analyzed samples only the DorCL peak was detected when this 90:10 solvent fraction was analyzed by HPLC.

**ESI/MS.** Parent quasi-molecular ion peaks obtained for the DorCL mass spectrum (Fig. 3A) and for the MamCL sodium

**FIG. 2.** High-performance TLC analysis of the isolated DorCL and phospholipid standards. (A) SAPG = Lane 1, MamCL = 2, DorCL = 3, PE = 4, DGDG = 5, and MGDG = 6 were dissolved in chloroform/methanol solution (2:1, vol/vol) and subjected to solvent system 1 (methyl acetate/isopropanol/chloroform/methanol/3 M KCl, 10:10:10:4:3.6, by vol). (B) The polar solvent system 2 (chloroform/methanol/0.5 M CaCl<sub>2</sub>, 65:40:4, by vol) was used for the TLC analysis of CL (DorCL = Lane 1, MamCL = 2, O<sub>4</sub>CL = 3, M<sub>4</sub>CL = 4, CL mixture = 5) and PG [(SAPG + M<sub>2</sub>PG) = 6] with different acyl chain compositions; the compounds were applied in chloroform/methanol/1 M CaCl<sub>2</sub> (65:25:3, by vol) solution at equivalent concentrations. Developed compounds were visualized by cupric acid treatment and charring. SAPG, 1-stearoyl-2-arachidonoyl-*sn*-glycero-3-phosphoglycerol; O<sub>4</sub>CL, 1',3'-bis[1,2-dioleoyl-*sn*-glycero-3-phospho]-*rac*-glycerol; M<sub>4</sub>CL, 1',3'-bis[1,2-dimyristoyl-*sn*-glycero-3-phospho]-*rac*-glycerol; CL, cardiolipin; M<sub>2</sub>PG, 1,2-dimyristoyl-*sn*-glycero-3-phosphoglycerol. For other abbreviations see Figure 1.

salt form mass spectrum (Fig. 3B) revealed the mass difference between these two CL. For MamCL, the mass-to-charge ( $m/z$ ) 1515.9 corresponds to the Na<sup>+</sup> adduct of the sodium salt form of a CL with four linoleoyl chains (L<sub>4</sub>CL). There is a 192 u difference between a sodiated ion at  $m/z$  1707.9 in the DorCL mass spectrum and the quasi-molecular ion of MamCL at  $m/z$  1515.9. This value corresponds exactly to the mass difference between a CL (DorCL) with four 22:6n-3 acyl chains and a CL (MamCL) with four 18:2n-6 chains. Moreover, the comparison between the two positive ion mass spectra shows that a similar fragmentation occurred. Indeed, there are differences of 144 u between the fragment at 1357.4 of DorCL and the fragment at 1213.5 of MamCL, 96 u between fragments at 995.5, 893.4, and 735.6 of DorCL, and fragments at 899.4, 797.5, and 639.5 of MamCL, or 48 u between the fragment at 373.2 of DorCL and the fragment at 325.2 of MamCL. These differences correspond to the mass differences between three, two, or one chains of 22:6n-3 and 18:2n-6. A comparison of M<sub>4</sub>CL and O<sub>4</sub>CL standard spectra (data not shown) gave the same results.

The collision-induced dissociation study (MS-MS) of the quasi-molecular ion of DorCL produced an equivalent product-ion pattern as the ESI+/MS analysis, except for the fragments at  $m/z$  735.6 and 1967.9. The minor sodiated fragment ion at  $m/z$  1357.8 may correspond to a complex fragmentation that resulted in a loss of one FA chain plus Na<sup>+</sup>. Fragment ions at 995.6 and 893.4 were shown to correspond,

respectively, to the analogs of PG, [(PG-H + PO<sub>3</sub>Na) + Na]<sup>+</sup> and [PG-H + Na]<sup>+</sup>, resulting from a loss of one diacylglycerol fragment (DG) and one PA fragment, respectively. There was also a peak at  $m/z$  645.3, which was believed to be from the fragment ion  $m/z$  995.6 with the loss of one FA chain plus Na<sup>+</sup>. The fragment at  $m/z$  735.6, which was absent from the positive-ion MS-MS, corresponds to a didocosaheptaenoyl-glycerol sodiated ion [DG + Na]<sup>+</sup>. The peak at  $m/z$  1967.9 for DorCL (also absent in the positive-ion MS-MS) shows a 192 u difference, with the corresponding peak at  $m/z$  1775.8 for MamCL. These particular ions were confirmed to be the dimer of a fragment ion [2(PG-H + PO<sub>3</sub>Na) + Na]<sup>+</sup> detected at  $m/z$  995.5 for DorCL and  $m/z$  899.4 for MamCL.

Finally, the exact mass of the quasi-molecular ion of 1707.9270 (Fig. 4), compared to the value of 1707.9259 calculated for a molecular formula C<sub>97</sub>H<sub>140</sub>O<sub>17</sub>P<sub>2</sub>Na<sub>3</sub>, further supports the assignment of this four-22:6n-3 O-acyl cardiolipin structure (Do<sub>4</sub>CL). The presence of a minor peak corresponding to the quasi-molecular ion of Do<sub>3</sub>PCL (tridocosaheptaenoyl-palmitoyl CL) was also noticed at  $m/z$  1636.9.

**NMR spectrometry.** Characteristic resonances of the sugar proton region of MGDG (3.5–4 ppm) or of the <sup>+</sup>NCH<sub>2</sub> multiplet (3.65 ppm) of a choline derivative were not apparent in the <sup>1</sup>H resonance spectrum (Fig. 5). This excluded the presence of carbohydrate moieties or of nitrogen in the DorCL fraction. The presence of unsaturated acyl chains was character-

**FIG. 3.** Positive ion electrospray ionization (ESI) mass spectra. (A) DorCL. (B) MamCL. ized by the  $^1\text{H}$  and  $^{13}\text{C}$  resonances of olefinic  $-\text{CH}=\text{CH}-$ , bis-allylic and allylic methylene protons (Table 2) and validated by the  $^1\text{H}$  DQF-COSY and HMQC measurements (data not shown). Protons from terminal methyl groups show one triplet at 0.95 ppm (from unsaturated n-3 acyl chains) and one of weaker intensity at 0.88 ppm (mainly from 16:0 acyl chains). The integral ratio of these two triplets indicates a proportion of 82 mol% of n-3 PUFA. The integral ratio of triplet at 0.95 ppm and multiplet at 2.36 ppm ( $-\text{C}_\alpha\text{H}_2$  and  $-\text{C}_\beta\text{H}_2$ ) (where  $\alpha$  and  $\beta$  positions are relative to the carbonyl group) confirms that most of unsaturated n-3 acyl chains are constituted by 22:6n-3.

In considering the phospholipid backbone, the high-field single proton of C-2 outer glycerols resonated typically at 5.21 ppm ( $^1\text{H}$ ) and 71.56 ppm ( $^{13}\text{C}$ ). The other glycerol protons of the two quasi-equivalent outer glycerols and of the

**FIG. 4.** High-resolution ESI+MS measurement of  $(\text{M} + \text{Na})^+$ . (A) Experimental isotopic distribution. (B) Theoretical isotopic distribution.

central glycerol could be assigned from a comprehensive set of NMR data in the area 3.5–4.5 ppm (for details see the Materials and Methods section) (Fig. 5, Table 2). The eight-line multiplet at 4.38 and 4.16 ppm ( $^1\text{H}$ ), corresponding to an AB part of an ABX type system, was assigned to the magnetically inequivalent methylene protons ( $\text{C}-1-\text{H}_1$ ,  $\text{C}-1-\text{H}'_1$ ) of outer glycerols C-1. When the integral ratio of the proton signals of outer glycerols C-2 + C-1 to the remaining resonances at 3.98 and around 3.9 ppm ( $^1\text{H}$ ) (outer glycerols C-3 plus central glycerol protons) was calculated, it indicated a ratio of 0.62 ( $\approx 6:9$ ) corresponding to a CL. This is in good agreement with the ratio of 0.646 ( $\approx 6:9$ ) calculated for the MamCL standard. The corresponding integral ratios for PG and PA were 0.411 ( $\approx 3:7$ ) and 1.5 (3:2), respectively. The HMQC spectrum of DorCL (Fig. 6) allows the specific assignments of the nine protons from the two equivalent outer glycerols C-3 and from the C'-1, C'-2 and C'-3 of central glycerol. The methylene

**FIG. 5.**  $^1\text{H}$  resonance spectrum of DorCL. Detailed NMR data are depicted in Table 2. For abbreviation see Figure 1.

	$-\text{CH}_3$ (sat) <sup>g</sup>	0.86	<i>t</i>	14.50	
	$-\text{CH}_2-$ (sat) <sup>h</sup>	1.25	<i>m</i>	30.53	

<sup>a</sup>Carbons of the cardiolipin backbone are designated as: C-1 (*sn*-1 O-acyl chain), C-2 (*sn*-2 O-acyl chain), or C-3 (-phosphate group) for the two outer glycerols and C'-1 (-phosphate group), C'-2 (-OH), or C'-3 (-phosphate group) for central glycerol.

<sup>b</sup>The protons of the methylene group show couplings to  $^{31}\text{P}$  (which shows a single resonance at +0.15 ppm relative to external  $\text{H}_3\text{PO}_4$ ).

<sup>c</sup>Allylic protons.

<sup>d</sup>Bis-allylic protons.

<sup>e</sup>Relatively to carbonyl group.

<sup>f</sup>From unsaturated (n-3) acyl chains.

<sup>g</sup>From saturated or unsaturated >(n-3) acyl chains.

<sup>h</sup>Non-desielding methylene protons. Hydrogen/carbon assignment was validated by  $^1\text{H}$  DQF-COSY double-quantum filter correlated spectroscopy and heteronuclear multiple quantum coherence.

**FIG. 6.** Heteronuclear multiple quantum coherence of the glycerol backbone region of DorCL. C' = central glycerol; C = phosphatidylglycerols. Assignments between H1 and H'1 may have to be reversed. <sup>a</sup>Proportion of hydrogen atoms in each signal, based on signal integration, are calculated relatively to  $\text{CH}_3$  peak integral [ $\text{CH}_3$ (n-3) for DorCL = 12]. For abbreviation see Figure 1.

protons from both C-3 outer glycerols at 64.42 ppm ( $^{13}\text{C}$ ) appear as a multiplet at 3.98 ppm ( $^1\text{H}$ ) ( $^1\text{H}$  DQF-COSY not represented). Part of the 3.98 ppm ( $^1\text{H}$ ) resonances and the most shielded resonances around 3.90 ppm have been assigned to the central glycerol protons. All these resonances are nearly synchronous and show a complex multiplet from spin-spin interactions between phosphorus  $^{31}\text{P}$  vicinal and geminal protons. However, two carbon resonances are clearly resolved at 66.55 and 70.5 ppm ( $^{13}\text{C}$ ). The signal at 66.55 ppm ( $^{13}\text{C}$ ) has been assigned to both phosphorylated C'-1 and C'-3 methylene groups. The other has been attributed to the C'-2 proton. Consequently, in DorCL (Fig. 6), the integral ratio of the multiplet (resonances at 3.98 ppm) to the nearby resonances (around 3.90 ppm) gave a ratio of  $\approx 6:3$ .

## DISCUSSION

Through isolation and chemical and structural analyses using a combination of HPLC, HPTLC, LC, GC, ESI+/MS, ESI+/MS-MS, and NMR, the present study provides evidence of the existence of a DHA-rich (22:6n-3 > 80 mol%) CL, in the three bivalve species *C. gigas*, *M. edulis*, and *P. maximus*. Although DorCL accounted for no more than 1 mol% of the total phospholipids in these three bivalve species, it contains up to 13.6 mol% of total DHA content of the polar lipids.

As shown from the results of the present study and from previous investigations (1–4), employing HPLC (Fig. 1B) or HPTLC (Fig. 2A,B) alone was unable to link the DorCL to any phospholipid class because chromatographic behaviors

of the former differed from the common CL. Chromatographic properties of acidic phospholipids on adsorption chromatography are, to some extent, dependent on the cations with which they are associated (5,6). In taking this into account, the results from HPTLC analysis of phospholipid extracts and standards after converting into a single salt form confirmed that the higher mobility of DorCL shown in HPTLC is more likely due to the presence of fatty acyl chains with higher degrees of unsaturation (i.e., 4 DHA) rather than the effects of associated cations.

Information on the analysis of CL by ESI is limited, and the reported analyses were conducted solely in the negative ion mode (16,17). The present study provides information about the fragmentation processes of CL generated in the positive ion mode. Furthermore, the use of MS-MS allowed the structural interpretation of most ions obtained by ESI+/MS and confirmed that they were the results of Na<sup>+</sup> adduct fragment ions from a Do<sub>4</sub>CL. Surprisingly, MS-MS did not detect the main [DG + Na]<sup>+</sup> fragment ion, despite its presence in all of the ESI+/MS CL spectra. This ion was thought to be generated by a protonation process in the ionization chamber when using CHCl<sub>3</sub> as solvent. It was also noted that fragment ions were able to form dimers in ESI+. Although dimers of parent quasi-molecular ions have been noted previously (8), formation of dimers from fragment ions was first described in ESI+. Also, there are only a few studies analyzing CL using NMR (7,18). Results from the present study provide additional interpretations in the most interesting region, 3.9–4.5 ppm (<sup>1</sup>H) corresponding to proton resonances from the glycerol backbone.

In bacteria and fungi, CL contain mostly saturated and monoenoic FA with 14–18 carbon chain lengths (19,20). CL from mammalian species, which have been studied extensively (see Ref. 20 for review), are essentially restricted to 18-carbon chain length and dominated by 18:2n-6 (linoleic acid; >80 mol%). In marine animals, minor phospholipid classes such as CL have not received as much attention as other phospholipid classes (21); thus, there is little available information in this area. A CL with a relatively high content of 22:6n-3 (53.8 mol% of 22:6n-3) in the eastern oyster, *C. virginica*, had been previously reported (22). However, the results reported differed from a later study conducted on the same species and other bivalve species, the hard clam, *Mercentaria mercenaria* (total n-3 PUFA < 43% in CL of both species) (23). High amounts of both n-3 and n-6 PUFA in CL were reported in marine animals although no specific PUFA was found to be predominant in CL (10,24,25). In the three bivalve species analyzed, the DorCL mass spectrum, showed that the molecular form with four docosahexaenoyl chains (Do<sub>4</sub>CL) was the main peak. There was only a minor quantity of the Do<sub>3</sub>PCL form. With respect to the few molecular species compositions of CL from other organisms analyzed, (7,19,26), the presence of a molecular form with four identical acyl chains has regularly been reported.

Bivalves have low, limited, or no ability for synthesis of C<sub>20</sub>–C<sub>22</sub> PUFA with more than three double bonds. They must

acquire these *via* diet (27,28). In fact, molluscan phytoplanktonic diets are rich in C<sub>20</sub>–C<sub>22</sub> PUFA, including 22:6n-3, particularly 20:5n-3 (EPA) (29). Interestingly, in *P. maximus*, a relatively constant 22:6n-3 content in the DorCL fraction was found in both female and male gonads despite the possibility of drastic changes in the 22:6n-3 contents of their diets (2,3). In mammals, 18:2n-6 was replaceable by up to 30 mol% 22:6n-3 when rats were fed with DHA-enriched diets (30,31). Moreover, rats fed on a diet containing sardine oil, with EPA >> DHA, preferentially incorporated DHA rather than EPA in CL (32). Thus, for mammals, when DHA is bioavailable its incorporation into CL is favored among PUFA. Consequently, a common and beneficial effect likely could explain this 22:6n-3 selectivity.

CL is exclusively found in the inner mitochondrial membrane (33). It is required for maintenance of the mitochondrial structural integrity and for proper respiratory functioning (electron transport chain) and ATP-synthesizing enzyme complexes (20,33,34). Although most isolated membrane lipids are known to form bilayer aggregates, CL have been shown to promote phase transition from bilayer (lamellar, L<sub>α</sub>) to nonbilayer aggregate structures (inverted hexagonal phase, H<sub>II</sub>) (35). The unique pattern with four 22:6n-3 acyl chains, increasing the volume of the hydrophobic moiety of CL, may make it more prone to form nonbilayer H<sub>II</sub> phases (36). In addition it was shown that increase of 22:6n-3 residue in CL reduced cytochrome *c* oxidase activity (31) and increased the activity of the oligomycin-sensitive ATPase complex (32). Thus, it is speculated that this DorCL may reflect a specific adaptation in bivalves by enhancing the functionality of mechanisms of membrane phase transformation or/and allowing an optimal activity of the oxidative phosphorylation in response to fluctuation in environmental conditions (temperature, salinity, emersion).

In summary, results from the present study provide the first evidence of the existence of a specific CL with the main molecular form constituted with four 22:6n-3 acyl chains in *P. maximus*, *M. edulis*, and *C. gigas*. The dominance of 22:6n-3 acyl chains in CL from these three bivalve species renders the general opinion that “eukaryotic cardiolipins are mostly restricted to C<sub>18</sub> acyl chains” debatable. Future studies should look into whether this DHA-dominant CL is also present in other bivalve species.

## ACKNOWLEDGMENTS

The authors would like to thank Dr. Fu-Lin Chu, Virginia Institute of Marine Science (Gloucester Point, VA), for the critical review of the first draft of the manuscript. We thank Dr. Pierre Guenot for expert MS assistance and Dr. Roger Pichon for help in NMR interpretation. This work was supported by a grant from Ministère de l'Éducation Nationale de la Recherche et de la Technologie (M.E.N.R.T., France).

**ABSTRACT:** A sensitive HPLC procedure with postcolumn reduction and electrochemical detection was developed for the analysis of vitamin E and its oxidation products,  $\alpha$ -tocopherylquinone, epoxy- $\alpha$ -tocopherylquinones, and 8a-(lipid-dioxy)- $\alpha$ -tocopherones. After the separation on a reversed-phase column, on-line zinc-catalyzed reduction allowed the detection of  $\alpha$ -tocopherylquinone and epoxy- $\alpha$ -tocopherylquinones, whereas platinum-catalyzed reduction allowed the detection of 8a-(lipid-dioxy)- $\alpha$ -tocopherones. The lowest detectable level of each compound was about 0.2 pmol at the signal-to-noise ratio of 3. This method was applied to the detection of  $\alpha$ -tocopherol products in peroxidized human plasma. When the plasma was peroxidized by the addition of a free radical initiator, peaks corresponding to  $\alpha$ -tocopherylquinone, epoxy- $\alpha$ -tocopherylquinones, and the addition products of  $\alpha$ -tocopherol with peroxy radicals derived from cholesteryl ester hydroperoxides and PC hydroperoxides were observed. The amount of these oxidation products in the plasma increased with the depletion of endogenous  $\alpha$ -tocopherol. The results indicate that the method is useful to detect the oxidation products formed by the peroxy radical-trapping reactions of  $\alpha$ -tocopherol in biological systems. Paper no. L8957 in *Lipids* 37, 515–522 (May 2002).

Lipid peroxidation in biological tissues and fluids is implicated in a variety of damaging pathological events (1,2).  $\alpha$ -Tocopherol ( $\alpha$ -TH), the most active form of vitamin E in biological systems, inhibits peroxidation of unsaturated lipids by trapping peroxy radicals (3).  $\alpha$ -TH efficiently transfers a hydrogen atom to a peroxy radical, giving a hydroperoxide

and an  $\alpha$ -tocopheroxyl radical. The  $\alpha$ -tocopheroxyl radical then reacts with a second peroxy radical to form a nonradical product. The peroxy radical-trapping reaction of  $\alpha$ -TH yields 8a-substituted tocopherones and isomeric epoxytocopherones as the primary oxidation products (4,5). Therefore, the formation of these products is consistent with the behavior of  $\alpha$ -TH as a chain-breaking antioxidant in biological systems. In most biological samples, the amount of  $\alpha$ -TH is very small compared with the lipid contents. Therefore, we need a highly sensitive and specific methodology to analyze the oxidation products of  $\alpha$ -TH in biological samples. We previously reported the chemiluminescence-based HPLC method for the analysis of the addition products of  $\alpha$ -TH with peroxy radicals of PC, 8a-(phosphatidylcholine-dioxy)- $\alpha$ -tocopherones (TOO-PC) (6). This HPLC technique was found advantageous for the sensitive and specific determination of TOO-PC in biological samples. However, other  $\alpha$ -TH products such as  $\alpha$ -tocopherylquinone ( $\alpha$ -TQ) could not be detected by this chemiluminescence-based assay.

Electrochemical detection provides the most sensitive measurement of compounds that undergo redox reactions. On-line reduction by a postcolumn reactor (7–9) or by a coulometric method (10–12) has been reported for the parallel electrochemical detection of TH,  $\alpha$ -TH oxidation products, ubiquinols, and ubiquinones, in which the quinone ring was reduced to give the corresponding hydroquinone. In the present study, we developed a sensitive method for the assay of  $\alpha$ -TH and its oxidation products (see Fig. 1) in biological samples using an HPLC separation, postcolumn zinc or platinum reduction, and electrochemical detection. We applied this method for the detection of  $\alpha$ -TH products in peroxidized human blood plasma. The main lipids in human plasma are cholesteryl esters (ChE) and phospholipids (13). Particularly, cholesteryl linoleate (ChL) is the major oxidizable lipid substrate in LDL and other lipoproteins. Therefore, we expected the formation of the addition products of  $\alpha$ -TH with peroxy radicals of ChL during the peroxidation of human plasma.

## MATERIALS AND METHODS

**Chemicals.** *RRR*- $\alpha$ -TH was purchased from Sigma Chemical Co. (St. Louis, MO) and purified by reversed-phase HPLC (14). *RRR*- $\gamma$ - and *RRR*- $\delta$ -TH were prepared from mixed isomers of

**FIG. 1.** Structures of tocopherols (TH),  $\alpha$ -tocopherylquinone ( $\alpha$ -TQ), and epoxy- $\alpha$ -tocopherylquinones (epoxy- $\alpha$ -TQ), and typical structures of 8a-(lipid-dioxy)- $\alpha$ -tocopherones, cholesteryl (9*Z*,11*E*)-13-(8a-dioxy- $\alpha$ -tocopherone)-(9,11)-octadecadienoate (13-TOO-ChL), cholesteryl (*E*)-9-(8a-dioxy- $\alpha$ -tocopherone)-12,13-epoxy-10-octadecenoate (9-TOO-epoxyChL), 1-palmitoyl-2-[(9*Z*,11*E*)-13-(8a-dioxy- $\alpha$ -tocopherone)-(9,11)-octadecadienoyl]-3-*sn*-phosphatidylcholine (13-TOO-PLPC), and 1-palmitoyl-2-[(*E*)-9-(8a-dioxy- $\alpha$ -tocopherone)-12,13-epoxy-10-octadecenoyl]-3-*sn*-phosphatidylcholine (9-TOO-epoxyPLPC).

TH (Hohnen Oil Co., Tokyo, Japan) (15). Authentic  $\alpha$ -TQ, 2,3-epoxy- $\alpha$ -TQ, and 5,6-epoxy- $\alpha$ -TQ were prepared as described previously (16). Cholesteryl linoleate hydroperoxides (ChL-OOH) were prepared by autoxidation of ChL in the presence of  $\alpha$ -TH (17). Cholesteryl (8a-dioxy- $\alpha$ -tocopherone)-octadecadienoates (TOO-ChL) and cholesteryl (8a-dioxy- $\alpha$ -tocopherone)-epoxyoctadecenoates (TOO-epoxyChL) were prepared by the iron-catalyzed reaction of  $\alpha$ -TH with ChL-OOH (18). 1-Palmitoyl-2-[(9*Z*,11*E*)-(*S*)-13-hydroperoxy-9,11-octadecadienoyl]-3-*sn*-phosphatidylcholine (13-PLPC-OOH) was prepared by the oxidation of 1-palmitoyl-2-linoleoyl-3-*sn*-PC (PLPC) with soybean lipoxygenase-1 (Sigma Chemical Co.) in the presence of deoxycholate (19).

1-Palmitoyl-2-[(8a-dioxy- $\alpha$ -tocopherone)-octadecadienoyl]-3-*sn*-phosphatidylcholines (TOO-PLPC) were prepared by reacting  $\alpha$ -TH with PLPC (20). 1-Palmitoyl-2-[(8a-dioxy- $\alpha$ -tocopherone)-12,13-epoxy-octadecenoyl]-3-*sn*-phosphatidylcholines (TOO-epoxyPLPC) were prepared by the iron-catalyzed reaction of  $\alpha$ -TH with 13-PLPC-OOH in methanol (21). The structures of these  $\alpha$ -TH products were characterized using MS and NMR spectrometry (16–21). 2,2'-Azobis(2-amidinopropane) dihydrochloride (AAPH) was obtained from Wako Pure Chemical Co. (Osaka, Japan). All solvents used were of HPLC grade.

**HPLC system.** The HPLC system used in the present study was essentially the same as that reported by Yamashita and

Yamamoto (8) and Leray *et al.* (9). HPLC was carried out with a Waters Model 600E system connected to a Waters Model 486 UV/Vis detector and an ED623 electrochemical detector. For the simultaneous analysis of TH and  $\alpha$ -TQ, the mobile phase of methanol/water (95:5, vol/vol) containing 10 mM lithium acetate and 5 mM trifluoroacetate was passed through a J'sphere ODS-H80 column (150  $\times$  4.6 mm i.d., carbon content of 22%; YMC Co., Kyoto, Japan) at a flow rate of 1.0 mL/min. The mobile phase was maintained oxygen-free by continuous bubbling with helium gas. The column eluate was monitored at 280 nm and subsequently passed to a solid-phase postcolumn reactor (10  $\times$  4.0 mm i.d.), which was made by dry-packing of zinc particles (particle size of <75  $\mu$ m; Wako Pure Chemical Co.) under vibration (9). Then TH and the reduced  $\alpha$ -TQ were detected by an amperometric electrochemical detector (ECD) with a glassy carbon working electrode and an Ag/AgCl reference electrode. The applied oxidation potential was set at +700 mV (9). For the analysis of 8a-(lipid-dioxy)- $\alpha$ -tocopherones, a mobile phase of methanol/water (98.5:1.5, vol/vol) containing 10 mM lithium acetate [for the analysis of 8a-(cholesterylester-dioxy)- $\alpha$ -tocopherones (TOO-ChE)] or methanol/water (97.5:2.5, vol/vol) containing 20 mM choline chloride (for the analysis of TOO-PC) was passed through a J'sphere ODS-L80 column (150  $\times$  4.6 mm i.d., carbon content of 9%) at a flow rate of 1.0 mL/min. The column eluate was monitored at 240 nm and subsequently passed to a solid-phase postcolumn reactor (50  $\times$  4.0 mm i.d.), which was made by dry-packing of platinum catalyst (5% platinum on alumina, -325 mesh; Aldrich Chemical Co., Milwaukee, WI) (7). The reduced tocopherones were detected by an amperometric ECD at the oxidation potential of +700 mV. Chromatographic data were recorded by a MacLab data acquisition system with a Peaks application program (AD Instruments Pty. Ltd., Castle Hill, Australia).

**Peroxidation of human plasma.** The fresh, heparinized blood from a healthy 24-old male was centrifuged at 1000  $\times$  g for 10 min to separate plasma. The plasma (4.0 mL) was kept for 5 min at 37°C in a shaking water bath under air, and then 1.0 mL of 100 mM AAPH in 10 mM sodium phosphate buffer (pH 7.4, containing 125 mM NaCl) was added to start lipid peroxidation (the final concentration of AAPH was 20 mM).

**Quantification.** At specific intervals, a 0.5-mL aliquot of the reaction mixture was taken for lipid extraction. Total lipids were extracted by the method of Bligh and Dyer (22). The extraction solvents (methanol and chloroform) contained 0.03% BHT. The lipid extracts were evaporated to dryness under a stream of nitrogen gas, dissolved in 0.5 mL of chloroform, and applied on a Supelclean LC-NH2 (Supelco, Bellefonte, PA) minicolumn made from Pasteur pipettes (filling height of 4 cm). The column was eluted with chloroform (4 mL) and then with methanol (4 mL). The chloroform and methanol fractions were pooled, respectively, and each solvent was evaporated under nitrogen gas. The chloroform fraction was dissolved in 100  $\mu$ L of 2-propanol and analyzed for TH,  $\alpha$ -TQ, ChE-OOH, and TOO-ChE; the methanol fraction was dissolved in 100  $\mu$ L of ethanol and analyzed for PC-OOH

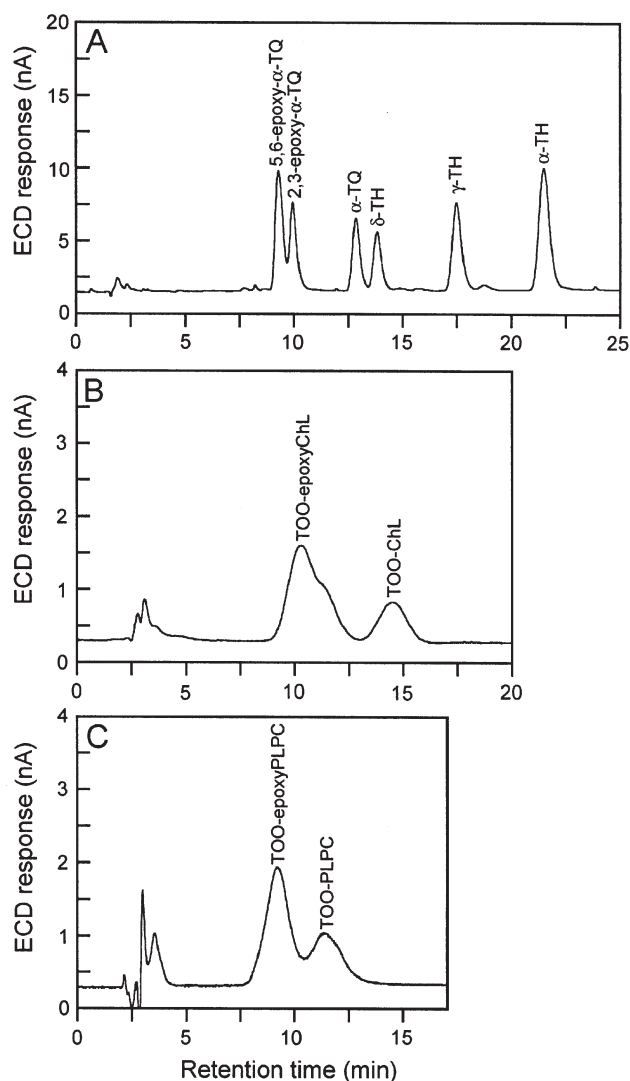

and TOO-PC, respectively. TH,  $\alpha$ -TQ, TOO-ChE, and TOO-PC were quantified by the established HPLC method described in the present study. To determine the percentage recovery of compounds, authentic compounds were spiked into the diluted plasma sample (0.5 mL) and then extracted with chloroform/methanol followed by the solid-phase extraction as described above. ChE-OOH and PC-OOH were quantified by chemiluminescent-based HPLC (6). The concentration of each hydroperoxide was calculated from the standard curve of authentic ChL-OOH or 13-PLPC-OOH. For isolation of the product peak, the sample solution was injected into a J'sphere ODS-M80 column (150  $\times$  4.6 mm i.d., carbon content of 14%) with a solvent system of methanol (for the isolation of TH and  $\alpha$ -TQ), methanol/2-propanol/hexane (50:35:15, by vol; for the isolation of TOO-ChE), or methanol/ethanol (2:3, vol/vol; for the isolation of TOO-PC) at 1.0 mL/min and detected at 240 or 285 nm.

**HPLC coupled with on-line MS (LC-MS).** LC-MS was carried out using a Shimadzu LCMS-QP8000 $\alpha$  quadrupole instrument equipped with an atmospheric pressure chemical ionization (APCI) source. Sample lipids were separated isocratically on a Luna 3- $\mu$ m C18(2) column (150  $\times$  2.0 mm i.d.; Phenomenex, Torrance, CA) with methanol/water (98:2, vol/vol) for TH and  $\alpha$ -TQ, methanol/2-propanol/hexane (50:35:15, by vol) for TOO-ChE, or methanol/ethanol (2:3, vol/vol) for TOO-PC at 0.2 mL/min. The separation sample was introduced into the APCI source. The APCI probe was maintained at 4.5 kV with a temperature of 400°C. Nebulizing gas (nitrogen) was delivered at a flow rate of 2.5 L/min. The curved desolvation line voltage was at -40 V with a temperature of 250°C. The deflector voltage was maintained at +40 V for the analysis of TH and  $\alpha$ -TQ or at +80 V for the analysis of TOO-ChE and TOO-PC. Ionization was performed in the positive mode, and mass spectra were acquired between  $m/z$  100 and 500 at a scan rate of 2 s per spectrum (for TH and  $\alpha$ -TQ) or between  $m/z$  300 and 1300 at a scan rate of 4 s (for TOO-ChE or TOO-PC).

## RESULTS AND DISCUSSION

HPLC techniques have been widely accepted and applied for the analysis of TH and  $\alpha$ -TQ in biological samples (9,10,12,23,24). The combination of UV or fluorescent detection with HPLC separation lacks sufficient sensitivity for biological samples (23,24). On the other hand, electrochemical detection provides the most sensitive measurement of TH and  $\alpha$ -TQ (9,10,12,24). Therefore, we examined the HPLC system with a postcolumn reactor and electrochemical detection to measure the oxidation products of  $\alpha$ -TH. The system consisted of a pump, an injector, a separation column, a solid-phase postcolumn reactor containing zinc or platinum catalyst, and an ECD. Figure 2A shows a typical chromatogram of the standard TH,  $\alpha$ -TQ, and  $\alpha$ -TQ using postcolumn zinc reduction and electrochemical detection. A standard mixture of  $\alpha$ -,  $\gamma$ -, and  $\delta$ -TH,  $\alpha$ -TQ, and epoxy- $\alpha$ -TQ was well separated, and very intense peaks appeared on the chromatogram. On

**FIG. 2.** HPLC of TH and  $\alpha$ -TH products using postcolumn reduction and electrochemical detection. (A) A standard mixture of  $\alpha$ -TH (100 pmol),  $\gamma$ -TH (100 pmol),  $\delta$ -TH (100 pmol),  $\alpha$ -TQ (93 pmol), 2,3-epoxy- $\alpha$ -TQ (68 pmol), and 5,6-epoxy- $\alpha$ -TQ (71 pmol) was injected into a J'sphere ODS-80H column developed with 95% methanol containing 10 mM lithium acetate and 5 mM trifluoroacetate followed by postcolumn zinc reduction. (B) A standard mixture of TOO-ChL (25 pmol) and TOO-epoxyChL (74 pmol) was injected into a J'sphere ODS-80L column developed with 98.5% methanol containing 10 mM lithium acetate followed by postcolumn platinum reduction. (C) A standard mixture of TOO-PLPC (21 pmol) and TOO-epoxyPLPC (36 pmol) was injected into a J'sphere ODS-80L column developed with 97.5% methanol containing 20 mM choline chloride followed by postcolumn platinum reduction. Each eluate was monitored by an electrochemical detector (ECD) at +700 mV. See Figure 1 for abbreviations.

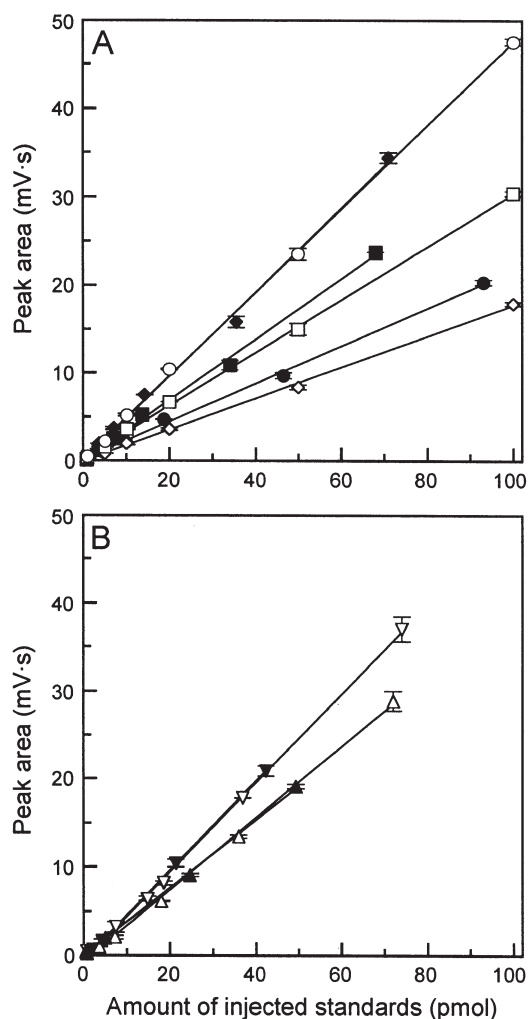

the other hand, peaks of only weak intensity were observed by the UV detection (data not shown). The zinc catalyst was useful for reducing both  $\alpha$ -TQ and epoxy- $\alpha$ -TQ to  $\alpha$ -tocopherylhydroquinone under the acidic solvent condition, and the resulting hydroquinone could be detected at an applied oxidation potential of +700 mV (9). The zinc catalyst was more effective in reducing  $\alpha$ -TQ at a column length of 10 mm,

compared with 50 mm. The longer reducing column resulted in peak broadening.

The 8 $\alpha$ -substituted  $\alpha$ -tocopherone products hydrolyze to  $\alpha$ -TQ immediately in the presence of acid (16,25). Therefore, it is impossible to analyze these products with the above HPLC condition using postcolumn zinc reduction. Alternatively, a postcolumn reactor containing platinum catalyst can reduce quinone compounds to the corresponding hydroquinones in the absence of acid (7,8). Using the platinum column reactor, we analyzed two types of 8 $\alpha$ -(lipid-dioxy)- $\alpha$ -tocopherone compounds: TOO-ChL and TOO-epoxyChL from the reaction between  $\alpha$ -TH and ChL-derived peroxy radicals, and TOO-PLPC and TOO-epoxyPLPC from the reaction between  $\alpha$ -TH and PLPC-derived peroxy radicals. Typical chromatograms of authentic compounds are shown in Figures 2B and 2C. On each chromatogram, very intense peaks corresponding to the 8 $\alpha$ -(lipid-dioxy)- $\alpha$ -tocopherone compounds were observed. The platinum catalyst was most effective in reducing 8 $\alpha$ -(lipid-dioxy)- $\alpha$ -tocopherones at a column length of 50 mm. If the shorter column was used, the reduction ability of the platinum catalyst went down with successive injections of sample solutions. On the contrary, the platinum catalyst did not reduce epoxy- $\alpha$ -TQ under the present conditions (data not shown).

Figure 3 shows the standard curves for the determination of TH,  $\alpha$ -TQ, epoxy- $\alpha$ -TQ, TOO-ChL, TOO-epoxyChL, TOO-PLPC, and TOO-epoxyPLPC. Each standard curve showed a good correlation between the peak area measured by electrochemical detection and the amount of each compound, with the regression equations of  $y = 0.469x + 0.626$  ( $r = 0.999$ ) for  $\alpha$ -TH,  $y = 0.297x + 0.251$  ( $r = 0.998$ ) for  $\gamma$ -TH,  $y = 0.175x + 0.152$  ( $r = 0.995$ ) for  $\delta$ -TH,  $y = 0.214x + 0.250$  ( $r = 0.999$ ) for  $\alpha$ -TQ,  $y = 0.343x + 0.117$  ( $r = 0.998$ ) for 2,3-epoxy- $\alpha$ -TQ,  $y = 0.474x + 0.203$  ( $r = 0.999$ ) for 5,6-epoxy- $\alpha$ -TQ,  $y = 0.381x + 0.075$  ( $r = 0.999$ ) for TOO-ChL,  $y = 0.407x - 0.743$  ( $r = 0.999$ ) for TOO-epoxyChL,  $y = 0.504x - 0.435$  ( $r = 0.999$ ) for TOO-PLPC, and  $y = 0.503x - 0.499$  ( $r = 0.999$ ) for TOO-epoxyPLPC. The lowest detectable level of each compound as a signal-to-noise ratio was estimated to be about 0.2 pmol, respectively. We have previously reported that the detection limit for TOO-PC by the chemiluminescence-based HPLC method is about 1 pmol (6). Thus, the present method using electrochemical detection is very highly sensitive for the detection of  $\alpha$ -TH products.

We applied the above HPLC system for the analysis of the oxidative fate of endogenous  $\alpha$ -TH in human blood plasma. Before the HPLC analysis, the plasma lipids extracted with chloroform/methanol were treated with a solid-phase extraction on silica-NH<sub>2</sub>. TH,  $\alpha$ -TQ, and TOO-ChE were eluted in the chloroform fraction, and then TOO-PC were eluted in the methanol fraction. In using this sample treatment, the recoveries of TH and  $\alpha$ -TH products were checked by the addition of known amounts of the standards into the diluted human plasma (Table 1). TH and  $\alpha$ -TQ were recovered almost satisfactorily, but the recoveries of the 8 $\alpha$ -substituted tocopherone

**FIG. 4.** HPLC of TH and  $\alpha$ -TH products from the peroxidized human plasma using postcolumn reduction and electrochemical detection. The human plasma (4.0 mL) was incubated at 37°C for 0 and 6 h by the addition of 1.0 mL of 100 mM 2,2'-azobis(2-amidinopropane) dihydrochloride (AAPH; final concentration, 20 mM). The reaction mixture was extracted with chloroform/methanol, and the total lipid fraction was passed through a silica-NH<sub>2</sub> column using chloroform and methanol. The chloroform and methanol fractions were injected into HPLC and detected by an ECD at +700 mV after postcolumn zinc or platinum reduction. The HPLC conditions are the same as described in Figure 2. (A) The chloroform fraction was injected into HPLC followed by postcolumn zinc reduction. (B) The chloroform fraction was injected into HPLC followed by postcolumn platinum reduction. The arrow indicates the elution position of authentic TOO-epoxyChL. (C) The methanol fraction was injected into HPLC followed by postcolumn platinum reduction. The arrow indicates the elution position of authentic TOO-epoxyPLPC. See Figures 1 and 2 for abbreviations.

products were somewhat poorer due to their instability during the sample preparation process.

The human plasma was reacted with peroxy radicals that had been generated in the aqueous phase by the thermal decomposition of AAPH. The starting plasma sample contained

**FIG. 5.** HPLC coupled with on-line MS analysis of 8a-(cholesteryl ester-dioxy)- $\alpha$ -tocopherones (TOO-epoxyChE) fraction from the peroxidized human plasma. The peak corresponding to TOO-epoxyChE, as shown in Figure 4B, was collected and injected into a Luna C18 column ( $2 \times 150$  mm i.d.; Phenomenex, Torrance, CA) developed with methanol/2-propanol/hexane (50:35:15, by vol) at 0.2 mL/min. UV detection at 240 nm, the total ion chromatogram (TIC) of atmospheric pressure chemical ionization-MS, and mass spectrum of the peak indicated by arrows are shown. See Figure 2 for abbreviations.

endogenous  $\alpha$ -TH ( $22.3 \pm 2.1$   $\mu$ M) and  $\gamma$ -TH ( $4.1 \pm 0.6$   $\mu$ M). Figure 4A shows the HPLC chromatogram of the TH and  $\alpha$ -TQ compounds during the AAPH-initiated peroxidation of human plasma. A peak corresponding to  $\alpha$ -TH decreased after the 6-h reaction, and peaks corresponding to  $\alpha$ -TQ and epoxy- $\alpha$ -TQ appeared as the oxidation products of  $\alpha$ -TH. The identity of each peak was confirmed by co-elution against the authentic standards and by LC-MS analysis: two isomeric epoxy- $\alpha$ -TQ, APCI-MS  $m/z$  463 ( $[M + H]^+$ , 6%) and 445 ( $[M - OH]^+$ , 100%);  $\alpha$ -TQ, APCI-MS  $m/z$  445 ( $[M + H]^+$ , 1%) and 429 ( $[M - OH]^+$ , 100%);  $\gamma$ -TH, APCI-MS  $m/z$  417 ( $[M + H]^+$ , 70%) and 151 (100%); and  $\alpha$ -TH, APCI-MS  $m/z$  431 ( $[M + H]^+$ , 100%) and 165 (63%). The HPLC chromatograms of the product fractions of ChE and PC are shown in Figures 4B and 4C. An intense peak corresponding to TOO-epoxyChE appeared around 10.7 min of retention time as the ChE products (Fig. 4B). This peak was collected by preparative HPLC and analyzed by LC-MS (Fig. 5). The APCI-MS showed a protonated molecular ion at  $m/z$  1125 ( $[M + H]^+$ , 14%) and significant ions at  $m/z$  1107 ( $[M - OH]^+$ , 4%), 942 (22%), 875 (13%), 573 (34%), 445 ( $[\alpha$ -tocopherone + O] $^+$ , 17%), 430 ( $[\alpha$ -tocopherone] $^+$ , 36%), and 369 ( $[\text{cholesterol} - OH]^+$ , 100%). Thus, this peak was identified as TOO-epoxyChL, the addition products of  $\alpha$ -TH with cholesteryl epoxy-

linoleate-peroxyl radicals. On the analysis of PC products, only a smaller peak corresponding to TOO-epoxyPC appeared around 7.5 min of retention time after the 6-h reaction (Fig. 4C). This peak was also collected by preparative HPLC and analyzed by LC-MS. The APCI-MS indicated the presence of the  $\alpha$ -tocopherone structure at  $m/z$  430 together with the presence of some other unknown compounds (data not shown). Therefore, we could not identify its structure from the APCI-MS. This peak was assigned as TOO-epoxyPC only by comparison of the HPLC behavior with that of authentic TOO-epoxyPLPC.

The disappearance of endogenous antioxidants in human blood plasma has been reported in relation to the appearance of various lipid hydroperoxides (26). In the present study, the consumption of endogenous  $\alpha$ -TH was observed with the formation of lipid hydroperoxides, ChE-OOH and PC-OOH, when the peroxidation was initiated by AAPH (Fig. 6). The oxidation products of  $\alpha$ -TH,  $\alpha$ -TQ, epoxy- $\alpha$ -TQ, TOO-epoxyChL, and TOO-epoxyPC appeared with depletion of  $\alpha$ -TH. The oxidation products formed in the 4-h plasma sample accounted for 32% of the consumed  $\alpha$ -TH. A similar product distribution has been reported in the AAPH-initiated peroxidation of PLPC liposomes containing  $\alpha$ -TH, although the type of 8a-substituted tocopherones was different (20).

**FIG. 6.** Changes of cholesteryl ester hydroperoxides (ChE-OOH), PC hydroperoxides (PC-OOH), endogenous TH, and  $\alpha$ -TH products during the AAPH-initiated peroxidation of human plasma. The human plasma (4.0 mL) was incubated at 37°C by the addition of 1.0 mL of 100 mM AAPH (final concentration, 20 mM). Formation of ChE-OOH ( $\blacklozenge$ ) and PC-OOH ( $\diamond$ ), the consumption of  $\alpha$ -TH ( $\circ$ ) and  $\gamma$ -TH ( $\square$ ), and the formation of  $\alpha$ -TQ ( $\bullet$ ), 2,3-epoxy- $\alpha$ -TQ ( $\blacksquare$ ), 5,6-epoxy- $\alpha$ -TQ ( $\blacklozenge$ ), TOO-epoxyPC ( $\triangle$ ), and TOO-epoxyChE ( $\nabla$ ) are shown. Each value is expressed as mean  $\pm$  SD of three different experiments. See Figures 1 and 4 for abbreviations.

The classical action of  $\alpha$ -TH is that of a chain-breaking antioxidant that reflects its ability to react rapidly with chain-carrying lipid peroxy radicals (3–5). Alternatively,  $\alpha$ -TH can directly scavenge the radical that initiates peroxidation (27). In both cases, the relatively nonreactive  $\alpha$ -tocopheroxyl radical is formed. This radical rapidly reacts with another available radical to yield nonradical products. If the  $\alpha$ -tocopheroxyl radical traps the chain-propagating peroxy radicals formed from ChE or PC directly, the primary products are 8a-(ChE-dioxy)- $\alpha$ -tocopherones or 8a-(PC-dioxy)- $\alpha$ -tocopherones (20). However, we could not detect such 8a-substituted tocopherone products in the peroxidized plasma. Instead, the products we detected were the addition products of  $\alpha$ -TH with epoxy lipid-peroxy radicals, TOO-epoxyChL, and TOO-epoxyPC, in addition to  $\alpha$ -TQ and epoxy- $\alpha$ -TQ (Fig. 4). The epoxy lipid-peroxy radicals can be produced from the metal ion-catalyzed decomposition of lipid hydroperoxides such as ChE-OOH and PC-OOH (28,29). Thus, the  $\alpha$ -TH in human plasma may react only with such secondary produced peroxy radicals. Frei *et al.* (26) demonstrated that  $\alpha$ -TH in plasma was considerably less effective in preventing peroxidative damage to lipids induced by aqueous oxidants. Moreover,

$\alpha$ -TH can exert prooxidant activity on lipoprotein lipids, and a model of TH-mediated peroxidation has been developed to explain such prooxidant activity of  $\alpha$ -TH during lipoprotein peroxidation (30,31). Therefore, the accumulation of hydroperoxides before the depletion of  $\alpha$ -TH and the formation of 8a-(epoxy lipid-dioxy)- $\alpha$ -tocopherones indicates that  $\alpha$ -TH is less effective in preventing lipid peroxidation in human plasma.

Liebler *et al.* (32) have developed the most sensitive methodology of a stable isotope dilution GC-MS for analyzing  $\alpha$ -TH,  $\alpha$ -TQ, and epoxy- $\alpha$ -TQ in biological samples. They concluded that 8a-substituted  $\alpha$ -tocopherones and epoxytocopherones, rather than their hydrolyzed products, were the principal oxidation products of  $\alpha$ -TH in biological systems (32,33). However, this was only assumed from the evidence that the additional release of  $\alpha$ -TQ was observed in the acid-treated samples. The HPLC with electrochemical detection described in the present study could detect such tocopherone products in biological samples directly.

In conclusion, the HPLC technique presented here is found advantageous for the sensitive and specific determination of the 8a-substituted  $\alpha$ -tocopherones in biological samples. The oxidation products of  $\alpha$ -TH might be useful markers for the antioxidant and prooxidant reactions in biological samples. We are studying further application of the present HPLC methodology to some biological samples.

**ABSTRACT:** A convenient method was developed for preparation of FAME in small amounts from glycerolipids of blood or breast milk. Initially, 0.04–0.06 mL blood or breast milk was spotted onto a small piece of filter paper (1.5 × 1.5 cm) that had been washed with acetone containing 0.05% 2,6-di-*tert*-butyl-*p*-cresol (BHT). Each piece, once it had dried, was put in a small test tube, to which 2 mL hexane and 0.2 mL 2 M KOH/methanol were added. After vigorous mixing or sonication for 2 min at room temperature, the solution was neutralized or acidified by the addition of a few drops of acetic acid. To the solution was added 2 mL H<sub>2</sub>O, and then the hexane layer that separated was concentrated to dryness *in vacuo*. The FAME obtained were analyzed by GC. The method was applicable to the analysis of a large number of blood and breast milk samples, and the arachidonate/(eicosapentaenoate + docosahexaenoate) ratios could be determined rapidly.

Paper no. L8916 in *Lipids* 37, 523–526 (May 2002).

Arachidonic acid (ARA, 20:4n-6), EPA (20:5n-3), and DHA (22:6n-3) are major C<sub>20-22</sub> long-chain PUFA in humans and are ubiquitous components of membrane phospholipids that make up the structural matrix of cellular membranes. ARA and EPA are utilized for eicosanoid synthesis and involved in signal transduction (1); there is also increasing recognition that some diseases may be associated with an imbalance of the ratio of n-6/n-3 PUFA in the human diet (2–7). DHA is also an important structural component of photoreceptor and cortical neuronal membranes (8). Since the human brain grows rapidly between the sixth month of gestation and the first month after birth (8) and the vision of human infants develops for several months after birth (9), the FA composition of breast milk can affect the retinal and brain development of breast-fed infants (10,11). Analyses of the FA compositions of human blood and breast milk therefore have increasing nutritional and health implications (12,13), and they will be used more widely for indications of nutritional conditions in the near future.

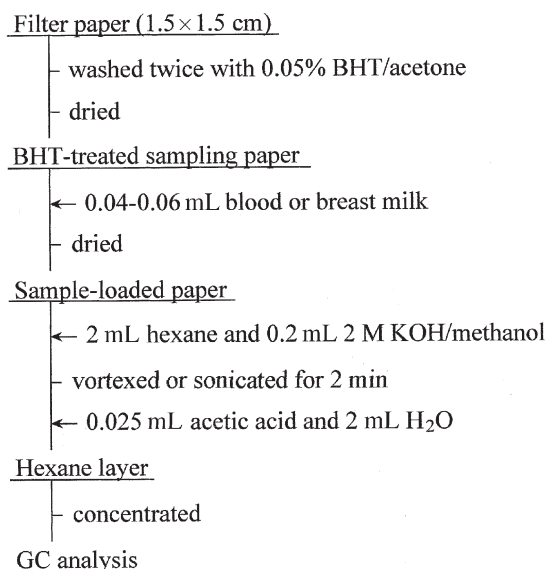

The composition of FA is determined by using GC to analyze their methyl esters. However, many preparative methods for FAME from blood or breast milk include time-consuming procedures. Some methods require more than 1 mL of blood or breast milk. Here, we report a convenient method for preparation of FAME from a few drops of blood or breast

milk; the method also can be used in analyzing a large number of samples. The procedure includes the direct transesterification of samples on filter papers with KOH/methanol.

## MATERIALS AND METHODS

**Reagents.** Authentic FA were purchased from Avanti Polar Lipids (Alabaster, AL), Cayman Chemical (Ann Arbor, MI), Doosan Serdary Research Laboratories (Englewood Cliffs, NJ), Larodan Fine Chemicals AB (Malmö, Sweden), Nacalai Tesque (Kyoto, Japan), Nu-Chek-Prep (Elysian, MN), Sigma (St. Louis, MO), and Wako Pure Chemical Industries (Osaka, Japan). Organic solvents and other chemicals including BHT were of reagent grade and were used without further purification.

**Preparation of sampling papers.** Sheets of filter paper, Whatman 3MM (Whatman Inc., Clifton, NJ), were cut into small pieces (1.5 × 1.5 cm) and then soaked for a few minutes in acetone that contained 0.05% BHT so as to wash out contaminants in the filter paper and to impregnate it with the antioxidant (Scheme 1). This treatment was repeated with a fresh BHT-containing acetone solution without drying between immersions. The sampling papers thus prepared were air-dried and stored at room temperature until use.

Abbreviations: 18:2, linoleic acid; 18:3,  $\alpha$ -linolenic acid; ARA, arachidonic acid.

**Preparation of FAME from blood or breast milk.** Sampling papers were spotted with 0.04–0.06 mL blood, serum, or breast milk and were air-dried overnight or dried for 30 min *in vacuo*. They were inserted individually into small test tubes, and 2 mL hexane and 0.2 mL 2 M KOH/methanol per test tube were added. The tubes were vigorously mixed with a vortex mixer for 2 min at 25°C (room temperature) or above. When the methanolysis was thus completed, the alkaline solution was neutralized with a few drops (0.025 mL or more) of acetic acid. To each tube was added 2–3 mL H<sub>2</sub>O without vigorous mixing, which causes gelatinization of the contents of blood samples. An aliquot (1.5–1.8 mL) of the hexane layer was transferred to a vial, and the hexane solution was evaporated to dryness *in vacuo*.

**GC analysis.** For rapid analysis, we used a glass column (4 mm × 2 m) packed with a thermostable liquid phase, 10% SP-2340 on 100–120 mesh Chromosorb WAW (Supelco, Bellefonte, PA). FAME obtained were dissolved in 0.02 mL methyl acetate or hexane and were analyzed by GC (220°C, N<sub>2</sub> 30 mL/min; or 235°C, N<sub>2</sub> 55 mL/min). Methyl acetate was somewhat better than hexane to minimize the tailing of injection solvent. Although fast-eluting peaks in GC analysis were not completely separated from each other under the above conditions, the C<sub>20–22</sub> PUFA composition was determined with a data-processor, CHROMATOPAC C-R1B (Shimadzu, Kyoto, Japan).

## RESULTS AND DISCUSSION

In an alcoholic solution of the hydroxide of an alkali metal, the hydroxide–alkoxide equilibrium greatly favors alkoxide formation [ROH + OH<sup>−</sup> ⇌ RO<sup>−</sup> + H<sub>2</sub>O], and most of the total base is the alkoxide, but not the hydroxide (14). When esters are treated with alcoholic alkali/hydroxide solutions, alcoholysis of the esters therefore proceeds much faster than saponification. The relative difference in rates is of the order of 1,500-fold (15). This reaction, alkali-catalyzed alcoholysis, has been used for preparation of FAME from glycerolipids (16), and the FA components of glycerolipids are almost quantitatively converted to their methyl esters within 1–2 min at room temperature (17). The data presented here demonstrate that the rapid and convenient methanolysis previously reported (17) can be applied to small amounts of blood and breast milk and also to a large number of the samples.

**Prevention of autoxidation of PUFA.** Small pieces of filter paper were used as blood- or breast milk-sampling papers. Pieces of filter paper that have been spotted can easily be transported by mail, for example, from hospitals to laboratories for analysis. A large number of spotted papers can also be stored compactly. Nishio *et al.* (18) proposed a method for the diagnosis of a disease using blood spot samples. However, when spots of dried blood or breast milk are exposed to the air, the oxidation of PUFA will probably proceed rapidly. In fact, when authentic PUFA were stored on filter paper at room temperature in the dark, more than 60% of each PUFA disappeared after 1 d (Fig. 1). The order of oxidation rates was DHA > EPA > ARA. To prevent autoxidation of PUFA during storage, small pieces of filter paper were soaked twice in

**FIG. 1.** Effects of BHT on autoxidation of PUFA on filter paper. Each PUFA, along with 11-eicosenoic acid as an internal standard, were applied on sampling papers that had been treated with 0% (Δ), 0.025% (○), or 0.05% (●) BHT in acetone. The spotted sampling papers were allowed to stand at room temperature for autoxidation, and then the remaining amount of the PUFA was followed by GC. Methylation for GC analysis was carried out on the spotted sampling papers with 10% BF<sub>3</sub> in methanol for 30 min at room temperature, and the methyl esters formed were extracted with hexane. Data on EPA are not presented, but they were similar to those for ARA and DHA.

acetone containing 0.025 or 0.05% BHT as an antioxidant. Impurities that had been adsorbed by the filter paper were simultaneously washed out with the solvent. A hexane solution of authentic ARA, EPA, or DHA was dropped onto the BHT-impregnated sampling papers. 11-Eicosenoic acid was used as the internal standard, because the monounsaturated FA was not apparently oxidized during the period of subsequent exposure. When the filter paper was washed with 0.05% BHT-containing acetone, none of the PUFA tested were significantly oxidized within 8 d (Fig. 1). With 0.025% BHT, DHA slightly decreased at day 8. When spotted sampling papers were air-dried overnight or dried *in vacuo* for 30 min before methanolysis, no significant differences in the PUFA composition were found between the two methods of drying.

**Quality of filter paper.** Autoxidation of PUFA in blood was measured on various kinds of filter paper (Whatman No. 2, No. 42, 3MM, and Advantec No. 131) for 5 d. Of the filter papers tested, Whatman 3MM gave the most reliable data (Table 1). ARA, EPA, and DHA did not apparently decrease for 5 d. Because Whatman 3MM is the thickest among the filter papers tested, it is probable that blood was well absorbed by the thick filter paper and that blood lipids and BHT could consequently come into intimate contact.

The analysis of serum for FA content confirmed that appli-

**TABLE 1**  
Dependence of Autoxidation of Blood C<sub>20-22</sub> PUFA on the Quality of Filter Paper<sup>a</sup>

FA	Remaining FA (%)			
	(filter paper)			
	No. 2	No. 42	3MM	No. 131
ARA	90.9	101.0	96.2	91.4
EPA	68.7	71.6	96.3	68.5
DHA	80.8	96.3	95.2	68.5

<sup>a</sup>The sampling papers treated with 0.025% BHT in acetone were spotted with 0.04 mL blood. They were stored at room temperature for 5 d, and the remaining PUFA were determined. ARA, arachidonic acid.

cation of sample volumes in the range of 0.04–0.12 mL did not affect the analytical data on the PUFA compositions (Table 2).

**Mixing for reaction.** When many samples were to be treated, vortexing was replaced by sonication. Spotted sampling papers and the reagents were placed in small test tubes and sonicated in a water bath of an ultrasonic cleaner at 25°C or above. The reaction time of 2 min was the same as that for vortexing. The efficiency of methanolysis under sonication was the same as that for vortexing (data not shown).

**Accuracy.** The C<sub>20-22</sub> PUFA composition of blood was determined by the present filter paper/KOH/methanol method, and it was compared with that determined according to the following conventional procedure. To 2 mL blood were added 1 mL water, 4 mL methanol, 4 mL chloroform, and a trace amount of BHT. The mixture was vortexed for 2 min and then centrifuged at 1,500 × g for 3 min. The chloroform layer was washed with an equal volume of water. After centrifugation, the chloroform solution was dried with anhydrous sodium sulfate and concentrated *in vacuo*. The lipids obtained were converted into FAME by the KOH/methanol method previously described (17) and analyzed by GC (Table 3). There was no significant difference between the FA composition determined by the filter paper/KOH/methanol method and that determined by the conventional extraction/methanolysis method.

**Application of the present method and measurement of ARA/(EPA + DHA) ratios in blood.** Unsaturated FA of the n-3

and n-6 series have biological functions different from each other (1,2). They also compete with each other in regulation of cellular functions. Blood or breast milk contains 18:2 and ARA as the major n-6 PUFA and also contains 18:3, EPA, and DHA as the major n-3 PUFA. In GC analysis of FAME, the C<sub>18</sub> PUFA (18:2 and 18:3) are eluted faster than the C<sub>20-22</sub> PUFA (ARA, EPA, and DHA). However, GC analysis restricted to the C<sub>20-22</sub> PUFA is much faster than that of all of the FA components including both the C<sub>18</sub> and C<sub>20-22</sub> PUFA. The C<sub>18</sub> PUFA *in vivo* were elongated and desaturated to the corresponding C<sub>20-22</sub> PUFA, which physiologically function or are further metabolized to eicosanoids. Because ARA, EPA, and DHA are thus the major functional PUFA, the ARA/(EPA + DHA) ratios of blood glycerolipids were determined and compared with the ratios of (18:2 + ARA)/(18:3 + EPA + DHA). The latter ratios essentially represent those of n-3/n-6. As a model experiment, blood samples of 17 humans practicing a fasting cure were analyzed. Figure 2 shows that the ARA/(EPA + DHA) ratio correlates strongly with the (18:2 + ARA)/(18:3 + EPA + DHA) ratio. This means that the measurement of n-6/n-3 ratio can be replaced by the measurement of ARA/(EPA + DHA) ratio, although other n-3 and n-6 PUFA are also present in blood and breast-milk lipids. Taking these into consideration, we routinely measure ARA/(EPA + DHA) ratios instead of n-6/n-3 ratios, and we recommend the use of the ARA/(EPA + DHA) ratio as a practical index of the n-6/n-3 ratio. Figure 3 is a typical gas chromatogram focused on C<sub>20-22</sub> PUFA methyl esters derived from blood and breast milk by the present method. Although

**FIG. 2.** Relationship between the ARA/(EPA + DHA) ratio and the (18:2 + ARA)/(18:3 + EPA + DHA) ratio in blood glycerolipids. For details, see text.

FIG. 3. GC analyses of the C<sub>20-22</sub> PUFA methyl esters prepared from blood (A) and breast milk (B). Column temperature, 235°C; N<sub>2</sub> gas, 55 mL/min.

packed-column GC is inferior to capillary GC in resolution, the former possesses the advantage of long column-life for injection of crude FAME samples. Capillary GC requires a purification procedure, such as TLC or column chromatography with small silica gel cartridges, of FAME prepared from crude samples, whereas FAME prepared from blood or breast milk can be directly injected onto a packed column without purification as described here. In general, retention times in packed-column GC are also shorter than those in capillary GC. In our laboratories, more than 600 samples have been successively analyzed on a packed column of SP-2340. Probably, it is possible to analyze more than a thousand samples with one column. Packed-column GC is therefore suitable for routine FAME analyses of a large number of crude lipid samples.

The two major merits of the method—it requires only small amounts of samples, and the procedure is simple and rapid—permitted us to follow the successive changes in the C<sub>20-22</sub> PUFA composition of blood lipids taken from subjects after they had eaten (data not shown).

FAME can be prepared from many samples of small amounts of blood or breast milk by alkaline methanolysis on small pieces of filter paper. The method requires neither sophisticated apparatus nor expensive reagents. Although the FA components of steryl esters and sphingomyelins do not react and FFA are not esterified under the conditions employed here, the present method will be useful for analysis of the PUFA composition of glycerolipids in blood and breast milk. This is the case especially for analysis of breast milk, because more than 97% of lipids in breast milk are TAG (19).

## ACKNOWLEDGMENTS

We thank Associate Professor Kumiko Morikawa (Osaka Prefecture College of Health Sciences, Habikino, Japan) for providing samples of breast milk and Nippon Oil & Fats Co. (Amagasaki, Japan) for supplying oleic and linoleic acids.

# Base-Catalyzed Derivatization Methodology for FA Analysis. Application to Milk Fat and Celery Seed Lipid TAG

Frédéric Destailats and Paul Angers\*

Department of Food Science and Nutrition, and Dairy Research Center (STELA),  
Université Laval, Sainte-Foy, Québec, Canada, G1K 7P4

**ABSTRACT:** In this paper, an alternative base-catalyzed methodology for the facile derivatization in mild conditions of lipid TAG prior to FA analysis is proposed. Reagents were prepared by proton exchange between potassium *tert*-butoxide and either ethanol, *n*-propanol, *n*-butanol, or 2-methoxyethanol and used for the synthesis, at 40°C for 15 min, of the corresponding derivatives, which were directly analyzed by GC. This methodology can be used on a routine basis and has been applied to standard and complex natural lipid samples. Tripalmitin was used to determine optimal reaction conditions; and bovine milk fat, containing C<sub>4</sub> to C<sub>22</sub> acids, and celery (*Apium graveolens*) seed oil, characterized by a high level of petroselinic acid, were comparatively analyzed as their ethyl, *n*-propyl, *n*-butyl, and 2-methoxyethyl esters.

Paper no. L8924 in *Lipids* 37, 527–532 (May 2002).

Derivatization of FA esterified to glycerol is a prerequisite step for their analysis by GC, TLC, and HPLC. FAME are the derivatives most widely used by lipid analysts. Various methodologies have been developed for their synthesis from glycerides, which were reviewed by Christie (1,2). Acid-catalyzed methylation is usually performed in methanol using either boron trifluoride (3,4), hydrochloric acid, or sulfuric acid as catalysts, and at temperatures of 80 to 100°C for 30 to 60 min. Although FAME derivatives are well suited for most analytical needs, other ester derivatives have been synthesized in acidic conditions for specific purposes, such as conferring lower volatility to short-chain FA or improving peak resolution of isomeric FA. Isopropyl esters were initially used successfully to enhance resolution of complex lipid samples such as bovine or human milk fat (5–8), oil samples containing petroselinic acid (9–11), and geometrical isomers of  $\alpha$ -linolenic acid (11–15). CLA isomers from French cheeses were also analyzed using isopropyl ester derivatives (16), whereas *n*-butyl esters were used for studies on FA composition of butterfat and cheeses (17,18). Moreover, both FA *n*-butyl and phenylethyl esters have been used for analysis of petroselinic acid in seed oils (19,20).

The use of strong acidic reagents such as boron trifluoride, hydrochloric or sulfuric acids, and of moderate to high temperature conditions may, however, result in the presence of some artifact peaks of degradation products on the chromatograms that compromise the accuracy of GC analysis (21).

Base-catalyzed methylation of glyceride FA is, like its acid counterpart, an equilibrium reaction that can be driven to near completion by the use of an excess of the derivatizing alcohol. Sodium methoxide in methanol is the usual reagent for the synthesis of FAME derivatives from glycerides (2,22). This transesterification reaction is performed at room to moderately elevated temperatures for 5 to 15 min for TAG, and at 40 to 50°C for 15 min for samples containing cholesteryl esters, in order to ensure complete derivatization. Unlike the acidic derivatization procedures, literature reporting on either the practical disadvantages resulting from the mild reaction conditions used in base-catalyzed methylation of acylated FA or base-catalyzed formation of other FA derivatives than methyl esters is scarce (23,24).

The present paper proposes a general mild methodology for the synthesis of ethyl, *n*-propyl, *n*-butyl, and 2-methoxyethyl FA derivatives by base-catalyzed transesterification of glycerides, and their use for high-resolution GC analysis of bovine milk fat and celery seed oil.

## MATERIALS AND METHODS

**Reference compounds and reagents.** Dipalmitin, monopalmitin, tributyrin, tricaprin, tricaproin, tricapylin, trilaurin, trilinolenin, trimyristin, triolein, tripalmitin, and tristearin were obtained from Sigma Chemicals (St. Louis, MO). *n*-Butanol, ethanol, 2-methoxyethanol, potassium *tert*-butoxide (1.0 M in THF), and *n*-propanol were obtained from Aldrich Chemicals (Milwaukee, WI).

**Bovine milk fat.** The winter milk fat was a sample from Parmalat (Montréal, Québec, Canada). A 25-kg block was tempered and then divided into samples of 100 g, which were rapidly melted, washed with deionized water, dried over anhydrous sodium sulfate and filtered in a heated (60°C) oven, and kept under N<sub>2</sub> in closed vials at –35°C until utilization.

**Oil extraction.** Mature dry seeds (10 g) of celery (*Apium graveolens*), purchased from a local seed retailer, were washed and finely grounded in a mortar. Oil was extracted with hexane on a Soxhlet apparatus and then recovered by filtering and drying the extract over anhydrous sodium sulfate and evaporating the solvent under vacuum at 30°C on a rotary evaporator (21% yield). The oil was stored under N<sub>2</sub> at –35°C until further use.

**General TAG derivatization methodology.** A solution of potassium *tert*-butoxide in THF (100  $\mu$ L, 1.0 M) was added to

anhydrous ethanol, *n*-propanol, *n*-butanol, or 2-methoxyethanol (200  $\mu$ L each) in closed vials for the preparation of the corresponding potassium alkoxides. After homogenization, a solution of a lipid sample (10 mg) in hexane (1 mL) was added to one of the reagent solutions (300  $\mu$ L), and the mixture was held at 40°C for 15 min. After cooling to room temperature, water (1 mL) and hexane (2 mL) were successively added. For milk fat samples, FA esters were extracted with 3  $\times$  1 mL of hexane to ensure complete extraction of short-chain FA. The tube was vortexed for *ca.* 5 s and allowed to stand for 1 min. If necessary, addition of a droplet of a saturated aqueous solution of sodium chloride usually broke up any emulsions that formed. The organic phase was dried over anhydrous sodium sulfate and filtered. FA ester solutions were kept under N<sub>2</sub> in closed vials, at -18°C, until analysis. Stock solutions of the reagents were also prepared and proved stable for weeks at 5°C.

**Optimization of reaction conditions.** A solution of tripalmitin (10 mg) in hexane (1 mL) was added to a solution of either potassium ethoxide, *n*-propoxide, *n*-butoxide, or 2-methoxyethoxide in THF (300  $\mu$ L), and rates of transesterification were monitored at different temperatures by GC on a 6890 Series II gas chromatograph (Hewlett-Packard, Palo Alto, CA), equipped with a fused-silica RTX-65 TG capillary column (30 m  $\times$  0.25 mm i.d., 0.10  $\mu$ m film thickness; Restek, Bellefonte, PA) and connected to a ChemStation (Hewlett-Packard, Palo Alto, CA). The injection (split mode) and detection (FID) were performed at 400°C, with an oven temperature of 190°C isothermal for 8 min, increased to 360°C at 10°C min<sup>-1</sup>, and isothermal for 5 min at 360°C. The inlet pressure of the carrier gas (H<sub>2</sub>) was 100 kPa. Under these conditions, FA esters, MAG, DAG, and TAG are fully resolved.

**FA ester analysis.** Analysis of FA esters was performed on the same apparatus. The injector (split mode) and detector temperatures were maintained at 250°C. Celery seed oil was analyzed on a DB-225 capillary column (30 m  $\times$  0.25 mm i.d., 0.25  $\mu$ m film thickness; J&W, Folsom, CA) at 190°C isothermal for 30 min, with H<sub>2</sub> as carrier gas (140 kPa). Butterfat analysis was performed on a BPX-70 capillary column (SGE, Melbourne, Australia; 60 m  $\times$  0.25 mm i.d., 0.25  $\mu$ m film thickness) with temperature programming from 60 to 210°C at 5°C min<sup>-1</sup> and isothermal for 30 min at this temperature. H<sub>2</sub> was also used as carrier gas with a head pressure of 130 kPa. Determination of response factors was performed by derivatization of simple acid TAG standards from C<sub>4</sub> to C<sub>18</sub>.

## RESULTS AND DISCUSSION

**Formation of catalysts.** In base-catalyzed transesterification reactions, the conjugated base of an alcohol acts as a nucleophile to form the new derivative. However, only a limited number of alkoxides that can form FA derivatives suitable for GC analysis are commercially available. To overcome this limitation, we readily synthesized conjugated bases of primary alcohols (ethanol, *n*-propanol, *n*-butanol, and 2-methoxyethanol) by proton exchange with a stronger base, potassium *tert*-butoxide, the conjugated base of *tert*-butanol, a tertiary alcohol. It is well

known that pK<sub>a</sub> values for tertiary alcohols are 2 to 3 units higher than those for primary alcohols, thus resulting in an almost exclusive formation of the desired base. This strategy proved itself more convenient for the formation of primary alkoxides than the use of metallic sodium or potassium, since solutions of potassium *tert*-butoxide are commercially available.

**FA derivatization.** Solutions of tripalmitin in hexane were added to solutions of potassium ethoxide, *n*-propoxide, *n*-butoxide, and 2-methoxyethoxide in THF, and rates of transesterification were monitored at different temperatures by GC. Complete derivatization was observed after 10 to 20 min at room temperature for all derivatives (Fig. 1), while at 40°C, the reaction was complete in less than 10 min. As expected, owing to increasing chelating character from TAG to DAG to MAG, the latter species was transesterified at a higher rate than both DAG and TAG, as shown by the very low levels of MAG on the chromatograms at 30 s and at 3 min (Fig. 1), while DAG were transesterified more rapidly than TAG. Although transesterification of TAG can be efficiently performed at room temperature, to ensure complete derivatization of all O-acyl species, reactions should be carried out at a temperature of 40°C for 15 min, reserving the lower temperatures for more heat-sensitive samples.

**GC analysis.** With respect to GC analysis of the different FA derivatives, two parameters were considered; response factors and resolution of positional isomers of unsaturated FA. Response factors for FA ester derivatives were determined from results of transesterification of standard solutions of simple TG in the range of 4:0 to 18:3 in order to ensure that transesterification proceeded equally well on different TG, because somewhat bulky alkoxides can act both as nucleophiles, which would result in the desired transesterification reaction, or as a base, thus leading to condensation products. As expected, in the mild conditions used, the latter reaction was not detected for any of the alkoxides tested. These results from derivatization of standards confirmed that only minor corrections to area percentage values were required to obtain accurate quantitative results for esters of medium- to long-chain FA with *n*-propyl, *n*-butyl, and 2-methoxyethyl ester derivatives (Table 1) (23). However, 2-methoxyethyl esters, which exhibited the lowest overall FID signal (*ca.* 40% lower), were least affected by the presence of carbon-carbon double bonds. *n*-Butyl esters were the most sensitive to the presence of such unsaturations. Differences between theoretical and experimental values in FA quantitation by FID are not unusual and have previously been detailed (23). Obviously, losses of short-chain FA were limited during the derivatization step because vapor pressures and hydrophilic characteristics were reduced compared to methyl ester derivatives. These observations correspond to results from studies on milk fat analysis using isopropyl (7) and *n*-butyl (17,18,23) ester derivatives.

Milk fat was analyzed for its FA composition after derivatization with potassium alkoxides of ethanol, *n*-propanol, *n*-butanol, and 2-methoxyethanol in the corresponding alcohols (Fig. 2). Results are in agreement with literature data (7,25), which make obvious the reliability and the accuracy of the new procedures

**FIG. 1.** Gas-liquid chromatogram of products from transesterification at 25°C of tripalmitin by potassium 2-methoxyethoxide in 2-methoxyethanol and THF after (A) 30 s reaction time, (B) 3 min reaction time, (C) 10 min reaction time, and (D) 20 min reaction time, on a 30-m RTX-65TG capillary column (Restek, Bellefonte, PA) on temperature-programming mode (see Materials and Methods section for detailed procedure). Peak identification: (1) 2-methoxyethyl palmitate; (2) monopalmitin (mixture of isomers); (3) dipalmitin (mixture of isomers); and (4) tripalmitin.

(Table 2). In addition, results for all FA, among the different derivatives, are close, with only small observed differences.

GC separation of petroselinic acid (*cis*-6 18:1), as found in *Apiaceae* seed oils, from oleic acid (*cis*-9 18:1) requires alternative FA derivatives to FAME, which either co-elute or show only a partial resolution (10) on long (e.g., 50- or 100-m) polar

capillary columns. These acids have, however, been resolved as isopropyl (9–11), *n*-butyl (19), and phenylethyl (20) esters, and as dibutyrate derivatives of MAG (26). Using the new derivatization procedures, we performed GC FA analysis of celery seed oil as ethyl, *n*-propyl, *n*-butyl, and 2-methoxyethyl derivatives on a 25-m 50% cyanopropyl phenyl methyl silicone open tubular capillary column (Fig. 3). Resolution between petroselinic and oleic acid isomers increased with increasing chain length of the alcohol moiety, resulting in  $R_S$  (resolution) values for ethyl, *n*-propyl, and *n*-butyl of 0.40, 0.55 and 0.90, respectively. Resolution was also enhanced by increasing the polarity of the derivative, as a baseline resolution ( $R_S = 1.57$ ) was obtained with the new 2-methoxyethyl derivative. However, *cis* and *trans* isomers of 18:1 acid were not fully resolved with the latter. Celery seed oil was mainly composed of palmitic (6.9%), stearic (1.4%), petroselinic (64.3%), oleic (8.1%), and linoleic (18.0%) acids; minor FA included hexadecenoic (0.1%),  $\alpha$ -linolenic (0.6%), and *cis*-vaccenic (0.5%) acids.

In this paper, we have demonstrated that different ester derivatives of FA may be easily prepared by transesterification of TAG using base catalysts. In the proposed reaction conditions, sample degradations were minimized, and the procedure gave good quantitative and qualitative results on com-

**ABSTRACT:** The initial steps in the autoxidation of CLA methyl ester are poorly understood. The aim of this study was to determine the stereochemistry of the hydroperoxides formed during autoxidation of CLA methyl ester in the presence of a good hydrogen atom donor. For this purpose, 9-*cis*,11-*trans* CLA methyl ester was autoxidized in the presence of  $\alpha$ -tocopherol under atmospheric oxygen at 40°C in the dark. The CLA methyl ester hydroperoxides were isolated, reduced to the corresponding hydroxy derivatives, and separated by HPLC. The stereochemistry of seven hydroxy-CLA methyl esters was investigated. The position of the hydroxy group was determined by GC-MS. The geometry as well as the position of the double bonds in the alkyl chain was determined by NMR. In addition, the <sup>13</sup>C NMR spectra of six hydroxy-CLA methyl esters were assigned using COSY, gradient heteronuclear multiple bond correlation, gradient heteronuclear single quantum correlation, and total correlation spectroscopy experiments. The autoxidation of 9-*cis*,11-*trans* CLA methyl ester in the presence of a good hydrogen atom donor is stereoselective in favor of one geometric isomer, namely the 13-(*R,S*)-hydroperoxy-9-*cis*,11-*trans*-octadecadienoic acid methyl ester. Three types of conjugated diene hydroperoxides are formed as primary hydroperoxides: *trans,trans* hydroperoxides (12-OOH-8*t*,10*t* and 9-OOH-10*t*,12*t*), a *cis,trans* hydroperoxide with the *trans* double bond adjacent to the hydroperoxide-bearing carbon atom (13-OOH-9*c*,11*t*), and a new type of *cis,trans* lipid hydroperoxide with the *cis* double bond adjacent to the hydroperoxide-bearing carbon atom (8-OOH-9*c*,11*t*). In addition, three nonkinetic hydroperoxides (13-OOH-9*t*,11*t*, 8-OOH-9*t*,11*t*, and 9-OOH-10*t*,12*c*) are formed. This study supports the theory that CLA methyl ester autoxidizes at least partly through an autocatalytic

free radical reaction. The complexity of the hydroperoxide mixture is due to formation of two different pentadienyl radicals. Moreover, the stereoselectivity in favor of one geometric isomer can be explained by the selectivity of the two previous steps: the preferential formation of a *W*-conformer of the pentadienyl radical over the *Z*-conformer, and regioselectivity of the oxygen addition to the pentadienyl radical.

Paper no. L9005 in *Lipids* 37, 533–540 (June 2002).

The hydroperoxide theory of autoxidation was developed and successfully applied to FA by Farmer and co-workers in the early 1940s (1). The hydroperoxides formed in the autoxidation of methyl oleate and methyl linoleate, the two model compounds in the FA autoxidation studies, were fully characterized after the development of appropriate analytical techniques in the late 1970s and early 1980s (reviewed in Refs. 2,3). Today, the hydroperoxide theory is generally accepted in explaining the autoxidation of monounsaturated and nonconjugated PUFA. However, the autoxidation mechanism of conjugated PUFA has been less studied. Moreover, the autoxidation mechanism of conjugated FA is thought to be different from that of the nonconjugated FA and to produce different reaction products (1,4). For example, the initial steps in the autoxidation of CLA, which has been the subject of an increasing number of scientific studies owing to its beneficial physiological effects, are still poorly understood (4,5). Very recently, we were able to provide evidence that hydroperoxides are also formed during the autoxidation of CLA methyl ester (6). Furthermore, it was shown, contrary to earlier beliefs, that the main isomers of CLA methyl ester hydroperoxides have a conjugated diene monohydroperoxide structure similar to the methyl linoleate hydroperoxides.

In continuation of our previous work (6), we now report on an investigation into the autoxidation of pure 9-*cis*,11-*trans* CLA methyl ester performed in the presence of  $\alpha$ -tocopherol (20% per weight) under atmospheric oxygen at 40°C in the dark. The primary objective was to determine the stereochemistry of the main CLA methyl ester hydroperoxides. The hydroperoxides were separated as their hydroxy derivatives by HPLC and characterized by UV; GC-MS; and <sup>1</sup>H, <sup>13</sup>C, and 2-D NMR techniques. With well-characterized products it was possible to propose a mechanism for the autoxidation

of CLA methyl ester in the presence of a good hydrogen atom donor.

## EXPERIMENTAL PROCEDURES

**Materials.** 9-*cis*,11-*trans* CLA methyl ester was purchased from Matreya Inc. (Pleasant Gap, PA). The presence of only one CLA methyl ester isomer was confirmed by  $^{13}\text{C}$  NMR (7).  $\alpha$ -Tocopherol was obtained from Merck (Darmstadt, Germany). Isopropanol was purchased from Fisher Scientific (Loughborough, United Kingdom) and it was dried by distillation over calcium hydride before use. Calcium hydride and sodium borohydride were obtained from Fluka (Buchs, Switzerland). *t*-Butyl methyl ether and heptane were from Rathburn Chemicals (Walkerburn, Scotland), bis(trimethylsilyl)-trifluoroacetamide (BSTFA) and trimethylchlorosilane (TMCS) from Merck, and platinum(IV) oxide from Fluka.

**Autoxidation.** The 9-*cis*,11-*trans* CLA methyl ester ( $3 \times 0.5$  g/20 mL glass vial) was autoxidized for 19 d in the presence of  $\alpha$ -tocopherol (20% per weight) under atmospheric oxygen at 40°C in the dark. The extent of oxidation measured as consumption of the 9-*cis*,11-*trans* CLA methyl ester by GC was 13%. The yield of hydroperoxides was approximately 9% based on peroxide value (PV = 586 meq/kg), which was measured by the ferric thiocyanate method (8). Nonoxidized 9-*cis*,11-*trans* CLA methyl ester (approx. 1.2 g) was recovered.

**Preparation of the hydroxy-CLA methyl esters.** The CLA methyl ester hydroperoxides were isolated from the autoxidation reaction mixture by silica gel column (2 g; Varian, Harbor City, CA) chromatography followed by TLC and reduced to the corresponding hydroxy derivatives using  $\text{NaBH}_4$  in dry isopropanol at 0°C as reported previously (6). The hydroper-

oxides and the hydroxy derivatives were stored as dilute heptane solutions at -20°C under nitrogen.

**Isocratic normal-phase HPLC.** The mixture of the hydroxy-CLA methyl esters was analyzed by HPLC using a Supelco silica column (Supelcosil LC-SI, 25.0 cm  $\times$  2.1 mm i.d., particle size 5  $\mu\text{m}$ ; Bellefonte, PA) and 7% *t*-butyl methyl ether in heptane as an eluent at 0.4 mL/min flow rate (Fig. 1A). The isomers were separated using a semipreparative Merck silica column (LiChrospher Si 60, 25.0  $\times$  1.0 cm i.d., particle size 5  $\mu\text{m}$ ) and 8% *t*-butyl methyl ether in heptane as an eluent at 2.0 mL/min flow rate. Approximately 4 mg of the mixture of the hydroxy-CLA methyl esters was repeatedly injected, and seven fractions were collected (Fig. 1B). Fractions 2, 3, and 4 were further purified using the analytical column, and fraction 6 was purified using the semipreparative column. The columns were equipped with a Waters 501 HPLC pump, Waters Pump Control Module, Waters WISP 710B, and Waters 996 Photodiode Array Detector (from 200 to 400 nm; Milford, MA) set at 234 nm.

**Derivatization to trimethylsilyl ethers and GC-MS.** Analysis of the different hydroxy isomers as corresponding hydroxystearates enables the unambiguous determination of the positional isomers (9). Hydrogenation of the separated hydroxy-CLA methyl esters to the corresponding hydroxystearates was performed using platinum(IV) oxide (5 mg) as a catalyst in methanol (5 mL). A slow stream of  $\text{H}_2$  was introduced into the mixture for 30 min while stirring. Chloroform (2 mL) was added. The reaction mixture was filtered and the solvent was removed under a stream of nitrogen gas. The residue was silylated by adding anhydrous pyridine (100  $\mu\text{L}$ ) and the derivatization reagent (100  $\mu\text{L}$ ) containing 99% of BSTFA and 1% of TMCS. The reaction mixture was allowed

**FIG. 1.** (A) HPLC analysis of the hydroxy-CLA methyl esters using Supelco silica column (Supelcosil LC-SI, 25.0 cm  $\times$  2.1 mm i.d., particle size 5  $\mu\text{m}$ ; Bellefonte, PA) and 7% *t*-butyl methyl ether in heptane (Rathburn Chemicals, Walkerburn, Scotland) as an eluent at a 0.4 mL/min flow rate with UV detection at 234 nm. (B) Semipreparative (4 mg) HPLC separation of the hydroxy-CLA methyl esters using a Merck silica column (LiChrospher So 60, 25.0 cm  $\times$  1.0 cm i.d., particle size 5  $\mu\text{m}$ ; Darmstadt, Germany) and 8% *t*-butyl methyl ether in heptane (Rathburn Chemicals) as an eluent at a 2.0 mL/min flow rate with UV detection at 234 nm. Peaks: 1 = 13-(*R,S*)-hydroxy-9-*cis*,11-*trans*-octadecadienoic acid methyl ester (13-OH-9*c*,11*t*); 2 = 13-(*R,S*)-hydroxy-9-*trans*,11-*trans*-octadecadienoic acid methyl ester (13-OH-9*t*,11*t*); 3 = 12-(*R,S*)-hydroxy-8-*trans*,10-*trans*-octadecadienoic acid methyl ester (12-OH-8*t*,10*t*); 4 = 9-(*R,S*)-hydroxy-10-*trans*,12-*cis*-octadecadienoic acid methyl ester (9-OH-10*t*,12*c*); 5 = 9-(*R,S*)-hydroxy-10-*trans*,12-*trans*-octadecadienoic acid methyl ester (9-OH-10*t*,12*t*); 6 = 8-(*R,S*)-hydroxy-9-*cis*,11-*trans*-octadecadienoic acid methyl ester (8-OH-9*c*,11*t*); 7 = 8-(*R,S*)-hydroxy-9-*trans*,11-*trans*-octadecadienoic acid methyl ester (8-OH-9*t*,11*t*). \*Unidentified compound.

to stand overnight in the dark at room temperature. The trimethylsilyl ethers were analyzed on an Agilent 5973 mass spectrometer connected to a Hewlett-Packard gas chromatograph (HP 6890 Series GC System). The gas chromatograph was equipped with an Rtx-5MS (crossbond 5% diphenyl polysiloxane, 95% dimethyl polysiloxane) capillary column (Restek Corporation, Bellefonte, PA), 60 m × 0.25 mm i.d., film thickness 0.1 μm; carrier gas: helium, 1.2 mL/min. Samples (0.5–1 μL) were injected using on-column injection. Column temperature program: 70°C (1 min), 40°C min<sup>-1</sup> to 170°C; 170°C (2 min), 5°C min<sup>-1</sup> to 250°C; 250°C (20 min); interface temperature: 280°C; ion source temperature: 230°C; ionization: electron impact 70 eV; mass range: 100–400 u; sampling rate: 4.72 scans/s; scan threshold: 150.

**UV spectroscopy.** The hydroxy-CLA methyl esters with conjugated diene chromophores were quantified by UV spectroscopy (λ = 234 nm). UV spectra were recorded in ethanol solution on a PerkinElmer UV/vis spectrometer Lambda Bio. Molar absorbance (ε) values used in calculations were from Reference 10. The ε value of 13-(*R,S*)-hydroxy-9-*trans*,11-*trans*-octadecadienoic acid methyl ester (13-OH-9*t*,11*t*) was used in calculations for the 12-(*R,S*)-hydroxy-8-*trans*, 10-*trans*-octadecadienoic acid methyl ester (12-OH-8*t*,10*t*) and the ε values of the 9-hydroxy isomers for the 8-hydroxy isomers.

**NMR spectroscopy.** <sup>1</sup>H, <sup>13</sup>C, and 2-D NMR spectra were recorded on a Bruker 500 Avance spectrometer with ν (<sup>1</sup>H) = 500 MHz and ν (<sup>13</sup>C) = 125 MHz in deuteriochloroform [Aldrich, Milwaukee, WI; contains 0.1% (vol/vol) tetramethylsilane, 99.8% <sup>2</sup>H] at 27°C. Chemical shifts (δ) are given in parts per million (ppm) relative to tetramethylsilane (δ 0.00).

## RESULTS AND DISCUSSION

**Autoxidation and HPLC of the hydroxy-CLA methyl esters.** The autoxidation of 9-*cis*,11-*trans* CLA methyl ester was

performed in the presence of a large amount of  $\alpha$ -tocopherol in order to produce a sufficient amount of primary hydroperoxides for characterization and to simplify the mixture of hydroperoxides formed, as has been observed for the autoxidation of methyl linoleate (11). The autoxidation was stopped when the extent of oxidation was 13%. At this oxidation level under the conditions of the investigation, hydroperoxides are formed but are not yet degraded to secondary oxidation products to a degree that would cause problems during purification. The hydroperoxides were isolated by column chromatography. In the  $^1\text{H}$  NMR spectrum of the mixture of CLA methyl ester hydroperoxides, the hydroperoxide protons appear as partly overlapping singlets at  $\delta$  7.89–7.73. Unlike the linoleate hydroperoxides, the CLA methyl ester hydroperoxides are formed in unequal amounts judging from the integrals of the hydroperoxide proton signals. In particular, one isomer (resolved OOH singlet at  $\delta$  7.87) accounted for approximately 42% of all the different hydroperoxide protons. Since the primary objective was not to investigate the properties of the hydroperoxides but rather the stereochemical distribution of the isomers formed, the hydroperoxides were converted chemoselectively (12) to the corresponding hydroxy compounds. Furthermore, as reported for the methyl hydroxylinoleates, this was expected to reduce the risk of isomerization under HPLC conditions (13) and to improve the HPLC separation of the different isomers (10).

Separation and analysis of the mixture of the hydroxy-CLA methyl esters into seven components using 7–8% *t*-butyl methyl ether in heptane is depicted in Figure 1. As expected, based on the  $^1\text{H}$  NMR spectrum of the CLA methyl ester hydroperoxides, the HPLC chromatogram revealed an unequal distribution of the hydroxy isomers. HPLC analysis of the mixture at  $\lambda = 234$  nm gave the following elution order and area percentage composition of the hydroxy-CLA methyl esters: 13-OH-9*c*,11*t* (50%), 13-OH-9*t*,11*t* (<1%), 12-OH-8*t*,10*t* (12%), 9-OH-10*t*,12*c* (13%), 9-OH-10*t*,12*t* (15%), 8-OH-9*c*,11*t* (2%), and 8-OH-9*t*,11*t* (8%).

*Characterization of the hydroxy-CLA methyl ester isomers by UV, GC-MS, and NMR.* The separated hydroxy-CLA methyl esters were analyzed by HPLC, and UV spectra were recorded. Three different  $\lambda_{\text{max}}$  values for the three different types of isomers were recorded. The absorption maximum of the *cis,trans* isomers (allylic methine is adjacent to the *trans* double bond) (fractions 1 and 4) was at 234.4 nm, that of the *cis,trans* isomer (allylic methine is adjacent to the *cis* double bond) (fraction 6) at 232.1 nm, and that of the *trans,trans* isomers (fractions 2, 3, 5, and 7) at 230.9 nm.

The position of the hydroxy group of the individual hydroxy-CLA methyl esters was determined by GC-MS using trimethylsilyl ethers of the corresponding hydroxystearates, which gave two characteristic fragment ions in MS. The results are summarized in Table 1.

*Methyl 13-hydroxy-9-cis,11-trans octadecadienoate (fraction 1).* Easily recognizable groups in the  $^1\text{H}$  NMR spectrum of the 13-hydroxy isomer were the olefinic, allylic methine, methoxy, H-2, allylic methylene, and H-18 proton signals.

**TABLE 1**  
Fragment Ions from Trimethylsilyl Ethers of Stearic Acid Methyl Esters Prepared by  $\text{PtO}_2$ -Catalyzed Hydrogenation of the Fractions Containing Hydroxy-CLA Methyl Esters

Fraction	Fragment ions ( <i>m/z</i> )	Corresponding hydroxystearate
1	173, 315	13-OH
2	173, 315	13-OH
3	187, 301	12-OH
4	229, 259	9-OH
5	229, 259	9-OH
6	243, 245	8-OH
7	243, 245	8-OH

The four multiplets in the olefinic region are characteristic of a conjugated diene structure with two lower-field “inner” protons at  $\delta$  6.48 (*dddd*, H-11) and 5.97 (*dddd*, H-10) and two higher-field “outer” protons at  $\delta$  5.67 (*dd*, H-12) and 5.43 (*dt*, H-9). The geometry of the double bonds was determined based on the vicinal coupling constants ( $^3J = 15.2$  Hz for a *trans* and  $^3J \approx 11.0$  Hz for a *cis* double bond) and was further confirmed by characteristic chemical shifts of allylic methine and methylene carbons in the  $^{13}\text{C}$  NMR spectrum. The chemical shift at  $\delta$  72.90 (C-13) was characteristic of an allylic methine carbon atom adjacent to a *trans* double bond (14) and the chemical shift at  $\delta$  27.68 (C-8) confirmed that the allylic methylene carbon was adjacent to a *cis* double bond (15,16).

An H-H-COSY experiment confirmed the assignments of the  $^1\text{H}$  NMR spectrum and was used to identify the signals of the methylene groups adjacent to the allylic protons (H-7 and H-14) as well as the H-3 signal. In addition, based on the cross-peak signals in the COSY spectrum, the diastereotopic protons (H-14 and H-14') adjacent to the allylic methine group resonated at different frequencies ( $\delta$  1.57 and 1.51). Since geminal couplings are generally  $-10$  to  $-20$  Hz and  $|\Delta\nu| \approx 30$  Hz, the signals are higher-order multiplets. Owing to rapid tumbling of the molecule in solution at room temperature, the coupling constants of the diastereotopic protons to the allylic methine proton were averaged to 6.6 Hz (measured from the allylic methine multiplet).

Windowing [the acquired free induction decay data were zero-filled and multiplied by a negative exponential function ( $\text{lb} = -0.10$  Hz) before Fourier transformation] was used to improve the resolution of the  $^1\text{H}$  NMR spectrum, and it enabled the determination of some coupling constants between nuclei that were four bonds apart ( $^4J$ ). A long-range COSY experiment was used to determine the coupled nuclei.

The position of the double bond system in the alkyl chain was determined using a 2-D total correlation spectroscopy (TOCSY) experiment by establishing which allylic resonance was closest to the methyl group. The TOCSY spectrum showed the protons belonging to the same coupled spin system; and by using a suitable mixing time in the pulse program, it was possible to control how far the magnetization was transferred within the spin system. Figure 2A shows an expanded plot of a portion of the 2-D TOCSY spectrum for the 13-hydroxy isomer run with the relatively long mixing

FIG. 2. Expanded plots of the 2-D total correlation spectroscopy spectra of the 13-OH-9*c*,11*t* isomer (69 mM); (A) mixing time 140 ms; (B) mixing time 180 ms.

time of 140 ms. The methyl group protons correlate with the allylic methine proton but not with the allylic methylene protons; thus, the position of the double bond system must be 9-*cis*,11-*trans*. This is in accord with the methyl group resonance correlating more strongly with the protons in the *trans* double bond than with the more remote protons in the *cis* double bond. When the TOCSY spectrum was run using a mixing time of 180 ms, the correlation cross-peaks between the methyl group protons and the different olefinic protons became more intense, and the interaction of the methyl group with the allylic methylene protons started to appear (Fig. 2B).

The previously identified protons could be correlated with the carbons directly attached in a gradient heteronuclear single quantum correlation (gHSQC) spectrum, allowing the identification of olefinic (C-9 to C-12), allylic methine (C-13), allylic methylene (C-8) and methylene carbons adjacent to the allylic positions (C-7 and C-14), C-2, C-3, and C-18. Further assignments could be made by observing the correlations between protons and carbons over two and three bonds in a gradient heteronuclear multiple bond correlation (gHMBC) spectrum. In particular, the H-18 methyl group protons had two strong correlation cross-peaks, which allowed the distinction of carbons C-16 from C-17 on chemical shift grounds. C-15 could be identified based on correlations to the previously assigned protons H-14 and H-13. More importantly, the position of the double bond system was confirmed by the correlation of C-16 to H-14, which in turn was correlated to the allylic methine carbon C-13.

**Other isomers.** The 13-hydroxy isomer of fraction 2 was characterized based on  $^1\text{H}$  NMR alone, owing to the small amount of compound. By using a combination of 2-D NMR techniques (COSY, gHSQC, gHMBC, and TOCSY), the  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra of the other hydroxy-CLA methyl esters (fractions 3–7) were assigned in a manner similar to that

of the 13-OH-9*c*,11*t* isomer. The proton assignments are listed in the Experimental Procedures section, and the carbon data collected are shown in Table 2. The assignments of the  $^{13}\text{C}$  NMR spectra of the 13-hydroxy isomer and the 9-hydroxy isomers are in agreement with the results of Frankel *et al.* (14).

It should be noted that in the  $^{13}\text{C}$  NMR spectrum of the 8-hydroxy-9-*cis*,11-*trans* isomer (fraction 6), the chemical shift at  $\delta$  67.94 is characteristic of an allylic methine adjacent to a *cis* double bond (12). This hydroxy compound corresponds to a new type of allylic monohydroperoxide conjugated diene isomer formed in the autoxidation of polyunsaturated FA esters. The related 2-hydroperoxy-3-*cis*,5-*trans*-heptadiene is known to be formed in the autoxidation of 2-*cis*,5-*trans*-heptadiene (17).

**Mechanism.** The most striking feature in the autoxidation of the 9-*cis*,11-*trans* CLA methyl ester is that under the conditions used in this study, the reaction was clearly stereoselective in favor of one geometric isomer (as a pair of enantiomers). The most feasible mechanism for an autoxidation reaction, that proceeds through hydroperoxide intermediates is the autocatalytic free radical pathway. The initial step in the autoxidation of the 9-*cis*,11-*trans* CLA methyl ester can be envisaged as an abstraction of one of the four allylic hydrogens. In the  $^1\text{H}$  NMR spectrum of the 9-*cis*,11-*trans* CLA methyl ester, the methylene protons adjacent to the *cis* double bond resonated at a slightly lower field ( $\delta$  2.15) compared to the methylene protons adjacent to a *trans* double bond ( $\delta$  2.09). This implies that the chemical surroundings of the two allylic groups are slightly different. Furthermore, the allylic position, in the conformations that are most likely to undergo fragmentation (the C–H bond undergoing fragmentation perpendicular to the diene  $\pi$  system), is sterically more crowded when adjacent to a *cis* double bond than to a *trans* double

<sup>a</sup>13-OH-9*c*,11*t*, 13-(*R,S*)-hydroxy-9-*cis*,11-*trans*-octadecadienoic acid methyl ester; 12-OH-8*t*,10*t*, 12-(*R,S*)-hydroxy-8-*trans*,10-*trans*-octadecadienoic acid methyl ester; 9-OH-10*t*,12*c*, 9-(*R,S*)-hydroxy-10-*trans*,12-*cis*-octadecadienoic acid methyl ester; 9-OH-10*t*,12*t*, 9-(*R,S*)-hydroxy-10-*trans*,12-*trans*-octadecadienoic acid methyl ester; 8-OH-9*c*,11*t*, 8-(*R,S*)-hydroxy-9-*cis*,11-*trans*-octadecadienoic acid methyl ester; 8-OH-9*t*,11*t*, 8-(*R,S*)-hydroxy-9-*trans*,11-*trans*-octadecadienoic acid methyl ester.

bond. However, the electronic or the steric factors alone at the two allylic positions are hardly large enough to account for the observed stereoselectivity.

Abstraction of a hydrogen atom from the allylic positions adjacent to a *trans* double bond leads to the formation of a pentadienyl radical delocalized between carbons 9 and 13 (**2**), whereas hydrogen abstraction from the alternative allylic position leads to the formation of a pentadienyl radical delocalized between carbons 8 and 12 (**3**) (Scheme 1, where TocH =  $\alpha$ -tocopherol and Toc• =  $\alpha$ -tocopherol radical). The delocalization of the pentadienyl radicals **2** and **3** is represented by three resonance structures (**a** to **c**). The resonance structures (**2b** and **3b**) in which the double bonds are not conjugated are energetically less favorable, and thus the contribution to the resonance hybrids is smaller than that of the other conjugated resonance structures. The spatial arrangement of the double bonds in both of the conjugated resonance structures, **2a** and **2c**, that contribute to the pentadienyl radical **2** is *s-trans*, whereas that of the conjugated resonance structures **3a** and **3c** that contributes to the pentadienyl radical **3** is such that only one is *s-trans* and the other *s-cis*. Thus, the radical **2** (*W*-shaped conformation) is energetically more stable than radical **3** (*Z*-shaped conformation). Invoking the Hammond postulate, we can assume that the geometry of the transition state resembles that of the pentadienyl radical. Hence, the transition state leading to radical **2** should be more stable than the one leading to radical **3**, and thereby the activation energy ( $\Delta G^\ddagger$ ) for the formation of radical **2** is smaller than it is for the formation of radical **3**; and thus radical **2** is formed faster.

The propagation step consists of the radical–radical coupling reaction between the pentadienyl radical and molecular

oxygen. Since this reaction proceeds under normal oxygen pressures at or near the diffusion control rate (18), the geometry of the double bonds is not expected to change through isomerization of the pentadienyl radical. Furthermore, the isomerization of the *W*-conformer **2** is energetically unfavorable based on the analogy with the pentadienyl radical itself (19). The resonance-stabilized pentadienyl radicals are essentially planar, and the new chiral center is formed without stereoselection. However, the studies performed with methyl oleate (20) and with four different geometric isomers of methyl linoleate (21) under kinetic conditions show that the attack of oxygen on the carbons of the allylic or the pentadienyl radical is regioselective. In particular, as indicated in the methyl linoleate study (21), the pentadienyl radical terminus having a partial *trans* double bond character reacts faster than the terminus having a partial *cis* double bond character. Thus, addition of oxygen to the pentadienyl radical **2**, which is the same radical as the one formed from methyl 9-*cis*,12-*trans*-linoleate, leads to the preferential formation of the 13-peroxyl radical **6** having a *cis,trans* geometry over the 9-peroxyl radical **4**, which has the more stable *trans,trans* configuration. When the oxidation occurs in the presence of the good hydrogen atom donor,  $\alpha$ -tocopherol, the next step is relatively fast and selectively produces 13-OOH-9*c*,11*t* (**7**). Smaller amounts of the other three primary or kinetic hydroperoxides, **5**, **12**, and **14**, are also expected to form.

Because the high level of a strong hydrogen donor was expected to stabilize the kinetic autoxidation products, the formation of the nonkinetic hydroperoxides, **10** and **16**, was unexpected and is not easily explained. The autoxidation under the conditions employed in this investigation was selective, leading

SCHEME 1

to preferential formation of the 13-peroxyl radical **6**, which is involved in competing hydrogen atom abstraction and  $\beta$ -scission reactions. Hydrogen atom abstraction occurs rapidly in the presence of a good hydrogen atom donor compared to  $\beta$ -scission. However, isomerization of the peroxyl radical **6** through  $\beta$ -scission of the conformer **6'** would ultimately lead to the formation of 9-OOH-10*t*,12*c* (**10**) as has been demonstrated previously (22–24). Furthermore, it has been suggested that at high  $\alpha$ -tocopherol concentration the hydrogen atom abstraction reaction between the  $\alpha$ -tocopherol and peroxyl radical is reversible (2). The  $\beta$ -scission pathway also explains the formation of a small amount of the 13-OOH-9*t*,11*t* from the peroxyl radical **4**. More of this isomer was expected to form in the absence of  $\alpha$ -tocopherol, which is the topic of further studies.

Presuming that under normal oxygen pressures the pentadienyl radical *Z*-conformation does not isomerize before it is trapped by oxygen, 8-OOH-9*t*,11*t* (**16**) should be formed by isomerization of the primary peroxyl radicals **11** or **13**. Isomerization through the  $\beta$ -scission pathway of the radical **11** would initially lead to the formation of an 8-peroxy-9-*trans*,11-*cis* radical, and that of the radical **13** would lead to a 12-peroxy-8-*cis*,10-*trans* radical. Since neither of the hydroperoxides was found from the reaction mixture, this pathway seems unlikely. Because both termini of the pentadienyl radical **3** have a partial *trans* double bond character, we would expect about the same amount of the radical **13** to be formed as the radical **11**. However, significantly less 8-OOH-9*c*,11*t*

(**14**) than 12-OOH-8*t*,10*t* (**12**) was formed based on the HPLC analysis of the corresponding hydroxy esters. Therefore, if the hydroperoxide **12** is not formed by some other mechanism, the peroxyl radical **13** isomerizes and/or decomposes to secondary autoxidation products faster than the peroxyl radical **11**. The origin of the lability of the radical **13** could be that, unlike the other peroxyl isomers, the carbon atom bearing the peroxy group is adjacent to a *cis* double bond. Moreover, the isomerization of the radical **13** by two successive [2,3] allylperoxyl rearrangements, proceeding through a cyclic transition state as the oleate allylperoxyl rearrangement (25), leads, after hydrogen atom abstraction, to the formation not only of hydroperoxide **16** but also of **12**.

Although the isomerization of the peroxyl radical **13** by addition of oxygen at C-10 is feasible, the autoxidation conditions used are not purely kinetic, and this study does not provide evidence ruling out direct isomerization of the *Z*-conformation pentadienyl radical (**3**). With the pentadienyl radical itself, isomerization of the *Z*-conformation to the *W*-conformation is expected to be diffusion-controlled, and at above  $-63^\circ\text{C}$  the *Z*-conformer is fully converted into the *W*-conformer (26). The direct isomerization of the *Z*-conformer **3** leads to the more stable *W*-conformer, which is, at least in theory, a precursor of hydroperoxides **16** and **12**. However, this alternative pathway is possible only if the conformational isomerization occurs at a rate that competes successfully with the diffusion-controlled peroxidation of the radical **3**.

The autoxidation of conjugated FA has been suggested to differ from the autoxidation of nonconjugated PUFA. In the light of the results of this investigation, it can be concluded that the eminent feature of the autoxidation of 9-*cis*,11-*trans* CLA methyl ester in the presence of a good hydrogen atom donor is that one hydroperoxide (as a pair of enantiomers) is formed predominantly at the expense of other isomers. When methyl linoleate is autoxidized in the presence of  $\alpha$ -tocopherol at 40°C, the formation of two kinetic *cis,trans* hydroperoxides in 1:1 ratio is favored over the two thermodynamic *trans,trans* hydroperoxides (11), whereas the autoxidation of CLA methyl esters leads to the formation of a more complex isomeric mixture. There are four instead of two different positional isomers owing to the formation of two different pentadienyl radicals. Furthermore, conjugated diene hydroperoxides with *trans,trans* geometry and a new type of *cis,trans* hydroperoxide with a *cis* double bond adjacent to the hydroperoxide-bearing carbon atom are formed as kinetic hydroperoxides. Since oxidation reactions and formation of hydroperoxides of specific stereochemistry play an important role in many biological reactions, these differences in hydroperoxide formation may partly explain the unique bioactive properties of CLA.

**ABSTRACT:** A regiospecific oxygenation of the allylic carbon 10 of *cis*-vaccenic acid has been observed in senescent cells of the halophilic purple sulfur bacterium *Thiohalocapsa halophila* incubated under aerobic conditions in darkness. The results obtained strongly suggest that these enzymatic processes involve the initial dioxygenase-mediated formation of 10-hydroperoxy-octadec-*cis*-11-enoic acid, which is not accumulated in the cells of *T. halophila* owing to its high cytotoxic properties. Deuterium labeling and GC-MS analyses enabled us to demonstrate that subsequent enzymatic conversions of this allylic hydroperoxide involved reduction, cleavage, isomerization, and saturation reactions. Some of the specific oxidation products thus formed could constitute potential *T. halophila* biomarkers.

Paper no. L8991 in *Lipids* 37, 541–548 (June 2002).

Lipoxygenases (formerly called lipoxidases in plants) are a family of related nonheme iron-containing enzymes that are widely distributed in humans, animals, and plants (1). Although lipoxygenase was originally discovered in leguminous plants, it soon became clear that lipoxygenases are widespread throughout the plant kingdom, including algae (2,3) and bryophytes (4). These enzymes dioxygenate PUFA containing all-*cis*-methylene-interrupted double bonds such as octadeca-9,12-all-*cis*-dienoic acid (linoleic acid), octadeca-9,12,15-all-*cis*-trienoic acid (linolenic acid), eicosa-5,8,11,14-all-*cis*-tetraenoic acid (arachidonic acid), or eicosa-5,8,11,14,17-all-*cis*-pentaenoic acid, yielding unsaturated hydroperoxy FA with one pair of conjugated double bonds (5). The dioxygenation of PUFA by a lipoxygenase formally consists of three steps: (i) removal of one hydrogen atom from the double allylic methylene carbon atom forming a FA radical, (ii) conjugation of the double bonds with a *trans*-isomerization of the shifted double bond (the conjugation being accompanied by a rearrangement of the radical electron), and (iii) insertion of dioxygen (5). Lipoxygenases may also catalyze the oxygenation of monounsaturated FA such as oleic (6–9) and octadec-*cis*-12-enoic (9) acids, these processes mainly affording hydroxy-, hydroperoxy-, or oxoacids.

The reactive properties attributed to hydroperoxides have

Abbreviations: BSTFA, bis(trimethylsilyl) trifluoroacetamide; DMDS, dimethyl disulfide; TMS, trimethylsilyl.

led to speculation that lipoxygenase participates in the senescence process in plants (10). However, conflicting experimental evidence leaves this question unanswered for the moment (11,12).

During aerobic incubation of senescent cells of the halophilic purple sulfur bacterium *Thiohalocapsa halophila* in darkness, we observed a regiospecific peroxidation of the allylic carbon 10 of octadec-11-*cis*-enoic acid (*cis*-vaccenic acid), which was attributed to the involvement of a dioxygenase. The subsequent enzymatic conversions of the 10-hydroperoxyoctadec-11-*cis*-enoic acid thus formed have been studied by deuterium labeling and involve reduction, cleavage, isomerization, and saturation reactions.

## EXPERIMENTAL PROCEDURES

*Source of strain.* *Thiocapsa halophila* strain SG 3202 was isolated from the red layer occurring all year around in the laminar microbial mat at the sediment surface of hypersaline ponds in the saltern of Salin-de-Giraud (Camargue, France) (13) and was renamed *Thiohalocapsa halophila* DSM 6210 by Imhoff *et al.* (14) after examination of its 16S rDNA.

*Culture conditions.* The final synthetic medium for maintenance and growth of *T. halophila* was prepared according to the method of Pfennig and Trüper (15), and contained (per litre of distilled water): KH<sub>2</sub>PO<sub>4</sub> (0.3 g), KCl (0.3 g), NH<sub>4</sub>Cl (0.5 g), NaCl (100 g), MgSO<sub>4</sub>·7H<sub>2</sub>O (3 g), MgCl<sub>2</sub>·6H<sub>2</sub>O (6 g), and CaCl<sub>2</sub> (0.05 g). After sterilization, the liquid medium was supplemented with Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub> (0.08 g), NaHCO<sub>3</sub> (1.5 g), Na<sub>2</sub>S·9H<sub>2</sub>O (0.48 g), CH<sub>3</sub>COONa (0.16 g), trace element solution [SL12 (16)] (1 mL), and vitamin solution [VA (17)] (1 mL) under a mixture of gas (N<sub>2</sub>/CO<sub>2</sub>, 90:10). The pH was finally adjusted between 7.2 and 7.4, and the medium was distributed in 250-mL sterile screwcap bottles. To minimize the gaseous volume, the flasks were brimmed. Cultures were incubated at 20°C under an illumination of 110 μmol photons m<sup>-2</sup> s<sup>-1</sup> (12 h light and dark cycle) provided by a mix of 30 W fluorescent (Osram, fluora) and 60 W tungsten lamps (one of each). Aerobic incubations were carried out in 250-mL Erlenmeyer flasks under the same conditions with magnetic stirring.

*Experiments with senescent cells.* After growth, cultures were distributed in 250-mL Erlenmeyer flasks and taken through several freeze-thaw cycles to provide some disruption

of cellular structure. The flasks were then incubated at 20°C under aerobic and anaerobic conditions in darkness.

**Treatment.** After incubation, the content of each flask was filtered on GF/F (Whatman) paper, and the filters were saponified directly or after reduction.

**Reduction of hydroperoxides to alcohols.** Hydroperoxides were reduced to the corresponding alcohols in methanol (25 mL) by excess NaBH<sub>4</sub> or NaBD<sub>4</sub> (10 mg/mg of extract) using magnetic stirring (15 min at 0°C) (18). During this treatment ketones are also reduced, and the possibility of some ester cleavage cannot be excluded.

**Alkaline hydrolysis.** Saponification was carried out on both reduced and nonreduced samples. After reduction, 25 mL of water and 2.8 g of potassium hydroxide were added, and the mixture was directly saponified by refluxing for 2 h. In the case of nonreduced samples, an additional 25 mL of methanol was added before saponification. After cooling, the contents of the flask were extracted three times with *n*-hexane. The combined *n*-hexane extracts were dried over anhydrous Na<sub>2</sub>SO<sub>4</sub>, filtered, and concentrated by using a rotary evaporator to give the unsaponified fraction. The aqueous phase was then acidified with hydrochloric acid (pH 1) and subsequently extracted three times with dichloromethane. Treatment of the combined dichloromethane extracts as described above gave the saponified fraction.

**Derivatization.** After evaporation of solvents, the residues were taken up in 400 µL of a mixture of pyridine and bis(trimethylsilyl) trifluoroacetamide (BSTFA) (Supelco, St Quentin Fallavier, France) (3:1, vol/vol) and silylated for 1 h at 50°C. After evaporation to dryness under nitrogen, the residues were taken up in a mixture of ethyl acetate and BSTFA and analyzed by GC–EIMS.

**Dimethyldisulfide (DMDS) treatment.** Following the procedure initially described by Vincenti *et al.* (19), the extract to be derivatized was dissolved in 250 µL of hexane, 250 µL of DMDS, and 125 µL of an iodine solution (60 mg of iodine in 1 mL of diethyl ether). The reaction mixture was held at 50°C for 24 h and then diluted with hexane. The reaction was quenched with 2 mL of 5% Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub>, and the hexane layer was pipetted off. The solution was extracted twice with hexane; the hexane extracts were combined, dried on Na<sub>2</sub>SO<sub>4</sub>, filtered, and the solvent was evaporated by using a rotary evaporator. The residue was then silylated as described above and analyzed by GC–EIMS.

**Hydrogenation.** Lipid extracts were hydrogenated overnight under magnetic stirring in methanol with Pd/CaCO<sub>3</sub> (10–20 mg/mg of extract) (Aldrich, St Quentin Fallavier, France) as a catalyst. After hydrogenation, the catalyst was removed by filtration, and the filtrate was concentrated by rotary evaporation.

**Identification of FA and their oxidation products.** These compounds were identified by comparison of retention times and mass spectra with those of standards and quantified (calibration with external standards) by GC–EIMS. Derivatives of regioisomeric hydroxy compounds, which often coeluted, can be distinguished by their EI mass spectra to a great extent,

since the main fragments are caused by α-cleavage at the site of the functional group. These isomers could thus be detected and quantified by measurement of the ion currents of these specific fragment ions. Characterization of *cis* and *trans* allylic hydroxyacids was based on comparison of their retention times with those of standard compounds.

GC–EIMS analyses were carried out with an HP 5890 series II plus gas chromatograph connected to an HP 5972 mass spectrometer. The following conditions were used: 30 m × 0.25 mm (i.d.) fused-silica capillary column coated with HP5 (Hewlett-Packard; film thickness, 0.25 µm); oven temperature programmed from 60 to 130°C at 30°C min<sup>-1</sup> and then from 130 to 300°C at 4°C min<sup>-1</sup>; carrier gas (He) maintained at 1.04 bar until the end of the temperature program and then programmed from 1.04 bar to 1.5 bar at 0.04 bar min<sup>-1</sup>; injector (splitless) temperature, 300°C; electron energy, 70 eV; source temperature, 170°C; cycle time, 1.5 s.

**Standard compounds.** Palmitoleic, oleic, and *cis*- and *trans*-vaccenic acids were purchased from Sigma (St Quentin Fallavier, France). Fe<sup>2+</sup>/ascorbate-induced autoxidation (20) of *cis*-vaccenic acid produced a mixture of allylic hydroperoxides containing significant amounts of *cis*- and *trans*-10-hydroperoxyoctadec-11-enoic acids (21). Subsequent reduction of these different hydroperoxides in methanol with excess NaBH<sub>4</sub> afforded the corresponding hydroxyacids. Oxoacids were obtained by dehydration of the corresponding hydroperoxides in a mixture of pyridine and acetic anhydride (22). Hydrogenation of hydroxyacids and oxoacids was carried out in methanol with Pd/CaCO<sub>3</sub> as catalyst. A mixture of diastereoisomeric 10,11-, 9,10-, and 8,9-dihydroxyoctadecanoic acids was obtained after (i) photosensitized oxidation of oleic acid (in pyridine in the presence of hematoporphyrin as sensitizer) (23), (ii) NaBH<sub>4</sub> reduction of the resulting 9-hydroperoxyoctadec-*trans*-10-enoic and 10-hydroperoxyoctadec-*trans*-8-enoic acids, (iii) hydrogenation of the corresponding allylic hydroxyacids, (iv) dehydration (overnight) of the mixture of 9- and 10-hydroxyoctadecanoic acids thus formed in benzene with *p*-toluenesulfonic acid as catalyst, and (v) subsequent OsO<sub>4</sub> treatment (24).

## RESULTS AND DISCUSSION

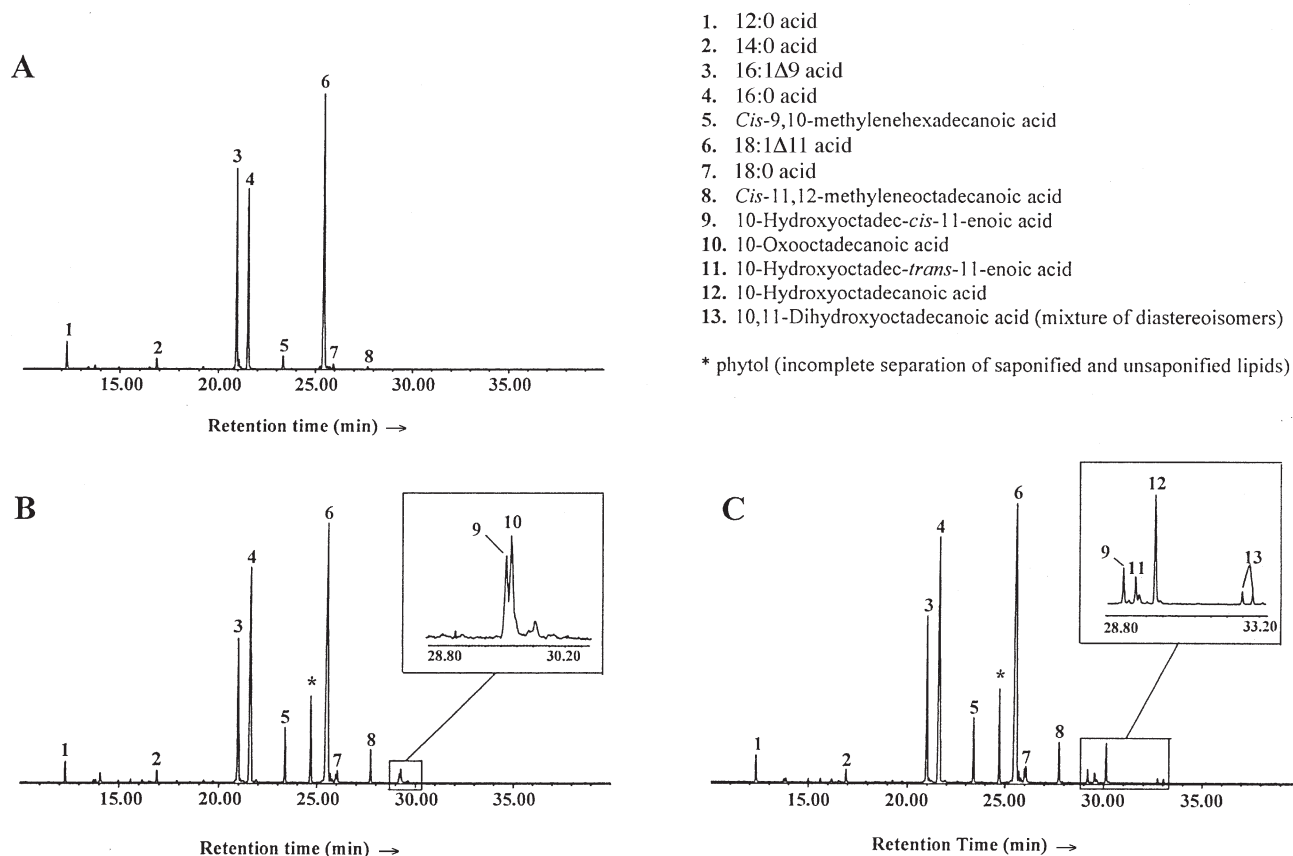

Purple sulfur bacteria generally constitute the most prominent anoxygenic phototrophs in microbial mats. Because of the fluctuating gradients of oxygen and sulfide in the mats, these organisms may be exposed to oxygen. It is well established that purple sulfur bacteria resident in microbial mats not only are oxygen tolerant but can also continue anoxygenic photosynthesis even under fully aerobic conditions. Some species are even capable of performing an aerobic mode of metabolism, either as chemoorganotrophs or chemolithotrophs (25,26). Consequently, we have compared the lipidic composition of healthy and senescent cells of *T. halophila* incubated under aerobic and anaerobic conditions.

The unsaponified lipidic fraction obtained after alkaline hydrolysis of cells of *T. halophila* grown under anaerobic

conditions is dominated by a single component, assigned by GC-EIMS as phytol. This isoprenoid alcohol arises from the hydrolysis of bacteriochlorophyll *a*, which constitutes with okenone the major photosynthetic pigments of this purple sulfur bacterium (13). Okenone, which was thought to be present in large amounts in this fraction, was not amenable to GC with the operating conditions described in the Experimental Procedures section. GC-EIMS analysis of the corresponding saponifiable fraction revealed the presence of 12:0, 14:0, 16:0, 16:1, 18:0, and 18:1 FA (Fig. 1A). To establish the position of the double bond in the monounsaturated FA, the saponified fraction was treated with DMDS (19). The position of the double bond was determined from the mass spectra of the DMDS derivatives on the basis of the fragments formed by cleavage between the carbons bearing the thioether groups. The main monounsaturated FA present in *T. halophila* are 16:1 $\Delta$ 9 and 18:1 $\Delta$ 11 FA. Comparison of their retention times with those of standards showed that these compounds are, respectively, palmitoleic and *cis*-vaccenic acids. This saponified fraction also contains small amounts of *cis*-9,10-methylenehexadecanoic and *cis*-11,12-methyleneoctadecanoic acids (Fig. 1A), formed by the addition of a methylene group across the double bond of palmitoleic and *cis*-vaccenic acids, respectively (27). These cyclopropane FA have been

differentiated from their corresponding olefinic isomers after catalytic hydrogenation (28).

The saponified and unsaponified fractions of healthy cells of *T. halophila* remained practically unchanged after incubation under aerobic conditions. In contrast, aerobic and anaerobic incubations of senescent cells of *T. halophila* resulted in a significant increase in the amounts of cyclopropane FA (Fig. 1). In most bacteria, the amount of cyclopropane FA depends very much on the growth conditions, and the level generally increases when the growth rate decreases (27). This statement is in good agreement with the increasing amounts of *cis*-9,10-methylenehexadecanoic and *cis*-11,12-methyleneoctadecanoic acids observed during the senescence of *T. halophila*. After aerobic incubation of senescent cells of *T. halophila*, some interesting additional peaks appeared in the total ion current chromatograms of the NaBH<sub>4</sub> reduced and nonreduced saponified fractions (peaks 9–13; Fig. 1). These new compounds were unambiguously identified by comparison of their retention times and EI mass spectra with those of suitable standards. Peaks 9 and 11 were, respectively, attributed to *cis*- and *trans*-10-hydroxyoctadec-11-enoic acids. The EI mass spectra of these silylated compounds exhibit a strong fragment ion at *m/z* 213 corresponding to the cleavage at the carbon bearing the –OSiMe<sub>3</sub> group (Fig. 2). Characterization

**FIG. 1.** Total ion chromatograms obtained after injection of saponified lipids of (A) healthy cells of *Thiohalocapsa halophila* incubated under anoxic conditions, (B) senescent cells of *T. halophila* incubated under oxic conditions for 10 d, and (C) senescent cells of *T. halophila* incubated under oxic conditions for 10 d and reduced with NaBH<sub>4</sub>.

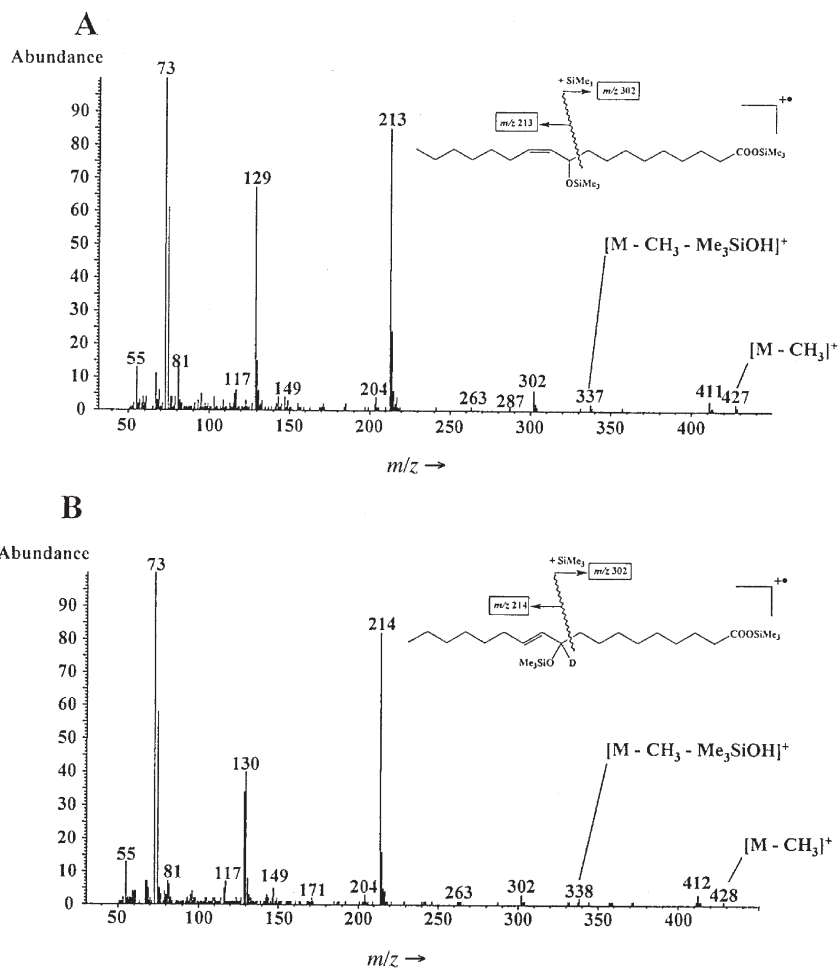

FIG. 2. Electron impact mass spectra of (A) 10-hydroxyoctadec-*cis*-11-enoic and (B) NaBD<sub>4</sub>-reduced 10-oxooctadec-*trans*-11-enoic acids (silylated).

of *cis* and *trans* isomers was based on comparison of their retention times with those of standard compounds. 10-Hydroxyoctadec-*trans*-11-enoic acid only appears if the samples are reduced with NaBH<sub>4</sub> before the alkaline hydrolysis (Fig. 1C), whereas the amount of 10-hydroxyoctadec-*cis*-11-enoic acids

increases slightly (25%) after this treatment (Figs. 1B,1C). Some attempts at reduction with NaBD<sub>4</sub> instead of NaBH<sub>4</sub> have been carried out in order to determine whether the additional production of hydroxyacids results from the reduction of the corresponding hydroperoxy- or oxoacids (Fig. 3). The

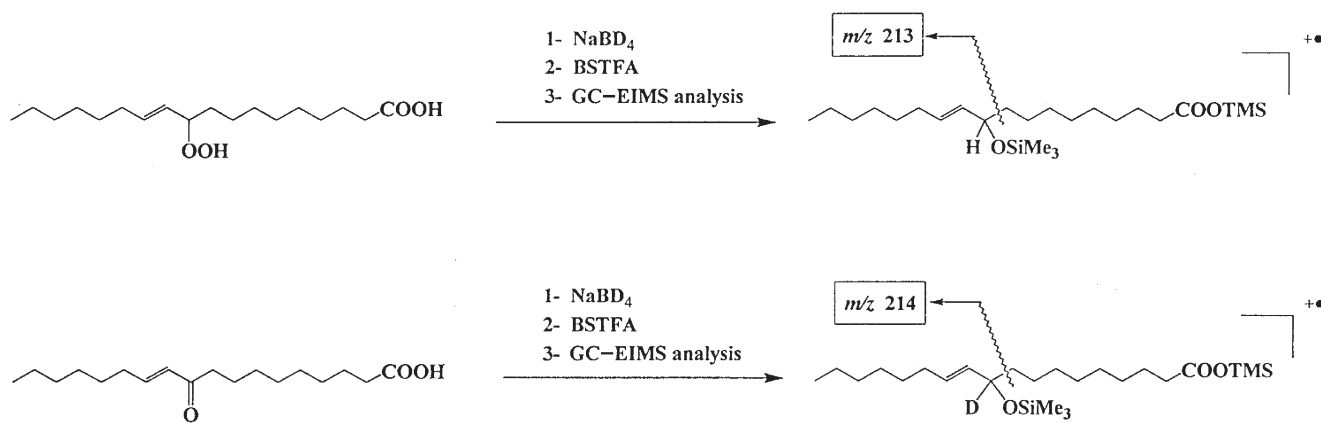

FIG. 3. Mass spectrometric characterization of hydroperoxy- and oxoacids after NaBD<sub>4</sub> reduction. BSTFA, bis(trimethylsilyl) trifluoroacetamide; TMS, trimethylsilyl.

results obtained with this deuterium labeling demonstrate that this additional production results from the reduction of the corresponding oxoacids (Fig. 2B). These oxoacids could not be directly characterized in nonreduced samples since they do not survive alkaline hydrolysis and are cleaved after hydration and retro-aldol reactions (21). Surprisingly, the original extracts of senescent cells of *T. halophila* contained 10-oxooctadec-*trans*-11-enoic, 10-oxooctadec-*cis*-11-enoic, and 10-hydroxy-octadec-*cis*-11-enoic acids.

Peak 10 (Fig. 1B) has been attributed to 10-oxooctadecanoic acid. The EI mass spectrum of this silylated compound (Fig. 4A) shows odd-electron fragment ions arising

from McLafferty rearrangement ( $m/z$  272, 156, and 58) and a prominent ion corresponding to  $\beta$ -cleavage relative to the keto group ( $m/z$  215) (28). This compound (which is not affected by alkaline hydrolysis) is quantitatively reduced to the corresponding hydroxyacid (peak 12; Fig. 1C) after  $\text{NaBD}_4$  treatment (Fig. 4B). It is interesting to note that peak 12 was lacking in the nonreduced extract (Fig. 1B).

Two peaks corresponding to diastereoisomeric 10,11-dihydroxyoctadecanoic acids appeared after  $\text{NaBH}_4$  reduction of the samples (peaks 13; Fig. 1C). The mass spectra of these compounds obtained after reduction with  $\text{NaBD}_4$  instead of  $\text{NaBH}_4$  provided a basis for demonstrating that they arise

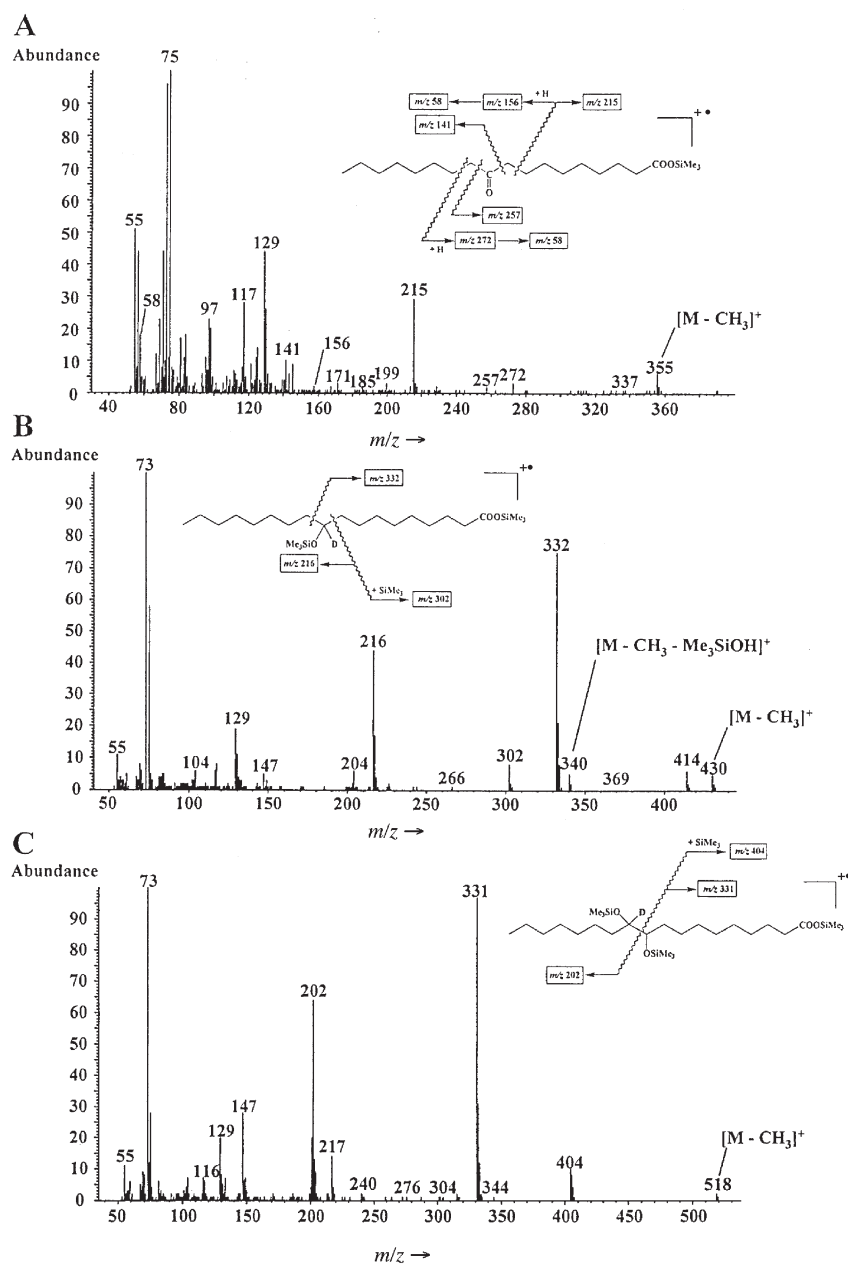

FIG. 4. Electron impact mass spectra of (A) 10-oxooctadecanoic, (B)  $\text{NaBD}_4$ -reduced 10-oxooctadecanoic, and (C)  $\text{NaBD}_4$ -reduced 10-hydroxy-11-oxooctadecanoic acids (silylated).

from the reduction of 10-hydroxy-11-oxooctadecanoic acid (Fig. 4C), which does not survive alkaline hydrolysis. It was previously demonstrated that an enzyme named hydroperoxide dehydrase catalyzes the conversion of 13- or 9-hydroperoxide of linoleic or linolenic acids to allene oxides (29), whose spontaneous nonenzymatic hydrolysis afforded  $\alpha$ -ketols (30). Although hydroperoxide dehydrase generally acts on hydroperoxides having a pair of conjugated double bonds (30), the specific formation of 10-hydroxy-11-oxooctadecanoic acid observed in the cells of *T. halophila* can be attributed to the dehydration of 10-hydroperoxyoctadec-11-enoic acid by a similar enzyme, followed by the nonenzymatic hydrolysis of the allene oxide thus formed (Fig. 5). This further suggests that the different oxidation products detected result from an initial peroxidation at C10 of *cis*-vaccenic acid.

Autoxidation of this acid yields mainly a mixture of *trans* 10-, *cis* 10-, *trans* 11-, *trans* 12-, *trans* 13- and *cis* 13-hydroperoxides, with minor amounts of *cis* 11- and *cis* 12-hydroperoxides (21), while its photosensitized oxidation produces a mixture of *trans* 11- and *trans* 12-hydroperoxides (31). Consequently, the specific oxidation at C10 of *cis*-vaccenic acid observed in senescent cells of *T. halophila* can be attributed to enzymatic peroxidation. It is generally considered that dioxygenases are not expressed in bacteria or yeast (32). However, Guerrero *et al.* (7) reported oxidation of oleic acid to 10-hydroperoxyoctadec-*trans*-8-enoic and 10-hydroxyoctadec-*trans*-8-enoic acids by *Pseudomonas* sp. 42A2. These authors also demonstrated that the conversion enzyme has dioxygenase activity. Our results suggest that such enzymes may also be present in some strains of purple sulfur bacteria.

A kinetic study of the production of *cis*-vaccenic acid oxidation products allowed us to show that this enzymatic process initially produces 10-hydroperoxyoctadec-*cis*-11-enoic acid, which in turn is converted to the different oxida-

tion products identified (Fig. 6). These compounds constitute 16% of the parent *cis*-vaccenic acid after incubation for 10 d. The dioxygenase catalyzing this peroxidation appeared to be highly regiospecific. Although the configuration of the carbon 10 of 10-hydroperoxyoctadec-*cis*-11-enoic acid has not been determined, one would expect that this enzyme introduces oxygen stereospecifically, forming only one of the possible optical isomers. Indeed, the formation of racemic products by dioxygenases is always accompanied by the occurrence of positional isomers (5), and such isomers are lacking in the different extracts analyzed. We could not find evidence of high amounts of intact hydroperoxides in the cells of *T. halophila*; this is not surprising since these compounds are not generally found in healthy plant cells. They are extremely cytotoxic and cause damage to membranes and proteins in particular (33). Several enzymatic processes causing further reactions of the hydroperoxides and inhibiting their accumulation have been previously described. These processes involve: (i) reduction to the corresponding hydroxyacids (33), (ii) homolytic cleavage of the O–O bond resulting in the formation of oxoacids (1), (iii) dehydration to allene oxides and subsequent hydrolysis of these unstable intermediates (29), and (iv) direct cleavage of the hydroperoxides to aldehydes and oxoacids (34).

The reduction of hydroperoxides of linoleic or linolenic acids to the corresponding hydroxyacids has been attributed to dioxygenase itself (33). The production of 10-hydroxyoctadec-*cis*-11-enoic acid in *T. halophila* cells may result from the reduction of the corresponding hydroperoxyacid by a similar enzyme (Fig. 5). The breakdown of hydroperoxy-polyenoic FA *via* the lipohydroperoxidase reaction affords oxopolyenoic FA (1). It is interesting to note that Clapp *et al.* (9) reported the soybean lipoxygenase-mediated oxygenation of monounsaturated FA to allylic oxoacids. These authors assume that the formation of such products may involve a typical

FIG. 5. Proposed pathways for the enzymatic oxygenation of *cis*-vaccenic acid in senescent cells of *T. halophila* incubated under aerobic conditions. For name see Figure 1.

**FIG. 6.** Partial total ion chromatograms obtained after injection of  $\text{NaBH}_4$ -reduced saponified lipids of (A) healthy cells of *T. halophila* incubated under oxic conditions for 10 d, (B) senescent cells of *T. halophila* incubated under oxic conditions for 2 d, and (C) senescent cells of *T. halophila* incubated under oxic conditions for 10 d (\* represents contaminants). The numbers refer to structures given in Figure 1. For name see Figure 1.

dioxygenation reaction to form an allylic hydroperoxide and its subsequent conversion to a ketone by loss of water. A similar conversion of 10-hydroperoxyoctadec-*cis*-11-enoic acids to the corresponding oxoacid seems to intervene in *T. halophila* cells (Fig. 5). As stated above, a small part of the 10-hydroperoxyoctadec-*cis*-11-enoic acid undergoes dehydration to allene oxide and spontaneous hydrolysis to 10-hydroxy-11-oxooctadecanoic acid. Hydroperoxide lyase catalyzes the cleavage of FA hydroperoxides into aldehydes and oxoacid fragments (35). Such an enzyme does not intervene in cells of *T. halophila*, since we failed to detect significant amounts of octanal and  $\text{C}_{10}$  oxoacid corresponding to the fragmentation of 10-hydroperoxyoctadec-*cis*-11-enoic acid.

As well as enzymatic conversion, the hydroperoxides formed may also undergo chemical decomposition under mild conditions. The majority of these decomposition reactions involve free radicals and are promoted by heat, photolysis, metal ions, and metalloproteins. The products of these reactions are similar to those of enzymatic transformations or are either homologs or isomers of the enzymatically produced compounds (33). The involvement of such abiotic processes during the degradation of 10-hydroperoxyoctadec-*cis*-11-enoic acid cannot be totally excluded.

The 10-oxooctadec-*cis*-11-enoic acid formed undergoes subsequent saturation to 10-oxooctadecanoic acid (Fig. 5). The saturation of unsaturated FA in the gut of some animals has long been recognized (36). This biohydrogenation is brought about by the mixed culture of rumen bacteria and

involves several enzyme-catalyzed steps. In the present case, the formation of 10-oxooctadecanoic acid can be attributed to the involvement of similar enzymatic processes. It was previously demonstrated that anaerobic incubation of oleic and elaidic acids with strained rumen contents lead to the formation of their saturated counterpart (stearic acid) and to a lesser extent to the isomerization of each monounsaturated FA to its geometric isomer (37). Consequently, the formation of 10-oxooctadec-*trans*-11-enoic acid may be attributed to the isomerization of its geometrical isomer during the biohydrogenation (Fig. 5).

The enzymatic oxygenation of PUFA is very specific with respect to the double bond position in the FA that is oxygenated (32,38). Although palmitoleic and *cis*-vaccenic acids both possess a *cis*-double bond located in position n-7, we detected only trace amounts of compounds resulting from the oxidation of the carbon 8 of palmitoleic acid after aerobic incubation of senescent cells of *T. halophila*. The enzyme catalyzing the oxygenation of monounsaturated FA seems to have a strong affinity toward the *cis*-vaccenic acid. This process, which is induced during senescence, acts during dark and illuminated aerobic incubation of cells of *T. halophila*.

It is interesting to note that we failed to detect the different compounds deriving from the enzymatic oxygenation of the allylic carbon 10 of *cis*-vaccenic acid in senescent cells of *Halochromatium glycolicum* DSM 11080 and *Halochromatium salexigens* DSM 4395, which constitute the halophilic *Chromatiaceae* most closely related phylogenetically to *T. halophila* (39). These compounds could thus constitute potential *T. halophila* biomarkers. Some of these markers could notably facilitate determining the presence of this purple sulfur bacterium in modern and perhaps also in ancient ecosystems.

## ACKNOWLEDGMENTS

Thanks are due to Drs. Pierre Caumette and Robert Matheron for their generous gift of the strains *H. glycolicum* DSM 11080, *H. salexigens* DSM 4395, and *T. halophila* DSM 6210. We also thank Michael Paul for his careful reading of the English. This work was supported by grants from the MATBIOPOL European Project (contract EVK3-CT-1999-00010).

# Dietary Fish Oil and Vitamin E Enhance Doxorubicin Effects in P388 Tumor-Bearing Mice

Qi-Yuan Liu and Benny K.H. Tan\*

Department of Pharmacology, Faculty of Medicine, National University of Singapore, Singapore 117597, Republic of Singapore

**ABSTRACT:** In this study, four kinds of rodent diets, CO, FO, CVe, and FVe, were used by addition of canola oil, oil mixture (fish oil + canola oil), canola oil plus vitamin E, and oil mixture plus vitamin E, respectively, to a basic diet, AIN-93G, to investigate the influence of dietary fish oil and vitamin E on doxorubicin (DOX) treatment in P388 ascitic mice. Animal life span (LS) and heart damage were recorded in mice fed the four different diets and treated with different doses of DOX. The optimal doses of DOX for antitumor effect as manifested by increased LS were 6.0 and 9.0 mg/kg. Both fish oil and vitamin E significantly enhanced this effect. On the other hand, DOX at 12.0 mg/kg induced severe heart damage, which was also significantly aggravated by both fish oil and vitamin E, as shown by both decreased LS and increased serum creatine phosphokinase activity. Fish oil and vitamin E appeared to enhance the antitumor effect of optimal doses of DOX but to aggravate cardiotoxicity owing to DOX overdose.

Paper no. L8891 in *Lipids* 37, 549–556 (June 2002).

The effects of PUFA on tumor development and tumor growth have been intensively investigated in both animal models and humans in the past two decades. Although rigid scientific proof has yet to be obtained, it is generally believed that n-6 PUFA in terrestrial plant oils enhance tumor growth, but n-3 PUFA in fish oil have a protective effect (1). Furthermore, two long-chain n-3 PUFA that are found in significant amounts in fish oil, *viz.*, EPA (20:5n-3) and DHA (22:6n-3), may exert multiple activities to retard the growth of tumor cells and xenografts (2,3). On the other hand, it is known that certain physical and functional properties of cell membranes can be modified when PUFA content is changed, and lipid nutrition directed at producing this modification has been suggested in cancer therapy (4). By altering the properties of membrane lipids, FA-based diets may provide a new approach for enhancing the effectiveness of certain antineoplastic therapies.

Vitamin E (vit E) includes eight naturally occurring compounds of two classes, tocopherols and tocotrienols, with different biological activities. Tocopherols are the most important chain-breaking antioxidants within cellular membranes, mainly owing to their ability to donate phenolic hydrogens to lipid free radicals (5). They are present in oily seeds, leaves, and other

Abbreviations: CPK, creatine phosphokinase; DOX, doxorubicin; HNE, 4-hydroxynonenal; LS, life span; MDA, malondialdehyde, vit E, vitamin E.

green parts of higher plants. It is generally agreed that the relative antioxidant activity of the tocopherols *in vivo* is in the order of  $\alpha > \beta > \gamma > \delta$  (6). In addition to their antioxidant property, tocopherols and their derivatives have been reported to have pro-oxidant properties in some biological systems (7,8).

Doxorubicin (DOX) has been widely used in the treatment of a variety of solid tumors and hematological malignancies. Several of its biological effects are supposedly derived from its quinone moiety acting as an alkylating/aryllating electrophile or a pro-oxidant. The quinone structure permits DOX to act as an electron acceptor in reactions mediated by oxoreductases, such as cytochrome P450 reductase (9), NADH dehydrogenase (10), and xanthine oxidase (11), to convert the quinone to a semiquinone free radical. Under anaerobic conditions, the semiquinone undergoes further reduction accompanied by reductive cleavage of the sugar residue to generate a quinone methide, which binds covalently to nucleophiles and is known to form adducts with DNA (12). In the presence of O<sub>2</sub>, however, this semiquinone radical is spontaneously and rapidly reoxidized in a process that generates a superoxide radical (13). The superoxide radical and its dismutation product, hydrogen peroxide, undergo Haber–Weiss and Fenton reactions, respectively, to form the hydroxyl radical, which is able to extract a doubly allylic hydrogen atom from PUFA and thus initiate lipid peroxidation (14). The nonenzymatic formation of reactive oxygen species is mediated by the formation of complexes between DOX and iron, which can either react with O<sub>2</sub> to yield superoxide radical and hydrogen peroxide or bind O<sub>2</sub> in a superoxo- or peroxo-like form (15). Despite its antitumor effect, clinical effectiveness of DOX is hindered by its unique dose-limiting cardiotoxicity (16), possibly because of the sensitivity of the heart to reactive free radicals, due to a low activity of antioxidant enzymes (17). Separate studies, however, have found both effectiveness (18,19) and ineffectiveness (20) of vit E in cardioprotection in DOX-treated animals.

In this study, we prepared four experimental diets by adding natural oils to the basic components of AIN-93G, a purified diet for laboratory rodent growth (21). These diets differed in their contents of n-3 PUFA and tocopherols. We tested their effects on the therapeutic efficacy of various doses of DOX in mice induced with P388 ascitic tumor [which is the standard transplantable murine tumor most sensitive to DOX (18)], recording life span (LS) of the tumor-bearing mice, and examining animal heart damage by measurement of serum creatine phosphokinase (CPK) level (a biochemical marker of animal myocardial damage).

## EXPERIMENTAL PROCEDURES

**Cell lines and chemicals.** The P388 cell line was obtained from ATCC (American Type Culture Collection, Manassas, VA), and the cells were grown in DBA/2 mice for one generation before use in the following animal experiments. All chemicals were purchased from Sigma-Aldrich (St. Louis, MO) unless otherwise stated.

**Diets.** Four experimental diets with AIN-93G as a base food were prepared by Specialty Feed Service (Glen Forest, Australia) as follows: (i) CO: AIN-93G + 10% canola oil; (ii) FO: AIN-93G + 8.5% fish oil + 1.5% canola oil; (iii) CVe: AIN-93G + 500 mg/kg natural vit E + 10% canola oil; (iv) FVe: AIN-93G + 500 mg/kg natural vit E + 8.5% fish oil + 1.5% canola oil.

