** Into a 15-mL round-bottomed flask were placed the trimethylsilyloxy nitriles (0.06–0.18 g, 0.19–0.54 mmol) in 4 mL of dimethoxyethane (DME). Concentrated HCl (4 mL) was added, and the reaction mixture was heated at  $90^\circ\text{C}$  for 24 h. The reaction mixture was then cooled (ice bath) and made alkaline by the slow addition of 50% NaOH (5 mL). The reaction mixture was heated again for 2 h at  $90^\circ\text{C}$ . The mixture was then acidified with 5 mL of 6 M HCl, and the product was extracted with ether ( $2 \times 8$  mL). The organic layer was dried over  $\text{Na}_2\text{SO}_4$ , filtered, and evaporated *in vacuo*, affording 0.03–0.12 g (0.13–0.44 mmol) of either the anteiso or iso 2-hydroxy FA (68–70% isolated yields) with spectral data identical to those previously reported (15–17).

**Methylation of the 2-hydroxy FA.** Into a 15-mL round-bottomed flask provided with a magnetic stirrer and under a nitrogen atmosphere was placed 0.03–0.10 g (0.10–0.37 mmol) of the 2-hydroxy FA in 3 mL of DMSO. Two equivalents of NaH were dissolved in 2 mL of DMSO and added dropwise, after which the reaction mixture was stirred at room temperature for 10 min. An excess of  $\text{CH}_3\text{I}$  (0.18–0.74 mmol) was then added dropwise, and the reaction mixture was further stirred for 20 min, after which it was diluted with hexane/ether (1:1) and washed with  $\text{H}_2\text{O}$  ( $2 \times 8$  mL) to remove the remaining DMSO. The organic phase was dried over  $\text{MgSO}_4$ , filtered, and evaporated *in vacuo* affording 0.02–0.08 g (0.07–0.28 mmol) of the 2-methoxylated methyl esters (73–76% isolated yields). Spectral data not previously reported in the literature are presented below.

(i) *Methyl 2-methoxy-14-methylpentadecanoate.*  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 500.1 MHz)  $\delta$  3.75 (3H, *s*,  $-\text{CO}_2\text{CH}_3$ ), 3.75 (1H, X

part of ABX system, H-2), 3.37 (3H, *s*, -OCH<sub>3</sub>), 1.69 (2H, *m*, H-3), 1.50 (1H, *m*, H-14), 1.36 (2H, *m*, H-4), 1.24 (16H, *brs*, CH<sub>2</sub>), 1.13 (2H, *m*, CH<sub>2</sub>), 0.85 [6H, *d*, *J* = 6.6 Hz, CH(CH<sub>3</sub>)<sub>2</sub>]; <sup>13</sup>C NMR (CDCl<sub>3</sub>, 125.8 MHz) δ 173.3 (*s*, C-1), 80.7 (*d*, C-2), 58.1 (*q*, -OCH<sub>3</sub>), 51.7 (*q*, -CO<sub>2</sub>CH<sub>3</sub>), 39.0 (*t*, C-13), 32.8 (*t*, C-3), 29.9 (*t*), 29.7 (*t*), 29.63 (*t*), 29.60 (*t*), 29.5 (*t*), 29.4 (*t*), 29.3 (*t*), 27.9 (*d*, C-14), 27.4 (*t*), 25.1 (*t*, C-4), 22.6 [*q*, CH(CH<sub>3</sub>)<sub>2</sub>].

## RESULTS AND DISCUSSION

As previously reported (4), TLC showed that the main phospholipids from *A. dispar* were PE, PS, and PC. Transesterification with 1.0 M HCl/MeOH permitted the characterization of the FA as methyl esters using GC-MS. A total of 40 phospholipid FA were identified in *A. dispar*. DMDS derivatives were used to locate the double bonds in the monounsaturated methyl esters, whereas pyrrolidides were used mainly to locate methyl branching. The total phospholipid FA composition of *A. dispar* is presented in Table 1. Methyl-branched FA between C<sub>14</sub> and C<sub>20</sub> predominated in these phospholipids (59%), and in particular phytanic acid was the most abundant in this family (12.1%), but 10-methylhexadecanoic acid (9.8%) and 11-methyloctadecanoic acid (6.2%) were also abundant. The common origin of branched FA is bacterial, but phytanic acids derive from the phytol portion of chlorophyll (4). Branched-chain iso and anteiso FA accounted for 28% of the total composition, but most of these FA had chain lengths between C<sub>14</sub> and C<sub>17</sub>, which are typical chain lengths of iso and anteiso bacterial FA. The most abundant normal-chain saturated FA was palmitic acid (12.1%).

Our primary focus was the three 2-methoxylated FA that constituted 1.5% of the total phospholipid FA composition of *A. dispar*. We recently reported the presence of two of these FA, 2-methoxytetradecanoic acid and 2-methoxy-14-methylpentadecanoic acid, in two Caribbean sponges (3,18). Characterization of the remaining saturated 2-methoxylated acid (as the methyl ester) was possible using GC-MS and GC ECL values as compared to synthetic standards. For example, the mass spectrum of the novel methyl ester **2** displayed a molecular ion peak at *m/z* 314 and a strong [M<sup>+</sup>-59] peak at *m/z* 255 (100%), together with a small peak at *m/z* 104 (McLafferty

<sup>a</sup>Relative abundance with respect to phospholipid FA.

<sup>b</sup>This FA is unprecedented in nature.

rearrangement) typical of an  $\alpha$ -methoxylated saturated methyl ester (3,18).

Despite the fact that the 2-methoxy functionality was established in these compounds by MS, the relative GC retention times of two of the 2-methoxylated methyl esters from *A. dispar* could only be explained by iso and anteiso methyl branching. For example, the methoxylated ester **1** presented an ECL value of 16.85, whereas the ester **2** had an ECL value of 17.93. Normal-chain  $\alpha$ -methoxylated FA normally have fractional chain length values of 0.17 (19). For example, the normal-chain methyl 2-methoxytetradecanoate, also identified in *A. dispar*, presented an ECL value of 15.18. These unusual ECL values of 16.85 and 17.93 could only be accommodated if **1** is an iso methyl-branched methyl ester and **2** an anteiso methyl ester (4). Therefore, we decided that it was important to confirm these structural assignments rigorously by

total synthesis since the first structures of this type were mainly confirmed by relative GC retention times. Therefore, we developed a practical synthesis for the  $\alpha$ -methoxylated methyl esters **1** and **2**.

The synthesis of **1** started with commercially available (Sigma) 13-methyltetradecanoic acid, which was converted to 13-methyltetradecanal by first reducing the acid to 13-methyltetradecanol with lithium aluminum hydride in ether and then oxidizing the alcohol to the aldehyde with pyridinium chlorochromate in  $\text{CH}_2\text{Cl}_2$  in very high yield reactions (Fig. 1). The aldehyde was then reacted with trimethylsilyl cyanide and triethylamine affording the 14-methyl-2-trimethylsilyloxypentadecanonitrile in a 93% yield. The silyloxynitrile was then transformed into the known 2-hydroxy-14-methylpentadecanoic acid by first reacting the nitrile with concentrated HCl in DME followed by saponification with 50% NaOH. Final conversion into methyl 2-methoxy-14-methylpentadecanoate (**1**) was achieved by methyl esterification with 1 M HCl/MeOH and subsequent methylation of the hydroxy group with methyl iodide and sodium hydride in DMSO. The overall yield for this synthesis was 45%. The methoxylated iso ester **1** co-eluted in capillary GC with the naturally occurring methyl 2-methoxy-14-methylpentadecanoate from *A. dispar*, thus confirming the structural assignment of the iso methoxylated ester.

The synthesis of methyl 2-methoxy-14-methylhexadecanoate (**2**) was also achieved following the same synthetic scheme as described above but starting with commercially available methyl 13-methylpentadecanoate (Fig 1). The overall yield in this case was 48%. The methoxylated anteiso ester

**2** also co-eluted in capillary GC with the naturally occurring methyl 2-methoxy-14-methylhexadecanoate (**2**) from *A. dispar*, which further confirmed the structural assignment of the anteiso methoxylated ester **2**.

The noteworthy finding in this *Agelas* is that it biosynthesizes three different kinds of 2-methoxylated FA, namely, normal-chain, iso and anteiso FA. The present work is only the second report of branched  $\alpha$ -methoxylated phospholipid FA from any natural source, the first being our previous report from the sponge *Amphimedon complanata* (3). The structural similarity of these branched methoxylated FA with the known iso and anteiso 2-hydroxylated  $\text{C}_{16}$ – $\text{C}_{17}$  FA implies that these compounds could have originated, although not necessarily, from the branched 2-hydroxylated FA. For example, 2-hydroxy-14-methylpentadecanoic acid was identified in *Arthrobacter simplex* (20), and 2-hydroxy-14-methylhexadecanoic acid was found in species of the genera *Thermus* and *Meiothermus*, identified in Antarctic lake sediments, and isolated from the Actinomycetales (15–17).

The structural similarity between the iso and anteiso 2-methoxylated phospholipid FA reported here and the analogous 2-hydroxylated phospholipid FA points in the direction of a common bacterial origin for these compounds, since the 2-hydroxylated iso and anteiso  $\text{C}_{16}$ – $\text{C}_{17}$  FA are indeed bacterial (21). For example, some myxobacteria contain PE as the major phospholipid with 2-hydroxy iso-17:0 FA at the 2-position and nonhydroxy FA at the 1-position (21). Therefore, it is most likely that in *A. dispar* a novel symbiotic marine bacterium could actually contain novel PE with iso and anteiso methyl-branched 2-methoxylated FA at the 2-position (21).

**FIG. 1.** Synthesis of methoxylated ester of (A) 2-methoxy-14-methylpentadecanoic acid (**1**) and (B) 2-methoxy-14-methylhexadecanoic acid (**2**). (i)  $\text{LiAlH}_4$ -ether,  $0^\circ\text{C}$ ; (ii) PCC (1.5 eq)  $\text{CH}_2\text{Cl}_2$ ; (iii) TMS-CN,  $\text{Et}_3\text{N}$ ,  $\text{CH}_2\text{Cl}_2$ ,  $0^\circ\text{C}$ ; (iv) HCl (conc.), DME 24 h; (v) 50% NaOH, heat, 3 h; (vi) 1 N HCl-MeOH; (vii) NaH/DMSO,  $\text{CH}_3\text{I}$ . PCC, pyridinium chlorochromate; TMS-CN, trimethylsilyl cyanide; DME, dimethoxyethane.

<sup>a</sup>Institut National de la Recherche Agronomique, Unité de Nutrition Lipidique, 21065 Dijon, France, and <sup>b</sup>Commissariat à l'Énergie Atomique Saclay, Service des Molécules Marquées, 91191 Gif sur Yvette, France

**ABSTRACT:** Various nutritional studies on CLA, a mixture of isomers of linoleic acid, have reported the occurrence of conjugated long-chain PUFA after feeding experimental animals with rumenic acid, 9*c*,11*t*-18:2, the major CLA isomer, probably as a result of successive desaturation and chain elongation. In the present work, *in vitro* studies were carried out to obtain information on the conversion of rumenic acid. Experiments were first focused on the *in vitro* Δ6-desaturation of rumenic acid, the regulatory step in the biosynthesis of long-chain n-6 PUFA. The conversion of rumenic acid was compared to that of linoleic acid (9*c*,12*c*-18:2). Isolated rat liver microsomes were incubated with radiolabeled 9*c*,12*c*-18:2 and 9*c*,11*t*-18:2 under desaturation conditions. The data indicated that [1-<sup>14</sup>C]9*c*,11*t*-18:2 was a poorer substrate for Δ6-desaturase than [1-<sup>14</sup>C]-9*c*,12*c*-18:2. Next, *in vitro* elongation of 6*c*,9*c*,11*t*-18:3 and 6*c*,9*c*,12*c*-18:3 (γ-linolenic acid) was investigated in rat liver microsomes. Under elongation conditions, [1-<sup>14</sup>C]6*c*,9*c*,11*t*-18:3 was 1.5-fold better converted into [3-<sup>14</sup>C]8*c*,11*c*,13*t*-20:3 than [1-<sup>14</sup>C]6*c*,9*c*,12*c*-18:3 into [3-<sup>14</sup>C]8*c*,11*c*,14*c*-20:3. Finally, *in vitro* Δ5-desaturation of 8*c*,11*c*,13*t*-20:3 compared to 8*c*,11*c*,14*c*-20:3 was investigated. The conversion level of [1-<sup>14</sup>C]8*c*,11*c*,13*t*-20:3 into [1-<sup>14</sup>C]5*c*,8*c*,11*c*,13*t*-20:4 was 10 times lower than that of [1-<sup>14</sup>C]8*c*,11*c*,14*c*-20:3 into [1-<sup>14</sup>C]-5*c*,8*c*,11*c*,14*c*-20:4 at low substrate concentrations and 4 times lower at the saturating substrate level, suggesting that conjugated 20:3 is a poor substrate for the Δ5-desaturase.

Paper no. L8665 in *Lipids* 37, 1039–1045 (November 2002).

CLA refers to a mixture of positional and geometrical isomers of linoleic acid having two conjugated double bonds. Rumenic acid (9*c*,11*t*-18:2) is the most abundant of the CLA isomers in milk, dairy products, and meat from ruminants. It is formed as a stable intermediate in the biohydrogenation sequence of linoleic acid by anaerobic bacteria in the rumen (1,2) and also by Δ9-desaturation of vaccenic acid in the mammary gland. In addition, CLA isomers, including rumenic acid, are produced by free radical-induced isomerization of linoleic acid (4) or during commercial hydrogenation of vegetable oils (5).

Abbreviations and acid names: Arachidonic acid, 5*c*,8*c*,11*c*,14*c*-20:4n-6; behenic acid, 23:0; dihomo-γ-linolenic acid, 8*c*,11*c*,14*c*-20:3; lignoceric acid, 24:0; linoleic acid, 9*c*,12*c*-18:2; γ-linolenic acid, 6*c*,9*c*,12*c*-18:3; rumenic acid, 9*c*,11*t*-18:2.

Research on CLA and its metabolism has been carried out in many animal experiments *in vivo* and *in vitro*. Feeding studies on animals often used synthetic mixtures of CLA, in which 9*c*,11*t*- and 10*t*,12*c*-18:2 accounted for about 90–95% of the total CLA. It has been suggested that CLA may have beneficial effects, such as anticarcinogenic and antiatherogenic effects (6–8). Moreover, it was suggested that CLA might influence body composition, as it reduced the fat-to-lean body mass ratio in various animal experiments (9,10). The mechanisms by which CLA isomers act are not yet exactly known. It has been hypothesized that CLA may modify the eicosanoid biosynthesis (11). *In vivo* feeding studies of rats by Banni *et al.* (11) and Sébédio *et al.* (12) have demonstrated the appearance of 18:3 and 20:3 conjugated metabolites from the two major CLA isomers. Recent nutritional studies on the metabolism of the 9*c*,11*t*- and 10*t*,12*c*-18:2 isomers have shown that 9*c*,11*t*-18:2 can be converted into 8*c*,11*c*,13*t*-20:3 and 10*t*,12*c*-18:3 can be converted into 6*c*,10*t*,12*c*-18:3 (11,13), probably by successive desaturation and chain elongation in the same way as 18:2n-6 into 18:3n-6 and 20:3n-6. To test the ability of CLA to act as substrate for Δ6-desaturase, a radiolabeled isomeric mixture of CLA obtained by alkaline isomerization was incubated with liver microsomes (14). It was suggested that the metabolites were the Δ6-desaturated products of CLA. But neither a differentiation in the metabolism of the individual CLA isomers nor an exact structural identification of the conversion products was carried out.

Moreover, Bretillon *et al.* (15) demonstrated the inhibitory effect of 9*c*,11*t*-18:2 on the Δ6-desaturation of linoleic acid in a dose-dependent manner, whereas 10*t*,12*c*-18:2 exhibited the same effect only at the highest concentration.

The present work describes the *in vitro* Δ6-desaturation of 9*c*,11*t*-18:2, the elongation of 6*c*,9*c*,11*t*-18:3, and the Δ5-desaturation of 8*c*,11*c*,13*t*-20:3 in comparison with their natural respective homologs using rat liver microsomes in order to obtain information on the conversion of rumenic acid into conjugated 18:3, 20:3, and 20:4 FA.

## MATERIALS AND METHODS

**Chemicals.** The FFA form of 9*c*,12*c*-18:2 was purchased from Sigma Chemicals (l'Isle d'Abeau, France). [1-<sup>14</sup>C]9*c*,12*c*-18:2 was purchased from NEN Life Science (Les Ulis, France). The 9*c*,11*t*-18:2 isomer was purchased from Natural

Lipid (Hovdebygda, Norway), and the [1-<sup>14</sup>C]9c,11t-18:2 was obtained by total synthesis as previously reported (16) with a radiochemical purity >99%. [1-<sup>14</sup>C]6c,9c,11t-18:3, [1-<sup>14</sup>C]-8c,11c,13t-20:3, and their unlabeled homologs were obtained by total synthesis (17). Coenzymes and chemicals were supplied by Sigma Chemicals.

**Animals and diets.** All animal procedures were conducted according to French regulation (authorization A21200 and 3273). Twenty-four weaning male Wistar rats (Elevage Janvier, Saint Genest, France) were fed a fat-free semisynthetic diet for 2 wk, as previously described (18). Rats (166 ± 5.9 g) were killed by decapitation.

**Microsomes preparation and incubations.** Liver microsomes were prepared at 4°C as previously reported (15). Briefly, each liver (9.4 ± 0.9 g) was homogenized in sucrose and phosphate buffer (pH 7.4). The homogenate was centrifuged at 400 × g for 5 min to pellet cellular debris. The supernatant was centrifuged at 15,000 × g for 15 min to eliminate nuclei, mitochondria, lysosomes, and peroxisomes. Finally, the supernatant was ultracentrifuged at 105,000 × g for 60 min. The pellet was resuspended in a phosphate buffer (pH 7.4)/cytosol mixture (2:1, vol/vol). Microsomal proteins were quantified according to the method of Lowry *et al.* (19).

The desaturation studies were performed at 37°C for 15 min as previously described (15). Each incubation medium contained 72 mM phosphate buffer (pH 7.4), 4.8 mM MgCl<sub>2</sub>, 0.5 mM CoA, 3.8 mM ATP, and 1.2 mM NADPH in a final volume of 2 mL. [1-<sup>14</sup>C]9c,12c-18:2, [1-<sup>14</sup>C]9c,11t-18:2, [1-<sup>14</sup>C]8c,11c,13t-20:3, and [1-<sup>14</sup>C]8c,11c,14c-20:3 were diluted in ethanol with the corresponding unlabeled molecule to a specific activity of 10 mCi/mmol. For the Δ<sup>6</sup>-desaturation studies, microsomal suspensions containing 5 mg protein were incubated in an open flask with [1-<sup>14</sup>C]9c,12c-18:2 or [1-<sup>14</sup>C]-9c,11t-18:2 at concentrations of 30, 60, 90, and 120 nmol. For the Δ<sup>5</sup>-desaturation studies, microsomal suspensions containing 5 mg protein were incubated in an open flask with [1-<sup>14</sup>C]-8c,11c,13t-20:3 or [1-<sup>14</sup>C]8c,11c,14c-20:3 at concentrations of 10, 20, 40, 60, 80, and 100 nmol.

The elongation studies were performed at 37°C for 30 min under anaerobic conditions as described by Mohrhauer *et al.* (20). Each incubation medium contained 120 mM phosphate buffer (pH 7), 3.5 mM ATP, 0.1 mM malonyl-CoA, 0.8 mM NADPH, 1.4 mM MgCl<sub>2</sub>, 0.75 mM glutathione, 0.5 mM KCN, 20 mM KF, 0.1 mM CoA, and 0.2 mM nicotinamide in a final volume of 3 mL. [1-<sup>14</sup>C]6c,9c,11t-18:3 and [1-<sup>14</sup>C]-6c,9c,12c,18:3 were diluted in ethanol with the corresponding unlabeled molecule to a specific activity of 10 mCi/mmol. Microsomal suspensions containing 5 mg protein were incubated for 30 min in a closed flask under an argon atmosphere with [1-<sup>14</sup>C]6c,9c,12c-18:3 or [1-<sup>14</sup>C]6c,9c,11t-18:3 at concentrations of 10, 20, 40, and 60 nmol.

**Analysis of the conversion product.** The incubations were stopped by the addition of KOH (12%) in ethanol. Lipids were saponified by heating at 75°C for 1 h. After extraction with hexane, the FFA were esterified into FAME using boron triflu-

oride (14%) in methanol for 15 min at room temperature. The FAME were dissolved in 600 μL of acetone and analyzed by HPLC (Waters 600; Saint Quentin en Yvelines, France) using a Nucleosil C<sub>18</sub> column (5 μm particle size, 250 × 4.6 mm i.d.; Interchim, Montluçon, France). The mobile phase was acetonitrile at a flow rate of 0.5 mL·min<sup>-1</sup>. The radioactivity was measured in the counting cell of a radiochromatographic Flo-One β detector (Series A-100; Radiomatic Instruments, Tampa, FL) after mixing the column effluent with a Uniscint BD scintillation cocktail (National Diagnostics, Atlanta, GA) in a ratio of 1:1.2 (effluent/scintillation cocktail).

Microsomal FAME were also analyzed on a Hewlett-Packard 5890 gas chromatograph (Palo Alto, CA), equipped with a splitless/split injector and a Stabilwax wide-bore column (60 m × 0.53 mm i.d.; film thickness, 0.50 μm, Restek, Evry, France) as previously described (15). The column was connected to a FID and to a radio-GC-detector (GC RAM Lablogic, Sheffield, United Kingdom). The temperatures of the injector and detector were 250 and 280°C, respectively. Helium was the carrier gas. The output flow from the column was split between the FID and the radio-GC-detector in a ratio 10:90. The data were computed using Laura software (Lablogic).

**Identification of the conversion product.** Two Hewlett-Packard HP 5890 Series II (Hewlett-Packard Ltd., Wokingham, United Kingdom) were used for GC analysis. The first was equipped with a splitless/split injector and a FID. The temperatures of the injector and detector were 250 and 280°C, respectively. Helium was the carrier gas. The analyses were performed using a BPX-70 capillary column (50 m × 0.33 mm i.d., film thickness, 0.25 μm; SGE Ltd., Melbourne, Australia). The oven temperature was programmed from 60 to 170°C at 20°C·min<sup>-1</sup>. The second one was equipped with a splitless/split injector and an FID. The temperatures of the injector and detector were 250 and 280°C, respectively. Hydrogen was the carrier gas. The analyses were performed using a CP-SIL capillary column (100 m × 0.25 mm i.d.; film thickness, 0.25 μm; Varian, Les Ulis, France). The oven temperature was programmed from 60 to 190°C at 20°C·min<sup>-1</sup>.

Data were collected using a Borwin workstation (JMBS Developments) including an acquisition interface, software, and a computer. GC-MS analyses were effected with a Hewlett-Packard 6890 gas chromatograph coupled to an HP model 5973 mass selective detector (Hewlett-Packard Ltd.). The latter was used in the EI mode at 70 eV with a source temperature of 250°C. The GC separation was performed on an HP-5-MS column (30 m × 0.25 mm i.d., film thickness 0.25 μm, Hewlett-Packard Ltd.) using helium as carrier gas. The oven temperature was programmed from 60 to 300°C at 18°C·min<sup>-1</sup>. Splitless injection was used with the injection port maintained at 250°C.

**Expression of results.** Results are expressed as means ± SD. The means were compared using an ANOVA and the Student-Newman-Keuls test using SAS software (Cary, NC). Significant differences (*P* < 0.05) are indicated by different superscript letters.

## RESULTS AND DISCUSSION

In the present work, young rats were fed a fat-free diet for 2 wk so that there would be no effect of dietary FA when, at the end of the feeding period, conversion of EFA by liver microsomes was evaluated. The FA composition of liver microsomal total lipids was determined (data not shown). Rats presented an EFA deficiency, according to the criterion accepted for EFA deficiency of Mohrhauer and Holman (21) with a 5*c*,8*c*,11*c*-20:3/5*c*,8*c*,11*c*,14*c*-20:4 ratio of 0.49. No trace of CLA or *trans* FA was present in liver microsome total lipids.

**$\Delta 6$ -Desaturation study.** In a first set of experiments, the  $\Delta 6$ -desaturation of 9*c*,11*t*-18:2 was compared to that of linoleic acid.  $\Delta 6$ -Desaturation is the rate-limiting step in the conversion of linoleic acid to arachidonic acid (20:4n-6) (22). It could be hypothesized that the conversion of CLA by  $\Delta 6$ -desaturase is essential to form further conjugated 20:4 from 9*c*,11*t*-18:2. Table 1 shows the results of the conversion of [1-<sup>14</sup>C]9*c*,12*c*-18:2 or [1-<sup>14</sup>C]9*c*,11*t*-18:2 (30–120 nmol) by liver microsomes under desaturation. Rumenic and linoleic acids were both desaturated. However, the extent of conversion of 9*c*,11*t*-18:2 was significantly lower ( $P < 0.05$ ) than that of 9*c*,12*c*-18:2 at all substrate concentrations (6.3 ± 1.0 vs. 8.7 ± 0.6 nmol at 30 nmol of substrate, and 10.2 ± 1.6 vs. 16.9 ± 1.1 nmol at 120 nmol of substrate), suggesting that rumenic acid is not as good a substrate for  $\Delta 6$ -desaturase as linoleic acid. At 120 nmol the saturating substrate concentration was reached for the conversion of linoleic acid, whereas the conversion of rumenic acid did not reach a plateau, suggesting a higher saturating substrate concentration for rumenic acid than for linoleic acid under our experimental conditions.

Under similar experimental conditions the conversion product of 9*c*,12*c*-18:2 was identified as 6*c*,9*c*,12*c*-18:3 (18,23). In contrast, the *in vitro* desaturated product of 9*c*,11*t*-18:2 had to be identified. With classical chemical methods (24) this is difficult because of the low conversion levels and low metabolite concentrations. Radio-GC, GC–MS, and GC on a high-polarity column were used to analyze the structure of the metabolites formed from 9*c*,11*t*-18:2. Radio-GC revealed two labeled compounds for FAME from liver microsomes incubated in the presence of either [1-<sup>14</sup>C]-9*c*,12*c*-18:2 (Fig. 1B) or [1-<sup>14</sup>C]9*c*,11*t*-18:2 (Fig. 1C). The retention times for rumenic acid and its desaturation product varied from

those of 9*c*,12*c*-18:2 as shown in Figures 1B and 1C because of the conjugated double bonds. GC–MS analyses showed that the desaturated compounds had molecular ions at *m/z* 292 and 294, which correspond to the M.W. of unlabeled and labeled methyl octadecatrienoate, respectively. The conjugated 18:3 metabolite formed from 9*c*,11*t*-18:2 in liver microsomes was identified as 6*c*,9*c*,11*t*-18:3 by GC on a polar column (BPX-70) by comparison with a standard obtained by total synthesis with an isomeric purity >95% (17). Moreover, 19:0 and 22:0 (behenic acid) were added to the conjugated 18:3 metabolite formed from 9*c*,11*t*-18:2 in liver microsomes and to the synthetic 6*c*,9*c*,11*t*-18:3 standard for calculation of the ECL by GC on a polar column (CP-Sil, 60–190°C). The two experimental ECL values are identical (ECL: 21.56). The formation of a metabolite by  $\Delta 6$ -desaturation of 9*c*,11*t*-18:2 is in agreement with earlier results published by Belury and Kempa-Stecko (14). They observed that a radiolabeled CLA mixture was desaturated into an 18:3 product, which was not further identified in a similar way as linoleic acid was converted into  $\gamma$ -linolenic acid.

**Elongation study.** To investigate further the hypothetical metabolic pathway of rumenic acid into conjugated PUFA, an *in vitro* elongation study was carried out using radiolabeled 6*c*,9*c*,11*t*-18:3 obtained by total stereoselective synthesis (17). The elongation of 6*c*,9*c*,11*t*-18:3 was compared to that of  $\gamma$ -linolenic acid as its nonconjugated homolog.

The chain elongation of [1-<sup>14</sup>C]6*c*,9*c*,11*t*-18:3 was carried out in the presence of malonyl-CoA and under an argon atmosphere in order to avoid desaturation (25). Table 2 shows the conversion of [1-<sup>14</sup>C]6*c*,9*c*,12*c*-18:3 into [3-<sup>14</sup>C]-8*c*,11*c*,14*c*-20:3 and [1-<sup>14</sup>C]6*c*,9*c*,11*t*-18:3 into [3-<sup>14</sup>C]-8*c*,11*c*,13*t*-20:3 at various substrate concentrations (10–60 nmol) by rat liver microsomes under elongation conditions. The [1-<sup>14</sup>C]6*c*,9*c*,11*t*-18:3 was elongated in a similar way as  $\gamma$ -linolenic acid, and its conversion rates were 1.5-fold higher ( $P < 0.05$ ) than those of [1-<sup>14</sup>C]6*c*,9*c*,12*c*-18:3 at all substrate concentrations (7.9 ± 0.3 vs. 6.3 ± 0.3 nmol with 10 nmol of substrate and 9.1 ± 1.0 vs. 5.5 ± 1.2 with 60 nmol of substrate, respectively). This suggests that 6*c*,9*c*,11*t*-18:3 is a better substrate for the chain elongation enzyme than  $\gamma$ -linolenic acid under our experimental conditions.

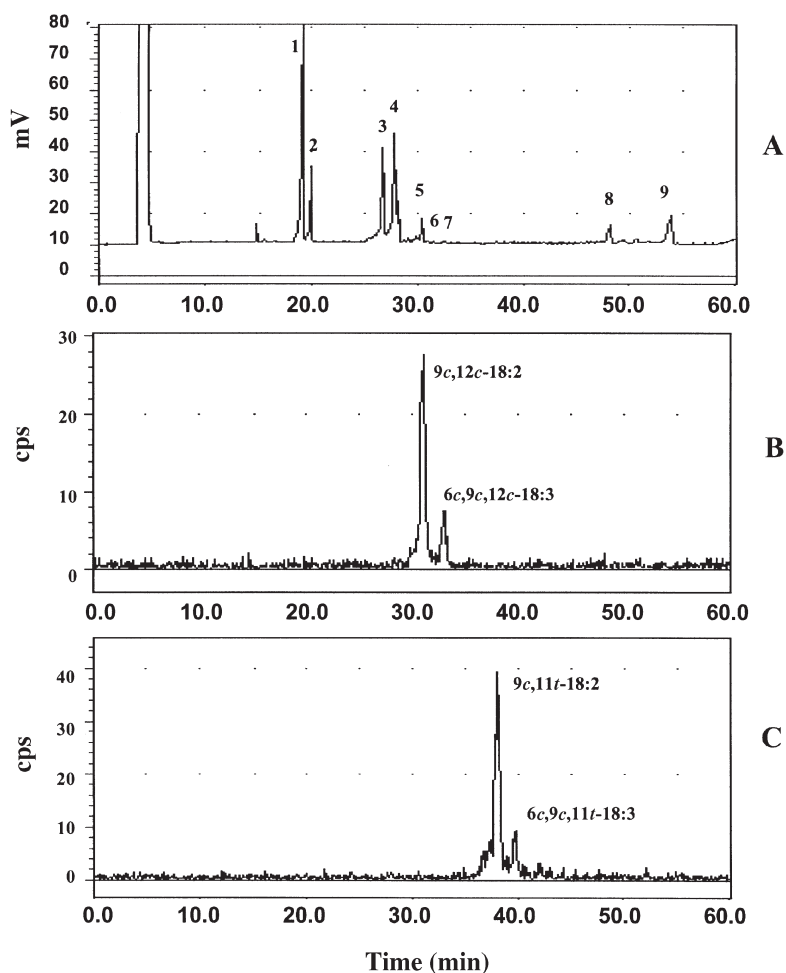

$\gamma$ -Linolenic acid and 6*c*,9*c*,11*t*-18:3 reached the saturating substrate level at 20 nmol. The slight decrease in the conversion

**TABLE 1**  
Formation of the  $\Delta 6$ -Desaturated Products (in % conversion and nmol) from Radiolabeled 9*c*,12*c*-18:2 (linoleic acid) and 9*c*,11*t*-18:2 (rumenic acid) by Rat Liver Microsomes<sup>a</sup>

<sup>a</sup>The conditions for incubations are described in the Materials and Methods section. Results are expressed as mean ± SD of four independent determinations. After ANOVA, means were compared according to the least difference and classified in decreasing order. Means in rows with different superscript letters were significantly different ( $P < 0.05$ ).

**FIG. 1.** GC analysis of the FAME obtained from liver microsomes (5 mg protein) incubated for 15 min with 60 nmol of  $[1-^{14}\text{C}]9c,12c-18:2$  (trace A: FID, trace B: radioactive signal) or with 120 nmol of  $[1-^{14}\text{C}]9c,11t-18:2$  (trace C: radioactive signal). Peak 1: 16:0; 2: 16:1; 3: 18:0; 4: 18:1; 5: 18:2n-6; 6: 18:3n-6; 7: 18:3n-3; 8: 20:3n-9; 9: 20:4n-6.

rates above this concentration could be related to an inhibitory effect of the substrate or of the metabolites. The radio-GC and GC-FID results obtained after injection on a BPX-70 column (Fig. 2B) confirmed that the  $6c,9c,11t-18:3$  was elongated into its corresponding conjugated 20:3, as evidenced by comparing the retention time with that of the  $8c,11c,13t-20:3$  standard obtained by total synthesis (17). Moreover, 23:0 and 24:0 (lignoceric acid) were added to the conjugated 20:3 metabolite formed from  $6c,9c,11t-18:3$  in liver microsomes and to  $8c,11c,13t-20:3$  standard to calculate the ECL by GC on a polar column (CP-Sil, 60–190°C) as carried out for the  $\Delta 6$ -desaturation study. The two experimental ECL values are identical (ECL: 23.55).

**$\Delta 5$ -Desaturation study.** Finally, the  $\Delta 5$ -desaturation of the  $8c,11c,13t-20:3$  was investigated in comparison to dihomo- $\gamma$ -linolenic acid ( $8c,11c,14c-20:3$ ). Table 3 presents the conversion of  $[1-^{14}\text{C}]8c,11c,13t-20:3$  and  $[1-^{14}\text{C}]8c,11c,14c-20:3$  (10–100 nmol) by liver microsomes into their corresponding  $\Delta 5$ -desaturated metabolites. Conjugated 20:3 was converted into  $5c,8c,11c,13t-20:4$ . In comparing the two incubated sub-

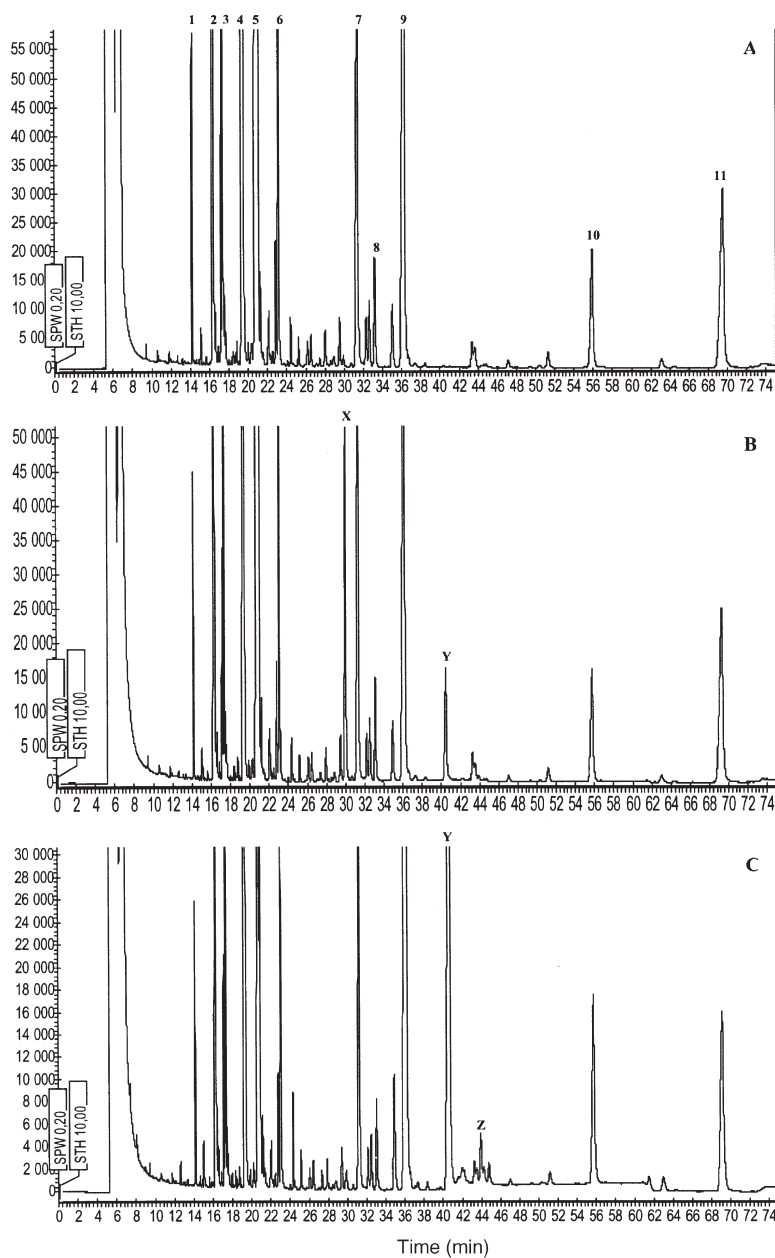

strates, the rate of conversion of  $[1-^{14}\text{C}]8c,11c,13t-20:3$  was about one-tenth that of  $8c,11c,14c-20:3$  ( $0.8 \pm 0.1$  vs.  $7.8 \pm 0.1$  nmol, respectively) at 10 nmol concentration and about one-fifth that of its natural homolog at the highest concentration ( $4.1 \pm 1.0$  vs.  $19.6 \pm 1.5$  nmol) at 100 nmol. The saturating substrate level for  $[1-^{14}\text{C}]8c,11c,14c-20:3$  was reached at 60 nmol whereas for  $[1-^{14}\text{C}]8c,11c,13t-20:3$  the plateau seemed to be reached at 100 nmol. The desaturation product of  $8c,11c,13t-20:3$  was clearly identified as  $5c,8c,11c,13t-20:4$  by GC-FID on a BPX-70 column (Fig. 2C) by comparing the retention time of the desaturation product to that of an authentic standard previously purified and characterized from adipose tissue of rats fed ruminic acid (13). Moreover, when 24:0 and 26:0 were added to the conjugated 20:4 metabolite formed from  $8c,11c,13t-20:3$  in liver microsomes and to the authentic standard containing  $5c,8c,11c,13t-20:4$  for calculation of the ECL by GC on a polar column (CP-Sil, 60–190°C), the two experimental ECL values were identical (ECL: 25.13).

The level of conversion of  $8c,11c,13t-20:3$  into  $5c,8c,11c,13t-20:4$  (arachidonic acid) was considerably lower than

for dihomog- $\gamma$ -linolenic acid, indicating that 8c,11c,13t-20:3 was a poorer substrate for the  $\Delta^5$ -desaturase.

The results obtained are in agreement with the data from the nutritional studies on rats and mice. Recently, Banni *et al.* (26) reported the occurrence of conjugated 18:3 and 20:3 FA in different lipid classes of the liver after administration of 9c,11t-18:2 to rats. The content of conjugated 20:3 FA was about fourfold higher than that of conjugated 18:3 or 20:4 FA. They measured 0.7  $\mu$ g/mg lipid of conjugated 18:3, 3.9  $\mu$ g/mg lipid of conjugated 20:3, and 1.0  $\mu$ g/mg lipid of conjugated 20:4 (26). Similar results were obtained in a feeding study on rats using pure CLA isomers (13).

Our results indicate rumenic acid (9c,11t-18:2) was mainly converted into conjugated 20:3 (8c,11c,13t-20:3), as it was only slightly converted into 6c,9c,11t-18:3 by  $\Delta^6$ -desaturation, and 6c,9c,11t-18:3 was well elongated into 8c,11c,13t-20:3. The conversion of 8c,11c,13t-20:3 to the corresponding conjugated 20:4 was very low. Rumenic acid may likely follow the same *in vivo* metabolic pathway of conversion into long-chain FA as linoleic acid. In this view, the detection of conjugated 18:3, 20:3, and 20:4 FA in tissues of CLA-fed animals would result from successive  $\Delta^6$ -desaturation, elongation, and  $\Delta^5$ -desaturation of rumenic acid.

Ciro Balestrieri, and Lucio Quagliuolo\*

Department of Biochemistry and Biophysics, Second University of Naples, 80138 Napoli, Italy

**ABSTRACT:** Release of FFA from membrane phospholipids was observed after incubation of umbilical cord vein-derived endothelial cells (HUVEC) with vascular endothelial growth factor (VEGF). In particular, we found an increase of arachidonate, stearate, and palmitate in a time-dependent manner with a peak at 30 min. The maximum increase was reached by arachidonate (4.4-fold), followed by stearate (2.2-fold) and palmitate (1.3-fold). The arachidonate increase can be ascribed to the activation of phospholipase A<sub>2</sub> (PLA<sub>2</sub>). In fact, cells preincubated with arachidonyl trifluoromethyl ketone, a PLA<sub>2</sub> inhibitor, showed a marked reduction in arachidonate mobilization. The role of Ca<sup>2+</sup> in PLA<sub>2</sub> activation was also investigated. Cells incubated with VEGF in the presence of EGTA showed a marked decrease in arachidonate mobilization, whereas incubation with the calcium ionophore A23187 alone produced an increase in arachidonate, although to a lesser extent compared with the VEGF stimulation. Incubation with A23187 in association with PMA produced the same increase in arachidonate as the VEGF treatment. Mitogen-activated protein kinase (MAPK) activity was also found to increase as a consequence of VEGF stimulation. Taken together, these results suggest that the VEGF-mediated activation of PLA<sub>2</sub> in HUVEC is dependent on both MAPK-mediated phosphorylation and Ca<sup>2+</sup> increase. Furthermore, the increase in stearate and palmitate likely is brought about by the activation of a pathway involving phospholipase D, phosphatidate phosphohydrolase (PAP), and DAG lipase. In fact, the increase in those FFA was prevented when HUVEC were stimulated with VEGF in the presence of ethanol (which inhibits the formation of phosphatidate), propranolol (a specific inhibitor of PAP), or RHC-80267 (a specific inhibitor of DAG lipase).

Paper no. L9096 in *Lipids* 37, 1047–1052 (November 2002).

Vascular endothelial growth factor (VEGF), also known as vascular permeability factor, is a potent mitogen for vascular endothelial cells. This cytokine has been shown to play a central role in the angiogenesis associated with physiological and pathological processes (1–4). Angiogenesis, the process by which new blood vessels are formed *via* proliferation of vascular endothelial cells (5), is essential in reproduction,

development, and wound repair (6). The mechanisms involved in the initiation and progression of angioproliferative disease processes are poorly understood. Recent evidence indicates that VEGF is essential for embryonic angiogenesis (7), for angiogenesis in the female reproductive tract (8–10), and for morphogenesis of the epiphyseal growth plate and endochondral bone formation (11). Additional studies indicate that VEGF has a relevant role in pathological angiogenesis. Indeed anti-VEGF monoclonal antibodies or other VEGF inhibitors block the growth of several human tumor cell lines in nude mice (12), whereas augmented VEGF expression is correlated with increased tumor growth and vascularity (13,14).

The action of VEGF is mediated by two receptors, the human *fms*-like tyrosine kinase (Flt-1) (15) and fetal liver kinase 1 (Flk-1) (16,17), the mouse homolog of the human kinase insert domain receptor (KDR) (18). The distal signaling pathway for VEGF receptors has not been completely determined, although it is known that VEGF rapidly increases the intracellular Ca<sup>2+</sup> concentration in endothelial cells (19), causes a striking and transient increase in mitogen-activated protein kinase (MAPK) activity, and stimulates phospholipase C- $\gamma$  tyrosine phosphorylation (20). When stimulated with VEGF, human endothelial cells in culture release arachidonic acid from their phospholipid storage sites (21). Lipid metabolism plays a crucial role in cell signaling, and considerable efforts have been made to identify the pathways for arachidonate mobilization from cellular phospholipids (22). Although it is assumed that the main step involves the action of phospholipase A<sub>2</sub> (PLA<sub>2</sub>), another pathway has been suggested to play a role in arachidonate mobilization, i.e., the activation of phospholipase D (PLD), which catalyzes the hydrolysis of PC to produce choline and PA with subsequent liberation of arachidonate (23,24). However, PA itself possesses signaling properties, including the stimulation of actin stress fiber formation in porcine aortic endothelial cells (25). Furthermore, PA was found to induce the chemotactic migration of endothelial cells from established monolayers, which is an important step in angiogenesis (26).

The aim of this work was to investigate the pathways involved in the release of FFA in VEGF-stimulated human umbilical cord vein-derived endothelial cells (HUVEC). Herein we report evidence that, upon VEGF stimulation, palmitate and stearate, as well as arachidonate, are increased. This finding suggests the involvement of at least two different pathways, one taking place *via* cPLA<sub>2</sub> activation, which generates

Abbreviations: AACOCF<sub>3</sub>, arachidonyl trifluoromethyl ketone; ADAM, 9-anthryldiazomethane; HUVEC, human umbilical cord vein-derived endothelial cells; KDR, kinase insert domain receptor; MAPK, mitogen-activated protein kinase; PAP, phosphatidate phosphohydrolase; PKC, protein kinase C; PLA<sub>2</sub>, phospholipase A<sub>2</sub>; PLD, phospholipase D; RHC-80267, a DAG lipase inhibitor; VEGF, vascular endothelial growth factor.

arachidonate, and the other involving PLD, phosphatidate phosphohydrolase (PAP), and DAG lipase, which brings about increases in stearate and palmitate.

## EXPERIMENTAL PROCEDURES

**Materials.** Collagenase from *Clostridium histolyticum* was from Roche S.p.A. (Monza, Italy). Human von Willebrand antiserum was from Nordic Immunology (Tilberg, The Netherlands). Anti-human histocompatibility antigens class I and class II were purchased from Becton, Dickinson, and Co. (Franklin Lakes, NJ). [ $\gamma$ - $^{32}$ P]ATP (3000 Ci/mmol) was purchased from Amersham (Arlington Heights, IL). Myelin basic protein, the calcium ionophore A23187, porcine sodium heparin, endothelial cell growth factor, PMA, BSA, and FFA standards were from Sigma (St. Louis, MO). Arachidonyl trifluoromethyl ketone (AACOCF<sub>3</sub>, a PLA<sub>2</sub> inhibitor) and 1,6-bis(cyclohexyloximino-carbonylamino) hexane (RHC-80267, a specific inhibitor of DAG lipase) were from Alexis Biochemicals (c/o Vinci-Biochem, Vinci, Italy). Fetal calf serum was from Hyclone Lab (Logan, UT). Recombinant human VEGF was from Genzyme Diagnostics (Cambridge, MA). 9-Anthryldiazomethane (ADAM) was from Molecular Probes Inc. (Eugene, OR). All other reagents were of analytical grade.

**Endothelial cell culture.** HUVEC were isolated by treatment of human umbilical cord veins with 0.2% collagenase from *C. histolyticum* (20 min, 37°C) and cultured as described previously (27) until they reached confluence. The cells were characterized by morphologic criteria and positive immunofluorescence for von Willebrand factor and class I, but not class II, histocompatibility antigens (27). Cells between passages 3 and 10 were used. Cell viability was assessed following the release of cytosolic lactate dehydrogenase activity by a cytotoxicity detection kit (Roche).

**FFA determination.** FFA were determined by HPLC using a fluorescence detector after derivatization with ADAM, a fluorescent probe that specifically reacts with free carboxyl groups. To profile the FFA released by HUVEC, cells were grown on 35 mm-diameter dishes until the cell number reached  $4.6 \times 10^5 \pm 3.2 \times 10^4$ . Cells were starved in medium without serum and growth factor for 18 h, then washed three times with PBS and incubated at 37°C in 2 mL RPMI-1640 medium with VEGF (50 ng/mL) and/or other stimuli for the appropriate time. After incubation the medium was removed, 1 nmol of eicosanoate was added as internal standard, and the incubation was stopped by adding methanol (2 mL/dish). Cells were scraped from the dish, the suspension was transferred to borosilicate tubes, and lipids were extracted according to the procedure of Bligh and Dyer (28). Total lipids were extracted into chloroform by shaking vigorously for 90 s. After centrifugation ( $1500 \times g$ , 5 min), the chloroform solution was transferred into another tube and dried under vacuum by using the Univapor Concentrator Centrifuge, model Univapo 100 H (Uni Equip, Martinsried, Germany). The dried lipids were dissolved in 450  $\mu$ L acetonitrile; 50  $\mu$ L solution containing 1 mg/mL of ADAM in acetonitrile was then

added and the mixture was incubated overnight at room temperature (29). After incubation, 100  $\mu$ L of the mixture was directly analyzed by HPLC.

The separation of ADAM-derivatized FFA was performed on a Symmetry C<sub>18</sub> reversed-phase column,  $4.6 \times 150$  mm, filled with a stationary phase of 3.5  $\mu$ m average particle size (Waters, Milford, MA), by a gradient liquid chromatograph consisting of a controller (model 600) and a pump (model 626) (Waters). The column was eluted with methanol/water (85:15, vol/vol) for 10 min, then with 100% methanol. The flow rate was 1.0 mL/min. The peaks were detected with a Shimadzu Model 160 fluorescence spectrometer equipped with a computer with the Millennium software (Waters). The excitation and emission wavelengths were 364 and 412 nm, respectively. The amount of derivatized FFA was calculated by comparing the peak area with authentic standards and, using the eicosanoate as internal standard, a recovery of  $92 \pm 5\%$  was calculated.

**MAPK assay.** Cells ( $10^5$ ) were plated on 60-mm dishes and cultured for 24 h. Confluent cells were serum-starved for 18 h and stimulated with VEGF (50 ng/mL) at different times in 1 mL of M199 medium. Incubations were terminated by aspiration of the medium and addition of 500  $\mu$ L of lysis buffer [1% Triton X-100, 20 mM Tris/HCl (pH 8), 137 mM NaCl, 10% (vol/vol) glycerol, 2 mM EDTA, 0.14 unit/mL of aprotinin, 20  $\mu$ M leupeptin, and 1 mM sodium orthovanadate] at 4°C for 20 min (30). Cells were scraped from the dish, the lysate was centrifuged at  $14,000 \times g$  for 10 min at 4°C, the supernatant was collected, and the protein concentrations were determined by the method of Bradford (31). Approximately 20  $\mu$ g of proteins were immunoprecipitated overnight at 4°C with 5  $\mu$ g/mL MAPK polyclonal antiserum (erk1-CT). Immune complexes were purified by incubation for 3 h at 4°C with 80  $\mu$ L of protein A-Sepharose slurry (40  $\mu$ L bead volume). The resin was then washed three times with Tris-buffered saline and once with kinase buffer (30 mM Tris/HCl, pH 8.0; 20 mM MgCl<sub>2</sub>; 1 mM DTT) and resuspended in 30  $\mu$ L of kinase buffer containing 7  $\mu$ g of myelin basic protein, 2  $\mu$ M ATP, and 5  $\mu$ Ci of [ $\gamma$ - $^{32}$ P]ATP (32). After incubation for 20 min at 30°C, a BSA solution was added to the suspension at final concentration of 1 mg/mL, and proteins were precipitated by adding 1 mL of 5% TCA. The samples were filtered on a glass fiber filter AP40 (Millipore, Milford, MA) and washed three times with 2 mL of 5% TCA to remove unincorporated radioactivity. The filters were transferred to scintillation vials and counted for radioactivity; counts were normalized for the amount of protein used in the immunoprecipitation step. Owing to a possible contamination of protein kinase C (PKC) in the immunoprecipitate, the substrate phosphorylation was ruled out in parallel experiments by using bisindolylmaleimide, a selective inhibitor of the PKC.

## RESULTS

**FFA release by HUVEC stimulated with VEGF.** Serum-deprived HUVEC were stimulated at various times with 50 ng/mL VEGF. After total lipids were extracted, FFA were

**FIG. 1.** Chromatogram of 9-anthryldiazomethane-derivatized FA extracted from human umbilical cord vein-derived endothelial cells (HUVEC). Cells were stimulated with vascular endothelial growth factor (VEGF) for 30 min. Eicosanoate was added as internal standard. AA, arachidonate; OLE, oleate; PAL, palmitate; STE, stearate; EICO, eicosanoate.

derivatized with ADAM and analyzed by HPLC, as described in the Experimental Procedures section. Figure 1 shows a typical chromatographic pattern of ADAM-derivatized FFA obtained from a representative experiment in which HUVEC were stimulated with VEGF for 30 min. When confluent cultures of HUVEC were treated with VEGF, a time-dependent increase in FFA occurred in the cells. As shown in Figure 2, the amount of arachidonate, palmitate, and stearate increased in the cell, with a maximum at 30 min followed by a decrease that, after 60 min, restored the initial conditions. VEGF stimulated an increase in arachidonate from 445 to 1950 pmol/ $10^6$  cells after 30 min, whereas the palmitate and stearate increases were from 4580 to 6150 pmol/ $10^6$  cells and from 2140 to 4660 pmol/ $10^6$  cells, respectively. Oleate mobiliza-

**FIG. 2.** Time course of FFA production in HUVEC stimulated with VEGF. Cells were stimulated with VEGF (50 ng/mL) for the indicated times. FFA were extracted and their amounts measured by HPLC. Data are mean  $\pm$  SD of triplicate experiments. The amount of each FFA was measured at incubation time zero and used as a control. No substantial difference was found in unstimulated cells among incubation time zero and other time points. For abbreviations see Figure 1.

tion showed a different behavior, with a limited decrease that had a minimum at 30 min (from 1550 to 1070). By expressing the data as fold of FFA increase with respect to the unstimulated cells (at the same time points), we found that the increases in arachidonate, stearate, and palmitate were 4.4-, 2.2-, and 1.3-fold, respectively, whereas oleate had a decrease of 0.7-fold.

**Role of the  $PLA_2$  in FFA release induced by VEGF.** HUVEC were preincubated for 5 min in the presence of the  $PLA_2$  inhibitor AACOCF<sub>3</sub> at a concentration of 25  $\mu$ M, followed by VEGF stimulation for an additional 30 min at 37°C. In these conditions a marked inhibition of arachidonate mobilization was observed, from 4.4- to 2.1-fold (Fig. 3), compared with VEGF alone. Instead, the  $PLA_2$  inhibitor poorly affected the production of saturated and monounsaturated FFA; however, the increase in oleate was higher than that observed with VEGF alone.

The role of calcium ions in FA mobilization was also investigated. HUVEC were incubated with either VEGF for 30 min in the presence of 2 mM EGTA, with 10  $\mu$ M calcium ionophore A23187 for 10 min, or with 1  $\mu$ M PMA for 5 min followed by A23187 (10  $\mu$ M) for 10 min. As shown in Figure 3, the chelation of divalent cations was accompanied by a reduction in arachidonate mobilization from 4.4- to 1.8-fold, indicating that the VEGF-stimulated arachidonate production is basically calcium dependent. In fact, cells incubated for 10 min with A23187 showed a consistent increase in arachidonate production, which became more pronounced when the cells were preincubated for 5 min with PMA followed by an additional 10 min in the presence of 10  $\mu$ M A23187.

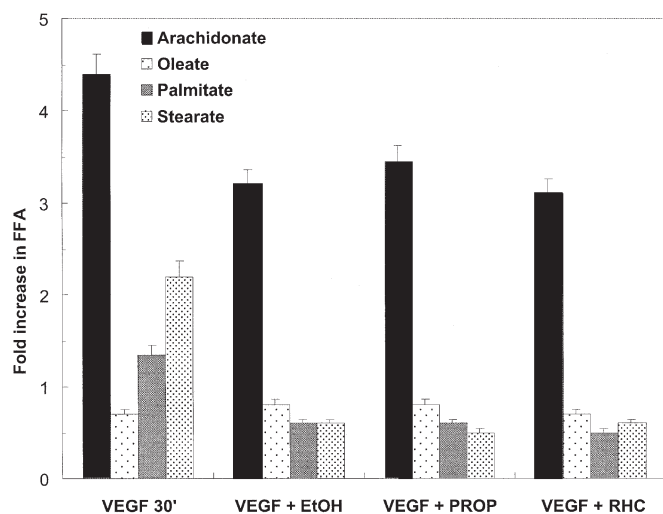

**FIG. 3.** Role of phospholipase A<sub>2</sub> ( $PLA_2$ ) on FFA production in VEGF-stimulated HUVEC. Cells were stimulated with VEGF (50 ng/mL) for 30 min, or incubated with arachidonyl trifluoromethyl ketone (AACOCF<sub>3</sub>, a  $PLA_2$  inhibitor) (25  $\mu$ M) for 5 min and then for an additional 30 min in the presence of VEGF (50 ng/mL), or with VEGF in the presence of 2 mM EGTA for 30 min. Cells were also incubated with the calcium ionophore A23187 (10  $\mu$ M) for 10 min, or with PMA (1  $\mu$ M) for 5 min and then for an additional 10 min in the presence of A23187. For other abbreviations see Figure 1.

Although the A23187 incubation produced only an increase in arachidonate, the preincubation with PMA also resulted in increases in palmitate and stearate.

**Role of PLD in the FFA release induced by VEGF.** VEGF is known to induce an increase in arachidonate in HUVEC (21) due to the activation of PLA<sub>2</sub>, which specifically hydrolyzes arachidonic acid at the *sn*-2 position of phospholipids. However, the increase in saturated FFA in HUVEC stimulated with VEGF has not been reported so far. The mobilization of saturated FA could be the result of a metabolic pathway involving PLD, PAP, and DAG lipase. To verify this hypothesis, we used specific inhibitors acting at the level of each of these metabolic steps. As shown in Figure 4, cells incubated with VEGF in the presence of 2% (vol/vol) ethanol, which prevents the formation of PA by PLD, did not show any increase in stearate and palmitate, and the arachidonate production was scarcely affected. Similar results were obtained using propranolol (200 μM), which is a PAP inhibitor, and the DAG lipase inhibitor RHC-80267 (6 μM).

**Effect of VEGF on MAPK activity.** To investigate the mechanism involved in PLA<sub>2</sub> activation responsible for the arachidonate release triggered by VEGF, the role of MAPK in signal transduction was also evaluated. Indeed, the role of MAPK phosphorylation in the activation of cytosolic PLA<sub>2</sub> by phosphorylation is now recognized. As shown in Figure 5, MAPK activity, as evaluated by the incorporation of <sup>32</sup>P into the myelin basic protein (see the Experimental Procedures section), displayed a ninefold increase and reached a maximum 20 min after stimulation with VEGF. MAPK activity

**FIG. 4.** Role of phospholipase D on FFA production in VEGF-stimulated HUVEC. Cells were preincubated for 10 min with ethanol (which inhibits the formation of phosphatidate) (2%, vol/vol), for 15 min with propranolol (PROP, a specific inhibitor of phosphatidate phosphohydrolyase) (200 μM), for 5 min with RHC-80267 (a specific inhibitor of DAG lipase) (6 μM), and then stimulated with VEGF (50 ng/mL) for an additional 30 min. Following the treatment, FFA were extracted and analyzed by HPLC as described in the Experimental Procedures section. The results are expressed as the fold increase with respect to untreated cells used as a control. Data are mean ± SD of triplicate experiments. For other abbreviations see Figure 1.

**FIG. 5.** Time course of mitogen-activated protein kinase (MAPK) activity in VEGF-stimulated HUVEC. Cells were stimulated with VEGF (50 ng/mL) for the indicated times and cell lysates were immunoprecipitated with the anti-MAPK antibody. The kinase activity was determined in the immunoprecipitate by incorporation of <sup>32</sup>P into the myelin basic protein used as substrate. Results are mean ± SD of triplicate experiments. Data were corrected for radioactivity background by omitting the substrate from the incubation mixture. For other abbreviations see Figure 1.

was undetectable in unstimulated control cells. Furthermore, by using bisindolylmaleimide, a selective inhibitor of PKC, we confirmed that the phosphorylation was due only to the MAPK. In fact, since PKC is involved in the phosphorylation cascade of MAPK (33), it could be coprecipitated by the MAPK antiserum.

## DISCUSSION

The results reported herein demonstrate that in VEGF-stimulated HUVEC, at least two cell-signaling pathways, involving PLA<sub>2</sub> and PLD, are activated. It is well documented that PLA<sub>2</sub> participates in the mobilization of arachidonic acid from the *sn*-2 position of phospholipids, and recently (21,34) the activation of PLA<sub>2</sub> has been shown to take place in VEGF-mediated HUVEC stimulation in an extracellular-regulated kinase- and PKC-sensitive manner. Usually, the way to monitor the mobilization of arachidonate consists of measuring the release, following an appropriate stimulus, of radioactive arachidonate previously incorporated into the cell. This method, although very simple, does not allow the evaluation of other FFA. In this work we used a different approach based on the HPLC determination of FFA derivatized with the fluorescent agent anthryldiazomethane, which selectively reacts with the free carboxyl groups. In this way, we were able to determine different FFA at pmol levels simultaneously and to measure their relative amounts as a consequence of the cellular stimulation. In time-course experiments (Fig. 2), we observed that in VEGF-stimulated HUVEC, the amount of arachidonate increased, reaching the maximum at 30 min. The arachidonate increase was also accompanied by increases

in stearate and palmitate and by a slight decrease in oleate. The more sustained increase, however, concerned arachidonate, whose amount increased 4.4-fold, whereas the amounts of stearate and palmitate were augmented by 2.2- and 1.3-fold, respectively. The increase in arachidonate was essentially due to activation of PLA<sub>2</sub>, since we found that the inhibitor of a calcium dependent PLA<sub>2</sub>, AACOCF<sub>3</sub>, greatly reduced the VEGF-mediated release of arachidonate (Fig. 3). Furthermore, when cells were incubated with VEGF in the presence of the calcium chelator EGTA, the same result was obtained. Instead, the incubation of HUVEC with the calcium ionophore A23187 resulted in an arachidonate production that equaled that induced by VEGF when the ionophore was used in association with PMA. In fact, phorbol esters stimulate PKC, which activates PLA<sub>2</sub> via MAPK (35); therefore, calcium-dependent translocation from the cytosol to the membrane and MAPK phosphorylation act synergistically to activate PLA<sub>2</sub> (22). The involvement of MAPK was also confirmed by the increase in its activity in VEGF-stimulated HUVEC (Fig. 5). The activation of MAPK in VEGF-stimulated HUVEC was already demonstrated following the phosphorylation of PLA<sub>2</sub> (21); however, here we provide direct evidence that an increase in MAPK activity takes place.

Moreover, using the HPLC analysis, we were able to determine increases in saturated FFA, such as stearate and palmitate, that have not been reported so far in VEGF-stimulated HUVEC. Increases in saturated FFA could originate from a remodeling pathway using DAG as substrate. However, DAG can be produced directly by the action of PLC or by the combined action of PLD and PAP. The finding that in porcine aortic endothelial cells PLC activation generates essentially polyunsaturated DAG species, whereas PLD activation generates saturated/monounsaturated DAG species (36), led us to investigate the role played by PLD in VEGF-stimulated HUVEC. In fact, an increase of PLD activity in endothelial cells stimulated by VEGF was reported previously (37). Consistent with this notion, we found that HUVEC treated with VEGF in the presence of ethanol showed a strong reduction in stearate and palmitate with respect to VEGF alone (Fig. 4). In fact, PLD utilizes ethanol in a transphosphatidyl reaction, leading to the formation of phosphatidylethanol, which is a poor substrate for PAP. When propranolol, a specific inhibitor of PAP, is used in association with VEGF, we also observed a reduction in stearate and palmitate with respect to VEGF-stimulated cells. These results were further confirmed by experiments carried out using RHC-80267, a DAG lipase inhibitor. Taken together, these data clearly demonstrate that unsaturated FFA production was generated by a PLD-dependent pathway. In fact, PLD activation leads to the formation of PA, which is converted to DAG by the action of PAP (38). DAG is then involved in the phospholipid remodeling pathway through DAG lipase, which brings about the increase in saturated FFA. Unlike the mobilization of palmitate and stearate, that of oleate showed a behavior that is difficult to explain. In fact, the amount of this FFA decreased in HUVEC incubated for 30 min with VEGF.

A probable explanation for this finding is that oleate could be used in replacing the arachidonate in the lysophospholipids generated by the action of PLA<sub>2</sub>.

The results we report suggest that when HUVEC are stimulated with VEGF, at least two different pathways are activated, involving PLA<sub>2</sub> and PLD. Since PLD triggers the production of PA and DAG, which possess signaling properties (25,26), the elucidation of the PLD-dependent pathway(s) could be of great interest in understanding the molecular basis of the VEGF action in endothelial cells.

# Olive Oil Phenolics Protect LDL and Spare Vitamin E in the Hamster

Sheila A. Wiseman, Lilian B.M. Tijburg, and Frans H.M.M. van de Put\*

Unilever Health Institute, 3133 AT Vlaardingen, The Netherlands

**ABSTRACT:** An animal feeding trial was conducted to investigate whether olive oil phenolics can act as functional antioxidants *in vivo*. To this end, hamsters were exposed for a period of 5 wk to a dietary regime with either a phenol-rich extra virgin olive oil or extra virgin olive oil from which phenols were removed by ethanol/water-washing. The original oil used in the high olive phenol diet was also used for the preparation of the low phenol diet in order to keep the FA compositions exactly the same. In addition, the vitamin E content was kept identical in both diets. This careful preparation of the diets was undertaken in order to prevent these factors from influencing the antioxidative status in plasma and LDL. Removal of olive oil phenols was shown to reduce both the vitamin E level in plasma and the resistance of LDL to *ex vivo* oxidation. The results of this study support the idea that extra virgin olive oil phenols improve the antioxidant defense system in plasma by sparing the consumption of vitamin E under normal physiological circumstances.

Paper no. L9075 in *Lipids* 37, 1053–1057 (November 2002).

The oxidation of LDL is believed to be an important factor in the onset of the pathogenesis of atherosclerosis. Diets rich in antioxidants, such as the Mediterranean diet, are believed to provide protection against the potentially deleterious effects of oxidative stress. Epidemiological evidence supports this idea since the rate of coronary heart disease is low in Mediterranean countries (1–3).

Extra virgin olive oil (EVOV) is an important constituent of the Mediterranean diet and has a unique composition compared to refined oils, one of the main differences being that the former contains significant amounts of phenols in addition to vitamin E. Major phenolic components in EVOV are oleuropein- and ligstroside-aglycones and their respective hydrolysis products hydroxytyrosol and tyrosol. The properties of hydroxytyrosol and tyrosol have been extensively studied and have led to the conclusion that these phenols, especially hydroxytyrosol, possess powerful antioxidant properties (1).

Various studies have demonstrated that olive oil phenols strongly protect LDL against oxidation *in vitro*, possibly by retarding the consumption of vitamin E endogenously present in these particles (1,4–6). Further support has been obtained with

feeding trials in rabbits in which diets enriched with EVOV extend the resistance of LDL to oxidation compared to diets enriched with refined olive oil (7–9). Whether olive oil phenols have similar effects in humans is less clear. The bioavailability of olive oil phenols has been demonstrated by several groups (10–12). Hydroxytyrosol, tyrosol, and their metabolites are detected in urine following an oral dose of olive oil. The administration of phenol-rich olive oils also leads to a reduced urinary excretion of isoprostanes, a sensitive biomarker for lipid peroxidation (11). Whether olive oil phenols increase the antioxidant capacity in plasma and protect LDL against peroxidation in humans is, however, less clear. In men with peripheral vascular disease, EVOV increased the resistance to LDL oxidation more than refined olive oil (13). Other studies, however, failed to demonstrate a clear difference between EVOV and refined olive oil (or oleic acid-rich oils) on *ex vivo* LDL oxidizability (14–16). Not only differences in phenols but also differences in vitamin E content and lipid composition between the oils used in the same study may account for the presence or absence of these effects.

The aim of the present animal study was to investigate whether olive oil phenolics can act as functional antioxidants *in vivo*. To this end, hamsters were supplemented with a diet containing either a phenol-rich EVOV or EVOV from which phenols had been removed by ethanol/water-washing. Great care was taken in the preparation of the diets. The FA composition and the vitamin E content were identical in both diets to prevent these factors from influencing the antioxidant status. This study describes the effects of dietary supplementation of EVOV phenols on the plasma antioxidant status and on the resistance of LDL to oxidation in the hamster.

## MATERIALS AND METHODS

**Study design.** The experimental protocol was approved by the Animal Welfare Officer and the Animal Experimentation Committee of Unilever Research Vlaardingen. Twenty male F<sub>1</sub>B hybrid Syrian golden hamsters, aged 11 wk on arrival, were obtained from BioBreeders Inc. (Fitchburg, MA). The animals were individually housed in Makrolon type II cages under standard conditions (temperature 18 ± 1°C, relative humidity 65 ± 10%, and day/night cycles of 12/12 h). A layer of sawdust was provided as bedding. During the 14-d period, all animals received a semipurified diet containing refined olive oil (zero phenols) as the only fat source. At the end of the prestudy

\*To whom correspondence should be addressed at Erasmus University, Department of Health Physics, Groene Hilledijk 301, 3075 EA Rotterdam, The Netherlands. E-mail: f.h.m.m.vandeput@azr.nl

Abbreviations: EVOV, extra virgin olive oil; FRAP, ferric-reducing ability of plasma; TEAC, Trolox Equivalent Activity.

period, the animals were allocated to two groups of 10 animals each on the basis of body weight and received one of the experimental olive oil diets for a period of 5 wk. Food and drinking water were freely available throughout the prestudy and the study periods. All animals were clinically observed and weighed weekly. Food consumption was determined at 2-wk intervals. At the end of the experiment (5 wk) after fasting for 16 h, the animals were anesthetized under halothane, and retro-orbital blood samples were collected into sodium heparin-coated tubes and plasma was prepared immediately at 4°C. Plasma samples for LDL isolation were mixed with 0.6% sucrose and stored at -70°C, together with plasma samples for lipid and antioxidant activity analysis. The animals were then killed by decapitation and internal organs inspected macroscopically. Liver weights were noted, and samples of the right median lobe were fixed in 10% neutral buffered formalin. Sections of the liver were cut, stained with hematoxylin azaphloxin, and examined microscopically.

**Experimental diets.** Both semipurified olive oil diets were based on a single batch of EVOV (Van den Berg Foods, Crema, Italy) that contained 196 mg olive oil phenols per kg oil. (The method to measure the phenol concentration and composition is described below in further detail.) EVOV was washed with ethanol/water to obtain a reduction of the phenol concentration to 26 mg of olive oil phenols per kg. The washing procedure was performed by adding ethanol/water (1:1, w/w) to 10 kg of EVOV in the ratio 15:85 (vol/vol) and stirring for 15 min at 50°C. The extraction was repeated twice with an ethanol/water-olive oil ratio of 10:90 (vol/vol). This washing did not remove minor components such as chlorophyll and sterols (results not shown) but did remove about 49 mg/kg oil of  $\alpha$ -tocopherol from the resulting oil. Vitamin E was equalized to 299 mg  $\alpha$ -tocopherol per kg oil (the measured value in the original batch of EVOV) in both diets by the addition of 67% *d*- $\alpha$ -tocopherol in soybean oil (Sigma-Aldrich, Zwijndrecht, The Netherlands). The minor amount of soybean oil has a negligible influence on the composition of the treated oil (EVOV-EtOH/H<sub>2</sub>O).

All diets contained 30 energy % as olive oil, of which 4.7 energy % was saturated FA, 22.7 energy % monounsaturated FA, and 2.6 energy % PUFA. The FA composition of the original EVOV was analyzed by GC as described previously (7).

**TABLE 1**  
Characterization of the Experimental Olive Oils

Antioxidant parameter	Olive oil <sup>a</sup>	
	EVOV	EVOV-EtOH/H <sub>2</sub> O
Total phenols (ppm)	196	26
Tyrosol (ppm)	41	2
Hydroxytyrosol (ppm)	31	0
Antioxidant activity (mmol Trolox equivalents per gram oil)	1.37	0.53
$\alpha$ -Tocopherol (ppm)	270	261
$\gamma$ -Tocopherol (ppm)	< 20	< 20

<sup>a</sup>EVOV, extra virgin olive oil; EVOV-EtOH/H<sub>2</sub>O, ethanol/water-treated EVOV.

[FA distribution in percentage of the total FA in the EVOV is as follows: 14:0 (not detected), 16:0 (12.4%), 16:1 (1.0%), 18:0 (2.6%), 18:1 (74.1%), 18:2 (8.2%), 20:0 (0.8%), 20:1 (0.4%), 22:0 (0.2%), 22:1 (not detected), 24:0 (0.1%), and 24:1 (not detected)]. Various parameters were determined in the oils. The phenol and vitamin E concentrations of the olive oils were determined by HPLC as previously described (7). The total antioxidant activity in the oils was determined by accurately weighing 1 g of each oil (0.9 g/mL) into a screw-topped tube. One milliliter of heptane (0.68 g/mL) was added to give a solution of olive oil in heptane of 474 mg/mL. Aliquots of these heptane solutions were then analyzed in duplicate for the total antioxidant activity using the Trolox Equivalent Activity (TEAC) assay (17). The results of the phenol analysis and the total antioxidant activity of the experimental oils are presented in Table 1. The composition of the experimental diets is given in Table 2. Cholesterol (Merck, Darmstadt, Germany) was added to all diets at a final concentration of 0.1 g per kg.

**Plasma and LDL analyses.** (i) *Analyses of lipid and antioxidant parameters in plasma and lipoproteins.* Cholesterol and total glycerol were determined in plasma and LDL (cholesterol only) using commercial enzymatic colorimetric methods (Boehringer, Mannheim, Germany). Vitamin E was determined in plasma by HPLC as previously described (7). The plasma antioxidant activity was determined using the ferric-reducing ability of plasma assay (FRAP assay) (18).

(ii) *Isolation of LDL and determination of copper-mediated oxidizability.* LDL was isolated by means of density ultracentrifugation using a Beckman Optima tabletop centrifuge and TLA-120.2 near-vertical rotor according to the method described by Himber and coworkers (19). The protein concentration of the LDL fraction was determined with a modified Lowry protein assay (20). A sample of 20  $\mu$ g LDL protein was diluted to a total volume of 1 mL with PBS, and this solution was placed in a cuvette thermostated to a temperature of 30°C.

**TABLE 2**  
Composition of the Experimental Diets

Ingredient (g/100 g)	Group/diet	
	EVOV	EVOV-EtOH/H <sub>2</sub> O

Solkafloc	5.8	5.8
Mineral mix RMH88 <sup>a</sup>	1.39	1.39
Vitamin mix Vit 96 <sup>b</sup>	0.32	0.32
Cholesterol	0.01	0.01
Total	100.0	100.0

<sup>a</sup>Composition of mineral mix RMH88 (mg/MJ): KCl, 83.18; MgHPO<sub>4</sub>·3H<sub>2</sub>O, 227.21; KH<sub>2</sub>PO<sub>4</sub>, 112.89; KHCO<sub>3</sub>, 170.88; CaCO<sub>3</sub>, 70.11; C<sub>6</sub>H<sub>5</sub>O<sub>7</sub>Na<sub>3</sub>·2H<sub>2</sub>O, 168.98; MnSO<sub>4</sub>·H<sub>2</sub>O, 12.22; ferric citrate, 10.43; zinc citrate, 2.97; cupric citrate, 1.12; KIO, 0.017.

<sup>b</sup>Composition of vitamin mix Vit 96 (without vitamin E) (mg/MJ): choline chloride 50%, 119.5; myoinositol, 5.98; vitamin A 325,000 IE/g, 1.84; vitamin B<sub>1</sub>, 0.36; vitamin B<sub>2</sub>, 0.36; vitamin B<sub>6</sub>, 0.38; vitamin B<sub>12</sub> 0.1%, 3.10; vitamin D<sub>3</sub> 100,000 IE/g, 0.60; vitamin K<sub>3</sub>, 0.24; calcium panthothenate, 1.20; nicotinamide, 1.20; folic acid, 0.06; *d*-biotin, 0.012; maize starch, 43.7; calcium silicate 11.95. For abbreviations see Table 1.

The oxidation of LDL was initiated by the addition  $\text{CuCl}_2$  at a final concentration of  $1 \mu\text{M}$ . The formation of conjugated dienes was monitored spectrophotometrically at a wavelength of 234 nm at 2-min intervals using a UV-vis spectrophotometer equipped with a thermostated multicuvette holder for a period of 240 min or until oxidation was complete (Shimadzu UV 2101PC Spectrophotometer). The oxidation profile of each LDL sample was plotted against time. The lag phase before propagation of oxidation, the maximal rate of oxidation, and the maximal amounts of conjugated dienes formed were determined as described by Esterbauer *et al.* (21).

**Statistical analysis.** Data are presented as mean  $\pm$  SEM, and the Student *t*-test was used to compare the two treatments. Antioxidant parameters were tested using one-tailed comparisons. All other parameters were tested using two-tailed tests. The maximal rate of diene formation and the maximal amount of dienes formed during LDL oxidation were log-transformed before analysis. All data were evaluated using the statistical package SAS (Cary, NC).

## RESULTS

**Animals.** No differences in food consumption or body weight gain were observed in the different treatment groups. The mean weight of the hamsters was  $106.0 \pm 0.8$  g on arrival and  $120.1 \pm 1.7$  g at the end of the study. Mean food consumption was  $5.9 \pm 0.2$  g per day. All animals remained in apparent good health throughout the period of the study, and histopathological examination gave no suggestion of compromised health status.

**The antioxidant activity and the composition of the experimental olive oils.** The antioxidant activity in the oils was determined by means of the commonly used TEAC assay (17), and the results are presented in Table 1. The phenolic content of the oils is also presented in Table 1. As expected, the phenols present in the oils contributed significantly to the total antioxidant activity of the oils. Ethanol/water washing of EVOV led to a considerable loss in both phenols and antioxidant activity. The antioxidant activity in the processed oil can be explained by the presence of vitamin E, which is not removed during the ethanol/water washing of the oil. The following FA distribution was observed in the olive oil used for both diets: 74% oleic acid, 9% PUFA, 16% saturated FA, and 1% monounsaturated FA other than oleic acid. The main difference between the experimental diets was their different phenol content, and as a consequence, their antioxidant activity.

**Plasma lipids, vitamin E, antioxidant activity, and LDL lipids.** No differences were observed in the plasma and LDL cholesterol and plasma glycerol levels between the groups receiving the olive oil diets. The dietary treatments also had no effect on the total antioxidant status in plasma as measured with the FRAP assay. Plasma vitamin E concentrations were significantly reduced in the group receiving the diet containing ethanol/water-washed EVOV compared to the group receiving the original EVOV (Table 3).

**Ex vivo LDL oxidizability.** Three parameters were used to define susceptibility of LDL to copper-mediated oxidation: the

**TABLE 3**  
**Plasma Antioxidant Activity and Plasma Lipids<sup>a</sup>**

	Group/Diet	
	EVOV	EVOV-EtOH/H <sub>2</sub> O
Vitamin E ( $\mu\text{g}/\text{mL}$ )	$12.7 \pm 0.75$	$10.1 \pm 0.49^b$
Antioxidant activity (mM)	$0.51 \pm 0.01$	$0.50 \pm 0.01$
Total cholesterol (mM)	$3.90 \pm 0.18$	$3.65 \pm 0.15$
Total glycerol (mM)	$1.29 \pm 0.14$	$1.26 \pm 0.15$

<sup>a</sup>All values are the mean  $\pm$  SEM;  $n = 10$  animals for each group.

<sup>b</sup>Statistical difference compared to EVOV group, two-tailed *t*-test  $P < 0.01$ . For abbreviations see Table 1.

lag phase before initiation of oxidation, the maximal rate of LDL oxidation, and the maximal amount of conjugated dienes formed during the oxidation process (22). Similar to observations made for the plasma vitamin E content, the removal of olive oil phenols by ethanol/water-washing of EVOV diet resulted in a reduction in the lag phase compared to the diet containing the original EVOV (Table 4). The 24% reduction in the lag phase reached statistical significance ( $P = 0.05$ ). No differences were observed between the olive oil groups in terms of maximal rate of oxidation and the maximal amount of conjugated dienes formed during the copper-induced oxidation process (Table 4).

## DISCUSSION

The purpose of the present study was to investigate the effect of the phenol content in olive oil fed to hamsters as part of a semipurified diet over a period of 5 wk on the antioxidant activity in plasma and LDL. To this end, a diet containing a phenol-rich EVOV was compared with a diet containing EVOV from which virtually all phenols had been removed by ethanol/water washing. The results showed that the absence of olive oil phenols in the diet decreased the resistance of LDL to copper-mediated oxidation *ex vivo* and reduced vitamin E levels in plasma.

To rule out any effect of differences in FA composition, the FA composition in both semipurified diets was designed to be identical in the present study by using the same olive oil as the principal fat source. In addition, the  $\alpha$ -tocopherol content was equalized in both oils used in this study. It is important that these two elements not be dietary variables, as they both

**TABLE 4**  
**LDL Oxidation Resistance<sup>a</sup>**

	Group/diet	
	EVOV	EVOV-EtOH/H <sub>2</sub> O
Lag phase (min)	$62 \pm 7.2$	$47 \pm 5.4^b$
Maximal oxidation rate ( $\text{nmol dienes} \cdot \text{min}^{-1} \cdot \text{mg LDL}^{-1}$ )	$4.9 \pm 0.3$	$5.4 \pm 0.5$
Maximal amount dienes (nM)	$593 \pm 18$	$544 \pm 14$
LDL-cholesterol (mM)	$1.23 \pm 0.08$	$1.25 \pm 0.08$

<sup>a</sup>All values are the mean  $\pm$  SEM;  $n = 10$  animals for each group.

<sup>b</sup>Statistical difference compared to EVOV group, one-tailed *t*-test  $P < 0.05$ . For abbreviations see Table 1.

significantly affect the *ex vivo* oxidizability of LDL (22). In fact, several human and animal studies in which the effect of EVOV is compared with refined olive have a poor control over dietary intake of  $\alpha$ -tocopherol (8,9,13,16). This confounding element makes interpretation of the data very difficult as the difference between the oils may be explained by the differences in phenols and/or  $\alpha$ -tocopherol.

The resistance of LDL to oxidation was not the only antioxidant activity marker that was evaluated in this study. The antioxidant capacity in the plasma of the hamsters was also investigated by means of the FRAP assay following the dietary regimes. The measurements showed that the plasma antioxidant capacity did not differ between the groups. Our observations were in line with an intervention trial in humans, in which it was shown that a 3-wk supplementation of phenol-rich EVOV oil failed to increase the FRAP value of plasma prepared from fasting blood samples. Even if olive oil phenols would have increased plasma antioxidant capacity under the conditions applied in this study, it is expected that the overnight fasting reduced the circulating phenol levels to negligible levels since bioavailability studies have demonstrated that the majority of olive oil phenols are excreted in urine within 4 h following administration (5,23,24). One should, however, take into consideration that the biological relevance and the specificity of total antioxidant capacity assays are frequently questioned. One of the reasons for this is that many endogenous and exogenous antioxidants in plasma contribute in a variable manner to the measured antioxidant capacity (25).

Although dietary intake of vitamin E was the same in both groups, the plasma levels of the hamsters receiving the ethanol/water-washed EVOV were significantly lower than values observed in hamsters receiving the EVOV diets. The increased protection provided by EVOV compared to the ethanol/water-washed EVOV in the resistance of LDL to oxidation may be explained by the fact that (i) olive oil phenols have a vitamin E-sparing effect *in vivo* or, alternatively, (ii) olive oil phenols accumulate in LDL and thereby increase the resistance of LDL to oxidation. Binding of phenols to LDL is likely to occur *in vivo*, but a significant proportion is probably lost during the isolation and dilution of LDL from plasma (26,27). Their relatively poor lipophilicity compared to  $\alpha$ -tocopherol prevents the integration of phenols in the lipophilic core of the LDL particles. A consequence of this poor interaction is that the majority of phenols dissociate from LDL during isolation. This loss of phenols has been demonstrated for red wine phenolic compounds that are lost during the dialysis of LDL (27). Similar observations have been made with plasma incubated with EVOV phenols. The phenol concentration required to protect LDL after isolation is considerably higher when phenols are added directly to isolated LDL (5,6). The higher vitamin E content in plasma of the EVOV-treated group therefore explains the increased resistance of LDL to oxidation *ex vivo*. In other words, the most likely explanation for the observed protective action of the phenols present in the olive oil is that they possess a vitamin E-sparing potential *in vivo*.

This vitamin E-sparing potential of phenols and polyphenols

has been observed *in vitro* in LDL and other model membrane systems (28–30). Also, olive oil phenols retard both lipid peroxidation and vitamin E consumption in LDL subjected to an oxidative stress (4,31). The ability of phenols to interact with vitamin E has been studied in great detail with caffeic acid, a monophenolic antioxidant that structurally resembles hydroxytyrosol (32,33). Caffeic acid interacts with the surface of the LDL particle and can recycle vitamin E. During this process a radical is removed from this lipophilic environment into the surrounding aqueous medium where the radical is further stabilized. Other studies have also shown that vitamin E is only functional as a chain-breaking antioxidant provided hydrophilic co-antioxidants are present in the aqueous surroundings. This is especially relevant when radicals become trapped in LDL particles when they are exposed to a low flux of radicals (34). Indeed, vitamin C, which is even more hydrophilic than phenols and polyphenols, is efficacious in protecting lipids in LDL and plasma against peroxidation (35).

It can be reasoned that similar conditions apply in the hamster *in vivo*. Healthy hamsters experience only low levels of oxidative stress. LDL in blood plasma is, under normal physiological circumstances, protected from oxidation due to the presence of endogenous antioxidants such as ascorbate. Supplementation of olive oil phenols may further enhance this level of protection by interacting with the surface of the LDL particle. Through this interaction, olive oil phenols can either prevent oxidation of LDL by directly scavenging aqueous radicals or, in the event that radicals enter the LDL, can act as chain-breaking antioxidants by recycling vitamin E. This vitamin E-sparing potential is a continuous process that does not become apparent during a brief *in vitro* incubation of plasma with olive oil phenols (6) but appears to require a longer incubation period to become apparent. Such a condition is created during a supplementation period of 5 wk. In conclusion, the findings of this trial with hamsters are consistent with the hypothesis that olive oil phenols protect LDL *in vivo*. Phenols endogenously present in EVOV improve the antioxidant defense system in plasma by sparing the consumption of vitamin E.

# Dietary Flax Oil Reduces Renal Injury, Oxidized LDL Content, and Tissue n-6/n-3 FA Ratio in Experimental Polycystic Kidney Disease

Malcolm R. Ogborn\*, Evan Nitschmann, Neda Bankovic-Calic, Hope A. Weiler, and Harold Aukema

University of Manitoba, Winnipeg, Manitoba, R3E 3P4 Canada

**ABSTRACT:** As whole flaxseed is beneficial in the treatment of experimental renal disease, we undertook a study to determine whether previously documented benefits of whole flaxseed could be reproduced with dietary low-lignan flax oil (FO), a rich source of  $\alpha$ -linolenic acid, in experimental polycystic kidney disease. Male offspring of Han:SPRD-*cy* heterozygous rats were fed a synthetic diet containing FO or corn oil (CO) for 8 wk from the time of weaning. Renal inflammation, fibrosis, proliferation, cystic change, and oxidized-LDL were assessed morphometrically. Hepatic and renal lipid composition was assessed using GC. FO feeding produced hepatic and renal enrichment of n-3 PUFA and an increase in C18:>C18 PUFA ratios (18-carbon PUFA compared to longer-chain PUFA), with a reduction in proportion of hepatic long-chain PUFA. The FO-based diet was associated with lower mean cystic change by 29.7% ( $P = 0.018$ ), fibrosis by 21.7% ( $P = 0.017$ ), macrophage infiltration by 31.5% ( $P < 0.0001$ ), epithelial proliferation by 18.7% ( $P = 0.0035$ ), and ox-LDL detection by 31.4% ( $P < 0.0001$ ) in Han:SPRD-*cy* heterozygotes. Serum creatinine was significantly lower in FO-fed diseased animals. A small hypocholesterolemic effect was noted in all animals fed FO. FO feeding moderates renal injury, modifies the profile of substrates available for elongation to eicosanoid precursors, and inhibits the elongation of C<sub>18</sub> PUFA in this model. The consumption of FO-based products may prove a more practical way of obtaining health benefit than attempts to increase dietary content of unrefined seed.

Paper no. L9093 in *Lipids* 37, 1059–1065 (November 2002).

Flaxseed has possible benefits in the reduction of inflammation in rheumatic disease, reduction of atherosclerosis, and modification of hormone-dependent tumor growth (1–4). A possible mechanism for health benefits of flaxseed includes increased dietary consumption of the PUFA  $\alpha$ -linolenic acid (ALA). Such enrichment has been associated with reduction in proinflammatory prostanoids or cytokines in circulating mononuclear cells (5), particularly tumor necrosis factor  $\alpha$  and interleukin-1 $\beta$  (4). Flaxseed is also the richest natural source of mammalian lignans, present in the husk of the seed as an ester secoisolaricoresinol diglycoside (SDG) that is hydro-

lyzed in the intestinal lumen to enterodiol and enterolactone (6). SDG or its hydrolyzed products may influence health or disease through estrogenic pathways, through an antioxidant effect, or through antagonism of platelet-activating factor (3). SDG is, however, lipophobic, and refined flax oil contains only negligible amounts of SDG, making it possible to separate the contribution of the oil and the lignan experimentally.

We have demonstrated that partial dietary substitution of ground flaxseed into standard rat chow to a level of 10% by weight of diet reduced renal cystic, inflammatory, and fibrotic change in the Han:SPRD-*cy* rat (7,8). This complements previous studies that showed benefits of flaxseed or flax oil (FO) in the rat-5/6 nephrectomy model (9) and murine or human lupus erythematosus (10,11). The Han:SPRD-*cy* model of polycystic kidney disease (PKD), characterized by autosomal dominant inheritance with marked sexual dimorphism in expression, is an excellent system in which to explore the modification of chronic renal injury (12). Epithelial proliferation and progressive dilatation of nephrons, marked interstitial inflammation, and fibrosis characterize the disease (13). Oxidant injury has been implicated in its pathogenesis (14). It can be ameliorated with methyl prednisolone (15), angiotensin blockade or -converting enzyme inhibition (16,17), and lovastatin (18). Amelioration occurs with dietary soy protein substitution (19,20), protein restriction (21), and citrate supplementation (22). We showed that both soy protein- and flaxseed-based diets are associated with amelioration of this disease (8,20). In both instances, this was associated with the alteration of the renal and hepatic PUFA proportion, with evidence of a reduced conversion of linoleic acid (LA) to arachidonic acid (AA) for animals on a soy diet and an increase of n-3 FA with flaxseed. A pure animal protein-based diet is associated with more rapid disease progression than that seen with mixed vegetable and animal protein-based rat chows (8,20).

To test the hypothesis that amelioration of this disease by the administration of dietary flaxseed is related to changes in PUFA composition, we undertook this study to determine the effects of FO on renal injury in Han:SPRD-*cy* rat PKD.

## MATERIALS AND METHODS

**Animals.** All animal procedures and care were examined by the University of Manitoba Committee on Animal Use and were within the guidelines of the Canadian Council on

\*To whom correspondence should be addressed at AE 208-840 Sherbrook St., Winnipeg, MB R3A 1S1, Canada. E-mail ogborn@cc.umanitoba.ca

Abbreviations: AA, arachidonic acid; ALA,  $\alpha$ -linolenic acid; CO, corn oil as dietary lipid source; FO, flax oil as dietary lipid source; GLA,  $\gamma$ -linolenic acid; LA, linoleic acid; LC-PUFA, long-chain PUFA; ox-LDL, oxidized LDL; PKD, polycystic kidney disease; SDG, secoisolaricoresinol diglycoside.

Animal Care. Male offspring of known Han:SPRD-*cy* heterozygotes from our own breeding colony were randomly assigned to treatment or control groups at weaning (3 wk of age). Males only, two-thirds of which would be heterozygous as homozygotes do not survive beyond weaning, are used owing to the more rapid progress of this disease in male animals. Animals were killed after 8 wk on the diet and kidney and liver tissue and serum collected for analysis. Diets were based on the AIN 76 formula using casein as the protein source and 5% corn oil (CO) or 5% FO (Omega Nutrition, Vancouver, Canada) as the lipid source. The diets differed mainly in LA proportion (CO, 60.5% of dietary fat; FO, 15.8%) and ALA (CO, 0.9% of dietary fat; FO, 52.3%). Cages containing one to three animals fed the CO diet were paired to cages of animals on the FO diet, with CO diet intake limited to the amount consumed by the paired FO diet cage the previous day.

**Histology and immunohistochemistry.** Tissue from the left kidney was processed using our previously described methods (8,20) for histologic and immunohistochemical analysis. These studies included hematoxylin and eosin, aniline blue staining for fibrosis, proliferating cell nuclear antigen (M 0879; Dako A/S, Glostrup, Denmark), and macrophages (MAB1435; Chemicon International Inc., Temecula, CA). Oxidized LDL (ox-LDL) staining was used as a marker of oxidant injury (23), using a polyclonal antibody (AB3230; Chemicon International Inc.). Animals were classified by one of two experienced observers (NBC, MRO) as affected on the basis of the characteristic cystic and inflammatory pathology of this disease.

**Image analysis and morphometric assessment.** Image analysis procedures were performed with a system consisting of a Cohu high-resolution black and white camera connected to a computer via a PCVisionPlus video capture board. The observer was blinded to dietary treatment, although disease status is obvious on microscopic examination. Images were captured using the Image Pro software package (Phoenix Biotechnology, Seattle, WA). Raw image analysis data was processed as previously described (8,20). Measurements of fibrosis and cellular markers were corrected to solid tissue areas of sections as we have done previously (8,20). This prevents underestimation of these parameters due to the presence of empty cystic areas on the section.

**Chemistry.** Biochemical measurements were performed by an observer (EN) blinded to disease and dietary status. Serum creatinine and cholesterol in serum were determined

by spectrophotometric methods using Sigma kits (creatinine kit #555-A, cholesterol kit #402-20; Sigma Chemical Co., St. Louis, MO) adapted to a 96-well plate reader.

**GC.** Lipids were extracted from kidney and liver and methylated for GC as previously described (8,20). GC was performed on a Varian Chrompack 3800 instrument, using a Zebron ZB Wax 30-m column (Phenomenex, Torrance, CA).

**Statistical analysis.** Morphometric data involving comparisons relevant only to cystic groups were analyzed with Student's *t*-test with the Welch correction for unequal variances. Data from both normal and PKD animals were analyzed using a general linear model ANOVA and Tukey's *post-hoc* pairwise comparisons, using the Minitab v13 software package (Minitab Inc., State College, PA).

## RESULTS

Disease was associated with significantly lower weights in both dietary groups but was not influenced by diet. Serum creatinine was elevated in Han:SPRD-*cy* heterozygotes with PKD but was significantly lower in *post-hoc* analysis in FO-fed heterozygotes compared to CO-fed heterozygotes ( $P < 0.03$ ). Both diet and disease significantly influenced serum cholesterol, with FO producing a reduction ( $P < 0.001$ ) and disease expression producing an elevation in serum cholesterol on both diets ( $P = 0.029$ ). Serum TG was not different between diet or disease groups (Table 1).

FO supplementation was associated with significant reductions in cystic change (Figs. 1A, 1B, 2), with a decrease in epithelial proliferation (Fig. 3) that was proportionate to the observed decrease in cystic change. A comparable reduction was also seen in interstitial fibrosis (Fig. 4). Macrophage infiltration (Fig. 5) and ox-LDL detection (Fig. 6) were reduced to a similar extent by FO feeding. Data from normal animals are not shown in figures, as most of these parameters are barely detectable in normal tissue.

FO-fed animals showed a higher renal proportion of ALA, EPA, and n-3 DHA. FO-fed animals with PKD also had lower renal proportions of n-6  $\gamma$ -linolenic acid (GLA) and n-6 LA, but there were no changes in FO-fed animals without PKD (Table 2). The relative amount of AA in renal lipids did not change with diet (Table 2).

Increased relative amounts of ALA, EPA, and DHA were seen in liver tissue from all animals, with or without PKD

**TABLE 1**  
Serum Biochemistry and Weight Results<sup>a</sup>

	CO normal (n = 8)	FO normal (n = 6)	CO PKD (n = 19)	FO PKD (n = 23)	Diet effect	PKD effect
Weight (g)	370 (7.3)	373 (8.6)	320 (5.3)	315 (5.7)	NS	$P < 0.001$
Creatinine (mmol/L)	101 (15.9)	98 (18.3)	199 (10.3)	159 <sup>b</sup> (9.4)	NS	$P < 0.001$

<sup>b</sup>Significantly different from polycystic kidney disease (PKD) animals fed the corn oil (CO) diet,  $P < 0.03$ . FO, flax oil; NS, not significant.

**FIG. 1.** Hematoxylin- and eosin-stained section from an 11-wk-old Han:SPRD-cy rat (A) fed corn oil (CO) diet, and (B) fed flax oil (FO) diet; 20x magnification.

(Table 2). LA, GLA, AA, and eicosatrienoic acid (20:3n-6) in liver were also significantly lower in the animals fed the FO diet.

Total long-chain PUFA (LC-PUFA) was significantly decreased in the liver by FO feeding, and increased by PKD in the livers of animals on the CO diet only (Table 4). The ratio of LA/AA, although not significantly altered in kidney by diet or disease, was increased in liver by diet but was decreased in the presence of renal disease (Table 4). The ALA/(EPA + DHA) ratio was chosen as a measure of elongation of n-3 PUFA in preference to the ALA/EPA ratio owing to our inability to detect EPA in a significant number of CO samples.

22:6n-3 (DHA)	0.6 (0.1)	1.5 (0.1)	0.5 (0.1)	1.1 (0.1)	<0.001	0.021

<sup>a</sup>Results are expressed as group mean percentage of total lipids with SEM in parentheses.

<sup>b</sup>Significantly different from CO in same disease category,  $P < 0.001$  *post-hoc* testing.

<sup>c</sup>EPA was not detectable in seven samples from the CO normal group and nine samples in the CO PKD group, thus violating assumptions of normality; therefore,  $P$  values are not reported. LA, linoleic acid; GLA,  $\gamma$ -linolenic acid; ALA,  $\alpha$ -linolenic acid; AA, arachidonic acid; for other abbreviations see Table 1.

Diet produced a significant increase in this ratio in kidney and liver (Table 4). Total n-6/n-3 ratios were decreased significantly by diet in the kidney and liver (Table 4) but were significantly increased in the liver in the presence of PDK.

## DISCUSSION

Early interest in the use of FO in the treatment of renal disease was somewhat indirect, focusing on potential benefits on hypertension through modification of the renin-angiotensin system (24). Ingram *et al.* (9) demonstrated that both flaxseed and FO were protective against glomerulosclerosis in the 5/6-nephrectomy model of renal disease. FO had a greater effect on renal lipid composition and on prostanoid physiology in that model, with greater overall enrichment with n-3 PUFA and a statistically significant increase in the proportion of DHA. With mice and with humans, Hall *et al.* (10) and Clark *et al.* (11), respectively, demonstrated evidence of reduction in renal injury in lupus nephritis with use of a whole flaxseed supplement. Our earlier study in the Han:SPRD-cy rat also showed that flaxseed supplementation

was beneficial, particularly with respect to the inflammatory component of injury that is a prominent part of the Han:SPRD-cy model (8).

An important difference between this report and our earlier study is that the FO diet did result in a significant difference in the relative renal proportion of DHA (8). In our previous study, the flaxseed-supplemented diet did not increase DHA above the level seen with standard chow (control, 1.7% total lipids; flaxseed, 1.3% total lipids). This is of interest because DHA has been shown *in vitro* to inhibit macrophage response, reduce the production of pro-inflammatory cytokines, and inhibit induction of neutrophil nitric oxide synthase, a regulatory point in inflammatory events (25–28). DHA, but not EPA, *in vivo* reduces mesangial proliferation and has been proposed as a potential explanation of the apparent benefit of dietary fish oil in immunoglobulin A nephropathy (29). Expression of PKD was associated with a reduction in DHA in this study, a phenomenon also observed in the *pcy* mouse (30). In the 5/6-nephrectomy rat, Ingram *et al.* (9) demonstrated renal enrichment with ALA by both flaxseed and flax oil, and EPA only by flax oil; DHA was actually reduced by

both flax diets (9). The reported levels of renal DHA for animals fed their standard diet were substantially higher than seen in our control animals; dietary FA analysis was not presented. In that study, AA also was increased by the flaxseed diet, causing the authors to speculate that AA metabolism to prostanoids was reduced by competition with EPA generated from increased dietary ALA. The changes in AA proportion are, however, reminiscent of those we found in Han:SPRD-cy rats fed soy protein (20), and a separate effect on FA metabolism of modification of dietary protein source, which was controlled in the study reported here, cannot be excluded as part explanation of their results.

The alterations in liver of the LA/AA ratio, ALA/(EPA + DHA) ratio, and total LC-PUFA seen in this study suggest that FO may have an inhibitory effect on  $\Delta 6$ -desaturase similar to that reported with soy protein (31). Cherian *et al.* (32) reported such inhibition in response to flaxseed supplementation in poultry. Direct modification of desaturase pathways has been proposed as a possible explanation for the anti-inflammatory and antiproliferative effects of CLA, a group of isomers of LA (33), and our results suggest a further line of inquiry to explain possible similar benefits of FO. These changes were less marked in renal tissue, with a significant difference, however, observed in ALA/(EPA + DHA). In diseased animals fed the CO diet, increased hepatic proportions of total LC-PUFA were found, and disease was also associated with lower LA/AA ratios, suggesting that the uremic state opposes diet-induced mechanisms for inhibiting elongation. The uremic state has been recognized as a proinflammatory state for many body tissues (34), but an altered content of prostanoid precursors has not yet been explored as a potential mechanism in this process.

The level of substitution of FO that we fed in these studies (approximately 2.5–3 g/kg body weight/d as ALA) would be difficult to achieve in human studies. Biologically significant effects in humans, however, are possible with dietary substitutions involving PUFA that are practical. A daily oral dose of 1800 mg of purified EPA reduces the levels of circulating remnant lipoproteins in dialysis patients, potentially stabilizing LDL and conferring some resistance to oxidation (35). Kre-

mer *et al.* (36,37) reported clinical improvements in rheumatoid arthritis patients receiving EPA-rich fish oil supplements that correlated with altered monocyte prostanoid and cytokine production. Caughey *et al.* (4) demonstrated that substitution of deodorized FO for cooking oil and in margarine-like spread caused a 74% reduction in monocyte production of tumor necrosis factor  $\alpha$  and interleukin 1 $\beta$  in healthy volunteers. Both of these cytokines have been linked to the progression of renal injury in human PKD (38). The average daily intake in that study was 13 g of FO (approximately 170 mg/kg/d assuming an average patient mass of 75 kg) (4). The study by Caughey *et al.* also represents a rare example of a direct comparison between FO and the other major dietary source of n-3 PUFA, fish oil. They found that the cytokine reduction effects correlated with the monocyte proportion of EPA (20:5), irrespective of whether FO or fish oil was the source. FO substitution in human diets has been associated with reduction in cholesterol, which may benefit renal disease progression (39) through reduced production of farnesyl phosphate and subsequent down-regulation of G-protein-mediated signaling (18). The reduction we observed in this study was very modest, however, and we failed to link hypocholesterolemic effects to disease modification in previous dietary studies (8,20).

The observation of reduced amounts of ox-LDL suggests a possible role for FO in reducing susceptibility to oxidant stress. The Han:SPRD-cy rat model of PKD involves compromised resistance to oxidant injury, both as decreased expression of antioxidant enzymes (14) and aggravation of disease by inhibition of glutathione synthesis (40). Dietary antioxidant therapy with  $\alpha$ -tocopherol, however, did not produce improvement in the prevalence of renal injury (41).

The observation that both diet and expression of renal disease were associated with significant alterations in hepatic lipids also supports previous studies in both modification of renal injury and nonrenal metabolism in early uremia (20,42). The basis for such metabolic effects in mild uremia remains as yet unexplored.

Han:SPRD-cy rat PKD is associated with a marked inflammatory component, and the infiltrating cells arise outside the kidney. As such, the profile of PUFA in these circulation-

derived cells may be important in determining the type of inflammatory lipid products released. This profile may be more dependent on hepatic regulation of FA production than the local renal lipid environment. The effect of our dietary interventions on circulating inflammatory cells in this model will be a future line of inquiry.

Boyd-Eaton *et al.* (43) pointed out that the sophistication of human society has been associated with a 10- to 20-fold increase in the ratio of n-6/n-3 FA in the human diet. Manipulations of animal diets that reproduce these trends in FA intake are associated with worsening of inflammatory and malignant disease, and, in certain models, the development of insulin resistance (24). In this anthropologic context, the intervention studied here might be viewed as a return to the dietary pattern on which our metabolic responses evolved.

Our studies confirm the importance of testing specific food ingredients in dietary intervention in renal disease, rather than broad categories such as total protein or fat content. Our results demonstrate that FO, either incorporated into common foodstuffs or given as a therapeutic supplement, may be of similar value to administration of whole flaxseed in the amelioration of renal injury.

**ABSTRACT:** Enriching foods with long-chain n-3 PUFA (LC n-3 PUFA) is an important approach to increasing the dietary intake of these beneficial nutrients. Enrichment of meat and eggs can be achieved by adding flaxseed, fish oil, or fishmeal to pig or poultry feeds. However, utilization of these sources, particularly fishmeal, has been limited by concerns about adverse effects on sensory qualities. In this study, we evaluated the use of PorcOmega™ (POM), a stabilized tuna fishmeal formulation, as a source of DHA for enrichment of pork and poultry products. Pigs, broilers, and laying hens were fed rations containing varying levels of POM for varying time periods, and its impact on the LC n-3 PUFA content and sensory qualities of cooked meat and eggs was examined. Pork and chicken products, including chops, sausages, and eggs, with substantially increased (up to sevenfold) levels of LC n-3 PUFA (predominantly DHA) were achieved by including up to 10% POM in rations. The increases were retained after cooking. Some sensory deficits were noted when using higher levels of POM (exceeding 15% in meat and 10% in eggs). However, at modest rates of feeding (5–10% POM), palatable meat and eggs were obtained with worthwhile levels of enrichment. The fishmeal feeding strategy used in this study offers a viable means of producing a range of alternative dietary sources of LC n-3 PUFA.

Paper no. L9070 in *Lipids* 37, 1067–1076 (November 2002).

There is increasing awareness of potential health benefits, especially cardiovascular, to be gained by increasing the consumption of long-chain n-3 PUFA (LC n-3 PUFA), *viz.*, EPA, docosapentaenoic acid (DPA), and DHA (1,2). Recommendations for dietary intakes for LC n-3 PUFA range from 200 to 1000 mg/d, the most recent being 650 mg/d as an adequate intake for adults, of which at least 200 mg/d should be DHA (3). This target is surpassed in countries with a high consumption of fish, e.g., approximately 700 mg/d in Norway and 1500 mg/d in Japan (4). However, in countries such as the United States and Australia where the relative consumption of meat is much greater, the average dietary intake of LC n-3 PUFA (150 and 190 mg/d, respectively) falls well short of recommendations (5,6). The demand in these countries for alternative dietary sources has

Abbreviations: ALA,  $\alpha$ -linolenic acid; DPA, docosapentaenoic acid; FQ, forequarter; FSANZ, Foods Standards Australia New Zealand; GC, gas chromatograph; LC n-3 PUFA, long-chain n-3 PUFA; POM, PorcOmega™.

prompted the food industry to add LC n-3 PUFA to a wide variety of processed foods, usually in a microencapsulated or emulsified form to protect the LC n-3 PUFA from oxidative degradation. The products of degradation may cause tainting, *i.e.*, adversely affecting the taste and flavor of the food.

Another strategy is to enrich meat and eggs naturally with LC n-3 PUFA by including appropriate sources in livestock rations. Pigs and poultry readily incorporate dietary FA in body tissues so that significant increases in the n-3 content of pork (7–9), chicken, and eggs (10–15) have been achieved by adding marine sources such as fish oil, fishmeal, or microalgae to rations. This approach is less effective in ruminants, however, unless the FA are delivered in a protective coating (16,17). As with other approaches to n-3 enrichment of foods, feeding n-3 sources to livestock may lead to tainting of the meat and egg products, thus reducing their consumer acceptability (18–23). Feeding strategies are required that aim for optimal n-3 enrichment with minimal tainting of the product.

Vegetable sources of  $\alpha$ -linolenic acid (ALA) are cheaper than marine sources of n-3 PUFA for enrichment, with possibly less likelihood of tainting (11,12,24). However, the conversion of ALA to LC n-3 PUFA is limited in animals as in humans (25). Flaxseed is therefore of limited value for increasing the LC n-3 PUFA content of pork, and it still has the capacity to cause tainting if degraded (18,24). On the other hand, flaxseed and canola have been used in poultry feeds either alone or in combination with fish oil to enrich chicken meat and eggs, the relative proportion of vegetable to fish oil influencing the cost and extent of LC n-3 PUFA enrichment (10–12).

Fishmeal offers a cheaper and more plentiful source of LC n-3 PUFA than fish oil for direct n-3 enrichment of pork and poultry (26,27). However, the potential for fishmeal to taint meat and eggs, even at relatively low rates of inclusion in rations, is widely recognized. Moreover, tainted feeds reduce feed consumption and impair livestock productivity. For this reason, it has been recommended that inclusion of fishmeal in grower and finisher pig rations be limited to 5% (28). In a previous study, however, we found that feeding a high level (20%) of stabilized tuna fishmeal (PorcOmega™, POM) to pigs resulted in substantial n-3 enrichment of pork with minimal detrimental effects (7). Tuna meal has a higher content of DHA relative to EPA than fish oil or fishmeals of many other species (other fishmeals may contain a higher content of EPA relative to DHA). As DHA is the predominant LC n-3 PUFA in animal tissues, feeding an n-3 source in which DHA

predominates is likely to be more efficient than using either an EPA- or ALA-rich source.

Following these initial promising observations, we conducted a series of studies to evaluate the use of tuna fishmeal to enrich chicken meat and eggs and pork products. Our goal was to produce foods with acceptable sensory qualities that would qualify for a new nutrition claim introduced by Foods Standards Australia New Zealand (FSANZ) in its Revised Food Standards Code, *viz.*, foods can be labeled as “a good source of omega-3” if they contain at least 60 mg of EPA and/or DHA per serving with less than 5% saturated/*trans* fat (29). The current report describes the extent of n-3 enrichment achieved and its impact on the sensory qualities of the products.

## MATERIALS AND METHODS

Production trials with pigs and poultry were conducted at the Camden Campus of The University of Sydney to compare effects of feeding experimental rations containing POM. Approval for the feeding trials was obtained from The University of Sydney’s Animal Ethics Committee. Meats and eggs obtained from the trials were used for chemical and sensory evaluation at the Smart Foods Centre, University of Wollongong. Wollongong University’s Human Research Ethics Committee approved the evaluation of products by volunteer panelists.

*Formulation of rations.* The rations were formulated to be isonitrogenous and isocaloric and to meet nutritional requirements for pigs (30) and broiler chickens and laying hens (31). POM, a tuna fishmeal formulation containing a complex antioxidant system and flavorings designed to eliminate objectionable fish odor and taint, was provided by Bartlett Grain Pty. Ltd., Sydney, Australia. POM was substituted for other ingredients typically used in a least-cost formulation, e.g., meat and bone, soy and canola meals, while maintaining an

appropriate macronutrient profile. Total fat contents of the rations averaged 4.5% of total energy for layer, 3.7% for broiler starter, 5.2% for broiler finisher, and 3.2% for pig finisher rations. Table 1 shows the FA compositions of POM and of representative finisher rations.

*Production of eggs.* Groups of 14 mature laying hens were randomized to one of seven feeding strategies as follows: (i) control diet for 42 d; (ii) 5, 10, 15, or 20% POM diet for 42 d; (iii) control diet for 14 d followed by 20% POM diet for 28 d; (iv) control diet for 28 d followed by 20% POM diet for 14 d. Eggs were collected at the end of each treatment period ( $\pm 2$  d) and were stored at 0–4°C. The logistics of conducting the sensory panels necessitated keeping eggs for up to 1 mon prior to evaluation.

*Production of chicken meat.* Groups of 54-d-old male broilers were randomized to one of nine feeding strategies as follows: (i) control diet for 42 d; (ii) 5, 10, 15, or 20% POM diet for 42 d; (iii) control diet for 18 d followed by 5, 10, 15, or 20% POM diet for 24 d. At the end of the treatment period, birds were processed to obtain skinless breast, thigh fillets, and typical aggregate meat for sausage production from each treatment group. Samples were individually wrapped and stored frozen at –15°C for subsequent chemical and sensory analysis.

*Production of pork.* Groups of three male and three female pigs were fed 15% POM for 6 wk or 20% POM for 4 wk prior to slaughter. A group of four male and four female pigs was maintained on the control ration. Samples of forequarter chops, loin chops, and leg fillets were obtained from each pig. Equal portions of suitable meat for sausages were also taken from each pig and pooled for each treatment group to produce sausages. All meat samples were individually wrapped and stored frozen at –15°C for subsequent chemical and sensory analysis.

*Chemical analysis.* Determinations of FA and cholesterol composition were made on five individual eggs from each

<sup>a</sup>POM, tuna fishmeal formulation containing a complex antioxidant system and flavorings designed to eliminate objectionable fish odor and taint (Bartlett Grain Pty. Ltd., Sydney, Australia).

treatment group. Eggs were broken, yolks and whites separated, and weights recorded. The yolks were gently stirred, then 100  $\mu$ L aliquots were homogenized in chloroform/methanol containing a FA internal standard (21:0; Sigma Chemical Co., St. Louis, MO) and extracted for FA analysis using a direct transesterification procedure (32). FAME were measured on a Shimadzu gas chromatograph (GC; Shimadzu Corporation, Kyoto, Japan) fitted with an FID and using a fused-silica Crossbond® polyethylene glycol capillary column (0.32 mm i.d. and 0.25  $\mu$ m film thickness, Restek Corporation, Bellefonte, PA). Samples were injected at 150°C. The oven temperature was set to increase by 20°C/min to 190°C, then by 5°C/min to 210°C, then by 1.5°C/min to 220°C, then by 2°C/min to 230°C, then by 5°C/min to a final temperature of 240°C, which was held for 3 min. The injector and detectors were maintained at 250°C and hydrogen was used as the carrier gas. Peak areas and FA percentages were quantified on an IBM-compatible workstation using Shimadzu software. A standard mixture of FAME (Sigma Chemical Co.) was used to calibrate the GC and to determine response factors. FA concentrations were estimated by reference to the recovery of the standard.

The cholesterol content of yolks was measured by an enzymatic colorimetric test on a Cobas autoanalyzer (Roche Diagnostics Corporation, Indianapolis, IN) using Roche Diagnostics test kits (Roche Diagnostics Corporation). The autoanalyzer was calibrated using a calibrator for automated systems (Roche Diagnostics Corporation).

Frozen portions of uncooked chicken breasts, thighs, and sausages were thawed and sampled for FA analyses. Three portions of each were randomly selected from each treatment group.

Portions of chicken meat that had been cooked for sensory evaluation were also used for FA analysis. Core samples weighing approximately 100 mg were obtained from lean regions of the meat using a cork borer. The total fat content of uncooked meat was also assayed in randomly selected whole untrimmed portions by Weston Analytical Laboratories (Sydney, Australia) using a Soxhlet extraction procedure (33).

Raw and cooked portions of pork loin, leg, and shoulder chops and sausages were similarly used for analyses of total fat and FA contents. One portion of each type of raw meat was randomly selected from each pig in each treatment group except for sausages, which were prepared from meat pooled from all pigs in each group.

**Sensory evaluation.** Panelists (5 men and 11 women recruited by advertisement) were specifically trained to conduct organoleptic analysis for each type of food being evaluated. Potential panelists were screened on a number of standard sensory discrimination tests assessing sweet, sour, bitter, and salt flavors. After passing these tests, they progressed to the second phase of training, which comprised 5 h of tasting regular supermarket foods over a period of 4 wk. Panelists were trained to use a common vocabulary for either meat or egg tasting and to practice discriminating the sensory attributes of flavor, texture, color, and odor. Tasting was conducted under

standard conditions. Panelists were given extensive feedback at each training session on their responses and were shown how their responses compared to the group. Panelists were thus given multiple practice and feedback sessions to improve their discrimination skills.

Tasting sessions of approximately 25 min duration were repeated on three occasions for each food tested. Eggs were served soft-boiled. All meats used for tasting were cooked in random order on a Breville Professional Grill and Sandwich Press TG-900, set to highest heat. Samples were cut into 1-cm squares and presented to the panelists on coded toothpicks. Panelists were requested to refresh their palate with water after each sample tasted. The sensory qualities tested were specific attributes related to taste, texture, aroma, mouthfeel, and hedonics. The wording of the sensory attributes and the line scale dimensions were made by the panelists in conjunction with the investigators during the training phase. This procedure ensured that all panelists were concordant with the attributes and their meaning and could agree to score quality consistently.

**Statistical analysis.** Biochemical data are presented as mean  $\pm$  SEM. Student's *t*-test was used to determine the significance of differences between means;  $P < 0.05$  was considered significant. ANOVA was applied to the sensory analysis for each variable (color, texture, odor, flavor, liking) to determine significances of differences between mean scores for these variables. *t*-Tests with Bonferroni adjustments were used to compare individual treatments.

## RESULTS

**Chemical analysis of eggs.** Table 2 shows the effect of feeding POM to laying hens on the total LC n-3 PUFA content of eggs. The concentration in yolks rose with increasing POM content of rations, reaching a maximum at 10% by weight of the feed. At the highest inclusion rate (20%), there was no apparent effect of varying the duration of feeding from 14 to 42 d. Feeding DHA-rich fishmeal resulted in a selective increase of DHA (Fig. 1). Even at the lowest POM inclusion rate (5%),

<sup>a</sup>Data are presented as mean  $\pm$  SEM,  $n = 5$  per group.

<sup>b</sup>Significantly different from control ( $P < 0.01$ ). For abbreviation and manufacturer see Table 1.

**FIG. 1.** PUFA composition (% of total FA) of egg yolks from poultry fed different levels (5–20%) of PorcOmega™ tuna fishmeal (POM) for 28 and 42 d and unsupplemented poultry (control). POM: tuna fishmeal formulation containing a complex antioxidant system and flavorings designed to eliminate objectionable fish odor and taint (Bartlett Grain Pty. Ltd., Sydney, Australia).

there was a threefold increase in DHA content, accounting for almost all of the LC n-3 PUFA increase (from 51 mg in control eggs to 177 mg). This is equivalent to that of commercially available n-3-enriched eggs and, by yielding more than 60 mg of LC n-3 PUFA per serving, would qualify for FSANZ's "good source of omega-3" claim (29). The cholesterol content of yolks was unaffected by feeding 5 or 10% POM. However, higher rates of POM inclusion tended to raise cholesterol content. The proportions of saturated fat and PUFA in yolks remained relatively constant across treatment groups (31–34% and 15–18%, respectively).

**Sensory evaluation of eggs.** Owing to logistical limitations, eggs from only two POM treatment protocols (10% for 42 d and 20% for 14 d) were used for sensory evaluation. These treatments had resulted in the highest levels of LC n-3 PUFA enrichment (at least six times higher than control). They were compared with eggs from hens fed the control diet and with a commercial n-3-enriched egg (Body Egg™, Chanteclair Farms, Quakers Hill, NSW, Australia). The LC n-3 PUFA content of the latter was similar to that of the 5% POM eggs (approximately three times higher than controls).

Figure 2 summarizes overall assessments for the eggs, based on criteria related to each of the six sensory attributes evaluated, *viz.*, color, texture, mouthfeel, aroma, flavor, and hedonics. The experimental n-3-enriched eggs were less desirable in most characteristics than the Body Egg and, to a lesser extent, the control egg. The Body Egg was superior in color to the eggs produced in this study, probably due to the use of pigment additives. Although there were no quantitative differences in odor, more than half of the panelists detected a fishy odor in the 20% POM eggs. Overall, the 10 and 20% POM eggs were liked less than the other eggs.

**Chemical analysis of chicken.** The n-3 PUFA content of chicken meat was also increased by feeding POM-enriched diets to poultry for either 21 or 42 d. Table 3 shows the total LC n-3 PUFA concentrations in uncooked samples of chicken

breasts, thighs, and sausages from each treatment group. The group fed 15% POM for 21 d showed the greatest n-3 enrichment, with 7- to 14-fold increases in the LC n-3 PUFA content of chicken meat. Even 5% POM fed for 21 or 42 d gave three- to sixfold increases, reaching the level required for a "good source of omega-3" claim. As with the eggs, the n-3 enrichment of chicken meat was due almost entirely to increased DHA content, as exemplified by changes in the PUFA profile of chicken breasts (Fig. 3). In breasts from birds fed 10% POM for 21 d, the relative content of DHA actually exceeded that of linoleic acid (18:2n-6).

When samples of n-3 PUFA-enriched chicken breasts and thighs were cooked by grilling (Table 4), the absolute concentrations of FA, including LC n-3 PUFA, tended to be higher than in raw meat. This is probably due to loss of moisture content, as the LC n-3 PUFA content expressed as a percentage of total FA was similar. Thus, it appears that there was no selective loss of LC n-3 PUFA due to cooking.

**TABLE 3**  
Total LC n-3 PUFA (mg/100 g) in Chicken Breast, Thigh, and Sausage from Chickens Fed 5–20% of POM for 42 d and from Chickens Fed 5–20% of POM for 21 d, Compared with Unsupplemented Chickens<sup>a</sup> (control)

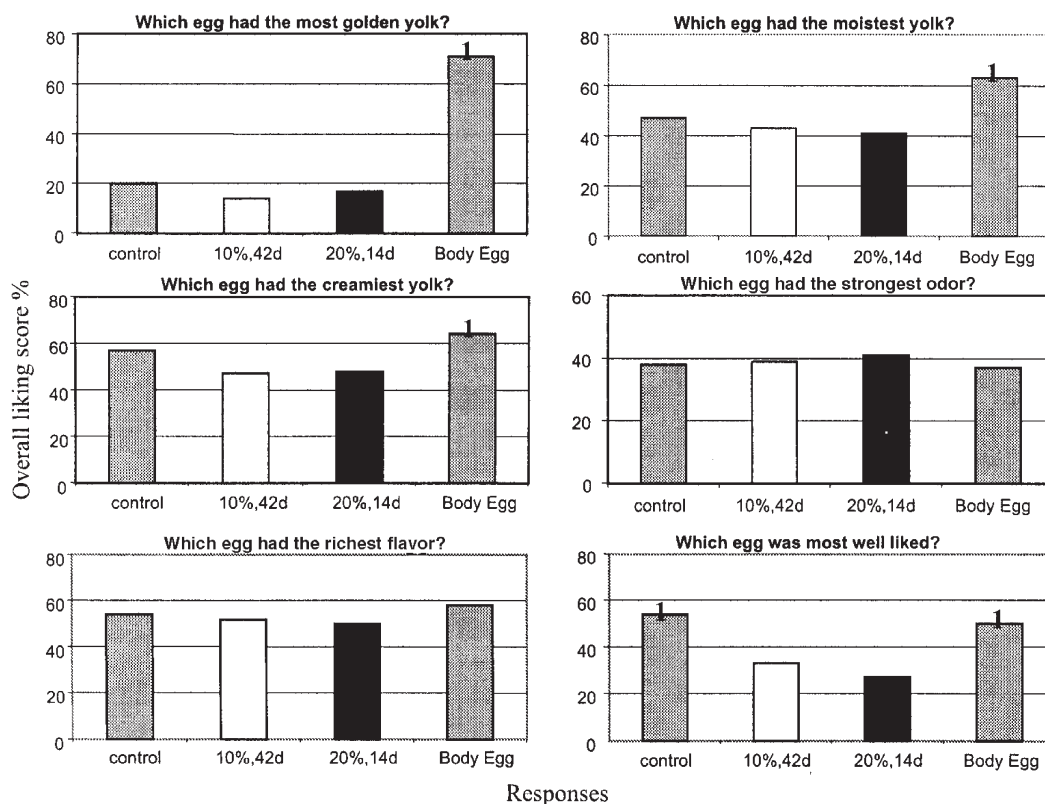

FIG. 2. Sensory evaluation (overall liking scores; %) of eggs enriched with 5 and 15% POM and unenriched (control) eggs. <sup>1</sup>Significantly different ( $P < 0.01$ ) from 10 and 20% POM treatment eggs (ANOVA). Body Egg™, commercial n-3 enriched egg (Chanteclair Farms, Quakers Hill, NSW, Australia). For abbreviation see Figure 1.

The total fat content of whole untrimmed portions of chicken was determined by the Soxhlet method (33). Average concentrations were 1.6, 6.2, and 2.3 g/100 g for breasts, thighs, and sausages, respectively. Neither the total fat content nor the proportion of saturated fat in chicken meat was significantly affected by the POM treatments. Considering that approximately one-third of total FA were saturated, it appears that the n-3 PUFA-enriched meats would qualify as

“good sources of omega-3” with respect to the disqualifying limit of 5 g/100 g for saturated/*trans* fat content (29).

*Sensory evaluation of chicken.* Samples of chicken meat from birds fed both 5 and 15% POM rations were compared with those from birds fed control rations. Breasts, thighs, and sausages were individually evaluated. Apart from having more tender texture, breasts from birds fed POM did not differ significantly from control breasts in any quantitative

<sup>a</sup>Data are averaged from two or three samples in each case. For abbreviation see Table 1.

assessments. There were no significant differences in any characteristics between POM-treated and control thighs and sausages, with the exception that the 15% POM-treated thighs were liked less than the controls and a mildly fishy flavor was detected in both breasts and thighs with 15% POM. Overall, there was a clear tendency for meat from birds fed 15% POM to be less well liked (Fig. 4), whereas that of birds fed 5% POM appeared to be equivalent to control chicken.

**Chemical analysis of pork.** Table 5 shows the total LC n-3 PUFA concentrations in pork chops and sausages from groups of male or female pigs fed control or POM-containing rations. Both enrichment strategies (15% POM for 42 d and 20% POM for 28 d) caused significant increases in LC n-3 PUFA levels in pork, with threefold increases in forequarter and leg chops and a 3.5-fold increase in sausages. Figure 5 shows a typical example of changes in individual FA composition of pork following n-3 enrichment. Data are averaged from samples of forequarter chops taken from control ( $n = 8$ ) and treated pigs ( $n = 12$ ). Total LC n-3 PUFA content rose from 1% of total FA in controls to 4% in forequarter chops from POM-fed pigs. As in meat from poultry fed POM, DHA increased far more than the other PUFA in pork. Cooking raised the absolute concentrations of all FA, including LC n-3 PUFA, due to loss of moisture from the meat. As with chicken, the proportionate increase of LC n-3 PUFA, especially DHA, in the pork was largely retained after cooking (Table 6).

**Fat content of pork.** Soxhlet determinations of the total fat content of pork products indicated that the forequarter and loin chops (25 and 27 g/100 g, respectively) would be unlikely to qualify for the Australian n-3 nutrition claim (requiring saturated/trans fat <5 g/100 g) without significant trim-

ming of adipose tissue. However, the leg chops, with total fat content around 5 g/100 g, would qualify. Indirect assessment of total fat in the lean portions of meat used for the GC analysis of FA indicated that interstitial fat amounted to less than 2 g/100 g, of which one-third was saturated fat. Pork sausages as prepared in this study (saturated fat approximately 5.7 g/100 g) would have marginal acceptability. As with the eggs and chicken meat, the proportion of saturated fat in pork was not affected by the n-3 enrichment.

**Sensory evaluation of pork.** Loin, forequarter, and leg chops and sausages were individually evaluated for sensory qualities. Comparisons were made between each of six treatment groups, i.e., male or female pigs fed the control, 15 or 20% POM ration. There were minor but inconsistent differences in sensory qualities of enriched meat between male and female pigs, e.g., loin and forequarter chops were more tender and juicy from male (especially POM-treated) than from female pigs but female POM-treated leg chops were more tender and juicy than male leg chops. Fishy odor or flavor was detected in forequarter and loin chops from POM-treated pigs but not in leg chops. Figure 6 shows overall liking scores for pork. POM treatment caused only forequarter chops to be significantly less liked than controls. There were no significant differences in any sensory qualities of sausages between any of the treatment groups.

## DISCUSSION

Enriching foods with LC n-3 PUFA is an important approach to increase consumption of these beneficial nutrients. In this study we have demonstrated that a stabilized fishmeal product can be successfully incorporated into pig and poultry

**FIG. 4.** Sensory evaluation (overall liking scores; %) of chicken (breast, thigh, and sausage) enriched with 5 and 15% POM and unenriched (control) chicken. For abbreviation see Figure 1. <sup>1</sup>Significantly different ( $P < 0.01$ ) from control (ANOVA).

feeding strategies to enrich meat and eggs without tainting the foods.

**Enrichment of pork.** This study confirms the effectiveness of fishmeal as a dietary source of LC n-3 PUFA for producing n-3-enriched pork. Moreover, by feeding DHA-rich tuna fishmeal, the enrichment was highly selective for DHA. The LC n-3 PUFA concentrations in the pork chops were lower than those achieved previously (7). In that study, however, pigs were fed 20% POM for 11 wk, whereas in the present study, an acceptable level of LC n-3 PUFA enrichment was attained after only 4 wk of feeding at that level.

LC n-3 PUFA concentrations have been measured directly in samples of lean meat (comprising muscle tissue and interstitial fat), which is likely to contain a higher relative proportion of LC n-3 PUFA than adipose tissue (15). In the previous study, the percentage of LC n-3 PUFA assayed in a lean sample of meat was multiplied by the total fat content of the whole portion of meat to estimate the LC n-3 PUFA concentration indirectly, which is likely to have been overestimated. However, the data now obtained for forequarter, loin, and leg chops by direct measurement of FA in lean samples of meat

(Table 5) is likely to underestimate the LC n-3 PUFA content of even a well-trimmed serving of pork. There is considerable latitude to increase the LC n-3 PUFA content per serving of pork by allowing more residual fat. Pork sausages give an indication of the maximal LC n-3 PUFA concentration attainable: >200 mg/100 g in sausages that had a 14% fat content (saturated fat approximately 6 g/100 g). Pork chops and sausages enriched with LC n-3 PUFA by short-term feeding of rations containing 15–20% POM could readily qualify for FSANZ's new n-3 nutrition claim (29) simply by adjusting the fat content of the products during processing.

In previous attempts to increase the LC n-3 PUFA content of pork, researchers have usually used fish oil and flaxseed oil and meal rather than fishmeal. Fishmeal is an important source of protein for pig rations, but its potential for tainting pork has led to restrictions on its use (25). Trials have been undertaken to develop recommendations for the use of fishmeal, which will minimize the retention of LC n-3 PUFA in pork and the associated risk of tainting (18,19). The same concern applies, however, if fish oil or flaxseed is used for n-3 PUFA enrichment. In fact, feeding flaxseed to pigs caused tainting of bacon without raising DHA content (24). Using a premium-quality tuna fishmeal, we sought to ascertain the highest level of LC n-3 PUFA enrichment of meat that could be attained without compromising quality.

The most important criterion for consumer acceptance of n-3 PUFA-enriched foods is sensory quality, which appears to be inversely related to the n-3 PUFA content (18–20). A compromise must therefore be reached between the extent of enrichment and deterioration of quality. The mode of enrichment will influence this relationship. Encapsulation, for example, is an important strategy for delivering n-3 PUFA in processed foods in a protected form that will minimize adverse effects on quality. Similarly, LC n-3 PUFA incorporated in muscle membrane phospholipids may be less susceptible to degradation than in adipose tissue stores (15). Presumably this accounts for the high levels of DHA retained in lean meat

**FIG. 5.** Individual LC PUFA composition (% of total FA) of control and POM pork forequarter (FQ) chops. FQ control: raw meat from untreated pigs; FQ POM: raw meat from pigs fed 15 or 20% POM; grilled FQ POM: cooked meat from pigs fed 15 and 20% POM. For abbreviation see Figure 1.

<sup>a</sup>Data averaged from 4 to 8 pigs/group. For abbreviation see Table 1.

in the present study after feeding DHA-rich POM. The level of inclusion for POM was three to four times higher than the recommended upper limit for fishmeal in pig rations (25). However, the proprietary product used in this study has been fortified with antioxidants to minimize degradation of LC PUFA. Others have shown that inclusion of selected antioxidants in rations can improve the stability of n-3 PUFA in enriched meat (20–23). Livestock performance data (Downing, J., Howe, P., and Bryden, W., unpublished data) and sensory evaluation of the LC n-3 PUFA-enriched pork products justify the higher rates of inclusion of POM in rations.

It was encouraging to note that there was good retention of LC n-3 PUFA during grilling in both chops and sausages. In fact, LC n-3 PUFA concentrations actually increased, owing to loss of moisture during grilling at high temperature, but the proportionate increases in LC n-3 PUFA relative to other FA were largely unaffected. Presumably the LC n-3 PUFA in meat are also less susceptible to degradation during cooking than, for example, a LC n-3 PUFA-rich cooking oil. Except for the eggs, all foods used for sensory evaluation were frozen for at least 1 mon and thawed prior to cooking. Others have noted off-flavors and rancidity after long-term frozen storage in pork from pigs fed fishmeal (18,19). However, with the exception of forequarter chops, containing high levels of adipose tissue (25% fat), there were few consistent differences in sensory qualities between control and n-3 PUFA-enriched pork. Sausages in particular, with their high fat content and level of enrichment, were well accepted by

panelists. Sausages and other processed meat products may be preferable products for enrichment, affording greater resistance to LC n-3 PUFA degradation during storage and cooking than other cuts of meat.

*Enrichment of chicken and eggs.* Birds readily accumulate n-3 PUFA in tissues and appear more efficient than mammals at converting ALA to LC n-3 PUFA (34). There are many good examples of LC n-3 PUFA enrichment of poultry products using fish oil or microalgal sources of LC n-3 PUFA, alone or in combination with ALA sources such as flaxseed or canola (10–15). ALA accumulates in the TG fraction, whereas LC n-3 PUFA are incorporated into phospholipids, and accumulation of high levels of ALA contributes to tainting of foods (12,18,24). Direct sources of preformed LC n-3 PUFA are preferred. Fishmeal is widely used as a source of protein in poultry rations at inclusion rates of 2–5% (26). As with pigs, however, there are few reports of its use for n-3 PUFA enrichment of poultry (18,19), even though it represents a more abundant and cost-effective source than fish oil. Leskanich and Noble (10) have reviewed the use of fishmeal, fish oil, and other sources for LC n-3 PUFA enrichment in poultry and recommend using high-quality fishmeal or fish oil, together with supplemental antioxidants, and limiting inclusion rates in rations to 12 or 1%, respectively, to avoid taint.

We have now demonstrated the suitability of POM (tuna fishmeal) for n-3 PUFA enrichment of poultry. Indeed, greater relative increases in LC n-3 PUFA, particularly DHA, can be

**FIG. 6.** Sensory evaluation (overall liking scores; %) of pork (loin, leg, forequarter chop, and sausage) enriched with 15 and 20% POM and unenriched (control) pork. <sup>1</sup>Significantly different ( $P < 0.01$ ) from control (ANOVA).

achieved at lower rates of POM feeding in poultry than in pork. The increases obtained by feeding 5% POM exceeded those achieved in other studies using <12% redfish meal in broiler rations (15). This may be attributable to the substantially higher content of DHA and ratio of DHA to EPA in tuna meal compared with herring meal. When feeding 15% POM to broilers, we found that the overall liking score for chicken thighs was significantly reduced, whereas with 5% POM, there were no discernible differences in sensory characteristics from the control meat. The n-3 PUFA-enriched chicken sausages were particularly well accepted. As with pork, the LC n-3 PUFA enrichment of chicken meat appeared to be sustained during high-temperature cooking.

Numerous strategies have been used for n-3 PUFA enrichment of eggs, with DHA and total LC n-3 PUFA ranging as high as 660 and 780 mg/egg, respectively (10). High levels are obtained by including high levels of fish oil in rations. Lower levels of fish oil, with or without flaxseed oil, result in more modest levels of LC n-3 PUFA enrichment and have been used to produce a wide range of commercial eggs with acceptable sensory characteristics. Nevertheless, the high cost of the dietary oils and the special conditions for production necessitate premium prices for n-3-enriched eggs.

Fishmeal may represent a cheaper alternative source of LC n-3 PUFA for enrichment of eggs. Using tuna fishmeal, we achieved increases in the DHA and total LC n-3 PUFA content of eggs that compared favorably with results obtained using other n-3 sources in published studies and in commercial production of n-3-enriched eggs. There were insufficient eggs available in this study to assess the effect of cooking on increased n-3 content. However, experience with commercially enriched eggs indicates that there is generally satisfactory retention of LC n-3 PUFA after cooking. As fresh eggs were required for the sensory evaluation, we were unaware of their n-3 content at the time of selecting treatment groups for evaluation. Unfortunately, the levels of POM inclusion chosen for sensory evaluation proved to be unacceptably high, resulting in significant sensory deficits. In retrospect, it would have been preferable to conduct sensory evaluation on eggs from hens fed 5% POM. At this level of feeding, the LC n-3 PUFA enrichment (approximately 180 mg/egg) compared favorably with that of feeding 12% herring meal (approximately 100 mg EPA and DHA/yolk) in the only other published report on n-3 PUFA enrichment of eggs with fishmeal (14).

The present study confirms that suitably processed tuna fishmeal, a by-product of the tuna processing industry that has traditionally been used as a protein source for livestock rations, may also be used as an alternative source of LC n-3 PUFA for enrichment of meat and eggs. It demonstrates that appropriate feeding strategies can be developed to avoid sensory deficits traditionally associated with the use of fishmeal in livestock rations. Compared with the use of other LC n-3 PUFA sources, high concentrations of DHA can be achieved with a relatively low dietary inclusion rate and duration of fishmeal feeding, permitting economical production of quality n-3 enriched foods. Consumer interest in these foods will

be stimulated by new labeling options such as the nutrition claim for n-3 PUFA recently introduced in Australia and New Zealand (29), which will help to differentiate them as premium products in the market place. Although qualification for n-3 PUFA nutrition claims is based on the LC n-3 PUFA content of uncooked foods, it is essential that cooked foods deliver the n-3 benefits. We have been able to confirm that the LC n-3 PUFA in enriched chicken and pork are retained after cooking. Further studies are now being undertaken with POM to refine the livestock feeding strategies required for the n-3 PUFA enrichment of specific food products and to optimize both sensory and shelf-life characteristics.