Canola oil, a favorable dietary oil, is an appropriate control to use to study the effect of long-chain n-3 PUFA in fish oil because it contains a relatively high proportion of linoleic acid (18:2n-6) and  $\alpha$ -linolenic acid (18:3n-6), and a low proportion of EPA and DHA. Canola oil (1.5%) was added to fish oil (8.5%) in FO and FVe diets in order to increase linoleic acid content to above 1%, which is the requirement for optimal rodent growth. The FA composition of the four diets is shown in Table 1. Total n-6 PUFA content was similar in the four diets, whereas n-3 PUFA contents, particularly EPA and DHA, were greater in FO and FVe than in CO and CVe. On the other hand,

**TABLE 1**  
**FA Composition in Four Experimental Diets<sup>a</sup>**

<sup>a</sup>Diet CO, AIN-93G + 10% canola oil; FO, AIN-93G + 8.5% fish oil + 1.5% canola oil; CVe, AIN-93G + 500 mg/kg natural vitamin E + 10% canola oil; FVe, AIN-93G + 500 mg/kg natural vitamin E + 8.5% fish oil + 1.5% canola oil; ND, not detected.

<sup>b</sup>SFA, saturated FA; MUFA, monounsaturated FA.

<sup>c</sup>"Average double bond" means average number of double bonds per molecule of FA.

AIN-93G basic diet contains 75 mg/kg *d*- $\alpha$ -tocopherol acetate (21). The natural vit E used in our experiments is a mixed tocopherol concentrate, Covi-ox<sup>®</sup> T-70 (Cognis Nutrition & Health, Broadmeadows, Victoria, Australia), with relative amounts of  $\alpha$ - (14%),  $\beta$ - (1%),  $\gamma$ - (62%), and  $\delta$ -tocopherols (23%). Five hundred milligrams of Covi-ox<sup>®</sup> T-70 contains 350 mg of total tocopherols. According to the manufacturer (Specialty Feed Service, Glen Forest, Australia), canola oil contained 330, 16, 846 and 56 mg/kg of  $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\delta$ -tocopherols, respectively, whereas fish oil contained 340 mg/kg of  $\alpha$ -tocopherol only. The calculated contents of individual vit E species in four diets are shown in Table 2, indicating that CVe and FVe contained a significantly higher content of all tocopherol species compared to CO and FO, respectively.

Comparisons between CO and FO and between CVe and FVe were made to evaluate the effect of fish oil, whereas comparisons between CO and CVe and between FO and FVe were made to examine the effect of vit E on tumor-bearing or normal mice with or without DOX treatment.

**Measurements of LS.** All experiments with animals were conducted according to guidelines in "International Guiding Principles for Animal Research," *WHO Chronicles*, Vol. 39, 1985. Male BDF1 mice purchased from Animal Resources Center (Canning Vale, Western Australia) were used at 6–8 wk of age when their body weights ranged between 19.0 and 21.0 g. The animals were kept in filter-covered plastic cages, housed in a temperature-controlled room with a diurnal 12 h light cycle, and provided with tap water and the assigned experimental diets *ad libitum* for 10 d prior to experimentation and continuously thereafter. This period of time was found to be sufficient to modify the PUFA composition of phospholipids in most organs to stable levels in mice (22). The animals were inoculated intraperitoneally on day 0 with P388 cells ( $10^6$  cells/mouse), followed by injection of DOX or saline also intraperitoneally on days 1 and 6. Deaths among the experimental animals were recorded at least twice a day.

**Determination of DOX cardiotoxicity.** In the second experiment, the BDF1 mice were maintained, fed, and administered DOX or saline as described above without the inoculation of tumor cells. The animals were killed on day 7 by cervical dislocation, blood was collected by cardiac puncture, and serum was obtained after the clotting of blood at room temperature for 1 h. Serum was kept frozen ( $-76^{\circ}\text{C}$ ) until analysis. Cardiotoxicity was determined by measuring serum CPK activity, calculated according to the Sigma Diagnostics Procedure No. 47-UV. A

**TABLE 2**  
**Vitamin E Content (mg/kg) in Four Experimental Diets<sup>a</sup>**

Species of vitamin E	CO	FO	CVe	FVe
$\alpha$ -Tocopherol acetate	75	75	75	75
$\alpha$ -Tocopherol	33	33.9	82	82.9
$\beta$ -Tocopherol	1.6	0.2	5.1	3.7
$\gamma$ -Tocopherol	84.6	12.7	301.6	229.7
$\delta$ -Tocopherol	5.6	0.8	86.1	81.3
Total	200	122.2	549.8	472.6

<sup>a</sup>For description of diets see Table 1.

CPK Test kit (CK-20; Sigma Chemical Co.) based on the method described by Szasz *et al.* (23) was used in the study.

*Lipid analysis of P388 ascitic tumor cells and cardiac tissue.* In the third experiment, BDF1 mice were fed experimental diets 10 d prior to the experimentation and thereafter. P388 cells ( $10^7$  cells/mouse) were intraperitoneally inoculated into animals on day 0. On day 7, the mice were killed by cervical dislocation. The hearts were collected and ascitic tumor cells obtained by lavage of the peritoneum with ice-cold saline. The tumor cells were pelleted at  $700 \times g$  for 5 min and washed twice with the same buffer solution. Total lipid was extracted using a method described by Folch *et al.* (24). The phospholipid fraction was separated by silicic acid chromatography (25), saponified in alkali (26), and methylated with  $\text{BF}_3/\text{methanol}$  (27). The fractions of FAME with different chain lengths and unsaturations were separated in a Hewlett-Packard 5890 gas chromatograph using a DB-225 column (J&W Scientific, Folsom, CA). Peaks were identified by comparison with the retention times of known standards and peak areas quantified.

*Statistical analysis.* Data were analyzed by Student's *t*-test or ANOVA as shown in the text and the legends for the tables and figures. Experimental data are shown as mean  $\pm$  SD.  $P < 0.05$  was set as the level of significance throughout the study.

Fish oil $\times$ vit E	0.601	

<sup>a</sup>Canola oil served as the control for fish oil. Column P0 considers data on the LS of animals without doxorubicin (DOX) treatment; P12, with 12.0 mg/kg DOX treatment; and P6,9, with 6.0 and 9.0 mg/kg DOX treatment; n, number of mice; vit E, vitamin E.

## RESULTS

*LS of P388 ascitic mice.* The individual LS of P388 ascitic mice fed the four experimental diets and administered vari-

**FIG. 1.** Effects of different doses of doxorubicin (DOX) and experimental diets on life span (LS) of P388 ascitic mice. Each column represents the LS of one animal, whereas the value above the cluster of columns represents the mean LS in each group. \* $P < 0.05$  represents the difference between the saline and DOX-treated groups on the same diet (Student's *t*-test). Diets: CO, AIN-93G + 10% canola oil; FO, AIN-93G + 8.5% fish oil + 1.5% canola oil; CVe, AIN-93G + 500 mg/kg natural vitamin E + 10% canola oil; FVe, AIN-93G + 500 mg/kg natural vitamin E + 8.5% fish oil + 1.5% canola oil.

**FIG. 2.** Effects of fish oil and vitamin E (vit E) on LS of P388 ascitic mice treated with various doses of DOX. The values outside and inside the parentheses at each point represent the mean LS and number of animals, respectively, in the group. (A) Effect of fish oil; (B) effect of vit E. Canola oil served as the control for fish oil. For abbreviations see Figure 1.

ous doses of DOX are shown in Figure 1. The results of statistical analyses of the data are shown in Figures 1 and 2 and Table 3. In the absence of DOX treatment, vit E supplement increased the mean LS from 17.7 to 18.8 d ( $P = 0.010$ , two-way ANOVA) (Fig. 2B, Table 3). Both 6.0 and 9.0 mg/kg DOX significantly increased animal LS in all diet groups ( $P < 0.05$ , Student's *t*-test) (Fig. 1), but there was no significant difference ( $P = 0.262$ , multiway ANOVA) in therapeutic efficacy between these two doses (Table 3). Both fish oil and vit E, however, were found to significantly enhance the effect of DOX at these doses ( $P = 0.025$  and  $<0.001$ , respectively, multiway ANOVA) (Table 3). Fish oil increased the mean LS from 40.8 to 49.6 d in mice treated with 6.0 mg/kg DOX and from 43.6 to 58.3 d in mice treated with 9.0 mg/kg DOX (Fig. 2A). Vit E increased the mean LS from 33.8 to 56.6 d in mice treated with 6.0 mg/kg DOX and from 40.5 to 61.4 d in mice treated with 9.0 mg/kg DOX (Fig. 2B). When DOX dose was increased to 12.0 from 9.0 mg/kg, animal LS was significantly decreased ( $P < 0.001$ , multiway ANOVA followed by Tukey's test for DOX only), suggesting the negative effect of DOX at this high dose. Both fish oil and vit E significantly aggravated this negative effect ( $P = 0.018$  and  $0.023$ , respectively, two-way ANOVA) (Table 3), with fish oil decreasing the mean LS from 28.2 to 20.8 d (Fig. 2A), and vit E decreasing the mean LS from 28.0 to 21.0 d (Fig. 2B).

**DOX-induced CPK activity.** The experimental data of plasma CPK levels in mice fed the four experimental diets and treated with various doses of DOX are shown in Table 4, part A. The results of statistical analysis on the data are shown in Table 4, part B, and Figure 3. DOX increased plasma CPK activity dose-dependently (Table 4). Two-way ANOVA (Table 4) showed that vit E inhibited plasma CPK activity in mice without DOX (decrease of 0.3 unit/mL serum;  $P < 0.001$ ) or with 6.0 mg/kg DOX (decrease of 0.3 unit/mL serum;  $P = 0.007$ ) but did not significantly modify CPK activity with 9.0 mg/kg DOX. In contrast, vit E enhanced CPK activity in the presence

of 12.0 mg/kg DOX (increase of 0.7 unit/mL serum;  $P = 0.002$ , two-way ANOVA). On the other hand, fish oil increased DOX-induced CPK activity to an extent proportional to DOX dose (increases of 0, 0.3, 0.6, and 1.5 unit/mL serum in 0, 6.0, 9.0, and 12.0 mg/kg DOX-treated mice with  $P = 0.935$ , 0.005,  $<0.001$ , and  $<0.001$ , respectively, two-way ANOVA) (Fig. 3).

**FA composition of ascitic tumors and animal hearts.** Lipid analysis of the FA composition in phospholipids indicated that n-6 PUFA content was comparable in both P388 ascitic tumor and mouse heart of all four groups, whereas n-3 PUFA as well as total PUFA content was significantly larger in both tissues of FO- and FVe-fed mice than those in CO- and CVe-fed mice

**TABLE 4**  
Effects of Fish Oil and Vit E on CPK Activity in Mice Treated with Various Doses of DOX<sup>a</sup>

Diet	DOX (mg/kg)			
	0	6.0	9.0	12.0

Fish oil × vit E	0.142	0.456	0.965	0.687

<sup>a</sup>The experimental data are shown as mean ± SD of six determinations on the samples obtained from four mice in each diet group. Canola oil served as the control of fish oil. Column *P*0 considers the data on groups given saline treatment; *P*6, with 6.0 mg/kg DOX treatment; *P*9, with 9.0 mg/kg DOX treatment; and *P*12, with 12.0 mg/kg DOX treatment. *n*, number of determinations.

<sup>b</sup>Multiway ANOVA followed by Tukey's test for DOX only,  $P < 0.001$  for 0 vs. 6.0 mg/kg,  $P < 0.001$  for 6.0 vs. 9.0 mg/kg, and  $P < 0.001$  for 9.0 vs. 12.0 mg/kg. For description of diets see Table 1. For abbreviations see Table 3.

**FIG. 3.** Effects of fish oil/vit E interactions with DOX on CPK activity in normal mice. The value at each point represents the mean CPK activity from 12 determinations on the samples from eight mice in each group. (A) Effect of fish oil; (B) effect of vit E. Canola oil served as the control for fish oil. CPK, creatine phosphokinase; for other abbreviations see Figures 1 and 2.

**FIG. 4.** Effects of experimental diets on PUFA in phospholipids of P388 ascitic tumor and mouse heart. (A) P388 ascitic tumor; (B) animal heart. The columns represent mean  $\pm$  SD from five separate determinations on samples from three mice in each group. For diets see Figure 1. Key: n-3 PUFA, bars with stippling; n-6 PUFA, bars with vertical and horizontal lines.

(Fig. 4). The increased content of n-3 PUFA in FO and FVe groups can be attributed largely to EPA and DHA (data not shown), both of which were present in large amounts in FO and FVe diets.

## DISCUSSION

Four AIN-93G-based rodent diets, CO, FO, CVe, and FVe, were designed for this study. CO and CVe contained 10% canola oil, whereas FO and FVe contained 8.5% fish oil plus 1.5% canola oil. CVe and FVe additionally included 500 mg/kg natural vit E. FO and FVe with CO and CVe as their respective controls were used to investigate the effect of fish oil, and CVe and FVe with CO and FO as their respective controls were applied to assess the effect of vit E.

This study demonstrated the therapeutic effect of vit E in P388 mice (6.2% increase in mean LS;  $P = 0.010$ , two-way ANOVA). This was consistent with the previous reports of tumor inhibitory and chemopreventive effects of tocopherols

(28–30). Vit E may inhibit tumor growth *via* the cytotoxic effects of tocopherols and their derivatives (31–33), induction of apoptosis through activation of P21<sup>WAF1/CIP1</sup> (34), reduction of prostaglandin E<sub>2</sub> production (35), and abatement of muscle wasting in cancer cachexia (36).

In the present study, the optimal DOX antitumor effect was observed at 6.0 and 9.0 mg/kg doses. When DOX dose was increased to 12.0 mg/kg, the animal LS significantly decreased, indicating that DOX at this high dose produced a severe negative effect. The major negative effect of DOX might be its cardiotoxicity, as it was shown that serum CPK activity increased dose-dependently. Transmission electron microscopy also demonstrated that DOX at 12.0 mg/kg induced myofibrillar fragmentation and damaged mitochondria in the heart (data not shown).

The effects of DOX at various doses were modified by both fish oil and vit E. Fish oil not only significantly enhanced 6.0 and 9.0 mg/kg DOX therapeutic efficacy in P388 ascitic mice (21.6 and 33.7% increases in mean LS, respectively;

$P = 0.025$ , multiway ANOVA) but also elevated mouse plasma CPK level to an extent proportional to the DOX dose administered, implying that fish oil might enhance DOX cytotoxicity in both tumor cells and heart. The chemistry of DOX lends itself to enzymatic and nonenzymatic generation of superoxide radical and the secondary reactive oxygen species derived from superoxide, including hydrogen peroxide and hydroxyl radical (10,14). The hydroxyl radical is able to extract a doubly allylic hydrogen atom from the unsaturated lipids to form lipid radicals (37), which may react quickly with  $O_2$  to form lipid peroxy radicals that in turn produce lipid endoperoxides (37), or else initiate the lipid peroxidation cycle, converting other unsaturated lipids into lipid hydroperoxides (38). A number of lipid endoperoxides and hydroperoxides and their aldehyde derivatives have been implicated as causative agents for cytotoxic processes in cells (39). Lipid peroxidation has been suggested to be the cause of DOX cytotoxicity in both tumor (40) and heart tissue (41). The increased membrane lipid unsaturation would consequently provide more targets for peroxidative events generated by the metabolism of DOX, thus increasing the cytotoxicity to tissues. On the other hand, the interaction between fish oil and DOX cytotoxicity might also occur through the enhancement of DOX accumulation owing to the increased membrane lipid unsaturation and thus fluidity (4,42). The lipid analysis in the present study showed that PUFA content (an index of cell membrane unsaturation) was increased in both ascitic tumor and animal heart in mice fed FO and FVE, suggesting the possibility that dietary fish oil could directly enhance DOX-induced lipid peroxidation as well as elevate intracellular DOX accumulation in both tumors and heart. Although fish oil markedly exacerbated 12.0 mg/kg DOX cardiotoxicity and abolished the DOX therapeutic effect, the increased LS was achieved when DOX was administered at optimal doses, i.e., tumor inhibition could be achieved with DOX at optimal doses while deleterious effects on the heart occurred only with DOX overdose. This suggests that heart and tumor may have differential responses to the interaction of fish oil and DOX and/or differential sensitivities to the cytotoxicity induced by DOX combined with fish oil.

Vit E seemed to have an inhibitory effect on 6.0 mg/kg DOX-induced CPK release. Many studies found that vit E injection protected against DOX cardiotoxicity (18,19). The cardioprotective effect was achieved in the present study by dietary vit E. The scavenging activity of vit E on lipid peroxidation has been proposed to account for the cardioprotective effect of DOX in DOX-treated animals (18,19), although mechanism(s) other than its antioxidant activity might also contribute to the cardioprotection (43). On the other hand, vit E has been reported to directly enhance the inhibitory effect of DOX on tumor growth (34), and this may partly explain the enhanced therapeutic effectiveness of 9.0 mg/kg DOX. It is thus possible that vit E might enhance the therapeutic efficacy of DOX at optimal doses *via* cardioprotection and/or enhancement of tumor growth inhibition.

Through a synergistic interaction between tocopherols and

overdose DOX, vit E supplement aggravated 12.0 mg/kg DOX cardiotoxicity and thus decreased animal LS (25%;  $P = 0.023$  in two-way ANOVA). Tocopherols transform to chromanoxyl radicals in the scavenging of lipid radicals. In the absence of adequate reductants, such as ascorbic acid, the chromanoxyl radicals will be irreversibly degraded to tocopheryl quinones (44), which are able to initiate and/or enhance lipid peroxidation (6). Owing to the potential pro-oxidant activity of vit E, it may interact synergistically with DOX to produce reactive free radicals and induce lipid peroxidation. Overdose DOX treatment produces oxidative stress, which may overwhelm and/or reduce the antioxidant capability in cells. In the absence of an efficient antioxidant apparatus, such as in the heart, the reactive oxygen metabolites of tocopherols, together with DOX, engender the production of vast amounts of oxygen free radicals, thereby causing extreme cytotoxicity to cells through drastically increased lipid peroxidation.

It thus seems that, at least in animals, vit E may express antioxidant or other activities to protect against heart damage when combined with DOX at optimal doses, but produce a pro-oxidant effect to enhance DOX-induced cardiotoxicity when combined with overdose DOX. This may explain why, in some studies, vit E was reported to be ineffective in cardioprotection (20) or even to be deleterious to the heart of DOX-treated animals (45). Another point to note is that, although  $\alpha$ -tocopherol content was similar between fish oil and canola oil, the latter had a greater  $\gamma$ -tocopherol content than fish oil. However, fish oil but not canola oil enhanced the therapeutic efficacy of DOX, implying that  $\alpha$ -tocopherol, but not  $\gamma$ -tocopherol, may be the dominant species of vit E with respect to its activity. This is consistent with the fact that  $\alpha$ -tocopherol has both a higher (absolute value) tissue distribution (46) and a higher antioxidant activity (6) than  $\gamma$ -tocopherol.

In addition, the function of both PUFA and tocopherols as alkylating/aryllating agents is known to account for some of their biological effects. The electrophiles generated from lipid peroxidation, such as malondialdehyde (MDA) and 4-hydroxynonenal (HNE), may react with DNA bases. MDA modifies purine bases to generate a tricyclic adduct with guanine (47) and an acyclic adduct with adenine (48). HNE reacts directly with 2'-deoxyguanosine to produce a tricyclic substituted propane adduct and is readily oxidized to the epoxide derivative, which can covalently modify both 2'-deoxyguanosine and 2'-deoxyadenosine to form etheno adducts (49). Failure to repair these DNA lesions can lead to apoptosis (50). On the other hand,  $\gamma$ - and  $\delta$ -tocopherol quinones generated from  $\gamma$ - and  $\delta$ -tocopherols, respectively, are cytotoxic aryllating electrophiles because they contain an  $\alpha,\beta$  unsaturated carbonyl structure that forms Michael adducts with compounds containing a thiol nucleophilic group, such as glutathione and proteins (51). Whether treatment with PUFA, tocopherols, and DOX leads to the interactions through their alkylating/aryllating activities and thereby enhances therapeutic efficacy remains to be studied.

Animal xenograft studies found that human lung cancer (52) and mammary carcinoma (53) in nude mice showed a greater sensitivity to DOX when the mice were fed fish oil.

Furthermore, the present work comprehensively investigated the influence of dietary fish oil and vit E, individually and in combination, on the therapeutic efficacy of DOX and has shown their additively enhancing effects on optimal doses of DOX in P388 ascitic mice. Increasing DOX dose, however, led to severe heart damage, which was exacerbated by fish oil and vit E. Thus overall, it appears that both fish oil and vit E modulate the effects of DOX in the laboratory mouse like a double-edged sword, on the one hand enhancing its antitumor effect and on the other, aggravating its cardiotoxicity.

## ACKNOWLEDGMENTS

This work was supported by a Research Grant from the National University of Singapore (No. R-184-000-018-112). The authors thank Annie Hsu for technical assistance in animal experiments and Frances Lim for her help in the use of the gas chromatograph for the estimation of FAME.

**ABSTRACT:** Biological therapies are new additions to breast cancer treatment. Among biological compounds,  $\beta$ -carotene has been reported to have immune modulatory effects, in particular, enhancement of natural killer cell activity and tumor necrosis factor- $\alpha$  production by macrophages. The objective of this study was to investigate the effect of palm carotene supplementation on the tumorigenicity of MCF-7 human breast cancer cells injected into athymic nude mice and to explore the mechanism by which palm carotenes suppress tumorigenesis. Forty-eight 4-wk-old mice were injected with  $1 \times 10^6$  MCF-7 cells into their mammary fat pad. The experimental group was supplemented with palm carotene whereas the control group was not. Significant differences were observed in tumor incidence ( $P < 0.001$ ) and tumor surface area and metastasis to lung ( $P < 0.005$ ) between the two groups. Natural killer (NK) cells and B-lymphocytes in the peripheral blood of carotene-supplemented mice were significantly increased ( $P < 0.05$  and  $P < 0.001$ , respectively) compared with controls. These results suggest that palm oil carotene is able to modulate the immune system by increasing peripheral blood NK cells and B-lymphocytes and suppress the growth of MCF-7 human breast cancer cells.

Paper no. L8967 in *Lipids* 37, 557–560 (June 2002).

Cancer of the breast is the most common cancer and cause of death from cancer in women. An estimated 570,000 cases occurred in 1999, accounting for 9% of all new cases of cancer (1). The development of effective biological agents for prevention and treatment of breast cancer is under intense investigation. Naturally occurring agents such as carotenoids and retinoids and their derivatives are appealing biological agents. Unrefined palm oil represents the richest natural source of carotenoids with  $\alpha$ - and  $\beta$ -carotene being the major components (2). Carotenoids have been proposed as cancer-preventive agents (3). *In vitro* studies showed that carotenoids, especially lycopene and  $\alpha$ -carotene, have antioxidant and antiproliferative properties that are thought to be responsible for the anticancer effects of carotenoids (4,5). Carotenoid-induced enhancement of immune functions has been investigated in some experimental studies using animal models. Beneficial

effects of  $\beta$ -carotene have been demonstrated on T- and B-cell proliferation, number of T-helper cells, and cytotoxicity of natural killer cells (6). Fernandes *et al.* (7) studied the effects of  $\beta$ -carotene on the activity of natural killer (NK) cells in athymic nude mice. The results showed a significant modulation of NK cell activity in these mice.

This study was designed to explore the effect of palm carotene supplementation on breast cancer tumorigenicity and changes in the immune status of nude mice.

## MATERIALS AND METHODS

Female athymic nude mice (NCRnu/nu), 3- to 4-wk old, were housed under pathogen-free conditions in microisolators. The care and treatment of the experimental animals conformed to the guidelines of the Institute for Medical Research for the ethical treatment of laboratory animals. Mice were obtained from the Institute for Medical Research, Kuala Lumpur. Both the control and the experimental groups were fed a commercial mouse pellet diet; the only difference in their diets was that mice in the experimental group were supplemented with 1000 ppm of carotene emulsion, which was provided daily as drinking water for the 20 wk of the experiment.

*Experimental procedure.* The mice were anesthetized with Phenobarbital and a 50- $\mu$ L volume of inoculum containing  $1 \times 10^6$  MCF-7 (human breast cancer) cells was injected into a right-sided thoracic mammary fat pad (mfp) that had been exposed by a small incision (5 mm). The mice were weighed and palpated at weekly intervals. At necropsy, body and tumor weights were determined, and the extent of lung metastases was assessed.

*Isolation of mouse peripheral blood leukocytes.* Mice were sacrificed and blood was collected through heart puncture in heparinized tubes. The blood was spun at  $900 \times g$  for 5 min at 4°C. The plasma was removed, and the red blood cells were lysed by addition of 900  $\mu$ L of sterile water for 30 s followed by addition of  $10 \times$  PBS. The tubes were inverted three or four times and leukocytes were recovered by centrifugation at  $900 \times g$  for 5 min. The cells were resuspended with 1 mL of cold fluorescence-activated cell sorter (FACS 1% BSA in PBS with 0.1% sodium azide; Becton Dickinson, San Jose, CA) blocking buffer. The tubes were again centrifuged at  $900 \times g$  for 5 min. The supernatant was discarded, and the cells

were resuspended in cold FACS blocking buffer and aliquoted appropriately for staining with conjugated antibodies for flow cytometer analysis.

**Flow cytometer assay.** Appropriately diluted conjugated antibodies [antimouse CD2 (stains T-cells and NK cells), antimouse CD19 (stains B-lymphocytes), antimouse  $\gamma\delta$  T-cell receptor (TCR: stains T-lymphocytes), and antimouse Pan NK (stains NK cells); Pharmingen, San Diego, CA] were added to the corresponding blood samples and mixed. After 45 min incubation on ice in the dark, 1 mL of FACS (0.1% BSA and 0.1% sodium azide) wash buffer was added to each tube. The cells were recovered by centrifugation ( $900 \times g$  for 5 min at  $4^\circ\text{C}$ ) and resuspended in 400  $\mu\text{L}$  of FACS fix Solution 1 (1% BSA and 0.1% sodium azide), and 400  $\mu\text{L}$  of FACS fix Solution 2 (4% formalin in PBS) was added. The cells were mixed thoroughly and analyzed on Becton-Dickinson cell sorter Cell-Quest software. For each sample 10,000 cells were collected for analysis.

**Carotene analysis.** The  $\alpha$ - and  $\beta$ -carotene were analyzed by HPLC. The system used was a Shimadzu LC-10AT HPLC coupled with a Shimadzu Model SPD 10A UV-vis detector, Shimadzu class VP data acquisition software, and Crestpak C18S metaphase column (Biosains, Kuala Lumpur, Malaysia). The eluting solvent (mobile phase) was a mixture of 89% acetonitrile and 11% dichloromethane. The flow rate was 1.0 mL/min. The detector was set at a wavelength of 450 nm. A standard solution of a mixture of  $\alpha$ - and  $\beta$ -carotene was loaded onto the HPLC column before loading the samples.

**Statistical analysis.** Statistical analysis was performed using the SPSS (Chicago, IL) program. Fisher's exact test was used to test for a significant difference in the tumor incidence between experimental and control mice. An independent-sample *t*-test was used to test for a difference in the tumor surface and carotene deposition between experimental and control mice.

## RESULTS

**Effect of palm oil carotene supplementation on mammary fat pad tumorigenesis.** The cumulative incidence of mfp tumorigenesis in control and experimental mice is summarized in Figure 1. Tumors in experimental mice first appeared 6 wk after injection with MCF-7 cells with a cumulative incidence of 20% compared to controls; the latter developed tumors in the second week after injection. The cumulative incidence of tumors in the experimental animals was 60% at 20 wk. The difference in the tumor incidence rate over the 20 wk of the study in the experimental and control groups was statistically significant ( $P < 0.001$ ).

**Tumor growth and metastases.** Tumor surface area (Fig. 2) in experimental mice with primary tumors was significantly lower ( $P < 0.05$ ) than that of control mice. Three (12.5%) of the 24 mice in the control group and one (4.1%) in the carotene-supplemented group had visible pulmonary metastatic nodules. There was a significant difference ( $P < 0.05$ ) in the total metastatic incidence of control (50%) and experimental mice (17%) at autopsy (Table 1).

**FIG. 1.** Rate of appearance of palpable tumors at MCF-7 inoculation site in athymic nude mice. Data points show the percentage of mice with palpable primary tumors in mice supplemented with 1000 ppm palm oil carotene (experimental) vs. control over the 20 wk ( $n = 24$  for each group).

**TABLE 1**  
Effect of Palm Oil Carotene Supplementation on the Incidence of Grossly Visible Pulmonary Metastatic Nodules and Micrometastases from MCF-7 Human Breast Cancer Solid Tumor in Mammary Fat Pads of Nude Mice<sup>a</sup>

Animal groups	Grossly visible nodules	Micrometastases	Total metastatic incidence
Control	3/24 (12.5)	9/24 (37.5)	12/24 (50)
Experimental <sup>b</sup>	1/24 (4.2)	3/24 (12.5)	4/24 (17) <sup>c</sup>

<sup>a</sup>Numbers in parentheses indicate percentages.

<sup>b</sup>Carotene-supplemented mice.

<sup>c</sup>Significantly different from control group ( $P < 0.05$ ).

**TABLE 2**  
Flow Cytometry Analysis of Peripheral Blood Leukocytes of Experimental and Control Mice

Animal groups	Percentage of leukocyte count $\pm$ SD <sup>a</sup>		
	NK cells	$\gamma\delta$ -TCR T-lymphocytes	B-Lymphocytes
Control	27 $\pm$ 4.5	19.8 $\pm$ 3.6	26.9 $\pm$ 5.4
Experimental <sup>b</sup>	45 $\pm$ 4.2 <sup>c</sup>	19.97 $\pm$ 3.9	57.8 $\pm$ 7.0 <sup>c</sup>

<sup>a</sup>Results are expressed as mean percentage  $\pm$  SD of the respective leukocytes present in the 10,000 cells that were collected for analysis. Each sample was done in duplicate. TCR, T-cell receptor; NK, natural killer.

<sup>b</sup>Carotene-supplemented mice.

<sup>c</sup>Significantly different ( $P < 0.05$ ) from control.

**FIG. 2.** Tumor surface area of palpable primary tumors in athymic nude mice. Data points show the mean tumor surface area as calculated from weekly external measurements over a 20-wk period. The primary tumors in control mice grew faster than those in mice supplemented with palm oil carotenes (experimental). The difference in tumor surface area between the two groups was found to be statistically significant ( $P < 0.05$ ).

#### *Effect of carotene supplementation on the immune system.*

Twenty weeks of palm oil carotene supplementation in nude mice resulted in an increase of peripheral blood NK cell population compared with control mice (Table 2). Mice supplemented with carotene had a mean NK cell population of  $45 \pm 4.25\%$  (mean  $\pm$  SD) of the leukocyte population, whereas the mean NK population in control mice was only  $27 \pm 4.15\%$  ( $P < 0.05$ ). The B-lymphocyte population in the carotene-treated mice ( $57.8 \pm 7.0\%$ ) was also increased when compared with the control ( $26.98 \pm 5.4\%$ ).

**HPLC analysis of mice adipose tissue and liver.** HPLC analysis of fat extracted from adipose tissue of experimental mice revealed deposition of  $0.78 \pm 0.15$  ppm ( $\mu\text{g/g}$  tissue)  $\alpha$ -carotene and  $1.35 \pm 0.23$  ppm  $\beta$ -carotene (total carotene =  $2.13 \pm 0.17$  ppm). Similarly, for liver  $\alpha$ -carotene reached  $2.78 \pm 0.45$  ppm and  $\beta$ -carotene averaged  $5.52 \pm 0.92$  ppm (total carotene =  $8.30 \pm 0.34$  ppm). No  $\alpha$ - or  $\beta$ -carotene was found in adipose or liver tissues of control animals.

## DISCUSSION

In this study, the time to appearance of palpable tumors at the inoculation site increased in the carotene-supplemented group, and these animals also had a significantly lower tumor

incidence compared to the control group. In addition, the mean tumor surface area and lung metastases in experimental mice with primary tumors were significantly lower than those of control mice. These findings suggest that palm oil carotene can induce anticancer and antimetastatic effects against MCF-7 cells injected into nude mice.

The results also showed a significant increase in the peripheral blood NK cell population and B-lymphocytes in nude mice supplemented with palm oil carotene compared with untreated control mice. It might be possible to connect these observations with what previous studies have shown about retinoid-induced enhancement of the immune system: that  $\beta$ -carotene derived from palm oil may stimulate or enhance the immune system through local conversion to retinoic acid at the tissue level (8). Based on the findings of the present study together with previous study results (9), it is possible that  $\beta$ -carotene from palm oil is converted to retinoic acid by the oxidative cleavage of  $\beta$ -apocarotenoid acid, formed by asymmetric cleavage of  $\beta$ -carotene in the intestinal mucosa, as reviewed by Wang *et al.* (10). Interestingly, analysis of  $\beta$ -carotene deposition in the adipose tissue and liver of carotene-supplemented mice showed only trace amounts of  $\beta$ -carotene deposited in their adipose tissue although a substantial amount of carotenes was supplemented to these mice over the 20 wk of the study. A possible explanation for this observation is that most of the  $\beta$ -carotene was converted to retinoic acid and/or its derivatives.

The binding of retinoic acid to its receptors results in an autocrine production of interferon (IFN) (9): IFN- $\alpha$  and IFN- $\beta$  will potentiate the activity of NK cells, and IFN- $\gamma$  will activate macrophages. Activated macrophages produce interleukin-12, which stimulates the proliferation of and IFN- $\gamma$  production by NK cells. We speculate that increased numbers of NK cells elicited by palm oil carotene may play a crucial role in the suppression of the growth of injected MCF-7 cells. B-cells increased in number in the peripheral blood of carotene-supplemented mice. However, Boven *et al.* (11) found that B-cells in nude mice do not play an important immune function because their production of immunoglobulins is limited only to the immunoglobulin M isotype. The number of  $\gamma\delta$ -TCR T-lymphocytes did not differ significantly between control and experimental mice. This finding may indicate that these cells do not play an important role in mediating the immune surveillance against malignancy, at least in nude mice.

# Antihypertensive Effects of a Dietary Unsaturated FA Mixture in Spontaneously Hypertensive Rats

S. Bellenger-Germain, J.-P. Poisson, and M. Narce\*

UPRES Lipides et Nutrition, Faculté des Sciences Gabriel, Université de Bourgogne, Dijon, France

**ABSTRACT:** The aim of the present study was to investigate whether a mixture of dietary n-6 and n-3 PUFA could lower blood pressure in spontaneously hypertensive rats (SHR) of different ages. In addition, we studied how such a treatment could normalize the FA composition of plasma TAG and cholesterol esters (CE), and of red blood cell (RBC) total lipids. SHR (ages 4, 19, and 50 wk) were fed a normal diet (control groups) or a semi-synthetic diet containing a mixture of  $\gamma$ -linolenic acid (GLA), EPA, and DHA (experimental groups). Systolic blood pressure was measured at regular intervals. After 11 wk of consuming this diet, plasma TAG and CE were separated by TLC and analyzed for their FA composition. Total FA composition of RBC was also determined. The degree to which blood pressure was elevated was reduced in SHR after 11 wk of diet. The largest decrease was obtained with the oldest animals. In RBC, EPA and DHA contents increased. In plasma TAG and CE, EPA, DHA, and GLA increased whereas arachidonic acid decreased. The n-6 and n-3 unsaturated FA mix slowed the development of hypertension in young SHR and decreased blood pressure in adult and aged SHR. In addition, the present treatment altered the n-3 and n-6 PUFA content of SHR lipids to that seen in normotensive rats.

Paper no. L8626 in *Lipids* 37, 561–567 (June 2002).

The hypotensive effects of dietary n-3 PUFA have been observed with marine oil supplementations, both in humans (1–3) and spontaneously hypertensive rats (SHR) (4,5). Experiments using purified forms of the major components of these oils—EPA (20:5n-3) and DHA (22:6n-3)—have shown a decrease in blood pressure in patients suffering from hypertension (6) and in SHR (7,8). Contradictory reports show no protective effect of the consumption of fish oil—or of its derivatives—on hypertension (9–11), if used at low doses. These discrepancies can also be explained by study design differences, as for example the composition and doses of administered fats, the balance between n-6 and n-3 PUFA, the age of animals, and the duration of the treatment.

In earlier work, we showed that treatment of SHR with a dietary EPA and DHA combination (EPA30) did not decrease blood pressure (12). Moreover, it is well known that prolonged supplementation with only n-3 PUFA is accompanied by

changes in FA composition of various organs and tissues (13–15). These FA, incorporated at the expense of n-6 FA (16), can induce n-6 PUFA reduction in same-cell types (17). Evidence has been found for a competition between these two families of FA for entry into and release from cellular phospholipids and for a competition for the desaturase enzymes that catalyze their bioconversion into longer and more unsaturated FA, precursors of eicosanoids (18,19). Such changes can lead to a deficit in n-6 PUFA derivatives (17,20) and possibly alter the influence of such lipid mediators on blood pressure regulation, vasodilation, and platelet aggregation (21,22). Blood dihomo- $\gamma$ -linolenic acid (DGLA, 20:3n-6) level is a strong predictor of both coronary heart disease and stroke (23,24). On the other hand, the hypotensive effect of evening primrose oil, rich in  $\gamma$ -linolenic acid (GLA, 18:3n-6), has been described (25,26), and a similar effect has been shown with purified GLA, administered by peritoneal injection (27).

In a preliminary study we observed that a mixture of n-3 FA (EPA30) failed to decrease adult SHR blood pressure. The aim of the present investigation was to evaluate the possible effect of a dietary GLA/EPA/DHA combination (GLA80/EPA30) on blood pressure in SHR at three different ages, corresponding to prehypertensive, hypertensive, and aged hypertensive rats. Such a mixture would bypass the  $\Delta 6$  desaturation step in the process of EFA metabolism, which has been shown to be inhibited in SHR (28). Thus, the metabolic products from n-6 EFA, known to be involved in membrane fluidity and to be precursors of second messengers regulating blood pressure, would be maintained. In addition, plasma lipid derangement is known to be one of the primary factors associated with developing and maintaining hypertension (29,30). Consequently, we have determined the impact of such a treatment on the FA profiles of plasma lipids and red blood cell (RBC) membranes.

## MATERIALS AND METHODS

**Animals and diets.** All aspects of the animal experiments were approved by the Ethics Committee for Experimental Animals of the University of Burgundy, Dijon. Forty-two SHR were provided by IFFA-Credo (Domaine des Oncins, L'Arbresle, France). On arrival, rats were fed commercial standard pellets (Souriffarat, U.A.R A04, Villemoisson sur Orge, France) for 1 wk. During the whole experiment, animals were kept in individual metabolic cages. The room was maintained at  $22 \pm 2^\circ\text{C}$ ,  $60 \pm 5\%$  RH, and with a day/night alternation of 12 h/12 h. Animals had free access to food and tap water. Next, twelve

Part of this study was presented at the 90th Annual Meeting of the American Oil Chemist's Society (Orlando, Florida, May 9–12, 1999).

<sup>a</sup>Values were determined by GLC. Boldface used to emphasize certain FA in mixture.

4-wk-old, sixteen 19-wk-old, and fourteen 50-wk-old SHR (groups A, B, and C, respectively) were adapted for 1 wk to a semisynthetic diet (used as control diet and stored at 4°C) containing (g/100 g): 58.7 cornstarch, 20 casein, 5 cellulose powder, 5 saccharose, 4 minerals, 2 vitamins (Usine d'Alimentation Rationnelle), 0.3 methionine (Sigma Chemical Co., St. Louis, MO) and 5 lipids (ISIO 4 oil; Lesieur, Boulogne Billancourt, France). As human diets are generally high in linoleic acid, we chose as the control a commercial oil recommended by nutritionists that is high in n-6 PUFA as compared to the diet usually provided to rodents. The animals of each age group were then randomly assigned to groups of 6–8 rats each to either the control diet (containing 5% of lipids as ISIO 4 oil) or the semisynthetic diet containing 5% of lipids including a mixture composed of 26% EPA30 and 12.5% GLA80 (Callanish Ltd. Breasclate, Isle of Lewis, United Kingdom) and 61.5% ISIO 4 oil for 11 wk. The FA composition of EPA30, GLA80, and ISIO4 oils and control and experimental diets is presented in Table 1. The fresh mixture of GLA80/EPA30, prepared daily, was added to the diet in the form of ethyl esters just before being given to animals. The stability of the ethyl esters of the mixture, under these conditions, after exposure to air was confirmed by GLC. In order to administer the same amounts of GLA/EPA/DHA mixture to each experimental animal, the diet was given as follows: 13 g of the experimental diet was administered during the evening, and the ration was complemented the following morning with the control diet, *ad libitum*. Control animals (normotensive Wistar Kyoto rats: WKY) were fed the control diet under the same conditions as the experimental animals. Food intake was

measured daily and body weight weekly. Indirect systolic blood pressure was determined as follows: The rats were prewarmed for half an hour in a warming cupboard at 35°C, in order to prepare the rat's tail for the measurement with a plethysmographic method (BP Recorder 8005; M+M Electronic Inc., Basel-Müchensee, Switzerland). Four blind readings were obtained from each rat and averaged, after the highest and the lowest values were excluded.

At the end of the feeding period, animals were anesthetized with 0.1 mL/100 g body weight sodium pentobarbital (Sanofi, Paris, France). Blood from the abdominal aorta was collected in heparinized tubes and centrifuged at 1,700 × g for 10 min (Janetzki, T32c; Bioblock, Strasbourg, France) to separate plasma. RBC and plasma were then frozen (−20°C) under nitrogen before analysis.

*Plasma and RBC lipid analyses.* RBC were washed three times at 4°C (12,100 × g for 3 min) (J-21B, rotor JA20; Beckman Instruments, Fullerton, CA) with isotonic Tris buffer (NaCl 150 mmol/L, EDTA 1 mmol/L, Tris 10 mmol/L), pH 7.8. RBC membranes were prepared by centrifugation (12,100 × g for 10 min) in a hypotonic Tris buffer (NaCl 7 mmol/L, EDTA 1 mmol/L, Tris 5 mmol/L), pH 7.8 at 4°C and washed in distilled water at 4°C during 10 min at 12,100 × g. RBC and plasma lipids were extracted (31). TAG were separated from cholesterol esters (CE) by TLC using hexane/ethyl ether/acetic acid/methanol (180:40:4:6, by vol) as solvent system. Areas corresponding to TAG and CE were immediately scraped off the plates, extracted with chloroform/methanol (9:1, vol/vol) and then analyzed for FA composition. FAME were prepared by transmethylation using 14%

**FIG. 1.** Effect of experimental diet on blood pressure of groups A–C: systolic blood pressure from control rats (◆) and experimental rats (group A: ■, group B: ▲, and group C: ●). Results are shown as mean  $\pm$  SEM for  $n = 6$  (group A),  $n = 8$  (group B), and  $n = 7$  (group C). Each blood pressure is the mean of four measurements, after exclusion of the highest and the lowest values. Significantly different from control rats: \* $P < 0.05$ , \*\* $P < 0.01$ .

boron trifluoride in methanol (32), then separated by GLC (Packard model 417 gas–liquid chromatograph; Packard, Downers Grove, IL) equipped with an FID and a 30-m capillary glass column coated with Carbowax 20M (Applied Science Labs, State College, PA), and identified by their relative retention times (FA standards; Nu-Chek-Prep, Elysian, MN).

**Statistical analyses.** Results are expressed as the arithmetic mean for each group with their standard error (mean  $\pm$  SEM). Unpaired Student's *t*-test was used to determine significant differences between experimental and control groups for each age. Statistical difference was accepted at  $P < 0.05$  (\*) and  $P < 0.01$  (\*\*). For each diet, the means from groups A, B, and C were classified after ANOVA using Duncan's multiple range test. In each line, means assigned different superscript letters (b, c, d, e) were significantly different ( $P < 0.05$ ).

## RESULTS

**Food intake and body weight.** Food intake ( $16.9 \pm 0.7$  g/d) and body weights of experimental groups A and B were similar to controls during the whole experiment. Before killing, body weights were  $354 \pm 9$  g and  $388 \pm 3$  g in groups A and B, respectively. Moreover, the food intake of group C was significantly increased in the experimental group during the last 3 wk of the experiment ( $19.0 \pm 0.4$  vs.  $17.0 \pm 0.3$  g/d). The body weight was also significantly increased in this group during the last weeks of diet ( $476 \pm 13$  vs.  $439 \pm 12$  g).

**Blood pressure.** Results related to the blood pressure are presented in Figure 1. No difference was observed between SHR control groups at the end of the experiment. In the three age groups, the treatment with GLA80/EPA30 decreased blood pressure in SHR ( $-19$ ,  $-14$ , and  $-32$  mm Hg for groups A, B, and C, respectively). The duration required to lower systolic blood pressure was different according to the age: 5 wk of treatment for groups A and C and 8 wk for group B. In the three treated groups, systolic blood pressure remained at the lowest level until the end of the experiment.

**Total FA composition of RBC membranes.** The FA composition of RBC membranes from groups A and B is presented in Table 2. Compared to control group A, the levels of 18:0 and 22:5n-3 were higher in control group B, whereas 18:1 was lower. After treatment, we observed a significant increase of GLA, EPA, and DHA in the animals fed the GLA80/EPA30 mixture. The acid 22:4n-6 decreased in the two experimental groups compared to controls. However, 18:2n-6 and 20:4n-6, which are EFA of the n-6 family, remained unchanged after treatment.

**TAG and CE FA composition of plasma.** Table 3 shows the FA composition of plasma TG. When comparing SHR control groups with each other, plasma TAG of group C had increased 18:3 n-6 (about threefold vs. the two other groups) and 20:4n-6 (+50% vs. group A). In each age group, treatment increased the levels of 20:5n-3, 22:6n-3, and 18:3n-6. In

<sup>a</sup>Results are shown as mean ± SEM for control group A ( $n = 4$ ) and for groups B and C and experimental group A ( $n = 5$ /group). \* $P < 0.05$  and \*\* $P < 0.01$  when compared with the corresponding control. Boldface used to emphasize certain FA in mixture. See Table 2 for abbreviation.

<sup>b-e</sup> $P < 0.05$  for groups A–C compared inside each diet (control or experimental).

group C, 20:5n-3 increased in greater proportion than in groups A and B (+90 and +166%, respectively). In the same way, the increase of 22:6n-3 was higher in group C than in groups B and A (6.7-fold vs. group B and 2.5-fold vs. group A). Compound 20:4n-6 was decreased in all treated groups (–48, –55, and –60% in groups A, B, and C, respectively), whereas 22:4n-6 and 22:5n-6 were not detectable in treated animals. Linoleic acid (18:2n-6) decreased in all groups, and significantly in group A. As for the other FA, 16:0 increased in treated groups A and B and 16:1n-7 and 18:0 increased in treated group A. Acid 18:1 decreased in all groups, significantly in groups A and C.

Table 4 shows the FA composition of plasma CE. There is no significant difference between control groups except for 16:1n-7, which was higher for group B. In the three treated SHR groups, 18:3n-6, 20:5n-3, and 22:6n-3 increased significantly. A marked decrease of 20:4n-6 and a slight decrease of 18:2n-6 appeared in the three experimental groups. Compounds 18:1 and 16:1n-7 increased in groups A and B but remained unchanged in group C. Compounds 16:0 and 18:0 in-

creased whatever the age of animals, but less so in group C. We did not detect any 22:4n-6, 22:5n-6, or 22:5n-3, whatever the group of rats.

## DISCUSSION

To our knowledge, this study is the first to compare the effects of a specific FA mixture from vegetable and fish origin in SHR at different ages. The treatment has been administered to young rats (group A) during the development of the pathogenesis of hypertension; to adults (group B) when hypertension is well established; and to aging rats (group C). Body weights of experimental groups A and B remained similar to controls during the treatment. These observations indicate good acceptance by SHR of the treatment. However, in group C, the body weights of experimental rats increased significantly compared to controls after 8 and 10 wk of diet. This phenomenon was associated with an increased food intake after 10 wk of treatment although the treatment mode was identical in the three groups. Surprisingly, the animals from group C ate more and

<sup>a</sup>Results are shown as mean ± SEM for control groups A–C ( $n = 5$ /group) and experimental group A ( $n = 5$ ). \* $P < 0.05$  and \*\* $P < 0.01$  when compared with corresponding control. Boldface used to emphasize certain FA in mixture. See Table 2 for abbreviation.

<sup>b-d</sup> $P < 0.05$  for groups A–C compared inside each diet (control or experimental).

gained more weight than their controls, especially at the end of the feeding period. In this group, the lowering of blood pressure started earlier than in groups A and B—from week 5 to week 11 of the treatment. As SHR are usually smaller than the nonhypertensive control rats (WKY) used in these experiments once hypertension has been stabilized (33), we can hypothesize that the blood pressure-lowering effect of the treatment leads to a long-range weight compensation.

Based on our findings, this treatment with GLA80/EPA30 attenuated the development of elevated blood pressure in SHR. The greatest reduction of blood pressure was obtained with the oldest animals. For young (group A) and aged (group C) rats, the treatment effect was evident after 5 wk of administration of the experimental diet, while 8 wk were needed for adults (group B). Using purified PUFA, other authors have shown the ability of GLA (27) and EPA/DHA (7,8,34,35) to decrease blood pressure. Until now, the only studies that have reported GLA reduced blood pressure involved GLA administration by peritoneal injection (27) or by force-feeding (36); other studies have found no effect or opposite effects (9–11). It has been considered that DHA is the principal n-3 FA responsible for lowering blood pressure in humans (37). None of these studies included GLA, EPA, and DHA combined together, nor did they include investigations from young to aged rats. In an earlier part of this work, using the same control diet and the same strain, we investigated the effect of EPA30 alone and found no decrease in blood pressure in the experimental SHR group (12). Indeed, we showed that EPA30 increased the level of trienoic prostaglandin precursors and decreased the level of dienoic prostaglandin precursors. In the present work, we added GLA80 to EPA30 because the low cardiovascular morbidity of Greenland Eskimos has been linked to their unique diet of seafood rich in n-3 PUFA, and to their accumulation of GLA and DGLA (38), thus suggesting an inhibition of  $\Delta 5$  desaturase. The mixture used in the present experiment mimics such physiological conditions.

We showed that elevated blood pressure was related to changes in cell membrane lipids and fluidity (39), which could induce changes in receptor–effector coupling (40). The FA composition of RBC also has been studied, since membrane PUFA influence some transmembrane ion transport systems and since membrane cation fluxes in RBC may be altered in essential hypertension. We did not observe any decrease of 18:2n-6, as reported in the literature (14), when, consistent with a previous study (41), increased EPA and DHA levels were induced by the treatment. This can be explained by the addition of GLA, which is the  $\Delta 6$  desaturated product of 18:2n-6, in the treatment and by the fact that ISIO4 oil contains a high level of 18:2n-6. Arachidonic acid (20:4n-6) content was not affected by the age of the animals and the treatment. Therefore, a GLA supply appears required to avoid a decrease of 20:4n-6 in erythrocyte membranes, a phenomenon that is usually observed in essential hypertension (42). All together, the GLA80/EPA30 diet induced the positive expected effects of EPA and DHA, i.e., it prevented the reduction of n-6 PUFA.

The plasma PUFA composition reflects the treatment with GLA80/EPA30, in agreement with previous studies showing increased n-3 PUFA levels with marine oil dietary supplementation (15). The decrease of 20:4n-6 and of its elongation/desaturation products (22:4n-6 and 22:5n-6) indicates that the n-3 FA increased at the expense of n-6 PUFA. In young rats, the level of 18:2n-6 decreased, as previously observed with dietary fish oil supplementation (5). Indeed, this decrease was smaller in adults, and no difference was observed in the oldest rats. Although GLA is a 20:4n-6 precursor, we found a decrease of plasma 20:4n-6. This result is probably due to a partial inhibition of  $\Delta 6$  n-6 and/or  $\Delta 5$  n-6 desaturation steps by n-3 PUFA, as described by Christiansen *et al.* (43). These changes in arachidonic acid content could, as a consequence, induce a decrease of thromboxane A<sub>2</sub>, a strong vasoconstrictor and pro-aggregant lipid mediator, as observed in platelets of mice consuming a diet supplemented with n-3 PUFA (44).

Serum n-3 PUFA have been inversely correlated with cardiovascular disease (29), and n-3 FA intake may reduce not only blood pressure but also platelet aggregability (1,42) and consequently lower the risk of atherosclerosis (45). We found an increase of serum n-3 PUFA in both TAG and CE that was associated with reduced blood pressure, whatever the age of the animals, counterbalancing the high levels of 20:4n-6 in plasma CE generally described in hypertension (46). The present treatment appears to be efficient in decreasing the level of this plasma FA in all groups.

In summary, in contrast to what we observed with EPA30 alone (12), the treatment of SHR with GLA80/EPA30 reduced blood pressure, particularly in the oldest animals. The treatment appeared also to be active when administered during the prehypertensive phase. In light of the current findings, if such a FA mixture is relevant for laboratory studies involving experimental models of hypertension, given the different fat and FA metabolism in SHR vs. humans, how relevant these observations are to humans remains to be determined.

## ACKNOWLEDGMENTS

This investigation was supported by Ministère de l'Éducation Nationale, de la Recherche et de la Technologie and Région de Bourgogne, France. Sandrine Bellenger-Germain was recognized for this work at the 91st Annual Meeting of the AOCS (San Diego, CA, April 25–28, 2000). The authors are indebted to Callanish Ltd. Breaslete for providing purified EPA30 and GLA80, to Joseph Gresti for technical advice, and to Jérôme Bellenger for technical assistance.

**ABSTRACT:** Lauric acid desaturation was investigated and described in liver homogenates and in cultured rat hepatocytes. The identification of the desaturated product of lauric acid has been performed using the oxidative cleavage method, and we showed that the obtained monoene was mainly 12:1n-3. This result suggests that lauric acid desaturation could be the first step in the biosynthesis of  $\alpha$ -linolenic acid in animal cells.

Paper no. L8861 in *Lipids* 37, 569–572 (June 2002).

Desaturation of saturated FA is well known and documented for stearic acid (18:0) and palmitic acid (16:0). Concerning myristic acid (14:0), the presence of myristoleic acid has been detected in several tissues (1,2) as well as in a muscular cell line (3), and we have recently shown the biosynthesis and identification of 14:1n-5 by a  $\Delta 9$ -desaturation in cultured rat hepatocytes (4). Conversely, lauric acid desaturation has not yet been investigated although small amounts of lauroleic acid (12:1) are known to be present in milk lipids (5,6). The aim of this report was to study the desaturation of lauric acid in homogenates of fresh liver and in cultured rat hepatocytes. We demonstrated that, in the absence of competing substrate, lauric acid is desaturated at the  $\Delta 9$ -position, producing 12:1n-3.

## MATERIALS AND METHODS

**Chemicals.** BSA, HEPES, Williams' medium E (catalog no. W 4125), insulin (bovine), dexamethasone, collagenase, and unlabeled FA were purchased from Sigma (St Quentin Fallavier, France). Penicillin–streptomycin antibiotic mixture was provided by GIBCO BRL (Eragny, France). FBS was purchased from J. Boy S.A. (Reims, France). [1-<sup>14</sup>C]Lauric acid was purchased from Amersham-Pharmacia-Biotech (Orsay, France). [1-<sup>14</sup>C]Myristic acid, [1-<sup>14</sup>C]palmitic acid, and [1-<sup>14</sup>C]stearic acid were purchased from DuPont NEN (Le Blanc Mesnil, France). Solvent and other chemicals were obtained from Prolabo (Paris, France) or Merck (Darmstadt, Germany), except high-purity reagents for HPLC application, which were from Fisher (Elancourt, France). Falcon Primaria petri culture dishes, 60 mm in diameter (AES, Combourg, France), were used.

**Animals and diet.** Male Sprague–Dawley rats (body weight 250 g) obtained from the R. Janvier breeding center

(Le Genest-St Isle, France) were freely fed rat chow. They were food-deprived 12 h prior to sacrifice, liver removal, or hepatocyte preparation. The experimental protocol was in compliance with applicable guidelines from the French Ministry of Agriculture.

**Desaturase assay in rat liver.** Immediately after each rat was killed, the liver was removed and utilized for postmitochondrial supernatant preparation (7). A 4-g sample of liver was minced and homogenized in 16 mL of 50 mmol/L phosphate buffer (pH 7.4) containing 0.25 mol/L sucrose. The homogenate was centrifuged for 30 min at 10,000  $\times$  g. The resulting postmitochondrial supernatant was collected, diluted threefold with the phosphate buffer, and used for  $\Delta 9$ -desaturase assay as previously described (8). Enzymatic activity was determined using a 1-mL assay mixture that contained the following: 100  $\mu$ L supernatant (containing 100 to 500  $\mu$ g protein), 150 mmol/L phosphate buffer (pH 7.16), 6 mmol/L MgCl<sub>2</sub>, 7.2 mmol/L ATP, 0.54 mmol/L CoA, and 0.8 mmol/L NADH. The reaction was started with the addition of various amounts (usually 80 nmol) of [1-<sup>14</sup>C]lauric acid (660 MBq/mmol). Comparative  $\Delta 9$ -desaturase assays were also performed with 80 nmol [1-<sup>14</sup>C]myristic acid, [1-<sup>14</sup>C]palmitic acid, and [1-<sup>14</sup>C]stearic acid. The incubation was carried out in a shaking water bath at 37°C for 20 min. The reaction was stopped by adding 1 mL 2 mol/L KOH in ethanol. Each assay mixture was then heated for 30 min at 70°C. The FA were liberated by acidification, extracted with diethylether, and dried. For each desaturase assay, a control was performed whereby the reaction was stopped by addition of KOH before addition of the radiolabeled lauric acid. The percentage of apparent conversion in the control was subtracted from the one in the assay.

**Incubation of cultured rat hepatocytes with radiolabeled lauric acid.** Hepatocytes were obtained by collagenase perfusion *in situ*, as previously described (4). The culture medium (Williams' E) was supplemented with 26 mM NaHCO<sub>3</sub>, 12.5 mM HEPES, 15  $\mu$ M BSA, antibiotic mixture (50,000 IU/L penicillin, 50 mg/L streptomycin), 1  $\mu$ M insulin, and 1  $\mu$ M dexamethasone. For plating only (1.5  $\cdot$  10<sup>6</sup> cells/dish), the culture medium was supplemented with 7% (by vol) FBS. After plating, the cells were maintained in a humidified incubator at 37°C under 5% CO<sub>2</sub> in air. After 4 h, the plating medium was changed to a serum-free culture medium.

[1-<sup>14</sup>C]Lauric acid, diluted with the nonradiolabeled lauric acid to the final specific activity (183 MBq/mmol), was

\*To whom correspondence should be addressed at Laboratoire de Biochimie, INRA-ENSA, 65 rue de Saint Briec, CS 84215, 35042 Rennes Cedex, France. E-mail: Philippe.Legrand@agrennes.educagri.fr

incubated for 30 min at 70°C with 300  $\mu\text{L}$  KOH (2 mol/L) in ethanol. The FA salt obtained was dissolved at pH 10 in Williams' medium E containing 0.15 mmol/L BSA. The FA/albumin molar ratio was equal to 0.67:1. After 24 h of gentle shaking, the pH was adjusted to 7.35 and the medium was filtered through a medium with average pore size of 0.2  $\mu\text{m}$ . The solution obtained was used as incubation medium (4). The final FA concentration was 0.1 mmol/L. At 24 h of culture, incubation was initiated by replacing the culture medium with 2 mL (per dish) of [1- $^{14}\text{C}$ ]lauric acid-containing medium. Incubation was carried out for 12 h at 37°C in a 5%  $\text{CO}_2$  atmosphere.

At the end of the incubation, the medium was removed, the cells were washed twice with ice-cold PBS (150 mmol/L NaCl, 0.94 mmol/L  $\text{NaH}_2\text{PO}_4$ , 4 mmol/L  $\text{Na}_2\text{HPO}_4$ , pH 7.4) and harvested with a rubber policeman in PBS. The cell suspension was centrifuged at  $800 \times g$  for 4 min. The supernatant was discarded and the cell pellet kept for lipid extraction. Cellular lipids were extracted twice with 4 and 2 mL each hexane/isopropanol (3:2, by vol) (4). Lipid extracts were then saponified for 30 min at 70°C by 1 mL of 2 mol/L KOH in ethanol. The FA were liberated by acidification and extracted twice with diethylether. Cellular FA were then converted to FA naphthacyl esters as described below and separated on HPLC.

**FA analysis by HPLC separation.** FA from either desaturase assay or cultured hepatocyte incubation were converted to FA naphthacyl esters as recently described (9). The derivatization procedure was started by addition of 500  $\mu\text{L}$  2-bromo-2'-acetonaphthone (0.04 mol/L in acetone) and 500  $\mu\text{L}$  triethylamine (0.1 mol/L in acetone) to the FA extracts. After 15 min in a boiling water bath, 1 mL of acetic acid solution (0.033 mol/L in acetone) was added for an additional 10 min at 100°C. After evaporation, naphthacyl derivatives were dissolved with 200  $\mu\text{L}$  of a mixture of methanol/dichloromethane (3:1, by vol.). Twenty microliters of the derivative solution was used for analysis. FA naphthacyl esters were separated on HPLC (Alliance integrated system; Waters, St Quentin en Yvelines, France) using a Nova-Pak C18 column ( $4.6 \times 250$  mm; Waters) and a guard column (Nova-Pak C18;  $3.9 \times 20$  mm; Waters). The separation was performed by elution (1 mL/min) with a gradient of methanol/acetonitrile/water starting at 10:80:10 (by vol) and increasing to 0:90:10 (by vol) over a period of 50 min. Elution of naphthacyl derivatives was monitored by UV absorbance at 246 nm (tunable absorbance detector 486; Waters). Peaks corresponding to radiolabeled FA (substrate and product of the desaturase assays) were collected (fraction collector, Waters) and subjected to liquid scintillation counting (Packard Tri-Carb 1600 TR, Meriden, CT).

Preliminary identification of FA naphthacyl esters was based on retention times obtained for naphthacyl esters prepared from radiolabeled and nonradiolabeled FA standards (9).

From the amount of radioactivity found in the monoene product vs. the radioactivity recovered in the saturated sub-

strate, the enzyme activity could be determined and expressed as pmol substrate converted to product/mg protein/min.

**Identification of radiolabeled monounsaturated FA by oxidative cleavage.** To identify the radiolabeled monounsaturated FA derived from [1- $^{14}\text{C}$ ]lauric acid, the position of the double bond was determined according to the method of Von Rudloff (10), adapted in this laboratory for FA naphthacyl esters (9). Unsaturated FA naphthacyl esters separated by HPLC were collected. They were then submitted to oxidative cleavage by a mixture of permanganate-periodate for 6 h. The mono- and dicarboxylic acids obtained were extracted by addition of diethylether, converted to naphthacyl esters as previously described, and separated by HPLC first with an isocratic elution (1 mL/min) of acetonitrile/water (50:50, vol/vol) for 10 min, then by increasing linearly to (100:0, vol/vol) for 40 min. Retention times of mono- and dicarboxylic acids were previously determined by standard analysis (Fluka, St Quentin Fallavier, France). Radiolabeled dicarboxylic acids were collected and subjected to liquid scintillation counting. The radioactivity recovered in dicarboxylic acids and the chain length indicate the double-bond position on the monounsaturated FA.

**Protein measurement.** Protein was determined by a modified Lowry procedure (11), either in the supernatant used for the  $\Delta 9$ -desaturase assays or in the cells as total cellular protein.

**Expression of results and statistical analysis.** The values reported are means  $\pm$  SD. *P*-values were calculated by using Student's test for two-group comparisons. The differences were considered significant at a *P*-value of less than 0.05.

## RESULTS AND DISCUSSION

Lauric acid desaturation activity was first obtained using a post-mitochondrial supernatant of rat liver. The routinely used  $\Delta 9$ -desaturase assay was adapted for [1- $^{14}\text{C}$ ]lauric acid as substrate: we incubated 80 nmol of [1- $^{14}\text{C}$ ]lauric acid (660 MBq/mmol), i.e., about  $3 \cdot 10^6$  dpm/assay with the postmitochondrial fraction from rat liver. Only 10% of the total FA extracted from the assay was injected and analyzed by HPLC so that the column was not overloaded (i.e., about  $3 \cdot 10^5$  dpm/injection). We usually recovered about 6,000 dpm in the monounsaturated product after HPLC separation. The percentage of desaturation was obtained from these two values (about 2%). Moreover, for each  $\Delta 9$ -desaturase assay, a control was performed where by the reaction was stopped by addition of KOH before addition of the radiolabeled lauric acid. This control was also analyzed by HPLC in order to measure the background value of dpm in the collected fraction corresponding to the 12:1 peak (less than 500 dpm), showing the presence of impurities (12:1) in the 12:0 radiolabeled preparation.

The desaturation activity was measured with different substrate concentrations (Fig. 1). We showed a curve reaching a plateau at about 80  $\mu\text{M}$  lauric acid concentration. At this substrate concentration, lauric acid desaturase activity was measured in six animals, and we obtained a mean value of 120

FIG. 1.  $\Delta 9$ -Desaturase activity as a function of lauric acid concentration. Each point is the mean of three measurements  $\pm$  SD. The insert presents the Lineweaver-Burke plot of the desaturase activity (estimated apparent  $K_m \approx 75 \mu\text{M}$ ).

pmol/min/mg protein. The comparison with the  $\Delta 9$ -desaturation activity of the other substrates (myristic, palmitic, and stearic acids) was performed on three animals, showing a clear increase in activity as a function of the chain length of the substrate (Fig. 2).

Identification of the desaturated product of lauric acid has been performed on the  $C_{12}$  monoene using the oxidative cleavage method described above (see the Materials and Methods section). After the oxidative cleavage of the  $C_{12}$  monoene, we obtained a  $C_9$  dicarboxylic acid carrying 70% of the radioactivity (Fig. 3). We thus demonstrated that the product of lauric desaturation was mainly 12:1n-3, obtained by a  $\Delta 9$ -desaturase.

A second experiment was performed using a cultured rat hepatocyte system. [ $1\text{-}^{14}\text{C}$ ]Lauric acid substrate was added to the culture medium in the form of an albuminic complex, and analysis of the different labeled FA after 12 h incubation demonstrated the presence of a labeled 12:1 monoene (Fig. 4). Its identification using the oxidative cleavage method (see above) and analysis of labeled dicarboxylic fragments showed that this monoene was mainly 12:1n-3. The desaturation of lauric acid was quantitatively low compared to other metabolic fats: Only 35% of the initial radioactivity was still in FA form after 12 h incubation, suggesting a high  $\beta$ -oxidation level. Thus, besides  $\beta$ -oxidation, we could observe that lauric acid was mainly converted to myristic and palmitic acids.

Our results indicate for the first time that lauric acid is desaturated in rat liver homogenate and in cell culture. This is

FIG. 2. Comparative desaturation activity of lauric, myristic, palmitic, and stearic acids in rat liver. Postmitochondrial supernatant from liver homogenate (same amount of protein) was used for desaturase assay as described in the Materials and Methods section. Each point is the mean of three measurements  $\pm$  SD. Significant differences ( $P < 0.2$ ) are indicated by differing letters. The apparent  $K_m$  are 34, 22, and 10  $\mu\text{M}$  for myristic, palmitic, and stearic acids, respectively, in our experimental conditions.

in agreement with an observation (12) reported in 1976 that dodecanoyl-CoA was the substrate (very low activity) of a reconstructed desaturase system.

The principal interest of the present work is to show that the main product of lauric acid desaturation under our condi-

FIG. 3. Radioactivity recovered in dicarboxylic acids following the oxidative cleavage of 12:1. The identification of the 12:1 produced by lauric acid desaturation was performed by oxidative cleavage by a permanganate-periodate mixture for 6 h and by HPLC separation of the obtained dicarboxylic acids (identified by retention time) as described in the Materials and Methods section. Each value is the mean of three measurements  $\pm$  SD.

**FIG. 4.** Radioactivity of the FA obtained after a 12-h incubation of [ $^{14}\text{C}$ ]lauric acid with cultured rat hepatocytes (see the Materials and Methods section). FA were separated by HPLC and collected every 10 s. They were identified by comparison of retention times with those of standard FA. Each fraction was submitted to liquid scintillation counting, and the radioactivity vs. retention time was plotted.

tions is a member of the n-3 series. We propose a possible pathway that requires neither  $\Delta 12$ -desaturase nor  $\Delta 15$ -desaturase. Indeed, from successive conversion of 12:0 by  $\Delta 9$ -desaturation,  $\Delta 6$ -desaturation, elongation,  $\Delta 5$ -desaturation, and two final elongations, 18:3n-3 could be obtained. We may bear in mind here that the last elongation step of our putative pathway was described by Klenk in 1965 (13) and confirmed by Cunnane *et al.* (14), who obtained 18:3n-3 from 16:3n-3.

Although, in the present conditions, we did not observe biosynthesis of 12:1n-6 from 12:0, we suggest that 18:2n-6 biosynthesis from 12:0 might be possible using exclusively  $\Delta 6$ - and  $\Delta 5$ -desaturations and elongations. The two last steps of this putative pathway have been demonstrated in the past by Sprecher in 1968 (15), who showed a biosynthesis of 18:2n-6 from 14:2n-6 and 16:2n-6 in fat-deficient rats. Later, Cunnane *et al.* (14) confirmed these results using 16:2n-6 as a precursor. In the experimentation by Sprecher (15), neither 10:1n-6 nor 12:2n-6 was transformed into linoleic acid. Using rats fed a fat-free diet would be of great interest to further investigate our putative pathway. We have already observed (data not shown) 30 generations of a lineage of lipid-deprived rats that were healthy and exhibited only a reduction in pup growth, described up to the fifth generation (16).

In conclusion, the present results showing the  $\Delta 9$ -desaturation of lauric acid into 12:1n-3 in cultured cells and liver homogenates have led us to ask whether a possible biosynthesis of "essential" FA could exist under some circumstances in animals.

**ABSTRACT:** Lipid emulsions used in parenteral nutrition interact with lipoproteins leading to exchanges of lipids and acquisition of several apolipoproteins (apo). It has been previously observed that, during *in vitro* incubation of emulsions with purified LDL, a variable fraction of LDL binds to TG-rich emulsion particles. The purpose of this study was to better characterize such an interaction. Two emulsions containing 20% soybean oil (Endolipid®, B. Braun AG, Melsungen, Germany) or fish oil were incubated with LDL, either alone or in the presence of various plasma subfractions, for different durations and at different temperatures. The fraction named M-LE (containing TG-rich particles modified after incubation) was separated by ultracentrifugation or gel filtration chromatography, and the apoB content was measured as an index of LDL binding to TG-rich emulsion particles. The formation of such complexes was visualized by freeze-fracture electron microscopy. LDL binding was not influenced by the method used for M-LE isolation. Binding occurred quickly, did not increase with prolonged incubation, was inversely related to increasing incubation or ultracentrifugation temperature, and withstood 40 h of ultracentrifugation at 163,000 × *g*. The presence of glycerol or excess phospholipids in the emulsion did not markedly affect the formation of the complexes. In contrast, adding very small amounts of lipoprotein-poor plasma (*d* > 1.210 g/mL) or HDL markedly reduced the process, and albumin had no effect. The TG composition of the emulsion influenced the binding of LDL to TG-rich particles, since more apoB was found in M-LE from fish oil than from soybean oil emulsion.

Paper no. L8965 in *Lipids* 37, 573–580 (June 2002).

Lipid emulsions used in parenteral nutrition contain a majority of TG-rich particles that resemble endogenous chylomicrons with respect to size and structural assembly. They differ from chylomicrons mainly by the absence of structural apolipoproteins (apo) such as apoB-48 and apoA-1. These particles are suspended in a mesophase, containing glycerol and an excess of phospholipid (PL) emulsifier, that can be isolated by ultracentrifugation as a fraction of PL-rich particles (1).

Like TG-rich lipoproteins (TRL), infused emulsion particles interact with endogenous lipoproteins and acquire sev-

Abbreviations: apo, apolipoproteins; CE, cholesteryl esters; CETP, cholesteryl ester transfer protein; M-LE, modified-lipid emulsion particles; PL, phospholipids; TRL, TG-rich lipoproteins.

eral exchangeable apo, namely, apoC and apoE, from HDL (2–6). They also transfer some of the exogenous PL to plasma lipoproteins (7). In addition, cholesteryl ester (CE) and TG exchanges, regulated by the cholesteryl ester transfer protein (CETP), take place between TG-rich particles and CE-rich lipoproteins (8–10). Exchanges of lipids, apo, and other proteins also take place during *in vitro* incubations of emulsions with lipoproteins (3,4,11). More specifically, inverse changes in the overall fluidity of both TG-rich particles and LDL have been observed after incubation (12).

Preliminary studies showed that the incubation of various emulsions with purified LDL resulted in the enrichment of emulsion TG-rich particles with both CE and apoB, despite the absence of CETP (13). Since apoB is a nontransferable structural apo deeply anchored in LDL (14,15), this finding suggested some binding of LDL to emulsion particles and the formation of complexes. As could be expected, adding lipoprotein-poor plasma as a source of CETP (16) to the incubation mixture increased the CE transfer to TG-rich particles but markedly reduced apoB binding (17). This binding process could display some analogy with the phenomenon of fusion or attachment of LDL to artificial microemulsion particles that occurs *in vitro*, as previously reported (18,19).

The purpose of the present study was to better characterize LDL binding to TG-rich particles of lipid emulsions by using various incubation conditions. LDL binding was assessed by measuring the apoB content in the fraction containing the TG-rich particles modified by incubation (named M-LE), and was visualized by electron microscopy after cryofracture. The effects on the binding process of duration and temperature for incubation or ultracentrifugation were also studied. The potential role of other emulsion components, such as glycerol and PL-rich particles, was also examined, as well as the effect of adding albumin or other plasma components, such as the lipoprotein-poor subfraction or various lipoprotein subfractions, to the incubation mixture. The influence of the emulsion TG content was addressed by incubating LDL with emulsions manufactured with long-chain TG from soybean oil (Endolipid®) or with long- and very long chain TG from fish oil.

## EXPERIMENTAL PROCEDURES

**Plasma pool.** Sixteen healthy overnight-fasted subjects (2 males and 14 females, 25–50 yr old) volunteered for the study

and signed an informed consent. Blood samples were collected in tubes containing EDTA (1 mg/mL) and  $\text{NaN}_3$  (0.2 mg/mL) and immediately placed in iced water. Plasma samples were separated at 4°C in a Beckman J2.21 centrifuge (Beckman Instruments Inc., Fullerton, CA) at  $2,000 \times g$  for 10 min. Plasma samples were pooled, and the various lipoprotein subfractions were immediately separated.

**Preparation of plasma subfractions.** Different plasma subfractions were separated by sequential ultracentrifugation in a Beckman L8-55 ultracentrifuge using an angular Beckman 50.2Ti rotor (16). The TRL-free subfraction was obtained at  $d > 1.019$  g/mL (20 h; 5°C;  $227,000 \times g$ ). LDL subfraction was separated at  $1.030 < d < 1.055$  g/mL (20 h; 5°C;  $227,000 \times g$ ) to obtain a homogeneous population of mid-sized LDL particles (17). HDL ( $1.063 < d < 1.210$  g/mL) and the lipoprotein-poor ( $d > 1.210$  g/mL) plasma subfraction were also separated (48 h; 5°C;  $227,000 \times g$ ). After isolation, each subfraction was dialyzed in the dark against 40 vol of saline solution (0.19 M NaCl with 0.02% EDTA,  $\text{NaN}_3$  0.02%, pH 7.4) with three changes of dialysis solution over a 24-h period (18). The LDL and the TRL-free subfractions were enriched with sucrose to obtain final concentrations of 5 and 1% sucrose, respectively (19). Aliquots of TRL-free ( $d > 1.019$  g/mL), LDL, HDL, and lipoprotein-free ( $d > 1.210$  g/mL) plasma subfractions were frozen at -70°C for a maximum of 5 mon. Immediately prior to each experiment, aliquots of LDL and of other plasma subfractions were thawed by immersion in a 37°C water bath. Sucrose was removed from LDL and from the TRL-free subfraction by dialysis (three changes of 100  $\times$  sample volume over a 1-h period) in the same saline solution as described above (18).

**Intact and fractionated lipid emulsions.** Intact emulsions (B. Braun Melsungen AG, Melsungen, Germany) contained 200 g/L TG, 12 g/L egg yolk PL emulsifier, and 25 g/L glycerol. They consisted of a commercially available emulsion containing long-chain TG from soybean oil (20% Endolipid®) and of an experimental emulsion containing long- and very long chain TG from fish oil. The commercial soybean oil emulsion was used either intact, or after dialysis (as described above for the plasma subfractions) to remove glycerol, or after fractionation to isolate TG-rich particles from the mesophase, as previously reported (12,24). In brief, a 40-mL sample was ultracentrifuged (1 h; 15°C;  $20,000 \times g$ ) using a Beckman 50.2Ti rotor. The tube was cut with a Beckman tube-slicer just under the limit of the lipid cake (which contains TG-rich particles), and the mesophase (glycerol and PL-rich particles) was discarded. The lipid cake was resuspended in a KBr solution of  $d = 1.006$  g/mL and washed by a second ultracentrifugation run (1 h; 15°C;  $20,000 \times g$ ). TG-rich particles were then resuspended to the initial volume with a KBr solution of  $d = 1.006$  g/mL at a TG concentration of 200 g/L. According to previous experiments using this procedure, 75–80% of the total PL content of the soybean emulsion is distributed in TG-rich particles and the rest in the mesophase PL-rich particles (24).

**Incubation protocol.** Aliquots of the plasma subfractions were thawed and the sucrose was removed as described above. Samples of LDL ( $1.030 > d > 1.055$  g/mL) containing 0.58 mg

apoB, or samples of TRL-free plasma subfraction ( $d > 1.019$  g/mL) containing 44 mg protein, were incubated with soybean or fish oil emulsion samples in sealed Beckman polyallomer Opti-Seal tubes, using a fixed emulsion-TG/LDL-apoB ratio of 12:1 (w/w). In most of the assays, 0.2 mL of native or fractionated emulsion was incubated with 2.5–3.5 mL of LDL either alone or in the presence of other plasma subfractions or protein components. Briefly, lipoprotein-poor plasma, BSA, or HDL was added to the incubation mixture at protein concentrations ranging from 0 up to four times the usual mean normal plasma concentration of the lipoprotein-poor plasma subfraction (70 g/L), serum albumin (40 g/L), or HDL (1.2 g/L apoA-1). These conditions were defined to ensure that TG, plasma apoB, apoA-1, total protein, and albumin concentrations were below, at, or above those currently found in physiological conditions. Incubations were carried out in a shaking water bath at 4, 20, or 37°C for 0, 1, 4, or 20 h. In routine assays, incubations were performed at 37°C for 4 h.

**Separation of postincubation modified emulsion TG-rich particles (M-LE).** After incubation, the M-LE fraction, containing the modified emulsion TG-rich particles, was separated by ultracentrifugation ( $163,000 \times g$ ) at  $d = 1.006$  g/mL using a Beckman 50.4Ti rotor. Different ultracentrifugation durations (3, 20, or 40 h) and temperatures (5 or 20°C) were used for specific assays, but M-LE fractions were routinely obtained after ultracentrifugation for 20 h at 5°C. The tubes were cut at 1.5 cm from the bottom, and M-LE was recovered in the supernatant.

Alternatively, to check that the binding process was not an artifact due to the ultracentrifugation procedure, postincubation TG-rich particles were separated from the other components of the incubation mixture by gel filtration chromatography on a 2% agarose column (Sephacose CL-2B,  $1.6 \times 90$  cm; Pharmacia, Uppsala, Sweden). The column was eluted with a phosphate buffer (containing 0.15 M NaCl, 0.01% EDTA, and 0.01%  $\text{NaN}_3$ ; pH 7.4) at a flow rate of 0.6 mL/min for 340 min. Sixty minutes after the start of the run, fractions were collected every 5 min; TG was measured in each fraction. The TG-rich fractions eluting in the void volume of the column were pooled to obtain the M-LE fraction for subsequent analyses.

**Freeze-fracture electron microscopy.** After incubation of the soybean oil emulsion with LDL alone (4 h at 37°C), both the intact incubation mixture and the M-LE fraction isolated by ultracentrifugation (20 h at 5°C) were examined by freeze-fracture electron microscopy and compared to the intact emulsion. The method has been described previously (25), and the LDL particles were identified according to Gulik-Krzywicki *et al.* (26). In brief, a small drop of each sample, containing 30% glycerol as a cryoprotectant, was set down on a conventional copper planchet and rapidly frozen in liquid propane. Fracturing and replication were done with Balzers BAF 301 freeze-etching unit (Balzers, Balzers, Liechtenstein) using platinum carbon shadowing. Organic material was digested with 20% SDS and thereafter with sulfochromic acid. Replicas were then washed with distilled water and observed using a Philips 410 electron microscope (Philips, Eindhoven, The Netherlands).

**Analytical procedures.** All assays were performed in duplicate. Lipid analyses were performed on LDL; on intact, washed, and dialyzed emulsions; and on M-LE fractions obtained by ultracentrifugation or by gel filtration chromatography. TG were measured enzymatically using a commercial test kit (Triglycerides GPO-PAP, Roche Diagnostic, Mannheim, Germany). ApoB and apoA-1 were determined using a specific ELISA as previously described (27). Total protein content was measured in the lipoprotein and plasma fractions as described by Lowry *et al.* (28). All reagents, including KBr, were analytical grade products.

**Statistical analysis.** The results are expressed as mean values  $\pm$  SEM. Statistical differences between results obtained with different emulsion fractions under various conditions were determined by multivariate analysis (ANOVA) followed by a Fisher multiple comparison test. A value of  $P < 0.05$  was the criterion of significance.

## RESULTS

**Separation of M-LE by ultracentrifugation vs. gel filtration chromatography.** After incubation of soybean oil emulsion with LDL alone (4 h at 37°C), TG-rich particles were isolated by ultracentrifugation (20 h at 5°C) or by HPLC. The two methods gave comparable results, since  $6.16 \pm 1.70\%$  of the initial apoB amount in LDL was recovered in M-LE separated by centrifugation vs.  $5.50 \pm 0.63\%$  ( $n = 12$ ) in M-LE isolated by chromatography ( $n = 12$ ) (a nonsignificant difference).

**Effect of incubation, ultracentrifugation duration, and temperature on LDL binding to TG-rich particles.** When soybean oil emulsion was incubated with LDL alone for different durations at 37°C, apoB recovery in M-LE separated by ultracentrifugation (20 h at 5°C) was significantly higher when TG-rich particles were isolated immediately after mixing LDL and emulsion (0 h incubation duration) than after prolonged (1, 4, or 20 h) incubation, as illustrated in Figure 1. Various ultracentrifugation durations to separate the postincubation emulsion TG-rich particles did not significantly modify apoB recovery in M-LE, which averaged  $8.67 \pm 1.18$  ( $n = 3$ ),  $7.41 \pm 0.64$  ( $n = 4$ ), and  $9.86\%$  ( $n = 2$ ) of the initial LDL apoB content after 3, 20, and 40 h, respectively.

Incubations of soybean oil emulsion with LDL alone were carried out to test the effect of different temperatures for incubation (4, 20, or 37°C) and for ultracentrifugation (5 or 20°C), and different incubation durations (0, 1, or 4 h) on apoB recovery in M-LE (Fig. 2). Regardless of the incubation conditions, apoB recovery was significantly higher in M-LE separated by ultracentrifugation at 5°C than at 20°C. Moreover, a significant effect of incubation temperature was found, with the lowest apoB recovery observed at 37°C and the highest at 4°C.

**Effect of emulsion components on LDL binding to TG-rich particles.** The effect of emulsion glycerol and PL-rich particles on the LDL binding process was studied by incubating the native or fractionated soybean oil emulsion with LDL alone, or after adding the lipoprotein-poor plasma fraction, at a protein concentration similar to that usually found in human plasma

**FIG. 1.** Effect of incubation duration on apolipoprotein (apo)B recovery in modified emulsion TG-rich particles. Soybean oil emulsion was incubated with LDL alone at 37°C for 0, 1, 4, or 20 h. The modified emulsion TG-rich particles (M-LE fraction) were separated by ultracentrifugation (20 h; 5°C;  $163,000 \times g$ ) at  $d = 1.006$  g/mL, and apoB recovery in M-LE was expressed in percent of the initial LDL apoB content (mean  $\pm$  SEM for  $n > 2$ ). Different roman letter superscripts indicate significant differences at  $P < 0.05$ , by ANOVA and the Fisher *post hoc* test. ApoB recovery was significantly higher when M-LE was isolated immediately after mixing emulsion and LDL (0 h) than after prolonged incubations for 2, 4, or 20 h.

(Table 1). In both conditions, removing glycerol by dialysis significantly increased apoB recovery in M-LE, whereas removing the whole mesophase (glycerol plus PL-rich particles) by washing had no effect, compared with the intact emulsion. Whatever the treatment of the emulsion (intact, dialyzed, or washed), adding lipoprotein-poor plasma to the incubation mixture markedly reduced LDL binding to TG-rich particles.

**Effect of adding different plasma subfractions or protein components on LDL binding to TG-rich particles. (i) Lipoprotein-poor ( $d > 1.210$  g/mL) subfraction.** The inhibitory effect of lipoprotein-poor plasma on the LDL binding process was investigated by adding increasing amounts of this plasma

**FIG. 2.** Effect of incubation and ultracentrifugation temperatures on LDL binding to emulsion TG-rich particles. TG-rich particles from soybean oil emulsion were incubated with LDL alone for 0, 1, or 4 h, at 4, 20, or 37°C. The M-LE fraction was separated by ultracentrifugation at  $d = 1.006$  g/mL (20 h,  $163,000 \times g$ ) at 5 or 20°C, and apoB recovery in M-LE was expressed as percentage of the initial LDL apoB content (mean  $\pm$  SEM). Different roman letter superscripts indicate significant differences at  $P < 0.05$ , by ANOVA and the Fisher *post hoc* test. The effect of ultracentrifugation (5 vs. 20°C) was significant at  $P < 0.001$ , and the effect of incubation temperature was significant at  $P < 0.0001$  (20 vs. 37°C),  $P = 0.0001$  (20 vs. 4°C) or  $P = 0.028$  (37 vs. 4°C). Incubation duration had no significant effect. For abbreviations, see Figure 1.

**TABLE 1**  
**ApoB Recovery in Modified Emulsion TG-rich Particles According to the Treatment of the Lipid Emulsion and Incubation Without or With Lipoprotein-poor Plasma<sup>a</sup>**

Incubation conditions	Percent recovery of apoB	
	Without LPP	With LPP
Intact	9.19 ± 1.55 <sup>a</sup> (n = 6)	0.77 ± 0.26 <sup>c</sup> (n = 6)
Dialyzed	14.76 ± 2.76 <sup>b</sup> (n = 4)	0.93 ± 0.10 <sup>c</sup> (n = 4)
Washed	7.99 ± 1.22 <sup>a</sup> (n = 9)	0.50 ± 0.12 <sup>c</sup> (n = 7)

<sup>a</sup>Soybean oil emulsion was used intact, dialyzed (to eliminate glycerol), or washed (to eliminate glycerol and phospholipid-rich particles). After incubation (4 h; 37°C) of emulsion samples with LDL alone or in the presence of lipoprotein-poor plasma (LPP), the fraction containing the modified emulsion TG-rich particles (M-LE) was separated by ultracentrifugation (20 h; 5°C; 163,000 × g) at  $d = 1.006$  g/mL. Results are expressed as percentage of the initial LDL apolipoprotein B (apoB) amount recovered in M-LE (mean ± SEM). Different roman letter superscripts indicate significant differences, by ANOVA and the Fisher *post hoc* test. The effect of adding LPP is significant at  $P < 0.0001$ , and the effect of dialysis, at  $P = 0.046$ .

( $d > 1.210$  g/mL) subfraction to the incubation mixture. When the concentration was above (from one to four times) the usual protein concentration of this fraction in human plasma, apoB recovery in M-LE remained very low (Fig. 3A). Reducing this concentration had no effect on the LDL binding until very low concentrations were reached (lower than 0.10 of the usual protein concentration). Indeed, apoB recovery in M-LE sharply decreased from the highest value ( $5.38 \pm 0.51\%$ ,  $n = 9$ ) found when the emulsion was incubated with LDL alone, to  $3.75 \pm 0.50$ ,  $2.22 \pm 0.0.13$ ,  $1.07 \pm 0.07$ ,  $0.38 \pm 0.02$ , and  $0.17 \pm 0.04\%$  ( $n = 7$ ) when the protein concentration of the added subfraction increased from 2 to 3, 6, 13, and 25%, respectively, of the usual value in human plasma.

(ii) HDL ( $1.063 < d < 1.210$  g/mL) subfraction. Increasing the HDL protein concentration in the incubation mixture (from zero to four times the usual apoA-1 concentration in human plasma) reduced apoB recovery in M-LE (Fig. 3B). At protein concentrations below the usual HDL plasma concentration, the inhibitory effect of HDL on LDL binding to TG-rich particles was less pronounced than that of lipoprotein-poor plasma (Fig. 3A). ApoB recovery in M-LE ( $n = 4$ ), which reached  $8.16 \pm 0.56\%$  when no HDL was added to the mixture, decreased to  $3.51 \pm 0.37$ ,  $3.26 \pm 0.09$ ,  $2.96 \pm 0.17$ ,  $2.58 \pm 0.15$ , and  $1.94 \pm 0.25\%$  when the HDL concentration increased to 2, 3, 6, 13, and 25% of the normal plasma apoA-1 concentration, respectively.

(iii) TRL-free ( $d > 1.019$  g/mL) subfraction. While apoB recovery in M-LE was markedly lower in the presence than in the absence of lipoprotein-poor plasma ( $0.24 \pm 0.04$  vs.  $6.36 \pm 0.93\%$ ,  $P < 0.0001$ ,  $n = 25$ ), it was further reduced when the whole TRL-free plasma subfraction was used instead of LDL plus lipoprotein-free plasma ( $0.05 \pm 0.01$  vs.  $0.24 \pm 0.04\%$ ,  $P < 0.0001$ ,  $n = 25$ ).

(iv) BSA. When soybean oil emulsion was incubated with LDL in the presence of BSA at concentrations ranging from

**FIG. 3.** Effect of increasing amounts of lipoprotein-poor plasma (LPP) subfraction (A) or HDL (B) on emulsion TG-rich particles. TG-rich particles from soybean oil emulsion were incubated (4 h; 37°C) with LDL in the presence of increasing amounts of LPP subfraction or of HDL (ranging from zero to four times their respective usual total protein or apoA-1 concentration in human plasma) in the incubation mixture. The M-LE fraction was separated by ultracentrifugation, and apoB recovery in M-LE was calculated as percentage of initial LDL apoB content (mean ± SEM). Different roman letter superscripts indicate significant differences ( $P < 0.05$ ) by ANOVA and the Fisher *post hoc* test. ApoB recovery was highest and significantly different from all the other values when emulsion was incubated with LDL alone. The lowest apoB recoveries were observed for LPP or HDL concentrations above 0.1 and 2 times their usual protein concentrations, respectively. For abbreviations and technical details, see Figure 1.

zero to four times the usual albumin concentration in human plasma, apoB recovery in M-LE remained relatively stable (between 5 and 12% of the initial LDL content), with no correlation to BSA concentration (results not shown).

*Effect of the emulsion TG composition on LDL binding to TG-rich particles, according to the method used for protein measurement in M-LE.* After incubation of soybean or fish oil emulsion with LDL alone, the M-LE fractions were separated by ultracentrifugation and assayed for apoB content by ELISA and for total protein content by the method of Lowry *et al.* (28) (Table 2). Regardless of the technique used for protein measurement, a striking difference in LDL binding to TG-rich particles was observed between the two emulsions, since the recovery of either apoB or total proteins in M-LE was about threefold higher for fish oil than for soybean oil emulsion. However, for the two emulsions tested, the total protein amount measured by the method of Lowry *et al.* was about fourfold higher than the apoB amount routinely assessed by ELISA, a difference that was highly significant. The two techniques, however, were checked on LDL prior to incubation and gave comparable values for apoB and protein content (data not shown).

**TABLE 2**  
**Effect of Emulsion TG Composition on LDL Binding to TG-Rich Particles Calculated on the Basis of the Recovery of the Initial LDL ApoB or Total Protein Content<sup>a</sup>**

Emulsion	Percent recovery of LDL	
	ApoB	Total proteins
Soybean oil ( <i>n</i> = 3)	3.03 ± 0.38 <sup>a</sup>	13.70 ± 5.74 <sup>a</sup>
Fish oil ( <i>n</i> = 9)	9.52 ± 0.64 <sup>a</sup>	39.94 ± 5.19 <sup>b</sup>

<sup>a</sup>After incubation (4 h; 37°C) of soybean or fish oil emulsion with LDL alone, the fraction containing M-LE was separated by ultracentrifugation (20 h; 5°C; 163,000 × *g*) at *d* = 1.006 g/mL. ApoB was measured by ELISA and total protein content according to Lowry *et al.* (28). Results are expressed as percentage of the initial LDL apoB or total protein amount recovered in M-LE (mean ± SEM). Different roman letter superscripts indicate significant differences by ANOVA and the Fisher *post hoc* test. The effect of TG composition of emulsions is significant at *P* = 0.003 and the effect of the method used to assess the protein contents at *P* < 0.0001.

**Freeze-fracture electron microscopy analysis.** Freeze-fracture electron microscopy of intact 20% Endolipid® showed a majority of TG-rich particles (typical cross fracture) together with a small number of liposomes or PL-rich particles (typical concave or convex fracture surface) (Fig. 4A). After incubating the emulsion with LDL, examination of the intact mixture revealed the presence of LDL particles tightly bound to TG-rich particles (Fig. 4B). Similarly, LDL particles were also found on the surface of TG-rich particles separated by ultracentrifugation from the incubation mixture (Fig. 4C). Fused liposomes, large liposomes, and fused structures of liposomes and TG-rich particles were also present, probably generated by the ultracentrifugation process.

## DISCUSSION

Our preliminary results strongly suggested that a binding process can occur *in vitro* between purified LDL and emulsion particles (13). The aim of the present study was to better characterize this interaction between LDL and emulsion particles, which was shown to be independent of CETP present in the lipoprotein-poor plasma fraction (19). An *in vitro* model was used to incubate purified LDL with two emulsions (20% Endolipid® or a 20% fish oil emulsion) under various conditions but to keep an emulsion-TG/LDL-apoB ratio close to that currently observed in clinical conditions during parenteral infusion of lipid emulsions. After ultracentrifugation, the amount of apoB recovered in the M-LE fraction was used as an index of LDL binding to TG-rich particles.

In contrast to CETP-mediated enrichment of TG-rich lipoproteins with esterified cholesterol, which increases with incubation duration (29), LDL binding to TG-rich particles is a very rapid process, since apoB was detected in the M-LE fraction isolated immediately after putting LDL in presence of the emulsion (Fig. 1). Moreover, the extent of LDL binding appeared to be inversely related to both incubation and ultracentrifugation temperatures (Fig. 2). Indeed, the strongest interactions between the particles took place at incubation temperatures below 37°C, and apoB recovery was higher when M-LE was separated by ultracentrifugation at 5

**FIG. 4.** Freeze-fracture electron microscopy of intact and postincubation lipid emulsion. After incubating (4 h; 37°C) soybean oil emulsion with LDL alone, the M-LE fraction was separated by ultracentrifugation. (A) The intact emulsion contains large TG-rich particles (cross fracture) and smaller liposomes (concave or convex surface); (B) the incubation mixture shows TG-rich lipoproteins (1), liposomes (2), very small free LDL particles (3), LDL bound to the surface of TG-rich particles (4); (C) the M-LE fraction contains TG-rich particles (1), liposomes (2), free LDL (3), LDL bound to the surface of TG-rich particles (4), and liposomes fused with TG-rich particles (5) or with other liposomes (6). The scale bars correspond to 200 nm.

than at 20°C. These observations suggest that LDL binding to TG-rich particles is favored by lipid-protein interactions, which are stronger at temperatures below 37°C.

That apoB recovery in M-LE was not influenced by the method used to isolate modified TG-rich particles after incubation (ultracentrifugation or chromatography) indicates that the formation of complexes between LDL and artificial particles is not an artifact of ultracentrifugation. Furthermore, the cohesive forces stabilizing these complexes must be very high, since they were not dissociated after ultracentrifugation for 20 or 40 h at  $163,000 \times g$ , whereas such ultracentrifugation can pull some apo (such as apoE, apoC, or apoA-1) out of the lipoprotein particle surface (30,31).

Freeze-fracture electron microscopic analysis of the incubation mixture and of the M-LE fraction showed LDL particles tightly associated with the surface of TG-rich particles in crude incubation mixtures (Fig. 4B). The mechanism by which such an interaction takes place may be analogous to the process described for endogenous TG-rich lipoprotein formation, involving the fusion of a large TG-rich particle with a smaller apoB-containing particle (32). It is noteworthy that *in vitro* fusion of LDL to artificial microemulsion particles has also been observed by electron microscopy (18,19).

We have previously reported that emulsion TG-rich particles are substantially more fluid than LDL and that incubation modifies the fluidity of reisolated particles (12). Indeed, the fluidity of TG-rich particles is decreased, but that of LDL is increased, owing to lipid and protein exchanges between the particles. Moreover, the TG core composition, which influences the physical properties of the PL surface of TG-rich particles (33,34), markedly affects LDL binding to TG-rich particles (35). After incubation, TG-rich particles from the fish oil emulsion acquired larger amounts of ordering components (cholesterol and protein) from LDL than TG-rich particles from soybean oil emulsion, which displayed a relatively lower increase in structural order (12). As a confirmation, apoB recovery was significantly higher in M-LE from fish oil than from soybean oil emulsion. These results suggest that the extent of LDL binding may depend on the initial fluidity of emulsion TG-rich particles, which is related to the TG composition of lipid emulsions (12).

Earlier observations indicated that many plasma proteins (namely, albumin present in large amounts in lipoprotein-poor plasma) are able to bind to emulsion TG-rich particles *in vitro* (36). In the present study, even very small amounts of the plasma lipoprotein-poor ( $d > 1.210$  g/mL) subfraction (which contains the bulk of plasma proteins, including CETP) inhibited the binding process without abolishing it completely. Indeed, after incubation of soybean oil emulsion with LDL in the presence of lipoprotein-poor plasma (at and above the usual concentration in human plasma), less than 1% of the initial apoB amount was recovered in M-LE, vs. 5% or more when LDL were incubated alone. Similarly, adding HDL to the incubation mixture efficiently reduced LDL binding with a concentration-dependent effect. Likewise, apoA-1 has been reported to inhibit LDL fusion to microemulsion particles

(19). In the present study, LDL binding to TG-rich particles was even more markedly reduced when both LDL and lipoprotein-poor plasma were replaced by the whole TRL-free ( $d > 1.019$  g/mL) subfraction (containing LDL + HDL + lipoprotein-poor fraction). This confirms the inhibitory role of HDL and of other plasma components on the binding process. However, albumin probably does not play a prominent part in LDL binding to TG-rich particles, confirming previous studies on LDL binding to microemulsion particles (19). In contrast to other results (4), some apoA-1 was detected (by ELISA and by electrophoresis) in M-LE isolated from lipid emulsion incubated with LDL in the presence of HDL or lipoprotein-poor plasma (data not shown). Unexpectedly, after incubation of soybean or fish oil emulsion with LDL alone, the amount of total protein measured in M-LE according to Lowry *et al.* (28) was about fourfold higher than the apoB amount estimated by ELISA, while apoB represents more than 95% of the protein content of LDL (37). Such discrepancy suggests that ELISA may underestimate LDL binding to TG-rich particles (38,39). We speculate that LDL interaction with large TG-rich particles may have hidden some apoB epitopes, either by masking them or by inducing modifications in their structure, thereby reducing their recognition by antibodies raised against intact LDL. If this was the case, the amount of LDL bound to TG-rich particles would be substantially higher than that estimated by ELISA.

Thus, LDL may quickly bind to emulsion TG-rich particles *in vitro*. The complexes formed between LDL and TG-rich particles can be visualized by electron microscopy, even in a crude incubation mixture. The binding process is influenced by the TG composition of the emulsion, since it is particularly marked for fish oil compared with soybean oil emulsion. In contrast, LDL binding to TG-rich particles is reduced by several denser plasma subfractions, such as HDL and the lipoprotein-poor ( $d > 1.21$  g/mL) plasma subfraction, but not by albumin. The formation of complexes between LDL and emulsion particles seems to be reduced when incubation conditions mimic *in vivo* conditions. Taking into account the fact that the extent of the LDL-binding could be underestimated by ELISA apoB measurements in M-LE, our results raise the question of the actual magnitude, as well as the metabolic relevance, of such binding process *in vivo*. However, detecting the complexes formed by LDL and exogenous lipid particles in the serum of infused patients may be difficult because of the presence of other circulating TG-rich lipoproteins containing apoB. The formation of such complexes could be influenced not only by the composition of infused emulsions but also by the LDL composition specific to each patient. The possible consequences on the metabolism of circulating emulsion particles and LDL are currently unknown.

## ACKNOWLEDGMENTS

We would like to dedicate this paper to the memory of Jean-François Lontie, Ph.D. We would like to express our appreciation to Patricia D'Hont, Annie Louche, Ingrid Laurent, Jean-Claude Dedieu, and Marc Moqué for their excellent technical assistance. We also wish

to thank Prof. Richard J. Deckelbaum (Institute of Human Nutrition, Columbia University, New York) and Prof. Jacques Winand (Laboratory of Biochemistry and Nutrition, Université Libre de Bruxelles, Brussels, Belgium) for helpful advice. The emulsions were kindly provided by B. Braun Medical (Melsungen, Germany). Part of this work was presented at the Congress of the Société Francophone de Nutrition Entérale et Parentérale (SFNEP) (Paris, 1997) and was awarded the 1997 Annual Prize. Nathalie F. Chanson was supported by a CIFRE fellowship from B. Braun Medical (France).

# Transfer of Lipids Between Hemolymph and Hepatopancreas in the Shrimp *Macrobrachium borellii*

Fernando García, María González-Baró, and Ricardo Pollero\*

Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET)—Universidad Nacional de La Plata (UNLP), La Plata, Argentina

**ABSTRACT:** Crustacean lipids are transported in the hemolymph by an HDL. The hepatopancreas is the most important and active organ regarding lipid metabolism, so we studied the interchange of FA and acylglycerols between both components of the hepatopancreas–hemolymph system in the decapod crustacean *Macrobrachium borellii*. The hepatopancreas and a sole plasma lipoprotein were labeled by *in vivo* incubations with  $^{14}\text{C}$  palmitic acid injected into the hemolymph. Then they were incubated *in vitro* with unlabeled hepatopancreas and hemolymph, and the transfer of lipids between them was measured by radiochromatographic techniques. It was determined *in vivo* that more than 80% of the circulating palmitic acid was taken up by the hepatopancreas and incorporated into PC and TAG. Both classes of lipids, but mainly PC, were transferred back from tissues to the hemolymph. Lipid transfer was also demonstrated *in vitro*. The transfer of PC (30% of labeling) as well as that of FFA (48% of labeling) from hemolymph to hepatopancreas was determined. On the other hand, FFA were released more efficiently than the acylglycerols from intact hepatopancreas to hemolymph, and they were the only lipid transferred when the hepatopancreas had been previously washed.

Paper no. L8959 in *Lipids* 37, 581–585 (June 2002).

For several years, we have carried out certain metabolic studies using the hepatopancreas of the shrimp *Macrobrachium borellii* as a model. We first reported that the seasonal distribution of lipids was closely related to the diet (1). Afterward, we explored the consumption of lipids under stressful conditions (2), the effect of temperature upon the FA  $\beta$ -oxidation system (3), and the metabolism of palmitic acid as a precursor of TAG (4). We therefore postulated that the hepatopancreas is the main organ in *M. borellii* responsible for the synthesis and the degradation of TAG. Liver and fat body are the organs analogous to the hepatopancreas in vertebrates and insects, respectively. The hepatopancreas also performs digestive functions, enzyme secretion, and excretion of waste materials (5,6).

Although the occurrence of very high density lipoproteins (VHDL) has been reported in hemolymph of some crab and shrimp species (7,8), plasma lipid transport in crustaceans is mainly carried out by HDL. These lipoproteins are structurally much simpler than the ones present in vertebrates, and up to now there has been no evidence for the presence of any

LDL in crustacean plasma (9). Recently, we characterized the plasma lipoproteins of *M. borellii* and found that their compositions are similar to those of other crustaceans (García, F., unpublished results). We observed two different lipoproteins: one HDL found in animals of both sexes, and another HDL, found exclusively in the hemolymph of females during the reproductive season, that is involved in vitellogenesis.

These studies led to the hypotheses that the hepatopancreas, as a biosynthetic organ, transfers lipids to the hemolymph HDL for distribution among other tissues and that the hemolymph transfers to the hepatopancreas the lipids resulting from absorption across the digestive tract. In this way, biochemical interactions must be involved. The mechanism of interchange of lipids between hemolymph lipoproteins and tissues in crustaceans is still unknown. The results reported here deal with investigations performed *in vitro* on the transfer of FFA and other lipids between plasma HDL and the hepatopancreas of *M. borellii*, as well as between isolated lipoprotein and artificial membranes.

## MATERIALS AND METHODS

**Biological and chemical materials.** Male and nonovogenic female adult specimens of *M. borellii* were collected in summer from a water course close to the Río de la Plata, Argentina. They were kept in glass aquaria containing tap water at room temperature (20–25°C) until used for the experiments.  $1\text{-}^{14}\text{C}$  Palmitic acid (57.0 mCi/mmol, 99% radiochemically pure) and PC, L- $\alpha$ -dipalmitoyl (dipalmitoyl- $1\text{-}^{14}\text{C}$ , 111 mCi/mmol, 97% radiochemically pure) were purchased from New England Nuclear Corp. (Boston, MA). All chemicals were of analytical grade.

**In vivo labeling with radioactive FA.** Radioactive palmitic acid was administered to groups of 4–8 shrimp. They were maintained in aquaria at room temperature for 1, 4, 7, or 16 h. The cephalic sinus of each animal was injected with 5  $\mu\text{L}$  of an aqueous solution containing 2  $\mu\text{Ci}$  (35 nmol) radioactive FA as the ammonium salt. A syringe with a needle designed for animal injection (Hamilton Co.) was used. After incubations, hepatopancreas and hemolymph were separated. Labeled hepatopancreas were used either for radioactive lipid analysis or for the transference studies between hepatopancreas and hemolymph. Hemolymph was obtained by puncturing the cephalic sinus using a syringe containing 0.1 N sodium citrate as anticoagulant. Hematic cells were separated by centrifugation at  $100 \times g$  for 10 min. Labeled plasma was used for lipid

E-mail: pollero@atlas.med.unlp.edu.ar

analysis in the experiments of transference between plasma and hepatopancreas as well as for lipoprotein isolation.

**Plasma lipoprotein isolation.** Plasma lipoprotein was isolated by density gradient ultracentrifugation. Aliquots of plasma were overlaid on sodium bromide solutions (density 1.25 g/mL) containing 0.01% sodium azide and centrifuged at  $178,000 \times g$  for 24 h in a Beckman L8 70M centrifuge, using an SW 60 Ti rotor. The total volume of the tubes was fractionated from top to bottom into 0.2-mL aliquots. The protein content of each fraction was monitored spectrophotometrically at 280 nm. Radioactivity in each fraction was measured by liquid scintillation counting in Wallac 1214 Rack Beta equipment. One tube containing a NaCl solution (density 1.04 g/mL) instead of plasma was centrifuged simultaneously and fractionated in order to determine the density of the fractions by monitoring the refractive indices. Fractions corresponding to densities of 1.10–1.14 g/mL and showing increases in absorbance at 280 nm and in radioactivity were pooled, and the protein content was determined colorimetrically (10).

**Lipid extraction and analysis.** Lipids from hepatopancreas and hemolymph plasma were extracted following the procedure of Folch *et al.* (11), and the extracts were utilized for lipid separation by TLC. Lipid classes were separated by high-performance-TLC on Merck plates (Darmstadt, Germany), using hexane/diethyl ether/acetic acid (80:20:1.5 by vol) for neutral lipids and chloroform/methanol/acetic acid/water (65:25:4:4 by vol) for phospholipids.

Radioactivity distribution in different lipid classes was detected by scanning proportional counting using a Berthold LB-2723 Dunnschicht Scanner II apparatus (Wildbad, Germany). Appropriate standards, run simultaneously, were visualized by exposure to iodine vapors.

**Lipid transfer assays between hepatopancreas and hemolymph.** To explore the transfer of lipids from the hepatopancreas to the hemolymph, the palmitic acid-labeled hepatopancreas (donor) was incubated with unlabeled hemolymph plasma (acceptor). Incubations were done in 50 mM potassium phosphate buffer pH 7.4, 0.25 M sucrose, with the addition of 5  $\mu$ L aprotinin as protease inhibitor in a final volume of 330  $\mu$ L. Assays were carried out at 27°C for 30 min, with shaking. The donor/acceptor ratio was a whole hepatopancreas (70–90 mg) /125  $\mu$ L hemolymph. On the other hand, palmitic acid-labeled plasma (donor) was incubated under similar conditions with unlabeled hepatopancreas (acceptor). In another series of experiments, labeled hepatopancreas extensively rinsed with 3% albumin in 50 mM potassium phosphate buffer pH 7.4, were incubated with unlabeled hemolymph. After incubations, tissue and medium were separated, and lipids were extracted and analyzed as described above. All transfer experiments were done at least in triplicate.

Data collected from the transfer experiments were analyzed by a Mann–Witney nonparametric test. It was applied to radioactivity values in original and remaining lipids. Differences were considered with a significance level of 0.05.

**Lipid transfer between liposomes and HDL.** Liposome (multilamellar vesicle) preparations were done basically as

described previously (12). A stock solution of radioactive (45 nCi) and unlabeled (1 mg) PC in chloroform/methanol (2:1 vol/vol) was placed in round-bottomed flasks, and the solvent was completely evaporated. Dry phospholipid was hydrated with 1 mL 50 mM Tris-HCl buffer, pH 8.4, and thoroughly vortexed for 30 s 10 times in a bath at 60°C. Liposomes (donor) and isolated plasma lipoprotein (acceptor) in a ratio of 500  $\mu$ g phospholipid/450  $\mu$ g protein were incubated in a final volume of 1 mL at 27°C for 2 h. After incubation, the liposomes were pelleted by centrifuging the sample twice at  $167,000 \times g$  for 90 min in a 70.1 Ti rotor as above. Lipoprotein remained in the supernatant. A tube containing labeled liposomes and buffer was centrifuged simultaneously as a blank.

## RESULTS

**Palmitic acid uptake and incorporation into the hepatopancreas and hemolymph.** Different classes of circulating radioactive lipids in hemolymph were detected after having injected labeled palmitic acid into the cephalic sinus and sacrificing the animals after different incubation times. The results obtained are shown in Figure 1. A marked decrease of the label detected in FFA was observed that, after 16 h, reached less than 20% of its initial values. At the same time, radioactivity in the PC frac-

**FIG. 1.** Distribution of radioactivity into lipid classes after injection of  $^{14}\text{C}$  palmitate into the hemolymph of *Macrobrachium borellii*. Radioactive palmitate as ammonium salt (2  $\mu\text{Ci}$ : 35 nmol) was injected into the cephalic sinus and incubated *in vivo* for different times. Error bars indicate SD of the mean ( $n = 3$ ). ●, PC; ○, DAG; ▼, FFA; ▽, TAG.

FIG. 2. Total proteins (●, absorbance at 280 nm), radioactivity (■), and density (▲) distribution in plasma fractions of *M. borellii*. Shrimp were incubated *in vivo* with 2  $\mu\text{Ci}$  (35 nmol)  $^{14}\text{C}$ -palmitate for 5 h. Plasma was ultracentrifuged in a NaBr gradient and fractionated. For abbreviation see Figure 1.

tion increased with the incubation time, whereas the labeling in neutral lipids remained nearly constant.

To elucidate the role of the plasma lipoprotein in the uptake of lipids, the plasma was fractionated by ultracentrifugation in a density gradient. Radioactivity and protein content were measured in each fraction. The results are shown in the profiles in Figure 2, in which the highest labeling correlates with a protein peak at a density of 1.10–1.14 g/mL. This corresponded to the sole plasma lipoprotein present in the hemolymph of the specimens of *M. borellii* that we analyzed and is consistent with the density of the HDL.

Palmitic acid injected into the hemolymph was rapidly taken up by the hepatopancreas and then incorporated into several acylglycerols. The percentage of the label incorporated into different lipid classes as a function of time is presented in Figure 3. An even distribution of radioactivity between the neutral and glycerophospholipids occurred with short-time incubations, whereas at longer times, the label accumulated mainly in PC and to a lesser proportion in neutral acylglycerols. It is evident that DAG, with the minimal labeling concentration, are only intermediates in the synthesis of the other lipids.

*Lipid transfer between the hemolymph and the hepatopancreas.* When unlabeled hepatopancreas was incubated for 30 min with hemolymph labeled mainly in the FFA fraction, around one-half of the radioactivity was transferred to the tissue (Fig. 4A). At longer *in vivo* incubation times (16 h), the hemolymph contained the label distributed in PC as well as in FFA and TAG. When it was used as donor in incubations with unlabeled hepatopancreas, only the transfer of PC was observed (Fig. 4B).

Figure 5 shows the results from experiments in which radioactive hepatopancreas was incubated *in vitro* with unla-

beled hemolymph under two different experimental conditions. After 30 min of incubation, a substantial amount of PC, most of the labeled FFA, and a small amount of TAG were transferred from intact hepatopancreas to hemolymph (Fig. 5A). In another set of experiments, labeled hepatopancreas were washed prior to incubation with BSA, which removes the FA associated with the external face of the hepatopancreas membrane. Figure 5B shows that the FFA is the only lipid transferred to hemolymph, whereas the total radioactivity of

phospholipids and neutral lipids remains in the tissue. In another experimental model, an artificial liposome preparation containing labeled PC was used as donor of lipids to the hemolymph. Under these conditions, no transfer of phospholipid from the liposomes to the lipoprotein was observed; in fact when we reisolated the lipoprotein after the incubation with labeled liposomes, no radioactivity was detected in the lipoprotein fraction.

## DISCUSSION

The decrease of the FFA circulating in the hemolymph during the incubation, together with an increase of phospholipids and neutral lipids, clearly indicates that the precursor injected into hemolymph is rapidly incorporated into tissues that synthesize acylglycerols, which then release them back to circulation. The increase in total circulating lipids is mainly attributable to PC, whereas the content of TAG and DAG remains unaltered. It may be inferred that the phospholipid synthesis

**FIG. 5.** *In vitro* transfer of labeled lipids from the hepatopancreas to the hemolymph. Whole labeled hepatopancreas were exposed to unlabeled hemolymph for 30 min. (A) Transfer from hepatopancreas without treatment (FFA and PC:  $P < 0.05$ ). (B) Transfer from hepatopancreas extensively rinsed with albumin-buffer solution (FFA:  $P < 0.05$ ). For key see Figure 4. Error bars represent SD of the mean ( $n = 3$ ).

in tissues is more active than that of neutral lipids. However, the radioactivity distribution among hepatopancreas lipids after *in vivo* FFA incorporation suggests that this organ is active in PC synthesis at longer times, although at shorter times it is able to synthesize both lipids. A similar observation was previously reported when we studied the lipid metabolism of *M. borellii* hepatopancreas (4). Also, the tissues are likely to retain the TAG synthesized, preferentially transferring PC to hemolymph. This fact is coincident with the results obtained from studies on the lipid composition of this and some other crustaceans, where PC was found to be the predominant circulating lipid (13) and TAG are accumulated by the hepatopancreas (1). These observations led us to suggest that those phospholipids synthesized in the hepatopancreas could be easily transferred to hemolymph. The presence of the circulating label only in the high-density plasma fraction demonstrated the role of HDL in taking up lipids from tissues. All the animals used in these experiments were males and nonvitellogenic females; thus, plasma did not contain any vitellogenin, but only the HDL common to both sexes (14).

The study of the *in vitro* transfer of lipids from hemolymph

to the hepatopancreas showed a clear trend of hemolymph to supply the tissue with FFA as well as PC, depending on their relative labeling in hemolymph. The transfer of FFA corroborates the preceding observations dealing with the components of the hemolymph–hepatopancreas system, where hemolymph is likely to provide the FA necessary for the synthesis of acylglycerols, a task that is performed by a tissue of greater activity like the hepatopancreas. *In vitro* experiments were carried out for short times in order to avoid the possibility of lipid synthesis within the hepatopancreas masking the transfer results. In other organisms, the release of the circulating FFA to tissues is produced by HDL structures that are poor in lipids. This is the case of the albumin–FFA complex in vertebrates or the VHDL in certain molluscs (15) and in insects (16). It is evident that this role in *M. borellii* is done by the HDL since it is the only circulating lipoprotein.

*In vivo*-labeled hepatopancreas, where radioactivity was mainly accumulated in PC and also in smaller amounts in TAG and FFA, were used for *in vitro* experiments. The transfer of these lipids to the hemolymph was demonstrated. In this case, the FFA were comparatively the most efficiently transferred lipid group. Even though PC was highly labeled, it was less efficiently transferred than FFA, whereas the transference of TAG was slight. This also shows a markedly different behavior between glycerophospholipids and neutral lipids, coincident with a large amount of PC in the circulating lipoprotein and an accumulation of TAG in the hepatopancreas under natural conditions. There is a marked change when the experiments are performed using washed hepatopancreas since only the FFA are transferred. As a consequence, it appeared that no carrier would be involved in the FFA transfer, whereas that of glycerophospholipids could be mediated by a transfer factor. If this is the case, this factor could be associated with the hepatopancreas membrane, and it could be removed by the albumin buffer used for washing the tissue. These results led us to another experiment using an artificial membrane as donor. Thus, we tried to transfer labeled PC from liposomes to hemolymph; we found plasma HDL was not able to take up the phospholipid under our experimental conditions. This result reinforces the above assumption about the occurrence of a carrier that would transport lipids from tissue membranes to circulation.

**ABSTRACT:** The lipid, FA, and sterol composition of the New Zealand green lipped mussel (NZGLM, *Perna canaliculus*) and of the Tasmanian blue mussel (TBM, *Mytilus edulis*) were compared using TLC-FID and GC-MS. The respective mussel species were obtained from three different sites in both New Zealand (NZ) and Tasmania. Lipid class distribution of both mussel species was characterized by a high proportion of phospholipid (PL, 57–79%) and TG (10–25%), FFA (7–12%), and sterols (ST, 12–18%). The NZGLM had higher proportions of TG, FFA, and ST ( $P < 0.01$ ), whereas the TBM had a higher proportion of PL ( $P < 0.01$ ). There were higher proportions of total PUFA, saturated FA, n-3 FA, and hydroxy and nonmethylene-interrupted FA ( $P < 0.05$ ) in the TBM compared with the NZGLM. The major FA in the NZGLM were 16:0 (15–17%), 20:5n-3 (14–20%), and 22:6n-3 (11–17%). The same FA dominated lipids in the TBM, although there were significantly higher proportions of 16:0 ( $P = 0.000$ ) and 22:6 n-3 ( $P = 0.003$ ) and lower proportions of 20:5n-3 ( $P = 0.0072$ ) in the TBM. A novel PUFA, 28:8n-3, was detected in both mussels with higher amounts in the TBM, which probably reflects a greater dietary contribution of dinoflagellates for this species. Cholesterol was the dominant sterol in both mussels. Other major sterols included brassicasterol, 22-methylcholesterol, *trans*-22-dehydrocholesterol, and desmosterol. There were significant differences ( $P < 0.05$ ) between the NZGLM and TBM for 12 of the 20 sterols measured. Six sterols showed significant site differences for the NZGLM, and 10 for the TBM. The differences in the FA and sterol composition between the two species may be due to the diet of the NZGLM being more diatom-derived and the diet of the TBM having a greater dinoflagellate component.

Paper no. L8863 in *Lipids* 37, 587–595 (June 2002).

Molluscs are divided into seven classes; however, literature on their lipid composition is only available for a select group, one being the bivalvia (1). The New Zealand green lipped mussel (NZGLM), *Perna canaliculus* [not to be confused with the green lipped mussel *Perna viridis* from the region of

Hong Kong as investigated by Ching *et al.* (2), Li *et al.* (3), and Chong *et al.* (4)], is a bivalve marine mussel native to New Zealand (NZ), from the molluscan family Mytilidae, found in the deep-sea beds in the Hauraki Gulf in NZ's North Island waters (5,6). It is distinguished from other bivalve species by the presence of a bright green stripe around the posterior ventral margin of the shell and its distinctive green lip, which is visible on the inside of the shell. The flesh and ligaments of the NZGLM tend to be larger than those of the common blue mussel found in Tasmanian waters and referred to in this study as the Tasmanian blue mussel (TBM). It possesses a shape similar to the common blue mussel (*Mytilus edulis*) and can exceed 120 mm in size (6). The external color of the TBM can vary from blue to purple or black. It is found in coastal waters off the southern coast of Australia, spreading from the lower west to the lower east coast and into Tasmanian waters. TBM vary in size up to 130 mm; however, they are more commonly found to be less than 90 mm in size (7).

Lipid constitutes around 2% of the wet weight in the blue mussel (7–9) of which approximately 75% is structural lipids (10). Depending on season and/or the life cycle of the mussel, lipid content and composition may vary. During various stages of the life cycle, particularly in female mussels, the blue mussel is able to synthesize 16:0 and 18:0 and their derivatives *de novo* (10). Other biochemical changes in the mussel may result from variability in metabolic activity, location, sex, and spawning (11).

*Mytilus edulis* and *P. canaliculus*, like several other marine organisms such as molluscs in general and fish, not only are low in dietary cholesterol but also contain cholesterol-lowering phytosterols (12) and abundant n-3 PUFA, particularly the long-chain FA such as 22:6n-3 and 20:5n-3 (1); this is unlike most terrestrial organisms, which are rich in n-6 FA (13). The n-3 PUFA from marine sources have been linked with reducing certain risk factors for cardiovascular disease, such as lowering plasma TG (14) and reducing potential thrombosis as well as alleviating the symptoms of inflammatory conditions such as arthritis and skin disorders (15–19). Literature has not reported any research conducted on defining the similarities and or differences in lipid composition of the NZGLM and the TBM, and to our knowledge this is the first study that compares the lipid composition of both mussels.

## MATERIALS AND METHODS

NZGLM were obtained from three sites in NZ (South Island, Marlborough Sound, Coromandel, with water temperatures of 14.6, 16.5, and 16°C, respectively) and transported frozen by air to CSIRO Marine Research in Hobart, Tasmania, Australia, and stored at -20°C for 3–5 d, until analysis. Upon harvest, mussels were chilled and frozen within 24–36 h of collection. TBM were collected from three sites in Tasmania, Australia (Deep Bay 1, Deep Bay 2, Great Oyster Bay; water temperatures unknown) and stored at -20°C for 3–5 d until analysis. Upon harvest, mussels were chilled and frozen within 24 h of collection. Both species of mussels were collected in late spring (October). Data relating to food sources and availability and water quality are unknown; however, it is known that TBM from Deep Bay were collected during a dinoflagellate bloom. Lipids were extracted overnight from three individual animals from each site using a modification of the one-phase chloroform/methanol/water (2:1:0.8, by vol) Bligh and Dyer extraction (20). After phase separation by the addition of chloroform and water (final solvent ratio, 1:1:0.9, by vol), the lipids were recovered in the lower chloroform phase and the total solvent extract was evaporated *in vacuo* at 40°C. Lipid content to a constant weight was determined under a stream of nitrogen gas. Lipid class analyses were conducted immediately and, where other analyses were to be performed, samples were stored at -20°C for no more than 3 d in a known volume of chloroform.

A portion of the lipid extract for each mussel was analyzed using an Iatroscan MK V TH10 TLC-FID analyser (Iatron Laboratories, Tokyo, Japan) to determine the amounts of individual lipid classes. Samples were analyzed in duplicate using silica gel SIII Chromarods (5 µm particle size) (Drummond Scientific Company, Broomall, PA) and applied by 1-µL disposable micropipettes. Separation was achieved using a polar solvent system of hexane/diethyl ether/glacial acetic acid (60:17:0.1, by vol) to resolve nonpolar components including wax ester (WE), TG, FFA, and sterols (ST). A second nonpolar solvent system (hexane/diethyl ether, 96:4, vol/vol) was used for selected samples to resolve nonpolar components such as hydrocarbon (HC) from WE and TG from diacylglycerol ether. After development, the Chromarods were dried at 80°C to evaporate all remaining solvent and scanned immediately, thus minimizing adsorption of atmospheric contaminants. The TLC-FID unit was calibrated using known standards for each lipid class (21). Peaks were quantified using an IBM PC using DAPA software (Kalamunda, Western Australia, Australia).

An aliquot of the total lipid extract, including methyl ester internal standards (19:0 and 23:0), was transmethylated using a mild acid methylation to obtain FAME and fatty aldehydes (21). ST were obtained by alkaline saponification of another aliquot of the lipid extract and were then converted to their corresponding trimethylsilyl ethers by the addition of 150 µL of *N,O*-bis(trimethylsilyl) trifluoroacetamide and heating overnight at 60°C. GC analyses were performed using a

Hewlett-Packard 5890 GC on HP7673 A Autosampler, a split/splitless injector, with an FID and an HP5 nonpolar 50-m cross-linked methyl (5% phenyl) silicone fused-silica capillary column with an i.d. of 0.32 mm and 0.17 µm film thickness (Hewlett-Packard). Samples were injected at 50°C and held for 1 min. The oven temperature was increased at 30°C/min to 150°C, then at 2°C/min to 250°C, and then 5°C/min to a final temperature of 300°C, which was held for 15 min. The injector and detector were maintained at 290 and 310°C, respectively, and hydrogen was used as the carrier gas. Peak areas were quantified on an IBM-compatible computer using Millennium 32 V.3.05.01 software (Waters Corporation, Milford, MA).

GC-MS analyses were performed on a ThermoQuest GCQ system (Thermoquest, Austin, TX) fitted with an on-column injector. The GC was fitted with a capillary column similar to that described above, and GC conditions were the same as described above.

Statistical analyses were conducted using Minitab Version 12.0 for Windows (State College, PA). Where mussel groups were compared, a two-sample *t*-test and confidence interval were conducted. Where sites were compared within mussel groups, a one-way ANOVA was used. Data are reported as mean ± SD ( $n = 9$ , three animals from three sites for each species) in both text and tables, and  $P < 0.05$  was considered significantly different.

## RESULTS

**Lipid composition.** Total lipid on a wet weight basis was 17.9 mg/g (4.4 SD) in the NZGLM and 12.3 mg/g (4.0 SD) in the TBM ( $P = 0.013$ ). The predominant lipid class in both the NZGLM and TBM was PL, 60 and 74% (of total lipid), respectively, followed by TG (22 and 13%, respectively), with lower levels of FFA (12 and 7%, respectively) (Table 1). Both mussel species had a low percentage of WE (<0.3%). There was a significantly higher percentage of TG ( $P = 0.038$ ), FFA ( $P = 0.016$ ), and ST ( $P = 0.0085$ ) in the NZGLM compared with the TBM, and a significantly higher proportion of PL in the TBM ( $P = 0.010$ ). There were no significant differences in the lipid class composition between sites for the TBM. However, there was a significant difference for FFA in the NZGLM between sites ( $P = 0.042$ ).

**FA.** Fifty individual FA and fatty aldehydes were identified in the mussels (Table 2; data in table not in order of elution shown in Fig. 1). The predominant FA were palmitic acid (16:0), 20:5n-3 (EPA), and 22:6n-3 (DHA) in both mussels, with 16:0 in significantly higher proportions in the TBM. There were significantly higher percentages of 14:0, 16:1n-7c, 16:1n-7t, 16:1n-9c, 17:0, 18:1n-7c, 18:2n-6, 20:1n-7c, 20:2 nonmethylene interrupted (NMI), 20:3n-6, 20:4n-6, 20:5n-3, 21:5n-3, 22:0, 22:4n-6, 22:5n-6, and 22:5n-3 in the NZGLM ( $P < 0.05$ ). The TBM had significantly higher percentages of 15:0, 16:0,  $\alpha$ -hydroxy 16:0 FA, 4,8,12-trimethyl tetradecanoic acid (4,8,12-TMTD), isomer of 18:0 FA (i18:0), 19:1, 20:2n-6, 22:2 NMI, 22:5n-6, and 22:6n-3 ( $P < 0.05$ ).

<sup>a</sup>Data for each species, as determined by Iatroscan, are the mean of nine individual animals, representing three animals from each of three sites (values are expressed as mean ± SD). ND, not detectable

<sup>b</sup>Significantly higher than the TBM based on paired *t*-tests ( $P < 0.05$ ).

<sup>c</sup>Significantly higher than the NZGLM based on paired *t*-tests ( $P < 0.05$ ).

<sup>d</sup>Site significantly different from other sites (NZGLM) based on ANOVA ( $P < 0.05$ ).

The novel very long chain PUFA 28:8n-3 was detected in both the NZGLM (0.2%) and TBM (0.8%), with significantly higher levels ( $P < 0.0001$ ) in the TBM.

Pseudo iso 16:0 and 18:0 were recognized as degradation products of dimethylacetals formed from the original corresponding aldehydes.

There were several significant differences between sites for the percent FA composition in both the NZGLM and TBM. The differences between sites for the NZGLM were between 15:0, 16:1n-7c, 18:3n-6, 18:1n-9c, 20:5n-3, 20:1n-11c, 21:5n-3, 22:5n-6, and 22:6n-3 ( $P < 0.05$ ) and between sites for the TBM for 20:3n-6, i18:0, 4,8,12-TMTD, and 28:8n-3 ( $P < 0.05$ ).

PUFA were the dominant class of FA in both mussels (Table 3). Saturated FA (SFA) were the next most abundant group, with a higher proportion in the TBM, followed by mono-unsaturated FA (MUFA). The NZGLM had a significantly higher percentage of MUFA ( $P < 0.0001$ ), whereas the TBM had a significantly higher percentage of SFA, total n-3 PUFA, fatty aldehydes, NMI FA,  $\alpha$ -hydroxy FA, and several unidentified PUFA ( $P < 0.05$ ) compared with the NZGLM. There were no significant differences found between sites in the proportions of SFA, MUFA, and PUFA for either mussel species.

**Sterols.** Twenty sterols were identified in the TBM and NZGLM (Table 4, Fig. 2). Relative levels of individual sterols ranged from <0.5 to 32% (of total sterols). Cholesterol was the major sterol in both mussels (30% TBM and 29% NZGLM). The other sterols common to both the NZGLM and TBM were brassicasterol, 24-methylcholesterol, *trans*-22-dehydrocholesterol, desmosterol, and isofucosterol. The NZGLM had a significantly higher amount of brassicasterol, 24-nordehydrocholesterol, ocellasterol, lathosterol, 24-methylcholesterol, 23,24-dimethylcholesta-5,22E-dien-3 $\beta$ -ol, and isofucosterol ( $P < 0.05$ ). The TBM had significantly higher amounts of cholestanol, desmosterol, 24-methylenecholesterol, 24-ethylcholesterol ( $P < 0.05$ ), and an unidentified sterol (peak 14). Both mussel types contained around 2% of the C<sub>30</sub> sterol dinosterol, and a second C<sub>30</sub> sterol, 4,23,24-

trimethyl-5 $\alpha$ -cholest-7-en-3 $\beta$ -ol, was also present in the NZGLM. In the NZGLM, animals from site 3 (Coromandel) had significantly higher proportions of 23,24-dimethylcholesta-5,22E-dien-3 $\beta$ -ol ( $P = 0.002$ ), 24-methylenecholesterol, isofucosterol, and 4,23,24-trimethyl-5 $\alpha$ -cholest-7-en-3 $\beta$ -ol ( $P < 0.05$ ). Mussels from site 1 (South Island) had a significantly higher amount of dinosterol ( $P = 0.047$ ) and site 2 animals (Marlborough Sound) had a significantly higher amount of 22-*trans*-dehydrocholesterol ( $P = 0.015$ ).

For the TBM, site 1 mussels (Deep Bay 1) had significantly higher amounts of 24-nordehydrocholesterol, 22-*trans*-dehydrocholesterol, brassicasterol, 24-methylenecholesterol, and an unidentified sterol ( $P < 0.05$ ). Site 2 animals (Deep Bay 2) had a significantly higher amount of 24-methylcholesterol, and Site 3 animals (Great Oyster Bay) had significantly higher amounts of cholesterol, cholestanol, lathosterol, and 23,24-dimethylcholesterol ( $P < 0.05$ ).

## DISCUSSION

**Lipid composition.** Lipid contents in the TBM and NZGLM (1.2 to 1.8%) were similar to values reported in a study investigating the lipid composition of marine invertebrates of the Pacific Northwest (8). That study found the common blue mussel to have a lipid content of 1.8% in comparison to clams (1.5–1.7%), cockles (0.9–1.7%), horse clams (2%), and fresh oysters (2.5–4%), with crustacea such as crab and shrimp at around 1 and 1.5%, respectively. Yearsley *et al.* (7) and Nichols *et al.* (9) reported a lipid content in the TBM of 1.7% wet weight. Perry (22) investigated the lipid content of various mollusca and found the lipid content varied from 1.5% in a female mollusc *Subnina undulata* to 4% in the limpet *Cellana transerica*. The lipid content results for the TBM and the NZGLM in this study are in agreement with earlier studies of the blue mussel and other molluscs. The main lipid class of NZGLM and TBM was PL (up to 74%), which is consistent with other data for molluscs (7–9,22).

<sup>a</sup>Data for each species are the mean of nine individual animals, representing three animals from each of three sites (values are expressed as mean ± SD).

<sup>b</sup>4,8,12-TMTD, 4,8,12-trimethyl tetradecanoic acid; NMI, nonmethylene interrupted; α-OH 16:0, α-hydroxy 16:0 FA. Other (includes 17:2 and C<sub>22</sub> PUFA, and pseudo iso 16:0 and 18:0 degradation products of dimethylacetal). For other abbreviations see Table 1.

<sup>c</sup>Significantly higher than the TBM based on paired *t*-tests (*P* < 0.05).

<sup>d</sup>Significantly higher than the NZGLM based on paired *t*-tests (*P* < 0.05).

<sup>e</sup>Site significantly different from other sites (NZGLM) based on ANOVA (*P* < 0.05).

<sup>f</sup>Site significantly different from other sites (TBM) based on ANOVA (*P* < 0.05).

<sup>g</sup>16:1n-7c is clearly separated from 16:1n-13t on the HP5 capillary column (Hewlett-Packard).

Depending on the length of storage, temperature, and climatic conditions, marine invertebrates such as molluscs can undergo various changes in their lipid profiles owing to the activity of various enzymes. Jeong *et al.* (23) and Jeong (24) studied the effect of temperature and storage on lipid oxidation and composition of total lipid and lipid fractions of the oyster *Crassostrea gigas* and the giant ezo scallop *Patinopecten yessoensis*. In any marine source containing unsaturated FA, particularly long-chain n-3 PUFA, there is the risk of lipid de-

terioration during storage. Both studies showed that with increased storage time and with an increase in temperature of up to 35°C, there was a significant increase in oxidation as measured by TBARS, a significant decrease in total lipids, polar lipids, and PUFA, and a significant increase in nonpolar lipids and FFA. These data suggest the activity of various lipases and lipolytic enzymes responsible for enzymatic hydrolysis. In the study by Jeong *et al.* (23), after 12 mon of frozen storage there was a decrease in PL leading to an accu-

**FIG. 1.** Typical FAME profile of Tasmanian blue mussel. Samples were separated on an HP5 (nonpolar) 50-m cross-linked methyl (5% phenyl) silicone fused-silica capillary column, using a Hewlett-Packard 5890 gas chromatograph with FID. IS, internal standard.

mulation of FFA, causing an increase in the relative proportion of neutral lipids. This study reports the presence of significant proportions of FFA in both the NZGLM and TBM. Since these were not present in lipid extracts for mussels that were placed into extraction solvents within 10 min of harvesting, it is likely that the FFA represent hydrolytic degradation as reported by others (23,24). Generally, FFA are quite low in concentration; however, as Jeong *et al.* (23) and Jeong (24) showed in their studies with decreasing temperature and during storage, there is an increase in nonpolar lipids and FFA due to the action of lipolytic enzymes. Perhaps in the present study lipid hydrolysis had occurred during storage, which would account for the high levels of FFA in both mussels.

The differences in lipid content and lipid class composition between the NZGLM and TBM may be due to seasonal variation, as there are differences in climate between New Zealand and Tasmania. Differences may also reflect the stage

of development of the mussel, particularly the gonadal development (1). In addition, the sex of the mussel can alter lipid content and lipid class composition, since female mussels tend to have lower levels of total lipid (1). The dietary intake of the mussels and the availability of food may also reflect the differences seen between species. Perry (22) reported that HC in molluscs are derived mainly from environmental pollution such as fuel oil, crude oil, or motorboat oil; however, uncontaminated scallops were found to have a limited range of naturally occurring HC. HC profiles characteristic of pollution, such as a lack of odd-chain dominance and the presence of unresolved complex material and other specific biomarkers, were not observed in our samples. These observations are consistent with the pristine nature of the sampling locations from which all mussels were collected.

*FA.* Nearly half of the FA in each mussel species were PUFA, and up to 42% of the FA in both mussels were n-3

<sup>a</sup>Data for each species are the mean of nine individual animals, representing three animals from each of three sites (values are expressed as mean ± SD).

<sup>b</sup>Significantly higher than the TBM based on paired *t*-tests ( $P < 0.05$ ).

<sup>c</sup>Site significantly different from other sites (TBM) based on ANOVA ( $P < 0.05$ ).

<sup>d</sup>Site significantly different from other sites (NZGLM) based on ANOVA ( $P < 0.05$ ).

<sup>e</sup>Significantly higher than the NZGLM based on paired *t*-tests ( $P < 0.05$ ).

<sup>f</sup>Trace, less than 0.1%, for other abbreviations see Table 1.

**FIG. 2.** Typical sterol profile of New Zealand green lipped mussel. Separated on an HP5 (nonpolar) 50-m cross-linked methyl (5% phenyl) silicone fused-silica capillary column, using a Hewlett-Packard 5890 GC with FID.

PUFA, while approximately 5% were n-6 PUFA. The predominant n-3 PUFA were 20:5n-3 and 22:6n-3. The NZ mollusc *M. canaliculus* contains a similar FA profile, dominated by 20:5n-3 and 22:6n-3 PUFA (9). Many marine species of molluscs are rich in 20:5n-3, with lower levels of 22:5n-3 and 22:6n-3. Other bivalvia species, such as *Ostrea lutaria* and *C. gigas*, have also been found to contain high levels of 20:5n-3 and 22:6n-3, with the former being the predominant PUFA. In the present study, there was a significantly higher amount of 22:6n-3 (14–20%), particularly in the TBM. In contrast to previous studies, the high proportion of 22:6n-3 in the NZGLM and TBM probably largely reflects the composition of the planktonic diet. Various algal species are known to contain elevated levels of 22:6n-3, including dinoflagellates, cryptomonads, and certain thraustochytrids as well as zooplankton (25,26).

Mollusc FA profiles usually contain about 30–40% SFA (1,8,21), a level which was found in the present study. The SFA profiles were similar for both species and also to profiles for other molluscs.

The presence of 28:8n-3, along with the C<sub>30</sub> sterol dinosterol, indicates a strong dietary influence, in particular for the TBM. The TBM were collected during an algal bloom of the dinoflagellate *Gymnodinium catenatum* that occurs in southern Tasmanian waters. *Gymnodinium catenatum* recently has been reported to contain 28:8n-3 and cholesterol as a major sterol (27). Van Pelt *et al.* (28) reported the presence of 28:8n-3 in the dinoflagellate *Cryptocodinium cohnii*. This dietary link is further supported by the presence of 24-methyl-5 $\alpha$ -cholest-7-en-3 $\beta$ -ol in the TBM. This sterol is also found in *G. catenatum* (29). The higher amounts of 28:8n-3 in the TBM than in the NZGLM suggest a greater dietary dinoflagellate contribution with this species.

The fatty acid 18:5n-3 has also been used as a marker for dinoflagellate ingestion (29), although it is also present in a few other algal species (25). The dinoflagellate biomarkers dinosterol and C<sub>28</sub> PUFA were present in the TBM at higher levels than in the NZGLM, whereas 18:5n-3 was only a minor component in both mussels and in similar proportions (0.2 to 0.3%).

The anti-inflammatory properties of fish oils are thought to be due to the presence of 20:5n-3 and 22:6n-3 (15); correspondingly, Whitehouse *et al.* (18) have reported that the anti-inflammatory activity in an oil extract of lipids from the NZGLM is associated with PUFA, which have 4, 5, and 6 double bonds. In the present study the total proportion of PUFA with 4, 5, and 6 double bonds was 40% in the NZGLM and 43% in the TBM ( $P = 0.92$ ), indicating little difference between species.

The 20:2 and 22:2 NMI FA were found in similar concentrations (3–5%) to levels occurring in a variety of marine molluscs such as gastropods (30). Zhukova and Svetashev (31) reported similar proportions of these FA in *M. edulis* (4.6%), the oyster *C. virginica* (5.8%), and the northern quahog *Merccenaria mercenaria* (2.9%). The presence of these NMI indicates a dietary contribution, as they may be derived from algae and zooplanktonic pteropods such as *Limacina helicina* and result from desaturation of 20:1n-9 and 20:1n-7 (22,31,32). In the study of oysters by Abad *et al.* (32), NMI were present in concentrations from 2 to 10%, depending on the season.

The presence of 4,8,12-TMTD has also been previously reported in various molluscs (30). The American oyster *C. virginica* contained small amounts of 4,8,12-TMTD and NMI dienoic acids (31). The NMI 20:2 and 22:2 are constituents of red algae; thus, their presence may also indicate direct dietary contribution.

**Sterols.** Compared with other marine invertebrates, molluscs are unique, as they contain a wide range of sterols besides cholesterol (8). Both mussels in the current study contained a similar range of sterols, however, in differing proportions, with cholesterol the most prominent sterol ranging from 27 to 32%. Another NZ mussel, *M. planulatus*, has been reported to contain at least eight of the sterols identified in our mussels (22). It may be difficult to compare sterol profiles due to varying extraction techniques and sensitivity of analytical methods. Sterols in *M. planulatus* included *trans*-22-dehydrocholesterol (10%), cholesterol (46%), desmosterol (6%), 24-methylenecholesterol (10%), 24-methylcholesterol (4%), 24-ethylcholesterol (4%), and stigmaterol (1%). Perry (22) also reported similar sterol composition in the BM. Plant sterols such as sitosterol and stigmaterol as identified in both mussel species are believed to aid in cholesterol-lowering in humans (12). Cholesterol was the main sterol (46%) followed by brassicasterol (13%), 24-methylcholesterol and 24-ethylcholesterol (both 4%), and *trans*-22-dehydrocholesterol (2%). Cholesterol was also identified in scallops, up to 60% (22), with some additional more complex C<sub>28</sub> and C<sub>29</sub> sterols.

Gordon (8) reported desmosterol and brassicasterol in similar amounts in the BM. Desmosterol is thought to be an intermediate in cholesterol biosynthesis. The clam *Saxidomus giganteus* has the ability to bioconvert 24-methylenecholesterol and 7-cholestenol, but it is not known if sterols other than cholesterol are synthesized by the mussels.

Teshima and Kanazawa (11) found sterols in the BM and abalone to be predominantly composed of cholesterol (30 and 93%, respectively), followed by 22-dehydrocholesterol (25 and 6%, respectively) and 24-methylenecholesterol (12% and a trace, respectively). The BM contained desmosterol,  $\beta$ -sitosterol, and three unidentified sterols (7%). Gordon (8) reported cholesterol as the dominant sterol in oysters (50%) followed by brassicasterol/desmosterol (25%) and 24-methylenecholesterol (25%). Teshima and Kanazawa (11) showed that molluscs have the ability to synthesize cholesterol; however, this ability is dependent on the mussel's life cycle, sexual maturation, and sex.

This study provides data for the whole tissue of the NZGLM, about which considerable interest exists due to the reported bioactivity in the oil from this species (18,19). The NZGLM had similar lipid content and lipid class composition to the TBM. Differences observed between the two species were probably due to dietary differences and also may reflect seasonal variation, the development of the mussel, particularly the gonads, and/or the sex of the mussel, which can alter the lipid content and lipid class composition.

## ACKNOWLEDGMENTS

This study was funded in part by the Fisheries Research and Development Corporation (99/331). We thank Danny Holdsworth for his assistance with GC-MS, in particular CI/GC-MS experiments; John Croft, MacFarlane Laboratories New Zealand; Dr. Vicky Wadley; and the Mussel and Fish Co-op. Taseas, kindly provided the mussels used in this study.

# Two Novel Glucosylceramides from Gonads and Body Walls of the Patagonian Starfish *Allostichaster inaequalis*

María E. Díaz de Vivar<sup>a</sup>, Alicia M. Seldes<sup>b</sup>, and Marta S. Maier<sup>b,\*</sup>

<sup>a</sup>Facultad de Ciencias Naturales (Sede Puerto Madryn), Universidad Nacional de la Patagonia "San Juan Bosco," 9120 Chubut, Argentina, and <sup>b</sup>Departamento de Química Orgánica, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, 1428 Buenos Aires, Argentina

**ABSTRACT:** From the water-insoluble lipid fraction of the chloroform/methanol/water extract of the gonads and body walls of the Patagonian starfish *Allostichaster inaequalis*, two new glucosylceramides (**4** and **7**) were isolated together with the known phalluside-1 (**1**) and two glucosylceramides (**2** and **3**) previously isolated from the starfish *Cosmasterias lurida*. The new compounds were characterized as (2*S*,3*R*,4*E*,8*E*,10*E*)-1-(β-D-glucopyranosyloxy)-3-hydroxy-2-[(*R*)-2-hydroxy-15-tetracosenoyl] amino-4,8,10-octadecatriene (**4**) and (2*S*,3*R*,4*E*,15*Z*)-1-(β-D-glucopyranosyloxy)-3-hydroxy-2-[(*R*)-2-hydroxyhexadecanoyl] amino-4,15-docosadiene (**7**) by means of spectroscopic and chemical methods.

Paper no. L8958 in *Lipids* 37, 597–603 (June 2002).

Glucosylceramides and related compounds have been isolated from several marine invertebrates, such as echinoderms (1–10), sponges (11–13), ascidians (14), sea anemones (15), bryozoa (16), and gorgonians (17). These compounds have shown a variety of biological activities, such as cytotoxicity against L1210 leukemia cells *in vitro* (8), histidine decarboxylase (1) and DNA topoisomerase I (16) inhibition, and moderate wound-healing activity (9). These biological activities may be related to the amphipathic nature of the molecule (18).

As part of our investigation on polar metabolites from cold-water echinoderms of the South Atlantic, we previously reported the isolation and structural elucidation of glucosylceramides from the starfish *Cosmasterias lurida* Philippi (19). The present paper deals with the isolation and structural elucidation of glucosylceramides from gonads and body walls of *Allostichaster inaequalis* Koehler, a starfish of the Patagonian coast of Argentina. This is the first report on the comparative study of glucosylceramides of gonads and body walls from a dissected starfish.

## EXPERIMENTAL PROCEDURES

*Chromatographic and instrumental methods.* Preparative HPLC was carried out in a Spectra Physics chromatograph

Abbreviations: Ac<sub>2</sub>O, acetic anhydride; BW, glucosylceramide mixture from body walls of the starfish; CC, column chromatography; DMDS, dimethyl disulfide; G, glucosylceramide mixture from gonads of the starfish; LCB, long-chain bases; RP-TLC, reversed-phase TLC; TFA, trifluoroacetic acid.

(Fremont, CA) with a solvent delivery system Spectra Series P100, a Thermo Separation Products refractive index detector (Fremont, CA), and a Spectra Series UV100 UV detector (Fremont, CA) using a Phenomenex Ultracarb ODS 20 column (250 × 10 mm, 5 μm) (Torrance, CA) at a flow rate of 2.0 mL/min, eluting with MeOH/H<sub>2</sub>O (99:1, vol/vol) for the glucosylceramide mixture from the body walls (BW) and MeOH/H<sub>2</sub>O (98:2, vol/vol) for the glucosylceramide mixture from the gonads (G). GC was performed on a Hewlett-Packard 5890 A chromatograph (Avondale, PA) equipped with a FID. An Ultra-2 column (0.2 mm i.d. × 50 m) (Hewlett-Packard) was used with nitrogen as the carrier gas. The column temperature was programmed from 160 to 280°C at a rate of 10°C/min. GC-MS analyses were performed on a VG Trio-2 instrument (Manchester, United Kingdom) employing the electron impact (EI) mode (ionizing potential 70 eV). Helium was used as carrier gas, a capillary column (CP-Sil 5 CB, 0.25 mm i.d. × 50 m length; Chrompack, Middleburg, The Netherlands) (column temperature: 100–290°C; rate: 10°C/min) was used for FAME and long-chain base (LCB) analyses, and an SP 2340 fused-silica column (0.32 mm i.d. × 30 m) (column temperature: 80–270°C; rate: 12°C/min, and then isothermic at 270°C for 20 min) was used for the dimethyl disulfide (DMDS) derivative analyses. Optical rotations were measured on a PerkinElmer 343 polarimeter (Überlingen, Germany). Melting points were measured on a Fisher-Johns m.p. apparatus model 2572 A and are uncorrected.

<sup>1</sup>H and <sup>13</sup>C NMR and 2-D NMR spectra were recorded in a Bruker AM 500 spectrometer (Karlsruhe, Germany) at 500 MHz for <sup>1</sup>H and 125 MHz for <sup>13</sup>C NMR; tetramethylsilane was used as internal standard, and coupling constants (*J*) were represented in Hz. FABMS spectra were registered in a VG-ZAB BEQ spectrometer.

*Materials.* Dry flash-column chromatography (flash-CC) was performed on silica gel H (230–400 mesh; Merck, Darmstadt, Germany) with the solvents indicated in each case. Normal-phase TLC was performed on silica gel F<sub>254</sub> (Merck) with CH<sub>2</sub>Cl<sub>2</sub>/MeOH/AcOEt/H<sub>2</sub>O (8.5:1.5:2:0.1, by vol). Reversed-phase (RP)-TLC was performed on C<sub>18</sub> silica gel 60 F<sub>254</sub> (Merck) with MeOH. CC was performed on silica gel (70–230 mesh; Merck) with CH<sub>2</sub>Cl<sub>2</sub>/MeOH/H<sub>2</sub>O (8:1.3:0.1, by vol).

Fresh specimens of *A. inaequalis* were collected in Bahía Nueva (Puerto Madryn, Chubut, Argentina) and identified by Dr. Alejandro Tablado from the Museo Argentino de Ciencias

<sup>b</sup>Signals superimposed with the solvent.

Naturales “Bernardino Rivadavia,” Buenos Aires, Argentina, where a voucher specimen is preserved (MACN 34396).

**Extraction and isolation.** Animals (45 specimens, 910 g wet weight) were collected and dipped in sea water. Gonads of both sexes and body walls were dissected out. Body walls (649 g) and gonads (148.5 g) were extracted twice by the method of Bligh and Dyer (20) with a solvent mixture of CHCl<sub>3</sub>/MeOH/H<sub>2</sub>O (1:2:0.8, by vol) (2 L/kg) for 72 h at room temperature. The solvent mixture was then diluted to CHCl<sub>3</sub>/MeOH/H<sub>2</sub>O (2:2:1.8, by vol) by addition of CHCl<sub>3</sub> and H<sub>2</sub>O. After filtration *in vacuo*, each chloroformic layer was evaporated to dryness under reduced pressure, thus rendering total lipids (11.9 g from body walls and 4.0 g from gonads). The extracts were fractionated into lipid classes by flash-CC eluting with CHCl<sub>3</sub>; CHCl<sub>3</sub>/AcOEt (80:20, vol/vol); acetone and MeOH. The eluted fractions were analyzed by TLC; spots were revealed with specific reagents (21). Acetone eluates (1.32 g from body walls and 729.6 mg from gonads) contained glycolipids and were repurified by CC, yielding BW (563 mg) and G (534.5 mg).

**Separation of glucosylceramides.** A part of each mixture of glucosylceramides was repeatedly submitted to RP-HPLC. Mixture BW (320.4 mg) (solvent MeOH/H<sub>2</sub>O 99:1, vol/vol) rendered six major fractions: **1**, *R<sub>t</sub>* = 38.0 min, 16.7 mg; **2**, *R<sub>t</sub>* = 44.4 min, 8.2 mg; **3**, *R<sub>t</sub>* = 53.2 min, 8.7 mg; **4**, *R<sub>t</sub>* = 94.8 min, 8.1 mg; **5**, *R<sub>t</sub>* = 110.8 min, 12.3 mg; **6**, *R<sub>t</sub>* = 114.0 min, 4.1 mg. Mixture G (165.0 mg) (solvent MeOH/H<sub>2</sub>O 98:2, vol/vol) furnished three major fractions: **1**, *R<sub>t</sub>* = 50.0 min, 7.1 mg; **7**, *R<sub>t</sub>* = 85.0 min, 8.9 mg; **4**, *R<sub>t</sub>* = 127.0 min, 9.4 mg.

was extracted with cyclohexane (1.0 mL). The extract was evaporated to dryness under reduced pressure, and the residue (DMDS derivative) was redissolved in CH<sub>2</sub>Cl<sub>2</sub> and analyzed by GC–MS.