## ACKNOWLEDGMENTS

PorcOmega™ tuna fishmeal and financial support for this study were kindly provided by Bartlett Grain Pty. Ltd. The authors are grateful to John Wingate for advice on formulation of rations, to Samantha Reis for assistance with the sensory evaluation, and Dr. Karen Murphy for assistance with revision of the manuscript. The Smart Foods Centre is a Key Centre of Teaching and Research funded by the Australian Research Council.

# Effects of Dietary $\alpha$ -Linolenic Acid from Blended Oils on Biochemical Indices of Coronary Heart Disease in Indians

Ghafoorunissa\*, A. Vani, R. Laxmi, and B. Sesikeran

National Institute of Nutrition (ICMR), Hyderabad-500 007, A.P., India

**ABSTRACT:** PUFA of the n-6 and n-3 series have beneficial effects on key risk factors of coronary heart disease (CHD). Our earlier studies on the intake of FA and on the FA composition of plasma and platelet phospholipids suggested the need to improve the n-3 PUFA nutritional status in the Indian population. The present long-term study was conducted on 80 middle-aged Indian subjects (40 men and 40 women) using the subjects' own home-prepared diets to evaluate the effects of dietary n-3 PUFA on biochemical indices of CHD risk. Substitution of Blend G (equal proportions of groundnut and canola oils) for groundnut oil or substitution of Blend S (equal proportions of sunflower oil and canola oils) for sunflower oil increased  $\alpha$ -linolenic acid (ALNA) fourfold and decreased the linoleic acid (LA)/ALNA ratio from 35 to 6 and 65 to 9, respectively. Twelve subjects (six men and six women) who received Blend G were switched back to groundnut oil and were administered 0.3 g daily of long-chain (LC) n-3 PUFA from fish oil. At the end of the trial period for both blends in both sexes, plasma lipid and apolipoprotein levels had not changed, and ADP-induced aggregation had decreased. In plasma and platelet phospholipids, LA as well as LCn-3 PUFA had increased, suggesting competition between LA and ALNA for metabolism into the respective LC-PUFA. Fish oil supplementation increased LCn-3 PUFA in plasma and platelet phospholipids, decreased ADP-induced platelet aggregation, and increased plasma cholesterol. On the basis of the increased LCn-3 PUFA in plasma phospholipids, it was calculated that 0.75% energy (en%) (2.2 g) ALNA (from vegetable oils) may be required to increase LCn-3 PUFA to about the same extent as 0.1 en% (0.3 g) LCn-3 PUFA (from fish oils). Since both n-6 and n-3 PUFA play a critical role in fetal growth and development and in the programming of diet-related chronic diseases in adults, an improvement in the n-3 PUFA nutritional status in cereal-based diets through long-term use of cooking oils containing 25–40% LA and 4% ALNA may contribute to the prevention of CHD in Indians.

Paper no. L9046 in *Lipids* 37, 1077–1086 (November 2002).

PUFA comprise the parent EFA [linoleic acid (LA) and  $\alpha$ -linolenic acid (ALNA)] and their respective long-chain (LC) more unsaturated derivatives. Since the time the essentiality of PUFA was established in 1929, studies on the nutritional

effects of LA have received wide attention. However, following the Eskimo studies (1), several lines of evidence showed that the LCn-3 PUFA downregulate factors that have atherogenic potential and enhance factors that have anti-atherogenic potential (2–4). Recent studies also have focused on the effects of ALNA in preventing coronary heart disease (CHD) (5–8). Studies on FA intakes among Indians showed that LA requirements are fully met owing to their high levels in cereal, millet, and vegetable oils, but ALNA intake is low and therefore the n-6/n-3 ratio is high (9). Further, data on the FA profile of plasma and platelet phospholipids in apparently normal subjects suggested the need to improve the n-3 PUFA nutritional status in Indians (9). Metabolic studies conducted to investigate the effects of using canola oil (ALNA) or fish oil supplements (LCn-3 PUFA) compared to groundnut oil (negligible ALNA) showed that ~1.4% energy (en%) ALNA, (n-6/n-3, ~4) or 0.2 to 0.5 en% LCn-3 PUFA (n-6/n-3, ~7 to 12, respectively) may produce anti-atherogenic effects (9,10). To achieve the above levels of ALNA and an optimal n-6/n-3 ratio (5:1 to 10:1), the use of ALNA-containing oils (canola, soybean, or mustard) along with other oil(s) has been recommended (11). The present study was carried out to evaluate the long-term effects of increasing ALNA intake using combinations of ALNA-containing oil (canola) with two edible oils commonly used in south India (groundnut and sunflower) compared to the effects of fish oil supplementation on biochemical parameters of cardiovascular risk.

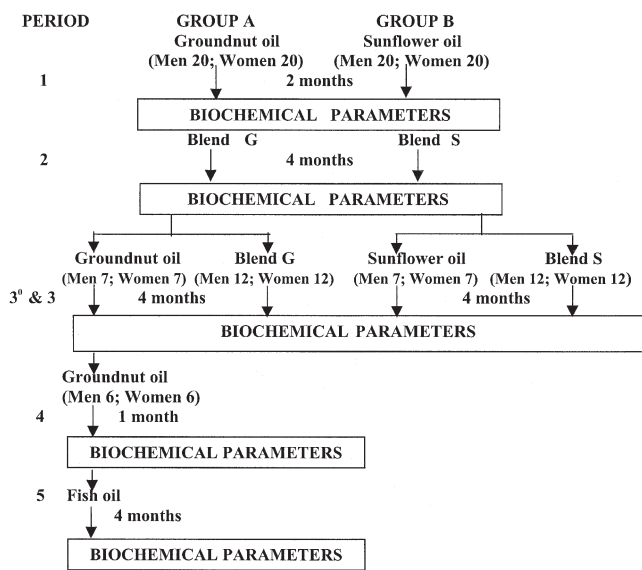

## MATERIALS AND METHODS

**Subjects.** Out of a total of 70 families to whom the study was explained, 40 were enrolled. Criteria for their selection included age between 30 and 50 years, a normal ECG, and no history of diabetes or CHD. In addition, the subjects were not in the habit of consuming frequent meals or snacks outside their homes, did not take anti-inflammatory drugs, and consumed neither tobacco nor alcohol. The subjects' diets provided >30 g/d of cooking oil. The study was approved by the Institute's ethical committee, and written consent was obtained from both husband and wife.

**Study design. (i) Period 1.** Twenty families (Scheme 1) who had used groundnut oil as the major cooking oil for more than 2 mon were provided the traditionally consumed refined groundnut oil (Postman, Ahamed Mills, Mumbai, India), and 20 families who had used sunflower oil as the major cooking oil for more than 2 mon were provided sunflower oil [Dhara,

Abbreviations: ALNA,  $\alpha$ -linolenic acid; CHD, coronary heart disease; DPA, docosapentaenoic acid; EMR, estimated maximal response; LA, linoleic acid; LC, long-chain; NDDB, National Dairy Development Board; PPP, platelet-poor plasma; PRP, platelet-rich plasma; WB, whole blood.

SCHEME 1

National Dairy Development Board (NDDB), Anand, Gujarat, India]. Both oils were supplied in sealed containers with instructions to use it as the only cooking fat source for a period of 2 mon.

(ii) *Period 2.* The families in Group A (Scheme 1) were switched to Blend G (equal proportions of groundnut and canola) and those in Group B were switched to Blend S (equal proportions of sunflower and canola) for a period of 4 mon. Blended oils were obtained from the NDDB. The percentage FA in Blend G and Blend S, respectively, were as follows: total saturates, 17 and 9; total monounsaturates, 52 and 44; and LA, 26 and 42. Both blends furnished ~4% ALNA compared to negligible levels in the single oils (groundnut or sunflower). The blended oils were prepared and supplied by the NDDB in 1- and 4-kg sealed containers.

(iii) *Period 3.* Twelve families each from Groups A and B continued to consume Blend G and Blend S, respectively, for the next 4 mon (Period 3), whereas seven families from each group (A and B) were switched back to the single oils (Period 3<sup>0</sup>) on which they were stabilized earlier.

(iv) *Periods 4 and 5.* Six families (six men and six women) who were switched back to groundnut oil (Period 3<sup>0</sup>) were continued for another month on groundnut oil (Period 4) and subsequently were administered one capsule of fish oil daily (MaxEPA, 180 mg; DHA, 120 mg) as well as 100 mg  $\alpha$ -tocopherol twice a week for 4 mon (Period 5).

*Diets.* During each of the study periods (1, 2, and 3), individual diet surveys were done (one on the weekend and two on weekdays) using a 24-h recall questionnaire (12), and subjects' average daily intakes of major food groups, macronutrients, and individual FA from all food items (invisible fat) were calculated using food composition tables (9,13). The intake of fat and individual FA from the total diet (invisible + visible) was calculated for each oil period. In order to monitor compliance, the subjects were requested to record the total number of meals and snacks eaten outside the home. These

records were collected at biweekly intervals throughout the study period. At the end of Period 1, body weight, height, and blood pressure were recorded; body weight was again recorded at the end of Periods 2 and 3.

*Biochemical parameters.* Fasting blood samples were collected in the morning at the end of each period after ensuring that the subjects had not taken anti-inflammatory drugs in the previous 2 wk. For platelet aggregation studies, blood was collected in a 3.8% trisodium citrate solution (9:1 vol/vol). For analysis of plasma lipids and lipoproteins, blood was collected into tubes containing EDTA (1 mg/mL).

(i) *Lipids, lipoproteins, and FA.* Blood collected in tubes with EDTA was spun at  $120 \times g$  for 10 min. The platelet-rich plasma (PRP) that was obtained was spun at  $1000 \times g$  for 15 min to get a platelet pellet and platelet-poor plasma (PPP). The platelet pellet was washed with saline and the cells were lysed. The PPP was used for analysis of lipids, apolipoproteins, and phospholipid FA composition. Total cholesterol, HDL-cholesterol, and TAG were analyzed by enzymatic methods using kits obtained from Dr. Reddy's Laboratories (Hyderabad, India). The levels of apolipoproteins B and A-1 were determined by a quantitative, immunoturbidimetric method using kits obtained from Sigma Diagnostics (St. Louis, MO). Lipids were extracted from both plasma and lysed platelets with chloroform/methanol (2:1 vol/vol) containing BHT, and the phospholipid band was separated by TLC and methylated (14). FAME were analyzed by flame ionization capillary GLC using a PC-based Perkin-Elmer autoanalyzer (Buckinghamshire, United Kingdom) as described previously (14).

(ii) *Platelet aggregation and plasma fibrinogen.* Citrated blood was diluted with saline (1:1 vol/vol), and whole blood (WB) aggregation was measured with  $2 \mu g$  collagen by the impedance method (15) using a Model 530 WB aggregometer (Chronolog Corporation, Havertown, PA); aggregation rate (slope) and lag time were calculated. PRP was obtained by spinning citrated blood as described previously (14). ADP-induced aggregation was measured in  $250 \mu L$  PRP ( $250,000$  cells/ $\mu L$ ) with varying concentrations of ADP (0.02 to  $2 \mu M$ ) as described previously (14). The threshold for ADP (dose at which no aggregation was recorded) and aggregation rate (slope) with  $2 \mu M$  ADP were determined. Plasma fibrinogen was estimated in citrated PPP by an optimized microturbidimetric assay using a two-step addition of ammonium sulfate reagent and timed turbidity measurements after 120 and 190 s at 340 nm (16).

*Statistical analysis.* The biochemical parameters were analyzed by a multi-way ANOVA to test the differences, if any, among sex, oils, and time period, and paired *t*-tests were done between single and blended oils (Period 1 vs. 2). Because the responses on the biochemical parameters were similar after 4 mon on Blend G and Blend S, the data on the two blends were pooled. A one-way ANOVA was done to determine the effects of the single oil consumed for 4 mon and the blends for 4 and 8 mon (periods 1, 2, and 3), as well as on the effects of changing back to the single oil after 4 mon of blend consumption

(Periods 1, 2, and 3<sup>0</sup>). Statistical analyses were done by using SPSS version 10 for Windows (SPSS Inc., Chicago, IL).

## RESULTS

**Compliance and dietary intake.** The clinical characteristics of subjects are given in Table 1. The average daily intakes of each of the food groups and macronutrients are presented in Table 2. The number of meals and snacks eaten outside the home were similar in Groups A and B during the 10-mon study period (70% of subjects consumed <50 and 30% of subjects consumed 51–100 meals and snacks during the entire period of the study). In 40% of the families, the average consumption of oil was higher during Periods 2 and 3 (0.9–1.8 kg/mon/family) compared to Period 1. The contribution of meals and snacks eaten outside the home and the consequent difference in the amount and type of oil was not accounted for in calculating food and nutrient intakes. The data presented in Table 3 show that the use of both Blend G and Blend S increased ALNA from ~0.2 to ~0.9 and 0.8 en%, respectively, compared to the single oils (Table 3). The intake of other FA was similar during Blend G and groundnut oil periods. The intakes of total monounsaturates were high, and LA was low during consumption of Blend S compared to sunflower oil. The ratio of LA/ALNA (n-6/n-3) was reduced from 35 during intake of groundnut oil to 6 during intake of Blend G, and from 65 during intake of sunflower oil to 9 during intake of Blend S (Table 3). During fish oil supplementation, the LA/ALNA + LCn-3 PUFA (n-6/n-3) ratio was 25.

**Effect of 4-mon intake of blended oil.** In both the groups (men and women), at the end of each oil consumption period (4 and 8 mon) body weight (data not given), plasma total cholesterol, HDL-cholesterol, TAG, and apolipoprotein A-1 and B levels were not altered (Table 4). The data on plasma phospholipid FA composition showed that during the single-oil period, ALNA and 20:5n-3 were not detectable (Table 5). At the end of trials for each blend in both sexes, ALNA could be detected only in some subjects and LA, 20:5n-3, 22:5n-3, and 22:6n-3 (LCn-3 PUFA) increased. The use of blends lowered total saturates, and only at the end of the Blend S period did monounsaturates increase. In platelet phospholipids, the use of either of the blends increased LA and 20:5n-3, and decreased 22:6n-3, dihomo- $\gamma$ -linolenic acid (20:3n-6), and docosatraenoic acid 22:4n-6 (Table 6).

**TABLE 1**

<sup>a</sup>Values are mean  $\pm$  SEM; n = 40 for each sex. en%, percent energy; g/p, gram/person. Visible fat, cooking oil and ghee; invisible fat, fat from all food items.

<sup>b</sup>Eighteen men and 18 women. Fish (eight men, eight women), 5 g.

In both sexes, following consumption of each blend the lag time for collagen-induced aggregation in WB was shorter and ADP-induced platelet aggregation (slope) in PRP decreased (except in men on Blend S; see Table 7). The threshold for ADP-induced aggregation and plasma fibrinogen levels was not altered (Table 7). Irrespective of the type of oil used, women had lower levels of TAG and apolipoprotein B as well as higher levels of HDL-cholesterol (Table 4), higher aggregation rates with both collagen and ADP, and lower thresholds for ADP-induced aggregation than men (Table 7).

**Effect of continued intake of blended oils or switching back to single oils.** Continued consumption of blended oils for an additional period of 4 mon (Period 3) or switching back to single oils (Period 3<sup>0</sup>) affected neither plasma lipids (TAG, cholesterol, and HDL-cholesterol) nor apolipoproteins (data not shown). In plasma phospholipids, the magnitude of increase in total LCn-3 PUFA was similar at the end of 4 and 8 mon on blends (Table 8). At the end of 4 mon after switching to the single oils (Period 3<sup>0</sup>), the total LCn-3 PUFA levels decreased; these values were higher than those of the single-oil period (Period 1). At the end of 8 mon (Period 3) of blended oil consumption, an increase in total LCn-3 PUFA in platelet phospholipids was due to 20:5n-3 and 22:5n-3.

The lag time for collagen-induced aggregation in WB decreased to the same extent at the end of 4 and 8 mon on blends compared to the single-oil period (Table 8). In subjects who were switched back to single oils (Period 3<sup>0</sup>), the lag time for collagen-induced aggregation in WB increased to the basal value. ADP-induced aggregation in PRP decreased after both 4 and 8 mon of blend consumption as well as after switching back to single oils (statistical significance was not consistent).

**Effects of blended oil vs. fish oil intake.** The data presented in Table 9 show the response of subjects to the dietary increase in ALNA from blended oils (Periods 1 and 2) compared to the increase in LCn-3 PUFA from fish oil (Periods 4 and 5) over a

<sup>c</sup>*P* < 0.05; statistically different from Period 1 by paired *t*-test.

period of 4 mon. In plasma phospholipids, blended oil as well as fish oil supplementation increased LA, 20:5n-3, 22:5n-3, and 22:6n-3 (total LCn-3 PUFA). In platelet phospholipids, blended oil increased LA and 20:5n-3 and decreased 20:3n-6. Fish oil supplementation increased LA, 20:5n-3, 22:5n-3, and 22:6n-3 and decreased 20:3n-6. Supplementation with fish oil decreased ADP-induced platelet aggregation in PRP (Table 9) and increased plasma total cholesterol (Fig. 1). The apolipoproteins A-1 and B and HDL-cholesterol were not altered, whereas TAG were decreased (not statistically significant). The decrease in lag time observed for WB aggregation after blended oil supplementation was not seen after fish oil supplementation (Table 9).

## DISCUSSION

**Dietary intake of FA.** The present study documents the long-term effects of increasing ALNA on various biochemical parameters associated with CHD in middle-aged Indian subjects. The use of Blend G (26% LA, 4% ALNA) increased ALNA and decreased the n-6/n-3 ratio without any change in other dietary FA. On the other hand, the use of Blend S (42% LA, 4% ALNA) increased ALNA and MUFA and decreased LA and the n-6/n-3 ratio. During the single-oil period, the daily ALNA intake was 0.6 g (0.2 en%) and LCn-3 PUFA intake was negligible compared to the ALNA + LCn-3 PUFA intake

<sup>b</sup>*P* < 0.001; <sup>c</sup>*P* < 0.01; <sup>d</sup>*P* < 0.05; statistically different from Period 1 by paired *t*-test.

<sup>e</sup>Includes 20:3n-6, 20:4n-6, 22:4n-6, and 22:5n-6.

<sup>f</sup>Includes 20:5n-3, 22:5n-3, and 22:6n-3.

of 1–2 g common in most Western diets (17,18). In Eskimos and in populations in Japan (fishing villages) with low CHD morbidity, the daily intake of LCN-3 PUFA was about 7 and 4 g, respectively (19,20). Since subjects showed good compliance by using the oil supplied as the major cooking oil in their

homes and by eating home-prepared food, and because their body weights were similar at the end of the single-oil and blended-oil regimens, the data presented in Tables 4–8 can be attributed to differences in the type of oil consumed.

**FA composition in plasma and platelet phospholipids.** Despite having no differences in the intake of saturates, subjects' use of either of the blends decreased the total saturates in plasma phospholipids; the higher intake of oleic acid in subjects who used Blend S was reflected in plasma phospholipid values. The total LCN-3 PUFA levels in plasma and platelet phospholipids were low in the subjects studied here compared to populations consuming ALNA-rich edible oils (21,22) or fish (23–25). The observation that the magnitude of increase in total LCN-3 PUFA (20:5n-3, 22:5n-3, and 22:6n-3) in plasma phospholipids was similar at the end of 4 and 8 mon suggests that with a low dose of ALNA, the maximum improvement in n-3 PUFA status was achieved in 4 mon. At the end of 4 mon on either of the blends, 20:5n-3 increased but 22:6n-3 decreased in platelets. The reason for the decrease in 22:6n-3 is not clear. However, at the end of 8 mon, the increases in 20:5n-3 and 22:5n-3 contributed to a twofold increase in total LCN-3 PUFA. Published work on the effects of

**FIG. 1.** Effects of blended oils vs. fish oil on plasma lipids and apolipoproteins. Values are mean ± SEM (*n* = 12). \*Significantly different by ANOVA from Period 1 (*P* < 0.05). <sup>a</sup>Values are mean  $\pm$  SEM;  $n = 24$  in each period for each sex (Periods 1, 2, and 3) and  $n = 14$  in each period for each sex (Periods 1, 2, and 3<sup>0</sup>). Statistically different by ANOVA from <sup>b</sup>Period 1 and <sup>c</sup>Period 2 ( $P < 0.05$ ). Period 1, groundnut oil or sunflower oil; Period 2, Blend G or Blend S for 4 mon; Period 3, Blend G or Blend S for 8 mon; Period 3<sup>0</sup>, groundnut oil or sunflower oil for 4 mon. For blend components see Table 3. For abbreviations see Table 7.

ALNA from flaxseed or canola oil have shown either no increase in 20:5n-3 and 22:6n-3 or only a modest increase in 20:5n-3 in plasma and platelet phospholipids. This wide variability has been attributed to differences in the dose of ALNA, duration of the experiment, LA intake, the n-6/n-3 ratio, or other nutritional and hormonal variations (21,26–29). The increase in LA in both plasma and platelet phospholipids and the decrease in 20:3n-6 in platelet phospholipids could be due to competition of ALNA with LA for the desaturases. It therefore appears that a modest increase in ALNA in cereal-based diets providing 5–7 en% LA may inhibit desaturation of LA and increase the conversion of ALNA to LCn-3 PUFA.

To determine the extent to which vegetable oils can substitute for fish oils, we studied the effects of increasing dietary ALNA compared to supplementation with LCn-3 PUFA (20:5n-3 + 22:6n-3) on plasma and platelet FA composition (Table 9). These data were obtained from the same subjects after a washout period of 5 mon so as to minimize interindividual variations. However, after the washout period LA and LCn-3 PUFA levels were higher than in the single-oil con-

sumption period, indicating that the carryover effects of blended oils may exceed 5 mon. The increase in LA in both plasma and platelet phospholipids and the decrease in 20:3n-6 in platelet phospholipids indicate that 20:5n-3 and 22:6n-3 from fish oil may inhibit the desaturation of LA (Table 9). The magnitude of increase in the LCn-3 PUFA period calculated in comparison to the respective single-oil period showed that dietary intake of  $\sim 2.2$  g (0.75 en%) ALNA or 0.3 g (0.1 en%) LCn-3 PUFA increased LCn-3 PUFA to the same extent in plasma phospholipids (efficiency of conversion was 7.5:1). However, the efficiency of conversion of ALNA to 20:5n-3 and 22:6n-3 was  $\sim 12:1$  and  $30:1$ , respectively. In our earlier short-term metabolic studies with twice the dose of ALNA or LCn-3 PUFA, the efficiency of conversion of ALNA to LCn-3 PUFA was 11:1 (10). Bioequivalence in functional responses have been achieved in some, but not all, studies by providing ALNA at levels 7–10 times that of the corresponding amounts of 22:6n-3 (29), and the efficiency of 20:5n-3 to prolong bleeding time is about twofold greater than that of ALNA (30).

**TABLE 9**  
**Effects for Blended Oils vs. Fish Oil<sup>a</sup> on Plasma and Platelet Total Phospholipid FA and Platelet Aggregation**

<sup>a</sup>Values are mean ± SEM; *n* = 12 (six men, six women) in each period. Statistically different by ANOVA from <sup>b</sup>Period 1, <sup>c</sup>Period 2, and <sup>d</sup>Period 4 (*P* < 0.05). Period 1, groundnut oil; Period 2, Blend G for 4 mon; Period 4, reversal to groundnut oil; Period 5, groundnut oil + 0.3 g LCn-3 PUFA. For blend components see Table 3.

<sup>e</sup>Includes 20:3n-6, 20:4n-6, 22:4n-6, and 22:5n-6.

<sup>f</sup>Includes 20:5n-3, 22:5n-3, and 22:6n-3. For abbreviations see Tables 5 and 7.

**Platelet aggregation and fibrinogen.** The measurements of platelet aggregation *in vitro* and fibrinogen were done to assess the hemostatic effect of n-3 PUFA. ADP-induced aggregation in PRP measured by turbidometry has been widely used to assess platelet reactivity. The responsiveness to ADP-induced aggregation in PRP has been reported to be higher in a high-risk CHD group compared to a low-risk group. Further, dietary saturates (31) increase but n-3 PUFA decrease the ADP-induced platelet aggregation rate (32). Increasing dietary ALNA (Table 7) as well as supplementing with LCn-3 PUFA (Table 9) decreased ADP-induced aggregation. This decrease persisted (though statistical significance was not achieved for all values) both with the continuation of blended oils and after subjects were switched back to single oils for an additional period of 4 mon (Table 8). It is interesting that the carryover effects of ALNA in reducing ADP-induced aggregation (Table 8) parallel those observed in LCn-3 PUFA in plasma and platelet phospholipids (Table 8). However, it is not clear whether the decrease in ADP-induced aggregation rate without a corresponding change in other parameters of

coagulation (threshold for ADP and fibrinogen) will contribute to a decrease in platelet reactivity. In our earlier studies with 2–5 times higher doses of fish oil supplements, decreases in ADP-induced aggregation (33) were reported, but doubling the intake of saturates had no effect (14).

The impedance method of assessing agonist-induced WB aggregation permits measurement of platelet aggregation in its natural milieu. It reveals the formation of the first aggregates but provides scanty information about changes in platelet size (15,34). The lag time observed in collagen-induced aggregation is due to polymerization of collagen to collagen fibrils as well as stimulation and secretion of platelet contents following adhesion of platelets to collagen fibrils. Studies on collagen-induced aggregation in PRP and WB showed that n-3 PUFA decreased the aggregation rate (15,34). In Indian men, an increase in either ALNA or LCn-3 PUFA intake decreased the collagen-induced aggregation rate in WB (10). That the collagen-induced aggregation rate was not inhibited in WB, as observed in this study, could be attributed to the lower levels of either ALNA or LCn-3 PUFA. However, it is not clear whether the decrease in

lag time without a change in aggregation rate observed at the end of the blended oil period will affect the overall reactivity of platelets and would be of physiological or clinical relevance.

Platelet reactivity was higher in women as assessed by the ADP-induced aggregation rate, threshold for ADP in PRP, and collagen-induced WB aggregation rate. Johnson *et al.* (35) reported that ADP-induced aggregation increased in both sexes with age and that platelet sensitivity was greater in women. In our earlier studies, WB aggregation was measured with different levels of collagen; we found that EMR (estimated maximal response) was high in women but that the dose required for half-maximal response and lag times were similar in both sexes (14).

This study shows that a modest increase in dietary ALNA (the maximum achievable levels in cereal-based diets) leads to significant improvement in n-3 PUFA nutritional status. The observed beneficial effects are particularly important for vegetarians and for those who for various reasons do not include fish in their regular diets. We observed that although long-term use of LCn-3 PUFA from fish oils may confer benefits by having hypotriglyceridemic effects and by being about seven times more effective than ALNA in increasing total LCn-3 PUFA in plasma phospholipids, they may adversely affect cholesterol metabolism. In a recent review of epidemiological studies, Marckmann and Gronbaek (36) concluded that CHD mortality is high in people not eating fish at all, but daily consumption of 40–60 g fish is associated with reduced CHD mortality in high-risk populations. Since ALNA intake is inversely associated with risk of CHD (3,5–8), daily intake of ~2 g ALNA and an LA/ALNA ratio lower than 10:1 is recommended (6). The data presented here show that daily intake of ~2 g ALNA (vegetable oil blends) or 20:5n-3 plus 22:6n-3, which can be furnished from 20–50 g fish (2–5% fat), can improve n-3 PUFA nutritional status and reduce platelet reactivity. In India, chronic undernutrition, particularly a low intake of fat, n-3 PUFA (11), and micronutrients, may contribute to the high prevalence of low birth weights and the poor growth and development of babies (37–39). Both n-6 and n-3 PUFA play a critical role in gene regulation (40), fetal growth and development (41,42), and programming of diet-related chronic diseases in adults (43). Therefore, an improvement in the n-3 PUFA nutritional status of the Indian population throughout the life span may contribute to several health benefits, including the prevention of diet-related chronic diseases.

## ACKNOWLEDGMENTS

This project was funded (in part) by a grant-in-aid from the National Dairy Development Board (NDDB), Anand, Gujarat. The authors are grateful to Dr. Kamala Krishnaswamy, former director, NIN, and Dr. Amrita Patel, chairman, NDDB, for their keen interest and encouragement. We thank Dr. M. Vishnuvardhan Rao for help with the statistical analysis.

**ABSTRACT:** Most lipid extraction procedures [Folch, J., Lees, M., and Sloane-Stanley, G.H. (1957) A Simple Method for the Isolation and Purification of Total Lipids from Animal Tissues, *J. Biol. Chem.* 226, 497–509; Bligh, E.G., and Dyer, W.J. (1959) A Rapid Method of Total Lipid Extraction and Purification, *Can. J. Biochem. Physiol.* 37, 911–917] employ biphasic solvent mixtures designed to dissolve the lipids in an organic phase and remove impurities in an aqueous phase. However, when applying these protocols to biological matrices such as that of the ocular lens, the formation of an emulsion layer between the organic and aqueous phases causes poor reproducibility in extraction yields and gives only a small amount of the lipid-containing chloroform phase. In this study, we quantified phospholipids at each step of the Folch *et al.* extraction protocol and compared the yield of human and bovine lens phospholipids obtained by the Folch-based approach and a novel monophasic methanol extraction method designed to circumvent the problems associated with biphasic extraction protocols. A monophasic methanol extraction coupled with <sup>31</sup>P NMR spectroscopy was found to be the simplest, quickest, and most effective method for quantifying the phospholipid content of the lens.

Paper no. L9008 in *Lipids* 37, 1087–1092 (November 2002).

Most lipid extraction procedures (1,2) employ biphasic solvent mixtures designed to dissolve the lipids in an organic phase and remove impurities in an aqueous phase. Upon addition of the KCl-containing aqueous buffer, however, biological matrices such as that of the ocular lens yield an emulsion layer between the organic and aqueous phases that causes low extraction yields and poor reproducibility.

These problems were circumvented in lens (3) and fungus (4) tissues by using an initial monophasic extraction with either methanol or a mixture of chloroform and methanol. The preferential solubility of phospholipids in methanol has been reported (5,6). It is reasonable, then, to expect better extraction yields using only methanol, a relatively polar solvent, rather than the less polar chloroform/methanol mixture. For this reason, we have explored the efficiency of a monophasic, methanol-based protocol for the extraction of lens phospholipids.

We have demonstrated that phospholipids obtained with a single methanolic extraction, without further purification, can be quantified by <sup>31</sup>P NMR spectroscopy. We have also determined the relative loss of phospholipids at each step of the extraction procedure and have compared the yield and composition of human and bovine lens phospholipids obtained by the Folch-based (1) approach and a monophasic methanol extraction method.

## METHODS

Through the Kentucky Lions Eye Bank and the Wisconsin Lions Eye Bank, Medical College of Wisconsin, clear human lenses were obtained within 8 h postmortem and frozen in liquid nitrogen. Bovine eyes were obtained fresh from a slaughterhouse. The lenses were removed and immediately frozen at –70°C. Spectrophotometric-grade solvents and all other chemicals were purchased from Sigma Chemicals (St. Louis, MO). All solutions and solvents were bubbled with argon gas for at least 10 min to remove oxygen. Glassware was used instead of plastic to avoid impurities present in plastics.

Buffer A was prepared as follows: 0.3 M sucrose; 10 mM *N*-2-hydroxyethylpiperazine-*N'*-2-ethane sulfonic acid, pH 7.4; and 2 mM DTT, added fresh. Buffer B was prepared as follows: 8 M urea; 0.08 M tris(hydroxymethyl)amino-methane, pH 7.4; and 2 mM DTT, added fresh.

Figure 1 shows the sequence of steps followed to compare the extraction efficiency of the most commonly used chloroform/methanol approach (Paths A1 and A2) with that of a monophasic methanol method (Path A3). The percent yields obtained with and without the use of a centrifugation step to remove water-soluble proteins prior to the Folch-based extraction are indicated (Paths A1 and A2). The loss of lipid caused by ultracentrifugation (Path A2 vs. Path A3) was also quantified.

*Paths A1, A2 (Fig. 1): Centrifugation fractionation of soluble and insoluble proteins.* We prepared three samples, S1, S2, and S3, each containing four bovine lenses. Lenses were thawed, weighed, and homogenized in 40 mL of buffer A using a mechanical tissue tearer (Biospec Products Inc., Bartlesville, OK). We dispersed the homogenate three times with 15-s bursts from a Branson Sonifier Cell disrupter 185 (Danbury, CT) at a power setting of 5, allowing 2 min between sonication periods to avoid heating the samples.

We placed samples S1 and S2 in ultracentrifuge tubes and spun them at 70,000 × *g* for 1.5 h. After centrifugation, we

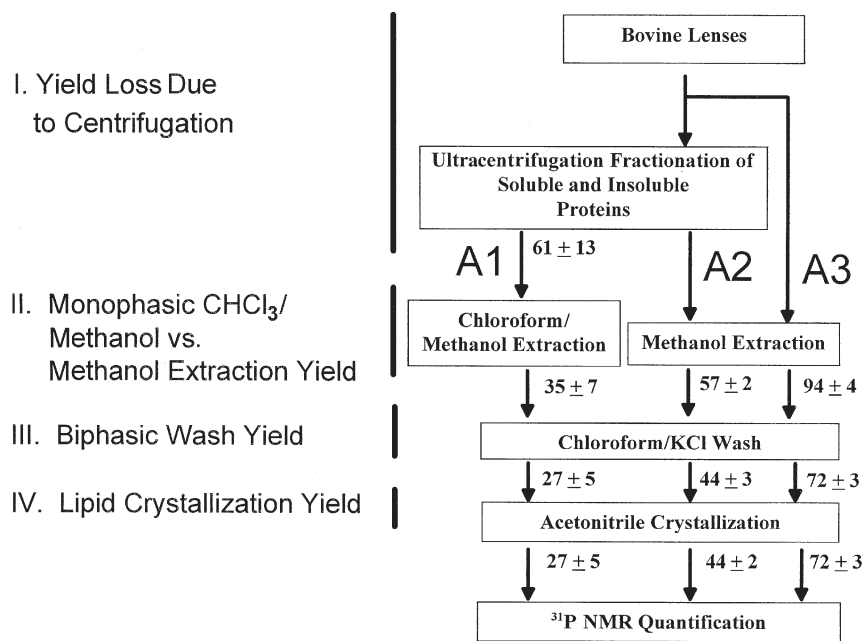

FIG. 1. Bovine lens lipid purification protocol. Data are mean (percent yields)  $\pm$  SEM ( $n = 8$ ).

decanted the supernatants and transferred the two resulting pellets to 50-mL centrifuge tubes, then added 15 mL of buffer B to each pellet. Each sample was mixed with a vortex mixer (Scientific Industries Inc., Bohemia, NY).

**Path A1 (Fig. 1): Chloroform/methanol bovine lipid extraction.** We added 30 mL of a 2:1 (vol/vol) chloroform/methanol mixture to the pellet in buffer B from sample S1. The sample was then mixed with a vortex mixer (Scientific Industries Inc.) and centrifuged at  $1,700 \times g$  for 10 min. Using a syringe with a cannula, we removed the lower (chloroform) layer and placed it in another centrifuge tube. We split the sample into two centrifuge tubes to accommodate the volume necessary for reextraction with 30 mL of chloroform/methanol. We then recombined the chloroform layers from the two tubes and evaporated the chloroform to dryness under argon. We reconstituted the resulting residue by adding 20 mL of chloroform and transferred this solution to a 50-mL centrifuge tube.

**Paths A2 and A3 (Fig. 1): Monophasic methanol bovine lipid extraction.** After centrifuging sample S2 in buffer B at  $70,000 \times g$  for 1.5 h, we decanted the supernatant and transferred the resulting pellet to a 50-mL centrifuge tube to which we added 40 mL of methanol. Samples S2 and S3 were each mixed with a vortex mixer (Scientific Industries Inc.) and spun at  $1,700 \times g$  for 10 min. We transferred the supernatants to a 100-mL rotary evaporator (Buchi Roto-Vap) flask and evaporated them to complete dryness in a water bath at  $60^\circ\text{C}$  using house vacuum. Failure to achieve complete dryness at this point resulted in cloudiness in the next step, even after centrifugation of the chloroform layer. We reconstituted the resulting residues by adding 20 mL of chloroform to each flask while swirling its contents and using a spatula to help dislodge the residue. Each solution was transferred to a 50-mL centrifuge tube.

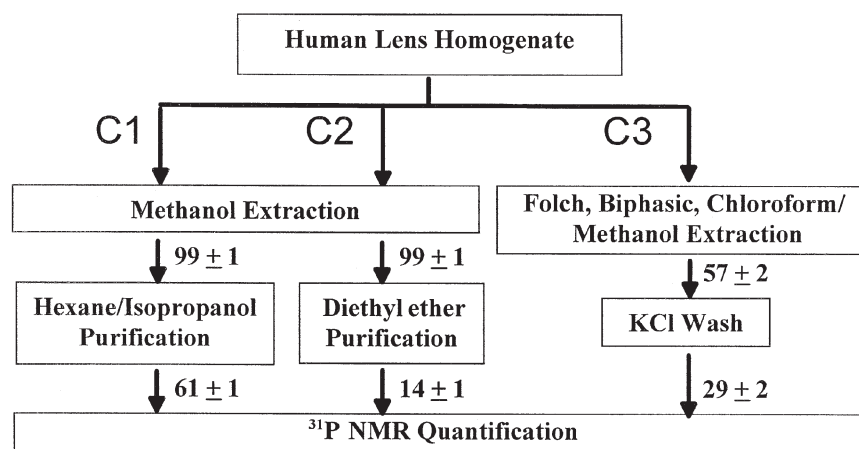

**Paths A1–A3 (Fig. 1): Chloroform/KCl wash.** We washed S1 samples from the chloroform/methanol extraction step and S2 and S3 samples from the methanol extraction step with 6 mL of 0.74% KCl solution. (NaCl was also used, with identical results.) We spun each mixture at  $1,700 \times g$  for 10 min, then aspirated off the top layer. The total volume of each sample was reduced to 1.5 mL under a stream of argon gas. Each sample was then transferred to a tared microtube.

**Paths A1–A3 (Fig. 1): Acetonitrile crystallization.** We added 20 mL of pure acetonitrile to samples S1, S2, and S3, then mixed each sample with a vortex mixer (Scientific Industries Inc.). This immediately caused precipitation of the product as a white flocculent material. We then centrifuged each tube at  $1,700 \times g$  for 10 min, and decanted and discarded the supernatant.

**Paths A1–A3 (Fig. 1): Quantification of bovine lipid.** We used eight samples for each path each time we performed the procedure in Figure 1. The percent recovery at each juncture in Figure 1 was determined by taking each sample to dryness under argon, dissolving it in 1.5 mL chloroform, and transferring it to tared microtubes. We took each sample to dryness under argon for weight determination and <sup>31</sup>P NMR analysis.

**Characterization of impurities.** Thirty-three bovine lenses that had been kept at  $-70^\circ\text{C}$  for 3 wk were thawed and weighed. We extracted lipid from these lenses as outlined in the methanol extraction protocol (Fig. 1, Path A3) except that we used a 250-mL volume of methanol. We added a 100-mL aliquot of chloroform to half the extracted and dried lipid. An insoluble white impurity was isolated by decanting the supernatant after spinning at  $1,700 \times g$  for 20 min. To the other half of the dried lipid methanol extract we added 100 mL of hexane/isopropanol (2:1, vol/vol), then followed the protocol for the hexane/isopropanol purification (Fig. 2, Path C1). The pellet from both centrifugation steps was saved for UV, IR, and <sup>31</sup>P NMR spectroscopic analysis.

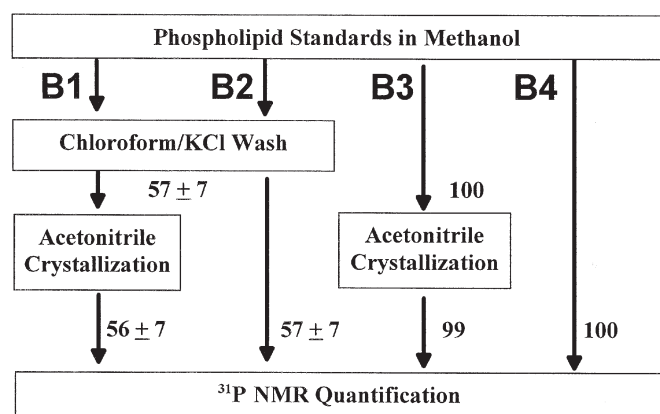

**FIG. 2.** Human lens lipid purification protocol. Data are mean (percent yields)  $\pm$  deviation ( $n = 2$ ). The amount of lipid extracted by two methanol extractions was determined to be 100% of the total lipid.

*Paths B1–B4 (Fig. 3): Purification of a synthetic mixture of phospholipids and cholesterol.* To assess the effect of the KCl wash and the acetonitrile precipitation in our method, we prepared mixtures of commercially available PS, PE, PC, and sphingomyelin, each to a concentration of 1  $\mu\text{g}/\text{mL}$ , then added cholesterol to give a final concentration of 4  $\mu\text{g}/\text{mL}$ . We analyzed an aliquot of each mixture before the extraction procedure using  $^{31}\text{P}$  NMR spectroscopy. We extracted aliquots of the standard by the method previously used to extract bovine lipids (Paths A1 and A2) with the KCl wash (Paths B1 and B2), with the acetonitrile precipitation (Paths B1 and B3), and without the KCl wash (Paths B3 and B4). PA was added as an internal standard before spectral acquisition.

*Paths C1–C3 (Fig. 2): Human lens lipid extraction and purification.* Fifteen pairs of human lenses  $44 \pm 18$  (SD) yr old were used for the extraction procedure. The lenses were weighed and homogenized in 150 mL of methanol using a mechanical tissue tearer (Biospec Products Inc.). The ho-

**FIG. 3.** Lipid standard purification protocol. PC, PS, PE, sphingomyelin, and cholesterol were used. Data are mean (percent yields)  $\pm$  SEM ( $n = 3$ ). The amount of lipid extracted by two sequential methanol extractions was determined to be 100% of the total lipid.

mogenate was dispersed by sonication as described above. We centrifuged samples at  $1,700 \times g$  for 10 min. We decanted and saved the supernatant, then added 150 mL of methanol to the pellet. We mixed, dispersed, and spun the pellet as described previously, then combined it with that from the first spin. Each sample was evenly divided into six tubes and weighed. The methanol in all tubes was evaporated under vacuum at  $60^\circ\text{C}$  and dried in a lyophilizer (Labconco, Kansas City, MO) for 12 h. These samples were all labeled A.

*Human lens phospholipid percent composition and quantification.* We evaluated the phospholipid composition of one of the samples labeled A by  $^{31}\text{P}$  NMR spectroscopy. To quantify the total phospholipid, we added 100  $\mu\text{L}$  of a PA solution (28 mg/mL methanol) as an internal standard. The linearity of the standard curve was demonstrated by adding known amounts of the internal standard.

*Path C1 (Fig. 2): Hexane/isopropanol purification.* We added 50 mL of hexane/isopropanol (2:1, vol/vol) to each of two samples labeled A and dispersed these samples three times with sonication as described above. We spun the mixtures at  $1,700 \times g$  for 10 min and decanted the supernatant carefully to avoid mixing the pellet. The supernatant was dried under argon. Phospholipid composition and total content were determined by  $^{31}\text{P}$  NMR spectroscopy.

*Human lens lipid diethyl ether purification (Fig. 2, Path C2).* We added 50 mL of diethyl ether to one sample labeled A and dispersed it with sonication as explained above. We spun the mixture at  $1,700 \times g$  for 10 min and decanted the supernatant. We dried the supernatant under argon and determined its phospholipid composition and total content by  $^{31}\text{P}$  NMR spectroscopy.

*Folch extraction of human lens tissue (Fig. 2, Path C3).* We added 50 mL of chloroform/methanol (2:1, vol/vol) to each of two samples labeled A and dispersed them with sonication as explained above. We added 10 mL of a 0.75% KCl aqueous solution, spun the samples at  $1,700 \times g$  for 10 min, and then removed the lower layer. We dried each lower layer under argon. Total phospholipid was determined by  $^{31}\text{P}$  NMR

**FIG. 4.** A typical  $^{31}\text{P}$  NMR spectrum of bovine lens lipid. SM, sphingomyelin; PE plas, PE plasmalogen; DHSM, dihydrosphingomyelin; PG, phosphatidylglycerol; U, unknown phospholipid.

spectroscopy. This procedure was repeated two times to assess reproducibility.

**$^{31}\text{P}$  NMR phospholipid compositional analysis and quantification.** For spectrometric compositional studies, we added 100  $\mu\text{L}$  of an internal standard solution consisting of 20 mg PA/mL of deuterated chloroform to each of the dried, extracted phospholipid samples. We then added a 400- $\mu\text{L}$  aliquot of deuterated chloroform to make a chloroform volume of 500  $\mu\text{L}$ . We vortexed this sample in the microtube and pipetted it into a 5-mm NMR tube for phospholipid quantification. We prepared a reagent consisting of 0.1 M EDTA (pH 6)/methanol (1:4, vol/vol) using KOH as the counter-cation source. At least 15 min before spectral acquisition, we added 250  $\mu\text{L}$  of the EDTA/methanol reagent (7,8) and shook the mixture. The aqueous phase was allowed to separate before analysis.

We quantified all samples using  $^{31}\text{P}$  NMR. For data acquisition, a Bruker AMX500 NMR spectrometer operating at 202.4 MHz  $^{31}\text{P}$  resonance frequency was used with the following spectral acquisition parameters: spectral width, 2032.5 Hz; resolution, 0.50 Hz; acquisition time, 1.0 s; interscan delay, 1.0 s; pulse length, 10  $\mu\text{s}$ ; dwell time, 246  $\mu\text{s}$ ; number of scans, 1,000. We treated spectral data on a personal computer using Bruker WINNMR software. All spectra were phase and baseline corrected. Deconvolution and curve fit were applied to obtain the area of each peak. A typical spectrum is shown in Figure 4. The spectral assignments are based on the chemical shifts reported previously (7,8) as well as on the spectral shifts obtained for the standard phospholipids PE, PS, sphingomyelin, and PC.

The number of moles of each phospholipid was evaluated from the ratio of the areas of the spectral bands corresponding to each phospholipid and the internal standard, for which the number of moles was known. We multiplied the number of moles thus obtained by 800 g/mol, an average phospholipid M.W., to obtain the weight of each extracted lipid. We referenced these weights to the initial amount of lens material.

## RESULTS

**Problems with the Folch extraction.** The advantage of using  $^{31}\text{P}$  NMR spectroscopy to quantify phospholipids is that purification is not necessary: A single-step methanolic extraction yields most, if not all, of the phospholipids at a level of purity adequate for quantification by NMR spectroscopy. However, along with the lipids, contaminants such as flavins and polysaccharides are also present. To remove these impurities, an aqueous wash is often used, as first reported by Folch *et al.* (1). This step leads to the separation of phases and results in lipid loss. Indeed, only about a third of the total phospholipid was recovered from human lenses (Fig. 2, Path C3) when using this approach.

**Comparison of extraction yields.** Centrifugation as pretreatment (Fig. 1, Paths A2 and A3) caused a twofold decrease in the yield of phospholipid as a result of lipid within the soluble-protein phase. The yield when methanol was used as the single extraction solvent was 65% higher than the yield when chloroform and methanol were used.

The effects of the KCl wash and the acetonitrile crystallization step were examined by extracting a mixture of standard phospholipids to which cholesterol had been added to emulate more closely the composition of lens membranes. As shown in Figure 3, elimination of the KCl wash produced significant increases in the amounts of phospholipid extracted. Under this condition, the average yield was 1.25 mg phospholipid/g of lens.

A monophasic extraction using methanol and no aqueous wash was advantageous as compared to the other extraction procedures. As measured by  $^{31}\text{P}$  NMR spectroscopy, 5.9 mg of phospholipid was extracted per gram of wet weight of human lens tissue. The use of a second methanol or chloroform extraction yielded undetectable levels of phospholipid, indicating that most of the total phospholipid from human lenses is recovered in a single methanol extraction. With bovine lens material, a second extraction recovered an additional 2 to 10% of phospholipid. No detectable phospholipids were recovered by a third extraction. Thus, the monophasic methanolic extraction of phospholipids coupled with  $^{31}\text{P}$  NMR is the simplest, quickest, and most precise method for quantifying phospholipid composition. In contrast, the Folch extraction and various other purification protocols decrease the yield of phospholipids.

**The characteristics of impurities and phospholipid purification.** Various nonphospholipid impurities are present in the initial methanol extract of human and bovine lenses. These impurities do not interfere with the quantification of lipid using  $^{31}\text{P}$  NMR spectroscopy. The major impurity is a white hygroscopic powder that is completely soluble in water and methanol, slightly soluble in chloroform, and insoluble in hexane/isopropanol. This impurity is also composed of less than 3% protein by weight, as determined by a modified Lowry assay (9). The absorption band exhibited by the impurity at 262 nm (absorptivity = 2.2  $\text{mg}^{-1} \text{mL cm}^{-1}$ ) suggests the presence of mononucleotides or oligonucleotides (Fig. 5).

**FIG. 5.** UV absorbance spectrum of a methanol- and chloroform-soluble, hexane/isopropanol insoluble impurity in methanol as isolated from bovine lenses.

From the IR spectrum, shown in Figure 6, it appears that another component of the impurity may be a polysaccharide. Further evaluation will be necessary to confirm this assignment. Because of the high solubility of the white impurity in water, the KCl wash in the Folch (1) extraction completely removes it. Unfortunately, a considerable percentage of lipid is also lost in this step. Therefore, a purification procedure that avoids phase separation was developed.

**Purification by chloroform extraction.** Our first attempt to purify phospholipid involved evaporating the methanol from the initial phospholipid extraction and adding chloroform to the dried lipid film. The flocculent white impurity would not form a pellet even when it was centrifuged at  $200,000 \times g$  for 90 min. This indicates that the density of the impurity is similar to that of chloroform.

**FIG. 6.** IR spectrum of a methanol-soluble impurity lyophilized on a silver chloride window. The  $1049 \text{ cm}^{-1}$  band suggests that one of the impurities may be polysaccharide.

**Purification by hexane/isopropanol extraction.** The white impurity is insoluble in hexane/isopropanol, which is much less dense than chloroform. Consequently, centrifugation causes the impurity to form a pellet, leaving the purified phospholipid in the supernatant. No absorbance was detected in the supernatant at 262 nm, indicating complete removal of the impurity. When we used hexane/isopropanol purification, 60% of human phospholipid was recovered; a twofold improvement in the yield was achieved over the Folch (1) procedure (Fig. 2).

**Purification by diethyl ether extraction.** Diethyl ether is often used as an extraction solvent. However, the recovery was less than 15% of the total lipids (Fig. 2).

## DISCUSSION

We found that extraction of bovine and human lens lipids with methanol gives about 40% higher yield of phospholipids than does extraction with chloroform and methanol. Similar results have been reported using other tissues (4,5), but methanol extraction is not widely used. We also found that a 30–50% loss of phospholipids occurs at the KCl-wash step of the Folch procedure (1) even when using a mixture of phospholipid standards devoid of proteins. A centrifugation step to circumvent problems associated with insoluble protein at the aqueous–chloroform interface caused an additional 40% loss of phospholipids. The phospholipid yields at each step of the Folch extraction have never before been reported.

Because of the low yield of phospholipids obtained by the Folch protocol (1), we developed a method to extract and quantify phospholipids using a single methanol extraction. The loss of phospholipids is minimized because purification is unnecessary.  $^{31}\text{P}$  NMR spectroscopy (7,8) allows the quantification of phospholipids even when impurities are present.

When purification of phospholipids is essential, such as for biophysical characterization studies or the determination of lipid phosphate by chemical assays, we found that the addition of hexane/isopropanol to the initial dried methanol extract maintained a single phase and effectively removed the impurities. With this approach, the yield was two times higher than that obtained with the Folch (1) purification.

In conclusion, the biphasic nature of most solvent mixtures used in lipid extractions produces a lower yield of phospholipids than does the monophasic methanol extraction we have described. A single-step methanolic extraction followed by  $^{31}\text{P}$  NMR detection provides a simple, quick, and effective method for quantifying lens phospholipid. The methanol extraction followed by hexane/isopropanol purification provides the highest yield of purified phospholipids. These protocols should be advantageous for the analysis of phospholipids in all biological tissues.

**ABSTRACT:** A simple method for the determination of bile acids in adult human fecal samples using GC–MS is described. Bile acids are directly extracted from feces by ethanol (95%) containing 0.1 N NaOH. Extracts are purified by passage through a reversed-phase C<sub>18</sub> silica cartridge and then analyzed by GC–MS. The present study has shown that lyophilized human feces contain mainly free bile acids, with lithocholic acid (LCA) and deoxycholic acid (DCA) as the major bile acids; however, isomers of LCA and DCA, keto-bile acids, and cholic acid are also present. Any traces of conjugated bile acids are hydrolyzed before the C<sub>18</sub> extraction by deconjugating enzymes, which are present in feces and are activated by the addition of water during the homogenization step. Thus, the analysis of fecal bile acids can be performed without the hydrolysis step in less than 4 h in comparison to traditional techniques, which usually require at least 48 h.

Paper no. L9079 in *Lipids* 37, 1093–1100 (November 2002).

Bile acids are the by-product of cholesterol and serve many important physiological functions in the maintenance of cholesterol homeostasis and the excretion and recirculation of drugs, vitamins, and lipids as well as endogenous and exogenous toxins. During their enterohepatic circulation, approximately 5% of bile acids escape into the colon, where they are modified by the intestinal flora and excreted in the feces (1–3). In recent years the analysis of fecal bile acids has been of interest because several studies have claimed a role for bile acids in colon cancer; it has been suggested that analysis of bile acid in feces may be a useful indicator of the susceptibility of individuals and populations in the development of colon cancer (4–8).

Despite the many studies reported for the analysis of fecal bile acids, data comparison is difficult principally because of the marked differences in the extraction procedures and the lack of a sensitive and accurate method. The extraction of bile acids from feces may be affected by (i) the presence of microorganisms, which hydrolyze peptide bonds of conjugated bile acids as well as dehydroxylate the 7  $\alpha$ -OH group, and (ii) binding of bile acids to particulate material (9,10). Several methods for bile acid determination in feces have been reported

Abbreviations: CA, cholic acid; DCA, deoxycholic acid; ES-MS-MS, electrospray tandem MS; LCA, lithocholic acid.

over the last three decades including GLC–MS, which is currently considered as the most reliable technique (11–14). The present study shows that bile acids present in adult human feces are mainly free bile acids, which contain lithocholic acid (LCA) and deoxycholic acid (DCA) as the major bile acids followed by isomers of LCA and DCA, keto-bile acids, cholic acid (CA), and traces of conjugated bile acids. Therefore, because bile acids are present mainly as free acids, it is possible to eliminate the hydrolysis step usually involved in fecal bile acid analysis. The present method allows the direct extraction of bile acids from feces by refluxing samples in alkaline ethanol at 80°C for 1 h followed by purification with C<sub>18</sub> columns. This procedure eliminates the time-consuming steps of homogenization and hydrolysis.

## MATERIALS AND METHODS

**Reagents.** Bile acid standards [cholic acid (CA), chenodeoxycholic acid, DCA, LCA, 5 $\beta$ -cholanic acid, and their glycine- and taurine-conjugated forms] were obtained from Calbiochem (San Diego, CA) and were at least 98% pure. Octadecyl (C<sub>18</sub>) Bakerbond™ extraction columns were obtained from J.T.Baker Inc. (Phillipsburg, NJ). All other solvents and chemicals used were either of HPLC grade or of known analytical purity and obtained from Sigma-Aldrich Chemical (St. Louis, MO).

**Preparation of standards.** Glycine and taurine conjugates of CA, chenodeoxycholic acid, DCA, and LCA as well as the internal standards (5 $\beta$ -cholanic acid) were dissolved individually in methanol at a concentration of 1 mg/mL. These solutions were kept refrigerated and were used as stock solutions.

**Homogenization of fecal samples.** Human fecal samples obtained from 14 volunteers were lyophilized and kept at –20°C until required for analysis. Cold distilled water (1 mL) was added to 200 mg of lyophilized fecal sample and homogenized for 3–5 min using a Polytron homogenizer, then incubated for 1 h at 37°C. The homogenized fecal samples were centrifuged at 1500  $\times$  g for 10 min. The supernatant (fecal water) was separated from the fecal pellet. To test the effect of incubation of lyophilized fecal samples in water on the deconjugation process, 50  $\mu$ g of taurine-conjugated LCA, DCA, and CA were added to the same fecal samples before the incubation step, and both free and conjugated bile acids were analyzed by GC–MS and electrospray tandem MS (ES-MS-MS).

**Extraction of bile acid.** Lyophilized human fecal samples (200 mg each) were directly refluxed in ethanol (5 mL)

containing 0.1 N NaOH (0.4 mL) and 100 µg of internal standard (5β-cholanic acid) at 80°C for 1 h. Samples were cooled on ice and then centrifuged at 1500 × *g* for 10 min. The supernatant was removed and dried under nitrogen, redissolved in 1 mL of HPLC water, and then subjected to a solid-phase extraction using an octadecyl (C<sub>18</sub>) Bakerbond™ cartridge. The C<sub>18</sub> cartridge was preconditioned, prior to loading the samples, with successive elutions of 2 mL of chloroform/methanol (2:1), methanol, and HPLC water solutions. After loading the samples, the column was washed with 2 mL of HPLC water and then *n*-hexane. The column was left for 10 min to drain any excess solvents. Bile acids were eluted from the cartridge with methanol (5 mL). The eluate was divided into two aliquots, which were evaporated to dryness under nitrogen. One aliquot was hydrolyzed, methylated, and acetylated; the other was methylated and acetylated but not hydrolyzed before GC–MS analysis.

**GC–MS.** The extracted samples were hydrolyzed, methylated, and acetylated as previously described (14). Identification and quantification of the bile acids were achieved by GC–MS using a Hewlett-Packard 5890 gas chromatograph equipped with a Hewlett-Packard 5971A mass selective detector employing the selected ion monitoring mode. In this method the selected ions for the different bile acids were, for CA, *m/z* 253, 368; chenodeoxycholic acid, 255, 370; DCA, 255, 370; ursodeoxycholic acid, 255, 370, keto-bile acids, 231, 446; LCA 257, 372; and 5β-cholanic acids, 217 and 374. Quantification was carried out by employing a correction factor obtained using 5β-cholanic acid as internal standard. Bile acid standards were processed and analyzed in a similar manner. The remaining half of the samples were not subjected to hydrolysis but were directly methylated and acetylated.

**Presence of deconjugating enzymes in human fecal samples.** To test for the presence of deconjugating enzymes in lyophilized human fecal samples, 100 µL of rat bile was incubated with 100 mg of lyophilized human feces homogenized in 1 mL of cold distilled water and incubated at 37°C for 1 h. Bile acids were extracted after incubation as described above and analyzed by ES-MS-MS.

**ES-MS-MS.** The ES-MS-MS methodology used for the identification of bile acids was similar to that previously described (14). The system used included a Hewlett-Packard high-performance liquid chromatograph (series 1100) equipped with an automatic sample injector that was connected to a Quattro electrospray tandem mass spectrometer (Micromass, Manchester, United Kingdom). The HPLC system was used only for injecting the samples into the mass spectrometer. Liquid nitrogen was used as nebulizer and argon as collision gas. The HPLC system was operated isocratically at a flow rate of 10 µL/min for the mobile phase (acetonitrile/water 1:1) at room temperature. Sample (10 µL) was injected into the ES-MS-MS by automatic injector. Negative ion mass spectra of the eluents were recorded using full scan mode.

**Statistical analysis.** An ANOVA test was used to evaluate the difference between the results obtained from groups analyzed with and without the hydrolysis step. A *P* value of <0.05 was considered significant.

## RESULTS

**Analysis of bile acids in human feces by GC–MS (with incubation in water).** The determination of the bile acid composition of adult human fecal samples analyzed with GC–MS was carried out in triplicate and results are presented in Tables 1 and 2. The amount of total and individual bile acids showed considerable variation between samples. The main bile acids in each fecal sample were LCA (45–50%) and DCA (30–40%), followed by isomers of LCA and DCA (10–15%), keto-bile acids (6–8%), and CA (1–2%). The concentration of total bile acid obtained by GC–MS varied between 284.72 and 678.23 µg bile acids/100 mg of feces (Tables 1 and 2). There was no significant difference between the amounts of total bile acids observed between samples that were or were not subjected to alkaline hydrolysis. To test for the presence of deconjugating enzymes, these fecal samples were spiked with 50 µg of standards of taurine-conjugated LCA, DCA, and CA and measured in a similar manner. The results obtained again showed no significant difference between the

<sup>a</sup>Values are expressed as  $\mu\text{g}$  of bile acids/100 mg of dried feces. Each value represents the average of three determinations  $\pm$  SD.

<sup>b</sup>Samples were obtained from five healthy adult subjects (A1–A5). Samples S1–S5 were the same set of samples (A1–A5) but spiked with 50  $\mu\text{g}$  of taurine conjugates of LCA, DCA, and CA. Others = isomers of LCA and DCA. For abbreviations see Table 1.

groups that had or had not undergone alkaline hydrolysis (Tables 1 and 2).

*Analysis of bile acids in human feces by GC–MS (without incubation in water).* Tables 3 and 4 illustrate the bile acid profiles of five human fecal samples, not incubated in water, that were analyzed by GC–MS. The major bile acids present in all the fecal samples were LCA followed by DCA, followed by isomers of LCA and DCA (10–15%), keto-bile acids (6–8%), and CA (1–2%). The amount of total bile acids ranged from 247.0 to 415.05  $\mu\text{g}$  bile acids/100 mg of feces (Tables 3 and 4). There was no significant difference between the amount of total bile acid observed for the samples analyzed after alkaline hydrolysis and those not subjected to alkaline hydrolysis. But in the samples spiked with 50  $\mu\text{g}$  of standards of taurine-conjugated LCA, DCA, and CA, there was a significant difference in total bile acids between the groups analyzed after alkaline hydrolysis and those not exposed to alkaline hydrolysis by GC–MS. This proves that human fecal samples contain only free bile acids, and that addition of water to the lyophilized fecal sample stimulates the bacterial enzymes responsible for the deconjugation of conjugated bile acids (Tables 3 and 4).

*Fecal bile acids analyzed by ES-MS-MS.* To test the profile of bile acids as well as the presence of deconjugating enzymes in human feces, ES-MS-MS techniques were used. Figure 1 illustrates the ES-MS-MS spectrum obtained from the fecal sample, which shows the presence of only free bile acids and keto-bile acids. The ions obtained at  $m/z$  373.7, 375.7, 389.7, 391.7, and 407.8 correspond to mono-keto, mono-OH, mono-keto-mono-OH, di-OH, and trihydroxylated free bile acids, respectively (Fig. 1). There was no evidence of sulfated and glucuronidated bile acids in these samples. The other ions present in Figure 1 do not correspond to any known bile acids, and the chromatogram obtained by GC–MS (Fig. 2) confirms the presence of LCA, DCA, CA, isomers of LCA and DCA, and keto-bile acids. Figure 3 shows the full-scan spectrum of rat bile obtained by ES-MS-MS showing only taurine-conjugated di- ( $m/z$  498.7) and trihydroxylated ( $m/z$  514.7) bile acids. Figure 4 shows the spectrum obtained from ES-MS-MS after incubating 100  $\mu\text{L}$  of rat bile with fecal samples in cold distilled water. The result clearly illustrates the deconjugation of taurine-conjugated di- and trihydroxylated bile acids into their respective free forms ( $m/z$  391.7 and 407.7).

## DISCUSSION

Most of the procedures currently used for the extraction and analysis (HPLC, GLC, GC–MS) of bile acids (10–15) from feces show very little advance upon the methods developed in the 1960s. The results from the present method clearly show the presence of deconjugating enzymes in the lyophilized fecal samples. Therefore, addition of water during the homogenization step causes the deconjugation of conjugated bile acids in feces into their respective free forms. Thus, fecal samples can be analyzed without the alkaline hydrolysis step.

Several studies have considered the microbial transformation of bile acid by mixed microbial cultures from human feces (8,9). In the present study, the spectrum obtained from ES-MS-MS (Fig. 1) shows that human feces contain mainly free bile acids (LCA, DCA, CA, and keto-bile acids); thus, if any conjugated bile acid is present, deconjugation occurs by the addition of water during the homogenization step as a result of the activation of deconjugating enzymes. Figure 2 further identifies the presence of the isomers of LCA and DCA. The ES-MS-MS spectra (Figs. 3 and 4) confirm the deconjugation of bile acids by deconjugating enzymes. The bile acids present in rat bile are mainly taurine-conjugated di- and tri-hydroxylated bile acids (Fig. 3), but after incubation of the same rat bile with a lyophilized human fecal sample in cold distilled water, the conjugated bile acids are significantly hydrolyzed to their respective free bile acids (Fig. 4).

For the identification and quantification of conjugated bile acids by GC–MS, alkaline hydrolysis is a necessary step to hydrolyze the peptide bond between taurine/glycine and bile acids before derivatization. Tables 1 and 2 depict the bile acid analysis by GC–MS of five adult human fecal samples following incubation in water. The results show no significant difference in the amount of total bile acid between the samples that were hydrolyzed and those that were not hydrolyzed with alkali. This proves that human feces contain only the free bile acids (Tables 1 and 4). To test the effect of water on the hydrolysis of conjugated bile acids, the same sets of fecal samples were spiked with 50 µg of standards of taurine-conjugated

LCA, DCA, and CA and analyzed in a manner similar to that for nonspiked human fecal samples. The results obtained show there was no significant difference between the groups subjected or not to alkaline hydrolysis, which further proves that hydrolysis of taurine-conjugated bile acids occurred owing to activation of bacterial enzymes when fecal samples were incubated in cold distilled water (Tables 1 and 2).

Tables 3 and 4 show the bile acid analysis by GC–MS of another five adult human fecal samples that were not incubated in water. The results obtained show no difference in the amount of total bile acids between groups analyzed with alkaline hydrolysis and without alkaline hydrolysis (Tables 3 and 4). But when the same samples were spiked with 50 µg of standards of taurine-conjugated LCA, DCA, and CA and analyzed in a manner similar to that in Tables 1 and 2, the amounts of total bile acid were significantly different between the groups analyzed with and without the alkaline hydrolysis step.

Thus, fecal bile acids can be easily extracted by refluxing the fecal samples directly in alkaline ethanol solution followed by derivatization for GC–MS analysis without the time-consuming step of the traditional alkaline hydrolysis. This method also enables fast determination (<4 h) of fecal bile acids—including extraction time, purification step, derivatization, and GC–MS analysis time—in comparison to other techniques.

**ABSTRACT:** Simultaneous evaluation of HMG-CoA reductase and cholesterol 7 $\alpha$ -hydroxylase activities by electrospray tandem mass spectrometry (ES-MS-MS) was performed. The assay was based on the measurement of mevalonolactone (MVL) and 7 $\alpha$ -hydroxycholesterol (7 $\alpha$ -OHC) produced by the incubation of HMG-CoA with hepatic microsomes in the presence of NADPH and glucose-6-phosphate dehydrogenase. Following extraction and purification using a cyanopropyl cartridge, MVL and 7 $\alpha$ -OHC were analyzed, without derivatization, by ES-MS-MS. The analysis was achieved in 5 min. Calibration curves were made for MVL and 7 $\alpha$ -OHC, and were linear from 0 to 100  $\mu$ g. The recovery was >97%. The procedure was validated under similar calibration and recovery experiments, by measuring the above mentioned products as dimethylethylsilyl ether derivatives using the classical technique of GC-MS. Data obtained by ES-MS-MS and GC-MS showed a good correlation, with no significant differences. ES-MS-MS is a simple and reliable method for the evaluation of HMG-CoA reductase and cholesterol 7 $\alpha$ -hydroxylase activities in liver microsomal preparations.

Paper no. L9101 in *Lipids* 37, 1101–1107 (November 2002).

Cholesterol homeostasis in the body is preserved mainly through the modulation of the activities of two enzymes located in the endoplasmic reticulum: HMG-CoA reductase, which catalyzes the formation of mevalonic acid (MVA) from HMG-CoA, considered as the rate-determining step in cholesterol synthesis (1), and cholesterol 7 $\alpha$ -hydroxylase, which catalyzes the rate-limiting step in the major pathway of degradation of cholesterol to bile acids (2).

In view of the critical role played by these enzymes in cholesterol metabolism, many efforts have been made to develop rapid and accurate methods for the simultaneous estimation of their activities. The measurement of the actual amount of mevalonolactone (MVL) and 7 $\alpha$ -hydroxycholesterol (7 $\alpha$ -OHC) enzymatically formed is considered to be a more accurate indication of the activities of HMG-CoA reductase and cholesterol 7 $\alpha$ -hydroxylase, respectively (3). For this pur-

pose, several approaches, direct and indirect, are available for measuring the mass of these products. These include double-labeling techniques (4–6), ion-exchange column chromatography (7), paper chromatography (8), HPLC (9,10), and GC-MS with selected ion monitoring (SIM) (3,11–13). GC-MS is considered to be the best method because of its superior sensitivity and accuracy, but its use entails a laborious sample preparation and a long analytical process. Although the availability of electrospray tandem mass spectrometry (ES-MS-MS) offers opportunities to overcome these disadvantages, there has been no study using this technique to evaluate HMG-CoA reductase and cholesterol 7 $\alpha$ -hydroxylase activities simultaneously. The purpose of the present work is to test this technique for this assay in rat liver microsomal preparations.

## MATERIALS AND METHODS

**Chemicals.** NADPH, EDTA, mevalonic acid lactone, HMG-CoA, glucose-6-phosphate dehydrogenase (500 U/mL), and glucose-6-phosphate were purchased from Sigma Chemical Co. (St Louis, MO). 7 $\alpha$ -OHC and 6 $\beta$ -hydroxycholestanol (6 $\beta$ -OHC) were available from Steraloids Inc. (Wilton, NH). Dimethylethylsilyl imidazole (DMESI) was obtained from Kogyo Inc. (Tokyo, Japan), and Bond Elut cyanopropyl (CN; 500 mg) from Varian (Harbor City, CA). All other reagents and solvents were of analytical grade and used without further purification.

**Preparation of internal standard for the MVL quantification.** MVL (1 mg) was acetylated in 1 mL of a mixture of 7 mL glacial acetic acid, 5 mL acetic anhydride, and 10 drops of 70% perchloric acid. Following incubation at 37°C for 60 min, 5 mL of water and 10 mL of diethyl ether were added, and tubes were mixed for 20 min. The ether layer was then transferred to other tubes and dried under nitrogen. The residue was redissolved in 1 mL methanol and stored at –20°C, then used as stock solution in the following analyses.

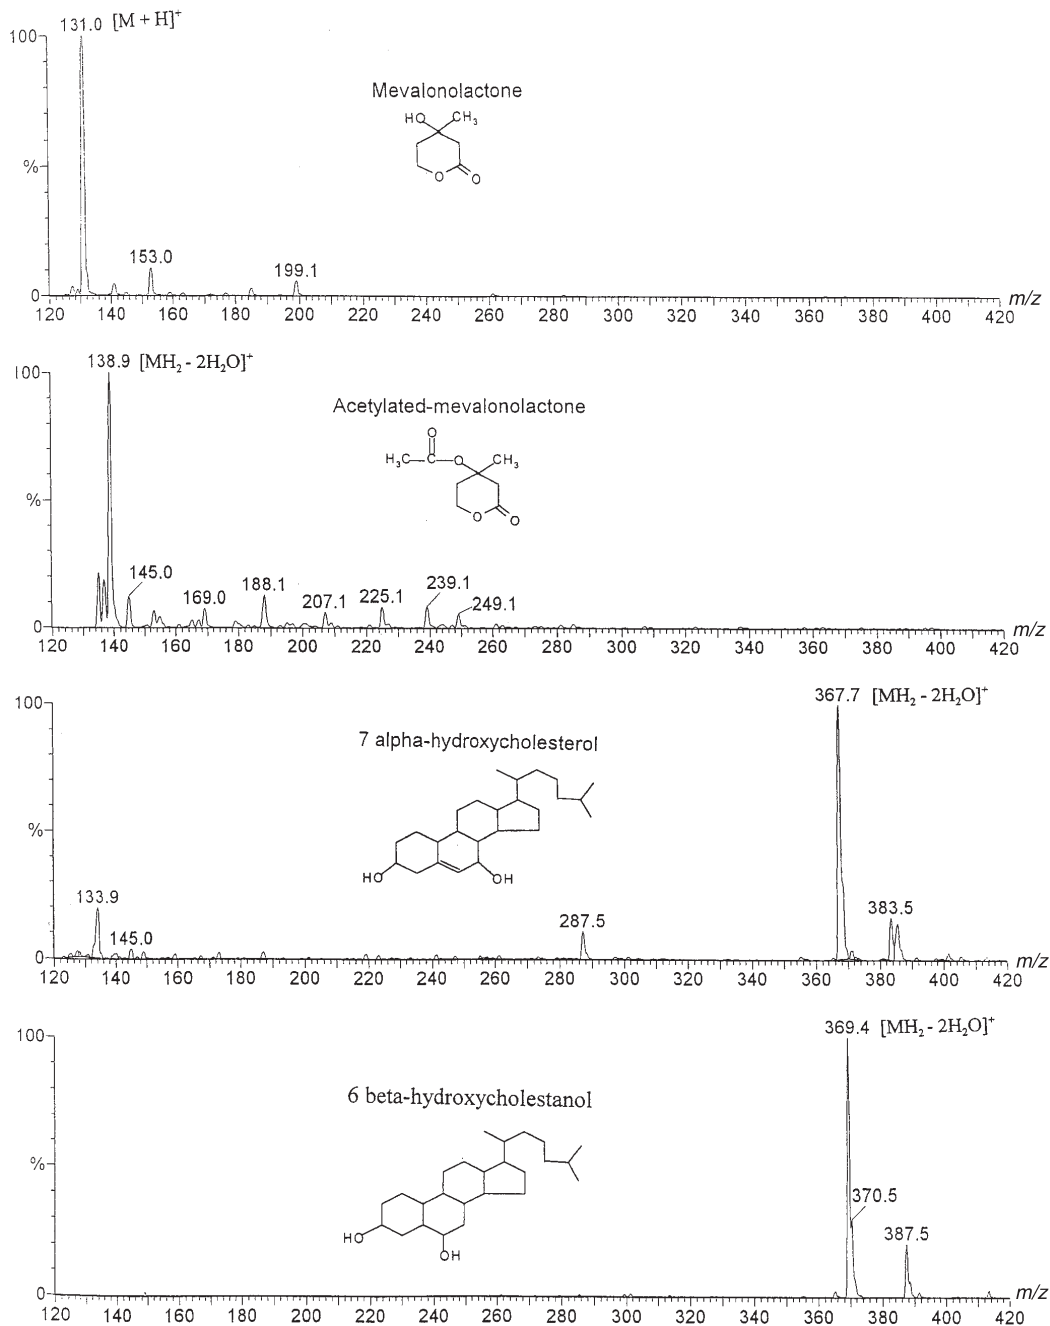

**Preparation of liver microsomes.** Liver microsomes were prepared at 4°C as described previously (11). Briefly, rat livers were excised, washed in ice-cold saline solution, weighed, and placed into 3 mL of ice-cold 50 mM Tris-HCl buffer (pH 7.4), containing 0.3 M sucrose, 10 mM DTT, 10 mM EDTA, and 50 mM sodium fluoride. The livers were minced with scissors and homogenized in a Dounce homogenizer with a loosely fitting

Abbreviations: CN, cyanopropyl; DMES, dimethylethylsilyl; DMESI, DMES imidazole; ES-MS-MS, electrospray tandem mass spectrometry; MVA, mevalonic acid; MVL, mevalonolactone; 6 $\beta$ -OHC, 6 $\beta$ -hydroxy-cholestanol; 7 $\alpha$ -OHC, 7 $\alpha$ -hydroxycholesterol; SIM, selected ion monitoring.

Teflon pestle. The homogenate (10%) was centrifuged at  $18,000 \times g$  for 20 min (SS-34 rotor, Sorval RC2-B refrigerated centrifuge), and the supernatant was centrifuged at  $100,000 \times g$  for 60 min (50.2 Ti rotor, Beckman L centrifuge). The resulting microsomal fraction was suspended in 3 mL of 0.1 M potassium phosphate buffer (pH 7.4), containing 1 mM EDTA and 5 mM DTT. Aliquots were immediately frozen in liquid nitrogen and stored at  $-80^\circ\text{C}$  to be used as the enzymatic and endogenous cholesterol sources. A small aliquot was used for protein determination according to Lowry *et al.* (14).

*Simultaneous assay of HMG-CoA reductase and 7 $\alpha$ -hydroxylase activities.* A microsomal suspension of 500  $\mu\text{L}$ , containing 5 mg protein, was preincubated for 5 min at  $37^\circ\text{C}$  with 450  $\mu\text{L}$  of 0.1 M potassium phosphate buffer, pH 7.4, containing 1 mM EDTA and 12 mM glucose-6-phosphate. The assay was initiated by adding 50  $\mu\text{L}$  of cofactor-substrate solution (0.1 mM HMG-CoA, 3 mM NADPH, and 2 U/mL glucose-6-phosphate dehydrogenase), and the incubation was performed for 30 min at  $37^\circ\text{C}$ . Care was taken to avoid exposure to light to prevent cholesterol autoxidation. The incubation

**FIG. 1.** Positive ion electrospray mass spectra of mevalonolactone, acetylated mevalonolactone, 7 $\alpha$ -hydroxycholesterol, and 6 $\beta$ -hydroxycholestanol. Electrospray tandem MS conditions are described in the Materials and Methods section.

was terminated by the addition of 50  $\mu\text{L}$  of 1 M NaOH, 10  $\mu\text{g}$  each of acetylated-MVL and 6 $\beta$ -OHC dissolved in methanol were added as internal standards. The sample was applied to the CN cartridge (preconditioned by successive elution with 2 mL each of hexane, methanol, and distilled water) and washed with 4 mL of acetonitrile/water (2:3, vol/vol) to extract MVA. After removing cholesterol with 4 mL of hexane, 7 $\alpha$ -OHC was eluted with 4 mL of methanol.

The fraction containing MVA was acidified to pH 1 with 0.6 N HCl to promote the generation of MVL. Following incubation at 37°C for 60 min, the suspension was applied to a CN cartridge (cleaned in advance with 2 mL each of hexane, methanol, and distilled water, successively), and MVL was eluted with 4 mL of acetonitrile.

Both eluate fractions were mixed and divided into two portions. One portion was used for ES-MS-MS analysis and the other for the GC-MS analysis.

**Analysis by ES-MS-MS.** The eluate mixture was evaporated under nitrogen, and the residue was analyzed by the ES-MS-MS after reconstitution in 100  $\mu\text{L}$  of methanol.

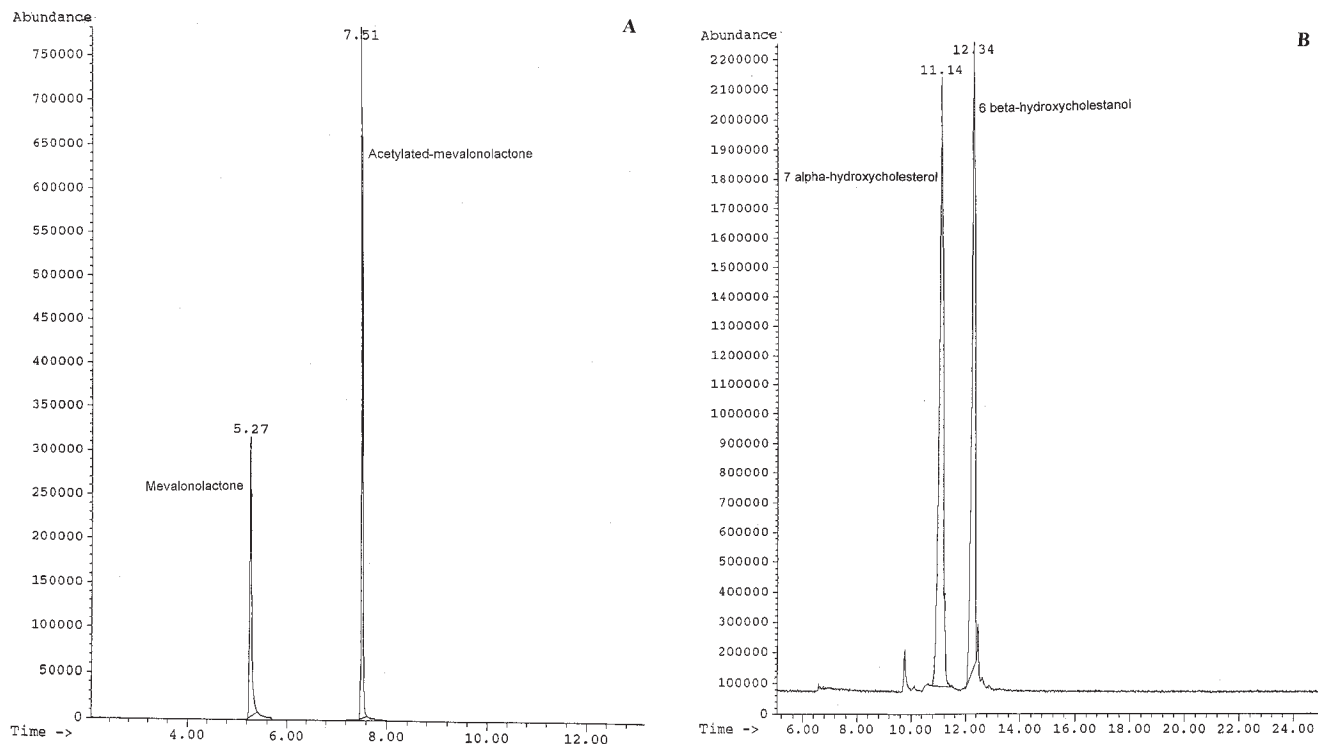

The ES-MS-MS system consisted of a Hewlett-Packard model HP1100 liquid chromatograph (HPLC) connected to a Quattro II electrospray tandem mass spectrometer (ES-MS-MS) obtained from Micromass (Manchester, United Kingdom). The HPLC system was operated isocratically without column at a 10  $\mu\text{L}/\text{min}$  flow rate for a mobile phase (acetonitrile/water; 1:1) at room temperature. Sample (10  $\mu\text{L}$ ) was injected in the ES-MS-MS by the automatic injector. Liquid ni-

trogen was used as nebulizer, and argon was used as collision gas. Cone voltage was set at 25 volts. Positive ion mass spectra of the eluents were recorded using the selective ion-recording mode. Quantification of MVL and 7 $\alpha$ -OHC was carried out using Micromass Mass Lynx 2.22 software by determining the peak area ratios of each compound with its internal standard. The enzymatic activities, expressed as pmol/min/mg of protein, were calculated by subtracting the amount present at zero time from that at the end of the incubation. Zero time was realized using microsomes previously inactivated with 1 M NaOH.

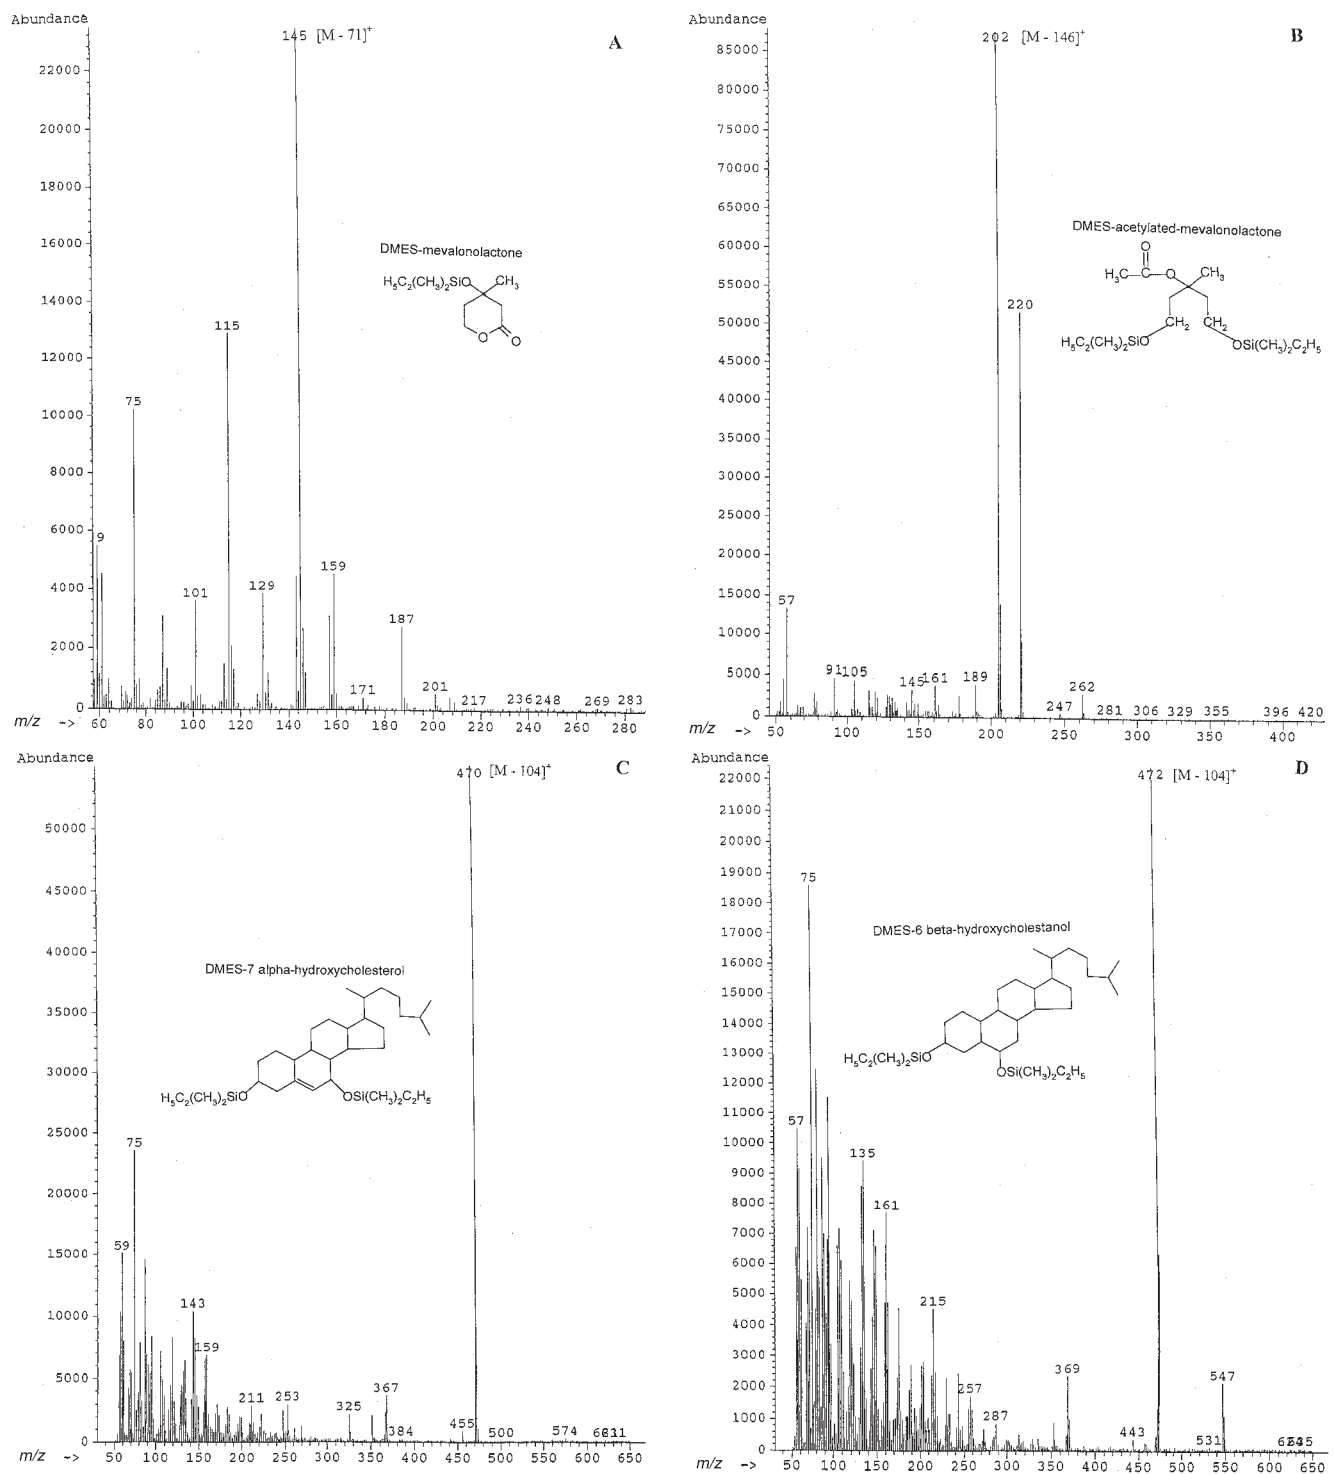

**Analysis by GC-MS.** After evaporation of the eluate mixture (MVL and 7 $\alpha$ -OHC) under nitrogen, the products were converted to dimethylethylsilyl (DMES) ether by treatment with 50  $\mu\text{L}$  pyridine-DMESI (10:2, vol/vol) at 80°C for 60 min. The derivatization solution was evaporated under nitrogen. The residue was dissolved in 100  $\mu\text{L}$  of chloroform.

GC-MS analysis was performed on an Hewlett-Packard 5890 series II gas chromatograph equipped with an HP-5 MS capillary column and connected to an HP 5971A mass spectrometer. Helium was used as the carrier gas. The column was maintained at 100°C for 2 min, then programmed from 100 to 160°C at 10°C/min and from 160 to 280°C at 20°C/min. The column temperature was kept at 280°C for 5 min. The MS transfer line was maintained at 280°C while the injection port was at 250°C. Samples (2  $\mu\text{L}$ ) were injected manually, and the SIM mode was used for quantitative determination.

**Assay validation.** The assay was validated with calibration

**FIG. 2.** Representative GC-MS chromatograms of the mixture of (A) mevalonolactone and its internal standard, acetylated-mevalonolactone, and (B) 7 $\alpha$ -hydroxycholesterol and 6 $\beta$ -hydroxycholestanol, used as internal standard. See the Materials and Methods section for derivatization and GC-MS conditions.

**FIG. 3.** Electron impact mass spectra of the dimethylethylsilyl (DMES) ether derivatives of (A) mevalonolactone, (B) acetylated mevalonolactone, (C)  $7\alpha$ -hydroxycholesterol, and (D)  $6\beta$ -hydroxycholesterol obtained by GC-MS. For conditions see the Materials and Methods section.

standards prepared by adding a constant amount (10  $\mu\text{g}$ ) of acetylated-MVL or  $6\beta$ -OHC as internal standards, to a series of tubes containing varied amounts (1–100  $\mu\text{g}$ ) of MVL or  $7\alpha$ -OHC, respectively. The content of each tube was subjected to the same procedure as microsomal preparations and analyzed by ES-MS-MS or GC-MS. A linear regression line

was fitted over the concentration range for both assays. Reproducibility of the assay was investigated in five samples, each processed in triplicate, while the recovery study was carried out by adding 15, 30, or 60  $\mu\text{g}$  of MVL and  $7\alpha$ -OHC to duplicate samples of 500  $\mu\text{L}$  of the microsomal suspension. Recoveries were calculated using the following equation:

$$\text{recovery} = \frac{(\text{amount found} - \text{basic amount})}{\text{amount added}} \times 100 \quad [1]$$

**Statistical analysis.** The statistical significance of differences between the ES-MS-MS and GC-MS methods was evaluated by one-way ANOVA, and statistical significance was accepted at the level of  $P < 0.05$ .

## RESULTS

**ES-MS-MS analysis.** Figure 1 shows the mass spectra of MVL, acetylated-MVL, 7 $\alpha$ -OHC, and 6 $\beta$ -OHC obtained in positive mode. MVL gave a high-abundance fragment ion at  $m/z$  131, which corresponded to the peak of its protonated molecule. The molecular ions of acetylated-MVL, 7 $\alpha$ -OHC, and 6 $\beta$ -OHC were not observed. However, a high-abundance fragment ion, which is formed by the loss of 2 H<sub>2</sub>O from each molecule, was detected at  $m/z$  138.9, 367, and 369 for acetylated-MVL, 7 $\alpha$ -OHC, and 6 $\beta$ -OHC, respectively.

**GC-MS analysis.** The DMES ether derivatives of MVL and its internal standard produced symmetrical peaks with elution times of 5.27 and 7.51 min, respectively (Fig. 2A). The DMES ether derivative of 7 $\alpha$ -OHC eluted from the GC column at 11.14 min, whereas the DMES ether derivative of its internal standard appeared at 12.34 min (Fig. 2B). Figure 3 shows the mass spectra of DMES ether derivatives obtained in the electron ionization mode. The fragment ions of  $[M - 71]^+$  produced at  $m/z$  145 for MVL,  $[M - 146]^+$  at  $m/z$  202 for acetylated-MVL,  $[M - 104]^+$  at  $m/z$  470 for 7 $\alpha$ -OHC, and  $[M - 104]^+$  at  $m/z$  472 for 6 $\beta$ -OHC had the highest abundances and were selected for ion monitoring analysis.

**Linearity, precision, and accuracy of the assay.** The assay was validated over the range 1–100  $\mu\text{g}$ . Representative calibration curves for MVL and 7 $\alpha$ -OHC generated by ES-MS-MS are shown in Figure 4. Table 1 lists parameters for cali-

**FIG. 4.** Calibration curves for (A) mevalonolactone and (B) 7 $\alpha$ -hydroxycholesterol obtained by linear regression analysis of the peak-area ratios of the compound to the internal standard vs. the concentrations of the compound ( $\mu\text{g}/\mu\text{L}$ ). Calibration standards were prepared as described in the Materials and Methods section.

**TABLE 1**  
Parameters for Calibration Curves Generated by Electrospray Tandem Mass Spectroscopy (ES-MS-MS) and GC-MS<sup>a</sup>

Methods	Analytes	Correlation coefficients	Calibration curve equations
ES-MS-MS	MVL	0.98	$Y = 0.190458 X$
	Acetylated-MVL	0.97	$Y = 0.008223 X$
	7 $\alpha$ -OHC 6 $\beta$ -OHC		
GC-MS	MVL	0.99	$Y = 0.085332 X$
	Acetylated-MVL	0.98	$Y = 0.008135 X$
	7 $\alpha$ -OHC 6 $\beta$ -OHC		

<sup>a</sup>Calibration curves were obtained by adding a constant amount (10  $\mu\text{g}$ ) of acetylated mevalonolactone (MVL) or 6 $\beta$ -hydroxycholesterol (6 $\beta$ -OHC), as internal standards, to a series of tubes containing varied amounts (1–100  $\mu\text{g}$ ) of MVL or 7 $\alpha$ -hydroxycholesterol (7 $\alpha$ -OHC), respectively. The contents of each tube were submitted to the same procedure as the microsomes.

**TABLE 2**  
Reproducibilities of HMG-CoA Reductase and 7 $\alpha$ -Hydroxylase Activities in the Rat Liver Microsomes<sup>a</sup>

Methods	Samples	HMG-CoA reductase		7 $\alpha$ -Hydroxylase	
		Activity (pmol/min/mg protein)	CV (%)	Activity (pmol/min/mg protein)	CV (%)
ES-MS-MS	A	141.73 $\pm$ 0.25	0.17	33.00 $\pm$ 0.08	0.24
	B	131.01 $\pm$ 0.10	0.08	27.74 $\pm$ 0.06	0.21
	C	133.90 $\pm$ 0.06	0.07	34.05 $\pm$ 0.12	0.35
	D	136.52 $\pm$ 0.27	0.19	30.00 $\pm$ 0.10	0.33
	E	142.32 $\pm$ 0.10	0.04	36.38 $\pm$ 0.15	0.41
GC-MS	A	140.43 $\pm$ 0.24	0.17	31.69 $\pm$ 0.02	0.06
	B	134.18 $\pm$ 0.09	0.06	27.24 $\pm$ 0.16	0.58
	C	134.25 $\pm$ 0.06	0.04	32.50 $\pm$ 0.11	0.33
	D	137.44 $\pm$ 0.16	0.11	31.66 $\pm$ 0.10	0.31
	E	141.57 $\pm$ 0.06	0.04	36.14 $\pm$ 0.19	0.52

<sup>a</sup>Each sample was processed in triplicate. CV is the intra-assay CV and was calculated using the following formula:  $CV = (SD/\text{mean}) \times 100$ . For abbreviation see Table 1.

bration curves obtained by ES-MS-MS and GC-MS. The correlation coefficients were  $\geq 0.97$  for all curves.

The precision and accuracy were checked by calculating the intra-assay variation for five different samples processed in triplicate. As shown in Table 2, the CV for each sample was less than 1%. The recoveries of MVL and 7 $\alpha$ -OHC determined at three different levels varied from 97 to 100% (Table 3). There were no significant differences between data obtained using both ES-MS-MS and GC-MS analytical techniques.

## DISCUSSION

The high incidence of diseases associated with increased levels of cholesterol in plasma and liver continually stimulates the interest in development of rapid and sensitive methods for the determination of the activities of HMG-CoA reductase

**TABLE 3**  
**Recovery of Mevalonolactone and 7 $\alpha$ -Hydroxycholesterol from Microsomes Analyzed by ES-MS-MS and GC-MS<sup>a</sup>**

Methods	Amount added ( $\mu$ g)	MVL		7 $\alpha$ -OHC	
		Amount found ( $\mu$ g)	Recovery (%)	Amount found ( $\mu$ g)	Recovery (%)
ES-MS-MS	0	10.72 $\pm$ 0.03		7.24 $\pm$ 0.24	
	15	25.42 $\pm$ 0.18	98.30 $\pm$ 1.17	22.06 $\pm$ 0.12	98.83 $\pm$ 0.93

<sup>a</sup>Values are mean  $\pm$  SD ( $n = 3$ ) and represent the recovery of different amounts of MVL and 7 $\alpha$ -OHC added to aliquots of 500  $\mu$ L of the microsomal suspension, containing 5 mg of protein. The assay recovery at each amount was calculated using the following equation: recovery = 100  $\times$  (amount found – basic amount)/amount added. For abbreviations see Table 1.

and cholesterol 7 $\alpha$ -hydroxylase, two key enzymes in the synthesis and degradation pathways of cholesterol (1,2). Because of the high sensitivity and accuracy of GC-MS, it is widely used in the evaluation of activities of these enzymes *in vitro*. In this method, the mass of MVL and 7 $\alpha$ -OHC formed is determined. However, this method has the drawback of being labor-intensive and slow. In the method described here, we demonstrated that the use of ES-MS-MS offers the opportunity to overcome these disadvantages. Indeed, the use of ES-MS-MS does not require preliminary derivatization procedures and takes only 5 min for analysis. Compounds are identified by their molecular mass and their characteristic fragmentations. The fragment ions at  $m/z$  131 and 367.7 were selected to identify MVL and 7 $\alpha$ -OHC, respectively. Quantitative determination of these compounds requires the addition of internal standards. Deuterated-MVL (3) and 6 $\beta$ -OHC (15) have been reported to be suitable internal standards for MVL and 7 $\alpha$ -OHC, respectively. However, since deuterated-MVL is not commercially available and is difficult to synthesize, we made an alternative internal standard, acetylated-MVL. This compound was not present in the microsomal preparation and was separated clearly from MVL by GC, suggesting that it could be a suitable internal standard. In addition, the fragment ions at  $m/z$  131 for MVL and 138.9 for acetylated-MVL, selected for the ES-MS-MS analysis, were detected with the same degree of sensitivity. The validity of this approach was achieved by comparing the results obtained by the ES-MS-MS with those obtained by the more traditional GC-MS technique, using similar conditions. No significant differences were noted. In addition, the values obtained were in agreement with the values reported by other investigators (16–23). The internal standard described is another advantage since it could be prepared easily and was found to be stable during storage and sample preparation.

We have also simplified the solid-phase extraction procedure used for the simultaneous extraction and purification of 7 $\alpha$ -OHC and MVL by reducing the number of different Bond Elut cartridges used. We used only CN cartridges to extract

and purify these two reaction products. Del Puppo *et al.* (24) found that the lactone was more readily extracted and purified than the free acid. However, the lactonization of MVA requires the use of a strong monobasic mineral acid such as hydrochloric acid, but cholesterol oxidation products are sensitive to acids (25). It was therefore necessary to separate MVA from 7 $\alpha$ -OHC prior to lactonization. For this procedure, it was necessary to demonstrate that significant quantities of MVL or 7 $\alpha$ -OHC are not lost during sample preparation, and that the preparation leads to adequate recovery of these products. These two aspects were examined by adding MVL or 7 $\alpha$ -OHC directly to a fraction of microsomal suspension. Extraction and purification were then carried out as described. An adequate separation of MVA and 7 $\alpha$ -OHC was achieved on the CN cartridges. With the purification conditions chosen, excellent recoveries of 7 $\alpha$ -OHC and the lactone form of MVA, were obtained. The use of Bond Elut CN cartridges to perform the extraction and purification simultaneously simplified the pre-analytic preparation of samples greatly and offered greater potential for automation.

The approach described here has significant advantages over other procedures used for the evaluation of HMG-CoA reductase and cholesterol 7 $\alpha$ -hydroxylase activities in liver microsomal preparations. First, the sample preparation time is dramatically reduced, and no derivatization steps are required. Second, the data acquisition time is considerably reduced when the analysis is processed by ES-MS-MS. In conclusion, we have developed a simple, rapid, and accurate method for the simultaneous evaluation of the activities of hepatic microsomal HMG-CoA reductase and cholesterol 7 $\alpha$ -hydroxylase, using the ES-MS-MS technique, a new internal standard, and a simple pre-analytic procedure.

# 5,9,23-Triacontatrienoic Methyl Ester, an Elastase Inhibitor from the Marine Sponge *Chondrilla nucula*

Michèle Meyer and Michèle Guyot\*

Laboratoire de Chimie, ESA 8041 C.N.R.S., Muséum National d'Histoire Naturelle, F-75005 Paris, France

**ABSTRACT:** A polyethylenic fatty ester was isolated from the marine sponge *Chondrilla nucula*. The structure was elucidated through NMR spectral data and MS analysis as 5,9,23-triacontatrienoic methyl ester **1**. Compound **1** is an elastase inhibitor [ $ID_{50} = 10 \mu\text{g/mL}$  ( $2 \cdot 10^{-5} \text{ M}$ )].

Paper no. L8864 in *Lipids* 37, 1109–1111 (November 2002).

Marine sponges of the class Demospongiae biosynthesize long-chain FA,  $C_{24}$ – $C_{30}$ , commonly called “desmospongiac acids” (1). A number of  $C_{30}$  FA have been isolated; the most common, 5,9,23-30:3 $\Delta$ , was first isolated from *Chondrilla nucula* (2), then from *Trikenrion loeve* (along with 9,23-30:2, 23-30:1, 5,9,25-30:3, *Pseudaxinella* cf. *lunaecharta* (3), *Higginsia tethyoides* (4), and *Cinachyrella alloclada* (5). Acid 5,9-30:2 was found in *Petrosia pellasarca* (6) along with a very long chain FA, 19,22,25,28,31-34:5. Another 34:4 acid was isolated from the sponge *Amphimedon compressa* (7), and other highly unsaturated  $C_{30}$  FA, 15,18,21,24-30:4 and 15,18,21,24,27-30:5, were found in *Cliona celata* (8). All of these unsaturated acids were isolated from phospholipids. Acid 5,9,21-30:3 was isolated from *Amphimedon* sp. and described as a DNA topoisomerase I inhibitor (9).

In the course of our program devoted to the search for bioactive metabolites from marine invertebrates of the northern Mediterranean shore, the dichloromethane extract of the sponge *Chondrilla nucula* ([collected by J. Vacelet, Centre d'Océanologie de Marseille (CNRS-Université de la Méditerranée, UMR 6540 DIMAR), Station Marine d'Endoume, 13007 Marseille, France]) showed noticeable inhibition of amidolysis of Suc(Ala)<sub>3</sub>pNA by porcine pancreatic elastase (PPE) (10). Elastase inhibitors have the potential to be therapeutic agents in pulmonary emphysema (11), chronic bronchitis (12), adult respiratory distress syndrome (13), and other inflammatory disorders (14). It has been hypothesized that appropriate small-M.W. inhibitors would be therapeutically useful in the treatment of such diseases (15). Hence, we engaged

in the study of the chemistry of this sponge to isolate the active compound.

## EXPERIMENTAL PROCEDURES

<sup>1</sup>H and <sup>13</sup>C NMR spectra were recorded on a Bruker AC 300 MHz spectrometer. Chemical shifts ( $\delta$ ) are expressed in ppm from residual  $\text{CHCl}_3$  (7.25 ppm) as internal standard. Mass spectra were recorded on a Nermag 10-10 (CI,  $\text{NH}_3$ ). IR spectra were recorded on a Nicolet (impact 400D) FTIR spectrometer. TLC analyses were performed on thin-layer analytical plates 60F254 (Merck, Darmstadt, Germany).

*Chondrilla nucula* was collected near Marseille, washed with seawater, and immersed in methanol for shipping. After arrival, the methanol/water mixture was removed, and specimens were extracted with dichloromethane/methanol (1:1, vol/vol). Solvents were evaporated, and the residue was extracted with dichloromethane. The purification procedure was monitored by measuring amidolysis of *N*-succinyl-alanyl-alanyl-alanyl-*p*-nitroanilide [Suc(Ala)<sub>3</sub>pNA] (Sigma, St. Louis, MO) by PPE (Biosys, Compiègne, France) at 410 nm. Assays were performed in 0.1 M Tris buffer, pH 8, using a Ceres 900 kinetic microplate reader (Bio-Tek Instruments, Winooski, VT) in 96-well microplates. Aliquots (95  $\mu\text{L}$ ) of 40 nM PPE in 200  $\mu\text{L}$  pH 8 buffer and 25  $\mu\text{L}$  of products (25 or 2.5  $\mu\text{g}$ ) in DMSO were mixed at 25°C for 30 min prior to addition of 10  $\mu\text{L}$  of substrate solution [30  $\mu\text{mol}$  of Suc(Ala)<sub>3</sub>pNA in 1 mL of DMSO], and plates were read after 10 min. Oleic acid and methyl oleate were purchased from Sigma.

The crude dichloromethane extract was first separated by chromatography on a silica gel column using  $\text{CH}_2\text{Cl}_2$  with increasing amounts of acetone as eluent. The fraction eluted with  $\text{CH}_2\text{Cl}_2$  retained activity and was further purified on another silica gel column eluted with dichloromethane/pentane (2:8, vol/vol) to yield active compound **1**. <sup>13</sup>C NMR ( $\text{CDCl}_3$ ,  $\delta$  ppm): 174.8, 130.5, 130.4, 129.9, 129.9, 128.9, 128.8, 51.9, 39.5, 37.1, 34.1, 33.5, 32.7, 31.9, 30.6–29.1, 27.8, 27.5, 26.7, 25.3, 23.1, 14.5.

Hydrolysis of **1** was performed with  $\text{CO}_3\text{Na}_2$  in dioxane (16). After addition of water, the mixture was extracted with dichloromethane and the residue obtained after evaporation of the solvent purified through a short column of silica gel using dichloromethane as eluant to give pure **2**, MS  $m/z$  446.

SCHEME 1

## RESULTS AND DISCUSSION

Active compound **1** was obtained as an oil (0.005% dry weight). It exhibits inhibition of PPE at an  $ID_{50}$  (inhibitory dose for 50% of assays) of 10  $\mu\text{g/mL}$  ( $2 \cdot 10^{-5}$  M). High-resolution MS furnished the formula  $C_{31}H_{56}O_2$  by the peak at  $m/z$  460.4275 (calculated 460.4280). The IR spectrum exhibited vibration bands corresponding to one carbonyl ( $1720\text{ cm}^{-1}$ ), ethylenic double bonds ( $1534, 1583, 1613\text{ cm}^{-1}$ ), and an ether function ( $1100\text{ cm}^{-1}$ ). There was no prominent absorption in the  $970\text{ cm}^{-1}$  region, so all double bonds were of *cis* configuration (2).

$^1\text{H}$  NMR spectrum showed signals at  $\delta$  5.35 (*m*, 6H), 3.65 (*s*, 3H,  $\text{OCH}_3$ ), 2.3 (*m*, 2H), 2.1 (*m*, 2H), 1.95 (*m*, 2H), 1.7 (*m*, 4H), 1.25 (*br s*, 32H), and 0.9 ppm (*t*, 3H,  $\text{CH}_3$ ), suggesting a triethylenic FAME. No signal at  $\delta$  2.7 ppm for a methylene-interrupted double bond was observed.

$^{13}\text{C}$  NMR spectrum of **1** showed resonances for 31 carbons: one carbonyl ester at  $\delta$  174.8 ppm, six ethylenic carbons at  $\delta$  130.5, 130.4, 129.9, 129.90, 128.9, 128.8 ppm, one methoxyl group at  $\delta$  51.9 ppm, and signals between 40 and 25 ppm, corresponding to methylene groups.  $^1\text{H}$  COSY allowed unambiguous assignment of the position of the first double bond at C-5.

In the mass spectrum (EI), the typical fragments at  $m/z$  386 and 74, the consequence of a McLafferty rearrangement of methyl esters, are observed along with the base peak at  $m/z$  81 (100%) characteristic of a  $\Delta^{5-9}$  ethylenic acid (6). Other diagnostic fragmentations are shown in Scheme 1 (above), which allowed us to propose locations of the double bonds at the 5,9,23 positions. Upon comparison of the MS spectrum of **1** with that of an authentic sample (Barnathan, G., and Kornprobst, J.M., personal communication), the two spectra were almost identical.

Previous chemical studies of *C. nucula* have led, after hydrolysis of phospholipids, to the isolation of two new 5,9 unsaturated acids. *Chondrilla nucula* collected in Florida contained 5,9,23-triacontatrienoic acid (2). Later, another sample of *C. nucula* collected in Puerto Rico furnished the unusual *cis*-5,9-hexadecadienoic acid, with 9-hexadecenoic and palmitic as the major FA (17), but it lacked 5,9,23-triacontatrienoic acid. This suggests that seasonal and (or) geographic variations may be observed in FA distribution of marine sponges.

However, previous analyses of the long-chain FA contents in *C. nucula* were carried out after acidic methanolysis of the total lipids, so if a methyl ester was present it would not have been detected. Examples of esterified FA as natural products are not rare; we can cite the isolation of the ethyl ester of a

bromopolyacetylenic acid from a sponge (18) or methyl ester of a prostaglandin from a gorgonian (19).

Little is known about biological activities of these long-chain unsaturated FA, except the DNA topoisomerase I inhibition of  $\Delta 5,9,21$ -30:3 (9). To the best of our knowledge, this is the first report of a long-chain fatty ester as an elastase inhibitor. For comparison, the free acid **2** was assayed in the same conditions but was found inactive until 100  $\mu\text{g/mL}$ , as was methyl oleate. However oleic acid gave 35% inhibition at 350  $\mu\text{M}$ , a somewhat higher concentration than that needed to inhibit human leucocyte elastase (20). We concluded that the biological activity of **1** must be accounted for by its unique structure. Synthetic studies and examination of a series of FA and their esters will be necessary to investigate this promising new antielastase agent.

## ACKNOWLEDGMENTS

We express our thanks to Arlette Longeon for the elastase assay, Maurice Baran-Marszak for recording the NMR spectra, Jean-Paul Brouard for mass spectra, and Jean-Michel Kornprobst and George Barnathan for providing the methyl ester mass spectra.

# What Is the Role of $\alpha$ -Linolenic Acid for Mammals?

Andrew J. Sinclair<sup>a,\*</sup>, Nadia M. Attar-Bashi<sup>a</sup>, and Duo Li<sup>b</sup>

<sup>a</sup>Department of Food Science, RMIT University, Melbourne, Victoria, 3001, Australia, and <sup>b</sup>Department of Food Science, Hangzhou University of Commerce, Hangzhou, China

**ABSTRACT:** This review examines the data pertaining to an important and often underrated EFA,  $\alpha$ -linolenic acid (ALA). It examines its sources, metabolism, and biological effects in various population studies, *in vitro*, animal, and human intervention studies. The main role of ALA was assumed to be as a precursor to the longer-chain n-3 PUFA, EPA and DHA, and particularly for supplying DHA for neural tissue. This paper reveals that the major metabolic route of ALA metabolism is  $\beta$ -oxidation. Furthermore, ALA accumulates in specific sites in the body of mammals (carcass, adipose, and skin), and only a small proportion of the fed ALA is converted to DHA. There is some evidence that ALA may be involved with skin and fur function. There is continuing debate regarding whether ALA has actions of its own in relation to the cardiovascular system and neural function. Cardiovascular disease and cancer are two of the major burdens of disease in the 21st century, and emerging evidence suggests that diets containing ALA are associated with reductions in total deaths and sudden cardiac death. There may be aspects of the action and, more importantly, the metabolism of ALA that need to be elucidated, and these will help us understand the biological effects of this compound better. Additionally, we must not forget that ALA is part of the whole diet and should be seen in this context, not in isolation.

Paper no. L9029 in *Lipids* 37, 1113–1123 (December 2002).

Linoleic and  $\alpha$ -linolenic acids are essential fatty acids (EFA), which means that, like vitamins, they must be obtained in the diet. The essential nature of these PUFA was established in the 1930s (1). Linoleic acid was found to be the parent or precursor for a series of PUFA, now known as the n-6 PUFA since linoleic acid itself is an n-6 PUFA; likewise,  $\alpha$ -linolenic acid (ALA) is the parent FA for the n-3 PUFA.  $\alpha$ -Linolenic acid is called ALA in order to distinguish it from  $\gamma$ -linolenic acid, an n-6 PUFA found in evening primrose oil and borage oil. All FA in the linoleic acid (n-6) PUFA family have their first double bond 6 carbons from the terminal methyl end of the molecule. Similarly, all FA in the ALA (n-3) PUFA family have their first double bond 3 carbons from the methyl end.

ALA is an EFA for mammals because they do not possess the ability to insert double bonds in 18-carbon PUFA between the methyl end and the middle of the molecule. The position of the first double bond from the methyl end of the molecule has led to describing ALA as an n-3 PUFA, since the first

double bond is 3 carbons from the methyl (omega) end of the FA. All FA with this double bond system starting 3 carbons from the methyl end are known as n-3 PUFA. ALA has three *cis* double bonds in positions 9-10, 12-13, and 15-16 counting from the carboxyl end of the FA (all-*cis*-9,12,15-octadecatrienoic acid).

ALA is found in plant chloroplast membranes where it is synthesized from linoleic acid, which in turn is derived from acetate. Cunnane *et al.* (2) argue that because human diets contain 16:2n-6 and 16:3n-3, found in green leafy vegetables, it is possible for humans to synthesize linoleic acid (18:2n-6) and ALA (18:3n-3) by chain elongation, although he concedes the amount of synthesis would be limited. Chloroplast membranes contain a very high content of ALA, which is considered to protect plants against damage during cold spells, with recent evidence showing that transgenic tobacco plants with reduced ALA, due to a silenced n-3 FA desaturase, were better able to acclimate to higher temperatures (3). Lipoxygenase products of ALA in plants include jasmonic acid and related phytohormones produced *via* the oxylipin cascade (4).

ALA is found in plants, animals, zooplankton, phytoplankton, and marine species. The most highly unsaturated FA found in terrestrial plants usually is ALA, although Simopoulos and Salem (5) have reported the presence of trace amounts of long-chain PUFA in some plants. In plants, ALA is found in leaves, mainly in glycolipids, and as TAG in certain seed oils (rapeseed, flaxseed, perilla seed, chia seed), beans (soybeans, navy beans) and nuts (walnuts) (6,7). In fresh green, leafy vegetables the ALA content ranges from 28 to 195 mg/100 g wet weight (8). In mammals, ALA is deposited in most tissues in different lipid fractions (cholesterol esters, TAG, and phospholipids) where it can subsequently be metabolized *via* a number of different metabolic routes (see below).

## FUNCTIONS OF THE n-3 FA

In mammals, linoleic acid is important for growth, reproduction, and skin function and as the precursor of arachidonic acid (9). This latter FA is the main substrate for a series of enzymes that produce the eicosanoids, such as thromboxane, prostaglandins, prostacyclins, leukotrienes and lipoxins (10). Cunnane (11) has argued that we really know little about the effects of linoleic acid deficiency, since researchers study the effect either of combined EFA deficiency (using fat-free diets) or of ALA deficiency (using diets rich in LA). He contends

\*To whom correspondence should be addressed.

E-mail: andrew.sinclair@rmit.edu.au

Abbreviations: ALA,  $\alpha$ -linolenic acid; CE, cholesterol ester; DPA, docosapentaenoic acid; PG, prostaglandin.

that the requirement for linoleic acid is lower when diets contain ALA (11).

Following the discovery of the essential nature of fat by Burr and Burr in 1930 (1), they and other authors investigated which FA were able to correct failure to grow, which FA prevented skin lesions, and which FA corrected high intake of water (presumed to be related to water loss through the skin). The initial studies of Burr and colleagues suggested that both linoleic and linolenic acids increased growth of fat-deficient rats and improved skin lesions (12). Work conducted with pure FA by Mohrhauer and Holman showed that both linoleic and linolenic acids increased the growth of fat-deficient rats; however, the final average weight of the rats fed linoleic acid was significantly greater than those fed ALA (13). This difference in weight might be regarded as significant in today's world and is supported by studies by Pan and Storlien (14), who showed that safflower oil-fed rats were heavier than rats fed diets containing a higher n-3 PUFA content.

Until the late 1970s, n-3 PUFA were regarded as being important only in marine species. Indeed, Tinoco *et al.* (15) suggested that ALA was not needed for terrestrial mammals based on a three-generation deficiency study in rats, although this was hotly contested (16). At this time, it was recognized that DHA was found in high proportions in mammalian brain and retina (17–19) and Anderson's group (20) had already reported that the maximal response of the retina to light was found in diets containing 2% (by weight) of ALA compared with diets containing 2% linoleic acid or 1% of each of the two EFA. It is now recognized that ALA, through its metabolite DHA, is essential for normal visual function based on studies in rats, monkeys, guinea pigs, and infants (21). Furthermore, a putative role for ALA as a messenger of excitation has been described in *Drosophila* photoreceptors (22).

The high levels of brain DHA across mammalian species led to early speculations that this molecule was playing a crucial role in the nervous system (18). Many studies using ALA-deficient diets in different animal species have shown reductions in the level of DHA in brain. Associated changes in brain function (auditory, olfactory, learning, memory, appetite events, neuron size, nerve growth factor levels) have been reported (23–29).

Various mechanisms have been suggested to account for these physiological changes in the brain and retina, as reviewed recently by Kurlack and Stephenson (30), Lauritzen *et al.* (31) and Salem *et al.* (32). Briefly, DHA plays a crucial role in the following: (i) membrane disorder (membrane fluidity), which can influence the function of membrane receptors such as rhodopsin (33,34); (ii) regulation of membrane-bound enzymes (Na/K-dependent ATPase) (35); (iii) dopaminergic and serotonergic neurotransmission (36); (iv) signal transduction *via* effects on inositol phosphates, DAG kinase, and protein kinase C (37); (v) regulation of the synthesis of eicosanoids derived from arachidonic acid (30); (vi) regulation of gene expression (38–40); (vii) regulation of phosphatidylserine levels (41); (viii) protection of neural cells from apoptotic death (42); (ix) stimulation of neurite outgrowth in PC12 cells

(43,44); (x) selective accumulation of DHA by synaptic growth cones during neuronal development (43,44); (xi) regulation of nerve growth factor (29); and (xii) regulation of neuron size (27,28).

There has been considerable discussion whether the true essentiality resides with the EFA themselves or with their long-chain derivatives [arachidonic acid in the case of the n-6 family, and EPA, docosapentaenoic acid (DPA), and DHA in the case of the n-3 family]. For example, dietary ALA has been shown to prevent neuronal death in an animal model of global ischemia and to protect animals treated with kainate against seizures and hippocampal lesions (45). Mixtures of linoleic acid and ALA, as FFA, have been reported to prevent elevations of blood cortisol and cholesterol levels that accompany stressful situations and to prevent rapid and repeated eye blinking in rats following chemical induction of dopamine depletion (46). Whether these effects are mediated *via* the EFA themselves, their long-chain metabolites, or eicosanoids is unknown.

Specific functions have been described for linoleic acid in skin, where there is evidence that it is required to control water permeability (47). Linoleic acid also can be metabolized to an antiproliferative compound, 13-hydroxyoctadecadienoic acid, *via* the 15-lipoxygenase pathway (48).

In plants, specific functions have been described for ALA or ALA metabolites. Plant membranes contain an abundance of ALA, which is thought to be involved in a number of important processes, including (i) being the precursor of jasmonic acid, a plant growth regulator (49); (ii) being a lipoxygenase substrate producing hydroperoxy FA, which mediate defense responses against injury or infection (50); being the substrate for phytoprostanes (dinor isoprostanes) found in high concentration during drying and storage of plants and in pollen (51); being the precursor of a stress-induced  $\alpha$ -ketol derivative of ALA, which has strong flower-inducing activity (52); and being a potent inhibitor of a wound-induced mitogen-activated protein kinase (53).

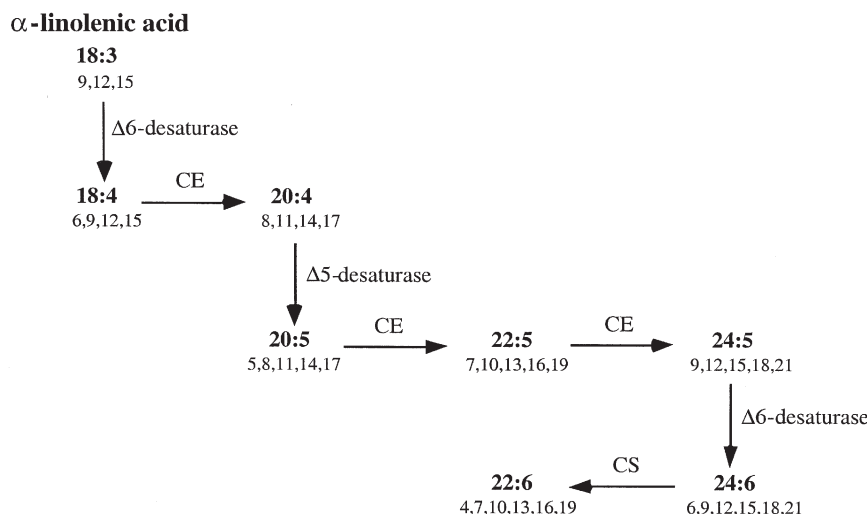

In mammals, the functions that have been described for ALA include being the precursor of the long-chain n-3 FA, being a preferred substrate for  $\beta$ -oxidation and for carbon recycling in the brain and other tissues (54), and having a putative role in skin and fur (55–57).

## $\alpha$ -LINOLENIC ACID METABOLIC PATHWAYS

**$\beta$ -Oxidation.** Studies in humans and animals reveal that a major catabolic route of metabolism of ALA is  $\beta$ -oxidation. In the rat, approximately 60% of an oral dose of labeled ALA was expired as CO<sub>2</sub> in 24 h compared with less than 20% for palmitic, stearic, and arachidonic acids (58). Pan and Storlien (14) reported that the higher the proportion of PUFA in the diet, the higher the rate of  $\beta$ -oxidation of labeled ALA in rats. In humans, between 16 and 20% of ALA was expired as CO<sub>2</sub> in 12 h (59,60); of the 18-carbon FA, ALA was the most highly oxidized while linoleic acid appeared to be somewhat conserved in humans (61).

**Carbon recycling.** Another major route of metabolism of

**FIG. 1.** Metabolic steps involved in converting  $\alpha$ -linolenic acid (18:3n-3) to docosahexaenoic acid (22:6n-3). CE = chain elongation; CS = chain-shortening reaction (peroxisomal oxidation).

ALA in rats and primates involves carbon recycling into *de novo* lipogenesis in the brain and other tissues in pregnant, lactating, fetal, and infant animals (60). When labeled ALA is fed to animals, a substantial proportion of the label ends up in brain saturated and monounsaturated FA and cholesterol (54,62,63). It is not known whether this is due to  $\beta$ -oxidation of ALA in the brain or in nonneural tissues such as liver and muscle and transport and uptake of ketones by the brain. In developing rats fed labeled ALA, the labeling of cholesterol exceeded the labeling of DHA by 4- to 16-fold (63). Edmond *et al.* (64) showed that orally fed deuterium-labeled palmitate, stearate, and oleate did not enter the brain; however, these FA were labeled in the brain owing to new synthesis (recycled deuterium). This implies that the process of  $\beta$ -oxidation in nonneural tissue is important for the supply of substrates such as ketone bodies for brain synthesis of these lipids.

**Precursor of EPA and DHA.** A third metabolic pathway for ALA, and often thought of as the main pathway, is as the precursor of longer-chain, more unsaturated FA, such as EPA, DPA (22:5n-3), and DHA (60,65). The pathway involves seven different steps, of which three are desaturases, three are chain elongations, and one is a chain-shortening reaction (Fig. 1). This pathway takes place mainly in the endoplasmic reticulum, but the final chain-shortening step involves peroxisomal oxidation of 24:6n-3 to 22:6n-3 (65,66). Patients with a peroxisomal disorder known as Zellweger syndrome cannot synthesize 22:6n-3 (67). A critical issue is whether dietary ALA can supply tissues with all the EPA and DHA needed for optimal function or whether there are some tissues that may require a dietary supply of EPA and DHA (see later).

**Skin and fur.** A putative pathway of ALA metabolism is deposition in skin (57,68,69) and secretion onto fur of small mammals (57). In a recent study in guinea pigs, more than 46% of an oral dose of  $^{14}\text{C}$ -ALA was found in the skin and fur lipids, with the highest proportion of the label being found

in the fur (57). In that study, the proportion oxidized to  $\text{CO}_2$  was estimated to be 39% of the oral dose, indicating that nearly 90% of the ALA was unavailable for other metabolic pathways. It was proposed that ALA was secreted from the skin and onto the fur by the sebaceous glands, and that its function was to protect the fur from damage by water, light, or other agents. Sebaceous gland secretion was shown to be a major route of vitamin E delivery to the skin; this mechanism was proposed to protect skin surface lipids and the upper stratum corneum from harmful oxidation (70). Preliminary data from this laboratory reveal that ALA is similarly metabolized by this route (onto the fur) in rats and mice (Sinclair, A., and Fu, Z., unpublished observations). This observation may be related to the commonly reported use of flaxseed oil (linseed oil) as a dietary supplement by dog and horse owners to provide shine to the coats of these species (71).

Several different studies have reported that ALA may play a role in skin and fur function in other species. For example, an early study in rats showed that linseed oil (rich in ALA) contained a factor that promoted fur growth compared with a fat-deficient control group, and that ALA was more effective than linoleic acid in restoring fur growth (55). A later study in capuchin monkeys reported skin lesions, fur loss, and abnormal behavior on a diet very low in ALA but rich in linoleic acid, and that there was a restoration of normal skin and fur appearance following the inclusion of linseed oil in the diet (56).

Both linoleic acid and ALA have been shown to lighten skin following UV-induced hyperpigmentation of skin in guinea pigs (72), which was believed to be due to the suppression of melanin production and enhanced desquamation of the pigment from the epidermis.

Linoleic acid prevents abnormal water loss through the skin, which occurs in EFA deficiency, with comparative studies in the rat showing ALA was not effective in reducing water loss (12,47,73). An explanation offered is that linoleic

acid is incorporated into skin acyl ceramides, whereas ALA is not (47).

**Water homeostasis studies.** In rhesus monkeys, ALA deficiency was associated with an increased water intake; however, this was balanced by increased urination rather than water loss through the skin (74). A recent report involving rats indicated that perinatal n-3 deficiency altered sodium and water homeostasis (75) and that this was associated with an increased blood pressure by the time the rats were adults (76). This suggests an important role for dietary ALA during pregnancy in rats to prevent hypertension in adults. Similar data have been obtained by Langley-Evans (77), who showed that low-protein diets containing corn oil (very low ALA levels) were associated with an elevated blood pressure, whereas low-protein diets containing soy oil were not associated with altered blood pressure.

### HOW EFFECTIVELY IS ALA METABOLIZED TO DHA?

There has been considerable discussion about the effectiveness of dietary ALA as a substrate for tissue EPA and DHA (60,78). To examine this question, several different approaches have been used, including feeding animals and humans with ALA and DHA and comparing tissue levels of DHA; using isotopically labeled ALA and determining the fractional metabolism to DHA in available tissue compartments (such as in plasma or in various tissues in the case of animal studies); and more recently measuring the amount of mRNA for the  $\Delta 6$ - and 5-desaturases in tissues.

Feeding and labeling studies indicate that DHA is a more effective source of tissue DHA than is ALA on a gram-for-gram basis. Early studies in weanling rats revealed that 0.16% of a radiolabeled oral dose of DHA was recovered in brain DHA compared with 0.008% of a radiolabeled oral dose of ALA being found in brain DHA, a 20-fold difference (62). In the guinea pig, it has been estimated that 10 times more dietary ALA than dietary DHA was required to maintain a given brain DHA level (79), whereas DHA was seven times more effective as a substrate for neural DHA than dietary ALA in baboons (80–82). When rats were fed a diet supplied with 0.45% of dietary energy as DHA, they accumulated a twofold higher amount of 22:6n-3 than rats fed a diet supplied with the same amount of ALA for 5 wk (69). In other words, in various mammalian species, dietary DHA is a more effective source of tissue DHA than dietary ALA. Woods *et al.* (82) reported that the brain DHA level was the same in artificially reared rat pups fed high intakes of ALA as in dam-reared pups (who were receiving DHA in the milk); however, retinal DHA levels in the artificially reared groups fed ALA were significantly lower than the dam-reared group.

### DIETS RICH IN ALA DO NOT NECESSARILY LEAD TO HIGH TISSUE DHA LEVELS

There is a view that most dietary ALA is either  $\beta$ -oxidized or converted to long-chain n-3 acids. We have addressed this

issue in studies using diets low or high in ALA with the same LA content (84). Guinea pigs were fed diets for 3 wk containing the same amount of LA (18% of FA) but varying in ALA content (0.3 or 17% of FA). Animals in the high-ALA diet had significantly more whole-body ALA than the low-ALA diet group (8.8 vs. 2.3 g/whole body). There was also significantly more whole-body EPA (0.06 vs. 0.01 g), but on the high-ALA diet the whole-body DPA and DHA did not increase significantly. In other words, ALA does accumulate when fed at high levels, and in the whole body even on a diet low in ALA, the major n-3 FA is ALA (>90% of total n-3 PUFA). The tissues where the most ALA accumulated were muscle, skin, and adipose tissue (approximately 90% of whole-body ALA). These data show that DHA represents a very small proportion of the whole-body n-3 content (90 mg DHA out of a total of 9140 mg). It is also revealing that brain DHA content was only approximately one-quarter of the total DHA in the body, with the carcass representing about 50% of the whole-body DHA (84).

In humans, feeding high-ALA diets (up to 15 g/d) in 4-wk studies led to small but significant increases in ALA, EPA, and 22:5n-3 in plasma TG and phospholipids and very little, if any, detectable increase in DHA in plasma, platelets, and white and red blood cells (78,85,86). Deuterium-labeling studies with ALA in humans showed that the percentage conversion of ALA to EPA and other long-chain n-3 PUFA was between 11 and 19% of the dose, and that the conversion rate was reduced by 40–54% when the diet was rich in linoleic acid (87). In a recent study, physiological compartmental analysis of ALA metabolism in adult humans was carried out. Subjects received a 1-g oral dose of an isotope tracer of ALA; only about 0.2% of the plasma ALA was destined for synthesis of EPA, approximately 63% of the plasma EPA was accessible for production of 22:5n-3, and 37% of 22:5n-3 was available for synthesis of DHA (88). The very limited conversion of ALA to EPA indicates that the biosynthesis of long-chain n-3 PUFA from ALA is limited in healthy individuals. Recently, it has been reported in studies using  $^{13}\text{C}$ -ALA that young women have a greater capacity than young men to convert ALA to DHA (89,90).

Subjects fed a liquid formula diet for 2 wk containing up to 16 energy % of ALA (approximately 35 g/d) and 4 energy% linoleic acid (9 g/d) showed marked increases in ALA in the plasma cholesterol esters (about 7% of CE FA) and also substantial increases in ALA in plasma phosphatidylcholine (PC), with significant rises in EPA in both these fractions (1 and 1.5% of PC and CE fractions, respectively) (91). The increases in ALA were accompanied by equivalent decreases in oleic acid with no significant changes in the arachidonic acid levels in either fraction. Subjects on these diets showed a 52 to 85% decrease in urinary metabolites of total prostaglandins (PG) and  $\text{PGE}_2$ , and a 74% decrease in  $\text{PGF}_{2\alpha}$  levels on the highest ALA diet. An earlier study in healthy subjects who received 30 mL linseed oil daily for 4 wk reported there was an increase in EPA by 150% and in DHA by 70% in the serum phospholipids (92). The large increase in DHA in plasma has not been reported in subsequent studies using

doses of up to 15 g ALA/d (79,86,87). Longer-term studies in adults, who increased their ALA intake by 3 g/d by substituting soy oil for perilla oil for 10 mon, demonstrated an increase in plasma DHA levels by more than 20% (93).

There could be a number of reasons for the relatively poor efficiency of the conversion of ALA to EPA and DHA. First, as noted above, a substantial proportion of the ALA is either diverted to  $\beta$ -oxidation or found distributed throughout all major tissue lipid pools (adipose, carcass, skin) as ALA; in addition, in animals ALA may be excreted onto the fur. Second, linoleic acid (the major dietary PUFA) is a competitive inhibitor of the metabolism of ALA to 18:4n-3, which is a precursor of long-chain n-3 PUFA (Fig. 1). Furthermore, diets rich in linoleic acid decrease the expression of the hepatic  $\Delta 6$ -desaturase compared with a diet rich in oleic acid, which presumably also reduces the possibility of conversion of ALA to 18:4n-3 and 24:5n-3 to 24:6n-3 (94). Based on the data that linoleic acid reduces the  $\Delta 6$ -desaturase levels (94), an obvious mechanism to promote EPA and DHA synthesis from ALA would be to reduce the dietary linoleic acid level and at the same time to increase the ALA level. This strategy has been used successfully in human dietary studies (86) and rat studies (95) to promote synthesis of EPA and DHA from ALA.

With respect to infants, there has been a substantial debate about rates of synthesis of arachidonic acid and DHA from their 18-carbon precursors, especially in preterm infants. This discussion arose when it was realized that formula-fed infants had reduced DHA levels in plasma, red blood cell, muscle, and brain compared with breast-fed infants (above) and that restoration of levels only occurred when arachidonic acid and DHA were added to the infant formula. Many commercial infant formulas contain high levels of linoleic acid and do not contain arachidonic acid and DHA, whereas breast milk contains a small proportion of arachidonic acid and DHA. There is now evidence that ALA is converted to DHA in both preterm and term infants (96,97), although there is wide variability between individual subjects. Despite the apparent ability of infants to make long-chain PUFA, Cunnane *et al.* (98) argue that this production is not sufficient to meet the accretion rate of DHA in the brain. Perhaps the period of rapid brain growth is a situation when DHA, rather than ALA alone, is required to support the accretion rate of brain DHA. It is possible that  $\Delta 6$ -desaturase is especially sensitive to linoleic acid in infants and that high levels of linoleic acid in infant formulas reduce the activity of this enzyme, thus increasing the likely requirement of arachidonic acid and DHA to maintain plasma and other tissue levels of these PUFA.

#### DO PLASMA DHA LEVELS REFLECT DHA STATUS IN OTHER TISSUES?

In studies in humans (infants and adults) with either  $^{13}\text{C}$ - or  $^2\text{H}$ -ALA, the main compartment that can be accessed is plasma. All these studies report that labeled DHA is found in plasma lipids with time, with substantial variability in stable isotope labeled-DHA formation being reported in infants

(96). It is presumed that most of the DHA found in these studies is derived from synthesis in the liver since this tissue is often considered a major site of PUFA synthesis. If other tissues have specific capacities for PUFA formation, such as the brain and testes, then examining the plasma might not reveal this capacity. For example, in the guinea pig fed 0.7% ALA in the diet (0.7 g/100 g diet), liver and heart DHA levels were less than 1% of phospholipid FA (suggesting little DHA synthesis), whereas retina and brain levels of DHA were 16 and 11%, respectively, implying DHA synthesis in these tissues (80). In other words, there are tissue-specific levels of PUFA that presumably depend on a number of factors, including the activity of the desaturases and elongases in the specific tissues, preferential transport, and decreased degradation. A possible explanation for the high brain DHA levels might be the presence of a brain FA-binding protein that supplies DHA to the developing neurons (99). In the cat, the liver apparently has the capacity to synthesize 22:5n-3 from ALA, which is then transported to the brain where DHA can be synthesized, presumably because of the presence of brain-specific enzymes (100). Recent studies on the cloning and expression of mammalian  $\Delta 6$ - and  $\Delta 5$ -desaturases provide support for the idea that tissues other than liver have high levels of desaturase activity. For example, Cho *et al.* (94,101) showed that brain had a higher  $\Delta 6$ -desaturase mRNA level than liver, lung, heart, and skeletal muscle (in mice) and that liver, brain, and heart had a higher abundance of  $\Delta 5$ -desaturase mRNA than other human tissues.

#### CAN DIETARY ALA SUPPORT ADEQUATE PHYSIOLOGICAL OUTCOMES?

In spite of the apparent differences between ALA and DHA in their efficiencies as a source of tissue DHA, it is relevant to ask "does it really matter if all that is needed is a larger dose of ALA than would be required if only DHA were supplied"?