## RESULTS AND DISCUSSION

Two water-insoluble lipid fractions were obtained from the chloroform/methanol/water extracts of gonads and body walls of the Patagonian starfish *A. inaequalis*. These extracts were subjected to flash-CC and CC to render glycosylceramide mixtures BW and G. Both fractions exhibited the characteristic signals of a sphingosine-type glycosylceramide possessing 2-hydroxy FA and β-glucopyranose moieties in their <sup>1</sup>H NMR spectra: two terminal methyls at δ 0.95 ppm (*d*, *J* = 7.5 Hz) and 0.89 ppm (*d*, *J* = 7.5 Hz), methylenes at δ 1.24–1.30 ppm (*brs*), a singlet at δ 1.70 ppm, due to a methyl group attached to an olefinic carbon, and olefinic signals at δ 5.48 ppm (*dd*, *J* = 14.1, 7.1 Hz), δ 5.56 ppm (*dt*, *J* = 15.7, 6.8 Hz), δ 5.76 ppm (*dt*, *J* = 15.3, 6.2 Hz) and δ 6.04 ppm (*d*, *J* = 15.5 Hz), together with one anomeric doublet at δ 4.26 ppm (*d*, *J* = 7.8 Hz) and hexose proton signals between δ 3.6 and 4.0 ppm. FABMS (negative ion mode) spectra of each mixture showed several [M]<sup>−</sup> or [M – H]<sup>−</sup> peaks, revealing the presence of complex mixtures of monohexosylceramides. Before separation of the mixtures BW and G into individual glyco-

sylceramides, the FA constituents and LCB moieties of these molecular species were investigated. BW and G were methanolized (22) with 1 N HCl in 82% (by vol) aqueous MeOH to yield each a mixture of FAME and a mixture of LCB together with methyl-D-glucopyranose. GC analysis of the peracetylated alditol derivative (23) confirmed glucose as the hexosyl moiety (*R*<sub>t</sub> = 10.31 min, *R*<sub>t</sub> of reference peracetylated D-glucitol = 10.33 min).

Analysis of the FAME mixture of BW by GC–MS showed the presence of 18 compounds (FAME 1–18) (Scheme 1), which were characterized by comparing their spectral data with those reported previously (5,7). The 2-hydroxy-substituted saturated FAME were characterized as methyl-(2*R*)-hydroxy-tetradecanoate (FAME-1) (*R*<sub>t</sub> = 14.20 min, *m/z* 258 [M]<sup>+</sup>, 199 [M – 59]<sup>+</sup>), -pentadecanoate (FAME-2) (*R*<sub>t</sub> = 15.30 min, *m/z* 272 [M]<sup>+</sup>, 213 [M – 59]<sup>+</sup>), -hexadecanoate (FAME-3) (*R*<sub>t</sub> = 16.43 min, *m/z* 286 [M]<sup>+</sup>, 227 [M – 59]<sup>+</sup>), -heptadecanoate (FAME-4) (*R*<sub>t</sub> = 17.20 min, *m/z* 300 [M]<sup>+</sup>, 241 [M – 59]<sup>+</sup>), -octadecanoate (FAME-5) (*R*<sub>t</sub> = 18.43 min, *m/z* 314 [M]<sup>+</sup>, 255 [M – 59]<sup>+</sup>), -nonadecanoate (FAME-6) (*R*<sub>t</sub> = 19.05 min, *m/z* 328 [M]<sup>+</sup>, 269 [M – 59]<sup>+</sup>), -eicosanoate (FAME-7) (*R*<sub>t</sub> = 20.18 min, *m/z* 342 [M]<sup>+</sup>, 284 [M – 59]<sup>+</sup>), -docosanoate (FAME-8) (*R*<sub>t</sub> = 22.15 min, *m/z* 370 [M]<sup>+</sup>, 311 [M – 59]<sup>+</sup>), -tricosanoate (FAME-9) (*R*<sub>t</sub> = 23.17 min, *m/z* 384 [M]<sup>+</sup>, 326 [M – 59]<sup>+</sup>), -tetracosanoate (FAME-10) (*R*<sub>t</sub> = 24.47 min, *m/z* 398 [M]<sup>+</sup>, 339 [M – 59]<sup>+</sup>), and -pentacosanoate (FAME-11)

SCHEME 1

( $R_t = 25.67$  min,  $m/z$  412  $[M]^+$ , 353  $[M - 59]^+$ ). Four unsaturated and one nonsubstituted FAME were identified as methyl-(2*R*)-hydroxy-docosenoate (FAME-12) ( $R_t = 21.87$  min,  $m/z$  369  $[M + H]^+$ , 309  $[M - 59]^+$ ), -tricosenoate (FAME-13) ( $R_t = 22.85$  min,  $m/z$  382  $[M]^+$ , 323  $[M - 59]^+$ ), -tetracosenoate (FAME-14 and FAME-15) ( $R_t = 24.13$  min,  $m/z$  396  $[M]^+$ , 337  $[M - 59]^+$ ), -pentacosenoate (FAME-16 and FAME-17) ( $R_t = 25.38$  min,  $m/z$  410  $[M]^+$ , 352  $[M - 59]^+$ ). The position of the double bond in the unsaturated methyl-(2*R*)-hydroxyacids (FAME 12–17) was determined by GC–MS analysis of the DMDS derivatives (24). The following unsaturated FAME were identified: methyl-(2*R*)-hydroxy-15-docosenoate (FAME-12) ( $R_t = 19.53$  min,  $m/z$  392  $[M - 60]^+$ , 247  $[392 - 145]^+$ , 145  $[CH_3(CH_2)_5CH=SCH_3]^+$ ), -14-tricosenoate (FAME-13) ( $R_t = 22.58$  min,  $m/z$  418  $[M - 59 + H]^+$ , 245  $[418 - 173]^+$ , 173  $[CH_3(CH_2)_7-CH=SCH_3]^+$ ), -15-tetracosenoate (FAME-14) ( $R_t = 24.12$  min,  $m/z$  432  $[M - 59 + H]^+$ , 259  $[432 - 173]^+$ , 173), -10-tetracosenoate (FAME-15) ( $R_t = 24.12$  min,  $m/z$  432  $[M - 59 + H]^+$ , 243  $[CH_3-(CH_2)_{12}-CH=SCH_3]^+$ , 189  $[432 - 243]^+$ ), -16-pentacosenoate (FAME-16) ( $R_t = 26.55$  min,  $m/z$  446  $[M - 59 + H]^+$ , 273  $[446 - 173]^+$ , 173), and -18-pentacosenoate (FAME-17) ( $R_t = 26.73$  min,  $m/z$  446  $[M - 59 + H]^+$ , 301  $[446 - 145]^+$ , 145). The only nonsubstituted FAME was identified as methyl-ocotadecanoate (FAME-18) ( $R_t = 15.15$  min,  $m/z$  298  $[M]^+$ , 239  $[M - 59]^+$ , 74). The main FAME were the 2-hydroxy-substituted saturated ones: FAME-4 (17.9%), FAME-5 (5.6%), FAME-6 (7.8%), FAME-9 (10.4%), FAME-10 (12.2%), and FAME-11 (22.8%).

Analysis of the FAME mixture of G by GC–MS allowed identification of eight 2-hydroxy-substituted saturated FAME (1–5 and 8–10), methyl-(2*R*)-hydroxy-tetracosenoate (FAME-15) ( $R_t = 24.12$  min,  $m/z$  396  $[M]^+$ , 339  $[M - 59]^+$ ), and four nonsubstituted FAME: methyltetradecanoate (FAME-19) ( $R_t = 12.80$  min,  $m/z$  242  $[M]^+$ , 211  $[M - 31]^+$ ), -14-methylpentadecanoate (FAME-20) ( $R_t = 15.10$  min,  $m/z$  270  $[M]^+$ , 239  $[M - 31]^+$ , 227  $[M - 43]^+$ ), -16-methylheptadecanoate (FAME-21) ( $R_t = 17.17$  min,  $m/z$  298  $[M]^+$ , 267  $[M - 31]^+$ , 255  $[M - 43]^+$ , 74), and -eicosanoate (FAME-22)

( $R_t = 19.02$  min,  $m/z$  326  $[M]^+$ , 295  $[M - 31]^+$ , 267  $[M - 59]^+$ , 74) (Scheme 1). The main FAME was FAME-4 (28.4%) along with smaller proportions of FAME-3 (6.6%) and FAME-6 (7.4%). Optical rotations of FAME mixtures from BW ( $[\alpha]_D = -2.4^\circ$  ( $c = 1.3$ ,  $CHCl_3$ )) and G ( $[\alpha]_D = -16.4^\circ$  ( $c = 0.73$ ,  $CHCl_3$ )) are in good agreement with the data reported in the literature (25); therefore, the absolute stereochemistry at C-2' is suggested to be *R*.

LCB mixtures derived from methanolysis of BW and G were acetylated with acetic anhydride ( $Ac_2O$ )/pyridine at  $70^\circ C$  and analyzed by GC–MS, showing the presence of 2-acetamido-1,3-diacetoxy-9-methyl-4,8,10-octadecatriene (acetylated LCB-1) ( $R_t = 20.5$  min,  $m/z$  375  $[M - CH_3COOH]^+$ , 316  $[M - CH_3COOH - CH_3COO]^+$ , 256, 178, 85), 2-acetamido-1,3-diacetoxy-4,8,10-octadecatriene (acetylated LCB-2) ( $R_t = 19.87$  min,  $m/z$  361  $[M - CH_3COOH]^+$ , 302  $[M - CH_3COOH - CH_3COO]^+$ , 256, 164, 85), and 2-acetamido-1,3-diacetoxy-4,15-docosadiene (acetylated LCB-3) ( $R_t = 23.3$  min,  $m/z$  421  $[M - CH_3COO + H]^+$ , 376  $[M - 43 - CH_3COOH]^+$ , 316  $[M - 43 - 2 \times CH_3COOH]^+$ , 281  $[M - CH_3COO - C_{10}H_{39}]^+$ , 207  $[M - 43 - C_9H_{17}]^+$  (Scheme 2). The relative stereochemistry at C-2 and C-3 was proposed as 2*S*,3*R* from optical rotation data of the acetylated LCB mixtures ( $[\alpha]_D = -17.2^\circ$  ( $c = 0.3$ ,  $Cl_3CH$ ), in good agreement with data for synthetic 1-*O*-2-*N*-3-*O*-triacetyl-*D*-erythro-sphingosine (26).

Fraction BW (320.4 mg) was separated repeatedly by RP-HPLC into six major fractions (1–6), whereas fraction G (165.0 mg) yielded three fractions (1, 4, and 7). Each fraction displayed a single peak on RP-HPLC. Fractions 1–4 and 7 revealed single molecular ion peaks in their negative FAB mass spectra, but fractions 5 and 6 exhibited two and three molecular ions, respectively.

Acetylated LCB-1 R = CH<sub>3</sub>

Acetylated LCB-2 R = H

Acetylated LCB-3

SCHEME 2

SCHEME 3

Fractions **1–3**, **5**, and **6** (Scheme 3) showed the same characteristic <sup>1</sup>H and <sup>13</sup>C NMR signals due to C-1-C-11, C-1', C-2', C-1''-C-6'' of a 1-*O*-β-glucopyranoside of a (2*S*,3*R*,4*E*,8*E*,10*E*)-2-amino-1,3-dihydroxy-9-methyl-4,8,10-octadecatriene ceramide possessing a (2*R*)-hydroxy FA (Tables 1 and 2). The presence of a singlet at δ 1.71 ppm in the <sup>1</sup>H NMR spectrum and of the corresponding signal at δ 12.8 ppm in the <sup>13</sup>C NMR spectrum was diagnostic for the presence of a methyl group (C-19) attached to an olefinic carbon. <sup>13</sup>C NMR spectra (Table 2) confirmed the ceramide nature of the compounds (δ 177.0 ppm, C=O) with normal-chain bases and FA (terminal methyl at δ 14.4 ppm) and a (2*S*,3*R*,4*E*)-sphingosine-type base indicated by C-2 and C-3 chemical shifts at δ 54.6 and 72.8 ppm (5).

These spectra were almost superimposable with those of ophidiacerebroside C (8) and of glucosylceramides isolated from *C. lurida* (20) containing (2*S*,3*R*,4*E*,8*E*,10*E*)-2-amino-9-methyl-4,8,10-octadecatrien-1,3-diol as the LCB moiety.

Fractions **1–3**, **5**, and **6** were methanolized (23) and the FAME analyzed by GC-MS; a single FAME was detected for fractions **1** (FAME-3), **2** (FAME-4), and **3** (FAME-5), two kinds of FAME were obtained for fraction **5** (FAME-8 and FAME-14) and four kinds of FAME for fraction **6** (FAME-8, FAME-9, FAME-14, and FAME-11). Double-bond position in FAME-14 was determined from the GC-MS analysis of the DMDS derivative (24) according to ions at *m/z* 490 [M]<sup>+</sup>, 317 [M - 173]<sup>+</sup>, and 173.

LCB obtained from methanolysis of **1–3**, **5**, and **6** were acetylated and analyzed by GC-MS. Results showed the presence of 2-acetamido-1,3-diacetoxy-9-methyl-4,8,10-octadecatriene as evidenced by the ions at *m/z* 435 [M]<sup>+</sup>, 375 [M - CH<sub>3</sub>COOH]<sup>+</sup>, 315 [M - 2 × CH<sub>3</sub>COOH]<sup>+</sup> and 256 (β-cleavage from Δ<sup>4</sup>).

Taking into account the FABMS spectra and the methanolysis products of each fraction, one can determine that three fractions are homogeneous. These fractions are assigned to compounds **1**, **2**, and **3** (Scheme 3). Glucosylceramide **1** was identified as phalluside-1, previously isolated from the ascidian *Phallusia fumigata* (14), whereas **2** and **3** are also known compounds previously isolated from *C. lurida* (20). Fraction **5** (Scheme 3) is a mixture of glucosylceramide **5a**, previously isolated from *Ophidiaster ophidiamus* (ophidiacerebroside C)

(8) and *C. lurida* (19) and the new **5b** {(2*S*,3*R*,4*E*,8*E*,10*E*)-1-(β-D-glucopyranosyloxy)-3-hydroxy-2-[(*R*)-2-hydroxy-15-tetracosenoyl]amino-9-methyl-4,8,10-octadecatriene}. Fraction **6** (Scheme 3) is a mixture of the known glucosylceramides ophidiacerebroside C (**5a**) and **6a**, previously isolated from *O. ophidiamus* (8), and the new glucosylceramides **5b** and **6b** (2*S*,3*R*,4*E*,8*E*,10*E*)-1-(β-D-glucopyranosyloxy)-3-hydroxy-2-[(*R*)-2-hydroxypentacosanoyl]amino-9-methyl-4,8,10-octadecatriene. Scarcity of material prevented our attempt to isolate new glucosylceramides **5b** and **6b** as pure compounds.

Compound **4** (Scheme 4) was obtained as a white amorphous powder. The FABMS (negative ion mode) spectrum showed a single [M - H]<sup>-</sup> peak at *m/z* 820 and the corresponding [M - 162]<sup>-</sup> ion at *m/z* 658 due to the loss of the hexose unit. The <sup>13</sup>C NMR spectrum (Table 2) of **4** was similar to that of glucosylceramides **1–3**, **5**, and **6** except that its structure lacked the methyl group at C-9 as reflected by the absence of the signal at δ 12.8 ppm and the singlet at δ 1.70 ppm in the <sup>1</sup>H NMR spectrum (Table 1). Signals at δ 73.1 (C-2') and 25.1 ppm (C-3'), shifted downfield compared with those of an unsubstituted acid, indicated the presence of a 2-hydroxyacid moiety (27). The unsaturation pattern in the <sup>1</sup>H NMR spectrum showed a double doublet at δ 5.48 ppm (*J* = 15.4, 7.5 Hz, H-4) and a double triplet at δ 5.73 ppm (*J* = 15.1, 6.4 Hz, H-5), characteristic of a Δ<sup>4</sup> sphingosine with *trans* configuration and multiplets at δ 5.54, 5.56, 5.96, and 5.99 ppm. This pattern differed from the olefinic pattern observed for glucosylceramides **1–3**, **5**, and **6** with the methyl group at C-9 in the LCB moiety (Table 1). The COSY <sup>1</sup>H-<sup>1</sup>H spectrum of **4** showed correlations between the H-4 signal (δ 5.48 ppm), the broad triplet at δ 4.14 ppm (H-3), and the double triplet at δ 5.73 ppm (H-5). The latter signal also correlated with a multiplet at δ 2.15 ppm (H-6). Further correlations

SCHEME 4

between olefinic signals at  $\delta$  5.54, 5.56, 5.96, and 5.99 ppm and vicinal methylene groups at positions 7 and 12 allowed us to establish the olefinic pattern of the LCB unit as a 4,8,10-triene. The conjugated diene structure was also supported by a UV absorbance band at 224 nm. The same LCB moiety was identified for the first time in a mixture of LCB obtained by hydrolysis of the glucosylceramide mixture isolated from the spermatozoa of the starfish *Asterias amurensis* (28) and further in a ceramide isolated from the gorgonian *Acabaria undulata* (17). A LCB also containing a 4,8,10-triene but whose structure was not completely defined was reported in a glucosylceramide isolated from the ascidian *P. fumigata* (14).

The isolated olefinic triplet at  $\delta$  5.35 ppm ( $J = 4.8$  Hz), which correlated only with a methylene signal at  $\delta$  1.98 ppm, was therefore assigned to the acid moiety. *Z* geometry was deduced from the  $J$  value and the triplet shape of the signal (5) in the  $^1\text{H}$  NMR spectrum and was confirmed by the chemical upfield shift of allylic methylene carbon signals at  $\delta$  28.1 ppm (27). The presence of eight olefinic signals in the  $^{13}\text{C}$  NMR spectrum of **4** confirmed the presence of three unsaturations in the base and one in the acid moiety. Assignment of these signals was derived from  $^1\text{H}$ - $^1\text{H}$  COSY and bidimensional NMR experiments.

Acidic methanolysis of **4** yielded a FAME, a methyl glycoside, and a LCB. GC analysis of the peracetylated alditol derivative (23) confirmed glucose as the hexosyl moiety. GC-MS analysis of the FAME showed a single peak at  $R_t = 23.90$  min. The molecular ion peak at  $m/z$  396  $[\text{M}]^+$  and fragment ion peaks at  $m/z$  365  $[\text{M} - 31]^+$  and 338  $[\text{M} - \text{CH}_3\text{COO} + \text{H}]^+$  confirmed the presence of methyl-2-hydroxytetra-cosenoate (FAME-14, Scheme 1). The double-bond position in FAME-14 was determined by GC-MS analysis of the DMDS derivative (24) according to peaks at  $m/z$  490  $[\text{M}]^+$ , 431  $[\text{M} - \text{CH}_3\text{COO}]^+$ , 384  $[431 - \text{SCH}_3]^+$ , 257  $[431 - 173 - \text{H}]^+$ , and 173.

Acetylation of LCB derived from methanolysis of **4** and GC-MS analysis of the acetylated LCB showed the presence of a C-18 sphingosine-type base (acetylated LCB-2, Scheme 2) on the basis of peaks at  $m/z$  421  $[\text{M}]^+$ , 243 (C-5/C-6 cleavage), and 85 ( $\beta$ -cleavage to  $\Delta^{10}$ ).

All these data allowed us to determine the structure of the new glucosylceramide **4** as (2*S*,3*R*,4*E*,8*E*,10*E*)-1-( $\beta$ -D-glucopyranosyloxy)-3-hydroxy-2-[(*R*)-2-hydroxy-15-tetra-cosenoyl]amino-4,8,10-octadecatriene. The LCB and FA moieties of **4** have been detected in the LCB and FAME mixtures isolated from the glucosylceramide mixture of *A. amurensis* (28), but because no attempt was made in the reference work to obtain the pure cerebrosides, it cannot be inferred whether glucosylceramide **4** was present in spermatozoa of *A. amurensis*.

The  $^1\text{H}$  NMR spectrum of **7** (Table 1) showed characteristic signals at  $\delta$  3.71 (H-1), 4.11 (H-1, H-3), 3.97 (H-2, H-2'), 5.47 (H-4), and 5.72 ppm (H-5) for a glucosylceramide containing a sphingosine-type LCB moiety and a 2-hydroxy FA. The monosaccharide signals in the  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra (Tables 1 and 2) confirmed glucose as the hexose unit. Glu-

SCHEME 5

cosylceramide **7** (Scheme 4) showed the presence of an additional disubstituted double bond on the basis of a triplet at  $\delta$  5.35 ppm in the  $^1\text{H}$  NMR spectrum and two olefinic carbon signals at  $\delta$  130.4 and 131.2 ppm in the  $^{13}\text{C}$  NMR spectrum. In determining the identities of the FA and the LCB, compound **7** was methanolized with 1 N HCl in 82% (by vol) aqueous MeOH. FAME analysis of **7** allowed identification of methyl-2-hydroxyhexadecanoate (FAME-3) on the basis of ions at  $m/z$  286  $[\text{M}]^+$  and 227  $[\text{M} - \text{CH}_3\text{COO}]^+$ . GC-MS analysis of the acetylated LCB showed ions at  $m/z$  361  $[479 - 2 \times \text{CH}_3\text{COO}]^+$  and 216 (cleavage at C-3/C-4), suggesting the presence of a sphingosine-type base with 22 carbons and one isolated double bond in the chain. *Z* geometry of the double bond was deduced from the  $J$  value (5.9 Hz) and the shape of the signal at  $\delta$  5.35 ppm (5) in the  $^1\text{H}$  NMR spectrum and confirmed by the chemical upfield shift of allylic methylene carbon signals at  $\delta$  27.9 and 28.2 ppm (29). The position of the additional double bond in the LCB was determined to be  $\Delta^{15}$  from the CG-MS analysis of the DMDS derivative of the acetylated LCB (24), on the basis of the peaks shown in Scheme 5.

All these data allowed identification of **7** as (2*S*,3*R*,4*E*,15*Z*)-1-( $\beta$ -D-glucopyranosyloxy)-3-hydroxy-2-[(*R*)-2-hydroxyhexadecanoyl]amino-4,15-docosadiene, a new compound. Related glucosylceramides with  $\Delta^9$  and  $\Delta^{13}$  LCB moieties were isolated from the starfish *A. amurensis versicolor* (5).

A comparative analysis of the composition of both mixtures (BW and G) showed differences in the FA and LCB moieties. LCB-1 was the most frequent LCB found in BW, whereas LCB-1, LCB-2, and LCB-3 were equally distributed in G. As for the FAME composition, BW showed FAME-11 as the main component, but FAME-4 was the component in greater proportion in G. All FAME detected in BW had *normal* chains, whereas G showed FAME with *iso* chains as minor components.

## ACKNOWLEDGMENTS

This work was supported by the International Foundation for Science, Stockholm, Sweden, and the Organization for the Prohibition of Chemical Weapons, The Hague, The Netherlands, through a grant to M.S. Maier. We also wish to thank Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), Agencia Nacional de Promoción Científica y Tecnología, and the Universidad de Buenos Aires (UBA) for financial support of this work. We are indebted to Unidad de Servicio de Microanálisis y Métodos Físicos Aplicados

Organicos [CONICET-Facultad de Ciencias Exactas y Naturales (FCEN), UBA] for NMR spectra and Laboratorio Nacional de Análisis y Servicios-Espectrometría de masa de alta resolución (CONICET-FCEN, UBA) for mass spectra. We are also grateful to Dr. Alejandro Tablado from the Museo de Ciencias Naturales "Bernardino Rivadavia" for the taxonomic identification of the starfish. M.S.M. and A.M.S. are Research Members of the National Research Council of Argentina (CONICET).

# Positional Distribution of CLA in TAG of Lamb Tissues

Lyn J. Paterson<sup>a</sup>, Randall J. Weselake<sup>a,\*</sup>, Priya S. Mir<sup>b</sup>, and Zahir Mir<sup>b</sup>

<sup>a</sup>Department of Chemistry and Biochemistry, University of Lethbridge, Lethbridge, Alberta, T1K 3M4 Canada, and <sup>b</sup>Agriculture and Agri-Food Canada, Lethbridge Research Centre, Lethbridge, Alberta, T1J 4B1 Canada

**ABSTRACT:** The content and positional distribution of CLA in TAG fractions of lamb tissues was examined with either preformed CLA or the linoleic acid precursor of CLA in the diet as experimental treatments. The CLA content of phospholipid (PL) from these tissues was also examined. Thirteen lambs were randomized to the following dietary treatments: (i) control diet (no supplement); (ii) CLA supplementation (0.33 g d<sup>-1</sup> for 21 d prior to weaning) to milk-replacer of pre-ruminating lambs, or (iii) feeding linoleic acid-rich oil (6% safflower oil on a dry matter basis) to weaned ruminating lambs. At slaughter, tissue samples were procured from diaphragm, rib muscle, and subcutaneous (SC) adipose tissue. Safflower oil supplementation in the diet resulted in an increase in CLA content of the TAG from diaphragm, rib muscle, and SC adipose tissue by about threefold ( $P < 0.05$ ) on a mol% basis. CLA was localized to the *sn*-1/3 positions of TAG. Animals that received pre-formed CLA, however, had increased proportions of CLA at the *sn*-2 position of TAG from SC adipose tissue, suggesting that there were tissue-specific dietary effects and possible age-related effects on the mode of FA incorporation into TAG. Safflower oil supplementation in the diet had no effect on the CLA content of PL from diaphragm, rib muscle, and SC adipose tissue, suggesting that CLA was preferentially incorporated into the TAG of these tissues.

Paper no. L8792 in *Lipids* 37, 605–611 (June 2002).

CLA isomers are intermediary metabolites in the bioconversion of dietary linoleic acid (18:2) to stearic acid (18:0) by the microorganism *Butyrivibrio fibrisolvens* in ruminants (1). CLA includes several positional and geometric isomers of 18:2 with double bonds predominantly at the 9- and 11-, 10- and 12-, or 11- and 13-carbon atoms, with various combinations of *cis* and *trans* configuration at each double bond. CLA represents a relatively minor component of the total FA composition of foods, but ingestion of the isomers results in strong fat-to-lean repartitioning effects in rats (2), protection against the effects of carcinogens when present in the diet (in the range of 0.1–1%) (3,4), and stimulation of the immune system (5). Furthermore, CLA in milk has been implicated as a factor responsible for the inverse relationship between high milkfat consumption and low incidence of mammary cancer in humans (6).

In general, meat and dairy products from ruminants contain more CLA than products from nonruminants (7,8). The

concentration of CLA in beef ranges from 1.7 to 8.5 mg CLA g<sup>-1</sup> of fat and is affected by the nature of the feed (9,10). Canola oil or full-fat rapeseed supplementation of goat or dairy cow diets, respectively, increased CLA content in milk (11,12). A diet that included 5% free 18:2 significantly increased the CLA concentration of both the neutral lipid (NL) and phospholipid (PL) fractions of liver tissue samples from rats (2). As well, inclusion of preformed CLA in rat diets has been shown to result in a sixfold increase in the CLA content of the PL fraction compared to controls (13). In a more recent study using mice, a dose-dependent increase in CLA content was observed in epidermal NL and PL as CLA in the diet was increased from 0 to 1.5% (14). CLA and other conjugated diene intermediates also have been found in the PL fraction from lamb liver (15). A recent study with lactating dairy cows has indicated that *trans*-11 18:1 represents the major precursor of CLA in milk fat (16). The CLA was produced by the catalytic action of an endogenous  $\Delta 9$  desaturase. In another recent study, pigs were shown to produce back fat CLA by endogenous  $\Delta 9$  desaturation of dietary *trans*-11 18:1 (17).

Recently, we demonstrated that dietary safflower or sunflower oil supplementation enhanced the CLA content of various lamb tissues through provision of the 18:2 precursor of CLA (18,19). The current study extends our investigations on the inclusion of 18:2 in the diet of lambs to gain insight into the pathway of incorporation of CLA into the major glycerolipid classes of muscle and adipose tissue. Lipid samples were isolated from diaphragm, rib muscle and subcutaneous (SC) adipose tissue obtained at slaughter from lambs fed CLA as a free acid pre-weaning (pre-ruminating) and those fed a high-18:2 diet post-weaning (ruminating) to investigate effects on the CLA content of TAG and PL. Incorporation of CLA into TAG was further investigated through analyses of the positional distribution of CLA on the glycerol backbone.

## MATERIALS AND METHODS

**Lambs and dietary regimes.** The management protocol and diets fed to the crossbred (Suffolk  $\times$  Dorset) lambs (*Ovis aries*) used as a source of tissue in this study have been reported previously (18). Thirteen 4-wk-old lambs with an average weight of  $12.5 \pm 3.4$  kg ( $\pm$  SEM) were removed from ewes and then maintained in two pens with ready access to milk replacer from an artificial ewe feeding apparatus for 21 d. The lambs also had access to a pelleted creep feed composed of barley grain, alfalfa, and soybean meal. Five lambs in the control treatment and four lambs designated to receive

\*To whom correspondence should be addressed at Dept. of Chemistry and Biochemistry, University of Lethbridge, 4401 University Dr., Lethbridge, Alberta, T1K 3M4 Canada. E-mail: weselake@uleth.ca

Abbreviations: 16:0, palmitic acid; 18:0, stearic acid; 18:1, oleic acid; 18:2, linoleic acid;  $\alpha$ -18:3,  $\alpha$ -linolenic acid; NL, neutral lipid; PL, phospholipid; SC, subcutaneous; TL, total lipid.

6% safflower oil upon weaning were given 50 mL of milk replacer containing 5 mL of olive oil as a carrier on a daily basis by bottle. Four lambs constituting the CLA treatment group received 50 mL of milk replacer containing 0.33 g CLA (free acid) (catalog # 05507; Sigma-Aldrich Canada Ltd., Oakville, Ontario, Canada) dissolved in 5 mL of olive oil on a daily basis. The lambs were weaned off the artificial ewe after 21 d at an average weight of  $18.9 \pm 3.4$  kg ( $\pm$  SEM) and were then transferred to individual pens and provided a pelleted diet *ad libitum*. Control lambs and those that received CLA-supplemented milk replacer were supplied with the pelleted diet, whereas the lambs in the safflower oil treatment were administered a pelleted diet supplemented with 6% oil on a dry matter basis.

Safflower oil bought from a commercial source contained 78% 18:2. Commercial safflower oil has been reported to contain 0.7 mg CLA/g (20). The CLA from Sigma-Aldrich consisted of about 50% *trans*-9,*cis*-11 and *cis*-9,*trans*-11 combined, 40% *trans*-10,*cis*-12, and 10% *cis*-10,*cis*-12 CLA. The pelleted diet consisted of the following ingredients: barley, 56.2%; dehydrated alfalfa, 29.5%; soybean meal, 9.0%; molasses, 2.0%; mineral mixture, 1.05%; maxi-pel (a binder used to keep the pellet intact), 1.0%; calcium phosphate, 0.5%; ammonium chloride, 0.5%; dicalcium phosphate, 0.2%; 0.2% vitamin A (10 million IU  $\text{kg}^{-1}$ ); vitamin E (100,000 IU  $\text{kg}^{-1}$ ), 0.033%; and Deccox (to prevent coccidiosis) pre-mix, 0.018%. The diet had a crude protein content of 16.6%. The pelleted diet was low in fat content. Collectively, the dried alfalfa and barley contained less than 2% lipid (21). This diet was fed to the lambs for  $80 \pm 1.8$  d. The average weight of the animals at slaughter was  $45 \pm 2.9$  kg ( $\pm$  SEM).

**Tissue samples.** At the time of slaughter, samples were procured from diaphragm and SC adipose tissue. A double chop from the 12th and 13th ribs was sampled from each animal at the time of cutting. All tissue samples were obtained from the same half of the carcass. Tissue samples were stored in sterile plastic bags with as little air as possible, kept on ice for approximately 30 min and then frozen in liquid  $\text{N}_2$ . Tissues were stored at  $-20^\circ\text{C}$  until used. Samples were thawed at  $4^\circ\text{C}$ , and subsamples were ground with a hand grinder until completely blended and then refrozen and stored at  $-20^\circ\text{C}$ .

**Lipid extraction.** Lipids were extracted using  $\text{CHCl}_3/\text{CH}_3\text{OH}$  (2:1, vol/vol) (22). Stored tissue was thawed at  $4^\circ\text{C}$ , and 500 mg of tissue was weighed into a test tube and homogenized in 5 mL of  $\text{CHCl}_3/\text{CH}_3\text{OH}$  (2:1, vol/vol), using a Kinematica homogenizer model PT-10-35 (Brinkmann Instruments, Rexdale, Ontario, Canada) at speed setting 6 for 30 s. The probe was rinsed with 5 mL  $\text{CHCl}_3/\text{CH}_3\text{OH}$  (2:1, vol/vol), and the rinse and homogenate were combined and centrifuged at  $1600 \times g$  for 30 min. The supernatant was washed two times with 2 mL 0.29% NaCl (wt/vol), and the final organic phase was passed through a small column of anhydrous  $\text{Na}_2\text{SO}_4$ . The dehydrated lipid extract was then evaporated to dryness at 37 to  $40^\circ\text{C}$  under a gentle stream of  $\text{N}_2$ . The total lipid (TL) was dissolved in  $\text{CHCl}_3$  to a final concentration of  $150 \text{ mg mL}^{-1}$  and stored at  $-20^\circ\text{C}$  under  $\text{N}_2$ .

**Separation of lipid classes.** TL was fractionated into NL and PL fractions using a modification (2) of a previously described method (23). TL ( $30\text{--}60 \text{ mg}$  in  $500\text{--}1000 \mu\text{L}$   $\text{CHCl}_3$ ) was applied to a silica cartridge (Sep-Pak Classic; Waters Limited, Mississauga, Ontario, Canada) followed by a three-step elution procedure. The NL fraction was eluted with 20 mL  $\text{CHCl}_3$  injected by syringe at a flow rate of approximately  $25 \text{ mL min}^{-1}$ . MAG was eluted with 10 mL  $\text{CHCl}_3/\text{CH}_3\text{OH}$  (98:2, vol/vol) at a flow rate of approximately  $20 \text{ mL min}^{-1}$ . The PL fraction was eluted with 30 mL  $\text{CH}_3\text{OH}$  at a flow rate of  $25 \text{ mL min}^{-1}$ . The PL and NL fractions were evaporated to dryness under  $\text{N}_2$  gas and dissolved in  $\text{CHCl}_3$  to a final concentration  $10 \text{ mg mL}^{-1}$ , then stored under  $\text{N}_2$  at  $-20^\circ\text{C}$ .

**TAG isolation.** Two hundred microliters of  $150 \text{ mg TL mL}^{-1}$  ( $30 \text{ mg TL}$ ) were applied to a pre-run EM Science HPTLC-Fertigplatten Kieselgel 60 plate ( $10 \times 20 \text{ cm}$ , 0.25 mm thick) (VWR Canlab, Mississauga, Ontario, Canada). Fifty microliters of  $10 \text{ mg}$  trioleoylglycerol  $\text{mL}^{-1}$  were applied as a reference standard (Sigma-Aldrich Canada, Oakville, Ontario, Canada). Lipids were separated with one ascension of hexane/diethyl ether/acetic acid (80:20:1, by vol) (24). The isolated TAG were dissolved in  $\text{CHCl}_3$  to a concentration of  $10 \text{ mg mL}^{-1}$  and stored under  $\text{N}_2$  at  $-20^\circ\text{C}$ .

**Digestion of TAG using pancreatic lipase.** Pancreatic lipase was used to generate *sn*-2-MAG from TAG (25). Two milligrams of dried TAG was suspended in  $500 \mu\text{L}$  of pancreatic lipase buffer [1 M Tris-HCl, pH 8, containing 10% gum arabic (wt/vol) and 0.23 M  $\text{CaCl}_2$  (wt/vol)] by sonication. Five hundred microliters of pancreatic lipase buffer containing  $8 \text{ mg}$  pancreatic lipase  $\text{mL}^{-1}$  was added to the TAG suspension; the mixture was vortexed briefly and incubated at  $37^\circ\text{C}$  for 1 h in a shaking water bath. The reaction was stopped with  $500 \mu\text{L}$  of 0.1 N acetic acid, and the lipid was extracted three times with 2 mL diethyl ether. Each extract was passed through a small column of anhydrous  $\text{Na}_2\text{SO}_4$ , combined, and then evaporated to dryness under  $\text{N}_2$ . The extracted lipid was redissolved in  $100\text{--}200 \mu\text{L}$   $\text{CHCl}_3$  and applied to boric acid TLC plates (see below). Fifty microliters of a  $10 \text{ mg mL}^{-1}$  solution of *sn*-2-monooleoylglycerol (Sigma-Aldrich) was applied as a reference standard. Lipids were separated by one ascension of  $\text{CHCl}_3/\text{CH}_3\text{COCH}_3$  (88:12, vol/vol) (26).

**Elution of TAG and MAG from silica gel.** TAG and *sn*-2-MAG standards were visualized with iodine vapor. The silica containing the fraction of interest was removed from the TLC plate with a glass microscope slide onto glassine paper and transferred to a methanol-washed test tube. Lipids were eluted from silica by extracting twice with 5 mL and once with 2 mL of  $\text{CHCl}_3$ . The slurry was shaken vigorously and centrifuged at  $400 \times g$  for 5 min. Each eluent was passed through a column of anhydrous  $\text{Na}_2\text{SO}_4$ . The combined lipid fractions were stored at  $-20^\circ\text{C}$  under  $\text{N}_2$ .

**Preparation of boric acid TLC plates.** Boric acid TLC plates were prepared using a slurry of 60 g Silica Gel G (Sigma-Aldrich) and 160 mL 0.4 M boric acid to make five  $20 \times 20 \text{ cm}$ , 0.5 mm thick, TLC plates. The plates were air-

dried, heated for 2 h at 120°C, and then stored at room temperature in the presence of desiccant until use.

**Analysis of FA composition.** Tetramethylguanidine was used to transmethylate lipid samples (27,28). Lipid samples were dried under N<sub>2</sub> with 2 µL of 20 mg 21:0 methyl ester mL<sup>-1</sup> added as an internal standard. The dried lipid was suspended in 500 µL methanol/tetramethylguanidine (4:1, vol/vol) and incubated in a boiling water bath for 30 min. Five milliliters of saturated NaCl solution were added after cooling to room temperature, and the lipids were extracted three times with 2 mL of petroleum ether. The extracts were combined and passed through a column of anhydrous Na<sub>2</sub>SO<sub>4</sub>. The lipid extract was evaporated to dryness under N<sub>2</sub> and redissolved in 100 µL hexane. Analysis of FAME was carried out using a Supelcowax-10, 30 m × 0.25 mm × 0.25 µm column (Sigma-Aldrich) installed in a HP5890 Series Plus II gas chromatograph equipped with a FID and splitless injection (10). The initial temperature was 50°C. This was increased to 200°C at a rate of 25°C per minute. Following this, the temperature was then increased, sequentially, from 200 to 220°C and 220 to 240°C at a rate of 1°C per min and 15°C per min, respectively. Identification of FA was by comparison to retention times of known standards (Sigma-Aldrich), and quantification of the peaks was done by determining the area under each peak. Individual FA were calculated as a mol% of the following combined FA: 16:0, 18:0, 18:1, 18:2, α-18:3, and CLA. In the case of CLA, GLC peaks for all isomers were pooled and reported as mol% of 16:0, 18:0, 18:1, 18:2, α-18:3, and CLA.

**Calculations and statistical analysis.** The FA composition of the *sn*-1/3 positions of the TAG (29) was calculated from the mean values obtained from the TAG (combined *sn*-1, *sn*-2, and *sn*-3) and *sn*-2-MAG FA analysis as follows:

$$\text{sn-1/3 mol\%} = (\text{TAG mol\%} \times 3 - \text{sn-2-MAG mol\%})/2 \quad [1]$$

The methods used for determining positional distribution of FA were tested with standard TAG. FA composition data were analyzed using the JMP IN Version 3.2.1 statistical package (SAS Institute Inc., 1989–1997, Cary, NC). ANOVA was followed by a pairwise comparison of treatments to the control using Dunnett's test (30).

## RESULTS

**FA composition of TAG.** The FA compositions of the TAG fractions of diaphragm, rib muscle, and SC adipose tissue are shown in Tables 1–3. Long-chain PUFA (>C<sub>18</sub>) were not included in the analyses, and the isomers of CLA were not fully resolved. The mole percent of CLA in TAG was significantly higher ( $P < 0.05$ ) in animals fed 6% safflower oil compared to the controls. In general, the CLA content of the TAG fraction of diaphragm, rib muscle, and SC adipose tissue increased by about threefold in animals that received the safflower oil dietary treatment. No significant differences in the CLA content of TAG were observed between tissues of the CLA-supplemented group and controls. Regardless of diet, oleic acid (18:1) was the major component of the TAG

(46.2–54.5 mol%) in these three tissues. This was followed by palmitic acid (16:0) (24.7–33.1 mol%), stearic acid (18:0) (9.5–18.2 mol%), 18:2 (4.1–6.4 mol%), CLA (0.2–1.6 mol%) and α-linolenic acid (α-18:3) (0.5–1.1 mol%). The 16:0 content of TAG from the rib muscle of lambs fed safflower oil was significantly lower ( $P < 0.05$ ) than the control (27.6 vs. 31.5 mol%). This decrease was apparently compensated for by increases in the proportions of 18:0, 18:1, and 18:2. The proportion of α-18:3 also decreased significantly ( $P < 0.05$ ), from 1.0 mol% of the TAG in the control to 0.5 mol% of the TAG in the safflower oil-fed group.

**Positional distribution of CLA and other FA in TAG.** The FA compositions of the *sn*-2 and *sn*-1/3 positions of diaphragm, rib muscle, and SC adipose tissue TAG as determined by pancreatic lipase digestion are also shown in Tables 1–3. No significant differences in the proportions of FA in the *sn*-2 position of TAG from the diaphragm, rib muscle, or SC adipose tissue were seen, and CLA was more abundant in *sn*-1/3 positions of TAG than in the *sn*-2 position. The proportion of CLA detected at the *sn*-2 position was 0.2 mol% or lower in all categories with the exception of SC adipose tissue, where the proportion of CLA in the *sn*-2 position was 4 mol% (Table 3). The proportion of CLA present in the *sn*-1/3 positions of TAG from the three tissues of lambs that were fed the safflower oil-supplemented diet was significantly higher ( $P < 0.05$ ) than in *sn*-1/3 positions of TAG from controls. The proportion of CLA increased by about three- to fourfold at this position over the three tissue types. In general, the FA composition at the *sn*-2 position of TAG in the muscle tissues (diaphragm and rib) differed considerably from the TAG isolated from SC adipose tissue. For example, the proportion of 18:1 at the *sn*-2 position of TAG from SC adipose tissue ranged from 47.4 to 64.8 mol%, whereas the proportion of this FA ranged from 21.7 to 31.6 mol% in the two muscle types. In rib muscle, the proportion of  $\alpha$ -18:3 at the *sn*-1/3 position of TAG was significantly lower ( $P < 0.05$ ) in animals fed a diet supplemented with safflower oil than in the control (0.8 vs. 1.4 mol%) (Table 2).

**FA composition of PL.** CLA content ranged from 0–1.8 mol% in the PL of diaphragm, rib muscle, and SC adipose tissue (Table 4). The only significant changes ( $P < 0.05$ ) attributable to diet were for safflower oil-fed animals, which showed a decrease of over twofold in mol% of  $\alpha$ -18:3 in the PL of both diaphragm and rib. The major FA of diaphragm

<sup>a</sup>Mol% of the total FA listed. \* $P < 0.05$  by Dunnett's test compared to control; CLA, conjugated linoleic acid in diet as free acid pre-weaning; safflower, 6% safflower oil in diet post-weaning; control, no dietary treatment; SC, subcutaneous.

PL was 18:2 (32.5–43.3 mol%). The CLA content in the diaphragm was lower than in any of the other tissue PL, ranging from 0 to 0.03 mol%. The major FA of rib muscle PL were 18:1 (25.3–34.3 mol%) and 18:2 (24.0–44.2 mol%). The CLA content of rib muscle PL ranged from 0.05 to 1.8 mol%. The major FA of SC adipose tissue PL was 18:1 (45.6–54.7 mol%). The CLA content of SC adipose tissue PL ranged from 1.0 to 1.1 mol%. The 18:2 content of PL of SC adipose tissue was the lowest of all tissues studied at 6.1–10.7 mol%.

## DISCUSSION

Basal diets supplemented by unprotected polyunsaturated fats in vegetable oils have been shown to have little effect on FA composition of adipose tissue and skeletal muscle sampled from various sites in steers (31). For example, supplementation with 6% safflower oil resulted in a slight increase in the proportion of 16:0 and 18:0. Because dietary lipids are extensively hydrogenated in the rumen to produce saturated FA, incorporation of higher levels of polyunsaturated fats in ruminant tissues is usually accomplished by feeding protected fat supplements that pass through the rumen and are absorbed in the small intestine unchanged. The 18:2 present in safflower oil is biohydrogenated in the rumen ultimately to produce 18:0. Intermediates of the biohydrogenation of 18:2 are CLA and *trans*-11 18:1 (1). A recent investigation of the duodenal flow of FA in ewes has shown that CLA and *trans*-11 18:1 are equally abundant (32). In the current study, lambs fed a diet supplemented with 6% safflower oil showed a significant increase ( $P < 0.05$ ) in the proportion of CLA in the TAG fraction of diaphragm, rib muscle, and SC adipose tissue. No significant change in the content of other major FA components was observed. Increases of two- to fourfold in the CLA con-

tent of TL of tissues from lambs fed a diet supplemented with 6% safflower oil have been observed (18).

The polyunsaturated FA content in tissues of young ruminants has been shown to increase following feeding with milk replacers supplemented with 12.5–70 g sunflower oil d<sup>-1</sup> for up to 16 wk (31). The muscle and adipose tissue from animals on this supplemented diet contained up to 40% of 18:2 in the TAG fraction after 30 d. This increase in 18:2 content was accomplished owing to the bypass of the rumen when the esophageal groove was closed while suckling. In this way, the components of the diet were absorbed in the small intestine as in nonruminants. In the current study, the direct feeding of CLA to pre-weaned lambs for 21 d prior to weaning did not increase the CLA content of the TAG fraction of any of the tissues studied. The CLA may have been oxidized in the liver. The increased CLA content observed in the TAG of the animals receiving the safflower oil diet resulted in the incorporation and storage of CLA in the TAG fraction of diaphragm, rib muscle, and SC adipose tissue. The higher proportion of CLA in the TAG of the SC adipose tissue, which was twofold that of diaphragm and rib muscle (see Tables 1–3), suggested that CLA was preferentially stored in this fat depot. Since CLA was apparently oxidized in pre-ruminant animals fed pre-formed CLA, it is possible that the increased levels of tissue CLA observed with the diet supplemented with 6% safflower oil may be the result of endogenous  $\Delta^9$  desaturation of *trans*-11 18:1 produced in the rumen from 18:2.

In mammalian fat depots, unsaturated FA have a tendency to be localized to the *sn*-2 position of TAG, whereas saturated FA tend to be localized to the *sn*-1 and *sn*-3 positions (33). Recently, it was reported that TAG from human breast adipose tissue contained higher percentages of CLA at the *sn*-2 position and lower percentages of CLA at the *sn*-1/3 positions relative to TAG from adipose tissue from benign breast tumors (34). Changes in FA positional distribution as affected by diet also have been shown in bovine and ovine adipose tissues (35–37) and ovine liver (36), but the mechanism responsible for these diet-induced changes is unknown. In previous studies with ruminants fed a protected supplement, high proportions of additional 18:2 were incorporated into adipose tissues with preferential esterification to the *sn*-2 position and to a lesser extent the *sn*-3 position (31,36).

In the present study, the positional distribution analyses of the FA of TAG from the three tissues showed an increased proportion of CLA in the *sn*-1/3 positions in the safflower oil diet group that may be linked to the selectivity of the acyltransferases of TAG bioassembly. In contrast, CLA was detected in the *sn*-2 position of TAG of SC adipose tissue from the CLA-supplemented animals (Table 3). This observation indicated that feeding CLA to pre-weaning lambs had an effect on the placement of the CLA within TAG from SC adipose tissue. CLA supplied through duodenal flow from the rumen or conversion of duodenal *trans*-11 18:1 to CLA later in animal life, however, resulted in preferential incorporation of CLA at the *sn*-1/3 positions of TAG from this tissue. The availability of new molecular tools for TAG-biosynthetic enzymes is having a substantial

effect on investigations into the regulation of TAG bioassembly by nutrients, hormones, and physiological conditions (38). These molecular tools could prove useful in increasing our understanding of the mode of CLA incorporation into TAG.

*sn*-1,2-DAG produced during TAG biosynthesis can also be diverted to the biosynthesis of nitrogenous PL (38–40). Previous studies on incorporation of CLA have shown that CLA is readily incorporated into the PL fraction of the mammary gland and forestomach tissues of rodents (13,41). There is also evidence that CLA is preferentially incorporated into the NL fraction in mice (42). In the current study, safflower oil supplementation in the diet had no effect on the CLA content of PL from diaphragm, rib muscle, and SC adipose tissue, suggesting that CLA was preferentially incorporated into the TAG of these tissues. These observations suggested that there could be a threshold of CLA incorporation into the PL of ruminants. It has been suggested that the biological activity of CLA may be related more to deposition of fat rather than through effects on PL alteration (37). The relatively low levels of  $\alpha$ -18:3 in the PL of SC adipose tissue (Table 4) may have been due to the competitive metabolism of CLA vs. 18:2 to produce a conjugated form of 18:3 (15), which was not quantified in this study. Since *sn*-1,2-DAG is also a precursor of nitrogenous PL, the CLA composition of TAG at the *sn*-1/2 positions might be expected to reflect that of the PL to some extent, although deacylation–acylation mechanisms are known to further alter the fatty acyl composition of PL (43). The PL from muscle tissue, however, represented a combination of PL from both intramuscular adipocytes and muscle fibers. TAG biosynthesis has also been reported to occur in muscle fibers (40,44). Therefore, there may be differences in the incorporation of CLA into the TAG of adipocytes from that of muscle fibers.

Supplementation of lamb feedlot diet with safflower oil as a source of unprotected 18:2 resulted in a significant increase in the CLA content of TAG from various tissues. Dietary manipulation had no significant effect on the CLA content of the PL suggesting that the FA isomers were preferentially incorporated into TAG. The highest mol% CLA was observed in SC adipose tissue, indicating that CLA was preferentially stored in this fat depot. CLA was not detected in significant quantities at the *sn*-2 position of the TAG molecule in any of the tissues examined. There was, however, an increased amount of CLA in the *sn*-2 position of the SC adipose tissue from animals supplemented with pre-formed CLA prior to weaning. Although feeding CLA to pre-weaning lambs had no effect on the total CLA content of the TAG, it influenced the positional distribution of CLA on the TAG molecule. The described ruminant feeding model may be useful for investigating the enzymology of CLA production and incorporation into glycerolipids of ruminants. In addition to investigating endogenous production of CLA from *trans*-11 18:1, studies on the specificity and selectivity for CLA of the acyltransferases involved in TAG and PL biosynthesis should provide further insight into the mechanism of CLA incorporation into glycerolipids. In recent studies, we have characterized DAG acyltransferase involved in TAG biosynthesis in bovine muscle tissue using the diaphragm as a source of enzyme

because this is the only muscle tissue that is available within 30 min of slaughter in a commercial abattoir (45,46). The use of the diaphragm in our current study of the positional distribution of CLA in TAG will provide background knowledge for designing future experiments that will focus on the enzymology of CLA incorporation using this tissue. It will also be important to examine the relative contributions of intramuscular adipocytes vs. muscle fibers to CLA incorporation into glycerolipids.

## ACKNOWLEDGMENTS

The authors thank Tara Furukawa-Stoffer, Christopher Gregg, Chris Kazala, and Brenda Pink for technical help, and the farm staff at the sheep barn of the Lethbridge Research Centre for animal care. The authors also thank The Canada-Alberta Livestock Trust Fund for providing the animals, and Dr. Fred Lozeman and Chris Kazala for critical evaluations of the manuscript.

<sup>a</sup>Banting and Best Department of Medical Research, University of Toronto, Toronto, Ontario M5G 1L6, Canada, and <sup>b</sup>Department of Physiology, University of Kuopio, FIN-70211 Kuopio, Finland

**ABSTRACT:** Normal-phase HPLC resolution of *sn*-1,2(2,3)- and *x*-1,3-DAG generated by partial Grignard degradation from natural TAG was carried out with both (*R*)-(-) and (*S*)-(+)-1-(1-naphthyl)ethylurethane derivatives. The diastereomeric *sn*-1,2- and *sn*-2,3-DAG derivatives were resolved using two Supelcosil LC-Si (5  $\mu$ m, 25 cm  $\times$  4.6 mm i.d.) columns in series and an isocratic elution with 0.37% isopropanol in hexane at a flow rate of 0.7 mL/min. The DAG were detected by UV absorption at 280 nm and were identified by electrospray ionization MS in the positive ion mode following postcolumn addition of chloroform/methanol/30% ammonium hydroxide (75:24.5:0.5, by vol) at 0.6 mL/min. Application of the method to a stereospecific analysis of the molecular species of TAG of rat VLDL showed that the TAG composition of VLDL circulating under basal conditions differs markedly from that of VLDL secreted by the liver during inhibition of serum lipases. The inhibition of serum lipases resulted in a significant proportional decrease in 16:0 and PUFA and an increase in 18:0 and oligoenoic FA in the *sn*-1-position, whereas the FA compositions in the *sn*-2- and *sn*-3-positions were much less affected.

Paper no. L8997 in *Lipids* 37, 613–619 (June 2002).

Stereospecific normal-phase HPLC analysis of natural TAG via the diastereomeric naphthylethylurethanes (NEU) of the DAG derived by Grignard degradation has been proposed (1–4) as an inexpensive substitute for the more costly chiral-phase HPLC analyses (5–7). However, the method does not give a complete resolution of the diastereomeric DAG derivatives when applied to TAG with a wide range of FA (2,3). Partial overlaps among enantiomers during chiral-phase HPLC of the dinitrophenylurethanes (DNPU) of DAG have been successfully dealt with by combining it with on-line MS (5,6) or by resolving the enantiomers as bis-DNPU derivatives of the *sn*-1- and *sn*-3-MAG (7,8). The present study reports that a combination of normal-phase HPLC of the diastereomeric NEU of DAG with on-line electrospray ionization MS (ESI-MS) also permits an accurate determination of the positional distribution of FA in the acylglycerols, as indicated by stereospecific analyses of rat VLDL TAG. The quan-

tification of any remaining incompletely resolved molecular species of DAG was facilitated by utilizing both *R*-(-)- and *S*-(+)-forms of the derivatives. The study shows that a combination of normal-phase HPLC resolution of the diastereomeric *sn*-1,2- and *sn*-2,3-DAG NEU with on-line MS provides an effective alternative to chiral-phase HPLC resolution of the enantiomeric 3,5-DNPU.

## MATERIALS AND METHODS

**Materials.** All solvents were HPLC or reagent grade and were purchased from Caledon Chemicals (Toronto, Canada) or Aldrich Chemical Co. (Milwaukee, WI). Ethyl magnesium bromide and *R*-(-)- and *S*-(+)-1-(1-naphthyl)ethylisocyanate were also from Aldrich Chemical Co. Sep-Pak® C18-cartridges were purchased from Waters Corporation (Milford, MA). Tripalmitoylglycerol (99%) was obtained from Sigma (St. Louis, MO).

**Animal procedure.** Male Wistar rats weighing 300–350 g and maintained on standard chow were used. Rats were fasted for 4 h before they were anesthetized with Somnatol (pentobarbital, 50 mg/kg; M.T.C. Pharmaceuticals, Cambridge, Canada). A cannula was inserted into the femoral vein and Triton WR1339 (600 mg/kg, Tyloxapol; Sigma, St. Louis, MO) or saline was injected. Two hours after injection, blood was drawn and rats were killed by heart puncture. The blood samples were taken into 5% EDTA, and plasma was immediately separated by centrifugation. Plasma was overlain with a NaCl solution ( $d = 1.006$  g/mL), and VLDL were separated by ultracentrifugation at  $125,000 \times g$  in a 70.1 Ti rotor (Beckman Instruments, Palo Alto, Ca) for 16 h at 16°C. Livers were removed and frozen in  $-70^\circ\text{C}$ . These studies were approved by the Animal Care Committee of the University of Toronto.

**Isolation of TAG.** Rat plasma VLDL and rat liver were extracted with chloroform/methanol (2:1, vol/vol) (9). Liver samples (300–400 mg) were thoroughly minced with a scalpel and extracted twice. The TAG were isolated by TLC on silica gel H plates using heptane/isopropyl ether/acetic acid (60:40:4, by vol) as the developing solvent (10). The TAG band was located by spraying the plate with dichlorofluorescein, scraping off the spot, extracting the TAG with chloroform/methanol, and, after solvent evaporation, redissolving it in chloroform for storage at  $-20^\circ\text{C}$ .

**Preparation of DAG.** The plasma VLDL and liver TAG were partially deacylated to *sn*-1,2-, *sn*-2,3-, and *sn*-1,3-DAG by Grignard reaction (3). The TAG (about 1 mg) were dissolved in

Abbreviations: CapEx, capillary exit voltage; DNPU, dinitrophenylurethane; HPLC/ESI-MS, HPLC with on-line electrospray ionization MS; NEU, 1-(1-naphthyl)ethylurethane; 14:0, myristic acid; 16:0, palmitic acid; 18:0, stearic acid; 18:1, oleic acid; 18:2, linoleic acid; 18:3, linolenic acid; 20:4, arachidonic acid; 20:5, eicosapentaenoic acid; 22:4, docosatetraenoic acid; 22:5, docosapentaenoic acid; 22:6, docosahexaenoic acid.

dry diethyl ether (1 mL) and 3 M ethyl magnesium bromide in dry diethyl ether (40  $\mu$ L) was added. The mixture was shaken for 1 min before glacial acetic acid (50  $\mu$ L) in hexane (5 mL) and water (2 mL) were added to terminate the reaction. The organic layer was washed with 0.5% sodium bicarbonate (2 mL) and water (2 mL) and dried by passing through two Pasteur pipettes containing anhydrous sodium sulfate. The solvent was evaporated in a stream of dry nitrogen at room temperature, and the products were immediately derivatized.

**Preparation of NEU derivatives.** The Grignard products were dissolved in dry toluene (0.3 mL), and *R*-(-)- or *S*-(+)-1-(1-naphthyl)ethyl isocyanate (10  $\mu$ L) and 4-pyrrolidinopyridine (4 mg) were added. The derivatization was performed by heating the mixture at 50°C overnight (3). After evaporation of solvents in a stream of nitrogen, the reaction products were dissolved in methanol/water (95:5, vol/vol) and applied to a Sep-Pak C18 column, which had been solvated with the same solvent. An additional 15 mL of this solvent was passed through the column, and NEU derivatives were then eluted with acetone (10 mL).

**HPLC resolution of diastereomers.** The diastereomeric NEU derivatives of *sn*-1,2- and *sn*-2,3-DAG were separated (2) by normal-phase HPLC using in series two Supelcosil LC-Si columns (5  $\mu$ m, 25 cm  $\times$  4.6 mm i.d., Supelco Inc., Bellefonte, PA). The columns were installed in a Waters 550 liquid chromatograph connected to a Waters 990 photodiode array detector. The samples were injected in hexane (10  $\mu$ L). The columns were eluted with 0.37% isopropanol in hexane at a flow rate of 0.7 mL/min, and peaks were detected at 280 nm.

**HPLC/ESI-MS.** The molecular species of DAG were identified by passing the effluent of the normal-phase HPLC columns into a Hewlett-Packard 5989A single quadrupole mass spectrometer equipped with a Hewlett-Packard Model 59987A nebulizer-assisted ESI interface. Nitrogen gas was used as both nebulizing gas (60 psi) and drying gas (60 psi, 270°C). Positive ESI spectra were taken following postcolumn addition of chloroform/methanol/30% ammonium hydroxide (75:24.5:0.5, by vol) at 0.6 mL/min. The capillary exit voltage (CapEx) was 220 V (unless indicated otherwise), and the mass range scanned was 500–720 (200–1000 in test runs). Capillary, endplate, and cylinder voltages were –4, –3.5, and –5 kV, respectively, in the positive ion mode. The CapEx, which determines the extent of fragmentation by means of a collision-induced dissociation process, was varied between +90 and +270 V. Identification of the various unknown species was performed on the basis of retention time of standards, averaged full mass spectra, and the fragmentation patterns. The relative proportions of the molecular species of the DAG were calculated from the areas of the peaks obtained by single ion plots extracted from the total ion current spectra. The masses given in text and figures refer to protonated nominal, ammoniated, and sodiated ions.

**FA analysis.** FAME of NEU derivatives of DAG and TAG were prepared by acidic methanolysis using 6% H<sub>2</sub>SO<sub>4</sub> in methanol in sealed vials at 80°C for 2 h. The methyl esters were extracted with hexane and analyzed by GLC (Hewlett-Packard, Model 5890 Series II gas chromatograph) using a 15 m  $\times$  0.32 mm i.d. (film thickness 0.20  $\mu$ m) SP 2380 capillary column

(Supelco, Bellefonte, PA). The carrier gas was hydrogen at an inlet pressure of 3 psi. The column was held at 100°C for 0.5 min and then programmed at 20°C/min to 130°C and then at 5°C/min to 240°C (11). The FA were identified by comparing retention times of any peaks with those of standards.

## RESULTS

**Optimization of HPLC separations.** Previous work (2,3) had established isooctane with 0.33% isopropanol (containing 2% water) as an optimal mobile phase (flow rate 1 mL/min) for the resolution of the diastereomeric *sn*-1,2- and *sn*-2,3-DAG made up of the common FA. Under these conditions, the *sn*-1,3-DAG emerged as an early peak followed by *sn*-1,2- and *sn*-2,3-DAG in the case of the *S*-derivative, or *sn*-2,3- and *sn*-1,2-DAG in the case of the *R*-derivative. Usually, two to three peaks of approximately equal intensity were seen for each of the *sn*-1,2- and *sn*-2,3-diastereomers. Figure 1 shows the normal-phase separation of *R*-derivatives in the present study and demonstrates that a somewhat greater resolution of the *sn*-1,2- and *sn*-2,3-diastereomers may be obtained by the combination of slower flow rate (0.7 mL/min) and greater proportion (0.37%) of isopropanol in the eluant. As shown below, a complete resolution between the *sn*-1,2- and *sn*-2,3-diastereomers was not obtained. Thus, the species of the *sn*-2,3-diastereomers retained longest overlapped with the molecular species of the *sn*-1,2-diastereomers emerging earliest. The order of elution was reversed for the *S*-derivative. As shown below, ESI-MS can complement this resolution by allowing minor, unresolved components to be identified under these conditions. Other ratios and flow rates of isopropanol and hexane, and other polar modifiers (e.g., methanol and ethanol) failed to improve the resolution or significantly shorten the elution time without loss of resolution of the wide range of DAG derivatives analyzed here. A minor unknown peak (peak *x*, Fig. 1) appeared in the UV profile before the *sn*-2,3-

**FIG. 1.** Normal-phase HPLC separation of *sn*-1,3-, *sn*-2,3-, and *sn*-1,2-DAG prepared from rat plasma VLDL TAG (*x* = unknown peak). Chromatographic conditions were as described in text.

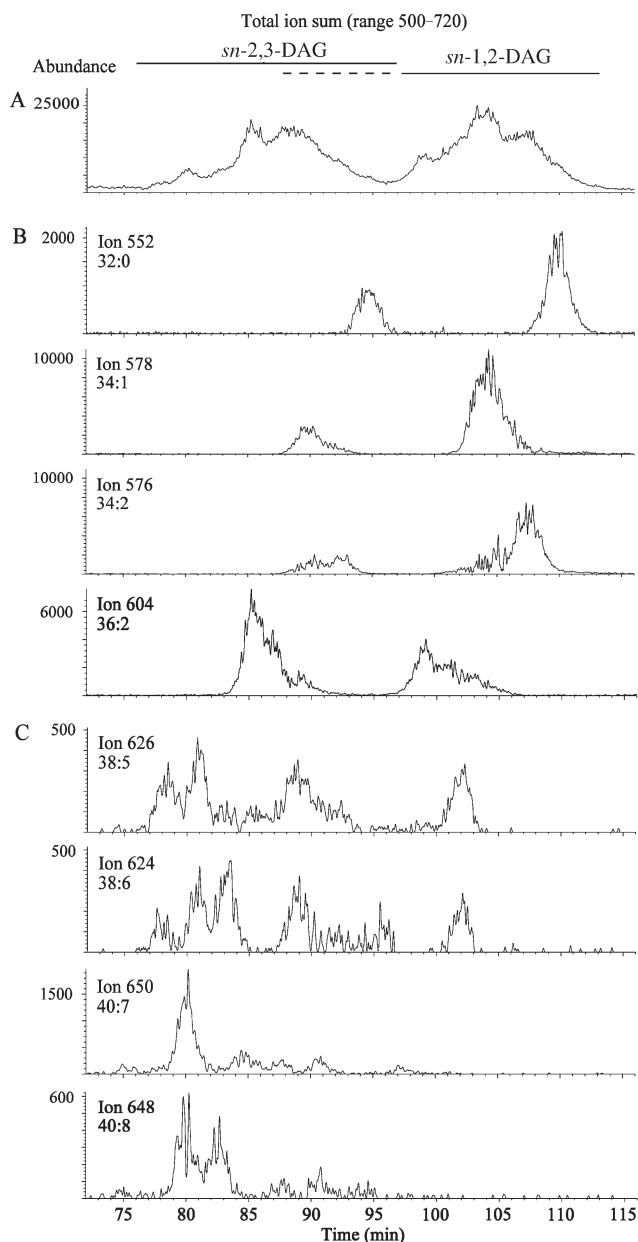

DAG peak. It had insufficient mass to be detected by positive ion MS, and FA were not found in the eluant.

**Optimization of HPLC/ESI-MS conditions.** Having optimized the HPLC resolution of the diastereomeric naphthylethylurethanes, we proceeded to optimize the ESI-MS detection and identification of the molecular species of the DAG derivatives. To take advantage of the positive ionization of the NEU, it was necessary to supplement the HPLC column flow with a polar solvent. Several combinations of solvents and different flow rates were tested, and the highest response at the normal ESI operating voltage of 170 V was obtained with chloroform/methanol/30% ammonium hydroxide (75:24.5:0.5, by vol) at 0.6 mL/min. This resulted in the near exclusive formation of the ammonia  $[M + 18]^+$  and sodium  $[M + 23]^+$  adducts, however, which complicated the identification of the molecular species of DAG using the single quadrupole mass spectrometer. This problem was resolved by increasing the CapEx voltage to 220 V. Under these conditions, proportionally correct yields were obtained for the DAG-like ions  $[M - NEU]^+$  without any reduction in the sensitivity of detection of the molecular species of the DAG derivatives. The formation of  $[M - NEU]^+$  ions was estimated on the basis of parallel analyses of standard mixtures of 14:0/16:0-, 16:0/16:0-, 16:0/18:1-, and 18:0/18:1-glycerol NEU derivatives and on the basis of test samples (NEU derivatives of liver DAG) analyzed using different CapEx levels. The  $[M - NEU]^+$  ions were extracted from the total ion current spectra by the computer. A mass spectrum of the NEU derivative of *sn*-1,2-dipalmitoylglycerol, derived from tripalmitoylglycerol by Grignard degradation, is shown in Figure 2. Both ammonia and sodium adducts ( $m/z$  784 and 789, respectively) are seen as well as a DAG-like ion ( $m/z$  552) along with a NEU derivative of monopalmitoylglycerol ( $m/z$  511), which can be depicted as  $[(M - RCOO) + H]^+$ .

**Application to natural TAG.** Figure 3A shows the total positive ion current profile recorded by HPLC/ESI-MS for the diastereomeric NEU (*R*-form) of the DAG derived from plasma VLDL TAG, along with the single ion mass chromatograms recorded for the selected *sn*-2,3- and *sn*-1,2-DAG species. Since the ions are plotted on an abridged time scale (70 to 115 min), the base widths of the peaks appear wider than those recorded for the same sample (30 to 115 min) by

**FIG. 2.** Mass spectra of naphthylethylurethane (NEU) derivative of *sn*-1,2-dipalmitoylglycerol prepared from tripalmitoylglycerol and separated by HPLC as described in text.

**FIG. 3.** HPLC/electrospray ionization (ESI)-MS analysis of *sn*-2,3-DAG (70–96 min) and *sn*-1,2-DAG (96–115 min, with some exceptions; see text) of rat plasma VLDL TAG. (A) Total positive ion chromatogram (ion sum from  $m/z$  500 to 720). (B) and (C), single ion mass chromatograms of some selected molecular species indicated by protonated nominal mass and carbon number/number of double bonds. HPLC/ESI-MS conditions were as described in text.

the UV detector (Fig. 1). True widening of the base widths of the peaks resulted from the postcolumn addition of the polar ionization solvent. However, almost baseline separation between the diastereomers was obtained. All molecular species of acyl carbons of 36 or less were completely resolved (Fig. 3B), whereas those with higher numbers of acyl carbons showed very minor overlaps (Fig. 3C). This was largely due to the shorter retention time of the higher molecular species and not to a lack of resolution of isobaric diastereomers. Although the oligoenoic (having few sites of unsaturation) species with the longest carbon chains were always eluted first

within each diastereomer, the number of double bonds affected the elution order in a rather irregular manner, which could nevertheless be sorted out by MS. Although the presence of monoenoic FA in 34 and 36 acyl carbon species decreased the retention time relative to the saturated species of the same carbon number, the presence of FA with two or more double bonds resulted in a delayed elution of the species. The HPLC separation of the diastereomeric NEU derivatives of DAG containing 20 and 22 acyl carbon PUFA was much more complicated than that observed for the other species. Thus, part of the *sn*-1,2-DAG species containing 22:4, 22:5, and 22:6 FA were eluted with the tail end of the *sn*-2,3-DAG species. Specifically, the *sn*-1,2-DAG species 38:5, 38:6, and 38:7, made up of combinations of 16- and 22-carbon FA, overlapped with the *sn*-2,3-DAG containing combinations of 18- and 20-carbon FA. These mixtures of species were eluted between 87 and 95 min and were represented by ions 624, 626, and 628. In addition, the *sn*-2,3-DAG species eluted between 75 and 87 min contained other major polyunsaturated species with *m/z* 626 (e.g., 16:0/22:5), 624 (e.g., 16:1/22:5; 16:0/22:6), 650 (e.g., 18:1/22:6; 18:2/22:5), and 648 (e.g., 18:2/22:6; 18:3/22:5). The elution order of species with 16 and 22 or 18 and 20 acyl carbon FA was determined on the basis of the fragment ion distribution  $\{[(M - RCOO) + H]^+$  and  $[RCO + 74]^+$  ions having 20:4, 22:5, or 22:6 as a single FA}. To obtain an accurate estimate of the quantities of the individual species emerging between 87 and 95 min, it was necessary to perform the analysis using the *S*-form of the NEU derivatives (Fig. 4), which reversed the order of elution of the diastereomers without changing the order of elution of the molecular species within the *sn*-1,2- and *sn*-2,3-species. As a result, the *sn*-1,2-DAG species, such as 16:0/22:6, was now eluted first without any overlapping with the oligoenoic species of the other diastereomer. In general, the separation of the *S*-form derivatives was not as good as that obtained for the *R*-form because the *sn*-2,3-DAG moieties of VLDL TAG contained much more of the long-chain polyunsaturated species, which as the *S*-derivatives eluted with the tail end of the *sn*-1,2-DAG.

Table 1 gives the composition of the *sn*-1,2- and *sn*-2,3-DAG moieties of the TAG of normal rat plasma VLDL and liver, whereas Table 2 gives the stereospecific distribution of the FA calculated for VLDL TAG from the *sn*-1,2- and *sn*-2,3-DAG given in Table 1. The stereospecific distribution of the FA was calculated according to Brockerhoff (12). The overall accuracy of the stereospecific analysis is indicated by the good reconstitution of the FA composition of the original TAG. Figure 5 shows the quantitative distribution of the molecular species of VLDL TAG from the Triton-treated and control rats. There is a significant change in the TAG composition of the plasma VLDL because of the inhibition of the serum lipases by the detergent, which resulted in a preservation of the FA composition in the *sn*-1-position of the TAG secreted by the liver.

## DISCUSSION

The present study demonstrates the advantages of combining MS with normal-phase HPLC resolution of diastereomeric

**FIG. 4.** Total positive ion chromatogram (A) and single ion chromatograms (B) of some selected molecular species of *sn*-1,2- and *sn*-2,3-DAG prepared from rat plasma VLDL TAG and separated as their (*S*-form NEU derivatives. HPLC/ESI-MS conditions were as described in text. For abbreviations see Figures 2 and 3.

**FIG. 5.** Content of some selected calculated TAG species in circulating (nontreated) and newly secreted (Triton-treated) VLDL. The FA in the *sn*-1 position is on the left in the abbreviated notation of molecular species.

<sup>a</sup>Results are expressed as average ± range/2 from two rats. The variations of ranges are less than 6% for major components (>2% of total mixture) and less than 17% for minor components. C, carbon number; DB, number of double bonds.

DAG for stereospecific analysis of natural TAG. To minimize co-elution of diastereomeric groups, it is necessary to utilize both (*R*)-(–)- and (*S*)-(+)–NEU derivatives, although ESI–MS with appropriate fragmentation can provide sufficient information to assign identities to unresolved species of DAG. The NEU derivatives of DAG yield characteristic  $[M - \text{NEU}]^+$ ,  $[(M - \text{RCOO}) + \text{H}]^+$ , and  $[\text{RCO} + 74]^+$  ions for each DAG species from which the molecular weight and exact pairing of FA can be unequivocally obtained. The characteristic ions appear to be generated in nearly correct mass proportions, as indicated by the quantitative comparisons of the reconstitution data.

The normal-phase HPLC described by Christie and co-workers (3) provides a rapid and complete resolution of the diastereomeric NEU derivatives of *sn*-1,2- and *sn*-2,3-DAG with identical FA, but separation of diastereomers containing different FA results in overlap or interdigitation of many molecular species, and identification of individual diastereomers becomes difficult or impossible. Furthermore, the solvent sys-

tems thus far employed for the normal phase HPLC of diastereomeric DAG fail to provide a complete separation of molecular species within either diastereomer class. In fact, previous work by Christie and co-workers (3) has led to the conclusion that no sensible pattern is discernible for the NEU derivatives containing 20- and 22-carbon PUFA species of fish oil TAG. In the present study, part of the *sn*-1,2-DAG species containing 22:4, 22:5, and 22:6 FA were eluted with the tail end of the *sn*-2,3-DAG derivatives. Specifically, the *sn*-1,2-DAG species 38:5, 38:6, and 38:7, made up of combinations of 16- and 22-carbon acids, overlapped with the *sn*-2,3-DAG containing combinations of 18- and 20-carbon FA, when run as the *R*-derivative. In order to obtain an accurate estimate of the quantities of the individual species, it was necessary to complete another HPLC analysis using the *S*-form of the NEU derivatives, which were eluted in the reverse order. As a result, the *sn*-1,2-DAG species, such as 16:0/22:6, were eluted first without any overlap.

An examination of the order of elution of the molecular species within each diastereomer group revealed that the species were actually eluted in an orderly fashion within each homologous series represented. The impression of a lack of discernible order had arisen from the complex mixture of homologous series represented in each diastereomer group. For any specific homologous series, the molecular species were resolved in a reproducible order arising from both polar and nonpolar interactions with the solid phase of the column, although the overall range of elution times was rather limited. Furthermore, the order of elution of the members of the various homologous series was the same for both diastereomer groups obtained with the same reagent.

The fully saturated species were resolved in the following order of increasing retention times: 18:0/18:0 < 16:0/18:0 < 16:0/17:0 < 16:0/16:0 < 14:0/16:0. Thus, the longer-chain saturates, being less polar, are eluted earlier than the shorter-chain saturates. Similarly, the monoenoic species were resolved in the following order of increasing retention times: 18:0/18:1 < 17:0/18:1 < 16:0/18:1 < 16:0/16:1. The dienoic species were eluted in the following order of increasing retention times: 18:0/20:2 < 18:0-18:2 < 16:0/18:2. The 16:0/18:2 species was retained slightly longer than the 16:0/18:1 species, indicating a somewhat higher polarity. Likewise, the 18:1/18:2 and 18:2/18:2 species were retained longer than the 18:1/18:1 species, which was also eluted slightly faster than 18:0/18:0. This is in accordance with results obtained with standard lipids (3). Within 36:4 species, 18:2/18:2 eluted before 16:0/20:4, and within species with a combination of 18 and 20 acyl carbon FA, species with 20:1, 20:2, and 20:3 eluted slightly earlier than species with 20:4 and 20:5, indicating increased polarity of species with 20:4 and 20:5.

Polyunsaturated species containing 22:4, 22:5, and 22:6

eluted before oligoenoic species, and they often produced more than one peak. For example, *sn*-2,3-DAG species with *m/z* 648 (40:8) were divided into two peaks with about equal size (Fig. 3C). This could have indicated a separation between the 18:2/22:6 and 18:3/22:5 species or a resolution of the reverse isomers (*sn*-2-18:2/*sn*-3-22:6 and *sn*-2-22:6/*sn*-3-18:2). A reverse isomer resolution for the DNPU derivatives of *sn*-1,2-DAG containing combinations of medium- and long-chain FA has recently been reported by Itabashi *et al.* (13) using RP-HPLC or silver ion HPLC. The small number of fragment ions of minor DAG species and the overlapping of different species giving the same fragment ions, however, made it impossible to definitely identify all such species in the present study.

Knowing the exact identity and quantity of all significant species of both *sn*-1,2- and *sn*-2,3-DAG greatly increases the accuracy of calculating the stereospecific distribution of the FA, although minor discrepancies may remain owing to limited isomerization of the DAG during Grignard degradation and subsequent sample workup. Nevertheless, it was possible to demonstrate significant differences in the composition of the molecular species of VLDL TAG between Triton-treated and control rats. The differences could be rationalized on the basis of the known FA and stereospecificity of plasma lipoprotein and hepatic lipases and on the inhibitory effects of the detergent, as reviewed elsewhere (Ågren, J.J., Ravandi, A., Kuksis, A., and Steiner, G., unpublished data). The normal-phase HPLC/ESI-MS method should be applicable to stereospecific analyses of TAG from other sources, including bovine milk fat and fish oils, which contain a wider range of FA than those found in plasma VLDL. Both of these fats have already been successfully analyzed following chiral-phase separation of the enantiomeric *sn*-1,2- and *sn*-2,3-DAG (6,14). A stereospecific analysis of TAG *via* the NEU derivatives of DAG derived from Grignard degradation provides an economic alternative to chiral-phase HPLC of the DNPU.

# Method for Analysis of 4-Hydroxy-2-(*E*)-nonenal with Solid-Phase Microextraction

Tatsuhiko Uchida, Naohiro Gotoh, and Shun Wada\*

Department of Food Science and Technology, Tokyo University of Fisheries, Tokyo 108-8477, Japan

**ABSTRACT:** A simple analytical method for 4-hydroxy-2-(*E*)-nonenal (HNE) using solid-phase microextraction (SPME) fiber was developed. HNE or the derivative of HNE formed by reaction with 2,4-dinitrophenylhydrazine (DNPH) was extracted from the sample solution by immersing the SPME fiber into the solution, and the amount of HNE was quantified by HPLC. The extraction conditions of HNE and HNE-DNPH were examined, using standard solutions, with respect to fiber coating, NaCl concentration, rate of stirring, adsorption temperature, and adsorption time. The recovery of HNE reached 80%, and the quantification limits of HNE and HNE-DNPH using standard compounds were 14.1 pmol/10 mL and 486.5 fmol/10 mL, respectively. This method can be applied to the detection of HNE in oxidized oil or samples of porcine liver.

Paper no. L8956 in *Lipids* 37, 621–626 (June 2002).

4-Hydroxy-2-(*E*)-nonenal (HNE) is one of the secondary oxidation products formed from n-6 PUFA and is found in many biological systems (1). HNE is cytotoxic, genotoxic, and mutagenic, and these properties are related to human diseases such as Alzheimer's (2), atherosclerosis (3), and Parkinson's (4). Thus, HNE is now regarded as a stress marker in biological systems (5).

A number of methods have been developed to detect and quantify HNE in lipids, cells, or tissues. Originally, HNE was analyzed by using an HPLC-spectrophotometric detector (SP) system with monitoring at 223 nm (6). However, HNE is not stable, and many compounds absorb near 220 nm; therefore, derivatives of HNE have also been used to detect and quantify HNE. Derivatization of HNE with 2,4-dinitrophenylhydrazine (DNPH) is the most common method, with measurement by an HPLC-SP system at 370 nm (6,7). HNE and HNE-DNPH also have been measured by an HPLC-electrochemical detector (ECD) system (8). Other derivatives have been also utilized. Derivatization of HNE with 1,3-cyclohexanedione (CHD) was detected with an HPLC-fluorescence detector (FL) system (9). A pentafluorobenzyl hydroxylamine hydrochloride derivative was determined by an HPLC-MS

system (10). Other chromatographic methods, such as GC (11–13), TLC (14), and micellar electrokinetic chromatography (15), also have been used for the analysis of HNE or derivatives of it. In measuring HNE levels in tissue, ELISA has been utilized (16). ELISA detects conjugation products of HNE with protein by use of monoclonal antibodies. However, the experimental procedures that these methods require are complex, and sample preparation requires several steps before analysis can begin.

Solid-phase microextraction (SPME) is a technique to concentrate volatile or nonvolatile components from a liquid, solid, or gas for GC or HPLC analysis. The SPME fiber is exposed in the sample to adsorb the component of interest and injected directly into the GC or HPLC (17). The SPME fiber is exposed in the sample to adsorb the components of interest. It is then injected directly into the GC or HPLC (17). That is, for GC the SPME fiber is directly injected into the injection port, where it is then exposed to the flowing gas; the exposure time depends on the sample species. For HPLC, the fiber is injected into the HPLC, which acts as a desorption chamber, and also is exposed to the solvent under the injection mode.

The SPME method can concentrate analytes without the use of any solvent and does not require any complicated apparatus. Furthermore, the SPME-GC or SPME-HPLC method can quantify the component at a level of parts per trillion. The SPME method has been used recently to extract kerosene from soil (18), flavor substances from air, organic compounds from water (18), alcohol from blood (19), and to analyze food (20). Since there has been no study of the HNE analysis by the SPME method, the aim of this study was to develop a facile and rapid method for the detection and quantification of HNE in oil and biological samples by the SPME method.

## EXPERIMENTAL PROCEDURES

**Chemicals and materials.** HNE was purchased from Calbiochem (Los Angeles, CA). DNPH was obtained from Aldrich Chemical Company, Inc. (Milwaukee, WI). All other chemicals and solvents were of reagent grade and were from common commercial sources. Direct immersion-SPME fused-silica fiber coated with polydimethylsiloxane (PDMS) (thickness of coating: 100  $\mu$ m), polyacrylate (85  $\mu$ m), polydimethylsiloxane/divinylbenzene (PDMS/DVB) (60  $\mu$ m), and carbowax/templated resin (50  $\mu$ m) were purchased from

Abbreviations: CW/TPR, carbowax/templated resin; CHD, 1,3-cyclohexanedione; DNPH, 2,4-dinitrophenylhydrazine; ECD, electrochemical detector; FL, fluorescence detector; HNE, 4-hydroxy-2-(*E*)-nonenal; PDMS, polydimethylsiloxane; PDMS/DVB, polydimethylsiloxane/divinylbenzene; SP, spectrophotometric detector; SPME, solid-phase microextraction.

Supelco (Bellefonte, PA). The polarities of the fibers increase in this order.

**DNPB derivatization.** Standard HNE-DNPB derivative was prepared by the reaction of HNE and DNPB (8). An HNE–water solution was mixed with an equal volume of DNPB solution (3.5 mg of DNPB dissolved in 10 mL of 1 M HCl) and stored in the dark at room temperature for 2 h. HNE-DNPB was extracted twice from the mixture with  $\text{CH}_2\text{Cl}_2$  and concentrated under nitrogen. HNE-DNPB was separated from the reaction mixture by TLC using  $\text{CH}_2\text{Cl}_2$  as developing solvent (14). The HNE-DNPB band was scraped off and extracted with methanol. The extract was filtered, dried under a nitrogen stream, and re-dissolved in methanol. The concentration of HNE-DNPB was measured by spectrophotometer at 370 nm and calculated by using the molar absorptivity  $\epsilon_{370\text{ nm}} = 28,000\text{ M}^{-1}\text{cm}^{-1}$ .

**HPLC analysis.** HNE and HNE-DNPB were detected and quantified by an RP-HPLC system comprising a pump (Type LC-6A, Shimadzu Co., Kyoto, Japan), spectrophotometric detector (Type SPD-10A, Shimadzu Co.), injector (SPME/HPLC interface, rheodyne valve version; Supelco, Bellefonte, PA), ODS column (4.6 × 250 mm; Kakoki Shouji Co., Tokyo, Japan), and Chromatopac integrator (Type C-R6A, Shimadzu Co). HNE was detected at 223 nm using acetonitrile/water (40:60, vol/vol) as mobile phase. HNE-DNPB was detected at 370 nm using 50 mM pH 4.6 acetate buffer/methanol (1:3, vol/vol) as elution solvent. Flow rates for both conditions were 1.0 mL/min. The fiber used was washed in the desorption chamber, SPME/HPLC interface rheodyne valve version, under the injection mode for 30 min.

**Evaluation of fibers.** Ten milliliters of standard HNE dissolved in distilled water was prepared in the range of 0.1–8 nmol/10 mL. The HNE concentration was calculated by using a molar absorptivity  $\epsilon_{223\text{ nm}} = 13,750\text{ M}^{-1}\text{cm}^{-1}$ . SPME fiber was introduced into the standard solution at 40°C for 10 min without agitation. Desorption of HNE or HNE-DNPB from fiber was conducted in the desorption chamber, SPME/HPLC interface rheodyne valve version, under static mode for 20 min. A calibration curve of HNE with each fiber was made, and the best fiber for analysis was determined by the slope of the calibration curve. Evaluation of fibers for HNE-DNPB analysis was conducted in the same manner at pH 7.0.

**Improvement of adsorbing condition.** The effects of temperature (30–60°C), rate of stirring (0–200 rpm), ionic strength (0–20% NaCl), and time on adsorption of HNE on fiber were investigated. The effect of adsorption time was evaluated under the optimal conditions of temperature, rate of stirring, and NaCl concentration.

**Recovery of HNE.** HNE extraction from soybean oil samples (100 mg) was investigated using the procedure of Lang *et al.* (21). An HNE-methanol solution (2.91 nmol and 0.29 nmol) was added to the oil sample in 1% volume. Methanol was removed from the oil sample under a nitrogen stream, and the sample was then extracted twice with 2 mL of distilled water containing 0.1% BHT. The two extracts were combined and centrifuged at 3,000 × *g* for 10 min. The water phase was transferred to a vial and made up to 10 mL with

NaCl solution. SPME fiber was introduced into the vial. HNE was adsorbed under the improved conditions determined in the previous paragraph and the recovery of HNE was analyzed with HPLC. In HNE-DNPB analysis, the extracts from oil samples were combined and immediately reacted with an equal volume of DNPB reagent (3.5 mg of DNPB dissolved in 10 mL of 1 M HCl). The mixture was stored in the dark at room temperature for 2 h. After the reaction, the pH of the reaction mixture was adjusted to 7.0 with 1 N NaOH and made to 10 mL with NaCl solution. HNE-DNPB was measured by the same procedure used in HNE analysis.

Porcine liver sample (1 g) was cut into small pieces, and HNE–methanol solution (2.91 nmol and 0.29 nmol) was added to it. The sample was homogenized with 2 mL of methanol containing 0.1% BHT for 2 min. The homogenate was centrifuged at 3000 × *g* for 10 min, and the supernatant was collected. The residue was re-extracted by the same procedure, and the supernatant was collected. The supernatants were combined and made to 10 mL with NaCl solution. The recovery of HNE was measured by the same method used for the oil sample. In HNE-DNPB analysis, the extract was reacted with an equal volume of DNPB solution (the same solution used in the oil sample) and stored in the dark at room temperature for 2 h. HNE-DNPB was measured by the same method carried out in the oil sample.

The recovery rate for HNE, or  $([\text{HNE found}]/[\text{HNE added}]) \times 100$ , is calculated by Equation 1 as

$$[\text{HNE found}] = [\text{HNE}]_{\text{measured}} - [\text{HNE}]_{\text{originally contained}} \quad [1]$$

where [HNE] added is the concentration of HNE added in soybean oil or porcine liver.

**Detection of HNE in oxidized oil and oxidized porcine liver sample.** Soybean oil was oxidized at 45°C in the dark for 24 h, and porcine liver (1 g) homogenate was oxidized with 1 μmol  $\text{Fe}_2\text{SO}_4$  at 40°C in the dark for 4 h. The HNE contents of these oxidized samples were analyzed by using the SPME-HPLC method.

**Statistical analysis.** Each analysis was conducted at least five times. ANOVA procedures were performed. The differences were determined by Fisher's least significant difference tests, and the significance level was set at  $P < 0.05$ . Regressions of the calibration curves were examined with the test for regression slope, and significance levels were set at  $P < 0.05$ . Furthermore, the two regression slopes were compared and significant differences were set at  $P < 0.05$ .

## RESULTS AND DISCUSSION

All the analyses were examined by two analysts on separate days, and each experiment was conducted at least five times. Physical limits of the fibers were about 50 uses; however, the reproducibility was maintained after 50 uses (data not shown).

Figure 1 shows the calibration curves of HNE using four kinds of fibers. All the calibration curves were drawn by regression line. The regressions were examined by test for

**FIG. 1.** Calibration curves for standard 4-hydroxy-2-(*E*)-nonenal (HNE) by polydimethylsiloxane/divinylbenzene (PDMS/DVB) (◆), polyacrylate (□), carbowax/templated resin (CW/TPR) (▲), and PDMS (◇) fiber. Conditions were as follows: adsorption time, 10 min; adsorption temperature, 40°C; stirring, none; NaCl, none added. The error bars indicate SD of at least five experiments. The regressions were examined by test for regression slope and were significant ( $P < 0.001$ ).

regression slope and they were significant ( $P < 0.001$ ). The best linearity ( $R^2 = 0.9938$ ) and the greatest slope were associated with the PDMS/DVB fiber. On the other hand, the PDMS fiber, which is nonpolar, could not adsorb HNE compared with other fibers. PDMS/DVB fiber has been used for the analysis of polar compounds (22), aromatic amines (23), and the like. It has also been used to adsorb volatile lipid oxidation products for GC analysis (24,25). The results of the present study show that PDMS/DVB fiber is suitable for analysis of HNE with the SPME-HPLC method.

The calibration curves for HNE-DNPH using four kinds of fibers were also drawn by regression line. The regressions were examined by the test for significance of the regression and were found to be different ( $P < 0.001$ ). PDMS/DVB fiber

**FIG. 2.** Calibration curves of standard HNE-2,4-dinitrophenylhydrazine (DNPH) derivative by PDMS/DVB (◆), polyacrylate (□), CW/TPR (▲), and PDMS (◇) fiber. Conditions were as follows: adsorption time, 10 min; adsorption temperature, 40°C; stirring, none; NaCl, none added. The error bars indicate SD of at least five experiments. The regressions were examined by test for regression slope and were significant ( $P < 0.001$ ).

was again the most sensitive fiber for HNE-DNPH analysis (Fig. 2). However, the linearity of the calibration curve was the worst among the four fibers ( $R^2 = 0.9702$ ). Polyacrylate fiber, having almost the same polarity as PDMS/DVB fiber, was also a sensitive fiber for the detection of HNE-DNPH, and the linearity of the calibration curve was the best ( $R^2 = 1.000$ ). A comparison of the regression slopes between calibration curves of PDMS/DVB fiber and polyacrylate fiber found no significant difference. Accordingly, polyacrylate fiber was employed for HNE-DNPH analysis.

SPME is an equilibrium sampling method. Therefore, to increase the distribution constant one must increase the amount of HNE or HNE-DNPH adsorbed on the SPME fiber. The distribution constant is affected by both the polarity of the fiber (Figs. 1 and 2) and the ionic strength (17). Normally, increasing the ionic strength of the solvent can increase the distribution constant of the organic compound between solvent and fiber coating and decrease the solubility of the organic compound in water. The amount of HNE adsorbed on the fiber increased with increasing NaCl concentration and reached a plateau at 7.5% NaCl (Fig. 3A), where the amount of HNE adsorbed was 50% higher than that with no added NaCl. The solubility of HNE in water is high (6.6 mg/mL), but increasing the NaCl concentration reduces its solubility and enhances the transfer of HNE from sample solution to the fiber.

The effect of adding NaCl on the adsorption of HNE-DNPH on SPME fiber was less than that of HNE. In the HNE-DNPH experiment, the concentration of NaCl was varied from 0 to 20% (Fig. 4A). However, the increase in the amount adsorbed onto the fiber was only 10% in 20% NaCl solution compared with 0% NaCl solution. Since the solubility of HNE-DNPH in pure water is less than that of HNE, the addition of NaCl would not affect the solubility of HNE-DNPH to the same extent as HNE.

Increasing the mobility of dissolved HNE or HNE-DNPH enhances the amounts absorbed on SPME fiber. Both stirring

**FIG. 3.** Improvement of adsorbing conditions of HNE on PDMS/DVB fiber as related to NaCl concentration (A), rate of stirring (B), adsorption temperature (C), and adsorption time (D). The error bars indicate SD of at least five experiments. In each column, means with different italic letters are significantly different at  $P < 0.05$ . For abbreviations see Figure 1.

**FIG. 4.** Improvement of adsorbing conditions of HNE-DNPH on polyacrylate fiber as related to NaCl concentration (A), rate of stirring (B), adsorption temperature (C), and adsorption time (D). The error bars indicate SD of at least five experiments. In each column, means with different italic letters are significantly different at  $P < 0.05$ . For abbreviations see Figures 1 and 2.

and increased temperature impart kinetic energy to the molecules. In our experiments, the stirring rate was varied from 0 to 200 rpm; the best agitation speeds were 100 (Fig. 3B, HNE) and 200 rpm (Fig. 4B, HNE-DNPH). For HNE-DNPH, the temperature was varied from 30 to 55°C (Fig. 4C); the greatest adsorption occurred at 55°C. On the other hand, the optimal temperature in the range of 30–50°C for adsorption of HNE was 40°C (Fig. 3C). These phenomena can be ascribed to the vaporization of HNE, a semivolatile compound (b.p. 84–87°C), into the headspace above the sample after acquisition of energy. This idea is supported by the results shown in Figure 4 where the amount of HNE-DNPH adsorbed increased with higher stirring rates and temperatures. HNE-DNPH has a large M.W. compared with HNE (336 vs. 156) and therefore is only very slightly volatile. As a result, HNE-DNPH would be efficiently adsorbed on the fiber without any loss to the headspace.

The adsorption time was also considered in our attempts to maximize the amount adsorbed on the fiber. For HNE, adsorption reached a plateau at 15 min (Fig. 3D), whereas for HNE-DNPH maximal adsorption was at 20 min (Fig. 4D).

The optimal conditions for adsorption of HNE and HNE-DNPH are summarized in Table 1. Calibration curves using these conditions are shown in Figure 5. A comparison of the regression slopes was conducted between calibration curves after and before optimization for HNE or HNE-DNPH analysis, and they were significantly different ( $P < 0.001$ ).

Calibration curves of both HNE and HNE-DNPH were

**FIG. 5.** Comparison of calibration curves before and after improvement of conditions. The initial conditions were: NaCl, 0%; no stirring; temperature, 40°C; adsorption time, 10 min. The improved conditions are listed in Table 1. The error bars indicate SD of at least five experiments. The regressions were examined by test for regression slope and were significant ( $P < 0.001$ ). The comparison of the regression slopes between calibration curves for HNE and HNE-DNPH before and after improvement revealed a significant difference ( $P < 0.001$ ).

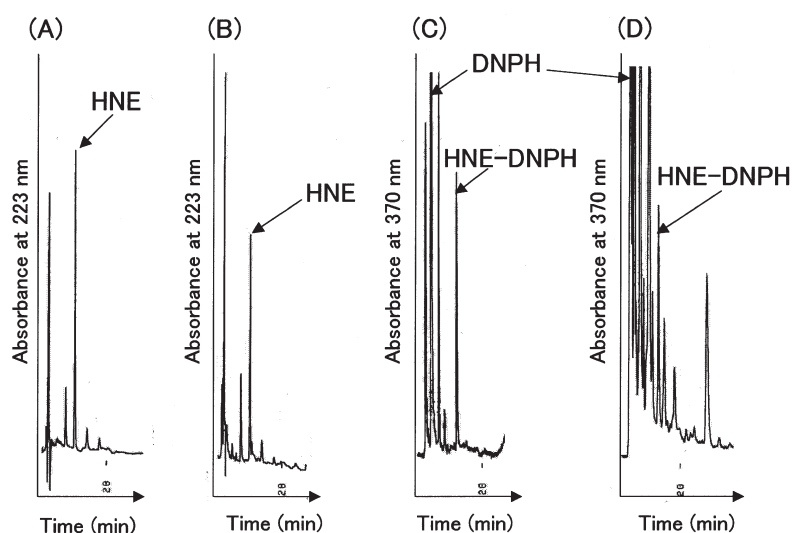

more sensitive than the original calibration curves. The quantification limit was set as a signal-to-noise ratio of 3 (8,9). The quantification limit of HNE was 14.1 pmol/10 mL and that of HNE-DNPH was 486.5 fmol/10 mL. The quantification limits of the HNE-HPLC-SP and HNE-DNPH-HPLC-SP methods, the conventional methods for HNE detection, were reported for HNE as 2 pmol/20  $\mu$ L (1000 pmol/10 mL) (6) and for HNE-DNPH as 1 pmol/20  $\mu$ L (500 pmol/10 mL) (6), respectively. Both the HNE-DNPH-HPLC-ECD (8) and HNE-CHD-HPLC-FL (9) methods are known as sensitive methods for the quantification of HNE, and the quantification limits are 15 and 50 fmol, respectively. The quantification limit of the HNE-DNPH-HPLC-ECD method was also calculated as 25 pmol/10 mL because the injection volume was 6  $\mu$ L. Similarly, the quantification limit of HNE-CHD-HPLC-FL was 25 pmol/10 mL because the injection volume was 20  $\mu$ L. These results indicate that the quantification limit of HNE with the SPME-HPLC method was better than with these other methods.

In Figure 6 the HPLC chromatogram of HNE standard sample (A) can be compared with that of an oil sample (B) mixed with HNE. The HPLC chromatogram of an HNE-DNPH standard sample (Fig. 6C) can also be compared with that of HNE-DNPH extracted from a DNPH-derived porcine liver sample containing HNE (Fig. 6D). Peak identification was based on retention time. Recovery of HNE was calculated (Table 2). Average recovery was about 80%. SPME is an equilibrium sampling method. That is, 100% recovery is

**TABLE 2**

**Recovery Rate of HNE from Soybean or Porcine Liver Mixed with Standard HNE Solution ( $n = 5$ )**

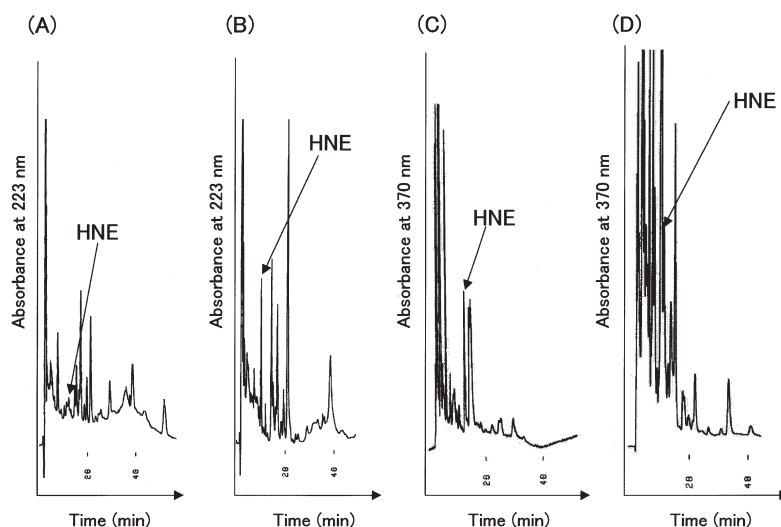

Sample	HNE present (nmol) <sup>a</sup>	Method	HNE added (nmol)	HNE found (nmol) <sup>b</sup>	Recovery of added HNE (%)
Soybean oil <sup>c</sup>	0.38 ± 0.09	HNE	2.91	2.53 ± 0.33	87
			0.29	0.18 ± 0.09	62
		HNE-DNPH	2.91	2.57 ± 0.15	88
			0.29	0.28 ± 0.08	76
Porcine liver <sup>d</sup>	0.88 ± 0.12	HNE	3.52	2.47 ± 0.52	70
			0.35	Trace	—
		HNE-DNPH	3.52	2.86 ± 0.53	81
			0.35	0.23 ± 0.05	66

<sup>a</sup>"HNE present" was analyzed by the HNE-DNPH method.

<sup>b</sup>"HNE found" was determined by subtracting the concentration of HNE originally contained in the sample, "HNE present," from the concentration of HNE measured in the sample to which HNE was added.

<sup>c</sup>Oil sample (100 mg) was extracted twice with 2 mL of distilled water.

<sup>d</sup>Porcine liver sample (1 g) was extracted twice with 2 mL of methanol. For abbreviations see Table 1.

**FIG. 7.** Chromatograms of HNE in (A) soybean oil and (B) oxidized soybean oil as detected by HPLC-SP, and of HNE in (C) porcine liver and (D) oxidized porcine liver derivatized with DNPH and detected by HPLC-SP. For abbreviations see Figures 1, 2, and 6.

impossible; thus, 80% recovery is a fairly high value. Recoveries of HNE by direct HNE analysis were lower in samples with trace additions of HNE (0.29 nmol). In particular, HNE was not detected in porcine liver samples to which trace amounts of HNE were added. HNE reacts primarily with amino acids such as histamine and lysine (3), and this reactivity is thought to be one of the causes of high toxicity of HNE in biological systems. This reaction also may interrupt the adsorption of HNE on the fiber in this system. On the other hand, the recovery of HNE by the HNE-DNPH method was almost constant, and the trace amount of HNE in the porcine liver sample could be detected.

Chromatograms of oxidized soybean oil analyzed directly for HNE (B) and of oxidized porcine liver samples analyzed by HNE-DNPH (D) are shown in Figure 7. The formation of HNE was observed in both samples. These results indicate that the method developed in this study also can be used to detect HNE in oxidized samples.

Conventional methods for HNE require the purification of the sample using TLC (26), solid-phase extraction (21), or column extraction (7) before analysis by GC or HPLC because the sample normally contains lipids, oxidized lipids, and oxidized protein, which interfere with HNE or HNE-DNPH analysis. In this experiment, HNE analysis using SPME was developed. SPME fibers can adsorb target molecules and the method is fast, sensitive, and quantitative. In addition, complicated apparatus is not needed. This methodology is available for not only fat and oil samples but also biological samples.

## A Critique of 50-m CP-Sil 88 Capillary Columns Used Alone to Assess *trans*-Unsaturated FA in Foods: The Case of the TRANSFAIR Study

Sir:

The industry-sponsored TRANSFAIR study, conducted by more than 70 participants, was aimed at determining reliable data on the total as well as on clusters of *trans*-unsaturated FA (*trans*-UFA) contents of several hundred food items purchased in 14 European countries (1–6). We wish here to comment on the results obtained in that study, particularly those for France and Germany, for which a wealth of detailed and accurate data on individual *trans* isomers has been accumulated by other authors for practically all kinds of major foods (7–17).

In the TRANSFAIR study, FA and *trans*-UFA in particular were determined on (a) 50-m CP-Sil 88 capillary column(s) (commercial source not mentioned; operated isothermally at 195°C). This column, however, is known to present several drawbacks, whether operated isothermally or with temperature programming, that preclude any complete separation of *trans*-UFA if a preliminary fractionation, e.g., by silver nitrate TLC, is not performed. We will describe, in this letter, the main limitations of this kind of column when used alone for the assessment of *trans* isomers.

First of all, the *trans*-16:1 isomers [present in rather low amounts in ruminant fats (18), human milk fat (19), and partially hydrogenated fish oils (18)] are not fully resolved from the *cis*-16:1 isomers and also overlap with branched-17:0 acids. In particular, the *trans*-9 16:1 acid (palmitelaidic acid, the single commercially available standard) may coincide with iso-17:0 acid (19,20) under most analytical conditions. The proportion of the latter FA in ruminant milk fat is considerably higher than that of palmitelaidic acid (8,19), which resulted in overestimates in the TRANSFAIR study by as much as 2,000% in some instances [1,200% on average (7)].

Second, the 50-m CP-Sil 88 column is known to give access to only the  $\Delta 4$  to  $\Delta 11$  *trans*-18:1 isomers (or to the  $\Delta 12$  and part of the  $\Delta 13/14$  isomers in the most favorable case with relatively low contents of oleic acid, and when the  $\Delta 4$  and  $\Delta 5$  isomers are taken into account by the integrator) while the other unsaturated *trans* isomers with a  $\Delta 12$ ,  $\Delta 13$ ,  $\Delta 14$ ,  $\Delta 15$ , and  $\Delta 16$  double bond are eluting under the main oleic ( $\Delta 9$  *cis*-18:1) acid peak, or even after it (21). It could be calculated that data from the TRANSFAIR study for all dairy products that were analyzed were indeed underestimated by an average of *ca.* 35% (9). However, this value is by no means applicable to individual analyses of ruminant fats for the

following reasons. The underreporting of *trans*-18:1 isomers from ruminant milk depends on the operating temperature of the column (being somewhat lower at higher temperatures), on the nature of the carrier gas and its linear velocity, and on the feed of the cattle (pasture vs. barn feeding: greater underreporting in the former conditions as compared to the latter). Note that in the TRANSFAIR study, the operating temperature of the column was 195°C, which precluded integration of the 4:0 to 7:0 acids. Together they represent *ca.* 6% of total FA in bovine milk lipids, implying that data for FA determined in the TRANSFAIR study must be divided by 1.06, thus contributing to underestimation of total *trans* isomers. Also, aging of the column appreciably modifies the resolution (skewing of peaks). This is important in view of the facts (i) that the group of *trans*-18:1 isomers represents the greatest part of dietary *trans*-UFA (more than 80% of total *trans*-UFA in ruminant fats and 90% in partially hydrogenated vegetable oils) (16,17), and (ii) that ruminant fats are the main source of dietary *trans*-18:1 acids in many European countries (12). Another consequence is that data for oleic acid in the TRANSFAIR study are overestimates. Unfortunately, no corrections can be made for other food items containing partially hydrogenated vegetable oils, as the correction factors for such oils are variable (21). However, approximations can be deduced for several categories of French and German foods from data in Reference 10.

Third, *trans*-18:3 isomers that are formed during the deodorization of  $\alpha$ -linolenic acid-containing vegetable oils (22) were likely mixed with 20:0 and/or *cis*- and/or *trans*-20:1 acids. The resolution of these FA is highly dependent on the operating temperature and the length of the CP-Sil 88 column and requires that special analytical precautions be taken (23). Oils containing  $\alpha$ -linolenic acid (mostly rapeseed and soybean oils) from France and Germany (and a few other European countries) have been described in detail in this respect and have been shown to present similar geometrical isomers in practically equal relative proportions (24–27). It is impossible to make any sound comments or to draw any conclusions regarding *trans* isomers of linoleic acid since no chromatograms were published in any of the many papers discussing the TRANSFAIR study (1–6,28). *Trans* isomers of linoleic acid are naturally present in ruminant fats and are otherwise found in vegetable oils after either deodorization or partial hydrogenation. Here too, depending on the column temperature, these isomers may interfere with other components in that complex chromatographic region, particularly in

ruminant fats (16,29). In brief, owing to the large uncertainties in clusters of *trans*-UFA (16:1, 18:1, 18:2, and 18:3 isomers) described above, the calculated total *trans*-UFA in foods in the TRANSFAIR study, based on inappropriate methodology, should not be considered accurate measurements of *trans* FA content of foods (7). The reader who is particularly interested in regulatory matters on food composition may now decide on the usefulness of such data.

Finally, in the concluding papers of the TRANSFAIR study (6,28), estimates of the daily individual intake of total *trans*-UFA by men and women separately (6), or by whole populations (29), were made for the 14 countries under investigation. These were 2.1 and 1.9 grams per person per day (g/p/d) for French and German women, respectively, and were slightly higher for men. These values are in contradiction with detailed data on human milk fat established for the two populations. The milk fat of German women contains *ca.* 3.8 g of total *trans*-UFA per 100 g of FA (30), whereas the corresponding value for French women is only *ca.* 2.3 g (12,31). Based solely on the TRANSFAIR study data, one would have to conclude that German women are able to concentrate considerably more *trans*-UFA in their milk, whereas French women are not. More seriously, we prefer to conclude that the TRANSFAIR study estimates are erroneous and unreliable because of a faulty analytical procedure applied to all foods under investigation. If there is a relationship between the quantity of dietary *trans*-UFA and that present in human milk, the consumption of *trans*-UFA by German women should then be at least 4 g/p/d, which is twice the value calculated in the TRANSFAIR study.

In conclusion, it should be added that because each individual *trans*-UFA has its own metabolic fate (32,33), mixing all categories of *trans*-UFA is of little use for nutritionists. Methods are presently available to clearly separate, identify, and quantify individual *trans*-UFA (14,34), which also permit rather accurate estimates of the relative contributions of ruminant fats and partially hydrogenated vegetable oils to the total per capita daily *trans*-UFA intake (12,30,35,36). These include an obligatory preliminary step, e.g., silver ion TLC, in order to suppress overlaps of *trans*-UFA with interfering FA, as described above. An alternative procedure, which has been less frequently used, is RP-HPLC, which allows simplified GC analyses of *trans*-PUFA (31), including CLA (not reported in the TRANSFAIR study). Also, 100-m or even longer columns should be preferred to improve the resolution of isomers. However, if the GC operating temperatures are not optimal, the separations will not be very different from those obtained with 50-m columns [compare, e.g., chromatograms displayed in Refs. 12 (50-m CP-Sil 88 column) and 37 (100-m CP-Sil 88 column)]. With these combinations of analytical methods, provided the operating conditions are optimized (generally, rather low temperatures), additional data on most individual isomers can be collected (38,39). This critique of the TRANSFAIR study obviously is applicable to all data on *trans*-UFA in the literature not obtained by the combinations of methods described above. The use of long to very long capillary columns coated with 100% cyanopropyl poly-

siloxane polymer still requires complementary fractionation techniques. This should be kept in mind when considering food FA labeling, including that of the so-called "*trans*-fatty acids."

**ABSTRACT:** The antioxidant action on lipid peroxidation of the synthesized selenium compounds 1-(11-selenadodecyl)-glycerol (SeG) and 1-(11-selenadodecyl)-3-Trolox-glycerol (SeTrG, where Trolox = 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid) was investigated. We compared the reactivity of the selenium compounds toward peroxy radicals and their inhibitory effect on lipid peroxidation, induced by several kinds of initiating species such as azo compounds, metal ions, and superoxide/nitric oxide in solution, micelles, membranes, and rat plasma. SeTrG, but not SeG, scavenged peroxy radicals. SeG reduced methyl linoleate hydroperoxides in organic solution and in methyl linoleate micelles oxidized by ferrous ion (Fe<sup>2+</sup>)/ascorbic acid. In rat plasma SeG and SeTrG decreased the formation of lipid hydroperoxides generated by hydrophilic azo compounds. SeG and SeTrG spared  $\alpha$ -tocopherol ( $\alpha$ -TOH) consumption in multilamellar vesicle membranes oxidized by hydrophilic or lipophilic initiators, and only SeTrG spared  $\alpha$ -TOH in superoxide/nitric oxide oxidized membranes. In rat plasma oxidized by radical initiators (either hydrophilic or lipophilic) or superoxide/nitric oxide, SeTrG suppressed  $\alpha$ -TOH consumption, but SeG had no effect. The two selenium-containing compounds showed inhibitory effects on lipid peroxidation that depended on their structure, the medium where they acted, and the oxidant used.

Paper no. L9010 in *Lipids* 37, 633–640 (July 2002).

The trace element selenium, constituent of selenoproteins, protects against viral (HIV and hepatitis) infections, cardiovascular diseases, and cancer. Selenium may stimulate the immune

Abbreviations: A, absorbance; AA, ascorbic acid; AAPH, 2,2'-azobis(2-amidinopropane) dihydrochloride; AMVN, 2,2'-azobis(2,4-dimethylvaleronitrile); CA, caffeic acid; DOPAC, 3,4-dihydroxyphenylacetic acid; DPBQ, *N,N'*-diphenyl-*p*-benzoquinone diimine; DPPD, *N,N'*-diphenyl-*p*-phenyldiamine; ebselen, 2-phenyl-1,2-benzoselenazol-3(2H)-one; MeO-AMVN, 2,2'-azobis(4-methoxy-2,4-dimethylvaleronitrile); MeLOH, methyl linoleate alcohols; MeLOOH, methyl linoleate hydroperoxides; MLV, multilamellar vesicles; PMC, 2,2,5,7,8-pentamethyl-6-chromanol; SeG, 1-(11-selenadodecyl)-glycerol; SeTrG, 1-(11-selenadodecyl)-3-Trolox-glycerol; SIN-1, 3-morpholinolonylamine hydrochloride; Trolox, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid;  $\alpha$ -TOH,  $\alpha$ -tocopherol; Toc-3, tocotrienols.

system and benefit thyroid function, reproduction, and mood (1,2). As a functional center of the glutathione peroxidases, selenium catalyzes the reduction of hydrogen peroxide and of lipid and phospholipid hydroperoxides to water and alcohols. It prevents the formation of free radicals and defends against oxidative stress (1,2). The antiatherogenic and anticancer potentials of selenium are related to its antioxidative properties (2). The biological potentials of organoselenium compounds have been extensively reviewed (3,4).

Sodium selenate, sodium selenite, selenourea, and selenomethionine (5), ebselen (6–8), tetradecylselenoacetic acid (9), the monoglyceride 1-(11-selenadodecyl)-glycerol (SeG) (10), and the triglyceride 1-( $\beta$ -apo-8'-carotenoyl)-2-(7-selenaocanoyl)-3-(6-hydroxy-2,5,7,8-tetramethylchroman-2-acyl)-glycerol (11) show antioxidant capacity. Selenoproteins and organoselenium compounds protect against pro-oxidants and peroxynitrite (12). Ebselen reduces the extent of hemolysis of human erythrocytes incubated with peroxynitrite (13) and the frequency of transformation of mouse embryo fibroblasts exposed to 2,2'-azobis(2-amidinopropane) dihydrochloride (AAPH) and 3-morpholinolonylamine hydrochloride (SIN-1) (14).

Nutritional sources of selenium are brazil nuts, kidney, crab, liver, fish, and meat (1). Selenium is one of the antioxidant components in garlic extract (15) and green tea (16).

Mixtures of selenium and vitamin E show a synergistic antioxidant effect *in vitro* (17). The effects of vitamin E and selenium against prostate cancer (18), radiation-induced injury (19), and fungal toxin (20) are related to their antioxidative action against lipid peroxidation.

The purpose of this work is to elucidate the relationship between the structure of the selenium compounds SeG and the recently synthesized 1-(11-selenadodecyl)-3-Trolox-glycerol (SeTrG) (Scheme 1), their reactivity toward oxidants, and antioxidant activity in various lipid systems. SeTrG combines two antioxidants chemically: selenium and the vitamin E derivative Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid). The radical-scavenging activity of SeG and SeTrG was tested in *N,N'*-diphenyl-*p*-phenyldiamine (DPPD) oxidation. Organic solutions, micelles, multilamellar

SCHEME 1

liposomes, and rat plasma were used as lipid substrates. Metal ions, hydrophilic initiators, or lipophilic radical initiators were used as oxidants. The reactions were performed at 37°C in air.

## MATERIALS AND METHODS

**Synthesis of SeG and SeTrG.** The synthesis of SeG was previously described (21). SeTrG was prepared by esterifying SeG with Trolox, 4-dimethylaminopyridine, and *N,N'*-dicyclohexylcarbodiimide at room temperature (21). After reaction, the product was purified by preparative TLC (32% yield). The structures of SeG and SeTrG were verified by MS and by <sup>1</sup>H and <sup>13</sup>C NMR (21).

**Materials.** Ascorbic acid (AA), AAPH, 2,2'-azobis(2,4-dimethylvaleronitrile) (AMVN), DPPD, 2,2'-azobis(4-methoxy-2,4-dimethylvaleronitrile) (MeO-AMVN), 2,2,5,7,8-pentamethyl-6-chromanol (PMC),  $\alpha$ -tocopherol ( $\alpha$ -TOH), and Trolox were purchased from Wako Pure Chemical Industries Ltd. (Osaka, Japan). Methyl linoleate and SIN-1 were obtained from Sigma Chemical Co. (St. Louis, MO). Tocotrienols (Toc-3) were from Fuji Chemical Co., Ltd. (Toyama, Japan). Soybean PC was purchased from Nichiyu Liposome Co., Inc. (Tokyo, Japan) and purified by column chromatography. Ethanol and 2-propanol were from Wako Pure Chemical Industries Ltd., and methanol and *n*-hexane from Kanto Chemical Co., Inc. (Tokyo, Japan). The *n*-hexane and 2-propanol were of HPLC grades. All other reagents were of analytical grade.

**Animals and diets.** All experimental procedures were conducted in compliance with the Teikyo University's policy on animal care and use. Several male rats, Sprague-Dawley strain, 5 wk old, were purchased from Saitama Experimental Animals Supply Co., Ltd. (Saitama, Japan). They were fed Certified-1 Diet (CRF-1), Oriental Yeast Co. (Tokyo, Japan)

for several weeks. During this period, a blood sample from the retro-ocular plexus of each animal was taken at certain intervals. The  $\alpha$ -TOH content in the plasma, obtained by centrifugation of rat blood, was in the range of 20–24  $\mu$ M.

**Estimation of antioxidant reactivity toward peroxy radicals.** DPPD reacts with free radicals to form *N,N'*-diphenyl-*p*-benzoquinone diimine (DPBQ), which has a strong absorbance at 440 nm (22). DPPD (100  $\mu$ M final concentration), mixed with SeG or SeTrG (500  $\mu$ M) in acetonitrile, was preincubated at 37°C for 3 min. AMVN (50 mM final concentration) was added to start the reaction under air at 37°C. DPPD oxidation was traced at 440 nm by means of a U-3310 Hitachi spectrophotometer (Tokyo, Japan).

**Inhibition of oxidation of lipids by SeG and SeTrG.** Methyl linoleate hydroperoxides (MeLOOH), synthesized from methyl linoleate by lipoxidase in methanol, at a concentration of 99  $\mu$ M, were incubated at 37°C under air with 200  $\mu$ M SeG. The MeLOOH and the corresponding methyl linoleate alcohols (MeLOH) were detected by an HPLC system (Shimadzu Corp., Kyoto, Japan), equipped with a UV detector and Wakosil-II 5C18 RS (4.6  $\times$  250 mm) column (Wako Pure Chemical Industries Ltd.). Acetonitrile/distilled water (9:1, vol/vol) at a flow rate of 0.7 mL/min was used as an eluent.

Methyl linoleate micelles were prepared by vigorously mixing with a vortex mixer for 2 min methyl linoleate (25 mM for measuring UV absorbance or 75 mM for measuring O<sub>2</sub> consumption) and SDS (0.5 M) in PBS (10 mM, pH 7.4). For measurement of UV absorbance at 234 nm (A<sub>234</sub>), 3 mL of the methyl linoleate micelle dispersion (25 mM in 0.5 M SDS containing PBS) was placed in a quartz cell of a U-3310 Hitachi spectrophotometer (Tokyo, Japan). Adding 5  $\mu$ L of 40 mM Fe<sup>2+</sup>/400 mM AA (final concentration 5  $\mu$ M Fe<sup>2+</sup>/50  $\mu$ M AA) induced the oxidation. The reaction was performed at 37°C under air. When SeG was used as antioxidant, 400  $\mu$ M SeG was added to the methyl linoleate micelle dispersion before oxidation. A<sub>234</sub> was scanned with time. A dispersion of unoxidized methyl linoleate micelles was used as a reference. The O<sub>2</sub> consumption was measured with a Galvani-type oxygen electrode, MD-1000 (Iijima Electronics Corp., Tokyo, Japan). The O<sub>2</sub>-concentration was set at 0  $\mu$ M with the meter in water containing 5% sodium bisulfite and at 220  $\mu$ M in water saturated with air at 35°C. The methyl linoleate micelle dispersion (75 mM in 0.5 M SDS containing PBS) was placed in the cell of the O<sub>2</sub> electrode having a volume of 2.25 mL. After 10 min, the addition of 5  $\mu$ L of 4 mM Fe<sup>2+</sup>/40 mM AA (final concentration 0.6  $\mu$ M Fe<sup>2+</sup>/6  $\mu$ M AA) induced the oxidation, which was performed at 35.8°C under air. After another 10 min, SeTrG (100  $\mu$ M final concentration) or SeG (500  $\mu$ M final concentration) was added, and the O<sub>2</sub> consumption was recorded.

In multilamellar vesicle (MLV) oxidations, SeG or SeTrG were externally added (i) or incorporated (ii) in the multilamellar liposomes.

(i) *SeG and SeTrG externally added to MLV suspensions.* When MLV suspensions were oxidized by AAPH, soybean PC (2.8 mM), and  $\alpha$ -TOH (15  $\mu$ M) were dissolved in chloroform

and mixed, and the solvent was evaporated completely under nitrogen ( $N_2$ ). PBS containing EDTA (0.1 mM) was added, and the mixture was treated with a vortex mixer to form an MLV suspension. The MLV suspension was divided into three tubes. SeG and SeTrG at concentration of 100  $\mu$ M were added to two of them. The MLV suspensions were placed in a water bath shaker (37°C, 150 oscillations per minute) and AAPH (20 mM final concentration) was added to start the oxidation. When MLV suspensions were oxidized by the internally incorporated AMVN, AMVN (6 mM) was mixed together with soybean PC and  $\alpha$ -TOH, and the same procedure as described above was used. The oxidation was started by placing the MLV suspensions in a water bath shaker (37°C, 150 oscillations per minute).

(ii) *SeG and SeTrG incorporated in MLV.* The same procedure as described above was used, but SeG or SeTrG, each 100  $\mu$ M, was added to a mixture of soybean PC,  $\alpha$ -TOH, and AMVN (when used) in the beginning of the preparation of MLV suspensions. In SIN-1 oxidation, 0.4 mL of MLV suspension, without or with externally added SeG or SeTrG at a concentration of 300  $\mu$ M, was oxidized at 37°C for 60 min by externally added SIN-1 (0.3–1 mM) in 1 mM EDTA solution. Aliquots of 0.2 mL of the oxidized MLV suspensions were withdrawn at measured time intervals and processed for measuring  $\alpha$ -TOH concentration. The oxidation was stopped by the addition of EDTA (100  $\mu$ M) and freezing (23).

Rat plasma was obtained by mixing the plasma from several rat blood samples, followed by centrifugation twice at  $950 \times g$  for 5 min. Fresh rat plasma (2 mL), without or with SeG or SeTrG in ethanol solution added beforehand at appropriate concentration, was incubated for 2–3 min at 37°C in a water bath shaker before the oxidants AAPH (20 mM) in 1 mM EDTA solution or MeO-AMVN (2 mM) in methanol solution were added to start the oxidation. The final concentrations of methanol and ethanol were 1 and 0.5 vol%, respectively. In SIN-1 oxidation, 0.4 mL rat plasma, without or with 300  $\mu$ M SeG or SeTrG, was oxidized at 37°C for 60 min by SIN-1 (0.3–1.2 mM) in 1 mM EDTA solution. Aliquots of 0.2 mL of oxidized rat plasma were withdrawn at measured time intervals and handled as described above. The samples were processed for measuring  $\alpha$ -TOH concentration.

*$\alpha$ -TOH extraction.*  $\alpha$ -TOH was extracted from rat plasma or MLV suspension by the modified method of Abe and Katsui (24), and Abe *et al.* (25) as described by Shabit *et al.* (26). A volume of 10  $\mu$ L ethanol containing 2  $\mu$ g 2,2,5,7,8-pentamethyl-6-chromanol (PMC) as an internal standard was added to oxidized rat plasma or MLV suspension (0.2 mL). The sample was diluted with distilled water (2.0 mL) and ethanol (2.0 mL) after consecutive mixings for 1 min with a vortex mixer. The  $\alpha$ -TOH was extracted with *n*-hexane (5.0 mL). A 0.9% NaCl water solution (2.0 mL) was added and mixed 2–3 min with a vortex mixer at which time rat plasma was used (for precipitation of the proteins). The mixture was centrifuged at  $1,500 \times g$  for 10 min at 4°C. The upper layer, containing  $\alpha$ -TOH, the internal standard, and the lipids, was pipetted. All procedures were performed at 4°C in an ice bath.

The *n*-hexane was evaporated under  $N_2$ . The residue was then dissolved in *n*-hexane (1.6 mL), and a volume of 20  $\mu$ L of the solution was injected into the column of the HPLC system.

*$\alpha$ -TOH detection by HPLC.* The HPLC system contained an injector (Rheodyne Incorporated, Cotati, CA), DGU-4A Shimadzu degasser (Shimadzu Corp., Kyoto, Japan), NH<sub>2</sub>-1251-N,  $4.6 \times 250$  mm, Senshu Pak column (Senshu Scientific Co., Ltd., Tokyo, Japan), LC-10 AD Shimadzu liquid chromatograph, RF-10 A Shimadzu spectrofluorometric detector, and C-R6A Shimadzu Chromatopac recorder. The  $\alpha$ -TOH was detected at an excitation wavelength of 298 nm and an emission wavelength of 325 nm. The mobile phase was *n*-hexane/2-propanol (98:2, vol/vol) at flow rate 1.0 mL/min.

*UV analysis of conjugated diene hydroperoxides.* Oxidized rat plasma, without or with antioxidants, was diluted with distilled water 80 times and was analyzed by a U-3310 Hitachi spectrophotometer by scanning from 300 to 200 nm at a rate of 60 nm/min. Unoxidized rat plasma, 80 times diluted, was used as a reference.

## RESULTS AND DISCUSSION

Antioxidants act by different mechanisms such as radical scavenging, hydroperoxide reduction, and metal ion sequestration (27). We examined the antioxidative properties of SeG and SeTrG mechanisms of action as antioxidants in different systems: organic solution, MeLOOH in methanol solution, methyl linoleate micelles, PC liposomes membranes, and rat plasma.

*SeG and SeTrG peroxy radical-scavenging activity.* The peroxy radicals act as chain-carrying species in lipid peroxidation. We investigated if SeG and SeTrG can act as chain-breaking antioxidants and compared their ability to scavenge peroxy radicals competing with DPPD in organic solution (acetonitrile). One molecule of DPPD rapidly scavenges two radicals and forms DPBQ (22), which has a strong absorbance at 440 nm. The absorbance increased with time due to the formation of DPBQ from DPPD by the reaction with the radicals generated by AMVN (Fig. 1). The addition of SeTrG decreased the rate of DPPD oxidation as compared with the control reaction because SeTrG scavenged radicals in competition with DPPD. SeTrG had no induction period. The curve for variation of the absorbance upon addition of SeG coincided with that of the control reaction, where no antioxidant was added. The results from DPPD oxidation showed that SeTrG was able to scavenge peroxy radicals, whereas SeG was not able to compete with DPPD in scavenging peroxy radicals.

*Reduction of lipid hydroperoxides.* Selenium compounds act as antioxidants by reducing lipid hydroperoxides. Hydroperoxide formation in sunflower oil was retarded by SeG (10). Ebselen, which exerts glutathione-peroxidase activity, also acts as antioxidant by reducing FA and lipid hydroperoxides (7,8). We examined the ability of SeG and SeTrG to reduce hydroperoxides in solution, micelles, and rat plasma.

SeG reduced MeLOOH to the corresponding alcohols in a time-dependent manner (Fig. 2). SeG also suppressed the

**FIG. 1.** Effect of 1-(11-selenadodecyl)-3-Trolox-glycerol (SeTrG) on the formation of *N,N'*-diphenyl-*p*-benzoquinone diimine (DPBQ) ( $\lambda_{\max} = 440$  nm) as a result of *N,N'*-diphenyl-*p*-phenylenediamine (DPPD) oxidation under air at 37°C. 2,2'-Azobis(2,4-dimethylvaleronitrile) (AMVN) (50 mM) was added to DPPD in acetonitrile or to a mixture of DPPD (100  $\mu$ M) and antioxidant (500  $\mu$ M) in acetonitrile. The increase in absorbance at 440 nm was monitored.

formation of hydroperoxides generated by metal ion-induced peroxidation of methyl linoleate micelles (Fig. 3). We conclude that (i) SeG reduces hydroperoxides, which are required for metal-ion catalyzed oxidation, and (ii) SeG cannot scavenge peroxy radicals. This behavior is similar to the antihypertensive drug carvedilol (28), which is effective against ferric ion-induced oxidation but fails to scavenge radicals.

We compared the activity of SeG and SeTrG against  $\text{Fe}^{2+}/\text{AA}$  oxidation by measuring  $\text{O}_2$  consumption (Fig. 4). SeTrG (100  $\mu$ M) showed much greater activity than SeG (500  $\mu$ M) because SeTrG incorporates the potent antioxidant Trolox group.

We examined the activity of SeG and SeTrG as antioxidants in the oxidation of rat plasma induced by the hydrophilic initiator AAPH. The change in absorbance  $A$  at 234 nm of oxidized rat plasma in the absence and presence of SeG or SeTrG is shown in Figure 5. The two selenium-containing

**FIG. 2.** Reduction of methyl linoleate hydroperoxides (MeLOOH) (initial concentration 99  $\mu$ M in methanol) to the corresponding methyl linoleate alcohols (MeLOH) by 200  $\mu$ M 1-(11-selenadodecyl)-glycerol (SeG) under air at 37°C.

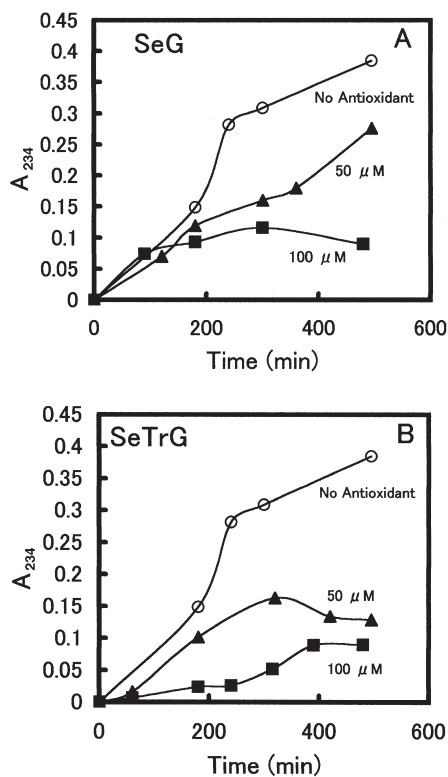

**FIG. 3.** Inhibitory effect of SeG at concentration 400  $\mu$ M (●) on the formation of conjugated diene hydroperoxides, measured by the time-dependent variation in absorbance at 234 nm ( $A_{234}$ ), in methyl linoleate micelle dispersion [25 mM methyl linoleate in 0.5 mM SDS-PBS (10 mM), pH = 7.4] oxidized by 5  $\mu$ M  $\text{Fe}^{2+}/50$   $\mu$ M AA ( $\text{FeSO}_4/\text{ascorbic acid}$ ) under air at 37°C. (○) Change in  $A_{234}$  with time without the addition of antioxidant. For abbreviation see Figure 2.

compounds suppressed the formation of conjugated diene hydroperoxides at concentrations of 50 and 100  $\mu$ M in rat plasma. SeTrG showed a greater effect than SeG.

*Inhibitory effect of SeG and SeTrG on  $\alpha$ -TOH consumption in MLV suspensions and rat plasma.* Antioxidants can act cooperatively or synergistically with other antioxidants. The synergistic action between vitamin E and vitamin C is well known (23,29).  $\alpha$ -TOH is the most abundant lipophilic antioxidant in LDL. It is located predominantly in the outer PC monolayer of organized LDL structures, and it places its active phenolic groups at the surface (23). The rate of lipid oxidation,  $\alpha$ -TOH consumption, and conjugated peroxide diene formation are correlated (29). Liposomes are widely used as models for biomembranes. We used multilamellar soybean PC liposomes, containing  $\alpha$ -TOH (Fig. 6). As oxidants we used the hydrophilic radical initiators AAPH or SIN-1 added to MLV suspensions (Figs. 6A, 6C, 7) or the lipophilic AMVN incorporated into membranes (Figs. 6B, 6D). SeG

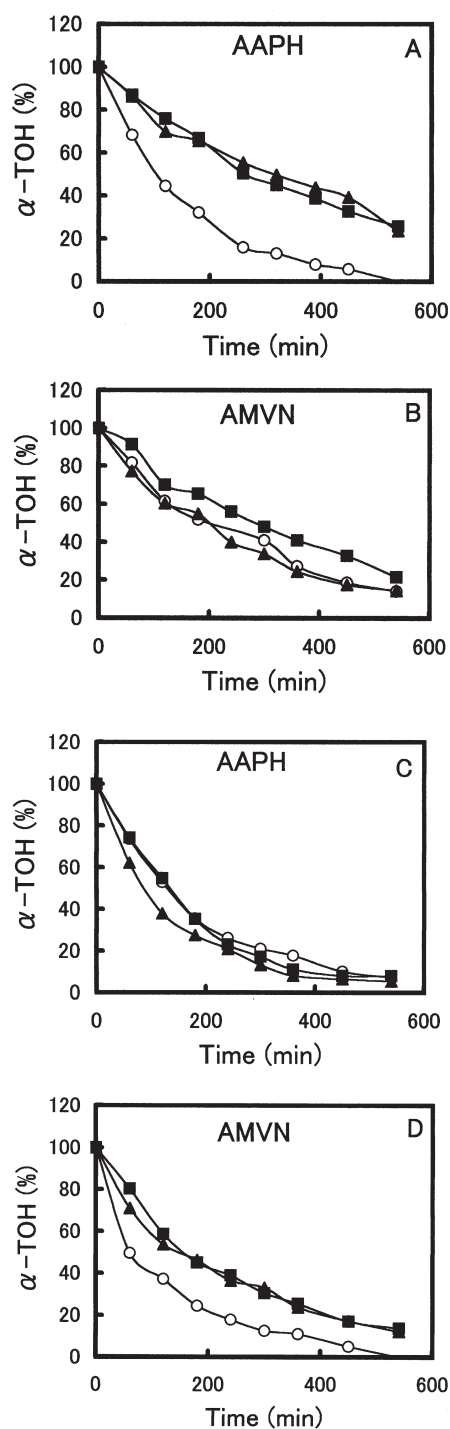

**FIG. 4.** Inhibitory effect of SeG (500  $\mu$ M) and SeTrG (100  $\mu$ M) on oxygen ( $\text{O}_2$ ) consumption in the oxidation under air at 35.8°C of methyl linoleate micelle dispersion (75 mM methyl linoleate in 0.5 M SDS PBS (10 mM), pH = 7.4) by 0.6  $\mu$ M  $\text{Fe}^{2+}/6$   $\mu$ M AA. For abbreviations see Figures 1–3.

**FIG. 5.** Inhibitory effect of SeG (A) and SeTrG (B) on the formation of conjugated diene hydroperoxides measured by time-dependent variation in  $A_{234}$  in rat plasma oxidized by 2,2'-azobis(2-amidinopropane) dihydrochloride (AAPH). SeG (A) and SeTrG (B) at concentrations of 50 ( $\blacktriangle$ ) and 100 ( $\blacksquare$ )  $\mu$ M were added to rat plasma (2 mL) before AAPH (20 mM) was finally added to start the oxidation under air at 37°C. Oxidized plasma (0.05 mL) was diluted with distilled water 80 times, and  $A_{234}$  was monitored. The spectrum was scanned from 300 to 200 nm at a speed of 60 nm/min. (○) Change in  $A_{234}$  with oxidation time without the addition of antioxidants. For abbreviations see Figures 1–3.

and SeTrG were externally added to MLV suspensions (Figs. 6A, 6B, 7) or incorporated into PC layers (Figs. 6C, 6D). The results from Figure 6 can be explained considering the structure of the selenium-containing compounds, their localization, and the character of the oxidant used—hydrophilic or lipophilic. SeG and SeTrG added externally to MLV oxidized by AAPH (Fig. 6A) are situated in the aqueous medium. They decompose the lipid hydroperoxides produced by the hydrophilic AAPH and protect  $\alpha$ -TOH. SeG and SeTrG externally added to MLV oxidized by internally incorporated AMVN (Fig. 6B) are situated in the aqueous phase, but the radicals are produced inside the PC layers. SeG and SeTrG cannot interact with lipid hydroperoxides due to dimensional restrictions. SeTrG shows some effect due to the presence of the Trolox group having radical-scavenging activity.

Incorporated in MLV oxidized by AAPH (Fig. 6C), SeG and SeTrG do not show antioxidant protection. The selenium compounds cannot act with the lipid hydroperoxides produced out of the vesicles by the water-soluble AAPH. SeTrG cannot scavenge peroxy radicals. It is known that the efficiency of vitamin E for radical scavenging decreases as the

**FIG. 6.** Inhibitory effects on  $\alpha$ -tocopherol ( $\alpha$ -TOH) consumption of SeG ( $\blacktriangle$ ) and SeTrG ( $\blacksquare$ ) at a concentration of 100  $\mu$ M externally added (A,B) or incorporated (C,D) in soybean PC multilamellar vesicles (MLV), containing 15  $\mu$ M  $\alpha$ -TOH, and oxidized under air at 37°C by 20 mM AAPH (A,C) or by incorporated 6 mM AMVN (B,D) (○)  $\alpha$ -TOH consumption without the addition of antioxidant. For abbreviations see Figures 1, 2, and 5.

radical goes deeper into the interior of the LDL structures (23). SeG showed slight prooxidative effect. The hydroxyl groups of SeG are oriented toward the aqueous phase and most probably are attacked by the hydrophilic initiators, thus

**FIG. 7.** Inhibitory effect of SeTrG at concentration of 300  $\mu\text{M}$  (●) on  $\alpha$ -TOH consumption in soybean PC MLV, containing 20  $\mu\text{M}$   $\alpha$ -TOH, oxidized for 60 min under air at 37°C by externally added 3-morpholinodisnonylamine hydrochloride (SIN-1) at concentrations of 0.3–1 mM. (○)  $\alpha$ -TOH consumption without the addition of antioxidant. For abbreviations see Figures 1 and 6.

propagating the oxidation. Incorporated in MLV and oxidized by internally incorporated AMVN (Fig. 6D), SeG and SeTrG can decompose the lipid hydroperoxides produced inside the PC layers, and SeTrG can scavenge radicals. SeTrG in the beginning of the process shows greater effect than SeG due to the presence of the potent antioxidant Trolox group.

We studied the inhibitory effect of SeG and SeTrG on  $\alpha$ -TOH consumption in MLV suspensions oxidized by the hydrophilic initiator SIN-1 (Fig. 7). Under air, SIN-1 thermally decomposes to nitric oxide and superoxide, which rapidly combine to peroxyntirite, which initiates lipid peroxidation (30). In MLV oxidation by SIN-1, SeTrG slightly spared  $\alpha$ -TOH. SeG did not show an effect.

The inhibitory effect of SeTrG on  $\alpha$ -TOH consumption in rat plasma oxidized by the hydrophilic initiator AAPH or MeO-AMVN, producing radicals both in the aqueous and the lipid phases, is shown in Figure 8. The kinetic curves of  $\alpha$ -

**FIG. 8.** Comparison of the effect of SeTrG at concentration 100  $\mu\text{M}$  (●,▲) on  $\alpha$ -TOH consumption in rat plasma oxidation under air at 37°C induced by 20 mM AAPH (●) or by 2 mM 2,2'-azobis(4-methoxy-2,4-dimethylvaleronitrile) (MeO-AMVN) (▲). Open symbols:  $\alpha$ -TOH consumption without the addition of SeTrG in rat plasma oxidation induced by 20 mM AAPH (○) or by 2 mM MeO-AMVN (△). For abbreviations see Figures 1, 5, and 6.

**FIG. 9.** Inhibitory effect of SeTrG (●) at concentration of 300  $\mu\text{M}$  on  $\alpha$ -TOH consumption in rat plasma oxidized for 60 min under air at 37°C by SIN-1 in the range of concentrations 0.3–1.2 mM. (○)  $\alpha$ -TOH consumption without the addition of SeTrG. For abbreviations see Figures 1, 6, and 7.

TOH consumption in AAPH and MeO-AMVN oxidations (open symbols) are almost identical. The presence of 100  $\mu\text{M}$  SeTrG (black symbols) induced a pronounced lag phase and delayed the oxidation rate. SeG did not spare  $\alpha$ -TOH in AAPH nor in MeO-AMVN rat plasma oxidations.

The effect of SeTrG on  $\alpha$ -TOH consumption against SIN-1 oxidation of rat plasma is shown in Figure 9. The presence of 300  $\mu\text{M}$  SeTrG spared the endogenous  $\alpha$ -TOH in plasma oxidized by SIN-1 at concentrations 0.3–1.2 mM (Fig. 9). In AAPH and MeO-AMVN oxidation of rat plasma, all of the endogenous  $\alpha$ -TOH was consumed, but in SIN-1 oxidation a considerable amount remained and was unchanged after 30 min of oxidation (data not shown). The same was seen in the erythrocyte hemolysis induced by SIN-1 (13). SeG was not effective against SIN-1 oxidation in rat plasma.

The efficiency of an antioxidant is dependent on the oxidant and model used. We showed that SeG reduced lipid hydroperoxides (Figs. 2, 3, 5) and protected  $\alpha$ -TOH in AAPH- or

**FIG. 10.** Comparison of the inhibitory effect of the antioxidants SeTrG (●), ascorbic acid (AA) (◇), tocotrienols (Toc-3) (◆), Trolox (△), 3,4-dihydroxyphenylacetic acid (DOPAC) (▲), and caffeic acid (CA) (■) at concentrations of 50  $\mu\text{M}$  on  $\alpha$ -TOH consumption in rat plasma oxidized by 20 mM AAPH under air at 37°C. (○)  $\alpha$ -TOH consumption without the addition of antioxidant. For abbreviations see Figures 1, 5, and 6.

AMVN-oxidized MLV suspensions, but not in rat plasma. Ebselen also reduced lipid hydroperoxides but had no radical-scavenging activities (7) and could not suppress the oxidations of LDL induced by AAPH (33). Ebselen spared  $\alpha$ -TOH during the initial stages of LDL oxidation initiated by a low flux of aqueous peroxy radicals (8). Both SeG and SeTrG inhibited the formation of lipid hydroperoxides (Fig. 5), but only SeTrG spared  $\alpha$ -TOH in plasma. We showed that only SeTrG had radical scavenging ability (Fig. 1). Also, in comparing the kinetic curves of  $\alpha$ -TOH consumption in rat plasma (Fig. 8) and in a liposome system (Fig. 6), it can be seen that in rat plasma  $\alpha$ -TOH is consumed with a pronounced lag phase, but in the MLV system without a lag phase. The same effect was seen in rat plasma oxidized by AAPH and explained "as a result of the reaction of the aqueous peroxy radicals with the aqueous antioxidants ascorbate, sulfhydryls, bilirubin and urate" (31). Rat plasma is a complex biological environment, containing lipids, proteins, and hydrophilic and lipophilic antioxidants (23,31). The relative importance of the different antioxidants may be influenced by factors such as mobility, reactivity with other antioxidants, and reactivity with oxidant radicals. This may explain why SeG did not spare  $\alpha$ -TOH in rat plasma but spared it in an MLV system when oxidized by the hydrophilic initiators AAPH or the lipophilic AMVN or MeO-AMVN. It was found previously that SeG reacts synergistically with tocopherols in sunflower oil (10). The presence of two hydroxyl groups in SeG may have an undesirable prooxidative effect (10). It is also possible that SeG has lower mobility in the membranes due to hydrogen bonding between the hydroxyl groups and the water (32).

In SIN-1 oxidations we showed that SeG did not spare  $\alpha$ -TOH, whereas ebselen suppressed erythrocyte hemolysis induced by peroxynitrite (13). Trolox does not effectively suppress erythrocyte hemolysis (13), but SeTrG, containing both Trolox and selenium, spared  $\alpha$ -TOH. SeTrG was more effective in rat plasma than in MLV. This could be explained by the fact that rat plasma contains micromolar concentrations of glutathione. Glutathione recycles the oxidized seleno-oxides (12). For example, the cellular selenium-containing enzymes glutathione peroxidases, phospholipid glutathione peroxidases, and selenoprotein P protect against peroxynitrite. They degrade peroxynitrite to nitric dioxide and water at the expense of glutathione, which is converted to glutathione disulfide (12).

To elucidate the structural role of the selenium compounds in the antioxidant properties, we compared the effects on  $\alpha$ -TOH consumption of SeTrG, Toc-3, and Trolox at a concentration of 50  $\mu$ M in rat plasma oxidized by 20 mM AAPH (Fig. 10). For comparison, the effects of the antioxidants AA, caffeic acid (CA), and 3,4-dihydroxyphenylacetic acid (DOPAC) (34) are shown in the same figure. SeTrG showed lower inhibitory effect than Toc-3 and Trolox, and Toc-3 had a lower inhibitory effect than Trolox. The phytol chain of chromanols has only a small effect on the inhibition of peroxidation, but is significant for the mobility of chromanols between membranes (23,32). Trolox, without a phytol chain,

can easily move between the membranes and shows potent antioxidant action. The glycerol part of SeTrG with the selenium-containing long hydrocarbon chain lowers its mobility in the membranes, which weakens the antioxidant activity of SeTrG compared to Trolox. The same comparison is valid for Toc-3 with their isoprenoid chain. Toc-3 are potent in decreasing rat plasma and LDL oxidizability (31,35).  $\alpha$ -Toc-3 activity is comparable to that of  $\alpha$ -TOH (31). CA and DOPAC show the strongest antioxidant effects owing to the presence of two hydroxyl groups in the *ortho* position (34).

In this paper we compared the inhibitory effect of the organic selenium compounds SeG and SeTrG *in vitro* on lipid peroxidation in organic solution, MeLOOH solution, methyl linoleate micelles, MLV suspensions, and rat plasma. SeTrG scavenged peroxy radicals. SeG reduced MeLOOH in methanol solution and in Fe<sup>2+</sup>/AA-catalyzed methyl linoleate micelle oxidation. SeTrG was more effective than SeG against Fe<sup>2+</sup>/AA-catalyzed methyl linoleate micelle oxidation. In rat plasma the two organoselenium compounds suppressed the formation of conjugated diene hydroperoxides in the AAPH-induced oxidation. In MLV suspensions SeG and SeTrG spared  $\alpha$ -TOH in AAPH- or AMVN-induced oxidations; SeTrG was effective in sparing  $\alpha$ -TOH during SIN-1 oxidation, but not SeG. In rat plasma SeTrG spared  $\alpha$ -TOH consumption in the AAPH-, MeO-AMVN-, or SIN-1-induced oxidations, but SeG was not effective. In conclusion, SeG and SeTrG showed antioxidant protection *in vitro*. They contain bound selenium, which is not available for the selenium pool, and are expected to be nontoxic to mammals.

## ACKNOWLEDGMENTS

The Japan Society for the Promotion of Science Postdoctoral Fellowship Program for Foreign Researchers supported this work. The authors are grateful to Dr. Ryota Maeba, Teikyo University School of Medicine, for advice on the preparation of the MLV suspensions and the experiments measuring the O<sub>2</sub> consumption.

**ABSTRACT:** In a previous study, CETP inhibitory peptide (3 kDa) was isolated from hog plasma. The peptide, synthesized chemically according to the amino acid sequence of the 3-kDa peptide (designated P<sub>28</sub>), showed CETP inhibitory activity both *in vitro* and *in vivo* [Cho *et al.* (1998) *Biochim. Biophys. Acta* 1391, 133–144]. We report herein further unique features of P<sub>28</sub> when it was associated with the cholesteryl ester (CE)-donor and -acceptor lipoproteins. Lipoprotein substrates with P<sub>28</sub> present in both HDL (as a CE-donor) and LDL (as a CE-acceptor) served as poor substrates, with CE-transfer activity decreased up to 60% compared to normal substrates without P<sub>28</sub>. P<sub>28</sub> was found to be located in HDL fractions of hog plasma and showed the same electromobility as that visualized by PAGE on 7% polyacrylamide gel under nondenaturing conditions. Addition of apolipoprotein A-1 (apoA-1) or apoB antibody to a normal CE-transfer mixture did not alter CE-transfer activity. However, addition of apoA-1 or -B antibody to a CETP-inhibition mixture decreased the inhibitory activity of P<sub>28</sub> by *ca.* 20%. Western blot analysis revealed that P<sub>28</sub> was associated only with human and hog HDL among several lipoproteins purified from human, hog, and rabbit. CETP-inhibition assays with various lipoprotein substrates revealed that P<sub>28</sub> exhibited substrate-specific inhibitory activity. The inhibitory activity of P<sub>28</sub> was highly dependent on the type of lipoprotein substrate (whether CE-donor or -acceptor); P<sub>28</sub> inhibited CE transfer from HDL to LDL, but it did not inhibit CE transfer from HDL to HDL.

Paper no. L8941 in *Lipids* 37, 641–646 (July 2002).

Human CETP redistributes cholesteryl ester (CE) and TAG between nonequilibrated lipoproteins in plasma. CETP, a 70–74 kDa hydrophobic glycoprotein (1,2), regulates the concentration of HDL-cholesterol in the blood stream (3,4). Even though the role of CETP in atherosclerosis is still controversial, many reports have concluded that CETP plays an atherogenic role in reversing cholesterol transport. Inhibition of CETP activity in animals having normal levels of CETP (5–7) and introduction of human CETP into CETP-deficient animals (8–12) have demonstrated that CETP accelerates the accumulation of CE in LDL, resulting in a retardation of cholesterol

removal from the blood stream. In addition, transgenic expression of simian CETP cDNA in mice (13) led to a decrease in HDL-cholesterol and a subsequent appearance of atherosclerotic lesions after prolonged feeding of a cholesterol-rich diet (14). Reduced plasma CETP activity induced by CETP vaccination resulted in an improved lipoprotein profile and a reduction in aortic lesions in a rabbit model (15). Recently, a chemical CETP inhibitor treatment with human subjects raised HDL-cholesterol levels in phase II clinical trial (16).

Although the precise mechanism of CE transfer by CETP has not been fully elucidated, it is generally accepted that neutral lipid exchange involves at least two key steps: (i) the interaction of CETP with lipoprotein particles, from which (ii) it picks up or deposits neutral lipid molecules (17). Three general models have been proposed in the light of data from kinetic studies (18–20). The first suggests that CETP could act as a shuttle carrying CE and TAG between distinct lipoprotein fractions (18). The second indicates that CETP could also mediate the formation of a ternary collision complex involving one lipoprotein donor, one lipoprotein acceptor, and CETP (19). The third model is similar to the second but includes the presence of dimeric CETP (20).

A few proteins from animal plasma have been used as modulators of CETP or lipid transfer inhibitor proteins (LTIP). Apolipoprotein F (apoF) was purified from human lipoprotein-deficient serum, associated with LDL (21). A peptide with high homology to the amino terminus of apoC-1 was purified from baboon plasma associated with HDL<sub>1</sub> (22). Those reports indicate that association characteristics of the CETP inhibitor and lipoprotein substrate are variable depending on their individual properties.