This question can be considered in the retina and in the cardiovascular system:

(i) *The retina.* The physiological response of the retina to light is positively correlated with the supply of n-3 FA (20,21). Few studies have compared the effect of dietary ALA with that of DHA on electroretinographic amplitude responses (102–104). In the first study (in guinea pigs) there were three dietary ALA levels (low, medium, and high) and another diet containing ALA, EPA and DHA (102). The maximum electroretinographic amplitude was found in the group with the highest ALA level (2% energy). The diet containing ALA and long-chain n-3 PUFA, as well as the highest total n-3 PUFA intake (3.1% energy), gave a reduced electroretinographic signal in comparison with the ALA alone diet. In this study, it was not established whether the reduced signal might have resulted from increased peroxidation of DHA or from too much light or perhaps even an imbalance between retinal AA and DHA levels. In the second study, monkeys were fed diets with safflower oil, soybean oil (8% ALA), and a blend including tuna oil (0.6% DHA); results showed no significant

differences between the photoreceptor function in the two diet groups containing significant quantities of the n-3 PUFA (103). In the third study, infant rhesus monkeys were fed either a control diet containing ALA as the sole n-3 PUFA (2% of FA) or a supplemented diet containing 1% DHA and 1% AA from birth. The results suggested that the supplementation with DHA and AA neither harmed nor provided any substantial benefit to the development of visual acuity or retinal function in the first four postnatal months compared with the diet containing only ALA (104).

(ii) *The cardiovascular system.* A substantial role for long-chain n-3 PUFA (EPA and DHA) in the cardiovascular system has been described. The effects include regulation of eicosanoid production from arachidonic acid, plasma TAG and blood pressure-lowering effects (105,106), regulation of ion flux in cardiac cells (107), and regulation of gene expression *via* the peroxisomal proliferation system (108). There have been successful trials of secondary prevention of myocardial infarction with both ALA-rich vegetable oils (109, 110) and oils rich in EPA and DHA (111). A higher intake of ALA was inversely related to the prevalence odds ratio of coronary artery disease (113). In other studies, ALA, EPA, and DHA all prevented fatal arrhythmia in dogs following infusions of them as FFA (113).

(iii) *Platelet behavior.* Renaud and Norday (114) showed that enriching the diet of French farmers with ALA was associated with marked improvements in platelet behavior. In 1992, analysis of data from the MRFIT study of 6250 men (115) in the usual care group showed significant inverse associations between ALA and mortality from CHD ( $P < 0.04$ ), all cardiovascular disease ( $P < 0.03$ ), and all cause mortality ( $P < 0.02$ ). In 1999, Hu *et al.* (116) reported that a higher intake of ALA in the Nurses Health study of 76,283 women was protective against fatal ischemic heart disease, in a prospective cohort study. The mechanism whereby these effects are mediated has not been elucidated; however, one hypothesis involves an alteration in the balance between vasoactive PG (reducing production of vasoconstrictive thromboxane and increasing vasodilatory prostacyclin). In support of this hypothesis is a study by Ferretti and Flanagan (117), who reported that one subject fed a diet containing 5% of the energy from each of linoleic acid and ALA for 5 wk showed a significant reduction in urine excretion of 11-dehydrothromboxane B<sub>2</sub>, which returned to baseline levels following resumption of a low-ALA diet (5.9% energy of linoleic acid, 0.2% energy ALA). The PGI<sub>2</sub>-metabolite levels in urine were similarly significantly reduced during the high-ALA diet phase; however, the level of this metabolite did return to baseline, but more slowly than for that of the thromboxane metabolite. There may also be effects of n-3 rich diets *via* vasoconstrictor response to stressor hormones and reduced blood viscosity (118). ALA may also improve the elasticity of the arterial system, since it has been shown that arterial compliance is improved in obese subjects consuming 20 g of ALA from flaxseed oil for 4 wk (119).

(iv) *Coronary heart disease.* Ventricular fibrillation is a

major fatal complication of coronary heart disease. The introduction of n-3 PUFA as marine n-3 oils into the diet of rats or the acute infusion of ALA, EPA, and DHA in dogs can reverse ventricular fibrillation, strengthening the rationale for the use of these FA in preventing rhythm disorders (120,121). The presence of n-3 PUFA in the myocardial cell membranes electrically stabilizes the cells and prolongs the relative refractory period (107).

(v) *Cardiovascular disease.* The Lyon Diet Heart study of secondary prevention trial aimed to reduce the risk of CVD deaths by diet modification (110). The experimental group ( $n = 302$ ), who consumed a Mediterranean diet rich in ALA, showed a significant reduction in cardiac deaths and nonfatal myocardial infarction compared with the control group. Another prospective, randomized clinical trial using n-3 FA was reported by Singh *et al.* (109). Patients presenting with suspected myocardial infarctions ( $n = 360$ ) were randomized to placebo, marine n-3 oil (2 g of EPA + DHA per day), or mustard seed oil (containing 2.9 g of ALA per day). After one year, CHD events were significantly reduced in both n-3 FA groups.

(vi) *Coronary artery disease.* A randomized, single-blind trial in 1000 patients with angina pectoris, myocardial infarction, or surrogate risk factors for coronary artery disease showed that subjects allocated to a diet rich in whole grains, fruits, vegetables, walnuts, and almonds with soy or mustard seed oil had significantly fewer total cardiac end points, including sudden cardiac deaths and nonfatal myocardial infarctions, compared with a local diet similar to the step 1 National Cholesterol Education Program prudent diet. The intervention diet group consumed a twofold higher intake of ALA (1.8 vs. 0.8 g/d) compared with the control group (122).

## ALA AND PROSTATE CANCER

A number of prospective and case-control studies have suggested there is a positive association between diet or plasma ALA levels and the incidence of prostate cancer (123–128); however, other studies have not supported this association (129–132). The studies above estimated ALA dietary intake by using food frequency questionnaires or by measuring ALA levels in plasma or adipose tissue. The one study that measured ALA levels in prostate tissue itself from patients undergoing radical prostatectomy (133) showed that prostatic ALA levels tended to be lower in cases than in control subjects, with significantly lower levels when tumors extended to anatomical or surgical margins.

The lack of consistency in findings from these studies may be due to methodological limitations related to measurement error in estimating past dietary exposure of a nutrient like ALA from food frequency questionnaires, in measuring ALA levels in plasma that may not represent long-term dietary intake, in assuming that ALA levels in plasma are representative of ALA levels in the prostate tissue, and in choosing the sample size of the studies, which may have been too small in some studies. Measuring prostatic levels of FA, as in the study by Freeman *et al.* (133), offers advantages over self-reported

usual dietary intake since it provides an estimate of exposure at the target organ level, where the concentrations likely reflect long-term dietary intake; however, the sample size for that study was small.

At least four distinct biological mechanisms have been postulated to explain an effect of PUFA on prostate cancer growth. These include alteration in (i) the immune system response *via* eicosanoid synthesis, (ii) membrane phospholipid composition affecting permeability and receptor activity, (iii) hormone metabolism such as interference with  $5\alpha$ -reductase activity, which converts testosterone to  $5\alpha$ -dihydrotestosterone, and (iv) free radical formation from FA oxidation (134–136).

The etiology of prostate cancer remains unknown; however, it is evident that both genetic and exogenous factors are important in causing prostate cancer. The evidence of a positive association between ALA and prostate cancer is very weak and conflicting. Future research should aim at looking at the prostatic levels of ALA rather than plasma or diet in patients with prostate cancer.

## ALA AND BREAST CANCER

Several recent papers have associated a low ALA content of breast adipose tissue with an increased risk of breast cancer. The first study was a case-control study that showed an inverse association between breast adipose tissue ALA and the risk of breast cancer in 123 women with invasive, non-metastatic breast carcinoma compared with 59 women with benign breast disease (137). The second study was also a case-control study that examined breast adipose tissue from 241 patients with invasive, nonmetastatic breast carcinoma and 88 patients with benign breast disease (138). There was an inverse association between breast cancer risk and n-3 FA levels in breast adipose tissue. Furthermore, there were significant reductions of risk for women in the highest tertile of both ALA and DHA and in the highest tertile for the ratio of long-chain n-3 to n-6 PUFA. Studies in animals fed a high level of ALA suggest that rat mammary tumor growth depended on the dietary oxidative status, with vitamin E added to the ALA in the diet resulting in increased tumor growth compared with the high-ALA diet without vitamin E and prooxidants (sodium ascorbate/2-methyl-1,4-naphthoquinone) decreasing tumor growth (139).

## CASE REPORTS OF ALA DEFICIENCY IN HUMANS

Two case reports of suspected ALA deficiency in children deserve mention (137,138). In the first, a 7-yr-old child fed intravenously for 5 mon on a high-linoleic and low-ALA emulsion was reported to have experienced episodes of numbness, paresthesia, weakness, inability to walk, pain in the legs, and blurring of vision. Use of an ALA-containing emulsion was associated with a gradual and complete resolution of the paresthesias and episodes of weakness in the first 12 wk and subsequently improved nerve conduction velocities (140). The authors concluded there was a requirement for ALA of

0.54% of energy. In the second study, a 7-yr-old girl fed solely by gastric tube, with a preparation containing 16.2% energy as linoleic acid and 0.07% as ALA, from the age of 3 to the age of 7 showed little evidence of growth in this period, with weight being constant for the last 15 mon at 10.3 kg. She was supplemented with a linseed- and cod liver-oil mixture (5:1, vol/vol) for 2 mon, during which time her weight increased 0.43 kg/mon; after 5 mon, the amount of cod liver oil was increased and the weight gain increased to 0.64 kg/mon and her length increased from 117 to 122 cm in 5 mon (141). The authors concluded the n-3 requirements for this child were in the range 1.1–1.2% energy.

## RECOMMENDED DAILY INTAKES OF ALA

In 1992, the National Health and Medical research Council of Australia recommended that Australians increase their intakes of n-3 PUFA without specifying a figure for the recommended intake (142). In 1998, a European group considered the evidence for a Recommended Daily Intake for ALA and judged there was no evidence to deviate from the value of 1% energy (105). This group highlighted the need for large-scale prospective studies and randomized controlled trials focusing specifically on ALA. In 1999, a workshop sponsored by the National Institute on Alcohol Abuse and Alcoholism–NIH, the Office of Dietary Supplements–NIH, The Centre for Genetics, Nutrition & Health, and the International Society for the Study of Fatty Acids & Other Lipids suggested that the adequate intake of ALA should be 1% energy (2.22 g/d on a 2000 kcal diet) (143) with the proviso that the adequate linoleic acid intake be 2% of energy. The rationale for this suggestion was that it is only at low intakes of linoleic acid that ALA is effectively metabolized to long-chain n-3 in plasma and tissues (144,145). There is a clear need for a physiological end point related to ALA in order that requirements can be more effectively determined.

**ABSTRACT:** The aim of the present work was to test the effects of large-dose supplementation of vitamin E (Vit E) and selenium (Se), either singly or in combination, on fish oil (FO)-induced tissue lipid peroxidation and hyperlipidemia. The supplementation of Se has been shown to lower blood cholesterol and increase tissue concentrations of the antioxidant glutathione (GSH); however, the effects of Se supplementation, either alone or in combination with supplemental Vit E, on FO-induced oxidative stress and hyperlipidemia have not been studied. Male Syrian hamsters received FO-based diets that contained 14.3 wt% fat and 0.46 wt% cholesterol supplemented with Vit E (129 IU D- $\alpha$ -tocopheryl acetate/kg diet) and/or Se (3.4 ppm as sodium selenate) or that contained basal requirements of both nutrients. The cardiac tissue of hamsters fed supplemental Se showed increased concentrations of lipid hydroperoxides (LPO) but decreased oxidized glutathione (GSSG) concentrations. The higher concentrations of LPO in the hearts of Se-supplemented hamsters were not lowered with concurrent Vit E supplementation. In the liver, Se supplementation was associated with higher Se-dependent glutathione peroxidase activity and an increase in the GSH/GSSG ratio, whereas a lower hepatic non-Se-dependent glutathione peroxidase activity was seen with Vit E supplementation. Supplemental intake of Se was associated with lower plasma concentrations of total cholesterol and low density lipoprotein cholesterol plus very low density lipoprotein cholesterol. In view of the pro-oxidative effects of Se supplementation on cardiac tissue, a cautionary approach needs to be taken regarding the plasma lipid-lowering properties of supplemental Se.

Paper No. L9017 in *Lipids* 37, 1125–1133 (December 2002).

Fish oil (FO) consumption generally has been associated with a beneficial lowering of plasma concentrations of triglycerides (TG) and very low density lipoprotein cholesterol (VLDL) (1). The effect of FO ingestion on plasma lipids, however, is not always beneficial, as demonstrated by increased concentrations of

plasma low density lipoprotein cholesterol (LDL) and a lowering of high density lipoprotein cholesterol (HDL) in some human and animal feeding trials (2). In addition, intake of FO without adequate antioxidant supplementation is commonly associated with increased *in vivo* lipid peroxidation and decreased tissue antioxidant content in the plasma, heart, and liver (3,4). The enhanced *in vivo* lipid peroxidation induced by FO has been attributed to an increased unsaturation of membrane phospholipids resulting from the intake of highly unsaturated n-3 PUFA, such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) found in FO (3,4). Because the enzymes of cholesterol biosynthesis reside in the plasma membrane of the endoplasmic reticulum, which is rich in PUFA content, the increased lipid peroxidation associated with FO intake has been related to FO-induced hyperlipidemia (5).

Lipid peroxidation results in the formation of lipid hydroperoxides (LPO), which are substrates for cytosolic glutathione peroxidase (GSHPx). Selenium (Se) is an essential component for Se-dependent glutathione peroxidase (SeGSHPx) and has been shown to inhibit lipid peroxidation and hyperlipidemia when supplemented at doses above basal requirements (6). There is also non-selenium-dependent glutathione peroxidase (non-SeGSHPx) activity found in the cytosol that consists of the activity of some glutathione S-transferases. These glutathione S-transferases catalyze reactions of organic peroxides but not hydrogen peroxide with GSH to form oxidized glutathione (GSSG) and alcohols. The distribution of cellular SeGSHPx and glutathione S-transferases varies among tissues and species. Total GSHPx activity is measured using *t*-butylperoxide, as it detects both SeGSHPx and glutathione S-transferases.

Supplementation of Se is associated with higher hepatic concentrations of GSH (7,8), a potent intracellular inhibitor of lipid peroxidation (9). Vitamin E (Vit E), known to inhibit the chain reaction of lipid peroxidation in the membrane, has a sparing effect on the requirement of Se (10). However, the effects of a combined supplemental intake of Vit E and Se on inhibiting *in vivo* lipid peroxidation and on modulating tissue levels of GSH, SeGSHPx, and non-SeGSHPx activity have not been examined previously. Since Vit E has been shown to be only partially effective at inhibiting *in vivo* lipid peroxidation induced by FO ingestion (11), a supplemental combination of Vit E and Se could be more effective in this regard. Moreover, as supplementation of Vit E (12) and Se (6) have both been associated with decreased plasma concentrations of total cholesterol (TC) and LDL, the combined supplementation of these nutrients may

Choline bitartrate	11.2	11.2	11.2	11.2
Sodium selenate	0.046	0.8229	0.046	0.8229
Vit E acetate	0.052	0.052	0.256	0.256
Metabolizable energy, MJ/kg	15.4	15.4	15.4	15.4

<sup>a</sup>FO = fish oil; FO + Se = fish oil + selenium; FO + Vit E = fish oil + vitamin E; FO + Vit E + Se = fish oil + vitamin E + selenium. All diets were formulated at McGill University and prepared in pellet form by Dyets Inc. (Bethlehem, PA).

<sup>b</sup>Menhaden oil (MO) was refined and antioxidant free. FA composition of FO is as follows (% by wt): 14:0, 6.85; 15:0, 0.46; 16:0, 14.83; 16:1, 9.74; 16:2, 1.62; 16:3, 1.51; 16:4, 1.53; 17:0, 0.38; 18:0, 2.55; 18:1, 9.58; 18:2, 1.93; 18:3, 1.48; 18:4, 3.09; 19:0, 0.00; 20:0, 0.17; 20:1, 1.48; 20:2, 0.18; 20:3, 0.37; 20:4, 2.09; 20:5, 14.16; 21:5, 0.76; 22:0, 0.10; 22:1, 0.33; 22:4, 0.24; 22:5, 2.82; 22:6, 10.26; 24:0, 0.60; 24:1, 0.22. Remaining percentage is composed of the weight of unidentified FA and glycerol. MO was analyzed for pesticides and found to contain 0.07 µg/g α-BHC and 0.20 µg/g *p,p'*-DDE [method detection limit (MDL) of 0.02 µg/g]. Results of mineral analysis of MO include (µg/g): mercury <0.05, copper 0.6 (MDL of 0.3 µg/g), lead <2.5, selenium <5, arsenic <6, tin <1.8, cadmium <0.3.

<sup>c</sup>Safflower oil (SAFF) was added to prevent EFA deficiency. Vit E concentration of SAFF is 350 ppm α-tocopherol, 180 ppm other tocopherols. FA profile of SAFF included (% by wt): 14:0, trace; 16:0, 6.9; 16:1, trace; 18:0, 2.9; 18:1, 12.2; 18:2, 78.0; 18:3, trace.

<sup>d</sup>Cholesterol, USP, added to MO 4.535 g/kg. MO contains 350 mg cholesterol/100 g MO.

<sup>e</sup>The mineral mix was free of Se and was composed of (g/kg): calcium carbonate 336.4; calcium phosphate, monobasic 285.0; magnesium oxide 2.985; potassium iodate (10 mg KI/g) 0.76; potassium phosphate, dibasic 40.76; sodium chloride 11.45; cupric carbonate 0.084; cobalt chloride 0.133; sodium fluoride 0.002; ferric citrate 25.45; manganous carbonate 0.229; ammonium paramolybdate 0.008; zinc carbonate 0.53; sucrose 296.209. Sodium selenate (10 mg/g sodium selenate) was added separately to make the diets; for basal Se diets 0.046; for high Se diets 0.8229.

<sup>f</sup>The vitamin mix was free of Vit E and was composed of (g/kg): vitamin A palmitate (500 IU/g) 6.88; vitamin D<sub>3</sub> (400,000 IU/g) 0.9315; vitamin K<sub>1</sub> premix (10 mg/g) 110.0; biotin 0.03; folic acid 0.3; niacin 13.5; pantothenate (Ca) 1.5; riboflavin 2.25; thiamine HCl 3.0; pyridoxine HCl 0.9; vitamin B<sub>12</sub> (0.1%) 1.5; sucrose 866.0885. Vit E acetate (500 IU/g) was added separately to make the diets; for basal Vit E diets 0.052; for high Vit E 0.260.

exert synergistic plasma cholesterol-lowering effects in association with FO feeding.

In the present study, the effects of Vit E and Se supplementation were studied in association with FO feeding with respect to: (i) endogenously produced GSH, SeGSHPx, and non-SeGSHPx activity; (ii) *in vivo* lipid peroxidation; and (iii) plasma lipid concentrations. The plasma, heart, and liver were examined to investigate whether these tissues respond similarly to the effects of Se and Vit E supplementation on FO-induced *in vivo* lipid peroxidation.

## MATERIALS AND METHODS

**Animals and diets.** Thirty-two male Golden Syrian hamsters weighing on average 112 ± 3 g at 10 wk of age were obtained from Charles River Laboratories (St-Constant, Québec, Canada). Eight animals were randomly assigned to each one of the four dietary treatments for 3 wk after being acclimatized for 4 wk. Hamsters began consuming their respective diets in a staggered manner. The staggered procedure involved the inclusion of one hamster randomly chosen from each diet so that four hamsters began consuming their respective diets, one hamster from each diet per day. The staggered

design was necessary in order to allow for equal sampling across treatment groups at the end of the experiment when animals were killed in a staggered manner over several days. Diets were prepared in pellet form and vacuum packed by Dyets (Bethlehem, PA). Diets were kept refrigerated at 4°C. One bag was opened every week to feed the hamsters for the upcoming week. The exact composition of the diets is given in Table 1. The basal diet consisted by weight of 15.9% vitamin-free casein, 12.9% FO, 1.38% safflower oil, 0.46% cholesterol, 30.24% cornstarch, 9.9% dextrinized cornstarch, 18.64% sucrose, 4.3% cellulose, 4.3% mineral mix (without Se), 0.86% vitamin mix (without Vit E), and 1.12% choline bitartrate. Suitable vitamin and mineral mixes for hamster needs were developed following the National Research Council (NRC) requirements (13) and were given at 1.3 times the requirements to ensure an adequate intake of those nutrients. Separate additions of Se and Vit E were made for the final formulations of the diets. The basal Se diet provided 0.19 mg of Se/kg diet, whereas the supplemental Se diet provided 3.4 mg of Se/kg diet as sodium selenate (Na<sub>2</sub>SeO<sub>3</sub>). The basal Vit E diet provided 27 IU tocopherol acetate/kg diet, whereas the supplemental Vit E diet provided 129 IU of tocopherol acetate/kg diet [10 tocopherol equivalents (TE) = 10 mg D-α-

tocopherol = 15 IU]. The diets included: (i) FO; (ii) FO + Vit E; (iii) FO + Se; and (iv) FO + Vit E + Se.

Hamsters were housed in a room of controlled light (light 0700–1900 h) in plastic-bottomed cages and fed diets and tap water *ad libitum*. Fresh diets were fed to the hamsters daily and uneaten food was discarded. Food consumption was measured daily and body weights were recorded weekly. Care and handling of the hamsters conformed to the guidelines of the McGill University Animal Care Committee and Canadian Council of Animal Care (14).

**Sample preparation.** At the end of the feeding period, the hamsters were fasted 13.5 to 20 h. They were anesthetized with CO<sub>2</sub> and killed by exsanguination after cardiac puncture. Blood was drawn into vacutainer tubes containing EDTA. The plasma was immediately isolated by centrifugation at 1,500 × *g*, 4°C, for 10 min and aliquoted into microcentrifuge tubes. Liver and heart were immediately removed, rinsed in ice-cold saline, blotted, and rapidly frozen in liquid nitrogen. Both plasma and tissues were stored at –80°C until analysis.

## EXPERIMENTAL PROCEDURES

**Plasma lipids.** Automated enzymatic methodology using the Abbott VP Super System (Abbott, Irving, TX) with Abbott enzymatic reagent kits measured plasma TG (Abbott Kit 6097), TC (Abbott Kit 6095), and HDL (Abbott Kit 6039). LDL + VLDL were calculated from the difference between TC and HDL.

**Plasma TBARS.** Plasma concentrations of TBARS were measured using a modified method of Asakawa and Matsushita (15) and Wong *et al.* (16). A standard curve was constructed using a 1,1,3,3-tetramethoxypropane solution (Sigma T 9889; St. Louis, MO) (1200 μmol/L 0.01M HCl). The assay consisted of 100 μL of plasma or standard, 12.5 μL of thiobarbituric acid solution (Sigma T 5500) (110.99 mmol/L, 0.1 M NaOH), 100 μL of 85% aqueous orthophosphoric acid solution (Fisher A242-1; Fairlawn, NJ) (11.56 mmol/L), and 12.5 μL of BHT solution (Sigma B 1378) (3 mmol/L ethanol) to a final volume of 225 μL. Samples and standards were heated for 45 min at 90°C in a boiling water bath. After cooling, 250 μL of *n*-butanol (Sigma 19417) and 25 μL of saturated sodium chloride were added. Following centrifugation, the extraction of both sample and standard was accomplished with removal of 200 μL of *n*-butanol upper phase to microtiter plate wells. Plasma TBARS were expressed as μmol/mL of plasma. Absorbance was read at 540 and 590 nm using the series 750 microtiter plate reader (Cambridge Technology, Inc., Cambridge, MA).

**Total GSHPx, SeGSHPx, and non-SeGSHPx (glutathione S-transferase) activity.** Tissue supernatants were assayed for total GSHPx and SeGSHPx activity using an automated modification (17) of the coupled assay of Paglia and Valentine (18). The assay mixture was prepared fresh daily and contained 150 mM potassium phosphate buffer (pH 7.0); potassium phosphate, monobasic (Sigma P 5379); potassium phosphate, dibasic (P 5504), 5 mM EDTA, disodium salt (Sigma E 5134); 0.5 mM sodium azide (Sigma S 2002); 2 mM GSH (reduced, crystalline-free acid) (Sigma G 6654); 0.24 mM NADPH (Sigma

N 6505); and 1 U/mL of glutathione reductase (GSSGRase, EC 1.6.4.2) (Sigma G 3664). Total GSHPx activity and SeGSHPx activity were determined using 1.2 mM and 0.3 mM *t*-butylperoxide (Sigma B 2633) as substrates, respectively. The blank activity was significantly lower with 0.3 mM *t*-butylperoxide than with hydrogen peroxide, and for this reason *t*-butylperoxide was used instead. The ability to detect only SeGSHPx activity using a concentration of 0.3 mM *t*-butylperoxide was also confirmed in a study by Prohaska (19). Non-SeGSHPx activity due to glutathione S-transferases was determined from the difference between total GSHPx activity and SeGSHPx activity. Reactions were carried out using the Abbott VP Super System at 37°C with a 340/380 nm filter. The sample cuvette contained 250 μL of the assay mixture and 5 μL of sample. The reaction was initiated by the addition of substrate. One unit (U) of activity catalyzes the oxidation of 1.0 μmol of reduced NADPH per min, and was expressed as mU/mg of protein.

**Tissue GSH and GSSG.** The detection of GSH and GSSG was done using a Cayman chemical kit (GSH Assay Kit Cat# 703002; Ann Arbor, MI). The kit protocol was modified by homogenizing tissue using a homogenizing buffer made up of 5% sulfosalicylic acid (wt/vol) at pH 1.0 in order to maintain the ratio of GSH/GSSG, which is subject to radical change without the acidic pH (20). Protein content was extracted by adding metaphosphoric acid (Aldrich 23,927-5; Milwaukee, WI) and centrifuging at 3,000 × *g* for 5 min. Supernatant was then stored at –80°C for later analysis. For the final analysis, the supernatant was adjusted to pH 7.0 with the addition of triethanolamine (Aldrich T5, 830-0) and diluted so that absorbance of the sample fell within the absorbance of the standard curve values specified by the kit protocol. GSSG was measured by derivatizing GSH with 2-vinylpyridine. The ELX 8081U Ultra Microplate reader (Bio-Tek, Inc., Winooski, VT) was used along with the KC4 Kinetic software for Windows version 2.6 RevXX (Bio-TEK) using a 405 nm filter.

**Tissue LPO.** Heart and liver were analyzed for LPO using an LPO kit assay (Kamiya Biomedical, Thousand Oaks, CA) based on the method of Oshishi *et al.* (21). The lipid was extracted by the method of Folch *et al.* (22). The absorbance of the sample was determined at 620 nm using the series 750 microtiter plate reader (Cambridge Technology, Inc.).

**Tissue Vit E.** α-Tocopherol content of heart and liver tissue was measured by the HPLC method of Thompson and Hatina (23). Tissues were homogenized in water, diluted 1:1 with ethanol to de-proteinize them, and the tocopherols were extracted with heptane. Samples of 100 μL volume were injected for HPLC separation on a silica column [25 cm × 4.6 mm i.d., 5 μm particle size, Supelcosil LC-SI (Supelco Canada Ltd., Oakville, Ontario, Canada)] using a Waters 717+ autosampler (Waters Scientific Ltd., Mississauga, Ontario, Canada), Waters model 510 pump, and PerkinElmer 650 fluorescence detector. The mobile phase (1% 2-propanol in hexane) was degassed by sonication and run at a flow rate of 2 mL/min at ambient temperature. Detector settings were as follows: excitation wavelength 290 nm and slit 10 nm, emission wavelength 320 nm and slit 12 nm. A threefold higher detector

**TABLE 2**  
ANOVA of the Effects of Dietary Vit E and Se Supplementation on Body Weight Gain and Average Daily Intake of Adult Male Syrian Hamsters Fed FO Diets for 3 wk<sup>a</sup>

Variable	Dietary treatment				Significance of main and interaction effects <sup>b</sup>		
	FO	FO + Se	FO + Vit E	FO + Vit E + Se	Vit E	Se	Vit E × Se
Average daily intake (g/d)	5.90 ± 0.12 <sup>a</sup>	6.03 ± 0.12 <sup>a</sup>	5.79 ± 0.12 <sup>b</sup>	5.58 ± 0.12 <sup>b</sup>	0.05	NS	NS
Body weight gain (g)	-1.4 ± 1.9	-0.60 ± 1.9	-4.5 ± 1.9	-4.9 ± 1.9	NS	NS	NS

<sup>a</sup>Values are mean ± SEM ( $n = 8$ ). Diets and abbreviations are as indicated in Table 1. Means within rows with no common roman superscript letter differ significantly ( $P < 0.05$ ). NS = nonsignificant.

<sup>b</sup>The four interaction effects include FO = basal Vit E × basal Se; FO + Se = basal Vit E × supplemental Se; FO + Vit E = supplemental Vit E × basal Se; and FO + Vit E + Se = supplemental Vit E × supplemental Se. Main effects include the effect of basal Vit E vs. supplemental Vit E and basal Se vs. supplemental Se.

sensitivity was used for measurement of  $\alpha$ -tocopherol in heart because of the lower levels of Vit E compared to liver.

**Tissue protein.** Protein concentrations of all supernatants were determined using the biuret assay (Abbott Total Protein Kit# LN5A13-26). BSA was used as standard. Homogenates were centrifuged for 5 min at 12,000 ×  $g$  and supernatants assayed. The Abbott VP Super System was used.

**Data analysis.** Data were tested using the mixed model procedure for all analyses of SAS 6.2 (24). The aim of the study was to determine whether Vit E and Se had independent or interaction effects on the dependent variables tested. Hence, the main effects of the Vit E and Se treatments and their possible interaction effects were assessed using a fixed-effect 2 × 2 factorial design. Data were assessed for normality (univariate) and homogeneity of variance using a mixed model procedure. Blocking was an integral part of the experimental design owing to the staggered feeding that occurred in distinct blocks over time. Blocking was therefore considered

to be a source of variation and was included as a variable in the statistical model to ensure that it did not interfere with or confound the significant effect of treatment on the dependent variable. The average daily food intake and body weight gain were considered in the statistical model as co-variables; however, these co-variables were found not to affect the results significantly and so were omitted from the model. The statistical significances of the differences between least square means were determined using the Scheffé test. Differences of  $P < 0.05$  were considered significant.

## RESULTS

**Average daily food intake.** A significant main effect of Vit E ( $P < 0.05$ ) on average daily food intake was observed. Fewer grams of diet were consumed by hamsters fed the diets supplemented with Vit E than by hamsters fed the diets not supplemented with Vit E (Table 2).

**TABLE 3**  
ANOVA of the Effects of Dietary Vit E and Se Supplementation on Plasma Lipid Concentrations (TC, LDL + VLDL, HDL, TG, and LDL + VLDL/HDL Ratios) of Adult Male Syrian Hamsters Fed FO Diets for 3 wk<sup>a</sup>

Variable	Dietary treatment				Significance of main and interaction effects <sup>b</sup>		
	FO	FO + Se	FO + Vit E	FO + Vit E + Se	Vit E	Se	Vit E × Se
TC (mg/dL)	285 ± 16 <sup>a</sup>	220 ± 16 <sup>b</sup>	265 ± 15 <sup>b</sup>	233 ± 16 <sup>b</sup>	NS	0.01	NS

ANOVA of the Effects of Dietary Vit E and Se Supplementation on Heart LPO, GSH, GSSG, SeGSHPx Activity, Non-SeGSHPx Activity, and Vit E of Adult Male Syrian Hamsters Fed FO Diets for 3 wk<sup>a</sup>

Variable	Dietary treatment				Significance of main and interaction effects <sup>b</sup>		
	FO	FO + Se	FO + Vit E	FO + Vit E + Se	Vit E	Se	Vit E × Se
LPO (nmol/g protein)	834 ± 170 <sup>a</sup>	1430 ± 170 <sup>b</sup>	883 ± 170 <sup>a</sup>	1080 ± 170 <sup>b</sup>	NS	0.05	NS
GSH (μmol/g protein)	16 ± 1	16 ± 1	16 ± 1	16 ± 1	NS	NS	NS
GSSG (μmol/g protein)	11 ± 2 <sup>a</sup>	5 ± 2 <sup>b</sup>	7 ± 2 <sup>a</sup>	6 ± 2 <sup>b</sup>	NS	0.05	NS
SeGSHPx (units/mg protein)	40 ± 4	50 ± 4	45 ± 4	44 ± 4	NS	NS	NS
Non-SeGSHPx (units/mg protein)	10 ± 2	11 ± 2	9 ± 2	13 ± 2	NS	NS	NA
Vit E (μg/g protein)	10 ± 10 <sup>a</sup>	12 ± 10 <sup>a</sup>	86 ± 10 <sup>b</sup>	73 ± 10 <sup>b</sup>	0.005	NS	NS

<sup>a</sup>Values are mean ± SEM ( $n = 8$ ). Means within rows with no common superscript roman letter differ significantly ( $P < 0.05$ ). LPO, lipid hydroperoxides; GSH, glutathione; GSSG, oxidized glutathione; SeGSHPx, Se-dependent glutathione peroxidase activity; Non-SeGSHPx, non-Se-dependent glutathione peroxidase activity. Diets and abbreviations are as indicated in Tables 1 and 3.

<sup>b</sup>The four interaction effects include FO = basal Vit E × basal Se; FO + Se = basal Vit E × supplemental Se, FO + Vit E = supplemental Vit E × basal Se, and FO + Vit E + Se = supplemental Vit E × supplemental Se. Main effects include the effect of basal Vit E vs. supplemental Vit E and basal Se vs. supplemental Se.

**Body weight gain.** Neither Vit E nor Se was associated with any significant effects on body weight gain (Table 2).

**Plasma lipids.** As shown in Table 3, a significant main effect of Se on plasma TC and LDL + VLDL concentrations ( $P < 0.01$  and  $P < 0.005$ , respectively) was observed. The plasma of hamsters supplemented with Se had 18% lower TC concentrations and 23% lower LDL + VLDL than plasma of the non-Se-supplemented groups (Table 3). A significant interaction effect of Vit E × Se on plasma HDL and TG concentrations was observed ( $P < 0.05$  and  $P < 0.05$ , respectively)

(Table 3); however, no significant difference between groups was observed *via* the Scheffé multiple comparison test. Blocking was shown to affect significantly the concentrations of TC ( $P < 0.005$ ), LDL + VLDL ( $P < 0.001$ ), and TG ( $P < 0.05$ ).

**Plasma TBARS.** Neither Vit E nor Se was associated with any significant effect on plasma TBARS concentrations (data not shown).

**Tissue LPO.** A significant main effect of Se ( $P < 0.05$ ) on concentrations of LPO was observed in the heart (Table 4). The supplementation of Se to FO diets resulted in a higher

<sup>a</sup>Values are mean ± SEM ( $n = 8$ ). Means within rows with no common superscript roman letter differ significantly ( $P < 0.05$ ). Diets and abbreviations are as indicated in Table 1. For other abbreviations see Tables 2–4.

<sup>b</sup>The four interaction effects include FO = basal Vit E × basal Se; FO + Se = basal Vit E × supplemental Se, FO + Vit E = supplemental Vit E × basal Se, and FO + Vit E + Se = supplemental Vit E × supplemental Se. Main effects include the effect of basal Vit E vs. supplemental Vit E and basal Se vs. supplemental Se.

heart concentration of LPO as compared to hamsters receiving FO alone. In the liver, neither Vit E nor Se was associated with any significant effect on LPO concentrations (Table 5). Blocking was associated with significant effects on heart and liver LPO ( $P < 0.01$ ).

**Tissue GSH.** Neither Vit E nor Se was associated with any significant effects on heart GSH concentrations (Table 4). Also in the liver, neither Vit E nor Se was associated with any significant effects on liver GSH concentrations (Table 5). Blocking was associated with significant effects on heart GSH ( $P < 0.0001$ ) and liver GSH ( $P < 0.05$ ).

**Tissue GSSG.** A significant main effect of Se ( $P < 0.05$ ) on heart GSSG concentration was observed (Table 4). The supplementation of Se was associated with significantly lower levels of GSSG in the heart as compared to the hamsters not supplemented with Se (Table 4). In the liver, neither Vit E nor Se was associated with any significant effects on GSSG concentrations (Table 5). Blocking was associated with significant differences in heart and hepatic GSSG concentrations ( $P < 0.005$ ).

**Tissue GSH/GSSG ratio.** Neither Vit E nor Se was associated with any significant effects on heart GSH/GSSG ratios (data not shown). In the liver, a significant main effect of Se ( $P < 0.05$ ) on GSH/GSSG ratios (Table 5) was seen. Hamsters fed the diets supplemented with Se had significantly higher liver GSH/GSSG ratios compared to hamsters not fed supplemental Se (Table 5). The hepatic GSH/GSSG ratio was affected significantly by blocking ( $P < 0.05$ ).

**Tissue SeGSHPx activity.** Neither Vit E nor Se was associated with any significant effects on heart SeGSHPx activity (Table 4). For liver SeGSHPx activity, a main effect of Se ( $P < 0.05$ ) was observed (Table 5). The supplementation of Se was shown to increase SeGSHPx activity in the liver. SeGSHPx activity was significantly affected by blocking in the heart ( $P < 0.05$ ) and liver ( $P < 0.0001$ ).

**Tissue non-SeGSHPx (glutathione S-transferase) activity.** Neither Vit E nor Se was associated with any significant effect on heart non-SeGSHPx activity (Table 4). In the liver, a significant main effect of Vit E ( $P < 0.05$ ) on non-SeGSHPx activity was observed (Table 5). The supplementation of Vit E was associated with a decrease in hepatic non-SeGSHPx activity. Liver non-SeGSHPx activity was affected significantly by blocking ( $P < 0.05$ ).

**Tissue Vit E.** A significant main effect of Vit E ( $P < 0.005$ ) on Vit E concentrations was observed in the heart (Table 4). The Vit E-supplemented hamsters had significantly higher concentrations of Vit E in the heart compared to the hamsters not supplemented with Vit E (Table 4). In the liver, a significant main effect of Vit E ( $P < 0.0005$ ) on Vit E concentrations was observed (Table 5). The Vit E-supplemented hamsters had significantly higher concentrations of Vit E in the liver compared to the hamsters not supplemented with Vit E (Table 5).

## DISCUSSION

The aim of the present work was to test the effects of large-dose supplementation of Vit E and Se, when provided either

singly or in combination, on FO-induced tissue lipid peroxidation and hyperlipidemia. Although Se supplementation was not associated with differences in indicators of oxidative stress in the liver and plasma, a higher cardiac LPO content was shown with Se supplementation. This observation is in marked contrast to the observations of Jamall *et al.* (25), who noted a decrease in cardiac TBARS content in myopathic Syrian Golden hamsters receiving dietary Se supplementation at a level of 1 ppm in a standard laboratory diet. In addition to differences in hamster strains, the 3.5 higher dose of Se used in the present study may have exerted a pro-oxidative action in concert with the FO-rich diet. The dose of Se (3.4 ppm) used in the present work was chosen to be comparable to, but more moderate than, the level of 5 ppm dietary Se used in the work of Vinson *et al.* (6), which showed significant plasma lipid- and plasma lipid peroxide-lowering effects in Syrian hamsters fed Se in conjunction with a low-fat diet.

The supplementation of Se also showed no detrimental effects on the histopathology of major organ systems when Syrian hamsters were fed 5 ppm Se for 25 wk in conjunction with a standard laboratory diet (26). In the present study, it is conceivable that a pro-oxidative action of Se supplementation in the heart may have been induced by the concurrent feeding of FO, as FO feeding has been shown to result in an increase in cardiac lipid peroxidation (27,28). The greater sensitivity of the heart to the pro-oxidative action of Se also may be explained by previous work showing heart tissue to be less capable than the liver of synthesizing dimethyl selenide, which is a major metabolic route for detoxifying subacute doses of Se (29). High doses of Se are processed for elimination by interacting with endogenously produced GSH, which results in the consequent methylation of Se for excretion (30). Selenotrisulfides formed inside the cell from the reaction of Se with GSH react with oxygen to produce reactive oxygen species involved in lipid peroxidation (29). In this regard, the decrease in heart GSSG content following Se supplementation could have been due to an increased formation of selenotrisulfides.

The pro-oxidant effect of Se supplementation also may have been associated with the unchanged cardiac SeGSHPx activity seen with Se supplementation. The higher LPO content in the heart tissue following Se supplementation could have inhibited the capability of Se to induce heart SeGSHPx activity, as lipid peroxidation negatively affects SeGSHPx activity (31). Alternatively, the capability of Se to induce heart SeGSHPx activity may be a species-specific effect in the hamster, as the guinea pig heart is refractory in this regard (32). It is thus possible that heart SeGSHPx activity in the hamster was not responsive to Se supplementation, although the hamster has not been studied to our knowledge in this regard. The capability of Se to induce SeGSHPx activity, however, was organ specific as SeGSHPx activity in liver tissue was increased with Se supplementation (Table 5). Previous work in the rat has shown that SeGSHPx activity in the liver is more sensitive to induction *via* Se supplementation than heart tissue (33).

The supplementation of Vit E was not associated with dif-

ferences in hepatic SeGSHPx activity, which agrees with the findings of Kaasgaard *et al.* (3), who also showed a lack of association between the Vit E supplementation and hepatic SeGSHPx activity in monkeys fed menhaden oil. On the other hand, the supplementation of Vit E was associated with a decrease in non-SeGSHPx activity in the liver (Table 5). The reasons for the lowering effect of Vit E supplementation on non-SeGSHPx activity are not clear; however, the activity of non-SeGSHPx in the hamster liver accounts for 43% of total GSHPx activity and for this reason plays an important role against oxidative stress. In the heart, both SeGSHPx and non-SeGSHPx activity were unchanged in the Vit E-supplemented hamsters, which agrees with a previous study that showed that cardiac total GSHPx activity was unaffected by Vit E in the normal Syrian hamster (34). Such differential responses of the heart and liver further illustrate that tissue-specific responses of antioxidant enzymatic defenses can occur with antioxidant supplementation.

The enhancement of lipid peroxidation with Se treatment was unaffected by the increased tocopherol content in heart tissue following Vit E supplementation (129 IU/kg diet), which provided a dietary intake approximately five times the NRC requirement for the hamster (13). Dietary supplementation of Vit E was also associated with significantly higher hepatic tocopherol concentrations. The level of Vit E supplementation used in the present work was based on the findings of Farwer *et al.* (35), which showed that 5.6 mg or 8.4 IU TE per MJ of diet were required to maintain adequate hepatic levels of Vit E in rats fed a diet high in PUFA. In both the heart and liver, however, higher tocopherol concentrations were not associated with lower tissue concentrations of LPO. Similarly, Demoz *et al.* (36) showed a lack of association between hepatic tocopherol concentrations and lipid peroxidation in the livers of EPA-fed rats. Higher dietary doses of Vit E may have been required to exert antioxidant action in hamsters fed diets containing FO-based diet; Kubow *et al.* (11) demonstrated lower hepatic lipid peroxidation concentrations in hamsters fed FO-based diets following supplementation with a 562 IU Vit E/kg diet. Supplementation of Vit E also was not associated with lower plasma concentrations of TBARS. This latter finding agrees with previous work showing an absence of effect of Vit E supplementation on decreasing plasma TBARS concentrations in humans (37) and hamsters fed FO (11).

In the present study, the supplementation of Se was associated with significantly higher hepatic GSH/GSSG ratios, which resulted in a ratio of 10:1 found in cells under normal conditions. Previous studies have shown depressed hepatic GSH concentrations in FO-fed rats (38,39); however, in the present study, hepatic GSH/GSSG ratios were within the normal range as seen in the rat fed a standard rodent diet (40,41). The effects of Se supplementation on tissue GSH concentrations have not been studied previously in association with FO-based diets. Earlier studies have shown, however, that supplementation of Se results in increased hepatic GSH concentrations in various species (7,8). In the present study, the supplementation of Se was not associated with changes in GSH/GSSG ratios in the heart and suggests tissue-specific effects in this regard.

A major decrease in plasma concentrations of LDL + VLDL and TC (Table 2) was observed with Se supplementation. Vinson *et al.* (6) reported a similar reduction in TC and LDL + VLDL in hamsters fed nonpurified diets supplemented with Se at a level of 5 mg/kg diet, comparable to the Se supplemental levels of 3.4 mg/kg diet used in the present study. The lack of significant lowering of TG concentrations shown in the present study is in contrast with previous studies that noted significant decreases in plasma TG concentrations with Se supplementation in the human (42) and the rat (43) but concurs with the findings of Vinson *et al.* (6), who observed no significant change in plasma TG concentrations in hamsters fed diets supplemented with Se.

The degree of plasma TC and LDL lowering (18 and 23%, respectively) observed with Se supplementation in the present work is similar to that observed with other potent cholesterol-lowering nutritional and pharmaceutical agents. For example, nicotinic acid is used therapeutically to lower LDL cholesterol by 15–30% and pharmaceuticals such as bile acid sequestrants and probucol lower LDL levels by 10–30% and 10–15%, respectively (44). The large magnitude of the plasma TC- and LDL-lowering effect of Se suggests that supplementation of Se could be a worthwhile avenue to explore as a treatment for diet-induced hypercholesterolemia. In this regard, a 6-wk supplementation with Se was associated with a decrease in plasma TC and LDL concentrations in a recent human study (42). Also, peroral sodium selenite therapy in hypothyroid patients was shown to be associated with lowered TC and LDL plasma concentrations (45). Thyroid hormone is one the most potent agents known to reduce serum LDL concentrations and is known to affect hepatic levels of LDL receptor by enhancing LDL receptor gene transcription when administered at physiological doses (46). As Se is needed for hepatic conversion of thyroxine ( $T_4$ ) to 3,3,5-triiodothyronine ( $T_3$ ) through Type I iodothyronine deiodinase, Se supplementation may lower plasma cholesterol concentrations indirectly *via* its key role in thyroid hormone metabolism.

Although previous work has shown the supplementation of Vit E to be associated with a reduction in plasma TC in the presence of FO feeding in the hamster (11), no significant effect of Vit E supplementation was noted in the present work. The reason for the difference between the previously mentioned studies may have been due to a 4.5-fold higher supplemental dose of Vit E provided in the earlier work. No significant effect of Se or Vit E supplementation was noted on plasma LDL/HDL ratios, which were comparable to those previously seen in hamsters fed FO diets (47). The relatively high LDL/HDL ratios may be due to the adverse lipidemic response of hamsters to FO intake; previous studies have shown that FO intake in the hamster is associated with depressed HDL concentrations (48).

Although tissue-specific effects were observed in the improvement of antioxidant indices following supplementation of Se and Vit E, antioxidant supplementation was shown to be ineffective in lowering tissue lipid peroxidation in FO-fed hamsters. Moreover, combined supplementation of Vit E and Se provided no additional benefit in terms of oxidative stress

or antioxidative indices in the presence of FO feeding. Although the supplementation of Se was associated with an increased hepatic GSH/GSSG ratio and SeGSHPx activity, no changes in liver concentrations of LPO were noted. Likewise, the higher hepatic and cardiac Vit E content following Vit E supplementation was not associated with lowered oxidative stress. In addition, the hamster heart showed a pro-oxidative response to Se supplementation in terms of lipid peroxidation despite an apparently favorable decrease in heart GSSG content. Plasma lipid peroxidation status was also refractory to both Vit E and Se supplementation. In contrast, Se supplementation showed favorable effects on plasma LDL + VLDL and TC concentrations, suggesting that antioxidative effects are unlikely to be involved in the hypolipidemic effects of Se. The mechanisms involved in the plasma lipid-lowering effects of Se supplementation and in the resistance of *in vivo* lipid peroxidation to high-dose Se and Vit E supplementation with FO feeding require additional study. In addition, the pro-oxidative effects of Se supplementation in heart tissue also need further investigation, particularly since the plasma lipid-lowering effect of Se supplementation is receiving increased research attention.

**ABSTRACT:** Endothelium-dependent vasodilation (EDV), LDL particle size, and antibodies against oxidized LDL (oxLDL<sub>ab</sub>) have been shown to be related to the development of atherosclerosis and cardiovascular disease. In this study, we investigated whether LDL particle size, oxLDL<sub>ab</sub>, apolipoproteins, and lipoproteins are related to endothelial vasodilatory function in a population sample of 58 apparently healthy subjects aged 20 to 69 yr. EDV and endothelium-independent vasodilation (EIDV) were studied in the forearm during local administration of methacholine chloride (2 and 4 µg/min) or sodium nitroprusside (5 and 10 µg/min). Forearm blood flow was determined with venous occlusion plethysmography. In multiple stepwise regression analyses, neither oxLDL<sub>ab</sub> nor small LDL particles were significantly predictive of endothelial vasodilatory function. Instead, a high level of apolipoprotein B (apoB) was an independent predictor of both attenuated EDV and EIDV ( $r = -0.43$ ,  $P < 0.01$ , and  $r = -0.34$ ,  $P < 0.05$ , respectively). HDL cholesterol, on the other hand, was the only lipid variable that was significantly related to the EDV to EIDV ratio, an index of endothelial vasodilatory function ( $r = 0.35$ ,  $P < 0.01$ ). The inverse associations between apoB and both EDV and EIDV indicate that apoB might be an early marker of structural vascular changes in healthy subjects, whereas HDL seems to be more specifically related to endothelial vasodilatory function.

Paper no. L8867 in *Lipids* 37, 1135–1140 (December 2002).

Elevated LDL cholesterol is an important predictor of cardiovascular morbidity and mortality (1). LDL particles constantly diffuse across the arterial wall and sometimes become trapped in the extracellular matrix that constitutes the subendothelial space (2). Once trapped, LDL becomes oxidized (oxLDL) (3) and takes part in the development of atheroma through a broad spectrum of mechanisms, such as inhibition of the release of nitric oxide (NO), smooth muscle cell proliferation, platelet activation, recruitment of monocytes, and uncontrolled endocytosis of oxLDL by macrophages, leading to foam cell formation (4,5). One potentially important consequence of oxLDL formation may be the elicitation of an immune response. Indeed, antibodies against oxLDL (oxLDL<sub>ab</sub>) have been detected in both human and rabbit plasma and in atherosclerotic lesions

Abbreviations: apoA-1, apolipoprotein A-1; apoB, apolipoprotein B; EDV, endothelium-dependent vasodilation; EFL, endothelial function index; EIDV, endothelium-independent vasodilation; FBF, forearm blood flow; Mch, methacholine chloride; MDA, malondialdehyde; NO, nitric oxide; oxLDL, oxidized LDL; oxLDL<sub>ab</sub>, antibodies against oxLDL; SNP, sodium nitroprusside.

(6,7). However, the role of oxLDL<sub>ab</sub> in atherosclerosis is unclear, as elevated oxLDL<sub>ab</sub> titers have been reported to predict myocardial infarction (8), as well as to be inversely related to the intima-media thickness of the carotid artery in humans (9).

OxLDL also has been shown to promote atherosclerosis by impairing endothelium-dependent vasodilation (EDV) (10,11). Indeed, statin therapy, apart from lowering LDL cholesterol, also improves EDV (12). An impaired EDV is an early event in atherosclerosis (13) and is associated with several of the major cardiovascular risk factors, such as diabetes mellitus, hypertension, hypercholesterolemia, and smoking (14–17).

The inflow rate of LDL particles into the arterial wall has been suggested to increase for small LDL particles (18). Indeed, according to several cross-sectional and prospective studies, individuals with small, dense LDL particles have a higher risk of coronary artery disease (19–21).

The primary aim of this study was to investigate whether LDL particle size, oxLDL<sub>ab</sub>, or other markers of cholesterol metabolism are related to endothelial vasodilatory function in a population sample of apparently healthy subjects. In addition, we wished to investigate whether different measures of cholesterol metabolism are associated with LDL particle size and antibody titers against oxLDL.

## METHODS

**Subjects.** Subjects were randomly chosen from the population registry of Uppsala, Sweden. The study sample (Table 1) consisted of 58 healthy subjects (31 men and 27 women, 12 of whom were postmenopausal), aged 20 to 69 yr. The subjects underwent a complete history, physical examination, and a high-resolution B-mode ultrasonographic examination of the carotid arteries (Acuson 128 XP/10 with a 7.5 MHz transducer). None of the subjects had atherosclerotic plaques or an intima-media thickness in their common carotid arteries above 1.20 mm (mean value  $0.76 \pm 0.17$  mm). None of the subjects was on regular medication or had a history of any disease known to affect the cardiovascular system, or a history of any metabolic or other chronic disease. None of the women was on contraceptive or estrogen replacement therapy. Subjects with blood pressures higher than 160/95 mm Hg, fasting hyperglycemia ( $>6.0$  mmol/L), or pronounced hypercholesterolemia ( $>7.0$  mmol/L) at the investigation were not included. The study was approved by the Ethics Committee of Uppsala University and informed consent was obtained from each participant.

**Experimental procedure.** The studies began at 8 A.M. after an overnight fast and were carried out with the subjects in supine position. Room temperature was maintained at 20–22°C. An arterial catheter (1.0 mm; Ohmeda, Swindon, United Kingdom) was inserted into the brachial artery for regional infusion of methacholine chloride (Mch; Metakolinklorid, Apoteksbolaget, Umeå, Sweden), and sodium nitroprusside (SNP; Nitropress®, Abbott Labs, Chicago, IL). The arterial catheter was also used for collection of blood samples for determination of lipid metabolism.

Forearm blood flow (FBF) was measured by venous occlusion plethysmography with mercury-in-Silastic strain gauges (Elektromedicin, Kullavik, Sweden) and expressed as mL/min per 100 mL of forearm volume. Venous occlusion pressure was 40 mm Hg, and FBF was calculated as the mean value of five consecutive readings. EDV was assessed as FBF during intra-arterial infusion of Mch at doses of 2 and 4  $\mu$ g/min in the brachial artery, whereas endothelium-independent vasodilation (EIDV) was assessed as FBF during intra-arterial infusion of SNP at doses of 5 and 10  $\mu$ g/min. EDV and EIDV are expressed as the relative increase (%) in FBF during vasodilation with Mch or SNP, respectively. Registrations were performed during the fifth minute of vasodilation. EDV and EIDV were registered in random order, and washout periods of 20 min were allowed between drugs. The endothelial function index (EFI), reflecting the endothelial contribution to vasodilation, was calculated as the EDV/EIDV ratio (during administration of 4  $\mu$ g/min Mch and 10  $\mu$ g/min SNP, respectively).

The short-term (2 h) and long-term (3 wk) reproducibility of FBF during vasodilation with Mch and SNP with this method has a CV of 5–7% (22). We have recently found that the highest dose of Mch (4  $\mu$ g/min) results in a significant increase in forearm venous plasma nitrite and nitrate concentrations in healthy volunteers. The arteriovenous difference in plasma nitrite and nitrate concentrations showed more than a 10-fold increase in venous blood, indicating that Mch mediates vasodilation by an increased NO production (23).

**Biochemical studies.** LDL, VLDL, and HDL were isolated by a combination of preparative ultracentrifugation (24) and precipitation with a sodium phosphotungstate and magnesium chloride solution (25). Cholesterol concentrations were determined enzymatically in serum and in lipoprotein fractions (IL Test Cholesterol 181618-10; Instrumentation Laboratory Company, Lexington, MA), using a Monarch apparatus. The concentrations of serum apolipoprotein (apo) A-1 and B were determined by immunoturbidimetry in a Monarch apparatus (Orion Diagnostica, Espoo, Finland). LDL particle size was assessed on commercially available nondenaturing 2 to 16% polyacrylamide gradient gels as described previously (26,27). The CV (same serum run on different gels on different days) for LDL peak particle size was 0.3%, with a correlation coefficient of  $r = 0.99$ . To minimize the reading error from the gels, each lane was scanned twice. Mean values from the two readings were used in the present study.

**Antibody titers against modified lipoproteins.** Antibody titers were determined with a solid phase ELISA, as described earlier (28,29). Malondialdehyde-treated LDL (MDA-LDL) was prepared as described by Palinski *et al.* (30). As a routine procedure, modifications were checked by controlling the electrophoretic mobility in agarose gel of the modified lipoproteins. The antibody titer was defined as

$$\text{titer} = \frac{\text{absorbance (value in patient serum} - \text{that in postcoat)}}{\text{internal standard serum} - \text{that in postcoat}} \quad [1]$$

For IgG the postcoated wells gave no absorbance. Therefore, this correction was only made for IgM. We chose to determine MDA-LDL antibodies because MDA is a prominent epitope of oxLDL and seems to be more sensitive than other ligands to antibody detection (31,32).

**Statistical analysis.** A principal component factor analysis was performed to investigate the interrelationships between different measures of cholesterol metabolism. Relationships between endothelial vasodilatory function and measures of cholesterol metabolism were evaluated by linear regression analysis. A multiple stepwise regression analysis was conducted to identify independent determinants of endothelial vasodilatory function. Age and gender are related to EDV and EIDV (33) and were therefore included as confounding variables, together with the cholesterol metabolism markers in all multiple regression analyses.  $P < 0.05$  was regarded as significant, and the present sample size thereby had the power to detect a partial correlation coefficient above 0.25 as significant. Data are expressed as mean values  $\pm$  SD unless otherwise specified.

## RESULTS

Basic characteristics of the study sample are given in Table 1.

**Factor analysis.** The factor analysis, which included total cholesterol, LDL cholesterol, HDL cholesterol, LDL peak particle size, apoB, and IgM and IgG titers against oxLDL, resulted in three oblique factors (Table 2). Factor 1 was composed mainly of total cholesterol, LDL cholesterol, and apoB. Factor 2 was composed mainly of HDL cholesterol, LDL

<sup>a</sup>Data are presented as correlation coefficients. EDV, forearm blood flow (FBF) during administration of intra-arterial methacholine (4  $\mu\text{g}/\text{min}$ ) measuring endothelium-dependent vasodilation; EIDV, FBF during intra-arterial administration of nitroprusside (10  $\mu\text{g}/\text{min}$ ) measuring endothelium-independent vasodilation; EFI, endothelial function index calculated as FBF during intra-arterial administration of methacholine (4  $\mu\text{g}/\text{min}$ ) divided by FBF during intra-arterial administration of nitroprusside (10  $\mu\text{g}/\text{min}$ ). For other abbreviations see Table 1. \* $P < 0.05$ ; \*\* $P < 0.01$ .

**FIG. 1.** Correlations between serum apolipoprotein B and endothelium-dependent vasodilation (EDV;  $r = -0.43, P < 0.01$ ) (A) and endothelium-independent vasodilation (EIDV;  $r = -0.34, P < 0.05$ ) (B). EDV and EIDV are expressed as the relative increase (%) in forearm blood flow during administration of methacholine (4  $\mu\text{g}/\text{min}$ ) and sodium nitroprusside (10  $\mu\text{g}/\text{min}$ ), respectively.

EDV ( $r = -0.38, P < 0.01$ , during administration of 4  $\mu\text{g}/\text{min}$  Mch and  $r = -0.28, P < 0.05$ , during administration of 2  $\mu\text{g}/\text{min}$  Mch). EIDV was associated with apoB [ $r = -0.34, P < 0.05$ , during administration of 10  $\mu\text{g}/\text{min}$  SNP (Fig. 1) and  $r = -0.42, P < 0.01$ , during administration of 5  $\mu\text{g}/\text{min}$  SNP], the first factor ( $r = -0.34, P < 0.05$ , during administration of 10  $\mu\text{g}/\text{min}$  SNP and  $r = -0.27, P < 0.05$ , during administration of 5  $\mu\text{g}/\text{min}$  SNP), LDL cholesterol ( $r = -0.26, P < 0.05$ , during administration of 10  $\mu\text{g}/\text{min}$  SNP and  $r = -0.31, P < 0.05$ , during administration of 5  $\mu\text{g}/\text{min}$  SNP), and total cholesterol ( $r = -0.29, P < 0.05$ , during administration of 10  $\mu\text{g}/\text{min}$  SNP and  $r = -0.31, P < 0.05$ , during administration of 5  $\mu\text{g}/\text{min}$  SNP). The only significant predictor of the EFI was HDL cholesterol ( $r = 0.35, P < 0.01$ ).

**Multiple stepwise regression analysis.** When indices of cholesterol metabolism that were significantly associated with EDV, EIDV, or EFI in the univariate regression analysis were introduced into a multiple stepwise regression model together

with age and gender, apoB was inversely and independently related to both EDV and EIDV when evaluated at the highest dose of Mch or SNP, respectively ( $r = -0.43$ ,  $P < 0.01$ , for EDV and  $r = -0.34$ ,  $P < 0.05$ , for EIDV). HDL cholesterol was the only predictor of EFI ( $r = 0.35$ ,  $P < 0.01$ ). Neither LDL peak particle size, nor IgM and IgG titers against oxLDL, nor the factors obtained by factor analysis were independent predictors of EDV, EIDV, or EFI.

## DISCUSSION

The major finding of the present study was that neither antibody titers against oxLDL nor small LDL particles are significantly associated with endothelial vasodilatory function in apparently healthy subjects. Instead, a high level of apoB predicts attenuation in both EDV and EIDV, whereas HDL seems to be protective of endothelial vasodilatory function.

*In vitro* studies have shown that oxLDL takes part in the development of atheroma through a broad spectrum of mechanisms, including endothelial dysfunction (4,5). Hence, oxLDL, or lysolecithin from oxLDL, has been shown to impair EDV in rabbit aortic strips (10) and in perfused rabbit renal arteries under high-pressure conditions (11). Furthermore, Toikka *et al.* (34) reported an inverse relationship between EDV and plasma oxLDL levels in young men. Although immunization with oxLDL suppresses atherogenesis in rabbit models (35), the role of the immune response to oxLDL in atherosclerosis is unclear. In the present study, factor analysis revealed that IgM titers against oxLDL are associated with HDL cholesterol, apoA-1, and LDL particle size. Because high levels of HDL and apoA-1 have been shown to be associated with a lower risk of coronary artery disease and lower intima-media thickness of the carotid artery, and small LDL particles have been associated with coronary artery disease (19–21,36,37), our finding might indicate that IgM titers against oxLDL are protective against atherosclerosis. Indeed, Fukumoto *et al.* (9) recently reported that oxLDL titers are inversely associated with carotid intima-media thickness in healthy subjects. Furthermore, lower IgM titers against oxLDL have been found in patients with a history of myocardial infarction as compared to controls (28). These findings would suggest that the immune response against oxLDL might be protective under certain circumstances. On the other hand, high oxLDL titers have been reported to predict myocardial infarction and progression of carotid atherosclerosis independently in humans (8,32). Furthermore, elevated oxLDL titers have been found in insulin-dependent diabetes mellitus and hypertension (38,39), whereas other studies found no relationship between oxLDL and atherosclerotic disease (40). However, whether endothelial vasodilatory function is related to oxLDL has not been investigated previously in healthy humans. In the present study neither EDV, EIDV, nor the EFI were significantly related to oxLDL. This result is in accordance with a recent study in patients with insulin-dependent diabetes mellitus, in which no correlation was found between EDV, measured as the vasodilatory response to acetylcholine

in forearm resistance vessels, and oxLDL (38) despite elevated titers of oxLDL. Taken together, these data do not support a relationship between immune responses to oxLDL and endothelial vasodilatory function.

According to several cross-sectional and prospective studies, individuals with small, dense LDL particles have a higher risk for coronary artery disease (19–21). Although Vakkilainen *et al.* (41) found a significant relationship between small LDL particles and impaired EDV, as assessed by venous occlusion plethysmography, in healthy middle-aged men, we found no relationship between LDL particle size and endothelial vasodilatory function in the present study. This could be explained by differences in the metabolic profiles of the samples. Thus, O'Brien *et al.* (42) found a relationship between LDL particle size and EDV, as assessed by venous occlusion plethysmography, in a sample of middle-aged men with non-insulin-dependent diabetes mellitus, whereas no relationship was found between LDL particle size and EDV in healthy controls. However, in the study by Vakkilainen *et al.* (41), mean values of body mass index, serum TG and cholesterol, and LDL particle size showed a closer resemblance to the non-insulin-dependent group in the study by O'Brien *et al.* (42) than to the healthy subjects in our present study. Furthermore, in the Québec Cardiovascular Study (21) small LDL particles were significant predictors of ischemic heart disease risk only at plasma apoB levels above 1.2 g/L. The low levels of apoB in our sample might therefore contribute to the lack of correlation between LDL particle size and EDV in the present study. Only four subjects had apoB levels above 1.2 g/L, which was not high enough to stratify the sample according to normal or high levels of apoB. Thus, LDL particle size may not be closely related to endothelial vasodilatory function in healthy subjects with a favorable risk factor profile.

The EFI, reflecting the endothelial contribution to vasodilation, was associated with HDL cholesterol in the present study. Our data are corroborated by other studies, in which decreased HDL cholesterol has been shown to predict endothelial dysfunction in healthy young men as well as in men with non-insulin-dependent diabetes mellitus (34,42). HDL also has been shown to reverse the inhibitory effect of oxLDL on EDV in rabbit arterial rings (11,43) and to be inversely associated with oxLDL in healthy humans (34). In the present study, the factor analysis showed low levels of HDL cholesterol to be associated with small LDL particles and decreased levels of apoA-1 in serum. These are some of the features of the insulin resistance syndrome (44). Thus, the independent relationship between HDL cholesterol and EFI in the present study further supports a protective role for HDL cholesterol on endothelial vasodilatory function.

ApoB was independently and inversely associated with both EDV and EIDV. ApoB is present mainly in the LDL fraction under fasting conditions, and an elevated apoB/LDL cholesterol ratio is frequently observed in atherosclerotic cardiovascular disease (45). However, whether endothelial vasodilatory function is related to apoB has hitherto not been thoroughly investigated. The inverse associations of both EDV

and EIDV to apoB in the present study would suggest that apoB predicts structural vascular changes rather than endothelial dysfunction *per se*. Indeed, an elevated level of apoB has been identified as an independent predictor of increased carotid intima-media thickness and arterial stiffness in healthy subjects (37,46). In our own recent cross-sectional study, apoB was an independent predictor of both arterial stiffness, assessed as the stroke volume to pulse pressure ratio, and carotid intima-media thickness in healthy women (47). ApoB is a constituent of LDL particles, and we did indeed find a weak association between LDL cholesterol and EIDV. Creager *et al.* (15) found that EIDV, measured by venous occlusion plethysmography, was significantly lower in hypercholesterolemic subjects as compared to healthy controls, and Goode and Heagerty (48) showed that EIDV was significantly impaired in arterial rings from hypercholesterolemic humans as compared to normocholesterolemic controls.

**Limitations.** Owing to sample size, only correlation coefficients above 0.25 were significant in the present study. Thus, weak associations could not be detected. However, associations below this limit could have explained only less than 7% of the variation in the dependent variable. A number of correlations were performed, and with the chosen significance level of 5%, one correlation in 20 might be significant merely by chance. Therefore, these results must be interpreted with caution until reproduced by other investigators in larger studies. Nevertheless, the fact that similar associations were seen for both dosages of Mch and SNP minimizes the chance of type 1 errors. Relatively normal apoB levels in the sample might explain the lack of correlation between LDL particle size and EDV, as the Québec Cardiovascular Study (21) showed small LDL particles to be significant predictors of risk of ischemic heart disease only at plasma apoB levels above 1.2 g/L. Only four subjects had apoB levels above 1.2 g/L, which was not enough to stratify the sample according to normal or high levels of apoB.

In conclusion, the inverse associations between apoB and both EDV and EIDV indicate that apoB might be an early marker of structural vascular changes in healthy subjects, whereas HDL seems to be more specifically related to EDV.

**ABSTRACT:** The objective of this study was to investigate the relationship between the composition of FA in serum lipids, a marker of dietary fat intake, and vascular reactivity using a combination of cross-sectional and intervention approaches. Fifty-six middle-aged subjects were evaluated in a cross-sectional protocol regarding the relationship between the proportion of FA in serum cholesterol esters and vascular reactivity using measurements of forearm blood flow (FBF) with venous occlusion plethysmography during hyperemia. Another 19 middle-aged subjects were given a rapeseed oil-based diet rich in mono- and polyunsaturated FA or a control diet rich in saturated FA during two consecutive 4-wk periods separated by a 4-wk washout period. In the cross-sectional protocol, the FA 18:0 and 20:3 were positively related to resting FBF, whereas an inverse relationship was seen for the FA 20:5 and 22:6 ( $P < 0.05$ – $0.01$ ). Opposite relationships were seen between these four FA and the relative increase in maximal FBF during hyperemia ( $P < 0.05$ – $0.01$ ). In the intervention protocol, the saturated diet increased resting FBF, as well as the relative increase in maximal FBF during reactive hyperemia, compared to the diet rich in unsaturated FA ( $P < 0.05$ ). Both the cross-sectional and intervention data support the view that the composition of serum FA, which at least partly reflects the quality of dietary fat, plays a role in determinations of vascular reactivity. Paper no. L9043 in *Lipids* 37, 1141–1145 (December 2002).

Lipids are known to have a major impact on the development of cardiovascular diseases, and serum cholesterol levels were early identified as a major cardiovascular risk factor (1). That a high dietary intake of saturated FA is associated with an increased risk of developing coronary heart disease (CHD) is also well established (2,3). However, no consensus exists whether saturated FA should be replaced mainly by mono-unsaturated FA, PUFA, or carbohydrates. Epidemiological studies investigating the effects of mono- and polyunsaturated FA have shown divergent results (2). Intervention studies have shown beneficial lipid-lowering effects (3) but also an increased susceptibility of lipoproteins to oxidation during interventions with diets rich in PUFA (4,5).

Since the discoveries that the endothelium takes an active part in the vasodilatory process (6), and that the major substance secreted from the endothelium responsible for this vasodilatory

process is nitric oxide (NO) (7), much attention has been paid to measuring the impact of NO on cardiovascular function.

For decades, the increase in forearm blood flow (FBF) seen during the hyperemic phase following obstruction of blood flow has been used to evaluate vascular reactivity. Previously, it was claimed that vascular anatomic changes, such as vascular hypertrophy, were the major determinants of FBF during hyperemia (8). However, recent studies have shown that FBF during hyperemia also is dependent on NO production (9). By the use of a local infusion of the NO antagonist L-NMMA, both the peak in FBF that occurs immediately after release of an arterial occlusion and the following reduction in FBF were shown to be NO-dependent. Resting FBF was also largely determined by NO production (10).

The purpose of the present study was to investigate the relationship between serum FA composition and vascular reactivity using the postocclusive hyperemia forearm model, which is in part NO dependent. The study used a dual approach. First, a population of apparently healthy middle-aged subjects was studied in a cross-sectional protocol to relate the FA composition of serum cholesterol esters to vascular reactivity. In this part of the study, the FA composition of serum cholesterol esters was used as a marker of the quality of fat ingested over the weeks preceding the investigation (11,12). In the second part, another group of middle-aged subjects were given either a diet high in saturated FA or a diet rich in PUFA in a randomized cross-over fashion. Vascular reactivity was evaluated in the same way in both the cross-sectional and the intervention protocols.

## MATERIALS AND METHODS

*Cross-sectional protocol: Subjects.* The population sample, recruited from the general population in Uppsala, Sweden, consisted of 56 healthy subjects (31 men and 25 women; see Table 1) who ranged in age from 20 to 69 yr (13). None of the subjects was taking regular medication or had a history of any disease known to affect the cardiovascular system. In addition, subjects with a history of any metabolic or other serious diseases were excluded from the study. None of the women was on contraceptive pills or estrogen replacement therapy. Subjects with blood pressure  $>160/95$  mm Hg, fasting hyperglycemia ( $>6.0$  mmol/L), or pronounced hypercholesterolemia ( $>8.0$  mmol/L) at the investigation were not included. Eight of the subjects were smokers.

Abbreviations: CHD, coronary heart disease; E%, energy percent; FBF, forearm blood flow; NO, nitric oxide; RO, rapeseed oil-based diet; SAT, control diet high in saturated FA.

*Intervention protocol. (i) Subjects.* Nineteen healthy subjects (6 female/13 male) aged  $50 \pm 8$  yr with normal or moderately increased body weight and blood lipids participated in the protocol. Subjects were recruited *via* posters in nearby companies. Eligible for the study were men (age 30 to 65) and women (age 50 to 65) with serum cholesterol  $<8.0$  mmol/L, serum TG 1.3 to 5.0 mmol/L, fasting blood glucose  $<6.0$  mmol/L, diastolic blood pressure  $<95$  mm Hg, and body mass index  $<30$  kg/m<sup>2</sup>. Exclusion criteria were treatment for CHD; liver, kidney, or thyroid disease; diabetes mellitus; hypertension; estrogen replacement therapy; and regular acetyl salicylic acid medication. Two subjects were smokers. All subjects were asked to maintain their habitual lifestyles during the study.

*(ii) Study design.* The protocol was conducted using a randomized cross-over design. Two consecutive 4-wk diet periods were separated by a 4-wk washout period. The two diets tested were a rapeseed oil-based (RO) diet rich in monounsaturated FA and  $\alpha$ -linolenic acid and a control (SAT) diet with a high proportion of saturated FA. Subjects were randomly assigned to start with one of the two diets. Measurements of vascular reactivity and determinations of FA composition in phospholipids were performed at the end of the two treatment periods.

The study was approved by the Ethics Committee at Uppsala University, and each participant gave informed consent.

*(iii) Diets.* The fat quality of the two test diets (RO and SAT) was controlled by supplying fat products and food items prepared with the fats tested, in combination with dietary advice to avoid fats from other dietary sources such as fatty dairy and meat products. The subjects met a nutritionist before and during the diet periods for dietary advice and instructions on preparing their diets to ensure good adherence to the diet. Specially prepared table margarine (without rapeseed oil) for the SAT diet and ice cream (with rapeseed oil) for the RO diet were produced in pilot plants by Van den Bergh Foods AB (Helsingborg, Sweden) and Karlshamns Mejeri AB (Karlshamn, Sweden), respectively. Commercial qualities of all other cooking fats, table margarines, oils, and ice creams were purchased on the market or obtained from Karlshamns AB (Karlshamn, Sweden). Lunch meals (five per week, 10 different meals), bread (three per day), and cookies (one per day) prepared with the fats tested were supplied weekly, as well as free amounts of cooking fat, table margarine (80% fat), and oil to use for cooking, spreads, and dressings. Double portions that included the daily supply of food items and an approximate daily intake of fat products supplied were prepared on the 12 MJ energy level for each of the 10 d. The test diets were planned to contain 37 energy percent (E%) fat, 12 E% protein, and 50 E% of carbohydrates. The composition of the RO diet was aimed to represent a normal mixed-RO diet composed according to dietary recommendations, but with a fat content corresponding to the average intake of a Swedish population. The control diet contained saturated fat products instead of rapeseed oil-based fat products. Two energy levels, 9 and 12 MJ, were prepared, and the energy requirement for each subject was approximated as 146 kJ/kg body weight. The body

weight of the subjects was checked once a week to avoid weight changes, and the energy level, together with dietary advice, was adjusted when needed. Dietary intake was monitored using 3-d food records (two weekdays and one weekend day) on five occasions, one at baseline and two during each diet period. The dietary food records were analyzed by using the software program Stor MATs 4.0 (Rudans Lättdata, Västerås, Sweden) based on a Swedish-specific food database from the Swedish National Food Administration (PC-Kost 1996, SLV, Uppsala, Sweden).

*(iv) Measurement of vascular reactivity.* The vascular reactivity studies were performed after an overnight fast. The subjects were supine in an air-conditioned room at a constant temperature (20°C). FBF (measured in mL/min/100 mL tissue) was measured by venous occlusion plethysmography (Elekromedicin, Kullavik, Sweden). A mercury-in-Silastic strain gauge was placed at the upper third of the forearm, which rested comfortably slightly above the level of the heart. The strain gauge was coupled to an calibrated plethysmograph. Venous occlusion was achieved by a blood pressure cuff applied proximal to the elbow and inflated to 40 mm Hg by a rapid cuff inflator. Blood flow during reactive hyperemia was measured after occlusion of the forearm circulation by inflating a cuff in the upper part of the arm to 200 mm mercury for 5 min. After release of the cuff, FBF was measured after 5 s to obtain the maximal blood flow. Blood flow measurements were performed each 20th s thereafter in the cross-sectional study and at 80 s of hyperemia only in the intervention study. FBF at 80 s of hyperemia was considered to be a measurement of recovery after the hyperemic phase. Relative maximal FBF was defined as maximal FBF minus resting FBF divided by resting FBF. We previously showed that maximal FBF is more closely related to the muscarinic-receptor agonist-induced increase in FBF than to the increase in FBF seen during local infusion of sodium nitroprusside in the forearm (14). Recalculation of data using the relative maximal FBF instead of the absolute number for maximal FBF gave similar results.

The reproducibility of the measurement of resting FBF was previously evaluated in 10 healthy young volunteers (14), in whom the investigation was performed before and after 2 h of i.v. saline infusion, as well as after 2–3 wk. Resting FBF showed a CV of less than 10%.

Systolic and diastolic blood pressures, as well as heart rate, were measured in the supine position after 15 min of rest. A mercury sphygmomanometer was used for the measurements.

*(v) Measurements of FA composition in serum lipids.* To analyze the FA composition of the serum cholesterol esters, serum was extracted with a hexane/isopropanol solution. Cholesterol esters were separated from the extract by TLC before interesterification, and the free cholesterol liberated in the reaction was removed by an aluminum oxide column to avoid contamination of the GLC column. The percentage composition of methylated FA was determined by GC (a 25-m NB-351 silica capillary column, i.d. 0.32 mm, phase layer 0.20  $\mu$ m) with use of an FID and with helium as carrier gas. Every 25th sample was a serum control pool. The preci-

sion of the between-series analysis ( $n = 35$ ) varied from 2 (large peaks) to 10% (smaller peaks) and between successive GC runs ( $n = 17$ ) from 0.2 to 5% (CV).

(vi) *Statistical analysis.* In the cross-sectional study the relationships between continuous variables were evaluated by linear regression analysis. Interactions between several independent variables were examined with stepwise multiple regression analysis. In the intervention study differences between the diets were evaluated with Student's paired *t*-test. A test for carryover effects was used according to Jones and Kenward (15). If the carryover test was significant, only data from the first diet period were used for comparisons of the two test diets.  $P < 0.05$  was regarded as significant.

## RESULTS

*Cross-sectional protocol.* Basic characteristics of the study population are given in Table 1. FBF at different time points during reactive hyperemia are shown in Figure 1.

In comparing the composition of FA in the serum cholesterol esters (see Table 2) to the different FBF characteristics, the proportion of 18:0 was significantly related to both resting FBF ( $r = 0.31$ ,  $P < 0.05$ ) and to FBF at 80 s during hyperemia ( $r = 0.41$ ,  $P < 0.01$ ). The proportion of 20:3 was also significantly related to resting FBF ( $r = 0.32$ ,  $P < 0.05$ ). On the contrary, the proportions of both 20:5 and 22:6 were inversely related to resting FBF ( $r = -0.31$  and  $r = -0.37$ ,  $P < 0.05$  and  $< 0.01$ , respectively). Furthermore, the proportion of 22:6 was correlated to the relative maximal FBF ( $r = 0.41$ ,  $P < 0.03$ ). Although an inverse relationship was seen between the proportion of 20:3 and the relative maximal FBF ( $r = -0.35$ ,  $P < 0.05$ ), a positive relationship was seen between this vascular reactivity variable and the proportion of 20:5 ( $r = 0.29$ ,  $P < 0.05$ ). None of the other FA measured were significantly related to the measured variables evaluating vascular reactivity.

All of the significant associations reported between the proportions of different FA and indices of vascular reactivity were still significant after the influences of age and sex were taken into account in multiple regression analyses.

*Intervention protocol.* When serum lipids were measured at the end of each intervention period, serum LDL cholesterol

**FIG. 1.** Mean  $\pm$  SEM for forearm blood flow (mL/min/100 mL tissue) at different time points during reactive hyperemia following 5 min of occlusion of the forearm in the cross-sectional study. Maximal flow was measured 5 s after release of occlusion.

levels were significantly higher for the SAT diet compared to the RO diet ( $4.33 \pm 0.34$  vs.  $3.85 \pm 0.85$  mmol/L,  $P < 0.001$ ). No significant difference between the two diets was seen for serum TG levels ( $1.43 \pm 0.96$  for the SA diet vs.  $1.24 \pm 0.65$  mmol/L for the RO diet,  $P = 0.18$ ).

The relative FA composition of serum phospholipids at the end of the two diet periods is given in Table 3. In general, the proportions of saturated FA were higher for the SAT diet than for the RO diet. The reverse was generally seen for the PUFA, except that the proportion of 20:3 was significantly higher for the SAT diet.

As can be seen in Table 4, no significant differences in blood pressure were seen between the two diets. However, there was a nonsignificant tendency for the heart rate to be higher for the SAT diet than for the RO diet ( $P = 0.066$ ).

As can also be seen in Table 4, the resting FBF was significantly higher for the SAT diet than for the diet rich in PUFA. FBF at 80 s during hyperemia was also significantly increased with the SAT diet compared to the RO diet. Although the maximum FBF during hyperemia did not differ between the diets, the relative maximal FBF was attenuated with the SAT diet compared to the RO diet.

<sup>a</sup>Mean ± SD are given.

There were significant carryover effects (especially from the SAT diet to the second diet period) for resting FBF and FBF at 80 s during hyperemia. Therefore, for these variables only the first diet period was used for calculations.

## DISCUSSION

In both the cross-sectional and the intervention protocols of the present study, the composition of FA in serum lipids was a major determinant of both resting FBF and vascular reactivity during the hyperemic phase.

The resting FBF variable has many different determinants. It is increased in males compared to females, probably due to the higher forearm muscle mass and the need for an increased nutrient blood flow in the male forearm. Resting FBF also has been shown to be governed by NO release, as local infusion of the NO blocker L-NMMA has been shown to cause a 25–50% decrease in resting FBF (10). Other factors, such as glucose infusion, euglycemic hyperinsulinemia, or an acute elevation of FFA by means of intralipid and heparin infusion, could also increase the resting FBF (16,17). At first glance it would seem favorable to increase FBF with saturated FA, as this blood flow characteristic is in part NO dependent. How-

ever, as both the proportions of 18:0 and 20:3 were positively associated with resting FBF, it seems highly unlikely that this FA profile would be of any benefit, as this profile has been associated with the development of CHD (18).

As could be seen in the intervention part of the present study, a dietary change can induce changes in the FA profile in serum. The FA profile in serum cholesterol esters has previously been found to reflect mainly the quality of fat intake during the last weeks (11,12). That genetic and metabolic factors also influence the FA profile cannot be excluded, however, and could, at least in part, be responsible for the associations found in the cross-sectional study.

Neither in the cross-sectional study nor in the intervention was an association found between the absolute level of the maximal FBF during hyperemia, in part being NO-dependent (9,19), and FA. However, the relative maximal FBF was attenuated during the SAT diet, and positive relationships were seen in the cross-sectional study when compared to proportions of some PUFA. Although the relationships described in the intervention study were mainly because the resting FBF, and thereby also the relative maximal FBF, were altered, the relative maximal FBF also is known to be more closely related to endothelium-dependent vasodilation than to endothelium-independent vasodilation (14).

A relationship between FA composition and FBF during the decremental part of the hyperemic phase (FBF at 80 s) was shown in both the cross-sectional and the intervention protocols, suggesting that these measurements are governed by similar mechanisms.

The proportion of FA in the cholesterol esters was measured in the cross-sectional study, but in the intervention the FA in phospholipids were determined. As seen in the tables, measurements in these two compartments gave different information on the proportions of the different FA. Measuring FA in cholesterol esters is our usual approach in cross-sectional studies in which the effects of long-term dietary intake are to be evaluated. However, the proportions of long-chain FA are quite small in that compartment. Therefore, in the intervention, measurements in phospholipids were used because the proportions of long-chain FA were higher and thus the sensitivity to detect a change in these FA would be better when food intake was altered. The results would, however, be quite similar with both types of measurements. Subjects with a relative lack of long-chain FA in cholesterol esters would also have a relative shortage of these FA in the phospholipids, and vice versa.

We recently showed that different FA in serum cholesterol esters could affect the endothelium in divergent ways in apparently healthy subjects (20). In the experimental setting, divergent effects of different FA also were described. Both oleic and palmitic acids were shown to impair NO-dependent vasodilation, whereas stearic acid did not induce this effect (21,22). Furthermore, in rats given a diet rich in n-3 PUFA an improvement in NO-dependent vasodilation was seen (23). Several mechanisms might be involved in the actions of FA on vascular function. First, different FA are associated with

different degrees of lipid oxidation, a process that could both inhibit NO formation and transform NO to inactive compounds such as peroxynitrite. Second, FA affect cell membrane fluidity in different ways, altering the permeability and action of different ion pumps in the membrane. In this way, transmembrane calcium ion fluxes involved in NO formation could be altered. Third, FA are involved in the formation of both vasodilatory and vasoconstrictive prostanoid metabolites, such as prostacycline and thromboxane A<sub>2</sub>.

These studies support the view emerging from the present study that the composition of FA is a determinant of vascular reactivity and that NO, at least in part, is involved in this process.

## Are *trans* Isomers of $\alpha$ -Linolenic Acid of Nutritional Significance for Certain Populations?

Sir:

In a recent study (1), Combe and Boué established the individual daily intake and identified the origins of  $\alpha$ -linolenic (18:3n-3) acid consumed by a population of women from the southwestern region of France (Aquitaine). They showed that vegetable oils contributed only 9% to this intake, the remainder coming from animal fats (73%; mainly dairy products) and vegetable lipids (27%). The total daily intake of 18:3n-3 acid by nonpregnant women ( $n = 79$ ) was  $0.6 \pm 0.2$  g/p/d ( $0.8 \pm 0.3$  for pregnant women;  $n = 61$ ). From these data, it can be estimated that only *ca.* 60 mg of  $\alpha$ -linolenic acid is attributable to vegetable oils. In the region considered, olive oil is a significant source of  $\alpha$ -linolenic acid, contributing approximately 25 mg/p/d (1).

Olive oil (virgin) and animal fats are a source of unaltered all-*cis*-18:3n-3 acid, whereas other vegetable oils are deodorized and contain  $\alpha$ -linolenic acid geometrical isomers ( $\alpha$ -LAGI) presenting at least one *trans*-ethylenic bond (2–5). A mean proportion of 17% for the latter components (relative to total 18:3n-3 acids) could be established for different oils from different countries (5). Thus, consumption of  $\alpha$ -LAGI should not exceed, on average, 5–6 mg/p/d for the population of Aquitaine women. This quantity would include *ca.* 2 mg for each of the *trans*-9,*cis*-12,*cis*-15 and *cis*-9,*cis*-12,*trans*-15 isomers, and 1 mg of both the *cis*-9,*trans*-12,*cis*-15 and *trans*-9,*cis*-12,*trans*-15 isomers (calculated according to Ref. 5). Because these isomers are rapidly catabolized (6), only a fraction of these quantities remains for either incorporation into tissue lipids or further desaturation and elongation to longer polyunsaturated chains (7). Such trivial amounts indicate that  $\alpha$ -LAGI should not be of major nutritional significance in the adult population considered and may explain why these isomers could not be detected by gas chromatograph in the adipose tissue of the same population (8). This likely also occurs in Mediterranean countries with similar diets rich in vegetables, dairy lipids, and olive oil. However, this should not be the case in those countries where rapeseed and soybean oils are the major sources of  $\alpha$ -linolenic acid (many European countries and North America). Even in France, where the use of rapeseed or soybean oil for deep-frying is forbidden by the law, exceptions were shown to occur, either in restaurants (9)

or by individual people (10). Thus, the Aquitaine study (1) may not be representative of the whole French population, and further studies are required.

On the other hand, the metabolic fate of  $\alpha$ -LAGI may be different in lactating women, as these isomers are directly incorporated into milk lipids (10,11).  $\alpha$ -LAGI also have been shown to occur in infant formulas from France and Canada (12,13), where deodorized  $\alpha$ -linolenic acid-containing oils are added to meet the requirements for 18:3n-3 acid intake, and they may then be of nutritional importance for neonates, whether they are fed breast milk or infant formulas. Consequently, in Europe  $\alpha$ -LAGI remain of nutritional concern.

# Reassessment of the Contribution of Bovine Milk Fats to the *trans*-18:1 Isomeric Acid Consumption by European Populations. Additional Data for Rumenic (*cis*-9,*trans*-11 18:2) Acid

Sir:

In 1995 (1), we published a detailed account of the contribution of ruminant fats to the daily *trans*-18:1 acid intake by European populations. New data on bovine milk consumption (2) have recently been published by the CNIEL (National Inter-Professional Center for Dairy Economics) for 15 countries of the European Union. Some slight trends could be noted between the two periods for the consumption of dairy fats in several (Mediterranean) countries; e.g., Italy, Spain, Greece, and Portugal had higher intakes, whereas other countries showed a significant decrease in their consumption (e.g., Denmark). Also, data were not available for countries such as Austria, Sweden, and Finland in our previous study.

Moreover, between our earlier study (1) and the present one, additional data were published on the accurate contents and profiles of *trans*-18:1 isomeric acids in bovine milk fats (e.g., Refs. 3 and 4). The main observation that was made was the dependence of these parameters on the manner of cattle feeding, e.g., barn vs. pasture feeding or transition times (barn to pasture feeding in spring and the reverse in late autumn). Furthermore, the negative energy balance during early lactation (*ca.* the first 10 wk of lactation) or special feeding conditions (e.g., ecological farming, supplementing the feed rations with fat additions) influence the *trans*-18:1 contents in milk fat (5). Hence, some geographical differences may exist, as cattle-raising habits in different countries may not be the same. Ireland represents an exception because cows are fed on pasture throughout the year, causing higher *trans*-18:1 contents (4).

In the present assessment, we chose a rounded average value of 3.7% for the *trans*-18:1 acid content of milk fat (4), which should take into account geographical variations as well as seasonal variations, and a mean content of 50% of vaccenic acid (6) (*trans*-11 18:1) relative to total *trans*-18:1 isomers (it itself varies with the feed). Furthermore, the daily per capita consumption of dairy fats was multiplied by 0.95 to take into account the proportion of FA in TG. Because the true values for individual countries may be slightly higher or lower, we give our data to the first decimal place only [except for rumenic (*cis*-9,*trans*-11 18:2) acid], and we do not consider at the moment the Irish conditions.

For most countries, the daily individual intake of *trans*-18:1 isomers from dairy products (Table 1) lies in the narrow range 1.0–1.6 g/p/d. Lower values are encountered in southern countries (Greece, Spain, and Portugal, 0.7), whereas higher values are observed in northern countries (Finland and Sweden: 1.6–1.8). Vaccenic acid evidently follows the same trends, from a low of 0.3 (Spain) to a high of 0.9 g/p/d (Finland). However, our data for Mediterranean countries are underestimates, as ewe and goat milk fats are nonnegligible dietary sources of *trans*-18:1 isomers in these countries (1). As an example, 5.9 million of goats are raised in Greece, but only 1.1 million in France. Corresponding data for lactating cows are 0.17 and 4.06 million (2). The respective human populations in these countries are 10.5 and 59.0 million inhabitants.

The CNIEL also provides data on the consumption of margarines and similar products, such as low-calorie spreads, but no reliable data are available for the *trans*-18:1 acid content in these foods. This is due to a switch from high- to low-*trans* partially hydrogenated vegetable oils being used for the manufacture of margarines in the years 1994–1995 in many European countries (7). On the other hand, *trans*-18:1 isomers are still present in foods containing partially hydrogenated vegetable oils, but they are so diverse and their *trans*-18:1 isomer content and profile so variable that a sound estimate can hardly be made.

Regarding the CLA rumenic acid, which has been quantified in 2,110 samples of European bovine milk (4), the daily per capita intakes are also given in Table 1 and have a mean value of 0.76% relative to total FA (4). This content nearly agrees with a newer value of 0.74% for French butters (4), but other French data from different seasons were somewhat lower (8). This may be attributable to the acid-catalyzed method employed to prepare FA derivatives in the latter study. Intakes of this CLA exactly follow the trend for total *trans*-18:1 acids as well as for *trans*-11 18:1 acid. For the 15 countries of the European Union, rumenic acid intake varies between 0.14 and 0.38 g/p/d, with higher values in the northern countries and lower values in the Mediterranean countries. Here too, ovine and caprine milks may contribute to higher rumenic acid intakes in Mediterranean countries (1). Apart from these particular cases, data in Table 1 may be increased by approximately 10% to take into account the contribution of beef and sheep meat lipids and tallow (1).

Taking mean contents of 5.9% *trans*-18:1, 3.5% vaccenic [unpublished data ( $n = 23$ )], and 1.4% rumenic acids from

## Recent Advances in Steroid Research

Presented at the 93rd AOCS Annual Meeting & Expo  
in Montréal, Canada, May 2002

**Edward J. Parish<sup>a</sup>, W. David Nes<sup>b</sup>, and John R. Williams<sup>c</sup>**

Departments of <sup>a</sup>Chemistry, Auburn University, Auburn, Alabama 36849, <sup>b</sup>Chemistry and Biochemistry, Texas Tech University, Lubbock, Texas 79409, and <sup>c</sup>Chemistry, Temple University, Philadelphia, Pennsylvania 19122

The AOCS has been a regular host to steroid symposia since 1970. The history of this symposium series has been published [Weete, J.D., Parish, E.J., and Nes, W.D. (2000) *Lipids* 35, 241]. These symposia have focused on current research in the areas of steroid structure, biosynthesis, chemistry, regulation, and function.

The 2002 Steroid Symposium, "Recent Advances in Steroid Research," was held at the AOCS Annual Meeting in Montréal, Canada. This year the symposium held special significance, for it hosted the presentation of the first G.J. Schroepfer Jr. Award for steroid research. The Award was established to honor the memory of Dr. George J. Schroepfer Jr., a prominent steroid biochemist and chemist who made major and lasting contributions to the steroid field. Much of his research dealt with the biosynthesis of cholesterol and its regulation. In addition, he maintained a strong organic synthesis program to support his biochemical studies. A biography describing many of Dr. Schroepfer's contributions can be found in this journal [Wilson, W.K. (2000) *Lipids* 35, 242]. Dr. Schroepfer was scheduled to be the keynote speaker at the last steroid symposium in Orlando, Florida in 1999, but unfortunately, he passed away on December 11, 1998. That

symposium was dedicated to Professor Schroepfer's memory and was a memorial symposium.

The first recipient of the G.J. Schroepfer Jr. Award for steroid research was Professor Geoffrey F. Gibbons of the Metabolic Research Laboratory at Oxford University. Professor Gibbons has made major contributions to the steroid field, and we were pleased with his nomination. Professor Gibbons was also our keynote speaker at the symposium and thus made a dual contribution to these proceedings.

As in past symposia, we are indebted to our corporate partners who helped make the symposium a success: AstraZeneca Pharmaceutical Co., Pharmacia Centre Source, and Steraloids, Inc. We appreciate their contribution and look forward to their continued support of our symposium series.

This symposium was sponsored by the Biotechnology Division of the AOCS. Speakers in the 2002 Sterol Symposium represented an international group of senior and junior scientists. We express here our appreciation to each of them for their cooperation during the planning process and for their participation in the symposium. By all accounts, the event was a success, and we are looking forward to the next steroid symposium.

# From Gallstones to Genes: Two Hundred Years of Sterol Research. A Tribute to George J. Schroepfer Jr.

Geoffrey F. Gibbons\*

Metabolic Research Laboratory, Nuffield Department of Clinical Medicine,  
University of Oxford, Oxford OX2 6HE, United Kingdom

**ABSTRACT:** The origins of cholesterol research can be traced to prerevolutionary France. The discovery of cholesterol as a single substance, present in human gallstones, owes much to the scientists of l'Académie Française, including Lavoisier, who contributed so much to the emergence of chemistry as a modern scientific discipline. Since that time, cholesterol probably has been the most intensively scrutinized natural product of all time, and it has been the subject of Nobel Prizes for several who have studied its structure, biosynthesis, and regulation. The pace of research into cholesterol shows no sign of diminishing, and recent discoveries have led to the recognition that the regulation of cholesterol metabolism is intimately linked with that of other metabolic pathways. Details of these interactions are only just emerging, but it is becoming apparent that under some circumstances it is difficult to reconcile, in a conventional manner, changes in regulatory gene expression with corresponding changes in pathway carbon flux. The present review includes some of our studies on the roles of the transcription factors sterol regulatory element-binding protein, liver X-receptor  $\alpha$ , and peroxisome proliferator activated receptor  $\alpha$  in the coordination of cholesterol and fatty acid synthesis and describes how some of the results obtained can best be interpreted from a Metabolic Control Analysis perspective of the regulation of pathway carbon fluxes.

Paper no. L9140 in *Lipids* 37, 1153–1162 (December 2002).

## A TRIBUTE TO GEORGE J. SCHROEPFER JR., JUNE 15, 1932–DECEMBER 11, 1998

I'd like to begin by saying how deeply honored I am to be the first recipient of the Schroepfer Medal. The award gives me particular pleasure, partly for nostalgic reasons, as it takes me back to my roots in steroid chemistry at the Medical Research Council Lipid Metabolism Unit at Hammersmith Hospital in West London. It was here, in 1973, that I first met George Schroepfer, who was passing through to visit old friends and acquaintances from the days when he worked as a young postdoc with George Popják in 1961. And it was at Hammersmith that Schroepfer made a major contribution to the momentous work of Popják and Cornforth in defining the com-

plete stereospecific enzymology of squalene biosynthesis from mevalonate, work that contributed to the award of the Nobel Prize in 1975 (1). Popják recognized Schroepfer's early contribution to this work in his memoir published in the *Journal of the American Oil Chemists' Society* in 1977 (2). George pursued his interest in the stereochemistry of enzymic catalysis during a further postdoctoral period in the laboratory of another Nobel Laureate, Konrad Bloch, at Harvard.

His work on the stereospecificity of lipid biosynthesis awakened Schroepfer's interest in the stereochemistry of steroids, which was reflected by his lifelong devotion to the study of oxygenated steroids. Many of those who read his recent monumental review in *Physiological Reviews*, which ran to 193 pages (3) and which he modestly described as only "fairly comprehensive," have wondered how long a "fully comprehensive" version would have been. But for George Schroepfer, this work was never an end in itself. As a clinician, he wanted to know the answer to the question "Why is a lot of cholesterol bad for you?" To this end, he devoted considerable effort to the development of oxygenated sterols as potential cholesterol-lowering drugs. As a chemist, George emphasized the need for unambiguous specification of steroid structure and rigorous proof of chemical and radiochemical purity before any conclusions could be made regarding biological function. He was often amazed by the slipshod methodology and unsubstantiated claims of some groups working in this area of research; the confusion caused by claims for a direct regulatory role for (im-pure) cholesterol in isolated cells comes to mind here.

Toward the end of George Schroepfer's life, it was becoming increasingly clear that oxysterols are important biological ligands for the transcription factor liver X-receptor  $\alpha$  (LXR $\alpha$ ), but the enzymology involved in the natural production of these ligands remained obscure. Together with colleagues at the Howard Hughes Institute, George showed that production of the cholesterol precursor, mevalonate, was essential for LXR $\alpha$  activation. The requirement for mevalonate could be spared by 20(*S*)-hydroxycholesterol and 22(*R*)-hydroxycholesterol, substances that he synthesized and characterized (4). It surely is a great pity that George's life was cut short and that he was unable to fully appreciate how much of his life's work is now bearing fruit.

## HISTORICAL BACKGROUND

Over a period of almost 250 years, cholesterol has been one of the most intensively studied of all natural products. It is

\*Address correspondence at Metabolic Research Laboratory, Radcliffe Infirmary, Woodstock Rd., Oxford OX2 6HE, United Kingdom.  
E-mail: geoff.gibbons@metabolic-research.oxford.ac.uk

Abbreviations: CYP7A1, cholesterol 7 $\alpha$ -hydroxylase; ER, endoplasmic reticulum; FAS, fatty acid synthase; LXR $\alpha$ , liver X-receptor  $\alpha$ ; MCA, Metabolic Control Analysis; PPAR $\alpha$ , peroxisome proliferator-activated receptor  $\alpha$ ; SCAP, SREBP cleavage-activating protein; SREBP, sterol regulatory element-binding protein.

only recently, however, that the substance has acquired a fearsome reputation, surpassed only by that of the Black Death in medieval Europe. But a lot of cholesterol is not bad for everyone. It has won the Nobel Prize for several of its more dedicated admirers, and the French chemist Michel Chevreul, to whom its discovery is normally attributed, lived to the grand old age of 103. Chevreul isolated cholesterol from human gallstones in 1815 and was the first to characterize it as a single, pure substance (5).

But the history of cholesterol predates even Chevreul. Its story goes back to the Cemetery of the Innocents in prerevolutionary Paris. In 1786 the Government commissioned the chemist Antoine Fourcroy, a member of the Academy of Sciences and a colleague of Lavoisier, to report on the condition of the Innocents' Cemetery as a potential health risk in view of its proximity to the nearby marketplace in the quartier des Halles. Fourcroy himself was an intriguing character who, following the overthrow of the *ancien régime*, subsequently became a member of the revolutionary government. Torn between his allegiance to his colleagues in the Academy and his apparatchik-like devotion to the aims of the revolution, he is often accused of betraying Lavoisier and thus being partly responsible for Lavoisier's execution in May 1794 during the Reign of Terror. But there is evidence that Fourcroy pleaded with Robespierre, the effective Head of the Revolutionary Government, to spare Lavoisier and almost ended up with his own neck on the block for his pains (6). Fourcroy's report on the condition of the Innocents' Cemetery involved an examination of the fat of putrefied corpses (7). He recognized that some of the properties of this *gras-de-cadavre* were similar to those of the substance that we now know as cholesterol, which he crystallized from human gallstones in 1789 (8) following the observation by F. Poulletier de la Salle, in 1770, that gallstone material was alcohol-soluble. It was also similar, in some respects, to spermaceti. Following Robert Boyle's maxim that if you can't prove that things are different, they must be the same, Fourcroy classified all these substances as "adipocire." Six years after Fourcroy's death in 1809, Chevreul distinguished chemically between these three substances on the basis of their saponifiability and baptized the gallstone material *cholestérine* the following year (9).

Cholesterol's story now moves eastward across the Rhine. The German chemists Heinrich Wieland and Adolf Windaus were awarded Nobel Prizes in 1927 and 1928, respectively, for their work on the structures of cholesterol and the bile acids. Windaus was the first to demonstrate the high cholesterol content of experimental atheroma (10). He also taught chemistry to several subsequent Nobel Laureates, including the young Hans Krebs, who was a medical student at Göttingen in 1919 after being discharged from the Imperial German Army at the end of World War I (11). It turned out, however, that the original proposed structure of the steroid nucleus (Fig. 1) was incorrect. In one of the first demonstrations of the enormous analytical power of X-ray crystallography, the studies of J.D. Bernal, working in the old Cavendish Laboratory in Cambridge (United Kingdom), showed clearly that the squat struc-

FIG. 1. Original Wieland and Windaus structure of the steroid nucleus.

ture suggested by the presence of the quaternary carbon atom was incompatible with the diffraction pattern obtained (12). Bernal never won the Nobel Prize, but he was awarded the Order of Lenin, which, given his political views, probably gave him a great deal more pleasure and satisfaction (13). The longer, more streamlined structure of the steroid nucleus that is familiar to us today was proposed independently by Wieland and Dane (14) and by Rosenheim and King in 1932 (15) and confirmed by chemical synthesis and degradation.

The discovery of the correct structure of cholesterol and the steroids now set the stage for the studies on their biosynthesis that were carried out mainly in Britain and the United States. The work of Rudolf Schoenheimer and David Rittenberg at Columbia was pivotal in this respect. Schoenheimer, who was of German origin, had worked with Adolf Windaus at Freiberg in 1926 and was one of the many Jewish intellectuals and scholars who fled Germany after the election of Hitler as Chancellor in January 1933. In 1937 Schoenheimer used deuterated water produced in Urey's laboratory at Columbia to show that cholesterol was produced in mammals as a result of the reductive polymerization of small molecules (16). In 1942, a year after Schoenheimer's untimely death, Konrad Bloch, another German emigré who had found refuge at Columbia, showed that the small monomeric building block was acetate. Bloch's later studies showed that acetate was linked biosynthetically with the cholesterol precursors squalene and lanosterol (for a review of this work, see Ref. 17). These crucial observations paved the way for the discovery, by Gordon Gould and his colleagues, that cholesterol feeding in dogs suppressed the reductive polymerization of acetate leading to cholesterol, but not to FA, in liver slices (18). This seminal work set the scene for the next 50 years' research on the regulation of cholesterol synthesis and, in more recent years, the physiological circumstances in which this regulation is integrated with that of FA synthesis (19). Another recent discovery, which emphasized the multifunctional role of cholesterol in nature, is that the proper functioning of the signaling molecule Hedgehog during vertebrate embryonic development is dependent on its covalent modification by cholesterol (20).

By 1960 it had become clear from the work of several groups, including those of Gould, Popják, Siperstein, and Lynen, that HMG-CoA reductase was an early target for the control of hepatic cholesterol synthesis, including that by dietary cholesterol. Early attempts to reproduce the *in vivo* effects of dietary cholesterol in isolated cells to which cholesterol was

added *in vitro* were apparently successful. Real life, unfortunately, is not so simple, and this rather facile concept of direct prokaryote-like feedback inhibition was scotched by Kandutsch and Chen, who clearly showed that highly purified cholesterol added to cell cultures in a strictly defined chemical environment inhibited neither HMG-CoA reductase nor cholesterol synthesis (21). The original observations were the result of the potent inhibitory effects of small quantities of oxygenated sterol impurities present in the cholesterol added to the culture dishes. This discovery marked the beginning of a long and productive collaboration between the laboratories of Kandutsch and Schroeffer, the results of which have made a major contribution to our current understanding of the role of oxysterols in the control of transcription factor activity. The remainder of this lecture will deal with the transcriptional regulation of cholesterol and FA synthesis and will be illustrated by some of our own work at the Metabolic Research Laboratory. In particular, I would like to show how some of our results can best be understood from a Metabolic Control Analysis (MCA) perspective (22) in describing changes in overall carbon flux through these pathways.

### TRANSCRIPTIONAL REGULATION OF LIPOGENIC AND CHOLESTEROGENIC CARBON FLUX

*Interactions between sterol regulatory element-binding protein (SREBP), LXR $\alpha$ , and insulin.* Naturally occurring cholesterol precursors and oxygenated sterol metabolites of cholesterol are potent activating ligands for the transcription factor LXR $\alpha$  (4,23,24). In its ligand-bound state, LXR $\alpha$  transcriptionally activates several genes involved in the maintenance of whole-body cholesterol balance such as cholesterol 7 $\alpha$ -hydroxylase (CYP7A1) in the bile acid pathway (24) and ABC-A1 in the reverse cholesterol transport pathway (25). In mouse liver, active LXR $\alpha$  also transactivates the gene encoding SREBP-1c, another transcription factor responsible for the regulation of a portfolio of genes encoding enzymes of the lipogenic pathway (26). Feeding cholesterol in the diet of mice gives rise to an increase in the hepatic concentration of oxysterol ligands of LXR $\alpha$  (3,27) with resultant effects on target genes including SREBP-1c (28). The transcription of SREBP-1c is also regulated by insulin in a mechanism by which the insulin signal is transduced *via* insulin receptor substrate 1 (IRS-1) and PI 3-kinase (29–31). This mechanism contributes to the overall means by which insulin increases *de novo* FA synthesis (32,33).

Using mice of the SV/129 strain, we have compared the physiological consequences of changes in hepatic SREBP-1c expression caused by insulin, on the one hand, and by an LXR $\alpha$ - and oxysterol-mediated process resulting from cholesterol feeding, on the other. First, starvation for 24 h (beginning at the midpoint of the dark phase of the diurnal cycle) followed by 6 h of refeeding with a high-carbohydrate, low-fat diet (34) gave rise, as expected, to a large increase in plasma insulin ( $P < 0.001$ ) (Fig. 2). An increase in the expression of SREBP-1c mRNA ( $P < 0.001$ ) accompanied the rise in plasma insulin levels. There was also a significant increase in the

**FIG. 2.** Effects of starvation and refeeding on the lipogenic gene expression and pathway flux. Mice were starved for 24 h beginning at the midpoint of the dark phase of the diurnal cycle. They were then either killed (open bars) or fed *ad libitum* for 6 h and killed (solid bars) ( $n = 4$  in each group). In each group, at the end of the test period, some animals were injected i.p. with  $^3\text{H}_2\text{O}$  (1 mCi) 2 h before killing ( $n = 4$  in each group). Portions of the livers were used for measurement of fatty acid synthase (FAS) mRNA (columns 2) (37) and sterol regulatory element-binding protein-1c (SREBP-1c) mRNA (columns 1) (38). Measurement of the incorporation of  $^3\text{H}_2\text{O}$  into hepatic total FA (columns 3) was carried out as described previously (39). Immediately before killing, the animals were anesthetized with pentobarbital and a blood sample was taken for measurements of plasma insulin and the specific radioactivity of the plasma water. Values are presented as the mean  $\pm$  SEM for each group.

expression of an SREBP-1c target gene, fatty acid synthase (FAS) ( $P < 0.01$ ), which was itself accompanied by an increased carbon flux through the lipogenic pathway ( $P < 0.001$ ). This latter parameter was measured by injecting  $^3\text{H}_2\text{O}$  intraperitoneally *in vivo* and determining the incorporation of tritium into hepatic FA 2 h later when the animals were killed. The stoichiometry between the molar incorporation of  $^3\text{H}_2\text{O}$  and the molar incorporation of acetyl-CoA has been established (35), so this relationship can be used to determine the effects of various physiological manipulations on lipogenic carbon flux *in vivo*.

In the second experiment, mice were fed *ad libitum* for 7 d either with the standard, high-carbohydrate diet or with a similar diet supplemented with 2% (w/w) cholesterol. Cholesterol treatment, like insulin, increased the expression of SREBP-1c mRNA (Fig. 3) ( $P < 0.01$ ). However, in this case, the increase in SREBP-1c mRNA gave rise neither to an increased expression of the SREBP-1c target gene FAS nor to an increased lipogenic carbon flux. As expected, tritiated water incorporation into hepatic cholesterol *in vivo*, a measure of cholesterogenic carbon flux (36), was virtually abolished by cholesterol feeding, and there was a large decline in the expression of mRNA for HMG-CoA reductase, an enzyme with high control strength for overall pathway flux (37).

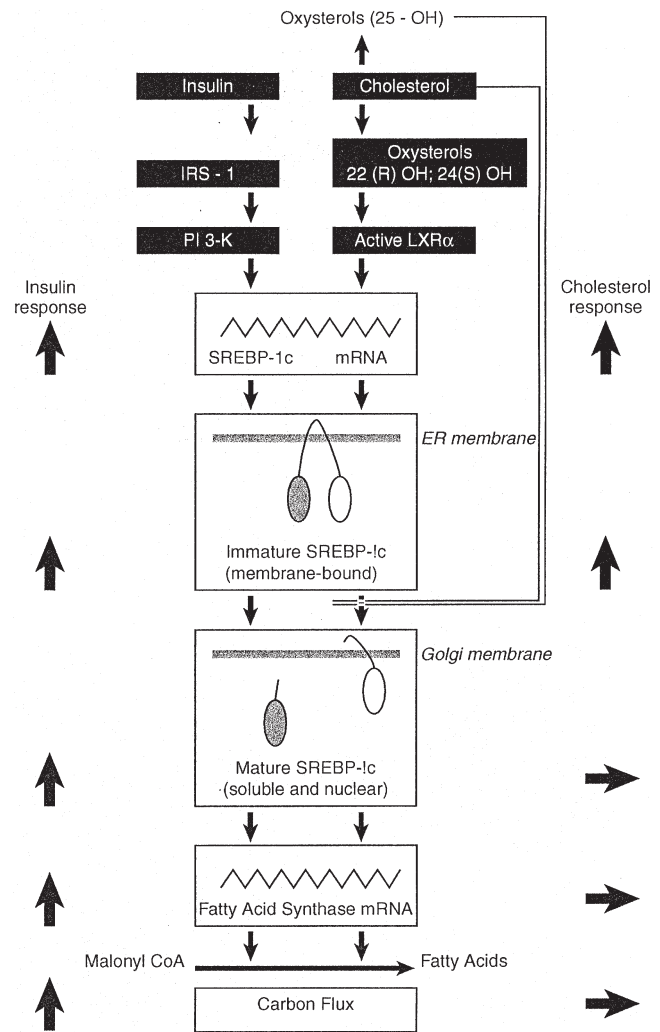

It might be argued that these results with cholesterol feeding merely confirm what has been known for many years in other mammalian species and serve to highlight the long-established fact that the effects of dietary cholesterol are specific for the hepatic cholesterogenic pathway. *De novo* lipogenic carbon flux from labeled acetate was apparently unaffected (18,40). Yet a paradox remains: What possible physiological purpose is served by an increased expression of

**FIG. 3.** Effects of dietary cholesterol on lipogenic gene expression and pathway flux. Mice were fed for 7 d with either a standard high-carbohydrate, low-fat diet (open bars) (37) or an identical diet containing 2% (w/w) cholesterol (solid bars). At the midpoint of the dark phase of the cycle, some animals from each group were killed and the livers removed for measurement of SREBP-1c mRNA (columns 1) (38) and FAS mRNA (columns 2) (37) ( $n = 4$  in each group). Other animals were injected i.p. with  $^3\text{H}_2\text{O}$  (1 mCi) and killed 2 h later ( $n = 4$  in each group) (columns 3). Values are presented as the mean  $\pm$  SEM. For abbreviations see Figure 2.

SREBP-1c mRNA when flux through a major pathway (lipogenesis) normally controlled by SREBP-1c target genes remains unchanged? The answer to this question may be found in terms of the posttranslational processing of SREBP-1c. The product of SREBP-1c mRNA translation is an immature transcription factor, which becomes active only following proteolytic cleavage (19,41). The increased expression of hepatic SREBP-1c mRNA following insulin administration either *in vivo* (30) or *in vitro* (33), which results in an increased lipogenic carbon flux (Fig. 2), was accompanied by an increase in the concentration of the mature form of SREBP (32). However, in the present work, immunoblotting of liver extracts from the cholesterol-fed mice did not show any change in the concentration of the mature form of SREBP-1c, despite the increased SREBP-1c mRNA expression (Fig. 3). This effect in mice appears to differ from the effects of cholesterol feeding in the liver of hamster, in which the mature form of SREBP-1c was reduced (42). Interestingly, the expression of SREBP-1c mRNA was not increased in the liver of the cholesterol-fed hamster (42), in contrast to that in the mouse (Fig. 3).

It has been established for some time that SREBP cleavage is sensitive to the sterol content of the intracellular membranes housing the proteolytic cleavage machinery (for reviews, see Refs. 19,41). In particular, mixtures of cholesterol and 25-hydroxycholesterol suppress the maturation of SREBP-1a in HeLa cells (43). In the absence of sterols, a specific peptide, SCAP (SREBP cleavage-activating protein) interacts with SREBP in the endoplasmic reticulum (ER) and escorts it to the Golgi, which houses the two proteases required for cleavage to give the mature form of SREBP that enters the nucleus (reviewed in Ref. 41) (Fig. 4). Sterols in some way prevent the transfer of the SCAP-SREBP complex from the ER to the Golgi, so maturation can no longer take place. It might be expected therefore that an increase in the sterol content of hepatic ER membranes following cholesterol

**FIG. 4.** Regulation and control of the SREBP-1c pathway by cholesterol and insulin in mouse liver. Insulin and cholesterol both increase SREBP-1c transcription but by different mechanisms. Cholesterol also results in a decreased cleavage of immature SREBP-1c, which imposes a constraint on the production of the mature transcription factor. The net effect of an increased transcription and translation coupled with a decreased cleavage ensures a constant production of the mature transcription factor and thus constant lipogenic carbon flux. In the absence of a constraint on cleavage, an insulin-mediated increase in transcription gives rise to an increased production of the mature transcription factor and an increased lipogenic carbon flux. IRS-1, insulin receptor substrate-1; PI 3-K, phosphatidylinositol 3-kinase; LXR $\alpha$ , liver X-receptor  $\alpha$ ; ER, endoplasmic reticulum; for other abbreviation see Figure 2.

feeding would suppress the maturation of SREBP-1c and lead to a decreased activation of its target genes. Previous experiments in the hamster have shown such a decrease in the nuclear forms of hepatic SREBP-1c and SREBP-2 following cholesterol feeding (42).

We have shown that hepatic SREBP-1c does not respond to cholesterol feeding in this manner in the mouse. In this species, in contrast to what occurs in the hamster, SREBP-1c mRNA expression increases but cleavage of the immature transcription factor remains unchanged. In the mouse, we propose that the upregulation of transcription and thus transla-

tion of SREBP-1c following cholesterol feeding compensate for an incipient sterol-mediated constraint on SREBP-1c maturation. The resulting constancy of mature SREBP-1c ensures a constant rate of target gene activation, including FAS, and thus a constant or only minimally reduced rate of lipogenic carbon flux (Figs. 3 and 4). This compensatory response in the mouse protects SREBP-1c-mediated regulation of metabolic pathways from interference by dietary cholesterol and ensures that the exogenous cholesterol response is restricted to cholesterologenic gene transcription only. In a previous study in mice, it is of interest that, although cholesterol feeding led to an almost fivefold increase in SREBP-1 mRNA expression, the expression of a target gene, FAS, was marginally decreased (44). In the liver of the hamster, however, dietary cholesterol was unable to activate hepatic LXR $\alpha$  and thus transcription of its target genes, including SREBP-1c and CYP7A1 was not increased (28). The inability of dietary cholesterol to upregulate the transcription and thus the translation of SREBP-1c in the hamster *via* a LXR $\alpha$ -mediated mechanism means that there is no opposition to the cholesterol-imposed constraint on cleavage, so the concentration of the mature form of SREBP-1c decreases. However, although there do not appear to be any reports of changes in hepatic FAS gene expression following cholesterol feeding in the hamster, rates of hepatic FA synthesis appear not to change (45).

In the liver of the rat, cholesterol feeding actually upregulated total lipogenic carbon flux (46) despite the previous conclusion (40) based on the use of  $^{14}\text{C}$ -acetate only. It would be of considerable interest to determine whether the nuclear form of SREBP-1c increases under these conditions in the rat. If this is the case, then cholesterol feeding may produce sufficient LXR $\alpha$  ligands so that activation of SREBP-1c transcription outstrips the constraints on SREBP-1c peptide cleavage. Cytochrome P450 is required for the formation of LXR $\alpha$  ligands from dietary cholesterol (for a review, see Ref. 3), and it is of interest that, in the rat, administration of the P450 inhibitor ketoconazole prevented the cholesterol-mediated increase in *de novo* hepatic FA synthesis (cholesterol only:  $11.2 \pm 2.0 \mu\text{mol } ^3\text{H}_2\text{O/h/g}$ ; cholesterol plus ketoconazole:  $5.7 \pm 1.3 \mu\text{mol } ^3\text{H}_2\text{O/h/g}$ ,  $n = 6$ ,  $P < 0.05$ ) (Gibbons, G.F., and Pullinger, C.R., unpublished work).

It may turn out that, in any species, the ability to maintain equilibrium in SREBP-1c-regulated pathways following a high-cholesterol diet may depend on the magnitude of the response mounted through LXR $\alpha$ . This response may itself be determined by changes in the P450-mediated production of LXR $\alpha$ -ligands.

#### PEROXISOME PROLIFERATOR-ACTIVATED RECEPTOR $\alpha$ (PPAR $\alpha$ ) DEFICIENCY RESULTS IN ABNORMAL INSULIN REGULATION OF SREBP-1c

Another transcription factor, besides LXR $\alpha$  and the SREBP family, that contributes to hepatic lipid homeostasis, is

PPAR $\alpha$ , which targets genes involved in the regulation of FA oxidation (for reviews, see Refs. 47,48). We have previously utilized PPAR $\alpha$ -knockout mice to study the role of PPAR $\alpha$  in the regulation of SREBP-dependent metabolic pathways in the liver (37). Normal mice showed an insulin-dependent circadian periodicity of lipogenesis in the liver that was abolished under conditions of PPAR $\alpha$  deficiency. The circadian rhythm of cholesterologenesis was also abolished, although the precise role of insulin, if any, in the regulation of cholesterol synthesis is not clear. In the PPAR $\alpha$ -knockout mice, abolition of these rhythms was accompanied by a significant attenuation of the normal diurnal variations of expression of the mRNA for FAS and HMG-CoA reductase, both of which failed to increase following the increase in plasma insulin that accompanied the start of feeding at the onset of the dark phase of the cycle (37). This apparent lack of response to insulin, particularly of the lipogenic pathway, raised the possibility that SREBP-1c was abnormally regulated under conditions of PPAR $\alpha$  deficiency. To test this, we determined the expression of SREBP-1c mRNA in the livers of the normal and PPAR $\alpha$ -deficient mice at the midpoint of the dark phase of the cycle. SREBP-1c expression was compared with expression of FAS mRNA and lipogenic carbon flux (measured by  $^3\text{H}_2\text{O}$  incorporation *in vivo*) in the two genotypes. Figure 5 shows that, despite the similarity in plasma insulin concentrations and the pattern of food intake (37), the expression of SREBP-1c mRNA was significantly decreased in the liver of PPAR $\alpha$ -knockout compared to normal animals ( $P < 0.01$ ) and that this difference was accompanied by a relative decrease in the expression of FAS mRNA ( $P < 0.05$ ) and of lipogenic pathway

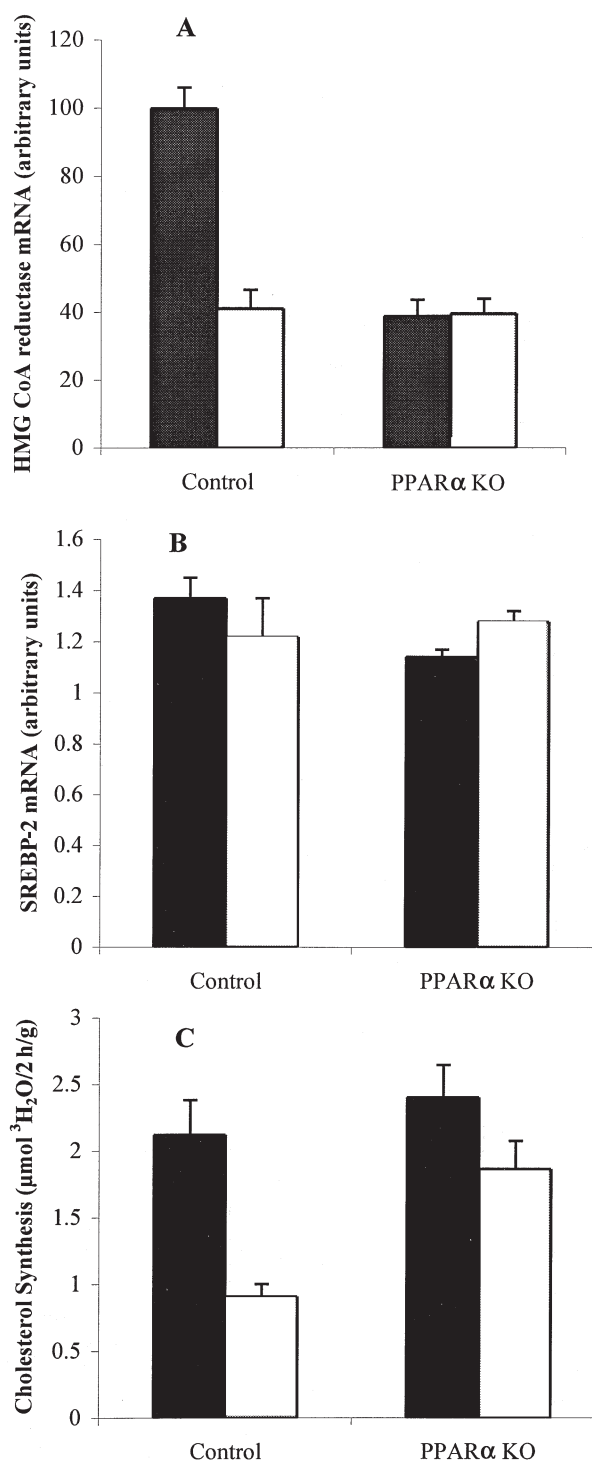

**FIG. 5.** Peroxisome proliferator-activated receptor  $\alpha$  (PPAR $\alpha$ ) deficiency results in abnormal regulation of SREBP-1c mRNA expression and lipogenic carbon flux. Groups of normal (solid bars) and PPAR $\alpha$ -knockout (open bars) mice were killed at the midpoint (sixth hour) of the dark phase of the diurnal cycle. The livers were removed and portions used to measure the concentration of the mRNA for SREBP-1c (columns 1) and FAS (columns 2) ( $n = 4$  in each group). At the same times other groups of mice were injected i.p. with  $^3\text{H}_2\text{O}$  (1 mCi) and killed 2 h later. The livers were removed for measurement of  $^3\text{H}_2\text{O}$  incorporation into FA (columns 3) (37). Immediately before killing, the animals were anesthetized with pentobarbital and blood samples taken from the descending *vena cava*. These were used for measurements of the plasma insulin concentration (columns 4) and for the specific radioactivity of plasma water. The values are presented as means  $\pm$  SEM. For abbreviations see Figure 2.

flux ( $P < 0.05$ ). Other insulin-dependent metabolic pathways in the liver also respond abnormally to starvation and refeeding in PPAR $\alpha$ -knockout mice (38), and under these conditions, the knockout mice show many of the metabolic characteristics of insulin resistance.

### PPAR $\alpha$ DEFICIENCY LEADS TO AN UNCOUPLING OF HMG-CoA REDUCTASE mRNA EXPRESSION FROM CHOLESTEROGENIC CARBON FLUX

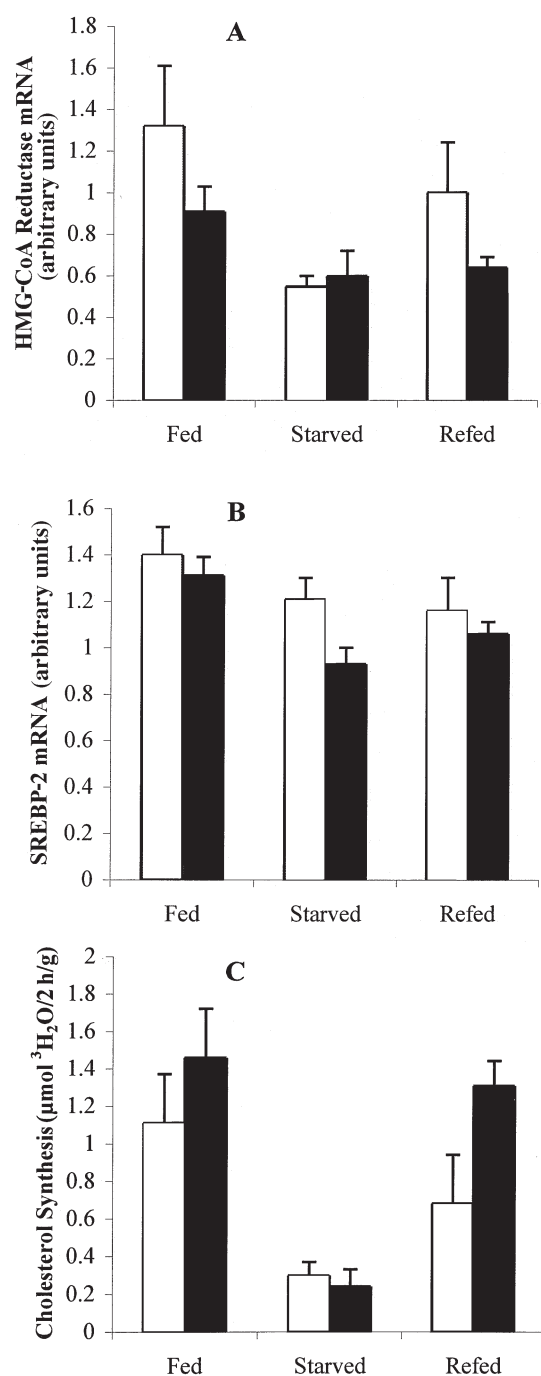

The diurnal rhythm studies showed that PPAR $\alpha$  deficiency led to an abolition of the normal variations of cholesterogenic carbon flux and HMG-CoA reductase mRNA expression. However, compared to the normal mice, carbon flux in the PPAR $\alpha$  knockout mice was maintained at a constantly high level, whereas HMG-CoA reductase mRNA remained constantly low (Fig. 6). Thus, compared to the normal mice, a higher rate of cholesterogenic carbon flux was supported by a lower expression of reductase mRNA. In other words, the functional efficiency of reductase mRNA expression for cholesterol synthesis was higher in the livers of the PPAR $\alpha$ -knockout mice than in the normal livers (34). SREBP-2 is generally considered to be a more important transcriptional activator of cholesterogenic genes, including HMG-CoA reductase, than is SREBP-1 (19). However, it is apparent from Figure 6 that there was no diurnal periodicity of SREBP-2 mRNA expression in either of the two mouse genotypes. Nor was there any difference in expression between the wild-type and the knockout mice.

It is well known that diurnal variations in cholesterogenesis and HMG-CoA reductase activity in rodents are associated with the changing pattern of food intake over the 24-h cycle (49,50), although the precise role of insulin is obscure. More extreme changes in food intake occur during starvation followed by refeeding, and these changes are again associated with parallel changes in cholesterogenic carbon flux and HMG-CoA reductase activity. We wanted to determine whether reductase expression and cholesterogenesis responded abnormally to starvation and refeeding under conditions of PPAR $\alpha$  deficiency as appeared to be the case over the diurnal cycle. To investigate this problem, mice of both genotypes were starved for 24 h (beginning at the midpoint of the dark phase of the diurnal cycle) and then either killed or refed *ad libitum* for a further 6 h. Normally fed mice of both genotypes were also tested at this point as controls (at the end of the dark phase of the cycle). Figure 7 shows that, following 24-h starvation of the normal mice, the expression of reductase mRNA decreased and then increased after refeeding. Similar changes also occurred in the rates of cholesterogenic fluxes, although the amplitudes of these changes were somewhat greater. In the liver of the PPAR $\alpha$ -knockout mice, however, although the amplitudes of the changes in cholesterogenic carbon flux were similar to or even higher than those in the normal mouse, there was very little or no change in the expression of reductase mRNA during starvation and refeeding. In particular, despite a sixfold increase in cholesterogenic

**FIG. 6.** Uncoupling of HMG-CoA reductase mRNA expression from cholesterogenic carbon flux in the livers of PPAR $\alpha$ -knockout mice. Normal (control) and PPAR $\alpha$ -knockout mice were killed at the midpoints (sixth hour) of the dark phase (solid bars) or of the light phase (open bars) of the diurnal cycle. The livers were removed, and the expression (A) of HMG-CoA reductase and (B) of SREBP-2 mRNA was determined (34) ( $n = 10$  in each group). For measurement of hepatic cholesterogenesis, other groups of mice (C) were injected with  $^3\text{H}_2\text{O}$  at the sixth hour of either the dark phase or the light phase and killed 2 h later ( $n = 12$  in each group). The values are presented as the means  $\pm$  SEM of each group. Reproduced from Reference 34 with permission. For abbreviations see Figures 2 and 5.

**FIG. 7.** Changes in cholesterogenic carbon flux are not accompanied by changes in the expression of HMG-CoA reductase mRNA during starvation and refeeding of PPAR $\alpha$ -knockout mice. Groups of normal (open bars) and PPAR $\alpha$ -deficient (solid bars) mice were starved for 24 h beginning at the midpoint of the dark phase of the diurnal cycle. Some mice in each group ( $n = 4$ ) were killed. Others were fed *ad libitum* and killed 6 h later ( $n = 4$ ). Livers were removed for measurement of SREBP-2 mRNA and HMG-CoA reductase mRNA. Identical groups of mice were used for measurement of  $^3\text{H}_2\text{O}$  incorporation into hepatic cholesterol ( $n = 4$  in each group; see legend to Fig. 2). Values are presented as the mean  $\pm$  SEM for each group. Reproduced from Reference 34 with permission. For abbreviations see Figures 2 and 5.

flux during refeeding, there was no change whatever in reductase mRNA expression.

Thus, the amounts of reductase mRNA required to support a given rate of carbon flux varied considerably in the livers of the knockout mice, whereas those in the wild-type remained relatively consistent (Table 1). Also, in the fed and refed states, the observed rates of cholesterogenesis in the livers of the knockout mice were supported by a lower level of reductase mRNA expression than those in the wild-type. In other words, the efficiency of reductase gene expression for cholesterogenic pathway flux was greater in the knockout than the wild-type animal (Table 1). Similar to the situation over the diurnal cycle, starvation and refeeding had little or no effect on the expression of SREBP-2 mRNA (Fig. 7).

To ascertain whether the abnormal responses of HMG-CoA reductase mRNA in the PPAR $\alpha$ -deficient mice described above were associated with an abnormal response to dietary cholesterol, mice of both genotypes were fed a diet enriched in cholesterol (2% w/w). In mice of both genotypes, HMG-CoA reductase mRNA expression was decreased to the same extent, as was cholesterogenic flux (34). Again, similar to the wild-type mice, cholesterol feeding increased SREBP-1c mRNA, but there was no change in the concentration of the mature form of the transcription factor.

#### MCA OF CHOLESTEROL SYNTHESIS

The above observations of uncoupling between reductase expression and cholesterogenic carbon flux in the PPAR $\alpha$ -knockout mice easily could be dismissed by assuming that, under these conditions, reductase is not “rate-limiting” for cholesterol synthesis. This is a somewhat facile explanation and begs a definition of exactly what is meant by the expression “rate-limiting step.” It is generally assumed that, within intact cells, “rate-limiting steps” are saturated with substrate and the supply of substrate for this step never becomes limiting for pathway flux. Furthermore, a quantitative relationship is considered to exist between the activity (or amount) of a rate-limiting enzyme and overall pathway flux. In other words, within a given pathway, changes in the activity (or amount) of a rate-limiting enzyme account for all of the changes in overall flux through the pathway. These assumptions have never been rigorously tested for HMG-CoA reductase, and the many instances in which experimental evidence suggests otherwise have been conveniently sidelined. On the other hand, evidence from a large number of experiments carried out in many areas of metabolic regulation suggests that overall pathway flux is determined by a number of steps, and the contribution of each step to changes in overall flux is defined by its “control strength” or “flux-control coefficient” (22). This concept, embodied in the MCA approach to the question of flux regulation, has been used successfully to explain the regulation of several pathways, including glycogen synthesis (51) and may be of universal applicability in the interpretation of functional genomic data (52) and in biotechnology and medicine (53). This approach also forces one to consider the effects, on the regulation of a particular pathway, of simultaneous changes in flux through other pathways,

**TABLE 1**  
**Efficiency<sup>a</sup> of HMG-CoA Reductase mRNA Expression for Cholesterogenic Carbon Flux<sup>b</sup>**

Fed		Starved		Refed	
Wild-type	KO	Wild-type	KO	Wild-type	KO

particularly those that provide and compete for common substrates.

A classic example of this situation relates to the supply and demand for the pool of acetyl-CoA in the cytosol of the cell. This pool is the common source of lipogenic and cholesterogenic carbon. One of the factors that determines supply of cytosolic acetyl-CoA is the activity of ATP:citrate lyase. This enzyme converts citrate, emerging from the mitochondrion, into cytosolic acetyl-CoA and oxaloacetate. Inhibition of ATP:citrate lyase with hydroxycitrate in cultured hepatocytes leads to a shortage of cholesterogenic precursor acetyl-CoA and a decreased cholesterogenic carbon flux. Under these conditions the  $V_{\text{max}}$  of reductase, measured under substrate-saturating conditions, increased twofold (54). This experiment suggests that reductase is not saturated with substrate in the intact cell and that enzymes affecting HMG-CoA substrate availability, such as ATP:citrate lyase, have, in terms of MCA, a high flux control coefficient for cholesterogenic pathway flux. Under these conditions, the  $V_{\text{max}}$  or capacity of reductase increases in an attempt to maintain cholesterogenic flux through the pathway. This is an analogous response to an increased LDL receptor capacity, which arises from a decreased availability of extracellular LDL cholesterol and which serves as a compensatory response to an incipient decline in cellular cholesterol influx. By the same token, an increased reductase activity does not always equate with an increased cholesterogenic pathway flux but reflects a compensatory response to a decreased substrate supply. Under these conditions of reduced substrate supply, the efficiency of reductase for maintaining cholesterol carbon flux is diminished.

Again, because lipogenesis and cholesterogenesis compete for the same common pool of acetyl-CoA, any change in lipogenic carbon flux may affect the availability of acetyl-CoA for cholesterol production. This is particularly true in organs such as the liver where the FA pathway is the "fat cat" and consumes 10 times more substrate than cholesterogenesis. In other lipogenic tissues, such as adipose tissue and lactating mammary gland, the cholesterol pathway faces even greater competition. In the latter organ, although flux into cholesterol is 10-fold lower than in the liver, HMG-CoA reductase capacity, or  $V_{\text{max}}$  (measured under substrate-saturating conditions in a cell-free preparation) is threefold higher (55). Reductase needs to operate at this high capacity simply to pump a small quantity of carbon into the cholesterol pathway in the face of a huge competitive demand for acetyl-CoA to meet the needs of FA synthesis for milk TAG production. In this

tissue therefore, the efficiency of reductase action for cholesterol synthesis is diminished. The demands of the lipogenic pathway for acetyl-CoA by the lactating mammary gland can be reduced by including fat in the diet. This manipulation also reduces *de novo* lipogenesis. Under these conditions, the rate of cholesterol synthesis does not change but remains exactly the same as that on a high-carbohydrate diet. Under these new circumstances, when a competing constraint has been partially alleviated, reductase has to work less hard to achieve a given flux, and its capacity, or  $V_{\text{max}}$ , decreases accordingly (55). The efficiency of reductase for cholesterol synthesis is now increased. Other similar compensatory effects in the cholesterol pathway for changes in flux through the lipogenic pathway have also been reported in hepatocytes (36).

To use an analogy for the effects of these changes in substrate availability, the efficiency of breathing at a Mt. Everest base camp, where atmospheric oxygen availability is limited, is obviously less than that at sea level. At high altitudes, breathing rates increase simply to maintain a constant supply of oxygen to the tissues. For an athlete competing in a track event at lower altitudes, a similar increase in breathing rate would obviously increase tissue oxygen supply in response to a greater demand by the exercising muscles. This rather mundane example serves to illustrate the fundamental principle that changes in the  $V_{\text{max}}$  of an enzyme can serve two purposes, depending on the physiological environment in which it has to operate: either to maintain flux homeostasis (regulation) or to change pathway flux (control).

The general concept of the metabolic efficiency of an enzyme is also applicable to transcription of the gene that encodes it. In this case, it is valid to refer to the functional efficiency of gene expression in terms of the amount of mRNA required to support a given flux rate through a pathway in different physiological, nutritional, or genetic environments. In the present work, when the PPAR $\alpha$  gene was deleted, a given expression of HMG-CoA reductase mRNA supported a higher rate of cholesterol pathway flux than when PPAR $\alpha$  was intact. This increased functional efficiency of reductase expression may have resulted from an increased availability of cytosolic acetyl-CoA arising from a decreased pathway flux of acetyl-CoA into FA in the PPAR $\alpha$ -knockout mouse (Fig. 5). It has also been noted recently that deletion of the LXR $\alpha$  gene was associated with an increased expression of cholesterogenic genes including HMG-CoA reductase. However, this increase was not accompanied by an increase in the rate of cholesterogenesis (44) and it is possible that, under

conditions of LXR $\alpha$  deficiency, cholesterologenic genes mount a concerted compensatory response to maintain pathway flux in the face of a constraint in substrate supply.