In a previous study, we purified CETP inhibitory peptide from hog plasma by ultracentrifugation, sequential column chromatographies, and finally electroelution from polyacrylamide gel (23). M.W. of the peptide was approximately 3 kDa. A peptide synthesized chemically according to the amino acid sequence of the 3-kDa peptide (designated P<sub>28</sub>) showed approximately the same degree of CETP inhibitory activity as the purified 3-kDa peptide. The sequence of P<sub>28</sub> was as follows: N-Glu-Asp-Thr-Ser-Pro-Glu-Asp-Lys-Met-Gln-Asp-Tyr-Val-Lys-Gln-Ala-Thr-Arg-Thr-Ala-Gln-Asp-Ala-Leu-Thr-Ser-Val-Lys-C.

In this study, we investigated the association properties of the synthesized peptide (P<sub>28</sub>) with lipoproteins, especially in

HDL and LDL, to determine accurately its properties in the lipoprotein–substrate complex and extended effects on the degree of CETP inhibition activity among various substrates.

## EXPERIMENTAL PROCEDURES

**Materials.** Radioactive  $1\alpha,2\alpha$ - $n$ - $[^3\text{H}]$ cholesteryl oleate was purchased from Amersham Life Sciences (Amersham, United Kingdom). CNBr-activated Sepharose 4B was obtained from Pharmacia (Uppsala, Sweden). Immobilon-P<sup>SQ</sup> membrane was purchased from Millipore (Bedford, MA). Antihuman apoA-1 IgG, antihuman apoB IgG, and enzyme-coupled secondary reagents were purchased from Boehringer Mannheim Biochemicals (Mannheim, Germany). All other reagents were obtained from Sigma (St. Louis, MO).

Human plasma was obtained from fresh EDTA-containing blood (donated by healthy male volunteers who had fasted for 16 h) by low-speed centrifugation ( $5,000 \times g$ ) for 15 min at  $4^\circ\text{C}$ . Hog and rabbit blood were collected in bottles containing  $\text{Na}_2\text{-EDTA}$  (final concentration = 1 mg/mL), and plasma was isolated by the same method as for human plasma. Aliquots of fresh plasma were placed in tubes containing sodium azide (0.02% wt/vol), phenyl-methyl-sulfonyl fluoride (1 mM in the final concentration), and chloramphenicol (50  $\mu\text{g}/\text{mL}$  in the final concentration), and stored at  $-70^\circ\text{C}$  until use.

**Isolation of lipoproteins and partial purification of CETP.** HDL ( $d = 1.063\text{--}1.21$ ), LDL ( $d = 1.019\text{--}1.063$ ), and VLDL

( $d = 0.95\text{--}1.006$ ) were isolated from normolipidemic human, rabbit, or hog plasma by a standard protocol including ultracentrifugation (24) and gel filtration column chromatography (25). The isolated lipoproteins were dialyzed against 10 mM ammonium bicarbonate/5 mM EDTA to remove excessive potassium bromide. The purified human LDL and HDL were used individually as CE-acceptors in the CE-transfer assays. Human CETP was partially purified to about 80% purity by ammonium sulfate precipitation (15% in the final concentration, wt/vol) and phenyl-Sepharose column chromatography, as previously described by Albers *et al.* (26). Purity of the CETP and its activity were determined by SDS-PAGE and CE-transfer assays. Protein concentration was determined by using the Pierce bicinchoninic acid (BCA) protein assay reagent (Rockford, IL) with BSA as a standard.

**Preparation of reconstituted HDL and LDL.** Reconstituted lipoproteins were used as artificial substrates for the CE-transfer assay, where tritiated reconstituted HDL ( $[^3\text{H}]\text{HDL}_R$ ) containing apoA-1 and reconstituted LDL ( $\text{LDL}_R$ ) containing apoB were used as the CE-donor and CE-acceptor, respectively, in the CETP assay. They were prepared by the sodium cholate dialysis method as described previously (27,28). For synthesis of both  $\text{HDL}_R$  and  $\text{LDL}_R$  lipoproteins containing

**FIG. 1.** Effect of lipoprotein substrates on cholesteryl ester (CE)-transfer activities in the presence or absence of  $\text{P}_{28}$ . Final concentration of  $\text{P}_{28}$  in reconstituted lipoproteins was 10  $\mu\text{M}$ . Lipoprotein reconstitution and CETP assay were carried out as described in the Experimental Procedures section. Line A, CE transfer from  $\text{HDL}_R$  (where R = reconstituted) to  $\text{LDL}_R$ ; line B, CE transfer from  $\text{P}_{28}\text{-HDL}_R$  to  $\text{LDL}_R$ ; line C, CE transfer from  $\text{HDL}_R$  to  $\text{P}_{28}\text{-LDL}_R$ ; line D, CE transfer from  $\text{P}_{28}\text{-HDL}_R$  to  $\text{P}_{28}\text{-LDL}_R$ . The substrates containing  $\text{P}_{28}$  (line D) showed CE-transfer activity diminished up to 60% compared to the normal substrates (line A). Data are expressed as mean  $\pm$  SD from triplicate determinations. For  $\text{P}_{28}$  sequence see text.

**FIG. 2.** Immunodetection of the 3-kDa peptide after SDS-PAGE with 7% nondenaturing polyacrylamide gel. Proteins were loaded onto the gel without denaturation. Immunoreacted bands were visualized by alkaline phosphatase conjugate (nitro blue tetrazolium/5-bromo-4-chloro-3-indolylphosphate; Sigma, St. Louis, MO). Lane 1, lipid transfer complex containing hog HDL (50  $\mu\text{g}$  of apolipoproteins),  $\text{LDL}_R$  (50  $\mu\text{g}$  of apoB), partially purified CETP (300  $\mu\text{g}$ ), and  $\text{P}_{28}$  (90  $\mu\text{g}$ ); lane 2,  $\text{P}_{28}$  (90  $\mu\text{g}$ ); lane 3,  $\text{LDL}_R$  (50  $\mu\text{g}$  of apoB); lane 4, hog HDL (50  $\mu\text{g}$  of apolipoproteins). Arrows indicate immunodetected band by anti- $\text{P}_{28}$ -IgG. For  $\text{P}_{28}$  sequence see text.

$P_{28}$ , concentrations of  $P_{28}$  in the reconstituted lipoproteins were adjusted to 10  $\mu$ M (final concentration).

**CETP and its inhibition assay.** A CE-transfer assay was carried out using tritiated HDL<sub>R</sub> as the CE-donor substrate for CETP. The HDL<sub>R</sub> was covalently immobilized on agarose for easy separation of [<sup>3</sup>H]HDL<sub>R</sub>-agarose after CE-transfer incubation, as described previously (23).

To determine the effect of apoA-1 or apoB antibody addition on CETP inhibition activity of  $P_{28}$ , antihuman apoA-1 or apoB IgG was pre-incubated with partially purified CETP for 30 min at 37°C to inactivate the CETP source. After pre-incubation,  $P_{28}$  was added to the mixture as an inhibitor source, and the total mixture was re-incubated for 1 h at 37°C. After incubation, normal substrates (LDL<sub>R</sub> and HDL<sub>R</sub>) were added to the mixture and incubated for another 2 h at 37°C with shaking. After incubation, the supernatant of the mixture was removed and counted in a scintillation analyzer (Packard Tri-carb 1600TR) to calculate specific CE-transfer activity compared to a control group without antibody addition during pre-incubation.

**Preparation of antibodies against  $P_{28}$  and immunoblotting.** Antibodies against the  $P_{28}$  were produced and IgG was isolated according to a standard method, described elsewhere (29). For immunoblotting experiments, protein samples to be tested were electrophoresed in two gel slabs in parallel: Pro-

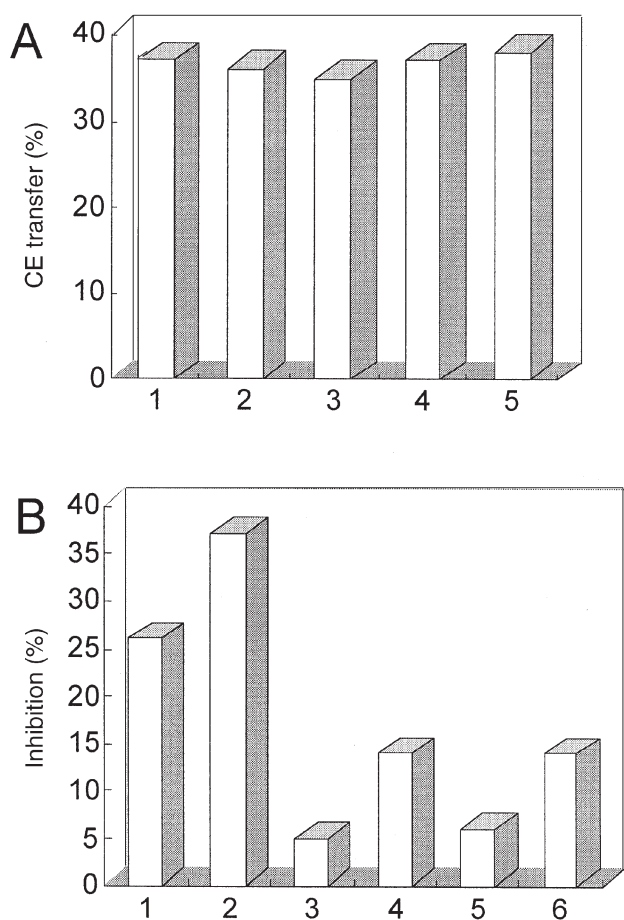

teins on one gel were stained with 0.125% Coomassie brilliant blue R-250 and the other gel was electroblotted onto the Immobilon-P<sup>SQ</sup> membrane using a Semi-Phor transfer unit (Hoefer Scientific Instruments, San Francisco, CA) at 50 mA for 90 min. The blotted membrane was incubated with the antibody against the  $P_{28}$  (diluted 1:10<sup>4</sup>) in the presence of 1% BSA/0.1% Tween-20 in PBS (pH 7.4). Immunoreacted bands were visualized as described by Towbin and Gordon (29).

To identify the original location of the 3 kDa peptide and the effect of  $P_{28}$  in the lipid transfer complex, we incubated 9  $\mu$ g of  $P_{28}$ , 300  $\mu$ g of partially purified CETP, 50  $\mu$ g of hog HDL, and 320  $\mu$ g of hog LDL at 37°C for 16 h to allow them to bind completely with the lipoproteins. After incubation, the mixture was loaded onto 7% polyacrylamide gel without SDS-treatment and boiled to allow migration with its native charge. After electrophoresis, proteins on the gel were blotted onto the PVDF membrane to analyze with anti- $P_{28}$  IgG to compare the preferential binding properties between lipoproteins and the  $P_{28}$ .

**Association properties of  $P_{28}$  and lipoproteins.** The purified LDL (10  $\mu$ g) and HDL (6  $\mu$ g) from human, hog, and rabbit were incubated individually with  $P_{28}$  (10  $\mu$ g) for 1 h at 37°C, and the incubation mixtures were concentrated completely by a SpeedVac<sup>®</sup> Plus (Savant Instruments, Farmingdale, NY). The concentrated mixtures were redissolved in 10

**FIG. 3.** Different association patterns of  $P_{28}$  with various lipoproteins. Ten micrograms of the  $P_{28}$  was incubated with 6  $\mu$ g of HDL or 10  $\mu$ g of LDL from hog, human, and rabbit, individually, in a shaking incubator for 1 h at 37°C. The mixtures were concentrated and electrophoresed in 8% polyacrylamide gel without SDS-treatment and sample boiling to allow migration with its native charge. Electrophoretic patterns were visualized by Coomassie staining (A) and immunodetection (B) using  $P_{28}$ -IgG. Incubation mixtures of each lane are as follows. Lane 1,  $P_{28}$  and hog HDL; lane 2,  $P_{28}$  and hog LDL; lane 3,  $P_{28}$  and human HDL; lane 4,  $P_{28}$  and human LDL; lane 5,  $P_{28}$  and rabbit HDL; lane 6,  $P_{28}$  and rabbit LDL. Arrows indicate immunodetected bands detected in lanes 1 and 3. For  $P_{28}$  sequence see text.

**FIG. 4.** Effect of adding apolipoprotein antibody on CE-transfer (A) and CETP-inhibition (B) assays. Data were expressed as a mean value from triplicate determinations. (A), Partially purified human CETP (30  $\mu$ L, 300  $\mu$ g) was pre-incubated with apoA-1 or -B IgG for 1 h at 37°C. The mixtures were incubated with assay substrates (LDL<sub>R</sub> and HDL<sub>R</sub>) for 2 h at 37°C to allow the CE-transfer reaction from HDL<sub>R</sub> to LDL<sub>R</sub>. 1, CETP source + TBS (50  $\mu$ L); 2, CETP source + apoA-1 IgG (1.5  $\mu$ g); 3, CETP source + apoA-1 IgG (15  $\mu$ g); 4, CETP source + apoB IgG (1.5  $\mu$ g); 5, CETP source + apoB IgG (15  $\mu$ g). (B), Partially purified human CETP (30  $\mu$ L, 300  $\mu$ g) was pre-incubated with P<sub>28</sub> for 30 min at 37°C. After pre-incubation, the mixture was incubated with apoA-1 or apoB IgG for 1 h at 37°C. The mixtures were re-incubated with the assay substrates (LDL<sub>R</sub> and HDL<sub>R</sub>) for 2 h at 37°C to allow the CE-transfer reaction. 1, CETP source + TBS (50  $\mu$ L) + P<sub>28</sub> (5  $\mu$ M); 2, CETP source + TBS (50  $\mu$ L) + P<sub>28</sub> (50  $\mu$ M); 3, CETP source + apoA-1 IgG (1.5  $\mu$ g) + P<sub>28</sub> (5  $\mu$ M); 4, CETP source + apoA-1 IgG (15  $\mu$ g) + P<sub>28</sub> (50  $\mu$ M); 5, CETP source + apoB IgG (1.5  $\mu$ g) + P<sub>28</sub> (5  $\mu$ M); 6, CETP source + apoB IgG (15  $\mu$ g) + P<sub>28</sub> (50  $\mu$ M). For other abbreviations see Figure 1. TBS, Tris-buffered saline; for P<sub>28</sub> sequence see text.

$\mu$ L of electrophoresis sample buffer without SDS. The mixtures were electrophoresed in 7% polyacrylamide gel under native conditions and the gel was blotted onto the PVDF membrane for immunodetection.

## RESULTS AND DISCUSSION

**Role of P<sub>28</sub> in the lipid-transfer complex.** The CE-donor (trinitated HDL<sub>R</sub>) and CE-acceptor (LDL<sub>R</sub>), both synthesized with

P<sub>28</sub> (designated P<sub>28</sub>-HDL<sub>R</sub> and P<sub>28</sub>-LDL<sub>R</sub>, respectively) according to previously described methods (23,25), were used to test the effect of P<sub>28</sub> in lipoprotein substrates, whether HDL<sub>R</sub> (CE-donor) or LDL<sub>R</sub> (CE-acceptor), in the CE-transfer mechanism of the lipid-CETP complex. As shown in Figure 1, normal substrates (from HDL<sub>R</sub> to LDL<sub>R</sub>) yielded 23.7  $\pm$  1% (mean  $\pm$  SD) of CE-transfer activity, and P<sub>28</sub>-containing substrates (from P<sub>28</sub>-HDL<sub>R</sub> to P<sub>28</sub>-LDL<sub>R</sub>) yielded only 6.8  $\pm$  2% of CE-transfer activity in the same condition. As shown in Figure 1, the presence of P<sub>28</sub> in lipoproteins (both HDL<sub>R</sub> and LDL<sub>R</sub>) decreased CE-transfer activity of the lipid-transfer complex by up to 60%. This result suggests that CE-transfer activity was altered by the presence of P<sub>28</sub> in substrates of both LDL and HDL. In human plasma, most of the CETP was associated with HDL particles (31,32), and kinetic studies revealed that either a carrier-mediated mechanism of transfer (19) or the formation of a ternary collision complex consisting of CETP and donor and acceptor lipoproteins was involved (18). The P<sub>28</sub> appears to interfere with the binding of CETP and lipoproteins by forming a lipid-transfer complex, as with other apolipoproteins, and this effect is equal in both HDL and LDL.

**Immunodetection of the 3 kDa in hog HDL fraction.** To determine the location of the 3-kDa peptide in the circulation of hog blood as well as the preferential binding properties of P<sub>28</sub> in the formation of a ternary collision complex, we incubated P<sub>28</sub>, the CETP source (human plasma), hog HDL, and hog LDL for 2 h at 37°C. After incubation, the mixture was electrophoresed on 7% polyacrylamide gel without sample denaturation. Proteins on the gel were blotted onto the PVDF membrane and immuno-detected with anti-P<sub>28</sub> IgG. Figure 2 illustrates that the mixture (lane 1) and the P<sub>28</sub> (lane 2) showed the same migration mobility on the gel, and a protein band was detected in the hog HDL fraction (lane 4) with the same band position as P<sub>28</sub> (lane 2). The mixture (lane 1) and the P<sub>28</sub> (lane 2) seemed to have similar electromobility, whereas the purified hog LDL did not show the same mobility. From this result, it is possible to predict that the 3-kDa peptide is associated with the hog HDL fraction in *in vivo* circulation.

**Association capabilities of P<sub>28</sub> and animal lipoproteins.** HDL and LDL fractions from normolipidemic animals (hog, human, and rabbit) were individually incubated with P<sub>28</sub> for 1 h at 37°C. The mixtures were concentrated completely and electrophoresed in 8% native polyacrylamide gel. As shown in panel B of Figure 3, the band detected in lanes 1 and 3 suggests that P<sub>28</sub> could form an association complex with hog and human HDL but not with rabbit HDL. On the contrary, the association of P<sub>28</sub> and LDL from the three species was not detected by the same immunoblotting analysis with P<sub>28</sub>-IgG (lanes 2, 4, and 6 of panel B). These results indicate that P<sub>28</sub> formed a lipoprotein complex with only hog and human HDL. Neither rabbit HDL nor LDL of the three species was associated with a lipoprotein complex, indicating that binding tendencies might be somewhat different in rabbit lipoproteins.

**Influence of apo antibodies on CE inhibition by P<sub>28</sub>.** Addition of the apoA-1 or -B antibody on the lipid-transfer com-

**FIG. 5.** CETP inhibition assay with various CE-acceptors. Reconstituted HDL (HDL<sub>R</sub>, 0.05 mL, 64 μg apolipoprotein, 30,000 dpm) was used as a CE-donor and reconstituted LDL (LDL<sub>R</sub>, 0.3 mL, 240 μg apolipoprotein), intact LDL (0.3 mL, 243 μg apolipoprotein), VLDL (0.3 mL, 56 μg apolipoprotein), or HDL (0.3 mL, 390 μg apolipoprotein) was used as a CE-acceptor. The CETP assay was carried out according to the method described by Cho *et al.* (23) using human plasma (0.05 mL) as a CETP source. The data were expressed as a mean ± SD of triplicate determinations. For other abbreviation see Figure 1.

plex involving HDL<sub>R</sub>, LDL<sub>R</sub>, and CETP did not reduce CE-transfer activity, as shown in panel A of Figure 4. This result suggests that the apoA-1 or apoB antibody did not affect normal transfer of CE from HDL to LDL. However, the inhibitory activity of P<sub>28</sub> decreased to 20% of the control value by adding the apoA-1 or apoB antibody to the incubation mixture, as shown in panel B of Figure 4. The P<sub>28</sub> showed 37% inhibition in the absence of the IgG (apoA-1 or -B), whereas it showed approximately 12% inhibition in the presence of apoA-1 or apoB IgG. These results indicate that the apoA-1 or apoB antibody might be effective in the CE-inhibition of P<sub>28</sub> by either association or interaction.

**Differential influence of CE-acceptors on CETP inhibition by P<sub>28</sub>.** CETP inhibition by P<sub>28</sub> in human plasma was shown to depend on the lipoprotein substrate, especially in CE-acceptors. The inhibitory activity was highly specific, depending on the type of substrate. When P<sub>28</sub> was incubated with LDL<sub>R</sub> as a CE-acceptor (Fig. 5), more than 40% of the CETP activity was inhibited. However, no inhibitory activity was shown when HDL was used as a CE-acceptor, indicating that P<sub>28</sub> could selectively inhibit CE-transfer from HDL to LDL. Under the same conditions, P<sub>28</sub> even facilitated CE transfer from donor to acceptor HDL.

Results of this study suggest that CETP, P<sub>28</sub>, and HDL operate together in the lipid transfer complex, as explained by others (32,33). The Morton group reported that CETP-VLDL and CETP-LDL complexes were much less stable than CETP-HDL complexes *in vitro* and that LTIP disrupts CETP

activity by binding to lipoproteins, interfering in the association of CETP with lipoproteins (32,34). The most acceptable hypothesis is that the formation of CETP-lipoprotein complexes is mediated by an electrostatic interaction between positively charged groups of CETP (35) and negatively charged lipoprotein surface components (33). Those reports strongly support the role of an electrostatic interaction in the formation of a lipid-transfer complex between CETP and lipoproteins. Since P<sub>28</sub> has a negatively charged group in its amino terminus, one possible hypothesis is that the presence of P<sub>28</sub> in lipoproteins may interfere with binding of CETP and lipoproteins, as demonstrated by Morton and Zilversmit (32). The presence of P<sub>28</sub> in HDL or LDL can alter CETP inhibition, and the effect is specific to the CE-acceptor.

**ABSTRACT:** Recent studies have yielded evidence that plant flavonoids reduce hepatic lipid and apolipoprotein B (apoB) secretion. However, the possible role of flavonoids in regulating lipid and apoB secretion by the intestine has not been studied. The purpose of our study was to examine the effects of quercetin, a common dietary flavonoid, on TAG and apoB secretion in a human intestinal cell-line, CaCo-2. Differentiated postconfluent CaCo-2 cells grown on filters and pretreated with quercetin for 8 h were shown by ELISA to inhibit basolateral apoB secretion in a dose-dependent manner. At 15  $\mu$ M, the secretion of both apoB-100 and apoB-48 were inhibited similarly. This effect was shown to be specific, as quercetin did not affect the incorporation of [ $^{35}$ S]methionine/cysteine into secreted TCA-precipitable proteins. To determine the mechanism underlying this inhibitory effect, we examined two regulatory points: TAG availability and lipid transfer to the lipoprotein particle. Quercetin inhibited TAG synthesis under both basal and lipid-rich conditions, indicating that lipid availability is a determining factor in the regulation of apoB secretion by quercetin. The reduction was due at least in part to a decrease in diacylglycerol acyltransferase activity. We next examined lipid transfer or lipidation of the lipoprotein particle by analyzing microsomal TAG transfer protein (MTP) activity. Quercetin decreased MTP activity moderately. In summary, the data demonstrated that pharmacological concentrations of quercetin are a potent inhibitor of intestinal apoB secretion and that reduced lipid availability and lipidation in the lipoprotein assembly step are the mechanism for the suppression of apoB-containing lipoprotein secretion by quercetin in CaCo-2 cells.

Paper no. L9011 in *Lipids* 37, 647–652 (July 2002).

Several epidemiological studies have demonstrated an association of a quercetin-rich diet with a lowered risk of developing cardiovascular disease (CVD) (1–3). Abundant in onions, apples, red wine, and tea, quercetin (Scheme 1) has been shown to be protective against CVD by influencing several processes, including a decrease in LDL oxidation (4), a decrease in platelet aggregation (5), and an improved endothelial function (6). Furthermore, researchers have recently

Abbreviations: apoB, apolipoprotein B; apoB-Lp, apoB-containing lipoprotein; ACAT, acyl CoA:cholesterol acyltransferase; CVD, cardiovascular disease; DMEM, Dulbecco's modified Eagle's medium; DGAT, diacylglycerol acyltransferase; HMG, hydroxymethylglutaryl; IgG, immunoglobulin G; LDH, lactate dehydrogenase; MTP, microsomal TAG transfer protein; PVDF, polyvinylidene difluoride; SF, serum-free.

SCHEME 1

claimed that quercetin (7) and other plant flavonoids (8–10) possess lipid-lowering action. Among Japanese women, quercetin intake was inversely correlated with both total cholesterol and LDL-cholesterol (7). This lipid-lowering activity has obvious clinical significance. Consequently, there has been an increased interest in the investigation of plant flavonoids with respect to their lipid-lowering activity.

The mechanism of action of plant flavonoids on lipoprotein production has been the subject of recent study. Work from Huff's laboratory has shown that the citrus flavonoids naringenin and hesperetin reduced apolipoprotein B-containing lipoprotein (apoB-Lp) secretion in the human hepatoma cell line, HepG2, *via* reduced activity and expression of acyl CoA:cholesterol acyltransferase (ACAT) and microsomal TAG transfer protein (MTP) (11). ACAT is responsible for the synthesis of cholesterol ester in lipoprotein assembly, whereas MTP plays a role in lipoprotein assembly by catalyzing the transfer of lipids to nascent apoB molecules. Our laboratory also showed similar results in HepG2 cells with the flavonoid taxifolin, which was also shown to reduce hydroxymethylglutaryl (HMG) CoA reductase activity (12) and diacylglycerol acyltransferase (DGAT) activity (13). HMG CoA reductase and DGAT are considered to be the rate-limiting enzyme in the synthesis of cholesterol and TAG, respectively.

Lipid availability and lipid transfer to the nascent apoB molecule are acknowledged to be key factors in regulating apoB-Lp secretion (reviewed in Ref. 14). Particularly, the availability and transfer of TAG and cholesterol esters are thought to be primarily involved in the regulation of apoB-Lp secretion. Although progress has been made in understanding the regulation of hepatic apoB-Lp secretion by plant flavonoids, the contribution of these compounds in regulating lipid and apoB production by the intestine, an important lipogenic organ, has not been studied. Since the intestine has several characteristics that differ

from the liver, it is probable that the regulatory mechanism may differ. Structural differences are apparent as the liver produces a full-length apoB molecule (apoB-100), whereas the intestine produces a shortened, edited apoB molecule (apoB-48). Also, hepatic apoB is used for assembly of VLDL, while intestinal apoB is used for chylomicron assembly. The purpose of the present study is to examine the role of quercetin, a common flavonoid of the human diet, on lipid and apoB synthesis and secretion using a well-established human colon cancer cell line, CaCo-2, as the model system. Our hypothesis tested whether quercetin can suppress intestinal apoB-Lp secretion *via* lipid synthesis and/or lipid transfer. Since the intestine is an important site of lipid synthesis and lipoprotein production, this study could contribute to our understanding of the therapeutic action of flavonoids in hyperlipidemia.

## MATERIALS AND METHODS

**Materials.** Quercetin (3,5,7,3',4'-pentahydroxyflavone) dihydrate was purchased from Sigma Chemical Co. (St. Louis, MO) and dissolved in ethanol. An appropriate amount of stock solution was diluted with culture medium to give a final ethanol concentration of 0.1%. CaCo-2 cells (HTB-37) were obtained from American Type Culture Collection (ATCC; Rockville, MD). Cell culture media, FBS (certified grade), antibiotic-antimycotic mixture, and other tissue culture reagents were from InVitrogen Life Technologies Corp. (Carlsbad, CA). Transwell filters were obtained from Corning Costar Corp. (Cambridge, MA). Electrophoresis reagents and polyvinylidene difluoride (PVDF) membranes were from Bio-Rad Laboratories (Hercules, CA). [<sup>35</sup>S]Protein labeling mix (1175 Ci/mmol), [2-<sup>3</sup>H]glycerol (5–20 Ci/mmol), [palmitoyl-1-<sup>14</sup>C]palmitoyl coenzyme A (40–60 mCi/mmol), and Reflection™ autoradiography films were purchased from Perkin-Elmer Life Science Research Products (Boston, MA). Monospecific goat anti-human apoB antiserum was obtained from Alexon-Trend (Ramsey, MN). Plastic-backed TLC plates (Silica Gel 60) were from Alltech Associates Inc. (Deerfield, IL). Cell toxicity lactate dehydrogenase (LDH) assay was purchased from Promega Corp. (Madison, WI). Sodium oleate, 1,2-dioleoyl-*sn*-glycerol, BSA, EDTA, horseradish peroxidase conjugate anti-goat IgG, and other common laboratory reagents were from Sigma Chemical Co. MTP activity kit was from Roar Biomedical (New York, NY).

**Cell culture.** Differentiated CaCo-2 cell cultures were maintained in Dulbecco's modified Eagle's medium (DMEM) with 20% FBS and 0.1 mM nonessential amino acids at 37°C with 5% CO<sub>2</sub> and 95% air and subcultured in 24-mm diameter Transwell filters and grown to about 2 wk postconfluent. In experiments without oleate, cells were treated with quercetin in 20% FBS-DMEM. In studies with oleate, a serum-free (SF) medium (15) consisting of DMEM/F-12, 0.1 mM nonessential amino acids, 35 mg/L human transferrin, 5 mg/L bovine insulin, 20 μM ethanolamine, and 25 μM sodium selenite was used. Quercetin was added to both apical and basolateral media. We chose an 8-h incubation and added a nontoxic con-

centration of EDTA (0.5 mM) to the cell culture medium to minimize chemical instability of the compound (16). Untreated control cells received 0.1% (vol/vol) ethanol and EDTA without quercetin.

**ApoB ELISA.** ApoB mass in the basolateral media was determined using a competitive-binding ELISA as previously described (17).

**Lipid analysis.** To measure the rate of TAG synthesis and secretion, postconfluent treated and untreated cells were labeled with 80 μCi/mL [<sup>3</sup>H]glycerol for 8 h. After labeling, basolateral media and cells were harvested, and radiolabeled lipids were extracted and measured using TLC as described by Theriault *et al.* (12). After lipid extraction, cell proteins were digested in 1 mL of 0.1 N NaOH and measured as described below.

**Protein synthesis analysis.** Total protein synthesis was measured by the incorporation of [<sup>35</sup>S]methionine/cysteine (50 μCi/mL) into proteins and quantitated by TCA precipitation as described by Theriault *et al.* (12).

**Western blotting.** Equal amounts of basolateral media proteins were loaded and separated by SDS-PAGE (6% gel). Transfer of apoB molecules onto PVDF membrane was performed at 45 mA for 18 h in a cooled blotting buffer [25 mM Tris pH 7.7, 192 mM glycine, 0.1% (wt/vol) SDS, and 20% (vol/vol) methanol]. Immunoblotting was carried out as follows: The membrane was blocked in a blocking buffer (1 M Tris pH 7.5, 0.15 M NaCl, 0.1% Tween 20, and 5% nonfat dry milk) for 1 h; incubated with goat anti-human apoB antiserum (1:5,000) in rinsing buffer (1 M Tris pH 7.5, 0.15 M NaCl, 0.1% Tween 20) containing 10% BSA for 1 h; washed three times with rinsing buffer; incubated with horseradish peroxidase conjugate anti-goat IgG (1:16,000) in rinsing buffer containing 10% BSA for 1 h; and washed as described above. All incubations were performed on a shaker at room temperature. ApoB-antibody complexes were visualized with ECL™ chemiluminescence blotting reagents according to the manufacturer's instructions (Amersham Pharmacia Biotech, Piscataway, NJ). Quantification of the apoB bands was performed on an AMBIS Radioanalytic System (San Diego, CA) within the linear range of detection.

**DGAT activity assay.** Treated and untreated cells were harvested into a Tris buffer (175 mM, pH 7.8) and homogenized with a sonicator. Esterification of DAG was measured by using labeled palmitoyl-CoA as described by Grigor and Bell (18). The assay was performed in a total volume of 250 μL of Tris buffer (175 mM, pH 7.8) containing FA-free BSA (1 mg/mL), MgCl<sub>2</sub> (4 mM), and [1-<sup>14</sup>C]palmitoyl-CoA (0.25 μCi/mL). After a 10-min pre-incubation at 23°C, the reaction was started by adding homogenized cells (100 μg cell protein/mL) and 1,2-DAG (400 μM) for 10 min. The reaction was terminated by the addition of hexane, and the TAG formed was extracted and subjected to TLC in chloroform/acetic acid (96:4). The assay was linear up to 200 μg/mL of cell protein.

**Other methods.** Cell protein content was measured according to Bradford (19) (i.e. Bio-Rad) using BSA as the standard. The activity of LDH released into the media was measured spectrophotometrically using the CytoTox 96 nonradioactive

cytotoxicity assay according to the manufacturer's protocol (Promega Corp.). MTP activity in cell extracts was measured by a fluorescent assay according to the manufacturer's protocol (Roar Biomedical).

**Statistics.** All results with apoB and lipids were normalized to the amount of cellular protein. Statistical differences were analyzed by using Student's *t*-test with the level of significance set at 0.05.

## RESULTS

**Quercetin inhibits apoB secretion in a dose-dependent manner.** We initially based our concentration and incubation time on an earlier study investigating the fate of quercetin in CaCo-2 cells (16). Quercetin is known to be labile and undergo considerable catabolism during prolonged exposure in cell culture conditions. The above study showed that a concentration of 15  $\mu$ M for up to 8 h in the presence of FBS and a nontoxic concentration of EDTA inhibited the main pathway for chemical degradation of quercetin. The study indicated the degradation pathway was dependent on the presence of ferrous ions and EDTA chelated this iron. Therefore, this information was taken into account when evaluating its biological properties on apoB metabolism.

As shown in Figure 1, quercetin added in concentrations of 5, 15, and 30  $\mu$ M to the culture medium and held for 8 h decreased apoB mass into the basolateral media in a dose-dependent manner. Percent inhibition was  $27 \pm 5\%$  at 5  $\mu$ M,  $38 \pm 6\%$  at 15  $\mu$ M, and  $59 \pm 5\%$  at 30  $\mu$ M. At or below 30  $\mu$ M, there was no significant release of LDH into the media, indicating no cytotoxicity effect (data not shown). As a control to determine whether the effect of quercetin was specific to apoB, the amount of proteins secreted in the presence and ab-

**FIG. 1.** Quercetin inhibits apolipoprotein B (apoB) secretion dose-dependently. CaCo-2 cells were treated with various concentrations of quercetin in 20% FBS-Dulbecco's modified Eagle's medium (DMEM) for 8 h. Untreated control cells received 0.1% ethanol without quercetin. The amount of apoB present in the basolateral media was determined by ELISA. Data are expressed as percent inhibition of untreated control cells (set as 100%). Values represent the mean  $\pm$  SD of two independent experiments performed in duplicate.

sence of quercetin was also analyzed by TCA-precipitation with cells labeled with [ $^{35}$ S]methionine/cysteine. As indicated in Figure 2, TCA-precipitable radioactivity from media incubated with up to 30  $\mu$ M quercetin remained essentially unchanged vs. the untreated control, indicating that the flavonoid did not alter protein secretion and that the effect on apoB secretion was specific. Subsequently, we chose the 15  $\mu$ M concentration in the following experiments since we felt this dose was well studied for its chemical stability in CaCo-2 cells. We consider this dose to be a pharmacological dose.

**Quercetin inhibits apoB-100 and -48 secretion.** CaCo-2 cells, unlike primary enterocytes, are known to synthesize two forms of apoB, which, together with lipids, assemble into a LDL/VLDL-sized lipoprotein particle (20). To further characterize the effect of quercetin on the secretion of the two M.W. forms of apoB (i.e., apoB-100 and apoB-48), we differentiated them by SDS-PAGE and immunoblotting. As shown in Figure 3, the secretion of apoB-100 and apoB-48 into the basolateral medium was inhibited by 35% ( $28,214 \pm 1,942$  vs.  $43,270 \pm 3,262$  arbitrary densitometric units) and 46% ( $18,395 \pm 1,193$  vs.  $9,950 \pm 2,934$  arbitrary densitometric units), respectively. The data suggest that quercetin is able to inhibit the assembly and secretion of intestinally derived lipoproteins, and the mechanism involved in the assembly of both forms of apoB in CaCo-2 cells may be similar.

**Quercetin inhibits apoB and TAG secretion under oleate treatment.** Oleate treatment is known to increase the secretion of apoB and a VLDL/chylomicron-sized lipoprotein in CaCo-2 cells (21). To investigate whether oleate can overcome the inhibitory effect of quercetin, we measured total apoB secretion by ELISA with cells treated with 15  $\mu$ M quercetin in the presence or absence of 0.8 mM oleic acid. In the presence of oleic acid, apoB secretion nearly doubled (Fig. 4). In the presence of quercetin, the inhibition of apoB secretion from oleate-treated cells was greater than non-oleate-treated cells (51% inhibition in the presence vs. 30% inhibition in the absence of oleate),

**FIG. 2.** Effect of quercetin on apoB secretion is specific. CaCo-2 cells were treated with and without quercetin for 6 h. Incubations were continued in the presence of [ $^{35}$ S]methionine/cysteine for 2 h. Total protein secretion was determined by TCA precipitation. Data are expressed relative to control (set as 100%). Values represent the mean  $\pm$  SD of two independent experiments performed in duplicate. For abbreviation see Figure 1.

**FIG. 3.** Quercetin inhibits apoB-100 and apoB-48 secretion. CaCo-2 cells were treated with and without quercetin (15  $\mu$ M) in 20% FBS-DMEM for 8 h. The amount of apoB-100 and apoB-48 present in the basolateral media was determined by Western blotting. The bottom figure is the data obtained from the densitometric scanning of the X-ray film (top figure) and is expressed as arbitrary densitometric units  $\pm$  SD. The figure is a representation of a typical experiment performed in triplicate. For abbreviations see Figure 1.

**FIG. 4.** Quercetin inhibits apoB secretion under lipid-rich condition. CaCo-2 cells were treated with and without quercetin (Qx) at 15  $\mu$ M in serum-free (SF) media containing BSA  $\pm$  oleic acid (OA) (0.81 mM) for 8 h. The amount of apoB secreted was analyzed by ELISA. Data are expressed relative to the BSA control (set as 100%). Values represent the results of two independent experiments performed in triplicate. \* $P$  < 0.05 vs. BSA control, \*\* $P$  < 0.05 vs. OA control. For abbreviation see Figure 1.

suggesting that quercetin can inhibit apoB secretion under lipid-rich conditions.

It has been reported that nascent TAG are preferentially used for the assembly of chylomicrons (20). Therefore, the effect of oleate and quercetin on TAG synthesis and secretion were assessed. As expected, oleate increased TAG synthesis and secretion by one- to twofold (Fig. 5). With respect to secretion, addition of quercetin resulted in a  $84 \pm 7\%$  inhibition in the presence of oleate and  $52 \pm 4\%$  in the absence of oleate ( $P$  < 0.05,  $n$  = 2). Quercetin inhibited TAG synthesis from oleate-treated cells by a similar percentage as in non-oleate-treated cells ( $40 \pm 5\%$

inhibition in the absence of oleate vs.  $55 \pm 5\%$  inhibition in the presence of oleate,  $P$  < 0.05,  $n$  = 2). Thus, it appears that supplementation of CaCo-2 cells with oleic acid is associated with a greater effect on apoB and TAG secretion by quercetin.

**Quercetin decreases DGAT and MTP activity.** The assembly process of intestinally derived lipoproteins depends on both the availability of TAG and the transfer of this lipid to apoB to form a primordial lipoprotein particle (20,21). DGAT is a critical enzyme for the synthesis of TAG for lipoprotein assembly, and MTP plays a role in lipoprotein assembly by catalyzing the transfer of lipids to nascent apoB molecules. Therefore, we examined the effect of quercetin on these two lipogenic enzymes, involved in TAG synthesis and secretion, in the presence of oleic acid. First, we tested the effect of quercetin on human CaCo-2 MTP activity by using fluorogenic-labeled donor liposomes and phospholipid acceptor liposomes. As shown in Figure 6, quercetin reduced MTP activity moderately ( $22 \pm 4\%$ ,  $P$  < 0.05,  $n$  = 2), but significantly, in oleate-treated cells. To determine the underlying mechanism of action of quercetin on TAG synthesis, we measured DGAT activity by means of the rate of incorporation of [ $^{14}$ C]palmitoylCoA into TAG. As shown in Figure 6, quercetin decreased DGAT activity by  $47 \pm 9\%$  ( $P$  < 0.05,  $n$  = 2). In combination, these results suggest that quercetin inhibited TAG-rich, apoB-48-containing lipoprotein secretion, in part through the reduction of both DGAT and MTP activity.

## DISCUSSION

Various dietary FA have been shown to exert effects on plasma TAG levels as a result of the altered assembly of intestinally derived lipoproteins (22,23). Like FA, a sizeable fraction of most flavonoids is absorbed by the small intestine (24). As a consequence, there is considerable interest in their biological

**FIG. 5.** Quercetin inhibits TAG synthesis and secretion. CaCo-2 cells were treated with and without quercetin (15  $\mu$ M) in SF media containing BSA  $\pm$  oleic acid (0.81 mM) in the presence of [ $^3$ H]glycerol for 8 h. Incorporation of glycerol into TAG was measured by TLC. Data are expressed as a percentage of BSA control (set as 100%). Values represent the mean  $\pm$  SD of two independent experiments performed in duplicate. \* $P$  < 0.05 BSA control; \*\* $P$  < 0.05 OA control. For abbreviations see Figure 4.

**FIG. 6.** Quercetin decreases diacylglycerol acyltransferase (DGAT) and microsomal TAG transfer protein (MTP) activity. CaCo-2 cells were treated with and without quercetin (15  $\mu$ M) in SF media containing BSA + oleic acid (0.81 mM) for 8 h. DGAT and MTP activities in whole cells were measured. Data are expressed as a percentage of the control (set as 100%). Values represent the mean  $\pm$  SD of two independent experiments performed in duplicate. \* $P < 0.05$  control.

effect on intestinal lipid metabolism. Despite recent reports on hepatic lipoprotein production (11,12), the effect of plant flavonoids on intestinal lipoprotein production has not been investigated previously. In this study, we examined the effect of quercetin, a common dietary flavonoid, on apoB and lipid synthesis and secretion using CaCo-2 cells as the model system. Our study showed that cells treated with quercetin for 8 h inhibited apoB secretion into the basolateral medium in a dose-dependent manner. The effect was shown to be specific, as general protein secretion remained essentially unchanged. We attributed this inhibitory action to quercetin and not its metabolites. A previous study indicated that, under our experimental conditions, quercetin was protected from metabolism and chemical degradation (15). The 50% inhibition concentration ( $IC_{50}$ ) was about 24  $\mu$ M, a concentration representing a pharmacological dose. Since CaCo-2 secretes two forms of apoB (i.e., apoB-100 and apoB-48), we examined whether quercetin exerted its effect on either form. It has been reported that MTP inhibitors added to CaCo-2 cells inhibited apoB-100, and not apoB-48 (15,25). In contrast, our results indicated a similar decrease in both forms of apoB, suggesting that mechanisms other than lipidation may be involved. To simulate postprandial conditions, cells were challenged with oleic acid. We have shown that apoB secretion can be stimulated by oleate supplementation. Addition of quercetin reversed the stimulatory effect of oleate, indicating that quercetin can inhibit apoB secretion under lipid-rich conditions. Consistent with the apoB studies, quercetin also inhibited the basolateral secretion of radiolabeled TAG in the absence and presence of oleic acid. These effects were more pronounced with oleate treatment.

To investigate the mechanism of action for the decrease in apoB-Lp secretion, we examined two possible regulatory points. First, we examined TAG availability, a major determining factor in the assembly and secretion of intestinally derived apoB-Lp. Upon addition of quercetin, *de novo* TAG synthesis

was markedly inhibited under basal and lipid-rich conditions, indicating TAG may be less available for the assembly of an apoB-Lp particle. This result is in agreement with our earlier report regarding a similar flavonoid of a different plant origin, taxifolin (12). In HepG2 cells taxifolin was shown to inhibit TAG synthesis; however, the molecular mechanism for this remained unresolved. In this study, we attempted to examine this question more closely. We chose to analyze the activity of DGAT, a key enzyme in TAG synthesis. It catalyzes the final reaction in the glycerol phosphate pathway, considered to be the main pathway for TAG synthesis (26). Supplementation of quercetin in the presence of oleic acid markedly reduced DGAT activity. This finding is novel as flavonoids have never been reported to decrease DGAT activity. Only a few naturally occurring compounds have been reported to inhibit DGAT activity (27–29). Thus, the inhibition of apoB-Lp secretion may be accounted for, in part, by low availability of TAG *via* reduced DGAT activity.

Transfer of lipids to the nascent apoB molecule to form the primordial lipoprotein is a second major determining factor in the assembly and secretion of intestinally derived apoB-Lp (25,30). Transfer of lipids, primarily TAG and cholesterol esters, is catalyzed by MTP. Since flavonoids reportedly inhibit MTP activity in HepG2 cells (11), we chose to examine this enzyme in CaCo-2 cells. Quercetin, in the presence of oleic acid, reduced MTP activity in CaCo-2 cells but to a lesser extent than was observed in HepG2 cells. A mildly inhibitory effect on the secretion of apoB also has been reported with BMS-200150, a specific MTP inhibitor, in CaCo-2 cells (25) and is consistent with our data. The moderate decrease in MTP activity caused by quercetin likely contributes to the reduction in apoB secretion. However, we cannot rule out that other steps in lipoprotein assembly and secretion may be involved with quercetin. Particularly, the marked reduction in apoB and TAG secretion under oleate treatment may not account for the modest decrease in both MTP and DGAT activity. ACAT activity and cholesterol ester availability may also be involved, as has been previously reported in HepG2 cells (11). However, since TAG is thought to be the preferentially used lipid for the assembly of intestinally-derived lipoprotein (20), we chose to examine only TAG synthesis in our CaCo-2 study.

The reduction of both DGAT and MTP activity by quercetin suggests that reduced availability and transfer of TAG to apoB may account for its lowering action on apoB-Lp secretion in CaCo-2 cells. These data are consistent with previous observations that flavonoids can inhibit TAG synthesis and MTP activity in HepG2 cells (11,12). Our data may have clinical relevance in the treatment of hypertriglyceridemia. However, the concentrations used in our study are not likely to be achieved by consuming quercetin-containing fruits and vegetables since flavonoids in general are considered micronutrients. Rather, our study allows for the identification of foods that could be genetically engineered to increase levels of specific flavonoids. Such metabolic engineering has recently been published with specific reference to flavonoids found in tomatoes (31). Our study also allows for new drug development in the area of hypertriglyceridemia.

**ABSTRACT:** The better to characterize enzymes hydrolyzing carboxyl ester bonds (carboxyl ester hydrolases), we have compared the kinetic behavior of various lipases and esterases against solutions and emulsions of vinyl esters and TAG. Short-chain vinyl esters are hydrolyzed at comparable rates by esterases and lipases and have higher limits of solubility in water than corresponding TAG. Therefore, they are suited to study the influence of the physical state of the substrate on carboxyl ester hydrolase activity within a large concentration range. Enzymes used in this study are TAG lipases from microorganisms, lipases from human and guinea pig pancreas, pig liver esterase, and acetylcholinesterase. This study also includes cutinase, a fungal enzyme that displays functional properties between esterases and lipases. Esterases display maximal activity against solutions of short-chain vinyl esters (vinyl acetate, vinyl propionate, and vinyl butyrate) and TAG (triacetin, tripropionin, and tributyrin). Half-maximal activity is reached at ester concentrations far below the solubility limit. The transition from solution to emulsion at substrate concentrations exceeding the solubility limit has no effect on esterase activity. Lipases are active on solutions of short-chain vinyl esters and TAG but, in contrast to esterases, they all display maximal activity against emulsified substrates and half-maximal activity is reached at substrate concentrations near the solubility limit of the esters. The kinetics of hydrolysis of soluble substrates by lipases are either hyperbolic or deviate from the Michaelis–Menten model and show no or weak interfacial activation. The presence of molecular aggregates in solutions of short-chain substrates, as evidenced by a spectral dye method, likely accounts for the activity of lipases against soluble esters. Unlike esterases, lipases hydrolyze emulsions of water-insoluble medium- and long-chain vinyl esters and TAG such as vinyl laurate, trioctanoin, and olive oil. In conclusion, comparisons of the kinetic behavior of carboxyl ester hydrolases against solutions and emulsions of vinyl esters and TAG allows the distinction between lipases and esterases. In this respect, it clearly appears that guinea pig pancreatic lipase and cutinase are unambiguously classified as lipases.

Paper no. L8990 in *Lipids* 37, 653–662 (July 2002).

Lipases (EC 3.1.1.3.) and esterases (EC 3.1.1.1.) both catalyze the hydrolysis of carboxyl ester bonds. For many years,

the distinction between lipases and esterases has been based on their substrate specificity and their capacity to hydrolyze esters in solution and emulsion, respectively (1–4). It is generally considered that lipases hydrolyze water-insoluble medium- and long-chain TAG, such as trioctanoin and triolein, although they also display high activity against emulsions of somewhat (slightly) water-soluble short-chain TAG such as tripropionin and tributyrin.

Esterases are defined as enzymes acting on solutions of short-chain fatty acyl esters such as methyl butyrate, ethyl butyrate and triacetin, which are poorly hydrolyzed by lipases. In contrast to classical lipases, typical esterases are not interfacially activated, i.e., they show no abrupt increase in activity at substrate concentrations exceeding the solubility limit. Esterases are inactive against emulsions of long-chain TAG.

During the past 10 yr, the determination of the 3-D structure of several lipases, including lipases secreted by microorganisms and by the pancreas of higher mammals, has revealed that the active site, which contains the same Ser-His-Asp/Glu catalytic triad as that found in serine proteases, is covered by a peptide loop (lid) that has to move away to give access to substrate (5–12). A correlation has been made between the existence of the lid structure and the specific action of lipases on aggregated forms of esters although it is not known whether the change in conformation corresponding to the opening of the lid is triggered by lipase–substrate interaction at lipid–water interfaces.

More recently, results of kinetic and structural studies carried out with cutinase (13) and lipase from guinea pig pancreas (14) have challenged the classical distinction between lipases and esterases. These enzymes, in which the lid domain is deleted or restricted to a small number of amino acid residues, were found to hydrolyze water-insoluble long-chain TAG as well as solution in tributyrin without showing interfacial activation. These observations have led to the conclusion that lipases may act on monomeric substrates and that the distinction between esterases and lipases should no longer be correlated with the physical state of the substrate and/or the presence of a lid domain in enzyme molecule. As a consequence, it is proposed that lipases should be simply classified as carboxyl ester hydrolases having the capacity to act on water-insoluble long-chain TAG (15).

Recently, we investigated the kinetic behavior of a large variety of well-characterized lipases of known 3-D structure in solutions and emulsions of vinyl esters so as to directly compare the biochemical properties of lipases acting on TAG and partial acylglycerols, respectively (16,17). As shown earlier by Brockerhoff, emulsions of vinyl esters are good substrates for porcine pancreatic lipase (18,19). Short-chain vinyl esters, whose solubility largely exceeds that of TAG such as tripropionin and tributyrin, are suited for studying the influence of the physical state of the substrate on activity by comparing the rates of hydrolysis of soluble and emulsified esters within a large range of concentrations. We have found that lipases from *Rhizomucor miehei*, *Rhizopus oryzae*, *Thermomyces lanuginosa*, *Penicillium camembertii*, *P. cyclopium* (lipases I and II), *Candida rugosa*, *C. antarctica* (lipase A), human pancreas, and guinea pig pancreas display different kinetic behavior against solutions of vinyl propionate and vinyl butyrate although they all expressed maximal activity against emulsions. Actually, some of these lipases hydrolyze solutions of vinyl esters at high relative rates compared to emulsions and follow Michaelis–Menten kinetics, while others, which are less active against soluble substrates, deviate from the Michaelis–Menten model. It was clear from these studies that interfacial activation could not be taken as the unique criterion to characterize lipases. In the present study, we compared the kinetic behavior of lipases and esterases against solutions and emulsions of vinyl esters and TAG for the purpose of better differentiating between the two classes of carboxyl ester-hydrolyzing enzymes. Esterases used in this study are pig liver esterase and acetylcholinesterase from *Electrophorus electricus*. Cutinase from *Fusarium solani pisi*, which, functionally speaking, is considered as a link between esterases and lipases, is included in this study.

## MATERIALS AND METHODS

**Enzymes and substrates.** Pig liver esterase and acetylcholinesterase from *Electrophorus electricus* were purchased from Sigma-Aldrich-Fluka (F-38297 St Quentin Fallavier, France). Human pancreatic lipase and colipase, guinea pig pancreatic lipase, and cutinase were kindly provided by Dr. R. Verger and Dr. F. Carrière (CNRS, Marseille, France). Lipase from *R. oryzae* was prepared in the laboratory as described previously (20). Lipases from *R. miehei* and *T. lanuginosa* were kindly provided by Dr. S. Patkar (Novo Nordisk A/S, Copenhagen, Denmark). The protein concentration of enzyme samples was estimated by the colorimetric method of Lowry *et al.* (21) using BSA as standard protein for calibration. Methyl butyrate, ethyl butyrate, vinyl acetate, vinyl propionate, vinyl butyrate, vinyl laurate, and benzopurpurin 4B were obtained from Sigma-Aldrich-Fluka. Triacetin, tripropionin, tributyrin, and trioctanoin were supplied by Acros Organics (F-93166 Noisy-le-Grand, France). Olive oil was from local origin. The solubility limit of vinyl acetate in 2.5 mM Tris-HCl buffer pH 7.0 containing 0.1 M NaCl was determined by the turbidimetric method, as reported before (17). The solubility limit of vinyl acetate is 315 mM, which corresponds to 0.9 mL of ester in 30

mL. The solubility limits of vinyl propionate and vinyl butyrate are 86 and 22 mM, respectively, which corresponds to 280 and 85  $\mu$ L of ester in 30 mL. The solubility limits of triacetin and tripropionin are 330 and 10 mM, which corresponds to 1.86 mL and 70  $\mu$ L in 30 mL, respectively. The solubility limit of tributyrin has been determined by different methods. Values ranging from 0.41 (22) to 0.8 mM (23) have been reported.

**Determination of enzymatic activity.** The enzymatic hydrolysis of solutions and emulsions of esters was followed potentiometrically at 25°C and pH 7.0 with a pH-stat (TTT 80 Radiometer, Copenhagen, Denmark). Assays with vinyl laurate and olive oil were carried out at pH 8.0 and 9.0, respectively. Assays were performed in 30 mL of 2.5 mM Tris-HCl buffer pH 7.0 containing 0.1 M NaCl. Standard conditions for measuring enzyme activity at increasing concentrations of substrate have been described previously (16). No detergent or emulsifier was added to measure activity against supersaturated solutions of partially soluble esters (vinyl acetate, vinyl propionate, and vinyl butyrate; triacetin, tripropionin, and tributyrin) and emulsions of water-insoluble vinyl laurate and trioctanoin. Released FA were titrated with 0.1 M NaOH. In the case of vinyl laurate, correction was made for partial dissociation of lauric (dodecanoic) acid at pH 8.0 assuming a  $pK_a$  of 7.4. Olive oil was emulsified with gum arabic (24). The amount of enzyme used in assays corresponds to 5–10 units measured at a substrate concentration ensuring maximal activity. The concentration of ester in solution or emulsion was arbitrarily expressed as millimoles per liter. Enzymatic activity was expressed as units. One enzyme unit corresponded to the liberation of one microequivalent of acid per minute under standard assay conditions. Specific activity was expressed as units per milligram of enzyme protein.

**Detection of molecular aggregates in solutions of vinyl acetate.** The existence of molecular aggregates in a solution of vinyl acetate was detected by the same spectral dye method as previously used in kinetic studies with vinyl propionate and vinyl butyrate (16) and with short-chain TAG (25). The experimental procedure was as follows: The dye solution was prepared in 25 mM Tris-HCl buffer pH 7.0 containing 0.05 M NaCl at a concentration of 50 mg benzopurpurin/L. A solution of vinyl acetate was prepared by adding 1.4 mL of vinyl acetate to 50 mL of the solution of benzopurpurin 4B (final concentration 304 mM, corresponding to 96.5% saturation). The solution of vinyl acetate was mixed with increasing volumes of the solution of benzopurpurin in stoppered vials, and absorbance was measured against the solution of benzopurpurin after 15 min at 510 nm in 1-cm cells. Differential absorbance was plotted against vinyl acetate concentration. As indicated by the curve shown in Figure 1, an apparent CMC around 70 mM was estimated for vinyl acetate.

## RESULTS

**Hydrolysis of vinyl acetate by pig liver esterase and acetylcholinesterase.** The kinetic behavior of pig liver esterase and acetylcholinesterase against vinyl acetate is shown in Figure 2.

**FIG. 1.** Differential absorbance of a solution of benzopurpurin 4B in the presence of vinyl acetate. The solution of benzopurpurin is prepared in 25 mM Tris-HCl buffer pH 7.0 with 0.05 M NaCl with increasing amounts of vinyl acetate at concentration below the solubility limit (315 mM). Absorbance is measured at 510 nm. A CMC of 70 mM is estimated for vinyl acetate from the intercept of the curve with the x axis.

**FIG. 2.** Effect of ester concentration on the rate of hydrolysis of solutions of vinyl acetate ( $v$ ) by pig liver esterase (open circles) and acetylcholinesterase (solid circles). Assays were performed at pH 7.0 and 25°C in Tris-HCl buffer with 0.1 M NaCl. Activity is expressed as percentage of maximal activity ( $V_{\max}$ ). The solubility limit of vinyl acetate (315 mM) is not indicated.

In both cases, the shape of the curves representative of the variation of the initial rate of hydrolysis of vinyl acetate ( $v$ ) as a function of substrate concentration ( $S$ ) is hyperbolic. Esterases display maximal activity ( $V_{\max}$ ) against soluble vinyl acetate. The ester concentration corresponding to half-maximal activity ( $K_{0.5}$ ) is around 4 mM. Specific activities, estimated from values of  $V_{\max}$ , are 320 and 970 units  $\text{mg}^{-1}$  for pig liver esterase and acetylcholinesterase, respectively. These values are in the same range as those found with esters commonly used to assay pig liver esterase activity, such as methyl butyrate and ethyl butyrate. The values of  $K_{0.5}$ , estimated from the hyperbolic  $v/S$  curves obtained with pig liver esterase on methyl butyrate and ethyl butyrate (not shown), are around 2 (specific activity: 190 units  $\text{mg}^{-1}$ ) and 1 mM (specific activity: 310 units  $\text{mg}^{-1}$ ), respectively.

*Hydrolysis of vinyl acetate by lipases from R. oryzae, R. miehei, T. lanuginosa, human pancreas, and guinea pig pancreas.* The substrate concentration dependency of the initial rate of hydrolysis of vinyl acetate by lipases from *R. oryzae* and *R. miehei* is shown in Figure 3. The shape of the curves representing the kinetic behavior of the lipases is similar to that of the curves obtained with pig liver esterase and acetylcholinesterase except that, at low concentration of substrate, the curves are sigmoidal. Likely, this is related to the low amount and/or type of molecular aggregates formed in the 0–0.75 mM range of concentration of vinyl acetate (see Fig.

1). It can be further observed that the two lipases are highly active against solutions of vinyl acetate as compared to emulsions. Activity continuously increases at ester concentration beyond the solubility limit and reaches its maximal value in the presence of emulsified particles. The values of  $K_{0.5}$  estimated from the  $v/S$  curves are as high as 130 (specific activity: 640 units  $\text{mg}^{-1}$ ) and 120 mM (specific activity: 1940 units  $\text{mg}^{-1}$ ) for lipases from *R. oryzae* and *R. miehei*, respectively.

Figure 4 shows the kinetic behavior of lipases from *T. lanuginosa*, human pancreas, and guinea pig pancreas against vinyl acetate. The three lipases display low activity against soluble vinyl acetate as compared to lipases from *R. miehei* and *R. oryzae*, and enzymatic activity sharply increases at ester concentrations near the solubility limit of the substrate. All lipases express maximal activity at a substrate concentration exceeding the solubility limit. Colipase, the protein co-factor of pancreatic lipase that forms a specific complex with lipase at the lipid–water interface, has a marked effect on activity against soluble vinyl acetate as well as ester in emulsion. Colipase enhances pancreatic lipase activity by enabling the enzyme to interact with aggregates formed in the 100–300 mM range of concentration of vinyl acetate and by stabilizing lipase adsorbed at the micelle–water interface in its open active conformation. Although it is difficult to estimate the values of  $K_{0.5}$  from the irregular kinetic curves of Figure 4, it appears that, in all cases, half-maximal activity is reached at

**FIG. 3.** Effect of vinyl acetate concentration on the rate of hydrolysis by lipases from *Rhizopus oryzae* (open circles) and *Rhizomucor miehei* (solid circles). Assays were performed as described in the legend of Figure 2. The solubility limit of vinyl acetate (315 mM) is indicated by the dotted line. The concentration of vinyl acetate is expressed as millimoles per liter below and above the solubility limit of the substrate. For experimental conditions, see Figure 2.

**FIG. 4.** Effect of vinyl acetate concentration on the rate of hydrolysis by lipases from *Thermomyces lanuginosa* (open squares), guinea pig pancreas (solid squares) and human pancreas. Assays with human pancreatic lipase were performed in the absence (open circles) and presence (solid circles) of colipase in fivefold molar excess to lipase. The dotted line represents the solubility limit of vinyl acetate. For experimental conditions, see Figure 2.

ester concentrations in the range 280–320 mM, near the solubility limit of vinyl acetate. The specific activities of lipases from *T. lanuginosa*, human pancreas, and guinea pig pancreas, measured against vinyl acetate, are 700, 200, and 90 units  $\text{mg}^{-1}$ , respectively.

*Hydrolysis of vinyl propionate, vinyl butyrate, and vinyl laurate by pig liver esterase and acetylcholinesterase. Comparison with TAG lipases.* Both pig liver esterase and acetylcholinesterase hydrolyze solutions of vinyl propionate (Fig. 5). The  $v/S$  curves are hyperbolic, and maximal activity is reached at low ester concentrations. The values of  $K_{0.5}$  for pig liver esterase and acetylcholinesterase are 5 (specific activity: 300 units  $\text{mg}^{-1}$ ) and 18 mM (specific activity: 210 units  $\text{mg}^{-1}$ ), respectively. Vinyl butyrate is hydrolyzed by pig liver esterase (Fig. 6) but not by acetylcholinesterase. The value of  $K_{0.5}$  is 2 mM, and the specific activity of the enzyme is 470 units  $\text{mg}^{-1}$ .

The kinetic curves obtained with *R. oryzae* lipase and human pancreatic lipase against vinyl propionate and vinyl butyrate have been reported previously (17). Values of  $K_{0.5}$  estimated from the  $v/S$  curves obtained with *R. oryzae* lipase and vinyl propionate or vinyl butyrate are 25 and 12 mM, respectively, with specific activities of 1600 and 3300  $\text{mg}^{-1}$ . The values of  $K_{0.5}$  for human pancreatic lipase against vinyl propionate and vinyl butyrate are 75 and 25 mM with specific activities of 960 and 750 units  $\text{mg}^{-1}$ , respectively. In Figures

5 and 6, the  $v/S$  curves of *R. miehei* lipase against vinyl propionate and vinyl butyrate are presented. Values of  $K_{0.5}$ , estimated from the curves, are 35 and 15 mM, and the specific activities are 7500 and 11,000 units  $\text{mg}^{-1}$ , respectively. As observed with vinyl acetate, vinyl propionate and vinyl butyrate, the values of  $K_{0.5}$  estimated for lipases are higher than those for esterases. Unlike human pancreatic lipase and other classical TAG lipases, pig liver esterase and acetylcholinesterase are inactive against emulsions of water-insoluble vinyl laurate. The specific activities of human pancreatic lipase and lipases from *R. oryzae* and *R. miehei* against vinyl laurate are 450, 2700, and 11,000 units  $\text{mg}^{-1}$  with  $K_{0.5}$  as low as 4, 2, and 2 mM, respectively (16).

*Hydrolysis of TAG by esterases. Comparison with lipases.* The activities of pig liver esterase and acetylcholinesterase were determined against short-, medium-, and long-chain TAG including triacetin, tripropionin, tributyrin, trioctanoin, and olive oil. The enzymes are totally devoid of activity against trioctanoin and olive oil, which are insoluble in water. The  $v/S$  curves obtained with pig liver esterase against triacetin, tripropionin, and tributyrin are shown in Figures 7A and 7B. Again, esterase activity against all substrates is maximal at low substrate concentrations, far below the solubility limit of the TAG. Specific activities of pig liver esterase against triacetin, tripropionin, and tributyrin are 60, 50, and 70 units  $\text{mg}^{-1}$ , with  $K_{0.5}$  of 3, 0.3, and 0.15 mM, respectively.

**FIG. 5.** Effect of vinyl propionate concentration on the rate of hydrolysis by pig liver esterase (solid circles), acetylcholinesterase (open circles), and lipase from *Rhizomucor miehei* (solid squares). The dotted line indicates the solubility limit of vinyl propionate (86 mM). For experimental conditions see Figure 2.

**FIG. 6.** Effect of vinyl butyrate concentration on the rate of hydrolysis by pig liver esterase (solid circles) and lipase from *Rhizomucor miehei* (open circles). The dotted line indicates the solubility limit of vinyl butyrate (22 mM). For experimental conditions see Figure 2.

Acetylcholinesterase hydrolyzes triacetin (specific activity: 450 units  $\text{mg}^{-1}$ ;  $K_{0.5}$ : 30 mM) but not tripropionin or tributyrin (Table 1). Results of kinetic studies carried out with TAG lipases under the same conditions have been presented in previous reports (16,17). For example, the specific activity of *R. oryzae* lipase against tripropionin is 110 units  $\text{mg}^{-1}$  with  $K_{0.5}$  of 4 mM, and that of human pancreatic lipase is 4,000 units  $\text{mg}^{-1}$  with  $K_{0.5}$  of 8 mM (17). As observed with vinyl esters, values of  $K_{0.5}$  for the hydrolysis of short-chain TAG by classical lipases are higher than those found for pig liver esterase.

*Hydrolysis of vinyl esters and TAG by cutinase.* Cutinase is an extracellular lipolytic enzyme of small molecular mass, secreted by the fungus *F. solani pisi*, which hydrolyzes TAG as efficiently as lipases. Kinetic studies carried out with tributyrin as substrate pointed out that cutinase differs from classical lipases in that it hydrolyzes soluble as well as emulsified substrate showing no interfacial activation. Longhi and Cambillau (13) concluded that cutinase had the capacity to hydrolyze monomeric substrates and showed function properties between esterases and lipases. This conclusion found support from the determination of the 3-D structure of the enzyme (13). Cutinase belongs to the family of proteins containing the  $\alpha/\beta$  hydrolase fold and the Ser-His-Asp/Glu catalytic triad found in serine hydrolases. Unlike other lipases, cutinase does not possess a lid domain, and, therefore, the active site is accessible to solvent. It seems that interpretation of the kinetics of hydrolysis of tributyrin by cutinase and the lack of interfacial activa-

tion should be reconsidered in the light of the data showing that solutions of short-chain vinyl esters or tripropionin are also readily hydrolyzed by classical lipases such as lipases from *R. oryzae* and *R. miehei* and that, as reported previously (17,25), solutions of short-chain esters contain not only monomers but also multimolecular aggregates. Unfortunately, the very low solubility of tributyrin (0.4 mM) does not allow assessment of the physical state of ester molecules dispersed in the aqueous phase. It is likely that, as previously shown for triacetin and tripropionin, molecules of tributyrin associate in solution in the presence of 0.1 M NaCl and that small aggregates present in the aqueous phase may account for the activity of cutinase on soluble tributyrin.

Here, we compared the kinetic behavior of cutinase with solutions and emulsions of vinyl esters and short-chain TAG with that of esterases and lipases. As can be seen from the  $v/S$  curves shown in Figure 8, the relative activity of cutinase against solutions of vinyl acetate, vinyl propionate, and vinyl butyrate is high compared with the maximal activity measured against emulsified esters. Specific activities are 650, 700, and 1375 units  $\text{mg}^{-1}$  with  $K_{0.5}$  values of 150, 40, and 12 mM, respectively. The kinetics of the hydrolysis of short-chain TAG by cutinase are illustrated in Figure 9. Specific activities measured against triacetin, tripropionin, and tributyrin are 320, 570, and 360 units  $\text{mg}^{-1}$  with  $K_{0.5}$  of 70, 10, and 0.25 mM, respectively. The kinetic behavior of cutinase with solutions and emulsions of partially water-soluble vinyl esters and TAG is comparable to that of lipases from *R. oryzae* and

**FIG. 7.** Hydrolysis of short-chain TAG by pig liver esterase. (A) Effect of triacetin concentration on the rate of hydrolysis by pig liver esterase. (B) Effect of the concentration of tripropionin (open circles) and tributyrin (solid circles) on the rate of hydrolysis by pig liver esterase. The solubility limits of triacetin (330 mM), tripropionin (10 mM), and tributyrin (0.41 mM) are not indicated. For experimental conditions see Figure 2.

*R. miehei* and markedly differs from that of typical esterases. Furthermore, cutinase, in contrast to pig liver esterase and acetylcholinesterase, hydrolyzes emulsions of water-insoluble vinyl laurate (specific activity: 775 units  $\text{mg}^{-1}$ ;  $K_{0.5}$ : 5 mM) and trioctanoin (specific activity: 830 units  $\text{mg}^{-1}$ ;  $K_{0.5}$ : 5 mM). Values of  $K_{0.5}$  are in the same range as those found

for classical lipases. For example, the value of  $K_{0.5}$  is 3.75 mM for the hydrolysis of vinyl laurate (specific activity: 450 units  $\text{mg}^{-1}$ ) and 3.25 mM for the hydrolysis of trioctanoin by *R. oryzae* lipase (specific activity: 7000 units  $\text{mg}^{-1}$ ). Specific activities of carboxyl ester-hydrolyzing enzymes used in this kinetic study are reported in Table 1.

**TABLE 1**  
**Specific Activities<sup>a</sup> of Esterases and Lipases Measured Against Vinyl Esters and TAG**

	Vinyl acetate	Vinyl propionate	Vinyl butyrate	Vinyl laurate	Triacetin	Tripropionin	Tributyrin	Trioctanoin	Olive oil
Pig liver esterase	320	300	470	0	60	50	70	0	0

## DISCUSSION

In early comparative studies of the hydrolysis of methyl butyrate and triacetin by horse liver esterase and porcine pancreatic lipase, large differences were found between the kinetic behaviors of the two classes of enzymes (26). Under the conditions used for assaying carboxyl ester hydrolase activity, pancreatic lipase displayed low activity against esters at concentration below the solubility limit, and hydrolysis sharply increased in the presence of emulsified particles, in

supersaturated solutions. In contrast to pancreatic lipase, the activity of liver esterase was maximal against solutions of methyl butyrate and triacetin and was not enhanced at ester concentrations beyond the point of saturation of the solution. Consequently, the increase in activity shown by pancreatic lipase in a heterogeneous assay system (interfacial activation) was considered as a typical feature of the mode of action of lipases at a lipid-water interface. It was further hypothesized that interfacial activation of lipases would result from a change in the conformation of enzymes specifically bound to

**TABLE 2**  
**Hydrolysis<sup>a</sup> of Vinyl Acetate and Tripropionin by Esterases and Lipases**

Vinyl acetate	4	4	140	295	130	120	280	315
Tripropionin	0.3	—	10	10.5	4	8	15	8.5

<sup>a</sup> $K_{0.5}$ , the ester concentration that corresponds to half-maximal activity ( $V_m/2$ ), is estimated from the  $v/S$  curves and expressed as millimoles per liter. The substrate concentration is arbitrarily expressed as millimoles per liter both in the soluble and emulsified concentration range of substrate. The solubility limits of vinyl acetate and tripropionin are 315 and 10 mM, respectively. For abbreviations see Table 1.

large-size particles of the emulsion (26,27). Later, this hypothesis found support from the determination of the 3-D structure of human pancreatic lipase (6) and lipases from the fungi *R. miehei* (7) and *Geotrichum candidum* (10). In these lipases, the active site is covered by a peptide loop (lid), which has to move away to give access to the substrate. It was proposed to correlate the interfacial activation with the transition between the closed (inactive) form and the open (active) form of lipase (7,15).

During the past decade, a large number of lipases have been isolated and characterized. Studies of their molecular and catalytic properties have challenged the classical distinction between lipases and esterases based on interfacial activation. Lipases from *Pseudomonas glumae* (28,29), *P. aeruginosa* (30,31), *C. antarctica* (lipase B) (32), and pancreatic lipase from coypu (*Myocastor coypus*) (33), which possess a lid domain; cutinase, a lipolytic enzyme from *F. solani pisi* (13); and lipase from guinea pig pancreas (14), in which the lid domain is absent or restricted to a few amino acid residues, hydrolyzed solutions of esters showing no or weak interfacial activation. In some cases, such as lipase from *Staphylococcus hyicus*, typical interfacial activation was found only with some substrates (34). Then, it was concluded that lipases had the capacity to act on monomeric solutions as well as emulsions and that lipases should simply be considered as a particular class of carboxyl ester hydrolases having, unlike esterases, the capacity to act on water-insoluble long-chain TAG (15). The possible existence of small aggregates (micelles) in solutions of esters was not taken into account and, from a mechanistic point of view, the possibility that lipases could be interfacially activated by micelles was not systematically considered.

Recently, we used vinyl esters as substrates to compare the kinetic properties of several lipases from filamentous fungi (*R. oryzae*, *R. miehei*, *T. lanuginosa*, *P. camembertii*), yeasts (*C. rugosa*, *C. antarctica*) and guinea pig and human pancreas (16,17). Studies of the kinetics of hydrolysis of vinyl propionate and vinyl butyrate clearly showed that lipases were active to some extent against solutions of short-chain vinyl esters although they all displayed maximal activity against emulsions. In some cases, enzyme kinetics did not follow the classical Michaelis–Menten model, suggesting that substrate concentration was not the only parameter governing enzyme activity against soluble substrates.

In the present study, we compared the kinetic behavior of classical lipases and typical esterases, namely, pig liver esterase and acetylcholinesterase, against vinyl esters and TAG

in solution and in emulsion. Lipolytic enzymes having functional properties between lipases and esterases, such as guinea pig pancreatic lipase and cutinase from *F. solani pisi*, were included in this study. In addition to vinyl propionate, vinyl butyrate, and vinyl laurate, we investigated the kinetics of enzymatic hydrolysis of vinyl acetate, whose solubility limit (315 mM) greatly exceeds that of vinyl propionate (86 mM), vinyl butyrate (22 mM), tripropionin (10 mM), and tributyrin (0.4 mM).

Our results show that classical lipases, together with pig liver esterase, cutinase, and guinea pig pancreatic lipase, hydrolyze slightly water-soluble short-chain vinyl esters (vinyl acetate, vinyl propionate, and vinyl butyrate). Acetylcholinesterase is active on vinyl acetate and vinyl propionate but, as expected, does not hydrolyze vinyl butyrate (Table 1). In comparing the kinetic behaviors of the enzymes with vinyl acetate, it appears that esterases express maximal activity in the soluble concentration range. The substrate concentration corresponding to half-maximal activity ( $K_{0.5}$ ) of esterases is around 4 mM (Table 2). In contrast, classical lipases, guinea pig pancreatic lipase and cutinase, which show limited activity against soluble vinyl acetate, display maximal activity against emulsions.  $K_{0.5}$  values of 120, 130, and 140 mM are found for lipases from *R. miehei* and *R. oryzae* and for cutinase, respectively (Table 2). Values of  $K_{0.5}$  for lipases from *T. lanuginosa*, human pancreas, and guinea pig pancreas are in the 280–315 mM range, near the solubility limit of vinyl acetate (315 mM). Similar observations can be made with vinyl propionate, vinyl butyrate, and short-chain TAG. Esterases are inactive against water-insoluble medium- and long-chain esters such as vinyl laurate, trioctanoin, and olive oil, which are hydrolyzed by classical lipases, guinea pig pancreatic lipase, and cutinase (Table 1). Consequently, guinea pig pancreas lipase and cutinase have to be classified unambiguously as lipases. It appears that the capacity of the enzymes to hydrolyze emulsions of vinyl laurate or trioctanoin, on the one hand, and the determination of the  $K_{0.5}$  values with short-chain vinyl esters, in particular vinyl acetate, on the other hand, should help to characterize carboxyl ester hydrolases and to distinguish between lipases and esterases (35).

Comparison of the specific activities (Table 1) and  $K_{0.5}$  values (Table 2) of lipases and esterases, measured against vinyl esters and TAG, clearly indicates that esterases show preference for short-chain vinyl esters and do not hydrolyze medium- and long-chain esters. In contrast, classical lipases preferentially act on emulsions of tripropionin and tributyrin,

which are slightly soluble in water, and on water-insoluble vinyl laurate, trioctanoin, and olive oil. Cutinase and guinea pig pancreatic lipase, in contrast to other carboxyl ester hydrolases, hydrolyze all types of esters at comparable rates. It is interesting to notice that lipases from *R. miehei*, *T. lanuginosa*, and human pancreas possess a full-length lid domain, whereas the lid structure is restricted to five amino acid residues in the guinea pig lipase and is absent in cutinase. In cutinase, however, the highly flexible peptide region around the active site is involved in substrate binding and plays the same role as the lid domain in other lipases (36,37). Taken together, these observations suggest, from an evolutionary point of view, that the presence of the lid domain in classical lipases is directly related to their capacity to specifically hydrolyze long-chain TAG. This conclusion is in accordance with results of earlier crystallographic studies of the 3-D structure of the lipase-colipase complex co-crystallized with mixed micelles of PC showing that the lid domain is an essential component of the active site as it interacts with an acyl chain of the phospholipid (12). It is expected that further studies of the physical state of ester molecules dispersed in water, together with studies of enzyme structures, will contribute to understanding the mode of action of lipases and to a better distinction between esterases and lipases.

## ACKNOWLEDGMENTS

The authors wish to thank Drs. Robert Verger and Frédéric Carrière (CNRS, Marseille) for their interest in this study, helpful advice, and stimulating discussions during the preparation of the manuscript.

# PC and PE Synthesis: Mixed Micellar Analysis of the Cholinephosphotransferase and Ethanolaminephosphotransferase Activities of Human Choline/Ethanolamine Phosphotransferase 1 (CEPT1)

Marcia M. Wright and Christopher R. McMaster\*

Atlantic Research Centre, Departments of Pediatrics and Biochemistry & Molecular Biology, IWK Health Centre, Dalhousie University, Halifax, Nova Scotia, B3H 4H7, Canada

**ABSTRACT:** The human choline/ethanolamine phosphotransferase 1 (CEPT1) gene codes for a dual-specificity enzyme that catalyzes the *de novo* synthesis of the two major phospholipids through the transfer of a phosphobase from CDP-choline or CDP-ethanolamine to DAG to form PC and PE. We used an expression system devoid of endogenous cholinephosphotransferase and ethanolaminephosphotransferase activities to assess the diradylglycerol specificity of CEPT1. A mixed micellar assay was used to ensure that the diradylglycerols delivered were not affecting the membrane environment in which CEPT1 resides. The CEPT1 enzyme displayed an apparent  $K_m$  of 36  $\mu\text{M}$  for CDP-choline and 4.2 mol% for di-18:1 DAG with a  $V_{\text{max}}$  of 14.3  $\text{nmol min}^{-1} \text{mg}^{-1}$ . When CDP-ethanolamine was used as substrate, the apparent  $K_m$  was 98  $\mu\text{M}$  for CDP-ethanolamine and 4.3 mol% for di-18:1 DAG with a  $V_{\text{max}}$  of 8.2  $\text{nmol min}^{-1} \text{mg}^{-1}$ . The preferred diradylglycerol substrates used by CEPT1 with CDP-choline as the phosphobase donor were di-18:1 DAG, di-16:1 DAG, and 16:0/18:1 DAG. A major difference between previous emulsion-based assay results and the mixed micelle results was a complete inability to use 16:0(O)/2:0 as a substrate for the *de novo* synthesis of platelet-activating factor when the mixed micelle assay was used. When CDP-ethanolamine was used as the phosphobase donor, 16:0/18:1 DAG, di-18:1 DAG, and di-16:1 DAG were the preferred substrates. The mixed micelle assay also allowed the lipid activation of CEPT to be measured, and both the cholinephosphotransferase and ethanolaminephosphotransferase activities displayed the unusual property of product activation at 5 mol%, implying that specific lipid activation binding sites exist on CEPT1. The protein kinase C inhibitor chelerythrine and the human DAG kinase inhibitor R59949 both inhibited CEPT1 activity with  $\text{IC}_{50}$  values of 40  $\mu\text{M}$ .

Paper no. L9042 in *Lipids* 37, 663–672 (July 2002).

PC and PE are the major membrane phospholipids found in eukaryotic cells, constituting approximately 50 and 25% of membrane mass, respectively. PC is synthesized by a

cholinephosphotransferase activity that forms a phosphoester bond through the transfer of phosphocholine from CDP-choline to DAG (1–8). PE is synthesized through an analogous reaction that substitutes CDP-ethanolamine as the phosphobase donor (1,3,9–11). An accurate determination of specificity with respect to fatty acyl chain length is of great interest in lipid enzymology, as this can explain the molecular mechanism by which these enzymes contribute to the distribution of FA within phospholipids of the lipid bilayer. The fatty acyl groups of PC and PE govern the membrane structure and function of the phospholipids and also serve as reservoirs for numerous signaling molecules. For example, highly saturated PC molecules are the major component of lung surfactant (12,13), and arachidonic acid is released from PC for the production of prostaglandins and leukotrienes (14,15). In addition, a cholinephosphotransferase reaction has been implicated in the synthesis of a platelet-activating factor (PAF) precursor and the inflammatory mediator PAF itself (16). The PAF precursor is identical in structure to PC except that it contains an ether-linked FA at the *sn*-1 position of the glycerol backbone, with arachidonic acid as the preferred FA at the *sn*-2 position. PAF itself also contains an ether-linked *sn*-1 FA, but the *sn*-2 group is an acetyl moiety (17,18). Metabolism of the PAF precursor to PAF is initiated by a  $\text{Ca}^{2+}$ -activated phospholipase  $\text{A}_2$  that will hydrolyze arachidonic acid containing PC or the PAF precursor for the release of arachidonic acid from both lipids (19), as well as to produce PAF from lysoPAF through the action of PAF acetyltransferase (20).

One of the major obstacles to characterizing integral membrane lipid-metabolizing enzymes is that essentially water-insoluble, exogenous lipid substrates are delivered to membrane fractions containing the enzyme of interest in an aqueous solution with water-soluble substrates and cofactors. A second complication is that the membrane fraction used as enzyme source may contain more than one isoform of an enzyme catalyzing the same reaction, thus complicating the interpretation of enzymatic kinetics and substrate specificities. One solution to the assay of several enzyme isoforms that reside in a particular membrane is to purify the enzyme to homogeneity; however, most integral membrane-bound enzymes are difficult

Abbreviations: CEPT1, choline/ethanolamine phosphotransferase 1; CPT1, choline phosphotransferase 1; PAF, platelet-activating factor.

to purify because they must be removed from their membrane environment by solubilization with detergents to be amenable to column chromatography. This process often inactivates the enzyme, and indeed a cholinephosphotransferase has yet to be purified to homogeneity. A second solution is to isolate a cDNA coding for the enzyme and its expression in a cell type devoid of its activity. Recently, two human genes/cDNA were isolated that encode cholinephosphotransferase and ethanolaminephosphotransferase activities, and that appear to provide the entire complement of these enzyme activities in humans, were expressed in a *Saccharomyces cerevisiae* strain devoid of its endogenous cholinephosphotransferase and ethanolaminephosphotransferase activities (1,2,21). Results showed the human choline phosphotransferase 1 (CPT1) gene encodes a CDP-choline-specific enzyme for the synthesis of PC, whereas the human choline/ethanolamine phosphotransferase 1 (CEPT1) gene codes for an enzyme that can use either CDP-choline or CDP-ethanol-amine as substrates to synthesize PC or PE, respectively. The diradylglycerol substrate specificity of CPT1 and CEPT1 were also determined in these studies, with a broad range of diradylglycerols being utilized. Most notably, both enzymes were found to be capable of *de novo* synthesis of PAF and the PAF precursor (2,16).

In these analyses the diradylglycerol substrate species specificity of CPT1 and CEPT1 was determined using an emulsion-based assay in which a small amount of detergent was used to solubilize the diradylglycerol substrates. This assay type is the major method by which cholinephosphotransferase activity has previously been characterized (4,6,8–11,16,22,23), and our use of this assay allowed the activities of the CPT1- and CEPT1-encoded cholinephosphotransferase activities to be compared to these previous studies. However, this assay method does suffer from two major disadvantages. First, the delivery of the different lipophilic diradylglycerol substrates variously alters the physical parameters of the membrane in which the cholinephosphotransferase enzyme resides, and the activity measurements for the different diradylglycerol substrates possibly reflect alterations in the physical parameters of the membrane rather than true substrate specificity of the active sites of the enzyme. Second, because the enzyme cannot be studied independent of its native lipid environment, lipid activation and lipophilic inhibitor studies cannot be performed, as these molecules can also affect the physical parameters of the membrane. Therefore, it is difficult to interpret whether alterations in activity are due to membrane perturbations or accurately reflect the effect of the lipid on the activity of the enzyme. Mammalian cholinephosphotransferase appears to be exquisitely sensitive to its membrane environment, as demonstrated by the various attempts to purify the enzyme (6,9,10,22,23). It was rapidly inactivated by most detergents, and its activity was partially reconstituted by the addition of specific phospholipids (22,23).

The use of mixed micelle surface-dilution kinetic assay systems has resulted in the accurate portrayal of acyl group specificity for several integral membrane lipid-metabolizing

enzymes (3,5,24–34). The mixed micelle method presents the lipid substrate in a uniform matrix and resolves the problem of the differing lipophilic substrates, activators, or inhibitors physically altering the membrane structure in which the enzyme resides (24). In this study, we have characterized the specificity of the diradylglycerol substrate, as well as the effects of soluble and lipophilic activators and inhibitors, on the cholinephosphotransferase and ethanolaminephosphotransferase activities of human CEPT1 using a mixed micelle assay method.

## MATERIALS AND METHODS

**Materials.** All materials used in the preparation of yeast media were purchased from Difco Laboratories (Detroit, MI). [Methyl-<sup>14</sup>C]cytidine 5'-diphosphocholine and [ethanolamine-1,2-<sup>14</sup>C]cytosine 5'-diphosphoethanolamine were purchased from American Radiolabeled Chemicals (St. Louis, MO). Lipids, di-8:0 ethylene glycol, di-10:0 ethylene glycol, and di-18:1 ethylene glycol were purchased from Avanti Polar Lipids (Alabaster, AL). Inhibitors used were products of BioMol (Plymouth Meeting, PA).

**Membrane isolation.** Yeast cells devoid of their endogenous cholinephosphotransferase activity (HJ091—a *ura3 his3 leu2 trp1 cpt1::LEU2 ept1*<sup>-</sup>) were transformed with pAH9 (CEPT1), pAH12 (CPT1), or p416GPD (vector control), which express the human cDNA from the constitutive glyceraldehyde dehydrogenase promoter; transformants were selected on minimal medium containing the required nutritional supplements to allow for plasmid maintenance (1–3). The yeast cells were grown to midlog phase, and cultures were centrifuged at 1000 × *g* for 10 min, decanted, and resuspended in 25 mL of ice-cold membrane isolation buffer that contained 20% glycerol, 50 mM Tris-HCl pH 7.4, and 1 mM EDTA. Cells were centrifuged at 1000 × *g* for 10 min, decanted, and resuspended in 0.7 mL isolation buffer, which was then transferred to a test tube containing 0.5 mL of 0.5-mm glass beads. This mixture was vortexed at high speed five times for 30 s each with 30 s on ice between each mixing. The resulting homogenate was transferred to a new tube and the beads were rinsed twice with 0.5 mL isolation buffer, with each rinse being added to the homogenate. To pellet unbroken cells, nuclei, and mitochondria, the homogenate was centrifuged at 15,000 × *g* for 15 min at 4°C. The supernatant was transferred to an ultracentrifuge tube and spun at 450,000 × *g* for 15 min at 4°C. The microsomal membrane pellet was resuspended by Teflon pestle homogenization in 0.5 mL isolation buffer. Protein concentration in the microsomal membranes was determined by the method of Lowry *et al.* (35).

**Enzyme assays.** In the mixed micelle assay to determine cholinephosphotransferase and ethanolaminephosphotransferase activities, the diradylglycerol substrates and lipid activators were dried under nitrogen gas and resuspended by sonication in an assay mixture that contained 50 mM Tris-HCl (pH 8.0), 20 mM MgCl<sub>2</sub>, 20% glycerol, 10 mol% diradylglycerol, and 10 mol% lipid activator (PC unless

otherwise noted) or lipophilic inhibitor in 1% sodium cholate. To the micelle were added 10–25  $\mu\text{g}$  of membrane protein as enzyme source, and the mixture was incubated at 25°C for 5 min to allow for mixed micelle formation. Soluble inhibitors were added to the assay mix at this stage, and the assay was initiated by the addition of [ $^{14}\text{C}$ ]CDP-choline (0.4 mM, 2000 dpm/nmol) or [ $^{14}\text{C}$ ]CDP-ethanolamine (0.4 mM, 2000 dpm/nmol) to a final volume of 100  $\mu\text{L}$ . Assays were incubated at 25°C for 20 min and terminated by the addition of 3 mL  $\text{CHCl}_3/\text{CH}_3\text{OH}$  (2:1, vol/vol) and 1.5 mL 0.9% (wt/vol) KCl. Tubes were vortexed, and phase separation was facilitated by centrifugation at  $2000 \times g$  for 10 min. The aqueous phase was aspirated, and the organic phase was washed twice with 2 mL 40%  $\text{CH}_3\text{OH}/\text{H}_2\text{O}$  (vol/vol). A sample of the organic phase was dried in a scintillation vial, and radioactivity was determined by scintillation counting. The organic phase was analyzed by TLC using the solvent  $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{NH}_4\text{OH}/\text{H}_2\text{O}$  (70:30:2:2, by vol) to ensure that PC or PE were the products. The mixed micellar assay described above satisfied the criteria of enzyme activities being dependent on the mole fraction of the lipid substrate and not dependent on micelle concentration at a fixed mole fraction of lipid components.

## RESULTS

**Kinetic analysis of CEPT1.** The human CEPT1 enzyme was expressed in an *S. cerevisiae* strain devoid of its endogenous cholinephosphotransferase and ethanolaminephosphotransferase activities by genetic inactivation of the genes coding for the yeast enzymes (1–3). This expression system ensured that all measurable activity was due to the expressed human CEPT1 enzyme. The mixed micelle system has previously been used to accurately assess the acyl specificity and lipid activation profiles of a number of integral membrane lipid-metabolizing enzymes (24–34). Hence, we sought to establish a mixed micelle method amenable to analysis of the human cholinephosphotransferase enzymes CPT1 and CEPT1. Surprisingly, both enzymes were completely inactive when the Triton X-100 micelle assay was used to characterize the yeast Cpt1p and Ept1p cholinephosphotransferase and choline/ethanolaminephosphotransferase enzymes (3). When searching for a detergent that could be used with the mixed micelle method for analysis of the mammalian enzymes, the researchers found that sodium cholate resulted in surface dilution kinetics (including complete dependence on the addition of exogenous DAG substrate) and bulk lipid concentration appropriate for a kinetic analysis of CEPT1. Surprisingly, sodium cholate micelles did not support the activity of human CPT1 despite the very high degree of primary amino acid and predicted similarities in secondary structure between CPT1 and CEPT1.

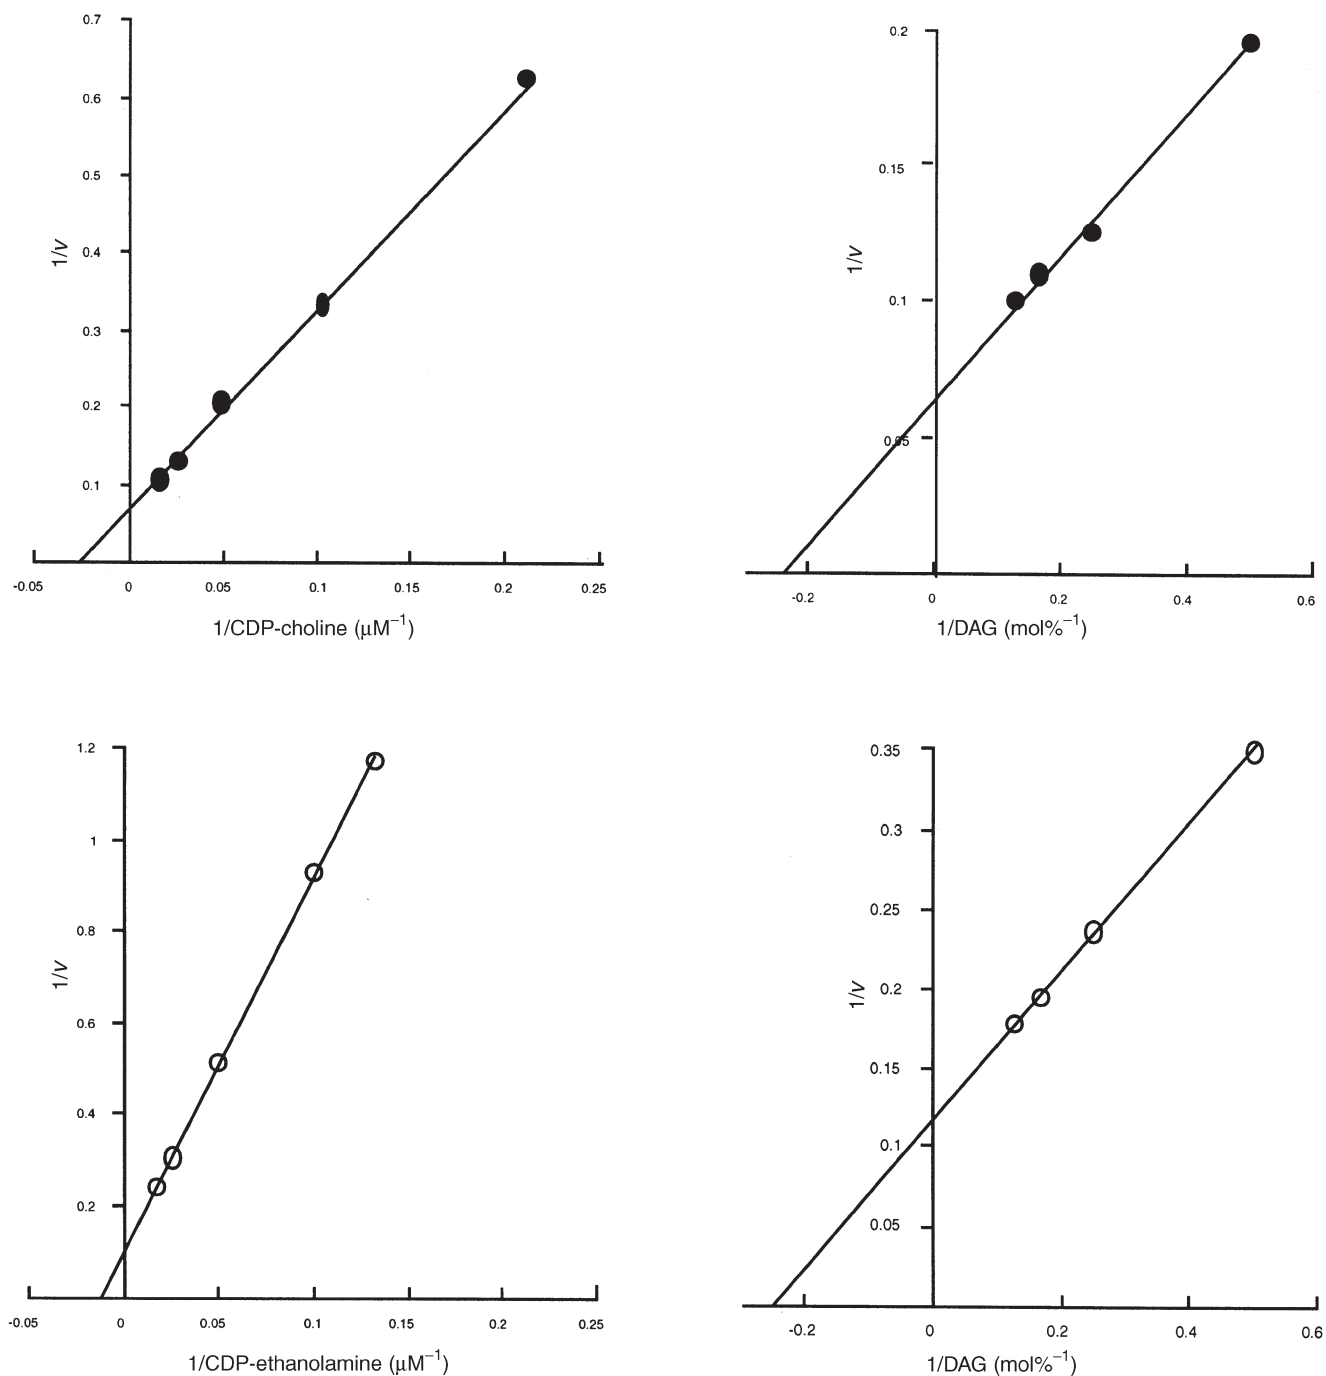

The kinetic parameters of apparent  $K_m$  and  $V_{\max}$  values were previously measured for CEPT1 using a Tween 20-based emulsion assay with CDP-choline and di-18:1 DAG as substrates. These results revealed an apparent  $K_m$  for CDP-

choline of 37  $\mu\text{M}$  and 850  $\mu\text{M}$  for di-18:1 DAG with a  $V_{\max}$  of 10.5  $\text{nmol min}^{-1} \text{mg}^{-1}$ . Using the mixed micelle assay, we determined that the apparent  $K_m$  for CDP-choline was 36  $\mu\text{M}$ , and for di-18:1 DAG it was 4.2 mol% with a  $V_{\max}$  of 14.3  $\text{nmol min}^{-1} \text{mg}^{-1}$ . The kinetic parameters of apparent  $K_m$  and  $V_{\max}$  values for CEPT1 using the Tween 20-based emulsion assay using CDP-ethanolamine and di-18:1 DAG as substrates previously revealed an apparent  $K_m$  of 101  $\mu\text{M}$  for CDP-ethanolamine and 890  $\mu\text{M}$  for di-18:1 DAG with a  $V_{\max}$  of 4.4  $\text{nmol min}^{-1} \text{mg}^{-1}$ . Using the mixed micelle assay, the apparent  $K_m$  for CDP-ethanolamine was 98  $\mu\text{M}$  and for di-18:1 DAG was 4.3 mol% with a  $V_{\max}$  of 8.2  $\text{nmol min}^{-1} \text{mg}^{-1}$  (Fig. 1). (Results are means of at least three separate experiments. SEM was less than 15% of the mean for each point.)

**Diradylglycerol specificity of CEPT1.** A comparison of the species specificity of various diradylglycerols for the cholinephosphotransferase activity of CEPT1 between the emulsion-based and mixed micelle assays revealed extreme differences. In our previous work using the emulsion-based assay, a very small amount of detergent was added to the diradylglycerol substrate to allow its solubilization, which can result in the various substrates altering the membrane environment in which CEPT1 resides (1). In that case, cholinephosphotransferase activity of CEPT1 preferred di-10:0 DAG = 16:0(O)/2:0  $\gg$  di-16:1 = di-8:0 = di-18:1 = 16:0/22:6  $>$  di-12:0  $>$  di-14:0 = di-16:0. When compared to the mixed micelle assay results, one of the most obvious differences was the inability to use 16:0(O)/2:0 as a substrate in the mixed micelle assay, revealing an inability to synthesize PAF *de novo* by CEPT1 (Table 1). In the mixed micelle assay, di-18:1 DAG, di-16:1 DAG, and 16:0/18:1 DAG were the preferred substrates, and CEPT1 could also use 16:0(O)/20:4 for *de novo* synthesis of the PAF precursor.

The diradylglycerol specificity of the ethanolaminephosphotransferase activity of CEPT1 was also assessed using the mixed micelle system and compared to the emulsion-based delivery of the diradylglycerol substrates. In the emulsion-based assay with CDP-ethanolamine as a substrate, the number of DAG species was limited, with di-18:1 DAG  $>$  16:0/18:1 = di-16:1  $>$  16:0/22:6, and the levels of ethanol-aminephosphotransferase activity were undetectable using any other diradylglycerol substrate (1). With the mixed micelle assay, the profile of DAG species that could be used as substrates by the ethanolaminephosphotransferase activity of CEPT1 was expanded, with 16:0/18:1 DAG = di-18:1 = di-16:1  $>$  18:0/20:4 = 16:0/22:6  $>$  di-16:0 used as substrates (Table 1).

**Lipid cofactor requirement of CEPT1.** The mixed micelle assay system is unique in that lipids can be added to the micelles without dramatically affecting the physical state of the environment in which CEPT1 resides. Thus, various lipid activators can be directly compared (3,24). In an emulsion-based system, on the other hand, very little or no detergent is added to the membrane in which CEPT1 resides such that the excess lipid added as either substrate or activator can dramatically alter the membrane environment and vary the physical

**FIG. 1.** Lineweaver–Burke analysis of human choline/ethanolamine phosphotransferase 1 (CEPT1)-catalyzed cholinephosphotransferase and ethanolaminephosphotransferase activities. Human CEPT1 was expressed in *Saccharomyces cerevisiae* cells devoid of their endogenous cholinephosphotransferase and ethanolaminephosphotransferase activities. CEPT1 cholinephosphotransferase (●) and ethanolaminephosphotransferase (○) activities were determined using the mixed micelle method, as described in the Materials and Methods section, with di-18:1 DAG as phosphobase acceptor and 10 mol% PC as lipid activator. The results represent the means of three separate experiments. SEM were less than 15% for each point.

state of the membrane. This makes it difficult to interpret whether the alterations in enzyme activity are due to specific lipid binding to CEPT1 or to gross alterations in the physical characteristics of the membrane.

Various lipid activators were tested at 10 mol% using the mixed micelle assay. This analysis revealed that several phospholipids were capable of altering both the cholinephosphotransferase and ethanolaminephosphotransferase activities of

<sup>a</sup>A mixed micelle assay was performed using CDP-choline or CDP-ethanolamine with di-18:1 DAG as substrate at 10 mol% activating lipid as described in the Materials and Methods section. Enzyme activity was 12.5 nmol min<sup>-1</sup> mg<sup>-1</sup> using CDP-choline and 7.6 nmol min<sup>-1</sup> mg<sup>-1</sup> for CDP-ethanolamine with PC as lipid activator. The results are means of at least three separate experiments. SEM was less than 15% of the mean for each point. LPC, lysophosphatidylcholine; PG, phosphatidylglycerol; CL, cardiolipin. For other abbreviation see Table 1.

**CEPT1.** CEPT1 did not absolutely require a lipid activator, since activity was noted in the absence of exogenously added phospholipid. Of the lipids that could activate CEPT1, the product of the CEPT1 cholinephosphotransferase reaction, PC, was one of the best activators of the cholinephosphotransferase activity of the enzyme, and the product of the ethanolaminephosphotransferase activity of CEPT1, PE, was one of the best activators of the ethanolaminephosphotransferase reaction (Table 2). PC and PE concentrations of approximately 5 mol% were required to fully activate CEPT1 (Fig. 2). The acyl specificity of the PC molecules required to activate the cholinephosphotransferase activity of CEPT1 was also analyzed: PC molecules with physiologic chain lengths were all equally capable of activation, whereas short-chain PC species were poor activators (Table 3). The ability of a broad range of long-chain PC molecular species to support CEPT1 activity in a mixed micelle assay was also observed for the yeast Cpt1p and Ept1p enzymes (3).

<sup>a</sup>A mixed micelle assay was performed using CDP-choline with di-18:1 DAG as substrate and 10 mol% PC as activating lipid as described in the Materials and Methods section. Lipophilic inhibitors are expressed as mol% and essentially soluble inhibitors as mM. Enzyme activity was 12.5 nmol min<sup>-1</sup> mg<sup>-1</sup> using CDP-choline as substrate and PC (egg) as lipid activator in the absence of inhibitor. The results are means of at least three separate experiments. SEM was less than 15% of the mean for each point. di-8:0 Ethylene glycol, di-10:0 ethylene glycol, and di-18:1 ethylene glycol were purchased from Avanti Polar Lipids (Alabaster, AL). All other inhibitors were from BioMol (Plymouth Meeting, PA).

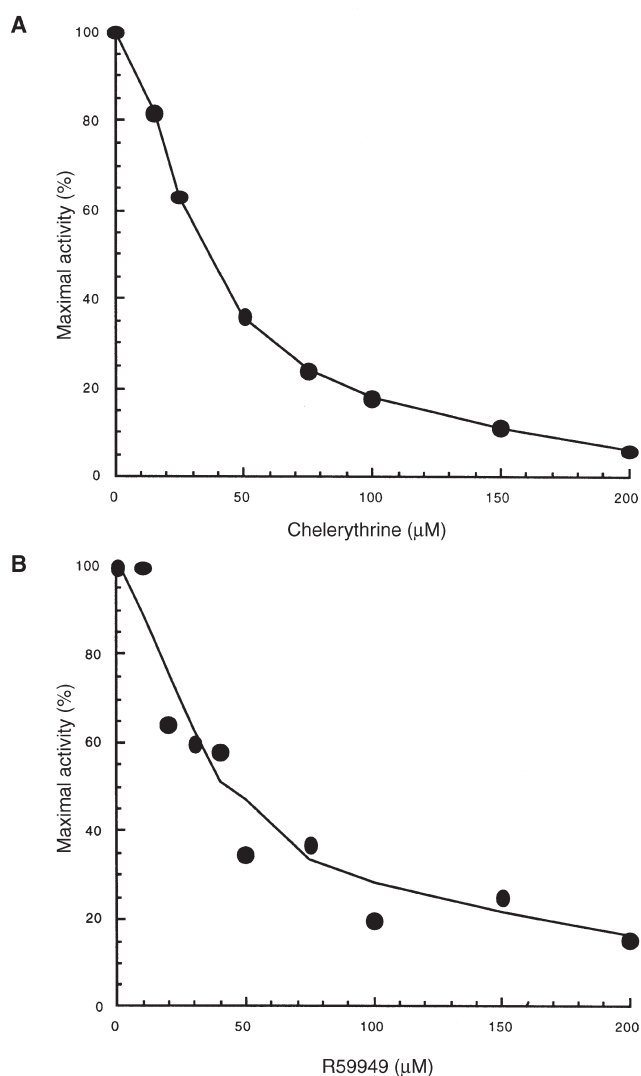

**Inhibitors of CEPT1 activity.** Previous reports using an emulsion-based assay (36,37) identified farnesol as an *in vitro* inhibitor of cholinephosphotransferase activity. Using a mixed micelle assay, we demonstrated that farnesol did not inhibit CEPT1 activity (21). The addition of large concentrations of farnesol apparently compromised the structure of the membrane in which CEPT1 resides, resulting in its inactivation rather than its inhibition (21,38). We investigated compounds that could be used in the mixed micelle assay as efficient inhibitors of CEPT1 that would not alter the physical parameters in which the CEPT1 enzymes resides when the lipophilic molecules were added. Compounds were chosen based on their ability to inhibit other DAG-utilizing enzymes (such as DAG kinase), alter the activity of DAG-responsive enzymes (such as proteins kinase C), inhibit PC phospholipases (which could work either by binding to the active site where PC is formed or by preventing the activation of CEPT1 by PC), or affect the attachment of lipophilic molecules to proteins. Of the compounds tested, cholinephosphotransferase activity was inhibited most efficiently by the protein kinase C inhibitor chelerythrine and the mammalian DAG kinase inhibitor R59949 (Table 4). To establish the efficacy of inhibition, the concentration dependence of these two inhibitors was examined. Both chelerythrine and R59949 exhibited an IC<sub>50</sub> of 40  $\mu$ M (Fig. 3).

## DISCUSSION

One of the major obstacles to accurately assessing the properties of mammalian cholinephosphotransferase enzymes has been the use of cellular membranes as the enzyme source. Our

recent isolation of two separate human cDNAs, CEPT1 coding for a dual-specificity choline/ethanolaminephosphotransferase enzyme (1) and CPT1 coding for a cholinephosphotransferase-specific enzyme (2), has complicated the interpretation of previous analyses of these enzyme activities. It is not known if one or both of these enzymes were present in the preparations used as the cholinephosphotransferase enzyme source (4,6,8–11,22,23,28,39,40). Previously, we developed an expression system in *S. cerevisiae* that was devoid of its endogenous cholinephosphotransferase and ethanolamine-phosphotransferase activities; mutational inactivation of the respective encoding genes allowed for the individual assessment of heterologously expressed cholinephosphotransferase and ethanolaminephosphotransferase enzymes. We also used this system to examine the kinetic properties and substrate specificities of the human CEPT1- and CPT1-encoded enzymes (1,2). In these studies a small amount of detergent was used to solubilize the diradylglycerol substrate to aid its delivery to the isolated membranes in an aqueous solution. This was the most popular method of assaying cholinephosphotransferase and ethanolaminephosphotransferase activities of these enzymes, and it allowed the properties of human CEPT1 and CPT1 to be compared to those in the literature. However, delivery of an excess of the CEPT1 lipophilic substrates in the presence of a small amount of detergent dramatically altered the physical state in which the enzyme resides. Thus, it was difficult to determine whether the observed differences in activity reflected true enzymatic and substrate specificity parameters or alterations in the membrane environment in which the integral membrane protein resides, which ultimately determine the activity of the enzyme. To circumvent this problem, a mixed micellar system was developed to study CEPT1. The current system solubilizes the membrane in which the enzyme resides (in the presence of excess detergent) such that exogenously added lipids represent 10 mol% or less of the detergent added to solubilize the membranes; thus, the physical parameters on the membrane are not altered by the exogenous lipids (24–34). This allows for a more accurate assessment of substrate specificity and lipid activation. The mixed micellar enzyme assay was used to determine kinetic parameters, diradylglycerol substrate specificity, lipid activation, and inhibition by both lipophilic and soluble compounds that were previously known to alter the activity of other DAG-utilizing or responsive enzymes toward the human CEPT1-encoded choline/ethanolaminephosphotransferase.

When mixed micelle conditions were established to examine CEPT1 properties, we discovered that neither human CEPT1 nor CPT1 was active when assayed using the Triton X-100-based mixed micelle assay we had previously used to characterize the yeast Cpt1p and Ept1p enzymes (3). This was surprising based on the high degree of predicted conservation of primary and secondary structures between the yeast and human enzymes. The ability to catalyze a CDP-alcohol phosphotransferase reaction using sodium cholate was found with

**FIG. 3.** Inhibition of CEPT1 activity by chelerythrine and R59949 (Bio-Mol, Plymouth Meeting, MA). Human CEPT1 was expressed in *S. cerevisiae* cells devoid of their endogenous cholinephosphotransferase and ethanolaminephosphotransferase activities. CEPT1 cholinephosphotransferase activity for the synthesis of PC was assayed using the mixed micelle method, as described in the Materials and Methods section, with the indicated concentrations of (A) chelerythrine or (B) R59949. The results are means of three separate experiments. SEM were less than 15% for each point. For abbreviations see Figure 1.

mammalian CEPT1 but not human CPT1. Based on this observation, we predicted that when assaying mammalian cellular membranes we could use the sodium cholate assay to measure enzyme activity for specific determination of CEPT1-dependent cholinephosphotransferase activity.

The kinetic parameters for substrate CDP-alcohol substrate affinity were similar for the emulsion (1,2) and the mixed micellar-based assay using di-18:1 DAG as the phosphobase acceptor. Apparent  $K_m$  values were 36–37  $\mu\text{M}$  for CDP-choline and 98–101  $\mu\text{M}$  for CDP-ethanolamine. Apparent  $V_{\text{max}}$  values were also similar. The cholinephosphotrans-

ferase reaction catalyzed at a rate of 10.5  $\text{nmol min}^{-1} \text{mg}^{-1}$  using the emulsion-based assay and 14.3  $\text{nmol min}^{-1} \text{mg}^{-1}$  for the mixed micelle assay, whereas the ethanolaminephosphotransferase reaction catalyzed at a rate of 4.4  $\text{nmol min}^{-1} \text{mg}^{-1}$  when the di-18:1 DAG was delivered as an emulsion and at 8.2  $\text{nmol min}^{-1} \text{mg}^{-1}$  when di-18:1 DAG was presented in mixed micelle form.

A comparison of the diradylglycerol substrate specificity of CEPT1 using emulsion-based vs. mixed micelle assays revealed major differences in substrate specificity. One of the main differences was in the ability of the cholinephosphotransferase reaction of CEPT1 to synthesize PAF *de novo*; it was very efficient in the emulsion assay but was undetectable in the mixed micelle assay (2,16). Indeed, with regard to the cholinephosphotransferase reaction of CEPT1 using the emulsion-based assay, the diradylglycerol substrate specificity by and large reflected the solubility of the lipophilic substrate in aqueous solutions. Using the mixed micelle assay, the preferred diradylglycerols reflected those normally found within cellular membranes. The differences in ethanolaminephosphotransferase activity of CEPT1 were not as drastic as for the cholinephosphotransferase activity, as the emulsion-based assay for ethanolaminephosphotransferase activity had a much narrower DAG species profile. A similar profile, although with a moderately expanded DAG substrate species capability, was observed for the ethanolaminephosphotransferase of CEPT1 using the mixed micelle assay.

The mixed micelle substrate specificity preferences were consistent with previous analyses of metabolic labeling of hepatocytes in cell cultures. Analysis of the DAG cellular specificity for PC that had been synthesized *de novo* through the CDP-choline pathway revealed that DAG containing saturated and monounsaturated FA were the preferred substrates (41). However, this same study revealed that PE synthesized *de novo* and catalyzed by ethanolaminephosphotransferase contained a higher percentage of polyunsaturated double bonds. A more recent study using deuterated precursors and MS analysis of the lipids synthesized in a hepatocyte cell line predicted that 16:0/18:1 DAG and di-18:1 DAG were the preferred substrates for the *de novo* synthesis of PC by cholinephosphotransferase and also that 16:0/18:1 DAG and di-18:1 DAG were the preferred substrates for *de novo* ethanolaminephosphotransferase synthesized PE (42). The results from this study closely parallel the DAG fatty acyl species specificity determined in our mixed micellar analysis of CEPT1 cholinephosphotransferase and ethanolaminephosphotransferase activities.

Similar to the yeast Cpt1p and Ept1p enzymes (3), human CEPT1 were activated by phospholipids. However, the yeast enzymes displayed an absolute requirement for phospholipid activation, whereas the human CEPT1 enzyme was active without the addition of exogenous phospholipids but could be further activated by including phospholipids in the micelle. In the mixed micelle assay, detergent was added in excess such that the lipid present in the enzyme source was diluted to negli-

gible levels. Similar to the yeast Cpt1p and Ept1p enzymes, human CEPT1 appears to possess distinct binding sites on the enzyme for phospholipid, and occupation of these site(s) alters enzyme activity. However, unlike the yeast enzyme activities, human CEPT1 activity was not completely dependent on exogenous phospholipid. At a fixed concentration of 10 mol%, several membrane phospholipids were capable of fully supporting CEPT1-derived cholinephosphotransferase and ethanolaminephosphotransferase activity. TAG was not an activator of CEPT1, implying that a phosphobase was required for activation. Interestingly, PC was one of the best activators of CEPT1, which implies that a form of product activation may exist *in vivo*. The local microconcentration of PC at the site of CEPT1 in the cell was expected to be high, as CEPT1 continually synthesizes PC. This was also true for PE activation of the ethanolaminephosphotransferase property of CEPT1, although it was far less pronounced than for the cholinephosphotransferase activity. As the cholinephosphotransferase and ethanolaminephosphotransferase steps are generally not rate limiting in the synthesis of PC and PE in cells, product activation might be a mechanism by which CEPT1 does not impinge on the rate of synthesis for PC and PE, as determined by the upstream rate-limiting enzymes (43–45).

Using an emulsion-based assay, farnesol was previously identified as an *in vitro* inhibitor of human CEPT1 activity (36,37). Further work with this assay demonstrated farnesol does not inhibit the CEPT1 enzyme but instead appears to inhibit CEPT1 over time by providing a membrane environment in which it is progressively inactivated (21,28). Using a mixed micelle method in which the added lipid did not dramatically alter the environment in which the enzyme resides, we were unable to detect significant inhibition of CEPT1 activity by farnesol (21). Using our method we investigated inhibitors of CEPT1 cholinephosphotransferase activity by using compounds previously identified as either inhibiting the activity of enzymes that also metabolize DAG or compounds that are known to interfere with DAG activation of proteins. Of the compounds tested, the human DAG kinase inhibitor R59949 (46) and the protein kinase C inhibitor chelerythrine (47) were the best inhibitors of CEPT1 activity. The  $IC_{50}$  concentrations required for *in vitro* inhibition of CEPT1 cholinephosphotransferase activity were 40  $\mu$ M for both compounds. This was dramatically higher than those for *in vitro* human DAG kinase inhibition by R59949 (0.3  $\mu$ M) and chelerythrine inhibition of protein kinase C (0.66  $\mu$ M). However, chelerythrine has been shown to inhibit PC synthesis and cause apoptosis in cells at concentrations that effectively inhibit CEPT1 activity *in vitro* (36). Induction of apoptosis by chelerythrine could be altered by the addition of exogenous PC, implying that PC metabolism may play a role in chelerythrine-mediated apoptosis (36). The role of CEPT1 inhibition by chelerythrine in the regulation of chelerythrine-induced apoptosis is currently under study.

An accurate determination of the fatty acyl specificity of lipid-metabolizing enzymes is of great interest, as this can de-

fine the molecular mechanism by which the enzyme contributes to the apportionment of FA within phospholipids. All of the characteristics observed in this study can be attributed to human CEPT1, as the expression system used resulted in human CEPT1 as the sole cholinephosphotransferase and ethanolaminephosphotransferase encoding activity being expressed. We characterized human CEPT1 using a mixed micellar assay system as a means to separate the physical effects of lipid substrates and activators on the membranes in which CEPT1 resides from true enzymatic effects of the added lipids. The results presented are more reflective of those observed in cell cultures for CEPT1 substrate specificity through metabolic labeling analyses than those in previous emulsion-based analyses of CEPT1. Notably, PAF could not be synthesized *de novo* by CEPT1 using the mixed micelle method even though it was synthesized in abundance when using the emulsion-based assay (2,16). As PAF is a very potent inflammatory mediator, a precise knowledge of its possible biosynthetic routes is essential.

## ACKNOWLEDGMENTS

This work was supported by operating and group grants from the CIHR to CRM. CRM is an IWK senior clinical research scholar. MMW is supported by a CaRE Nova Scotia Ph.D. studentship. The authors thank Annette Henneberry and Jason Williams for initial characterization of CEPT1 using the mixed micelle assay and Harold Cook, David Byers, and Neale Ridgway for helpful discussions throughout the course of this study.

# Effect of Fenitrothion on the Physical Properties of Crustacean Lipoproteins

C.F. Garcia, M. Cunningham, M.R. González-Baró, H. Garda\*, and R. Pollero

Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET)-Universidad Nacional de La Plata (UNLP), (1900) La Plata, Argentina

**ABSTRACT:** The effect of the liposoluble organophosphorus insecticide fenitrothion (FS) on lipid packing and rotation of two crustacean plasma HDL was investigated. These lipoproteins, HDL-1 and HDL-2, differed in their lipid composition, but their lipid/protein ratios were similar. The rotational behavior of the fluorescent probes 1,6-diphenyl-1,3,5-hexatriene (DPH) and 3-(*p*-(6-phenyl)-1,3,5-hexatrienyl) phenylpropionic acid (DPH-PA) was used to obtain information about the lipid dynamics in the outer and inner regions, respectively, of the lipid phase of the lipoproteins. Fluorescent steady-state anisotropy ( $r_s$ ), lifetime ( $\tau$ ), rotational correlation time ( $\tau_r$ ), and the limiting anisotropy ( $r_\infty$ ) of these probes were measured in the lipoproteins exposed to different concentrations of FS *in vitro*. The results showed the penetration of FS into both plasma lipoproteins, altering the lipid dynamics of the inner as well as the outer regions. The overall effect of the insecticide was to induce an increase in the lipid order in a concentration-dependent fashion. DPH and DPH-PA fluorescence-lifetime shortening indicated that FS increased the polarity of the probe environment, suggesting an enhanced water penetration into the lipoprotein lipid phase, may be due to the induction of failures in the lipid packing. Even in the absence of FS, a higher ordering of the lipid phase was found in HDL-2 compared to HDL-1, a fact that might be attributed to a higher percentage of sphingomyelin in HDL-2.

Paper no. L8954 in *Lipids* 37, 673–679 (July 2002).

The toxic effects of organophosphorus insecticides on target and nontarget organisms have been described in several studies, although only a few have reported the effects of these xenobiotics on the lipid metabolism. These insecticides are known to cause neurotoxic effects by inhibiting acetylcholinesterase and other enzymes (1,2). The proper function of integral membrane proteins depends on the environment, specifically, the membrane structure. This fact prompted several groups to investigate the alterations in the physicochemical properties of membranes produced when these insecticides, which are mostly liposoluble, are inserted into the lipid bilayers. In this regard, studies done in natural membranes from mammals and some other vertebrates (3–5), an invertebrate (6), and in artificial membranes (7,8) have shown the

Abbreviations:  $\Delta$ , polarized phase shift; DPH, 1,6-diphenyl-1,3,5-hexatriene; DPH-PA, 3-(*p*-(6-phenyl)-1,3,5-hexatrienyl) phenylpropionic acid; FPLC, fast-flow protein liquid chromatography; FS, fenitrothion;  $r_0$ , fundamental anisotropy;  $r_s$ , steady-state anisotropy;  $r_\infty$ , limiting anisotropy;  $\tau$ , lifetime;  $\tau_M$ , modulation lifetime;  $\tau_p$ , phase lifetime;  $\tau_r$ , rotational correlation time.

overall alterations on membrane lipid dynamics produced by organophosphorous insecticides.

We hypothesized that these liposoluble xenobiotics might also alter other lipoprotein systems such as the circulating lipoproteins, so we carried out the present work using as models the insecticide fenitrothion (FS) and two high-density hemolymphatic lipoproteins from the decapod crustacean *Macrobrachium borellii*. Lipids in crustaceans are transported by HDL-1 and HDL-2 (9). HDL-1 is present in the plasma of both males and females. In *M. borellii* it is a particle of 295 kDa composed of three apolipoproteins of 124, 26, and 23 kDa that transport exogenous and endogenous lipids. HDL-2, also called vitellogenin, is only present in females during the vitellogenic periods; its function is to carry the yolk precursors from extra-ovarian synthesis sites to the ovocyte. The *M. borellii* native lipoprotein (440 kDa) has three apolipoprotein subunits (94, 26, and 23 kDa) (Garcia, C.F., unpublished results). Although both serum lipoproteins have high phospholipid contents, their lipid compositions are different. Taking into account the different functions and phospholipid contents of HDL-1 and HDL-2, and their similar lipid/protein ratio, we considered them as an appropriate model to study the effect of insecticides on the physicochemical properties of lipoproteins, correlating their structural and functional characteristics with FS sensitivity. This may be of physiological interest since alterations in the physical properties of these lipoproteins affect lipid transport *in vitro*, and they may influence the lipid exchange among tissues.

The rotational behavior of 1,6-diphenyl-1,3,5-hexatriene (DPH) and 3-(*p*-(6-phenyl)-1,3,5-hexatrienyl) phenylpropionic acid (DPH-PA) was studied to investigate the effect of FS on the dynamics of the lipoprotein lipid phase. Whereas the neutral DPH senses mainly the hydrophobic deep interior of the lipoprotein lipid phase, the anionic DPH-PA is anchored to the interface through its carboxylate group, and it locates its fluorescent moiety more externally. Fluorescence lifetime, and steady-state and frequency-resolved anisotropy measurements were made. They allowed us to evaluate the polarity of the probe's environments, as well as to resolve the probe rotation in terms of rate and amplitude, which are indicative of the lipid phase fluidity and ordering, respectively.

## MATERIALS AND METHODS

*Sampling and isolation of lipoproteins.* Male and ovogenic female adult specimens of *M. borellii* were collected in a

watercourse close to the Rio de la Plata, Argentina. After severing their heads, the shrimps were placed in a tube and centrifuged at low speed to obtain hemolymph. The lipoproteins under study were isolated by density gradient ultracentrifugation. Aliquots of plasma were overlaid on 3 mL NaBr solution (density 1.26 g/mL) containing 0.01% sodium azide and centrifuged at  $178,000 \times g$  at  $10^\circ\text{C}$  for 24 h in a Beckman L8 70-M centrifuge, using a SW60 Ti rotor. The total volume of the tubes was fractionated from top to bottom into 0.2-mL aliquots. The protein content of each fraction was monitored spectrophotometrically at 280 nm. One tube containing a NaCl solution (density 1.04 g/mL) instead of plasma was centrifuged simultaneously and fractionated in order to determine the density of the fractions by monitoring the refraction indexes.

**Lipid and protein analysis.** Lipids were extracted following the method of Folch *et al.* (10). Quantitative determinations of lipid classes were performed by TLC coupled to an FID in an Iatroscan apparatus Model TH-10, after separation on Chromarods SIII, using a triple development solvent system as described previously (11). All lipid classes were quantified using MAG as internal standard. Total protein concentration in each fraction isolated from the density gradient was measured colorimetrically by the method of Lowry *et al.* (12).

**In vitro determination of FA binding to HDL-1.** Total serum of *M. borellii* was incubated with 0, 20, and 40 ppm FS for 2 h. Afterward, the FA-binding capacity was assayed with 0.5  $\mu\text{Ci}$  (9 nmol) of  $[1-^{14}\text{C}]$ palmitic acid (NEN, Boston, MA) as ammonium salt for 30 min. To isolate the labeled HDL-1, plasma hemolymph was analyzed under nondenaturing conditions by preparative gel filtration fast-flow protein liquid chromatography (FPLC) on a Superdex 200 HR 10/30 column (Amersham-Pharmacia, Uppsala, Sweden) using 0.1 M Tris-HCl pH 8.0 at a flow rate of 0.4 mL/min. Protein was detected at 280 nm. The column was calibrated with thyroglobulin, ferritin, BSA, and ribonuclease A (Amersham-Pharmacia) as protein markers. The HDL fraction was collected based on the retention time and relative mass ratio. The identity of HDL-1 was corroborated by PAGE, the protein concentration was determined (12), and the radioactivity of the palmitic acid bound to each protein peak was quantified by liquid scintillation counting.

**Fluorescent measurement.** All measurements were made in a SLM 4800 C phase-modulation spectrofluorometer (SLM Instruments Inc., Urbana, IL). For labeling, 3 mL of buffer solution lipoproteins (100  $\mu\text{g}/\text{mL}$ ) were mixed with a few microliters of concentrated DMSO solutions of DPH or DPH-PA (final concentration 4  $\mu\text{M}$ ). Blanks were prepared in the same way as samples, without the fluorescent probes but with addition of the same volume of DMSO as reference in order to correct fluorescence intensities for nonspecific fluorescence and light-scattering. Samples were gently swirled at  $20^\circ\text{C}$  for at least 2 h, in the absence of light, to allow a complete equilibration of the probes with the lipoproteins. FS from ethanolic concentrated solutions (1, 10, and 20 ppm) was added to samples prior to equilibration.

*Lifetime, steady-state, and dynamic polarization measure-*

*ments.* Polarized phase shift ( $\Delta$ ), steady-state anisotropy ( $r_s$ ), and lifetime ( $\tau$ ) were measured according to Lakowicz *et al.* (13,14) with modifications (15,16). The excitation wavelength was 361 nm, and the emitted light passed through a sharp cut-off filter at 389 nm to eliminate light of wavelengths below 389 nm.

Measurements of  $\tau$  were obtained with the exciting light amplitude-modulated at 18 and 30 MHz by a Debye-Sears modulator and vertically polarized by a Glan-Thompson polarizer. The emission light passed through the filter and then through a Glan-Thompson polarizer oriented  $55^\circ$  to the vertical to eliminate effects of Brownian motion (17). The phase shift and demodulation of the emitted light relative to a reference of known  $\tau$  were determined and used to compute the phase lifetime ( $\tau_p$ ), and the modulation lifetime ( $\tau_M$ ) of the sample (17). POPOP (1,4-bis(5-phenyloxazol-2-yl)benzene) in ethanol, which has a  $\tau$  of 1.35 ns (14–19) was used as reference. The differential polarized phase shift ( $\Delta$ ) was determined according to Lakowicz *et al.* (13,14) by exciting with light modulated at 18 and 30 MHz and vertically polarized, and by measuring the phase difference between the parallel and perpendicular components of the emitted light.

The measured values of  $r_s$ ,  $\tau$ , and  $\Delta$ , and the fundamental anisotropy ( $r_0$ ), which had previously been estimated as 0.390 (20), were used to calculate the limiting anisotropy ( $r_\infty$ ) and the rotational correlation time ( $\tau_r$ ), which is the inverse of the rotational rate, as previously described (15,16) in accordance with the theory developed by Weber (21).

## RESULTS

**Separation and analysis of lipoproteins.** Plasma hemolymph was separated by density gradient ultracentrifugation into HDL-1 (hydrated density 1.13 g/mL), which is found in animals of both sexes, and HDL-2 (hydrated density 1.18 g/mL), which is found only in females at the vitellogenic stage.

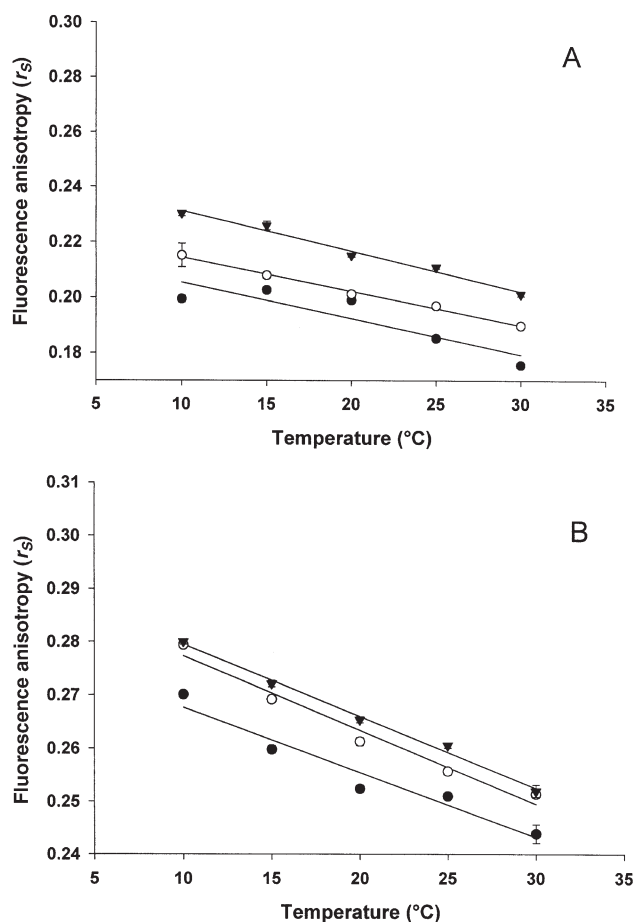

Lipid composition, determined by TLC-FID, is shown in Table 1. The predominant lipid class in both lipoproteins is PC, which is found in a higher proportion in HDL-1, whereas

**TABLE 1**  
Lipid Composition<sup>a</sup> and Lipid/Protein Ratio of Lipoproteins Isolated from Plasma of *Macrobrachium borellii*

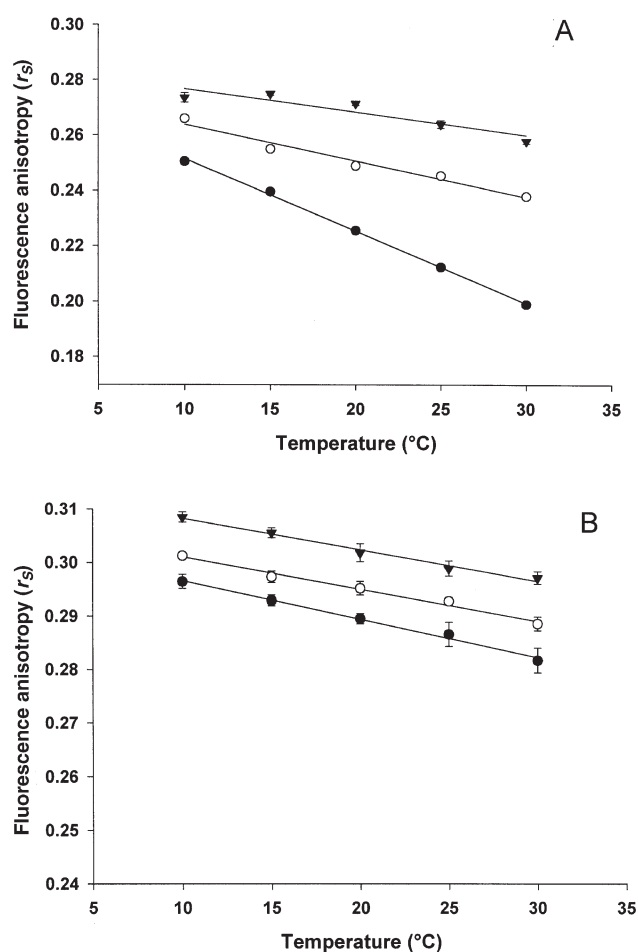

Lipid classes	Fraction	
	HDL-1	HDL-2
TAG (%)	15.2 $\pm$ 2.3	16.3 $\pm$ 0.8
FFA (%)	11.7 $\pm$ 0.6	12.3 $\pm$ 0.7
Cholesterol (%)	14.6 $\pm$ 2.0	12.3 $\pm$ 2.0
PE (%)	19.5 $\pm$ 0.3	16.9 $\pm$ 1.9
PC (%)	38.8 $\pm$ 4.5	22.1 $\pm$ 2.3
Sphingomyelin (%)	Trace	18.8 $\pm$ 1.7
Total lipids (mg/mL hemolymph)	3.3 $\pm$ 0.4	4.67 $\pm$ 0.4
Total proteins (mg/mL hemolymph)	2.9 $\pm$ 0.3	4.45 $\pm$ 0.2
Lipid/protein ratio	1.13	1.04
Hydrated density (g/mL)	1.11–1.13	1.16–1.19

<sup>a</sup>Data on lipid classes are expressed as weight percentage as determined and quantified by TLC-FID. Values represent the mean  $\pm$  SD of three independent analyses.

**FIG. 1.** Effect of fenitrothion (FS) on HDL-1. 1,6-Diphenyl-1,3,5-hexatriene (DPH) (A) and 3-(*p*-(6-phenyl)-1,3,5-hexatrienyl) phenylpropionic acid (DPH-PA) (B) fluorescence anisotropy ( $r_s$ ) vs. temperature, in the absence (●) and the presence of 10 (○) and 20 (▼) ppm of FS. Values represent the average of five different determinations  $\pm$  SD. The linear correlation coefficients ranged between 0.790 and 0.999.

**FIG. 2.** Effect of FS on HDL-2. DPH (A) and DPH-PA (B) fluorescence anisotropy ( $r_s$ ) vs. temperature, in the absence (●) and the presence of 10 (○) and 20 (▼) ppm of FS. Values represent the average of five different determinations  $\pm$  SD. The linear correlation coefficients ranged between 0.850 and 0.999. For abbreviations see Figure 1.

the percentages of PE, TAG, cholesterol, and FFA did not show significant differences between HDL-1 and HDL-2. A relatively high content of sphingomyelin was evident in HDL-2, but it was not present in HDL-1.

The lipid/protein ratio (lower in HDL-2) was consistent with the hydration densities (higher in HDL-2).

*FS increases steady-state anisotropy of DPH-derived fluorophores in HDL-1 and HDL-2.* Different concentrations (1–20 ppm) of FS affect the microenvironment of the fluorescent probes in HDL-1 (Fig. 1) and HDL-2 (Fig. 2). FS increases  $r_s$  either in the hydrophobic core of the lipoproteins, probed with DPH (Fig. 2A), or in the outer regions of the lipoproteins, probed with DPH-PA (Fig. 2B). The observed effect is dependent on the concentration of the pesticide, and it is constant within the temperature range 10–30°C. We used that temperature range because it represents the extremes of temperature recorded in the stream where these animals live.

*Effect of FS on the lifetimes of DPH and DPH-PA and on the lipid order of HDL-1 and HDL-2.* To better understand the effect of FS on the rotational behavior of DPH and DPH-PA,

lifetime and differential polarized phase shifts ( $\Delta$ ) were measured. They were used to calculate  $\tau_r$  and  $r_\infty$  in HDL-1 (Fig. 3) and HDL-2 (Fig. 4). These measurements were made at 18 and 30 MHz. Since the values obtained at both frequencies were similar, only the values of 18 MHz are shown. It is notable that calculation of  $\tau_r$  and  $r_\infty$  from measurements at discrete frequencies requires homogeneity in the rotamer fluorescence lifetime (15,16). For both probes, but especially for DPH (Figs. 3A and 4A), modulation lifetimes ( $\tau_M$ ) are somewhat higher than phase lifetimes ( $\tau_p$ ), indicating some heterogeneity in the fluorophore population. However, the fact that the values of  $\tau_r$  and  $r_\infty$  obtained are relatively independent of the frequency indicates that they are essentially correct average values of the different rotamer populations.

A significant shortening was observed in the fluorescence lifetime ( $\tau_p$  and  $\tau_M$ ) of DPH and DPH-PA incorporated into HDL-1 (Fig. 3) or HDL-2 (Fig. 4) in which different concentrations of FS were added at 10 or 30°C. In the case of HDL-1, FS incorporation did not alter the rotational correlation time ( $\tau_r$ ) of DPH or DPH-PA (Fig. 3). FS also evoked a concentration-

**FIG. 3.** Steady-state fluorescence anisotropy ( $r_s$ ), phase lifetime ( $\tau_p$ ), modulation lifetime ( $\tau_M$ ), rotational correlation time ( $\tau_r$ ), and limiting anisotropy ( $r_\infty$ ) of (A) DPH and (B) DPH-PA in HDL-1 of *Macrobrachium borellii*, measured in the absence or presence of 1, 10, and 20 ppm FS at 10 and 30°C. Student's *t*-test was used to compare the significance of the differences with respect to the sample without FS: \*\*\* $P < 0.001$ , \*\* $P < 0.01$ , \* $P < 0.05$ .

dependent increase in the steady-state and limiting anisotropy of both probes in HDL-1, at both temperatures.

Figure 4(A and B) shows the effect of FS incorporation on HDL-2. A decrease of  $\tau_r$  for DPH after the addition of the toxin was found at both temperatures, whereas for DPH-PA, it was observed only at 30°C. As was found for HDL-1, FS increased  $r_\infty$  significantly for both probes in HDL-2. These results indicate that FS incorporation generated a strong effect on the lipid phase dynamics of HDL-1 and HDL-2 at both temperatures.

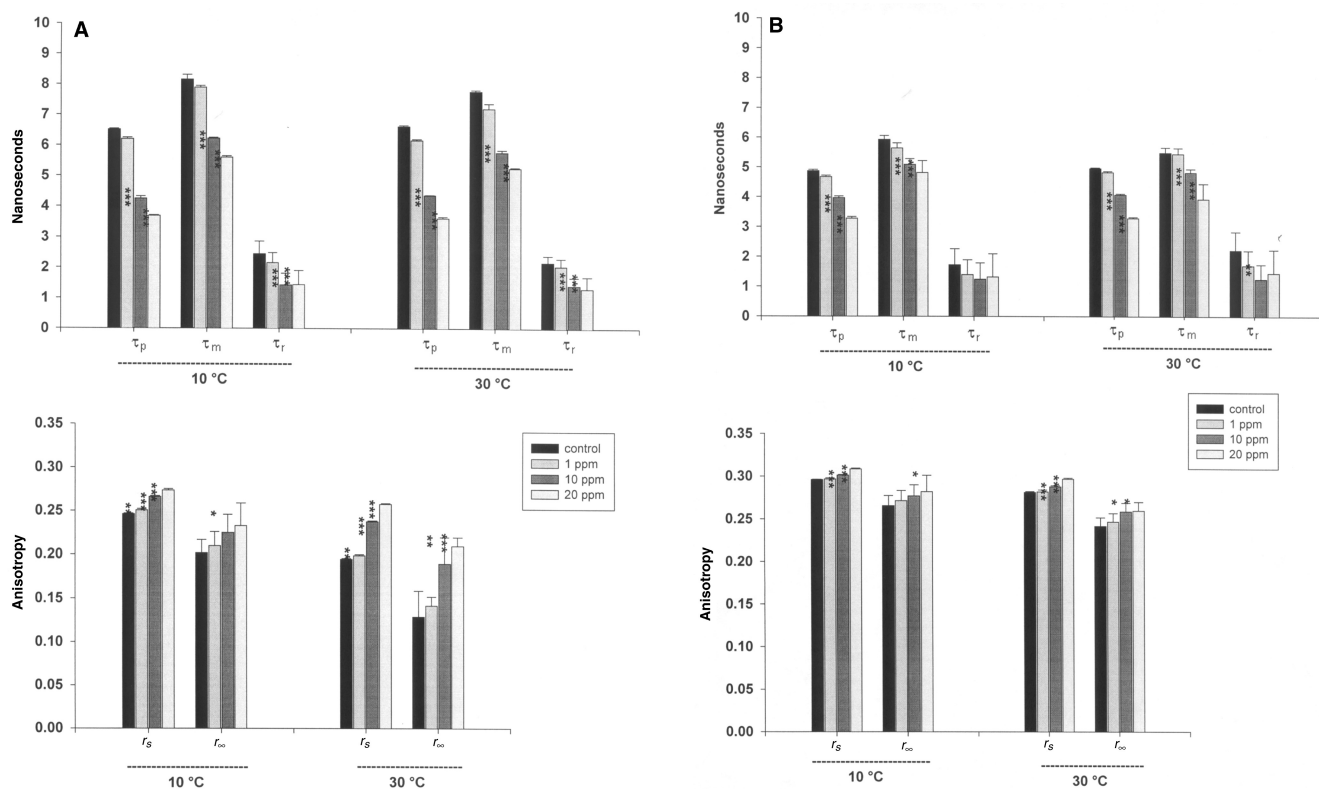

From comparison of both lipoproteins (Figs. 3 and 4), it is evident that for both probes, higher  $r_s$  and  $r_\infty$  values were obtained in HDL-2 than in HDL-1. This fact indicates that HDL-2 has a more ordered lipid phase than HDL-1. On the other hand, the fluorescence lifetimes and  $\tau_r$  of both probes were similar in both lipoproteins.

*FS decreases palmitic acid binding to HDL-1.* In the presence of  $^{14}\text{C}$ -labeled palmitic acid, the only radioactive fraction detected in nonvitellogenic *M. borellii* hemolymph was the one corresponding to the HDL-1. The FPLC retention time and PAGE of the eluted fractions corroborated its identity. When exposed to FS, palmitic acid bound to HDL-1 decreased 1.6-

(20 ppm FS) and 12.6-fold (40 ppm FS), i.e., the radioactivity was 64 and 9% compared to the control, respectively.

## DISCUSSION

Several organophosphorus, chlorinated, and pyrethroid insecticides were reported to affect the fluidity of native and model membranes (22–34). In previous studies using the same insecticide, we demonstrated on the basis of fluorescent anisotropy measurements that FS increases the lipid order in the bilayer of *M. borellii* microsomal membranes, but it does not alter the rotational rate of the DPH and DPH-PA (6). In the present study, the spectroscopic properties of two fluorescent probes located in different regions of the lipoprotein were used to investigate the influence of the insecticide FS, at different concentrations, on the physical state of the lipid phase of two *M. borellii* lipoproteins. One of the probes, DPH, is an elongated molecule, which is a useful fluorophore for studying alterations in the lipid packing and ordering. It penetrates the hydrophobic core of membranes and locates in the acyl chain region. The carboxylate group of the other fluorophore, DPH-PA, interacts with the polar headgroups of the phospholipids,

**FIG. 4.** Steady-state fluorescence anisotropy ( $r_s$ ), phase lifetime ( $\tau_p$ ), modulation lifetime ( $\tau_m$ ), rotational correlation time ( $\tau_r$ ), and limiting anisotropy ( $r_\infty$ ) of (A) DPH and (B) DPH-PA in HDL-2 of *M. borellii*, measured in the absence or presence of 1, 10, and 20 ppm FS at 10, and 30°C. Student's *t*-test was used to compare the significance of the differences with respect to the sample without FS: \*\*\* $P < 0.001$ , \*\* $P < 0.01$ , \* $P < 0.05$ .

locating the fluorescent moiety more outwardly than in the case of DPH. Both probes are preferentially oriented with their long axis parallel to the acyl chains, and the motion that causes depolarization is the wobbling that displaces this long axis.

The increase in  $r_s$  of DPH and DPH-PA generated by FS addition demonstrated that this insecticide modifies the physical properties of the lipid phases in the hydrophobic core as well as in the outer region of both lipoproteins. A rigidifying effect of FS is suggested by the increased  $r_s$  values, although this general parameter depends not only on the rotational behavior but also on the fluorescent lifetime. The shortening in the fluorescent lifetime produced by FS is one of the facts causing the increase in  $r_s$ . However, the results of the differential polarization phase measurements confirm that FS produces a rigidifying effect on these lipoproteins by increasing the lipid phase ordering, evoked through the hindering of the probes' wobbling amplitude resulting in an increased  $r_\infty$ . On the other hand, the rotational rate of these probes is not restricted by the incorporation of FS. At least at 30°C, FS seems to increase the rotational rate of both fluorophores slightly, as indicated by the decrease in  $\tau_r$ , in HDL-2, but  $\tau_r$  remained unchanged in HDL-1 after FS addition. We can therefore assume that the main parameter modified by FS is the lipid order.

The interaction of pyrethroids with liposomal phospholipids evidenced a lower lipid order and a shortening in the DPH lifetime (23). On the contrary, the present results showed that FS decreased DPH and DPH-PA fluorescence lifetime but increased the lipid order in HDL-1 and HDL-2. It is unlikely that this lifetime decrease is due to the direct quenching by FS of the probes' fluorescence, since as previously demonstrated the fluorescence intensity and lifetime of DPH in ethanol were not affected by a large excess of FS (6). Then, the observed decrease in the fluorescence lifetime of these probes is caused by the alterations produced by FS within the structure of the lipoprotein lipid phase. Defects caused by FS in the lipid packing can allow increased water penetration into the hydrophobic interior of these systems, consistent with observations in natural (6) and artificial membranes of 1-palmitoyl-2-oleoyl and dipalmitoyl PC (8).

The action of organophosphorus insecticides on membranes has been related to cholesterol content in those membranes (5). Thus, high proportions of cholesterol preclude the insecticide insertion into the membrane. Although cholesterol content is relatively high in both lipoproteins of *M. borellii*, this does not seem entirely to hinder FS insertion into the lipid phase.

The present results also indicate that HDL-2 has a higher ordering of the lipid phase than HDL-1, a fact that can be at-

tributed to the different lipid compositions of both lipoproteins. The main difference in composition is the presence of sphingomyelin in HDL-2 but not in HDL-1. It is well-known that sphingomyelin has a rigidifying effect on membranes (35), lipid monolayers (36), liposomes (37), and some human lipoproteins (38), but its physiological function in plasma is still controversial. It was postulated that sphingomyelin may act as an inhibitor of lipoprotein peroxidation because of its rigidifying effect, which may hinder the lateral propagation of the lipid-peroxy radicals (39). In this way, the presence of sphingomyelin in HDL-2 rather than in HDL-1 could be important for yolk synthesis. DNA damage in the embryo could be minimized if the precursor is peroxide-poor. This fact would explain the higher  $r_s$  and  $r_\infty$  values found in HDL-2. Thus, FS is able to penetrate the lipid phase of HDL-2 and produce a further ordering increase; this effect is especially noticeable at 30°C.

In brief, these results show that FS can be a perturbing agent to the circulating lipoproteins of *M. borellii*, increasing their lipid phase order, producing packing defects, and thus affecting their structures and functions. In HDL-1, a decrease in the binding of palmitic acid was observed, implying that the proper structure of the lipoprotein is essential for the lipid-binding capacity. Although PC is the major lipid class in HDL-1, we have previously observed in *in vivo* studies that HDL-1 can exchange FA with the hepatopancreas in *M. borellii* (40). In this regard, insecticide actions can be important from both the physiological and toxicological points of view.

**ABSTRACT:** *Cis*-9,*trans*-11 and *trans*-7,*cis*-9 CLA are the most prevalent CLA isomers in milkfat. The majority of *cis*-9,*trans*-11 CLA is synthesized endogenously by  $\Delta^9$ -desaturase. We tested the hypothesis that *trans*-7,*cis*-9 CLA originates from endogenous synthesis by inhibiting  $\Delta^9$ -desaturase with a source of cyclopropene FA (sterculic oil: SO) or with a *trans*-10,*cis*-12 CLA supplement. Experiment 1 (four cows; Latin square) involved four treatments: control, SO, partially hydrogenated vegetable oil (PHVO), and PHVO + SO. Milk, plasma, and rumen fluid were collected. Experiment 2 treatments (four cows) were 0 or 14.0 g/d of 10,12 CLA supplement; milk and plasma were collected. Samples were analyzed by GC and Ag<sup>+</sup>-HPLC to determine FA. In Experiment 1, SO decreased milkfat content of *trans*-7,*cis*-9 CLA by 68 to 71% and *cis*-9,*trans*-11 CLA by 61 to 65%. In Experiment 2, the 10,12 CLA supplement decreased milkfat content of *trans*-7,*cis*-9 CLA and *cis*-9,*trans*-11 by 44 and 25%, respectively. Correcting for the extent of treatment-induced inhibition of  $\Delta^9$ -desaturase based on changes in myristic and myristoleic acids, endogenous synthesis of *trans*-7,*cis*-9 CLA represented 85 and 102% in Experiments 1 and 2, respectively. Similar corrected values were 77 and 58% for endogenous synthesis of *cis*-9,*trans*-11 CLA. Thus, milkfat *cis*-9,*trans*-11 CLA was primarily from endogenous synthesis with a minor portion from rumen escape. In contrast, *trans*-7,*cis*-9 CLA was not present in rumen fluid in significant amounts. Results indicate this isomer in milkfat is derived almost exclusively from endogenous synthesis *via*  $\Delta^9$ -desaturase.

Paper no. L9018 in *Lipids* 37, 681–688 (July 2002).

CLA have been reported to have many positive health effects in biomedical studies with animal models (1). Given that CLA are simply positional and geometric isomers of octadecadienoic acid, many combinations of double bond positions and conformations are theoretically possible, and several have been detected in ruminant fat using highly selective methods. CLA were thought to be somewhat unique to ruminants because of ruminal biohydrogenation; at present, 19 isomers have been identified in milkfat (2), and 14 have been reported in beef fat (3). *Cis*-9,*trans*-11 CLA and *trans*-7,*cis*-9 CLA are the most prevalent isomers; together they generally account for 75 to 80% of the CLA found in food products derived from ruminants (2,4).

Abbreviations: PHVO, partially hydrogenated vegetable oil; SO, sterculic oil.

The overwhelmingly predominant CLA isomer found in foods of ruminant origin is *cis*-9,*trans*-11 CLA (2,4,5). This CLA isomer is an intermediate in ruminal biohydrogenation of linoleic acid. Initially, it was thought that the *cis*-9,*trans*-11 CLA in ruminant fats was of rumen origin (see Griinari and Bauman, Ref. 6). By using sterculic acid, a specific inhibitor of  $\Delta^9$ -desaturase, we recently demonstrated that the majority of *cis*-9,*trans*-11 CLA in milkfat is derived from endogenous synthesis *via*  $\Delta^9$ -desaturase with ruminally derived *trans*-11 18:1 as the substrate (7,8). *Trans*-11 18:1 is the only *trans* FA isomer currently described as an intermediate in biohydrogenation. However, many other *trans*-18:1 isomers are found in rumen fluid (9) and milkfat (10), and these are believed to originate from double bond migration or alternative pathways of biohydrogenation (6).

Under certain dietary conditions, *trans*-10,*cis*-12 CLA is found in milkfat, and it represents a contrast to the *cis*-9, *trans*-11 CLA isomer. *Trans*-10,*cis*-12 CLA appears to be exclusively ruminally derived and is a product of ruminal biohydrogenation in which the initial isomerization takes place at the *cis*-9 position of linoleic acid rather than at the *cis*-12 position, as in the more typical pathway (6). The *trans*-10,*cis*-12 CLA isomer causes a reduction in milkfat synthesis and a decrease in  $\Delta^9$ -desaturase in dairy cows (11,12), the latter resulting in a decrease in endogenous synthesis of *cis*-9,*trans*-11 CLA. In growing rodents, *trans*-10,*cis*-12 CLA also reduces body fat accretion (13) and has been shown to reduce the gene expression and enzyme activity for  $\Delta^9$ -desaturase (14–16).