The general principle of MCA also can be adopted to explain the increased transcription of SREBP-1c mRNA as a compensatory response to the constraints on SREBP-1c peptide cleavage imposed by cholesterol feeding in the mouse. The unchanged concentration of mature SREBP-1c is the result of these two opposing effects and ensures that lipogenic flux in mouse liver remains unchanged or only minimally decreased (Fig. 3). Responses such as this may reflect the biological equivalent of the physicochemical principle of Le Chatelier: "When a constraint is placed upon a system, the system reacts in a manner which tends to remove the constraint." In any event, it is becoming clear that changes at every level of regulation and control from that of the gene to that of the activity of its ultimate product may serve to maintain metabolic equilibrium rather than to change metabolic flux when physiological, nutritional, or genetic constraints are imposed on an organism.

## ACKNOWLEDGMENTS

I would like to thank all my former colleagues, particularly Dr. John Goad (University of Liverpool, United Kingdom), the late Professor William R. Nes (Drexel University, Philadelphia, PA), Dr. Nick B. Myant [Medical Research Council (MRC) Lipid Metabolism Unit, Hammersmith, United Kingdom], Dr. Andrew A. Kandutsch (Jackson Laboratory, Bar Harbor, ME) and the late Dr. Derek H. Williamson (University of Oxford, United Kingdom) for their help, advice, and encouragement. Thanks are also due to my colleagues in the Metabolic Research Laboratory, Oxford, particularly David Wiggins, Abdel Hebbachi, and Anna-Marie Brown. I am also indebted to my colleagues at the Imperial College School of Medicine, Hammersmith Hospital (London, United Kingdom), Drs. Brian Knight and Dilip Patel, who made important contributions to the experimental work described in this review. I am grateful to Drs. Jeffrey Peters and Frank Gonzalez (National Institutes of Health, Bethesda, MD) for providing the mating pairs of PPAR $\alpha$ -knockout mice. The experimental work described in this paper was funded by the MRC of the United Kingdom and the British Heart Foundation (BHF) (United Kingdom). I thank the MRC and BHF for their support.

# The Role of Cytochrome P450 in the Regulation of Cholesterol Biosynthesis

Geoffrey F. Gibbons\*

University of Oxford, Oxford OX2 6HE, United Kingdom

**ABSTRACT:** A ubiquitously expressed member of the cytochrome P450 superfamily, CYP51, encodes lanosterol 14 $\alpha$ -demethylase, the first step in the conversion of lanosterol into cholesterol in mammals. The biosynthetic intermediates of lanosterol 14 $\alpha$ -demethylation are oxysterols, which inhibit HMG-CoA reductase and sterol synthesis in mammalian cells *in vitro*. These oxysterols (5 $\alpha$ -lanost-8-en-3 $\beta$ ,32-diol and 3 $\beta$ -hydroxy-5 $\alpha$ -lanost-8-en-32-al) are efficiently converted into cholesterol *in vitro* and are generally considered to be natural cholesterol precursors. When added to hepatocytes in high concentrations, besides their conversion into cholesterol, they are also rapidly metabolized into more polar sterols and into steryl esters. The 15 $\alpha$ - and 15 $\beta$ -hydroxy epimers of 5 $\alpha$ -lanost-8-en-3 $\beta$ -ol are also rapidly metabolized into more polar sterols and steryl esters but are not converted efficiently into cholesterol. Polar sterol formation from all these oxysterols is dependent on an active form of cytochrome P450. Oxysterols are potent regulators of the activities of transcription factors of the sterol regulatory element-binding protein family and of liver X-receptor  $\alpha$ . It is proposed that the rapid, cytochrome P450-dependent metabolism of naturally occurring regulatory oxysterols provides a route for their deactivation so that they become incapable of affecting gene transcription. Inhibition of cytochrome P450 by the drug ketoconazole prevents the inactivation of such oxysterols, leading to a prolonged suppression of hepatic HMG-CoA reductase *in vivo* and *in vitro*.

Paper no. L9141 in *Lipids* 37, 1163–1170 (December 2002).

Early experiments designed to determine the stereochemistry of cholesterol biosynthesis from mevalonic acid showed that the 15 $\alpha$ -hydrogen of lanosterol (Scheme 1) was stereospecifically removed (1), resulting in the formation of 5 $\alpha$ -lanosta-8,14,24-trien-3 $\beta$ -ol (IV, Scheme 1) (for reviews, see Refs. 2,3). The conjugated 8,14-diene is the immediate steroidal product of lanosterol 14 $\alpha$ -demethylation, a process that in both mammalian liver and yeast was shown to require an active form of cytochrome P450 (4,5). Subsequent work showed that of the more than 1,000 known members of the cytochrome P450 superfamily, only this particular type is ubiquitously expressed throughout the animal and plant kingdoms (6,7) and is now known as CYP51 (8). The C-32 oxy-

gen-functionalized lanosterol derivatives 5 $\alpha$ -lanost-8-en-3 $\beta$ ,32-diol (II) and 3 $\beta$ -hydroxy-5 $\alpha$ -lanost-8-en-32-al (III, Scheme 1) are obligatory intermediates in the cytochrome P450-dependent removal of the 14 $\alpha$ -methyl group (9,10), and these oxysterols are now generally considered to be natural cholesterol precursors (11). On the other hand, the 15 $\alpha$ - and 15 $\beta$ -hydroxy epimers of lanost-8-en-3 $\beta$ -ol (V and VI, Scheme 1) are poor precursors of cholesterol and are probably not natural intermediates (9).

The seminal work of Kandutsch and colleagues showed convincingly that certain types of oxygenated sterol derivatives, rather than cholesterol itself, were potent inhibitory regulators of *de novo* sterol biosynthesis *in vitro* (12,13) and that an important target enzyme was HMG-CoA reductase. Subsequent work, summarized in the review by Schroepfer (14), related oxysterol structure to inhibitory potency. More recently, the discovery of the sterol regulatory element-binding protein (SREBP) family of transcription factors by Brown, Goldstein, and their colleagues (reviewed in Refs. 15,16) provided an explanation for the inhibitory action of oxysterols, particularly 25-hydroxycholesterol, on several cholesterologenic enzymes, including HMG-CoA reductase. Thus, interference with the proteolytic maturation of SREBP by oxysterols prevented the formation of the transcriptionally active N-terminal peptide of SREBP so that target genes were not activated. Later work demonstrated that other oxysterols regulated gene transcription by virtue of their role as activating ligands for the transcription factor liver X-receptor  $\alpha$  (LXR $\alpha$ ) (17–20). Target genes for activated LXR $\alpha$  include those involved in the regulation of whole-body cholesterol balance such as SREBP (21), cholesterol 7 $\alpha$ -hydroxylase (CYP7A1) (19), and the cholesterol transporter ABCA1 (22).

Despite the potency with which oxysterols regulate gene transcription by the SREBP and LXR $\alpha$  pathways, there remains uncertainty concerning the structure(s) of the naturally occurring regulatory oxysterols and the enzymology involved in their biosynthesis and metabolism. This paper revisits some of our previous work in this area (23–26), which suggests that the oxygenated, naturally occurring cholesterol precursors II and III (Scheme 1) may have a regulatory role, either as inhibitors of SREBP maturation or as activating ligands for LXR $\alpha$ . This paper will also reassess the results of some of our original studies on the regulation of cholesterol biosynthesis (27,28) in terms of factors that affect the steady-state concentration and turnover of natural regulatory oxysterols.

## MATERIALS AND METHODS

Preparation of the tritium-labeled sterols functionalized at C-32 was carried out by acetolysis of 3 $\beta$ -acetoxy-5 $\alpha$ -lanostan-7 $\alpha$ ,32-oxide (23). Sterols functionalized at C-15 were prepared from 3 $\beta$ -hydroxy-5 $\alpha$ -lanost-7-en-15-one (29) and were labeled with tritium at C-16 (30).

The formation of polar and nonpolar sterol products of the functionalized lanostenols by cells cultured *in vitro* was determined by solvent extraction of the total lipids followed by TLC (23). The metabolism of the labeled 15-hydroxy epimers of lanost-8-en-ol by subcellular fractions of rat liver was determined as described in Reference 25. Characterization of the polar sterols was carried out by GC-MS.

Measurement of HMG-CoA reductase activity in cell cultures was carried out using the method described by Gibbons *et al.* (23). Isolation of the microsomal fraction from rat liver was carried out as described by Marco de la Calle *et al.* (27). Measurement of HMG-CoA reductase activity in rat liver microsomes was carried out using the method of Brown *et al.* (31).

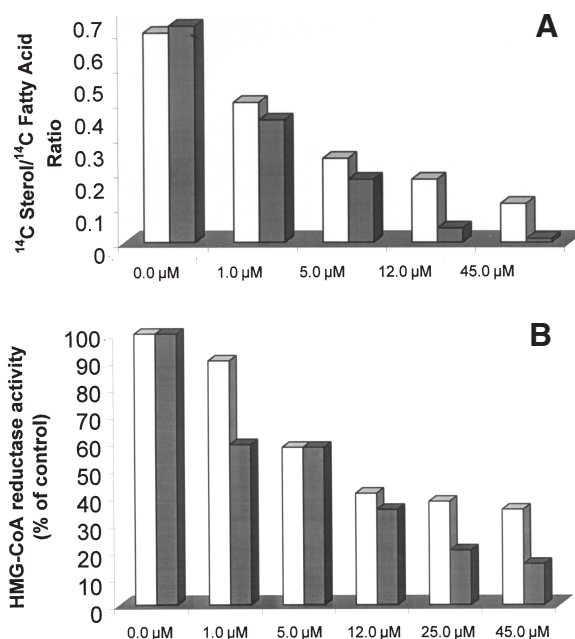

Rats (250–300 g) treated with ketoconazole received the drug intragastrically in 0.1 M HCl (1.5 mL of a 4.0 mg/mL solution). The drug was administered at different times (1, 6, 12, 17, and 24 h) before injection (i.p.) of  $^3\text{H}_2\text{O}$  (0.2 mL, 4.0 mCi), and the animals were killed 1 h later. The livers were removed and a portion was used for determination of tritium incorporation into sterols (27). The remainder was used for preparation of microsomes (see above).

Experiments using live animals were carried out in accordance with British Government Home Office-approved procedures under the authority of project licence number PPL 3001446.

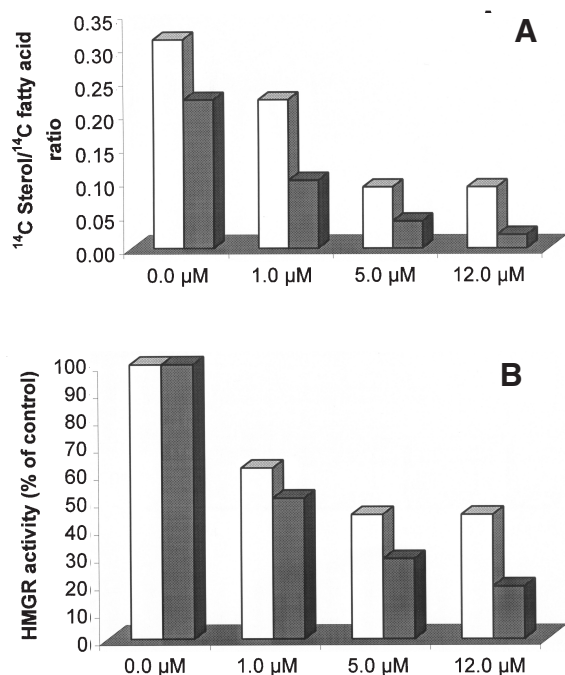

## RESULTS

*Oxysterol precursors of cholesterol inhibit HMG-CoA reductase.* The cholesterol precursors **II** and **III** (Scheme 1) were

added to primary cultures of mouse fetal liver cells at concentrations ranging from 0 to 45  $\mu\text{M}$  for 12 h. Cells from some of the flasks were harvested at this time, and HMG-CoA reductase activity was determined. To the remaining flasks was added [ $^{14}\text{C}$ ]acetate for a further 2 h, and the cells were harvested for measurement of sterol and fatty acid (FA)

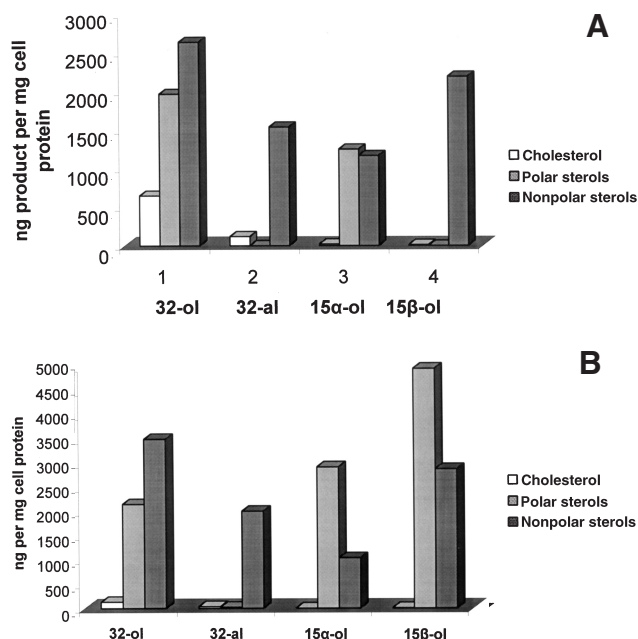

**FIG. 1.** Inhibition of (A) sterol synthesis and (B) HMG-CoA reductase by 32-functionalized lanost-8-en-ols in fetal liver. 5 $\alpha$ -Lanost-8-en-3 $\beta$ ,32-diol (open bars) and 3 $\beta$ -hydroxy-5 $\alpha$ -lanost-8-en-32-al (solid bars) were added to cultures of mouse fetal liver at concentrations ranging from 0–45  $\mu\text{M}$  (23) for 12 h. The cultures were then either harvested and used for measurement of HMG-CoA reductase activity (B) or cultured for a further 2 h in the presence of [ $^{14}\text{C}$ ]acetate (A). Measurements of HMG-CoA reductase and acetate incorporation into sterols and FA were carried out as described in Reference 23.

**FIG. 2.** Inhibition by 32-functionalized 5 $\alpha$ -lanost-8-enols of (A) sterol synthesis and (B) HMG-CoA reductase activity in Chinese hamster lung cells. Sterols as described in the caption of Figure 1 were incubated with Chinese hamster lung cells for 6 h. The cells were subsequently treated as described in the caption to Figure 1.

synthesis (23). Figure 1 shows that HMG-CoA reductase activity was inhibited by low concentrations of both **II** and **III**. Concentrations required for 50% inhibition of reductase were 6.7 and 4.9  $\mu$ M, respectively. The overall rates of sterol synthesis from [<sup>14</sup>C]acetate were somewhat more sensitive to inhibition by the 32-oxygenated lanostenols than were HMG-CoA reductase activities, particularly at the higher end of the concentration range (Fig. 1).

The experiment described above was repeated using a line of Chinese hamster lung (Dede) cells in which case the cells were cultured for 6 h in the presence of the sterols (0–12  $\mu$ M) before assay of HMG-CoA reductase. As with the fetal liver cells, [<sup>14</sup>C]acetate was added to some flasks for a further 2 h to measure rates of FA and sterol synthesis (23). The inhibitory effects of the sterols are shown in Figure 2. The rates of sterol synthesis and HMG-CoA reductase activities were somewhat more sensitive to inhibition by the 32-oxygenated

**FIG. 3.** Cholesterogenic and noncholesterogenic metabolism of oxygenated lanost-8-enols (A) and lanost-7-enols (B). The  $\Delta^7$  and  $\Delta^8$  isomers of labeled 5 $\alpha$ -lanosten-3 $\beta$ ,32-diol (32-ol), 3 $\beta$ -hydroxy-5 $\alpha$ -lanosten-3 $\beta$ ,15 $\alpha$ -diol (15 $\alpha$ -ol) and 5 $\alpha$ -lanosten-3 $\beta$ ,15 $\beta$ -diol (15 $\beta$ -ol) were incubated with fetal mouse liver cultures for 12 h. Metabolic products were separated and quantified as described in Reference 23.

sterols in the Dede cells than in the primary liver cell cultures. In this case, concentrations required for 50% inhibition of reductase were 2.8 and 1.4  $\mu$ M for **II** and **III** (Scheme 1), respectively. Again, in the Dede cells, the overall rates of sterol synthesis were more susceptible to inhibition than HMG-CoA reductase. A mutant strain of Dede cells (A2-1) selected for resistance to the metabolic effects of 25-hydroxycholesterol was also resistant to the inhibitory effect of the 32-oxygenated lanostenol derivatives on HMG-CoA reductase activity (23,24). Similar inhibitory effects of the lanostenol derivatives on rates of sterol synthesis and HMG-CoA reductase activities were also observed in L-cells, a subline of mouse fibroblasts (23). Like the Dede cells, HMG-CoA reductase activity was more sensitive to inhibition in the L-cell line than in the primary liver cell culture (concentrations required for 50% inhibitions were 2.5 and 2.8  $\mu$ M for **II** and **III**, respectively).

**TABLE 1**  
Metabolism of <sup>3</sup>H-Labeled C-32-Oxygenated Lanostenols<sup>a</sup> by L-Cells and Primary Cultures of Fetal Liver

	Cholesterol		Polar sterols		Nonpolar sterols	
	L-cells	Liver	L-cells	Liver	L-cells	Liver
Precursor sterol			(ng/mg protein)			
5 $\alpha$ -Lanost-8-ene 3 $\beta$ ,32-diol	182	643	ND	1960	368	2630
3 $\beta$ -Hydroxy-5 $\alpha$ -lanost-8-en-32-al	109	116	ND	ND	352	1532
5 $\alpha$ -Lanost-7-ene 3 $\beta$ ,32-diol	127	131	33	2153	729	3509
3 $\beta$ -Hydroxy-5 $\alpha$ -lanost-7-en-32-al	27	38	63	22	305	2005

<sup>a</sup>The values are adapted from those shown in Table IV of Reference 23. The labeled sterols were incubated for 5 h, and the labeled metabolites were separated by TLC. ND = not detected.

Oxygenated lanosterol derivatives are rapidly metabolized by noncholesterogenic pathways. The C-32 functionalized lanosterol derivatives **II** and **III** (Scheme 1) were labeled with tritium (9) and added to cultures of mouse fetal liver cells for 12 h (23). Their metabolism to cholesterol and to noncholesterol products was determined at the end of this period. Similar experiments were carried out with the  $\Delta^7$  isomers of these derivatives. Figure 3 shows that, although these substances were converted, as expected, into cholesterol, they were converted much more efficiently into nonpolar substances with the chromatographic properties of steryl esters. Alkaline hydrolysis of these substances yielded labeled materials with the same properties as the substrates, adding further support for their esterified nature (results not shown). The labeled C-32 alcohols were also extensively converted into more polar substances with the chromatographic properties of lanostenetriols. To determine whether these metabolic patterns were characteristic of noncholesterogenic as well as cholesterogenic oxygenated lanosterol derivatives, we utilized the labeled 15 $\alpha$ - and 15 $\beta$ -hydroxyl epimers of 5 $\alpha$ -lanost-8-en-3 $\beta$ -ol and 5 $\alpha$ -lanost-7-en-3 $\beta$ -ol, which we had previously shown to be much poorer cholesterol precursors than the naturally occurring 32-functionalized derivatives (9). Again, all these labeled compounds were extensively esterified to nonpolar derivatives, and three of them were converted even more efficiently into more polar sterols, which suggested the introduction of a further oxygen function (Fig. 3).

Similar experiments using mouse fibroblasts (L-cells) instead of fetal liver cells showed that, in this case, cholesterol was relatively a much more important metabolite of the C-32-functionalized lanost-8-enols (Table 1). The capacity of L-cells to esterify these labeled substances was decreased compared to that of the primary liver cells, and the capacity for polar sterol formation was almost abolished.

*Oxidative metabolism of oxygenated lanostenols is dependent on cytochrome P450.* Although L-cells and fetal liver cells were broadly similar in their ability to convert the  $\Delta^7$  and  $\Delta^8$  C-32 alcohols into cholesterol, in most cases polar sterol formation from these substances in the former cells was virtually abolished. Since many types of cytochrome P450 are more highly expressed in the liver than in nonhepatic tissues, we considered the possibility that the formation of polar sterols in the liver was a cytochrome P450-dependent process. To test this idea, we examined the effects of gas mixtures containing carbon monoxide (CO), a broad-range P450 inhibitor, on polar sterol formation from the labeled 15 $\alpha$ -hydroxy and 15 $\beta$ -hydroxy epimers of 5 $\alpha$ -lanost-8-en-3 $\beta$ -ol in subcellular fractions of rat liver (25). Our previous studies with this system used GC-MS to investigate the nature of the polar materials. The fragmentation patterns suggested that the polar structures consisted of 5 $\alpha$ -lanostenetriols in which the third hydroxyl group was situated at C-7 (results not shown). Figure 4 shows that replacement of N<sub>2</sub> with CO in gas mixtures containing oxygen resulted in a 50–60% decrease in the rate of oxidative metabolism of both the 3 $\beta$ ,15 $\alpha$  and 3 $\beta$ ,15 $\beta$  lanostenediols, suggesting the involvement of cytochrome

**FIG. 4.** Carbon monoxide inhibits the oxidative metabolism of the labeled (A) 15 $\alpha$ - and (B) 15 $\beta$ -hydroxy epimers of 5 $\alpha$ -lanost-8-enol. Tritium-labeled 5 $\alpha$ -lanost-8-en-3 $\beta$ ,15 $\alpha$ -diol (A) and 5 $\alpha$ -lanost-8-en-3 $\beta$ ,15 $\beta$ -diol (B) were incubated with subcellular fractions of rat liver for 45 min in the presence of gas mixtures consisting of nitrogen plus oxygen (9:1 vol/vol, ●) or carbon monoxide plus oxygen (9:1 vol/vol, ▲). The oxidative products (lanostenetriols) were separated and quantified by TLC as described in Reference 25.

P450. Another cytochrome P450 inhibitor, ketoconazole, also inhibited the metabolism of the C-32-functionalized lanost-8-enols into more polar sterols by cholesterogenically competent subcellular fractions of rat liver (32). Under similar conditions, when [<sup>14</sup>C]mevalonate was the sterol precursor, ketoconazole caused the accumulation of labeled sterols more polar than cholesterol, including the cholesterol precursor 3 $\beta$ -hydroxy-5 $\alpha$ -en-32-al (**II**, Scheme 1) (28).

*Inhibition of cytochrome P450 in vivo and in vitro suppresses hepatic HMG-CoA reductase activity and sterologenic carbon flux.* In view of the above inhibitory effects of CO, suggestive of the participation of cytochrome P450 in the oxidative metabolism of oxysterol regulators of HMG-CoA reductase, we determined the effects of administering the potent cytochrome P450 inhibitor ketoconazole on hepatic HMG-CoA reductase activity and carbon flux through the sterol pathway in intact animals (27) and in hepatocyte culture (28). In the experiments with intact animals, a solution of ketoconazole was administered intragastrically to groups of animals, and the animals were killed at various times thereafter. At each time point, 1 h before killing, <sup>3</sup>H<sub>2</sub>O was injected intraperitoneally. The livers were removed from the animals and

**FIG. 5.** Time course of the effects of ketoconazole on hepatic HMG-CoA reductase activity and sterologenes. Rats were treated intragastrically with a solution of ketoconazole and killed at various times later. One hour before killing, the rats were injected intraperitoneally with  $^3\text{H}_2\text{O}$  (4 mCi). Parts of each liver were used to prepare microsomes to measure the expressed (i.e., dephosphorylated) and total (phosphorylated plus dephosphorylated) forms of HMG-CoA reductase (31). The remaining liver was used to measure  $^3\text{H}_2\text{O}$  incorporation into nonsaponifiable lipids (sterologenes). (●) Expressed activity of HMG-CoA reductase; (▲) total activity of HMG-CoA reductase; (■)  $^3\text{H}_2\text{O}$  incorporation into nonsaponifiable lipids. Values marked \* and \*\* are significantly different ( $P < 0.05$  and  $P < 0.01$ ) from the corresponding zero time control value.

a portion was used for preparation of microsomes for the assay of the expressed (i.e., dephosphorylated) and total (phosphorylated plus dephosphorylated) forms of HMG-CoA reductase (31). The remainder was used for isolation of the  $^3\text{H}$ -labeled nonsaponifiable lipid and cholesterol-containing fractions (27). The  $^3\text{H}$  content of these fractions was determined, and the values were used as a measure of carbon flux through the sterol pathway (33). Figure 5 shows that at as little as 2 h after ketoconazole administration, both HMG-CoA reductase activity and sterologenic carbon flux were decreased. These activities remained suppressed for a further 10 h after which time suppression was abolished. At 24 h following ketoconazole treatment, there was an "overshoot" of HMG-CoA reductase activities and sterol carbon flux such that these values were significantly greater than those immediately before treatment. Addition of ketoconazole (0–2  $\mu\text{M}$ ) directly to primary cultures of rat hepatocytes also gave rise to a suppression of HMG-CoA reductase activity (28), showing that the hepatic effects observed *in vivo* were not an indirect result of ketoconazole action.

*Chronic exposure of the liver to ketoconazole induces CYP51 activity.* In the experiments with intact rats described above, samples of the hepatic microsomes were used to assay lanosterol 14 $\alpha$ -demethylase activity as measured by the amounts

of labeled cholesterol produced from [ $^{14}\text{C}$ ]lanosterol. At 24 h following ketoconazole treatment, when HMG-CoA reductase activity was significantly increased, cholesterol formation from [ $^{14}\text{C}$ ]lanosterol was also increased, suggesting an induction of 14 $\alpha$ -demethylase (CYP51) activity (27). Also, in subcellular fractions of rat liver capable of cholesterol synthesis from [ $^{14}\text{C}$ ]mevalonic acid, there is usually some accumulation of label in lanosterol. The proportion of such label was significantly decreased in liver fractions from rats that had consumed ketoconazole in the diet for the previous 24 h. Finally, in the livers of rats that had been continually pretreated with the drug (2 doses) over the previous 48 h, an acute dose of ketoconazole (2 h) was not so effective as suppressing sterol synthesis and lanosterol 14- $\alpha$  demethylation compared with that in nonpretreated animals (27).

## DISCUSSION

The functional role of a species of cytochrome P450 during lanosterol 14 $\alpha$ -demethylation was first described in mammalian liver in 1973 (4) and in yeast the following year (5). Since that time the enzyme involved, lanosterol 14 $\alpha$ -demethylase (P45014DM), has been the subject of increasing scrutiny, particularly in view of its role as a target enzyme for the azole group of antibiotics (34,35). The enzyme is encoded by CYP51 (8), the only member of the cytochrome P450 superfamily that is ubiquitously expressed in all the biological phyla (6). The importance of CYP51 is further emphasized by the finding that in mammals, the C-32-oxygenated intermediates of lanosterol 14 $\alpha$ -methylase (**II** and **III**, Scheme 1), which are natural cholesterol precursors (2,9,10), are potent inhibitors of sterol synthesis and HMG-CoA reductase activity in mammalian cells (23; reviewed in Ref. 11). The immediate steroidal product of lanosterol 14 $\alpha$ -demethylase is 5 $\alpha$ -lanosta-8,14,24-trien-3 $\beta$ -ol (2,3). Steroids containing the conjugated  $\Delta^{8,14}$  diene grouping are potently active stimulators of meiosis in oocytes (36,37) and also play a role as activating ligands for the transcription factor LXR $\alpha$  (17). Oxysterols suppress cholesterol synthesis by interfering with the proteolytic cleavage of the immature transcription factor SREBP-2 (16) to give a mature form that normally enters the nucleus and transactivates a large portfolio of cholesterol genes, including HMG-CoA reductase (15,38). It is likely that interference with SREBP-2 maturation is the means by which the oxygenated cholesterol precursors **II** and **III** suppress HMG-CoA reductase *in vitro*. However, in some cases, the rapidity with which effects are observed (e.g., Fig. 5) might suggest a mechanism in addition to that which involves changes in gene expression. In this respect, a recent report (39) has suggested that oxysterols in some way shift the balance of cellular cholesterol from the cell membrane to the endoplasmic reticulum. This may result in increased degradation of HMG-CoA reductase. Whether substances **II** and **III** (Scheme 1) play a natural regulatory role *in vivo* is more controversial, although **III** accumulates in cells during conditions in which HMG-CoA reductase becomes suppressed (11,40,41). If, as seems

likely, they do play a natural regulatory role, then the activity of CYP51 may be crucial in determining their steady-state concentration. In this respect, an accumulation of the C-32 aldehyde **III** (Scheme 1) decreases the catalytic activity of CYP51, leading to an accumulation of its substrate lanosterol (23,42). CYP51 is also regulated transcriptionally by SREBP-2, and this process is inhibited by oxysterols such as 25-hydroxycholesterol (6). Oxysterols of diverse structure are also activating ligands for the transcription factor LXR $\alpha$  (17,40). Although the C-32-oxygenated cholesterol precursors have not yet been tested for biological potency in this respect, such a role would provide a link between the regulation of cholesterol synthesis and regulation of bile acid production *via* CYP7A1, an LXR $\alpha$  target gene.

The availability of systems for the rapid inactivation of regulatory molecules is an obvious prerequisite for control of their effective concentration within the cell. Such mechanisms must exist for all natural oxysterol regulators of SREBP cleavage and LXR $\alpha$  activation. The present review shows that the liver has an extraordinarily high capacity for converting sterols such as this to more polar sterols *via* a mechanism that involves cytochrome P450 (Fig. 4, Scheme 1). The structure(s) of these more polar sterols remains a matter for conjecture. Nevertheless, it has been reported that introduction of a third hydroxyl group into certain active oxysterol inhibitors of HMG-CoA reductase decreases their inhibitory potency (44,45), an effect that is also shown following 7 $\alpha$ -hydroxylation of 27-hydroxycholesterol by CYP7B (46). Multiple hydroxylation of the cholesterol side chain also decreases the potency of the resultant triols as activating ligands for LXR $\alpha$  (43).

It is likely that hepatic cholesterol balance is normally maintained, at least in part, by the steady-state concentration of natural oxysterol regulators operating *via* SREBP-2 maturation or by activation of LXR $\alpha$ . These oxysterols originate during both *de novo* cholesterol synthesis and cholesterol metabolism (14), and their effective concentration would be determined by the balance of their production and degradation. The present review provides evidence that cytochrome P450 is required for the oxidative degradation of oxysterols. Interference with this natural regulatory process in the liver by inhibition of cytochrome P450 might be expected to lead to abnormalities of *de novo* cholesterol synthesis. Thus, inhibition of hepatic cytochrome P450 action *in vivo* by ketoconazole led acutely to a downregulation of HMG-CoA reductase and sterologenic carbon flux (Fig. 5), possibly by preventing the inactivation of natural endogenous oxysterol regulators. Similar conditions in hepatocytes give rise to an accumulation of 3 $\beta$ -hydroxylanost-8-en-32-al (28) and, probably, to other natural oxysterols. Chronic administration of ketoconazole induces P45014DM, as evidenced by the increased lanosterol 14 $\alpha$ -demethylase activity (27), and it is likely that other members of the cytochrome P450 family such as CYP7A are similarly induced under these conditions (47). Such an effect would explain the enhanced hepatic HMG-CoA reductase ac-

tivity and sterologenic carbon flux observed 24 h following ketoconazole treatment that would result from an increased P450-mediated oxidative degradation of endogenously produced oxysterols. It is also of interest that chronic treatment of HepG2 cells with ketoconazole also gave rise to an increased HMG-CoA reductase activity, possibly *via* a similar mechanism (48).

## ACKNOWLEDGMENTS

This work was carried out over a number of years, and I am indebted to several colleagues who have made important contributions at different times. These include Clive Pullinger, Kostas Mitropoulos, Andrew Kandutsch, Webster Cavenee, Ken Alexander, Carmen Marco, and José Iglesias. I would also like to thank Nick Myant and the late Derek Williamson for their constant encouragement and support. The work described in this paper was funded by the Medical Research Council (United Kingdom), and I thank the Council for its support.

**ABSTRACT:** Cycloartenol synthase from *Arabidopsis thaliana* and lanosterol synthase from *Trypanosoma cruzi* and *Pneumocystis carinii* were expressed in yeast, and their subcellular distribution in the expressing cells was compared. Determination of enzymatic (oxidosqualene cyclase, OSC) activity and SDS-PAGE analysis of subcellular fractions proved that enzymes from *T. cruzi* and *A. thaliana* have high affinity for lipid particles, a subcellular compartment rich in triacylglycerols, and steryl esters, harboring several enzymes of lipid metabolism. In lipid particles of strains expressing the *P. carinii* enzyme, neither OSC activity nor the electrophoretic band at the appropriate M.W. were detected. Microsomes from the three expressing strains retained some OSC activity. Affinity of enzymes from *A. thaliana* and *T. cruzi* for lipid particles is similar to that of OSC of *Saccharomyces cerevisiae*, which is mainly located in this compartment. A different distribution of OSC in yeast cells suggests that they differ in some structural features critical for the interaction with the surface of lipid particles. Computer analysis supports the hypothesis of the structural difference since OSC from *S. cerevisiae*, *A. thaliana*, and *T. cruzi* lack or contain only one transmembrane spanning domain (a structural feature that makes a protein poorly inclined to associate with lipid particles), whereas OSC from *P. carinii* possesses six transmembrane domains. In the strain expressing cycloartenol synthase from *A. thaliana*, the accumulation of lipid particles largely exceeded that of the other strains.

Paper no. L9150 in *Lipids* 37, 1171–1176 (December 2002).

Oxidosqualene cyclases (OSC) are crucial enzymes of sterol biosynthesis in eukaryotes as they transform 2,3-oxidosqualene, the last acyclic precursor of the metabolic path, into a variety of cyclized products (1,2). These enzymes contribute to maintaining the physiological balance between precursors and end products of sterol biosynthesis by effectively channeling oxidosqualene into the metabolic path, thus preventing accumulation of acyclic precursors within the cell. In the last few years a great effort has been made to unravel questions of homeostasis and intracellular trafficking of sterols and sterol precursors and of the complex metabolic interactions among the different steps of sterol biosynthesis. An essential result of this effort was the determination of subcellular

localization of enzymes involved in the late steps of biosynthesis and of those responsible for steryl ester formation. In yeast (*Saccharomyces cerevisiae*), the picture of the subcellular distribution is almost complete, as localization of many enzymes has been identified, including squalene epoxidase (Erg1p) (3), sterol- $\Delta^{24}$ -methyltransferase (Erg6p) (4), OSC (Erg7p) (5), sterol C-24(28) reductase (Erg4p) (6), and steryl ester synthases Are1p and Are2p (7). Three of these enzymes, namely, Erg1p, Erg6p, and Erg7p, are located (Erg1p and Erg7p almost exclusively) in the so-called lipid particles, a compartment containing high levels of triacylglycerols and steryl esters and harboring several enzymes of lipid metabolism (8,9). Taking advantage of these studies, we considered using yeast mutants expressing OSC of other eukaryotes as models for studying the subcellular distribution of these enzymes. In the present work we compared the subcellular distribution of three OSC expressed in yeast: cycloartenol synthase from *Arabidopsis thaliana*, lanosterol synthase from *Trypanosoma cruzi*, and lanosterol synthase from *Pneumocystis carinii*. The first two enzymes already have been characterized, cloned, and expressed in yeast (10,11); the cloning and the expression of lanosterol synthase from *P. carinii* in yeast are reported here for the first time. The work also aimed to (i) evaluate whether the high affinity of yeast lanosterol synthase for lipid particles (5) is common to other oxidosqualene cyclases, (ii) recognize any structural features responsible for the addressing of OSC to subcellular compartments, and (iii) evaluate whether the possible propensity of other OSC expressed in yeast to accumulate into lipid particles could be used for their purification and characterization.

## EXPERIMENTAL PROCEDURES

**Strains and culture conditions.** The strains *S. cerevisiae* SMY8[pSM60.21] (MATa erg7::HIS3 hem1::TRP1 ura3-52 trp1- $\Delta$ 63 LEU2::CAS1 his3- $\Delta$ 200 ade2 Gal+), SMY8[pBJ1.21] (MATa erg7::HIS3 hem1::TRP1 ura3-52 trp1- $\Delta$ 63 LEU2::OSC *T. cruzi* his3- $\Delta$ 200 ade2 Gal+), and SMY8[pBJ4.21] (MATa erg7::HIS3 hem1::TRP1 ura3-52 trp1- $\Delta$ 63 LEU2::OSC *P. carinii* his3- $\Delta$ 200 ade2 Gal+) were used throughout this study. Cells were grown aerobically to the early stationary phase at 30°C in YPD medium containing 1% yeast extract (Oxoid, Basingstoke, England), 2% peptone (Oxoid), 2% glucose

Abbreviations: MES, morpholine ethanesulfonic acid; OSC, oxidosqualene cyclase; TM, transmembrane.

(Merck, Darmstadt, Germany), and supplemented with heme (13  $\mu\text{g}/\text{mL}$ , added from a stock solution of 1.3  $\text{mg}/\text{mL}$  heme in 1:1 ethanol/10  $\text{mM}$  NaOH) and ergosterol (20  $\mu\text{g}/\text{mL}$ , added from a stock solution of 2  $\text{mg}/\text{mL}$  ergosterol in 1:1 ethanol/Tween 80). Precultures were grown aerobically for 48 h. For the expression, cells (1 mL of inocula per 100 mL of expression medium) were grown for 48–72 h in 1% yeast extract, 2% peptone, 2% galactose, and 13  $\mu\text{g}/\text{mL}$  heme.

**Cloning and characterization of a *P. carinii* lanosterol synthase.** A BLAST search (<http://biology.uky.edu/Pc/>) for putative OSC sequences uncovered the partially sequenced *P. carinii* cDNA S18F10. Dr. Charles Staben kindly provided the clone, which was completely sequenced on both strands using vector-derived primers and synthetic oligonucleotides corresponding to the cDNA sequence. To facilitate yeast expression, restriction sites for subcloning into expression vectors were introduced by PCR (40 cycles of 95°C for 30 s, 56°C for 30 s, 72°C for 4 min). The S18F10 plasmid was used as a template with the oligonucleotides Pca7.3 (gggtcgacaaaatgattatgggtatcc) and Pca7.4 (cgcggcgcgtaaggtcttaaatattacc) and *Pfu* high-fidelity polymerase (Stratagene, La Jolla, CA) in the reaction. The resulting 2.2 kbp fragment was subcloned into the integrative, galactose-inducible yeast expression vector pRS305GAL (12) and the high-copy, galactose-inducible yeast expression vector pRS426GAL (13) to generate pBJ4.21 and pBJ4.22, respectively. These constructs and a positive control plasmid expressing *S. cerevisiae* lanosterol synthase (12) from pRS305GAL were transformed into the *S. cerevisiae* lanosterol synthase mutant SMY8 (12) to test for genetic complementation and into the *S. cerevisiae* squalene synthase/lanosterol synthase double mutant LHY4 (13) to accurately quantify triterpene alcohol production. Complementation was tested on 1% yeast extract, 2% peptone, and 2% galactose supplemented with 13  $\text{mg}/\text{L}$  hemin chloride. A preparative-scale (1-L culture) incubation with substrate was conducted essentially as described previously (13). A 40% slurry of LHY4[pBJ4.22] yeast cells in 100  $\text{mM}$  potassium phosphate (pH 6.2) buffer was lysed using a French press, and then the slurry was diluted to 20% with the same buffer and incubated with 50  $\text{mg}$  of racemic oxidosqualene (14) (final concentration: 1  $\text{mg}/\text{mL}$  oxidosqualene, 1% Triton X-100) for 24 h at 25°C. Triterpene alcohols were isolated as described (13). The crude triterpene alcohol product was chromatographed (5:1 hexane/methylene chloride) on silica gel to provide 11  $\text{mg}$  (44% yield) of pure triterpene alcohol.

**Isolation of yeast subcellular fractions.** Lipid particles were obtained at high purity by the method of Leber *et al.* (4). Briefly, yeast cells were grown in expression medium to the late exponential phase and converted to spheroplasts (15). Spheroplasts were washed twice with 20  $\text{mM}$  potassium phosphate buffer (pH 7.4) containing 1.2  $\text{M}$  sorbitol and then homogenized in breaking buffer containing 10  $\text{mM}$  morpholine ethanesulfonic acid (MES)/Tris (pH 6.9)/12% Ficoll 400/0.2  $\text{mM}$  EDTA/1  $\text{mM}$  phenylmethylsulfonyl fluoride (PMSF) at a final concentration of 0.5 g of cell wet weight per mL. The homogenate was centrifuged at 5,000  $\times g$  for 5 min, and the resulting supernatant was overlaid with breaking buffer and

centrifuged for 1 h at 28,000 rpm (100,000  $\times g$ ) in a Beckman SW-28 swing-out rotor. The floating layer was collected from the top of the gradient and subjected to two additional sequential flotation steps in (i) 10  $\text{mM}$  MES/Tris (pH 6.9)/8% Ficoll 400/0.2  $\text{mM}$  EDTA, and (ii) 10  $\text{mM}$  MES/Tris (pH 6.9)/0.25  $\text{M}$  sorbitol/0.2  $\text{mM}$  EDTA at 28,000  $\times g$  for 30 min each. The floating layer from the top of the last gradient contained lipid particles at high purity.

For the preparation of microsomes, yeast cells were grown in expression medium and converted to spheroplasts (15). Spheroplasts were homogenized in 10  $\text{mM}$  Tris/HCl (pH 7.4)/0.6  $\text{M}$  mannitol, and the homogenate was centrifuged for 30 min at 20,000  $\times g$ . The resulting supernatant was centrifuged at 30,000  $\times g$  for 30 min. To obtain highly purified 30,000  $\times g$  microsomes, the respective pellet was subjected to two additional washing steps by suspension in 10  $\text{mM}$  Tris/HCl (pH 7.5) and centrifugation at 30,000  $\times g$ .

**Characterization of subcellular fractions.** Protein was quantified by the method of Lowry *et al.* (16) using BSA as a standard. Proteins of microsomal and cytosolic fractions were precipitated from the aqueous phase with TCA (10% final concentration) and solubilized in 0.1% SDS/0.1% NaOH. Prior to protein analysis of the lipid particle fraction, samples were delipidated: Nonpolar lipids were extracted with 2 vol of diethyl ether, the organic phase was withdrawn, residual diethyl ether was removed under a stream of nitrogen, and proteins were precipitated from the extracted aqueous phase as described above.

SDS-PAGE was carried out by the method of Laemmli (17) on 10% SDS-polyacrylamide gel. Protein was precipitated with 10% TCA, washed twice with ethanol/diethyl ether (1:1, vol/vol), and dissolved in dissociation buffer. Prior to precipitation of protein in the lipid particle fraction, samples were delipidated as described. Protein bands on the gel were stained with Coomassie Brilliant Blue B.

**Incorporation of [ $^{14}\text{C}$ ]acetate into sterols.** Sterol biosynthesis in whole yeast cells was followed by incorporation of [ $^{14}\text{C}$ ]acetate into nonsaponifiable lipids as described (18). Briefly, washed cells (10–20  $\times 10^6$  cells) were suspended in 5 mL of 25  $\text{mM}$   $\text{KH}_2\text{PO}_4/\text{NaOH}$  buffer (pH 6.5) containing 1% galactose and 0.1  $\text{mg}/\text{mL}$  Tween 80, incubated with 2  $\mu\text{Ci}$  [ $^{14}\text{C}$ ]acetate (50  $\text{mCi}/\text{mM}$ ), and shaken for 3 h at 30°C. Cells were then harvested by centrifugation and saponified in 50% ethanol containing 15% KOH for 2 h at 80°C. Nonsaponifiable lipids were extracted twice with 1 mL light petroleum and separated on silica gel plates (Merck) using *n*-hexane/ethyl acetate (85:15, vol/vol) as developing solvent and authentic standards of ergosterol, lanosterol, dioxidosqualene, oxidosqualene, and squalene. Radioactivity in separated bands was measured using a System 2000 Imaging Scanner (Packard, Downers Grove, IL).

**OSC assay.** [ $^{14}\text{C}$ ]3S-2,3-Oxidosqualene was prepared as described in Reference 5. OSC activity in total yeast homogenate (6  $\text{mg}$  protein/mL), lipid particles (0.03  $\text{mg}$  protein/mL), and microsomes (0.5  $\text{mg}$  protein/mL) was determined as described elsewhere (18). Briefly, 0.5 mL of the different subcellular fractions was incubated with [ $^{14}\text{C}$ ]3S-2,3-oxidosqualene (2000 cpm, 25  $\mu\text{M}$ ) in the presence of Tween 80 (0.2  $\text{mg}/\text{mL}$ ) and Triton X-100 (1  $\text{mg}/\text{mL}$ ) in 10

mM MES/Tris (pH 6.9) and 0.2 mM EDTA for 30 min at 35°C under vigorous shaking. The reaction was stopped by adding 1 mL of 15% KOH in methanol, and lipids were saponified at 80°C for 30 min. The nonsaponifiable lipids were extracted twice with 1 mL of light petroleum and separated on silica gel plates using dichloromethane as developing solvent. Radioactivity in 2,3-oxidosqualene and lanosterol (or cycloartenol) was counted using a System 2000 Imaging Scanner (Packard). The amount of product formed was used to calculate the enzyme activity.

*In silico sequence analysis.* Determination of hypothetical transmembrane spanning domains was performed with HMMTOP 2.0 on-line software (<http://www.enzim.hu/hmmtop/server>) (19,20). Hydrophobicity analysis was performed according to Kyte and Doolittle (21) with a window size of 15 amino acids.

## RESULTS

*Characterization of a P. carinii OSC cDNA and development of a yeast expression strain.* The 2.3-kbp S18F10 cDNA clone (GenBank accession number AF285825) encodes a predicted 720-residue protein that is 57–62% identical to known lanosterol synthases and 50–57% identical to known cycloartenol synthases. This clone genetically complemented the sterol auxotrophy in the lanosterol synthase mutant SMY8 when expressed from the GAL1 promoter, consistent with the cDNA encoding a functional lanosterol synthase. Triterpene alcohol isolated from an *in vitro* reaction was shown to be lanosterol by NMR. Key <sup>1</sup>H NMR (400 MHz) signals were within 0.007 ppm of literature values (22) for lanosterol:  $\delta$  0.687 (C-18, 3H, s), 0.808 (C-29, 3H, s), 0.873 (C-30, 3H, s), 0.909 (C-21, 3H, d, *J* = 6.4 Hz), 0.980 (C-19, 3H, s), 0.998 (C-28, 3H, s), 1.599 (C-27, 3H, s), 1.681 (C-26, 3H, s), 3.23 (C-3, 1H, m), 5.10 (C-24, 1H, m). The alcohol product was acetylated and analyzed by GC as previously described (13). Lanosteryl acetate was the sole triterpenyl acetate observed; neither parkeyl acetate nor cycloartenyl acetate was present at detectable levels (<1% of lanosteryl acetate if any). No unidentified signals suggesting other triterpene products were observed. These ex-

periments establish that *P. carinii* clone S18F10 encodes a lanosterol synthase.

*Expression of active OSC in cell culture.* The level of expression of cycloartenol and lanosterol synthases in different strains were evaluated by incorporation of [<sup>14</sup>C]acetate into nonsaponifiable lipids extracted from cells grown under aerobic conditions. In strains expressing lanosterol synthases from *T. cruzi* and *P. carinii*, the bulk of radioactivity accumulated into ergosterol, indicating that the expressed enzymes perfectly complemented the yeast lanosterol synthase activity. In strains expressing cycloartenol synthase, a major fraction of radioactivity was entrapped by cycloartenol and compounds co-chromatographing with 4-monomethyl sterols such as cycloeucaenol and obtusifoliol (Table 1, Fig. 1), while a minor fraction of radioactivity accumulated into a compound co-chromatographing with ergosterol. The negligible level of radioactive oxidosqualene in all three expressing strains indicated that the ability of the expressed enzymes to channel their substrate into the metabolic path is comparable with that of the wild-type strain.

*Subcellular distribution of OSC expressed in yeast.* Subcellular distribution of activity of the different OSC expressed in yeast was compared with that of a wild-type strain (Table 2). In strains expressing enzymes from *A. thaliana* and *T. cruzi*, distribution was comparable with that of the wild-type: The enrichment relative to the homogenate indicates a clear preference of the expressed OSC for the lipid particles compartment, even though some activity was retained in microsomes to a higher extent than in the wild-type. No activity was detected in lipid particles of the strain expressing lanosterol synthase from *P. carinii*. The homogenate was as active as that of the other expressing strains, and the enrichment of the activity in microsomes was comparable and not so high as to support the hypothesis of the preference for the endoplasmic reticulum. The enzyme might then not be properly shaped for insertion in lipid particles as suggested by computer analysis (Table 3).

In the strain expressing cycloartenol synthase, production of lipid particles largely exceeded the production of the other strains, as judged by (i) the total amount of proteins recovered in lipid particles (Table 2) and (ii) the thickness of the

**FIG. 1.** Incorporation of [ $^{14}\text{C}$ ]acetate into nonsaponifiable lipids of the strain expressing cycloartenol synthase from *Arabidopsis thaliana*. Cells were cultured aerobically as described in the Experimental Procedures section. Nonsaponifiable lipids were then chromatographed on silica gel plates (see Experimental Procedures section) with authentic references of ergosterol (1), obtusifoliol (2), cycloeucaenol (3), cycloartenol (4), dioxidosqualene (5), oxidosqualene (6), and squalene (7).

lipid floating layer recovered at the end of gradient centrifugation passages (see the Experimental Procedures section).

**Protein pattern of subcellular fractions isolated from expressing strains.** The protein content of lipid particles and microsomes isolated from the three expressing strains was analyzed by SDS-PAGE. Results confirmed the high preference of cycloartenol synthase from *A. thaliana* and lanosterol synthase from *T. cruzi* for yeast lipid particles, as indicated by the intense protein bands at 86 and 101 kDa, respectively (Fig. 2). In lipid particles of the strain expressing cycloartenol synthase, the enzyme represents the large majority of proteins. No band at 83 kDa, the predicted M.W. of lanosterol synthase of *P. carinii*, was visible among the proteins from the lipid particles of the strain expressing enzyme of *P. carinii* (Fig. 2). In microsomal preparations, protein bands corresponding to OSC were barely detectable.

**In silico sequence analysis.** Computer analysis revealed that OSC from *A. thaliana* and *S. cerevisiae* (8) lack transmembrane (TM) spanning domains, and OSC from *T. cruzi* contains only one hypothetical TM domain (Table 3). Inter-

estingly, six TM domains were present in the OSC from *P. carinii*. Structure prediction seems to agree with the observation that proteins lacking TM domains are highly inclined to associate with the phospholipid monolayer of lipid particles, whereas proteins containing multiple TM domains may hardly interact with the organelle surface (8).

## DISCUSSION

The phylogenetic position of *P. carinii* has been controversial, and the presence of lanosterol synthase in *P. carinii* supports the view that this pathogen is a fungus rather than an amoeba. Fungi, animals, and kinetoplastid protists share a sterol biosynthetic route through lanosterol, whereas plants and numerous other protists (e.g., *Naegleria*, *Dictyostelium*, and *Euglena*) make sterols from cycloartenol. The yeast strain expressing the *P. carinii* OSC, described here for the first time, will allow convenient screening for derivatives of known OSC inhibitors active on the *P. carinii* lanosterol synthase without cultivation of the pathogen. The heterologous

expression system will also be useful for high-throughput screening of unbiased chemical libraries for potential chemotherapeutic agents.

The *P. carinii* lanosterol synthase conserves residues known to be catalytically essential in *S. cerevisiae* lanosterol synthase [Asp456 (23), His146 (23), His234 (23), Tyr410 (24), and Val454 (25)]. These similarities between the *P. carinii* and *S. cerevisiae* lanosterol synthases probably underlie the observation that several established lanosterol synthase inhibitors also inhibit *P. carinii* growth (26), consistent with the two enzymes employing similar catalytic motifs.

Cycloartenol synthase from *A. thaliana* and lanosterol synthase from *T. cruzi* expressed in yeast *S. cerevisiae* showed a high propensity to associate with yeast lipid particles, as demonstrated by the high specific OSC activity of lipid particles prepared from the expressing strains and by the results of SDS-PAGE analysis of subcellular fractions. The affinity of the expressed enzymes for yeast lipid particles is similar to that of the endogenous yeast lanosterol synthase, which has recently been recognized as a peculiar protein of this subcellular compartment (5). It was suggested (8) that the preferential occurrence of a protein in the surface monolayer surrounding lipid particles depends on the lack or paucity of transmembrane spanning domains, a structural feature that seems shared by OSC of

*Arabidopsis* and *Trypanosoma*. Distribution of OSC from *S. cerevisiae*, *A. thaliana*, and *T. cruzi* in yeast cells provides indirect evidence of the structural similarity of the different eukaryotic cyclases, suggesting that they are properly shaped for the insertion in oil body-like organelles. The high sequence homology between the above-mentioned OSC and squalene hopene cyclase of *Alicyclobacillus acidocaldarius*, the structure of which was solved a few years ago (27,28), reinforces the view of the OSC as proteins shaped for association with lipid particles. The bacterial membrane protein, in fact, belongs to the so-called monotopic proteins, membrane proteins that are shaped so as to submerge from one side of the membrane into the non-polar part of the phospholipid bilayer without protruding through it (28). If the OSC are similarly shaped, their preferential association with lipid particles might be easily described by the "budding model," recently proposed for the formation of lipid particles from endoplasmic reticulum in yeast (8). According to this model, lipid particles arise from droplets of neutral lipids formed between the two leaflets of the endoplasmic reticulum membrane bilayer. After reaching a certain size, droplets, wrapped with the outer phospholipid leaflet of the endoplasmic reticulum, bud off, carrying proteins associated with the outer leaflet. Undoubtedly, the monotopic-shaped proteins have a high probability of remaining associated with the phospholipid monolayer during such a budding process.

The absence of OSC activity in lipid particles of the strain expressing the enzyme of *P. carinii* suggests that the enzyme is not properly shaped for association with lipid particles. Computer analysis seems to support the structural hypothesis, since OSC from *S. cerevisiae*, *A. thaliana*, and *T. cruzi* have no or few transmembrane domains, whereas lanosterol synthase from *P. carinii* possesses six transmembrane domains (Table 3), a structural feature that makes a protein poorly inclined to associate with lipid particles (8).

In the strain expressing cycloartenol synthase, the production of lipid particles largely exceeded that of the other strains. This result, together with the comparison of protein patterns of subcellular fractions prepared from different strains, might shed new light on the question of the driving force leading to the production of lipid particles in yeast. In the strain expressing cycloartenol synthase, in fact, the large majority of lipid particle proteins is represented by cycloartenol synthase; the enrichment over the homogenate is so high that the electrophoretic protein pattern of lipid particles looks like that of the final steps of a purification process. Our hypothesis is that the overexpression of a protein highly inclined to associate with lipid particles, such as cycloartenol synthase, forces the cell to accumulate the compartment material associated with the protein. An additional driving force could result, in the strain expressing cycloartenol synthase, from the formation of cycloartenol instead of lanosterol. The experiments with labeled acetate indicate that the channeling of cycloartenol into ergosterol biosynthesis is difficult in this strain, resulting in an accumulation of cycloartenol and possibly other intermediates of sterol biosynthesis. These precursors, bearing "extra" methyl groups compared to ergosterol, the final product, are considered less effective than the final product as membrane

**FIG. 2.** SDS-PAGE analysis of proteins of lipid particles and microsomes isolated from yeast strain expressing cycloartenol synthase from *A. thaliana* (*At*) and lanosterol synthase from *Trypanosoma cruzi* (*Tc*) and *Pneumocystis carinii* (*Pc*). Lanes 1, 2, and 3, 10 µg of lipid particles from expressors *At*, *Tc*, and *Pc*, respectively; lanes 4, 5, and 6, 30 µg of 30,000 × g microsomes from expressors *At*, *Tc*, and *Pc*, respectively.

reinforcers, as inferred from a study on comparative properties of cholesterol and its precursors as growth factors for sterol auxotrophs (29). A strain accumulating these intermediates may be induced to accumulate the lipid particle compartment for storing, as ester derivatives, possible membrane-weakening compounds. The above observations are in agreement with the cited "budding hypothesis" suggested by Daum for the formation of lipid particles in yeast (8).

The overexpression of three OSC in yeast was a useful tool for comparing their structural/functional properties and shed new light on the process of lipid particle formation in yeast. Results of the work suggested also that lipid particles may be regarded as a natural enrichment device for purifying eukaryotic OSC through their expression in yeast.

**ABSTRACT:** The sterol composition of *Pneumocystis carinii*, an opportunistic pathogen responsible for life-threatening pneumonia in immunocompromised patients, was determined. Our purpose was to identify pathway-specific enzymes to impair using sterol biosynthesis inhibitors. Prior to this study, cholesterol **15** (ca. 80% of total sterols), lanosterol **1**, and several phytosterols common to plants (sitosterol **31**, 24 $\alpha$ -ethyl and campesterol, 24 $\alpha$ -methyl **30**) were demonstrated in the fungus. In this investigation, we isolated all the previous sterols and many new compounds from *P. carinii* by culturing the microorganism in steroid-immunosuppressed rats. Thirty-one sterols were identified from the fungus (total sterol = 100 fg/cell), and seven sterols were identified from rat chow. Unusual sterols in the fungus not present in the diet included, 24(28)-methyl-enlanosterol **2**; 24(28)*E*-ethylidene lanosterol **3**; 24(28)*Z*-ethylidene lanosterol **4**; 24 $\beta$ -ethyl lanosta-25(27)-dienol **5**; 24 $\beta$ -ethylcholest-7-enol **6**; 24 $\beta$ -ethylcholesterol **7**; 24 $\beta$ -ethylcholesta-5,25(27)-dienol **8**; 24-methyl lanosta-7-enol **9**; 24-methyl-desmosterol **10**; 24(28)-methylenecholest-7-enol **11**; 24 $\beta$ -methylcholest-7-enol **12**; and 24 $\beta$ -methylcholesterol **13**. The structural relationships of the 24-alkyl groups in the sterol side chain were demonstrated chromatographically relative to authentic specimens, by MS and high-resolution <sup>1</sup>H NMR. The hypothetical order of these compounds poses multiple phytosterol pathways that diverge from a common intermediate to generate 24 $\beta$ -methyl sterols: route 1, **1** → **2** → **11** → **12** → **13**; route 2, **1** → **2** → **9** → **10** → **13**; or 24 $\beta$ -ethyl sterols: route 3, **1** → **2** → **4** → **6** → **7**; route 4, **1** → **2** → **5** → **8** → **7**. Formation of **3** is considered to form an interrupted sterol pathway. Taken together, operation of distinct sterol methyl transferase (SMT) pathways that generate 24 $\beta$ -alkyl sterols in *P. carinii* with no counterpart in human biochemistry suggests a close taxonomic affinity with fungi and provides a basis for mechanism-based inactivation of SMT enzyme to treat *Pneumocystis pneumonia*.

Paper no. L9139 in *Lipids* 37, 1177–1186 (December 2002).

The sterols of *Pneumocystis carinii*, an opportunistic pathogen responsible for life-threatening pneumonia in immunocompromised patients, have been studied extensively and found to be unusual structurally (1–4). An important pe-

culiarity of this fungus is the presence of several phytosterols as well as a high level of cholesterol. Lanosterol, the central intermediate in the biosynthesis of phytosterols and cholesterol, was detected in *P. carinii* (3). A lanosterol-based pathway is consistent with this organism being a fungus (5). Several distinct pathways of sterol biosynthesis can occur that involve transformation of the lanosterol side chain. The evolutionary history of these pathways and the response of enzymes along the pathway to sterol biosynthesis inhibitors (SBI) is of considerable interest since *P. carinii* recently was proposed to have a close phylogenetic affinity to advanced fungal forms, particularly the Ascomycetes (6,7), and to be resistant to common antifungal SBI that target 14 $\alpha$ -demethylase activity (8). Another peculiarity is that 24-ethyl sterols, a characteristic of plant biochemistry (5), were found in *P. carinii* (Table 1). In fungi, as in plants (9), 24-ethyl sterols can function as membrane inserts (10,11) or act as intermediates to steroid hormones that control sexual reproduction (12). The configuration of the 24-ethyl group of *P. carinii* sterols has not been determined to date but is tacitly assumed to be  $\beta$ -oriented (1).

Sterol evolution in fungi proceeded down a different path

from plants. For fungi, two extreme categories of sterol structure modification exist. In category I, represented by the primitive fungi consisting of the Chytridomycetes and Oomycetes, cholesterol and 24-ethylidene sterol are the major sterols, whereas in category II, consisting of the most advanced fungi and represented by the Ascomycetes and Basidiomycetes, 24 $\beta$ -methyl sterols are the major sterols (13–15). 24(28)-Ethylidene sterols occur variably in fungi, with the E-geometry synthesized by primitive forms (12,16) and the Z-geometry synthesized by advanced forms (17). When a sterol auxotroph, *Saccharomyces cerevisiae* strain GL7, was fed fucosterol [24(28)E-ethylidene] and isofucosterol [24(28)Z-ethylidene], the cells reduced stereoselectively only the 24(28)Z-ethylidene side chain to produce a 24 $\beta$ -ethyl sterol (18), suggesting that 24 $\beta$ -ethyl sterols can also be a characteristic of the fungal sterol mixture. For plants, two extreme categories of sterol side chain structure exist. In category I, represented by less-advanced plants, including the algae, the major sterols contain a 24 $\beta$ -methyl group. In category II, the major sterols of advanced plants, represented by vascular plants, contain a 24 $\alpha$ -ethyl group (4,19). Cholesterol with a 24-hydrogen atom is usually a minor sterol in plants. The differences in sterol C-methylation patterns in fungi and plants suggest that the evolutionary history of the sterol methyl transferase (SMT) enzyme contributed to the evolution of *P. carinii* and can provide a basis for rational drug design.

In this investigation we analyzed the sterol composition of a mixed population of *P. carinii* trophic and cyst forms isolated from rat-infected lung, determined the sterol composition of the rat chow, and deduced the evolution of an SMT that constitutes the phytosterol pathway from less-advanced to more-advanced fungi. Our findings of a unique sterol profile for *P. carinii* compared to the sterol profiles described for related fungi raised certain important questions. What is the endogenous sterol pathway in this organism? Can the sterol composition of the species reveal something about its evolutionary history? At what stage of development are these sterols actually synthesized, and how do they function during membrane assembly and in sexual reproduction? What role does oxygen from the lungs play in controlling sterol biosynthesis and sterol absorption during infection? What group of SBI or complexing agents can be used to treat the disease? In the present investigation, we have explored the answers to the first two questions. A second paper is forthcoming that will address the latter questions.

## MATERIALS AND METHODS

**Fungal cultures.** Mixed life-cycle preparations of *P. carinii* f. sp. *carinii*, consisting of approximately 80% trophic forms and 20% cystic forms, were isolated from lungs of corticosteroid-immunosuppressed rats and purified from host contaminants by a series of gravity sedimentation steps and by microfiltration as described previously (20,21). The animals were fed balanced rat chow (Teklad type LM-485 sterilizable rat chow; Harlan, Madison, WI) and hyperchlorinated water.

*Pneumocystis* was isolated from infected lungs ca. 8 to 10 wk postinoculation when the animals were moribund with the disease. Approximately 900  $\mu$ g of fresh fungal culture representing  $1.2 \times 10^{10}$  cells was used to establish the sterol composition.

**Sterol analysis.** Total sterols were extracted and separated from the neutral lipids after saponification and analyzed initially by GLC (3% SE-30 packed column operated isothermally at 245°C) and reversed-phase HPLC [Phenomenex 25-cm semipreparative (10- $\mu$ m) column eluted with methanol at ambient temperature]. The chromatographs were attached to a multiple-wavelength diode array detector (Agilent 1100 series) to monitor each of the fractions by the peak purity method (22). The 4,4-dimethyl, 4-monomethyl, and 4,4-desmethyl sterols in the nonsaponifiable lipid fraction (NSF) were separated by analytical TLC (Alltech silica gel plates, 250  $\mu$ m) and  $R_f$  values for individual compounds were determined using two developments with benzene/diethyl ether (85:15, vol/vol). Sterol mixtures eluted from the TLC plate were injected into the high-performance liquid chromatograph to resolve compounds for GC-MS and  $^1\text{H}$  NMR analysis (22). Data from the GLC, HPLC, and  $^1\text{H}$  NMR analyses were used for quantification of the individual components. Authentic specimens used as reference samples were part of our steroid collection (18,19,22–26). Retention times of sterols in GLC are relative to the retention time of cholesterol (RRT<sub>c</sub>).

The instrumentation and techniques for the GLC (Hewlett-Packard 5890 series II) and HPLC (Agilent 1100 series) have been described earlier (22–24). Mass spectra were obtained by GC-MS using a Hewlett-Packard 6890 gas chromatograph coupled to a 5973 mass selective detector.  $^1\text{H}$  NMR spectroscopy was performed at 500 MHz at ambient temperature on a Varian Unity Inova 500, in  $\text{CDCl}_3$ , with tetramethylsilane as internal standard.

## RESULTS

Previous investigations of the sterol content of *P. carinii* revealed the presence of 18 sterols in the organism tentatively identified by GC-MS and HPLC (Table 1) (1–4). In one report, the published gas-liquid chromatogram of the total sterol fraction showed at least 23 peaks that corresponded to sterols (2), suggesting that several additional sterols could be present in the sterol mixture. In none of the earlier studies was the configuration at C-24 of the 24-alkyl group in the sterol side chain determined. Several  $\Delta^7$ -sterols not present in rat lung controls were common to all the investigations (24-methylcholest-7-enol, 24(28)-ethylcholest-7-enol, and 24-ethylidenecholest-7-enol), suggesting that these sterols are formed endogenously (1–3). Alternatively, the  $\Delta^5$ -sterols campesterol and sitosterol, identified in rat lungs not infected with *P. carinii*, are assumed to be of dietary origin (2).

We found, as others reported (1–3), that the cells of *P. carinii* contained predominantly cholesterol (ca. 80% of the total sterol). In addition, a substantial amount (ca. 20%) of

<sup>a</sup>Structure of sterols is shown in Figure 2.<sup>b</sup>Trace, less than 1% of the total sterol.<sup>c</sup>The ratio of epimers was determined by HPLC or <sup>1</sup>H NMR.<sup>d</sup>NC, not considered. As shown in Figure 1, cholesterol constitutes ca. 80% of total sterol.

phytosterol was detected in the organism (Table 2). All the sterols reported by earlier investigators, except for stigmasterol and brassicasterol, were detected, as well as 13 additional sterols that eluted in GLC (Fig. 1A and Table 2). Some 24-alkyl sterols coeluted in GLC, particularly sterols that occurred as C-24 epimers. The 29 sterols detected in GLC could be grouped into two series based on the metabolism of the Δ<sup>24</sup>-bond: as a 24-desalkyl series (24-hydrogen) and as a 24-alkyl (24-methyl or 24-ethyl). The two series of compounds gave rise to paths **a** and **b**, respectively, as shown in Figure 2. By using TLC fractionation of the NSF to separate sterols based on the degree of C-4 substitution (22), a total of ten 4,4-dimethyl, three 4-monomethyl, and sixteen 4-desmethyl sterols were detected. Of the ten 4,4-dimethyl sterols, only three (**1**, **2**, and **4**) were reported previously (2,3). Of the 4-desmethyl sterols, two pairs of 24-alkyl sterols were found to be an epimeric mixture: 24-methylcholesterol and 24-ethylcholesterol. The absolute amounts and the percent compositions of each of these sterols are given in Table 2. On a per cell basis, the amount of total sterol was calculated to be 108 fg/cell. The minor sterols in the sterol mixture were also estimated from the gas-liquid chro-

matogram (Fig. 1), based on the absence of cholesterol, to highlight their contribution to sterol synthesis in *P. carinii*.

Cholesta-5,7,24-trienol **21**, a 4-desmethyl sterol, was identified for the first time in the organism. Its structure was supported by a comparison of its elution time and mass spectrum to the elution time and mass spectrum of an authentic specimen (23). A maximum absorption at λ<sub>max</sub> 282 nm in the UV spectrum of the sample is characteristic of a Δ<sup>5,7</sup>-steroid (22). All the other sterols eluting in HPLC exhibited end-absorption UV spectra, except for compound **23**. Its spectrum contained a fingerprint at 248 nm characteristic of a Δ<sup>8,14</sup>-diene steroid (22), consistent with the assigned structures reported in Table 2. The presence of common 24-methyl sterols found in yeast (26) and of unusual 24-alkylated Δ<sup>24(25)</sup>-sterols, such as 24-methyl desmosterol and 24-ethylidenelanosterol, found in the fungus *Gibberella fujikuroi* (25), were detected in varying amounts in the sterol mixture (Table 2).