The origin of *trans*-7,*cis*-9 CLA found in ruminant fat has not been established. Given ruminal production of *trans*-7 18:1, we hypothesized that *trans*-7,*cis*-9 CLA would be derived from endogenous synthesis *via*  $\Delta^9$ -desaturase. Our objective was to test this hypothesis using two different *in vivo* approaches to inhibit  $\Delta^9$ -desaturase in lactating dairy cows, one involving the use of cyclopropenoid FA and the other involving a dietary supplement of *trans*-10,*cis*-12 CLA.

## EXPERIMENTAL PROCEDURES

Study protocols and procedures for these experiments were approved by the Cornell University Institutional Animal Care and Use Committee. Studies utilized lactating Holstein cows fitted with rumen fistulae and housed in metabolic tie stalls at the Large Animal Research and Teaching Unit at Cornell University. Cows were fed a total mixed ration formulated using the Cornell Net Carbohydrate and Protein System (17) to meet or exceed predicted nutrient requirements (18). Cows

were given *ad libitum* access to feed with equal portions of fresh feed offered before milking at 0600 and 1800 h.

**Cows and experimental design.** Details of Experiment 1 have been described previously (8). Briefly, four cows ( $115 \pm 9$  d in milk) were used in a  $4 \times 4$  Latin square design. The four treatments were: skim milk (500 mL/d; control), partially hydrogenated vegetable oil (250 g/d; PHVO), sterculic oil (8.8 g/d; SO), and PHVO + SO. Treatments were abomasally infused *via* polyvinyl chloride tubing (0.5 cm i.d.) that passed through the rumen fistula and sulcus omasi into the abomasum (19). One-fourth of the daily treatment dose was infused every 6 h for 4 d with a 6-d interval between treatment periods. Milk samples, collected at both milkings on the last day of treatment, and a plasma sample, collected after the evening milking on the last day of the treatment period, were stored at  $-20^{\circ}\text{C}$  until further analyses. Rumen fluid samples were collected on the last day of each treatment period at 1, 2, and 4 h after the morning feeding. Sampling times were chosen to coincide with maximal rates of biohydrogenation to optimize detection of CLA isomers normally produced in very low amounts (20,21). Rumen samples were centrifuged at  $1,200 \times g$  for 10 min, and the pellet was saved and frozen at  $-20^{\circ}\text{C}$  until further analysis. This fraction represents the fine particles and associated bacteria; the FA intermediates have been shown to be bound to the fine particulate matter in the rumen (22,23).

Details of Experiment 2 have been described previously (24). Briefly, four cows ( $228 \pm 54$  d in milk) were used in a  $4 \times 4$  Latin square design. Treatments were abomasal infusion of four doses of *trans*-10,*cis*-12 CLA. For the present study, only the low-dose (0 g/d; control) and high-dose (14.0 g/d; 10,12 CLA supplement) treatments were utilized. The 10,12 CLA supplement was emulsified in skim milk and infused continuously for 5 d with 7 to 8 d between treatment periods. Milk samples were collected at both milkings on the last day of treatment and stored at  $-20^{\circ}\text{C}$  until further analysis. On day 5 of infusion, seven blood samples were obtained *via* jugular catheter over a 45 min interval at 0900 and 1400 h. Plasma was harvested immediately and stored at  $-20^{\circ}\text{C}$ . Prior to analysis, plasma samples were thawed and pooled by individual animal.

**GC analysis.** Extraction of lipid from milk and plasma samples and preparation of FAME by base-catalyzed transmethylation have been described previously (8,25). The FA of SO were transmethylated by the same procedure used for milkfat. For analysis, the PHVO and the *trans*-10,*cis*-12 CLA supplements were methylated using 1% sulfuric acid in methanol as described by Christie (26).

Rumen sample pellets were freeze-dried and then ground in liquid nitrogen using a mortar and pestle. A composite (0.5 g) was made for individual animals and transferred to a screw-top extraction tube. Water (0.5 mL) was added and the tube was vortexed for 30 s. The sample was acidified by adding 3–4 drops of 2 M HCl and then vortexed for 30 s, sonicated for 5 min, and extracted twice with 4.0 mL hexane/isopropanol (3:2) according to Hara and Radin (27). The combined organic phases were washed with 2.0 mL distilled water

and dried over 1 g sodium sulfate for 30 min. Solvent was evaporated under a stream of  $\text{N}_2$ , and the lipid was stored at  $-20^{\circ}\text{C}$ . FFA were separated from other lipids using 1 g aminopropyl columns (Mega Bond-Elut; Varian Corp.) as described by Bateman and Jenkins (28). Columns were prepared with 6 mL hexane, and lipid samples were dissolved in 1.0 mL hexane and applied to the column. Neutral lipids were eluted from the column with 8.0 mL hexane/isopropanol (3:1). FFA were eluted with 9.0 mL 2% acetic acid in ether and collected. The solvent was then evaporated under a stream of  $\text{N}_2$ , and the lipid was stored at  $-20^{\circ}\text{C}$ . Rumen FFA were methylated using trimethylsilyldiazomethane according to the procedure of Hashimoto *et al.* (29) with modifications. Briefly, FFA were dissolved in 0.4 mL methanol and 1.6 mL toluene. One mL 30 mM trimethylsilyldiazomethane was added and the solution was incubated at room temperature for 30 min. The reaction was stopped using 5–10 drops acetic acid. Five milliliters of water and 1 mL hexane were added and the solution was vortexed. The organic phase was dried over 1 g sodium sulfate for 30 min. The organic phase was transferred to a new tube, and the solvent was evaporated under a stream of  $\text{N}_2$ . The FAME were then dissolved in 0.45 mL hexane for GC analysis.

The FAME from milkfat, plasma, rumen samples, and infused supplements were quantified by GC (Hewlett-Packard GC system 6890+ with an FID) using a SP-2560 capillary column (100 m  $\times$  0.25 mm i.d. with 0.2  $\mu\text{m}$  film thickness; Supelco Inc., Bellefonte, PA). GC parameters for milkfat, plasma, and infused supplements were described previously (8,24). GC parameters for rumen samples were similar except for temperature programming, where the oven temperature was initially held at  $160^{\circ}\text{C}$  for 28 min and then increased at  $5^{\circ}\text{C}/\text{min}$  to  $220^{\circ}\text{C}$  and held at this temperature for 10 min. Each peak was identified and quantified using pure methyl ester standards (Nu-Chek-Prep, Elysian, MN). A butter reference standard (CRM 164; Commission of the European Communities, Community Bureau of Reference, Brussels, Belgium) was used to determine recoveries and correction factors for individual FA.

**HPLC.** The FAME prepared from the samples were also analyzed using an HPLC system consisting of a Waters 996 photodiode array detector, a Waters 2690 separations module (Alliance), and the Millennium<sup>32</sup> chromatography manager, version 3.20 (Waters Corporation, Milford, MA). Three silver ion columns (ChromSpher 5 Lipids,  $250 \times 4.6$  mm; Varian Analytical Supplies, Harbor City, CA) were used in series for the separation of the lipids. The solvent consisted of UV-grade hexane with 0.1% acetonitrile and 0.5% ethyl ether, prepared fresh daily. Ethyl ether was used to reduce analysis time and minimize retention volume drift, which is a well-known problem encountered in working with  $\text{Ag}^+$  HPLC. The column was pretreated daily by eluting with 1% acetonitrile/hexane for 30–60 min prior to sample analysis. A commercial CLA FAME reference was injected two or three times before test portion injections commenced. Typical injections of test portion volumes were 5–15  $\mu\text{L}$ , representing  $<250 \mu\text{g}$

lipid. Identifications were made by co-injection with a reference material or by confirming the retention volume relative to both toluene (0.5% was added to each sample prior to injection) and *cis-9,trans-11* CLA. All the CLA isomers were available commercially, synthesized by isomerization of a commercially available reference with I<sub>2</sub>, or synthesized by conjugation of partially hydrogenated linolenic acids ( $\alpha$  or  $\gamma$ ; Refs. 30,31).

**Calculations and statistical analyses.** The *cis-9,trans-11* CLA peak in the GC analysis method co-elutes with two other CLA isomers—*trans-7,cis-9* CLA and *trans-8,cis-10* CLA (32). Using data from the HPLC analysis, areas for *trans-7,cis-9* CLA, *trans-8,cis-10* CLA, and *cis-9,trans-11* CLA were summed, and the percentage of each isomer contained in the three isomer peak from GC analysis was used to calculate the content of each isomer in a sample. The content of other CLA isomers in samples was then calculated based on their area from HPLC analysis relative to the area for the three isomer peak.

Statistical analysis of Experiment 1 was as a 4 × 4 Latin square using the mixed procedure of SAS (33). The model included effects for period, cow, and treatment. Treatment effects were determined to be significant at  $P < 0.05$  and when this occurred, individual treatments were compared for significant differences using a *t*-test. For Experiment 2, data were analyzed statistically using a two-factor ANOVA for effects of cow and treatment. Treatment effects were determined to be significant at  $P < 0.05$ .

## RESULTS

**Experiment 1.** PHVO was infused to supply additional *trans-11* 18:1 for endogenous synthesis of *cis-9,trans-11* CLA, but it also contained substantial amounts of other *trans-18:1* FA (Table 1). Although no CLA was detectable in the PHVO by GC analysis, isomers were detected by the more sensitive HPLC method. Of the CLA isomers detected, 67% were *trans,trans*, 27% were *cis/trans*, and 4% were *cis,cis*. For the SO supplement, sterculic acid was the major cyclopropenoic FA, but lesser amounts of malvalic acid were also present (Table 1). The SO supplement contained no CLA isomers as determined by GC analysis and was not further analyzed for CLA isomers by more sensitive methods.

Supplements were abomasally infused as an experimental means to bypass possible modification by rumen bacteria. Milk yield was unaffected by treatment, although treatments did modestly reduce milkfat yield and the fat content of milk (8 to 17%; Table 2). Additional details on infusions and performance data, including milk FA composition, have been presented elsewhere (8).

The concentration of *trans-7,cis-9* CLA in FA extracted from rumen fluid samples did not statistically differ from zero ( $P > 0.2$ ), although trace levels were detected in an occasional sample (Table 3). *Trans-7,cis-9* CLA was present in plasma lipids, but no treatment effects were observed (Table 3). In contrast, treatment effects were obvious in milkfat with *trans-7,cis-9* CLA, decreasing 71% when SO and control treatments

**TABLE 1**

<sup>a</sup>Cyclo refers to presence of a cyclopropene ring. In 18:1, cyclo is 7-(2-octyl-1-cyclopropenyl) heptanoic acid (malvalic acid) and in 19:1, cyclo is 8-(2-octyl-1-cyclopropenyl) octanoic acid (sterculic acid).

were compared and 68% when PHVO + SO with PHVO treatments were compared. Relative to the control treatment, infusion of PHVO increased milk content of *trans-7,cis-9* CLA by 26%.

*Cis-9,trans-11* CLA was the most abundant CLA isomer present in rumen fluid, plasma, and milk (Table 3). Treatment effects were observed on the content of this CLA isomer in milk, but not for rumen fluid or plasma. In milk, infusion PHVO increased *cis-9,trans-11* CLA, whereas SO infusion markedly decreased *cis-9,trans-11* CLA by 65% (SO vs. control treatments) and 61% (PHVO + SO vs. PHVO treatments).

*Trans-10,cis-12* CLA was present in FA extracted from rumen fluid, plasma, and milk (Table 3). Treatments that included infusion of PHVO resulted in small increases in the milkfat content of *trans-10,cis-12* CLA, but no changes were observed in rumen fluid or plasma. Small amounts of several other *cis/trans* CLA isomers were also present in plasma and milkfat and there were minor quantitative differences related to treatment (data not presented). However, these isomers were detected at extraordinarily low levels in a region of the chromatogram with known interferences and inadequate confirmation. In rumen fluid, other *cis/trans* CLA isomers were detected only in an occasional sample and the means for these isomers were not statistically different from zero. Several *trans,trans* CLA isomers were also detected, and these minor components were summed into total *trans,trans* CLA isomers (Table 3). Treatments that involved abomasal infusion of PHVO resulted in a small increase in the milkfat content of total *trans,trans* CLA isomers.

The ratio of *cis-9,trans-11* to *trans-11* 18:1 was evaluated because they are intermediates in ruminal biohydrogenation and are related as product and substrate for endogenous

synthesis by  $\Delta^9$ -desaturase. No treatment effects were observed for rumen fluid or plasma, but the ratio in milk was affected (Fig. 1). The SO and PHVO + SO treatments reduced the ratio by 70 and 75% as compared to the control and PHVO treatments, respectively, and PHVO caused a 19% reduction in the ratio as compared to the control treatment. The

ratios of *trans*-7,*cis*-9 CLA to *trans*-6,7,8 18:1 were also evaluated; they followed a similar pattern for the different biological samples and treatments. No treatment differences were observed in the ratio for FA from rumen fluid or plasma. However, SO and PHVO + SO treatments reduced the ratio by 75 and 80%, respectively, when compared with the con-

<sup>a</sup>Cows were abomasally infused with skim milk (control), SO, PHVO, or PHVO + SO. For abbreviations see Table 1.

<sup>b</sup>Statistical probability of treatment effects. When a treatment effect was significant ( $P < 0.05$ ), differences among treatments were compared by *t*-test as indicated by lowercase roman superscripts (a–d) within a row ( $P < 0.05$ ).

<sup>c</sup>These CLA isomers were not detected (ND) in all samples analyzed, and means for these isomers were not statistically different from zero ( $P > 0.2$ ).

**FIG. 1.** Ratios of *cis-9,trans-11* CLA/*trans-11* 18:1; *trans-7,cis-9* CLA/*trans-6,7,8* 18:1; and *trans-10,cis-12* CLA/*trans-10* 18:1 in FA from rumen fluid, plasma, and milk. Cows were abomasally infused with skim milk (control), stercularic oil (SO), partially hydrogenated vegetable oil (PHVO), or partially hydrogenated vegetable oil plus stercularic oil (PHVO + SO). For ratios of *cis-9,trans-11* CLA/*trans-11* 18:1, the respective SEM were 0.003, 0.012, and 0.005 for rumen fluid, plasma, and milkfat. For ratios of *trans-7,cis-9* CLA/*trans-6,7,8* 18:1, the SEM were 0.013 and 0.006 for plasma and milkfat, respectively. Ratios for *trans-7,cis-9* CLA/*trans-6,7,8* 18:1 are not shown for rumen fluid because the concentrations were not significantly different from zero ( $P > 0.2$ ). For ratios of *trans-10,cis-12* CLA/*trans-10* 18:1, the respective SEM were 0.003, 0.006, and 0.001 for rumen fluid, plasma, and milkfat. When a treatment effect was significant ( $P < 0.05$ ), differences among treatments were compared by *t*-test as indicated by letters above columns (a,b,c).

control and PHVO treatments. In contrast, the infusion of PHVO reduced the ratio of *trans-7,cis-9* CLA to *trans-6,7,8* 18:1 by 24% when compared to the control (Fig. 1). Endogenous synthesis of CLA involves addition of a *cis* double bond between carbons 9 and 10 of the substrate FA, either *trans-11* 18:1 or *trans-7* 18:1. Thus, ratio changes for both *cis-9,trans-11* CLA and *trans-7,cis-9* CLA are consistent with endogenous synthesis in the mammary gland via  $\Delta^9$ -desaturase.

The ratio of *trans-10,cis-12* CLA to *trans-10* 18:1 serves as a reference for comparison; both of these FA are intermediates in an alternative pathway in the rumen biohydrogenation of linoleic acid, but there is no known pathway for the endogenous synthesis of *trans-10,cis-12* CLA (6). Infusions of SO had no effect on the ratio in rumen fluid, plasma FA, or milk. Consis-

tent with the presence of *trans-10* 18:1 in PHVO, the treatments involving abomasal infusion of PHVO reduced the ratio in milk (Fig. 1).

**Experiment 2.** To inhibit  $\Delta^9$ -desaturase with *trans-10,cis-12* CLA, the 10,12 CLA supplement was abomasally infused to avoid modification by rumen microbes. Of the CLA isomers present in the supplement, 98.3% was *trans-10,cis-12* CLA and 1.4% was *cis-9,trans-11* CLA. Additional details about the infusion and performance data, including milk FA composition, have been presented (24). Infusion of the 10,12 CLA supplement reduced milkfat content and yield by 46 and 50%, respectively (Table 2).

The CLA compositions of plasma and milk are shown in Table 4; rumen fluid was not sampled. Infusion of the 10,12 CLA supplement resulted in the expected increase in plasma lipid and milkfat content of *trans-10,cis-12* CLA (Table 4). In the case of *trans-7,cis-9* CLA and *cis-9,trans-11* CLA, treatment had no effect on the concentration of these isomers in plasma. However, milk content of *trans-7,cis-9* CLA and *cis-9,trans-11* CLA was decreased by 44 and 25%, respectively, with infusion of 10,12 CLA supplement. Small amounts of other *cis/trans* CLA isomers were detected in plasma lipids and milkfat, and the 10,12 CLA supplement increased their concentration. However, these CLA isomers were detected at very low levels and eluted in a region of the chromatogram with known interferences (data not presented).

The effect of the 10,12 CLA supplement on the ratios of *cis-9,trans-11* CLA to *trans-11* 18:1 and *trans-7,cis-9* CLA to *trans-6,7,8* 18:1 are compared in Figure 2. The ratio of *cis-9,trans-11* CLA to *trans-11* 18:1 was slightly greater in plasma but was markedly reduced in milk (a 46.9% decrease). The ratio of *trans-7,cis-9* CLA to *trans-6,7,8* 18:1 in plasma was not affected by the 10,12 CLA supplement treatment, but was decreased by 64.0% in milkfat (Fig. 2). As expected, infusion of the 10,12 CLA supplement dramatically increased the ratio of *trans-10,cis-12* CLA to *trans-10* 18:1 in both plasma and milk (Fig. 2).

## DISCUSSION

CLA isomers have received a great deal of attention because of the health benefits observed in biomedical studies with animal models (1). Most research with pure isomers has been related to *cis-9,trans-11* CLA with its anticarcinogenic effects and *trans-10,cis-12* CLA for its effects on lipid metabolism. The biological effects of these isomers have been characterized more completely because of their availability in relatively pure form, but it is reasonable that other CLA isomers will also have biological effects. Synthetically produced CLA often contains significant quantities of several isomers and minor quantities of many others. Even ruminant food products, in which the predominant CLA isomer is *cis-9,trans-11*, contain minor quantities of several other CLA isomers (2,4). We have previously shown that *cis-9,trans-11* CLA found in milkfat from dairy cows originates predominantly from endogenous synthesis by  $\Delta^9$ -desaturase (7,8). The second-most

For ratios of *cis*-9,*trans*-11 CLA/*trans*-11 18:1; *trans*-7,*cis*-9 CLA/*trans*-6,7,8 18:1; and *trans*-10,*cis*-12 CLA/*trans*-10 18:1, the respective SEM were 0.002, 0.006, and 0.242 (plasma); and 0.003, 0.013, and 0.099 (milkfat). A significant treatment effect ( $P < 0.05$ ) is indicated by letters above columns (a,b).

prevalent CLA isomer found in the milkfat of dairy cows is *trans*-7,*cis*-9 (2,4). Given that this isomer also contains a *cis*-9 double bond, our objective was to examine the extent to which *trans*-7,*cis*-9 CLA originates *via* endogenous synthesis involving  $\Delta^9$ -desaturase.

Endogenous synthesis of *trans*-7,*cis*-9 CLA would utilize the *trans*-7 18:1 that originates from the metabolism of PUFA by rumen bacteria (6,9). To quantify *trans*-7,*cis*-9 CLA endogenous synthesis, we conducted *in vivo* studies with two inhibitors of  $\Delta^9$ -desaturase, cyclopropenoid FA and *trans*-10,*cis*-12 CLA. *In vivo* studies with chickens, rats, mice, pigs, and cows (see review, Ref. 34) and *in vitro* experiments with cellular extracts (e.g., 35,36) have established that cyclopropenoid FA are potent inhibitors of  $\Delta^9$ -desaturase. Cook *et al.* (37) demonstrated that feeding SO that was formulated to bypass rumen fermentation inhibited  $\Delta^9$ -desaturase and modified milk FA composition in lactating dairy cows. Bickerstaffe and Johnson (38) showed similar results with intravenous infusions of SO to a lactating goat. Experiment 1 utilized SO that was isolated from seeds of the *Sterculia foetida* tree. Two cyclopropenoid FA constituted 62% of the oil: sterculic acid with a ring at the 9-10 position, and malvalic acid with the ring at the 8-9 position. The second method to inhibit  $\Delta^9$ -desaturase used a *trans*-10,*cis*-12 CLA supplement. This specific CLA isomer has been shown to reduce gene expression and inhibit enzyme activity for  $\Delta^9$ -desaturase in hepatic tissue from rodents (14–16). We similarly demonstrated that *trans*-10,*cis*-12 CLA was a very potent inhibitor of  $\Delta^9$ -desaturase activity in lactating cows based on alterations in milk FA composition (11), and it also markedly reduced mRNA abundance for  $\Delta^9$ -desaturase in mammary tissue (12). However, use of *trans*-10,*cis*-12 CLA presents some complications because, in addition to effects on  $\Delta^9$ -desaturase, *trans*-10,*cis*-12 CLA also causes a reduction in milkfat yield (11,24,39).

We observed that the milkfat content of *trans-7,cis-9* CLA was affected by both inhibitors of  $\Delta^9$ -desaturase. The *trans-7,cis-9* CLA concentration was reduced by 70% with the SO infusion (Experiment 1) and by 44% with infusion of the 10,12 CLA supplement (Experiment 2). Quantitatively, this represents a minimal estimate of endogenous synthesis because the inhibition of  $\Delta^9$ -desaturase is not complete. A correction factor for the extent of  $\Delta^9$ -desaturase inhibition can be calculated based on changes in the milkfat content of myristic and myristoleic acids. Milk FA with 14 carbons are almost exclusively synthesized *de novo* by the mammary gland of the dairy cow. Therefore, the magnitude of the reduction in milk content of *cis-9* 14:1 provides a correction factor for the extent of the treatment-induced inhibition of  $\Delta^9$ -desaturase (7,8). Milk content of *cis-9* 14:1 was reduced 84% in response to SO infusion and 43% in response to 10,12 supplement infusion. In applying these correction factors, endogenous synthesis accounted for 85 and 102% of the *trans-7,cis-9* CLA in milkfat for Experiments 1 and 2, respectively. Thus, the *trans-7,cis-9* CLA in milkfat would appear to originate predominantly from endogenous synthesis.

Consistent with *trans-7,cis-9* CLA originating almost exclusively from endogenous synthesis, this CLA isomer was not detected in FA extracted from rumen fluid whereas *cis-9,trans-11* CLA was readily detected. Trace levels of *trans-7,cis-9* CLA were detected in plasma, and this probably relates to *trans-7,cis-9* CLA originating from endogenous synthesis in the small intestine and adipose tissue. We have previously shown that some *cis-9,trans-11* CLA in milkfat is formed from desaturation of *trans-11* 18:1 by tissues other than the mammary gland (8). Approximately 50% of the FA found in milkfat of ruminants are taken up from circulating FA (40). A portion of the circulating lipids originates from FA absorbed from the digestive tract, and  $\Delta^9$ -desaturase has been reported in the small intestine of ruminants (41). The other portion of circulating FA are derived from the mobilization of body fat reserves. In a well-fed lactating cow, approximately 8% of milk FA originate from body reserves, and this percentage increases if intake is inadequate to meet requirements (42,43). The presence of  $\Delta^9$ -desaturase in adipose tissue from sheep and cattle has been established (44,45), and *trans-7* 18:1 of dietary origin is most likely desaturated to *trans-7,cis-9* CLA in this tissue. Indeed, Fritsche *et al.* (3) reported that *trans-7,cis-9* CLA was the second-most prevalent CLA isomer in body fat of cattle. However,  $\Delta^9$ -desaturase is very active in mammary tissue of ruminants (44,46,47), and based on our data, the mammary gland must be the major site for the endogenous synthesis of *trans-7,cis-9* CLA. This is clearly evident by the substantial increase in the ratios of  $\Delta^9$ -desaturase products to substrates when plasma lipids and milkfat (mammary gland) are compared (Figs. 1 and 2). As expected,  $\Delta^9$ -desaturase was also implicated in the endogenous synthesis of *cis-9,trans-11* CLA in both experiments. In applying the correction factor based on myristic and myristoleic acids, endogenous synthesis accounted for 77% of the *cis-9,trans-11* CLA in milkfat in Experiment 1. Likewise, the corrected estimate for Experiment 2 was 58% of *cis-9,trans-11* CLA from

endogenous synthesis, although this estimate was complicated by the marked reduction (50%) in milkfat yield that also occurred. These estimates for endogenous synthesis of *cis-9,trans-11* CLA agree with our previous analysis of the data in Experiment 1 using less sophisticated analytical techniques (8) and other published studies (7).

This is the first investigation to specifically examine the origin of *trans-7,cis-9* CLA found in milkfat of dairy cows. Through the use of two different inhibitors of  $\Delta^9$ -desaturase, we demonstrated that the *trans-7,cis-9* CLA found in the milkfat of dairy cows originates almost exclusively *via* endogenous synthesis by  $\Delta^9$ -desaturase. Consistent with this result, the *trans-7,cis-9* CLA isomer was not present in FA isolated from rumen fluid. Results for *cis-9,trans-11* CLA indicate that endogenous synthesis is also the major source of this isomer in milkfat, but in this case a portion of the *cis-9,trans-11* CLA originates as an intermediate formed in rumen biohydrogenation of linoleic acid.

#### ACKNOWLEDGMENTS

The contributions of Debra A. Dwyer and Dottie I. Ceuter are greatly appreciated. The assistance of Laxminarayan Venkat Ratnam and Kandukuri V. Raman for acquiring *S. foetida* seeds is also gratefully acknowledged. These investigations were supported in part by the National Dairy Council (Rosemont, IL), Valio Ltd. (Helsinki, Finland), the Cornell Northeast Dairy Foods Research Center and the Cornell Agricultural Experiment Station (Ithaca, NY).

**ABSTRACT:** CLA has a range of biological properties, including effects on lipid metabolism and body composition in experimental animals. The prevalent isomer of CLA found in the human diet is 9*c*,11*t*-CLA, and it is predominantly found in products containing fat from ruminant animals. This study investigated the effect of dietary CLA on energy balance in mice. Synthetic CLA reduced body fat in growing male BALB/c mice in a dose-dependent manner over the range 0.25–1.0% w/w CLA in the diet. Weight gain was also reduced at the highest levels of dietary CLA, being only 5.88 ± 2.68 g/4 mice (mean ± 1 SD) after 4 wk of 2.0% CLA in the diet, compared with weight gains of 7.51 ± 2.22 to 8.17 ± 2.34 g/4 mice in the 0–0.5% CLA groups. There was no significant effect on weight gain if diets contained 0.5% synthetic CLA or less. These results suggest that high levels of a synthetic mixture of CLA isomers modify energy metabolism and body composition and that high levels of synthetic CLA impair weight gain and reduce body fat pad mass in growing mice.

Paper no. L8693 in *Lipids* 37, 689–692 (July 2002).

CLA comprises a mixture of positional and geometric isomers of linoleic acid (18:2). Because the major isomer found in tissue is 9*c*,11*t*, it has been suggested that this isomer is the most biologically active. CLA in the human diet comes predominantly from food derived from ruminant animals, especially dairy products. Milkfat typically provides 3–6 mg CLA/g fat, in which the predominant isomer is 9*c*,11*t*. However, recent research indicates that 10*t*,12*c*-CLA is the isomer that most influences body composition (1). By using semipurified CLA isomers or CLA isomer mixtures enriched with 9*c*,11*t*-CLA or 10*t*,12*c*-CLA, Park *et al.* (1) concluded that body composition changes in mice (reduced body fat and increased body water, protein, and body ash) were associated with dietary 10*t*,12*c*-CLA. They found no effects with semipurified 9*c*,11*t*-CLA. Nevertheless, these results are consistent with previous reports that dietary supplementation with synthetic CLA reduces the amount of body fat in experimental mice, rats, and pigs (2–9).

The present study investigated the effect of a range of dietary levels of synthetic CLA, containing a mixture of 9*c*,11*t*-CLA (37%) and 10*t*,12*c*-CLA (46%), on energy balance and body fat mass in mice.

## EXPERIMENTAL PROCEDURES

**Animals and diets.** All the experiments had the prior approval of the Massey University Animal Ethics Committee.

One hundred twenty male weaned but growing BALB/c mice aged 7–8 wk were used. They were kept in stainless steel cages with a mesh front and floor. A sliding tray collected spilled food and waste 2 cm beneath the floor. The animals were maintained at 22 ± 2°C, with a regular 12-h light/dark cycle. For 1 wk prior to the study the mice were fed a standard, milk-free rodent chow pellet (Sharpes Grain and Seed, Palmerston North, New Zealand). The mice were divided into six equal groups that were fed standard isoenergetic diets supplemented with 0.0, 0.1, 0.25, 0.5, 1.0, and 2.0% w/w synthetic CLA (Tonalin; Pharmanutrients, Lake Bluff, IL) for a period of 4 wk.

The aspects of energy balance measured in this study were: (i) food and energy intake; (ii) energy expenditure, by both indirect calorimetry and observed physical activity; (iii) stored energy, obtained from total carcass mass, chemical analysis of body fat, and the mass of dissectible adipose tissue deposits (fat pads).

The diet consisted of approximately 54% bovine skim milk powder, 30% corn flour, and 5% corn oil. In addition, it contained 5% of a mineral and vitamin supplement and 1% cellulose. In mixes where Tonalin was added, the quantity of corn oil included was reduced *pro rata*. Gross energy content of the diet was determined by bomb calorimetry (Gallenramp Autobomb; Watson Victor Ltd., Wellington, New Zealand). The fat content of the diets was determined by the Soxhlet method, using diethyl ether for fat extraction. The protein content was determined by measuring total nitrogen using the Leco® auto-analysis technique (10). In addition, ash was measured by overnight burning in a muffle furnace at 500°C, and dry matter was assessed by drying samples for 16 h at 105°C. CLA was analyzed following accelerated solvent extraction and conversion to methyl esters using boron trifluoride (11). FAME samples were analyzed using a Shimadzu GC-17A gas chromatograph (Shimadzu Corporation, Kyoto, Japan) equipped with an FID, BPX70 capillary column (50 m × 0.22 mm i.d. × 0.25 μm film thickness), and a pre-column (1 m × 0.53 mm i.d., deactivated fused-silica open tubular). Samples were injected on-column, and the FAME separated using a temperature gradient (80–150–220°C) with hydrogen as the carrier gas. Tridecanoic acid was added to the sample before extraction as an internal standard as well as BHT to protect CLA from oxidation.

**Energy intake.** Energy intake was calculated from measurements of the gross energy content of the diet and weekly

measurements of food intake. Since the mice were housed in pairs, energy intake was derived per pair of mice.

**Energy expenditure.** Energy expenditure was calculated from measurements of respiratory gas exchange using an indirect calorimeter. The indirect calorimeter consisted of a Perspex™ box 280 × 350 mm side and 160 mm in height with an open base, under which the caged animals were placed. Gas was drawn from the calorimeter using a Jun ACO 5503 air pump and passed through a Fleisch head (size 00; OEM Medical, Richmond, VA), heated to prevent condensation. A Validyne differential pressure transducer (DP45-16; VacuMed, Ventura, CA) across the Fleisch head measured gas flow through the system. A rotameter in the system was used to calibrate the Fleisch head and provided visual evidence of airflow during the experiment. A flow rate of 500 mL/min was used, and this resulted in a CO<sub>2</sub> concentration in the calorimeter of approximately 1%. Gas passed to a mixing chamber with an internal volume of approximately 200 mL where the temperature was measured using a thermistor previously calibrated against a mercury-in-glass thermometer. Gases were desiccated (Drierite; Hammond Drierite Co., Xenia, OH) and analyzed by a Servomex OA 137 oxygen analyzer (Servomex Controls, Crowborough, England) and a Datex Normcap carbon dioxide analyzer (Datex Medical, Helsinki, Finland). Both gas analyzers had been modified to have an analog output accurate to ±0.01% and were calibrated using room air, nitrogen, and a beta standard gas (BOC Gases, Inc.) of known composition. The output from the analyzers, temperature, and airflow were captured using a MacLab 8/s A/D converter (ADI Instruments, Sydney, Australia) using MacLab Chart software (Version 3.5.6/s; ADI Instruments) and VO<sub>2</sub>, VCO<sub>2</sub>, and the respiratory exchange ratio were calculated on-line.

Measurements of metabolic rate were made at the end of each 4-wk dietary intervention. Mice were studied in groups of four, from both the same diet treatment and the same group, to ensure that the gas leaving the calorimeter had an oxygen concentration in the order of 20%. On each occasion the mice were in the calorimeter for 45 min, and recordings were made during the last 10 min to allow the gas concentrations to stabilize, and for the animals to become accustomed to being in the calorimeter.

**Physical activity.** Visual, subjective observations of mouse activity were recorded at 5-min intervals during calorimetry. For each mouse these were scored as: 1 = asleep; 2 = drowsy, shuffling feet, not moving, cleaning, grooming; 3 = a little movement around cage, feeding, tunneling in wood shavings; 4 = moderate movement around cage, climbing on feeder, playing vigorously with wood shavings, picking up and moving shavings; 5 = vigorous movement around cage, running, jumping, climbing/hanging with all four feet on roof bars. The data for each calorimeter run could, therefore, range between 4 and 20, and this figure was divided by 4 to give a single value of individual murine activity.

**Stored energy.** (i) *Live weight.* Individual animals were weighed before and after the dietary interventions to the nearest 0.01 g (Watson-Victor Mettler Ltd., PM6000), and weight gain over 4 wk was calculated.

(ii) *Body composition by dissection.* Immediately after euthanasia by isoflurane, the intestine was cut below the stomach between the pylorus and duodenum, and the remaining gastrointestinal tract removed. The small amount of adipose tissue adhering to the intestine was removed by dissection and kept with the carcass, and the intestine was discarded.

Carcasses were frozen and subsequently analyzed for body composition. Each carcass was weighed, the stomach removed, and the carcass weighed again. This carcass weight, which had the stomach, intestine, and 1–2 mL of blood removed, was used in subsequent calculations of percentage body fat by dissection (fat pad mass) of individual mice.

The upper body fat was removed and weighed. It comprised interscapular brown adipose tissue, that is, any subcutaneous adipose tissue located on the upper back and where the thoracic limbs insert. The lower body fat located in the abdominal region, the genital region, surrounding the kidneys, and lining the anterior of the abdominal cavity and on the pelvic limbs was similarly treated. The total body fat by dissection was the sum of the upper and lower body fat. Body fat percentage by dissection was calculated relative to the carcass weight at the start of dissection. The dissected adipose deposits and the carcass (without stomach and intestine) were recombined and weighed again for subsequent chemical analysis.

*Body composition by chemical analyses.* Samples were prepared for chemical analysis in the groups of four that were used for indirect calorimetry. The four carcasses were homogenized in a food blender (Waring), weighed, frozen, and then freeze-dried (Cuddon Model 0610 Freeze Drier; W.G.G. Cuddon Ltd., Blenheim, New Zealand). The freeze-dried material was ground in a rotating hammer mill (Thomas Scientific, Swedesboro, NJ) and passed through a 2-mm screen before it was chemically analyzed.

*Chemical determination of body composition.* The energy, fat, protein, ash, and moisture content of the animal bodies were determined using the same procedures described for the diets.

*Statistics.* Differences between diet groups were initially analyzed using a one-way ANOVA, and means were compared using the Tukey test (MINITAB, version 12.1). Each data point represented either individual mice or cages of mice, as appropriate. A second analysis using two-way ANOVA and regression equations was carried out using the statistical packages in GraphPad Prism (version 2.01, GraphPad Software, San Diego, CA). All results are shown as the mean ± 1 SD.

## RESULTS

**Diet composition.** The control rodent diet provided 16.40 kJ/g of energy and comprised 18.4% protein, 2.7% fat, 5.5% ash, 11.3% moisture (w/w) with the balance being carbohydrate (w/w). Ingredient composition of the experimental diets is shown in Table 1. The Tonalin used to supply the CLA contained 59.14% CLA as well as oleic (22.19%), palmitic (6.47%), linoleic (4.53%), and stearic (4.14%) acids.

**Food and energy intake.** Food intake between groups ranged from 8.12 ± 0.75 (1% CLA group) to 9.5 ± 0.73

**TABLE 1**  
Added Fat Composition of CLA-Modified Mouse Diets (ingredient g/100 g diet)

	CLA concentration					
	Control	0.1%	0.25%	0.5%	1.0%	2.0%
Corn oil	5.300	5.146	4.915	4.531	3.762	2.223
Tonalin <sup>a</sup>	—	0.154	0.385	0.769	1.538	3.077

<sup>a</sup>Tonalin (Pharmanutrients, Lake Bluff, IL), in FFA form (approximately 60% CLA).

g/d/pair of mice (0.25% CLA group). This was equivalent to a range of 140 ± 13 to 163 ± 13 kJ/d. The food and energy intake of the 0.25% group was significantly higher than that of the zero CLA and 1% CLA groups (*P* < 0.05).

All the mice gained weight during the study. Although it appeared that weight gain was markedly reduced after either the first or second week of the study (Fig. 1), this was not the case. Linear regression of the data from all diet groups, with a *post hoc* runs test, indicated that the reduction in weight gain was linear. The 4-wk weight gain of the animals fed 2.0% CLA in the diet was 5.88 ± 2.68 g/pair. This was significantly less than the weight gain of pairs of mice fed no CLA (7.81 ± 2.01 g; *P* < 0.05), 0.1% CLA (7.75 ± 2.03 g; *P* < 0.01), 0.25% CLA (7.51 ± 2.22 g; *P* < 0.05), and 0.5% CLA (8.17 ± 2.34 g; *P* < 0.001). The 4-wk weight gain of the pairs of mice fed 1% CLA was 7.15 ± 1.17 g, which was not significantly different from any other group.

**Energy expenditure and physical activity.** There was no difference in energy expenditure or activity between the groups of mice as measured by indirect calorimetry or observation of activity. Metabolic rate ranged from 0.12 ± 0.03 in the 0.25 and 0.50% CLA groups to 0.14 ± 0.01 kJ/min/4 mice. There was no significant difference in respiratory exchange ratio between groups, which varied between 0.92 and 0.96. Physical activity scores ranged from 1.97 ± 0.9 in the 0.5% CLA group to 2.84 ± 1.17 in the 0.1% CLA group. There was a strong positive linear correlation between metabolic rate and the subjective physical activity score (*R*<sup>2</sup> = 0.79).

**Body composition.** Tables 2–4 show body composition

**FIG. 1.** Weekly weight gain during the experiment. All diet groups appeared to show a rapid reduction in growth at the end of the first (1% CLA) or second week (control and 2% CLA). However linear regression of the data from all groups indicated the reduction in weight gain was progressive. (Mean ± SD; only three groups are shown for clarity.)

**TABLE 2**  
Live Weight at the End of Trial and Weight Gain During Experiment; Comparison of Group Means

Diet CLA %	<i>n</i>	Live weight after 4 wk on diet (g)	Weight gain during trial (g)
0.0	20	25.88 ± 1.57	3.90 ± 1.07
0.1	20	25.49 ± 2.02	3.88 ± 1.20
0.25	18	24.88 ± 1.30	3.76 ± 1.20
0.5	16	25.72 ± 1.77	4.09 ± 1.19
1.0	18	24.55 ± 1.53	3.57 ± 0.74
2.0	14	24.69 ± 2.12	2.94 ± 1.43

data. There was a highly significant (*P* < 0.001) dose-dependent reduction in body fat pad mass as measured by weighing dissected fat with increasing dietary CLA (Fig. 2). The total body energy content of the mice obtained by chemical analysis of the carcass also decreased (Table 4). Conversely, the percentage of lean body mass (derived from chemical analyses of body protein, moisture, and ash) appeared to increase as body fat pad mass decreased. However, this observation did not reach statistical significance in the current study.

**DISCUSSION**

Synthetic CLA fed to 6-wk-old, male BALB/c mice in a 4-wk trial (0.0, 0.1, 0.25, 0.5, 1.0, and 2.0% w/w CLA) reduced body fat pad mass in a dose-dependent manner. It was effective in reducing body fat over the range 0.25 to 1.0%. The observed reduction in body fat in mice has been reported in previous studies (2–5). The dose/response pattern of body fat reduction seen in this feeding trial indicated an effective CLA intake range (0.5–1.0%) over which CLA supplementation could influence body composition. Furthermore, no additional body fat reduction could be obtained by feeding above this level (>1.0% synthetic CLA in the diet). The reduction in non-fat pad lean

body mass at the higher levels of dietary CLA has previously been reported in one study (4), but not in others (2,5).

Although a graded reduction in total body fat and energy was seen in mice fed 0.25 to 1.0% w/w synthetic CLA, this was not balanced by measurable reductions in feed intake or increased energy expenditure. The mechanism by which equivalent energy intakes from diets differing only in a small portion of their total FA profile can result in a change in body fat from 8.65 (control) to 2.90% (1.0% CLA) is not clear from the present study. However, a recent study indicated that CLA may, in part, act by preventing energy absorption by the gut, not only from fat but also from other components, such as protein and carbohydrate (12).

**FIG. 2.** Reduction in fat content with increasing levels of dietary CLA. Increasing the dietary intake of CLA up to 1% w/w of the diet produced a progressive decrease in both the fat pad mass and the fat content obtained by chemical analysis of the carcass after the abdominal viscera had been removed (total fat). A further increase of dietary CLA to 2% produced no further decrease in either fat pool. (Data = mean ± SD.)

The results from this study suggest that reasonable levels of a synthetic mixture of CLA isomers are biologically active and influence energy metabolism and body composition. Body fat, both fat pad mass and carcass fat content, was reduced in a dose-related manner over the range 0.25 to 1.0% CLA. There was no significant further body fat reduction in the group of mice fed more than 1.0% synthetic CLA. In addition, levels of 1.0 and 2.0% synthetic CLA fed to growing mice reduced weight gain.

**ABSTRACT:** The objective of the present study was to determine the mechanisms by which dietary proteins interact with dietary lipids in the regulation of triglyceridemia in rats. Male Sprague-Dawley rats ( $n = 56$ ) were subjected to 28-d experimental diets containing different combinations of proteins (20% w/w) and lipid sources (14% w/w): (i) casein–menhaden oil, (ii) casein–beef tallow, (iii) soy protein–menhaden oil, and (iv) soy protein–beef tallow. Significant protein–lipid interactions were observed on triglyceridemia and hepatic cholesterol in fasted rats. The combination of casein and beef tallow was associated with high plasma TG and hepatic cholesterol concentrations, which were reduced by substitution either of soy for casein or of menhaden oil for beef tallow. Therefore, triglyceridemia and liver cholesterol remained low with soy protein feeding, independently of the lipid source, as well as with menhaden oil feeding, regardless of the protein source. The menhaden oil diets reduced plasma cholesterol, hepatic TG, and TG secretion compared with beef tallow diets independently of the dietary protein source. Modifying the source of dietary proteins and lipids had no effect on post-heparin plasma lipoprotein lipase activity. These results demonstrate that soy protein can lower rat triglyceridemia relative to casein when associated with beef tallow consumption, whereas menhaden oil can attenuate hypertriglyceridemia when rats are fed casein. The data further suggest that part of the hypotriglyceridemic effect of soy protein in the rat may be mediated by reduced hepatic lipid synthesis, as is the case for menhaden oil.

Paper no. L9050 in *Lipids* 37, 693–699 (July 2002).

Both dietary proteins and fish oil have been shown to influence plasma lipid concentrations. The hypocholesterolemic effect of soy protein compared with animal proteins is well known (1–4). Several mechanisms have been proposed to explain the hypocholesterolemic effect of soy protein. These include a reduction in intestinal absorption of cholesterol and bile acids (5), a decrease in the insulin-to-glucagon ratio (6), a rise in thyroid hormone concentrations (7), and an increase in the activity of apolipoprotein (apo) B/E receptors (5,8). However, the effect of soy protein on triglyceridemia is less well documented. A diminution of plasma TG concentrations has been observed in some rat (1,9) and human studies (3).

Abbreviations: apoB, apolipoprotein B; HTGL, hepatic TG lipase; LPL, lipoprotein lipase; PHP-LPL, post-heparin lipoprotein lipase.

The protein itself and its amino acid composition, as well as nonprotein constituents naturally present in soy protein isolate, such as isoflavones, may be implicated (8).

Omega (n)-3 PUFA present in fish oil also have potent hypotriglyceridemic effects (10). The mechanisms responsible for the decrease in plasma TG concentrations associated with consumption of n-3 FA of fish oil involve a reduction in hepatic TG and VLDL synthesis (11,12), and an increase in VLDL and chylomicron degradation by lipoprotein lipase (LPL) (13).

Little is known so far on the effects and mechanisms involved in the interactions between dietary proteins and lipids on the modulation of plasma lipid concentrations. Our previous study (9) demonstrated that dietary proteins may modify the effects of fish oil on triglyceridemia in the rat. Indeed, the hypotriglyceridemic effect of fish oil was more pronounced in rats fed soy protein than in rats fed casein (9). The present study was thus undertaken to understand the mechanisms by which dietary proteins interact with dietary lipids in regulating plasma TG levels. The distinct and interactive effects of two dietary proteins (soy protein and casein) and two dietary lipids (menhaden oil and beef tallow) on plasma and hepatic lipid concentrations, TG secretion rates, post-heparin lipoprotein lipase (PHP-LPL), and hepatic TG lipase (HTGL) activity were investigated in rats.

## MATERIALS AND METHODS

**Experimental animals.** Sprague-Dawley rats (Charles River) initially weighing approximately 200 g were housed in individual stainless-steel wire-bottom mesh cages. The temperature ( $20 \pm 2^\circ\text{C}$ ) and relative humidity (45–55%) of the animal room were constant, and the rats were kept under a daily inverted light-dark cycle (light: 2100 to 0900). During an adaptation period of 2–6 d, rats were fed a nonpurified commercial diet (Purina, St. Louis, MO). They were then randomly assigned to one of four dietary groups ( $n = 14$  per group). For a 28-d period, purified diets and water were provided once daily on an *ad libitum* basis. Records of food intake were taken daily, and body weight was monitored three times a week. The protocol was approved by the Animal Care Committee of Laval University according to the guidelines of the Canadian Council on Animal Care.

**Purified diets.** Diets were similar except for the protein (20%) and the lipid (14%) source (Table 1). The four experi-

mental diets were composed of the following protein–lipid mixtures: casein–menhaden oil, casein–beef tallow, soy protein–menhaden oil, or soy protein–beef tallow. Beef tallow and menhaden oil were supplied by ICN Biomedicals Inc. (Aurora, OH), and soybean oil was purchased from a local supermarket. According to manufacturer information, the composition of menhaden oil was (by weight): saturated FA 28.2%, monounsaturated FA 23.0%, EPA 16.0%, DHA 10.8%, linoleic acid 1.8%, and arachidonic acid 2.3%. Beef tallow contained (by weight): saturated FA 49.8%, mainly from palmitic (24.9%) and stearic (18.9%) acids; monounsaturated FA 41.8%, mainly from oleic acid (36.0%); and PUFA 4.0%. The cholesterol content of menhaden oil and beef tallow was 5.23 and 1.09 mg/g, respectively. Therefore, menhaden oil provided only 0.5 g cholesterol/kg in menhaden oil diets, and beef tallow provided only 0.1 g cholesterol/kg in beef tallow diets. These amounts were considered as negligible. As proposed by Fritsche and Johnston (14),  $\alpha$ -tocopherol, BHA, and BHT (ICN Biomedicals Inc.) were added to the diets to minimize the oxidation of n-3 and n-6 FA in menhaden oil, and n-6 PUFA in soybean oil and beef tallow. Highly purified casein, soybean protein isolate, cornstarch, cellulose (Alphacel), cholesterol, rat AIN-93 mineral mix, AIN-93 vitamin mix, and choline bitartrate were purchased from ICN Biomedicals Inc. The protein content ( $N \times 6.25$ ) of casein (87.6% protein) and soybean protein isolate (86.5% protein) was determined using a Kjeldahl–Foss autoanalyzer (Model 16216; Foss Co., Hillerod, Denmark). The level of protein in the diets was adjusted at the expense of cornstarch on an isonitrogenous basis. The residual lipid content of casein (0.05%) and soy protein (0.45%) was assayed using a Goldfish Lipid Extractor (Model 35001; Labconco Corp., Kansas City, MO). The energy content of the diets was measured in an automatic adiabatic calorimeter (Model 1241; Parr Instruments, Moline, IL), and the diets were found to be isoenergetic with values ranging from 19.4 to 19.9 kJ/g.

*Experimental procedures and measurement of post-heparin lipoprotein and hepatic lipase activities.* On day 23 of the

experimental period, rats were cannulated *via* the jugular vein under isoflurane anesthesia. They were allowed to recover for 3 d before being subjected to the following procedure. On day 26, after a 12-h fast, the rats were administered 200 IU/kg body weight of heparin through the jugular catheter. A 0.25-mL blood sample was collected 10 min later and centrifuged (1,500  $\times g$ , 4°C) to obtain plasma, which was stored at –80°C for subsequent determination of lipoprotein lipase (LPL) and HTGL activities. Post-heparin plasma LPL and HTGL activities were determined by measuring the amount of *in vitro* hydrolysis by post-heparin plasma samples of a labeled triolein emulsion in the presence of 0.1 or 1 mol/L NaCl (15).

*Determination of TG secretion rate.* On day 28, TG secretion rate was measured according to the method of Otway and Robinson (16). After a 12-h fast, rats were injected through the jugular catheter with 300 mg/kg body weight of Triton WR-1339, a detergent that prevents intravascular TG catabolism. Blood samples (0.15 mL) were taken before (0 min) and 20, 40, and 60 min after Triton injection, centrifuged (1,500  $\times g$ , 4°C, 10 min) to obtain plasma, and stored at –80°C for subsequent determination of TG concentrations. Fasting plasma lipid levels were determined in the pre-Triton (0 min) samples. Rats were then killed by CO<sub>2</sub> after O<sub>2</sub>/CO<sub>2</sub> anesthesia. Rates of VLDL TG secretion were determined from regression analysis of TG accumulation in plasma vs. time and adjusted for plasma volume.

*Plasma, lipoprotein, and hepatic lipid analyses.* Total plasma TG concentrations were determined in all blood samples by an enzymatic method using the Triglycerides/GB kit provided by Roche Diagnostics (Laval, Québec, Canada). Total plasma cholesterol concentrations were measured by an enzymatic method (CHOD-PAP kit of Boehringer Mannheim provided by Roche Diagnostics) only in blood samples collected before Triton injection. The liver of rats was removed after sacrifice and stored at –80°C. Hepatic lipids were extracted with chloroform/methanol (2:1, vol/vol) according to Folch *et al.* (17), and cholesterol and TG were determined enzymatically as described above.

**Statistical analyses.** The results are expressed as mean  $\pm$  SEM. To determine the main protein and lipid effects, as well as interactions between dietary proteins and lipids, data were subjected to an ANOVA according to a  $2 \times 2$  factorial arrangement, using the general linear model (GLM) procedure of the Statistical Analysis System (SAS Institute, Cary, NC). A  $P$  value  $<0.05$  was considered significant. When statistically significant protein–lipid interactions were detected, Duncan's New Multiple Range test was performed to identify differences among diet groups.

## RESULTS

**Food consumption and weight gain.** Table 2 shows the mean food consumption and body weight gain of rats fed the experimental diets. Food intake was similar for all dietary groups. Weight gain was slightly lower in rats fed soy protein than in those fed casein and in rats fed beef tallow compared to those fed menhaden oil, but these differences were not statistically significant ( $P = 0.30$ ). Likewise, food efficiency (g body weight gain/g food ingested) tended to be lower in rats fed soy protein compared to those given casein, but the difference was not significant.

**Plasma and hepatic cholesterol.** Total plasma cholesterol concentrations are presented in Table 3. The overall ANOVA and multiple comparisons are shown in the bottom half of the table. The lipid source had a significant effect ( $P = 0.002$ ) on

plasma cholesterol concentrations, which were lower in menhaden oil-fed than in beef tallow-fed rats. The two protein sources had a similar impact on plasma cholesterol levels.

Diet effects on hepatic cholesterol concentrations are shown in Table 3 and Figure 1. A significant ( $P = 0.02$ ) protein–lipid interaction was observed. The combination of casein and beef tallow resulted in high liver cholesterol concentrations, which were reduced by substitution either of soy for casein or of menhaden oil for beef tallow. Hence, liver cholesterol remained low with soy protein feeding, independently of the lipid source, as well as with menhaden oil consumption, regardless of the protein source.

**Plasma and hepatic TG concentrations, TG secretion rates, and lipase activities.** Plasma and hepatic TG concentrations and TG secretion rates are presented in Table 4. A significant ( $P = 0.05$ ) protein–lipid interaction was observed on fasting triglyceridemia (Fig. 2). The combination of casein and beef tallow was associated with high plasma TG concentrations, which were reduced by substitution either of soy protein for casein or of menhaden oil for beef tallow. Triglyceridemia therefore remained low with soy protein feeding, independently of the lipid source, as well as with menhaden oil feeding, regardless of the protein source.

The protein and lipid sources independently affected hepatic TG concentrations (Table 4). Soy protein feeding resulted in lower hepatic TG content compared with casein feeding ( $P = 0.01$ ). TG concentrations in the liver were also

decreased after menhaden oil consumption compared with beef tallow consumption ( $P = 0.0001$ ). The lowest values of hepatic TG content were thus observed in soy protein–menhaden oil-fed rats, whereas the highest hepatic TG concentrations were noted in casein–beef tallow-fed animals. In menhaden oil-fed rats, TG secretion rates were lower than in those fed beef tallow ( $P = 0.008$ ) regardless of the protein source. Hepatic TG ( $r = 0.51$ ,  $P = 0.02$ ,  $n = 22$ ) and cholesterol ( $r = 0.47$ ,  $P = 0.026$ ,  $n = 22$ ) concentrations were positively correlated with TG secretion rates.

No significant difference was observed in LPL activity between the four experimental groups. On the other hand, the lipid source had an independent effect on HTGL activity ( $P = 0.02$ ), which was lower in menhaden oil-fed rats than in beef tallow-fed rats. Soy protein strongly ( $P = 0.06$ ) tended to lower HTGL activity when compared with casein. There was

also a trend ( $r = 0.37$ ,  $P = 0.07$ ,  $n = 25$ ) for a positive correlation between HTGL activities and plasma TG concentrations in fasted rats.

## DISCUSSION

The results of this study support the concept, previously described (9), of an interaction between dietary proteins and fish oil in the modulation of triglyceridemia in rats. The findings show that soy protein exerted a hypotriglyceridemic effect similar to that of menhaden oil in the rat, which may be related in part to the reduction in hepatic lipid concentrations consequent to soy protein and menhaden oil consumption.

In the present study, menhaden oil feeding resulted in low plasma TG concentrations in both casein- and soy protein-fed rats, whereas beef tallow resulted in high triglyceridemia

when combined with casein but low triglyceridemia when combined with soy protein. The lowering effect of fish oil in comparison with saturated FA on triglyceridemia has previously been observed in the rat (11). The results of the present study suggest that the hypotriglyceridemic impact of fish oil may not be affected by the dietary source of proteins. This is in accordance with the data reported by Sakono *et al.* (18) showing in the rat a hypotriglyceridemic effect of fish oil (compared with safflower oil) when combined with either casein or soy protein. In the present study, the lowering effect of fish oil on triglyceridemia was associated with a concomitant reduction in hepatic TG concentrations. A reduced TG synthesis by the liver previously reported in several studies (12,19,20) may be responsible for this effect. Moreover, in the present study TG secretion rates were lower in menhaden oil-fed rats than in those fed beef tallow, and a positive correlation was observed between hepatic TG concentrations and TG secretion rates. Therefore, it is very likely that menhaden oil reduced TG synthesis and their incorporation into VLDL, resulting in a diminished secretion of VLDL by the liver.

Soy protein consumption maintained low plasma TG concentrations relative to casein and attenuated the hypertriglyceridemic effect associated with beef tallow consumption. A hypotriglyceridemic effect of soy protein has been reported previously in rats (1) and in hamsters (21). In humans, the impact of soy protein on triglyceridemia remains unclear. A meta-analysis of 38 controlled clinical studies concluded that substituting soy protein for animal protein significantly lowered total cholesterol, LDL cholesterol, and TG (the latter by approximately 11%) without affecting HDL cholesterol (3). Our own study in children with familial hypercholesterolemia found a 22% decrease in plasma TG, with no change in plasma or LDL cholesterol, following the consumption of a soy-protein beverage compared to cow's milk, either of which

replaced 35% of the energy from protein (4). In contrast, other studies reported an absence of effect of soy protein on triglyceridemia, either when compared to casein in normolipidemic men (22) or to milk protein in hypercholesterolemic postmenopausal women (23). Differences in experimental design or in baseline lipemia may explain such discrepancies, but, taken together, the data suggest that at least in some conditions soy protein also can lower triglyceridemia in humans.

Recent results from our laboratory suggested that the isoflavones naturally present in soy protein isolate may be involved in the hypotriglyceridemic effect of soy protein (24). In the present study, a reducing effect of soy protein compared with casein on hepatic TG concentrations and a correlation between hepatic TG levels and TG secretion rates were observed. This is consistent with the results obtained by Iritani *et al.* (25) showing a lower activity of lipogenic enzymes associated with lower hepatic and plasma TG levels in rats fed soy protein compared with casein. It is therefore likely that the hypotriglyceridemic effect of soy protein observed in the present study was consequent to a reduction in hepatic TG concentrations resulting from a diminution in TG synthesis.

Although soy protein diets resulted in low plasma and hepatic TG concentrations, they had no significant effect on TG secretion rates in the present study. This is in accordance with the results of another study undertaken in our laboratory showing a hypotriglyceridemic effect of soy protein in cornstarch-fed rats but no effect on TG secretion rates (24). Pfeuffer and Barth (26) demonstrated that the lowering effect of soy protein consumption on TG secretion rates was observed in rats fed a high-sucrose diet but was not detected in rats whose triglyceridemia was lowered by a high-cornstarch soy protein diet. Therefore, the possibility remains that the hypotriglyceridemic effect of soy protein in the rat may be mediated in part by changes in TG secretion rates by the liver, as

previously observed in sucrose-fed rats (26), but that this effect is below detectability levels when cornstarch is the carbohydrate source.

A major determinant of triglyceridemia is the intravascular hydrolysis of TG by LPL (27). In the present study, diets had no significant effect on PHP-LPL activity, suggesting that the hypotriglyceridemic effects of soy protein and menhaden oil were not due to changes in LPL activity. HTGL activity was significantly lowered in menhaden oil-fed rats compared with beef tallow-fed rats. This is in accordance with the results of a recent study that showed reduced plasma TG concentrations and hepatic lipase activity when the degree of saturation of the lipid sources fed to rats was decreased (28). As proposed by Benhizia *et al.* (20), the decrease in intravascular hepatic lipase activity observed in the present study after menhaden oil consumption may have been consequent to the decrease in plasma concentrations of TG-rich lipoproteins. The decrease in triglyceridemia observed in soy protein-fed rats may have contributed in the same way to the diminution of HTGL activity ( $P = 0.06$ ) in this group.

In addition to its hypotriglyceridemic effect, the hypocholesterolemic effect of n-3 PUFA from fish oil in comparison with saturated FA frequently has been observed in the rat (9,20,29,30). This effect was reproduced in the present study: Menhaden oil consumption significantly lowered plasma cholesterol concentrations in comparison with beef tallow consumption. The mechanism for this effect may involve an increase in the activity of LDL receptors in the liver and in the transport of apoB-containing lipoproteins by these receptors (29,30). An inhibition of hepatic TG synthesis and cholesterol esterification, leading to a reduced secretion of VLDL-cholesterol by the liver, also may be implicated (29). In the present study, a significant protein-lipid interaction was observed on hepatic cholesterol concentrations. Beef tallow maintained a high hepatic cholesterol content when combined with casein but not when combined with soy protein, whereas menhaden oil maintained low hepatic cholesterol concentrations in the presence of either soy protein or casein. Although no correlation between hepatic and plasma cholesterol concentrations was detected, it remains possible that decreased hepatic cholesterol concentrations may have contributed in part to lower cholesterolemia in menhaden oil-fed rats. Interestingly, Avramoglu *et al.* (31) have shown that VLDL secretion correlates with total mass of cholesterol esters within HepG2 cells. In the present study, TG secretion rates were positively correlated with hepatic cholesterol concentrations ( $P = 0.026$ ,  $r = 0.47$ ,  $n = 12$ ). Therefore, the lower hepatic cholesterol levels observed in menhaden oil-fed rats may have contributed in part to the reduction of TG secretion rates and the hypotriglyceridemic effect observed after menhaden oil consumption.

The hypocholesterolemic effect of soy protein relative to casein is fairly well established, particularly in hypercholesterolemic human subjects (3,32–34), and has been reproduced in some, but not all, studies in the rat model (1,32,35). In the present experiment, there was no significant effect of dietary

proteins on plasma cholesterol concentrations. This may be due in part to the use of cornstarch as a carbohydrate source. Indeed, it has previously been shown that the effects of dietary proteins on cholesterolemia are less pronounced in rats when fed with cornstarch than with sucrose (26,36).

The highest cholesterol concentrations in the liver were observed in casein-beef tallow-fed rats. These data are in good agreement with those showing that saturated FA increase hepatic cholesterol content in comparison with PUFA (39). Casein, compared to soy protein, also increased hepatic cholesterol concentrations in the rat (37,38). The mechanism for the protein effect may involve a rise in intestinal absorption of cholesterol (28,34), which leads to an increased cholesterol transport from gut to liver and a consequent rise in hepatic cholesterol concentrations. The present results suggest that the effect of casein may be additive to that of beef tallow, resulting in high hepatic cholesterol concentrations in casein-beef tallow-fed rats. On the other hand, although soy protein did not modify cholesterolemia overall in the present study, it did result in lower hepatic cholesterol concentrations, compared to casein, in beef tallow-fed rats. Earlier studies also showed that soy protein compared to casein reduced hepatic cholesterol concentrations in the rat (9,39). Therefore, the present results indicate that soy protein may prevent the increasing effect of beef tallow on hepatic cholesterol levels.

The present results support the concept of an interaction between dietary proteins and lipids in the modulation of triglyceridemia in the rat. The present study also demonstrates that soy protein can lower triglyceridemia relative to casein when associated with beef tallow consumption in the rat. On the other hand, menhaden oil can attenuate hypertriglyceridemia induced by casein feeding. Although the mechanisms may differ somewhat, decreased hepatic TG and cholesterol concentrations in rats fed soy protein and menhaden oil suggest that the lowering effect of soy protein on triglyceridemia may be partly mediated by a reduced hepatic lipid synthesis, as is the case for menhaden oil. Studies on liver lipid synthesis should help to clarify the mechanisms by which dietary proteins interact with dietary lipids in the modulation of triglyceridemia in the rat.

# Correlation Between Fatty Acyl Composition in Neutral and Polar Lipids and Enzyme Activities from Various Tissues of Calcium-Deficient Rats

Carlos A. Marra\*, Omar Rimoldi, and María J.T. de Alaniz

Instituto de Investigaciones Bioquímicas de La Plata, Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET)—Universidad Nacional de La Plata (UNLP), Facultad de Ciencias Médicas, UNLP, La Plata, Argentina

**ABSTRACT:** In this study we investigated the changes induced by feeding rats a calcium-deficient diet (0.5 g Ca/kg diet) during 65 d after weaning. Phospholipase A<sub>2</sub>, acyl-Co synthetase and FA  $\Delta$ 9-,  $\Delta$ 6-, and  $\Delta$ 5-desaturase activities were also determined. Calcium deficiency evoked a general alteration in the quality and proportion of the FA chains acylated to neutral and polar lipids from liver, lungs, spleen, brain, kidneys, fat, articular cartilage, erythrocyte ghosts, and plasmas, characterized by an increment of saturated FA and a significant depletion of polyunsaturated acids derived from linoleate and  $\alpha$ -linolenate. Several interlipid and lipid/protein relationships were also modified in microsomes from calcium-deprived rats, with a concomitant reduction in the rotational mobility of the probe diphenylhexatriene. Phospholipase A<sub>2</sub> and acyl-CoA synthetase activities were also decreased and increased, respectively, in some tissues from calcium-deficient rats, whereas  $\Delta$ 9-,  $\Delta$ 6- and  $\Delta$ 5-desaturases were significantly depressed. We conclude that changes in tissue fatty acyl composition evoked by calcium deprivation are due to alterations in the acylation/deacylation cycles *via* inhibition of the phospholipase A<sub>2</sub>. These changes were reflected in the physicochemical properties of the membranes, which in turn inhibits desaturase activities. A possible failure in the transcription rate for desaturase-mRNA was also discussed.

Paper no. L8980 in *Lipids* 37, 701–714 (July 2002).

Previous works from our laboratory have documented that the content of dietary calcium plays an important role in PUFA metabolism since a calcium-deficient (CaD) diet fed to rats for 65 d caused a significant inhibition of  $\Delta$ 5-,  $\Delta$ 6-, and  $\Delta$ 9-desaturase activities in liver microsomes (1). It was also reported by Huang *et al.* (2) that deprivation of calcium may cause a decrease in the rate of elongation of  $\gamma$ -linolenic acid (18:3n-6) (2). The authors supported this conclusion by the analysis of microsomal fatty acyl composition obtained from calcium-deprived rats whose diets were supplemented—or not—with 18:3n-6 acid. Previously, Bierenbaum *et al.* (3) suggested that calcium may limit the availability of 18:3n-6 for the elongase system by forming insoluble complexes with this cation. We also demonstrated that a CaD diet was able to produce a marked stimulation in acyl-CoA synthetase activ-

ity (4) and a significant reduction in phospholipase A<sub>2</sub> activity that evokes permanent alterations in the physicochemical properties of the liver microsomal membranes (1). The picture that emerges from those results is that the changes in the desaturase activities correlate well with both the rotational mobility of the diphenylhexatriene probe and the analytical changes produced on the microsomal lipids by the CaD diet. Whether these changes were completely developed in liver tissue or whether they were the consequence of a general alteration in the lipid metabolism that, in fact, involved various tissues of the animal is not clear. In addition, the importance of the inhibition of FA desaturase activities induced by calcium depletion on the FA composition of lipids from tissues other than liver still remains unexplored. The central role of liver FA desaturases in supplying PUFA for the rest of the body prompted us to investigate the possible correlation between calcium content and lipid composition among several tissues from both sufficient (S) and CaD rats. The aim of the present study was to obtain a general description of the changes induced by calcium deficiency and to evaluate the contribution of some key enzyme activities—involved in FA metabolism—to changes observed under the CaD condition.

## MATERIALS AND METHODS

**FA and other chemicals.** The unlabeled FA used as standards for GLC or employed in the enzymatic determinations were obtained from Nu-Chek-Prep (Elysian, MN). ATP (disodium salt), NADH, *N*-acetylcysteine, CoA (lithium salt), snake venom (*Crotalus atrox*) Western Diamondback Rattlesnake, and sodium deoxycholate (grade II) were purchased from Sigma Chemicals Co. (St. Louis, MO). Unlabeled phospholipids were obtained from Serdary Research Laboratories (London, Ontario, Canada). The procedure to obtain labeled PC was developed in our laboratory after assaying different experimental conditions (1). The following radioactive FA were supplied by Amersham International (Buckinghamshire, UK) (specific activity as mCi/mmol and percent degree of radiochemical purity are indicated, respectively, in parentheses: [1-<sup>14</sup>C]palmitic (58.0, 99), [1-<sup>14</sup>C]linoleic (55.5, 99), and [1-<sup>14</sup>C]jeicosa-8,11,14-trienoic (58.5, 99). The concentration and degree of purity of the FA were routinely checked by liquid scintillation counting and GLC of their FAME prepared by using 14% boron trifluoride in methanol (Alltech Associ-

Abbreviations: 18:3n-6,  $\gamma$ -linolenic acid; 20:4n-6, arachidonic acid; CaD, calcium-deficient; DBI, double bond index; DPH, 1,6-diphenyl-1,3,5-hexatriene; ED, elongation-desaturation index; PDIA, palmitoyl desaturase index activity; S, sufficient (control); SDIA, stearoyl desaturase activity index.

ates Inc., Deerfield, IL). Eicosa-11-monoenoic acid was used as internal standard. FA were appropriately diluted in absolute ethanol (Riedel-de-Haen, Seelze, Germany) and stored in the dark at  $-20^{\circ}\text{C}$  under an atmosphere of  $\text{N}_2$  until used. Solvents for HPLC were provided by Carlo Erba (Milano, Italy). 1,6-Diphenyl-1,3,5-hexatriene (DPH) probe was obtained from Fluka Chemie AG GmbH & Co. (Buenos Aires, Argentina). Other chemicals used were supplied by commercial sources.

**Animal treatment.** Female Wistar rats from Comisión Nacional de Energía Atómica (Buenos Aires, Argentina) weighing  $170 \pm 10$  g were bred and maintained on a control diet (Cargill type "C," Rosario, Argentina) throughout gestation and lactation. The dams were housed in plastic cages (one animal per cage) in a vivarium kept at  $22 \pm 1^{\circ}\text{C}$  with a 12-h light/dark cycle and a RH of  $60 \pm 10\%$ . After weaning, 24 female pups (weighing  $47 \pm 4$  g/animal) were randomly divided into two groups of 12 animals each and fed *ad libitum* either on a CaD diet (group CaD) or on a balanced one (group S). The composition of the CaD diet prepared in our laboratory was reported in detail in a previous paper (4). The  $\text{Ca}^{2+}$  content of the diet (0.5 g/kg) was determined in a Shimadzu Atomic Absorption Spectrophotometer AA-630-12 (Shimadzu Corp., Kyoto, Japan) following the mineralization procedure described elsewhere (5). Control animals were fed a standard balanced diet supplemented with 5.0 g/kg calcium in order to supply the mineral at a level equivalent to that recommended by The American Institute of Nutrition for the Formulation of the AIN-93 Purified Diets for Laboratory Rodents (6). The content of  $\text{Ca}^{2+}$  in drinking water (given *ad libitum*) was determined either by atomic absorption or by calcium-selective electrode (Orion model 93-20; Orion Research Inc., Cambridge, MA), and it was generally below 15 ppm. During the feeding period, body weight, water consumption, and food intake were determined every day. Samples of blood (100 to 150  $\mu\text{L}$ ) were collected from the tail vein once a week in order to determine plasma calcium levels. Animals were sacrificed on day 65 after feeding. In order to avoid individual differences among animals that might result from an *ad libitum* feeding, on day 64 all the rats were fasted for 24 h, re-fed with the corresponding diet for 2 h, and then killed by decapitation without prior anesthesia 12 h after the refeeding period. All the diet components used were purchased from Carlo Erba (Milano, Italy) or Mallinckrodt Chem. Works (Oneonta, NY). The casein was depleted of calcium by EGTA treatment and then defatted with boiling acetone. The calcium content in the extracted casein was negligible. Animal maintenance and handling were in accordance with the NIH guide for the care and use of laboratory animals (7).

**Collection of samples and preparation of microsomal suspensions.** Liver, heart, kidneys, skeletal muscle (psoas major and quadriceps), lungs, brain, and spleen from S and CaD rats were rapidly excised and immediately placed in an ice-cold homogenizing medium (8). The homogenates were processed individually at  $1^{\circ}\text{C}$ , and the microsomal fractions were separated by differential centrifugation at  $110,000 \times g$  as described previously (8). Microsomal pellets were resuspended in cold

homogenizing solution up to a final protein concentration of 30–40 mg/mL. Other tissues such as perirenal fat, large bones (femur and tibiotarsal), and articular cartilage from S and CaD rats were also used to obtain homogenates from whole tissue samples because, in these cases, microsomal suspensions were not prepared. Cortical (parietal) and tibiotarsal bones—with intact articular and epiphyseal cartilages—were carefully excised; chilled on ice; and thoroughly cleaned of connective tissues, fatty inclusions, and vessels; weighed; and stored at  $-80^{\circ}\text{C}$  under  $\text{N}_2$  atmosphere until further use. Thin-sliced cartilage samples were prepared as shavings from the articular surfaces of femoral condyles and tibial plateaus from six S or CaD rats. They were processed and assayed separately. Epiphyseal and diaphyseal zones of one femur per rat were also excised and processed independently. They were carefully rinsed in ice-cold saline to remove adherent tissues and/or body fluids and homogenized using a powerful homogenizer with a rotating blade (Ultra-Turrax Type TP 18/10; Janke & Kunkel, Staufen, Germany). Blood was also collected after killing the rats by decapitation. Samples were individually dispensed into heparinized tubes and fractionated by centrifugation at  $50 \times g$  for 10 min. Plasmas were immediately processed for calcium determination and lipid analysis. Erythrocyte ghosts were prepared by hypotonic lysis according to the procedure of Dodge *et al.* (9), as modified by Berlin *et al.* (10). An aliquot from the erythrocyte membranes was processed for steady-state fluorescence anisotropy determinations ( $r_s$ ) following the procedure described in Reference 11. The rest was employed for lipid analysis.

**Lipid analysis.** Product identification and quantification after FA desaturase activity assays were performed by RP-HPLC according to previously described methods (1,12). GLC of the FAME was performed as indicated in a previous paper (13) except that in this case we used a capillary column mounted in a Hewlett-Packard HP 6890 Series GC System Plus (Avondale, PA) equipped with a terminal computer integrator. The FAME were identified by comparison of their relative retention times with authentic standards, and the mass distribution was calculated electronically by quantification of the peak areas. Total lipids were extracted from S and CaD samples by the method of Folch *et al.* (14). Phospholipid and neutral lipid fractions were separated from the Folch extracts by a micro-column chromatography method described elsewhere (15). Cholesterol content was enzymatically measured according to Allain *et al.* (16). Total lipids and neutral lipids were estimated gravimetrically after evaporation of an aliquot of the corresponding lipid extract (Folch or silicic acid subfraction, respectively) up to constant weight (17). Phospholipids were measured as phosphorus content (18) after mineralization of an aliquot from the silicic acid partition.

**Enzymatic determinations.** Phospholipase  $\text{A}_2$  activity was determined in microsomal fractions from various tissues with [ $^{14}\text{C}$ ]PC (24.0 mCi/mmol, 99% pure) as substrate according to the method of Hirata *et al.* (19) with the modifications described in a previous paper (1). To determine the FA desaturase activities in microsomal suspensions from various tissues of S

and CaD rats, each FA used as substrate ( $[1-^{14}\text{C}]16:0$ ,  $[1-^{14}\text{C}]18:2n-6$ , or  $[1-^{14}\text{C}]20:3n-3$ ) was diluted to a specific activity of 0.20 to 0.25  $\mu\text{Ci/mol}$  with the respective pure unlabeled FA. In order to compare results, the enzymatic assays were conducted at saturated substrate concentrations. Each assay was performed by incubation of 1.25 mg of liver microsomal protein or 5 mg of brain, kidney, lung, heart, or spleen microsomal protein in an open test tube with  $5 \cdot 10^3$  pmol of diluted labeled substrate for liver or  $10^4$  pmol for the other tissues, in a Dubnoff shaker at  $37^\circ\text{C}$  for 10 min. The total volume of the incubation medium was 0.8 mL. Details of the assay procedure were described in previous papers (1,20,21). Acyl-CoA activity assays were performed on cytosol fractions obtained as supernatants of  $110,000 \times g$ , according to the method of Tanaka *et al.* (22) as modified previously (4).

**Measurement of  $\Delta 6$ -desaturase mRNA.** Total liver RNA of six S or CaD animals were isolated by means of Wizard RNA Isolation System (Promega, Madison, WI) according to the manufacturer's instructions. Total RNA (20  $\mu\text{g}$ ) was size-fractionated on a 1% formaldehyde gel and then transferred to a Zeta-Probe nylon membrane (Bio-Rad, Hercules, CA). The  $\Delta 6$ -desaturase and  $\beta$ -actin probes were prepared by incorporating  $[^{32}\text{P}]\text{dCTP}$  by random primer labeling. Northern blot hybridization analysis was performed as described by Sambrook *et al.* (23). The autoradiographic signal for  $\Delta 6$ -desaturase mRNA was quantified and normalized to mRNA for  $\beta$ -actin, with all mRNA probed on the same gel.

**Other analytical determinations.** Calcium content in liver microsomal suspensions was determined after mineralization (5) by atomic absorption or calcium-sensitive electrode as described elsewhere (1,4). The protein content was determined by the micro-method of Lowry *et al.* (24) with crystalline serum albumin as standard. Fluorescence anisotropy measurements 352 nm excitation, 435 nm emission were done at  $37^\circ\text{C}$  following the procedure of Shinitzky and Barenholz (25,26). The apparatus used, a detailed description of the method employed, and the calculations/corrections made appeared in a previous paper (11).

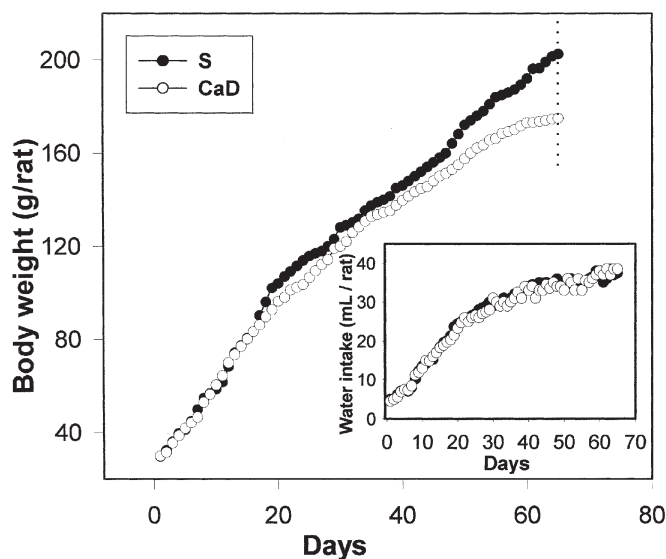

**Graphic software and statistical treatment of the data.** All values represent the mean of 3 to 6 individual determinations (assayed in duplicate or triplicate)  $\pm 1$  SEM. To test the statistical significance of numerical differences in results, data were analyzed by either the Student *t*-test or by ANOVA, with the aid of Systat (version 8.0 for Windows) from SPSS Science (Chicago, IL). Data were also plotted and analyzed using Sigma Scientific Graphing Software (version 8.0) from Sigma Chemical Co. and/or GB-STAT Professional Statistics Program (version 4.0) from Dynamic Microsystems Inc. (Silver Spring, MD). The autoradiographic signal for  $\Delta 6$ -desaturase mRNA was quantified using 1-D Image Analysis Software (Kodak, Rochester, NY) from multiple exposures. It was normalized to mRNA for  $\beta$ -actin, with all mRNA probed on the same gel.

## RESULTS

In our experimental model of calcium deficiency, we observed that both S and CaD rats grew at a similar rate for the initial

15 d after feeding. Then, the CaD group grew at a rate that was reduced—but not statistically significant—until day 65, when differences between groups became significant (Fig. 1). Water intake expressed as mL/rat was very similar in both groups of animals throughout the entire experimental period (Fig. 1, inset). As shown in Figure 2, food intakes, expressed as grams of food per rat or relative to body weight (inset), were not significantly different between both groups of rats despite the fact that in the initial 10 d of feeding, CaD animals exhibited an increased food intake compared to that of S ones. After the first week of feeding, a progressive decline in plasma calcium concentration was observed in CaD rats (from  $2.63 \pm 0.10$  mM at day 0 to  $2.11 \pm 0.15$ ,  $1.73 \pm 0.12$ , or  $1.58 \pm 0.07$  mM at days 8, 16, and 24, respectively) up to day 28 in which the values remained essentially constant and significantly lower ( $1.50 \pm 0.08$  mM) than those from the S group ( $2.63 \pm 0.10$  mM). Table 1 shows calcium content determinations in various tissues on the day of sacrifice.

With the exception of fat, brain, and lung, the rest of the tissue homogenates showed an important decrease in Ca content. In large bones the loss of calcium represented *ca.* 60% decrease with respect to control samples. Liver, kidney, erythrocytes, cortical bone, and articular cartilage showed 30 to 50% decreases in calcium content, but heart and skeletal muscle were affected to a minor extent (20%). When the microsomal suspension of some tissues was examined for their calcium content, only liver, kidney, and spleen showed significant decrease in the concentration of this cation (a loss of 42 to 47% with respect to control determinations). These findings were reflected in the total calcium content of plasma, which decreased 43% with respect to that of S rats. The proportion of ionic calcium in the plasma of CaD animals also decreased 66% with respect

**FIG. 1.** Body weight (expressed as g per rat) and water intake (mL/rat, inset) were registered during the entire experimental period. Each datum is the mean of six rats per group. SEM, omitted for simplicity, never exceeded 6% of the corresponding mean value. The vertical dotted line represents the first significant difference between control (S) and calcium-deficient (CaD) rats.

FIG. 2. Food intake was registered during the entire experimental period and expressed as g of aliment per rat or as the ratio g of food/g of body weight (insert). Each datum is the mean of six rats per group. SEM, omitted for simplicity, never exceeded 8% of the corresponding mean value. Points from days 2 to 9 (inclusive) were significantly different between S and CaD groups. For abbreviations see Figure 1.

to control ones, and the percentage of bound calcium in the blood of treated animals ( $78.0 \pm 2.1$ ) was significantly higher than that found in the control group ( $62.2 \pm 1.8$ ).

The fatty acyl composition of neutral and polar lipids was profoundly modified under CaD conditions. The most important changes were found in liver, followed by kidney, spleen, and cartilage. Table 2 shows the result obtained when we analyzed microsomal neutral lipids from liver, brain, kidney, and heart. Neutral lipids from brain microsomes exhibited a

decreased content of arachidonate and docosahexaenoate (n-3). By contrast, heart microsomes showed no significant changes. Palmitate and stearate content were increased in microsomal neutral lipids from both liver and kidney, with no concomitant modifications in the proportion of the corresponding monoenoates. In liver, the content of linoleate was diminished by 47% with respect to control values, and the proportion of 20:4n-6 (arachidonate) was dramatically reduced with a simultaneous increase in the level of its direct

<sup>a</sup>GLC of the FAME was performed as indicated in the Materials and Methods section. Each value is expressed as  $\mu\text{g}/\text{mg}$  protein and corresponds to the mean  $\pm 1$  SEM of three independent determinations performed on randomly selected samples. Other FA not listed in the table are present in minor amounts. \*Significantly different ( $P < 0.01$ ) with respect to the corresponding control value. Amounts below 0.1  $\mu\text{g}/\text{mg}$  protein are indicated as "Trace." SEM below 0.1 are indicated as "0.0."

precursor (20:3n-6). The fall in 20:4n-6 was also observed in neutral lipids from kidney microsomes, but it was of lesser extent (44%) than that of liver (98%). Within the C<sub>22</sub> FA homologs, we observed in liver microsomes a minor increase in the proportion of 22:0. Phospholipid fatty acyl composition was also modified by calcium deficiency (Table 3). The composition of brain and heart microsomes showed no significant modifications, whereas liver and kidney exhibited an altered pattern. The extent of these changes, especially in liver microsomes, was more pronounced in both number and extension than that observed in neutral lipids. The saturated FA 14:0, 16:0, 18:0, and 22:0 were increased in liver phospholipids from CaD rats, whereas kidney phospholipids contained elevated levels of palmitate and stearate relative to those found in S rats. The most striking difference between the phospholipid fatty acyl composition from CaD and S animals was the higher proportion of linoleate in liver and kidney (72 and 40% over control data, respectively). Arachidonate was decreased *ca.* 60% in liver without any modification in the proportion of its metabolic precursor (20:3n-6). In contrast, the content of 20:4n-6 in phospholipids from kidney microsomes remained unchanged. In phospholipids of microsomes from CaD rats, the highest homologs derived from  $\alpha$ -linolenate, such as 20:5n-3 and 22:6n-3, were decreased 75 and 48%, respectively, with a concomitant increase of 50% in their metabolic precursor (18:3n-3).

Tables 4 and 5 summarize analytical data of fatty acyl composition from neutral and polar lipids of spleen and lung microsomes, fat, and articular cartilage. In neutral lipids from

spleen microsomes (Table 4), saturated FA were increased but arachidonate was decreased *ca.* 83% with respect to the values obtained in S rats. An important increase of 20:3n-6 (400%) was also observed. Neutral lipids of fat from CaD rats showed an increased proportion of arachidonate that was the only change associated with dietary manipulation. Lung microsomes evidenced no significant changes under calcium restriction, but in the case of articular cartilage, an increase in 20:3n-9 and 22:1n-9 FA with a simultaneous decrease in 20:4n-6 and 22:2n-6 were observed (Table 4). The phospholipid fraction from spleen microsomes (Table 5) showed alterations similar to those described for the neutral lipids, that is, an increased proportion of 16:0, 18:0, and 20:3n-6 with a reduced relative amount of 20:4n-6. Contrary to what was seen with neutral lipids, in phospholipids of fat from CaD rats an 86% reduction in arachidonate content was observed. Table 5 also shows that phospholipids from both lung and articular cartilage exhibited a marked decrease in arachidonate proportion. It is also important to remark that, in articular cartilage, we found a large amount of 20:3n-9 FA and low levels of n-6 PUFA (<10%), as previously reported by other authors (27,28). This particular composition is more evident in phospholipids than in neutral lipids of S rats. Interestingly, 20:3n-9 accumulated in neutral and polar lipids of articular cartilage under the CaD condition (Table 5).

The composition of fatty acyl chains in neutral lipids from erythrocyte ghosts or plasmas obtained from CaD animals remained unchanged with respect to that of S rats (Table 6). However, in phospholipids from erythrocyte ghosts a

decrease of 45% in the relative content of arachidonate and a 37% reduction in the 22:6n-3 level were observed. In the plasma phospholipid fraction we found much increased percentages of palmitate and  $\alpha$ -linoleate and decreased arachidonate levels relative to those of control animals (Table 6).

The analytical changes described above correlate well with various metabolic indicators that account for the rate of supply and/or utilization of the different FA chains acylated to lipids (29,30). In Table 7 are summarized some of these parameters for liver and kidney, calculated from the results in Tables 2 and 3. The double-bond index (DBI), obtained as PUFA/saturated FA ratio, was significantly decreased (50 to 60%) in neutral and polar lipids from both liver and kidney microsomes. One possible explanation is that this result may be the consequence of a general failure in FA desaturation capacity together with an accumulation of saturated FA. In all fractions studied, the decrease in the PUFA relative content was evoked through a similar contribution of the n-3 and n-6 FA, resulting in a very similar n-3/n-6 ratio for control and treated animals. However, it was not the same with the essential/nonessential FA ratio. This parameter was significantly diminished in both neutral and polar lipids from the liver and kidney of CaD rats. This alteration may be produced through both a selective loss of unsaturated FA derived from linoleate and/or  $\alpha$ -linolenate and the increment in the FA members of the n-7 and n-9 series. In fact, results from Table 7 indicate that these two possibilities are in agreement with the results obtained. The inhibition in the metabolic transformation of linoleate was clearly indicated through the decreased values of the ED (elongation-desaturation) 18:2n-6 index. Moreover, comparison between this index and ED 20:4n-6 also indicates that the impairment for linoleate utilization was greater in the  $\Delta 6$  desaturation step than in the  $\Delta 5$  one.

Similar conclusions can be derived from comparison between the sum of the desaturase index activity— $\Delta 6 + \Delta 5$  DIA—and the individual index for  $\Delta 6$  and  $\Delta 5$  desaturase enzymes. With regard to this metabolic pathway in kidney phospholipids,  $\Delta 5$ -desaturase activity not only remained at control levels under CaD conditions but also was stimulated (Table 7). The significant decrease in the palmitoyl- and stearoyl-desaturase activity indexes indicates that calcium deficiency also evoked an impairment in the metabolic utilization of both palmitate and stearate, the precursors of the n-7 and n-9 FA series, respectively.

Lipid relationships and data from fluorescence anisotropy measurement of various tissues from CaD rats are shown in Tables 8 and 9. Cholesterol/phospholipid ratio was diminished in heart and kidney microsomes and also in erythrocyte ghosts, articular cartilage, and plasmas. With the sole exception of brain microsomes, in all samples studied a significant reduction in the cholesterol/protein ratio was observed. In most of the tissues, the total lipid/cholesterol ratio was also diminished, indicating that the reduction in the proportion of total lipids was greater than that of cholesterol. The total lipid/protein ratio was significantly reduced in spleen, erythrocyte ghosts, cartilage, and plasmas from CaD rats. Articular cartilage was the only tissue that exhibited a significant decrease in the proportion of total lipids to phospholipids, whereas all the other examined tissues showed an important increase in neutral lipid content relative to polar lipids. Measurements of neutral and polar lipid contents relative to the amount of total protein demonstrated that the general increase observed in the neutral lipid/polar lipid ratio was evoked primarily by the reduction in the phospholipid/protein ratio rather than the increase in the neutral lipid/protein ratio (Table 7).

Steady-state DPH fluorescence anisotropy determinations

<sup>a</sup>Results are expressed as the mean ± 1 SEM of three independent determinations randomly selected from both experimental groups, whether S or CaD. For details see the Materials and Methods section. Diphenylhexatriene (DPH) steady-state fluorescence anisotropy in membrane suspensions was measured at 37°C using the probe DPH as described in the Materials and Methods section. Results for DPH determinations are expressed as the mean ± 1 SEM of six independent determinations assayed in duplicate. \*Significantly different ( $P < 0.01$ ) from the respective control value. ND, not determined.

were carried out in microsomal suspensions from both S and CaD rats (Tables 8 and 9). Experimental data show that calcium deficiency produces microsomal membranes in which acyl chain packing is disordered relative to the membranes of the S group. A similar conclusion was obtained from plasma membranes of erythrocyte ghosts from CaD rats. Fluorescence anisotropy determinations in suspensions from CaD brain microsomes showed no significant changes with respect to the control, as expected from the minor alterations observed in the proportion of membrane lipids under calcium deficiency (Tables 2, 3, and 8).

Some enzyme activities closely related to lipid metabolism were determined in various tissues from S and CaD rats (Table 10). As regards FA desaturases, the most striking difference observed was the very low levels of activities that all tissues studied exhibited with respect to that of liver microsomes. These differences were observed irrespective of the substrate assayed. Kidney and heart microsomes were more active than spleen, lung, or brain. However, specific activity in liver was much greater than that determined in kidney or heart microsomes. The CaD diet evoked an important reduction (54 to 59% respect to control values) in  $\Delta 5$ ,  $\Delta 6$ , and  $\Delta 9$  liver desaturase activities. This reduction was also observed for the rest of the tissues studied except for heart, in which only  $\Delta 9$ -desaturase capacity was affected (Table 10). Basal activity for phospholipase A<sub>2</sub> varied from a maximum for kidney microsomes to a minimum for spleen ones. Lung, heart, and liver displayed similar activities. Calcium deficiency did not modify phospholipase A<sub>2</sub> activity of brain, lung, or heart, but the activities in microsomes from kidney, liver, and spleen were significantly reduced: *ca.* 80% for the former tissues and 35% for the latter (Table 10). The most active tissue acylating free FA to CoA-SH was the liver, which exhibited a basal acyl-CoA synthetase activity three times greater than that of kidney, lung, or heart. Brain and spleen were the least active

tissues studied, with a basal enzyme activity that was almost 80% smaller than that of control liver. In microsomes from CaD rats, an increased acyl-CoA synthetase activity was determined in both kidney and liver (32 and 76% higher, respectively, than that of controls).

Finally, we found a significant reduction in the transcription rate for mRNA that encodes for liver  $\Delta 6$ -desaturase (Fig. 3). The ratio mRNA ( $\Delta 6$ -desaturase)/mRNA ( $\beta$ -actin) was reduced from  $1.62 \pm 0.17$  for S rats to  $0.93 \pm 0.06$  for CaD ones (-43% with respect to control values).

## DISCUSSION

From these results it is evident that calcium levels are, indeed, involved in FA metabolism, and that its deficiency evoked many alterations in several tissues from CaD rats. Taking into account that desaturases are key enzymes in FA metabolism, the main question arising from our findings is whether the analytical changes are the cause or the consequence of the altered desaturase activities. Several studies from this and other laboratories have extensively documented that alterations in desaturase activities, evoked by hormonal and/or dietary manipulations, are usually reflected in the acyl composition of cellular lipids (1,31-36). On the other hand, previous studies from our laboratory demonstrated that fasting and/or energy restriction profoundly modifies desaturase activities, and the gain in body weight is directly involved in this regulatory effect (31,32,37,38). It is generally accepted that desaturase activities determine the final FA profile of a tissue and, in turn, its particular lipid metabolism (31,32,34-36). As stated before, a modified desaturase activity can be ascribed to a change in the body weight gain under certain dietary conditions; therefore, subsequent alterations in the FA profile may be considered as a natural consequence of such a modification. However, in our experimental conditions changes ob-

<sup>a</sup>Results are expressed as <sup>a</sup>pmol of substrate transformed/min-mg protein, <sup>b</sup>dpm/mg protein, or <sup>c</sup>nmol/min-mg protein. Data are given as the mean ± 1 SEM of four independent determinations performed on samples randomly selected from both experimental groups, whether S or CaD. \*Significantly different with respect to the corresponding control value ( $P < 0.01$ ). For technical details see the Materials and Methods section. Trace, below 5 pmol/min/mg protein; ND, nondetectable amount.

**FIG. 3.** Amount of mRNA of  $\Delta 6$  desaturase from livers of S and CaD rats as measured by blot hybridization. Total mRNA isolated from livers was processed independently and subjected to electrophoresis in 1% formaldehyde gel. Blot hybridization was performed as described in the text with the indicated  $^{32}\text{P}$ -labeled probe. The amount of radioactivity in each band was quantified and normalized by means of an image analysis software system. "RT" indicates the relative content of mRNA for  $\Delta 6$ -desaturase gene with respect to the mRNA for  $\beta$ -actin; the latter was chosen to normalize the results for loading differences. Individual ratios are shown below each blot. Means  $\pm$  1 SEM were  $1.62 \pm 0.12$  and  $0.93 \pm 0.06$  for S and CaD rats, respectively. For abbreviations see Figure 1.

served in both the FA profile of several tissues (Tables 2 to 5) and the activities of the desaturase enzymes (Table 10) can be ascribed to calcium deprivation (Table 1) rather than to a difference in food intake (Fig. 1) and/or body weight gain (Fig. 2) between CaD and S rats. Dietary calcium is known to make calcium soaps with FA in the gut, resulting in increased excretion of dietary fats. In the CaD diet group, fat absorption can be expected to be greater than in the S group, thus providing another possible mechanism for the observed differences in tissue FA composition. However, we think the diet employed in our experiments contained standard (normal) amounts of lipids, as previously demonstrated (7). If the phenomenon of low fat absorption plays a particular role in the changes we observed, the analytical and enzymatic modifications would be expected to result from a general lack of availability of calories from fat (or a simultaneous depletion in saturated FA and PUFA as diet precursors). On the contrary, our observations suggest a PUFA deficiency with a selective depletion of FA keeping constant the ratio (n-3)/(n-6). Moreover, previous works from this and other laboratories have demonstrated that low-fat diets evoked a stimulation of  $\Delta 9$ - and  $\Delta 6$ -desaturase activities rather than an inhibition (32,39,40).

Previous experiments clearly demonstrated that the regulatory step in the desaturation mechanism is located at the level of the desaturase protein itself (41,42). Additional evidence from our laboratory led us to discard, rather confidently, a direct effect of calcium ions on the desaturase enzyme itself or on another component involved in the transport of electrons to the terminal component of the desaturase system (1). At present, no experimental evidence that relates to the possible role of a calcium as a desaturase cofactor and/or any other function of this cation as an essential component during the catalytic process has been presented. The results of our previous experiments, performed on the  $\Delta 9$  and  $\Delta 5$  liver microsomal desaturase activities in CaD rats, also led us to discard the idea of the involvement of a soluble (cytosolic) factor or of a problem related to the activation of the substrate

by acylation to CoA-SH (1). Moreover, in the present study we found a significant increase in the acyl-CoA synthetase activity in various tissues from CaD rats (Table 10) in which desaturase activities were simultaneously depressed. A similar conclusion was obtained in the case of the acyl-CoA synthetase activity from livers of CaD rats (1,4). From these considerations, it seems that the effect of calcium deficiency on the desaturase activities may result from an indirect modification that would be produced through a common metabolic disturbance that involves the three desaturase systems we have studied.

The CaD diet clearly induced important modifications in the quality and/or quantity of the FA chains acylated to neutral and polar lipid fractions from microsomal membranes of several tissues (Tables 2 to 5). These changes were closely related to the measured Ca level in tissues (Table 1), and they were observed even in tissues with FA profiles generally considered very stable, such as brain (Table 2) and cartilage (Tables 4 and 5), in which there is not much metabolic diversity owing to their very specialized functions. They were also reflected, though in minor extension, in lipids from erythrocyte ghosts and plasmas from CaD rats (Table 6). Calculations made from the analytical data demonstrated in general that these changes are characterized by an increased saturated FA proportion and a significant decrease in PUFA and DBI (Table 7). All the analytical parameters calculated for the estimation of the metabolic conversion of the saturated and unsaturated FA precursors (29,30) suggest a general loss of desaturation capacity in microsomes from CaD rats (Table 7). In all the tissues studied from CaD rats, we found a significant decrease in the membrane packing order with respect to S rats that was closely associated with several changes in the interlipid and lipid/protein ratios (Tables 8 and 9). It is generally accepted that the main factors that determine the fluidity of membrane lipids are the cholesterol/phospholipid molar ratio and the degree of unsaturation of the phospholipid acyl chains (43–45). In relation to this, the proportion of cholesterol—usually associated with a diminished membrane

fluidity—was significantly reduced in CaD rats with respect to S ones (1,2; Tables 8 and 9). We also found a decrease in those indices determined by the PUFA and DBI. The data presented in Tables 2 to 7 compared to those from Tables 8 and 9 may indicate an apparent contradiction since the CaD condition caused a large decrease in PUFA and an increase in saturated FA, while acyl packing order decreased as a result.

As is well known, the cholesterol/phospholipid ratio, together with DBI values, is the main determinant of acyl chain packing order in membranes (41–43). Tables 8 and 9 show a significant decrease in  $r_s$  values that directly correlates with a decrease of more than 40% in the cholesterol/phospholipid ratio. Apparently, two different changes in membrane composition produce opposite effects on acyl chain packing order: One of them decreases this physicochemical parameter and the other one increases it. The resulting DPH data show that the reduction in cholesterol drives the change measured in the packing state of the membrane. Previous work has documented that, in microsomes from animals fed a fat-deficient diet, the common feature is a depletion in the FA derived from the precursor linoleic and  $\alpha$ -linolenic acids (46,47). The physicochemical state of the membrane is well-known as a key question in determining the activities of the desaturase systems (31,32,41,48–51). As was previously suggested (52), an increased fluidity leads to a depletion in PUFA biosynthesis, and vice versa. This is one aspect of a general regulatory mechanism that controls several membrane functions and that has been designated “viscotropic regulation” (47,52).

Additional experimental support for a central role of the decreased desaturase activities in the effects evoked by calcium deprivation was obtained by determining the transcriptional rate of the mRNA that encodes for rat liver  $\Delta 6$ -desaturase enzyme. In recent reports by Kan *et al.* (53) and Xing and Insel (54), it was demonstrated that a calcium increase in cytosol gives rise to the release of arachidonic acid into the nucleus by means of phospholipase  $A_2$  translocation to the nuclear envelope. This fact is related to the stimulated transcription of desaturase genes described by Landschulz *et al.* (55). Thus, a decrease in calcium availability would imply a reduced transcription rate of FA desaturase from CaD rats.

We think that at least two different mechanisms leading to the same biochemical effect exist. In one, calcium deprivation in rats evoked an important alteration in acylation/deacylation cycles through the inhibition of the calcium-dependent phospholipase  $A_2$ . This primary effect results in a significant modification of the physicochemical properties of the microsomal membranes that, in turn, leads to a subsequent inhibition of the desaturase activities by viscotropic effect. In the other postulated mechanism, deprivation of calcium leads to a general failure in the transcriptional rate for the corresponding FA desaturase mRNA. As a result of these two mechanisms, the modifications in the analytical FA pattern and membrane composition would be the consequence of the adaptation to the CaD condition, which seems to be of general influence rather than limited to a central organ such as liver.

The relationship between FA metabolism in humans and calcium deprivation was recently reviewed (56). Especially in elderly people, calcium loss is related to altered membrane functions and several changes in lipid composition (57). Although this field of study has received some attention during recent years, we think that the interactions between FA metabolism and calcium availability deserve more investigation since they offer novel approaches for understanding human illnesses of increasing incidence such as osteoporosis (56).

**ABSTRACT:** The technique of comprehensive GC (GC × GC) was applied to the analysis of a standard mixture of FAME. The methodology involved the use of two directly coupled capillary GC columns providing different retention mechanisms, with a pulsing modulator located near their union. The first column was chosen to elute analytes based on b.p. variations, and the second column was based on polarity. Thus, the separation in the two dimensions was orthogonal, since solutes delivered simultaneously to the second column had similar b.p., and the second column separated these primarily on their differentiating mechanisms of polarity. Greater sensitivity of detection and narrower peak widths were obtained; here, peak response increases of about 20-fold were obtained, with pulsed peak widths of about 150 ms. Peaks were displayed in a 2-D contour plot to allow the complexity of the compounds to be seen and their b.p. and polarity properties to be readily recognized. Chromatographic separation of geometric and positional isomers of FAME in the 2-D space is possible. Since retention can be related to the degree and manner of unsaturation and isomerization, and as peak positions are highly reproducible in the 2-D retention map, this is a useful aid for component identification in the absence of appropriate standards. In this work, two column combinations were used to examine the effects of polarity changes on component separation. Improved quantitation based on FID area measurement was demonstrated. A sample of marine oil gave 49 resolved, identified peaks, with at least an additional 20 peaks resolved but not identified.

Paper no. L8946 in *Lipids* 37, 715–724 (July 2002).

For dietary, nutritional, and therapeutic reasons, the analysis of FA contained in animal fats and vegetable and other oils has been of considerable interest for some time (1). Analysis of these carboxylic acids has generally been achieved by the formation of the FAME, followed by GC separation and identification. Maximizing the efficiency of separation is now required because of the increasing awareness that these individual compounds may play an important role in human and animal health and because of the structural significance of the compounds. Complex samples comprising components of similar physicochemical properties may make complete reso-

lution difficult or impossible. The need to separately identify individual FAME must therefore increasingly rely on the use of the highest-resolution separation methods available. The ability to separate and uniquely identify such isomers in complex samples is a basic requirement to support their accurate quantitation.

FAME are relatively simple to prepare by established methods, their elution temperatures are lower than the underivatized FA, their GC elution characteristics are more favorable, and a large body of retention index data is available. GC separation of FAME geometric and positional isomers by utilizing the subtle differences between these compounds and specific solute/stationary phase interaction is possible to some degree, but rarely will all peaks be resolved to baseline (2) even when exceedingly long, highly polar (100 m CP Sil 88) columns are used. The increased length requires slow programming rates (<1°C/min) for maximum efficiency; consequently, analysis times are longer. An added complication is that the polar columns required for single-dimension separation can cause the polyunsaturated FAME (PUFA) to elute at similar times as the more saturated higher-M.W. FAME (3), requiring higher resolution (longer columns and slower temperature programming) than would otherwise be necessary (2–6). This increases the complexity of component identification. Good component separation through increased chromatographic column length also enhances identification of components using the retention index.

The most effective (precise and accurate) analysis of any mixture using chromatographic techniques arises when all relevant components are fully resolved from both the other analytes of interest and matrix interferences. In order to minimize the effects of the latter, it is often necessary to perform complex sample cleanup, often decreasing the PUFA yield or recovery.

Multidimensional GC may offer a solution to the resolution and time limitations imposed by single-column analysis, but it cannot be readily applied to an analysis of the total sample. However, the comprehensive 2-D GC (GC × GC) method overcomes this limitation, and a complete 2-D resolution map of a sample may be realized. The present report investigates the possibilities of using GC × GC to maximize the separation efficiency by molecular size, degree of unsaturation, and positional and geometric isomerization of FAME through the significant increase in resolution that can be obtained by using this technique. Furthermore, chemical properties may be deduced from the position of the components in the 2-D separa-

tion, where the location of a compound in the 2-D space may be related to structural features of the molecule. The standard mixtures examined were chosen to demonstrate the application of this technique. Use of a marine oil illustrates the possibilities of the method for complex sample analysis.

## MATERIALS AND METHODS

**Gas chromatography.** All GC analyses were performed on an Agilent 6890 gas chromatograph (Agilent Technologies, Little Falls, DE) equipped with a split/splitless injector, an Agilent 6890 autosampler, and an FID. The data collection rate from the FID was performed at 20 Hz for “normal” GC and either at 100 or 200 Hz for GC  $\times$  GC studies. Chromatographic analyses used a single-temperature program ramp. Hydrogen carrier gas was used at an initial nominal pressure of 100 kPa, and pressure was programmed to maintain a constant average linear velocity. Two column sets were used: column set 1: 30 m  $\times$  0.25 mm i.d.  $\times$  0.25  $\mu$ m film thickness ( $d_f$ ) BPX5 (5% phenyl-equivalent polysilphenylene phase) coated column connected to a 0.8 m  $\times$  0.1 mm i.d.  $\times$  0.1  $\mu$ m  $d_f$  BP20 (polyethylene glycol phase) column. Column set 2: 25 m  $\times$  0.22 mm i.d.  $\times$  0.2  $\mu$ m  $d_f$  BP1 (100% polydimethylsiloxane) coated column connected to a 1.0 m  $\times$  0.1 mm i.d.  $\times$  0.2  $\mu$ m  $d_f$  BPX70 (cyanopropyl polysilphenylene—equivalent to 70% cyanopropyl siloxane). All columns were obtained from SGE International (Ringwood, Victoria, Australia). Temperature program conditions are given in figure legends.

**Description of cryogenic modulation and the GC  $\times$  GC technique.** GC  $\times$  GC is a relatively new technique (7,8), in which effluent from a primary analysis column (dimension 1, or D1) is compressed and/or pulsed as a narrow “re-injection” band onto a second column (dimension 2, or D2). For most applications, the primary column is a conventional nonpolar b.p. separation column, with solutes separated based on dispersion forces. The second column is chosen for its ability to separate those overlapping components from D1 that show differences in D2 sufficient to afford separation. Each re-injection step gives an individual chromatogram on the second column, normally of a few seconds duration, and each of these is contiguous with its neighboring pulsed chromatogram. Since the primary column separation is carried out on a nonpolar phase, the elution temperature is lower than would be expected on a polar column. This aids in extending the molar mass analysis range, since the maximal operating temperature is largely controlled by the upper temperature limit of the polar (second) column. The short second column does not add significantly to the total retention.

Scheme 1 is a diagram of the GC  $\times$  GC arrangement incorporating a longitudinally modulated cryogenic system (LMCS, Everest model; Chromatography Concepts, Doncaster, Australia) (9). A variety of applications of the technique have been reported (10–16). A cryotrap is mounted inside the oven around one of the columns (normally D2) near the union connecting D1 and D2. Expanding liquid CO<sub>2</sub> is used to cool the trap to approximately 100°C or more less than the oven temperature.

SCHEME 1

The movement of the trap is initiated by Agilent Chemstation software. The trap can be moved between the “trap” and “release” (desorb) positions in one of two modes. The most commonly used is the “modulation” mode, where, after a predetermined time, the sequence is initiated by the external events controller of the Agilent Chemstation. The trap then moves in an accurately controlled repetitive sequence of alternate trapping and releasing. Modulation can be varied from 1.5 to 9.9 s in steps of 0.1 s. A 3-s modulation period was used for all GC  $\times$  GC chromatograms in this research. Targeted trapping is an alternative mode. Here, each step is directly controlled by the Chemstation event controller. This mode maximizes solute sensitivity, because an individual component can be completely trapped (zone compressed) into a single cryogenic event before being released as a single narrow band onto the second column. This mode can also be used to determine absolute D2 retention time. Data processing of the resultant digital data stream is detailed elsewhere (16). The GC  $\times$  GC result is effectively a 2-D plot of b.p. separation in one (horizontal) dimension and polarity separation in the (vertical) second. The nonpolar/polar column arrangement allows coeluting solutes (of different polarities) on D1 to be separated by polar interactions on D2. The converse arrangement would mean that coeluting solutes of different polarities would then have to be separated on a nonpolar D2 column, which is less easily achieved.

Refocusing the solute stream near the end of the column set results in zone-compressed components whose sensitivity is significantly increased over the corresponding conventional, single-column analysis. This is a major benefit of the cryogenic modulation process used here (17). The dimensions of D2 must be chosen to complete each individual D2 separation in a relatively few (e.g., one or two) modulation cycles. D1 dimensions and operating conditions are similar to those

of normal single-capillary GC analysis. The D2 column is usually a short, narrow bore column of a thin stationary phase coating operating under fast, pseudo-isothermal conditions. It may be considered isothermal because of the short analysis time compared to the oven ramp rate (i.e., the temperature increment may be only 0.2°C for a 4-s elution time on D2 with a temperature program of 3°C/min).

de Geus *et al.* (18) showed the feasibility of characterizing FAME by 2-D GC. This group used a thermal sweeper modulator to resolve the analytes in FA mixtures contained in fish and vegetable oils. Separation of linear saturated and unsaturated compounds by size, degree of unsaturation, and positional isomerization was shown.

The cryotrapping modulation mechanism is shown in Scheme 2. With the cryomodulator resting in the trap position, solute molecules traveling in the carrier gas encounter the cooled zone and are sorbed in or on the stationary phase as a narrow band (Scheme 2A).

Movement of the trap a sufficient (short) distance along the column to its desorb position (Scheme 2C) causes it to pass over the trapped solutes (Scheme 2B). It travels far enough to clear the trapping section of the column, with that section now raised to the prevailing oven temperature through the forced air flow of the oven, and the trapped solute(s) are then remobilized (Scheme 2C). The bandwidth of the solute (when remobilized) at this point is estimated to be approximately 15 ms, and the trapped solute zone will be of the order of mm length.

At Scheme 2C, any solute that reaches the cooled section of column while the trap is in the desorb position condenses out into a narrow band at this new trap position. As the trap moves back to the start position (Scheme 2D), the condensed solute is again mobilized, moving with the carrier gas until it recondenses, along with any additional incoming solute,

ready for release in the next cycle (Scheme 2E). The process is repeated continually (modulation) or as required (targeted) over the required time segment of the chromatogram.

**Standards and sample.** All studies were carried out using the commercially available FAME mixture GLC 87 supplied by Nu-Chek-Prep Inc. (Elysian, MN) as pure standard material to aid in technique development. The GLC 87 mixture contains saturated and unsaturated FAME and a range of  $C_{16}$ ,  $C_{18}$ ,  $C_{20}$ ,  $C_{22}$ , and  $C_{24}$  mono- and polyunsaturated FAME. The concentration (by mass) of each compound present was as follows: 12:0 (3.0%); 13:0 (3.0%); 14:0 (3.0%); 15:0 (3.0%); 16:0 (18.5%); 17:0 (1.0%); 18:0 (6.5%); 19:0 (0.5%); 20:0 (0.5%); 22:0 (1.2%); 14:1n-5 (0.5%); 16:1n-7 (1.5%); 16:1n-7*t* (0.5%); 18:1n-9 (16.0%); 18:1n-9*t* (2.0%); 18:2n-6 (23.0%); 18:2n-6*t,t* (3.0%); 18:3n-3 (3.0%); 18:3n-6 (0.5%); 20:1n-9 (0.4%); 20:3n-3 (0.5%); 20:3n-6 (1.5%); 20:4n-6 (5.0%); 22:1n-6 (0.4%); 22:2n-6 (0.5%); 22:6n-3 (1.0%); 24:1n-9 (0.5%). The FAME mixture was diluted with analytical grade acetone and injected using split injection with a suitable split ratio.

The marine oil (blue mussel)-derived FAME sample was prepared by using standard procedures (19).

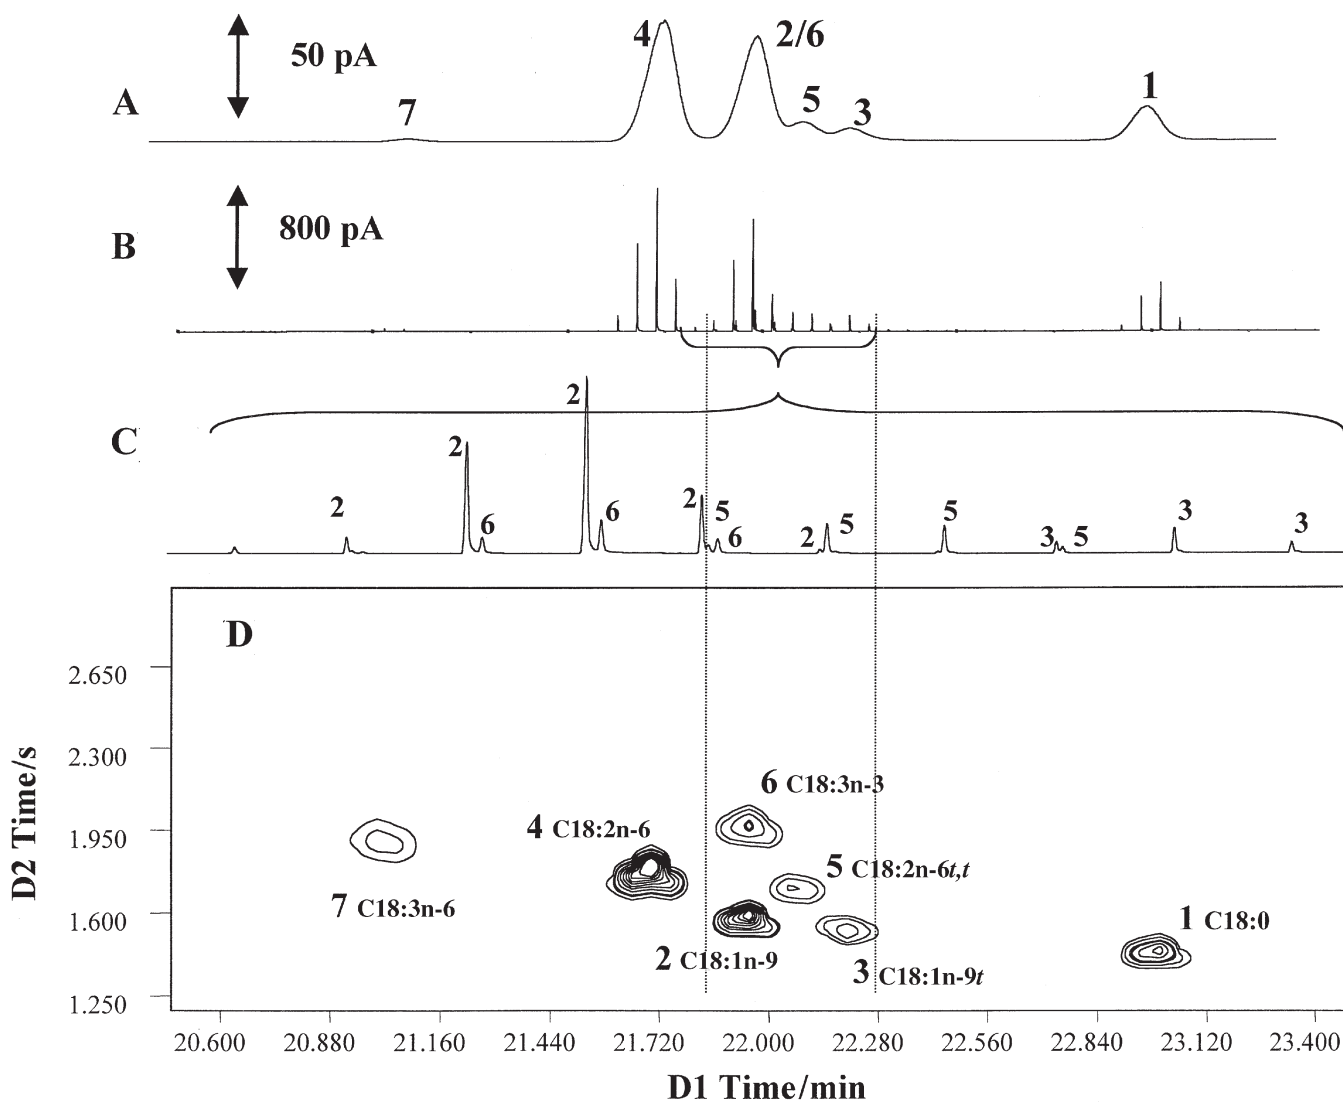

## RESULTS AND DISCUSSION

In this study, the interpretation of isomeric separations focused on the  $C_{18}$  and  $C_{20}$  FAME present in the mixture. The  $C_{18}$  region comprised the seven components 18:0, 18:1n-9, 18:1n-9*t*, 18:2n-6, 18:2n-6*t,t*, 18:3n-3, and 18:3n-6, having different degrees of unsaturation. The  $C_{20}$  region comprised 20:0, 20:1n-9, 20:3n-3, 20:3n-6, and 20:4n-6.

**BPX5/BP20 column set. (i)  $C_{18}$  region.** Figure 1 shows results of the  $C_{18}$  region obtained with column set 1. Figure 1A is a normal GC analysis obtained on the two-column set with-

SCHEME 2

**FIG. 1.** Comparative chromatograms of  $C_{18}$  FAME on column set 1. (A) Normal GC; (B) modulated GC  $\times$  GC chromatogram; (C) expanded region of (B); (D) GC  $\times$  GC 2-D contour plot. (A), (B), and (D) are aligned by dimension 1 (D1) retention times. The temperature program was 150 to 250°C at 2°C/min at a constant flow rate of 1.2 mL/min. The detector and injector temperatures were 260 and 250°C, respectively. A split ratio of 100:1 and a modulation period of 3 s were used. D2, dimension 2.

out using the modulator and shows a chromatogram with only three well-resolved peaks over the 20.50–23.50-min elution region; significant peak overlaps were observed with only six distinct peak maxima seen. Peak widths ( $4\sigma$ ) of about 9 s wide and maximal peak response of about 63 pA were observed. Figure 1B is the same sample run under the same conditions but with the modulator,  $CO_2$  coolant, and nitrogen shield gas operating. Peak widths are now about 0.14 s, and the height of the maximal pulse is 1370 pA (about 20 $\times$  taller than its normal GC peak response). Comparison of the two figures shows a similar overall peak profile; however, each compound in the modulated chromatogram (Fig. 1B) is now a sequence of about five pulses. Figures 1A, B, and D are arranged so that the peaks are aligned vertically, whereas Figure 1C shows an expansion of peaks 2, 3, 5, and 6 to illustrate the successive pulsed D2 chromatograms that eventually formed the 2-D contour plot.

Figure 1D shows a 2-D presentation of the GC  $\times$  GC chromatogram in the  $C_{18}$  region. All seven components are fully resolved; their individual presence is quite clearly seen on the 2-D contour plot. The full separation of these compounds took only 2.2 min in the first dimension, and 0.3 s in the second.

Manipulating the contour plot parameters can often disclose hidden peaks, as can varying the scaling contour. If the contour baseline used for peak plotting is too high, some partial overlap of peaks may be concealed. FAME with greater unsaturation, being more polar, appear with longer retention times in the second dimension. Increased resolution in the first (time-determining) dimension is only required for improved selectivity of positional isomers. The 18:1 component set here is simpler than might be present in regular samples, and as complexity increases, improvements in chromatography are required. An increase in the D2 column length would be sufficient to achieve this.

Figure 2 is the 2-D contour plot of the complete GLC 87 mixture, where complete separation of this mixture was achieved in 40 min. As an indication of the amount of separation required for high PUFA separation, the difference in D2 retention times between 22:0 and 22:6n-3 was approximately 1 s. Increased sample complexity, requiring an increase in D2 resolution, can be achieved by increasing the D2 column length.

Concentrations of the compounds in the original mixture are known, so it is possible to identify the positions of the various  $C_{18}$  isomers in the 2-D space based on their relative peak areas. Peak relative retentions were otherwise supported by GC-MS data using a column similar to that for GC analyses. Thus, the peaks in Figure 1 were identified (as shown in Table 1). For GC  $\times$  GC, peak abundances showed excellent correlation with expected amounts, where the summed areas of peak pulses for each component were compared with the total peak areas for all FAME. Component 6 was not observed as a separate peak in the normal GC analysis, so it could not be quantified. Likewise, some component areas were determined by peak skimming or vertical line drops at peak valleys. These could have led to the inaccurate peak area assignments noted. Where peaks were clearly individual components, GC  $\times$  GC and normal GC gave equivalent peak area percentage results in the present application.

(ii)  $C_{20}$  region. A similar comparison may be made for the  $C_{20}$  region. The unmodulated chromatogram gave peaks about 9.1 s wide ( $4\sigma$ ) and were of reasonably low response (*ca.* 12 pA). Run under modulated conditions, each peak was again a sequence of about five to six pulses, with the expected increases in peak height. Figure 3 shows the 27.5–31.0 min (the  $C_{20}$ ) region, with two separate sets of peak pulses (marked a and b) eluting between 29.5 and 29.9 min. Note that while their D1 retention time is the same, they are well separated in the D2 dimension. The 20:1/20:3n-3 peaks are located in a relative relationship in the 2-D space similar to that shown for 18:1/18:3n-3, suggesting that the relative location of peaks in the 2-D space may be correlated with molecular structure.

(iii) Homologous series trend and unsaturation retention trend. Figure 4 illustrates elution positions in the 2-D space, related by trends in degree of unsaturation (or iso-structural) lines and structure variation for FAME of particular carbon numbers. Positions enclosed by oval zones superimposed on the plot are similar to the lines proposed by de Geus *et al.* (18). Based on this model, it should be possible to identify, to a first approximation, the structure of other FAME eluting elsewhere in the chromatogram. Thus, on Figure 4 the curved lines refer to the trend in homologous series, with  $C_x$  representing the chain length and  $y$  showing an undifferentiated variable (at this

stage) included for completeness of definition. The zones marked C<sub>14</sub> through C<sub>22</sub> refer to trends for different isomers and components within a given carbon number set. Variations in the trend are somewhat variable depending on the nature of

the individual FAME, although one might anticipate that the fine detail of the relative positions of different FAME might be correlated with structural features, as is indicated to some extent in the pattern within the C<sub>18</sub> and C<sub>20</sub> compound sets.

FIG. 4. Correlated trends showing the degree of unsaturation retention and homologous series (curved lines are numbered according to the degree of unsaturation) in the 2-D space. For abbreviations see Figure 1.

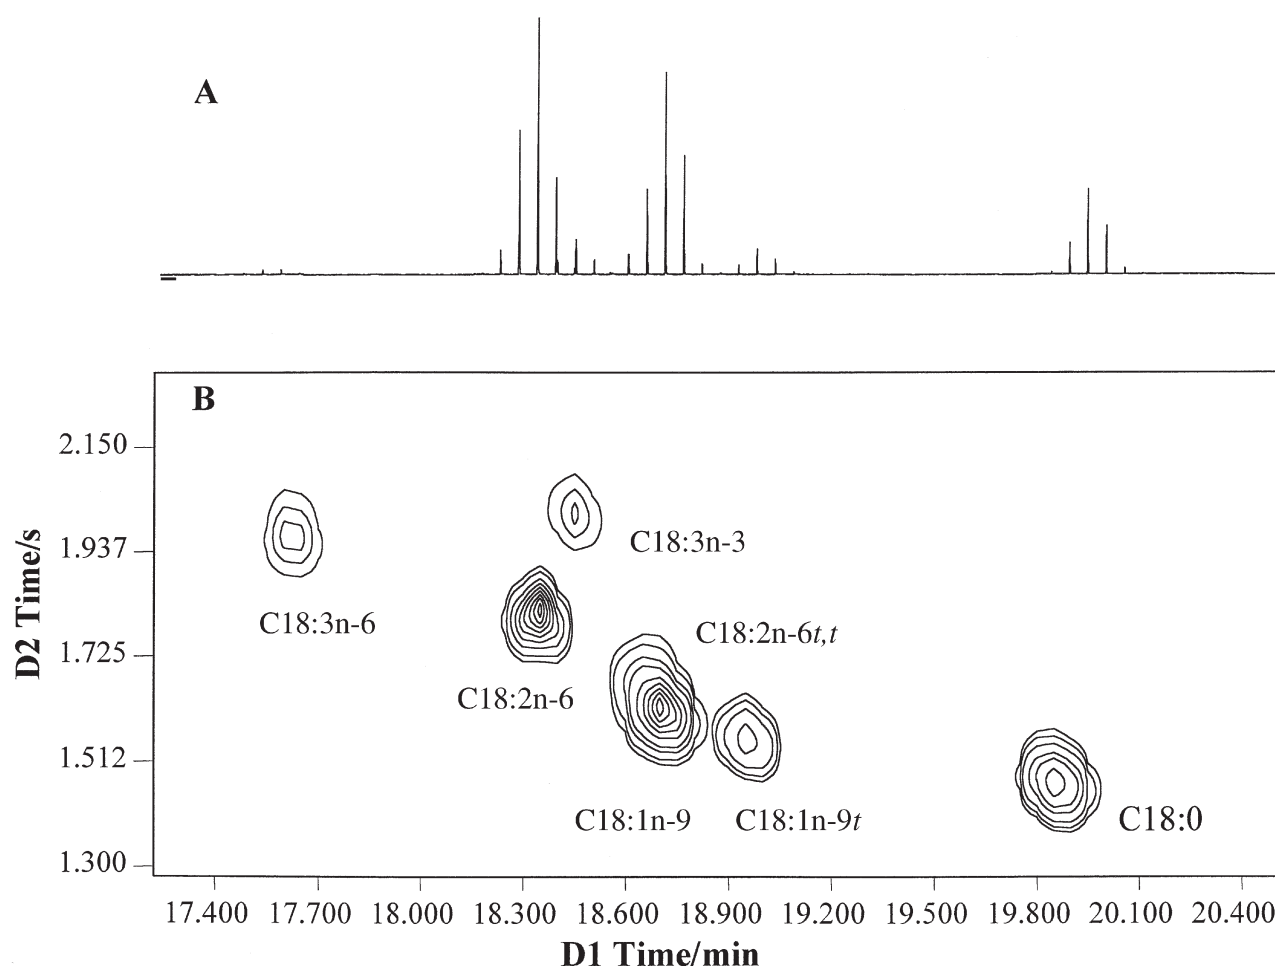

Such data presentation may then be used to facilitate the identification of FAME, especially under a situation where a standard is not available for confirmation purposes.

**BP1/BPX70 column set.** In order to increase resolution of the FAME mixture in the  $C_{18}$  isomer region, the study was repeated with column set 2. It was chosen to maximize the available difference in polarity between the BPX70 D2 column and the low-polarity BP1 D1 column. Along with CP Sil 88, BPX70 is sometimes reported to be the column phase of choice for FAME analysis. Figure 5 shows the modulated chromatogram and the 2-D contour plot of  $C_{18}$  FAME isomers. The compound 18:2n-6,t was not well resolved, being obscured by 18:1n-9, which is present in high abundance. It appears that the less polar BP20 column had better selectivity for these FAME. Figure 6 compares the 2-D plots for the two different column sets for  $C_{18}$  FAME, indicating the relative 2-D positions of 18:3n-3 and 18:2n-6,t; both these components shifted to shorter  $t_R$  compared with the other FAME in this region, which appear to have good pattern matching. In Figure 6B, 18:2n-6,t was placed at an approximate position based on the observation of a shoulder on the pulses of the main peak 18:1n-9. Therefore, 18:2n-6,t could not be seen as

a separate peak in Figure 5 and now co-elutes with 18:1n-9 on D1; these two peaks are vertically aligned in Figure 6B. This contributes to its lower resolution compared with Figure 6A, where 18:2n-6,t is offset from 18:1n-9. As with any chromatographic separation, a change in chromatographic conditions would overcome this problem.

The structural similarity of 18:3n-3 and 18:3n-6 should mean they do not have a large difference in their polarity. Thus, in both Figures 6A and 6B they have only a small difference in their D2 retention times but have a considerable difference in the D1 (b.p.) retention times. Compounds 18:2n-6 and 18:3n-3 have a greater D2 retention difference; this can be interpreted as showing a larger difference in polarity, corresponding to more double bonds in the latter species. However, the difference is larger in column set 2 (approximately 0.187 s) than in column set 1 (approximately 0.169 s), and the different elution temperatures may account for this.

**Marine oil sample.** Figure 7 shows the GC  $\times$  GC separation of a marine oil derived from blue mussel (19). The components were identified by both matching retention times from the present work, and manual spectral deconvolution of GC-MS analysis on a column with properties similar to the

**FIG. 5.** Comparative chromatograms of  $C_{18}$  FAME on column set 2. Conditions are as shown in Figure 1. (A) Modulated GC  $\times$  GC chromatogram; (B) GC  $\times$  GC 2-D contour plot. For abbreviations see Figure 1.

D1 column used in the GC  $\times$  GC studies reported here. The compounds identified are listed in Table 2. It should be noted that the FAME are separated from alkanes (identified by injection of alkane standards) and a suspected plasticizer peak, which are potential causes of interference in single-column chromatography. About 50 peaks are identified or tentatively identified in Figure 7, with an additional  $\sim 20$  peaks showing good resolution but for which identity is unknown. The precision of peak positions in the 2-D space means that the identification of given components in each sample may be as simple as comparing or overlaying the 2-D plots. In addition, identifying the difference between samples involves comparing the differences in peak positions in the 2-D plots.

GC  $\times$  GC separation using LMCS is a powerful technique for analyzing complicated FAME mixtures. Both resolution and sensitivity are increased compared with nonmodulated (conventional) GC. By use of the 2-D contour plot, the presence of all peaks can be detected and also peaks can be easily recognized. Furthermore, trends in both homologous series and unsaturation retention can be identified on the 2-D contour plot. This should aid in identifying unknowns. The approach should now be validated with increasingly complex FAME samples, especially those known to present difficulties

## Similar Effects of *c9,t11*-CLA and *t10,c12*-CLA on Immune Cell Functions in Mice

**ABSTRACT:** Published results regarding the effects of CLA on immune cell functions have ranged from stimulation to inhibition. In those studies, a mixture of CLA isomers were used, and food intake was not controlled. We have examined whether the discrepancies in the results of earlier studies may be due to the lack of controlled feeding and whether the two isomers of CLA may differ in their effects on immune cell functions. Three groups of C57BL/6 female mice were fed either a control, *c9,t11*-CLA-, or *t10,c12*-CLA (0.5 wt%)-supplemented diet, 5 g/d, for 56 d. At the end of the study, the number of immune cells in spleens, bone marrows, or in circulation; proliferation of splenocytes in response to T and B cell mitogens; and prostaglandin secretion *in vitro* did not differ among the three groups. Both CLA isomers significantly increased *in vitro* tumor necrosis factor  $\alpha$  and interleukin (IL)-6 secretion and decreased IL-4 secretion by splenocytes compared to those in the control group. Thus, the two CLA isomers had similar effects on all response variables tested. The discrepancies among the results from previous studies did not seem to be caused by the differences in the isomer composition of CLA used.

Paper no. L9027 in *Lipids* 37, 725–728 (July 2002).

CLA is a collective term for isomers of linoleic acid that have conjugated double bonds. Depending on the position and geometry of the double bonds, several isomers of CLA have been reported (1). Feeding a mixture of these isomers altered several indices of immune cell functions in animal models (2–11) but not in humans (12,13). Even in the animal models, the effects of dietary CLA on immune cell functions have been modest and variable. Thus, in one study splenocyte proliferation in response to the T cell mitogen phytohemagglutinin (PHA) was enhanced 3 wk after supplementing mouse diets with CLA, but not after 6 wk (4). Proliferation in response to another T cell mitogen, Concanavalin A (Con A), was not altered at 3 and 6 wk after CLA supplementation. In another study, 8 wk of CLA supplementation of young mice enhanced splenocyte proliferation at Con A concentrations of

0.5 and 5.0 mg/L, but not at 1.5 mg/L; CLA supplementation did not alter splenocyte proliferation in response to PHA (5). Similar inconsistencies were found regarding the effects of CLA feeding on cytokine secretion, delayed hypersensitivity skin response, and other indices of immune response (2–11). None of these studies controlled food intake or fed purified isomers of CLA, which may be partially responsible for some of the discrepancies. This study examined the effects of two purified isomers of CLA on immune cell functions under conditions of controlled food intake. Isomers used in our study were the *cis*-9 and *trans*-11 (*c9,t11*-CLA), and *trans*-10 and *cis*-12 (*t10,c12*-CLA), which are among the most abundant isomers found in the mixtures used in previous studies. We used a single concentration (0.5 wt%) of each isomer, which is equivalent to the concentrations of these isomers present in the CLA mixtures (0.1 to 1.5%) used in previous studies.

### MATERIALS AND METHODS

**Diets and animals.** Highly enriched *c9,t11*-CLA, and *t10,c12*-CLA isomers as FFA were a kind gift from Natural ASA (Hovdebygda, Norway). Both preparations contained more than 85% of the isomer of interest. AIN-93G mouse diet was used as the basal diet. Fat source in the diet was corn oil, 50 g/kg. CLA isomers were added at 5 g/kg by replacing an equivalent amount of corn oil. Diets were constantly flushed with nitrogen gas while being gently mixed in a blender and then stored at  $-20^{\circ}\text{C}$ . Fresh dietary packets were served each day.

Thirty-five 8-wk-old, pathogen-free C57BL/6N female mice were purchased from Charles River (Raleigh, NC) and divided into three groups (11 or 12/group). Animals were maintained in a sterile air curtain isolator at  $25^{\circ}\text{C}$ , with light and dark cycles of 12 h each. Based on our previous experience with food required by the mice in this age range (14), they were offered fresh food every day (5 g/animal/d) for 56 d. All food was consumed within 4–6 h in all groups. This avoided the need for paired feeding and reduced the possibility of CLA oxidation. At the end of the study, body weight of the mice fed the diet containing *t10,c12*-CLA was significantly lower than that of the other two groups, which did not differ from each other. All conditions and handling of the animals were approved by the Animal Care and Use Committee at the University of California–Davis.

Abbreviations: BrdU, 5-bromo-2-deoxyuridine; *c*, *cis*; Con A, Concanavalin A; DME, Dulbecco's modified Eagle medium; IL, interleukin; LPS, lipopolysaccharide; PGE<sub>2</sub>, prostaglandin E<sub>2</sub>; PHA, phytohemagglutinin; *t*, *trans*; TNF $\alpha$ , tumor necrosis factor  $\alpha$ .

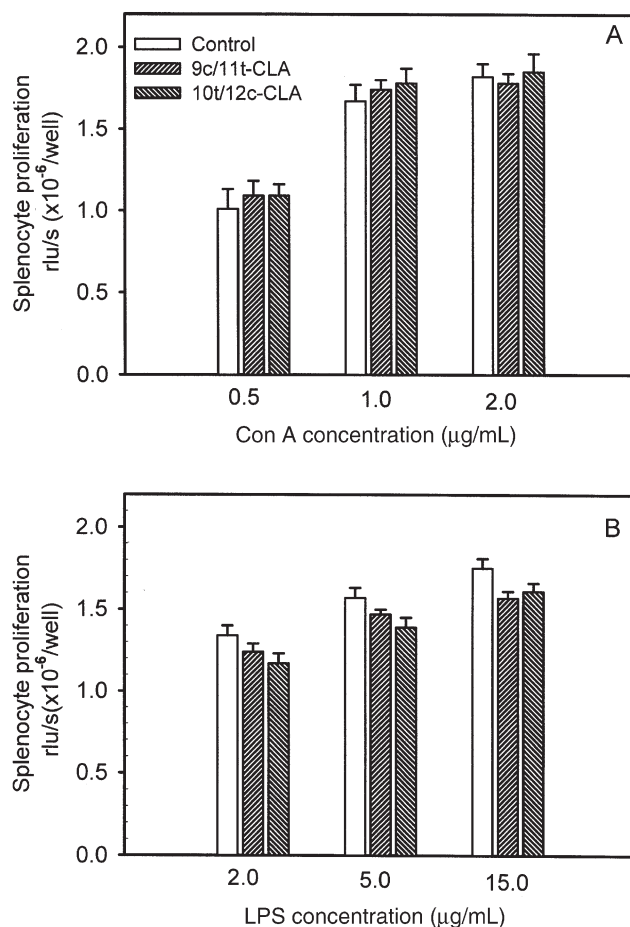

**Tissue collection and cell culture.** Mice were anesthetized, and blood was collected into EDTA-containing syringes by heart puncture. Spleens were aseptically removed, weighed, and placed in 5 mL Dulbecco's modified Eagle medium (DME; Sigma Chemical Co., St. Louis, MO) containing 5% FCS, 25 mmol Hepes, 8 mmol glutamine, penicillin 10 KU/L, and streptomycin 10 mg/L. Splenocytes were prepared as previously reported (15) and suspended in the DME medium containing 5% FCS. For cell proliferation assays, splenocyte concentrations were adjusted to 2 million/mL and 100  $\mu$ L cell suspensions were added to each well of 96-well plates (Falcon Labware, Gaithersburg, MD). This was followed by the addition of an extra 100  $\mu$ L media containing either the T cell mitogen, Con A (final concentrations 0, 0.5, 1.0, and 2.0 mg/L), or the B cell mitogen, lipopolysaccharide (LPS) (final concentrations 0, 2.0, 5.0, and 15.0 mg/L). Three wells were used for each mitogen concentration. Plates were then incubated at 37°C, 5% CO<sub>2</sub>, and 100% humidity for 72 h. Proliferation was determined by incorporation of 5-bromo-2-deoxyuridine (BrdU) into the DNA (16,17); the Proliferation ELISA BrdU chemiluminescence kit was purchased from Roche (Mannheim, Germany) and used as described by the manufacturer. Results are expressed as relative light units (rlu)/s/well; one rlu is equivalent to one million photons/s/well.

For cytokine and eicosanoid secretion assays, 2 million splenocytes in duplicates were incubated in 1.0 mL of media containing LPS (0, 1, and 10 mg/L) or Con A (0, 1, and 5 mg/L) in 24-well plates for 4, 24, and 48 h. The cell culture media were collected following centrifugation and stored frozen at -70°C. Media from LPS-treated cultures were used to monitor tumor necrosis factor  $\alpha$  (TNF $\alpha$ ), interleukin (IL)-6, and prostaglandin (PG) E<sub>2</sub>, while those from Con A-treated cells were used to determine IL-2 and IL-4 using ELISA assays. Mitogen concentrations and incubation times were selected based on preliminary experiments. ELISA kits for TNF $\alpha$ , IL-2, IL-4, and IL-6 were purchased from BD Pharmingen (San Diego, CA) and those for PGE<sub>2</sub> from Cayman (Ann Arbor, MI).

**Statistical analysis.** The data were subjected to one-way ANOVA between and within diets, using the SAS software (18). The one-tailed version of Dunnett's test was used to make comparisons of the test diet means with the control diet. Levene's test was used to examine the homogeneity of variance assumption. When heterogeneity was encountered, it was incorporated into the model using the SAS PROC MIXED.

## RESULTS

**Effect of CLA on cell numbers and splenocyte proliferation.** Both CLA isomers did not alter the total number of circulating white blood cells or their percentages as neutrophils, lymphocytes, monocytes, eosinophils, and basophils; nor did they alter the number of splenocytes or bone marrow cells (not shown). Figure 1 shows that neither of the CLA isomers altered splenocyte proliferation in response to both the T and B cell mitogens, although the proliferation was increased with increase in mitogen concentration in all groups.

**FIG. 1.** Effect of CLA on splenocyte proliferation in response to Concanavalin A (Con A) (A) and lipopolysaccharide (LPS) (B). Splenocytes were cultured with the indicated mitogen concentrations for 72 h. Lymphocyte proliferation was examined by the incorporation of 5-bromo-2-deoxyuridine into the cellular DNA during the last 24 h in culture. Results are expressed as mean  $\pm$  SEM of rlu (relative light units)/s/well. Neither of the CLA isomers altered splenocyte proliferation in response to both the mitogens.

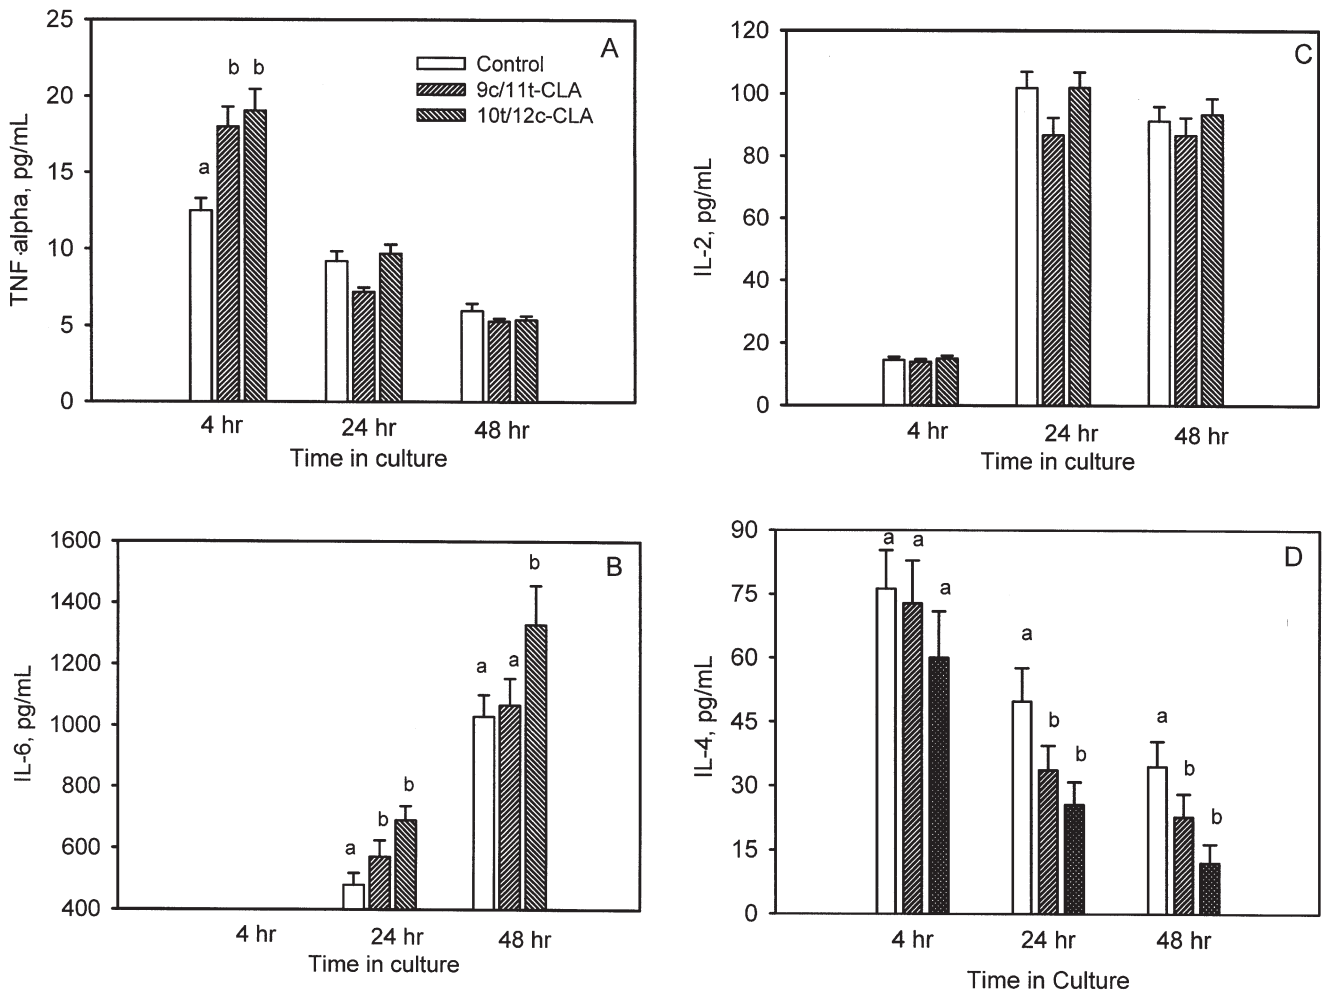

**Effect of CLA on eicosanoid and cytokine secretion.** We examined the effects of CLA feeding on markers for inflammation (PGE<sub>2</sub>, TNF $\alpha$ , and IL-6) and on representative cytokines for Th1 (IL-2) and Th2 (IL-4) cells. Treatment effects at the two mitogen concentrations were similar, but results are shown only for the higher mitogen concentrations (LPS, 10  $\mu$ g/mL, for PGE<sub>2</sub>, TNF $\alpha$ , and IL-6; Con A, 5  $\mu$ g/mL for IL-2 and IL-4). Concentrations of PGE<sub>2</sub> in the medium collected at 4, 24, and 48 h from the splenocytes isolated from the mice fed control diet were 5.0  $\pm$  0.6, 5.4  $\pm$  0.5, 5.3  $\pm$  0.6 pg/mL, respectively. The PGE<sub>2</sub> concentrations in the two CLA groups did not differ from those in the control group (not shown). Medium concentrations of TNF $\alpha$  and IL-4 decreased between 4 and 48 h, whereas those of IL-2 and IL-6 increased (Figs. 2A–D). TNF $\alpha$  secreted within 4 h of mitogen stimulation was significantly greater ( $P < 0.001$ ) in both the CLA groups than in the control group. Medium concentration of TNF $\alpha$  did not differ among the three groups at 24 and 48 h, and also

between the two CLA isomers at all three time points. IL-6 secreted into the medium after 4 h of LPS treatment was non-detectable in all three groups. Twenty-four hours after LPS treatment, secreted IL-6 was significantly ( $P < 0.01$ ) greater in both the CLA groups than in the control group, whereas after 48 h, the difference was significant only for *t10,c12*-CLA ( $P < 0.01$ ) (Fig. 2B).

The concentration of secreted IL-2 increased six- to seven-fold from 4 to 24 h in all three groups of cells but did not change between 24 and 48 h; there was no difference in its concentration among the three groups at all three time points (Fig. 2C). Neither of the CLA isomers altered the concentration of IL-4 secreted within 4 h of mitogen treatment, but it was significantly reduced by both the isomers at 24 and 48 h after mitogen treatment (Fig. 2D). There was no difference in IL-4 concentrations in the two CLA groups at all three time points.

## DISCUSSION

We compared the effects of feeding two purified isomers of CLA on several indices of immune and inflammatory responses in mice maintained on a controlled feeding regime. Effects of the two isomers on immune cell functions did not differ. Both the *c9,t11*-CLA and *t10,c12*-CLA did not alter the number of immune cells in circulation, in spleens, or in bone marrows. Neither of the isomers affected splenocyte proliferation in response to T and B cell mitogens, or the secretion of PGE<sub>2</sub> and IL-2. We had found similar results with feeding of a mixture of CLA isomers to healthy women (12,13). These results are in part consistent with those of earlier reports in mice (4,5). In one of these reports, 8 wk of CLA supplementation resulted in a modest increase in splenocyte proliferation at Con A concentrations of 0.5 and 5.0, but not

**FIG. 2.** Effect of dietary CLA on *in vitro* secretion of tumor necrosis factor  $\alpha$  (TNF $\alpha$ ) (A), interleukin (IL)-6 (B), IL-2 (C), and IL-4 (D) by splenocytes stimulated with 10  $\mu$ g/mL LPS (A and B) and 5  $\mu$ g/mL Con A (C and D). Bars with different letters are significantly different. Secreted TNF $\alpha$  at 4 h was significantly ( $P < 0.001$ ) greater in both CLA groups than in the control group; at 24 and 48 h there was no significant difference among all three groups. Secreted IL-6 at 24 h was significantly ( $P < 0.01$ ) greater in both CLA groups than the control group; at 48 h the difference was significant only for the *t10,c12*-CLA group. At all times, secreted IL-2 was not significantly different among the three groups. Secreted IL-4 was significantly less in both CLA groups than in the control group at 24 and 48 h ( $P < 0.03$ ) but not at 4 h.

at 1.5 mg/L (5). In the other report, 6 wk of CLA supplementation did not affect splenocyte proliferation (4). IL-2 secretion was increased in one (5) but not in the other study (4). Results regarding splenocyte proliferation differ from those of another study that found increased proliferation in response to both Con A and PHA in splenocytes isolated from mice fed a CLA-containing diet (2).

Both CLA isomers increased the secretion of TNF $\alpha$  and IL-6 and decreased that of IL-4 (Figs. 2A–D). These changes could have been easily missed if we had tested all cytokines only at a single time point. Our results regarding TNF $\alpha$  and IL-6 differ from those obtained with rat peritoneal macrophages, where feeding a mixture of CLA isomers decreased the secretion of both these cytokines (6). Those investigators reported that the effect of CLA varied with the n-6/n-3 FA ratio of the experimental diets. Results of our current study also differ from those found in humans (12,13), which most likely are due to the amount of CLA fed; the amount of CLA/kg body weight was 20 times greater in the mouse than in the human study. The amount of CLA needed in humans to match that used in the mice will require 75 g/d/60 kg person; this is greater than or equal to the total daily fat consumed by most humans and cannot be considered as a nutritional supplement.

Published effects of CLA on immune cell functions varied not only for the functions tested in this study but also for other functions including delayed type hypersensitivity response, ratios between helper and suppressor T cells, and serum immunoglobulin levels (4–10) as well. The results have ranged from stimulation to inhibition or no effect. These discrepancies do not seem to be due to the differences in isomer composition of the CLA mixtures used, because the effects of two isomers in the present study were similar. These may be due to lack of controlled feeding or other factors, including culture conditions (serum type and concentration, mitogen concentration and culture period), cell type (peritoneal vs. splenocyte vs. blood cells) composition, and storage of the diets, species, and age of the animals.

In conclusion, both CLA isomers have similar effects on several aspects on immune cell functions in mice; many indices were not altered by both isomers, whereas others were modestly affected by both isomers. Because of only modest effects, even at high concentrations of CLA intake, any clinical benefit to enhance immune status with nutritional supplements of CLA seems unlikely.

**ABSTRACT:** In mammalian cells, Sprecher has proposed that the synthesis of long-chain PUFA from the 20-carbon substrates involves two consecutive elongation steps, a  $\Delta 6$ -desaturation step followed by retroconversion (Sprecher, H., *Biochim. Biophys. Acta* 1486, 219–231, 2000). We searched the database using the translated sequence of human elongase ELOVL5, whose encoded enzyme elongates monounsaturated and polyunsaturated FA, as a query to identify the enzyme(s) involved in elongation of very long chain PUFA. The database search led to the isolation of two cDNA clones from human and mouse. These clones displayed deduced amino acid sequences that had 56.4 and 58% identity, respectively, to that of ELOVL5. The open reading frame of the human clone (ELOVL2) encodes a 296-amino acid peptide, whereas the mouse clone (Elov12) encodes a 292-amino acid peptide. Expression of these open reading frames in baker's yeast, *Saccharomyces cerevisiae*, demonstrated that the encoded proteins were involved in the elongation of both 20- and 22-carbon long-chain PUFA, as determined by the conversion of 20:4n-6 to 22:4n-6, 22:4n-6 to 24:4n-6, 20:5n-3 to 22:5n-3, and 22:5n-3 to 24:5n-3. The elongation activity of the mouse Elov12 was further demonstrated in the transformed mouse L cells incubated with long-chain ( $C_{20}$ - and  $C_{22}$ -carbon) n-6 and n-3 PUFA substrates by the significant increase in the levels of 24:4n-6 and 24:5n-3, respectively. This report demonstrates the isolation and identification of two mammalian genes that encode very long chain PUFA specific elongation enzymes in the Sprecher pathway for DHA synthesis.

Paper no. L9060 in *Lipids* 37, 733–740 (August 2002).

PUFA are involved in many biological functions including inflammatory response (1), fetal growth and development (2), retinal function, and brain development (3,4). The 20-carbon PUFA also serve as precursors to eicosanoids, such as prostaglandins, prostacyclins, thromboxanes, and leukotrienes (5). Small amounts of very long chain PUFA with a chain length of 22 carbons or more are also present in many animal tissues, especially in the testis, retina, brain, and liver (6).

PUFA of the n-6 and n-3 families are either obtained directly from the diet or derived from biosynthesis of dietary

Abbreviations: AA, arachidonic acid (20:4n-6); ALA,  $\alpha$ -linolenic acid (18:3n-3); LA, linoleic acid (18:2n-6); m-ELO, mouse L cells cloned with mouse elongase gene Elov12.

**FIG. 1.** Metabolic pathway of long-chain PUFA. The dashed arrows indicate the Sprecher pathway (Ref. 11).

EFA, linoleic acid (LA, 18:2n-6) and  $\alpha$ -linolenic acid (ALA, 18:3n-3). The biosynthesis of n-6 and n-3 long-chain PUFA requires several desaturation and elongation enzymes (Fig. 1). The  $\Delta 6$ -desaturase converts LA and ALA to  $\gamma$ -linolenic acid (18:3n-6) and stearidonic acid (18:4n-3), respectively. An elongation system adds two carbons to synthesize 20:3n-6 from 18:3n-6 and 20:4n-3 from 18:4n-3. The  $\Delta 5$ -desaturase then converts 20:3n-6 and 20:4n-3 to form arachidonic acid (AA, 20:4n-6) and EPA (20:5n-3), respectively. A second elongation system converts AA to 22:4n-6 and converts EPA to 22:5n-3. It was generally believed that 22:5n-6 and DHA (22:6n-3) were formed from 22:4n-6 and 22:5n-3 by the action of  $\Delta 4$ -desaturase. However, results from several studies have indicated that such a  $\Delta 4$ -desaturase does not exist in mammalian tissues (7–10). Sprecher and others have shown that DHA is produced in mammalian cells through a pathway involving two consecutive elongation steps (from 20:4n-6 to 22:4n-6 and from 22:4n-6 to 24:4n-6 in the n-6 metabolic pathway, and from 20:5n-3 to 22:5n-3 and from 22:5n-3 to 24:5n-3 in the n-3 metabolic pathway) (11–16), followed by a

$\Delta 6$ -desaturation (from 24:4n-6 to 24:5n-6 in the n-6 pathway and from 24:5n-3 to 24:6n-3 in the n-3 pathway) and retro-conversion (from 24:5n-6 to 22:5n-6 and from 24:6n-3 to DHA, by  $\beta$ -oxidation in the peroxisomes) (Fig. 1) (17).

According to Sprecher's pathway, synthesis of long-chain PUFA (i.e., DHA from ALA and 22:5n-6 from LA) requires at least three different elongation steps. Since recent evidence has suggested that chain length-specific PUFA-elongating enzymes are present in rat microsomes (16–18), it is possible that the three elongation steps in Sprecher's pathway are regulated by different elongation enzymes. Previously, we isolated ELOVL5 from human liver and demonstrated the ability of the encoded enzyme to elongate C<sub>18</sub>- and C<sub>20</sub>-PUFA when expressed in baker's yeast, *Saccharomyces cerevisiae* (19). However, no enzyme that is involved in the elongation of 22:4n-6 to 24:4n-6 and 22:5n-3 to 24:5n-3, respectively, has been identified (17).

Recently, Tvrdik *et al.* (20) isolated a series of mouse elongation genes (Elovl1, Elovl2, and Elovl3). They showed that Elovl1 and Elovl3 genes are homologs of yeast ELO3 and ELO2 genes, respectively (21), and that their encoded proteins are involved in the elongation of a broad group of saturated and monounsaturated FA up to 24 carbons, but not long-chain PUFA (21). The specific activity of Elovl2, on the other hand, had not been established. Since the level of expression of Elovl2 is high in testis, which is also rich in long-chain PUFA, it is possible that Elovl2 is involved in the metabolism of long-chain PUFA species (20). In this report, we describe the isolation of Elovl2 from mouse and its homolog ELOVL2 from human, and demonstrate the involvement of their respective encoded enzymes in elongation of very long chain PUFA when expressed in baker's yeast and mammalian cells. This is the first report of mammalian genes encoded for very long chain PUFA-specific elongation enzymes involved in the biosynthesis pathway proposed by Sprecher (11).

## EXPERIMENTAL PROCEDURES

**Identification and cloning of the Elovl2 and ELOVL2 cDNA.** A Basic Local Alignment Search Tool (BLAST) search of the databases through the National Center for Biotechnology Information (NCBI) (<http://ncbi.nlm.nih.gov>) was carried out using the DNA sequence of human ELOVL5 as a query. The search resulted in identifying the mouse and human expressed sequence tag (EST) sequences with high homology to the ELOVL5 sequence. Primers were designed to PCR-amplify the protein coding regions of Elovl2 and ELOVL2 from mouse and human brain Marathon-Ready™ cDNA (Clontech, Palo Alto, CA), respectively. Primers RO819 (5'-ATG ATG CCA TGG AGC AGC TGA AGG CCT TTG-3') and RO820 (5'-CAG TCT CTG CTT TAA AAC AAG CTC GTC-3') were designed based on the putative Elovl2 sequence, and primers RO869 (5'-TGC GGA CCA TGG AAC ATC TAA AGG CCT TTG-3') and RO870 (5'-TTA CTC AAG CTT ATT GTG CTT TCT TGT TC-3') were designed based on the putative ELOVL2 sequence. The DNA frag-

ments were then ligated into the pYX242(*NcoI/HindIII*) vector (Novagen, Madison, WI) to form plasmids designated as pRAE-84 (Elovl2) and pRAE-90 (ELOVL2), respectively.

**Expression of the mouse and human cDNA in baker's yeast.** The plasmid DNA, pRAE-84 and pRAE-90, were transformed into *S. cerevisiae* 334, and the resulting clones were screened for elongase activity (22). *S. cerevisiae* 334, which contains only the pYX242 vector, was used as the negative control. The cultures were grown for 44 h at 30°C in selective media containing saturated FA (16:0, 18:0, 20:0, 22:0), monounsaturated FA (16:1, 18:1, 20:1), and different PUFA (e.g., LA, ALA, 18:3n-6, 18:4n-3, 20:4n-6, 20:5n-3, 22:4n-6, and 22:5n-3) as substrates.

**Cloning and expression of the mouse cDNA in L cells.** In this study, the mouse L cells used to generate the cell lines were derivatives of the fibroblast-like LtK cells (23). The mouse Elovl2 DNA fragment was ligated into the pMET vector to form the plasmid pMET-mELONGASE-bGHpA. Mouse L cells were then transfected with this plasmid by the calcium phosphate precipitation procedure to generate stable cell lines (24). The presence of the integrated elongation enzyme sequences in individual L-cell clones was verified by DNA slot blot hybridization analysis using an [ $\alpha$ -<sup>32</sup>P]dCTP-labeled *SmaI/EcoRI* fragment from pRAE-84. The resulting clones were screened for elongating activity in the serum-free medium with or without the added substrate. Mouse L cells without the mouse elongation enzyme cDNA were used as the negative control. The cells were grown in T25 cm<sup>2</sup> flasks to 80% confluency in DMEM (High Glucose; Gibco, Grand Island, NY) containing 10% Nu-Serum, 50  $\mu$ g/mL gentamicin sulfate, 15  $\mu$ g/mL hypoxanthine, 1  $\mu$ g/mL aminopterin, and 5.15  $\mu$ g/mL thymidine. The cells were then washed two times with 6 mL of serum-free DMEM and incubated for 18 h in 10 mL DMEM, 50  $\mu$ g/mL gentamicin sulfate, 15  $\mu$ g/mL hypoxanthine, 1  $\mu$ g/mL aminopterin, and 5.15  $\mu$ g/mL thymidine with or without substrate. In this study, 100  $\mu$ M of long-chain PUFA (20:4n-6, 22:4n-6, 20:5n-3, and 22:5n-3) were used as substrates for determination of the expressed cDNA activity. Following incubation, the cells were isolated by trypsin treatment, resuspended in 1 mL serum-free DMEM and pelleted by low-speed centrifugation. The supernatant was removed and the cells were stored at -80°C until FA analysis.

**Distribution of Elovl2 in mouse tissues.** Male (C57 Black) mice were fed a normal diet for 24 wk. Total RNA was isolated from fresh tissues using RNA STAT-60™ (Tel-Test Inc., Friendswood, TX). Ten micrograms of total RNA was resolved on a 1% agarose gel containing 1% formaldehyde and then transferred to GeneScreen Plus (NEN, Boston, MA). Membranes were hybridized overnight in ULTRAhyb™ solution (Ambion, Inc., Austin, TX). The cDNA probe for Elovl2 was the *SmaI/EcoRI* fragment from pRAE-84. The probe was labeled with [ $\alpha$ -<sup>32</sup>P]dCTP using the Random Primed DNA Labeling Kit (Roche, Palo Alto, CA).

**FA analysis.** The FA distribution (as percentage of total FA) of recombinant yeast cells containing pRAE-84, pRAE-90, pYX242, and mouse L cells inoculated with pMET-

mELONGASE-bGHPA, in the presence of various substrates, was analyzed following the method described previously (24–26). Briefly, the rinsed cell pellet was extracted with 20 mL of chloroform/methanol (2:1, vol/vol) containing 16 µg triheptadecanoin (used as the internal standard). After extraction, the total cell lipids were saponified and methylated. FAME were then analyzed by GC using a Hewlett-Packard gas-liquid chromatograph (model 6890) equipped with an FID and a 30-m fused-silica capillary column (0.32 mm, i.d.) coated with 0.25 µm Omegawax (Supleco, Bellefonte, PA). The injector and detector temperatures were 230°C. The FAME were identified by comparison of their retention times with authentic standards. The identity of novel FA was verified by GC-MS using a Hewlett-Packard mass selective detector (model 5972) operating at an ionization voltage of 70 eV with a scan range of 20–500 Da. The mass spectra of new peaks obtained were compared with those of a standard prepared by H. Sprecher. The percent conversion was calculated as  $[\text{product}/(\text{substrate} + \text{product})] \times 100$ .

## RESULTS

*Isolation of putative mouse and human cDNA sequences.* The human ELOVL5 translated sequence was used as a query to search the database for a putative mammalian protein sequence involved in the long-chain PUFA elongation of the retroconversion pathway. The search resulted in two full-length sequences, mouse Elovl2 and human ELOVL2. Mouse Elovl2 consisted of 876 bp, which encoded for 292 amino acids. The translated sequence of Elovl2 exhibited 58% iden-

tity with that of human ELOVL5 (Fig. 2). The sequence of human ELOVL2 consisted of 888 bp, which encoded for 296 amino acids. The putative human elongase had 56.4% identity with the human ELOVL5 protein (Fig. 2).

*Expression of the mouse and human cDNA in yeast.* To examine the substrate specificity of Elovl2 and ELOVL2, the recombinant yeast strains 334(pRAE-84) containing Elovl2 and 334(pRAE-90) containing ELOVL2 were grown in minimal media supplemented with 25 µM of different FA substrates. In yeast strains incubated with either saturated FA (16:0, 18:0, 20:0, and 22:0), or monounsaturated FA (16:1, 18:1, and 20:1), no elongation of these substrates was detected (data not shown). To examine if Elovl2 and ELOVL2 had the ability to elongate long-chain n-6 PUFA, the recombinant yeast strains 334(pRAE-84) and 334(pRAE-90) were grown in minimal media supplemented with 25 µM of 18:2n-6, 18:3n-6, 20:4n-6, or 22:4n-6. No elongation products were observed in 334(pRAE-84) and 334(pRAE-90) yeasts incubated with 18:2n-6 (data not shown). When 18:3n-6 was added as the substrate, a small level of 20:3n-6 (0.43% by weight of total yeast FA), the elongation product of 18:3n-6, was found in yeast strain 334(pRAE-84) but not in 334(pRAE-90) (Table 1). When both yeast strains were incubated with the 20- and 22-carbon long-chain n-6 PUFA, significant proportions of these substrates were converted to their respective elongated products. For example, when 20:4n-6 was added as the substrate, a considerable amount of 20:4n-6 was converted to 22:4n-6: 3.29% in strain 334(pRAE-84) and 1.18% in strain 334(pRAE-90). In addition to 22:4n-6, a novel FA was also observed in yeast lipid

<sup>a</sup>pRAE-84, mouse ELOVL2 elongation enzyme gene; pRAE-90, human ELOVL2 elongation enzyme gene.

extracts. This FA had a retention time by GC and ion fragmentation pattern by GC–MS identical to those of the authentic 24:4n-6 standard (a gift from H. Sprecher) (Fig. 3). Thus, this novel FA was identified as 24:4n-6, an elongation product of 22:4n-6. The level of 24:4n-6 accounted for 3.22% in strain 334(pRAE-84), and 0.53% in strain 334(pRAE-90). Incubation with 22:4n-6 also resulted in an increase in the level of 24:4n-6 in both yeast strains (Table 1).

The recombinant yeast strains 334(pRAE-84) and 334(pRAE-90) were also grown in minimal media supplemented with 25  $\mu$ M of different n-3 long-chain PUFA substrates (e.g., 18:3n-3, 18:4n-3, 20:5n-3, and 22:5n-3). In yeasts incubated with 18:3n-3, no detectable amounts of 20:3n-3 (the elongation product of 18:3n-3) were found (data not shown). When incubated with 18:4n-3, a small portion of this FA (0.30%) in yeast strain 334(pRAE-84), but not 334(pRAE-90), was converted to its elongation product, 20:4n-3 (Table 2). When incubated with 20:5n-3 and 22:5n-3, both yeast strains showed the ability to elongate both n-3 PUFA (Table 2). Specifically, incubation with 20:5n-3 resulted in an increase in the levels of 22:5n-3, the direct elongation product of 20:5n-3. A novel FA was also detected in the yeast lipid extracts. The identity of this novel FA was confirmed to be 24:5n-3 based on its identical retention time and fragmentation pattern to that of the authentic 24:5n-3 standard (a gift from H. Sprecher) (Fig. 4). The levels of 24:5n-3 were found to be 3.38% in strain 334(pRAE-84) and 1.94% in strain 334(pRAE-90). Incubation with 22:5n-3 also significantly increased the levels of 24:5n-3: 2.02% in 334(pRAE-84) and 1.51% in 334(pRAE-90).

*Expression of the mouse cDNA in mouse L cells.* Control and Elov12-cloned mouse L cells (m-ELO) were incubated in serum-free medium containing 100  $\mu$ M of n-6 FA (i.e., 20:4n-6 and 22:4n-6). Results in Table 3 show that the FA profile of m-ELO cells was significantly different from that of the control cells. When 20:4n-6 was added as the substrate, the level of 24:4n-6 was significantly higher (3.01%) in cells inoculated with the Elov12 gene than that (0.59%) in the controls, an increase of more than fivefold. When 22:4n-6 was added as the substrate, the levels of 24:4n-6 in the m-ELO cells were significantly increased to 1.44% (vs. 0.06% in the controls). This represented a 24-fold increase.

Similar results were also seen in the control and m-ELO cells incubated in serum-free medium supplemented with two

different n-3 substrates, 20:5n-3 or 22:5n-3 (Table 4). In cells incubated with 20:5n-3, the level of 24:5n-3 was 1.69% in the m-ELO cells. When compared with the control cells (0.55%), there was a greater than threefold difference. When 22:5n-3 was added as the substrate, the level of 24:5n-3 was increased to 4.66% in the m-ELO cells. In comparison with the control cells (1.72%), this represents a threefold difference.

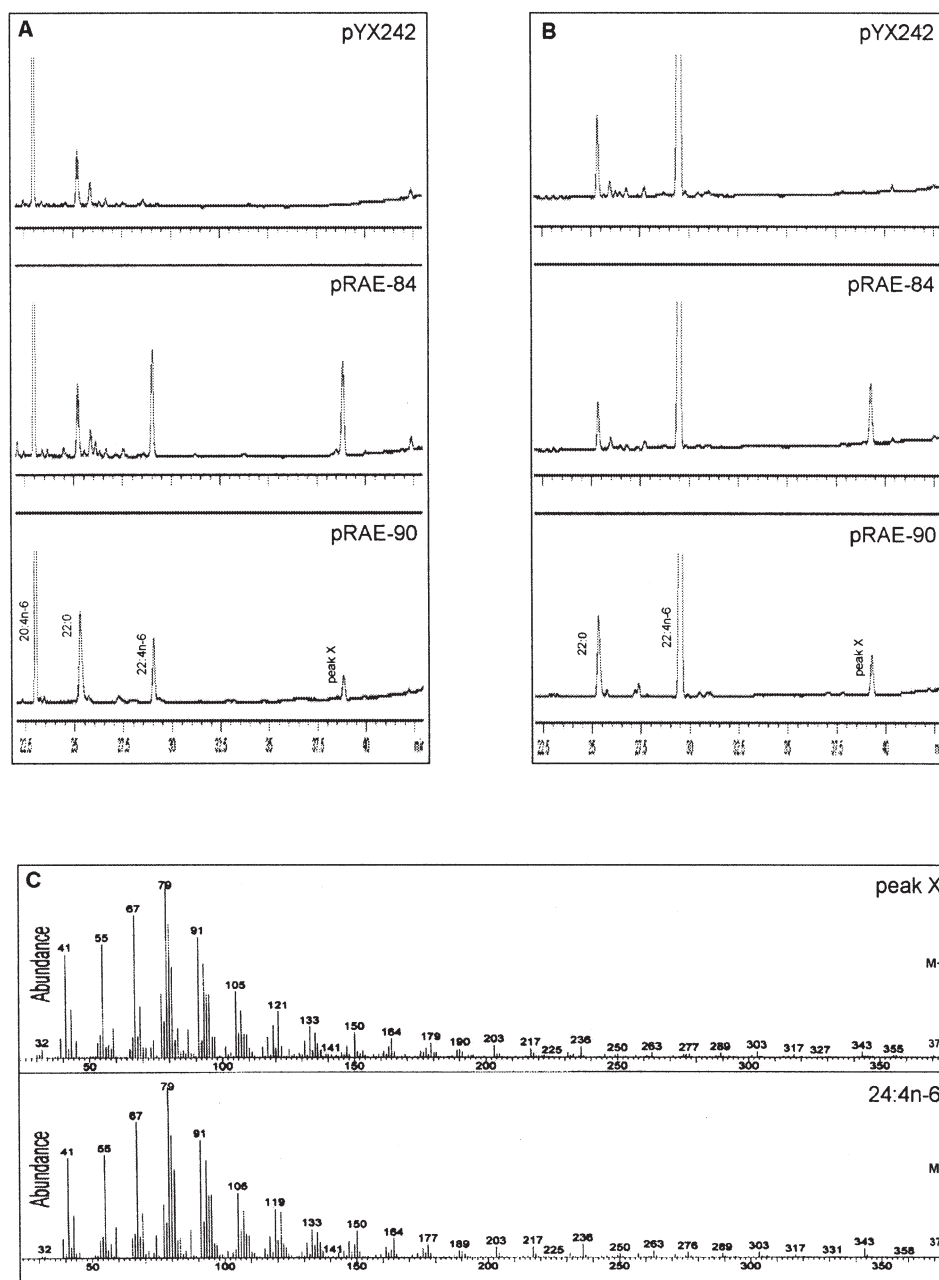

*Distribution of Elov12 mRNA in mouse tissues.* Northern blot analysis of Elov12 expression in several mouse tissues revealed that the highest levels of Elov12 mRNA were found in the testis and liver followed by brain and kidney (Fig. 5). A larger additional mRNA (5 Kb) was also found in the liver, and a smaller additional mRNA (1.3 Kb) in the testis of all mice.

## DISCUSSION

It was believed that DHA and 22:5n-6 were synthesized through the conversion of 22:5n-3 and 22:4n-6, respectively, by  $\Delta$ 4-desaturase. However, recent studies in mammalian cells by Sprecher and others (14,17) have shown that DHA and 22:5n-6 are produced from EPA and AA through a pathway involving two consecutive elongation steps, followed by a  $\Delta$ 6-desaturation and retroconversion by  $\beta$ -oxidation in the peroxisomes (7). Numerous elongation enzymes specific for saturated and monounsaturated FA (20,21), and a human enzyme, ELOVL5, responsible for the elongation of C<sub>18</sub>- and C<sub>20</sub>-PUFA, have previously been identified (19); however, the enzyme that elongates C<sub>20</sub>- and C<sub>22</sub>-PUFA, which is involved in Sprecher's pathway of long-chain PUFA synthesis, has not been identified. In this study, by comparing the identity of the known human PUFA elongation enzyme, ELOVL5, and mouse and human EST sequences, we have successfully identified the mouse Elov12 and human ELOVL2 cDNA sequences involved in long-chain PUFA biosynthesis.

When the mouse Elov12 cDNA was expressed in yeast cells, its encoded enzyme was actively involved in elongation of the added C<sub>20</sub>- to C<sub>22</sub>-PUFA and C<sub>22</sub>- to C<sub>24</sub>-PUFA. The encoded enzyme could also convert C<sub>18</sub>- to C<sub>20</sub>-PUFA to a lesser extent, but converted no saturated and monounsaturated FA substrates to their respective elongated products. This finding indicates that this mouse enzyme exhibits substrate specificity for both n-6 and n-3 long-chain PUFA.

**FIG. 3.** Gas chromatogram of long-chain FA in control yeast cells and yeast cells transformed with only the vector (pYX242), or with mouse Elov12 (pRAE-84) or human ELOVL2 (pRAE-90) elongation enzyme genes. The yeasts were incubated in 25  $\mu$ M of the substrate, either 20:4n-6 (panel A) or 22:4n-6 (panel B), for 44 h at 30°C. The GC-MS fragmentation pattern of peak X in yeast lipids was compared with that of the authentic 24:4n-6 (panel C).

When human ELOVL2 cDNA was expressed in yeast cells, its encoded elongation enzyme also converted the added C<sub>20</sub>- to C<sub>22</sub>-PUFA and C<sub>22</sub>- to C<sub>24</sub>-PUFA to their respective elongated products, but had no effect on C<sub>18</sub>-PUFA, saturated FA, or monounsaturated FA. This finding indicates that this human enzyme exhibited a substrate specificity for long-chain PUFA (C<sub>20</sub>- and C<sub>22</sub>-PUFA). However, unlike the mouse Elov12-encoded enzyme, this human enzyme had no effect on C<sub>18</sub>-PUFA. This suggests, in spite of high homology between

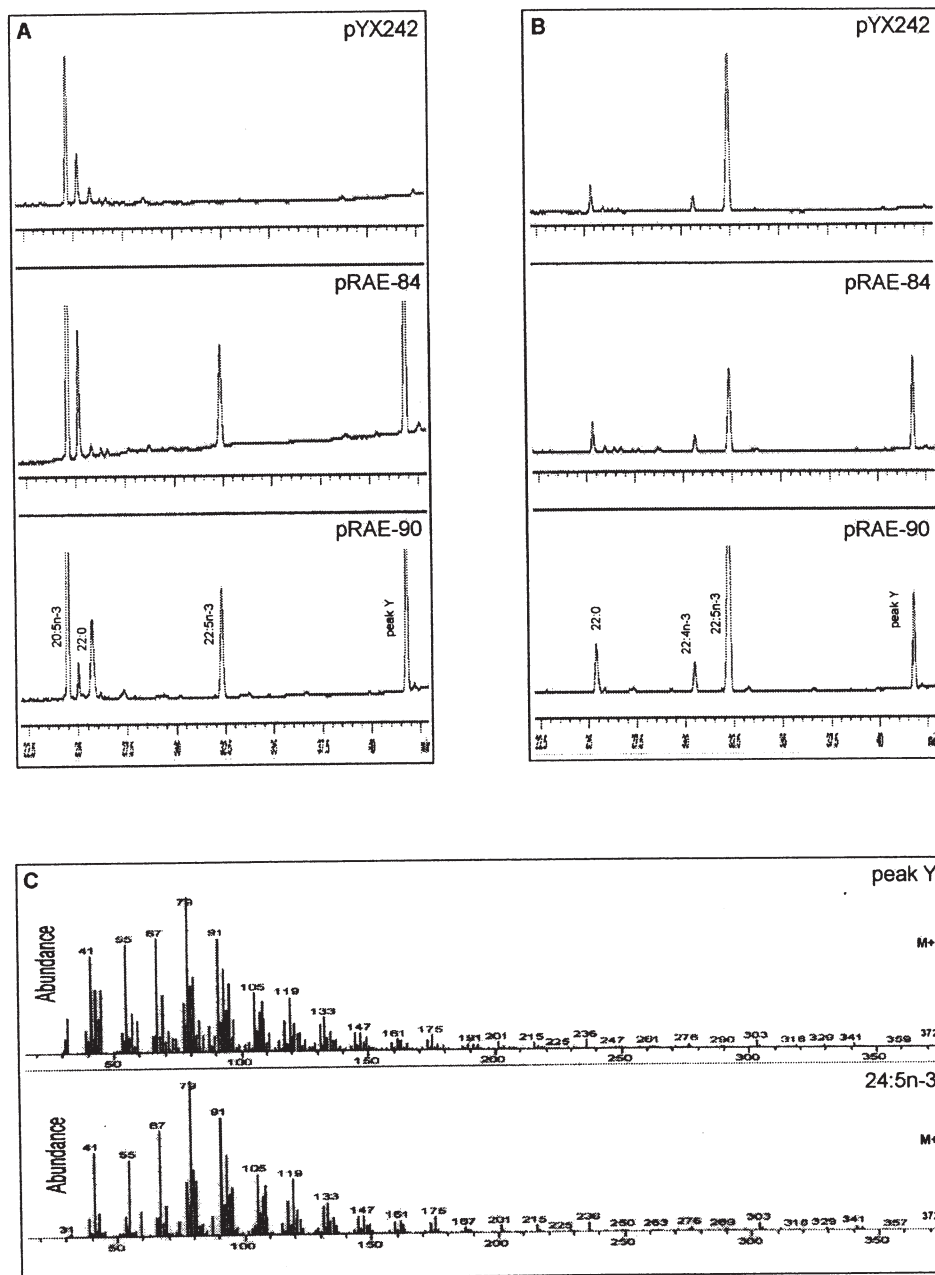

the human and mouse enzymes, there exists a species difference in substrate specificity. Nevertheless, our findings indicate that Elov12 and ELOVL2 are the enzymes responsible for the elongation of the long-chain PUFA in Sprecher's pathway in mouse and human tissues, respectively.

In a separate study, the mouse Elov12 cDNA was overexpressed in m-ELO cells. Results in Tables 3 and 4 show that when C<sub>20</sub>-PUFA were added as the substrate, there were marked accumulations of C<sub>22</sub>-PUFA and variable amounts of

C<sub>24</sub>-PUFA in both control and m-ELO cells. This finding suggests that the endogenous elongation enzyme in mouse cells was involved in elongation of C<sub>20</sub>-PUFA to C<sub>22</sub>-PUFA, and to a lesser extent the elongation of C<sub>22</sub>-PUFA to C<sub>24</sub>-PUFA. As results showed that the endogenous enzyme elongated C<sub>20</sub>-PUFA at a higher rate than the C<sub>22</sub>-PUFA, this step appeared to be rate-limiting. Nevertheless, the level of C<sub>24</sub>-PUFA of both n-3 and n-6 families was significantly higher in the m-ELO cells than in the control cells, whether the substrate was a C<sub>20</sub>- or a C<sub>22</sub>-PUFA, indicating an enhanced elongation of C<sub>22</sub>- to C<sub>24</sub>-PUFA in the m-ELO cells.

We have also examined the distribution of the Elov12 transcript in various mouse tissues and found that the levels of mRNA in the testis and liver were significantly higher than in other tissues examined (Fig. 5). These results parallel the higher levels of C<sub>22</sub> and C<sub>24</sub> FA detected in these tissues (6,27). Previously, Tvrđik *et al.* (20) hypothesized that due to high level in testis, Elov12 may be involved in long-chain

PUFA elongation. It is also noteworthy that a larger additional mRNA was found in the liver, and a smaller additional mRNA was found in the testis of all mice. The larger and smaller transcripts may express spliced variants of the Elov12 enzyme, which may be involved in the regulation of gene expression.

In summary, we have identified mouse and human genes that are homologs to the human ELOVL5 gene. Expression of Elov12 and ELOVL2 cDNA in baker's yeast and expression of Elov12 in mouse L cells produced an active enzyme involved in the elongation of C<sub>20</sub>- and C<sub>22</sub>-PUFA, but not saturated or monounsaturated FA. Our findings provide direct evidence of the existence of an elongation enzyme in mammalian cells that is involved in the biosynthesis pathway of long-chain PUFA (i.e., DHA and 22:5n-6), as proposed by Sprecher (11).

**ABSTRACT:** The purpose of this study was to investigate the effect of dietary CLA on accretion of 9*c*-18:1, 9*c*,12*c*-18:2, 10*t*,12*c*-18:2, and 9*c*,11*t*-18:2 and conversion of these FA to their desaturated, elongated, and chain-shortened metabolites. The subjects were six healthy adult women who had consumed normal diets supplemented with 6 g/d of sunflower oil or 3.9 g/d of CLA for 63 d. A mixture of 10*t*,12*c*-18:2-*d*<sub>4</sub>, 9*c*,11*t*-18:2-*d*<sub>6</sub>, 9*c*-18:1-*d*<sub>8</sub>, and 9*c*,12*c*-18:2-*d*<sub>2</sub>, as their ethyl esters, was fed to each subject, and nine blood samples were drawn over a 48-h period. The results show that dietary CLA supplementation had no effect on the metabolism of the deuterium-labeled FA. These metabolic results were consistent with the general lack of a CLA diet effect on a variety of physiological responses previously reported for these women. The <sup>2</sup>H-CLA isomers were metabolically different. The relative percent differences between the accumulation of 9*c*,11*t*-18:2-*d*<sub>6</sub> and 10*t*,12*c*-18:2-*d*<sub>4</sub> in plasma lipid classes ranged from 9 to 73%. The largest differences were a fourfold higher incorporation of 10*t*,12*c*-18:2-*d*<sub>4</sub> than 9*c*,11*t*-18:2-*d*<sub>6</sub> in 1-acyl PC and a two- to threefold higher incorporation of 9*c*,11*t*-18:2-*d*<sub>6</sub> than 10*t*,12*c*-18:2-*d*<sub>4</sub> in cholesterol esters. Compared to 9*c*-18:1-*d*<sub>8</sub> and 9*c*,12*c*-18:2-*d*<sub>2</sub>, the 10*t*,12*c*-18:2-*d*<sub>4</sub> and 9*c*,11*t*-18:2-*d*<sub>6</sub> isomers were 20–25% less well absorbed. Relative to 9*c*-18:1, incorporation of the CLA isomers into 2-acyl PC and cholesterol ester was 39–84% lower and incorporation of 10*t*,12*c*-18:2 was 50% higher in 1-acyl PC. This pattern of selective incorporation and discrimination is similar to the pattern generally observed for *trans* and *cis* 18:1 positional isomers. Elongated and desaturated CLA metabolites were detected. The concentration of 6*c*,10*t*,12*c*-18:3-*d*<sub>4</sub> in plasma TG was equal to 6.8% of the 10*t*,12*c*-18:2-*d*<sub>4</sub> present, and TG was the only lipid fraction that contained a CLA metabolite present at concentrations sufficient for reliable quantification. In conclusion, no effect of dietary CLA was observed, absorption of CLA was less than that of 9*c*-18:1, CLA positional isomers were metabolically different, and conversion of CLA isomers to desaturated and elongated metabolites was low.

Paper no. L9030 in *Lipids* 37, 741–750 (August 2002).

The geometrical and positional isomers of conjugated octa-decadienoic acid are commonly referred to as CLA and have been reported to produce a variety of physiological effects.

\*To whom correspondence should be addressed at Midwest Research Consultants, 11422 Princeville-Jubilee Rd., Princeville, IL 61559. E-mail: eaemken@npoint.net

Abbreviations: AUC, area under the curve; CE, cholesterol ester; Chylo-TL, chylomicron total lipid; PC-1, 1-acyl phosphatidylcholine; PC-2, 2-acyl phosphatidylcholine; PL Total, total phospholipid; THP, tetrahydropyranyl; TL, total lipid.

Examples include body fat loss, increased lean body mass, anticarcinogenic activity, antiatherogenic effects, reduced glucose levels, and enhanced immune function. Studies related to these and other physiological and health effects of CLA have recently been reviewed (1–3). The metabolism of CLA isomers in rats and yeast cells has been investigated (4–8), but no definitive data are available on the metabolism of CLA isomers in human subjects.

Three recent human studies have reported that supplementation with 0.36 to 3.2 g/d of CLA reduced the percent body fat compared to the control group (9–11). Differences in plasma lipid FA composition following dietary CLA supplementation suggested that CLA decreased Δ-6 and Δ-9 desaturase and increased Δ-5 desaturase activity (11). The results from a fourth study with adult women receiving 3.9 g/d of CLA for 63 d have been reported recently in a series of papers (12–18). In this study, CLA supplementation did not produce measurable effects on body composition, energy expenditure, lipolysis, plasma leptin concentrations, appetite, platelet function, blood coagulation, immune response, and mononuclear cell function (12–15). Diet did not influence cytokines and eicosanoid secretion *in vitro* and did not alter plasma cholesterol, LDL, HDL, or TG levels (16,18). An almost fourfold increase in the weight percentage of CLA in plasma lipid occurred, but there was no change in the CLA content of adipose tissue (18).

The purpose of this study was to address the following questions that relate to the metabolism of CLA isomers in a subgroup of adult women from the above dietary study. Does dietary CLA supplementation influence accretion and turnover of oleic acid, linoleic acid, and CLA isomers in plasma lipids? To what degree does conjugation of a *trans* double bond with a *cis*-9 or a *cis*-12 double bond influence unsaturated FA metabolism? Are there significant differences between the metabolism of the two CLA isomers (9*c*,11*t*-18:2 and 10*t*,12*c*-18:2) most prevalent in diets?

## EXPERIMENTAL PROCEDURES

**Study design.** Six Caucasian female subjects enrolled in a CLA diet study volunteered to participate in this stable isotope study. Three of the women were from the control group that had received a sunflower oil supplement (6 g/d), and three were from the experimental group that had received 6

<sup>e</sup>mg of total lipid FA per 100 mL of plasma.

g/d of a commercially produced CLA supplement for 60 d. The CLA supplement contained 65% CLA (3.9 g/d of CLA). The subjects were between the ages of 23 and 41 yr and were housed in a metabolic ward. Physical examinations and clinical blood profile data indicated that all subjects were in good health. Medical histories indicated no evidence of congenital ailments. The subjects' height/weight ratios, blood pressures, and fasting serum cholesterol and TG concentrations were within normal ranges. Physical characteristics and plasma lipid profiles for the subjects participating in this isotope study are summarized in Table 1. Plasma lipid data are for blood samples drawn at the end of the diet study. Institutional ethical approval was obtained for the study protocol from the Agricultural Research Service's Human Studies Institutional Review Committee and the University of California at Davis, Human Subjects Committee. Informed consent was obtained from each subject before initiation of the study. Complete information on the study design, diet compositions, and other details has been described previously (12,14).

**Deuterated FA.** The synthesis of deuterium-labeled methyl *cis*-9,*cis*-12-octadecadienoate-12,13-*d*<sub>2</sub> (9*c*,12*c*-18:2-*d*<sub>2</sub>) and methyl *trans*-10,*cis*-12-octadecadienoate-15,15,16,16-*d*<sub>4</sub> (10*t*,12*c*-18:2-*d*<sub>4</sub>) were synthesized and purified as previously reported (19,20). Methyl *cis*-9-octadecenoate-11,11,12,12,17,17,18,18-*d*<sub>8</sub> (9*c*-18:1-*d*<sub>8</sub>) was prepared in a manner analogous to that described for 9*c*-18:1-14,14,15,15,17,18-*d*<sub>6</sub> (21). To prepare the -*d*<sub>8</sub> analog, 5-hexyn-1-ol was converted to the tetrahydropyranyl (THP) ether, reduced (<sup>2</sup>H<sub>2</sub>; Wilkinson's catalyst) to yield the THP ether of hexanol-5,5,6,6-*d*<sub>4</sub>, and the THP ether was converted to the iodide (H<sub>3</sub>PO<sub>4</sub>/P<sub>2</sub>O<sub>5</sub>/KI). The C6 iodide was coupled (lithium metal/liquid NH<sub>3</sub>) with 2-propyn-1-ol to yield 2-nonyn-1-ol-8,8,9,9-*d*<sub>4</sub>. The nine-carbon acetylenic alcohol-*d*<sub>4</sub> was converted to the THP ether and reduced (Wilkinson's catalyst; <sup>2</sup>H<sub>2</sub>) to form the THP ether of nonanol-2,2,3,3,8,8,9,9-*d*<sub>8</sub>. The THP ether of nonanol-*d*<sub>8</sub> was converted to 1-iodononane-*d*<sub>8</sub> (H<sub>3</sub>PO<sub>4</sub>/P<sub>2</sub>O<sub>5</sub>/KI), then to 1-nonyl-*d*<sub>8</sub>-triphenylphosphonium iodide, and the phosphonium salt was coupled with methyl 9-oxononanoate (Wittig reaction) to yield 9*c*-18:1-*d*<sub>8</sub>. The synthesis of methyl *cis*-9,*trans*-11-octadecadienoate-14,14,15,15,17,18-*d*<sub>6</sub> (9*c*,11*t*-18:2-*d*<sub>6</sub>) was analogous to preparation of 9*c*,11*t*-18:2-17,17,18,18-*d*<sub>4</sub>

(20) except that the THP ether of hexanol-2,2,3,3,5,6-*d*<sub>6</sub> [2-(hexyloxy-2,2,3,3,5,6-*d*<sub>6</sub>) tetrahydropyran] was utilized as the deuterium-containing fragment. The hexanol-*d*<sub>6</sub> was prepared by reduction (Wilkinson's catalyst/D<sub>2</sub> gas) of the THP ether of 2-hexyn-5-ene-1-ol. The "ene-yne-ol" THP ether was prepared by coupling (Grignard) 1-bromo-prop-2-ene with the THP ether of 2-propyn-1-ol. The THP ether of hexanol-2,2,3,3,5,6-*d*<sub>6</sub> was converted to the iodide (H<sub>3</sub>PO<sub>4</sub>/P<sub>2</sub>O<sub>5</sub>/KI), then coupled with 2-propyn-1-ol to yield 2-nonyn-1-ol-*d*<sub>6</sub>, which was reduced (lithium metal/liquid NH<sub>3</sub>) to *trans*-2-nonen-1-ol-*d*<sub>6</sub>, converted to 1-bromo-*trans*-2-nonen-*d*<sub>6</sub> (with Ph<sub>3</sub>PBr<sub>2</sub>). This triphenylphosphonium salt was subsequently coupled (Wittig reaction) with methyl 9-oxononanoate to yield 9*c*,11*t*-18:2-*d*<sub>6</sub>. The deuterated FAME were converted to their ethyl esters using sodium metal in ethanol as previously described (22). The isotopic purity of the deuterated FA was: 85.8% for 9*c*-18:1-*d*<sub>8</sub>, 73.4% for 9*c*,12*c*-18:2-*d*<sub>2</sub>, 83.5% for 9*c*,11*t*-18:2-*d*<sub>6</sub>, and 83.7% for 10*t*,12*c*-18:2-*d*<sub>4</sub>. Chemical purity was 90.6% for 9*c*-18:1-*d*<sub>8</sub>, 78.9% for 9*c*,12*c*-18:2-*d*<sub>2</sub>, 91.6% for 9*c*,11*t*-18:2-*d*<sub>6</sub>, and 89.9% for 10*t*,12*c*-18:2-*d*<sub>4</sub>. Impurities were small amounts (1 to 5%) of deuterated odd chain-length and *trans* FA isomers. Nondeuterated 16:0, 18:0, and 9*c*-18:1 (13% total) were also present in 9*c*,12*c*-18:2-*d*<sub>2</sub>.

**Stable isotope study design.** A mixture of deuterated ethyl esters (62.4 g) containing 9*c*-18:1-*d*<sub>8</sub>, 9*c*,12*c*-18:2-*d*<sub>2</sub>, 9*c*,11*t*-18:2-*d*<sub>6</sub>, and 10*t*,12*c*-18:2-*d*<sub>4</sub> was blended for 1 min with 950 g of no-fat yogurt and 92.7 g of powdered sugar in a blender blanketed with nitrogen. The six subjects were fasted overnight (12 h), and each subject was fed a one-sixth portion of the deuterated ethyl ester mixture. The first subject was fed at 7:00 A.M. and the remaining subjects were fed at 10-min intervals in order to allow time for blood draws. The amount of deuterated ethyl esters fed to each subject was 1.77 g 9*c*-18:1-*d*<sub>8</sub>, 3.30 g 9*c*,12*c*-18:2-*d*<sub>2</sub>, 2.66 g 9*c*,11*t*-18:2-*d*<sub>6</sub>, and 2.68 g 10*t*,12*c*-18:2-*d*<sub>4</sub> after adjusting the actual weights for chemical and isotopic purity. Subjects were provided a no-fat breakfast at 8:00 A.M. A low-fat (ca.15% fat calories) lunch was provided at 12:00 noon. Following the noon meal, subjects returned to their respective control or CLA diet schedule.

**Sample collection.** Blood samples (14 mL each) were collected by venipuncture at 0, 2, 4, 6, 8, 12, 24, 36, and 48 h and

used for isolation of plasma lipid classes. Additional blood samples (*ca.* 14 mL) were collected at 2, 4, and 6 h and used for isolation of chylomicron total lipid (Chylo-TL). Chylomicron fractions were isolated by conventional preparative ultracentrifuge methods (23). Representative chylomicron samples were analyzed by electrophoresis to confirm the purity of the chylomicron fractions (24).

**Analysis of plasma lipid FA.** Plasma lipids were extracted with 2:1 chloroform/methanol (25). Preparative TLC was used to isolate TG, cholesterol ester (CE), and phospholipid fractions from plasma total lipid (TL) (26). Known weights of triheptadecanoin, cholesterol heptadecanoate, and diheptadecanyl-*sn*-phosphatidylcholine (Applied Science, State College, PA) were added as internal standards to the TL extract. Methanolic sodium methoxide was used to prepare methyl esters from the isolated lipid classes (22). The FA at the 1-acyl and 2-acyl positions of PC were determined by isolation and analysis of products produced following treatment of PC with *Ophiophagus hannah* venom (Kentucky Reptile Zoo, Slade, KY) (27).

The percentages of labeled and unlabeled FA in the plasma lipid classes were obtained by GC-MS analysis of their methyl esters (28). Weights of the 17:0 internal standards added were used to determine the concentrations (mg/mL) of each deuterated and nondeuterated FA. A Hewlett-Packard model 5988A quadrupole mass spectrometer operated in a positive CI mode with isobutane as the ionization reagent was used to analyze the methyl ester samples. The GC-MS methodology utilized selected ion monitoring of the appropriate ion masses for the FA in each GC peak. The areas for each of the ion masses monitored were obtained by integration of the selected ion peaks. The gas chromatograph-mass spectrometer was equipped with a SUPELCOWAX 10 fused-silica column (30 m  $\times$  0.25 mm; Supelco Inc., Bellefonte, PA). The column was temperature-programmed from 165 to 265°C at 5°C/min with a 20-min final hold. The specific operating conditions and computer-assisted storage and processing of the MS data have been described previously (28,29). Response factors were determined by analysis of standard mixtures containing weighed amounts of pure fatty methyl esters purchased from Nu-Chek- Prep Inc. (Elysian, MN) and Applied Science. The accuracy of the GC-MS data was determined by analysis of plasma TG, phospholipid, and CE samples containing known weights of 9*c*,18:1-*d*<sub>8</sub>, 9*c*,12*c*-18:2-*d*<sub>2</sub>, 9*c*,11*t*-18:2-*d*<sub>6</sub>, and 10*t*,12*c*-18:2-*d*<sub>4</sub>. The weight for each of the deuterated fatty esters added was equal to about 0.3% of the total unlabeled FA in the samples. SD were based on three replicate analyses. The SD for 9*c*,18:1-*d*<sub>8</sub>, 9*c*,12*c*-18:2-*d*<sub>2</sub>, 9*c*,11*t*-18:2-*d*<sub>6</sub>, and 10*t*,12*c*-18:2-*d*<sub>4</sub> in the TG, phospholipid, and CE-spiked samples ranged from  $\pm$ 0.002 to 0.004.

The accuracy of the GC-MS data for unlabeled methyl esters was confirmed by analysis of a subset of samples using a Varian model 3400 gas chromatograph. The GC was equipped with a 100 m  $\times$  0.25 mm SP2560 fused-silica capillary column (Supelco) and an FID. Operating conditions were: split ratio, 1:100; linear velocity of helium, 21 cm/s;

detector and injection temperature, 235°C. The identification and accuracy of the GC peaks areas were confirmed by comparison to data for authentic standards and mixtures of known composition.

**Statistical analysis and calculations.** A two-tailed, unpaired *t*-test was used to test for significant differences between control and experimental diet group data for the same FA. A two-tailed, paired *t*-test was used to test for significant differences between data for different deuterium-labeled FA (30). For comparisons of different labeled FA, the data for the individual control and experimental samples were pooled since the data for the two groups were not significantly different. The concentration data ( $\mu$ g/mL) for the deuterated FA and their metabolites were normalized to compensate for differences in plasma lipid concentrations of the subjects and for differences between the weights of <sup>2</sup>H-FA in the fed mixture. Normalization of the data to a per gram of deuterated FA fed basis was achieved by dividing the mg of deuterated FA per mL plasma data by the total concentration (mg/mL plasma) of the sample. The  $\mu$ g of deuterated FA per mg of TL data were then divided by the weights for the deuterated FA in the fed mixture. Time-course curves were produced by plotting the normalized  $\mu$ g deuterated FA/mg of TL data for the nine samples collected over the 48-h study period. The total area-under-curve (AUC) data were obtained by calculating the total area under the time-course curve, as described previously (31,32), and are similar to weighted-average data.

## RESULTS

**Absorption.** The time-course curves for Chylo-TL are shown in Figure 1 for 9*c*,11*t*-18:2-*d*<sub>6</sub>, 10*t*,12*c*-18:2-*d*<sub>4</sub>, 9*c*,12*c*-18:2-*d*<sub>2</sub> and 9*c*-18:1-*d*<sub>8</sub>. These curves provide a comparison of the relative absorption and clearance of these FA. Clearance of the labeled FA appears to be faster for the CLA diet group, but there were no significant differences between AUC data from the control and experimental groups. The Chylo-TL results show that 10*t*,12*c*-18:2-*d*<sub>4</sub> was about 10% less well absorbed than 9*c*,11*t*-18:2-*d*<sub>6</sub> ( $P < 0.001$  for pooled control plus experimental data) and that both CLA isomers were 20–25% less well absorbed than oleic and linoleic acid ( $P < 0.001$ ).

**Effect of diet.** Time-course curves for the major lipid classes in plasma are shown in Figures 2–6. Comparison of data plots from women fed the control and CLA-supplemented experimental diets show that dietary CLA had little influence on incorporation of the deuterium-labeled FA used in this study. The total areas for these curves are summarized in Table 2. The control vs. experimental diet data were not significantly different except for 9*c*,11*t*-18:2-*d*<sub>6</sub> CE and 9*c*-18:1-*d*<sub>8</sub> PE data. Accumulation of 9*c*,11*t*-18:2-*d*<sub>6</sub> in CE was low, but it was 65.5% higher ( $P < 0.02$ ) for subjects fed the control diet than for the experimental group subjects. In contrast, control vs. experimental group CE data for the 10*t*,12*c*-18:2-*d*<sub>4</sub> CLA isomer are not significantly different. The concentration of 9*c*-18:1-*d*<sub>8</sub> in PE was 6.5  $\mu$ g/mg/g higher for the CLA-supplemented diet than for the control diet ( $P < 0.02$ ),

**FIG. 1.** Time-course plots for uptake and clearance of  $9c$ - $18:1$ - $d_8$ ,  $9c,12c$ - $18:2$ - $d_2$ ,  $9c,11t$ - $18:2$ - $d_6$  and  $10t,12c$ - $18:2$ - $d_4$  in chylomicron total lipids of subjects fed the control and experimental diets. Each data point is the average for data from three subjects. Error bars equal SE. Error bars are not shown when less than the size of the symbol.

but the time-course curves show this minor difference was due to the 8-h sample data. Overall, the effect of dietary supplementation with 3.9 g/d of CLA on the accumulation and turnover of  $9c,11t$ - $18:2$ - $d_6$ ,  $10t,12c$ - $18:2$ - $d_4$ ,  $9c,12c$ - $18:2$ - $d_2$  and  $9c$ - $18:1$ - $d_8$  in plasma lipids was limited and consistent with the absence of a dietary supplementation effect.

**Comparisons of FA accretion in plasma lipid classes.** An overview of differences between the lipid class data is provided by the percent  $^2H$ -FA data in Figure 7. The percentage data illustrate the relative difference between incorporation of  $9c,11t$ - and  $10t,12c$ - $18:2$ , the general overall discrimination against incorporation of the CLA isomers, and the obvious (expected) preference for  $9c,12c$ - $18:2$ - $d_2$  incorporation. The differences between the percentages shown for Chyl-TL and the other lipid classes are a reflection of enzyme specificity for incorporation of the deuterated FA. For example, 78% of all the deuterated FA incorporated in total PC was  $9c,12c$ - $18:2$ - $d_2$ , which is consistent with the high  $9c,12c$ - $18:2$ - $d_2$  content observed for human plasma PC. The percentages for  $9c$ - $18:1$ - $d_8$  (7.5%) and  $9c,11t$ - $18:2$ - $d_6$  (6.0%) were not significantly different, but the percentage for  $10t,12c$ - $18:2$ - $d_4$  (8.4%) was significantly higher ( $P < 0.001$ ) than  $9c$ - $18:1$ - $d_8$  and  $9c,11t$ - $18:2$ - $d_6$  due to its selective incorporation in the 1-acyl PC (PC-1) position (34% of total deuterated FA). The lower percentage for the CLA isomers in plasma TL and TG than for  $9c$ - $18:1$ - $d_8$  suggests that the  $\beta$ -oxidation rates for the CLA isomers were higher than for  $9c$ - $18:1$ .

**FIG. 2.** Time-course plots for uptake and clearance of  $9c$ - $18:1$ - $d_8$ ,  $9c,12c$ - $18:2$ - $d_2$ ,  $9c,11t$ - $18:2$ - $d_6$  and  $10t,12c$ - $18:2$ - $d_4$  in plasma total lipid of subjects fed the control and experimental diets. Each data point is the average for data from three subjects. Error bars equal SE. Error bars are not shown when less than the size of the symbol.

**FIG. 3.** Time-course plots for uptake and clearance of  $9c$ - $18:1$ - $d_8$ ,  $9c,12c$ - $18:2$ - $d_2$ ,  $9c,11t$ - $18:2$ - $d_6$ , and  $10t,12c$ - $18:2$ - $d_4$  in plasma TG of subjects fed the control and experimental diets. Each data point is the average for data from three subjects. Error bars equal SE. Error bars are not shown when less than the size of the symbol.

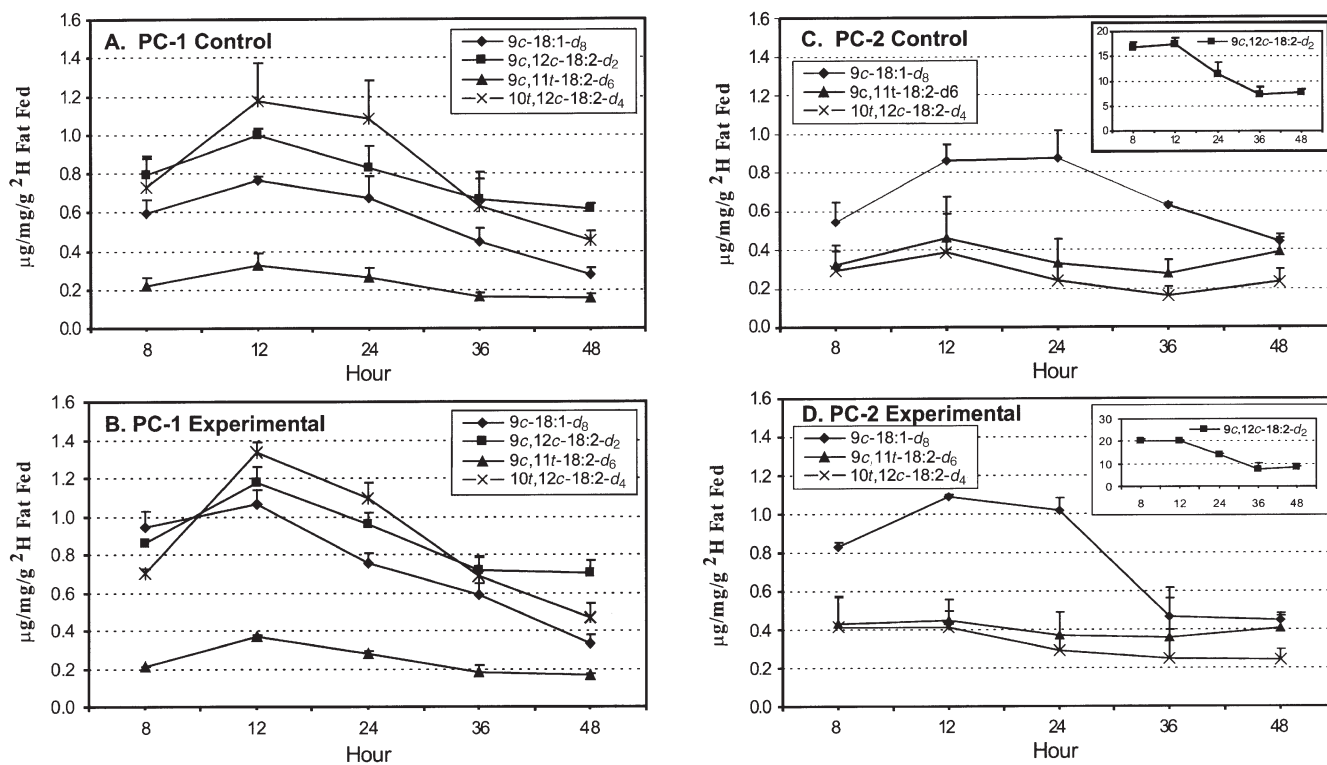

**FIG. 4.** Time-course plots for uptake and clearance of  $9c$ - $18:1-d_8$ ,  $9c,12c$ - $18:2-d_2$ ,  $9c,11t$ - $18:2-d_6$ , and  $10t,12c$ - $18:2-d_4$  in plasma PE of subjects fed the control and experimental diets. Each data point is the average for data from three subjects. Error bars equal SE. Error bars are not shown when less than the size of the symbol.

The selectivity ratios shown in Table 3 for  $9c,11t$ - $18:2-d_6$ ,  $10t,12c$ - $18:2-d_4$ , and  $9c,12c$ - $18:2-d_2$  are a measure of the acyltransferase selectivity for incorporation of these FA into the various plasma lipid classes. Previously reported (33–38) selectivity values for *trans*- and *cis*- $18:1$  positional isomers and  $18:0$  were recalculated as simple ratios and are included for comparison. Note that  $9c$ - $18:1$  is the reference FA and has a selectivity value of 1.0. Values less than 1.0 indicate discrimination and values greater than 1.0 indicate preferential incorporation. The selectivity values within a specific lipid class for  $9c,11t$ - $18:2-d_6$  and  $10t,12c$ - $18:2-d_4$  are in the same range as values listed for the positional  $18:1$  isomers. The exception is the PC-1 value for  $9c,11t$ - $18:2-d_6$  (0.46), which is much smaller than values listed for other isomers. The selectivity value of 0.46 for  $9c,11t$ - $18:2-d_6$  indicates that  $9c,11t$ - $18:2-d_6$  incorporation at the PC-1 position was about 50% lower than for  $9c$ - $18:1-d_8$  and 5–9 times less than for the other  $18:1$  isomers listed in Table 3. These results suggest that, compared to most other FA isomers,  $9c,11t$ - $18:2-d_6$  has an atypical configuration and is not a good substrate for PC transferase. However, a comparison of the selectivity values for accretion of  $9c,11t$ - $18:2-d_6$  and  $10t,12c$ - $18:2-d_4$  into all other plasma lipid classes shows that both CLA isomers are more metabolically characteristic of *trans*- and *cis*- $18:1$  positional isomers than of  $18:0$ ,  $9c$ - $18:1$ , or  $9c,12c$ - $18:2$ .

AUC data for the control and experimental diet groups listed in Table 2 were not significantly different and were

**FIG. 5.** Time course plots for uptake and clearance of  $9c$ - $18:1-d_8$ ,  $9c,12c$ - $18:2-d_2$ ,  $9c,11t$ - $18:2-d_6$ , and  $10t,12c$ - $18:2-d_4$  in plasma 1-acyl phosphatidylcholine (PC-1) and 2-acyl phosphatidylcholine (PC-2) of subjects fed the control and experimental diets. The plots for the  $9c,12c$ - $18:2-d_2$  PC-2 data are shown as inserts. Each data point is the average for data from three subjects. Error bars equal SE. Error bars are not shown when less than the size of the symbol.

**FIG. 6.** Time-course plots for uptake and clearance of  $9c$ - $18:1$ - $d_8$ ,  $9c$ , $12c$ - $18:2$ - $d_2$ ,  $9c$ , $11t$ - $18:2$ - $d_6$ , and  $10t$ , $12c$ - $18:2$ - $d_4$  in plasma cholesterol ester of subjects fed the control and experimental diets. Each data point is the average for data from three subjects. Error bars equal SE. Error bars are not shown when less than the size of the symbol.

therefore combined to test for statistical differences between individual FA within a lipid class. The following are some selected comparisons.

(i) *TG*. Incorporation of  $9c$ - $18:1$ - $d_8$  was 50–70% higher ( $P < 0.001$ ) than for the labeled CLA isomers, and the difference between the  $9c$ , $11t$ - $18:2$ - $d_6$  and  $10t$ , $12c$ - $18:2$ - $d_4$  isomers was small (13%) but significant ( $P < 0.001$ ).

(ii) *CE*. Incorporation of  $9c$ , $12c$ - $18:2$ - $d_2$  was about 7.7 times higher than  $9c$ - $18:1$ - $d_8$ , 33 times higher than  $9c$ , $11t$ - $18:2$ - $d_6$ , and 70 times higher than  $10t$ , $12c$ - $18:2$ - $d_4$  ( $P$  values all  $< 0.001$ ). The concentration of  $^2H$ -CLA in CE was the lowest for any plasma lipid class. AUC data for  $10t$ , $12c$ - $18:2$ - $d_4$  are 48 to 65% lower than for  $9c$ , $11t$ - $18:2$ - $d_6$  ( $P < 0.001$ ). This difference is both a reflection of LCAT selectivity and the lower concentrations of  $10t$ , $12c$ - $18:2$  in 2-acylphosphatidylcholine (PC-2).

(iii) *PC-1*. Accumulation of  $10t$ , $12c$ - $18:2$ - $d_4$  in PC-1 was three to four times higher than  $9c$ , $11t$ - $18:2$ - $d_6$  but was not different from  $9c$ , $12c$ - $18:2$ - $d_2$ . More (25–30%)  $10t$ , $12c$ - $18:2$ - $d_4$  than  $9c$ - $18:1$ - $d_8$  ( $P < 0.001$ ) was incorporated. In contrast, incorporation of  $9c$ , $11t$ - $18:2$ - $d_6$  in PC-1 was 60–70% less than  $9c$ - $18:1$ - $d_8$  ( $P < 0.001$ ). The striking difference between the incorporation in PC-1 for these two CLA isomers is evidence to support the suggestion that these CLA isomers have different physiological effects (39,40). The results are consistent with cultured cell and yeast studies that found these CLA isomers have different effects on apolipoprotein B secretion, TG levels, and stearyl-CoA desaturase activity (39–41).

<sup>a</sup>For comparisons of individual FA in a lipid class, data for Cntrl and Exp subjects are combined ( $n = 6$ ). All FA comparisons are significantly different at  $P < 0.001$  except for PC ( $9c$ , $11t$ - $18:2$ - $d_6$  vs.  $9c$ - $18:1$ - $d_8$ ), PE ( $9c$ , $11t$ - $18:2$ - $d_6$  vs.  $9c$ - $18:1$ - $d_8$ ), PE ( $10t$ , $12c$ - $18:2$ - $d_4$  vs.  $9c$ - $18:1$ - $d_8$ ) and PE ( $10t$ , $12c$ - $18:2$ - $d_4$  vs.  $9c$ , $11t$ - $18:2$ - $d_6$ ).

<sup>b</sup>Cntrl = control diet group; Exp = experimental diet group.

<sup>c</sup> $\mu\text{g}/\text{mg}/\text{g}$  =  $\mu\text{g}$  deuterated FA per mg of total FA in lipid class per g of deuterated fat fed ( $n = 3$ ).

<sup>d</sup>Chylomicron total lipid (Chylo-TL) and total phospholipid (Total PL) values represent area-under-curve data for 0-, 2-, 4-, and 6-h samples.

<sup>e</sup>Cntrl vs. Exp diet group for cholesterol esters  $9c$ , $11t$ - $18:2$ - $d_6$  ( $P < 0.01$ ). No other diet group comparisons for the same deuterium-labeled FA are significantly different.

<sup>f</sup>Values for PC represent area-under-curve data for the 8-, 12-, 24-, 36-, and 48-h samples. PC-1, 1-acyl phosphatidylcholine; PC-2, 2-acyl phosphatidylcholine; TL, total lipid.

FIG. 7. Percentage of 9c-18:1-d<sub>8</sub> (diagonal lines), 9c,12c-18:2-d<sub>2</sub> (vertical lines), 9c,11t-18:2-d<sub>6</sub> (cross-hatched), and 10t,12c-18:2-d<sub>4</sub> (solid) in human plasma lipid classes. Percentages are calculated from the combined average of area concentration data for subjects fed the control and experimental diets. Chylo-TL, chylomicron total lipid; TL, total lipid; PC-1, 1-acyl PC; PC-2, 2-acyl PC; CE, cholesterol ester.

(iv) *PC-2*. The concentration of 9c-18:1-d<sub>8</sub> was 2.0 to 2.7 times higher than that of the CLA isomers (*P* < 0.001), and 9c,11t-18:2-d<sub>6</sub> was 25% higher than 10t,12c-18:2-d<sub>4</sub> (*P* < 0.001). The concentration of 9c,12c-18:2-d<sub>2</sub> in the PC-2 position is about 16 times greater than 9c-18:1-d<sub>8</sub> and is typical of the high selectivity previously observed for linoleic acid (31,32,42).

(v) *PE*. Data for the CLA isomers were not significantly different, and 9c,12c-18:2-d<sub>2</sub> concentrations were about five times higher than for any other labeled FA. PE is the only lipid class where accumulation of 9c-18:1-d<sub>8</sub> was not significantly greater than that for 9c,11t-18:2-d<sub>6</sub> or 10t,12c-18:2-d<sub>4</sub>.

(vi) *TL*. Accumulation and turnover of 9c,12c-18:2-d<sub>2</sub> in plasma TL were significantly higher (*P* < 0.001) than for the CLA isomers and reflect the marked difference in the shapes of the time-course curves for plasma TL (Fig. 2). AUC TL values for 9c,12c-18:2-d<sub>2</sub> are four to five times larger (*P* < 0.001) than for the CLA isomers and three times larger than for 9c-18:1-d<sub>8</sub> (*P* < 0.001). Curve shape for 9c-18:1-d<sub>8</sub> incorporation and disappearance was similar to those of the CLA

isomers, but total curve area for 9c-18:1-d<sub>8</sub> was 25% higher than for 9c,11t-18:2-d<sub>6</sub> (*P* < 0.001) and 40% higher than for 10t,12c-18:2-d<sub>4</sub> (*P* < 0.001). The 9c,11t-18:2-d<sub>6</sub> data were 21% higher than for 10t,12c-18:2-d<sub>4</sub> (*P* < 0.001).

*Metabolites*. Only two deuterium-labeled FA metabolites were present at levels sufficient for accurate measurement. The chain-shortened 9c-18:1-d<sub>8</sub> metabolite (16:1-d<sub>8</sub>) was 1.8% in TL and 1.3% in TG of the 9c-18:1-d<sub>8</sub> present. The Δ6-desaturated 10t,12c-18:2 metabolite (6c,10t,12c-18:3-d<sub>4</sub>) was equal to 5% in TL and 6.8% in TG of the 10t,12c-18:2-d<sub>4</sub> present. Little or no 6c,10t,12c-18:3-d<sub>4</sub> was detected in the samples of other plasma lipid classes, and the Δ6-desaturated 9c,11t-18:2-d<sub>6</sub> metabolite (6c,9c,11t-18:3-d<sub>6</sub>) was not detected. Trace amounts of labeled 20:2, 20:3, and 20:4 containing a conjugated diene structure were present in a few (<5%) samples. Elongated and desaturated 9c,12c-18:2-d<sub>2</sub> metabolites were present in all plasma lipid classes, but concentrations of the dideuterated n-6 metabolites were not sufficiently higher than the m + 2 natural <sup>13</sup>C background levels to allow accurate quantification.

DISCUSSION

Accumulations of labeled FA in all plasma lipid classes were not significantly different for women receiving the control and CLA-supplemented diets, with one exception. The concentrations of 9c,11t-18:2-d<sub>6</sub> in CE were statistically different, but the difference probably does not indicate a biologically important effect of diet because the absolute difference is very small. Comparison of the control and experimental diet results shows that dietary CLA does not alter oleic acid or linoleic acid metabolism and suggests that dietary CLA would not produce physiological effects associated with oleic and linoleic acid metabolism. The lack of a measurable effect of dietary CLA on 9c-18:1-d<sub>8</sub> and 9c,12c-18:2-d<sub>2</sub> metabolism contrasts with results for 20:4n-6- and 22:6n-3-supplemented diets that showed both 20:4n-6 and 22:6n-3 have a major influence on the metabolism of deuterium-labeled 9c-18:1 and 9c,12c-18:2 (31,32,43). The results from this study are consistent with results from a study that found incorporation of

<sup>a</sup>Area-under-curve (AUC; μg/mg/g) data used for calculation of selectivity values. Selectivity values equal FA AUC data divided by the AUC data for 9c-18:1. Reference value for 9c-18:1 = 1.00. CLA and 9c,12c-18:2 selectivity values are the average of control plus experimental groups. All selectivity ratios are adjusted for reduced absorption of FA if appropriate. Selectivity values for *cis*- and *trans*-18:1 positional isomers and for 18:0 are from previously published studies.

<sup>b</sup>ND, not data; for other abbreviations see Table 2.

nonconjugated unsaturated FA in rat liver was not altered by dietary CLA (8).

The apparent lower absorption for the  $^2\text{H}$ -CLA isomers compared to  $9c$ -18:1- $d_8$  was unexpected. Previous studies showed absorption of  $^2\text{H}$ -20:3n-6 and  $^2\text{H}$ -20:4n-6 was lower than  $^2\text{H}$ -18:1 (43,44), but significantly lower absorption of 18-carbon FA was not observed for labeled *cis*- and *trans*-18:1 FA isomers (45) nor for  $^2\text{H}$ -18:0 (38). A possible explanation for this result is that 20–30% of the  $^2\text{H}$ -CLA was absorbed *via* the portal transport and is consistent with human jejunum data for linolenic acid (46). Alternatively, one or both of the pathways (MAG and glycerol-3-phosphate) responsible for FA incorporation into TG during absorption may partially discriminate against CLA isomers. Hydrolysis of CLA TG by pancreatic lipase *in vitro* was reported to be lower than for trilinolein (47), and may have been a factor with the deuterated CLA ethyl esters used in the present study. However, rat data showed that CLA and  $9c$ ,12*c*-18:2 TG were equally well absorbed (47), which is not consistent with the results from this study in humans.

Comparison of incorporation data shows that metabolism of the  $^2\text{H}$ -CLA isomers is clearly different from that for oleic and linoleic acids. These results suggest that conjugation of the *cis*-9 and the *cis*-12 double bonds with a *trans* double bond has a major impact on the selectivity of the acylation enzymes that are responsible for incorporation. Conjugation does not appear to influence turnover rates since all plasma lipid class time-course curves show that disappearance of the CLA isomers is similar to  $9c$ -18:1. The selectivity values listed in Table 3 show that there was discrimination against incorporation of the  $^2\text{H}$ -CLA isomers in TG and CE and preferential incorporation in phospholipid, PC, and PE relative to  $9c$ -18:1- $d_8$  and  $9c$ ,12*c*-18:2- $d_2$ . Comparison of selectivity values for the CLA isomers to  $9c$ ,12*c*-18:2- $d_2$  values and values previously reported for *cis*- and *trans*-18:1 positional isomers and 18:0 (34–39) shows that  $9c$ ,11*t*-18:2 and  $10t$ ,12*c*-18:2 are metabolized more like *trans*-18:1 isomers than 18:0,  $9c$ -18:1, or  $9c$ ,12*c*-18:2. For example, the selectivity ratio of 1.90 for  $10t$ ,12*c*-18:2 is between the values for 11*c*- and  $10t$ -18:1 and indicates preferential incorporation at the PC-1 position. The PC-1 selectivity ratio of 0.46 indicates discrimination against  $9c$ ,11*t*-18:2 incorporation and is unusual because  $9c$ ,11*t*-18:2 is the only *trans* FA in which discrimination has been observed to occur at the PC-1 position. The CE selectivity values for  $9c$ ,11*t*-18:2 (0.34) and  $10t$ ,12*c*-18:2 (0.16) reflect a strong discrimination against acylation of cholesterol, which is a consistent characteristic of *trans*- and *cis*-18:1 positional isomers.

The lower concentrations of CLA isomers in TG and TL compared to oleic acid are generally consistent with the selectivity ratios for 18:1 isomers. The  $10t$ ,12*c*-18:2/ $9c$ ,11*t*-18:2 in human plasma TL was 0.78 and indicated an overall 22% preferential accretion of  $9c$ ,11*t*-18:2. The TL selectivity values of 0.81 for  $10t$ ,12*c*-18:2 and 0.92 for  $9c$ ,11*t*-18:2 represent the entire plasma lipid pool and suggest that, like  $^{13}\text{C}$ -

labeled  $9t$ -18:1 (48), a larger portion of the CLA isomers than oleic acid are  $\beta$ -oxidized. This suggestion is supported by results from rats, where  $\beta$ -oxidation of  $^{14}\text{C}$ -CLA isomers was about 17% higher than  $9c$ ,12*c*-18:2 (49). Overall, the results for the metabolism of CLA isomers showed many similarities to our previously reported results for *trans*-18:1 positional isomers. This observation is an interesting anomaly since a plethora of positive health benefits have been reported for CLA (1–3) but *trans*-18:1 isomers are considered to have a negative effect on serum cholesterol and to constitute a risk for coronary heart disease (45).

Studies in rats and yeast cell models have reported chain-shortened, elongated, and desaturated metabolites of CLA (4–8). In rat liver, the two main metabolites of  $10t$ ,12*c*-18:2 were  $8t$ ,10*c*-16:2 and  $6c$ ,10*t*,12*c*-18:3, and the main metabolite of  $9c$ ,11*t*-18:2 was  $8c$ ,11*c*,13*t*-20:3 (5). In this study with adult women,  $6c$ ,10*t*,12*c*-18:3- $d_4$  was the only CLA metabolite present in measurable amounts, and it does not appear to be elongated to  $8c$ ,12*t*,14*c*-20:3. The detection of  $6c$ ,10*t*,12*c*-18:3 in plasma TG but not in phospholipid samples is consistent with results for rat liver lipids (5). The importance of the *cis*-12 double bond is well recognized, but conjugation of the *cis*-12 double bond with a *trans* double bond would reduce the  $\pi$  electron density of the *cis*-12 double bond and alter its spatial arrangement or conformation compared to  $9c$ ,12*c*-18:2. Thus, the relatively high conversion of  $10t$ ,12*c*-18:2- $d_4$  is an unexpected result.

For these women,  $9c$ ,11*t*-18:2- $d_6$  clearly was not a good substrate for  $\Delta 6$ -desaturation, and neither CLA isomer was a good substrate for elongation, but why CLA metabolite concentrations were much lower than reported for rats was not clear. The higher amount of dietary CLA fed per kilogram of body weight in the rat studies and the higher desaturase activity of rats compared to humans would account for some of the observed difference. A possible contributing factor is that desaturase and elongase activities for women appear to be considerably lower than for men. For example, in comparable previous studies with adult men, the concentrations of  $9c$ ,12*c*-18:2- $d_2$  desaturation and elongation products were sufficient for accurate measurements (31,32,42). In this study with adult females, levels of elongated and desaturated  $9c$ ,12*c*-18:2- $d_2$  metabolites were usually too low for accurate quantification.

We found no effect of dietary CLA supplementation on the metabolism of the  $^2\text{H}$ -FA investigated. CLA isomers were not as well absorbed as oleic and linoleic acids. The  $9c$ ,11*t*-18:2 and  $10t$ ,12*c*-18:2 isomers were metabolically different, and their accretion in plasma lipids was characteristic of *cis*- and *trans*-18:1 positional isomers. Conversion of the  $^2\text{H}$ -CLA isomers to 18- and 20-carbon PUFA was negligible, except for the conversion of  $10t$ ,12*c*-18:2 to  $6c$ ,10*t*,12*c*-18:2.

# Dietary CLA Alters Yolk and Tissue FA Composition and Hepatic Histopathology of Laying Hens

Gita Cherian<sup>a,\*</sup>, Troy B. Holsonbake<sup>a</sup>, Mary P. Goeger<sup>a</sup>, and Rob Bildfell<sup>b</sup>

<sup>a</sup>Department of Animal Sciences and <sup>b</sup>College of Veterinary Medicine, Oregon State University, Corvallis, Oregon 97331

**ABSTRACT:** The effect of dietary CLA along with n-3 PUFA on yolk FA profile and hepatic lipid accumulation was investigated. Laying hens ( $n = 40$ ) were randomly assigned to four experimental diets containing 0, 0.5, 1.0, or 2.0% CLA. Menhaden oil was used as the source of n-3 PUFA. Dietary CLA did not affect the total lipid content of egg yolk ( $P > 0.05$ ). The amounts of CLA isomers (*cis*-9 *trans*-11, *trans*-10 *cis*-12) in the egg yolk were proportional to the levels of CLA in the diet ( $P < 0.05$ ). The total CLA content in the egg yolk was 0, 0.97, 2.4, and 5.3 wt%, respectively ( $P < 0.05$ ). Addition of CLA resulted in an increase in saturated FA ( $P < 0.05$ ) with a concomitant reduction in monounsaturated FA ( $P < 0.05$ ) in the yolk, liver, abdominal fat, breast, and thigh muscle. No difference in saturated and monounsaturated FA content in heart and spleen tissue was noted. Dietary CLA at all concentrations resulted in an increase ( $P < 0.05$ ) in the total number of fat vacuoles and lipid infiltration in hepatocytes. The number of cells with 75% or higher lipid vacuolation in the cytoplasm was also increased ( $P < 0.05$ ) by 2.0% CLA. Dietary CLA at 0.5% levels resulted in an increase ( $P < 0.05$ ) in the total lipid content of hepatic tissue. The total lipid content in leg muscle was lower ( $P < 0.05$ ) in CLA-fed birds. However, no effect of CLA on lipid content of breast muscle, heart, spleen and adipose tissue was observed ( $P > 0.05$ ). The current study used CLA in a FFA form. The effects of using CLA in other form such as TG on avian hepatic tissue need to be investigated.

Paper no. L9044 in *Lipids* 37, 751–757 (August 2002).

Because of the controversy concerning dietary animal fat and potential links to human health problems such as cardiovascular disease and certain types of cancer, consumers are very interested in functional foods that can prevent or ameliorate disease processes. Several different strategies have been adopted by the animal food industry to enhance the nutritional value of animal foods. The major emphasis has been focused on modification of lipid and PUFA composition. Among the different PUFA, longer-chain n-3 PUFA and CLA have received considerable attention for their health-enhancing properties (1,2). These include the TG-lowering and antiatherosclerotic and antiarrhythmic properties of n-3 PUFA (3,4) as well as the anticarcinogenic and antiatherogenic properties of CLA (2). Other beneficial effects of CLA include body fat reduction, immunomodulation, and antioxidant properties (5,6).

Abbreviations: FLS, fatty liver syndrome; MUFA, monounsaturated FA; SFA, saturated fatty acid.

Animal products contribute 70% of total FA in typical Western diets. This includes CLA and n-3 PUFA, which are supplied predominantly by food lipids of ruminant animals and marine products. Current intake of CLA is estimated to be several hundred milligrams/day (7). Based on animal data, approximately 3 g/d of CLA would be required to produce beneficial effects in humans (8). However, as Americans are opting for low-fat dairy and beef products and choosing more poultry-based foods than beef, it is likely that the dietary contribution of CLA and n-3 PUFA will further be reduced in a typical U.S. diet. When associated with food, CLA reportedly has higher tissue retention and better anticancer effects than commercially available supplements (9). In this respect, CLA and n-3 PUFA-enriched chicken eggs may be an alternative vehicle for delivering health-promoting FA to consumers.

In chickens, the lymphatic system is rudimentary, and liver is the first tissue to be exposed to dietary lipids. The major route of fat absorption is by mixed micelle formations. The chylomicrons are absorbed directly into the portal blood for transport to the liver for further synthesis and subsequent tissue deposition. Such a feature also predisposes birds to a pathological condition called fatty liver syndrome (FLS). A high percentage of commercial layers in the United States develop FLS, causing the hepatocytes to distend with fat vacuoles and resulting in rupture and death (10). The ability of CLA to reduce body fat, increase lean body mass, and increase feed efficiency may have important implications for FLS. The use of CLA as a means to reduce fat deposition may be a method to control or reverse this process. The objectives of the present study were to investigate the effect of feeding CLA along with n-3 PUFA on the yolk and tissue FA incorporation and to assess the hepatic histopathology, lipid infiltration, and performance parameters of hens.

## MATERIALS AND METHODS

These experiments were reviewed by the Oregon State University Animal Care Committee to ensure adherence to Animal Care Guidelines.

**Birds and diets.** Thirty-two-week-old single Comb White Leghorn laying hens ( $n = 40$ ) were kept in individual cages and were fed a corn-soybean meal-based diet with added CLA at 0 (Diet 1), 0.5 (Diet 2), 1.0 (Diet 3), and 2.0% (Diet 4) (Table 1). All diets contained 3% menhaden oil, and the CLA source in Diets 2, 3, and 4 was substituted for menhaden oil on a weight/weight basis. The CLA source, which contained

75% FFA) was obtained from a commercial source and contained 34.9% *c9,t11*- and 35.9% *t10,c12*-CLA isomers (PharmaNutrients, Lake Bluff, IL). All the diets were isocaloric and isonitrogenous (Table 1). The diets were prepared biweekly and kept in a cold room (4°C) in air-tight containers. Hens were fed the experimental diet for a period of 42 d. Total feed consumption and daily egg production were monitored. Initial and final body weights of birds were recorded.

**Sample collection.** Hens were fed the experimental diet shown in Table 1 for 2 wk before eggs were collected for this study. Six eggs from each treatment were randomly selected for FA analysis ( $n = 6$ ). The eggs were weighed, and yolks were separated using an egg separator and weighed. The albumen weight was calculated by subtracting yolk and shell weight from total egg weight. The yolks were stored in freezer bags at -20°C until extraction. On day 42 of feeding, 6 birds per treatment were randomly selected. The birds were killed, and liver tissue was collected by a veterinary pathologist at the Oregon State University Veterinary Hospital. The liver tissue was weighed and recorded. The spleen, heart, breast, and leg muscle and abdominal fat were collected and were kept frozen (-20°C) until analysis.

**Lipid and FA analyses.** Total lipids were extracted from egg yolk and tissues with chloroform/methanol (2:1, vol/vol) by the method of Folch *et al.* (11). One gram of sample was weighed into a screw-capped test tube with 20 mL of chloroform/methanol (2:1, vol/vol) and homogenized with a Polytron for 5 to 10 s at high speed. The homogenate was filtered through Whatman #1 filter paper into a 100-mL graduated cylinder, and 5 mL of 0.88% sodium chloride solution was added and mixed. After phase separation, the volume of the lipid layer was recorded, and the top layer was completely siphoned off. Three milliliters of the lipid extracts was dried in a block heater under nitrogen and used for FA analyses. The dried lipids were redissolved in 2 mL of a boron trifluoride/

methanol methylation solution and were incubated in a boiling water bath for 1 h at 90–100°C (12). After cooling to room temperature, the FAME were separated by hexane and distilled water. Total lipids were determined gravimetrically.

Analysis of FA composition was performed with a HP 6890 gas chromatograph (Hewlett-Packard) equipped with an autosampler, FID, and a fused-silica capillary column, 100 m × 0.25 mm × 0.2 µm film thickness (Sp-2560; Supelco, Bellefonte, PA). Sample (1 µL) was injected with helium as a carrier gas onto the column programmed for ramped oven temperatures (initial temperature was 110°C, held for 1.0 min, then ramped at 15.0°C/min to 190°C and held for 55.0 min, then ramped at 5.0°C/min to 230°C and held for 5.0 min). Inlet and detector temperatures were both 220°C. Peak areas and percentages were calculated using Hewlett-Packard ChemStation software. FAME were identified by comparison with retention times of authentic standards (Matreya, Pleasant Gap, PA). FA values and total lipids are expressed as weight percentages.

**Hepatic histopathology and criteria for fat scoring.** A slice of liver about 1 × 1 × 0.5 cm thick was taken from the right lobe of each hen, fixed in 10% neutral buffered formalin for 48 h, embedded in paraffin, sectioned (8 µm), and stained with hematoxylin and eosin stain prior to microscopic examination. For each section of the liver, three randomly located areas were graded at 40× magnification using a grid within a 10× ocular piece. Approximately 20 hepatocytes would be expected to fall within the limits of the grid. Fat content of each grid was assessed in two patterns: (i) total number of fat vacuoles in the grid, (ii) number of cells within the grid having >75% lipid vacuolation of cytoplasm. For each method, the sum total from each bird was divided by three to give an average value per grid. A fat vacuole was considered to be any nonstaining area of cytoplasm with a sharply defined border. The two methods were used, as it is common for lipid-laden cells to be largely occupied by only one or two vacuoles in severe fatty metamorphosis. A single section from each bird was assessed in this manner. A final average for each group was then calculated.

**Statistical analysis.** The effect of dietary CLA on egg quality, production performance, tissue FA, and hepatic histopathology were analyzed by ANOVA using SAS (version 8.2) (SAS Institute, Cary, NC). Student-Newmann-Keuls multiple range test (13) was used to compare differences among treatment means ( $P < 0.05$ ). Mean values and SEM are reported.

## RESULTS AND DISCUSSION

The FA composition of the diet is shown in Table 2. Performance of hens was measured for 42 d (test period). No significant difference ( $P > 0.05$ ) was observed in feed consumption, initial and final body weights of birds, egg production, egg weight, yolk weight or total edible portion, yolk color and haugh unit (data not shown).

**Gross necropsy findings.** No significant abnormalities were noted in any of the birds examined with the exception of hepatic changes. When compared to Diet 1, livers from birds fed CLA-added diets were pale, with Diet 4 having the most

<sup>a</sup>n = 6. SFA, saturated FA. MUFA, monounsaturated FA.

severe hepatic pallor. Grossly visible hepatic hemorrhages were noticed in some birds fed Diet 4.

**Hepatic histopathology.** The liver tissue from hens fed Diet 4 had the most significant pathology, including the most extensive fat deposition, and number of cells with 75% vacuolation (Fig. 1). Fine droplets of fat were distributed diffusely through hepatocytes of birds fed Diet 1. However, more extensive hepatocytic vacuolation due to fat deposition was observed in the CLA-fed birds. Large vacuoles containing fat distended many hepatocytes. The total number of fat vacuoles per grid and the number of hepatocytes with greater than 75% cytoplasmic vacuolation was higher ( $P < 0.05$ ) in CLA-fed hens than controls.

In addition to scoring the liver for fat deposition, the sections were examined for other lesions. Abnormalities associated with fatty liver such as dilated sinusoids and intrasinusoidal fibrin deposition were noted in birds fed Diet 4. Single-cell necrosis

**FIG. 1.** Histopathology of liver tissues from hens fed diets containing CLA. (A) Typical histological section of liver tissue from hens fed 0% CLA; (B) hens fed 2.5% CLA; (C) number of fat vacuoles/grid; (D) number of cells with 75% or higher fat vacuolation. was more common in liver tissue of Diet 4 hens. Although no difference was found in liver weight as percentage of body weight, total fat content and lipid infiltration were significantly altered in hens fed with added CLA. A similar effect of CLA in enhancing liver lipid content in mice has been reported (14).

**Liver total lipids and FA.** When liver lipids were extracted and the lipid content was determined gravimetrically, a significant effect of dietary CLA and total lipid extract per gram liver tissue was noted (Table 3). Livers of hens fed even 0.5% CLA (Diet 2) contained approximately twice the amount of lipids compared to Diet 1. Increasing CLA to 1.0 and 2.0% did not result in further increase in hepatic total lipid content when compared to 0.5% (Table 3). A recent study by Twibell *et al.* (15) reported a decrease in liver total lipids in perch when diets contained CLA. However, Belury and Kempa-Stecko (14) reported that feeding CLA to rats increased the liver total lipid. Therefore, it appears that the effect of dietary CLA on hepatic lipid content is species-specific.

Liver FA concentrations were significantly affected by dietary lipids (Table 3). The increase in CLA isomers was higher ( $P < 0.05$ ) in birds fed Diets 2, 3, and 4. No CLA was detected in the control birds. Total CLA concentrations of birds fed 0.5, 1.0, and 2.0% CLA were 0.77, 1.35, and 2.67%, compared to 0% in the control birds. The *cis* 9,*trans* 11 isomer was the major CLA in liver tissue. The increase in CLA was at the expense of oleic acid. The saturated FA content increased significantly in liver of birds fed CLA. Even a minor increase in CLA (0.5%) resulted in a dramatic change in the concentration of palmitic (16:0) and stearic acids (18:0). No difference was observed for the content of total n-3 FA. Although fish oil

was at the highest concentration in Diet 1, no differences were observed in the 22:6n-3 and 20:5n-3 content in liver.

To our knowledge, effects of dietary CLA on lipid concentrations and infiltrations in hens have not been reported previously. Whether the enhanced liver lipid infiltration is a specific effect of CLA remains to be determined. The current study used CLA in a FFA form. The effects of using CLA in other forms such as TG need to be investigated. Positive energy balance has been reported to cause FLS and associated hepatic lipidosis in hens. In the current study, the experimental diets were isocaloric, and the total fat in the laying hen ration was within the ranges for laying chickens. No differences in body weight, liver weight as percentage of body weight, and feed consumption were noted among birds. The significant changes in hepatic histopathology observed in Diet 4 suggest that dietary CLA may influence hepatic lipid metabolism and subsequently may contribute to hepatic lipidosis.

**Egg yolk total lipids and FA.** The total fat content of the egg yolk was not affected by dietary treatment ( $P > 0.05$ ). However, the FA content was significantly altered by dietary CLA. The CLA content of the egg yolk increased significantly in a dose-dependent manner with the dietary CLA content (Table 4). At 2% inclusion levels (Diet 4), yolks showed the highest incorporation of CLA. The total yolk CLA constituted 5.3% in Diet 4 compared to 0% in Diet 1 ( $P < 0.05$ ). The major CLA isomer in the yolk lipids was *c9,t11* and constituted 0, 0.8, 1.6, and 3.6% in the yolk lipids of hens fed Diets 1, 2, 3, and 4, respectively. The content of *t10,c12* constituted 0, 0.16, 0.8, and 1.6% in yolk lipids from hens fed Diets 1, 2, 3, and 4, respectively. CLA added at a 2% level resulted in over 50% reduction of monounsaturated FA (MUFA) and replacement by saturated FA (SFA). These results corroborate Chamrusspollert and Sell (16), Du *et al.* (17), and Raes *et al.* (18). The  $\Delta^9$ -desaturase enzyme is responsible for the conversion of stearic acid (18:0) to oleic acid (18:1). Dietary CLA may have an inhibitory action on desaturases, thereby

<sup>a</sup>Means within a row with no common superscript (a-d) differ ( $P < 0.05$ );  $n = 6$ . SFA, saturated FA; MUFA, monounsaturated FA.

leading to the reduction of MUFA. A recent study also reported a decrease in mRNA expression of stearoyl CoA in CLA-fed rats, affecting the synthesis of MUFA and accumulation of SFA (19). The SFA contents of the eggs from hens fed Diets 3 and 4 were higher ( $P < 0.05$ ) than for hens fed Diets 1 and 2. A twofold increase in stearic acid was also observed in hens fed Diet 2. Higher levels of SFA in yolk lipids may be a health concern owing to the association of 14:0 and 16:0 FA with plasma cholesterol and cardiovascular diseases. No effect of CLA on linoleic acid was observed in the yolk. However, 20:4n-6 was reduced in birds fed Diet 2. These results suggest an inhibitory action of CLA on enzymes responsible for MUFA synthesis resulting in an accumulation of SFA. Dietary CLA did not alter the total n-6 and n-3 PUFA content of yolk. Although Diet 1 contained low CLA and high fish oil, Diets 2 and 3 incorporated higher percentages of 22:6n-3 than Diet 1 ( $P < 0.05$ ). The reason for this high incorporation of 22:6n-3 is not clear. The low content of 22:6n-3 in Diet 4 may be due to the low level of menhaden oil in these diets.

**Muscle tissue total lipids and FA.** Addition of CLA resulted in a significant increase in total CLA in the thigh and breast muscles (Fig. 2). The breast muscle incorporated more CLA than leg muscle. The total MUFA were reduced by feeding CLA (Fig. 3), which confirmed previous reports in poultry

(19). No difference was observed in the total PUFA. The total SFA was increased ( $P < 0.05$ ) by feeding CLA in Diets 3 and 2 in the breast and thigh muscle, respectively. Addition of CLA did not affect the incorporation of 20:5n-3 or 22:6n-3 in the thigh meat. However, the content of 20:4n-6 was significantly reduced in birds fed Diet 1. The concentrations in breast meat of 22:6n-3 and 20:5n-3 were highest in hens fed Diet 3. No difference was observed in the content of 20:4n-6 in the breast meat. The fat content of breast muscle was not affected by dietary CLA. The total fat was 1.1, 1.07, 0.88, and 0.88% for hens fed Diets 1, 2, 3, and 4, respectively. However, a significant decrease in thigh meat total fat was observed. The total fat varied from 5.1 to 1.9, 1.6, and 1.7% for hens fed Diets 1, 2, 3, and 4, respectively. The significant reduction in fat content observed in thigh meat from hens fed CLA is of importance in producing CLA-enriched low-fat chicken meat for human consumption. Although the meat from laying chickens is not sold commercially, these results may have implications in developing value-added FA-modified further processed products. However, further research on the sensory attributes of such meat products is needed.

The increased dietary intake of CLA was reflected in the FA composition of abdominal fat (Table 5). The total CLA constituted 3.0% in hens fed Diet 4 when compared to 0% in Diet 1. The percentage of oleic acid (18:1) was reduced by

**FIG. 2.** Total CLA content of (A) breast, leg muscle, (B) spleen, and (C) heart tissue of hens. <sup>a-d</sup>Means with no common superscript differ ( $P < 0.05$ );  $n = 6$ . Diets 1, 2, 3, and 4 represent diets containing CLA of 0.5, 1.0, and 2.0%.

**FIG. 3.** Saturated, monounsaturated, and polyunsaturated fatty acid content of breast and leg muscle of hens' diets containing different levels of CLA. <sup>a-d</sup>Means with no common superscript differ ( $P < 0.05$ );  $n = 6$ . Diets 1, 2, 3, and 4 represent hen diets containing CLA at 0.5, 1.0, and 2.0%. SFA = saturated FA; MUFA = monounsaturated FA. Error bars represent SEM.

feeding CLA, with a concomitant increase in stearic acid (18:0). The content of long-chain n-3 and n-6 FA was minimal in the abdominal fat and was not affected by the dietary treatment. No difference was observed in the total lipid content in the abdominal fat. Body fat reduction properties of CLA are controversial. At a 0.5% level, CLA has been reported to increase the abdominal fat in broiler birds (20). However, Delany *et al.* (21) reported a marked and rapid reduction in fat accumulation in rats. It appears that birds are not as sensitive to dietary CLA as mice.

The increase in CLA concentration resulting from feeding CLA to hens was observed in other hen tissues such as the spleen and heart. A dose-dependent increase ( $P < 0.05$ ) in CLA was observed in the heart and spleen (Fig. 2). However, the dramatic changes in SFA and MUFA content observed in yolk or liver was not noticed in heart or spleen. Feeding CLA did not alter the SFA, MUFA, or n-6 FA in these tissues. Therefore, it appears that the FA-modifying effect of CLA in

the hen is tissue-specific. Hens rely on spleen and lymph nodes for immune responses, as thymus and bursa wither as the birds mature. Therefore, the alteration in CLA content in these tissues and its effect on the long-term health of birds needs to be evaluated.

In conclusion, the results of these studies demonstrate the role of dietary CLA and n-3 PUFA in modulating CLA and PUFA concentration in different tissues of the hen. Consumption of chicken eggs enriched with CLA and n-3 PUFA would be an alternative vehicle for providing these FA to the human diet. Whether the dietary CLA-associated hepatic lipidosis observed in this study is a phenomenon peculiar to laying hens or one that may occur in any situation in which the metabolic activity of the liver is enhanced or chronically stressed is not known. The present findings indicate that specific dietary protocols instituted for the purpose of enriching shell eggs with CLA must be evaluated under commercial conditions for impact on FLS prior to large-scale adoption. The ef-

**ABSTRACT:** A previous study conducted in guinea pigs suggested that ingestion of diets high in EPA and DHA may result in suboptimal retinal function. The aim of the present study was to evaluate retinal function in pigmented (Long-Evans) rats, raised to a third generation on diets that were either deficient in n-3 PUFA or adequate (with the addition of DHA). Electroretinographic assessment employed full-field white flash stimulation. Photoreceptor responses were evaluated in terms of peak amplitudes and implicit times (a-wave, b-wave), intensity–response functions (Naka–Rushton), and the parameters of a model of transduction (P3). Retinal phospholipid FA composition was measured by capillary GLC. DHA levels were reduced by 55% in n-3-deficient animals compared with the n-3-adequate group, whereas the levels of docosapentaenoic acid n-6 were 44 times higher in n-3-deficient animals. The level of arachidonic acid was marginally higher (12.8%) in n-6-adequate animals. The n-3-deficient animals exhibited significantly reduced retinal sensitivity ( $\sigma$  and  $S$  values were both affected by 0.29 log units) and increased b-wave implicit times compared with those fed the n-3-adequate diet. These data suggest that n-3 PUFA are required for development of retinal sensitivity, more so than other indices of retinal function assessed by current methods, such as maximal response amplitude. However, the benefit for retinal function of adding preformed DHA to diets already replete in n-3 PUFA remains unclear.

Paper no. L8999 in *Lipids* 37, 759–765 (August 2002).

The retinal photoreceptors contain the highest levels of n-3 long-chain PUFA (LCPUFA) in the body (1,2). The major product of n-3 PUFA metabolism is DHA, which is found at concentrations approximating 50 mol% in the rod outer segment membranes (3,4).

The relevance of n-3 FA for the development of the ner-

This study was conducted at the Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health.

Abbreviations: AA, 20:4n-6 (arachidonic acid); ALA, 18:3n-3 ( $\alpha$ -linolenic acid); DPA, 22:5 (docosapentaenoic acid); ERG, electroretinogram; F3, third generation; FO, fish oil; LCPUFA, long-chain polyunsaturated fatty acid; n-3, omega-3; n-6, omega-6; P3, fast P3 model of phototransduction; RAS, renin–angiotensin system; RMS, root mean, squared (error term).

vous system is evident from the fact that human breast milk contains on the order of 0.6% of its total fat as n-3 FA, half of which is DHA (5). Furthermore, there is much evidence to suggest that an even slightly reduced n-3 FA status during infancy can have a measurable impact on development and subsequent function, particularly vision (6–11).

The first study to report the effect of dietary FA on retinal function was that of Benolken *et al.* (12) in which rats were fed a fat-free diet, resulting in a 60% reduction in retinal DHA. This was associated with reductions in electroretinographic (ERG) response amplitudes, attributed to anomalous photoreceptor activity. In a later study, the same authors (13) studied the effects of feeding rats a diet free of fat, or those associated with supplementation using either n-9, n-6, or n-3 substrate. They determined that the diets containing 2% 18:3n-3 ( $\alpha$ -linolenic acid, ALA) led to the greatest ERG amplitudes and concluded that n-3 FA are the most critical for the development of normal retinal function.

In a more recent study, Weisinger *et al.* (8) found that third-generation albino guinea pigs raised on diets adequate in n-3 PUFA substrate with the addition of fish oil [FO; containing the preformed LCPUFA (20:5n-3) EPA and DHA] displayed reduced ERG amplitudes compared with those raised on an n-3 adequate diet without FO. Moreover, FO-fed animals were found to perform no better than those fed an n-3-deficient diet. This finding is inconsistent with *in vitro* reconstituted membrane studies indicating that DHA-containing phospholipids are most effective at promoting the activity of membrane-bound proteins, such as those found in the retinal outer segments (14).

There are several possible explanations for the rather surprising findings. First, FO-fed animals may have suffered oxidative damage subsequent to elevated LCPUFA levels. Indeed, it has been demonstrated that animals raised on diets high in n-3 PUFA were more susceptible to retinal light damage (15) and that animals exposed to bright illuminations exhibited a selective loss of DHA in the retina (16,17). However, data for oxidative status and retinal histology were not obtained. Alternatively, since the FO contained high levels of EPA, retinal integrity or function may have been compromised by the resulting competitive reduction in arachidonic acid (AA) metabolism.

In a subsequent study, also performed in guinea pigs fed either safflower oil (n-3-deficient)- or canola oil (n-3-adequate)-based diets, Weisinger *et al.* (9) reported that depletion of n-3 PUFA in the retina affected the sensitivity [a parameter related to the amplification process of a fast P3 phototransduction (P3); Ref. 18] of the photoreceptor response far more than it did the response amplitude [i.e., a-wave, peak-to-peak, or the Naka–Rushton maximal response amplitude ( $R_{max}$ )]. This suggests that photoreceptor sensitivity is more susceptible to n-3 PUFA deficiency than is response amplitude, and supports the proposal that DHA influences membrane biophysical properties and thus its interactions with membrane-bound proteins [such as rhodopsin and transducin (19)]. Furthermore, it appears that direct provision of DHA and EPA by FO may be less consistent with optimal retinal function than provision of n-3 LCPUFA substrate (i.e., ALA) alone.

Bourre and coworkers (20) found that the functional differences observed between infant rats raised on diets either deficient or adequate in n-3 PUFA did not persist into adulthood. However, as previously argued by Vingrys *et al.* (21), the conclusions drawn by Bourre *et al.* need to be reconsidered in light of their age-related response reductions, which were more pronounced in the n-3-adequate group.

In the present study, we considered the retinal function of pigmented rats, raised through three generations on diets either deficient or adequate in n-3 FA; the latter diet contained both ALA and preformed DHA. The study differed from previous studies in rats in two important ways. First, the rats were tested at a later age to assess the purported reversibility of effects relating to n-3 PUFA deficiency. Second, the n-3-adequate diet was designed to minimize the reduction in neural AA accretion. Both diets contained antioxidant protection through the addition of vitamin E. This is the first study to assess retinal sensitivity in third-generation rats raised on diets that were deficient or adequate (with DHA) in n-3 PUFA.

## MATERIALS AND METHODS

**Animals and diets.** All procedures involving animals were conducted in accordance with the Association for Research in Vision and Ophthalmology (ARVO) Statement for the Use of Animals in Ophthalmic and Vision Research. They were approved by the NIAAA Animal Care Committee.

Animals in this experiment were raised on one of two semipurified diets (Table 1). Dietary fats were supplied by the supplementary oils added to the diets, thus creating one diet deficient in n-3 FA (n-3 Def) and the other n-3 adequate with the addition of preformed DHA (n-3 Adq). The assayed FA compositions of both experimental diets are given in Table 2. The diets contained vitamin E (75 IU/kg diet). Other details regarding the composition of the salt and vitamin mixes have been described previously (22).

Animals were raised for three generations (F3) to amplify the FA changes, as previously reported by this and other laboratories (23–25). Twelve F3 male, hooded rats (Long-Evans) were used for the study ( $n = 6$  per diet). Animals were fed

**ERG assessment.** Rats were dark-adapted overnight before deep anesthesia was induced by injection of ketamine (80 mg/kg, i.p.; Ketaset, Wyeth, Madison, NJ) and xylazine (20 mg/kg; Phoenix Pharmaceuticals, St. Joseph, MO). These doses resulted in effective anesthesia for a period of 60 min. Pupillary mydriasis was induced by instillation of one drop of tropicamide 0.5% (Mydracyl; Alcon, Ft. Worth, TX), and local anesthesia was achieved using proparacaine HCl 0.5% (Alcaine; Alcon).

Animals were positioned on a platform placed in the center of a Ganzfeld dome (LKC Technologies, Gaithersburg, MD) that provided full-field stimulation. Electrodes (Ag/AgCl) were positioned (+ve, cornea; -ve, buccal cavity; grnd, subcutaneous at the tail) and animals moved into place *via* the platform. Corneal contact was optimized by regular application of sterile saline. The light source (Vivitar 283; Vivitar, Newbury Park, CA) was mounted on the Ganzfeld dome such that neutral density filters (Wratten; Eastman Kodak, Rochester, NY) could be used to attenuate light passing into the dome. Flash energies spanned 4 log units; the unattenuated flash provided 3.5 log cd-sec-m<sup>-2</sup>. As previously described for the guinea pig (9), retinal illuminance (scot td-sec), was determined by integrating the spectral output of the unattenuated light source and the scotopic spectral sensitivity function for the rat (26). The highest retinal illuminance used in this study was 4.25 log scot td-sec. ERG assessment proceeded from lowest to highest flash intensity to preserve adaptation.

Two responses were averaged for each intensity with a variable interstimulus interval that ranged from 2 to 5 min, again to avoid light adaptation. ERG were amplified, filtered (gain × 1000, 3 dB at 1 Hz), digitized (8 bit, 6.7 kHz), and stored (internal gain, 4×) using a Neuroscientific recording system and analytical interface (Neuroscientific, New York, NY). The Ganzfeld dome, electrodes, and pre-amplifier were electrically shielded by a Faraday cage. Figure 1 shows a representative family of ERG curves, following on-line filtering and averaging.

**FIG. 1.** Representative electroretinographic (ERG) response family (diet adequate in n-3, n-3 Adq) for stimuli ranging from 0.25 to 4.25 log scot td-sec. Each wave form represents the average of two responses. Interstimulus intervals ranged from 2 to 5 min. Oscillatory potentials were filtered prior to analysis of the principal components.

(i) **Intensity-response characteristics—Naka–Rushton relationship.** Stimulation of the visual system results in a sigmoid response as a function of intensity (27,28). The Naka–Rushton plot can be used to describe this relationship as given by Equation 1,

$$R = R_{\max} \cdot \frac{I^n}{I^n + \sigma^n} \quad [1]$$

where  $R$  ( $\mu$ V) is the response amplitude and  $I$  (log scot td-sec) is the retinal illuminance. The derived parameters are:  $R_{\max}$  ( $\mu$ V), the maximal response amplitude;  $\sigma$  (log scot td-sec), the illuminance required to elicit a response equal to half  $R_{\max}$ ; and  $n$  (dimensionless), the slope of the curve.

(ii) **Photoreceptor response model—fast P3 (P3).** A measure of the photoreceptor contribution to the full-field flash ERG response was determined by applying the model described in Equation 2, in which P3 amplitude ( $\mu$ V) is a function of retinal illuminance ( $i$ , scot td-sec) and time after flash onset ( $t$ , sec).  $S$  [(scot td-sec)<sup>-1</sup>sec<sup>-2</sup>] is a sensitivity parameter that is scaled by retinal illuminance (18),  $R_{mP3}$  ( $\mu$ V) is the maximal photoreceptor response arising from the rods, and  $t_d$  (sec) is a brief delay, comprising several short delays inherent in the activation processes of phototransduction (29) or within the recording system itself (30). This model also takes account of the membrane capacitative time constant,  $\tau$ (sec), which enables more reliable fitting for responses to high-stimulus intensities (30).

$$P3(i,t) \equiv \left\{ 1 - \exp[-i \cdot S \cdot (t - t_d)^2] \right\} \otimes \left[ \exp\left(\frac{-t}{\tau}\right) \cdot \tau^{-1} \right] \cdot R_{mP3} \quad [2]$$

where  $t_d > t$ , and  $\otimes$  represents the convolution integral. The digital solution of Equation 2, described by Smith and Lamb (30), was used during ensemble fitting.

Optimization of the model was achieved by using a spreadsheet solver module (Microsoft Excel, Microsoft, Redmond, WA) to minimize the least-square error derived from a Levenberg–Marquardt routine, given by Equation 3 (31).

$$\text{Minimize over } R_{mP3}, S, t_d, \tau : \sum \sqrt{[y_i - y(x_i; R_{mP3}, S, t_d, \tau)]^2} \quad [3]$$

In this equation, the variables  $R_{mP3}$ ,  $S$ ,  $t_d$  and  $\tau$  were floated (simultaneously for all six a-waves) to optimize the least-square error term (RMS) for the fit of 1 to  $N$  data points ( $x_p$ ,  $y_i$ ), where  $y_i$  is the observed amplitude,  $x_i$  is the time,  $y$  is the predicted value from the fit, and  $N$  is the data point corresponding to the first local minimum or 15 msec, whichever came first. Since responses to brighter flashes contain fewer data points prior to b-wave intrusion, calculation of RMS was adjusted such that each response carried an equal weight.

Figure 2 illustrates ensemble analysis of the P3, performed on the leading edges of the a-waves.

**FA analysis.** Following all experiments, rats were killed by decapitation. Retinae were dissected into PBS prior to determination of lipid composition (modified after Folch *et al.*) (32). The total lipid extracts were transmethylated with 14% BF<sub>3</sub>-methanol at 100°C for 60 min. Methyl esters were then analyzed on a Hewlett-Packard 5890/Series II gas chromato-

**FIG. 2.** Representative ERG response family (n-3 Adq; truncated at 15 msec) for stimuli ranging from 0.25 to 4.25 log scot td-sec. Raw data are indicated by the symbols; fitted phototransduction model (P3) values are indicated by fine solid lines. For abbreviations see Figure 1.

graph equipped with an FID and fused-silica capillary column (DB-FFAP, 30 m × 0.25 mm × 0.25 µm; J&W, Folsom, CA) with carrier gas (hydrogen) at a linear velocity of 50 cm/sec. Injector and detector temperatures were set to 250°C and oven temperature program was as follows: 130 to 175°C at 4°C/min, 175 to 210°C at 1°C/min, and then to 245°C at 30°C/min, with a final hold for 15 min. The FAME from 10:0 to 24:1n-9 were identified by comparison to the retention times of a standard mixture (Nu-Chek-Prep 462; Nu-Chek-Prep, Elysian, MN).

**Statistical analysis.** Data were checked for normality and homogeneity of variances. Differences in retinal FA composition, Naka–Rushton values, and modeled P3 parameters were analyzed with a *t*-test, whereas peak amplitude and implicit times were analyzed using a two-way repeated measures ANOVA (Statview, SAS Institute, Cary, NC; Statistica, Statsoft, Tulsa, OK).

## RESULTS

**Animals.** The rats used in this study were normal in all respects. No differences in general appearance or activity were observed. However, animals in both groups were obese compared with animals of this species raised on standard chow diets, which contain only one-third of the lipid content.

**Retinal FA analysis.** The results of the FA analysis are provided in Table 3. There were no differences in the amounts of saturated FA, nor in the majority of monounsaturates found in retinal tissues. Animals in the n-3 Def group had very low levels of DHA (14.8% of total phospholipid FA) and high levels of docosapentaenoic acid (DPA) n-6 (17.5%). This finding was the opposite for the n-3 Adq group, in which DHA levels were 32.7% and DPA n-6 levels were 0.4% (Table 3). There was a small but significant change in AA between the two groups (n-3 Adq: 7.65 ± 0.15; n-3 Def: 8.78 ± 0.18). Thus, although the ratio of n-6/n-3 was different, the combined n-6 + n-3 were no different for the two groups.

<sup>a</sup>ND, not detected; \**P* < 0.05; \*\**P* < 0.01. For abbreviations see Table 1.

**ERG.** Data for peak amplitude and implicit times are given in Table 4. Animals fed the n-3 Def diet exhibited increased b-wave implicit times (mean increase = 3.2 ± 0.9 msec, *P* < 0.05) compared with those fed the n-3 Adq diet. However, there were no statistically significant differences between the two diet groups for a-wave amplitude (*P* = 0.23), b-wave (peak-to-peak) amplitude (*P* = 0.19), or a-wave implicit time (*P* = 0.10). Owing to high intragroup variability and noise inherent to the ERG procedure, the power of the test was low ( $\beta$  = 0.95).

**Naka–Rushton analysis.** Response kinetics of the a-wave amplitude were different for animals in the two diet groups (Table 5). The semisaturation constant ( $\sigma$ ) was significantly increased (*P* < 0.05) by 0.29 log units in the n-3 Def group compared with the n-3 Adq group. There was no significant difference in  $R_{max}$  (*P* = 0.58) between the two diet groups.

**P3 fitting and analysis.** The phototransduction sensitivity parameter (*S*) was significantly decreased (*P* < 0.05) by 0.29 log units in n-3 Def animals compared with the n-3 Adq group. There were no significant differences in the values between animals in the n-3 Adq and n-3 Def groups for  $t_d$  (2.9 ± 0.1 vs. 2.8 ± 0.2, *P* = 0.58) or  $\tau$  (1.3 ± 0.2 vs. 1.2 ± 0.4, *P* = 0.80). There was also no significant difference in fitted  $R_{mp3}$  amplitude (504.1 ± 50.2 vs. 492.2 ± 38.6, *P* = 0.85) (Table 5).

<sup>a</sup>Significantly different from n-3 Def animals;  $P < 0.05$ . For other abbreviations see Table 1.

## DISCUSSION

In agreement with previous studies utilizing dietary FA manipulation over three generations (23–25), animals showed alterations in their tissue FA compositions (Table 3). The well-established (inverse) relationship between the level of retinal DHA and DPA n-6 was also observed (33), i.e., there was no mean difference in the total amounts of n-3 + n-6 PUFA for the two groups. The elimination of high levels of EPA in the n-3 Adq diet ensured that retinal AA levels were slightly higher than those typically associated with the ingestion of diets high in n-3 PUFA (25).

The results of this study demonstrate that photoreceptor sensitivity ( $\sigma$ ) is affected by dietary manipulation, with animals in the n-3 Def group 0.29 log units less sensitive than those fed the n-3 Adq diet. From this result, it is inferred that n-3 PUFA-deficient animals require approximately twice as much light to reach a given response compared with those supplied adequate n-3 PUFA.

The reduction in photoreceptor sensitivity indicated by the Naka-Rushton analysis precisely reflected the results of the P3 analysis, in which the intensity scaling parameter ( $S$ ) was also significantly reduced by 0.29 log units. According to the model of Hood and Birch (34), a change in the sensitivity parameter is equivalent to a change in flash energy. Sensitivity is therefore determined by the quantal catch of the receptor that is, in turn, affected by structural parameters such as rod-packing density, receptor alignment, and pigment content.

However, following light capture, it is the amplification within the rhodopsin–transducin–phosphodiesterase cascade that determines sensitivity. As gross receptor morphology is reportedly unaffected by n-3 PUFA deficiency (35), it is likely that the reduction in sensitivity lies in the elements of the transduction cascade. This is consistent with our previous work in guinea pigs (9), in which we observed large losses in sensitivity (0.7 log units) independent of changes in  $R_{mp3}$ . The difference in sensitivity loss (i.e., 0.7 log units in n-3-deficient guinea pigs vs. n-3 Def rats in the present study) may be accounted for by interspecies differences, or by the fact that the control diet in the guinea pig study was canola oil-based and hence lacked DHA.

One way in which n-3 PUFA deficiency may affect retinal function is by modulating the function of membrane bound proteins in the retina. It is known that changes in the phospholipid FA profile alter the biophysical properties of reconstructed cell membranes (19,36,37). One mechanism by which n-3 deficiency may lead to diminished signal transduction in the retina is by decreasing the conversion of rhodopsin to its active isoform (metarhodopsin II) following light stimulation (19). In addition, new biophysical data (Niu, S.L., and Litman, B.J., personal communication) indicate that slower phosphodiesterase activation occurs in reconstituted membranes composed of PC-DPA n-6 compared with PC-DHA. As Bush *et al.* (38) found rhodopsin levels to be moderately increased subsequent to n-3 PUFA deficiency, reduced transductional efficiency may be coupled to increased expression of rhodopsin. This is consistent with the work of Calvert *et al.* (39), who demonstrated that a reduction in the amount of rhodopsin contained per lipid within the outer segment membranes resulted in faster G-protein to rhodopsin coupling and increased retinal sensitivity. It appears that a reduction in n-3 PUFA within the rod outer segment membrane and an increase in rhodopsin/lipid both slow transduction, thereby reducing sensitivity without affecting the maximal response amplitude.

One other possibility is that n-3 deficiency exerts its effect on retinal function by affecting the activity of the renin–angiotensin system (RAS). Recent investigations of the effects of n-3 PUFA deficiency on body fluid and metabolite homeostasis (40) and on blood pressure (41) suggest that functional

development of the RAS is affected by the neural phospholipid FA profile. Furthermore, Jacobi *et al.* (42) reported that the RAS has a neuromodulatory effect on the electroretinogram, in that pharmacological blockade of the RAS results in increased sensitivity measures.

Numerous studies have found differences in visual function between animals (or human infants) fed diets low in n-3 PUFA and those fed diets containing preformed DHA (6,11, 43,44). The failure of the present study to detect differences in the maximal response amplitudes is difficult to interpret owing to the low statistical power resulting from small sample size and highly variable data (the number of animals required for a power of 0.8 was calculated to be approximately 30 per group). It would, however, be consistent with an earlier study (8) in which electroretinographic response amplitudes recorded from guinea pigs raised on FO-based diets were no different from those from an n-3 PUFA-deficient group.

The finding of a delayed b-wave peak (i.e., increased implicit time) in n-3 Def animals is consistent with previous dietary FA manipulation studies in rats, cats, and monkeys but has not been observed in guinea pigs (for a review, see Jeffrey *et al.*, Ref. 11). It has been proposed that delays in ERG implicit times (11) may result from slower diffusion of transduction proteins through retinal photoreceptor membranes that are depleted of DHA (14). Furthermore, an increased b-wave implicit time may represent a delay in the transmission of the neural signal at the level of retinal bipolar cells. However, the interpretation of delayed b-waves is difficult, as they can be artifacts of an increase in amplitude of the underlying negatively directed voltage (i.e., slow P3).

These data do not support the notion that ERG deficits subsequent to n-3 deficiency subside with age, and suggest that P3 sensitivity is more susceptible to n-3 PUFA depletion than to other more conventionally used measures of retinal function, such as peak amplitude. The observed decrease in *S* is most likely due to modulation of the kinetics of one or more of the proteins involved in the P3 cascade, although possibly through another membrane-dependent receptor system such as the RAS. The way in which this translates to changes in visual perception or adaptation remains to be elucidated.

# n-3 FA Increase Liver Uptake of HDL-Cholesterol in Mice

Valérie le Morvan, Marie-France Dumon, Antonio Palos-Pinto, and Annie M. Béard\*

Laboratoire de Biochimie et de Biologie Moléculaire, Université Victor Ségalen Bordeaux 2, 33076 Bordeaux, France

**ABSTRACT:** In humans, diets rich in fish oil (containing n-3 FA) decrease the incidence of coronary artery diseases. This is thought to be caused by the induction in liver and skeletal muscle of genes involved in lipid oxidation, and to the repression in liver and adipose tissue of genes responsible for lipogenesis. n-3 FA are known to reduce the synthesis of FA and TG in the liver, resulting in a decrease of plasma concentrations of TG-rich lipoproteins. On the other hand, little is known of a possible effect of n-3 FA on HDL metabolism. To investigate this question, female C57Bl/6J mice were fed an n-3 FA-enriched diet for 16 wk. As expected from previous studies, we found that total cholesterol, TG, and phospholipids were reduced in the plasma of treated mice. We also found that HDL-cholesterol decreased after this treatment and that the *in vivo* fractional catabolic rate of HDL-cholesteryl ester was significantly higher in treated mice than in control mice fed a standard diet. Consistent with these results, treated mice exhibited increased uptake of HDL-cholesteryl ester in the liver. Moreover, quantitative reverse transcriptase-PCR analysis showed a two- to threefold increase in scavenger receptor B-1 gene expression. Taken together, these results suggest that an n-3 FA-enriched diet stimulates one step in the reverse cholesterol transport in mice, probably by increasing the amount of the scavenger receptor class B-1. These effects of n-3 FA on HDL metabolism may contribute to their beneficial effects on the vasculature.

Paper no. L9028 in *Lipids* 37, 767–772 (August 2002).

Interest in dietary fish oil has been stimulated by the observation that Greenland Eskimo populations, whose consumption of fish is high, have a decreased incidence of coronary artery disease compared to a Danish control population despite their high-fat diet (1). The components conferring such protective properties to fish oil are the n-3 FA, mainly EPA and DHA (2), long-chain highly polyunsaturated FA of 20 or 22 carbons with five or six double bonds (20:5- and 22:6n-3), respectively.

The beneficial effects of n-3 FA on coronary artery disease are best exemplified by a reduced frequency of reinfarction (3). The physiological response seems to include decreased platelet aggregation (4), reduced production of inflammatory and chemotactic substances by the endothelium (5–7), and modification of plasma lipid levels. Fish oil has been shown to lower fasting TG plasma concentrations, possibly by reducing TG synthesis in the liver (8–11). In addition, fish oil increases lipoprotein lipase activity leading to an accelerated

catabolism of VLDL (12) and chylomicrons, which contributes to the decrease in postprandial triglyceridemia (13,14). The molecular mechanism(s) of action of n-3 FA have remained speculative until recently, when evidence showed that these substances control the transcription of specific genes in the liver such as FA synthase, S14 protein, and lipoprotein lipase. One pathway seems to depend on the direct binding of these compounds to peroxisome proliferator-activated receptor  $\alpha$  (PPAR $\alpha$ ), while another might be due to a decrease in sterol regulatory element binding protein (SREBP-1c) mRNA (15,16).

Although the effects of fish oils on the metabolism of TG-rich lipoproteins are now well documented and can be explained in molecular terms, their potential effects on HDL metabolism are still unclear. Several epidemiological studies have shown that HDL-cholesterol concentrations tend to increase when the diet is rich in n-3 FA (12), but we are not aware of studies reporting an effect of n-3 FA on HDL-cholesterol transport to the liver. HDL are known to participate in a regulatory process called reverse cholesterol transport (17), by which peripheral cells transfer their excess cholesterol to circulating HDL before being taken up by the liver for excretion. Since HDL play a pivotal role in the transport of plasma cholesterol, it seemed promising to explore the possibility that some of the beneficial effects of n-3 FA could be due to an increase in reverse cholesterol transport and, if so, by which biochemical mechanism(s).

## MATERIALS AND METHODS

**Animals.** Normal female C57Bl/6 mice were obtained from Iffa Credo (L'Arbresle, France). They were housed in a full-barrier animal facility on a 12 h light/dark cycle, with free access to food and water. Since n-3 FA can be considered as a possible supplement or treatment in the human diet for their beneficial roles, we decided in this study to add these FA to the standard mouse diet. Mice were thus placed either on a regular diet or on a regular diet enriched in n-3 FA. The regular diet was rodent diet (no. 113; UAR, Epinay-sur-Orge, France). Its composition was (w/w) 5% fat; 51% carbohydrate; 22% protein; 4% fiber; 6% minerals; and added vitamins A, B, D, and E. The basal rodent diet was supplemented with 3.33% n-3 FA. The n-3 FA (w/w; 60% EPA and 40% DHA) were kindly provided by Pierre Fabre Santé Laboratoires (MAXEPA® capsules; Pierre Fabre Santé, Castres, France). The n-3-supplemented food was made each week, stored in individual packages at +4°C under nitrogen, and changed twice a day in order to avoid oxidation. FA composition of diets was measured by GC. The n-3 enriched diet con-

Abbreviations: FPLC, fast protein liquid chromatography; MEM, Eagle's minimal essential medium; PPAR $\alpha$ , peroxisome proliferator-activated receptor  $\alpha$ ; RT-PCR, reverse transcriptase-PCR; SR, scavenger receptor.

tained 19% EPA (20:5n-3) and 13% DHA (22:6n-3) from total FA. Mice were fed the diet for 16 wk. They did not lose weight and had normal hepatic tests (alanine aminotransferase, aspartate aminotransferase, lactate dehydrogenase) throughout the experiment. The use of the research protocol was in accordance with the French Ministry of Agriculture, section on Health and Animal Protection (approval 04476).

**Plasma lipid and lipoprotein analysis.** Mice were fasted 4 h and blood was drawn in tubes containing 4 mmol/L EDTA. Plasma was obtained by centrifugation at  $3,000 \times g$  for 20 min at 4°C. Plasma samples were separated, divided into aliquots, and stored frozen (-80°C) until analyzed. Total cholesterol and TG concentrations were measured in 10- $\mu$ L aliquots of plasma by using commercial enzymatic kits (Dade, Paris La Défense, France) and the Paramax automated chemistry analyzer (Dade). Free cholesterol and phospholipid concentrations were measured in 10- $\mu$ L aliquots of plasma by using commercial enzymatic kits (bioMérieux, Marcy l'Etoile, France) and the Uvikon 922 spectrophotometer (Kontron Instruments, Milano, Italy). Cholesteryl ester values were calculated as the difference between total cholesterol and free cholesterol concentrations. HDL were isolated from the supernatant obtained after selective precipitation of apolipoprotein B-containing lipoproteins with phosphotungstic acid in the presence of magnesium ions and centrifugation. HDL-cholesterol was then quantified by enzymatic determination (bioMérieux).

**Gel filtration chromatography.** After centrifugation of pooled fresh mouse plasmas at  $22,000 \times g$  for 20 min at 4°C, 200  $\mu$ L of clear supernatant was applied to a fast protein liquid chromatography (FPLC) system with two Superose columns connected in series (Pharmacia LKB, Orsay, France). Lipoproteins were eluted at 0.3 mL/min with PBS, pH = 7.4, containing 1 mmol/L EDTA and 0.02% sodium azide. After the first 10 mL was eluted, 60 fractions (0.51 mL each) were collected. Total cholesterol was quantified in each fraction to establish an FPLC profile. Since the FPLC were performed with pools, we have no direct information on the interindividual variability of the profiles. However, determination of cholesterol into HDL, the major lipoprotein in mice, could reflect variability.

**LCAT activity.** Plasma LCAT activity was determined as described previously (18) using 4  $\mu$ L of mouse plasma.

**FA determination.** Blood drawn from mice was collected into tubes containing 4 mmol/L EDTA and was centrifuged. HDL lipoproteins were isolated by sequential ultracentrifugation in 1.063 g/mL, followed by 1.210 g/mL (5 h) KBr solutions, at  $436,000 \times g$ , 4°C, in a TL100 rotor (Beckman Instruments, Gagny, France), and were kept at -80°C until analysis. Lipid extraction was done with hexane/isopropanol, and classes of lipids were separated by TLC (Merck-Clévenot, Nogent-sur-Marne, France) in diethyl ether/petroleum ether/acetic acid (270:30:3, by vol), associated with iodine detection. Phospholipids and cholesteryl esters were extracted with hexane/isopropanol. Isopropyl ester preparation of FA and their separation for further analysis by a fused-silica capillary column (CP Sil 88 column; Chrompack, Les

Ulis, France) with a Carlo Erba model 5160 gas chromatograph equipped with an FID were done as previously described (19). FA were identified by retention times obtained from various standards and from FA extracted from the diet and chromatographed under the same conditions.

**Cell culture and cholesterol efflux.** Normal human embryonic lung fibroblasts (MRC-5 cells; Bioproducts, BioWhittaker, Gagny, France) were grown in 24-well plates containing Eagle's minimal essential medium (MEM; Gibco BRL, Cergy-Pontoise, France) supplemented with 10% bovine calf serum, 2 mmol/L glutamine, 100 IU/mL penicillin, and 100  $\mu$ g/mL streptomycin (Gibco BRL). When subconfluent, the cells were incubated with MEM-10% bovine calf serum and 1  $\mu$ Ci/well of radiolabeled unesterified cholesterol ([1,2-<sup>3</sup>H]cholesterol; Dupont-New England Nuclear, Paris, France) until confluent monolayers were obtained. The cells were then washed three times with MEM/BSA and incubated with MEM/BSA for 24 h prior to performance of efflux assays in the presence of mouse plasmas prepared in 5% MEM/BSA. After the efflux period, media were collected and centrifuged to remove any detached cells. An aliquot of the medium was then counted by liquid scintillation. The radioactivity remaining in the cell pellet was determined after overnight extraction with isopropanol. Cholesterol efflux from the cells was determined as described previously (20). Efflux results are expressed in percentages after dividing the cpm in media by the sum of the cpm in media plus cells (21). At least three culture wells were incubated with each plasma sample. Mouse plasmas used as cholesterol acceptors were kept at -80°C until use. MEM/1% BSA without acceptor was used as a blank. To standardize the cellular response obtained with different batches of cells and labeling media, at least five aliquots of a standard plasma prepared from a pool of human plasmas were always included as test samples.

**HDL-cholesteryl ester metabolic studies.** Liposomes were generated by sonicating L- $\alpha$ -phosphatidylcholine (Sigma, L'Isle d'Abeau Chesnes, France), [<sup>3</sup>H]cholesteryl ester (Dupont-NEN), and butylated hydroxytoluene (Sigma) as described (22) and incubating for 18 h at 37°C with HDL (2 mg total protein) isolated from mice fed a regular diet or an n-3-enriched diet. Labeled lipoproteins were isolated by sequential ultracentrifugation in 1.063 g/mL (5 h) followed by 1.210 g/mL (12 h) KBr solution at 4°C and  $436,000 \times g$  in a TL100 rotor and analyzed as described previously (21). Isolated labeled HDL ( $10^6$  cpm) was injected in the saphenous vein of mice fed either a regular diet or an n-3-enriched diet. Mice were pre-anesthetized with ketamine (50 mg/kg) and xylazine (14 mg/kg). Injected radiolabeled HDL-cholesterol represented <5% of the pool sizes of recipient mice HDL-cholesteryl esters. Blood sampling was performed at 5, 15, 30, 60, 120, 240, 480, and 600 min after injection, and samples were counted in a Packard Tri-Carb liquid scintillation counter. The fractional catabolic rate for HDL-cholesteryl esters was calculated from the plasma decay curves of [<sup>3</sup>H]cholesteryl oleyl ester. To establish the rate of liver uptake, livers were harvested 2 h after injection, minced, extracted according to the

method of Folch *et al.* (23), and counted in a Packard Tri-Carb liquid scintillation counter.

**RNA isolation and analysis.** Mouse livers were obtained from mice on a standard diet or an n-3 FA-rich diet. All samples were immediately placed into a Trizol® solution (Gibco BRL) and stored at  $-80^{\circ}\text{C}$  pending RNA isolation. Total RNA were isolated according to the method of Chomczynski and Sacchi (24). The amount of RNA was determined by measuring absorption at 260 nm. Quality of the isolated RNA was controlled by the 260:280 nm ratio (1.8–2.0) and by denaturing gel electrophoresis. Tissue RNA were analyzed by Northern blot after fractionation on a 1.2% formaldehyde/agarose gel, and transferred to a Nylon Nitran Plus membrane (Schleicher & Schuell, Dassel, Germany) using the Turbo-blotter transfer system (Schleicher & Schuell). Hybridization was performed with  $^{32}\text{P}$ -labeled probes for mouse scavenger receptor (SR)-B1 (detecting both SR-B1 and SR-B2 transcripts) and  $\beta$ -actin. Autoradiographs were obtained by exposing Biomax MS films (Pharmacia-Amersham, Orsay, France) with two intensifying screens at  $-80^{\circ}\text{C}$ . The blots were analyzed using a PhosphorImager (Molecular Dynamics, Sunnyvale, CA). Northern blots were performed twice with pools of livers taken from four or five mice in each study group of mice maintained on specific diets for 16 wk. A second independent experiment was performed using an equal number of mice maintained on their respective diets for 6 wk.

For quantitative polymerase chain reaction (PCR) analysis, RNA were first reverse-transcribed to cDNA using random primers and a GeneAmp® RNA PCR kit (PE Biosystems, Courtaboeuf, France). The specific primers and TaqMan® probe were designed using Primer Express software (PE Biosystems) and synthesized by Genset (Paris, France). Each probe was double-labeled with the fluorescent reporter dye 6-carboxyfluorescein covalently linked to the 5' end of the probe and the quencher dye 6-carboxytetramethylrhodamine attached to the 3' end. Quantitative PCR was performed for SR-B1 transcripts in 96-well reaction plates with optical caps. Fluorescence was followed continuously for each reaction. Gene expression was normalized for the 18S amount. Quantitative PCR were performed three times with individual livers from four mice on an n-3-enriched diet for 16 wk and from five control mice. Data are expressed as a fold change in gene expression in treated mice compared to untreated mice.

**Statistical analysis.** A paired Student's *t*-test was used to compare values in groups of animals fed different diets. Statistical significance was defined as  $P < 0.05$ . Results are expressed as mean  $\pm$  SEM.

## RESULTS

**Characterization of plasma lipids and LCAT activity in C57Bl/6J mice fed an n-3-enriched diet.** Analysis of plasma lipids and lipoproteins in mice fed a regular diet or an n-3 FA-supplemented diet for 16 wk is shown in Table 1. Plasma concentrations of TG were significantly reduced in treated mice ( $P < 0.0003$ ), consistent with previous reports (25). In addition,

these mice showed a significant decrease in plasma concentrations of total cholesterol, phospholipids, and HDL-cholesterol. At 3 wk, TG concentrations decreased ( $0.62 \pm 0.01$  vs.  $0.40 \pm 0.07$  mg/dL,  $n = 20$  in each study group,  $P < 0.01$ ), whereas total cholesterol and HDL-cholesterol concentrations did not change significantly ( $P = 0.26$  and  $0.49$ , respectively). These results suggested that the long-term n-3-enriched diet was necessary to find changes in HDL-cholesterol concentrations in our study. A new batch of mice ( $n = 10$ ) was analyzed after 6 wk on the n-3-enriched diet. These data confirmed the 16-wk data. We found a decrease in the following plasma lipid concentrations: TG ( $52.4 \pm 4.4$  vs.  $56.8 \pm 5.9$  mg/dL,  $P < 0.02$ ), total cholesterol ( $62.2 \pm 3.7$  vs.  $79.1 \pm 7.6$  mg/dL,  $P < 0.0005$ ), free cholesterol ( $13.5 \pm 1.6$  vs.  $16.4 \pm 1.3$  mg/dL,  $P < 0.004$ ), phospholipids ( $110.3 \pm 7.7$  vs.  $139.1 \pm 10.0$  mg/dL,  $P < 0.0002$ ), and HDL-cholesterol ( $53.0 \pm 7.9$  vs.  $67.1 \pm 7.7$  mg/dL,  $P < 0.003$ ). Moreover, determination of LCAT activity in mouse plasma showed no effect from the diets ( $27.5 \pm 1.4$  vs.  $28.3 \pm 0.4$  nmol/mL/h in treated vs. untreated animals, respectively,  $P > 0.05$ ).

Analysis of plasma lipoproteins was also performed by FPLC (Fig. 1). In agreement with plasma lipoprotein determinations, FPLC analysis revealed a decrease in HDL-cholesterol. In addition, the size of the HDL particles present in the plasma of the mice on an n-3-enriched diet was increased compared to untreated mice, indicating an enrichment in cholesteryl ester. These results were confirmed by a second experiment with a new batch of mice treated for 6 wk (data not shown).

The above results, which showed that mice respond to n-3 FA by a series of changes also found in humans, encouraged us to continue to use mice as a model for further studies.

**An n-3-enriched diet modifies the FA composition of plasma HDL.** Analysis of the FA composition of plasma HDL by GC demonstrated that, although the concentration of n-3 FA-containing phospholipids increased from 22 to 26% of the total FA in treated mice, the concentration of n-3 FA in cholesteryl esters did not exceed 6 to 8% of the total FA (data not shown). We confirm here (26,27) that, quantitatively, EPA was distributed equally between plasma phospholipids and cholesteryl esters, whereas a greater concentration of DHA was present in phospholipids. The EPA/DHA ratio was much

TC/HDL-c	$1.38 \pm 0.04$	$1.44 \pm 0.04$

<sup>a</sup>Results are expressed as mean  $\pm$  SEM; \* $P < 0.0003$ , \*\* $P < 0.002$ , \*\*\* $P < 0.04$ . TC, total cholesterol; PL, phospholipids; FC, free cholesterol; CE, cholesteryl esters; HDL-c, HDL-cholesterol.

**FIG. 1.** Fast protein liquid chromatography analysis of plasma lipoproteins in mice. Figure shows the cholesterol distribution in the plasma lipoproteins from untreated mice (bold line,  $n = 20$ ) and mice treated with n-3 FA for 16 wk (dotted line,  $n = 20$ ) after analysis by FPLC. The elution positions of VLDL, IDL (intermediate density lipoprotein)/LDL, and HDL lipoproteins are indicated.

higher in cholesteryl esters than in the precursor phospholipids, showing a marked difference in the utilization of EPA by mouse LCAT.

**Analysis of changes in cholesterol efflux.** To evaluate the functional properties of n-3 FA-enriched HDL, we performed efflux studies in fibroblasts. MRC-5 cells were loaded with unesterified cholesterol and incubated with mouse plasma at 5%. Plasmas from treated mice ( $n = 6$ ) were not more efficient in stimulating cholesterol efflux than those from mice on a regular diet ( $n = 6$ ) even after correction of the cholesterol efflux data for plasma HDL-cholesterol concentrations (Table 2).

**n-3 FA increase HDL-cholesterol uptake by the liver.** The transfer of cholesteryl esters to the liver by HDL was significantly higher in mice fed an n-3-enriched diet compared to mice on a standard diet. The plasma decay of [ $^3$ H]cholesteryl ester of HDL from treated mice was faster than that of control HDL (Fig. 2): The fractional catabolic rate for HDL cholesteryl esters was increased 1.5-fold in treated mice compared to untreated mice (Table 2). In addition, accumulation of [ $^3$ H]cholesteryl esters derived from HDL in the liver was significantly increased by 23% in treated animals (Table 2).

**TABLE 2**

Corrected cholesterol efflux <sup>b</sup> (%)	17.7 $\pm$ 2.0	14.3 $\pm$ 1.0
	Without treatment ( $n = 7$ )	With treatment ( $n = 7$ )
FCR (d <sup>-1</sup> )	4.8 $\pm$ 0.3	7.1 $\pm$ 0.2*
Liver uptake (total cpm)	224015 $\pm$ 7916	275630 $\pm$ 7675**
Total hepatic lipids (10 <sup>-3</sup> mg/mg of tissue)	37 $\pm$ 4	43 $\pm$ 6

<sup>a</sup>Results are expressed as mean  $\pm$  SEM;  $P < 0.02$ , \*\* $P < 0.05$ . FCR, fractional catabolic rate.

<sup>b</sup>Corrected cholesterol efflux values were obtained from plasma HDL-cholesterol concentration values.

**FIG. 2.** Plasma decay of [ $^3$ H]cholesteryl ester HDL from control and treated mice. Plasma decay of [ $^3$ H]cholesteryl ester HDL from control ( $\diamond$ ,  $n = 7$ ) and treated mice ( $\bullet$ ,  $n = 7$ ) were evaluated after injection of radiolabeled lipoproteins in mice.

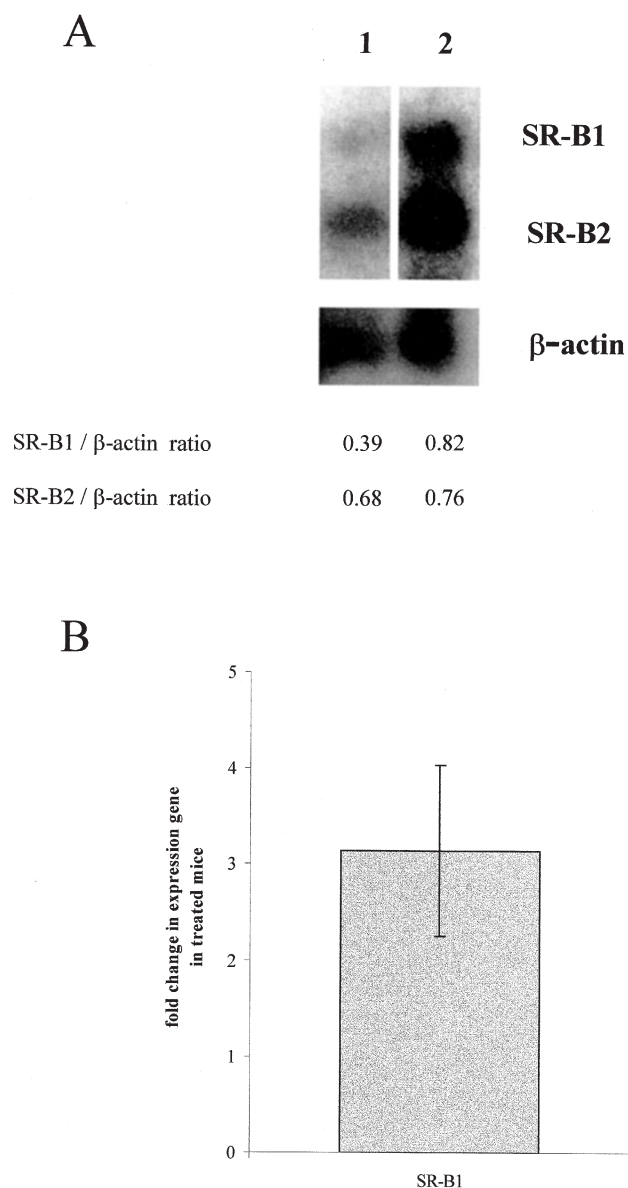

The above results show for the first time that an n-3 FA-enriched diet in the mouse accelerates the removal of HDL-cholesteryl esters from the plasma.

**n-3 FA increase hepatic SR-B1 mRNA in mice.** Since uptake of HDL-cholesteryl esters was increased in mice fed an n-3-rich diet, we explored liver SR-B1 mRNA levels by Northern blot and quantitative reverse transcriptase (RT)-PCR analysis. Compared to  $\beta$ -actin mRNA, which served as a control for message amounts for the tissue analyzed by Northern blot, SR-B1 transcripts markedly increased in livers from treated mice while changes in SR-B2 mRNA was not significant (Fig. 3A). Quantitative PCR analysis showed a threefold increase in SR-B1 mRNA ( $3.14 \pm 0.89$ -fold increase) in liver from mice on the omega-3 FA-enriched diet (Fig. 3B). Thus, an n-3 FA-enriched diet may increase SR-B1 protein expression, as suggested by the increase in its mRNA, and may explain the increased removal of HDL-cholesteryl esters from the plasma of treated mice.

## DISCUSSION

Evidence (28,29) is accumulating that cold-water fish or commercially available preparations of fish oil exert a protective effect against atherosclerosis, hypertension, thrombosis, and inflammation. This effect is thought to be due to the role of EPA and DHA of the n-3 FA family. Current interest in the effects of long-term ingestion of n-3 FA in lowering coronary artery disease risk has been stimulated by epidemiologic and clinical studies. These effects may include altered lipid metabolism. In this study using a murine model, EPA and DHA decreased TG and total cholesterol concentrations. The

**FIG. 3.** Scavenger receptor (SR)-B1 mRNA analysis in control and treated mice. (A) Northern blot analysis of RNA isolated from liver of untreated mice (lane 1,  $n = 5$ ) and mice treated with n-3 FA for 16 wk (lane 2,  $n = 4$ ). The autoradiograph for the hybridization with mouse SR-B1 cDNA is presented in the top panel and shows the two transcripts of SR-B1; mouse  $\beta$ -actin cDNA hybridization is presented in the bottom panel. The experiment was conducted with two batches of mice. (B) Quantitative PCR analysis shows the relative quantity of SR-B1 mRNA from individual livers of four mice on an n-3 FA-enriched diet compared to livers from five control mice. Target and endogenous control (18S) amplifications were done in separate tubes and results were normalized to 18S (three experiments). Data are expressed as the mean of the fold change in gene expression in treated mice compared to untreated mice. For other abbreviation see Figure 2.

decrease in total cholesterol level was due mainly to a decrease in HDL-cholesterol but also to that of LDL-cholesterol concentrations. The reduction of HDL-cholesterol in mice by n-3 FA may seem paradoxical because of the protective effect of HDL in humans and the fact that n-3 FA generally tend to

increase HDL concentrations in humans (12). However, a decrease in HDL does not necessarily imply that reverse cholesterol transport is impaired (30,31).

To study the impact of an n-3-enriched diet on reverse cholesterol transport, we first analyzed cholesterol efflux in a tissue culture model. We found that plasmas from mice being fed an n-3-enriched diet took up cellular cholesterol to a lesser degree than those from mice on a standard diet. However, since the HDL particle number was lower in treated mice, as shown by FPLC results, it is possible that on a per-particle basis, HDL from the treated mice were not impaired in their ability to extract cholesterol from cells. In the study plasmas, HDL particles were enriched in n-3 FA: EPA and DHA were incorporated into phospholipids and cholesteryl esters of HDL prepared from treated mice. Hence, we can conclude that the enrichment of HDL in n-3 FA does not provoke a modification in HDL function during the first step of reverse cholesterol transport. Gillotte *et al.* (32) also demonstrated that plasma from African green monkeys on a diet enriched in n-3 polyunsaturated fats did not influence cholesterol efflux. On the other hand, Dusserre *et al.* (33) demonstrated that cholesterol efflux from the cell membrane into the phospholipid bilayer of an artificial acceptor particle increased when EPA and DHA concentrations in cell phospholipids were higher. They hypothesized that alterations in plasma membrane fluidity or lipid domain structure might be responsible for the effects observed.

Cholesteryl esterification in HDL is another step in reverse cholesterol transport that can be evaluated by LCAT activity determination. However, LCAT activity values showed no change when mice were placed on an n-3-enriched diet, and the ratio of cholesteryl ester to total cholesterol did not increase significantly in mouse plasma.

To investigate the last step of reverse cholesterol transport, we quantified the hepatic uptake of HDL-cholesteryl esters and found that it was accelerated by n-3 FA. The fact that n-3 FA are ligands of PPAR $\alpha$  (15) is indicative of an effect of these substances at the gene level. In the mouse, the removal of HDL-cholesteryl esters from the plasma is thought to be mainly due to SR-B1 present on cells of different organs, including liver. We report here for the first time that n-3 FA induce a two- to threefold increase in SR-B1 mRNA, suggesting an increase in the amount of SR-B1 at the surface of liver cells. This effect on the last step of reverse cholesterol transport—an important mechanism by which HDL are thought to reduce the development of atherosclerosis—could account, at least in part, for the beneficial effect of diets rich in n-3 FA reported in epidemiological studies. We are presently using transcriptional arrays to identify other genes that could be targets for n-3 FA.

#### ACKNOWLEDGMENTS

We thank Prof. Yves Michel Darmon for reviewing our article and Prof. M. Clerc for discussions. We thank Dr. Dominique Breilh for providing assistance in kinetic study analysis, Anne Dupoirion for technical assistance, and H el ene Seguy for the preparation of the manuscript. **ABSTRACT:** The time course of changes in lipoprotein metabolism of obese offspring of mildly diabetic rats was studied with respect to serum lipoprotein composition as well as LCAT and tissue lipoprotein lipase (LPL) activities. Mild hyperglycemia in pregnant rats was induced by intraperitoneal injection of streptozotocin on day 5 of gestation. Control pregnant rats were injected with citrate buffer. At birth, obese pups had higher serum glucose, insulin, and lipoprotein (VLDL, LDL-HDL<sub>1</sub>, HDL<sub>2,3</sub>) levels than control pups. After 1 mon of life, all of these parameters in obese rats became similar to those of controls. However, LCAT, adipose tissue LPL, and hepatic triacylglycerol lipase activities were high. At 2 mon of age, VLDL-TAG levels were higher in obese females than in controls. By the age of 3 mon, obese offspring had developed insulin resistance with hyperglycemia, hyperinsulinemia, and higher serum lipoprotein concentrations. Indeed, qualitative abnormalities of lipoproteins were seen and were typical of obese and diabetic human beings. Fetal hyperinsulinemia should be considered as a risk factor for later metabolic diseases, including dyslipoproteinemia.

Paper no. L9012 in *Lipids* 37, 773–781 (August 2002).

Considerable interest has been generated over the last decade on the potential role of factors that disturb fetal growth in the development of chronic diseases including obesity, diabetes mellitus, and atherosclerosis in adulthood. Previous studies have found that fetal undernutrition as well as fetal overnutrition was associated with the acquisition of later risk factors for chronic diseases (1–4).

Maternal diabetes during pregnancy is an important risk factor for fetal overnutrition leading to fetal obesity, resulting from the combined effects of excessive transfer of maternal nutrients (glucose, amino acids, nonesterified FA) to fetal hyperinsulinemia (4–6). Fetal hyperinsulinemia was associated with the development of glucose intolerance, obesity, and diabetes during childhood and adulthood (1,3,7).

Obesity and diabetes mellitus are associated with compositional changes in serum lipoproteins (8–10). Plasma lipoprotein concentrations and compositions are determined

by many factors. Both secretion by liver and intestine and uptake and degradation by specific or nonspecific pathways are involved. In addition, the combined action of several enzymes, such as lipoprotein lipase (LPL), hepatic triacylglycerol lipase (HTGL) and LCAT, on lipoproteins and movements of lipids and apolipoproteins (apo) in plasma also control the lipoprotein levels. It is of interest to determine if fetal hyperinsulinemia is a risk factor for later dyslipoproteinemia. In humans, follow-up studies are difficult to carry out, in part because of long periods and multiple factors affecting growth performance. Therefore, there is a need to establish an animal model for investigation of this issue. Previous studies reported that induction of hyperglycemia in pregnant rats, by streptozotocin injection on day 5 of gestation, resulted in fetal hyperglycemia, hyperinsulinemia, and fetal obesity (11–13). The obese rat pups of diabetic dams maintained accelerated body weight gain, had increased fat storage, and developed glucose intolerance by 12 wk of age (11–13), which reflected an interesting analogy to human observations. Although most of the authors have focused on altered glucose homeostasis in obese hyperinsulinemic offspring of diabetic mothers, lipoprotein profiles that might be indicative of metabolic diseases remain to be discovered.

The purpose of the present investigation was to determine the time course of changes in serum lipoprotein (VLDL, LDL-HDL<sub>1</sub>, HDL<sub>2,3</sub>) concentrations and compositions as well as serum LCAT and tissue lipolytic activities (liver, adipose tissue, muscle) in obese offspring of streptozotocin-induced mildly hyperglycemic rats. This study would advance our knowledge on the adverse consequences of maternal diabetes, on the offspring.

## MATERIALS AND METHODS

*Animals and experimental protocol.* Adult Wistar rats were obtained from Iffa Credo (Lyon, France). After mating, the first day of gestation was estimated by the presence of spermatozooids in vaginal smears. Pregnant rats were housed individually in wood-chip bedded plastic cages at constant temperature (25°C) and humidity (60 ± 5%) with a 12-h light-dark cycle. They had free access to water and a commercial diet (UAR, Villemoisson-sur-Orge, France) containing 21% (w/w) protein, 4% (w/w) lipid, 53.5% (w/w) carbohydrate, 4.5% (w/w)

fiber, 5% (w/w) minerals, and 2% (w/w) vitamins. A total of 30 pregnant rats were made diabetic by intraperitoneal injection of streptozotocin (40 mg/kg body weight) in 0.1 M citrate buffer, pH 4.5, on the fifth day of gestation. Twelve pregnant dams were injected with citrate buffer alone as a control group. On days 13, 16, 18, and 20 of gestation, maternal blood was collected for plasma glucose concentrations by cutting off the tip of tail and squeezing it gently. Pregnant rats with plasma glucose levels between 5.55 and 16.65 mmol/L (compared with 5 mmol/L in controls) were designated as mildly hyperglycemic (13) and were included in the study. The success rate in obtaining these mildly hyperglycemic dams in the current series was 60%, or 18 of 30 streptozotocin-treated rats. A total of 150 pups from the 18 streptozotocin-treated dams and 110 pups from the 12 control dams were delivered spontaneously and weighed within 12 h. Pups from the streptozotocin-treated dams whose birth weights were 1.7 SD (above the 90th percentile) greater than the mean birth weight of the control pups were classified as obese pups (13) and included in the study. The mean birth weight of the control pups was  $5.95 \pm 0.45$  g. Therefore, experimental pups with birth weights greater than 6.8 g were included as obese in the study. The success rate of obtained obese pups was 60% (90 out of 150). The mean birth weight of the obese pups was  $8.10 \pm 0.50$  g. These obese pups were hyperglycemic and hyperinsulinemic at birth. The normal-sized offspring of diabetic mothers (60 out of 150) were excluded, as maternal diabetes related to fetal obesity was the criterion of our experimental population selection.

Twenty newborn rats of each group (control and experimental) were killed by decapitation, and blood was collected. To obtain sufficient serum samples for lipid and lipoprotein determinations, blood was pooled.

The remaining obese and control pups were left with their own mothers. Litter sizes were kept between six and eight pups per nursing dam to maintain a similar postnatal intake during the suckling period. Pups were weighed weekly up to 12 wk of age. The genders of the pups were identified at 3 wk by examining the external genitalia. Pups were weaned at 4 wk of age. Male and female rats were housed separately, two or three rats per cage, and allowed food (commercial diet, UAR) and water *ad libitum*. The general guidelines for the care and use of laboratory animals recommended by the Council of European Communities were followed.

**Blood and tissue samples.** At 4, 8, and 12 wk of age, after overnight fasting, eight rats from each group were anesthetized with pentobarbital (60 mg/kg body weight) and then bled from the abdominal aorta. Serum was obtained by low-speed centrifugation ( $1000 \times g$ , 20 min) and preserved with 0.26 mmol/L EDTA and 3 mmol/L sodium azide. Liver, gastrocnemius muscle, and fat tissue surrounding the kidney and epididymal areas for the male rats or ovary and fallopian tubes for the female rats were removed, washed with cold saline, quickly blotted, and weighed. For lipolytic activity determination, tissue homogenates in 0.9% NaCl containing heparin (Sigma, St. Louis) were prepared as described by

Mathe *et al.* (14) for liver, and by Inadera *et al.* (15) for adipose tissue and muscle.

**Isolation of lipoprotein fractions.** Serum lipoproteins of density  $<1.21$  kg/L were isolated by single ultracentrifugation flotation (Model L8-55 ultracentrifuge, 50 Ti rotor; Beckman Instruments, Palo Alto, CA), according to Havel *et al.* (16). The three fractions (VLDL, LDL-HDL<sub>1</sub>, HDL<sub>2-3</sub>) were isolated from total lipoproteins by a single-spin discontinuous gradient according to the method of Redgrave *et al.* (17) as modified by Meghelli-Bouchenak *et al.* (18). Purified fractions of VLDL ( $d < 1.006$ ), LDL-HDL<sub>1</sub> ( $1.006 < d < 1.06$ ), and HDL<sub>2-3</sub> ( $1.06 < d < 1.21$ ) were dialyzed against 0.15 mol/L NaCl and 1 mmol/L disodium EDTA, pH 7.4, at 4°C in spectra/por 2 dialysis tubing (Spectrum Laboratories, Rancho Dominguez, CA).

**Apo electrophoresis.** After partial delipidation, VLDL and HDL<sub>2-3</sub> apo were estimated by using a SDS-PAGE system with 2.5–20% acrylamide at 25 V for 18 h, according to Irwin *et al.* (19). After staining with Coomassie brilliant blue (G-250; Sigma, L'Isle d'Abeau, France), destained gels were scanned at 600 nm with a densitometer (model profil 26; Sébia, Issy les Moulineaux, France). Proportions of the various apo were determined from the densitometry tracings. Concentrations of each apo were calculated, based on the percentage of the area for each apo, relative to the total area for each serum sample. Data are expressed as arbitrary units (AU)/L serum. The apo samples for all groups of the rats were electrophoresed in parallel, but the staining affinity of each peptide was not determined. However, when 50–200 µg total protein was applied, the chromogenicity of each major band was shown to change linearly relative to the total amount of protein applied to the gel. To check the validity of our calculations, immunoelectrophoresis according to Laurell (20) was also used for apoA-I and B-100 quantitation.