Three 24-alkyl sterols in the 4-desmethyl fraction were isolated from the initial HPLC separation to assess the configurational purity at C-24: 24-methylcholesterol, 24-ethylcholesterol, and 24-ethylcholest-7-enol. The two 24-ethyl

**FIG. 1.** GC analysis (a total ion current chromatogram) of the nonsaponifiable lipids extracted from *Pneumocystis carinii* (A) or rat chow (B). Inset A-1 shows the GC trace corresponding to the hexane-extractable product of lanosterol used by the recombinant soybean sterol methyl transferase (SMT) (see text for details of the experiment). The sterols in the GC trace in Panel B labeled **a** to **g** are discussed in the Results section of the text.

sterols possessed similar M.W. ( $M^+$  414), suggesting one double bond in the molecule. They were isolated from HPLC in sufficient amounts for  $^1\text{H}$  NMR analysis. In the case of the 24-ethyl sterol, with a chromatographic behavior and fragmentation pattern of 24-ethylcholest-7-enol, the  $^1\text{H}$  NMR spectrum [H18 (0.531, *s*), H19 (0.791, *s*), H21 (0.926, *d*, 6.4), H26 (0.828, *d*, 6.9), H27 (0.807, *d*, 6.9), H29 (0.851, *t*, 7.4)] supported the structure with a 24 $\beta$ -ethyl group. Based on the signals for C-29 and C-21 in the  $^1\text{H}$  NMR, the 24-ethylcholest-7-enol was epimerically pure at C-24. In contrast to the configuration of the 24-ethyl group of 24-ethylcholest-7-enol, the sample with chromatographic behavior and a fragmentation pattern consistent with the structure 24-ethylcholest-5-enol was found by  $^1\text{H}$  NMR to be a mixture of 24 $\alpha/\beta$ -ethylcholesterol in a 4:1 ratio of 24 $\alpha/\beta$ -ethyl. Peaks in the  $^1\text{H}$  NMR detected for the mixture of sterols were as follows: H18 (0.679/0.679, *s*), H19 (1.009/1.009, *s*), H21 (0.921, *d*, 6.4/0.914, *d*, 6.6), H26 (0.834, *d*, 6.9/0.830, *d*, 6.9), H27 (0.812, *d*, 6.9/0.810, *d*, 6.9), H29 (0.845, *t*, 7.4/0.853, *t*, 7.4). The doublet for H21 and the triplet for H29 of the pair of 24-ethyl epimers sitosterol/

clionasterol is characteristic of an  $\alpha/\beta$ -ethyl group configuration (22,26). The 24-methyl sterol isolated from the initial HPLC (Phenomenex reversed-phase  $\text{C}_{18}$  column eluted with methanol at ambient temperature) as a single component was insufficient for  $^1\text{H}$  NMR; therefore, it was chromatographed further using a reversed-phase TSK gel  $\text{C}_{18}$  column (eluted with acetonitrile/isopropanol at 4°C) to separate the pair of 24 $\alpha/\beta$ -methyl sterols (23). The chromatographic mobility of the 24-methyl sterols relative to the elution of campesterol and 24-epicampesterol standards indicated an epimeric mixture of 24-methylcholesterols in a 1:1 ratio of 24 $\alpha/24\beta$ -methyl.

Four 4,4-dimethyl sterols eluting late in GLC, between 23 and 26 min (Fig. 1), possessed M.W. and fragmentation patterns suggesting a series of 24-ethylstanoid isomers ( $M^+$  454) and a 24-methylstanoid ( $M^+$  440) (Fig. 3). Standards of the three 24-ethyl sterol isomers were prepared by incubating the soybean SMT with 24(28)-methylene lanosterol (27), whereas standards of 24-methylstanoids were prepared in our study of ergosterol biosynthesis in *G. fujikuroi* (25). The plant SMT converted 24(28)-methylene lanosterol to a mixture

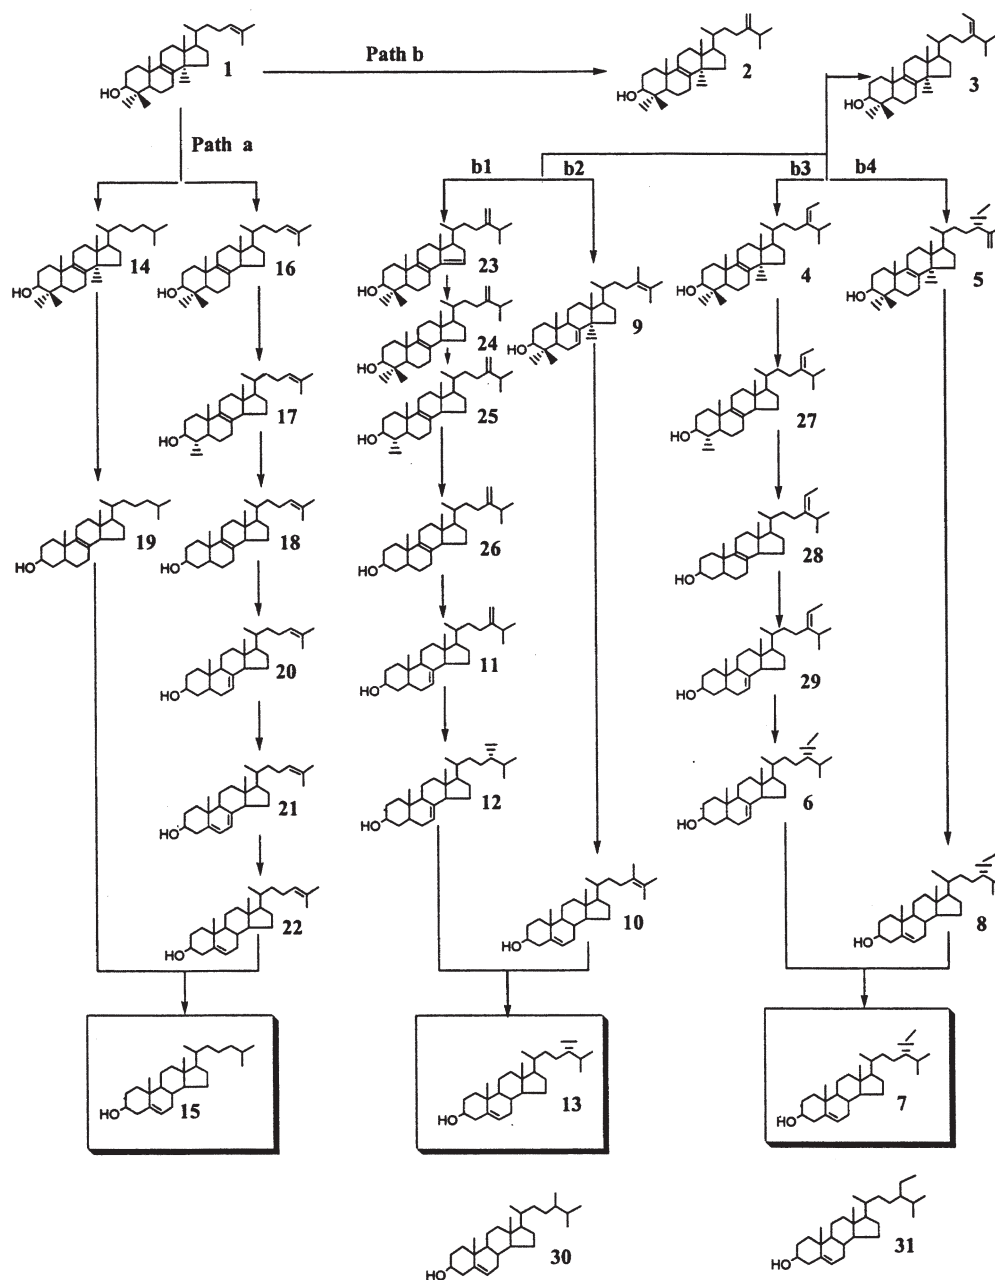

FIG. 2. Hypothetical sterol pathway for *P. carinii*.

of three 24-ethyl sterol isomers as shown in Figure 1, inset A-1. In a related study, 24(28)-methylene cycloartenol was converted to the same set of 24-ethyl sterol isomers. The individual enzyme-generated products were purified by HPLC, and the olefins were characterized by GC-MS and  $^1\text{H}$  NMR (23,27).

The sterol composition of rat chow is a mixture of cholesterol and phytosterols, including 24-methylcholesterol and 24-ethylcholesterol. Major compounds eluting in GLC, as shown in Figure 1B, and their mass spectra (M.W.,  $M^+$ ) are as follows: **a**, cholesterol ( $M^+$  386); **b**, campesterol ( $M^+$  400); **c**, campestanol ( $M^+$  402); **d**, stigmasterol ( $M^+$  412); **e**, sitosterol ( $M^+$  414); **f**, sitostanol ( $M^+$  416); and **g**, isofucosterol

( $M^+$  412). The ingredients listed for rat chow include soybean meal, wheat, cane, oats, alfalfa, fish, beets, wheat germ, corn, menadione dimethylpyrimidinol sulfite, and brewer's yeast, among other things. The source of phytosterols in the rat chow is plant material, and the source of cholesterol is likely fish. The amount of sterol in the rat chow was estimated at 0.43 mg sterol/g chow. The 24-methylcholesterol and 24-ethylcholesterol components of the rat chow were isolated from the sterol mixture by HPLC, and the configuration at C-24 was determined by  $^1\text{H}$  NMR and HPLC using a TSK gel  $C_{18}$  column. The 24-ethyl group in sitosterol was found to be pure 24 $\alpha$ -ethyl, whereas the "campesterol" sample, considered to be

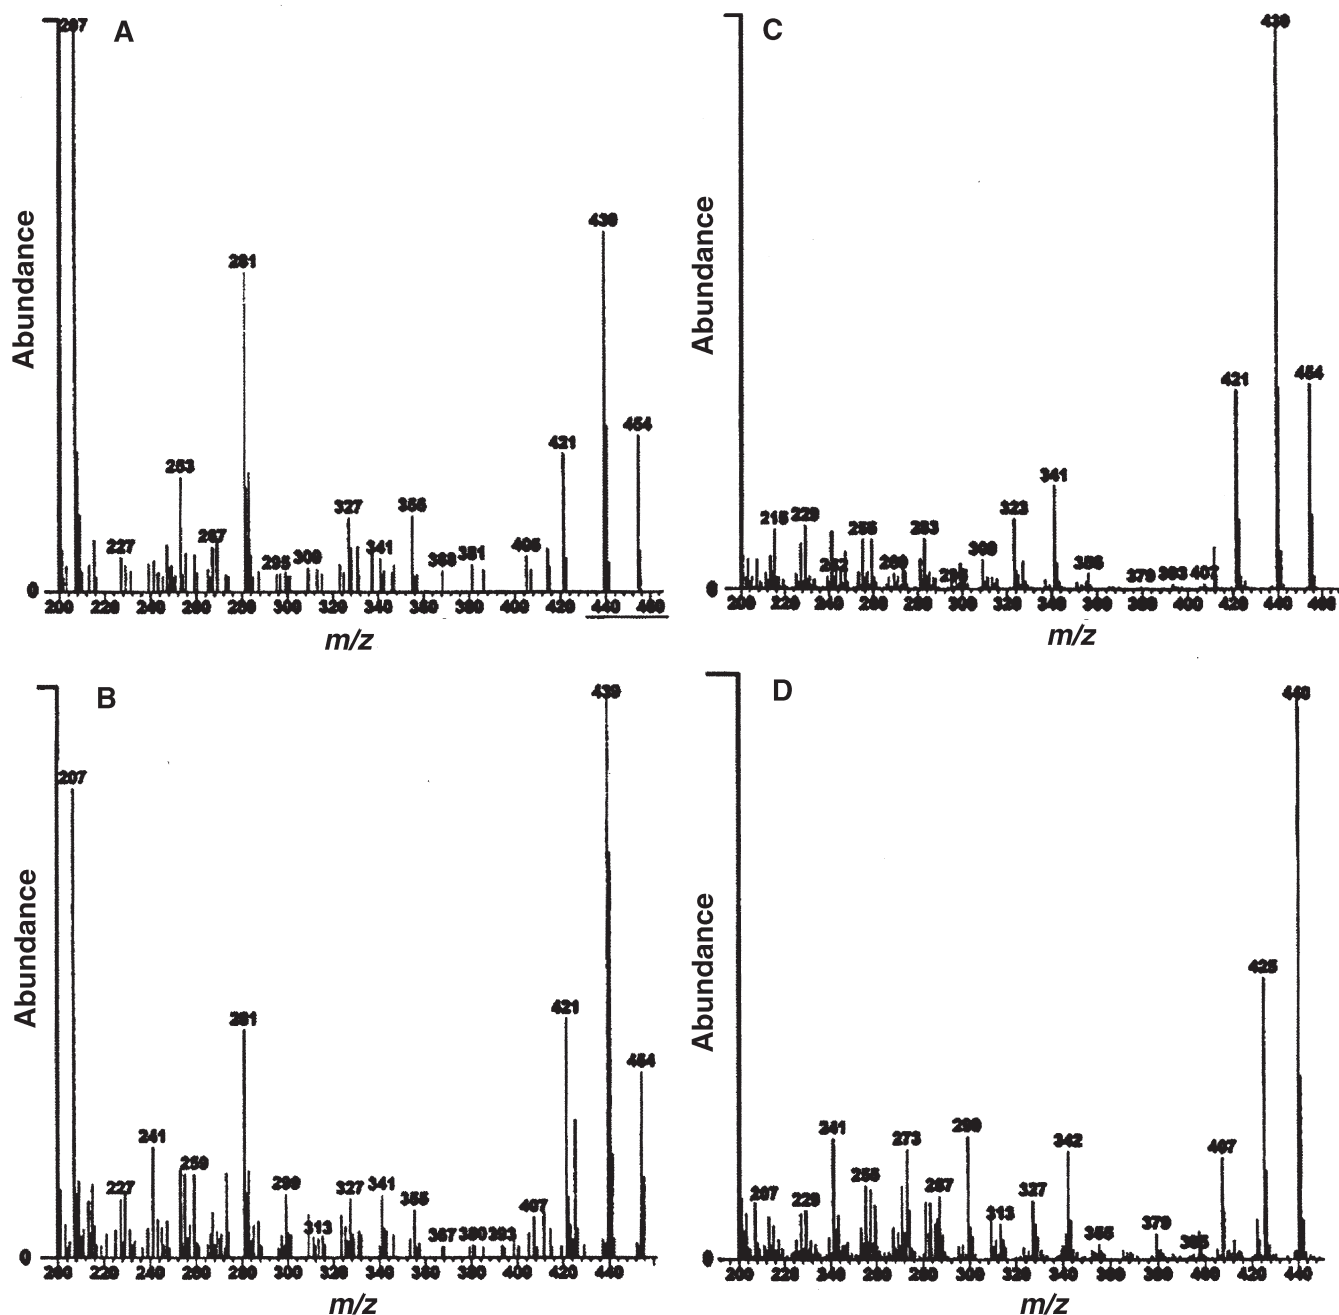

FIG. 3. Mass spectra of sterols detected in *P. carinii* by GC-MS. The mass spectrum reported in Panel A is for the GC peak at 23.7 min [relative retention time of cholesterol ( $RRT_c$ ) = 1.56], Panel B is for the GC peak at 24.4 min ( $RRT_c$  = 1.60), Panel C is for the GC peak at 25.0 min ( $RRT_c$  = 1.64), and Panel D is for the GC peak at 25.7 min ( $RRT_c$  = 1.69).

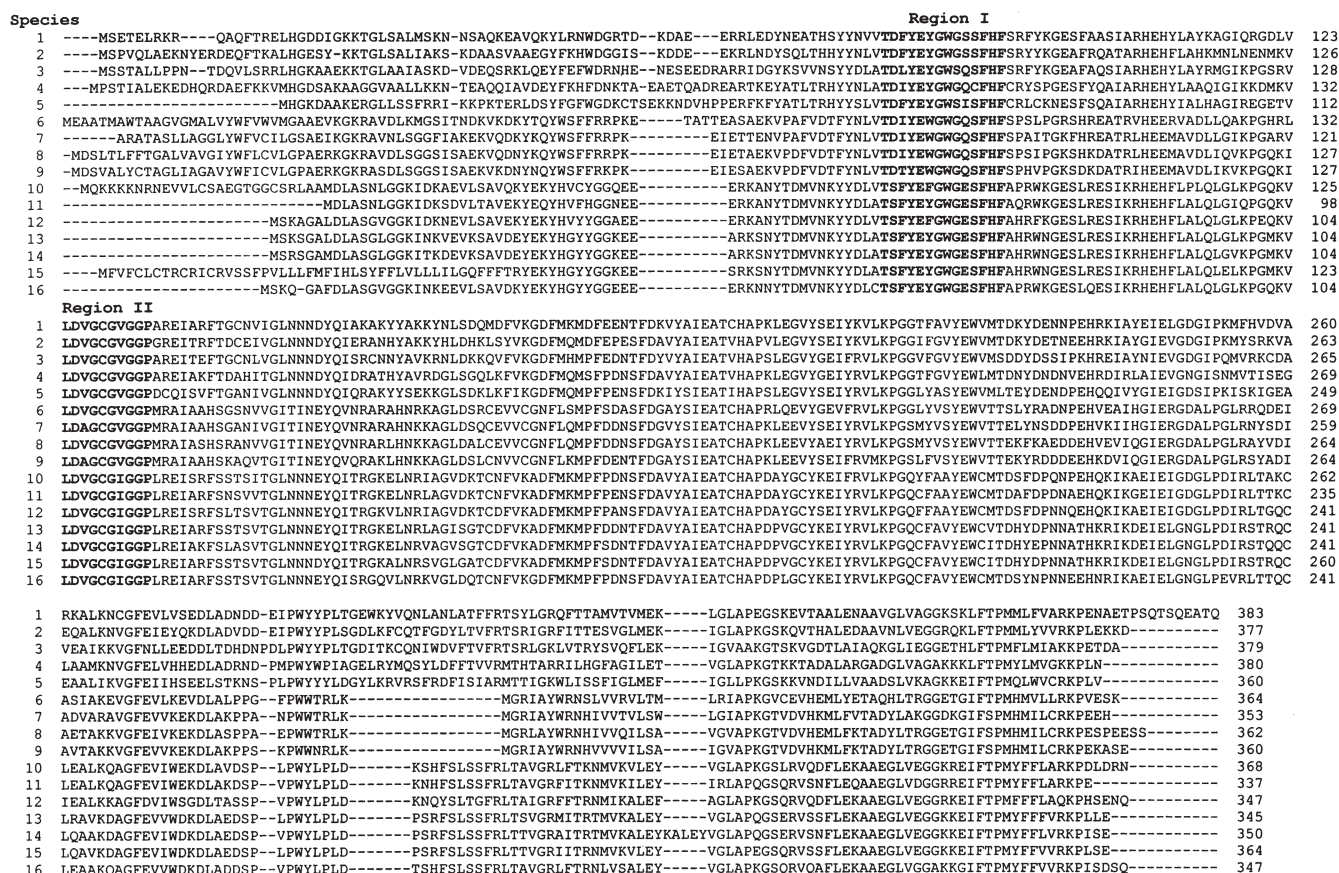

epimerically pure 24 $\alpha$ -methyl (2), was found to be a mixture of campesterol (24 $\alpha$ -methyl) and 24-epicampesterol (24 $\beta$ -methyl) in a *ca.* 2:1 mixture, consistent with the reported purity of 24-ethyl and 24-methyl sterols from vascular plants (28).

## DISCUSSION

The aim of these studies was to identify as many sterols as possible from *P. carinii* in order to establish a reasonable

sterol biosynthetic pathway for the organism after which its evolution could be considered and enzymes could be identified and targeted for rational drug design. Investigation of the sterol composition of *P. carinii* revealed interesting and noteworthy differences in comparison to related yeasts such as *Saccharomyces cerevisiae* (12). In contrast to *S. cerevisiae* and other yeasts, which usually contain predominantly ergosterol, *P. carinii* was found to contain cholesterol to about 80% of the total sterols. The enzymatic systems responsible for

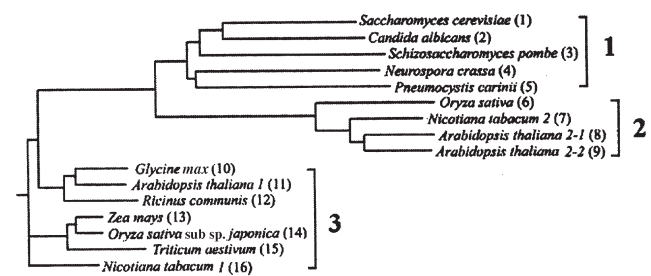

**FIG. 4.** Alignment of plant and fungal SMT. Sequences were aligned with the AlignX program (Vector NTI suite; Informax, Bethesda, MD). Region I, corresponding to the sterol binding domain, and Region II, corresponding to the AdoMet binding domain, are boldface. Complete amino acid sequences for each species of SMT are available in the GenBank corresponding to the following accession numbers: 1, CAA52308; 2, AAC26626; 3, CAB16897; 4, CAB97289; 5, AAK54439; 6, AAC34988; 7, AAC34989; 8, AAC34951; 9, T03848; 10, AAG28462; 11, CAA61966; 12, AAB62809; 13, AAB04057; 14, AAB62812; 15, AAC04265; 16, AAB37769. For abbreviation see Figure 1.

conversion of lanosterol to cholesterol accept a variety of closely related substrates, which have allowed many phytosterols structurally similar to cholesterol and to its intermediates to be detected in the organism. Eight intermediates that lie in the pathway between lanosterol and cholesterol were detected in the organism, suggesting an endogenous pathway to chole-

sterol: path **a** in Figure 2. The ability of an advanced fungus to synthesize and accumulate high levels of cholesterol was unexpected. However, cholesterol can accumulate in yeast cells. For instance, *S. cerevisiae* cultured anaerobically will absorb cholesterol from the medium and use the 24-desalkyl sterol as a bulk membrane insert replacing ergosterol (29). Anaerobic conditions are known to downregulate the postsqualene pathway in yeast, thereby upregulating sterol auxotrophy and permitting uptake of sterol from the medium (30). When deprived of oxygen, *P. carinii* growing as a parasite in the rat lung can mimic *S. cerevisiae* cultured anaerobically and absorb a significant amount of cholesterol synthesized by the host and phytosterol derived from the rat chow in a nondiscriminate manner. When the fungus is provided adequate oxygen, the organism can synthesize a portion of its cellular sterol by an acetate-mevalonate pathway (1,31). The degree to which cholesterol enters the organism may reflect a downregulation of phytosterol synthesis. This condition can affect whether the organism will resist treatment with a sterol biosynthesis inhibitor.

The *P. carinii* SMT catalyzing lanosterol **1** and 24(28)-methylenlanosterol **2** to phytosterols (32) is considered to be

**FIG. 5.** Dendrogram constructed for fungal and plant SMT. Boldface numbers refer to the grouping of SMT based on sequence homology. Sequence alignments of these enzymes are given in Figure 4. For abbreviation see Figure 1.

a key enzyme in fungi since it is not synthesized by animal systems. The enzyme also has attracted attention because of its regulatory role in phytosterol synthesis, thereby serving as a target for drug therapy (33). Indeed, as we will report elsewhere (Cushion, M.T., and Nes, W.D., unpublished report), the inhibitors of SMT action 24-aminolanosterol and 25-azalanosterol tested with *P. carinii* (33) were potent inhibitors in a cytotoxicity assay based on an ATP-driven bioluminescent reaction (6). Moreover, 24(*R,S*),25-epiminolanosterol, a potent inhibitor of SMT catalysis (33), was found to impair SMT action in whole cells of *P. carinii* (4).

Phytosterols of fungi are assumed to be of the 24 $\beta$ -alkyl series; therefore, the presence of 24 $\alpha$ -alkylsterols in *P. carinii* must be of dietary origin. Ten phytosterols with a 24-ethyl group were identified in the cells. Of these phytosterols, the  $\Delta^{25(27)}$ -olefins such as clerosterol **8** are unique to plants (5). Both  $\Delta^{24(28)}$ -*Z*-ethylidene and  $\Delta^{24(28)}$ -*E*-ethylidene sterols have been detected in fungi, but their co-occurrence with the  $\Delta^{25(27)}$ -olefin is unique to *P. carinii*. The C-24 configuration of 24-ethyl sterols from *P. carinii* showed a pattern similar to fungi (15), in which the 24 $\beta$ -ethyl stereochemistry is associated with a pathway routed through either a  $\Delta^{24(28)}$ -*Z*-ethylidene or a  $\Delta^{25(27)}$ -olefin to a  $\Delta^{24(28)}$ - or  $\Delta^{25(27)}$ -reductase-type enzyme (Fig. 2, paths **b3** and **b4**), whereas sterols lacking these specific pathways have a 24 $\alpha$ -ethyl stereochemistry. Unlike plants that can isomerize the  $\Delta^{24(28)}$ -bond to the  $\Delta^{24(25)}$ -position and in turn reduce the  $\Delta^{24(25)}$ -bond of a 24-methylsterol to either the 24 $\alpha$ - or 24 $\beta$ -configuration, fungi are known to reduce only the  $\Delta^{24(25)}$ -bond or the  $\Delta^{24(28)}$ -bond in the 24-methyl and 24-ethyl series to the 24 $\beta$ -methyl configuration. The presence of two distinct double bond series,  $\Delta^{24(28)}$ - and  $\Delta^{24(25)}$ - attached initially to a 24-methylstanostane skeleton implies the existence of two separate biosynthetic pathways to 24 $\beta$ -methylcholesterol (Fig. 2, paths **b1** and **b2**). Although the immediate precursor of 24 $\beta$ -methyl cholesterol in the **b1** pathway was not detected, the isolation of the corresponding  $\Delta^{5,7}$ -sterol in the cholesterol series suggests that the 24-alkyl compound is actually synthesized under physiological conditions.

Phylogenetic analyses based on sequence data for enzymes that constitute the sterol pathway of *P. carinii* are limited. From a comparison of the deduced amino acid sequence with that currently available, it appears that the SMT from *P. carinii* encodes an array similar to SMT enzymes from fungi and plants and belongs to the AdoMet-dependent methyl transferase superfamily (Fig. 4). As shown in the dendrogram in Figure 5, the SMT have a close evolutionary relationship to one another, with three classes based on sequence identity: In Group 1, the *P. carinii* gene shares at least 49 to 52% identity with other fungal *ERG6* genes, in Group 2, the *P. carinii* gene shares 37 to 40% identity with the plant SMT genes considered to catalyze "SMT2" activity (catalyze the second C<sub>1</sub>-transfer), and in Group 3, the *P. carinii* gene shares 32 to 38% identity with plant homologs that catalyze "SMT1" activity (catalyze the first C<sub>1</sub>-transfer). Pairwise sequence comparisons of the *ERG6* gene from *S. cerevisiae* or *P. carinii* with

related genes revealed a highly conserved hydrophobic region rich in aromatic amino acids, referred to as Region I, (Fig. 4) containing a signature motif Y81EYGWX86 not present in other AdoMet-dependent methyl transferases. As each of these enzymes uses zymosterol (cholest-8,24-dienol) as the sterol acceptor molecule, the aromatic-rich domain of Region I, spanning amino acids 78 to 91, has been proposed to be involved in substrate binding and possibly product formation by stabilizing intermediate carbenium ions generated during sterol C-methylation (34). Recent work from this laboratory has confirmed the role of Region I as part of the sterol binding site by chemical affinity labeling and site-directed mutagenesis experiments (34–36). A second highly conserved domain recently shown to be a part of the AdoMet binding site by photoaffinity labeling and site-directed mutagenesis experiments using the *S. cerevisiae* SMT spans amino acids 127 to 137 (Marshall, J.A., and Nes, W.D., unpublished report). We refer to this domain as Region II. Sequence homology analyses (37) and the structure of several AdoMet-dependent methyl transferase enzymes have been reported (38), supporting Region II as a wall of the AdoMet-binding site for the SMT. In a 3-D perspective of the crystal structures of AdoMet-dependent methyl transferases, a similar folding pattern with the central parallel  $\beta$ -sheet surrounded by  $\alpha$ -helices is observed. Although no information is available to date on the crystal structure of an SMT, all share with at least one other family member a minimum of 32 to 91% sequence identity over the entire length of the protein, ranging from 336 to 383 amino acids, and strongly indicate that SMT maintain similar 3-D conformations (39). One key feature of many AdoMet-dependent methyl transferase enzymes is the structural arrangement of their catalytic domain. This domain is built around a Rossmann fold, and it appears from the sequence alignment that SMT contain this domain at or near Region II. Regions I and II identified in the *ERG6p* gene are always found in the same order on the polypeptide chain and are separated by comparable intervals in SMT sequences. Evidence for a common fold and similar secondary structure in SMT is provided by the degree of shared amino acid identity and the fact that all family members align without large gaps connecting secondary structure elements (Bujnicki, J.M., and Nes, W.D., unpublished report). The sequence alignment data for the catalytic motifs of SMT, independent of the apparent substrate specificity, are consistent with *P. carinii* having a close phylogenetic association with yeast forms of the ascomycetous fungi.

The two sequence-related classes of plant SMT proteins catalyzing the first (SMT1) and second (SMT2) C<sub>1</sub>-transfer reactions and their strict specificity for cycloartenol and 24(28)-methylene lophenol, respectively, suggest their roles in distinct enzymatic steps in the pathway (40). A similar distinction for operation of the successive two-stage C-methylation activity in the SMT pathway of fungi is not observed, suggesting that a SMT1 and SMT2 are not required in the pathway of 24-ethyl sterols synthesized by fungi. The SMT from the yeast *S. cerevisiae* prefers zymosterol as substrate,

whereas *P. carinii* prefers lanosterol as substrate to catalyze the first C<sub>1</sub>-transfer reaction (32,33). The substrate specificity of the SMT for zymosterol or lanosterol has influenced the order of intermediates in the pathway, which can affect fungal sensitivity to C-methylation inhibitors (33). To explain the evolution in substrate specificity and the C-methylation activities that gave rise to more efficient SMT, we propose that a few amino acid substitutions in the topology of the active site occurred that affected catalytic competency and substrate channeling, as recently evidenced in site-directed mutagenesis experiments related to directed evolution of the SMT (35,36).

## ACKNOWLEDGMENTS

This study was funded in part by the Welch Foundation (D-1276) and the National Institutes of Health (NIH) (GM63477) to W.D.N. and the NIH (AI75319) to M.T.C. It represents partial fulfillment of the doctoral degree in chemistry at Texas Tech University for W.Z. A portion of this work was presented at the meeting of the American Oil Chemists' Society Steroid Symposium in May 2002 in Montréal, Canada.

# Transformations of DHEA and Its Metabolites by Rat Liver

Henry Lardy\*, Ashok Marwah, and Padma Marwah

Department of Biochemistry and Institute for Enzyme Research, University of Wisconsin–Madison, Madison, Wisconsin 53705

**ABSTRACT:** Because dehydroepiandrosterone (DHEA) has a wide variety of weak beneficial effects in experimental animals and humans, we searched for metabolites of this steroid in the hope of finding more active compounds that might qualify for the title “steroid hormone.” Incubation of DHEA with rat liver homogenate fortified with energy-yielding substrates resulted in rapid hydroxylation at the 7 $\alpha$ -position of the molecule and subsequent conversion to other 7-oxygenated steroids in the sequence DHEA  $\rightarrow$  7 $\alpha$ -hydroxyDHEA  $\rightarrow$  7-oxoDHEA  $\rightarrow$  7 $\beta$ -hydroxyDHEA, with branching to diols, triols, and sulfate esters. The ability of these metabolites to induce the formation of liver thermogenic enzyme activity increased from left to right in that sequence. A total of 25 different steroids were characterized, and at least six additional structures that are currently under study were produced from DHEA. 7-OxoDHEA is more effective than DHEA in enhancing memory performance in old mice and in reversing the amnesic effects of scopolamine.

Paper no. L9137 in *Lipids* 37, 1187–1191 (December 2002).

The study of naturally occurring steroids has been so extensive and has been conducted by such intellectually and experimentally gifted investigators that one might assume that there are no more interesting steroids to be found. However, as was the case when John Horgan (1) erroneously decreed in 1996 that we had reached the “twilight of the Scientific Age,” many interesting structures are still to be found among the steroids.

This essay deals with steroids derived metabolically from dehydroepiandrosterone (DHEA) (1, see Scheme 1), which is produced in the adrenals, testes, ovaries, and brain (2,3) and serves as an intermediate in the biosynthesis of testosterone and estrogens from cholesterol. In humans the adrenal glands are the main source of DHEA and of its sulfate ester (DHEAS), which is the main circulating form of this steroid. The prenatal adrenals are very active in synthesizing this steroid, but the fetal zone of the gland atrophies after birth and the synthesis is renewed in the zona reticularis at about 7 yr of age (adrenarch). The blood plasma concentration of DHEAS peaks at about 20 to 30 yr of age, when it reaches 200 to 500  $\mu\text{g}/100\text{ mL}$ —10 times the concentration of glucocorticoids (2). The concentration in blood plasma of women is somewhat lower. As humans age, blood DHEAS concen-

trations decrease so that at ages 70–80 the amount is only about 10% that in the prime years.

Orally administered DHEA exerts several beneficial effects in animals apart from its role in the formation of androgens and estrogens. It decreases obesity (4–8), decreases blood cholesterol (8–10), decreases blood sugar in diabetic animals (11), enhances the activity of the immune system (12,13), inhibits tumor development (14,15), and improves memory (16,17). DHEA has been found to have some limited beneficial effects in human subjects (18–27).

The suitability of DHEA as a therapeutic agent in humans is limited because of the large doses required and because it increases blood testosterone when given to women. The large amounts (*ca.* 0.5% of the diet) needed to obtain effects in animals and the fact that no receptor for DHEA has been isolated indicate that, in the systems that respond, DHEA may be acting as a precursor of a more active steroid just as it is a precursor of androgens and estrogens. We therefore initiated a search for possible metabolites of DHEA in the hope of finding more active steroids that would be more selective in their metabolic effects. That such a search requires a suitable assay system was clearly stated by Allen and Doisy in 1923 when they sought the substance responsible for their newly discovered estrogen activity: “Without a practicable test, the search for any hormone is obviously a very haphazard and uncertain task” (28). Such a “practicable test” for the DHEA problem was developed in our laboratory.

The suggestion, in 1958, from two different research groups (29,30) that mitochondrial glycerophosphate dehydrogenase (GPDH) could oxidize NADH generated by glycolysis using a pathway that skipped the mitochondrial phosphorylation site between NADH and ubiquinone at once indicated that this system (glycerophosphate shuttle) would be thermogenic. The best-known thermogenic agent in homeotherms is the thyroid hormone (31,32), which *ipso facto* increases the metabolic cost of work (33,34). We found that feeding desiccated thyroid substance increased liver mitochondrial GPDH 20-fold above that in normal animals and that thyroidectomy greatly decreased the enzyme (35,36). When DHEA was demonstrated to decrease metabolic efficiency (4) and to be thermogenic (37), we found that it too induced the formation of increased amounts of liver GPDH (38,39). Elsewhere (38,40) we have pointed out that sending electrons from glycolytically generated cytosolic NADH directly to ubiquinone could decrease metabolic efficiency only about 5%, whereas efficiency is decreased

SCHEME 1

about 35% in hyperthyroid subjects (33,34). We have described a system involving GPDH and malic enzyme in liver that can shunt electrons from the tricarboxylic acid cycle, bypassing the first phosphorylation site, and thus decrease metabolic efficiency by one-third. We had demonstrated earlier (41) that reducing equivalents generated in the tricarboxylic acid cycle directly reduce oxalacetate to form malate, which is transported from the mitochondria to the cytosol. In liver, malic enzyme converts malate to pyruvate, which can recirculate to the mitochondria. The NADPH generated is used to reduce dihydroxyacetone phosphate to glycerophosphate (42), the substrate for the dehydrogenase located on the mitochondrial membrane.

Muscle has high GPDH activity, and if a system exists to transfer reducing equivalents from mitochondria to the cytosol in that tissue, it could account for the increased energy cost of work by hyperthyroid subjects (34). We are currently searching for such a possible transport mechanism.

We have used the induction of these two enzymes as an assay for DHEA-like activity of a large number of new steroids

we have synthesized (38,39,43-47). In a parallel study we have examined the metabolic conversion of DHEA to related steroid structures (48). By following the conversion at short and frequent time intervals, it is possible to deduce the sequence by which DHEA moves on to become more active molecules.

*Metabolic conversions of DHEA.* Many investigators have studied the conversion of DHEA to a variety of metabolites. Usually a specific tissue fraction was used as the enzyme source, and only a few products were identified. We examined the conversion of DHEA to neutral free steroids as well as to acidic and neutral conjugated molecules in whole-liver homogenates so that the different types of relevant enzymes in different organelles or cell compartments could have access to all metabolites as they were formed, as might be the case in the intact liver. The product of one organelle can be the substrate for another.

The first experiments were conducted with 1  $\mu$ g of DHEA (Humanetics Corp., Chanhassen, MN) per 40 mg of liver homogenized in isotonic medium to retain mitochondrial structure (48). The incubation mixture contained NADPH and malic

acid to provide reducing power for the P450 oxidoreductase. After various incubation times, samples were removed, extracted with 50% acetonitrile, then with acetonitrile with methanol, and the solvents were evaporated. Detailed descriptions of the extraction, fractionation, and analytical procedures are presented elsewhere (48,49).

**FIG. 1.** Yield of metabolites from 1  $\mu$ g of dehydroepiandrosterone (DHEA) and homogenate from 40 mg of rat liver in 1 mL final volume. The isotonic medium was fortified with 2 mM malic acid,  $\text{MgSO}_4$ , and glucose 6-phosphate each at 1 mM, and ATP and NADPH each at 25  $\mu$ M, incubated at 37°C and sampled at the times indicated. AET, androstene triol.

All analyses by HPLC–MS were conducted after selecting columns and solvents that permitted separation of individual compounds in each of the fractions (48,49). External and internal standards of known, synthesized steroids defined retention times, recoveries, and fragmentation patterns.

Table 1 lists 25 compounds produced from DHEA that were isolated from the incubation mixtures and identified; their structures are depicted in Scheme 1. Steroids 1 to 4 readily form 3 $\beta$ -sulfate esters. The diol and triols formed are susceptible to sulfation at either the 3 $\beta$ - or 17 $\beta$ -positions.

We were astonished that nearly all the DHEA-related structures that have been found in nature were produced in these incubations. It is clear from Figure 1 that 7 $\alpha$ -hydroxyDHEA was the first product formed from DHEA. Nearly 10% of the added DHEA accumulated as the 7 $\alpha$  derivative in the first 2 min; very small amounts of 7-oxoDHEA, but no 7 $\beta$  derivative, were formed in that interval. 7 $\alpha$ -HydroxyDHEA reached a peak at 10 min and then declined as it was converted to 7-oxoDHEA and other metabolites. After 5 min of incubation, 7 $\beta$ -hydroxyDHEA was as abundant as the 7-oxo steroid, and small amounts of 7-oxodiols and 3 $\beta$ ,7 $\alpha$ ,17 $\beta$ -triol were present. The addition of pyruvate to keep cytosolic NAD<sup>+</sup> in the oxidized state retarded the hydroxylation and the formation of other metabolites.

In liver homogenate supplemented with lactate and NADH, 7 $\alpha$ -hydroxyDHEA was again the early product (Fig. 2). Despite the presumed continued production, the total amount declined as it was converted first to 7-oxoDHEA, then to 7 $\beta$ -hydroxyDHEA and the two triols. In incubations with DHEA as substrate, small amounts of sulfate esters were formed; much larger amounts were formed when the starting steroid was 7-oxoDHEA, 7 $\beta$ -hydroxyDHEA, or 7 $\beta$ -triol. Among the metabolites still to be characterized, there is evidence for glucuronides and possibly acyl esters.

The specific ability to induce the liver thermogenic enzymes, mitochondrial *sn*-glycerol-3-phosphate dehydrogenase

**FIG. 2.** Metabolites produced from liver homogenate. Conditions are as in Figure 1, except that 2 mM lactate replaced malate and NADH replaced NADPH. For abbreviations see Figure 1.

and cytosolic malic enzyme, increases in the order DHEA  $\rightarrow$  7 $\alpha$ -hydroxyDHEA  $\rightarrow$  7-oxoDHEA  $\rightarrow$  7 $\beta$ -hydroxyDHEA. At low steroid concentrations in the diet, 7-oxoDHEA induces levels of enzyme activity equivalent to those produced by three to four times as much DHEA (44). The activity of 7 $\alpha$ -hydroxyDHEA falls between these two, whereas 7 $\beta$ -hydroxyDHEA is considerably more active than 7-oxoDHEA. Androst-5-ene-3 $\beta$ ,7 $\beta$ ,17 $\beta$ -triol and 3 $\beta$ ,7 $\beta$ ,16 $\alpha$ -trihydroxyandrost-5-en-17-one are about as active as 7 $\beta$ -hydroxyDHEA. The comparisons must be made within a given experiment because the responses vary between different batches of rats.

7-OxoDHEA is also more active than DHEA as an enhancer of memory performance and in its ability to abolish the amnesic effect of scopolamine (50).

# Studies Toward the Synthesis of the Shark Repellent Pavoninin-5

John R. Williams\*, Deping Chai, Hua Gong, Wei Zhao, and Dominic Wright

Department of Chemistry, Temple University, Philadelphia, Pennsylvania 19122-2585

**ABSTRACT:** Sharks are the most dangerous predators of people in the sea, resulting in people being mauled and killed each year. A shark repellent could help to diminish this danger. The aglycone of the shark repellent pavoninin-5, (25*R*)-cholest-5-en-3 $\beta$ ,15 $\alpha$ ,26-triol (**5a**), was synthesized from diosgenin (**9**). Removing mercury from the Clemmensen reduction of **9** gave a higher yield of (25*R*)-cholest-5-en-3 $\beta$ ,16 $\beta$ ,26-triol, **10a**, and was also more environmentally friendly. Attempted methods for the transposition of the C-16 $\beta$  hydroxyl to the 15 $\alpha$  position are described. A successful method for this transposition *via* the 15 $\alpha$ -hydroxy-16-ketone, **8a**, using the Barton deoxygenation reaction on the 16-alcohol **14b**, is reported.

Paper no. L9136 in *Lipids* 37, 1193–1195 (December 2002).

Surveys by the National Geographic Society have shown that “shark” is the most feared word in the English language, probably as a result of the movie *Jaws*. This fear is well founded since sharks as a group are the most dangerous predators to humans in the sea.

Certain species of fish are known to kill other fish in the same tank without any traumatic device. These fish have special secretory cells that emit ichthyotoxic substances, and thus they are called ichthyocrinotoxic fish (1–3). *Paradachirus pavoninus*, a sole that lives in the tropical region of the western Pacific and eastern Indian Ocean, is an ichthyotoxic fish. The secretion from *P. pavoninus* has been isolated, separated, and characterized as pavoninins 1–6 (Scheme 1) (4). These shark-repelling pavoninins are ichthyotoxic steroids, *N*-acetylglucosaminides. It is believed that pavoninins are potent cell disrupters that should have important pharmacological properties. The toxicity of these steroid glycosides is believed to relate to their surfactant properties. The steroid backbone is considered to be the hydrophobic region, whereas the *N*-acetyl-D-glucosamide sugar is hydrophilic. The synthesis of pavoninin-1 (**1**) (5) and the aglycones of pavoninin-1 (**1a**) and -2 (**2a**) have been reported (6). In this article, we report our efforts to synthesize the aglycone of pavoninin-5 (**5a**).

Figure 1 outlines a retrosynthetic analysis of pavoninin-5 (**5**). The *N*-acetyl glucosamine (**7**) may be added to the aglycone **5a** to yield pavoninin-5. The aglycone **5a** can be prepared from the intermediate 15 $\alpha$ -hydroxy-16-ketone (**8**). This

can be prepared from the commercially available diosgenin (**9**).

## RESULTS AND DISCUSSION

The structure of pavoninin-5 aglycone (**5a**) may be described as cholesterol with two additional hydroxyl groups at C-15 $\alpha$  and C-26. A logical starting material for the synthesis of **5a** is the commercially available **9**, which has functionality in positions suitable for conversion to **5a**. Zinc and hydrochloric acid reduction of **9** afforded the 3 $\beta$ ,16 $\beta$ ,26-triol, **10a**, in 85% yield. This is a significant improvement over the original

FIG. 1. Retrosynthesis of pavoninin-5 (**5**). TBDMS, *tert*-butyldimethylsilyl.

Clemmensen reduction since the yield of **10a** is higher, 85 vs. ~60% previously (7). That mercury is not used in the reduction renders the reaction more environmentally friendly (8).

The 3 $\beta$ ,16 $\beta$ ,26-triol **10a** was selectively protected as the 3 $\beta$ ,26-bissilyloxy ether **10b** (9). Oxidation of the unprotected alcohol in **10b** with pyridinium chlorochromate afforded the 16-ketone **11** (Fig. 2).

A number of methods were used in attempts to  $\alpha$ -hydroxylate **11** into **8a** in one step. The first method utilizing the Davis reagent (10,11), was unsuccessful, probably owing to the large size of the Davis reagent, which prevented it from approaching the substrate. To reduce the steric congestion in this hydroxylation reaction, the second method used a small reagent, dimethyldioxirane (12). Again the reaction was unsuccessful.

Because of the difficulty of direct hydroxylation of **11**, we proposed another route to synthesize **12**, through silyl enol ether (13) (Fig. 4). Treatment of **11** with lithium diisopropylamide (LDA) yielded the thermodynamic enolate. After many attempts, the silyl enol ether **12** was finally synthesized by using the method of Corey and Gross (14). Adding lithium hexamethyldisilazane to the solution of **11** and trimethylsilyl chloride at  $-78^{\circ}\text{C}$ , followed by addition of redistilled triethylamine, then quenching the reaction with saturated  $\text{NaHCO}_3$ , afforded the enol ether **12**. The structure of **12** was confirmed by  $^1\text{H}$  NMR, which showed the chemical shift of 15-H at 4.6.

Enol ether **12** was not purified because it is sensitive to silica gel. Oxidation of **12** with dimethyldioxirane at  $-78^{\circ}\text{C}$  probably forms the labile  $\alpha$ -epoxysilyl ether **13**, which

**FIG. 3.** Formation of  $\alpha$ -hydroxy ketone (**8a**). LHMDS, lithium hexamethyldisilazane; TMSCl, trimethylsilyl chloride; TMS, trimethylsilyl; for other abbreviations see Figure 1.

**FIG. 4.** Coupling constant between 14 $\alpha$ -H and 15 $\beta$ -H in **8a** is 10–12 Hz.

decomposes in the presence of acid to afford the  $\alpha$ -hydroxy ketone **8a** (Fig. 3). The  $^1\text{H}$  NMR spectrum of **8a** showed a coupling constant between 15-H and 14-H of 12 Hz, which indicates the 15-H should be in the  $\beta$  position (Fig. 4). The formation of this structure may be explained by steric reasons. The large groups at the C-13 $\beta$  and C-17 $\beta$  positions shielded the  $\beta$  face, causing the oxidant to attack the  $\alpha$  face and resulting in the 15 $\alpha$ -hydroxy-16-ketone **8a**.

The next step was the deoxygenation of the C-16 ketone. Attempts to prepare the thioketal of **8a** were unsuccessful. One can rationalize the failure to form a thioketal as being due to steric congestion. Efforts to carry out a Wolff–Kishner reduction also were unsuccessful. A survey of the literature revealed an absence of a description of the deoxygenation of  $\alpha$ -hydroxy ketones.

Owing to the failure of direct deoxygenation of **8a**, we planned to reduce the 16-position carbonyl group to a hydroxyl group, then deoxygenate the alcohol using the Barton reaction (15). We proposed this scheme because the hydroxyl group in the Barton reaction functions as a nucleophile to attack carbon disulfide, which can avoid the steric congestion of the C-16 position. First we had to protect the hydroxyl group in the 15 $\alpha$ -position. Our initial choice was the methyl group as the protecting group because it had the smallest steric size, and we did not want the protecting group at the 15-position to block the Barton reaction in the later step.

Because of the sensitivity of the 15 $\beta$  hydrogen in **8a**, we used  $\text{CH}_3\text{I}$  and silver oxide under neutral, mild methylating conditions to protect the hydroxyl group. The C-16 ketone of the methyl ether **8b** was reduced to a mixture of 16 $\alpha$  and - $\beta$

**FIG. 5.** Synthesis of pavoninin-5 aglycone (**5a**). MEM, methoxyethoxymethyl; AIBN, 2,2'-azobisisobutyronitrile; TBAF, tetrabutylammonium fluoride; for other abbreviation see Figure 1.

alcohols (**14a**) by sodium borohydride. The Barton reaction on **14a** first afford a thioester, which on radical reduction gave the desoxy methyl ether **5b** (see Scheme 4). Unfortunately, the methyl ether could not be cleaved without the concomitant cleavage of the TBDMS groups (16). The methoxyethoxymethyl (MEM) group was chosen as a protecting group (17) because it is easier to cleave MEM ether than methyl ether. The hydroxy group in **8a** was first protected using MEM chloride to afford the MEM ether, **8c**. Then, as for the methyl ether, the ketone was reduced with sodium borohydride and the resulting alcohols were deoxygenated by the Barton reaction to give the MEM ether, **5c**. The general method for cleavage of a MEM group is to use anhydrous zinc bromide in dry methylene chloride (17), but in this reaction, ZnBr<sub>2</sub> again cleaved the TBDMS group as well. This now constitutes a successful route for the synthesis of pavoninin-5 aglycone, **5a**, in 10 steps with 12% overall yield.

To selectively cleave the MEM group in **5c** without affecting the TBDMS (Fig. 4), bromodimethylborane (18) was used and yielded the 3 $\beta$ ,26-bissilyloxy protected ether **5d**. The protected ether **5d** is a suitable substrate for the attachment of N-acetylglucosamine at C-15 $\alpha$ , and removal of the protecting groups should afford the shark-repelling 26-desacetyl-pavoninin-5 (4).

We report the first synthesis of pavoninin-5 aglycone, **5a**, in 10 steps in 12% overall yield. An improved method for the reductive cleavage of diosgenin, **9**, was exploited.  $\alpha$ -Hydroxy ketones were found to be resistant to the usual ketone deoxygenation methods. A way around this problem using Barton's method of deoxygenation of alcohols was developed. A regioselective method for the 1,2 transposition of an alcohol in a five-membered ring was devised.

## ACKNOWLEDGMENTS

Financial support for this research was provided by a grant from the Temple University Research Incentive Fund and a GlaxoSmithKline Fellowship (D.C.). Also, D.W. was supported in part by a Howard Hughes Medical Institute grant to the Undergraduate Biological Sciences Education Program at Temple University. Financial support was also provided by Wyeth-Ayerst, Bristol-Myers Squibb, and Merck. We thank Dr. Stephen Wilson of the Chemistry Department at New York University for suggesting the modified Clemmensen reduction conditions.

# New Chemical Syntheses of Cholest-4,6-dien-3-one

Edward J. Parish\*, Hang Sun, Ding Lu, Stephen A. Kizito, and Zhihai Qiu

Department of Chemistry, Auburn University, Alabama 36849-5312

**ABSTRACT:** Steroidal dienones represent a significant class of compounds that are useful intermediates in the further functionalization of the steroid nucleus. Their chemical synthesis can be problematic owing to the lack of a simplified method of preparation and the occurrence of impurities that can be difficult to remove. We have endeavored to develop new methods of chemical synthesis of cholest-4,6-dien-3-one that would yield a product of high purity.

Paper no. L9153 in *Lipids* 37, 1197–1200 (December 2002).

Steroidal 4,6-dien-3-ones are an important class of steroids that have been useful as intermediates in the synthesis of a variety of ring A and B modified steroids (1–10). During our studies on the synthesis of steroidal inhibitors of estrogen synthase (aromatase), we required a quantity of cholest-4,6-dien-3-one (**1**) for use as a model compound in our synthesis work. Typical literature syntheses of this compound required a multistep reaction sequence for the preparation of a purified sample. Other shortened procedures provided mixtures of products that would require extensive chromatographic purification or produce only poor yields of product. In the present work, we endeavored to develop new synthetic approaches to this compound that would make this product more readily available for experimental use.

## METHODS OF ORGANIC SYNTHESIS

The synthesis of cholesta-4,6-dien-3-one (**1**) has been reported by many research groups (2,11–13). Tachibana (2) treated cholesta-4,6-dien-3 $\beta$ -ol with various oxidizing agents [e.g., 2,3-dichloro-5,6-dicyano-1,4-benzoquinone, and pyridinium chlorochromate (PCC)] to give 50–85% yields (Scheme 1). Unfortunately, the starting material cholesta-4,6-dien-3 $\beta$ -ol is not easy to obtain; it requires many steps to be synthesized from commercially available steroids. Sondheimer *et al.* (11) found that cholesterol could be oxidized to **1** directly by means of manganese dioxide (MnO<sub>2</sub>). This method is interesting and facile but gives only a 27% yield. Wettstein (12) and Djerassi (13) also reported that cholesterol could be oxidized under the Oppenauer conditions with *p*-quinone as the hydrogen acceptor to afford **1** in one step. This reaction also gives poor yields (<50%). The reaction of steroidal-4-en-3-ones with chloranil (tetrachlorobenzo-

quinone) also gives steroidal-4,6-dien-3-ones in good yields (4). However, steroidal-4-en-3-ones may require an additional synthesis.

In the present work we developed new procedures to yield **1** in high purity. In our first attempt, using commercially available cholesterol as a starting material, we designed the chemical synthesis shown in Scheme 2 (where DMF = dimethylformamide and NBS = *N*-bromosuccinimide). In the last step, treatment of the bromide with base (2,4,6-trimethylpyridine, collidine; 1,5-diazabicyclo[4.3.0]non-5-ene, DBN; or 1,8-diazabicyclo[5.4.0]undec-7-ene, DBU) resulted in elimination of HBr to produce the products **1** and cholest-4-en-3-one (**2**) as a mixture. The enone **2** is difficult to remove and would require chromatographic separation.

We then turned our attention to the approach shown in Scheme 3. Again using cholesterol as a starting material, we treated the final dibromide (in the last reaction) with base (collidine, DBN, or DBU) and again observed a mixture of reaction products (**1** and **2**).

Using methods modified from the literature (14,15), we completed the synthesis shown in Scheme 4. This procedure resulted in the formation of **1** as the only product in high yield (90%). However, a synthesis of several steps was required.

To reduce the number of steps during the preparation of **1**, we focused our efforts on the use of manganese dioxide to yield **1** directly from cholesterol (Scheme 5). This type of reaction had been described previously for the direct conversion of steroidal 5-en-3 $\beta$ -ols to 4,6-dienones (11). Using cholesterol as a starting material, we were able to produce **1** in modest yields ranging from 11 to 21%.

The results obtained using manganese dioxide were encouraging. We then explored the use of similar reagents to improve the yield of **1**. One reagent, chromium dioxide (Magtrieve™, product brochure; Aldrich Chemical Co., Milwaukee, WI) was described as a more effective reagent than manganese dioxide in many organic reactions (16). When cholesterol was treated with Magtrieve, **1** was produced in good yields (Scheme 6). Using acetonitrile as a solvent resulted in the formation of **1** in 74% yield. In addition to the major product **1**, a small quantity of 7-hydroxycholest-4-en-3-one was produced. This polar product was easily removed by silica gel column chromatography to yield purified **1**. We feel this procedure is the most efficient preparation of **1** currently available.

In conclusion, we feel the results presented herein provide useful information concerning the chemical synthesis of cholest-4,6-dien-3-one (**1**). In addition, we have attempted to develop novel and efficient approaches to the synthesis of **1** that will be efficient and give **1** in good yields.

# Temperature-Enhanced Alumina HPLC Method for the Analysis of Wax Esters, Sterol Esters, and Methyl Esters

Robert A. Moreau<sup>a,\*</sup>, Karen Kohout<sup>a</sup>, and Vijay Singh<sup>b</sup>

<sup>a</sup>ERRC, ARS, USDA, Wyndmoor, Pennsylvania, and <sup>b</sup>Department of Agricultural Engineering, University of Illinois, Urbana, Illinois 61801

**ABSTRACT:** Previous attempts at separating nonpolar lipid esters (including wax esters, sterol esters, and methyl esters) have achieved only limited success. Among the several normal-phase methods tested, a single recent report of a method employing an alumina column at 30°C with a binary gradient system was the most promising. In the current study, modification of the alumina method by increasing the column temperature to 75°C improved the separation of standards of wax esters and sterol esters. Elevated column temperature also enhanced the separation of FAME with differing degrees of unsaturation. Evidence was also presented to indicate that the method similarly separated phytosterol esters, based on their levels of unsaturation. With the increased interest in phytosterol- and phytostanol ester-enriched functional foods, this method should provide a technique to characterize and compare these products.

Paper no. L9154 in *Lipids* 37, 1201–1204 (December 2002).

Numerous HPLC methods have been reported for the separation of polar and nonpolar lipids (1,2). Approaches to the separation of nonpolar lipid classes have included the use of Diol (3,4), cyanopropyl (CN) (5,6), and alumina (7) columns. Among the nonpolar lipid classes, wax esters (a wax ester is defined as a FA esterified to a fatty alcohol) and sterol esters (including phytosterol fatty acyl esters) have proven to be the most difficult to separate, and the evidence reported in the latter alumina method (with a column temperature of 30°C) indicates that it is the most promising one (7). While employing the alumina method to separate grain seed extracts that were high in both wax esters and phytosterol esters, we noted that when the temperature of the alumina column was increased (up to 75°C) the separation between wax esters and sterol esters was enhanced. In addition, the phytosterol esters were subfractionated into several distinct peaks that appeared to be related to the degree of unsaturation. With the increased interest in phytosterol- and phytostanol-ester enriched functional foods, this method should provide a way to characterize and compare the types of sterol esters in these products.

## MATERIALS AND METHODS

Lipid standards and jojoba oil were purchased from Sigma Chemical Co. (St. Louis, MO). Benecol and Take Control

\*To whom correspondence should be addressed at Eastern Regional Research Center, ARS, USDA, 600 E. Mermaid Lane, Wyndmoor, PA 19038. E-mail: rmoreau@arserrc.gov

margarines were purchased from local grocers and were extracted with hexane (150 mg sample per 30 mL hexane), rinsed in a separatory funnel with an equal volume of water, dried under N<sub>2</sub>, and redissolved in hexane (with 0.01% BHT) for HPLC injection. CookSmart, a phytosterol ester-enriched cooking oil, was purchased on-line from Procter & Gamble (Cincinnati, OH) during a limited test-market period. Corn fiber oil (unrefined) was extracted as previously described (3).

**Alumina HPLC method.** All HPLC analyses were performed with a Hewlett-Packard Model 1100 HPLC with autosampler, column heater, and detection by both an HP Model 1100 diode-array UV-vis detector (Agilent Technologies, Collegeville, PA) and a Sedex Model 55 Evaporative Light Scattering Detector (Richard Scientific, Modesto, CA) operated at 30°C and a nitrogen gas pressure of 2 bar. For alumina column separations, the column was an Aluspher Al 100, 5 μm column (125 × 4 mm), packed in a LiChroCART cartridge (Merck KGaA, Darmstadt, Germany). The binary gradient had a constant flow rate of 0.6 mL/min with Solvent A = hexane/THF, 1000:1, and Solvent B = isopropanol. The gradient timetable was as follows: at 0 min, 100% A/0% B; at 10 min, 100% A/0% B; at 20 min, 95% A/5% B; at 21 min, 100% A/0% B; and at 60 min, 100% A/0% B.

**Other HPLC methods.** A LiChrosorb 7 μm Diol column, a LiChrosorb Si 60 column, and a LiChrosorb CN column (all packed in ChromSep 3 × 100 mm cartridge columns by Chrompack, Raritan, NJ) were compared using the same gradient method except that the flow rate was decreased to 0.4 mL/min to compensate for the smaller column diameter.

## RESULTS AND DISCUSSION

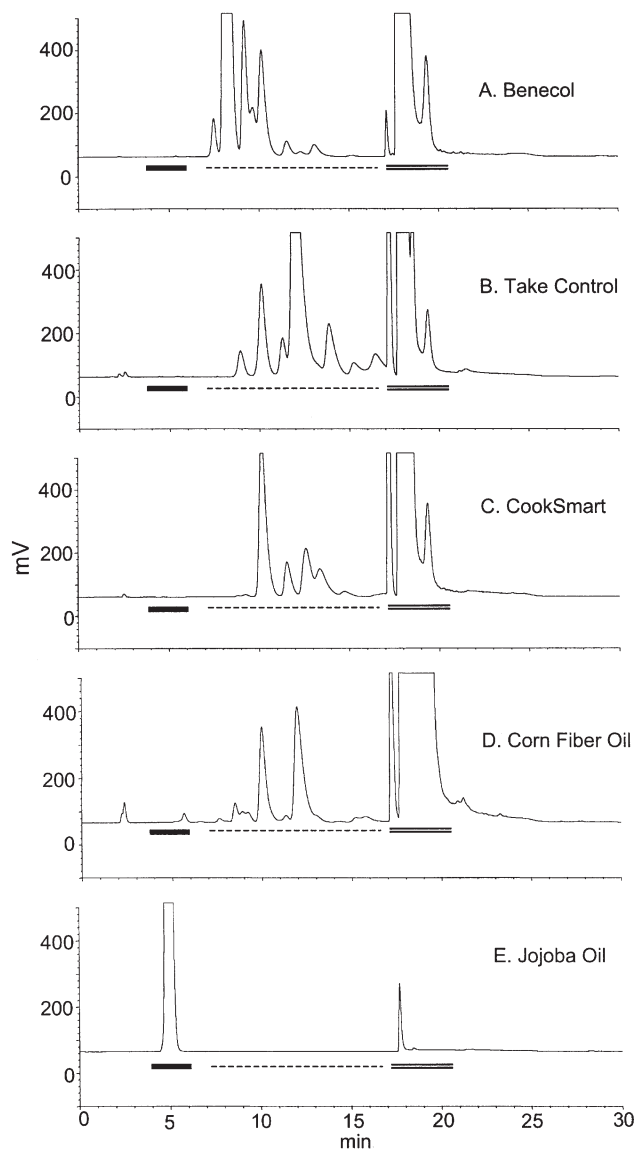

Standards of hydrocarbon (squalene), wax ester (stearyl stearate), and sterol ester (cholesterol stearate) were separated at a column temperature of 25°C (Fig. 1) using an Aluspher column and a gradient method very similar to that reported by Nordbäck and Lundburg (7). A fourth standard, methyl stearate, was also included in this mixture, and it appeared as a shoulder that preceded the peak of sterol ester. Increasing the column temperature to 50°C enhanced the separation of all four components, and further increasing it to 75°C had little effect on the first three peaks but increased the retention time of cholesterol stearate from about 6 to about 9 min.

Samples of four phytosterol ester-rich food products were injected into the HPLC system using this alumina method at

**FIG. 1.** Effect of column temperature on the separation of nonpolar lipid standards, separated on an alumina column (Aluspher Al 100, 5  $\mu$ m, 4  $\times$  125 mm, 0.6 mL/min solvent flow rate) with a binary gradient mobile phase. Abbreviations: a = squalene, b = stearyl stearate, c = methyl stearate, and d = cholesterol stearate, each at 0.5  $\mu$ g per injection.

75°C (Fig. 2), and the major components in each were TAG, eluting as a broad peak at 17 to 20 min. The chromatograms obtained for all four samples also contained multiple peaks in the retention time region of 7 to 16 min, and these peaks appeared to be subfractions of phytosterol esters. Benecol, a spread containing phytosterol (completely saturated phytosterols obtained by hydrogenating phytosterols) esters, had a major peak at 8 min, and TakeControl, another spread containing phytosterol esters, had a major peak at about 12 min. CookSmart (a phytosterol ester containing cooking oil that was test-marketed for a short time by Procter & Gamble) had a major peak at about 10 min. Corn fiber oil (3), which contains both phytosterol and phytosterol esters, had major peaks at 10 and 12 min. The Benecol and TakeControl chromatograms indicate that multiple peaks of phytosterol esters may be separated based on the degree of unsaturation, partially eluting in order of increasing number of carbon-carbon double bonds in the esters.

**FIG. 2.** Separation of nonpolar ester-rich samples with the alumina column method at 75°C. (A) Benecol (65  $\mu$ g lipid injected), (B) Take Control (40  $\mu$ g lipid), (C) CookSmart (69  $\mu$ g lipid), (D) corn fiber oil (165  $\mu$ g lipid), and (E) jojoba oil (7  $\mu$ g lipid). The solid line indicates the retention time range for wax esters, the dashed line indicates the retention time range for sterol esters, and the double solid line indicates the retention time region for TAG elution.

Jojoba oil is an unusual seed oil that contains no TAG, and the storage form of lipid in the oil is entirely wax esters (20- and 22-carbon FA esterified to 20- and 22-carbon fatty alcohols) (8). The chromatogram of jojoba oil contained a major broad peak at 5 min (Fig. 2), similar to that of the wax ester standard in Figure 1.

Various FAME were then injected in the 75°C alumina method (Fig. 3). A mixture of methyl esters of four saturated FA (myristate, palmitate, stearate, and arachidate) eluted as a single peak at about 5 min. A second mixture of 18-carbon methyl esters of stearate, oleate, linoleate, and linolenate

**FIG. 3.** Separation of FAME with the alumina column method at 75°C. (A) injection of saturated FAME. The injected mixture contained methyl myristate, methyl palmitate, methyl stearate, and methyl arachidate, with 0.5 µg of each component per injection. (B) Injection of C-18 saturated and unsaturated FAME. The injected mixture contained methyl myristate (a), methyl oleate (b), methyl linoleate (c), and methyl linolenate (d), with 0.5 µg of each component per injection. Detection *via* ELSD. (C) Same components as B with detection *via* UV at 205 nm.

exhibited peaks for each at 5, 6, 7, and 8 min, respectively, as detected with both the ELSD and the UV at 205 nm. The UV chromatogram verifies the increased signal of these four 18-carbon FAME, with increasing number of carbon-carbon double bonds. As conjectured for phytosterol esters in Figure 2, these FAME data (Fig. 3) similarly appear to demonstrate a separation based on the number of carbon-carbon double bonds (degree of unsaturation) of these esters.

Various cholesteryl fatty acyl esters were then injected to investigate their separation with this same elevated temperature alumina method (Fig. 4). A mixture of cholesteryl esters of stearate, oleate, linoleate, and linolenate exhibited peaks at about 8, 9, 10, and 12 min, respectively, as detected by both the ELSD (Fig. 4A) and UV205 nm detection (Fig. 4B). Cholesteryl palmitate eluted at a retention time nearly identical to cholesteryl stearates; as with the FAME (Fig. 3), the separation of cholesteryl esters correlated with the degree of unsaturation.

Because of the temperature-enhanced separation of nonpolar lipid classes displayed with the alumina column (Fig. 1), we then investigated the hypothesis that a similar temperature-enhanced separation of these same standards could be achieved with three other popular “normal-phase” columns. Increasing the temperature of the silica column caused two

**FIG. 4.** Separation of cholesteryl esters with the alumina column method at 75°C. (A) Injection of standards, 0.5 µg each, of cholesteryl stearate (a), cholesteryl oleate (b), cholesteryl linoleate (c), and cholesteryl linolenate (d) with detection *via* ELSD. (B) Same components as A with detection *via* UV at 205 nm.

effects: (i) It progressively increased the retention time of the FAME, and (ii) it worsened the separation of the wax ester and sterol ester at 50°C and slightly improved their separation at 75°C. Of these three types of esters, wax esters and sterol esters occur naturally in many types of plant and animal material. Elevated temperatures with the silica column did not significantly improve the separation of these natural esters (Fig. 5). FAME are rarely found in natural samples and are most often obtained by chemically methylating FFA. The temperature-enhanced separation of FAME on the silica column warrants further investigation.

Two other popular normal-phase columns, CN and Diol columns, were then evaluated to determine whether elevated temperature could increase the separation of nonpolar esters, as observed with the alumina (Fig. 1–4) and Si (Fig. 5) columns. With the CN or Diol columns, standards of wax ester, sterol ester, and FAME had nearly identical retention times, and increasing the column temperature had very little effect on the retention time of these three ester classes with both columns was about 2 min; data not shown).

Besides Nordbäck and Lundburg (7), the only previous report of the HPLC of lipids *via* an alumina column was a method for the separation of cholesterol oxides with a column consisting of 16% alumina/84% silica (9).

This alumina method at 75°C appears to separate nonpolar esters *via* typical normal-phase separation in order of increasing polarity, and it also appears to separate compounds of nearly identical polarity based on the degree of unsaturation (retention time is longer for each additional carbon-carbon double bond). Although the ability of the alumina method to separate nonpolar lipid esters based on degree of unsaturation appears to have similarities to the type of separation of unsaturated compounds that is achieved by silver ion chromatog-

**FIG. 5.** Effect of column temperature on the separation of nonpolar lipid standards, separated on a silica column (LiChrosorb Si 60-5, 5  $\mu\text{m}$ , 3  $\times$  100 mm, 0.4 mL/min solvent flow rate) with a binary gradient mobile phase. For abbreviations see Figure 1.

raphy (10), separation of free and derivatized FA, based solely on degree of unsaturation, was also previously described using normal-phase silica HPLC (11).

With the current high level of interest in the cholesterol-lowering properties of phytosterol and phytostanol esters (12), this new method provides a technique to compare intact esters in various natural and semisynthetic products.

Although it should be possible to separate molecular species of phytosterol and phytostanol esters *via* reversed-phase HPLC, as has been successfully achieved with TAG (1), we are not aware of any similar reverse-phase methods that have been published to separate phytosterol ester molecular species.