**Chemical analysis.** Serum glucose was determined by glucose oxidase method using a glucose analyzer (Beckman Instruments, Fullerton, CA). Serum insulin was analyzed by radioimmunoassay kit (Serono Diagnostic, Braintree, MA) using rat insulin standards.

Lipoprotein-TAG, phospholipid (PL), total cholesterol, and unesterified cholesterol (UC) contents were determined by Boehringer Mannheim (Mannheim, Germany) kits, using enzymatic methods. Esterified cholesterol (EC) concentrations were obtained as the difference between total cholesterol and UC values. Total apo contents of each lipoprotein fraction were determined according to Lowry *et al.* (21).

**Assay for LCAT activity.** Serum LCAT activity was assayed by conversion of <sup>3</sup>H-UC to <sup>3</sup>H-EC, according to the method of Glomset and Wright (22), modified by Knipping (23), as previously described (24). Serum LCAT activity was expressed as nanomoles esterified cholesterol per hour per milliliter of serum.

**Lipolytic activities determination.** Tissue homogenates were centrifuged at  $1500 \times g$  for 5 min, and the supernatants containing heparin-releasable lipase were assayed for LPL or HTGL activities according to the method of Nilsson-Ehle and

Ekman (25). For HTGL assay, the concentration of NaCl in 100  $\mu$ L of liver supernatant (the enzyme source) was adjusted to 1 mol/L NaCl, and the solution was incubated at 37°C, for 1 h, with 100  $\mu$ L of [<sup>3</sup>H]triolein emulsion substrate (final concentrations: 1.42 mmol/L triolein, 0.1 mmol/L lysophosphatidylcholine, 0.2% (wt/vol) albumin, 0.1 mmol/L Tris-HCl, pH 9, 0.5 mol/L NaCl). For adipose tissue or muscle LPL determinations, the incubation medium contained 1.42 mmol/L triolein, 0.1 mmol/L lysophosphatidylcholine, 0.2% (wt/vol) albumin, 5% (vol/vol) heart-inactivated serum (providing apoC-II, an activator of LPL), 0.1 mol/L Tris-HCl (pH 8), 0.15 mol/L NaCl. At the end of the incubation period, the FA released were extracted with chloroform/methanol/heptane (1.25:1.41:1, by vol) followed by 0.1 mol/L potassium carbonate/borate buffer, pH 10.5. <sup>3</sup>H radioactivity in 1.5-mL aliquots of the methanol/water upper phase was measured in 10 mL of scintillation liquid (Ready Solv. HP/6; Beckman) in a 7500 LS scintillation counter (Beckman, Palo Alto, CA). Enzyme activity was expressed as nanomoles of FA released per minute per milligram protein.

**Statistical analysis.** Results are expressed as means  $\pm$  SD. The significance of differences among groups was analyzed statistically by ANOVA, followed by Duncan's multiple-range test (26) for parameter changes with age. The significance of differences between obese and control rats at each age was assessed using Student's *t*-test. These calculations were performed using Statistica, Version 4.1 (Statsoft, Tulsa,

OK). Differences were considered statistically significant at *P* < 0.05.

## RESULTS

**Serum glucose and insulin concentrations, and body weight.** At birth, serum glucose and insulin concentrations were higher in obese pups than in controls (1.10  $\pm$  0.20 vs. 0.64  $\pm$  0.11 g/L and 95.3  $\pm$  13.2 vs. 48  $\pm$  10.6 pmol/L, respectively). These values were similar for obese and control rats at 30 and 60 d (results not shown). At day 90, however, obese rats, both males and females, showed higher glucose and insulin levels compared to controls (1.59  $\pm$  0.24 vs. 0.91  $\pm$  0.25 g/L and 284.5  $\pm$  55.7 vs. 187.6  $\pm$  35.6 pmol/L, respectively).

In addition, obese offspring of diabetic dams (both males and females) had significantly higher body weights than controls throughout the first 12 wk of life (results not shown). However, the normal-sized offspring of diabetic mothers (excluded from the present study) were not hyperinsulinemic at birth, had normal growth rates, and showed no significant differences from controls for all parameters studied (results not shown).

**VLDL mass and lipid concentrations.** VLDL mass and lipid contents increased with age in all groups with marked variations during the first month of life. At birth, VLDL mass and VLDL TAG were higher in obese pups than in controls (Table 1). At day 30 and day 60, VLDL mass and lipid contents were similar in control and obese male rats. However, at day 60,

<sup>a</sup>Values are means  $\pm$  SD of eight rats from each group. Males and females constitute separate groups. At day 0, the values for both control and obese rats are the same in both males and females, as gender could not be identified at this stage. Significant differences between obese and control rats at each age are indicated as: \**P* < 0.05; \*\**P* < 0.01. Means within the same group with different superscript letters (a–d) are significantly different according to age for each group (*P* < 0.05).

<sup>a</sup>For footnote see Table 1.

VLDL mass and TAG were significantly higher in obese females than in control females (+40 and +100, respectively). At day 90, VLDL levels and all components of VLDL were significantly greater in obese rats, both males and females, compared to controls. In terms of percentage, the relative composition of VLDL in obese males was close to that of control males, suggesting an increase in VLDL particles at day 90. However, in obese females, the surface to core components [(protein + PL + UC)/(TG + EC)] and EC to triacylglycerols (EC/TG) ratios were higher than control values ( $1.38 \pm 0.05$  and  $0.42 \pm 0.05$ , respectively, in obese females vs.  $1.20 \pm 0.04$  and  $0.22 \pm 0.06$ , respectively in control females). These data suggested an increase in VLDL particles that were enriched in EC in obese females at day 90.

**LDL-HDL<sub>1</sub> mass and lipid concentrations.** Serum LDL-HDL<sub>1</sub> levels showed a significant decrease in the course of the first month of life in both control and obese rats, accompanied by compositional changes (Table 2). In fact, LDL-HDL<sub>1</sub> particles became enriched in EC and depleted in TAG. Afterward, LDL-HDL<sub>1</sub> levels and composition remained constant in control males and females. In contrast, a significant increase in all lipid contents of LDL-HDL<sub>1</sub> was observed between day 30 and day 90 in obese offspring, both males and females.

At birth, LDL-HDL<sub>1</sub> amounts were significantly higher in obese pups compared to control values (+50%), as a result of an increase in all LDL-HDL<sub>1</sub> components. At day 30 and day 60, no significant differences in LDL-HDL<sub>1</sub> particles were observed among rat groups. At day 90, all lipid contents of

LDL-HDL<sub>1</sub> were greater in obese rats than in controls. As the relative composition of these fractions was not modified, the results suggested an increase in LDL-HDL<sub>1</sub> particles in adult obese rats.

**HDL<sub>2-3</sub> mass and lipid concentrations.** During the first month of life, HDL<sub>2-3</sub> levels increased in both obese and control rats due to a rise in PL, UC, and EC contents (Table 3). Afterward, the rise in HDL<sub>2-3</sub> amounts was reflected mainly by higher PL in control rats, by TAG and PL in obese males, and by TAG, PL, UC, and EC in obese females.

At birth, obese pups had higher HDL<sub>2-3</sub> amounts compared to controls (+39%). In addition, all apo and lipids of HDL<sub>2-3</sub> were increased, suggesting an increase in HDL particles in obese pups. At day 30 and day 60, HDL<sub>2-3</sub> lipid and apo levels became similar in control and obese rats. However, at day 90, HDL<sub>2-3</sub> amounts were significantly higher in obese males and females than in controls (32 and 33%, respectively). Indeed, HDL<sub>2-3</sub>-PL, TAG, and EC levels were higher in obese males and females than in their respective controls at day 90. The surface to core components ratio was higher in obese than in control males ( $0.32 \pm 0.04$  vs.  $0.24 \pm 0.03$ ) and in obese than in control females ( $0.35 \pm 0.05$  vs.  $0.26 \pm 0.04$ ), suggesting a modification of HDL relative composition in adult obese rats.

**VLDL and HDL<sub>2-3</sub> apo.** (i) **VLDL apo.** A significant age-related increase in VLDL-apo concentrations was observed in all groups (Table 4). There were no significant differences in VLDL-apo between obese and control groups at day 0, and

<sup>a</sup>For footnote see Table 1.

also at day 30 and day 60 (results not shown). At day 90, VLDL-apoB-100, -apoB-48, -apoE, -apoC-II and -apoC-III were markedly increased in both male and female obese rats, compared with controls. In addition, the apoC-II to apoC-III ratio in VLDL was higher in obese rats than in controls ( $0.50 \pm 0.03$  vs.  $0.37 \pm 0.02$  in males and  $0.52 \pm 0.04$  vs.  $0.38 \pm 0.02$  in females).

(ii) *HDL<sub>2-3</sub> apo*. HDL<sub>2-3</sub> apoA-I, -A-II, -A-IV, -C-II, and -C-III increased with age in both obese and control pups (Table 4). HDL<sub>2-3</sub> apoE levels did not vary significantly with age in any group. At birth, HDL<sub>2-3</sub> apoA-I, -A-II, -A-IV, -C-II, -C-III, and -E concentrations were higher in obese pups than in controls. At day 30 and day 60, no significant differences in HDL<sub>2-3</sub> apo profiles were observed between obese and control rats (results not shown). At day 90, HDL<sub>2-3</sub> apoC-II concentrations were greater in obese males and females compared to their respective controls (+91 and +90%, respectively). Indeed, the apoC-II/apoC-III ratio in HDL<sub>2-3</sub> was increased in obese offspring compared with controls ( $0.74 \pm 0.03$  vs.  $0.39 \pm 0.04$  in males and  $0.65 \pm 0.04$  vs.  $0.42 \pm 0.02$  in females).

*Serum LCAT activity*. LCAT activity increased gradually with age in both obese and control rats (Fig. 1). At birth, LCAT activity was significantly greater in obese pups than in controls (+57%). At days 30, 60, and 90, this activity was about 1.5-fold higher in both male and female obese rats compared with controls.

*Tissue lipolytic activities*. Because tissue lipolytic activities are low at birth, developmental changes in LPL activities were monitored after 1 mon of life. Adipose tissue LPL, as well as HTGL activities, decreased gradually with age in all groups (Fig. 2). Adipose tissue LPL activity, expressed as nmol FFA·min<sup>-1</sup>·mg<sup>-1</sup>protein), was significantly greater in both male and female obese rats than in their respective controls at day 30 and day 60. However, at day 90, values were similar in all groups. No difference in muscle LPL activity was observed between obese and control rats, whatever the age (results not shown). In contrast, HTGL activity was significantly greater in obese rats at all ages.

## DISCUSSION

Offspring of mildly diabetic rats were obese, hyperinsulinemic, and hyperlipidemic at birth and gained significantly more weight than control offspring (results not shown). The increased body weight was reflected by increased adipose tissue weight in these offspring (both males and females) at all ages (results not shown). Thus, the increase in adiposity seen in either male or female offspring of diabetic mothers was maintained throughout adulthood. However, the postnatal metabolic changes varied according to sex and age.

Our results showed that at birth, obese rats had higher VLDL amounts, which were accompanied by higher VLDL-TAG concentrations than control values, suggesting an

<sup>a</sup>Values are means ± SD of eight rats from each group. Males and females constitute separate groups. At day 0, the values for both control and obese rats are the same in both males and females as gender could not be identified at this stage. Significant differences between obese and control rats at each age are indicated as: \* $P < 0.05$ ; \*\* $P < 0.01$ . Means within the same group with different superscript letters (a,b) are significantly different according to age for each group ( $P < 0.05$ ).

<sup>b</sup>Expressed as AU/L (arbitrary units/L serum).

increase in hepatic TAG synthesis and secretion. Combined effects of fetal hyperinsulinemia and an enhancement in glucose and FFA transfer in the diabetic mother could explain elevated fetal hepatic VLDL secretion and hypertriglyceridemia, as reported by previous studies (27–29). At birth, obese offspring of diabetic dams also presented higher LDL-HDL<sub>1</sub> and HDL<sub>2-3</sub> levels, accompanied by higher lipid and apo contents of these fractions, suggesting an increase in the number of LDL-HDL<sub>1</sub> and HDL<sub>2-3</sub> particles, resulting probably from their enhanced synthesis. Since the HDL fraction is primarily responsible for lipid transport during fetal life in humans (30) and in rats (31), elevated HDL contents might reflect an increase in the requirement for cholesterol and PL for plasma membrane, hormone, and surfactant synthesis in obese fetuses. It is well known that high insulin levels lead to enhanced growth of fetal tissues (6). We have previously described similar results in human macrosomic newborns of type 1 diabetic mothers (32,33).

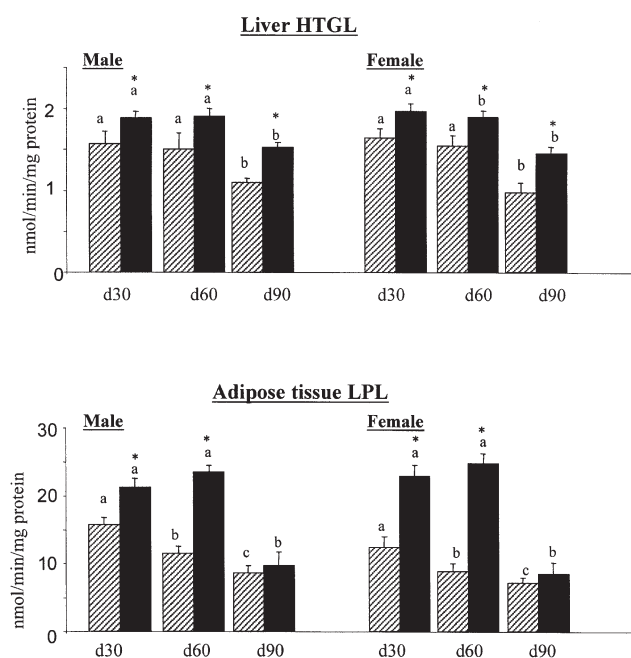

In this study, after 1 mon of life (day 30), which corresponded to the suckling period, serum glucose, insulin, and lipoprotein concentrations and compositions in male and female obese offspring of diabetic dams became similar to those of their respective controls. However, serum LCAT, adipose tissue LPL, and HTGL activities were higher in obese than in control rats. The early elevation of adipose tissue LPL activity associated with normal muscle LPL activity was a

contributory factor to the maintenance of obesity in offspring of diabetic rats. High LPL and HTGL activities are normally associated with enhanced lipoprotein and remnant catabolism, resulting especially in low TAG and VLDL levels, and

**FIG. 1.** LCAT activity of rat sera. Values are means ± SD of eight rats from each group. Males and females constitute separate groups. At day 0 (d0), the values for both control and obese rats are the same in both males and females as gender could not be identified at this stage. Significant differences between obese and control rats at each age are indicated as: \* $P < 0.05$ , \*\* $P < 0.01$ . Means within the same group with different superscript letters (a–c) are significantly different according to age for each group ( $P < 0.05$ ). Hatched and filled histograms represent, respectively, control and obese rats.

**FIG. 2.** Adipose tissue lipoprotein lipase (LPL) and hepatic TG lipase (HTGL) activities in obese and control rats. Values are means  $\pm$  SD of eight rats from each group. Males and females constitute separate groups. Significant differences between obese and control rats at each age are indicated as: \* $P < 0.05$ , \*\* $P < 0.01$ . Means within the same group with different superscript letters (a–c) are significantly different according to age for each group ( $P < 0.05$ ). Hatched and filled histograms represent, respectively, control and obese rats.

in high LDL and HDL<sub>1</sub> levels in the rats (14). These correlations were not found in our obese rats at day 30. On the other hand, the well-known correlation between LCAT activity and HDL levels also was not seen in these rats. These findings suggest that an increased rate of lipoprotein synthesis combined with an enhanced lipoprotein catabolism in obese offspring of diabetic rats might contribute to maintaining a normal lipoprotein profile at day 30. A higher demand for lipid during the phase of rapid growth could explain high lipoprotein turnover, knowing that most of the obese rats tissues were hypertrophic. Indeed, an increased insulin sensitivity could be envisaged, as suggested by other works (6,7). Therefore, persistence of a higher number of insulin receptors and/or greater insulin-binding affinity in the target tissue may contribute to enhanced anabolic effects despite normal serum insulin levels in these obese rats at day 30.

After 2 mon of life (day 60), which corresponded to 1 mon postweaning period, the obese rats again showed serum glucose, insulin, and lipoprotein levels similar to those in controls, except for VLDL-TAG levels, which were enhanced in obese females compared to control females. This could be the result of increased estrogen levels in obese females, since estrogen enhances hepatic TAG production and secretion (34).

After 3 mon of life (day 90), a period reflecting adulthood, the situation was different. Some metabolic alterations that had disappeared at birth and that had subsequently disap-

peared at day 30 and day 60 were present and were worsened. Adult obese offspring (both males and females) had elevated glucose, insulin, and lipoprotein levels compared to controls. They also displayed significant increases in LCAT and HTGL activities. In these adult obese rats, adipose tissue LPL activity became similar to that found in adult control rats. Taken together, the results strongly suggested that obese offspring of diabetic dams developed insulin resistance in adulthood, in agreement with other studies (11,13). It is well known that the development of obesity is linked with insulin sensitivity, whereas weight maintenance in the obese state is associated with insulin resistance (35). In several animal models, obesity and adipocyte hypertrophy precede the development of insulin resistance (36,37). At day 90, adult obese offspring of diabetic dams presented both quantitative and qualitative abnormalities of different lipoproteins. Compositional changes were more apparent when composition was expressed as the percentage of total lipoprotein mass rather than absolute concentration of the components. Adult obese rats showed high VLDL concentrations, accompanied by a concomitant increase in all VLDL-apo and lipid components, suggesting elevated VLDL particle numbers. Overproduction of VLDL, a common feature of human and various experimental obesities, is a direct consequence of hyperinsulinemia and hepatic hyperlipogenesis (8,9,36,38). Indeed, in obese females, VLDL particles were enriched in EC at day 90. This compositional abnormality is well documented in human diabetes and results from increased lipid transfer between VLDL and HDL (8,9). However, in the rat, which has low EC transfer protein activity, HDL concentrations would not be directly affected by interactions between HDL and TAG-rich lipoproteins. Thus, the increased cholesterol content in the VLDL fraction could reflect VLDL hepatic synthesis rich in cholesterol. These adult obese rats also presented enhanced HDL<sub>2-3</sub> levels. In contrast to reduced HDL concentrations observed in obesity and diabetes in man (9,10,39), a positive correlation between adiposity and HDL levels was seen in several animal models of obesity (40,41). Adult obese offspring of diabetic dams also presented compositional changes of HDL<sub>2-3</sub> particles, including enrichment in TAG, cholesterol, and PL.

In our study, adult obese offspring had high HDL-apoC-II contents compared to control values. Indeed, they also had high VLDL-apoC-II and -apoC-III concentrations. The apoC-II to apoC-III ratio was increased in both VLDL and HDL particles of these adult obese rats compared to control values. Since apoC-II is an activator of LPL and apoC-III is an inhibitor of LPL, high proportions of apoC-II compared to apoC-III in obese offspring at day 90 could be a physiological compensatory mechanism to establish TAG homeostasis during a period related to insulin resistance. In conclusion, obese offspring of mildly diabetic rats presented altered lipoprotein metabolism at birth and at adulthood.

Developmental lipoprotein profile changes in offspring of diabetic dams were characterized by two periods. A first period (days 0–60), with increased insulin sensitivity, was

associated with increased fat storage and high lipoprotein turnover leading to a normalization of lipoprotein profiles. A second period (day 90), with decreased insulin sensitivity and the appearance of insulin resistance, was associated with circulating lipoprotein abnormalities. Fetal hyperinsulinemia in diabetic pregnancy should then be considered as one of the potential risk factors for later metabolic diseases, including adult dyslipoproteinemia. Attention needs to be focused on the disordered lipoprotein profile in offspring of diabetic mothers.

**ABSTRACT:** This study was undertaken to estimate the effect of dietary high oleic acid oil (OA) on 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK)-induced lung tumorigenesis in mice. Diet containing 10% oil was fed to mice through experimental periods. On day 30 after NNK injection (100 mg/kg body weight, i.p.), the treatment increased the level of prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) as well as proliferating cell nuclear antigen, a marker of cell proliferation in a high linoleic acid oil (LA)-fed group but not in an OA-fed group. The NNK treatment also induced the activation of an extracellular signal-regulated kinase (Erk) cascade (Erk, Mek and Raf-1) in an LA-fed group. On the other hand, OA feeding abolished the NNK-induced activation of the Erk cascade. In conjugation with these events, OA feeding reduced lung tumor incidence and tumor multiplicity (percentage of mice with tumors) in mice compared with LA feeding at the 20th experimental week. These results suggest that OA suppresses lung tumorigenesis and that this suppression is correlated with the inhibition of PGE<sub>2</sub> production and inactivation of the Erk cascade.

Paper no. L9013 in *Lipids* 37, 783–788 (August 2002).

Cigarette smoking is the leading cause of lung cancer. A tobacco-specific nitrosamine, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), is formed from the nitrosation of nicotine during tobacco processing and cigarette smoking and has been suggested to play an important role in human tobacco-related cancers (1,2). In laboratory animals, NNK is the most potent lung carcinogen of tobacco-specific nitrosamines (3). In mouse lung tumors induced by NNK, mutational activation of *K-ras* gene caused by GC→AT transitions in the second base of codon 12 have been detected (4,5). The mutational activation of *K-ras* gene is then followed by proliferation and progression to a malignant tumor (5). From the similarity of the mutational activation of *K-ras* gene observed in human lung cancer and mouse lung tumors, the induction of lung tumors by NNK in mice is a

Abbreviations: Erk, extracellular signal-regulated kinase; LA, high linoleic acid sunflower oil; NNK, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone; OA, high oleic acid peanut oil; PCNA, proliferating cell nuclear antigen; PGE<sub>2</sub>, prostaglandin E<sub>2</sub>; RIPA, radioimmunoprecipitation assay.

well-established model for studying lung carcinogenesis and its modulating factors in humans (6).

Epidemiological and experimental studies suggest that an increased dietary intake of olive oil plays a beneficial role in the prevention of certain cancers (7–10). Although the proportion of smokers and total intake of dietary fat were the same between southern and northern Italy, the mortality rate for lung cancer was lower in the former (11). In southern Italy, the traditional diet is rich in olive oil, whereas in northern Italy the diet is rich in red meat and butter (11). This increased intake of olive oil may partly account for the low lung cancer mortality rate. A previous report indicates that oleic acid, a major component of olive oil, contributes to the oil-dependent inhibition of lung tumorigenesis (12). Other olive oil components, such as squalene, may have an antitumor-promoting effect (13). In order to establish the usefulness of oleic acid as a preventive component against lung cancer, it is necessary to further investigate an exact role of the FA in regulating the development of lung cancers.

Prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) from n-6 FA acts as a promoter in several types of cancers (14). On the other hand, other FA (n-3 and n-9) like oleic acid attenuate proliferation of colon cancer cells through the reduction of PGE<sub>2</sub> level (15). In previous reports, we demonstrated that pulmonary PGE<sub>2</sub> levels positively correlated with the development of lung tumors in mice treated with chemical carcinogens (16). The activation of the extracellular signal-regulated kinase (Erk) cascade based on the mutation of *K-ras* gene is required for the lung tumor promotion (17). Also, a recent report showed that PGE<sub>2</sub> stimulates the activation of Erk cascade in some tumor cells (18). Overall, it is likely that oleic acid attenuates the activation of Erk cascade in lung tumorigenesis *via* the suppression of PGE<sub>2</sub> levels and subsequently inhibits the development of lung tumors. In this context, the present study was designed to clarify the foregoing hypothesis. To avoid the influence of anticarcinogenic components other than oleic acid involved in olive oil, pure high oleic acid peanut oil (OA) from SunOleic Peanut was used in this study instead of olive oil (19). The composition of oleic acid in this peanut oil was fairly similar to that in olive oil (20). The composition of FA in pure OA, olive oil, and high linoleic acid sunflower oil (LA) is shown in Table 1.

## MATERIALS AND METHODS

**Animals and treatment.** Animal experiments were approved by our Academic Committee on Animal Experiments prior to the onset of the studies. Specific pathogen-free *AJ* strain female mice (SLC, Shizuoka, Japan) were used. The mice were maintained under a clean-rack system at  $22 \pm 1^\circ\text{C}$  and  $55 \pm 5\%$  RH with a 12-h diurnal system. Sterilized water was given *ad libitum*. The mice were fed AIN-76A diet containing 10% LA or OA for 2 wk. After that, the mice were given NNK (Chem-syn Science Laboratory, Shawnee Mission, KS) dissolved in saline at a dose of 100 mg/kg body weight or vehicle by a single i.p. injection. On day 30 after the injection, four mice for PGE<sub>2</sub> assay, three mice for proliferating cell nuclear antigen (PCNA) assay, three mice for Raf-1 kinase assay, and three mice for Mek and Erk assay were killed under anesthesia with pentobarbital. We have already shown that several tumor promotion and cell proliferation markers drastically increase on day 30 after the NNK injection and that the elevations closely relate to the development of lung tumors (16,17,21), so we selected this point to determine biochemical parameters in order to estimate the tumor promotion stage. At week 20 after the injection, 12 mice in each group were sacrificed to confirm the development of lung tumors according to the previous report (21).

**Determination of PGE<sub>2</sub> levels.** A 20% lung homogenate was prepared in 0.1 M Tris-HCl buffer (pH 7.4) containing 0.15 M azide for PGE<sub>2</sub> assay. After centrifugation at  $100,000 \times g$  for 1 h, the supernatant was acidified to pH 3.0, and PGE<sub>2</sub> from the supernatant was extracted with ethyl acetate. The extracted sample was passed through a SEP-PAK C<sub>18</sub> column (Waters Associates, Milford, MA), and the methanol eluate was then evaporated (22). PGE<sub>2</sub> level in the residue was estimated by an ELISA system (Cayman Chemical, Ann Arbor, MI).

**Raf-1 kinase activity assay.** Raf-1 kinase activity was determined using a single-step assay for the kinase based on phosphorylation of recombinant Mek-1, detected using an activation-specific Mek antibody (New England Biolabs, Beverly, MA) that recognized Mek only when specifically phosphorylated by Raf (23). A 20% lung homogenate was prepared in radioimmunoprecipitation assay (RIPA) buffer (25 mM Hepes,

pH 7.5, 150 mM NaCl, 1% Triton X-100, 10% glycerol, 10 mM MgCl<sub>2</sub>, 25 mM NaF, 10 mM Na<sub>3</sub>VO<sub>4</sub>, 1 mM phenylmethyl sulfonyl fluoride, 1 mM EDTA, 10 μg/mL leupeptin, 10 μg/mL aprotinin, and 0.1% deoxycholate). After the supernatant was prepared by centrifugation at  $100,000 \times g$  for 1 h, Raf-1 was immunoprecipitated from 500 μg of the supernatant protein using sheep polyclonal anti-c-Raf antibody (UBI, Lake Placid, NY). An *in vitro* kinase assay was performed using recombinant Mek-1 substrate (Santa Cruz Biotechnology, Santa Cruz, CA) at 30°C for 30 min. The reaction mixture contained Raf-1 immunocomplex, 20 μM ATP, 500 ng of Mek-1 substrate, 20 mM NaCl, 1 mM DTT, 10 mM MgCl<sub>2</sub>, 1 mM MnCl<sub>2</sub>, and 20 mM Tris-HCl buffer (pH 7.4). The samples were resolved by 10% SDS-PAGE and probed with polyclonal antiphosphorylated Mek (New England Biolabs), polyclonal anti-Raf (Santa Cruz Biotechnology) and monoclonal anti-Mek-1 (Transduction Labs, Lexington, KY) antibodies. Detection was accomplished using ECL (Amersham, Piscataway, NJ) and a cooled CCD camera-linked Cool Saver system (Atto, Tokyo, Japan). A 2-D densitometric evaluation of each band was performed using Atto Image Analysis Software (Atto). Molecular sizing was done using Rainbow M.W. marker (Amersham). Protein concentrations were determined using DC Protein Assay (BioRad, Hercules, CA).

**The assay of PCNA level.** The supernatant was prepared from 20% homogenate in RIPA buffer as described in the assay of Raf-1 kinase activity. The supernatant containing 100 μg protein was incubated overnight with p13suc1-agarose (UBI). The pellet was resolved by 10% SDS-PAGE and probed with monoclonal anti-PCNA antibody (Dako, Denmark). β-Actin was used as an internal standard, and this protein was separated on 10% SDS-PAGE and probed with anti-β-actin antibody (Sigma, St. Louis, MO). Each protein band was detected as mentioned above. PCNA-p13 complex was useful as a marker of cell proliferation during carcinogenesis (24), and we confirmed the level of PCNA-p13 complex is positively associated with PCNA labeling index in alveolar epithelial cells (a main progenitor cell of mouse lung tumor) (25). Thus, the level is a good marker to estimate proliferation of alveolar epithelial cells during lung tumorigenic process.

**The assay of Mek and Erk activations.** The activations of Mek and Erk were estimated by immunoblot analysis using antiphosphorylated Mek (Mek-P), phosphorylated Erk (Erk-P), and Mek and Erk antibodies (New England Biolabs). The supernatant containing 20 μg protein was resolved in 10% SDS-PAGE, and subsequently each protein band was detected as mentioned above.

**The estimation of lung tumors.** At autopsy, the lungs were fixed by intratracheal instillation of 10% buffered formalin. After separation of each pulmonary lobe, the number of induced tumors was counted under a dissecting microscope (21). These tumors were embedded in paraffin, sectioned, and stained with hematoxylin and eosin for histological analysis.

**Statistical analysis.** Comparisons were performed by the chi-square test for the percentage of tumor-bearing mouse, and other data were analyzed by one-way ANOVA followed

by Duncan's multiple-range test. *P* values of 0.05 or less were considered significant.

## RESULTS

The ratios of body weight final/initial were 1.30 in LA + vehicle-treated group (LA-vehicle), 1.29 in LA + NNK-treated group (LA-NNK), 1.31 in OA + vehicle-treated group (OA-vehicle), and 1.30 in OA + NNK-treated group (OA-NNK), respectively. There were no significant differences among these groups.

The level of PGE<sub>2</sub> in mouse lung on day 30 after NNK injection is shown in Figure 1. The level of PGE<sub>2</sub> in the LA-NNK group was about twofold greater than that in the LA-vehicle group, and the difference was statistically significant. On the other hand, the level of PGE<sub>2</sub> in the OA-NNK group showed only a slight insignificant increase compared with the OA-vehicle group.

Levels of PCNA-p13 complex (a marker of cell proliferation) and the densitometric evaluation are shown in Figures 2A and 2B, respectively. The level of the PCNA in the LA-NNK group showed a significant increase compared with that in the LA-vehicle group. Also, the difference in the PCNA level between the OA-vehicle and OA-NNK groups was similar to that between the LA-vehicle and the LA-NNK groups, but the level of PCNA-p13 in the OA-fed groups was much lower (*P* ≤ 0.05) than that in the LA-fed groups.

Changes in the activation of the Erk cascade on day 30 after NNK injection are shown in Figure 3. The activated level of the Erk cascade (Raf-1, and phosphorylated Mek and Erk) in the LA-NNK group was much higher than that in the other three groups (Figs. 3A–C), and this difference was statistically significant (Fig. 3D). There was no difference in the activated level of the Erk cascade among the three groups except for the LA-NNK group (Fig. 3D).

The effect of LA and OA feeding on NNK-induced lung tumorigenesis is summarized in Table 2. In the LA-NNK group lung tumors were found in 100% of the mice, with an

**FIG. 1.** The change of pulmonary prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) level in mice treated with 4-(methylnitrosoamino)-1-(3-pyridyl)-1-butanone (NNK). 1, High linoleic acid sunflower oil (LA)-vehicle; 2, LA-NNK; 3, high oleic acid peanut oil (OA)-vehicle; 4, OA-NNK. Each column represents the mean from four samples, and bars indicate SE. \*Significantly different from LA-vehicle, OA-vehicle, and OA-NNK. This experiment was carried out twice.

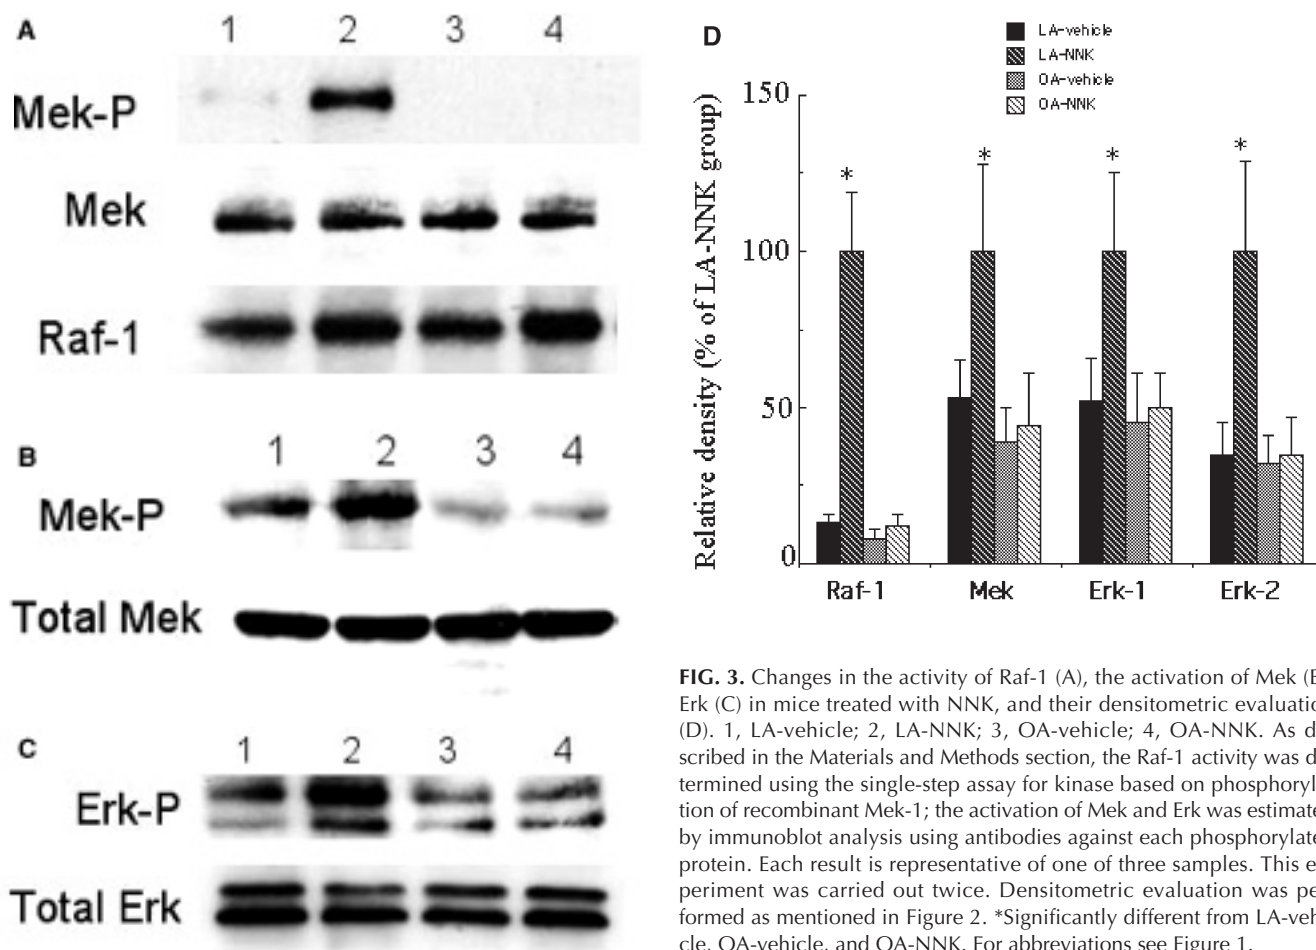

**FIG. 2.** The change of proliferating cell nuclear antigen (PCNA) level in mice treated with NNK (A) and its densitometric analysis (B). Immunoblot analysis of the level of PCNA precipitated with p13suc1-agarose and  $\beta$ -actin were carried out as detailed in the Materials and Methods section. This result is representative of one of three samples. This experiment was carried out twice. Densitometric evaluation was performed as discussed in the Materials and Methods section. Each intensity shown is the mean of three samples; vertical lines indicate SE. Each value is expressed as a relative ratio against the LA-NNK group, and the value in the group is shown as 100. \*Significantly different from LA-vehicle, OA-vehicle, and OA-NNK. \*\*Significantly different from LA-vehicle, LA-NNK and OA-NNK. \*\*\*Significantly different from LA-NNK and OA-vehicle. For abbreviations see Figure 1.

average of 6.3 tumors per mouse. Compared to the LA-NNK group, the OA-NNK group had a 25% lower incidence of lung tumors and a 31% reduced lung tumor level (4.8 tumors per mouse). These differences between the two groups were statistically significant. Furthermore, no difference between the LA-vehicle and OA-vehicle groups in the development of lung tumors was observed.

## DISCUSSION

The present study demonstrates that LA feeding compared with OA feeding reduced the development of lung tumors in mice treated with NNK. Changes in PGE<sub>2</sub> levels correlated with FA-induced changes in tumorigenesis.

During the carcinogenic process, at the initiation stage, the fixation of DNA damage induced by carcinogen exposure occurs (the appearance of the initiated cells). Subsequently, the

initiated cells begin to proliferate in response to various stimuli such as a promoter, finally leading to the development of tumors (26). In the murine NNK-induced lung tumorigenesis model, a high percentage of the lung tumors have mutational activation of the *K-ras* gene (4,5). We have also detected *K-ras* gene activation in lung with the same mutation as seen in NNK-induced lung tumors before the appearance of microscopically observable tumors (27). These reports suggest that NNK-initiated cells having a mutation of the *K-ras* gene appear to remain latent within pulmonary normal cells and require additional events (such as exposure to growth-promoting agents) to trigger neoplastic development. The present study indicates that the difference in the development of lung tumors between OA-NNK and LA-NNK groups is based on

the difference in cell proliferation at the promotion stage. On the other hand, we confirmed that there was no difference in the fixation of DNA injury at the initiation stage between the two groups (Yamaki, T., Yano, T., and Sakurai, H., unpublished data). These results suggest that promoter(s)-stimulated proliferation of the initiated cells in the OA-NNK group during the promotion stage is less than that in the LA-NNK group. We have observed that the level of pulmonary arachidonic acid as a main precursor of PGE<sub>2</sub> in the LA-fed group was higher than that in the OA-fed group (Yamaki, T., Yano, T., and Sakurai, H., unpublished data). Thus, we postulate that a difference in PGE<sub>2</sub> levels occurring between the two groups is due to the difference in the precursor level, and that the difference is key to regulating the development of lung tumors

**TABLE 2**  
Tumor Multiplicity of the 20th Experimental Week in the Lungs of Mice

LA + vehicle	12	0	0	0	0
OA + vehicle	12	0	0	0	0
LA + NNK	12	12	100	75	6.25 ± 2.15
OA + NNK	12	9	75 <sup>a</sup>	43	4.78 ± 2.80 <sup>a</sup>

<sup>a</sup>Significantly different from LA + NNK group ( $P < 0.05$ ). Abbreviations: LA, high linoleic acid sunflower oil; OA, high oleic acid peanut oil; NNK, 4-(methylnitrosoamino)-1-(3-pyridyl)-1-butanone.

in this model. In fact, we found that PGE<sub>2</sub> levels correlated with the development of lung tumors in mice treated with NNK.

In lung cancer cells with *K-ras* mutations, the constitutive activation of Erk cascade based on the mutations induces phospholipase A<sub>2</sub> and cyclooxygenase-2, and this induction is associated with a high generation of PGE<sub>2</sub> in the cells (28). Also, this study shows that the reduction of PGE<sub>2</sub> production by cyclooxygenase inhibitors contributes to negative growth control of the lung cancer cells. In a recent study, we demonstrated that PGE<sub>2</sub> stimulates proliferation of lung cancer cells with *K-ras* mutations by reinforcing the activation of the Erk cascade (29). In *in vivo* studies, we showed that the activation of the Erk cascade based on *K-ras* mutations and the induction of cyclooxygenase and oxygenase-mediated PGE<sub>2</sub> production are necessary for cell proliferation at the promotion stage of lung tumorigenesis in mice (16,17,21). It seems that high generation of PGE<sub>2</sub> associated with the induction of cyclooxygenase during the carcinogenic process in the lung contributes to the constitutive activation of the Erk cascade, abnormal cell proliferation, and the development of lung tumors. Thus, as we have shown, the regulation of PGE<sub>2</sub> production by OA feeding, perhaps owing to a reduction in the precursor FA levels, actually reduces the risk of lung carcinogenesis. Furthermore, our present results support the possibility that an increased intake of olive oil and oleic acid contributes to reduction of lung cancer mortality.

Although the level of PGE<sub>2</sub> in the LA-vehicle group was almost the same as that in the OA-vehicle group, cell proliferation in the former was significantly higher than that in the latter. These results suggest that other factors in addition to PGE<sub>2</sub> contribute to OA feeding-dependent suppression of cell proliferation in lung.

In previous reports FFA were demonstrated to influence cell growth directly through the induction of proto-oncogenes like *c-fos* via Ca<sup>2+</sup> and protein kinase C signaling (30). Different effects on cell growth were observed depending on the type of FFA (31). Thus, this effect of FFA may relate to the OA feeding-dependent decrease in cell proliferation. In comparing the relation of the PGE<sub>2</sub> level and cell proliferation between LA-NNK and OA-NNK groups, it is clear that the reduction in the level of PGE<sub>2</sub> by OA feeding correlates with the suppression of cell proliferation at the promotion stage. On the other hand, in comparing vehicle treatment, NNK-induced elevation of cell proliferation in the OA-fed group was higher than that of the NNK-induced increase of PGE<sub>2</sub> levels, suggesting that promoters other than PGE<sub>2</sub> stimulated the cell proliferation at the promotion stage. However, cell proliferation in the OA-NNK group was almost equal to that in the LA-vehicle group and was much lower than that in the LA-NNK group. Thus, a beneficial effect of OA feeding, the suppression of lung carcinogenesis, presumably depends on both the reduction of PGE<sub>2</sub> levels and other effects that are independent of PGE<sub>2</sub>.

# Enrichment of LDL with EPA and DHA Decreased Oxidized LDL-Induced Apoptosis in U937 Cells

Tianying Wu, Cissy Geigerman, Ye-Sun Lee, and Rosemary C. Wander\*

Human Nutrition Research Laboratory, University of North Carolina at Greensboro, Greensboro, North Carolina 27402-6170

**ABSTRACT:** Oxidized LDL (oxLDL) may contribute to the accumulation of apoptotic cells in atherosclerotic plaques. Although it is well established in monophasic chemical systems that the highly unsaturated EPA and DHA will oxidize more readily than FA that contain fewer double bonds, our previous studies showed that enrichment of LDL, which has discrete polar and nonpolar phases, with these FA did not increase oxidation. The objective of this study was to compare the extent of apoptosis induced by EPA/DHA-rich oxLDL to that induced by EPA/DHA-non-rich oxLDL in U937 cells. LDL was obtained from one healthy subject three times before and after supplementation for 5 wk with 15 g/d of fish oil (FO), an amount easily obtainable from a diet that contains fatty fish. After supplementation, an EPA/DHA-rich LDL was obtained. Oxidative susceptibility of LDL, as determined by measuring the formation of conjugated dienes and the accumulation of cholesteryl ester hydroperoxides, was not higher in EPA/DHA-rich LDL. The oxLDL-induced cell apoptosis was detected by the activation of caspase-3, the translocation of PS to the outer surface of the plasma membrane using the Annexin V-fluorescein isothiocyanate binding assay, and the presence of chromatin condensation and nuclear fragmentation using the 4,6-diamidino-2-phenylindole staining assay. All three measures showed that after FO supplementation, EPA/DHA-rich oxLDL-induced cell apoptosis decreased. The decrease was not related to the concentration of lipid hydroperoxides. This study suggests that a possible protective effect of EPA/DHA-rich diets on atherosclerosis may be through lessening cell apoptosis in the arterial wall.

Paper no. L8943 in *Lipids* 37, 789–796 (August 2002).

Recent findings show that apoptosis is responsible for much of the cell death seen during atherosclerosis. Indeed, apoptosis has been positively correlated with the localization and severity of atherosclerosis (1). Macrophages, smooth muscle cells, and lymphocytes undergoing apoptosis all have been found in human atherosclerotic lesions (2–4). Of the three cell types, macrophages appear to be the preferred cell population in atherosclerotic lesions to undergo apoptosis (2,5,6). Apoptotic macrophages have been implicated in the initiation and

enlargement of the cellular lipid-core in the advanced atherosclerotic lesion (7–9). Furthermore, this process can lead to the activation of thrombosis (7–9).

Oxidized LDL (oxLDL) plays a critical role in the development of atherosclerosis (10,11). Recently, oxLDL has been shown to induce apoptosis in human umbilical vein endothelial cells (12,13), smooth muscle cells and fibroblasts (14), and macrophages (15,16).

It is conceivable that the role of oxLDL in the development of atherosclerosis could be through induction of apoptosis. The mechanisms by which oxLDL induce apoptosis are not well understood. Lipid hydroperoxides (17), decomposition products (i.e., 4-hydroxynonenal) (18), and cholesterol oxidation products (oxysterols) (i.e., 25-hydroxycholesterol or 7- $\beta$  hydroxycholesterol) (13,19–21) are generated during oxidation of LDL and have been shown to induce apoptosis. However, the relative potencies of these different products are not yet known. Furthermore, upregulated Fas and Fas-ligand (22), the release of cytochrome *c* from mitochondria (21), the activation of caspase-8 (22), caspase-3 (13,15,21), and an increase in cellular calcium concentrations (23) have all been implicated in oxLDL-induced cell apoptosis.

Current research has attempted to identify those factors that regulate the oxidation of LDL and the production of its decomposition products. It is believed that an improved understanding of these factors may provide a therapeutic tool for controlling the development and progression of atherosclerosis. For example, dietary FA influence the rate and extent of LDL oxidation. EPA and DHA are FA mainly from fish that are associated with a decreased risk of cardiovascular disease. In a recent clinical trial, results showed that enriching LDL with EPA/DHA produced a lower concentration of lipid hydroperoxides compared to the LDL enriched with linoleic acid (24), when LDL was subjected to oxidation. Given that lipid hydroperoxides are the predominant lipid oxidation products found in atherosclerotic lesions (25), our findings support a role of EPA/DHA in reducing the severity of atherosclerosis. Moreover, reduced production of lipid hydroperoxides may lessen the formation of secondary oxidation products such as 4-hydroxynonenal, thereby reducing apoptosis.

The effect of oxidized LDL that has been enriched with EPA/DHA on cell apoptosis has not been investigated. In order to evaluate this, the oxidative susceptibility of EPA/DHA-rich LDL was compared to that of EPA/DHA-non-rich LDL. The extent of apoptosis of U937 cells induced by

\*To whom corresponding should be addressed at Dept. of Nutrition, P.O. Box 26170, University of North Carolina at Greensboro, Greensboro, NC 27402-6170. E-mail: rcwander@uncg.edu

Abbreviations: AMC, aminomethyl coumarin; CE18:200H, cholesteryl linoleate hydroperoxide; CEOOH, cholesteryl ester hydroperoxides; DAPI, 4,6-diamidino-2-phenylindole; FITC, fluorescein isothiocyanate; FO, fish oil; HDL-C, HDL-cholesterol; LDL-C, LDL-cholesterol; nLDL, native LDL; oxLDL, oxidized low-density lipoprotein; PI, propidium iodide.

EPA/DHA-rich oxLDL was compared to that of EPA/DHA-non-rich oxLDL. U937 cells are human pro-monocytic cells and share many characteristics with macrophages. Additionally, they are one of the easiest cell models in which to study apoptosis. EPA/DHA-rich oxLDL contained less or equivalent concentrations of lipid hydroperoxides as did EPA/DHA-non-rich oxLDL. Apoptosis of U937 cells was induced after 6–7 h of incubation with oxLDL, and was lower in cells treated with EPA/DHA-rich oxLDL compared to cells treated with EPA/DHA-non-rich oxLDL.

## MATERIALS AND METHODS

**Supplementation and experimental design.** The University of North Carolina at Greensboro Institutional Review Board approved the current study, and the subject signed informed consent prior to entering the study. A healthy, nonsmoking male (37 yr) was supplemented with 15 g/d fish oil (FO) for 5 wk. Plasma was collected on three separate days before and after supplementation. The FA profile of the oil was measured by GC using heptadecanoic acid (Nu-Chek-Prep, Elysian, MN) as an internal standard as previously described (26). The supplement (15 g) provided 1.26 g EPA and 1.08 g DHA. This amount (2.34 g) of n-3 FA is similar to that found in two servings (200 g) of Chinook salmon (27). FO supplements were kindly provided by OmegaPure™ (Houston, TX) in bulk and were then encapsulated by Banner Pharmacaps, Inc. (High Point, NC). A mixture of  $\alpha$ -,  $\gamma$ -, and  $\delta$ -tocopherols (courtesy of ADM Nutraceuticals, Decatur, IL) and TBHQ (Eastman Chemical Company, Kingsport, TN) were added to the oil. The vitamin E content of the oil was measured by HPLC (Agilent Technologies 1100 series, Palo Alto, CA) using a fluorometric detector set at 292 nm for excitation and 330 nm for emission (28). Recovery of  $\alpha$ -tocopherol added to the sample was 92%, and the interassay coefficient of variation was 5.6%. After these additions, the oil contained 0.540 mg  $\alpha$ -tocopherol/g oil, 0.689 mg  $\gamma$ -tocopherol/g oil, 0.177 mg  $\delta$ -tocopherol/g oil, and 0.02% TBHQ.

**Cell culture and treatment.** A week before the experiments, U937 cells (ATCC, Rockville, MD) were thawed from the frozen vials and maintained at  $1\text{--}5 \times 10^5/\text{mL}$  cells in T-75 culture flasks in RPMI 1640 medium supplemented with 10% FBS, 1% glutamine (200 mmol/L), 1% penicillin-streptomycin (10,000 IU/mL), and 0.2% amphotericin B (250  $\mu\text{g}/\text{mL}$ ) at 37°C in a 95% air/5% CO<sub>2</sub> humidified incubator. These cells were used in subsequent experiments.

**Preparation of lipoproteins and determination of LDL oxidative susceptibility.** Blood samples were collected into Vacutainer® tubes (Beckton Dickinson, Franklin Lakes, NJ) containing Na<sub>2</sub>EDTA (1 g/L) after an overnight fast ( $\geq 10$  h). Plasma was immediately isolated by centrifugation at  $1200 \times g$  for 15 min at 4°C (Jouan GR 4-12, Winchester, VA). An aliquot of plasma was stored at  $-80^\circ\text{C}$  for later measurement of the lipid profile. The lipid profile, including plasma concentrations of cholesterol, triacylglycerol (TAG), HDL-cholesterol (HDL-C), and LDL-cholesterol (LDL-C), were measured

to ensure that the subject was normolipemic. Plasma concentrations of cholesterol and TAG were measured as previously described (29). The cholesterol concentration of the HDL fraction was measured by an enzymatic method in samples after the precipitation of the LDL and VLDL fractions with phosphotungstic acid in conjunction with MgCl<sub>2</sub> (Sigma Kit #352-4, St. Louis, MO) (30). LDL-C concentration was calculated using the following formula: total cholesterol – HDL-C – TAG/5 (31). LDL was isolated from plasma by centrifugation using a modification of the method of Chung *et al.* (32) as modified by Chen and Loo (33). Briefly, 28 mL of NaCl (0.195 M) was carefully overlaid on 11.5 mL of plasma in a 39.5 mL tube (Beckman, Quick-seal, Palo Alto, CA). The ultracentrifuge tube was placed in a 50.2 Ti rotor (Beckman) and centrifuged at  $190,000 \times g$  (40,000 rpm) for 2 h in a Beckman L7-65 ultracentrifuge.

An aliquot of the isolated LDL was stored at  $-80^\circ\text{C}$  for measurement of the FA profile. The FA profile was measured by GC as previously described (26) using heptadecanoic acid (Nu-Chek-Prep) as an internal standard. Following removal of EDTA and KBr from a second aliquot of LDL by using a 10 DG disposable column (Bio-Rad Laboratories, Hercules, CA), the cholesterol concentration was determined enzymatically as previously described (29) and is referred to as LDL-C.

The EDTA/KBr-free LDL was oxidized; and cholesteryl ester hydroperoxide (CEOOH) concentration, apoptotic events, and conjugated diene formation were measured. CEOOH and apoptosis were measured in aliquots taken from the same oxidized solution. In this system 0.4 mg LDL-C/mL was oxidized with 5  $\mu\text{M}$  Cu<sup>2+</sup>. The formation of conjugated dienes was measured in a separate system by continuously monitoring their production at 234 nm in a Beckman DU-640 spectrophotometer, as we have previously reported (34), at 37°C over a 6-h time period. The concentration of conjugated dienes was calculated using the molar extinction coefficient 29,500 M<sup>-1</sup>cm<sup>-1</sup> (35). The three variables—lag time, rate of oxidation, and maximal concentration of conjugated dienes—were determined. Maximal rate was determined to be the slope of the line of best fit through the points that defined the steepest slope of the curve. The length of the lag phase was determined to be the time (value for  $x$ ) at the intersection of the line describing the maximal rate and the line describing the initial rate. The maximal concentration was determined from the maximum absorption measured during the 6-h oxidation. The absorption at 234 nm plateaued at about 5 h and then began to decrease, indicating that secondary oxidation products were being formed as the conjugated dienes degraded. As many products are formed during this time and their absorptivity is unknown, monitoring the absorbance at 234 nm would yield ambiguous results and was terminated at 6 h. The maximal rate of formation and the concentration of conjugated dienes were expressed relative to the protein content of the EDTA/KBr-free LDL. The protein content of the LDL was determined using a kit obtained from Bio-Rad Laboratories. It was previously determined that optimal performance for the measurement of conjugated dienes was obtained

when 55  $\mu\text{g}$  LDL protein/mL (0.25 mg LDL/mL) was used (34). However, to make comparisons between the system in which CEOOH and apoptosis were measured and that in which conjugated dienes were measured, the ratio of  $\text{Cu}^{2+}$  to LDL-C had to be constant. This was accomplished by measuring the protein content of the EDTA/KBr-free LDL and diluting it to 55  $\mu\text{g}$  protein/mL. Because the dilution factor was known, the concentration of cholesterol in this diluted solution could be calculated. Once the cholesterol concentration was known, the concentration of  $\text{CuSO}_4$  needed to maintain consistency across both systems could be calculated. This calculation was made for each sample.

To measure CEOOH concentration and apoptosis in the EDTA/KBr-free LDL sample before oxidation was initiated by the addition of  $\text{CuSO}_4$ , a sample of LDL was removed and EDTA (1.5 mg/mL) was immediately added to prevent oxidation. This sample is identified as native LDL (nLDL). The remaining EDTA/KBr-free LDL was oxidized. An aliquot was removed after 6 h, and EDTA (1.5 mg/mL) was added immediately to halt the oxidation reactions. The remaining EDTA/KBr-free LDL sample was oxidized four more hours (a total of 10 h), and again EDTA was added to terminate the oxidation reactions. HPLC with an isoluminol-dependent chemiluminescence detection method, as previously reported (24), with slight modification was used to analyze nLDL, 6-h oxLDL, and 10-h oxLDL for CEOOH formation. Briefly, nLDL and oxLDL were extracted with hexane, evaporated, and dissolved in ethanol. Samples were injected onto a C-18 column (Supelcosil LC-18, 5  $\mu\text{m}$ , 250  $\times$  4.6 mm; Supelco, Bellefonte, PA) using a mobile phase of methanol/*tert*-butanol (1:1, vol/vol) at a flow rate of 1.0 mL/min. A postcolumn chemiluminescence reagent consisting of 3:7 (vol/vol) methanol to 100 mM sodium borate buffer (pH 10) containing 1 mM isoluminol (6-amino-2,3-dihydro-1,4-phthalazine-dione; Sigma), and 3 mg/L microperoxidase (MP-11; Sigma) at a flow rate of 1.5 mL/min was added to the eluent. Cholesteryl linoleate hydroperoxide (CE18:2OOH) (Cayman Chemicals, Ann Arbor, MI) was used as an external standard to quantify the amount of CE18:2OOH present in the samples. The modifications gave a single peak from CEOOH rather than several peaks, each associated with a different CEOOH, as reported previously (24). Thus, a more global assessment of the oxidation of core lipids was obtained.

**Apoptosis assays.** Apoptosis was assessed by three methods: caspase-3 activity, translocation of PS, and condensed chromatin and nuclear fragmentation. In the caspase-3 method, acetyl-asp-glu-val-asp-aminomethyl coumarin (Ac-DEVD-AMC), a synthetic tetrapeptide fluorogenic substrate, was added to the samples. This substrate is cleaved in the presence of caspase-3, releasing the fluorescent AMC moiety, which can be quantified by fluorescence intensity spectrophotometrically (36) (PharMingen #6332K, San Diego, CA). For the second method, translocation of PS from the inner to the outer leaflet of the plasma membrane was measured by the Annexin V binding assay. In this assay Annexin V conjugated to fluorescein isothiocyanate (FITC) binds to the translocated PS, and the

amount of the conjugate can be quantified fluorometrically. This assay can be used as a marker of early apoptosis (37). In addition, in this assay cells were costained with propidium iodide (PI). This is used as a marker for cell membrane permeability, a change that occurs during the latter stages of apoptosis and in necrosis. Viable and early apoptotic cells, which have intact membranes, exclude PI, but necrotic cells do not. Apoptotic cells are FITC-positive and PI-negative, whereas necrotic cells are both FITC- and PI-positive. In the third assay, condensed chromatin and nuclear fragmentation were visualized microscopically after staining the cells with the fluorescent dye 4,6-diamidino-2-phenylindole (DAPI).

All three measures of apoptosis were made before and after supplementation with FO. Each treatment was performed in triplicate. The cells were incubated with unoxidized LDL (nLDL), LDL that was oxidized for 6 h (6-h oxLDL), and LDL that was oxidized for 10 h (10-h oxLDL). The concentration of LDL-C was maintained at 66  $\mu\text{g}/\text{mL}$  for caspase-3 activity and DAPI staining measurements and 133  $\mu\text{g}/\text{mL}$  for PS translocation. Incubations with the LDL were 6–7 h long. All experiments included positive and negative controls. For the negative control, cells were incubated in LDL-free medium. Two positive controls were used. One positive control was to treat the cells with 25-hydroxycholesterol (62.5–66.7  $\mu\text{g}/\text{mL}$ ) (Sigma-Aldrich, St. Louis, MO) for 6 h. The other one was to treat them with (1.5  $\mu\text{g}/\text{mL}$ ) camptothecin (Sigma-Aldrich) for 4 h. A shorter incubation was used for the camptothecin because it induced apoptosis more quickly. Since the supplementation lasted about 5 wk, the LDL that was enriched with EPA/DHA was obtained later than the LDL that was not enriched with these FA. The use of these two positive controls allowed us to establish that the U937 cells behaved in a similar fashion at both times.

For the measurement of caspase-3 activity,  $5 \times 10^5$  cells were incubated with the negative and two positive controls, nLDL, 6-h oxLDL, and 10-h oxLDL. Cells were harvested and washed 2 $\times$  with PBS (pH 7.4, 10 mmol/L), resuspended in lysis buffer (100  $\mu\text{L}$  buffer/L  $\times 10^6$  cells), and stored at  $-20^\circ\text{C}$  for batch analysis. Samples were analyzed using a fluorescence spectrophotometer (PerkinElmer LS 50B, Norwalk, CT) set at 380 nm for excitation and 420 nm for emission. Data are expressed as relative fluorescent intensity per  $10^5$  cells.

For the measurement of translocation of PS,  $2.5 \times 10^5$  cells were incubated in the same six systems: the negative and positive controls, nLDL, 6-h oxLDL, and 10-h oxLDL. After incubation, 0.3 mL of the cell suspension was removed from each well and washed 2 $\times$  with ice-cold PBS ( $\text{Ca}^{2+}$ : $\text{Mg}^{2+}$ -free). The resulting cell pellet was suspended in 0.1 mL binding buffer [10 mmol/L HEPES/NaOH (pH 7.4), 140 mmol/L NaCl, 2.5 mmol/L  $\text{CaCl}_2$ ], 5  $\mu\text{L}$  of Annexin V-FITC (as supplied by PharMingen #65874x, San Diego, CA), and 10  $\mu\text{L}$  of PI stock solution (50  $\mu\text{g}/\text{mL}$ ) and then incubated in the dark for 15 min. After incubation, an additional 0.4 mL aliquot of binding buffer was added to the cell solution. Cells were analyzed with a FACS Calibur flow cytometer (Becton Dickinson, San Jose, CA) using the FL1 channel to detect the

signal generated by Annexin V-FITC and the FL2 channel to detect the signal generated by PI. Data are expressed as the percentage of cells positively stained with Annexin V-FITC but negatively stained with PI.

For the DAPI staining assay  $2.5 \times 10^5$  cells were incubated with native LDL, 10-h oxLDL, and the controls. Cells were harvested and washed 2× with PBS (pH 7.4, 10 mmol/L) before being resuspended in 200  $\mu$ L of PBS and loaded on poly-L-lysine slides (Sigma #P-0425) in Cytospin Chambers (StatSpin, Inc. #CC03, Norwood, MA) for 10 min. Slides were cytospun in a Cytofuge<sup>®</sup>2 (StatSpin, Inc.) for 4 min at 850 rpm (40 × g), immersed in fresh 3.7% formaldehyde solution for 20 min at 4°C, and subsequently stored at least one night in ice-cold 70% ethanol at -20°C. Following storage, slides were washed 3× with PBS, immersed into a diluted DAPI solution (1  $\mu$ g/mL) for 10 min, and then viewed on an Olympus BX-60 fluorescence microscope (Melville, NY) equipped with a SPOT digital camera (Sterling Heights, MI). The excitation wavelength was 358 nm, and the emission wavelength was 461 nm. The apoptotic cells were identified by a bright blue nucleus, characteristic of either condensed or fragmented chromatin, whereas normal cells were characterized by a faint blue nucleus. At least 80 cells were counted from three randomly selected fields on each slide. Slides were examined for each sample. The percentage of apoptotic cells was calculated by dividing the number of apoptotic cells by the total number of cells × 100%.

**Statistical analysis.** The significance of supplementation with FO on the lipid profile, the FA profile, and LDL oxidative susceptibility was determined using a two-sample *t*-test (38). The repeated measure's procedure was used to determine statistically significant differences between time points as well as the FO supplements on CEOOH concentration (38). To determine the influence of the length of time that LDL was oxidized on the extent of apoptosis, the data were analyzed using a one-way ANOVA (38). When a significant difference was found, pair-wise comparisons were performed using the Tukey-Kramer test to determine significant differences among treatments (38). To determine the effect of FO supplementation on extent of apoptosis, a two-sample *t*-test was used (38). All experiments were repeated three times before and after supplementation. Analyses were completed using the SAS general linear model procedure (version 8; SAS Institute Inc., Cary, NC). A value of  $P < 0.05$  was considered significant.

## RESULTS

The TAG concentration in plasma was reduced ( $P = 0.02$ ) from baseline by 51% after FO supplementation. The FO supplementation did not significantly ( $P > 0.05$ ) alter the concentration of cholesterol, HDL-C, or calculated cholesterol in LDL. The LDL FA profile changed after supplementation with FO (Fig. 1). The concentration of EPA (20:5n-3) and DHA (22:6n-3) in LDL was 1100 and 110% higher after supplementation, respectively, compared to baseline ( $P < 0.05$  for both FA).

The lag time and maximal rate of production for conjugated dienes were significantly ( $P < 0.05$ ) different from baseline after FO supplementation (Table 1). The lag time was reduced by 32 min, and the maximal rate of production for conjugated dienes was reduced by 37%. However, the maximal amount of conjugated dienes produced in the LDL was similar ( $P > 0.05$ ) after FO supplementation compared to baseline.

The concentration of CEOOH in LDL both before and after supplementation with fish oil, i.e., the concentration in nLDL, was less than 180 pmol/mg LDL-C, the lower limit of detection of this assay (Fig. 2). The concentration of CEOOH produced in LDL oxidized for 6 h was 35% lower ( $P = 0.007$ ) after FO supplementation than before FO supplementation. In contrast, the concentration of CEOOH in the LDL before and after FO supplementation was statistically equivalent in the samples oxidized for 10 h ( $P > 0.05$ ) (Fig. 2).

For all measures of apoptosis, the response seen in the negative controls, i.e., those cells incubated in LDL-free medium (Fig. 3), was similar to the response seen in U937 cells treated with nLDL, suggesting that LDL did not initiate apoptosis. There were no significant differences ( $P > 0.05$ ) before and after FO supplementation for U937 cells treated with either 25-hydroxycholesterol or camptothecin, regardless of which measure of apoptosis was used. This suggests that the apoptotic response of the U937 cells was similar even when measures were separated by the 5-wk supplementation interval.

Two statistical assessments of the data were performed. One was to determine if the extent of apoptosis was influenced by the length of time that LDL was oxidized. This comparison was made separately for the samples obtained before and after supplementation with FO. The second evaluation was to determine if the supplementation with FO influenced the extent of apoptosis induced by LDL after the LDL was oxidized for a defined time.

**Influence of length of time that LDL was oxidized on extent of apoptosis.** For all three measures of apoptosis, oxidation of LDL increased the extent of apoptosis (Fig. 3). Both before and after supplementation with FO, the activity of caspase-3 was higher in cells treated with LDL oxidized for 6 or 10 h compared to cells treated with nLDL ( $P = 0.0001$  in all comparisons except for cells treated with LDL oxidized for 6 h after FO supplementation, where it was 0.0324). However, although

**FIG. 1.** FA concentration in LDL before (open bars) and after (solid bars) supplementation with fish oil. Data are least square means (LSM)  $\pm$  SEM. Bars with different letters above them for each FA are significantly different,  $P \leq 0.05$ .

TABLE 1

Lag Time, Rate of Formation of Conjugated Dienes, and Maximum Production of Conjugated Dienes in LDL Before and After Supplementation with Fish Oil<sup>a</sup>

	Lag time (min)	Maximum rate (nmol/mg LDL protein/min)	Maximum production (nmol/mg LDL protein)
Before FO	140 ± 2	1.87 ± 0.08	186 ± 17
After FO	108 ± 2	1.17 ± 0.08	171 ± 17
Before FO vs. after FO ( <i>P</i> values) <sup>b</sup>	0.0002	0.0032	0.5749

<sup>a</sup>Least square means (LSM) ± SEM calculated for triplicate determinations made from three independent experiments.

<sup>b</sup>*P* value from two-sample *t*-test.

the activity of caspase-3 was higher in the cells treated with LDL oxidized for 10 h compared to those treated with LDL oxidized for 6 h before supplementation with FO ( $P = 0.0001$ ), its activity was statistically equivalent in those cells treated with LDL oxidized for 6 and 10 h after supplementation with FO.

In using the Annexin V assay, both before and after supplementation with FO, the percentage of apoptotic cells was higher in cells treated with LDL oxidized for 6 and 10 h ( $P = 0.0001$ ) compared to cells treated with nLDL. However, in contrast to the caspase-3 assay, the extent of apoptosis was significantly higher in the cells treated with LDL oxidized for 10 h compared to LDL oxidized for 6 h both before ( $P = 0.0001$ ) and after FO supplementation ( $P = 0.0033$ ).

In using the DAPI staining assay both before and after FO supplementation, the percentage of apoptotic cells was higher in cells treated by LDL oxidized for 10 h compared to cells treated with nLDL ( $P = 0.0001$ ).

**Influence of FO supplementation on extent of apoptosis.** Apoptosis induced by oxLDL, regardless of assay used, was decreased by FO supplementation. The activity of caspase-3 in U937 cells treated with LDL oxidized for 6 and 10 h after supplementation with FO was reduced by 13 ( $P = 0.0053$ ) and 22% ( $P = 0.0001$ ), respectively, compared to treatment with LDL oxidized for the same length of time but obtained before

supplementation with FO (Fig. 3A). On the basis of the Annexin V assays, only after the LDL had been oxidized for 10 h was a significant difference measured in the extent of apoptosis before and after FO supplementation. It was 30% lower ( $P < 0.0001$ ) in U937 cells treated with EPA/DHA-rich LDL compared to EPA/DHA-non-rich LDL oxidized for 10 h (Fig. 3B). Results from the DAPI staining assays showed a 61% reduction ( $P = 0.0001$ ) in apoptosis for U937 cells treated with LDL oxidized for 10 h after FO supplementation compared to before supplementation (Fig. 3C).

## DISCUSSION

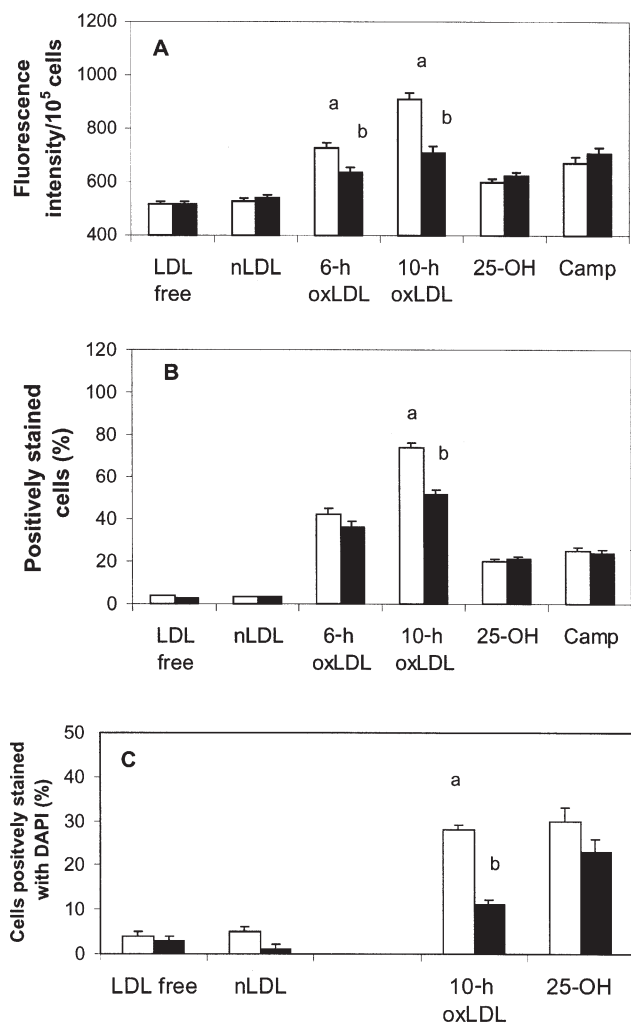

Apoptotic vascular cells have been found in atherosclerotic lesions (2–4). Since oxLDL has been reported to induce apoptosis of endothelial cells (12,13), smooth muscle cells and fibroblasts (14), and macrophages (15,16) *in vitro*, it may be a candidate for the induction of apoptosis of vascular cells *in vivo*. The oxidized lipids in oxLDL are thought to be responsible for apoptosis. Thus, events that modify the bioactive lipid profile of oxLDL may affect its ability to induce apoptosis. We showed in this study and previously (24,34) that LDL enriched with EPA and DHA has the intuitively predicted shorter lag time, suggesting increased oxidative susceptibility, but a paradoxical decrease in rate of formation of conjugated dienes, suggesting decreased oxidative susceptibility. The explanation that we have offered is that bicycloendoperoxides are formed in the presence of EPA and DHA and that they rapidly migrate to the surface of the LDL particle because of their polarity. Thus, since radicals are removed from the system, the rate of the propagation is slowed. These reactions would alter the lipid entities present in oxLDL that would induce apoptosis. Thus, the purpose of this study was to determine if EPA/DHA-rich oxLDL, obtained after FO supplementation, altered the extent of apoptosis as compared to the LDL obtained prior to FO supplementation. Several standard apoptotic markers were used to provide a better confirmation of apoptosis. The results showed that oxLDL induced apoptosis in U937 cells, as characterized by the activation of caspase-3, translocation of PS, and chromatin condensation and nuclear fragmentation. However, LDL obtained after supplementation with FO and then oxidized induced less apoptosis than LDL obtained before supplementation with FO.

LDL enriched with EPA/DHA and oxidized for 10 h in-

**FIG. 2.** Lipid peroxidation before (open bars) and after (solid bars) supplementation with fish oil as indicated by the concentration of cholesterol ester hydroperoxides in LDL. Each of the labels on the x-axis are defined as follows: nLDL, native LDL, is the LDL sample before any oxidation has occurred; 6-h oxLDL represents LDL oxidized for 6 h with copper; 10-h oxLDL represents LDL oxidized for 10 h. Data are least square means (LSM) ± SEM. Bars with different letters above them at each time for LDL oxidation are significantly different,  $P \leq 0.05$ .

duced significantly less apoptosis in U937 cells by all three measures used. However, when the U937 cells were treated with LDL oxidized for 6 h, the decrease was significant only

**FIG. 3.** Measurement of apoptosis in U937 cells induced by LDL. Cells were incubated with nLDL; 6-h oxLDL; and 10-h oxLDL. Cells were incubated without LDL (free LDL) as a negative control. They were incubated with 25-hydroxycholesterol (25-OH) or camptothecin (Camp) as positive controls. Two statistical assessments of the data were performed. One was to determine if the extent of apoptosis was influenced by the length of time that the LDL was oxidized. This comparison is discussed in the text. The second evaluation was to determine if the supplementation with fish oil influenced the extent of apoptosis induced by LDL oxidized for a defined length of oxidation (open bars, before supplementation with fish oil; solid bars, after supplementation). The results from this comparison are represented here. (A) Measurement of activity of caspase-3. The activity of caspase-3 was expressed as fluorescence intensity per 10<sup>5</sup> cells. (B) Measurement of U937 cells positively stained with Annexin V–fluorescein isothiocyanate (FITC), negatively stained with propidium iodide. Data are displayed as the percentage of 10<sup>4</sup> cells stained with Annexin V–FITC. (C) Measurement of 4,6-diamidino-2-phenylindole (DAPI) staining of U937 cells. Apoptotic cells were characterized by a bright blue nucleus and condensed and fragmented chromatin. Data are least square means (LSM)  $\pm$  SEM. Bars with different letters above them have a significant effect produced by the fish oil supplementation,  $P \leq 0.05$ . For other abbreviations see Figure 2.

when measured by caspase-3 activity. Caspase-3 causes the proteolysis of several substrates (39) and thereby brings about the characteristic morphological changes seen in apoptosis, such as the alteration of the cellular membranes and nuclei (40). Thus, the activation of caspase-3 occurs before the translocation of PS, chromatin condensation, or nuclear fragmentation. That the EPA/DHA-rich LDL oxidized for a shorter period of time (6 h) did not cause significant differences in the changes of the translocation of PS suggests that the changes in translocation of PS induced by the presence of these FA may require the activation of caspase-3 and occur after the activation of caspase-3 (41). It does not eliminate the possibility that other pathways are also associated with the translocation of PS and are triggered by oxLDL containing EPA/DHA. The release of cytochrome *c* from mitochondria (21), the activation of caspase-8 (22) and caspase-3 (13,15,21), and an increase in cellular calcium concentrations (23) all have been implicated in oxLDL-induced cell apoptosis. Whether they work together with caspase-3 or independently is not known.

Although the extent of apoptosis was higher in the cells treated with LDL oxidized for 10 h than LDL oxidized for 6 h, the concentration of CEOOH was higher in the LDL oxidized for 6 h than that in LDL oxidized for 10 h. This divergence suggests that CEOOH were not the causative agents. In this study, the concentration of conjugated dienes reached its maximum value after approximately 5 h of oxidation. It is well-established (35) that by the time the concentration of conjugated dienes plateaus, secondary oxidation products have begun to form. However, since secondary oxidation products were not measured in this study, it cannot be concluded that they were the causative factor.

The suggestion that the CEOOH generated by oxLDL were not responsible for mediating cell apoptosis is indirectly supported by Lizard *et al.* (19) and Harada-Shiba *et al.* (13). Both of these groups of investigators showed that oxysterols induced apoptosis in smooth muscle and endothelial cells. Liu *et al.* (18) also showed that a different form of secondary products, i.e., 4-hydroxynonenal, induced apoptosis in smooth muscle cells. However, Siow *et al.* (14) reported more apoptotic events in smooth muscle cells at the point of greatest lipid hydroperoxide production compared with secondary lipid oxidation products, i.e., aldehydes and ketones. The divergence among the above findings may reflect differences in the degree of LDL oxidation and/or the fact that a thorough evaluation of secondary oxidation products was not done.

A strength of this study is that the concentration of lipid hydroperoxides, CEOOH, was measured directly *via* HPLC with an isoluminol-dependent chemiluminescence detection method. This is among the most sensitive methods for detecting lipid hydroperoxides directly, rather than their presence being inferred, as is done with other measures. It clearly showed CEOOH was not the major compound responsible for apoptosis.

In conclusion, we have demonstrated that enrichment of oxLDL with EPA/DHA, obtained after supplementing a

human with FO, protected U937 cells against oxLDL-induced apoptosis and was not related to the concentration of CEOOH. However, the oxLDL used in these studies may not simulate oxLDL *in vivo*. Thus, the relevance of the data collected in this study to explain the bioactivity of oxLDL *in vivo* is unknown. Although copper is frequently used to mediate LDL oxidation, it may not be a physiologically relevant initiator for LDL oxidation. LDL oxidized *ex vivo* with copper may provide insight into the impact on the oxidation of LDL and vascular walls *in vivo* that occurs when individuals consume diets rich in EPA and DHA. This study suggests that an increased concentration of EPA/DHA in LDL may influence its oxidative susceptibility and subsequent pathology and that the major compounds responsible for apoptosis are not CEOOH.

## ACKNOWLEDGMENTS

This study was supported in part by the North Carolina Agriculture Experimental Station and the Linus Pauling Institute (Corvallis, OR). We would like to thank Dr. George Loo in the Department of Nutrition and Foodservice Systems at the University of North Carolina at Greensboro and Dr. Mark L. Failla in the Department of Human Nutrition and Foodservice Management at the Ohio State University for their invaluable advice.

# Eicosapentaenoic Acid Promotes Apoptosis in Ramos Cells *via* Activation of Caspase-3 and -9

Hilde Heimli<sup>a</sup>, Camilla Giske<sup>a</sup>, Soheil Naderi<sup>b</sup>, Christian A. Drevon<sup>a,\*</sup>, and Kristin Hollung<sup>a</sup>

<sup>a</sup>Institute for Nutrition Research and <sup>b</sup>Institute for Medical Biochemistry, University of Oslo, Norway

**ABSTRACT:** Eicosapentaenoic acid (EPA; 20:5n-3) may reduce the cell number in cultured leukemia/lymphoma cells owing to reduced cell proliferation, induction of cell death, or a combination of these processes. EPA has been shown to promote apoptosis in Ramos cells, and our present study was focused on a possible cell cycle arrest and the pathways by which the apoptotic process is induced. Apoptosis may proceed along the intrinsic (mitochondrial) or the extrinsic (death receptor) pathway, which are mediated *via* different caspases. Caspases are a class of homologous cysteine proteases recognized as pivotal mediators of apoptosis. We investigated whether EPA affects progression of the cell cycle or promotes apoptosis directly. By incorporation of [<sup>3</sup>H]thymidine and [<sup>3</sup>H]valine, we showed that DNA, as well as protein synthesis, was reduced after incubation of Ramos cells with EPA for 6 h. We monitored cell cycle distribution by 5-bromo-2'-deoxyuridine staining and observed no cell cycle arrest in the EPA-incubated cells. Incubation of cells with EPA caused PS-flipping, as demonstrated by annexin V-binding (flow cytometry), and cleavage of poly(ADP-ribose) polymerase measured by Western blot analysis. Furthermore, we observed increased activity of caspase-3 and -9, but not of caspase-8. Whereas inhibitors of caspase-3 and -9 reduced EPA-induced apoptosis, inhibition of caspase-8 did not. This suggests that EPA may promote apoptosis *via* the intrinsic pathway in Ramos cells. Thus, the reduction in cell number can be explained by a direct apoptotic effect of EPA rather than *via* cell cycle arrest.

Paper no. L9077 in *Lipids* 37, 797–802 (August 2002).

Cancer is a major cause of morbidity and mortality in developed societies. Observations in several cancer cell lines, animal models, and epidemiological studies suggest that n-3 PUFA may decrease cell proliferation and viability of cancer cells (1–6). We have previously reported that EPA induces apoptosis in Ramos cells and necrosis in Raji cells (7). The necrotic death mode is associated with oxidative stress as evaluated by an enhanced level of superoxide anion and by the protective effect of different antioxidants, whereas antioxidants had no protective effect on apoptotic cell death. We have also observed that n-3 as well as n-6 PUFA cause reduced

cell numbers after 48–72 h incubation in several leukemia/lymphoma cell lines (3,7). The reason for diminished cell numbers might be due to reduced cell proliferation, induction of cell death, or a combination of these processes. Albino and coworkers (1) have shown that PUFA-induced reduction in cell number corresponds with cell cycle arrest in malignant melanoma cell lines.

Apoptosis was first described by Kerr and coworkers in 1972 (8) and is characterized by cell shrinkage, membrane blebbing, chromatin condensation, and fragmentation of DNA. Repression of apoptosis is one of the main underlying problems in the development of cancer, and disruption of the apoptotic program can promote tumor initiation, progression, and resistance to treatment (9). The two major apoptotic pathways in mammalian cells use different initiator caspases in response to stimuli. Members of the death receptor superfamily, such as CD95R and tumor necrosis factor receptor, trigger the extrinsic pathway (10–12). Binding of ligand to the death receptors then induces formation of the death-inducing signaling complex, which recruits procaspase-8, leading to activation of initiator caspase-8. The other major apoptotic pathway is the intrinsic pathway (13,14), which is activated in response to other extracellular signals and intracellular insults such as DNA damage. Pro- and anti-apoptotic Bcl-2-like proteins may be located in the mitochondrial membrane, where they compete to regulate exit of cytochrome c (15,16). Excess of pro-apoptotic molecules causes release of cytochrome c, which is necessary for activation of caspase-9. The extrinsic and intrinsic pathways converge by activation of caspase-3. Downstream of caspase-3, the apoptotic pathway branches into a multitude of subpathways, which *in vivo* results in the ordered dismantling and removal of the cell (17). One of the first proteins identified as being cleaved by caspase-3 during apoptosis was poly(ADP-ribose) polymerase (PARP) (18). PARP is a nuclear enzyme that binds to DNA ends and catalyzes adenosine 5'-diphosphate (ADP)-ribosylation of nuclear proteins to facilitate DNA repair. PARP is cleaved at a single site by caspase-3, causing formation of a small fragment containing the DNA-binding domain and an 89 kDa catalytic domain (19). The small fragment retains its DNA-binding capacity, and by competing with full-length PARP for binding it prevents the repair enzymes from accessing damaged DNA (20).

In the present study, we observed apoptotic events in the lymphoma cell line Ramos as early as 4 h after addition of

Abbreviations: AnV, annexin V; BrdU, 5-bromo-2'-deoxyuridine; FACS, fluorescence-activated cell sorter; FCS, fetal calf serum; FITC, fluorescein isothiocyanate; HO342, Hoechst 33342; HRP, horseradish peroxidase; PARP, poly(ADP-ribose) polymerase; PI, propidium iodide.

EPA. This is shown by activation of caspase-9 and caspase-3, followed by cleavage of PARP. However, no cell cycle arrest was detected. Our study provides new insight into the primary mechanisms by which a specific EFA promotes apoptosis.

## MATERIALS AND METHODS

**Materials.** EPA, FA-free BSA, propidium iodide (PI), Hoechst 33342 (HO342), 5-bromo-2'-deoxyuridine (BrdU), cytochrome c, L-glutamine, streptomycin/penicillin, and staurosporine were purchased from Sigma Chemical Co. (St. Louis, MO). PBS, RPMI-1640, and fetal calf serum (FCS) were from BioWhittaker (Walkersville, MD). Fujichrome Provia 400 professional color reversal film was supplied by Fuji (Tokyo, Japan). The In Situ Cell Death Detection Kit, Fluorescein, was purchased from Boehringer Mannheim (Mannheim, Germany). Bicinchoninic acid Protein Assay Reagent was bought from Pierce (Rockford, IL). Fluorescein isothiocyanate (FITC)-labeled anti-BrdU and annexin V (AnV) were from BD PharMingen (San Diego, CA). Cleaved PARP (Asp214) antibody (Human Specific) and anti-rabbit IgG secondary antibody [horseradish peroxidase (HRP)-conjugated] for Western blot analysis were obtained from Cell Signaling (Beverly, MA). ECL Plus Western blotting detection reagents were bought from Amersham Biosciences (Piscataway, NJ). Caspase-9 inhibitor (Z-LEHD-FMK), caspase-3 inhibitor (Z-DEVD-FMK), and caspase-8 inhibitor (Z-IETD-FMK) were purchased from R & D Systems Inc. (Minneapolis, MN). Polyacrylamide gels were bought from Bio-Rad Laboratories (Hercules, CA). Nitrocellulose membranes were purchased from Schleicher & Schuell (Dassel, Germany). Other chemicals were of analytical grade from commercial suppliers.

**Cell cultures.** Ramos and Jurkat cells were purchased from BioWhittaker. The cell lines were cultured in RPMI medium supplemented with 10% heat-inactivated FCS, L-glutamine (2 mM), and streptomycin/penicillin (0.1 mg/mL). Cells were incubated with FA complexed to FA-free BSA at a molar ratio of 2.5:1, whereas control cells were incubated with FA-free BSA. FA-BSA complexes were added to cells immediately prior to seeding the cells in 96-well plates. Cells were routinely kept in logarithmic growth at  $0.3\text{--}1.2 \times 10^6$  cells/mL. For experiments, cells were seeded at a density of  $0.3 \times 10^6$  cells/mL.

**Incorporation of [ $^3\text{H}$ ]thymidine and [ $^3\text{H}$ ]valine.** For measurement of DNA and protein synthesis, 200  $\mu\text{L}$  of Ramos cell suspension ( $0.6 \times 10^6$  cells) was incubated in the absence or presence of 30  $\mu\text{M}$  EPA in 96-well microtiter plates from Costar (Cambridge, MA). For the last 60 min of incubation, 0.5  $\mu\text{Ci}$  [ $^3\text{H}$ ]thymidine or [ $^3\text{H}$ ]valine was added to each well. Cells were harvested and ice-cold ethanol was added to the [ $^3\text{H}$ ]thymidine-incubated cells, whereas 10% trichloroacetic acid was added to the [ $^3\text{H}$ ]valine-incubated cells. The precipitates were resuspended in 200  $\mu\text{L}$  0.2 M NaOH or 70 mM SDS with 10% Triton X-100. Cell lysates (100  $\mu\text{L}$ ) were then counted in a scintillation counter.

**DNA staining with PI and HO342.** For microscopic analyses of cell viability, 1 mL of the cell cultures was first incubated with 10  $\mu\text{L}$  of PI (0.5 mg/mL) in the dark for 20 min. Thereafter, 10  $\mu\text{L}$  of HO342 (1 mg/mL) was added to the same cultures and incubated for another 20 min in the dark. After staining, the cell pellets were resuspended in 10  $\mu\text{L}$  of FCS. Drops of the cell suspensions were placed on a microscope slide and air-dried before at least 200 cells were counted in a Leitz Ortholux II fluorescence microscope (Leica, Wetzlar, Germany). The cells were photographed with an MPS 48/52 camera (Leica Mikroskopie und Systeme, Wetzlar, Germany). The film was exposed as 800 ISO but developed as 400 ISO.

**Cell cycle distribution.** For analysis of cell cycle distribution after incubation with EPA, Ramos cells were incubated with 10  $\mu\text{M}$  of BrdU for the last 60 min. Cells ( $3 \times 10^6$ ) were fixed in 70% ethanol, stored at  $-20^\circ\text{C}$ , and then digested in a suspension of 0.2% pepsin dissolved in 2 M HCl. After 30 min of incubation in the dark at room temperature, the HCl was neutralized by 0.1 M tetraborate (pH 8.5). The pellets were then washed in 10 mM HEPES buffer containing 4% FCS and 0.5% Tween-20. After incubation with FITC-anti-BrdU for 30 min, the pellets were resuspended in PBS to which were added 20  $\mu\text{g}/\text{mL}$  of PI and 40  $\mu\text{g}/\text{mL}$  of RNase A. The samples were filtered through a 30- $\mu\text{m}$  nylon mesh, and 10,000 cells were analyzed by flow cytometry (Becton Dickinson FACScan; Becton Dickinson, Franklin Lakes, NJ) to assess cell cycle distribution patterns (G0/G1, S, and G2/M phases).

**PS translocation.** AnV-FITC binding and PI staining were performed according to the recommended protocol, and the cells were analyzed by flow cytometry (Becton Dickinson FACScan). Briefly, aliquots of cells were washed in PBS, resuspended in binding buffer supplied by the manufacturer, and mixed with AnV-FITC and PI. After 5 min of incubation in the dark at room temperature, 10,000 cells at each time point were analyzed by flow cytometry. The percentage of AnV-positive cells was calculated based on the fraction of PI-negative cells. Each data point represents fluorescence analysis of  $10^4$  cells from three independent experiments.

**Immunoblot analysis of PARP degradation.** Cell lysates were prepared in a buffer containing 20 mM HEPES, 250 mM NaCl, 2 mM EDTA, 0.1% Nonidet P-40, 2  $\mu\text{g}/\text{mL}$  leupeptin, 2  $\mu\text{g}/\text{mL}$  aprotinin, 0.5  $\mu\text{g}/\text{mL}$  benzamidin, 1 mM DTT, and 1 mM PMSF. Cellular proteins (40  $\mu\text{g}/\text{mL}$ ) were separated on a 7.5% SDS/polyacrylamide gel and electrotransferred onto a nitrocellulose membrane. The membrane was probed with cleaved-PARP (Asp214) antibody, which detects only the large fragment of human PARP (89 kDa) produced by caspase cleavage, and then with anti-mouse antibody conjugated to HRP. Protein bands were detected by chemiluminescence (ECL-plus). The positive control was prepared from a Jurkat cell lysate, which was incubated with 4 mM  $\text{MgCl}_2$ , 10 mM KCl, 1 mM EGTA, 2 mM dATP, and 250  $\mu\text{g}/\text{mL}$  cytochrome c for 60 min at  $30^\circ\text{C}$ .

**Caspase activity assays.** Activity of the caspase-3, -8, and -9 cysteine proteases was determined by colorimetric activation

assays according to the manufacturer's protocol (R & D Systems Inc.). Ability of the cell lysate to cleave the reporter molecule was quantified spectrophotometrically at a wavelength of 405 nm using a microplate reader (Bio-Rad). The time-dependent change in absorbance at 405 nm was converted to caspase activity (pmol/h/ $\mu$ g of total protein) according to the manufacturer's protocol (Promega Corp., Madison, WI). Pure *p*-nitroaniline was used for a standard curve.

**Caspase-3, -8, and -9 inhibitors.** For inhibition of caspase-3, -8, and -9 activities, Ramos cells were incubated with 50  $\mu$ M Z-DEVD-FMK, 100  $\mu$ M Z-IETD-FMK, or 4  $\mu$ M Z-LEHD-FMK, respectively (21,22), in combination with EPA. After 24 h the cells were stained with PI and HO342 and harvested for microscopic analysis.

**Statistics.** Results are presented as means  $\pm$  SD. Unless otherwise specified, a Student's *t*-test analysis was used to determine the significance level of differences among sample groups, with a significance criterion of  $P \leq 0.05$ . All reported *P*-values are two sided.

## RESULTS

**EPA induces reduction in synthesis of DNA and proteins, but no cell cycle arrest.** Previously, we have reported that EPA reduced the number of Ramos cells after 48 h incubation (7). Before that time point, we could not detect any effect of EPA on cell numbers. To clarify the events preceding the reduction in cell number, we measured the synthesis of DNA and proteins. Ramos cells were incubated with 30  $\mu$ M EPA for 3 and 6 h and assessed for [ $^3$ H]thymidine incorporation into DNA or for [ $^3$ H]valine incorporation into proteins. Figure 1 shows that [ $^3$ H]thymidine- and [ $^3$ H]valine-incorporation were reduced by  $33 \pm 13$  and  $39 \pm 16\%$ , respectively, after 6 h incubation, whereas there were no significant changes after 3 h. Apoptosis was not observed after 3 or 6 h by staining with PI and HO342 (data not shown).

We have also previously performed dose-response experiments and found that up to a 24-h incubation period, there were marginal differences between 30 and 60  $\mu$ M EPA regarding cell numbers (7). Therefore, in all the following experiments, 60  $\mu$ M EPA was used. To examine whether the reduced incorporation of [ $^3$ H]thymidine and [ $^3$ H]valine was caused by cell cycle arrest, Ramos cells were incubated for 0, 3, 6, 9, and 12 h with EPA, stained with FITC-antiBrdU, and analyzed by fluorescence-activated cell sorter (FACS). At all time points, no significant effect on cell cycle distribution was observed (Table 1).

**EPA induces apoptosis via the intrinsic apoptotic pathway.** During the apoptotic process, PS is translocated from the inner to the outer leaflet of the plasma membrane. FITC-labeled AnV is a membrane-impermeable protein that binds to cells only if PS is present on the outer leaflet of the plasma membrane. To examine whether the reduced incorporation of [ $^3$ H]thymidine and [ $^3$ H]valine at 6 h could be explained by induction of apoptosis rather than by cell cycle arrest, we assayed Ramos cells incubated with EPA for AnV binding.

**FIG. 1.** DNA and protein synthesis. Incorporation of [ $^3$ H]thymidine and [ $^3$ H]valine was measured in Ramos cells incubated with 30  $\mu$ M EPA for 3 or 6 h. Data represent means  $\pm$  SD of incorporated [ $^3$ H]thymidine or [ $^3$ H]valine as the percentage of control in three separate experiments performed in triplicate. \* $P \leq 0.05$ .

FITC-AnV binding was significantly increased at 14 h and increased during further EPA incubation, with 25% AnV-positive cells appearing after 24 h (Fig. 2).

To further investigate the time point for onset of apoptosis, Ramos cells were incubated with EPA up to 24 h. We detected cleaved PARP in Ramos cells 8–24 h after adding EPA (Fig. 3). Thus, our observations indicated that PS-flipping occurred concomitantly with cleavage of PARP in Ramos cells incubated with EPA.

Because PARP is one of the downstream targets of caspase-3, we assayed EPA-supplemented Ramos cells for caspase-3 activity. Caspase-3 activity was detected 4 h after EPA supplementation and reached a maximum after 10 h (Fig. 4A). Caspases are synthesized as inactive enzymes, and once activated by proteolytic cleavage, the apoptotic processes are switched on. Caspase activity was not detected in control cells (data not shown).

The activities of caspase-8 and -9 were assayed to elucidate whether EPA activates the extrinsic or the intrinsic pathway in Ramos cells. The cells were incubated with EPA for up to 24 h. Caspase-9 activity was first observed after 4 h incubation, and the activity was markedly above background for at least 12 h (Fig. 4B). Up to 24 h incubation, no significant activity of caspase-8 was observed (Fig. 4C). Jurkat cells incubated with 1  $\mu$ M staurosporine for 6 h were used as positive controls for caspase-8 activity (23). Our data indicate that EPA induces apoptosis *via* the intrinsic pathway rather than the extrinsic pathway in Ramos cells. To further challenge

**TABLE 1**  
Cell Cycle Distribution in Ramos Cells After 0–12 h of EPA Incubation<sup>a</sup>

	0 h	3 h	6 h	9 h	12 h

**FIG. 2.** EPA-induced PS translocation. Flipping of PS in Ramos cells incubated with 60  $\mu$ M EPA was measured by flow cytometry. Data represent the percentage of AnV-binding cells, given as means  $\pm$  SD from three separate experiments.

these findings, Ramos cells were incubated with specific inhibitors for caspase-9, caspase-3, or caspase-8 and exposed to EPA for 24 h. After 24 h incubation, EPA-induced apoptosis was microscopically detectable after staining with HO342 and PI (data not shown). Both caspase-9 and caspase-3 inhibitors significantly reduced EPA-induced apoptosis, whereas no significant reduction was observed by inhibition of caspase-8 (Fig. 5A). None of the applied inhibitors induced apoptosis *per se* (data not shown). The set of photographs shown in Figure 5B provides a qualitative impression of cell membrane integrity and nuclear structure. Staining with PI (red) indicates leaky plasma membranes since this dye cannot cross intact cell membranes. HO342, however, crosses intact as well as distorted plasma membranes and stains the nuclei in all cells (blue). When HO342 associates with condensed chromatin found in apoptotic cells, the blue color becomes more intense.

## DISCUSSION

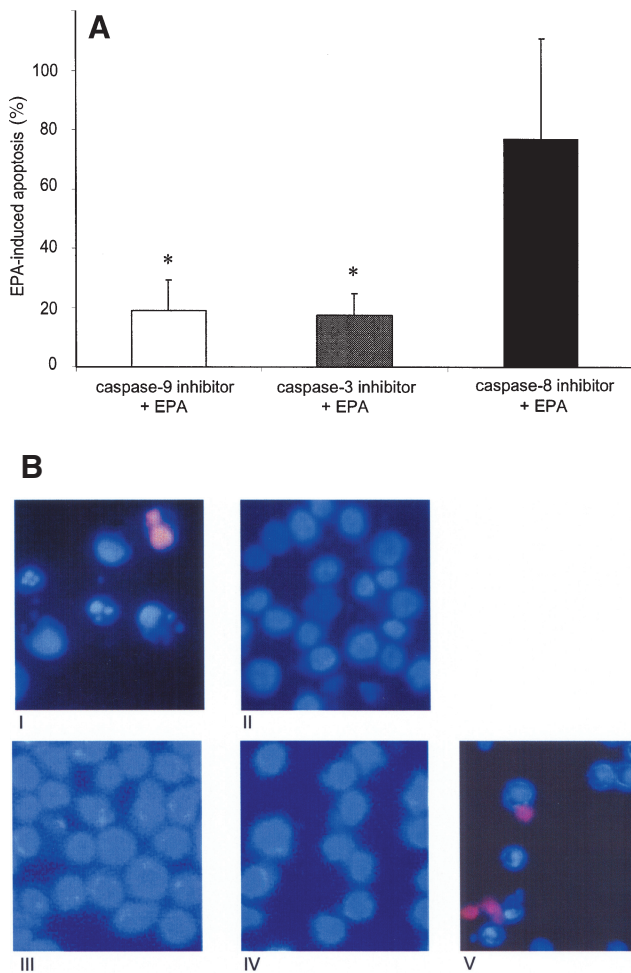

In the present study we have shown that EPA reduced cell numbers by induction of apoptosis *via* activation of caspases, rather than by causing cell cycle arrest in Ramos cells. Cas-

**FIG. 3.** Cleavage of poly(ADP-ribose) polymerase (PARP). Cells were incubated with 60  $\mu$ M of EPA for the indicated time points, lysed, and 100  $\mu$ g protein was loaded in each lane. Cleaved PARP (89 kDa fragment) was detected with anti-PARP polyclonal antibody. The lanes labeled with - and + refer to untreated and cytochrome c-treated (positive control) Jurkat cell lysate, respectively. Two individual parallels are shown for each time point. One of three experiments is presented.

**FIG. 4.** Caspase-3, -9, and -8 activity. Cells were incubated with 60  $\mu$ M EPA, and caspase activity was measured by a colorimetric assay as cleavage of the caspase-3 specific peptide DEVD-pNA (A), of the caspase-9 specific peptide LEHD-pNA (B), or of the caspase-8 specific peptide IETD-pNA (C). The lane labeled with + refers to staurosporine-treated Jurkat cells (1  $\mu$ M, 6 h), whereas the lane labeled - refers to untreated Jurkat cells. Data represent three separate experiments performed in duplicate (means  $\pm$  SD). A Mann-Whitney analysis was used to determine significance level of differences related to the zero time point, \* $P \leq 0.05$ .

**FIG. 5.** Effect of specific caspase inhibitors. Ramos cells were incubated for 24 h with 60  $\mu$ M of EPA and either 4  $\mu$ M of the caspase-9 inhibitor Z-LEHD-FMK, 50  $\mu$ M of the caspase-3 inhibitor Z-DEVD-FMK or 100  $\mu$ M of the caspase-8 inhibitor Z-IETD-FMK. Propidium iodide and Hoechst 33342 (HO342) associate with DNA and emit red and blue light, respectively, when exposed to UV light. Data are presented as the percentage of apoptotic cells induced by EPA (means  $\pm$  SD) and represent three separate experiments performed in duplicate  $*P \leq 0.05$  (A). One set of photographs is shown to provide qualitative information about cell viability after 24 h incubation with EPA (I), BSA control (II), or EPA in addition to caspase-9 inhibitor (III), caspase-3 inhibitor (IV), or caspase-8 inhibitor (V) (B).

pase-3 was significantly activated as early as 4 h after addition of EPA, which may explain the reduced synthesis of DNA and protein. We previously reported that 12 h incubation of 60  $\mu$ M EPA induced DNA fragmentation in Ramos cells ( $16 \pm 10\%$ , mean  $\pm$  SD), detected by the terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL) technique (3). To clarify early events during the induction of apoptosis, we assessed the effect of EPA on PS-flipping, which is suggested to be an early signal in the apoptotic process (24–26). We did not detect EPA-induced translocation of PS earlier than the previously observed DNA fragmentation monitored by TUNEL (3). This observation is in accordance with recent data from Span and coworkers (25),

showing that PS translocation is followed rapidly (within 1 h) by oligonucleosomal DNA fragmentation.

In addition to PS-flipping and DNA fragmentation, activation of caspases is of crucial importance in the apoptotic process. Usually, an active caspase molecule may activate an inactive procaspase by proteolytic cleavage. The downstream effector caspase-3 may be activated either by caspase-9 or caspase-8, representing the intrinsic and the extrinsic apoptotic pathways, respectively. The active form of caspase-9 is generated by association with a protein cofactor (Apaf), as well as cytochrome c (27), which may be released from the mitochondrial membrane by a Bcl-2-regulated process (15,28–30). To investigate by which pathway EPA initiates apoptosis in Ramos cells, we measured the activity of caspase-3 and caspase-9 and found that they were both activated, whereas caspase-8 activity was not significantly activated at any time point. We detected caspase-3 activated as early as 4 h after addition of EPA, and caspase-9 activity was also observed at 4 h, but no significant activation of caspase-9 was detected until 8 h. During the apoptotic process, caspase-3 activity increased relatively more than caspase-9 activity. Despite the statistically insignificant increase of caspase-9 activity at 4 h, we suggest that the activity is sufficient to transduce the apoptotic signal to the effector caspase-3. This would be in agreement with other observations reporting low activity of initiator caspases as compared to the activity of effector caspases (31–33). To challenge the involvement of the intrinsic, rather than the extrinsic, apoptotic pathway, we incubated Ramos cells with specific inhibitors of caspase-3, -8, and -9 in combination with EPA. The inhibitors of caspase-3 and -9 reduced the number of apoptotic cells toward the control level, whereas inhibition of caspase-8 did not. This is in agreement with increased caspase-3 and caspase-9 activities during EPA-induced apoptosis. Thus, our data indicate that EPA-induced apoptosis is mediated *via* the intrinsic apoptotic pathway rather than *via* the extrinsic pathway in Ramos cells. Based on our data we still cannot explain how EPA activates the first, most upstream caspases. Previous data from our laboratory have indicated that eicosanoids and reactive oxygen species are not involved in the EPA-induced reduction of Ramos cell proliferation (3,7,34). Further characterization of the initial mechanisms involved in EPA-induced apoptosis is important because PUFA might play a role in the prevention and treatment of certain types of cancer.

## ACKNOWLEDGMENTS

We thank Anne Randi Alvestad for excellent technical assistance, Hege Henriksen and Siv Kjølrsrud Bøhn for help with statistics and figures. This work was supported by grants from the Norwegian Cancer Society, Throne Holst Fond for Ernæringsforskning, Freia Medicinske Fond, and Eckbos Legat.

# Positional Distribution of FA in TAG of Enzymatically Modified Borage and Evening Primrose Oils

S.P.J. Namal Senanayake and Fereidoon Shahidi\*

Department of Biochemistry, Memorial University of Newfoundland, St. John's, Newfoundland, Canada A1B 3X9

**ABSTRACT:** Stereospecific analysis was carried out to establish positional distribution of FA in the TAG of DHA, EPA, and (EPA + DHA)-enriched oils. In this study, TAG of enzymatically modified oils were purified using a silicic acid column. The TAG were then subjected to positional distribution analysis using a modified procedure involving reductive cleavage with Grignard reagent. The results showed that in DHA-enriched borage oil (BO), DHA was randomly distributed over the three positions of TAG, whereas  $\gamma$ -linolenic acid (GLA) was mainly esterified at the *sn*-2 and -3 positions. In DHA-enriched evening primrose oil (EPO), however, DHA and GLA were concentrated in the *sn*-2 position. In EPA-enriched BO, EPA was randomly distributed over the three positions of TAG, similar to that observed for DHA. In EPA-enriched EPO, however, this FA was mainly located at the primary positions (*sn*-1 and *sn*-3) of TAG. In both oils, GLA was preferentially esterified at the *sn*-2 position. In (EPA + DHA)-enriched BO, EPA and DHA were mainly esterified at the *sn*-1 and -3 positions of TAG, whereas GLA was mainly located at the *sn*-2 position. In (EPA + DHA)-enriched EPO, GLA was mainly located at the *sn*-2 and -3 positions; EPA was preferentially esterified at the *sn*-1 and -3 positions, and DHA was found mainly at the *sn*-3 position.

Paper no. L8998 in *Lipids* 37, 803–810 (August 2002).

Borage oil (BO) and evening primrose oil (EPO) are major sources of  $\gamma$ -linolenic acid (18:3n-6; GLA), an essential n-6 polyunsaturated fatty acid (PUFA). GLA is an important intermediate in the bioconversion of linoleic acid (18:2n-6) to arachidonic acid (AA; 20:4n-6). GLA-rich oils have been used in the treatment of certain skin-related diseases, hypertension, premenstrual syndrome, diabetes, and cancer (1). Therefore, many research groups have actively pursued investigations on concentrating GLA from borage, evening primrose, blackcurrant, and fungal oils (2-5) for pharmaceutical and dietetic applications.

The n-3 PUFA, such as EPA (20:5n-3) and DHA (22:6n-3), have also gained recognition for their vital role in human health and nutrition. EPA has several health benefits related to cardiovascular disease, arthritis, thrombosis, psoriasis, inflammation, and renal and auto-immune disorders (6). DHA is important in the development of the central nervous system and visual acuity of infants (7).

The beneficial effects of both GLA (n-6) and n-3 FA are associated with the production of eicosanoids. Incorporation of n-3 PUFA from marine sources into BO and EPO may provide specialty oils for specific nutritional and clinical appli-

cations. This may be possible *via* lipase-catalyzed reactions. Lipase-assisted reactions, such as transesterification of plant oils with n-3 PUFA, have been successfully used for preparation of structured lipids (SL) (8–10). SL are TAG that contain mixtures of short-, medium- and long-chain FA in the same glycerol molecule and are believed to be effective in delivering desired FA to target specific diseases and certain pathological conditions.

The structure of the TAG molecule exerts a major impact on its nutritional and biochemical properties. Intestinal absorption of FA is reportedly dependent on their arrangement in the TAG molecules. Investigation of the absorption of FA in a canine model suggested that the positional distribution of FA within the TAG molecules might affect the metabolic fate of FA (11). During digestion, lipases hydrolyze TAG into FFA, predominantly from the *sn*-1 and -3 positions and 2-MAG (12), which will be absorbed into the intestinal mucosal cells of the small intestine. Although most dietary lipids are in the TAG form, relatively little is known about the importance of stereospecific composition of TAG on the biological activity of dietary FA (13). Differences in the positional distribution of FA have also been shown to have specific effects on the profile, structure, and composition of the lipoproteins (13).

Stereospecific analysis determines how the FA of TAG are distributed over the three different positions of the glycerol molecule (14). Differences in the distributions of FA among different positions in TAG from natural fats and oils were first demonstrated systematically by enzymatic hydrolysis procedures, especially pancreatic lipase hydrolysis for the analysis of the FA of position *sn*-2, before complex stereospecific hydrolysis procedures were developed that permitted determination of complete positional distributions of FA to be determined. Because of this historical analytical procedure development, there has been a tendency to assume that the composition of FA esterified to the sole secondary hydroxyl group must have greater importance than those of the two primary positions. It is certainly true that the composition of the *sn*-2 position is of great importance when TAG are consumed and digested by animals, since *sn*-2-MAG so produced can be absorbed by the intestine and utilized as such (15). On the other hand, the results of stereospecific analyses have shown that the compositions of all three positions in certain fats can be distinctive and can highlight important aspects of the biosynthetic processes.

The positional distribution of FA in TAG of both BO and EPO has previously been determined (16,17). In the present study, stereospecific analyses of TAG have been carried out for DHA-, EPA-, and (EPA + DHA)-enriched BO and EPO.

Abbreviations: AA, arachidonic acid, 20:4n-6; BO, borage oil; EPO, evening primrose oil; GLA,  $\gamma$ -linolenic acid, 18:3n-6; LA, linoleic acid; SL, structured lipids.

## EXPERIMENTAL PROCEDURES

**Materials.** BO was obtained from Bioriginal Food and Science Corporation (Saskatoon, Saskatchewan, Canada), and evening primrose oil was provided by Efamol, Inc. (Kentville, Nova Scotia, Canada). Algal oil containing 47.4% DHA was obtained from Martek Biosciences Corporation (Columbia, MD). EPA concentrate (93.1% EPA) was provided by Dr. T. Ohshima (Tokyo, Japan). Immobilized lipase from *Candida antarctica* (Novozym-435) was provided by Novo Nordisk Biochem North America, Inc. (Franklinton, NC). The nonspecific lipase from *Pseudomonas* sp. (PS-30) was supplied by Amano Enzymes U.S.A. Co., Ltd, (Troy, VA).

**Preparation of DHA concentrate from algal oil by urea-FA complexation.** DHA concentrate (up to 97.1%) was obtained from the hydrolyzed algal oil using the urea-FA complexation method as described by Senanayake and Shahidi (18).

**Determination of enzyme activity.** Lipase activity was measured as described by Senanayake and Shahidi (8). One unit (U) of lipase activity was defined as nanomoles of FA (oleic acid equivalents) produced per minute per gram of enzyme. Lipase activities of Novozym-435 and lipase PS-30 were 554 and 11,936 U, respectively.

**Enzymatic synthesis of DHA-enriched oils.** BO (300 mg) or EPO (297 mg) was mixed with DHA concentrate (120 mg) at a mole ratio of 1:1 in a screw-capped test tube, and then immobilized Novozym-435 lipase (250 enzyme activity units) and water (2% by weight of substrates plus enzyme) were added in hexane (3 mL). The mixture was stirred in an orbital shaker at 250 rpm and 45°C. Individual sample vials were removed and analyzed after 24 h. All reactions were performed in triplicate (9).

**Enzymatic synthesis of EPA-enriched oils.** Modified oils containing EPA were produced by acidolysis reactions using nonimmobilized lipase PS-30 from *Pseudomonas* sp. In this study, BO (300 mg) or EPO (297 mg) was mixed with EPA (115 mg) in a screw-capped test tube, and then lipase (250 enzyme activity units) and water (2% by weight of substrates plus enzyme) were added in hexane (3 mL). The mixture was stirred in an orbital shaker at 250 rpm and 45°C. Individual sample vials were removed and analyzed after 24 h. All reactions were performed in triplicate.

**Enzymatic synthesis of (EPA + DHA)-enriched oils.** BO (300 mg) or EPO (297 mg) was mixed with EPA (53.5 mg) and DHA (58.2 mg) at a mole ratio of 1:0.5:0.5, in a screw-capped test tube, and then lipase PS-30 preparation (250 enzyme activity units) and water (2% by weight of substrates plus enzyme) were added in hexane (3 mL). The mixture was stirred in an orbital shaker at 250 rpm and 45°C. Individual sample vials were removed and analyzed after 24 h. All reactions were performed in triplicate (8).

**Analysis of products.** The enzymes were removed by passing the reaction mixture through a bed of anhydrous sodium sulfate. Samples were placed in 250-mL conical flasks, to which 20 mL of a mixture of acetone/ethanol (1:1, vol/vol) were added. The reaction mixture was titrated with 0.5 N

NaOH to a phenolphthalein endpoint. The mixture was transferred to a separatory funnel and thoroughly mixed with 25 mL hexane. The lower aqueous layer was separated and discarded. The upper hexane layer containing acylglycerols was passed through a bed of anhydrous sodium sulfate. The acylglycerol fraction was subsequently recovered following hexane removal at 45°C using a rotary evaporator.

**Removal of non-TAG constituents from enzymatically modified oils.** Removal of non-TAG constituents from enzymatically modified BO and EPO was carried out using column chromatography (1.25 cm internal diameter and 10 cm height) on silicic acid (100–200 mesh size; Sigma, St. Louis, MO). The column was first washed with hexane, and then 1.25 g modified oil was introduced onto it. Hexane (50 mL) was added to the column, which was then eluted with 10% (vol/vol) diethyl ether in hexane (250 mL). The solvent was removed under vacuum at 40°C using a rotary evaporator. The recovered oil was then passed through a layer of anhydrous sodium sulfate. To prevent oxidation of purified oils, a few crystals of BHT were added to the mixture.

**Stereospecific analyses of enzymatically modified BO and EPO.** Stereospecific analysis was performed on purified modified oils according to the method described by Brockerhoff (14) and Brockerhoff *et al.* (19) with some modifications. The purified TAG (1.0 g) was dissolved in anhydrous diethyl ether (50 mL) and mixed with methyl magnesium bromide (3.5 mL, 3.0 M CH<sub>3</sub>MgBr; Sigma). The Grignard reaction was allowed to proceed with continuous stirring until a clear solution was obtained. To stop the reaction, glacial acetic acid (1.0 mL) was slowly added to the mixture followed by 10% (wt/vol) boric acid solution (10 mL; to minimize acyl migration). Stirring of the reaction mixture was continued for another 2 to 3 min. The whole mixture was then transferred to a separatory funnel and allowed to separate into two layers. The top ether layer was removed, and the lower aqueous layer was washed twice with diethyl ether. The combined ether layers were washed successively with 10 mL of water, 10 mL of 2% (wt/vol) aqueous sodium bicarbonate, and 10 mL of water, and then dried over anhydrous sodium sulfate.

**Separation of individual lipids after Grignard reaction.** Products of the Grignard reaction were dissolved in a minimum amount of chloroform and applied to several TLC plates (20 × 20 cm; silica gel, 60Å mean pore diameter, 2–25 µm mean particle size, 500 µm thickness, with dichlorofluorescein; Sigma) impregnated with 5% (wt/vol) boric acid. The plates were developed in two different solvent systems of diethyl ether/petroleum ether (boiling point 30–60°C) (8:92, vol/vol) and diethyl ether/petroleum ether (40:60, vol/vol), respectively. After drying, the bands were located by viewing under short (254 nm)- and long (356 nm)-wavelength UV lights (Spectraline, Model ENF-240C; Spectronics Co., Westbury, NY). From the separated bands of TAG ( $R_f = 0.99$ ), tertiary alcohol ( $R_f = 0.72$ ), 1,2-DAG and 2,3-DAG ( $R_f = 0.32$ ), 1,3-DAG ( $R_f = 0.41$ ), and MAG ( $R_f = 0.05$ ), 1,2- and 2,3-DAG bands were scraped off and then extracted with diethyl ether. The ether layer was evaporated under nitrogen to obtain 1,2- and 2,3-DAG. After re-

moving a small amount of sample for FA analysis, the DAG fractions were used to prepare synthetic phospholipids.

**Preparation of synthetic phospholipids from DAG fraction.** The 1,2- and 2,3-DAG were dissolved in 1.0 mL of diethyl ether and mixed with 2.5 mL pyridine/diethyl ether/phenyl dichlorophosphate (1:1:0.5, by vol). The reaction mixture was then allowed to stand at room temperature for 1 h, after which 5 mL of pyridine, 3.0 mL of diethyl ether, and a few drops of water were added while cooling in an ice bath. The content of flask was subsequently mixed with 86 mL of methanol/water/chloroform/triethylamine (30:25:30:1, by vol). After standing, the lower chloroform layer containing synthetic phospholipids (1,2-diacyl-3-phosphophenol and 2,3-diacyl-1-phosphophenol) was separated and the solvent removed at 40°C using a rotary evaporator. The recovered synthetic phospholipids were used for stereospecific hydrolysis by the phospholipase A<sub>2</sub> enzyme.

**Stereospecific hydrolysis of synthetic phospholipids by phospholipase A<sub>2</sub>.** The synthetic phospholipids (1,2-diacyl-3-phosphophenol and 2,3-diacyl-1-phosphophenol) obtained were dissolved in 3.0 mL of diethyl ether and transferred to a solution containing 15 mL of 0.1 M triethylammonium bicarbonate (pH 7.5), 100 µL of 0.1 M calcium chloride, and 2.0 mg of phospholipase A<sub>2</sub> (EC 3.1.1.4; Sigma) obtained from snake venom (*Crotalus adamantus*). The mixture was then shaken gently overnight in a Gyrotory water bath shaker (Model G76; New Brunswick Scientific Co., Inc., New Brunswick, NJ), and water in the mixture was evaporated at 40°C using a rotary evaporator. To prevent foaming during evaporation, 15 mL of isobutanol was added to the mixture.

The hydrolyzed products were dissolved in 1.0 mL of chloroform/methanol (1:1, vol/vol) containing one drop of glacial acetic acid. The dissolved hydrolytic products were

applied to silica gel TLC plates (20 × 20 cm; 60Å mean pore diameter, 2–25 µm mean particle size, 500 µm thickness, with dichlorofluorescein, Sigma) impregnated with 5% (wt/vol) boric acid. The plates were developed in diethyl ether/petroleum ether (40:60, vol/vol), dried in a fumehood, and then kept over concentrated aqueous ammonia for 10 min and subsequently redeveloped in aqueous ammonia/methanol/diethyl ether (2:15:83, by vol). After drying, the bands were located by viewing under short (254 nm)- and long (356 nm)-wavelength UV lights (Spectraline, Model ENF-240C; Spectronics Co.). The separated bands—FFA (hydrolyzed from *sn*-2 position of 1,2-diacyl-3-phosphophenol;  $R_f = 0.72$ ), unhydrolyzed 2,3-diacyl-1-phosphophenol ( $R_f = 0.49$ ), lysophosphatide ( $R_f = 0.08$ ), and small amounts of 1,2- and 2,3-DAG ( $R_f = 0.91$ )—were scraped off and extracted into chloroform/methanol (1:1, vol/vol). The L-lysophosphatide fraction permitted identification of the FA composition at the *sn*-1 position of TAG of modified oils. These results are reported in Tables 1–6. After having removed a small amount of sample for FA analysis, the unhydrolyzed 2,3-diacyl-1-phosphophenol fraction was subjected to porcine pancreatic lipase hydrolysis using the procedure described below in order to obtain 2-monoacyl-1-phosphatide and FFA (hydrolyzed from *sn*-3 position). All separated lipid fractions were analyzed for their FA composition by employing the GC procedure (18).

**Hydrolysis of enzymatically modified oils by pancreatic lipase.** Hydrolysis of purified oils as well as separated 2,3-diacyl-1-phosphophenol by pancreatic lipase was carried out according to the method described by Christie (20). Tris-hydrochloric buffer (5 mL; 1.0 M, pH 8.0), 0.5 mL of calcium chloride (2.2%, wt/vol), and 1.25 mL of sodium taurocholate (0.05%, wt/vol) were added to 25 mg of oil in a glass test tube. The whole mixture was allowed to equilibrate at 40°C

in a water bath for 1 min; subsequently, 5.0 mg of porcine pancreatic lipase (EC 3.1.1.3; Sigma) was added to it. The mixture was then placed in a Gyrotory water bath shaker (Model G76; New Brunswick Scientific Co. Inc.) at 200 rpm under nitrogen for 8 to 10 min at 40°C. Ethanol (5 mL) was added to stop the enzymatic hydrolysis followed by addition of 5.0 mL of 6.0 M HCl. The hydrolytic products were extracted three times with 50 mL of diethyl ether, and the ether layer was washed twice with distilled water and dried over anhydrous sodium sulfate. After removal of the solvent under vacuum at 30°C, the hydrolytic products were separated on

silica gel TLC plates (20 × 20 cm; 60Å mean pore diameter, 2–25 µm mean particle size, 500 µm thickness, with dichlorofluorescein; Sigma) impregnated with 5% (wt/vol) boric acid. The plates were developed using hexane/diethyl ether/acetic acid (70:30:1, by vol). After drying, the bands were located by viewing under short (254 nm)- and long (356 nm)-wavelength UV lights (Spectraline, Model ENF-240C; Spectronics Co.). The bands were scraped off and their lipids extracted into chloroform/methanol (1:1, vol/vol) or diethyl ether and subsequently used for FA analysis by the GC procedure described by Senanayake and Shahidi (18). It should

be noted that the FA profiles of 2-MAG fractions were used to give the results (FA distribution at the *sn*-2 position) in Tables 1–6. The hydrolytic products of 2,3-diacyl-1-phosphophenol provided the FA composition of the *sn*-3 position of TAG of modified oils. These results are also reported in Tables 1–6.

**Preparation of FAMES.** FA composition of the lipid fractions was determined following conversion to methyl esters. About 15 mg of each oil was weighed into a 6-mL well-cleaned Teflon-lined, screw-capped conical vial. The internal standard (250 ng/100 µL chloroform, methyl tricosanoate,

C<sub>23:0</sub>) was added to the vial, and the solvent in the oil–internal standard mixture was evaporated under a stream of nitrogen. Transmethylation reagent (2 mL; freshly prepared 6 mL of concentrated sulfuric acid made up to 100 mL with spectral grade methanol and 15 mg of hydroquinone as an antioxidant) was added to the sample vial and mixed by vortexing. The mixture was incubated overnight at 60°C and subsequently cooled (18). Distilled water (1 mL) was added to the mixture after thorough mixing, and it was extracted three times with 1.5 mL of pesticide-grade hexane. A few crystals

of hydroquinone were added to each vial prior to extraction with hexane. Hexane layers were separated, combined, and transferred to a clean tube and then washed two times with 1.5 mL of distilled water. In the first wash, the aqueous layer was removed, and in the second wash, the hexane layer was separated and evaporated under a stream of nitrogen. FAME were then dissolved in 1 mL of carbon disulfide and used for GC analysis.

**Analysis of FAME by GC.** A Hewlett-Packard 5890 Series II gas chromatograph (Hewlett-Packard, Toronto, Canada) equipped with a SUPELCOWAX 10 column (0.25 mm diameter, 30 m length, 0.25 µm film thickness; Supelco Canada Ltd., Oakville, Ontario) was used for analyzing FAME. The oven temperature was initially set at 220°C for 10.25 min and then ramped to 240°C at 30°C/min and then held there for 9 min. The injector and detector (FID) temperatures were both at 270°C. Ultra-high-purity helium was used as a carrier gas (15 mL/min). HP 3365 Series II ChemStation software (Hewlett-Packard, Toronto, Canada) was used for data handling. The relative content of FAME as mole percentages was calculated using methyl tricosanoate (C<sub>23:0</sub>) as an internal standard.

## RESULTS AND DISCUSSION

In the first step of stereospecific analyses, TAG of modified BO and EPO were hydrolyzed by porcine pancreatic lipase in order to split FA at the *sn*-1 and -3 positions, yielding 2-MAG. This reaction accurately provides the FA composition of the *sn*-2 position of the TAG. In the second step, the TAG of both oils were modified by Grignard degradation using methyl magnesium bromide (CH<sub>3</sub>MgBr). Laakso and Christie (21) and Nwosu and Boyd (22) used the Grignard reaction to obtain partially deacylated acylglycerols. The products of the Grignard degradation of TAG consist of MAG, 1,2- and 2,3-DAG, 1,3-DAG, and a tertiary alcohol. Among these, 1,2- and 2,3-DAG were isolated and used to prepare synthetic racemic phosphatides *via* the re-

action with dichlorophenyl-phosphate. This reaction produced 1,2-diacylglycero-3-phosphophenol and 2,3-diacylglycero-1-phosphophenol, which were subsequently hydrolyzed by stereospecific phospholipase A<sub>2</sub>.

Tables 1–6 show the FA compositions and positional distributions of FA in the modified TAG used in this study. The reproducibility of the stereospecific analysis was examined by triplicate analyses of modified product FA compositions. The CV was 1.5–4.2% for selected FA, such as linoleic acid (LA; 18:2n-6), GLA (18:3n-6) and DHA (22:6n-3), in the DHA-enriched oils. In EPA (20:5n-3)-enriched oils, the CV for LA, GLA, and EPA were in the range of 2.2–5.4%. The CV for the same FA (LA, GLA, EPA, and DHA) in the (EPA + DHA)-enriched oils were 3.2–11.5%.

Tables 1 and 2 show the positional distribution of FA in TAG of DHA-enriched oils examined. The results of this study showed that DHA was fairly evenly distributed over all three positions (34.6% at *sn*-1, 33.5% at *sn*-2, and 35.9% at *sn*-3) of the TAG molecules of DHA-enriched BO (Table 1). In DHA-enriched EPO, however, this FA was preferentially esterified at the *sn*-2 position (38.2%), followed by *sn*-3 (33.1%) and *sn*-1 (24.5%) positions (Table 2). In this study, DHA-enriched oils were synthesized using Novozym-435 from *C. antarctica* as the biocatalyst. The positional specificity of *C. antarctica* depends on the type of reactants employed. In some reactions, this enzyme functions as a nonspecific lipase, whereas in others it exhibits *sn*-1,3 positional specificity (24). The results showed that under assay conditions employed in this study, this enzyme acts as a nonspecific lipase. In DHA-enriched BO, the saturated FA 16:0 and 18:0 favored the *sn*-2 position (Table 1). However, in DHA-enriched EPO, these FA were concentrated in the *sn*-1 and -3 positions (Table 2).

The stereospecific distributions of FA in the native BO and EPO have previously been determined (16,17). In native BO, GLA was distributed asymmetrically and preferentially ester-

ified at the *sn*-2 (32.2–40.4%) and *sn*-3 (17.4–30.1%) positions (16,17). The *sn*-1 position of native BO contained 4% GLA (16). In native EPO, GLA was found to be concentrated in the *sn*-2 and -3 positions of TAG (16). The *sn*-2 and -3 positions of native EPO contained 10.3–10.7 and 10.2–13.5%, GLA, respectively (16,17). The *sn*-1 position of native EPO also had 3.5–4.9% GLA (16,17). LA was nearly evenly distributed in all positions of native EPO (73.3% at *sn*-1, 78.9% at *sn*-2, and 74.2% at *sn*-3), but was concentrated in the *sn*-1 (54.3%) and *sn*-2 (42.5%) positions of native BO (16). The *sn*-3 position of native BO also contained 17.6% LA (16). The results of our study showed that in DHA-enriched BO, GLA was mainly located in the *sn*-2 (18.4%) and *sn*-3 (19.2%) positions of TAG (Table 1). In DHA-enriched EPO, however, GLA was concentrated in the *sn*-2 (7.5%) position (Table 2). LA was randomly distributed over all three positions of TAG in both oils.

Lee and Akoh (25) performed pancreatic lipase hydrolysis on an SL synthesized *via* interesterification reaction between medium-chain TAG and EPA ethyl ester using *C. antarctica* lipase as the biocatalyst. Their results showed that EPA was mainly incorporated in the *sn*-2 position of the TAG. This demonstrated that *C. antarctica* lipase has a high specificity for the *sn*-2 position under experimental conditions employed in their work.

In another study, the positional distribution of FA in TAG of EPA-enriched oils was determined, and the corresponding results are shown in Tables 3 and 4. It should be noted that EPA-enriched oils were produced using lipase PS-30 from *Pseudomonas* sp. as the biocatalyst. The saturated FA 16:0 and 18:0 were concentrated at the *sn*-2 position of TAG of EPA-enriched oils (Tables 3 and 4). The EPA of EPA-enriched BO was randomly distributed in the TAG (33.4% at *sn*-1; 32.5% at *sn*-2; 30.9% at *sn*-3) (Table 3). In EPA-enriched EPO, however, this FA was mainly esterified at the primary positions (39.5% at *sn*-1 and 42.1% at *sn*-3) of TAG (Table 4) and was also present in appreciable amounts (23.2%) at the *sn*-2 position. Therefore, it is assumed that *Pseudomonas* sp. lipase shows no specificity and may incorporate EPA in all three positions of TAG of the oils. In both oils, GLA was esterified preferentially at the *sn*-2 position (18.6 and 7.2% in EPA-enriched BO and EPO, respectively), followed by the *sn*-3 position (4.8–13.4%). In EPA-enriched BO, LA in TAG was distributed randomly (23.6% at *sn*-1, 21.2% at *sn*-2, and 20.2% at *sn*-3) whereas in EPA-enriched EPO it was mainly located at the *sn*-2 (48.4%) position followed by *sn*-1 (39.1%) and *sn*-3 (37.5%) positions (Tables 3 and 4).

The positional distributions of FA in TAG of (EPA + DHA)-enriched oils were also determined, and the results are assembled in Tables 5 and 6. In this study, (EPA + DHA)-enriched oils were synthesized using lipase PS-30 from *Pseudomonas* sp. as the biocatalyst. In (EPA + DHA)-enriched BO and EPO, saturated FA such as 16:0 and 18:0 occurred mainly at the *sn*-1 and -3 positions of TAG. However, these modified oils were different in the dominancy and distribution of n-3 and n-6 PUFA in their TAG molecules. In (EPA + DHA)-enriched BO,

GLA was mainly located at the *sn*-2 position (32.9%), followed by the *sn*-3 position (15.1%) (Table 5). However, EPA and DHA were preferentially esterified at the *sn*-1 and -3 positions of TAG molecules (Table 5); and their quantities were EPA, 26.1 and 30.8% and DHA, 8.3 and 9.8%, respectively. In (EPA + DHA)-enriched EPO, GLA was located mainly at the *sn*-2 (10.8%) and *sn*-3 (9.0%) positions of TAG (Table 6). EPA was preferentially esterified at the *sn*-1 (31.5%) and *sn*-3 (24.1%) positions, but approximately half of the DHA was located in the *sn*-3 position (10.5%) of the TAG molecules (Table 6). Therefore, lipase from *Pseudomonas* sp., under the conditions employed in this study, has the ability to incorporate n-3 FA (EPA and DHA) preferentially at the *sn*-1 and -3 positions of the TAG molecules.

Brockerhoff *et al.* (26) reported that in fish oils the long-chain PUFA tend to be concentrated in the *sn*-2 position whereas in marine mammals they favored the *sn*-1 and -3 positions of TAG. Recently, Wanasundara and Shahidi (27) reported similar results for seal blubber and menhaden oils. Aursand *et al.* (28) investigated the positional distribution of n-3 PUFA in fish and marine mammal oils using high-resolution <sup>13</sup>C NMR spectroscopy. These authors found that in fish oils DHA was concentrated in the *sn*-2 position whereas EPA was more randomly distributed over the three positions of TAG. In seal oil, DHA was predominantly present in the *sn*-1 and -3 positions (27,29). Ando *et al.* (30) also determined the positional distribution of FA in the TAG of fish oils (capelin, herring, menhaden, sardine, and saury) by HPLC using a chiral stationary phase and found that in these oils DHA was present predominantly in the *sn*-2 position. Shimada *et al.* (31) synthesized a SL by acidolysis of tripalmitin with AA (20:4n-6) using 1,3-specific *Rhizopus delemar* lipase. They reported that in the SL so produced AA was predominantly present at the *sn*-1,3 positions (56.9%) of TAG.

Stereospecific analysis of TAG and hydrolysis products provides some useful information about the mechanism of gastric digestion. Intestinal absorption of FA reportedly depends on the arrangement of FA in the TAG molecules. The influence of FA specificity on intestinal absorption in adults has recently been reviewed and positively correlated with the TAG structure in chylomicrons (32). During digestion, FA in the *sn*-1 and -3 positions of TAG are liberated by a positionally specific enzyme such as pancreatic lipase, but the FA attached to the *sn*-2 position of the TAG are absorbed and distributed in the body in the chylomicron form (33). However, clinical studies need to be carried out to verify this latter assumption.

BO and EPO have been used as GLA-rich specialty oils. Enzymatic preparation of DHA and/or EPA-rich TAG from these oils is of recent interest (8–10). It is expected that synthesis of SL containing GLA, EPA, and DHA will provide optimal health benefits. Both n-3 and n-6 PUFA have been recognized for their salient roles in human health and nutrition (6,7). The special positional distribution of GLA, DHA, and EPA in these modified TAG may confirm the potential benefits in certain health and nutritional applications.

## ACKNOWLEDGMENTS

This research financially was supported by a research grant from the Natural Sciences and Engineering Research Council (NSERC) of Canada to the corresponding author. The supply of algal oil from Martek Biosciences Corporation (Columbia, MD), BO from Bioriginal Food and Science Corporation (Saskatoon, Canada), EPO from Efamol, Inc. (Kentville, Nova Scotia, Canada) and the enzymes from Amano Enzymes U.S.A. Co. Ltd. (Troy, VA) and Novo Nordisk Biochem North America, Inc. (Franklinton, NC) are gratefully acknowledged. We also thank Dr. T. Ohshima (Tokyo, Japan) for his generous supply of the EPA concentrate.

# Characterization of *trans*-Monounsaturated Alkenyl Chains in Total Plasmalogens (1-*O*-alk-1'-enyl-2-acyl glycerophospholipids) from Sheep Heart

Robert L. Wolff\*

INRA, Unité de Nutrition Lipidique, 21065 Dijon Cedex, France

**ABSTRACT:** In the present study, we investigated the alkenyl chains from sheep heart plasmalogens (1-*O*-alk-1'-enyl-2-acyl glycerophospholipids) after their conversion into trimethylene dioxyalkanyl (TMDOA) derivatives. Particular attention was given to monounsaturated alkenyl chains (C<sub>18</sub> mainly). For this purpose, a combination of silver ion TLC and GLC on highly polar, very long capillary columns was applied to TMDOA derivatives. Approximately 30 different alkenyl chains could be separated, and the main observation was that the component previously reported as a *cis*-9 18:1 alkenyl chain in plasmalogens embraces in fact a wide range of *trans* and *cis* isomers, in amounts equal to 7.9 and 5.6%, respectively, of total alkenyl chains. Concerning the *trans*-monoenoate fraction, isomers with their ethylenic bond spanning from  $\Delta 6$ – $\Delta 8$  to  $\Delta 16$  were tentatively identified on the basis of their distribution profile, which was similar to that of *trans*-18:1 acids prepared and isolated from sheep adipose tissue. The main *trans*-monoenoic C<sub>18</sub> alkenyl chain in sheep heart plasmalogens would thus have its double bond in position 11, which seems logical, as alkenyl chains are derived from the corresponding alcohols, themselves issued from the corresponding FA, and in this particular case, vaccenic (*trans*-11 18:1) acid. *cis*-Monoenoic C<sub>18</sub> alkenyl chains also appear more complex than realized earlier, showing in particular isomers with their ethylenic bond farther than the  $\Delta 9$  position, in addition to the main isomer derived from oleic acid. Several *trans*-16:1 alkenyl chains could be observed (totaling ca. 1%), but *cis*-16:1 isomers were present in trace amounts only.

Paper no. L8968 in *Lipids* 37, 811–816 (August 2002).

In the many studies devoted to the biochemical effects of dietary *trans*-monounsaturated FA (MUFA), plasmalogens (1-*O*-alk-1'-enyl-2-acyl-glycerophospholipids) seem to have been little investigated. In neither the monograph on *trans* FA edited in 1979 by Emken and Dutton (1) nor in that edited in 1998 by Sébédio and Christie (2) was the word “plasmalogen” indexed. However, a few observations on plasmalogens in relation to *trans*-MUFA were made in the past. Dietary *trans*-MUFA were shown to be incorporated, after their *in vivo* conversion to the corresponding alcohols, into rat heart plasmalogen alkenyl chains (3), and into rat heart and kidney

mitochondria plasmalogens (4–6). In the latter case, elaidic (*trans*-9 18:1) acid was used as a model for *trans*-MUFA, and both alkenyl and acyl chains were analyzed. It was also demonstrated that L-M cultured cells could accumulate elaidyl alcohol (a precursor in the biosynthesis of plasmalogens) when the medium was supplemented with elaidic acid (7,8). Cell-free systems from mouse preputial gland tumors are able to promote alcohol synthesis from elaidic acid when adequate cofactors are present (9). Moreover, addition of a mixture of radioactive *trans*-octadecenols to cultured L1210 or S180 ascite cells resulted in the incorporation of these components into plasmalogens (10). The same observation was made when the mixture was injected intracranially into rat brain (10).

Plasmalogens, mostly of the ethanolamine and choline forms, are common components of cellular membranes. Their proportions relative to total phospholipids, however, depend on the organ considered. Their alkenyl chain composition is generally considered a simple one, being essentially limited to 16:0, 18:0, and 18:1 chains, and to some minor branched and odd-numbered saturated chains in the case of ruminant organs. In considering 18:1 chains, there is little information regarding the position of the ethylenic bond, but it is generally admitted that it is principally located at the  $\Delta 9$  position, with a *cis* configuration (derived from oleic acid).

Plasmalogens in ruminant organs may be different, because the rumen microflora synthesizes *trans*-MUFA from PUFA present in the feed. Thus, ruminants may be considered as naturally consuming *trans*-MUFA and are a model of choice to study the metabolic fate of these components. In earlier studies on the rat (4–6), we observed that dietary elaidic acid (fed as trielaidin) could replace, after its conversion into elaidyl alcohol, an important proportion of the saturated alkenyl chains without affecting the percentage of the *cis*-9 18:1 chains. We thus suspected that *trans*-18:1 alkenyl chains might be present naturally in ruminant plasmalogens, which contain an important proportion of saturated alkenyl chains. We present evidence here that total plasmalogens from sheep heart, taken as a natural model, do contain *trans*-monounsaturated alkenyl chains with a distribution profile similar to that generally found in TAG from ruminant milk and adipose tissue lipids. Because plasmalogen alkenyl chains are derived from the corresponding alcohols, themselves produced from the corresponding FA, we also analyzed the FA from sheep adipose tissue.

## EXPERIMENTAL PROCEDURES

**Samples.** The heart of a sheep aged less than 6 mon was obtained from a local slaughterhouse and freed from apparent fatty tissues; the auricles were then removed. The ventricles were next divided into two parts (approximately 70 g each) and kept at  $-80^{\circ}\text{C}$  until use. Additionally, approximately 100 g of adipose tissue was taken off the animal and also stored at  $-80^{\circ}\text{C}$ .

**Lipid extraction and fractionation.** After thawing for 24 h at  $4^{\circ}\text{C}$ , one-half of the heart muscle was minced with scissors and homogenized with a household electric grinder. Fifteen grams of the homogenate was dispersed for 1 min in 80 mL methanol with an UltraTurrax T25 (Janke & Kunkel GmbH & Co. KG, Staufen, Germany) before adding 160 mL chloroform and performing a second 1-min homogenization with the UltraTurrax. The suspension was filtered on paper into a separatory funnel and washed with 50 mL of a 0.8% aqueous solution of NaCl (11). After standing for 1 h, the lower phase was withdrawn and the solvents were evaporated. The residue (775 mg) was dissolved in 7.7 mL of chloroform (*ca.* 100 mg/mL) and kept at  $-18^{\circ}\text{C}$  until use. Similarly, 5 g of adipose tissue was extracted with 20 mL of methanol, followed by 40 mL of chloroform. The final lipid extract (3.57 g) was dissolved in enough chloroform to make a 0.5 g lipid/mL solution.

An aliquot of the heart lipid solution (0.5 mL) was fractionated into neutral and polar lipids using a Sep-Pak<sup>®</sup> Plus silica cartridge (Waters Corporation, Milford, MA) eluted with 20 mL chloroform followed by 30 mL methanol. Polar lipids were dissolved in 1.5 mL of chloroform.

**Preparation of trimethylene dioxyalkanyl (TMDOA) derivatives.** A portion (250  $\mu\text{L}$ ) of the polar lipid solution was evaporated to dryness under a stream of  $\text{N}_2$  in a round-bottomed tube. The tube was inverted over a test tube cap containing 1 mL concentrated HCl for 5 min. The fumes cause complete hydrolysis of the alkenyl ether bond of the plasmalogens without affecting 1,2-diacyl- or 1-*O*-alkanyl-2-acyl glycerophospholipids (12,13). After flushing the tube with  $\text{N}_2$  to remove residual HCl vapors, the lipids were dissolved in 5 mL chloroform. Transformation of the released aldehydes into TMDOA was performed according to a modification of the method devised by Palmer *et al.* (14). To the preceding solution were added 10 mg of *p*-toluenesulfonic acid (Sigma-Aldrich Chimie S.à.r.l., Saint Quentin Fallavier, France) and 500  $\mu\text{L}$  of 1,3-propanediol (Sigma-Aldrich). The tube was tightly capped and the reaction was allowed to proceed for 3 h at  $80^{\circ}\text{C}$  with constant magnetic stirring. At the end of the reaction, the tube was cooled and the chloroform phase was washed with 5 mL distilled water. The chloroform phase was taken to dryness, and the residue dissolved in 0.5 mL of chloroform and fractionated into TMDOA and unreacted polar lipids on a Sep-Pak<sup>®</sup> cartridge as described above for neutral and polar lipids. TMDOA derivatives were further purified by TLC on precoated silica gel H plates (Merck, Darmstadt, Germany) with the solvents hexane/diethyl ether (80:20, vol/vol). TMDOA derivatives were visualized under UV light

(366 nm) after spraying a 0.2% ethanolic solution of 2',7'-dichlorofluorescein (DCF). The intense band with  $R_f = 0.66$  was scraped, and TMDOA derivatives were eluted with diethyl ether (three 2.5-mL portions). After filtration, the solvent was removed under a stream of  $\text{N}_2$ , and the residue was dissolved in 1 mL of hexane for further processing. A faint band observed near the origin was attributed to unreacted aldehydes or to residual 1,3-propanediol.

**FAME preparation.** To 250  $\mu\text{L}$  of the solution of lipids extracted from sheep adipose tissue was added 2.75 mL hexane, followed by 300  $\mu\text{L}$  of a 0.5 N solution of sodium methoxide in methanol. The mixture was thoroughly vortexed for 1 min and further heated for 10 min at  $50^{\circ}\text{C}$ . The reaction mixture was washed with 3 mL water, and the supernatant was withdrawn, evaporated to dryness, and dissolved in 1 mL of hexane.

**Fractionation of TMDOA derivatives and FAME.** TMDOA derivatives were fractionated according to the number and the configuration of ethylenic bonds by silver ion TLC as described elsewhere for FAME (15). The solvent was hexane/diethyl ether (75:25, vol/vol). The three bands ( $R_f = 0.50, 0.63,$  and  $0.75$ ) that were revealed as described above were scraped, and TMDOA derivatives were extracted with a biphasic solvent system that allowed removal of the DCF (15). FAME prepared from adipose tissue were processed in the same way, except that the proportions of solvents were 90:10 (vol/vol). Here too, the three main FAME bands with  $R_f = 0.82, 0.64,$  and  $0.45$  were scraped and the FAME eluted from the gel (15).

**GLC.** Unfractionated as well as fractionated TMDOA derivatives or FAME were analyzed on a HP 4890A chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a 100-m CP-Sil 88 capillary column [0.20 mm i.d., 0.25  $\mu\text{m}$  film (cyanopropyl siloxane polymer); Chrompack, Middelburg, The Netherlands]. Unless otherwise stated, the oven operating temperatures were:  $60^{\circ}\text{C}$  for 1 min, increase at  $20^{\circ}\text{C}/\text{min}$  to  $190^{\circ}\text{C}$  (TMDOA) or  $160^{\circ}\text{C}$  (FAME), then isothermal for 60 min, second increase at  $20^{\circ}\text{C}/\text{min}$  to  $210^{\circ}\text{C}$ , isothermal for 5 min. The injector (splitless; purge time set at 30 s) and the FID were maintained at 250 and  $280^{\circ}\text{C}$ , respectively. Hydrogen was the carrier gas, with a head pressure of 210 kPa. Injections (1  $\mu\text{L}$ ) were made automatically by an Agilent 6890 Series Injector (Hewlett-Packard). Alternatively, fractionated TMDOA were analyzed in a Hewlett-Packard 5890 Series II chromatograph, also equipped with an automatic injection system (same as above). The chromatograph was equipped with a 120-m BPX 70 capillary column [0.25 mm i.d., 0.20  $\mu\text{m}$  film (biscyanopropylsiloxane-silphenylene polymer); SGE, Melbourne, Australia] with  $\text{H}_2$  as a carrier gas (head pressure, 200 kPa). The injector and detector were maintained at 250 and  $280^{\circ}\text{C}$ , respectively. The column was operated under the same temperature programs as the CP-Sil 88 column. For specific purposes (separation of critical pairs), the temperature of the first plateau was lowered to  $140^{\circ}\text{C}$  (TMDOA and FAME).

**Identification and quantification of TMDOA derivatives and FAME.** Individual peaks of isomeric 18:1 FAME were

identified according to Wolff and Bayard (16). Identification of TMDOA was made by analogy with FAME isolated in comparable bands after silver ion TLC. Peaks were integrated and quantified with the Diamir software (© 1999 JMBS Inc., Fontaine, France; version 1.5.302.2). No correction factors were applied, and data are given as area percentages. Calculations of total *trans*- as well as *cis*-18:1 isomers were made through the use of *trans*-11 18:1 acid for *trans*-18:1 isomers, and of *cis*-9 18:1 acid, after subtraction of the *trans*-13 plus *trans*-14 critical pair, for *cis*-18:1 isomers.

**GLC-MS.** The analysis of TMDOA, either unfractionated or fractionated, was performed using an HP6890 chromatograph coupled to an HP5973 mass spectrometer (Hewlett-Packard). A BPX 70 capillary column (50 m × 0.33 i.d., 0.25 μm film; SGE) was used with a temperature program from 50 to 190°C at a rate of 15°C/min. Helium was the carrier gas at a velocity of 36 m·s<sup>-1</sup>. The splitless injector was maintained at 250°C. The electron impact mass spectra were recorded at 70 eV between 30 and 350 amu.

## RESULTS AND DISCUSSION

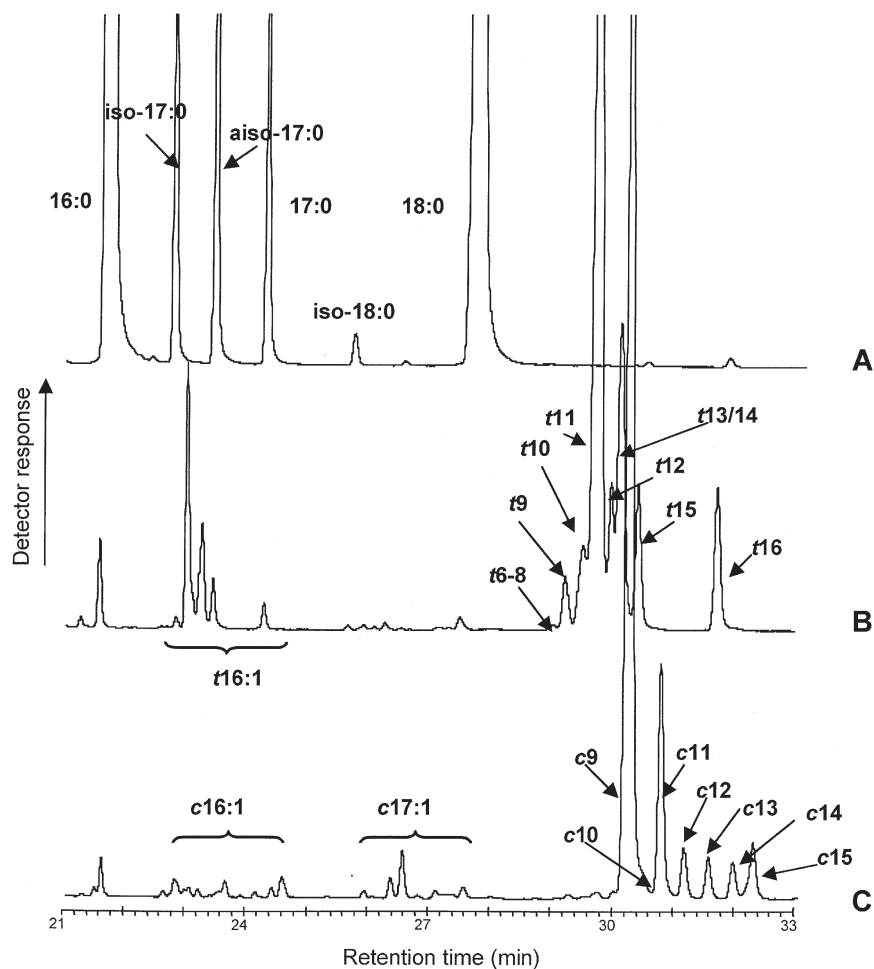

**Determination of alkenyl chain structures.** Recent information for sheep heart phospholipid composition unfortunately is lacking. However, in older studies (17,18), it was established that plasmalogens of the ethanolamine and choline

forms represent 31–41% (depending on the study), that is roughly one-third of total phospholipids in sheep heart. Sheep heart thus represents an interesting starting material for the study of plasmalogen alkenyl chains. Additionally, information on the composition of these alkenyl chains is lacking. However, it can be hypothesized that this composition should not be very different from that of beef heart, for which some compositions were published earlier (see Ref. 16). As indicated in the introductory statement, the alkenyl moieties are composed mostly of 16:0, 18:0, and 18:1 chains, to which minor amounts of branched (iso and anteiso forms) chains (odd- and even-numbered) should be added (19). Trials were made to use free aldehydes or dimethylacetals, but we could not obtain as good a resolution as with TMDOA by GLC at any operating temperature (results not shown).

As can be seen from the chromatogram of unfractionated TMDOA derivatives (Fig. 1), the profile of total plasmalogen alkenyl chains is more complex than recognized thus far. This undoubtedly results from the use of highly efficient polar capillary columns of great length. In most earlier studies, short packed columns with moderately polar stationary phases were used and obviously could not give such details. To simplify the identification of peaks, TMDOA derivatives fractionated by silver ion TLC were also analyzed under the same conditions (Fig. 2). The fraction with an  $R_f$  of 0.75 contained two main peaks, identified as 16:0 and 18:0. Three relatively

**FIG. 1.** Chromatogram of total trimethylene dioxyalkanyl derivatives of alkenyl chains from sheep heart plasmalogens. Analysis on a 100-m CP-Sil 88 capillary column operated under conditions described in the Experimental Procedures section (plateau at 190°C). Identification of peaks is given in Table 1 (UK, unknown structure).

**FIG. 2.** Partial chromatograms ( $C_{16}$  to  $C_{18}$  regions) of (A) saturated, (B) *trans*- and (C) *cis*-monoenoic trimethylene dioxyalkanyl derivatives of alkenyl chains from sheep heart plasmalogens fractionated by silver ion TLC. Analyses on a 100-m CP-Sil 88 capillary column operated under conditions described in the Experimental Procedures section (same as in Fig. 1).

minor peaks eluting between them were assigned the structures iso-17:0, anteiso-17:0, and 17:0. No peaks were found eluting after 18:0. Of the peaks eluting before 16:0, the identifications were based on those by Schmid *et al.* (19) for bovine heart plasmalogens: iso-14:0, 14:0, iso-15:0, anteiso-15:0, 15:0, and iso-16:0, in this elution order. The saturated FAME fraction ( $R_f = 0.82$ ) prepared from sheep adipose tissue showed exactly the same chain structure distribution (results not shown), with, however, different proportions (e.g., 18:0  $\gg$  16:0 in adipose tissue, instead of 16:0  $\gg$  18:0 in heart alkenyl chains).

The intermediate fraction of TMDOA with an  $R_f$  of 0.63 showed a GLC profile similar to that presented by *trans*-18:1 FAME prepared from milk or adipose tissue lipids from several ruminants (20–22), in particular to FAME prepared from sheep adipose tissue (results not shown), thus allowing the tentative identifications indicated in Figure 2. These identifications are also based on the principle that isomeric 18:1 isomers, such as FAME, FA isopropyl esters (16), or 2-alkenyl-4,4-dimethyloxazoline derivatives (23), are sequentially eluted as a function of the position of the ethylenic bond from

$\Delta 4$  to  $\Delta 16$ . With respect to the peak identified as  $\Delta 13/\Delta 14$  on the CP-Sil 88 column, the two isomers could be almost baseline-resolved with the BPX 70 column operated at low temperature (140°C; results not shown). The main peak is likely the  $\Delta 11$  isomer, biosynthetically derived from vaccenic (*trans*-11 18:1) acid through an intermediary alcohol. In addition to *trans*-monounsaturated  $C_{18}$  TMDOA derivatives, several minor *trans*-16:1 isomers could be observed in the same fraction (Fig. 2). According to a recent study on *trans*-16:1 isomers in ruminant milk fat, including ewes (24), the main *trans*-16:1 isomer would have its double bond in position  $\Delta 9$ . A *trans*-16:1 alkenyl chain was characterized in heart and kidney mitochondria of rats fed trielaidin (6), which would suggest possible chain-shortening of *trans*-octadecenoates to *trans*-hexadecenoates.

The slowest-moving TMDOA band collected after silver ion TLC corresponds to *cis*-monounsaturated TMDOA. This band contained one main *cis*-18:1 chain, likely the  $\Delta 9$  one. In addition, several minor peaks eluted after this peak are tentatively assigned the structures given in Figure 2, by analogy with the structures determined for FAME from ruminant fats

(20–22), in particular from sheep adipose tissue. Surprisingly, only traces of *cis*-16:1 isomers could be observed in the monounsaturated TMDOA fraction, in contrast to its FAME counterpart. On the other hand, *cis*-17:1 isomers were present in significant amounts.

GLC–MS of both unfractionated and fractionated TMDOA derivatives showed for all peaks a major fragment at  $m/z = 87$ , characteristic of the dioxane ring, as well as the molecular ion  $[M - 1]^+$  for each peak (Table 1). Unfortunately, no characteristic ions allowing determination of the position of the ethylenic bond are produced with these derivatives, and GC–MS could not confirm our tentative identifications of monounsaturated alkenyl chains.

**Quantitative aspects.** The proportions of the different alkenyl chains are given in Table 1. Total saturated chains account for *ca.* 85% of total alkenyl chains, with two components, 16:0 and 18:0, constituting the bulk of this group. As observed earlier by Schmid *et al.* (19) in alkenyl chains from beef heart, several odd-numbered as well as iso and anteiso forms occur in sheep heart plasmalogens. In particular, such chains with 17 carbon atoms represent 8.6% of total alkenyl chains (10% of saturated chains). Among the remaining

alkenyl chains, total *trans*-18:1 and *trans*-16:1 isomers account for 7.9 and 1%, respectively, whereas *cis*-18:1 isomers account for only 4.8% of the total. Thus, *cis*-18:1 isomers represent only slightly more than one-third of total 18:1 isomers.

In Table 2 are displayed the relative distributions of individual *trans*- and *cis*-18:1 isomers in heart plasmalogen alkenyl chains and in adipose tissue acyl chains (determined after silver ion TLC). The two earliest-eluting *trans* isomers ( $\Delta 4$  and  $\Delta 5$ ), present in adipose tissue, were not observed in heart plasmalogens. In both TMDOA and FAME fractions, one component is predominant: for FAME, it corresponds to vaccenic acid (*ca.* 74%), and it is inferred that the double bond in the major TMDOA (*ca.* 60%) similarly is at the  $\Delta 11$  position. The  $\Delta 13/\Delta 14$  pair (either in TMDOA or in FAME), not resolved at 190°C on the CP-Sil 88 column, could easily be split at 140°C on the BPX 70 column, allowing quantification of both isomers (they are present in almost similar amounts in both TMDOA and FAME). Isomers with their ethylenic bond between the  $\Delta 12$  and  $\Delta 16$  positions are present in higher proportions in heart plasmalogens than in adipose tissue TAG. This would suggest that some discrimination may exist between the utilization of isomeric *trans*-18:1 acids for their deposition in depot fats and their incorporation (after their reduction to fatty alcohols) into plasmalogens.

Regarding the *cis*-18:1 fraction, some differences also are visible between TMDOA (heart plasmalogens) and FAME

<sup>a</sup>Data were obtained by a combination of analyses of TMDOA and FAME on 100-m CP-Sil 88 and BPX 70 capillary columns operated as indicated in the Experimental Procedures section. The critical pair *t* $\Delta$ 13/*t* $\Delta$ 14, not separated under routine analytical conditions, was almost baseline-resolved at 140°C on the BPX 70 column.

<sup>b</sup>For abbreviations see Table 1.

<sup>c</sup>Not detected.

<sup>d</sup>Less than 0.2%.

<sup>e</sup>With both TMDOA and FAME, the *c* $\Delta$ 10 isomer could only be separated as a small shoulder at the base of the descending edge of the main *c* $\Delta$ 9 isomer and could not be correctly integrated.

(adipose tissue TAG) (Table 2). In FAME, the proportion of the  $\Delta 9$  isomer is higher than that in TMDOA, whereas the  $\Delta 11$  isomer is higher in TMDOA than in FAME. More generally, the proportions of isomers with their ethylenic bond between  $\Delta 11$  and  $\Delta 15$  are higher in TMDOA than in FAME. Here too, some discrimination may exist in targeting individual *cis*-18:1 isomers to plasmalogens or to TAG.

**ABSTRACT:** An analytical procedure was developed for regiodistribution analysis of TAG using  $\alpha$ -MAG prepared by an ethyl magnesium bromide deacylation. In the present communication, the deacylation procedure is shown to lead to representative  $\alpha$ -MAG, allowing the composition of the native TAG in the  $\alpha$ -position to be determined directly. The composition in the  $\beta$ -position can then be estimated from the composition of the  $\alpha$ -MAG and TAG according to the formula  $3 \times \text{TAG} - 2 \times \alpha\text{-MAG}$ . The estimates are superior to those obtained using the  $\alpha,\beta$ -DAG and Brockerhoff calculations as they come closer to the theoretical value and have smaller SD. The present procedure, first demonstrated on a synthetic TAG, was then successfully applied to the analysis of borage oil, milkfat, and tuna oil.

Paper no. L8939 in *Lipids* 37, 817–821 (August 2002).

Much work has been done to simplify the regiodistribution analysis of TAG using a chemical deacylation (1–4). Since the chemical deacylation makes most of the TAG accessible to a regiodistribution analysis (5–8), difficulties are due to the occurrence of some unavoidable acyl migration, which naturally changes analysis results (9). In order to improve the accuracy of analysis, suitable conditions need to be found to minimize the incidence of isomerization and, therefore, for the Grignard deacylation to produce acylglycerols representative of the original TAG structure. Accordingly, methods in the literature generally make use of  $\alpha,\beta$ -DAG (9–13) or  $\beta$ -MAG (2), with appropriate calculations. A shortcoming is that the FA composition of the  $\alpha$ -position is not analyzed directly but obtained by calculation and is therefore subject to cumulative errors of GC analysis (10,13). Some recent methods using both the  $\alpha$ - and  $\beta$ -MAG produced from TAG by a Grignard deacylation involve their analysis by HPLC on chiral columns (1,3). However, use of these methods on a routine basis is laborious, since they require special and expensive analytical equipment rather than the standard GC equipment.

In the present communication, we have examined the possibility of producing representative  $\alpha$ -MAG, i.e., with a random FA distribution, by an ethyl magnesium bromide deacylation of TAG. The classical procedure of deacylation is modified to (i) find suitable conditions for decreasing isomerization, (ii) determine the regiospecific distribution through the GC analysis of  $\alpha$ -MAG, and (iii) corroborate the results obtained with the pancreatic lipase hydrolysis (standardized procedure ISO 6800).

The method was first demonstrated by the regiodistribution analysis of a racemic *sn*-1,3-dipalmitoleyl-*sn*-2-oleoyl-glycerol (POP), then by the analysis of borage oil, milkfat, and tuna oil.

## EXPERIMENTAL PROCEDURES

**Materials.** Borage oil was obtained from Bertin (Lagny-lesec, France). Tuna oil was an industrial product from Sea Oil (Beaumont-Hague, France). Milkfat was obtained from Bel (Vendome, France). The racemic synthetic POP (99%+), a crude lipase from porcine pancreas, and a 0.2% solution of 2',7'-dichlorofluorescein in ethanol (DCF solution) were purchased from Sigma Chemical Company (St. Louis, MO). A 3.0-M solution of ethyl magnesium bromide ( $\text{C}_2\text{H}_5\text{MgBr}$ ) in diethyl ether was obtained from Aldrich (Milwaukee, WI). A methanolic solution of boron trifluoride (10%, wt/vol) was obtained from Fluka (Hauptpauge, New York). Silicic acid 60 F<sub>254</sub> TLC plates were obtained from Merck (Darmstadt, Germany). Anhydrous  $\text{NaHCO}_3$ , boric acid, and all organic solvents were also from Merck.

**Pancreatic lipase hydrolysis.** The standard pancreatic lipase hydrolysis procedure used to determine the FA composition in the  $\beta$ -position of TAG was modified from Luddy *et al.* (14).

**Chemical deacylation of TAG.** Forty milligrams of pure TAG was dissolved in 2 mL of dry diethyl ether. A  $\text{C}_2\text{H}_5\text{MgBr}$  solution (670  $\mu\text{L}$ ) was added directly using a pipette equipped with a positive displacement mechanism that isolated the aspirated liquid from the air (Gilson, Middleton, WI). The mixture was shaken for 15 s, then 300  $\mu\text{L}$  of glacial acetic acid was added, followed by 5 mL of a 0.4-M boric acid solution in water to stop the reaction. The lipid products (newly formed partial acylglycerols, tertiary alcohols, and residual TAG) were then extracted with the diethyl ether. This extract was washed with a 5-mL solution of aqueous boric acid (0.4 M)/aqueous  $\text{NaHCO}_3$  (2%), 50:50 (vol/vol) then resolved by TLC without further treatment.

The MAG were quickly isolated by preparative TLC on precoated silicic acid that was impregnated with a 5% boric acid solution in methanol (wt/vol) to prevent isomerization (15). The plates were developed with a chloroform/acetone/acetic acid solution (85:15:1, by vol) to isolate the *sn*-1(3)- from the *sn*-2-MAG. After development, bands were revealed and visualized with the DCF solution under UV light (366 nm). The following bands were observed:  $\alpha$ -MAG ( $R_f = 0.26$ );  $\beta$ -MAG ( $R_f = 0.38$ );  $\alpha,\beta$ -DAG ( $R_f = 0.76$ );  $\alpha,\alpha'$ -DAG ( $R_f = 0.85$ ); tertiary alcohols of the deacylated FA and residual TAG ( $R_f = 0.95$ ). The silica gel of corresponding bands

Abbreviations: DCF, 2',7'-dichlorofluorescein; POP, *sn*-1,3-dipalmitoleyl-*sn*-2-oleoyl-glycerol.

was scraped off and transferred to Teflon-lined screw-capped tubes for methyl ester preparation.

**Methyl ester preparation and analysis.** Methyl esters were prepared according to Morrison and Smith (16). A methanolic solution (0.5 to 0.8 mL) of boron trifluoride was added directly to the silica gel, and methylation was performed at 100°C for 60 min.

FAME were analyzed by GLC with a Carlo Erba GC 8000 Top apparatus (Erba Science, Paris, France) equipped with an FID. Methyl esters were separated in a glass capillary column (30 m × 0.32 mm i.d.) coated with CARBOWAX 20M, programmed from 185 to 210°C (4°C/min), and held isothermally for 10 min. Peak areas and percentages were calculated by a Merck D2000 integrator. Areas obtained with the integrator were divided by chain length to yield the mole percentage of FA.

## RESULTS

**Regiodistribution analysis of POP.** The degree of purity of the POP was first verified. Pancreatic lipase hydrolysis confirmed that the β-position was occupied almost entirely by oleic acid (98.5%) and that the α-position was occupied by palmitic acid (99.3%). Results of the analysis of partial acylglycerols obtained from the Grignard degradation of POP are detailed in Table 1. Results of the analysis of the α,β-DAG agreed well with the lipase hydrolysis, certainly within the limits of analysis errors. The α,α'-DAG was contaminated with isomerized α,β-DAG, as evidenced by the content of oleic acid (4.5%). The β-MAG were strongly contaminated with 5.6% palmitic acid that had migrated from the α-position. We observed only 1.8% contamination of α-MAG. Con-

sequently, the results from the α-MAG analysis were closer to the reference value and provided direct analysis of the α-position. The FA distribution in the β-position could then be analyzed by direct determination through the β-MAG or by calculation based on the composition of the different acylglycerols, as demonstrated at the bottom of Table 1. The most accurate estimate was obtained by calculation from  $3 \times \text{TAG} - 2 \times \alpha\text{-MAG}$ . The estimates were  $96.3 \pm 0.9\%$  (mean ± SD) oleic acid.

Although the FA profile of the α,β-DAG was closer to the FA distribution of the original TAG, the estimates based on the α,β-DAG composition gave negative values. This reflects the larger factors of the equation  $4 \times \alpha, \beta\text{-DAG} - 3 \times \text{TAG}$  than the equations used with α-MAG. The positional analysis obtained by calculation from the α,β-DAG was therefore subject to cumulative experimental errors of GC analysis.

**Regiodistribution analysis of borage oil.** The method was then applied to determine the regiospecific distribution of borage oil. First, pancreatic lipase hydrolysis was used to determine the composition at the β-position through the β-MAG. To verify the validity of the lipase hydrolysis, the TAG composition was recalculated from the composition of α,β-DAG and β-MAG through the equation  $3 \times \text{TAG} = 4 \times \alpha, \beta\text{-DAG} - \beta\text{-MAG}$  (Table 2). Results showed excellent agreement with the data for the composition of TAG (multiple correlation coefficient  $R = 0.993$ , with a confidence interval of 95%), confirming that the enzymatic deacylation generated a random mixture of representative acylglycerols. Table 2 gives the analysis of partial acylglycerols from the Grignard deacylation compared with the results obtained with pancreatic lipase. Nonreproducible results were obtained for the β-MAG analysis; the FA composition disagreed within 3% (absolute) for the minor component (palmitic acid). The composition in the β-position could then be estimated from the composition of α-MAG and TAG. The estimates compared favorably to those found using the pancreatic lipase procedure, as they came closer to the theoretical value and had smaller SD (Table 3). The composition of the FA at the α-position could be calculated from data for α,β-DAG and TAG or from TAG minus β-MAG. However, a direct analysis of α-MAG was preferable, since the results obtained were more accurate and showed smaller SD than those obtained by calculations from the α,β-DAG (Table 4).

**Regiodistribution analysis of tuna oil and milkfat.** The results obtained by the modified regiodistribution analysis of milkfat and tuna oil, respectively, are presented in Tables 5 and 6. These confirm previously published work on the FA regiodistribution of these substrates for the short- or medium-chain FA ( $C_{10}$  or less) (17,18) or for very long chain PUFA (19,20).

Regiodistribution analysis on the basis of the classical procedures involving α,β-DAG or β-MAG is often complicated for fats and oils with a widely diverse FA spectrum, such as milkfat or fish oils. The superposition of elution bands in the TLC technique is the main problem, so this analytical limitation was eliminated in our approach of using boric acid coated

silica plates in isolating the  $\alpha$ -MAG fraction. The strong affinity of the hydroxyl groups in the  $\alpha$ -MAG fraction—independent of their compositions—resulted in the lowest  $R_f$  values, which allowed an easy separation and contamination-free recovery of the  $\alpha$ -MAG.

## DISCUSSION

The present method gives an accurate analysis of the  $\alpha$ -position in the original TAG. The  $\alpha$ -MAG are present in sufficient quantities and a random FA distribution is obtained. This point deserves particular attention. As early as 1966, Yurkowski and Brockerhoff (9) reported that the MAG ( $\alpha$ - and  $\beta$ -MAG) from the Grignard deacylation reaction could not be used for analytical purposes, since their FA compositions were not representative of the original TAG structure. Extensive acyl migration took place during the deacylation procedure. In 1993, Becker *et al.* (2) discussed the positive effect of an excess amount of allyl magnesium bromide reagent to produce representative  $\beta$ -MAG.

Based on these observations, we modified deacylation conditions from the usual procedure by using a higher ratio of ethyl magnesium bromide to TAG for a shorter reaction time. Under these conditions, more acyl shifting was observed from the  $\alpha$ - to  $\beta$ -position (5.6% contamination of  $\beta$ -MAG) than

from the  $\beta$ - to  $\alpha$ -position (1.8% contamination of  $\alpha$ -MAG). These results are opposite those usually observed for this type of analysis (2,9,11) and for chemical equilibrium between the  $\alpha$ - and  $\beta$ -positions (21). However, as reported in the literature (4,22), deacylation is not random with regard to FA position on the glycerol molecule. Ethyl magnesium bromide exhibited a higher selectivity toward the  $\alpha$ -position than did allyl magnesium bromide, and the Grignard reagents generated opposite results regarding MAG production. Thus, the proportion of  $\alpha$ -MAG (30–35%) produced by ethyl magnesium bromide may have been overemphasized with a higher ratio of reagent and a shorter reaction time, leading to the formation of minute amounts of  $\beta$ -MAG (less than 10%).

The present procedure allows oils and fats that are not amenable to analysis with pancreatic lipase to be directly accessible to a regiodistribution analysis, without resorting to calculations. This method is particularly useful with TAG containing short-chain FA ( $C_{10}$  or less) or very long chain PUFA, as no significant selectivity was observed with respect to chain length or unsaturation of FA in the partial deacylation of TAG (2,22).

# Evaluation of Two GC Columns (60-m SUPELCOWAX 10 and 100-m CP Sil 88) for Analysis of Milkfat with Emphasis on CLA, 18:1, 18:2 and 18:3 Isomers, and Short- and Long-Chain FA

John K.G. Kramer\*, C. Brian Blackadar, and Jianqiang Zhou

Food Research Program, Agriculture and Agri-Food Canada, Guelph, Ontario, Canada N1G 5C9

**ABSTRACT:** Milkfat is a complex mixture of many diverse FA, some of which have demonstrated health benefits including anticancer properties. Attempts are under way to enrich milkfats with long-chain n-3 PUFA and CLA. It has been recommended that the analysis of these milkfats requires gas chromatography (GC) equipped with long, highly polar capillary columns. However, many analyses have been reported using CARBOWAX™ type (polyethylene glycol) capillary columns, such as SUPELCOWAX 10, even though the separation characteristics of many of the FA and their isomers present in milkfats have not been described in detail. This includes the isomers of CLA, *cis*- and *trans*-octadecenoic acid (18:1), linoleic acid (18:2n-6), and linolenic acid (18:3n-3), and the long-chain PUFA. On the other hand, the resolution of these FA and their isomers has been more fully described using the highly polar capillary columns, such as CP Sil 88 and SP2560 because of the improved resolution obtained using these polar columns. The present study was undertaken to characterize the separation of these FA present in milkfats using a 60-m SUPELCOWAX 10 column, to compare the results to those from a 100-m CP Sil 88 column, and to determine if these two columns could possibly serve to complement each other for the analysis of total milkfat. The advantages of the SUPELCOWAX 10 column were a better resolution of the short-chain saturated from their monounsaturated FA (MUFA) analogs, and a complete separation of the  $\alpha$ -linolenic (18:3n-3) and eicosadecenoic acid (20:1) isomers. It also provided an alternative elution order of the linoleic (18:2n-6), 18:3n-3 and  $\gamma$ -linolenic (18:3n-6) acid isomers. On the other hand, the CP Sil 88 column provided a better resolution of the CLA isomers, MUFA, the isolated *cis* and *trans* MUFA fractions, the PUFA, and many the 18:2n-6 and 18:3n-3 isomers. A complete analysis of milk lipids using the CP Sil 88 column required the prior separation of total FAME using silver ion-TLC. The results of the present study confirm that the 100-m highly polar capillary GC columns are mandatory for the analysis of milk lipids, and at best, the 60 m SUPELCOWAX 10 capillary column serves as a

complementary GC column to provide different separations in certain regions based on its intermediate polarity.

Paper no. L9065 in *Lipids* 37, 823–835 (August 2002).

The analysis of milkfats and fats from ruminant animals has taken on new importance in the last decade since the identification of CLA in these fats that possess anticarcinogenic, antiatherosclerotic, immune-stimulating, and fat-partitioning properties (1,2). At first the emphasis on the analysis was the resolution and identification of the CLA isomers (3–7). Now the analysis has been extended to include the complex mixture of *trans*-octadecenoic acids (*t*-18:1), since it was shown that 11*t*-18:1 converts to CLA by  $\Delta$ 9-desaturase in animals (8–11) and humans (12,13). In addition, there have been efforts to increase the contents of n-3 PUFA in milkfats for health reasons in adults (14) as well infants (15).

GC is by far the most widely used method for the analysis of FA, and the FA are generally analyzed as their FAME. Flexible fused silica columns coated with the highly polar cyanoalkyl polysiloxane stationary phases (marketed under such names as CP Sil 88, SP 2380, SP2560, and BPX-70) have been recommended for the analyses of milkfats that contain complex mixtures of geometric and positional isomers of monounsaturated FA (MUFA) (16–23) and CLA isomers (23–26), plus a range of FA from 4:0 to long-chain PUFA (23). These columns are generally available in 100 m length.

Flexible fused-silica capillary columns coated with CARBOWAX™ type (polyethylene glycol) stationary phases (i.e., SUPELCOWAX 10, DB-WAX, etc.) have been (7), and continue to be, used for the analyses of milkfats (27–29). The manufacturers claims that these columns have a low bleed, and lower minimum and higher upper temperature limits. However, we suspect that the main reason for the selection of these columns is their intermediate polarity, which is helpful in the identification of complex FAME mixtures, since the more common unsaturated FAME of even chain length *X* elute before the next saturated even FAME [(*X* + 2*C*):0]; i.e., 18:3 elute before 20:0, 20:5n-3 before 22:0, and 22:5n-3 before 24:0 (30–32). The exception is 22:6n-3, which elutes either before (31,32) or between 24:0 and 24:1 (30,32). Odd chain

Abbreviations: Ag<sup>+</sup>-TLC, silver ion-thin layer chromatography; MUFA, monounsaturated fatty acids. The  $\Delta$  nomenclature for double bond position is used throughout the text except for identification of most methylene-interrupted PUFA in which the terminal n position is identified.

length FA cause minimal interference since their content in milk products is generally low. Although these properties of the CARBOWAX-type stationary phases are rather helpful, the lack of polarity to resolve closely related geometric and positional isomers of FAME is a marked disadvantage.

Systematic characterizations of the different regions of the GC separation of total milk FAME using the highly polar cyanoalkyl polysiloxane capillary columns have been intensively investigated for their resolution of *cis* and *trans* MUFA (16–23,33,34), CLA (4–7,23–26), 18:2/18:3 (19,35–39), and 18:3/20:1 (38) regions. On the other hand, a similar evaluation of the same regions of milk FAME has not been reported using a capillary column coated with a CARBOWAX-type stationary phase, such as SUPELLOWAX 10. Several reports have detailed the elution order of selected FAME on CARBOWAX-type stationary phases under isothermal conditions (31,32,40–42). Even though these values are not strictly comparable, they can be helpful to predict the possible structure of unknown FAME.

The present study was therefore undertaken to evaluate the resolution characteristics of a typical CARBOWAX-type column, such as the 60-m SUPELLOWAX 10 column (Supelco Inc., Bellefonte, PA). The FA investigated are those typically found in milkfat, such as short-chain FA, branched chain FA, MUFA, and long-chain PUFA, including the geometric and positional isomers of 18:1, 18:2, 18:3, and CLA. In addition, hydrogen and helium were evaluated as carrier gases. The complex FAME standard #463 available from Nu-Chek-Prep (Elysian, MN) was used as a GC standard because it provided the spectrum of FAME from 4:0 to 22:6n-3 generally found in milkfats. Furthermore, the separations on the 60-m SUPELLOWAX 10 column were compared to those on a 100-m CP Sil 88 column to determine if these two columns could possibly serve to complement each other for the analysis of milkfats.

## MATERIALS AND METHODS

Bovine milk was purchased locally or was available from cooperative studies with Arthur R. Hill and Brian W. McBride, University of Guelph, Guelph, Ontario, Canada. Methyl ester

standards, GC reference standard FAME mixture #463, and a mixture of four positional CLA isomers (#UC-59M) were purchased from Nu-Chek-Prep Inc. (Elysian, MN). Pure 9*c*,11*t*-CLA and 10*t*,12*c*-CLA were obtained from Matreya Inc. (Pleasant Gap, PA). *p*-Toluenesulfonic acid, sodium salt was purchased from Sigma-Aldrich Ltd. (St. Louis, MO). All chemicals and solvents were of analytical grade.

Two identical gas chromatographs (Model 5890 Series II, Hewlett-Packard, Palo Alto, CA) were used that were equipped with FID, split/splitless injection ports, autosamplers (Hewlett-Packard, Model 7673), and a Hewlett-Packard ChemStation software data system (Version A.07; Hewlett-Packard, Avondale, PA). The injector and detector temperatures were set at 250°C. One GC was fitted with a SUPELLOWAX 10 flexible fused column (60 m × 0.25 mm i.d. × 0.2 μm film thickness) kindly donated by Len Sidisky, Supelco Inc. (Bellefonte, PA). The other was a CP Sil 88 flexible fused column (100 m × 0.25 mm i.d. × 0.2 μm film thickness; manufactured by Chrompack, Middelburg, The Netherlands, and available from Varian Inc., Mississauga, Canada). Both hydrogen and helium were evaluated as the carrier gas with each column. The column inlet pressure was set at 175 kPa for both columns, resulting in carrier gas flow rates of about 1 mL/min. Samples were dissolved in either hexane or isooctane containing about 1 to 2 μg/μL of total FAME, and 1 μL (CP Sil 88 column) or 3 μL volumes (SUPELLOWAX 10 column) were injected. A splitless injection system was used that was flushed after 0.3 s. The typical temperature programs used for the analysis of total milk FAME were from 45 to 215°C for the CP Sil 88 column and from 65 to 240°C for the SUPELLOWAX 10 column. To maximize the separation of the *trans* MUFA, a low-temperature stepwise isothermal program was selected for the CP Sil 88 column to separate the 16:1 isomers at 120°C, the 18:1 isomers just after increasing the temperature to 150°C, the 20:1 isomers at 175°C, and the 22:1 and 24:1 isomers at 220°C. The temperature settings were chosen to elute the MUFA during each of the isothermal steps to help sharpen the peaks. A similar stepwise temperature program was designed for the SUPELLOWAX 10 column. Details on the different temperature programs are listed in Table 1. Low temperature isothermal GC conditions have

been used successfully in the separation of *cis* and *trans* 16:1, 18:1 and 20:1 isomers from dairy fats (16–23).

The reference standard FAME mixture #463 from Nu-Chek-Prep (Elysian, MN) was found to be very useful to evaluate both the column characteristics and the FA range present in milkfat. The standard #463 consisted of 53 FAME from 4:0 to 22:6n-3 including several geometric isomers, but it lacked CLA. For this reason, a 5:1 mixture was prepared consisting of the GC reference FAME standard (#463) and CLA (#UC-59M); the latter consisted of four positional CLA isomers (8*t*,10*c*-, 9*c*,11*t*-, 10*t*,12*c*-, and 11*c*,13*t*-CLA). This mixture was often used as the FAME reference in this study.

Total milk FAME, which includes both neutral and phospholipids, were prepared using Na methoxide as catalyst (21–24,43,44). Total milk FAME were fractionated by silver ion TLC (Ag<sup>+</sup>-TLC) into three bands, i.e., saturates, mono *trans*, and mono *cis* plus CLA, by using a combination of previously described procedures (17,19,45). Briefly, precoated silica gel G glass plates (20 × 20 cm × 0.25 mm thickness; Fisher Scientific, Ottawa, Canada) were washed with chloroform/methanol (1:1), air-dried, and heated for 1 h at 110°C. After cooling, the plates were dipped into a solution of 5% AgNO<sub>3</sub> in acetonitrile (wt/vol) for 20 min. Next the plates were air-dried, then activated at 110°C for 1 h before use. Total milk FAME in hexane were applied onto the TLC plates using a TLC streaker (Applied Science, State College, PA) at a concentration of 0.4 mg/cm, and developed in a solvent mixture of hexane/diethyl ether (90:10). Bands were visualized under UV light after spraying with 2',7'-dichlorofluorescein and then scraped off, and the FAME were recovered from the silica after addition of 1.5 mL methanol, 1.5 mL 1 N aqueous NaCl, and 2 mL of hexane. Hexane extraction was repeated once more, and the combined hexane layers were dried over anhydrous Na<sub>2</sub>SO<sub>4</sub>, reduced appropriately with a stream of nitrogen, and analyzed by GC.

Pure 9*c*,11*t*- and 10*t*,12*c*-CLA were isomerized in hexane at room temperature and room light for 1 h using a dilute solution of iodine in hexane as a catalyst (26). The mixture of four positional CLA isomers was also isomerized to yield all eight possible *cis/trans* CLA isomers. Methyl linoleate (9*c*,12*c*-18:2; 18:2*n*-6),  $\alpha$ -linolenate (9*c*,12*c*,15*c*-18:2; 18:3*n*-3) and  $\gamma$ -linolenate (6*c*,9*c*,12*c*-18:2; 18:3*n*-6) were isomerized in dioxane at 100°C using *p*-toluenesulfinic acid as catalyst (46; Adlof, R., personal communication). Briefly, an aqueous solution of *p*-toluenesulfinic acid, sodium salt (2 g in 12 mL of water) was acidified with 6 N H<sub>2</sub>SO<sub>4</sub>. The precipitate was washed and filtered twice with 15 mL cold water, dissolve in 15 mL diethyl ether, and precipitated by adding 10 mL of hexane. The white crystals were filtered and dried under vacuum. Separate solutions of *p*-toluenesulfinic acid (10 mg in 2 mL) and PUFA (20 mg in 20 mL) were prepared in dioxane. Isomerizations were carried out in 5-mL culture tubes fitted with Teflon-lined screw caps by adding 1 mg of the PUFA in 1 mL and one drop of the *p*-toluenesulfinic acid solutions in dioxane. The tubes were flushed with nitrogen, mixed, and heated at 100°C for 7, 15, or 30 min. The tubes were cooled,

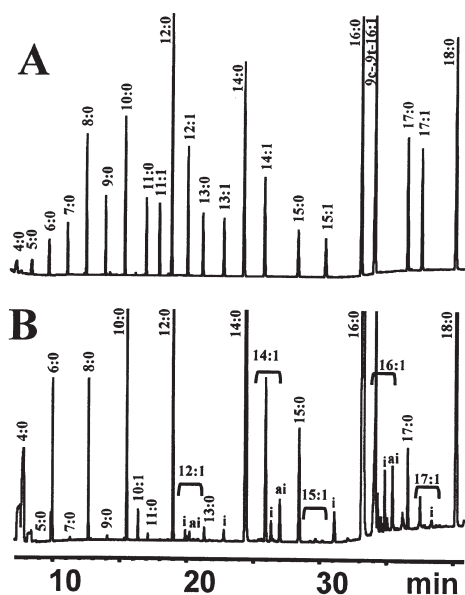

and 1 mL of 1 N NaOH and 2 mL of hexane were added and then mixed. The hexane layer was removed, dried over Na<sub>2</sub>SO<sub>4</sub>, and analyzed by GC. Various reaction times were selected to provide different ratios of the all-*trans* isomer, mixed *cis/trans* intermediates, and all-*cis* starting material for identification of isomers by GC. The isomerized product of 9*c*,12*c*-18:2 contained about equal proportions of the *cis/trans* intermediates, as were the three mono-*trans* and three di-*trans* intermediates from methyl  $\alpha$ - and  $\gamma$ -linolenate. To differentiate the individual *cis/trans* intermediates, the isomerized products of both 18:2 and 18:3 were separated by Ag<sup>+</sup>-TLC, and the *cis/trans* regions were split into an upper and a lower band, to obtain fractions containing unequal proportions of the *cis/trans* isomers that were used to differentiate the individual *cis/trans* isomers on the two GC columns.

## RESULTS AND DISCUSSION

Analyses of total milk FAME using the 60-m SUPELCOWAX 10 flexible fused-silica capillary column, and hydrogen as carrier gas, required a temperature program from 65°C to 240°C to elute all FAME from 4:0 to long-chain PUFA present in total milkfat in about 90 min (Table 1). Analyses of total milk FAME terminated at 190 to 225°C using the SUPELCOWAX 10 column, as is often the practice, would not allow for the complete elution of long-chain saturated FA and PUFA. The long-chain FAME will accumulate in the column and often cause interferences in subsequent analyses. The use of helium as carrier gas instead of hydrogen, increased the analysis time for total milk FAME from about 90 to 110 min using the same temperature program, but the relative elution order of the FAME was generally similar. No attempt was made to increase the temperature of this program to avoid altering the relative elution sequence of several FAME. Temperature effects on the relative elution patterns among isomers are well recognized; see effects of 18:3 isomers relative to 11*c*-20:1 (38), and mixtures of *trans*- and *cis*-18:1 isomers (17).

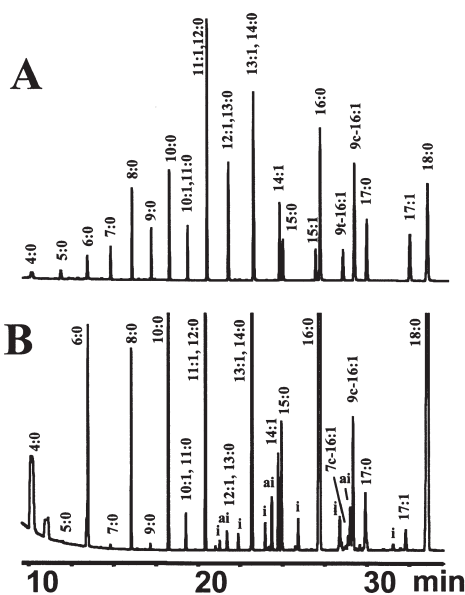

On the other hand, total milk FAME were resolved in about 90 min using a 100-m CP Sil 88 flexible fused-silica capillary column, hydrogen as the carrier gas, and a temperature program from 45 to 215°C (Table 1). Using helium as carrier gas increased the analysis time from about 90 to 110 min (Table 1), but the separations were not always as good as observed using hydrogen.

*The 4:0 to 18:0 FAME region.* Figure 1 shows a partial GC profile from 4:0 to 18:0 for the standard FAME mixture #463 (Fig. 1A) and total milk FAME (Fig. 1B) obtained by using the SUPELCOWAX 10 column and a typical temperature program (Table 1). The comparable GC regions for the standard FAME mixture #463 and for total milk FAME using the CP Sil 88 column are shown in Figures 2A and 2B, respectively. The SUPELCOWAX 10 column with its medium polarity effectively separated the saturated FAME from their MUFA analogs, whereas by using the CP Sil 88 column, the 10:1 to 13:1 FAME coeluted with their next higher saturated

**FIG. 1.** Partial gas chromatogram of the 4:0 to 18:0 FAME region using a 60-m SUPELCOWAX 10 capillary column, helium as carrier, and a typical temperature program from 65 to 240°C. FAME. For example, the presence of 10:1 in milk lipids was clearly identified using the SUPELCOWAX 10 column (Fig. 1B), but this FA coeluted with 11:0 when using the CP Sil 88 column (Fig. 2B). At a low sample load, 10:1 and 11:0 FAME occasionally could be separated on the CP Sil 88 column. The structure of 10:1 in dairy fat was previously identified as

**FIG. 2.** Partial gas chromatogram of the 4:0 to 18:0 FAME region using a 100-m CP Sil 88 capillary column, hydrogen as carrier, and a typical temperature program from 45 to 215°C. 10:1n-1 (47). For a more definitive identification of the saturated FA and MUFA of less than 15 carbons with the CP Sil 88 column, a prior fractionation of the *cis* and *trans* fractions by  $\text{Ag}^+$ -TLC was required. Analyzing milk FAME solutions in hexane or isooctane by GC resulted in a “chair-like” appearance of the 4:0 and 6:0 FAME peaks, as reported previously (48). A mass spectral analysis was performed, which showed that the entire chair-like peak consisted only of the FAME in question. Ulberth and Henniger (48) showed that the peak shapes of 4:0 and 6:0 could be improved by using polar solvents, such as diethyl ether or dichloromethane, but quantification was not affected. Replacing the hexane of milk FAME after methylation with a more polar solvent is not recommended since this would result in loss of 4:0 FAME.

On the SUPELCOWAX 10 column there was no separation of the geometric isomers of 14:1, 15:1 and 16:1, as evidenced by the coelution of 9*c*- and 9*t*-16:1 in both the standard #463 and milk FAME (Fig. 1). There was a partial separation of the positional isomers of MUFA on this column. On the other hand, there was a clear resolution of both the geometric (9*t*-16:1 before 9*c*-16:1; Fig. 2A) and positional MUFA isomers (7*c*-16:1 before 9*c*-16:1; Fig. 2B) on the CP Sil 88 column (Fig. 2).

Milkfats also contain branched-chain FA with odd-chain (iso and anteiso 13:0, 15:0, and 17:0) and even-chain lengths (iso 14:0, 16:0, and 18:0). The branched-chain FAME can easily be misidentified as MUFA isomers on both the SUPELCOWAX 10 and the CP Sil 88 columns from 12:1 to 17:1. The branched-chain iso and anteiso FAME eluted among the *cis* and *trans* MUFA isomers that elute over a wide range on both columns. Comparing the results from both columns may help to clarify a number of co-eluting peaks, but an unequivocal identification requires a prior  $\text{Ag}^+$ -TLC separation of the saturated, mono-*trans*, and mono-*cis* FAME. Overestimation of *trans*-16:1 content in human tissue as a consequence of including iso-17:0 led to the erroneous association of *trans*-16:1 intake and coronary heart disease (20).

In this study we restricted ourselves to the analysis of FAME. Isopropyl (45,49), butyl (47), and *tert*-butyl esters (50,51) have been used for the analysis of milk lipids. These derivatives have the benefit of not requiring correction factors to quantitate the area response of the FID of the short-chain FAME from 4:0 to 12:0 (45,52). Their use has been limited because the esterification solutions are not commercially available, the catalysts employed are strong acids that isomerize CLA, and the separation characteristics of all these esters have not been as well documented as FAME. A base-catalyzed method has just been reported that permits the preparation of longer-chain FA esters by using potassium *tert*-butoxide to prepare the potassium alkoxides of different alcohols (53).

*Resolution of the 18:1 cis and trans isomers and overlap with other FAME.* On the CP Sil 88 column there was a partial resolution of *trans*- and *cis*-18:1 isomers. The retention times for both the *cis*- and *trans*-18:1 isomers increased with increasing  $\Delta$  values. The *trans* 18:1 isomers 4*t*- to 11*t*-18:1

eluted before the *cis*- and remaining *trans*-18:1 isomers (Fig. 3A,B). Similar results were reported previously for a CP Sil 88 (16,17,23,54–56), SP-2560 (24,25,56), and SP-2340 (33) columns. The near-baseline resolution between 11*t*- and 12*t*-18:1 (see Fig. 3A) was used to quantify the total *trans*-18:1 content after separation of the *cis*- and *trans*-18:1 fractions by Ag<sup>+</sup>-TLC and analyses by GC using isothermal temperature operations (23). The isolated *trans*-18:1 fractions could then be completely resolved on the CP Sil 88 column starting at 120°C, except for 6*t*- to 8*t*-18:1 (19–23,34,49; see Fig. 3C). Attempts have been made to analyze all the 18:1 isomers at 165 to 190°C isothermal conditions (17,32,56), without the need for a prior Ag<sup>+</sup>-TLC fractionation. Under these isothermal conditions, many of the 18:1 *cis* and *trans* isomers could be identified, whereas other isomers were only partially resolved, or not resolved. The separations are dependent on temperature (32,56), and somewhat less so on the column make (56). Below 180°C there was a better resolution of the 4*t*- to 11*t*-18:1 region (17), but above 180°C this region was not as well resolved (56). The lack of separation of 4*t*- to 11*t*-18:1 may not pose a problem if only the total *trans* content is to be determined, but it is unsuitable for milk analyses in

which these 18:1 isomers are of biological interest. In fact, all of these isothermal operations are not practical for total milkfat analysis, since 4:0 to 10:0 FAME will elute with the solvent, and the low sample load required to give a good separation of the 18:1 isomers will make the detection and analysis of many minor long-chain PUFA difficult, if not impossible. A prior Ag<sup>+</sup>-TLC fractionation was mandatory. It should be noted that even when using a stepwise isothermal temperature condition starting at 120°C, there was no resolution of all the 18:1 isomers of total milk FAME. With this low-temperature stepwise isothermal condition, the pair 11*t*-18:1 and 6*c*- to 8*c*-18:1 were not resolved, nor were the pairs 9*c*- and 12*t*-18:1, 15*t*- and 12*c*-18:1, and 16*t* and 14*c*-18:1 (data not shown).

On the SUPELCOWAX 10 column there was no separation of the *cis*- and *trans*-18:1 isomers with either hydrogen or helium as carrier gas, and with a typical temperature program (Fig. 4A). The lack of separation was evident by comparing total milk FAME (Fig. 4A) to the isolated *trans*- (Fig. 4B) and *cis*-18:1 fractions (data not shown) isolated from total milk FAME by Ag<sup>+</sup>-TLC, and to the standard FAME mixture #463 (Fig. 4C). However, the elution sequence of the

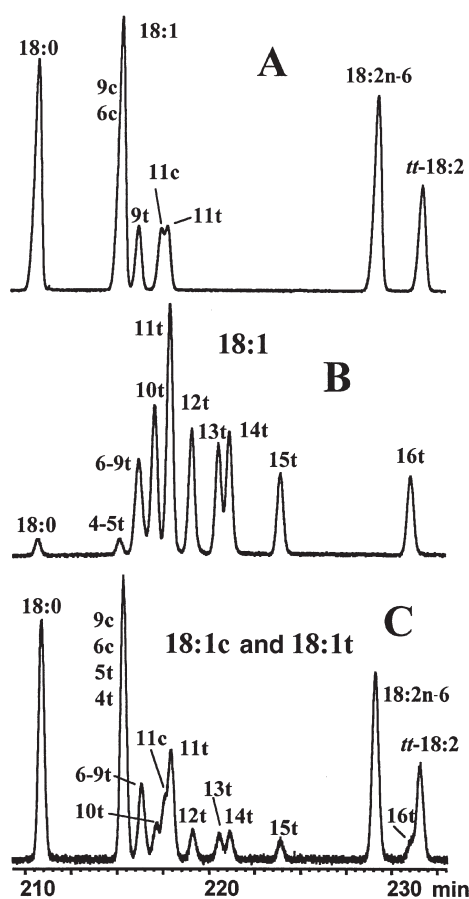

**FIG. 3.** Partial gas chromatogram of the 18:0 to 18:2n-6 FAME region using a 100-m CP Sil 88 capillary column, hydrogen as carrier, and a typical temperature program from 45 to 215°C. (A) Total milk FAME from cows fed a control diet; (B) *trans* fraction isolated from the same milkfat FAME as (A) using Ag<sup>+</sup>-TLC; (C) the same *trans* fraction as (B) but resolved using the stepwise isothermal GC program starting at 120°C.

**FIG. 4.** Partial gas chromatogram of the 18:0 to 18:2n-6 FAME region using a 60-m SUPELCOWAX 10 capillary column, hydrogen as carrier, and a typical temperature program from 65 to 240°C. (A) Total milk FAME from cows fed a control diet; (B) *trans* fraction isolated from the same milkfat FAME as (A) using Ag<sup>+</sup>-TLC; (C) FAME standard #463 from Nu-Chek-Prep (Elysian, MN).

individual *trans*- (Fig. 4B) and *cis*-18:1 positional isomers (data not shown) increased with increasing  $\Delta$ 18:1 values, similar to the results on the highly polar columns (Fig. 3B). With this temperature program, 4*t*- to 9*t*-18:1 and 13*t*- plus 14*t*-18:1 eluted as single peaks (Fig. 4B).

In an attempt to improve the resolution of the 18:1 region on the SUPELLOWAX 10 column, low-temperature stepwise isothermal separations were conducted starting at 130, 140, and 150°C; both 130 and 140°C provided good separations. The standard FAME mixture #463 (Fig. 5A) was compared to the *trans* fraction isolated from total milk FAME by Ag<sup>+</sup>-TLC (Fig. 5B). The identity of several *trans*-18:1 isomers and the relative elution of the *trans*-18:1 FA to that of other FA was established by co-injection of #463 with the total *trans* fraction isolated by Ag<sup>+</sup>-TLC (Fig. 5C). The results in Figure 5 were taken from a GC separation in which helium was the carrier gas, and the gas chromatograph was operated under a low-temperature stepwise isothermal condition; similar results were obtained using hydrogen as carrier gas.

**FIG. 5.** Partial gas chromatogram of the 18:0 to 9*t*,12*t*-18:2 FAME region using a 60 m SUPELLOWAX 10 capillary column, helium as carrier, and an isothermal temperature program of 130°C for 200 min followed by 75 min at 160°C. (A) FAME standard #463 from Nu-Chek-Prep (Elysian, MN); (B) *trans* fraction isolated from total milk FAME of cows fed a control diet; (C) FAME standard #463 from Nu-Chek-Prep spiked with the *trans* fraction in (B).

The results from this isothermal operation condition indicated that for a given positional isomer, *cis* eluted just before *trans* on the SUPELLOWAX 10 column (Fig. 5A), which was opposite to that observed using the highly polar capillary columns. Bannon *et al.* (40) also observed the reversed elution of geometric *cis*- and *trans*-18:1 isomer pairs, but noted that their relative elution changed depending on the isothermal column temperature and on the positional isomer. At lower temperatures (200°C), many *cis* isomers eluted just before *trans*, but slightly after *trans* at higher temperatures (240°C). However, the elution sequence of the *trans* 18:1 isomers was similar to that observed for the polar capillary columns, i.e., the retention times increased with increasing  $\Delta$ 18:1 values for both the SUPELLOWAX 10 (Fig. 5B) and CP Sil 88 columns (Fig. 3C). The separation distance between the geometric isomers was small. The *trans* isomer eluted about halfway to the next higher *cis* isomer. There were also differences in the resolution of the *trans* isomers between these two GC columns. On the SUPELLOWAX 10 column 4*t*- to 9*t*-18:1 coeluted, whereas 13*t*- and 14*t*-18:1 were resolved (Fig. 5B). This latter resolution appeared rather surprising since that pair of isomers provided such a challenge using the highly polar capillary columns (17–19). With the CP Sil 88 column, only 6*t*- to 8*t*-18:1 still remain unresolved at 120°C (Fig. 3C). The *trans*-18:1 isomers on the SUPELLOWAX 10 column were identified based on quantitative comparison of all the peaks in several *trans* fractions analyzed by both the SUPELLOWAX 10 and CP Sil 88 capillary columns. Analysis of the *cis* fraction of total milk FAME isolated by Ag<sup>+</sup>-TLC showed that the retention times of the *cis* isomers also increased with increased  $\Delta$  values (results not shown).

Of particular concern was the elution position of 16*t*-18:1 (a component generally found in milkfat) relative to the 18:2 FAME when using the SUPELLOWAX 10 column in either temperature operation. With a typical temperature program, 16*c*- and 16*t*-18:1 coeluted with 18:2*n*-6 (Fig. 4A,B), but during isothermal operation it eluted at the leading edge of 9*t*,12*t*-18:2 (Fig. 5C). By contrast, on the CP Sil 88 column, all *cis*- and *trans*-18:1 isomers eluted well before 18:2*n*-6 (Fig. 3A,B). Therefore, at best the SUPELLOWAX 10 column could provide an alternative total *cis*- plus *trans*-18:1 content by summing up all peaks from 18:0 up to and including 15*c*-/15*t*-18:1, except for 16*c*- plus 16*t*-18:1, since these geometric isomers eluted with (Fig. 4) or after 18:2*n*-6 (Fig. 5), depending on the temperature program chosen. By contrast, there was no overlap of 16*c*- and 16*t*-18:1 with 18:2*n*-6 during isothermal operations when using a 50-m SUPELLOWAX 10 column at either 200, 220, or 240°C (40).

*Separation of the synthetic geometric isomers of 18:2 and 18:3.* Many of the geometric and positional 18:2 and 18:3 isomers in milkfat have not been identified, and standards are not available. Therefore, we prepared all four geometric isomers of 9,12-18:2, and eight isomers of 9,12,15-18:3 and 6,9,12-18:3 from methyl linoleate (9*c*,12*c*-18:2; 18:2*n*-6),  $\alpha$ -linolenate (9*c*,12*c*,15*c*-18:3; 18:3*n*-3) and  $\gamma$ -linolenate (6*c*,9*c*,12*c*-18:3;

18:3n-6), respectively (see Materials and Methods). The elution sequences of the geometric isomers of these three FA using highly polar GC columns were previously characterized (19,35–39). On the other hand, the elution order of all these geometric isomers, and their possible interference with other FAME on the SUPELCOWAX 10 column, have received limited attention (36,39,40,42). To help in the identification, several reaction times were selected to obtain different ratios of the all-*trans*, to *cis/trans* intermediates, to all-*cis* starting material. To further distinguish the *cis/trans* intermediates, the isomerized mixtures were separated by  $\text{Ag}^+$ -TLC, and the *cis/trans* bands were divided into an upper and lower part in order to obtain *cis/trans* fractions of unequal distribution of the different mono-*trans* or di-*trans* isomers that could then be used to identify and compare the isomers on the two GC columns. The methylene-interrupted geometric isomers of all three PUFA were separated on the CP Sil 88 (Fig. 6) and the SUPELCOWAX 10 column (Fig. 7), using the typical temperature programs. The FAME mixture #463 was spiked with the CLA mixture and served as reference standard.

In general, all the isomerized products eluted before the all-*cis* isomer on the CP Sil 88 column (Fig. 6), but most of these isomers eluted after the all-*cis* isomer on SUPELCOWAX 10 column (Fig. 7). The elution order of the four 9,12-18:2 FAME isomers on the CP Sil 88 column was  $tt < ct < tc < cc$  (Fig. 6), and these isomers all eluted after the *cis*- and *trans*-18:1 isomers, except 15*c*- and 16*c*-18:1. On the SUPELCOWAX 10 column, the elution order was  $cc < tt < ct <$

**FIG. 7.** Partial gas chromatogram of the 18:0 to 20:1 FAME region using a 60-m SUPELCOWAX 10 capillary column, hydrogen as carrier, and a typical temperature program from 65 to 240°C. Lower panel: FAME standard #463 spiked with the CLA mixture #UC-59M, both from Nu-Chek-Prep; the isomeric mixture of linoleic (9,12-18:2),  $\alpha$ -linolenic (9,12,15-18:3), and  $\gamma$ -linolenic acid (6,9,12-18:3) are placed above the lower chromatogram in the appropriate elution positions.

(Fig. 7), but some isomers were not well resolved. When the column was operated isothermally, all four 18:2 isomers were resolved, but the relative elution sequence changed to  $cc < ct < tt < tc$  (Table 2). Based on the separation of the 9,12-18:2 isomers on the SUPELCOWAX 10 column several peaks eluting after 18:2n-6 in milk FAME could be accounted for, but none before 18:2n-6. Without standards, or GC/MS analyses as their 4,4-dimethyloxazoline derivatives, it remains unclear what FAME eluted between the 15*c*-/15*t*-18:1 peak and the 18:2n-6 of total milk FAME on this column and temperature program (Fig. 4A). We suspect that some non-methylene-interrupted 18:2 isomers eluted in this region, such as 9-*trans*,15-*cis*-18:2, a non-methylene-interrupted 18:2 isomer identified in milkfats (37). The elution order of the four 9,12-18:2 FAME [or 20:2 FAME (42)] isomers on polar (33–38,40,42) and CARBOWAX-type columns (36,40,42) is generally in agreement with our present findings. Occasionally, the *ct* isomers on the CARBOWAX-type columns may be reversed (42), which could be related to column type, column length, temperature program (40), and/or chain length.

The elution order of the isomers of 9,12,15-18:3 and 6,9,12-18:3 FAME on the CP Sil 88 column was generally  $tft < di\text{-}trans < mono\text{-}trans < ccc$  (Fig. 6). On the other hand, the elution order on the SUPELCOWAX 10 column was generally  $ccc < tft < di\text{-}trans < mono\text{-}trans$ , with minor exceptions (Fig. 7). The elution sequence within the di-*trans* ( $ctt < tct < ttc$ ) and mono-*trans* ( $cct < ctc < tcc$ ) 18:3 isomers was consistent and the same for both 18:3 FAME on both columns (Figs. 6 and 7). Among the di-*trans* isomers of both 18:3 FAME and both columns, there was little separation between *ctt* and *tct* (except for 9,12,15-18:3 on the SUPELCOWAX 10 column), while *ttc* was well resolved. All the mono-*trans* isomers of both 18:3 FAME were resolved on both columns,

**FIG. 6.** Partial gas chromatogram of the 18:0 to 20:2n-6 FAME region using a 100-m CP Sil 88 capillary column, hydrogen as carrier, and a typical temperature program from 45 to 215°C. Lower panel: FAME standard #463 spiked with the CLA mixture #UC-59M, both from Nu-Chek-Prep (Elysian, MN); the isomeric mixture of linoleic (9,12-18:2),  $\alpha$ -linolenic (9,12,15-18:3) and  $\gamma$ -linolenic acid (6,9,12-18:3) are placed above the lower chromatogram in the appropriate elution positions.

<sup>a</sup>The results of long stepwise isothermal GC programs are given only if the elution order was different.

<sup>b</sup>Temperature programs for the CP Sil 88 and the SUPELCOWAX 10 columns are given in Table 1.

<sup>c</sup>The stepwise isothermal temperature programs used for the CP Sil 88 and the SUPELCOWAX 10 columns are given in Table 1.  $c$ , *cis*;  $t$ , *trans*;  $c/t$  could be either  $c, t$  or  $t, c$ ; isomers that were not resolved are given in parentheses.

except for *ctc*- and *tcc*-9,12,15-18:3 on the SUPELCOWAX 10 column. Overlaps of the mono- and di-*trans* 18:3 FAME are shown in Figures 6 and 7 and listed in Table 2. The elution order of the eight 18:3 FAME [or 20:3 FAME (42)] isomers on polar (33,36,39,42) and CARBOWAX-type columns (39,42) is generally in agreement with our present findings. However, the relative elution sequence of the individual isomers, or their assignments, on the CARBOWAX-type columns may be reversed (39). Again this may be due to differences in column type, column length, temperature program used, and/or chain length. We based our geometric assignments on comparison with the demonstrated elution order on the polar GC columns (36).

On the CP Sil 88 column, many of the isomers from methyl  $\alpha$ -linolenate (9,12,15-18:3) eluted in the region of the 20:1 isomers present in milkfats (Fig. 6). Wolff (38) showed that the elution order of 11*c*-20:1 relative to the 9,12,15-18:3 isomers could be reversed when using these polar columns by decreasing the column temperature from 180°C to 155°C. However, this would not be a solution for the analysis of milkfats, since these fats contain many positional *cis*- and *trans*-20:1 isomers (23,34), several of which would overlap with the isomers of 9,12,15-18:3. By contrast, the SUPELCOWAX 10 column resulted in a marked separation of the isomers of 9,12,15-18:3 and 20:1 (Fig. 7), thus making this column particularly suited for their identification. Furthermore, on the SUPELCOWAX 10 column the 9,12,15-18:3 isomers eluted before the CLA region (Fig. 7). To identify the 9,12,15-18:3 and 20:1 isomers definitively using the CP Sil 88 column, the isolated Ag<sup>+</sup>-TLC fractions need to be examined.

Under isothermal conditions all eight isomers of 9,12,15-18:3 were separated on either the SUPELCOWAX 10 (Fig. 8A) or the CP Sil 88 columns (Fig. 8B), although the isomers were better resolved using the latter column. The elution order of a few mono-*trans* to di-*trans* 9,12,15-18:3 isomers changed slightly using the isothermal conditions compared to using the typical temperature program, but the order within these two groups was not affected (Fig. 8).

The resolution of all eight isomers of 6,9,12-18:3 (18:3n-6) under isothermal conditions was more successful using the SUPELCOWAX 10 column (Fig. 9A) than the CP Sil 88 column (Fig. 9B). However, several isomers remained unresolved when using either one of the GC columns, and the elution order of a number of mono-*trans* to di-*trans* 6,9,12-18:3 isomers changed relative to the separation using temperature programming. A complete list of the elution order of all the 18:2 and 18:3 isomers on both columns is summarized in Table 2.

*Separation of CLA isomers and overlap with other FAME.* On a CP Sil 88 column, all the CLA isomers eluted in a GC region between 18:3n-3 and 20:2n-6 (Fig. 10A, B). This region was shown to be rather free of interfering FAME except for 21:0, a minor component present in total milk FAME except in the sphingomyelin fraction (25,57), and trace amounts of some 20:2 isomers that were present at an order of magnitude less than the minor CLA isomers (57).

The elution order of the CLA isomers using the CP Sil 88 column was:  $c/t < c, c < t, t$  (Fig. 10B), as determined previously (7,23-26). The polar column completely resolved 10*t*, 12*c*- and 11*c*, 13*t*-CLA, but 9*c*, 11*t*- and 8*t*, 10*c*- were unresolved. All four

**FIG. 8.** Separation of isomerized methyl  $\alpha$ -linolenate (9,12,15-18:3) at 100°C for 7 min. Upper panel: a 60-m SUPELCOWAX 10 capillary column was operated isothermally at 130°C for 200 min followed by 75 min at 160°C. Lower panel: a 100-m CP Sil 88 capillary column operated isothermally at 120°C for 200 min followed by 70 min at 150°C. Hydrogen was used as carrier gas for both separations.

*cis,cis*-CLA isomers resolved in the elution order of 8,10-, 9,11-, 10,12-, and 11,13-CLA, whereas the *trans,trans*-CLA isomers gave rise to two peaks consisting of 11,13-CLA followed by a mixture of the remaining three positional isomers (7,23–26). A total separation of all the CLA isomers could not be achieved by GC, even by performing the analysis isothermally at 125°C and using the 100-m CP Sil 88 column (23; Fig. 10C).

On the SUPELCOWAX 10 column, the CLA isomers eluted after 18:3n-3 and stretched into the 20:1 isomer region when using helium or hydrogen as carrier gas and a typical

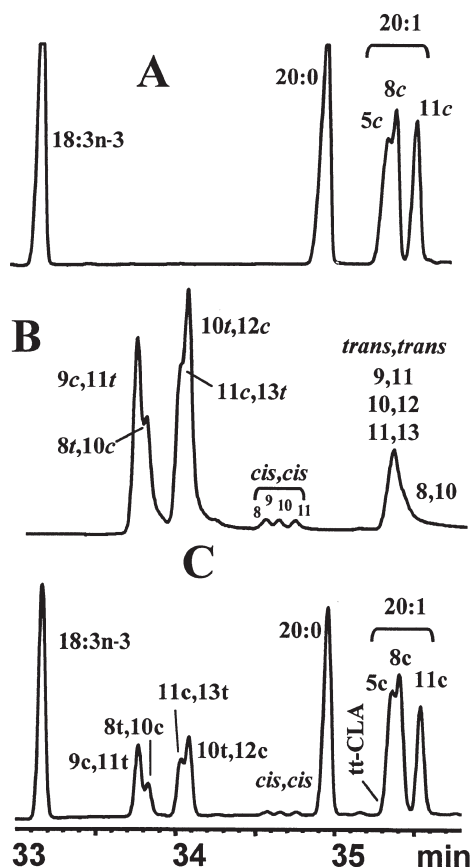

**FIG. 9.** Separation of isomerized methyl  $\gamma$ -linolenate (6,9,12-18:3) at 100°C for 15 min. Upper panel: a 60-m SUPELCOWAX 10 capillary column was operated isothermally at 130°C for 200 min followed by 75 min at 160°C. Lower panel: a 100-m CP Sil 88 capillary column operated isothermally at 120°C for 200 min followed by 70 min at 150°C. Hydrogen was used as carrier gas for both separations.

**FIG. 10.** Partial gas chromatogram of the 20:0 to 20:2n-6 FAME region using a 100-m CP Sil 88 capillary column, hydrogen as carrier, and a typical temperature program from 45 to 215°C. (A) FAME standard #463 from Nu-Chek-Prep (Elysian, MN); (B) CLA mixture #UC-59M from Nu-Chek-Prep; (C) CLA mixture #UC-59M from Nu-Chek-Prep separated isothermally at 120°C for 200 min followed by 70 min at 150°C.

temperature program (Fig. 11). However, the elution order was the same as on the CP Sil 88 column, *c/t* < *c,c* < *t,t* (Fig. 11B). There was only a limited resolution of the four positional *cis/trans*-CLA isomers; both 9*c*,11*t*- and 8*t*,10*c*-CLA, and 10*t*,12*c*- and 11*c*,13*t*-CLA were only partially separated (Fig. 11B). All four *cis,cis*-CLA isomers separated and eluted just before 20:0. The *trans,trans*-CLA isomers eluted as one broad peak with 8*t*,10*c*-CLA concentrated in the trailing edge, and all the *trans,trans*-CLA isomers eluted together with the 20:1 isomers (Fig. 11A, B). This was confirmed by co-injection of #463 and the CLA isomers (Fig. 11C).

The elution of the *trans,trans*-CLA isomers in the 20:1 region on the SUPELCOWAX 10 column was of particular concern, since milkfats are known to contain many 20:1 isomers and small amounts of *trans,trans*-CLA isomers (7,23,24,58). This interference is rather critical when evaluating methylation procedures. We showed that acid catalysts, but not base catalysts, increased the *trans,trans*-CLA content and produced methoxy artifacts (24). Therefore, the CP Sil

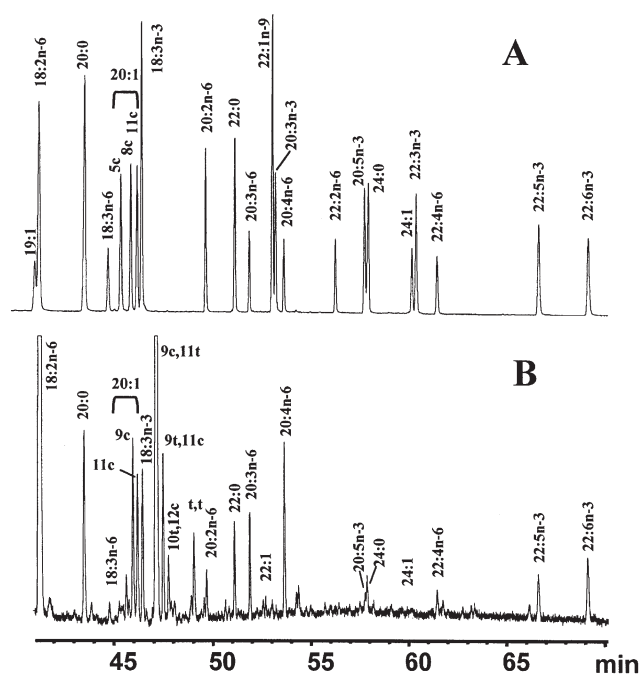

**FIG. 11.** Partial gas chromatogram of the 18:3n-3 to 20:1 FAME region using a 60-m SUPELCOWAX 10 capillary column, hydrogen as carrier, and a typical temperature program from 65 to 240°C. (A) FAME standard #463 from Nu-Chek-Prep (Elysian, MN); (B) CLA mixture #UC-59M from Nu-Chek-Prep; (C) FAME standard #463 spiked with the CLA mixture #UC-59M, both from Nu-Chek-Prep.

88 column, or similar polar columns (SP-2560 or BPX-70), are preferred since there is no interference in the *trans,trans*-CLA region. In two recent reports the methylation of CLA was re-evaluated (59,60), and, unfortunately, in both cases a SUPELCOWAX 10 column was used.

**The polyunsaturated FAME region.** Milkfats contain small amounts of C<sub>20</sub> and C<sub>22</sub> PUFA, which are identified by using both the CP Sil 88 (Fig. 12B) and the SUPELCOWAX 10 (Fig. 13B) columns. The analyses of the PUFA are important considering present-day efforts to increase the n-3 PUFA content in milkfats for health reasons through feeding cow diets containing fish meal (61), fish oil (62), or algae (50). The more prominent of the PUFA present in milkfats are: 20:3n-6, 20:4n-6 (arachidonic acid), 20:5n-3 (EPA), 22:4n-6, and 22:5n-3. DHA (22:6n-3) is present only in trace amounts in milkfat unless the cow's diet contained some fish or algal products (50,61,62); Figure 12B represents a milk from cows fed a fish meal diet, and Figure 13B a milk from cows fed a control diet.

All the long-chain C<sub>20</sub> and C<sub>22</sub> PUFA were well resolved

**FIG. 12.** Partial gas chromatogram of the 18:2n-6 to 22:6n-3 FAME region using a 100-m CP Sil 88 capillary column, hydrogen as carrier, and a typical temperature program from 45 to 215°C. (A) FAME standard #463 from Nu-Chek-Prep (Elysian, MN); (B) total milk FAME from cows fed a diet containing fish meal.

on the CP Sil 88 column by using the typical temperature program (Fig. 12). By programming the temperature to 215°C, all the long-chain PUFA eluted in about 70 min. However, a note of caution is appropriate. There may be slight differences between GC columns from the same supplier even when using identical GC conditions. In our case we observed that the elution order of 20:5n-3 and 24:0 was opposite on two different 100-m CP Sil 88 columns, even though all other parameters were kept the same. Closely eluting peaks would be most susceptible to minor column differences and to known column temperature effects that alter the relative elution sequence (32).

The SUPELCOWAX 10 column was programmed to 240°C to elute the long-chain PUFA that would otherwise accumulate in the column and cause interferences in subsequent GC analyses. The separation of the long-chain PUFA on the 60-m SUPELCOWAX 10 column provided a greater challenge, since 20:5n-3 coeluted with 22:0, 22:5n-3 with 24:0, and 22:6n-3 eluted after 24:1n-9 (Fig. 13A). In a previous study using a 30-m SUPELCOWAX 10 column, we showed that 20:5n-3 eluted before 22:0, 22:5n-3 before 24:0, and 22:6n-3 eluted between 24:0 and 24:1n-9 (30). This increase in the relative retention time of the long-chain PUFA relative to the saturated FAME was attributed to the longer column length. All the coeluting pairs of FAME could be resolved on the 60 m SUPELCOWAX 10 column by isothermal GC operations at 140°C (data not shown), but routine 6 h analyses are not practical.

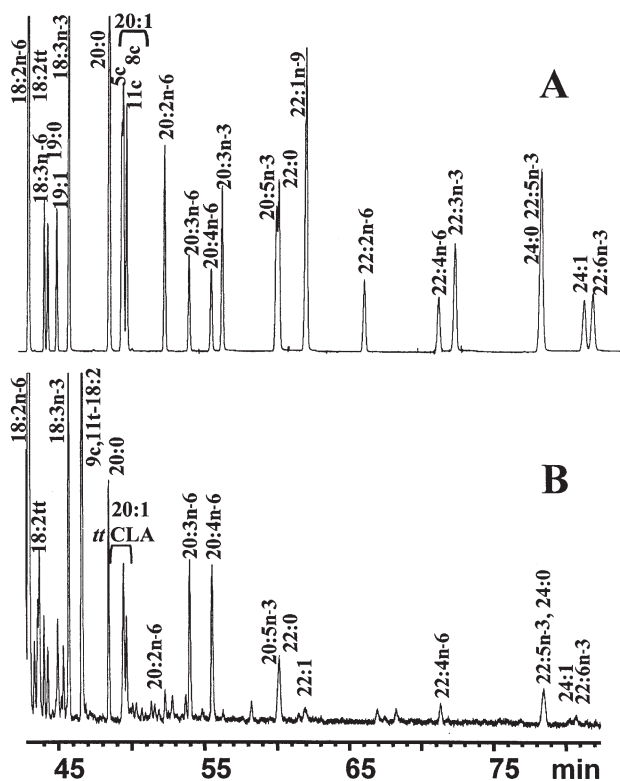

FIG. 13. Partial gas chromatogram of the 18:2n-6 to 22:6n-3 FAME region using a 60-m SUPELCOWAX 10 capillary column, hydrogen as carrier, and a typical temperature program from 65 to 240°C. (A) FAME standard #463 from Nu-Chek-Prep (Elysian, MN); (B) total milk FAME from cows fed a control diet.

In the present study the separation of the different FA regions of milkfats were evaluated using a 60-m SUPELCOWAX 10 column, and compare to that of a 100-m CP Sil 88 column whose separations are better characterized. The SUPELCOWAX 10 column was shown to give a better resolution of the short-chain saturated FA and their MUFA analogs, and it gave a complete separation of the 18:3n-3 and 20:1 isomers. The SUPELCOWAX 10 column provided an alternative approach to obtain the total 18:1 content, and to separate the isomers of 18:2n-6 and 18:3n-3. This column could also serve to confirm the identity of individual FA by comparison of the two columns. On the other hand, the CP Sil 88 column provided a better resolution of the CLA isomers, MUFA, the isolated *trans* and *cis* isomer fractions, the PUFA, and the 18:2n-6 and 18:3n-3 isomers. The lack of separation of the short-chain saturated FA and MUFA, and the overlap of the 9,12,15-18:3 and 20:1 isomers can be overcome by analyzing the isolated Ag<sup>+</sup>-TLC fractions. In conclusion it would appear that a 100-m highly polar capillary GC column is mandatory for the analysis of milk lipids, whereas the 60-m SUPELCOWAX 10 capillary column at best can serve as a complementary GC column mainly because of its intermediate polarity that often provides different separation characteristics.

**ABSTRACT:** Previous randomized clinical trials suggest that supplementation of the human infant diet with up to 0.35% DHA may benefit visual development. The aim of the current study was to assess the impact of including arachidonic acid (AA) and a higher level of DHA in the postnatal monkey diet on visual development. Infant rhesus monkeys were fed either a control diet (2.0%  $\alpha$ -linolenic acid as the sole n-3 FA) or a supplemented diet (1.0% DHA and 1.0% AA) from birth. Visual evoked potential acuity was measured at 3 mon of age. Rod and cone function were assessed in terms of parameters describing phototransduction. Electroretinogram (ERG) amplitudes and implicit times were recorded over a wide intensity range ( $-2.2$  to  $4.0$  log scot td-sec) and assessed in terms of intensity response functions. Plasma DHA and AA were significantly increased ( $P < 0.001$ ) in the diet-supplemented monkeys compared with the control monkeys. There was an approximately equal effect of diet for the rod phototransduction parameters, sensitivity, and capacitance but in the opposite directions. Diet-supplemented monkeys had significantly shorter b-wave implicit times at low retinal illuminances ( $< -0.6$  log scot td-sec). There were no significant effects of diet for visual acuity or the other 23 ERG parameters measured. The results suggest that supplementation of the infant monkey diet with 1.0% DHA and 1.0% AA neither harms nor provides substantial benefit to the development of visual acuity or retinal function in the first four postnatal months.

Paper no. L9080 in *Lipids* 37, 839–848 (September 2002).

Randomized clinical trials in both term and preterm human infants have sought to determine whether a supply of preformed DHA is required in the neonatal diet to achieve normal retinal and visual acuity development (1–14). Differences in visual acuity that have persisted beyond 3 mon of age between infants fed a DHA-supplemented formula and infants

fed a formula containing  $\alpha$ -linolenic acid (ALA) as the sole n-3 FA, have been reported in some (2,4,8,10,13,14) but not all studies (3,5–7,9,11,12). Although there are numerous differences between study protocols, which may account for the varying results, one important factor may be the level of DHA used in the supplemented formulas. Over the range of DHA supplementation used (0.1 to 0.36% of total FA), differences in visual acuity have generally been reported when the level of DHA in the supplemented formula was at the upper end of the range. The level of DHA used in supplemented formula milks has typically been based on the level of DHA found in breast milk from the region of study. The majority of these human trials have originated in North America, with additional trials from Australia and Europe. In the United States and Australia, the level of DHA reported in breast milk is typically less than 0.35% of total FA, which is at the lower end of breast milk DHA concentrations reported from around the world (15,16). Much higher DHA levels in breast milk have been reported in Nigeria (0.93%), among the Canadian Inuit (1.4%), and in Asian countries such as Japan, China, Malaysia, and India (0.7–0.9%) (15,16).

Whether supplementing human infant formulas with DHA levels greater than 0.35% would provide any additional benefit to the development of visual acuity or retinal function during development is unknown. Alternatively, experiments in guinea pigs suggest that very high levels of n-3 long-chain PUFA (LCPUFA) may be deleterious to the development of retinal function. Guinea pigs fed a fish oil-based diet containing high concentrations of DHA (2.8%) and EPA (4.3%) had significant reductions in electroretinogram (ERG) a- and b-wave amplitudes in comparison with guinea pigs fed a diet containing a high level of ALA (8%) as the only n-3 FA (17). Although the levels of DHA and EPA used in the guinea pig were very high, the results highlight the importance of determining whether supplementation of infant formulas with higher levels of LCPUFA than those used in previous human studies could affect retinal development.

There has been little investigation into the effect of altering dietary n-3 FA levels on the function of the cone photoreceptors. Birch *et al.* (1) reported alterations in rod- but not cone-isolated ERG at 6 wk postnatal age in preterm infants fed a corn oil-based formula (0.5% ALA) compared with

<sup>1</sup>Current address: Department of Neuroscience, Oregon National Primate Research Center, Oregon Health and Science University, Beaverton, OR 97006. This study was conducted at the Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Rockville, MD 20852.

Abbreviations: AA, 20:4n-6, arachidonic acid; ALA, 18:3n-3,  $\alpha$ -linolenic acid; ERG, electroretinogram; LCPUFA, long-chain PUFA; OP, oscillatory potentials; P2, postreceptor response; P3, phototransduction response; PCA, postconceptual age; VEP, visual evoked potential.

infants fed a fish oil-supplemented formula (0.35% DHA, 0.65% EPA). Recent studies suggest that altered activation and inactivation of the phototransduction cascade within the rod photoreceptors appear to account for the altered rod-driven ERG in n-3-deficient animals (18,19). However, the structure and function of cones is quite different from that of rods, and further investigation is required to determine whether the two classes of photoreceptors have different susceptibility to the level of DHA in the diet during early development.

The rhesus monkey is an ideal model for the long-term study of the effect of altering the n-3 content of the diet on retinal function. Only higher primates, including humans, apes, and old-world monkeys, have a fovea that enables high visual acuity and three classes of cones that enable trichromatic vision (20). Other similarities between the structure, function, and development of the retina of macaque monkeys, such as the rhesus, and the human are well described (20–24). The aim of the current study was to assess visual acuity and the function of both the rod and cone photoreceptors in infant monkeys fed a diet containing a substantially higher level of DHA (1.0% of total FA) and AA (1.0%) than those used in previous randomized human infant studies.

## MATERIALS AND METHODS

**Animals and diets.** All experiments were reviewed and approved by the Institutional Animal Care and Use Committee of the National Institute on Alcohol Abuse and Alcoholism (NIAAA) of the National Institutes of Health (NIH; Rockville, MD). Twenty rhesus monkeys (*Macaca mulatta*) were separated from their mothers at birth and randomized to receive a control ( $N = 10$ ) or LCPUFA-supplemented formula ( $N = 10$ ). The control formula milk consisted of 6 scoops of powdered primate infant milk (Primalac; Bio-Serv, Frenchtown, NJ) mixed in 2100 mL of water and combined with 1300 mL of human infant formula (Similac; Ross Products, Columbus, OH). The supplemented formula milk was created by adding 1 mL of DHA/AA (46% DHASCO and 54% ARASCO; Martek Biosciences, Columbia, MD) to the control formula to provide approximately 100  $\mu\text{g}/\text{mL}$  of DHA and AA in the final solution. Supplemented formula was mixed as needed, at least once per day. The FA contents of both diets are listed in Table 1. Each diet group had an identical number of males and females and approximately equal mean birth weights. For the first 30 d, infants were provided with 50 mL of fresh formula every 2 h from 8 A.M. to 8 P.M. Infants were provided with another 50-mL bottle overnight. At 30 d of age, infants were switched to receiving 200 mL of formula twice daily until 4 mon of age. From 2 wk of age, infants were provided with 2–4 chow blocks (see Table 1 for FA analysis) every few days. Water was provided *ad libitum*.

**FA analysis.** A blood sample was taken at 2, 4, 8, 12, and 16 wk of age and plasma was analyzed for FA content using GC. The method of FA analysis has been described in detail elsewhere (25).

<sup>a</sup>Values represent the mean  $\pm$  SD based on 14 independent measurements. ND, not detected.

**Visual acuity measurement.** Visual acuity was measured at 3 mon of age using visual evoked potentials (VEP). VEP were recorded from two channels while the infant monkey watched a grating stimulus on a high-resolution grayscale monitor. During each recording session, an assistant held the alert monkey and the monkey's attention was attracted to the screen using a variety of small, bright, and jangly toys. If the monkey became distracted or looked away, the stimulus was paused and restarted when the monkey was again looking at the screen. Two active electrodes, one for each channel, were positioned on the scalp over the foveal projection areas, located 10 mm superior and 20 mm posterior to the aural canals. The positioning of the active electrodes was based on mapping of the central visual field to the skull of a rhesus monkey using single-cell recordings (Lamme, V., personal communication). The ground electrode (Cz) was positioned over the midline between the aural canals, and the reference electrode (Fz 10-20 system) was positioned 3 cm anterior to the ground. All electrodes were 6 mm Ag/AgCl cups held in place with collodion glue. A conductive gel was inserted into the cup of each electrode to ensure low contact impedance with the skin. The differential VEP signal was fed to isolation amplifiers (Bio Amp; ADInstruments, Sydney, Australia) amplified by a factor of 20,000 and filtered between 0.3 and 50 Hz ( $-3$  dB points). The amplified signal was sampled at 300 Hz and digitized via an eight-bit analog-to-digital (A/D) converter and stored on a computer disc for subsequent off-line analysis.

**VEP acuity recording stimuli.** Steady-state VEP were recorded in response to a square wave grating contrast reversed 12 times per second. The VEP was recorded for

11 spatial frequencies between 1 and 12 cycles per degree (cyc/deg), excluding 11 cyc/deg, in 1-cyc/deg increments. The VEP was recorded for a 3-s presentation of each spatial frequency. Each spatial frequency was presented between 3 and 12 times depending on the alertness and cooperation of the monkey. The test distance was 100 cm for all spatial frequencies with the exception of 5 and 9 cyc/deg, where the test distance was 75 cm. At a viewing distance of 100 cm, the stimulus grating formed a  $15 \times 19^\circ$  field. Gratings had a contrast of 80% and screen luminance was  $35 \text{ cd/m}^2$ .

*VEP acuity analysis.* A discrete Fourier transform (DFT) was performed over each 3-s record to obtain the amplitude and phase of the signal at 12 Hz, the reversal rate of the grating stimulus. For each spatial frequency, mean VEP amplitude was calculated from the vectorial average of the recorded responses. The 95% confidence interval of the vectorial mean was calculated using  $T_{\text{circ}}^2$  (26). Visual acuity was derived by fitting a linear regression through those points that met the following criteria: (i) Amplitude increased monotonically with decreasing spatial frequency, and (ii)  $T_{\text{circ}}^2$  did not cross the zero amplitude axis. Visual acuity in cyc/deg was determined from the extrapolation of the regression line to the spatial frequency axis (27). As visual acuity is distributed normally on a logarithmic scale, each acuity was converted to the log of minimal angle of resolution (logMAR) for comparison between groups.

*ERG recording protocol: animal preparation.* Monkeys were anesthetized with intramuscular injections of ketamine (15 mg/kg and then 7.5 mg/kg at 30- to 50-min intervals as required), xylazine (1 mg/kg and then 0.5 mg/kg), and atropine sulfate (0.2 mg/kg) at induction only. Rectal temperature was maintained between  $36.5$  and  $39.5^\circ\text{C}$  with water-circulated heating pads placed beneath and on top of the monkey. Heart rate was monitored by electrocardiogram and respiratory function monitored by pulse oximetry. Pupils were dilated with phenylephrine (2.5%) and tropicamide (1%), and the monkey was dark-adapted for 30 min before the beginning of ERG recording. Full-field ERG were recorded from an infant monkey bipolar Burian–Allen contact lens electrode (Hansen Ophthalmic Development Lab, Iowa City, IA). After the cornea had been anesthetized with proparacaine (0.5%), the Burian–Allen electrode was inserted into the eye with a drop of methylcellulose (1%) placed on the contact lens. A needle electrode inserted subcutaneously in the middle of the back served as ground.

*Conventional ERG: stimulus and recording.* Flash stimulation was provided by a PS22 stimulator (Astro-Med/Grass, West Warwick, RI). Rod-isolated ERG were recorded scotopically to a series of short-wavelength flashes (“blue,” Wratten 47B;  $\lambda_{\text{max}} = 449 \text{ nm}$ , half-bandwidth = 47 nm) that produced retinal illuminances from  $-2.3$  to  $1.5 \text{ log scot td-sec}$  in 0.2-log steps. Cone ERG were obtained from 30-Hz white (1.1 log scot td-sec) flicker presented photopically (background = 2.7 log phot td). Eight or 16 (intensity <  $-1.2 \text{ log scot td-sec}$ ) responses were averaged at each intensity. ERG

were amplified by a gain of 20,000 or 100,000 (intensity <  $-1.2 \text{ log scot td-sec}$ ) and filtered ( $-3 \text{ dB}$  points at 1 and 1000 Hz) before being digitized at 1 kHz using an eight-bit A/D converter and stored on computer for off-line analysis.

*Conventional ERG analysis.* Amplitude and implicit time measurements were made for the a- and b-wave responses at each retinal illuminance and for the 30-Hz response. ERG a-wave and b-wave amplitudes were plotted against log retinal illuminance, and the data of each were fitted to the Naka–Rushton function (28,29):

$$V = V_{\text{max}} \frac{I^n}{I^n + K^n} \quad [1]$$

where  $V$  is amplitude ( $\mu\text{V}$ ) and  $I$  is retinal illuminance (scot td-sec). The derived parameters are  $V_{\text{max}}$ , maximum response ( $\mu\text{V}$ );  $K$ , log retinal illuminance that elicits half of  $V_{\text{max}}$  (log scot td-sec); and  $n$ , slope of the curve (dimensionless). The Naka–Rushton function was fitted to the data by regression using a linearized form of Equation 1.

*Isolation of photoreceptor function and postreceptor response.* Conventional ERG analysis cannot identify particular retinal mechanisms underlying the reported changes in ERG a- and b-waves because of the nonspecificity of the cellular origins of these ERG components when generated by low to moderate flash intensities (30). In Granit’s classic analysis (31), the ERG a-wave and b-wave are formed by the addition of two cellular responses, the P3 response from the photoreceptors and P2, a single postreceptor response. A quantitative model (P3 model) that describes the G-protein phototransduction cascade in single photoreceptors has been described (32). The same P3 model, or slight variants of it, has been used to fit the leading edges of ERG a-waves recorded to high-intensity flashes (e.g., Refs. 33 and 34). The a-wave recorded to a high-intensity flash represents the massed response of the photoreceptors, and the P3 model thereby provides an *in vivo* method of quantifying the phototransduction process. The isolated P2 response can be obtained by subtracting the P3 model from the ERG (35). The P2 response provides a more accurate assessment of bipolar cell function than does the ERG b-wave for a wide range of flash intensities (35).

*P3 and P2 stimulus and recording.* Flash stimulation was provided by a high-intensity camera flash (283; Vivitar, Newbury Park, CA). The ERG was recorded to a series of high-intensity white flashes (1.8 to 4.1 log scot td-sec) presented scotopically and then photopically (background = 2.7 log phot td). Rod-isolated ERG were obtained by subtracting the cone-isolated photopic ERG from the scotopic ERG at each flash intensity (36). Two responses were averaged at each intensity with interflash intervals ranging from 15 to 60 s. ERG were amplified by a gain of 20,000, filtered ( $-3 \text{ dB}$  points at 1 and 1000 Hz), and then digitized at 5 kHz.

*P3 analysis.* The following P3 model (37) was used to fit the leading edges of both the rod- and cone-isolated ERG a-waves derived from the high-intensity white flashes:

$$P3(i, t) \equiv \left( \left\{ 1 - \exp \left[ -i \cdot S \cdot (t - t_d)^2 \right] \right\} \otimes \left[ \exp(-t/\tau) \cdot 1/\tau \right] \right) \cdot R_{\max P3} \quad t_d > t \quad [2]$$

where  $\otimes$  represents the convolution integral and P3 is the leading edge of the a-wave at time  $t$  s, in response to a flash with a retinal illuminance of  $i$  scot td-sec. The parameters derived to fit the model were:  $S$ , the sensitivity parameter that scales retinal illuminance [(scot td-sec) $^{-1}$  s $^{-2}$ ];  $t_d$ , the delay due to the filter and finite duration of the flash (s);  $\tau$ , the time constant due to membrane capacitances; and  $R_{\max P3}$ , the maximum photoreceptor response ( $\mu$ V) (37,38). For cone ERG a-waves, retinal illuminances were measured in photopic trolands.

The parameters of the P3 model for the two classes of photoreceptors were determined by fitting Equation 2 simultaneously to the leading edges of the rod- and cone-isolated ERG a-waves (ensemble analysis). All analyses were performed with NONLIN (39), which uses a modified Gauss–Newton nonlinear least-squares algorithm (40), with subroutines specifying the P3 model written by the authors. The numerical solution of Equation 2 for discrete data (37) was used during the fitting process.

**P2 analysis.** The isolated P2 responses were derived by subtracting the P3 responses from the rod-isolated ERG. The amplitudes of the P2 responses were also plotted against log retinal illuminance, and the data were fitted to the Naka–Rushton function of Equation 1.

**Oscillatory potentials (OP).** The method for isolating the OP from the rod-isolated ERG recorded to high-intensity flash (4.1 log scot td-sec) has been described in detail previously (41). Briefly, before isolating the OP, the a-wave, as determined by Equation 2, was digitally subtracted from the rod-isolated ERG. The OP were then isolated using a digital, anticausal, Chebyshev type II filter [–3 dB points at 100 and 300 Hz, >30 dB attenuation in the stopbands (<75 and >400 Hz)]. The advantage of the anticausal filter is that the filtered response will have zero phase shift over the pass band.

**Statistical methods.** One of the authors (B.J.) was blinded to both the diets and groupings of monkeys during recording and analysis of all visual acuity and ERG results. Data were checked for normality and homogeneity of variance using either the Shapiro–Wilk test (for <50 observations, i.e., number of monkeys  $\times$  number of parameter measurements used in comparison) or the Kolmogorov–Smirnov test with a Lillifores correction (for number of observations >50). Implicit time data were compared using a two-way repeated-measures ANOVA. All other parameters were compared using a  $t$ -test for independent samples.

## RESULTS

**FA.** The results of plasma FA analysis at 4 mon of age are shown in Table 2. The diet-supplemented group had a slightly lower level of nonessential FA, but there were no significant differences in the amounts of saturated FA between the two

groups. As expected, DHA and AA were significantly elevated in the LCPUFA-supplemented group, but there was no significant difference in the total amount of polyunsaturates. Figure 1 shows plasma DHA and AA levels from 2 to 16 wk of age. Plasma DHA increased in the supplemented monkeys over the first two postnatal months before reaching a plateau of 4.4%, which was maintained until 4 mon of age. In the control group, plasma DHA fell postnatally to reach a low of 0.88% of total FA at 2 mon of age. At 3 and 4 mon of age, plasma DHA had increased to 1.08% of total FA, a 20% increase over the 2-mon low, probably reflecting that infants had started to consume some chow that contained 0.2% DHA. Plasma AA increased rapidly in diet-supplemented monkeys and remained high over the first four postnatal months but remained relatively constant in the control monkeys.

**Visual acuity.** Figure 2 shows the plot of 12-Hz amplitude and  $T_{\text{circ}}^2$  for each spatial frequency for a monkey fed the supplemented formula. When  $T_{\text{circ}}^2$  does not include the zero amplitude axis (solid circles), it can be said with 95% confidence that the signal is significantly different from zero. Visual acuity was determined from the extrapolation of the regression line to the spatial frequency axis (acuity = 11.3 cyc/deg = 0.24 logMAR). There was no significant difference ( $P$  = 0.74) in visual acuity between the supplemented (logMAR  $\pm$  SD = 0.31  $\pm$  0.08) and control monkeys (0.30  $\pm$  0.07). VEP acuity could not be measured in three monkeys from the control

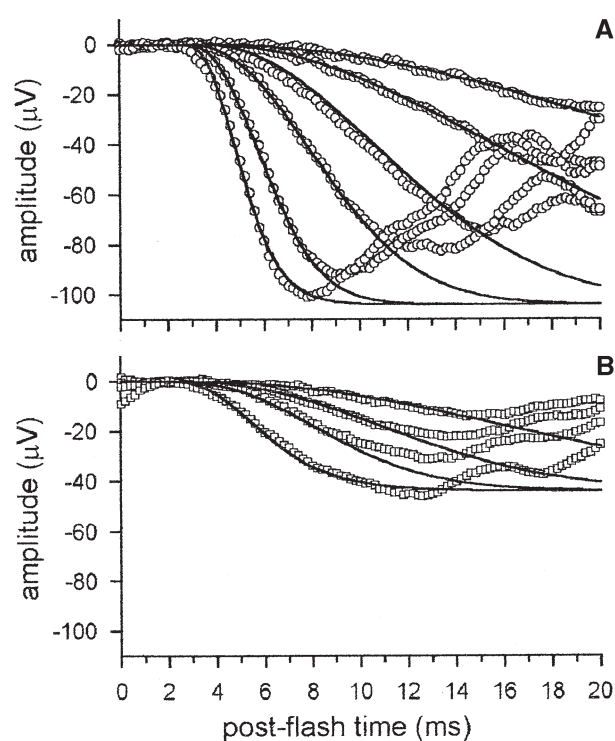

**FIG. 1.** (A) Plasma DHA expressed as a percentage of total FA plotted against postnatal age for the supplemented (solid circles) and control (open circles) monkeys. Error bars represent one SD. (B) Plasma arachidonic acid as a function of postnatal age (symbols are the same as for graph A).

group who became aggressive or uncooperative during testing. Detailed neurobehavioral assessment did not reveal any significant differences in temperament between the two dietary groups (42).

**Electroretinography.** Figure 3 shows representative rod (A) and cone-isolated ERG (B) from a DHA diet-supplemented monkey at 4 mon of age. The solid lines show the

**FIG. 2.** Visual evoked potential (VEP) amplitude at 12 Hz plotted against spatial frequency for a diet-supplemented monkey. Error bars indicate the 95% confidence interval of the vectorial mean calculated from  $T_{\text{circ}}^{-2}$ . The linear regression is applied to those points (solid circles) that lie on the linear portion of the graph and for which  $T_{\text{circ}}^{-2}$  does not cross the zero volt axis. A visual acuity of 11.3 cyc/deg was obtained from the extrapolation of the linear regression line to the spatial frequency axis.

**FIG. 3.** (A) Rod-isolated ERG (open circles) from a diet-supplemented monkey recorded to achromatic flashes that produced the retinal illuminances between 1.8 to 4.0 log scot td-sec (top to bottom). The dashed lines show the ensemble fit of Equation 2 (see text) to the leading edges of the rod-isolated ERG a-waves. The derived rod phototransduction parameters were  $S = 11.15$  (scot td-sec) $^{-1}$  s $^{-2}$ ,  $R_{\text{maxP3}} = 104$  μV,  $t_d = 2.65$  ms, and  $\tau = 0.89$  ms. (B) Cone-isolated ERG (open squares) from the same monkeys recorded to achromatic flashes that produced retinal illuminances of 1.8 to 3.3 log phot td-sec (top to bottom). The derived cone phototransduction parameters were  $S = 31.6$  (scot td-sec) $^{-1}$  s $^{-2}$ ,  $R_{\text{maxP3}} = 41.7$  μV,  $t_d = 1.79$  ms, and  $\tau = 1.92$  ms.

ensemble fits of Equation 2 to the leading edges of each set of a-waves.

Diet-supplemented monkeys had a significantly lower value of Rod $\tau$  ( $P < 0.05$ ) compared with the control monkeys, but there were no other significant differences in the rod phototransduction parameters between the two diet groups (Table 3). The parameter Rod $\tau$  represents the membrane capacitance time constant, and a lower value indicates that a shorter time is required for a change in the photocurrent following a flash. Supplemented monkeys also had a lower value for the rod phototransduction sensitivity parameter, Rod $S$ , compared with the control monkeys although the difference did not reach statistical significance ( $P = 0.07$ ). A lower value of Rod $S$  is considered poorer as it represents the gain of the phototransduction cascade (34).

There was no effect of diet for a-wave implicit times ( $P = 0.98$ ; Fig. 4A) or for any of the parameters describing rod or postphotoreceptor function derived from the fit of the Naka–Rushton function to the a-wave, b-wave, or P2 amplitudes (Table 3). There was also no effect of diet for the overall variation in b-wave implicit time with retinal illuminance ( $P = 0.2$ ; Fig. 4B). However, as can be seen in Figure 4B,

lower, diet-supplemented monkeys had significantly shorter b-wave implicit times in comparison with those of the control monkeys ( $P < 0.007$ ).

There was no effect of diet for any of the parameters describing either cone phototransduction or cone flicker (Table 4). There was also no effect of diet for the implicit times ( $P = 0.98$ ) or amplitudes ( $P = 0.4$ ) of the OP (Table 5).

Calculations were done to determine if the present study had sufficient power to identify real differences between the two diet groups if they existed. The magnitude of a meaningful effect was estimated for each parameter as follows: a 0.5-octave difference in acuity, a 50% difference in amplitude parameters, an octave difference for log  $K$  parameters, a value of 0.2 for  $n$  parameters, 0.5 ms for phototransduction  $t_d$  parameters, and 2.0 ms for 30 Hz latency. For visual acuity and the majority of ERG parameters, there was at least 80% power to detect a meaningful difference between the diet groups if a true effect was present (Tables 3, 4, and 5).

## DISCUSSION

Of the 25 parameters measured, there was a significant effect of diet for only two parameters, Rod $\tau$  and b-wave implicit times at low retinal illuminances. The reason for the decrease in ERG b-wave implicit times in the diet-supplemented monkeys below retinal illuminances of  $-0.6$  log scot td-sec may be attributable to the presence of another ERG component whose presence becomes more influential on the b-wave at low retinal illuminances. The scotopic threshold response, a small, late corneal negative potential that originates from the

proximal retina (43), has a significant influence on b-wave amplitude for retinal illuminances below  $-1.5$  log scot td-sec in human adults (44). One possibility is that the decrease in b-wave implicit time could be due to an alteration in the amplitude and/or timing of the scotopic threshold response in the diet-supplemented monkeys. The OP also originate from the proximal retina (45), although from different sources than the scotopic threshold response. There were no alterations in OP in the present study, but in Birch's preterm human study (1), the only ERG abnormality to persist in the low-ALA infants at 57 wk postconceptional age (PCA) was a delay in the OP. One possibility is that the function of the proximal retina is more selectively or more greatly affected than the distal retina by alteration of the n-3 content of the diet. Delayed b-wave implicit times have also been reported in n-3-deficient monkeys compared with monkeys fed a high-ALA diet (19,46). However, the implicit time delay observed in the n-3-deficient monkeys occurred at substantially higher retinal illuminances ( $>1000$  brighter) than in the current experiment, suggesting a different retinal mechanism or different retinal origin.

The effect of diet on Rod $_S$  was approximately equal to that for Rod $_{\tau}$  but the effect was in the opposite direction. There was a significant negative correlation between Rod $_S$  and Rod $_{\tau}$  ( $r = -0.82$ ,  $P < 0.006$ ), suggesting that both parameters may not be necessary to provide adequate fits of the leading edges of the ERG a-waves. A form of the P3 model (Eq. 2), without the capacitance term, has also been used to fit the leading edge of the ERG a-wave (33,34). Therefore, Equation 2 was refitted to the ensemble of the ERG a-waves for each monkey, with the capacitance term held constant at the mean value for all monkeys (Rod $_{\tau} = 0.94$ ), and only  $R_{\max P3}$ ,  $S$ , and  $t_d$  were allowed to vary. Under these conditions, Rod $_S$  was significantly lower ( $P < 0.046$ ) in the diet-supplemented monkeys [mean  $\pm$  SD =  $5.8 \pm 1.2$  (scot td-sec) $^{-1}$  s $^{-2}$ ] compared with the control monkeys [ $7.5 \pm 1.9$  (scot td-sec) $^{-1}$  s $^{-2}$ ]. This result is inconsistent with a recent study in which rod phototransduction was not altered in adult monkeys maintained on an n-3-deficient diet compared with monkeys fed a control diet similar to the one used here (19). Given the overall number of parameters measured, it would be predicted that one parameter would reach statistical significance of  $P < 0.05$  by chance alone, making it possible that the differences in rod phototransduction between the two diet groups is coincidental.

The level of DHA (1.0%) included in the supplemented monkey infant formula was 2.8 to 10 times higher than that used in LCPUFA-supplemented formulas in randomized studies involving human infants. The results of the current study suggest that the higher level of DHA is neither beneficial nor harmful to the development of visual acuity or retinal function in infant primates. The deleterious effect of fish oil supplementation on retinal function in the guinea pig may be related to the very high levels of DHA (2.8%) and/or EPA (4.3%) included in the diet (17). High levels of EPA, in particular, may inhibit the accretion of n-6 LCPUFA such as AA into membrane phospholipids (47). Both EPA and AA are the

precursors of families of eicosanoids and prostaglandins that are thought to mediate a number of biological functions within the retina, including vascular responses, modulation of protein kinase C, and the modulation of calcium influx in retinal membranes (48,49). The altered retinal function in the fish oil-supplemented guinea pigs may be related to the levels of EPA and/or AA accreted to the retina.

No retinal FA compositional data are available for the infant monkeys described here, as they are part on an ongoing long-term study. However, it is of interest to compare the ERG results of the present study with previous studies that have similarly measured retinal function in monkey and human infants following manipulation of dietary LCPUFA intake. Direct comparison of human and monkey retinal function at the same chronological age is difficult given their differing rates of retinal development. However, it is clear that the rod outer segments continue to develop in both humans and monkeys at least through the first 4 mon of life (23,50). Birch *et al.* (1) reported reduced maximal amplitude, decreased retinal sensitivity, and elevated rod thresholds in preterm infants (born at 28–33 wk gestation) fed a formula containing just 0.5% ALA compared with infants fed a DHA (0.35%)-supplemented formula when ERG were recorded at 36 wk PCA. In a recent study by the same group, only retinal sensitivity was reduced at 6 wk postnatal age in term infants fed a formula with 1.5% ALA compared with infants fed a supplemented formula containing 0.35% DHA (10). The two major differences between the preterm and term studies were the levels of ALA used and the gestational ages at birth and testing. In humans the bulk of *in utero* DHA and AA accretion to the retina occurs during the last trimester of pregnancy (51). Therefore, the preterm infants likely had lower retinal LCPUFA concentrations at birth than did the term infants. A reduction in retinal LCPUFA at birth may make infants born prematurely more sensitive to the amount and type of n-3 FA such as DHA in the postnatal diet. Similar comparisons may be made across monkey studies. Neuringer *et al.* (46) reported that infants born to mothers fed an n-3-deficient diet from 2 mon before conception and throughout pregnancy (165 d) had only half the level of DHA in the retina as infants born to mothers fed a high-ALA diet. In the present study, all mothers received a normal chow diet containing LCPUFA and, as a result, all infants received the full complement of maternal FA. One of the clear differences between the present study and those involving preterm infants (1) and n-3-deficient monkeys (46) is that the monkeys in the present study were likely born with the full complement of retinal LCPUFA. The difference in results between the current monkey study and the study involving human infants born at term (10) may relate to species differences or may be related to the earlier age at ERG testing in the human infants.

Another important difference between the monkey and human infant studies is the postnatal fall in plasma DHA in the various groups. In preterm infants fed the low-ALA (0.5%) corn oil diet, plasma DHA fell to 0.6% at 36 wk PCA and to 0.4% by 57 wk PCA (52). Similarly, plasma DHA fell

to less than 0.4% DHA by 3 mon of age in n-3-deficient monkeys (46). For both the preterm infants fed the corn oil diet and the n-3-deficient monkeys, the ERG was altered at some time during the first postnatal months. In contrast, plasma DHA fell to 0.95% at 57 wk PCA in term infants fed the control formula that supplied 1.5% ALA as the sole n-3 FA, and in the present study plasma DHA did not fall below 0.88%. How the changes in plasma DHA affected retinal FA in either the human infants or monkeys in the current study is not easily determined. The levels of DHA in erythrocytes and plasma do not correlate well with retinal DHA levels (53,54), and substantial amounts of DHA can be found in the retina of n-3-deficient animals in the presence of extremely low erythrocyte or plasma DHA (55,56). The disparity between retinal and plasma DHA levels is likely due to the efficiency of the retina at sequestering DHA from circulating blood supply (57–59) and the ability of the retina to conserve DHA even during periods of prolonged dietary n-3 deficiency (60–62). However, the n-3-deficient monkey study and the preterm human study appear to suggest that the combination of lowered retinal DHA at birth and large fall in plasma DHA postnatally are associated with marked alterations in the ERG in the first postnatal months. The human infant studies also suggest that the level of plasma DHA alone does not predict ERG changes as the ERG normalized by 57 wk PCA despite the continued fall in plasma DHA. By comparison, the same human and monkey studies also suggest that plasma levels of up to 3.2–3.5% DHA in humans (1,10,52) and 4.4–8.8% in monkeys (current study, Ref. 19) are not deleterious to retinal function.

Comparison of the acuity results from the present study with human nutrition studies requires an adjustment for chronological age. The rates of acuity development are quite different between humans and monkeys as the rhesus monkey has a more developed fovea at birth, which also develops more rapidly during infancy than the human fovea. As a result, each week of visual acuity development in the macaque monkey is comparable to about 1 mon in the human (63). The results from the present study suggest no benefit from a diet with 1.0% DHA and 1.0% AA to acuity in the monkey at a developmental age equivalent to 12 mon in the human. Our acuity result is consistent with several studies in human infants (3,5–7,11,12) but conflicts with others (2,4,8,10,14).

The other independent variable to be considered is which AA was supplied in a concentration approximately equal to DHA in the supplemented formula. The AA was added because a reduction in growth has been reported in preterm human infants fed an EPA/DHA-supplemented formula that caused a significant reduction in the plasma AA level (64). Pigs fed a formula supplemented with approximately equal amounts of DHA and AA have significantly higher retinal DHA but not AA compared with pigs fed a control diet with moderate levels of the EFA but no LCPUFA (65–67). Given that the diet-supplemented monkeys received approximately equal amounts of DHA and AA, it is speculated that the retinal AA levels may not have been elevated in the diet-supple-

mented group compared with the control group of monkeys. If this is the case, then the level of retinal AA likely did not contribute to the results described here.

## ACKNOWLEDGMENTS

The authors acknowledge the assistance of Dr. Mark Haines, Alan Dodson, and Margro Purple for additional assistance with anesthesia and animal handling. B.G.J. was funded by a Ph.D. scholarship from Meadow Lea Foods Australia (Sydney, Australia) and a Flinders University Overseas Research Trip Award (Adelaide, Australia). Martek Biosciences Corporation (Columbia, MD) supplied the formula supplement and provided financial support.

# FA Composition of Plasma, Red Blood Cell, and Liver Phospholipids of Newborn Piglets Fed *trans* Isomers of $\alpha$ -Linolenic Acid

Niyazi Acar, Jean-Michel Chardigny\*, Olivier Berdeaux, Simone Almanza, and Jean-Louis Sébédio

INRA, Unité de Nutrition Lipidique, 21065 Dijon Cedex, France

**ABSTRACT:** The effects of dietary *cis* and *trans*  $\alpha$ -linolenic acid (18:3n-3) on the FA composition of plasma, red blood cell, and liver phospholipids were studied in newborn piglets. Animals were fed for 14 d with one of three diets: a control diet (group A) containing *cis* 18:3n-3 at a level of 2.0% of total FA, a diet (group B) in which a part of the 18:3n-3 acid was isomerized (1.3% of *cis* 18:3n-3 and 0.7% of *trans* 18:3n-3), or a diet (group C) with 2.0% *cis* 18:3n-3 and 0.7% *trans* 18:3n-3. Feeding animals with diets containing *trans* 18:3n-3 resulted in the presence of *trans* isomers of 18:3n-3, *trans* isomers of EPA, and *trans* isomers of DHA in phospholipids; however, the level of total *trans* n-3 PUFA in tissues was less than 0.3% of total tissue FA. In group B, the reduction of dietary amounts of *cis* 18:3n-3 was associated with a decrease in individual and total *cis* n-3 PUFA. In contrast, in group C there was no decrease in tissue n-3 PUFA despite the increased dietary level of *trans* 18:3n-3. These results suggest that the isomerization of a part of dietary n-3 PUFA, leading to the reduction of their levels in the diet, could induce a decrease in n-3 PUFA in phospholipids. The physiological effects of *trans* PUFA are not known and should be considered in future studies.

Paper no. L9034 in *Lipids* 37, 849–852 (September 2002).

Lipids provide the major portion of food energy for infants fed breast milk or formula (1). They represent about 90% of all energy retained in the growing tissues of a full-term baby during the first 6 mon of life (2). Moreover, organ growth and development are closely related to dietary supply, metabolism, and physiological effects of EFA, including the precursors linoleic and  $\alpha$ -linolenic acids as well as their long-chain polyunsaturated metabolites with 20 or 22 carbon atoms (3). However, unusual lipids such as geometric isomers of unsaturated FA in *trans* configuration can be found in the diet of the newborn. Today, reliable quantitative data are available on the human milk and infant formula contents of *trans* FA (4–6).

Studies on rodents have shown that, after dietary intake, *trans* isomers of  $\alpha$ -linolenic acid can be elongated and desaturated into *trans* isomers of EPA (20:5n-3) and DHA (22:6n-3) (7,8). Since it is well known that *trans* FA can impair the

biosynthesis of PUFA (9,10), their effects on the metabolism and the bioavailability of EFA in the newborn is questioned.

The present study examines the FA composition of plasma, red blood cell (RBC), and liver phospholipids of newborn piglets receiving formulas differing in their levels of *trans* isomers of  $\alpha$ -linolenic acid. Three different formulas were studied: a control formula providing  $\alpha$ -linolenic acid in its natural isomeric form (diet A); a formula in which part of the  $\alpha$ -linolenic acid is given as geometrical isomers (diet B), and a formula that contains the same quantity of *cis*  $\alpha$ -linolenic acid as the control group and the same level of *trans*  $\alpha$ -linolenic acid as group B (diet C). This study was conducted for a relatively short time (14 d) in newborn piglets in order to examine acute effects in a rapidly growing animal fed only with the formulas studied.

## MATERIALS AND METHODS

**Animals and diets.** All animal use and care were conducted according to the French legislation (authorization no. 7676 delivered to I. Louveau). Pietrain piglets of term gestation were obtained from INRA–UMR Veau et Porc (Saint-Gilles, France). They were taken within 24 h after birth so that they still had passive immunity and were assigned randomly to one of the three groups ( $n = 6$ /group). Piglets were housed individually in a room controlled for temperature (28°C). Animals were bottle-fed every 2 h (from 7 to 21 h) until 15 d after birth with three standard formulas (in g/L: casein, 31; lactoserum, 21; lactose, 46; fat, 71; standard vitamin and mineral mix, 8). The formulas differed only in their contents of *cis* and *trans* isomers of  $\alpha$ -linolenic acid (Table 1). The three formulas were prepared by blédina sa (Steenvoorde, France) using oil mixtures provided by Lesieur (Coudekerque-Branche, France). Briefly, bleached canola oil was used after deodorization for 52.5 h at 205°C under 3 mbar (11) in order to provide *trans*  $\alpha$ -linolenic acid. In order to balance the *trans* linoleic acid levels in the mixtures, isomerized sunflower oil (270°C, 18 h, under nitrogen) was added (up to 0.2% of total oil).

**Tissue collection.** After 14 d of diet, piglets were killed by electrocution. The liver was removed and total blood was collected using EDTA as anticoagulant. Total blood was immediately centrifuged at  $1860 \times g$  at 4°C in order to separate plasma and RBC. The RBC pellet was then washed three times

<sup>a</sup>Values expressed as percentage of total FAME.

with an isotonic saline solution. All samples were stored at  $-80^{\circ}\text{C}$  until lipid analysis.

**Lipid analysis.** Total lipids from liver and RBC were extracted according to the procedure of Folch *et al.* (12), whereas plasma total lipids were extracted by the method of Moilanen and Nikkari (13). Total phospholipids were separated from neutral lipids by the method of Juanéda and Rocquelin (14) and were transesterified with sodium methylate according to Christie *et al.* (15). The FAME were analyzed on a Hewlett-Packard (Palo Alto, CA) 5890 series II gas chromatograph equipped with a split/splitless injector, an FID, and a BPX 70-silica capillary column (120 m  $\times$  0.25 mm i.d.; film thickness 0.25  $\mu\text{m}$ ; SGE, Melbourne, Australia). The injector and the detector were maintained at 250 and 280 $^{\circ}\text{C}$ , respectively. Hydrogen was used as carrier gas (inlet pressure 300 kPa). The oven temperature was operated at 60 $^{\circ}\text{C}$  for 1 min, then increased from 60 to 175 $^{\circ}\text{C}$  at a rate of 20 $^{\circ}\text{C}/\text{min}$  and left at this point until the end of the analysis. FAME were identified by comparison with commercial or synthetic standards and quantified using the Diamir software (JMBS Inc., Portage, MI).

**Statistical analysis.** Results are expressed as means  $\pm$  SD. Statistical analyses were performed using the Statistical Analysis System (SAS Institute, Cary, NC). The ANOVA procedure

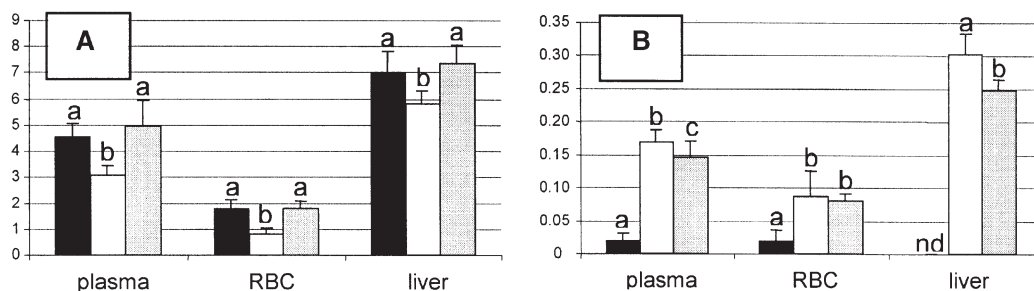

and the Newman-Keuls test were used between each group. *P* values of less than 0.05 were considered as significant.

## RESULTS AND DISCUSSION

The aim of this work was to study the effects of the partial isomerization of dietary  $\alpha$ -linolenic acid on the FA composition of plasma, RBC, and liver phospholipids in newborn piglets. This animal model constitutes an interesting model because of its resemblance to humans in terms of perinatal development. In our diets, isomerized sunflower oil (270 $^{\circ}\text{C}$  for 18 h) may have produced cyclic FA, polymers, hydroperoxides, and breakdown products of hydroperoxides. But since isomerized sunflower oil represented 200 g in the 100 kg of mix at the most, the relative proportions of these compounds may be insignificant compared to *trans* 18:3n-3.

Changing the levels of dietary *cis* and *trans* isomers of  $\alpha$ -linolenic acid did not result in any changes in saturated FA, monounsaturated FA, and n-6 PUFA (Table 2). Since the levels of arachidonic acid were unchanged, it seems that *trans*  $\alpha$ -linolenic did not compete with linoleic acid as suggested by Blond *et al.* (9). Only the levels of *cis* and *trans* n-3 PUFA were affected by the dietary treatments. Trace amounts of *trans* n-3 PUFA were detected in animals of the control group, whereas no *trans* FA were present in the control diet. This observation may be due to *trans* FA intake by the sow during the gestation period.

Isomerizing a part of the  $\alpha$ -linolenic acid in the diet (group B) resulted in the presence of *trans* isomers of  $\alpha$ -linolenic acid in all studied tissues. However, its incorporation into plasma, RBC, and liver phospholipids was low since it represented 0.2% of total FA at the most. The desaturation and elongation products of *trans*  $\alpha$ -linolenic acid, *trans* EPA, and *trans* DHA were also detected. Then, the amounts of total *trans* n-3 PUFA were significantly increased compared with the control group (Fig. 1B). However, the level of total *trans* PUFA was far lower than the level of total *cis* PUFA. On the other hand, the levels of *cis* n-3 PUFA were significantly decreased (Fig. 1A). This was particularly true for DHA, which was reduced by 20% in liver, by 40% in plasma, and by 60% in RBC phospholipids.

**FIG. 1.** Levels of total *cis* n-3 FA (A) and *trans* n-3 FA (B) (% of total FA) in plasma, red blood cell (RBC), and liver phospholipids of piglets fed 2.0% of *cis* 18:3n-3 (group A: solid bars), 1.3% of *cis* 18:3n-3 plus 0.7% of *trans* 18:3n-3 (group B: open bars), or 2.0% *cis* 18:3n-3 plus 0.7% *trans* 18:3n-3 (group C: gray bars); values are mean  $\pm$  SD; nd: not detected; a,b,c: significantly different between groups ( $P < 0.05$ ).

<sup>a</sup>Values are means, SD values are in parentheses.

<sup>b</sup>Trace, <0.01% of total FA; for a given tissue, values in columns followed by different letters are significantly different (P < 0.05).

To summarize, isomerizing a part of the dietary *cis*  $\alpha$ -linolenic acid into *trans*  $\alpha$ -linolenic reduced the amounts of *cis*  $\alpha$ -linolenic acid in the diet and led to a decrease in the levels of *cis* n-3 PUFA in phospholipids from plasma, liver, and RBC in animals. This is illustrated by the n-6/n-3 ratio, which was about twice as high as that in the control group for RBC phospholipids.

Correcting the levels of *cis*  $\alpha$ -linolenic acid in the diet by slightly increasing their levels (group C) succeeded in restoring *cis*  $\alpha$ -linolenic acid to levels equivalent to those of the control group in plasma, RBC, and liver phospholipids. The amounts of the longer-chain metabolites EPA and DHA were also recovered. As a consequence, the total *cis* n-3 PUFA levels and the n-6/n-3 ratio were restored. The geometrical isomers of  $\alpha$ -linolenic acid, EPA, and DHA were also present, but their levels were lower than those of group B. This is probably due to the increased dietary *cis* 18:3n-3/*trans* 18:3n-3 ratio in group C compared to group B. Even if the n-3 PUFA levels are restored, the physiological effects of *trans* PUFA have to be studied.

In conclusion, the main consequence of the isomerization of dietary  $\alpha$ -linolenic acid was a reduction of its levels in the diet, leading to an increase in the n-6/n-3 ratio, particularly in RBC. Since the FA composition of RBC membranes may reflect the neuronal membrane composition (16), the question of the effect of dietary EFA isomerization on brain composition and subsequently brain functioning is posed. An imbalanced diet may have several long-term consequences, particularly on major functions like vision or learning behavior (17,18).

## ACKNOWLEDGMENTS

The authors gratefully thank blédina sa and Lesieur for preparation of the formulas and the gift of the oils, respectively. The authors gratefully acknowledge Jean Le Dividich for supervising the nutritional experiment; Henri Renoult, Françoise Thomas, and Bruno Pasquis for technical assistance; and Pierre Juanéda and Jean-Pierre Sergiel for their help in bottle-feeding the animals. Niyazi Acar was funded by a fellowship from INRA and the Region of Burgundy (France).

# Effects of Dietary Conjugated Linoleic Acid on the Expression of Uncoupling Proteins in Mice and Rats

Kafi N. Ealey, Ahmed El-Sohemy, and Michael C. Archer\*

Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, Toronto, Canada M5S 3E2

**ABSTRACT:** CLA inhibits mammary cancer and reduces body fat accumulation in rodents. It is not known whether uncoupling proteins (UCP), which are modulators of energy balance and metabolism, play a role in these actions of CLA. To determine the effects of dietary CLA on the expression of UCP in various tissues, 5-wk-old Sprague-Dawley rats and C57Bl/6 mice were fed diets containing 1% CLA for 3 wk. CLA treatment reduced adipose depot weights in both rats and mice but had no significant effects on body weight. There was a species-specific effect of CLA on the expression of UCP. Whereas CLA did not affect the expression of UCP in most tissues in rats, mice fed CLA had increased expression of UCP2 in the mammary gland, brown adipose tissue (BAT), and white adipose tissue (WAT). Furthermore, UCP1 and UCP3 mRNA and protein levels in BAT were significantly lower in CLA-fed mice compared to controls. Skeletal muscle UCP3 mRNA was unchanged, but UCP3 protein levels were significantly increased in mice, suggesting translational or posttranslational regulation of this protein. Results from this study suggest that alterations in the expression of UCP in mice may be related to the previously reported effects of dietary CLA in lowering adiposity and increasing FA oxidation. In rats, however, induction of UCP is not likely to be responsible for fat reduction or for the inhibitory action of CLA on mammary carcinogenesis.

Paper no. L9087 in *Lipids* 37, 853–861 (September 2002).

Conjugated linoleic acid (CLA) is a collective term used to describe a group of geometric and positional isomers of linoleic acid that are found naturally in foods such as dairy products and meat (1). CLA has been shown to have a strong inhibitory effect on mammary tumorigenesis in rats (2,3). The mechanism responsible for this inhibition, however, is not known. Besides having anticarcinogenic properties, dietary CLA also has an effect on body composition and energy balance. Numerous studies have reported that feeding CLA to either rodents or humans decreases body fat accumulation and weight gain and increases FA oxidation and energy expenditure, often with no change in overall energy intake (4–6). It is possible that these effects on energy balance may mediate the effects of CLA on mammary cancer. The amount of usable energy available from the diet has a profound effect on the

development of mammary gland tumors in mice and rats (7). Diets rich in FA promote mammary tumorigenesis (8,9). This promoting effect may be due, in part, to the excess calories provided to the animal (7,10). Conversely, caloric restriction causes a marked inhibition of mammary tumorigenesis (11). Since uncoupling proteins (UCP) have been implicated in body composition changes and regulation of energy expenditure (12), it is possible that CLA regulates the expression of some or all of the UCP.

UCP are a class of transmembrane proteins found in the inner mitochondrial membrane. The first UCP discovered, UCP1, is expressed exclusively in brown adipose tissue (BAT) and functions by uncoupling ATP synthesis and mitochondrial electron transport, thereby allowing energy to be dissipated as heat (13). Recently identified homologs of UCP1 have raised the possibility that uncoupling of mitochondrial respiration in tissues other than BAT may play an important role in whole-body energy balance. UCP2 is expressed in most tissues (14), and UCP3 is expressed mainly in skeletal muscle and BAT (15). Although the physiological functions of UCP homologs in various tissues are not clear, proposed functions include mediation of cold- and diet-induced thermogenesis, regulation of energy expenditure, control of production of reactive oxygen species, and regulation of FA oxidation (12).

Dietary PUFA play a key role in regulating the expression of UCP genes (16–18). Rats fed fish oils rich in n-3 PUFA accumulate less body fat and have increased energy expenditure compared to rats fed diets rich in n-6 PUFA (19). These changes are accompanied by increased heat production and increased expression of UCP, suggesting that these mitochondrial proteins may play an important role in mediating the effects of fish oils on energy and lipid metabolism (19,20). Based on the similarity of the effects of CLA and fish oils on energy balance, we hypothesized that CLA may also increase expression of UCP in rodents.

An increase in UCP may increase metabolism at the whole-body level or in specific tissues such as the mammary gland. This has been demonstrated in UCP3 knockout mice that exhibit no changes in energy expenditure at the whole-body level, but have significantly altered mitochondrial energy metabolism in skeletal muscle (21). It is plausible that increased expression of UCP is an important mechanism by which dietary CLA regulates energy metabolism and inhibits mammary cancer in rodents. Like caloric restriction, a lack of

energy available to normal mammary tissue caused by a loss of energy as heat might affect mammary tumorigenesis.

Two studies to date in mice have reported different results in different strains on the effect of CLA on the expression of UCP (22,23). The only study to date in rats showed that a CLA-supplemented diet improved glucose tolerance, reduced adiposity, and increased UCP2 expression in muscle and adipose tissue in obese Zucker rats that develop type II diabetes (24). It is not known, however, whether CLA affects the expression of UCP in normal rats with no metabolic imbalances. Furthermore, the effects of CLA on UCP protein levels in mice and rats have not been examined. The main objective of this study therefore was to determine the effects of dietary CLA on the expression of UCP in various tissues, including the mammary glands of mice and rats, and to relate the findings to the protective effect of CLA on cancer development.

## MATERIALS AND METHODS

**Animals and diets.** All animal treatment protocols were reviewed by and were in compliance with the Animal Care and Use Committee of the University of Toronto. Forty 4-wk-old female C57BL/6 mice and eighteen 4-wk-old Sprague-Dawley rats were obtained from Charles River Laboratories (St. Constant, Quebec City, Canada). They were housed at  $22 \pm 2^\circ\text{C}$  and 50% RH with a 12-h light/dark cycle and acclimatized for 1 wk on the control AIN-93G diet (Dyets, Bethlehem, PA) with free access to food and water. The experimental diet was formulated by replacing the 7% soybean oil in the AIN-93G diet with 6% soybean oil + 1% CLA (Nu-Chek-Prep, Elysian, MN); approximate composition: 43% *c-9,t-11-* and *t-9,c-11-CLA*, 45% *t-10,c-12-CLA*, 6% *c-9,c-11-*, *c-10,c-12-*, *t-9,t-11-*, *t-10,t-12-CLA* with 2% linoleate and 4% unidentified material. The diets were stored under nitrogen at  $-20^\circ\text{C}$ , and the animals were given fresh diet every 2–3 d.

**Study protocol.** At 5 wk of age, the rats and mice were randomized into two groups each. One group was maintained on the AIN-93G diet while the other group was fed the 1% CLA diet. Body weights and food intake were measured twice weekly. After 3 wk of feeding, animals were killed by cervical dislocation, and livers, BAT, retroperitoneal and abdominal white adipose tissue (WAT), gastrocnemius muscles, and whole mammary glands were excised. All tissues were immediately frozen in liquid nitrogen for subsequent determination of UCP gene expression and UCP mitochondrial protein levels.

**Northern blot analysis.** Total RNA was isolated from frozen tissues using Trizol reagent (Life Technologies Inc., Gaithersburg, MD), and 10–20  $\mu\text{g}$  of RNA was electrophoresed in 1.0% agarose gels containing formaldehyde. RNA was transferred overnight to nylon membranes (Ambion, Austin, TX) and UV-cross-linked. Prehybridization and hybridization were carried out at  $42^\circ\text{C}$  using Northern Max (Ambion) hybridization buffer. Blots were hybridized overnight using UCP1, UCP2, and UCP3 probes labeled with  $\alpha$ - $^{32}\text{P}$ -dCTP by random prime labeling. All probes were synthesized by reverse transcription-polymerase chain reaction

as described (15,25,26). For UCP1, forward and reverse primer sequences were 5'-CGGACTTTGGCGGTGTCCAGCGGAAGGTGAT-3' and 5'-AGCACACAAACATGATGACGTTCC-3', which correspond to conserved domains 279–298 and 1021–1044 of rat UCP1, respectively (15). For UCP2, primers used were 5'-TTAGAGAAGCTTGACCTTGC-3' and 5'-CGTTCCAGGATCCCAAGCGG-3', which correspond to positions 145–164 and 1148–1129, respectively, of the mouse UCP2 (25). For UCP3, primers used were 5'-GGGAAATCCTGCTGCTACCT-3' and 5'-TTCTTGTGATGTTGGGCCAA-3', corresponding to positions 1–20 and 703–723 of the mouse UCP3. Northern blots were washed twice in a solution of sodium chloride/sodium citrate (SSC) and SDS ( $2\times$  SSC/0.1% SDS) for 5 min at  $42^\circ\text{C}$  and twice in  $0.1\times$  SSC/0.1% SDS at  $50^\circ\text{C}$ . To quantify the signal, total  $^{32}\text{P}$  counts were determined using a Packard Instant Imager (Canberra Packard Canada, Mississauga, Canada) and normalized to counts obtained after hybridization of the membrane with a 28S rRNA probe.

**Isolation of mitochondria.** For isolation of mitochondria, tissues were homogenized in 4–6 mL of buffer containing 250 mM sucrose, 10 mM HEPES, 0.5 mM EDTA, and 0.1% BSA, pH 7.2, and kept on ice (27). The homogenate was centrifuged at  $600\times g$  for 5 min at  $4^\circ\text{C}$ . The supernatant was collected and centrifuged at  $8000\times g$  for 10 min at  $4^\circ\text{C}$ . The mitochondrial pellet was washed twice and finally resuspended in buffer without BSA. Mitochondrial protein concentrations were determined using the BioRad Protein Assay (Bio-Rad Laboratories, Hercules, CA).

**Western blot analysis.** Mitochondrial proteins solubilized in Laemmli buffer containing  $\beta$ -mercaptoethanol were heated for 5 min at  $95^\circ\text{C}$ , separated by electrophoresis on 13% polyacrylamide gels under denaturing conditions, and transferred to polyvinylidene difluoride membranes. Membranes were incubated overnight at  $4^\circ\text{C}$  in blocking buffer (5% nonfat dry milk in Tris-buffered saline/0.1% Tween 20). UCP1 was detected with a goat polyclonal antibody to a conserved amino-terminal peptide sequence of mouse UCP1 (Santa Cruz Biotechnology, Inc., Santa Cruz, CA). UCP3 was detected with a rabbit polyclonal antibody to a human UCP3 carboxy-terminal peptide (Chemicon International Inc., Temecula, CA). We showed that the UCP1 antibody did not cross-react with UCP2 or UCP3 in Western blots using muscle mitochondrial protein (data not shown). Furthermore, the UCP3 antibody did not cross-react with UCP2 when mitochondrial protein isolated from liver or mammary gland tissue was used (data not shown). After extensive washing in Tris-buffered saline/0.1% Tween 20, membranes were incubated with anti-goat (UCP1) or anti-rabbit (UCP3) horseradish peroxidase-conjugated secondary antibodies (Santa Cruz Biotechnology, Inc.) and developed with a standard ECL kit (Santa Cruz Biotechnology, Inc.). Chemiluminescence was detected on Biomax MR Kodak film, and bands were quantified using a FluorChem Imaging System (Alpha Innotech Corp., San Leandro, CA). We were unable to perform Western blot analysis of UCP2 owing to the unavailability of a reliable commercial antibody.

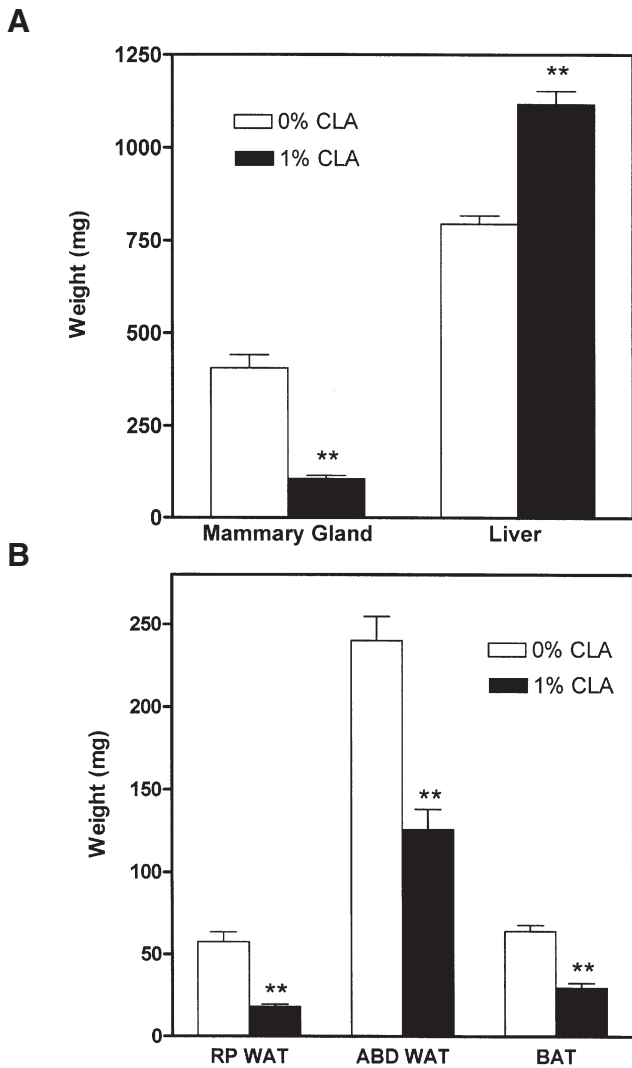

**Statistical analysis.** Results are expressed as means  $\pm$  SEM. Differences were determined by Student's unpaired *t*-test. Differences with  $P \leq 0.05$  were considered significant.

## RESULTS

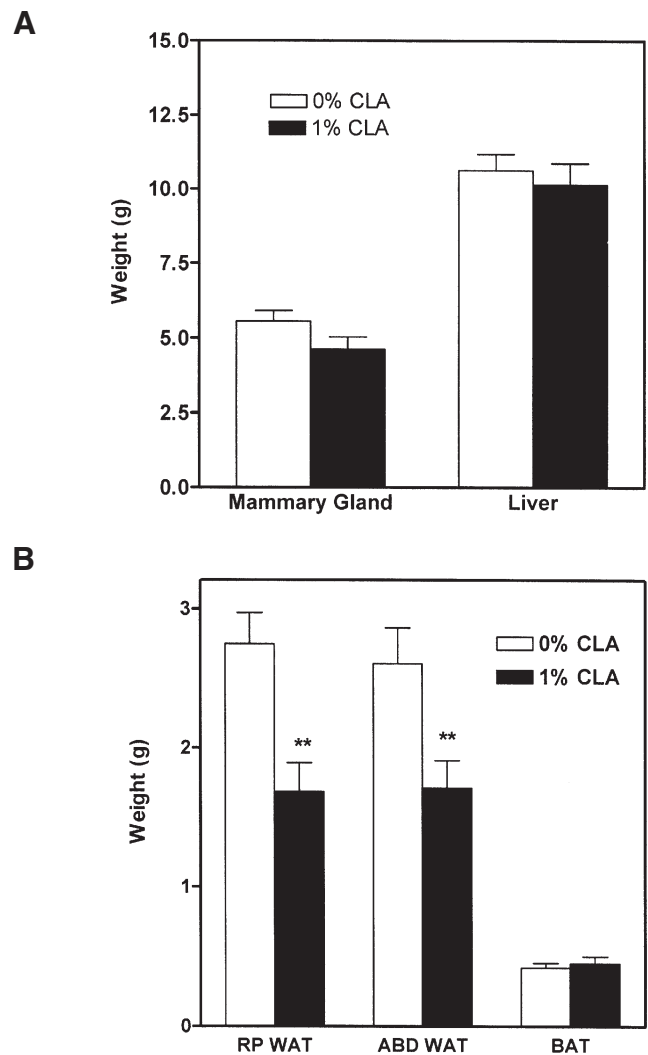

After 3 wk of feeding the AIN-93G control diet or the diet containing 1% CLA to C57BL/6 mice, food intake and body weights did not differ between the two groups ( $18.4 \pm 0.3$  g vs  $18.6 \pm 0.4$  g for control and CLA-fed mice, respectively). There was, however, a significant difference in weights of specific WAT depots and major organs. As shown in Figure 1A, mammary glands of CLA-fed mice weighed significantly less than those of control animals, and mice fed CLA had significantly larger livers that were also paler in color than the controls. Mice fed CLA also had significant decreases in wet

weights of several adipose depots (Fig. 1B). Retroperitoneal WAT was reduced by 68%, and the abdominal fat depot was reduced by approximately 50% in CLA-fed mice compared to those fed the control diet. A 50% reduction in BAT was observed in CLA-fed mice relative to controls.

Food intakes and body weights of female Sprague-Dawley rats fed diets containing CLA did not differ from rats fed the control diets ( $234.9 \pm 6.3$  vs.  $222.9 \pm 7.4$  g for control and CLA-fed rats, respectively). Unlike the mice, however, the wet weights of mammary glands and livers did not differ between the two groups of rats (Fig. 2A). As shown in Figure 2B, rats fed CLA had significantly lower wet weights of WAT depots. Retroperitoneal WAT was reduced by 40% in CLA-fed rats compared to those fed the control diet. A 35% reduction in weight was also observed in the abdominal WAT depots of CLA-fed rats compared to controls. The weight of the BAT depot in rats did not differ between the two dietary groups.

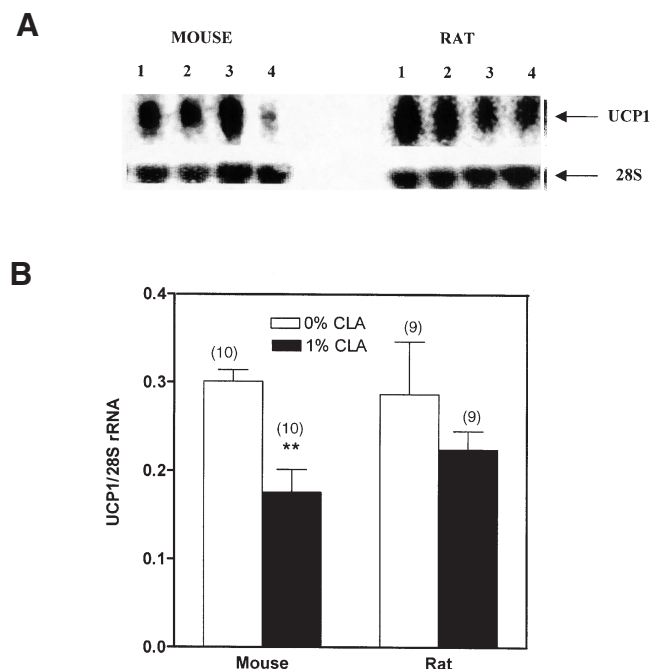

**FIG. 1.** Tissue weights of C57BL/6 mice fed a control or CLA-supplemented diet for 3 wk. (A) Wet weights of mammary glands and livers. (B) Wet weights of retroperitoneal (RP) white adipose tissue (WAT), abdominal (ABD) WAT, and brown adipose tissue (BAT) depots. (Means  $\pm$  SEM,  $n = 20$ /group, \*\* $P < 0.05$ .)

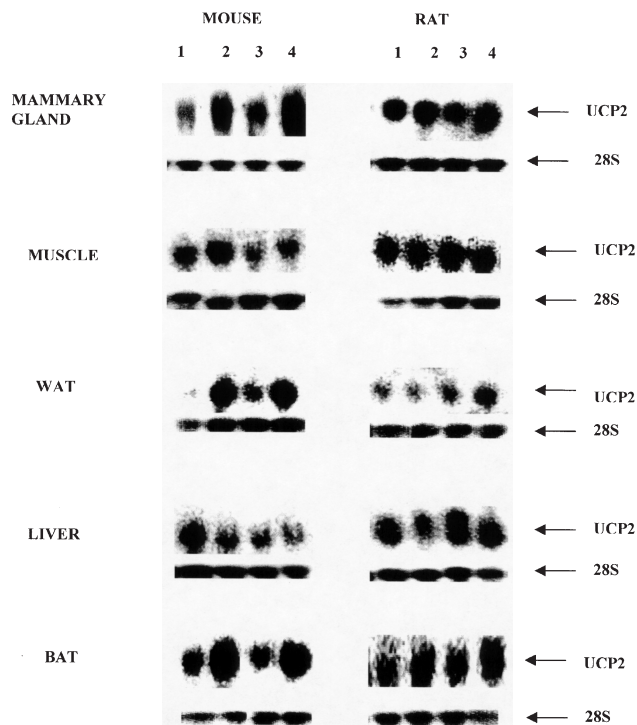

**FIG. 2.** Tissue weights of Sprague-Dawley rats fed a control or CLA-supplemented diet for 3 wk. (A) Wet weights of mammary glands and livers. (B) Wet weights of RP WAT, ABD WAT, and BAT depots. (Means  $\pm$  SEM,  $n = 9$ /group, \*\* $P < 0.05$ .) For abbreviations see Figure 1.

Northern blots were performed to determine the effects of CLA on the expression of various UCP genes. Representative blots showing mRNA from two animals in each experimental group are shown in Figures 3, 4, and 6. In addition, mean transcript levels from all of the animals in each group normalized to the 28S ribosomal band are shown graphically.

Figure 3 demonstrates the effects of dietary CLA on mRNA levels of UCP1 in both mice and rats. UCP1, expressed exclusively in BAT, was significantly decreased in CLA-fed mice compared to controls ( $P < 0.05$ ). There were no differences, however, in mRNA levels of UCP1 in rats fed the control diet compared to those fed the 1% CLA diet. UCP2 is expressed ubiquitously in rodent tissues. In this study, levels of UCP2 mRNA were examined in the mammary glands, livers, WAT, BAT, and skeletal muscle of mice and rats fed the control and experimental diets. Representative Northern blots of UCP2 in various tissues are shown in Figure 4. As shown in Figure 5A, in which bands from the Northern blots were quantified, UCP2 mRNA levels were significantly increased in the mammary gland, WAT, and BAT of mice fed CLA ( $P < 0.05$ ). In contrast, dietary CLA had no effect on the mRNA levels of UCP2 in any of the tissues studied in rats (Fig. 5B). UCP3 is expressed in the BAT and skeletal muscle of both mice and rats, as depicted in the representative Northern blots for UCP3 (Fig. 6). mRNA levels of UCP3 were decreased in BAT of CLA-fed mice ( $P = 0.05$ ) compared to controls, but expression of UCP3 in muscle

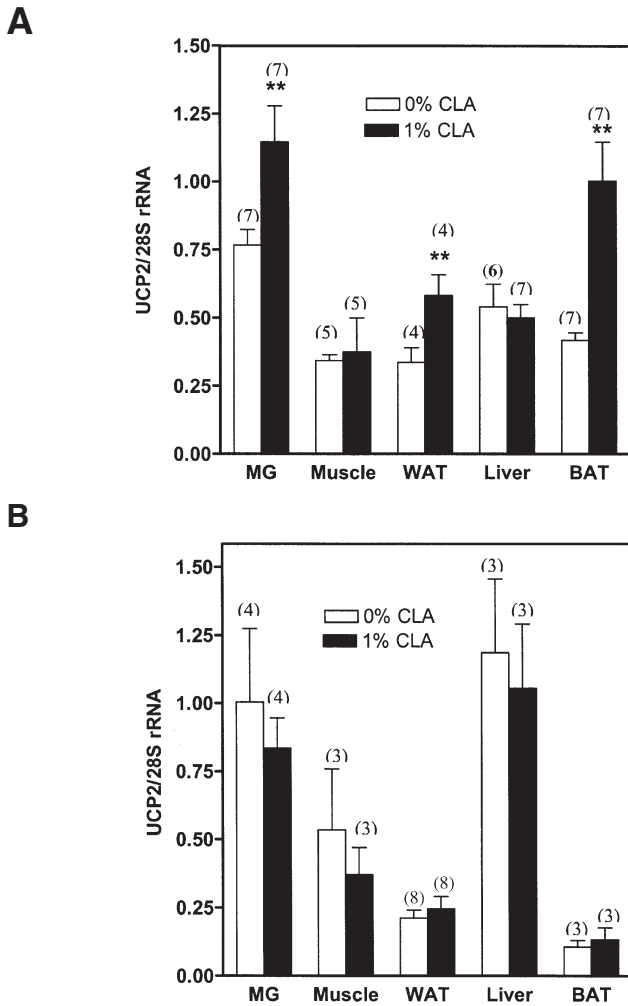

**FIG. 3.** Representative Northern blots showing the effects of a 1% CLA diet on uncoupling protein 1 (UCP1) mRNA levels in BAT from mice and rats. (A) Lanes 1 and 3 correspond to mRNA from controls, and lanes 2 and 4 correspond to mRNA from CLA-fed animals. Each lane is from a different animal. (B) Levels of UCP1 mRNA relative to 28S rRNA are shown. Numbers in parentheses indicate the number of animals/group for each tissue. (Means  $\pm$  SEM, \*\* $P < 0.05$ .) For abbreviations see Figure 1.

**FIG. 4.** Representative Northern blots showing the effects of a 1% CLA diet on UCP2 mRNA levels in various tissues in mice and rats. Lanes 1 and 3 correspond to mRNA from controls, and lanes 2 and 4 correspond to mRNA from CLA-fed animals. Each lane is from a different animal. For abbreviations see Figures 1 and 3.

tissue did not differ between the two groups (Fig. 7A). In rats, dietary CLA did not affect the mRNA levels of UCP3 in either BAT or muscle tissue (Fig. 7B).

To investigate whether the effects of CLA on UCP gene expression corresponded to changes in immunoreactive protein levels, we determined the UCP content of isolated mitochondria by Western blot analysis. Consistent with the effects on gene expression, CLA-fed mice had significantly lower UCP1 protein levels in BAT compared to controls ( $P < 0.05$ ), but UCP1 protein levels in CLA-fed rats were higher than the controls ( $P = 0.05$ ) (Fig. 8). UCP3 protein levels were also significantly decreased in the BAT of CLA-fed mice ( $P < 0.05$ ) compared to controls, but no differences were observed in rats. Skeletal muscle UCP3 protein levels were significantly increased in CLA-fed mice ( $P < 0.05$ ) compared to controls. In rats, there was no difference in skeletal muscle UCP3 protein content between the control and CLA groups. As mentioned in the Materials and Methods section, UCP2 protein levels were not determined in this study. We showed that an antibody we purchased to detect UCP2 reacted with proteins of similar size and was not useful for Western blot analysis. It has recently been shown that other commercially available antibodies for UCP2 are not specific for this protein and produce other bands of similar M.W. (28).

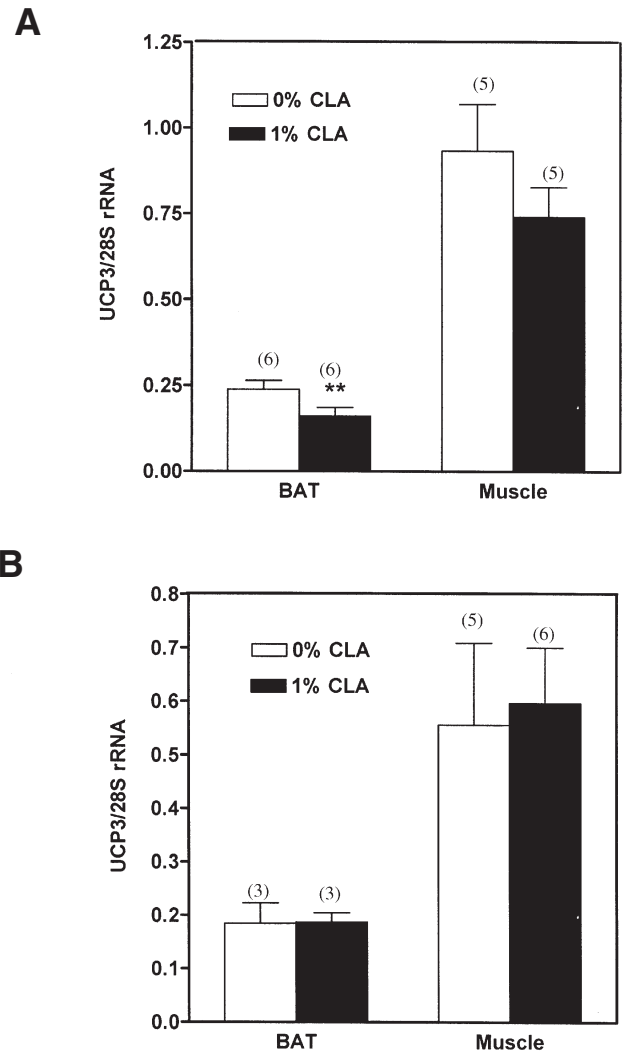

**FIG. 5.** Levels of mouse (A) and rat (B) mammary gland, muscle, WAT, liver, and BAT UCP2 mRNA relative to 28S rRNA. Numbers in parentheses indicate the number of animals/group for each tissue. (Means  $\pm$  SEM, \*\* $P < 0.05$ .) MG, mammary gland; for other abbreviations see Figures 1 and 3.

## DISCUSSION

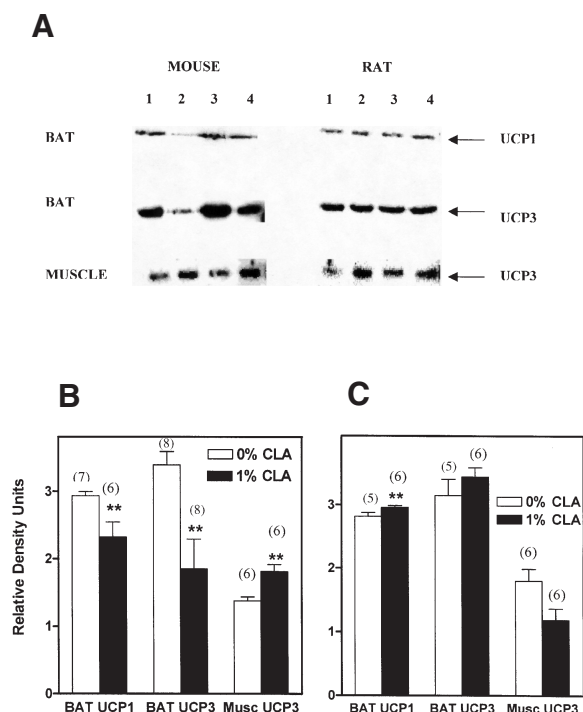

The objectives of this work were to investigate the effects of dietary CLA on the expression of UCP in rats and mice and to determine whether increased expression of UCP is a plausible mechanism by which CLA could directly or indirectly exert a protective effect on mammary gland tumorigenesis. We hypothesized that by regulating available energy, increased expressions of UCP, particularly UCP2, which is expressed in the mammary gland, could affect susceptibility to carcinogen-induced tumorigenesis in a manner similar to caloric restriction. It is likely that induction of UCP2 would reduce the efficiency of ATP synthesis, leading to global loss of cell membrane integrity and finally cell death by necrosis and/or apoptosis (23). A loss of epithelial cells in the mammary gland in this way could reduce the population of target cells for the carcinogen or, postinitiation, lead to a loss of pre-neoplastic cells.

**FIG. 6.** Representative Northern blots showing the effects of a 1% CLA diet on UCP3 mRNA levels in muscle and BAT of mice and rats. Lanes 1 and 3 correspond to mRNA from controls, and lanes 2 and 4 correspond to mRNA from CLA-fed animals. Each lane is from a different animal. For abbreviations see Figures 1 and 3.

**FIG. 7.** Levels of mouse (A) and rat (B) BAT and muscle UCP3 mRNA relative to 28S rRNA. Numbers in parentheses indicate the number of animals/group for each tissue. (Means  $\pm$  SEM, \*\* $P < 0.05$ .) For abbreviations see Figures 1 and 3.

**FIG. 8.** Representative Western blots of mitochondrial UCP1 and UCP3 from BAT and muscle of mice and rats. (A) Lanes 1 and 3 correspond to protein from controls, and lanes 2 and 4 correspond to protein from CLA-fed animals. Each lane is from a different animal. (B and C) Relative densities of UCP protein in mice (B) and rats (C). Numbers in parentheses indicate the number of animals/group for each tissue. (Means  $\pm$  SEM, \*\* $P < 0.05$ .) For abbreviations see Figures 1 and 3.

The rationale for investigating the effects of dietary CLA on UCP expression in both rats and mice in the present study was twofold. First, Sprague-Dawley rats initiated with 7,12-dimethylbenz[a]-anthracene or *N*-methyl-*N*-nitrosourea have been used to demonstrate the inhibitory effects of CLA on mammary carcinogenesis. Second, CLA has already been shown to increase energy expenditure in mice significantly (29), thus allowing mice to be used as controls for studies on UCP regulation. The mouse, however, is a poor model in which to study mammary tumorigenesis (30,31) and has not therefore been used to study the effects of CLA on cancer development.

As summarized in Table 1, our results show that regulation of UCP by CLA occurs in a different manner in rats and mice. Rats fed CLA had significantly reduced weights of WAT depots compared to controls, but no changes in total body weight. This lack of a change in body weight in rats, however, most likely reflects the fact that the WAT depots we measured represent only ~2% of total body weight. Thus, significant changes in the weights of these depots would not result in significant changes in body weight. There were no differences in the weights of any of the other tissues we analyzed in rats. Although previous studies in mice indicate that decreased body fat is associated with increased expression of UCP2 (32), this is not what we observed in rats. Indeed, CLA did not affect the expression of UCP2 in any of the tissues

**TABLE 1**  
Summary of the Effects of Dietary CLA on Uncoupling Proteins (UCP) in Mouse and Rat<sup>a</sup>

	Mouse		Rat	
	mRNA	Protein	mRNA	Protein
UCP1				
BAT	↓	↓	↔	↑
UCP2				
MG	↑	N/A	↔	N/A
WAT	↑	N/A	↔	N/A
BAT	↑	N/A	↔	N/A
Muscle	↔	N/A	↔	N/A
Liver	↔	N/A	↔	N/A
UCP3				
BAT	↓	↓	↔	↔
Muscle	↔	↑	↔	↔

<sup>a</sup>↓ (decrease), ↑ (increase), ↔ (no significant change), N/A = not available; BAT, brown adipose tissue; MG, mammary gland; WAT, white adipose tissue.

studied in rats, including the mammary gland. The expression of the other UCP homologs also was unaffected by CLA treatment in most of the tissues studied in rats. Dietary CLA given at the dose used in the current study (1%) and at levels 10-fold lower (0.1%) results in significant inhibition of mammary carcinogenesis in rats (2,3). Since the biochemical properties of early preneoplastic cells are likely to be similar to normal cells, the lack of an effect of 1% dietary CLA on UCP expression that we observed in the normal mammary gland of the rat suggests that it is unlikely that these proteins play a significant role in the inhibitory effect of CLA on cancer development.

In the present study, mice fed CLA had significantly lower weights of WAT, BAT, and whole mammary glands compared to controls, without any changes in total body weight. Our observations that the livers of CLA-fed mice weighed significantly more and were paler in color than livers from control animals are consistent with the reports of others that CLA-fed mice develop fatty livers (23,33). One reason for the lack of change in body weight of mice fed CLA may be that the loss of mass of the adipose depots is partially offset by the increase in the weight of the liver. Furthermore, although we did not measure total lean body mass in this study, it has been reported by others that dietary CLA significantly increases body protein accretion in mice (34). Despite the similarity in the effect of CLA on fat accumulation in rats and mice, our data indicate that the metabolic effect of CLA on UCP expression is quite different in the two species.

Consistent with studies in mice and humans suggesting that increased expression of UCP is associated with decreased body fat (32,35), in the present study, expression of UCP2 mRNA in WAT and BAT was significantly increased with CLA feeding. Indeed, our results confirm those from a recent study showing increased UCP2 in adipose tissues of mice fed CLA (23). In the liver there was no difference in UCP2 expression between either of the dietary groups. In the mouse mammary gland (including adipocytes, epithelial cells, and stromal cells) we showed increased UCP2 mRNA with CLA

feeding. It has been reported that, compared to animals fed a control diet, a diet containing CLA significantly decreases the growth rate of human breast cancer cells injected into the mammary fat pads of mice (36). Based on our data, a possible mechanism for this effect is through increased UCP2 expression, leading to reduced energy availability to the transplanted cells. Although we did not separate the mammary glands into individual cell types, a recent paper provides evidence that the stromal compartment within the mouse mammary gland expresses UCP1 and other genes involved in FA oxidation (37). These authors suggested that the coordinate regulation of genes involved in the  $\beta$ -oxidation of FA indicates the presence of BAT in the mammary gland. This suggests, in turn, a functional role for the mammary gland in adaptive thermogenesis (37). Tsuboyama-Kasaoka *et al.* reported that CLA induces apoptosis and increases UCP2 mRNA expression in adipose tissues of mice, suggesting that this may be a mechanism responsible for the reduced adipose tissue mass observed in CLA-fed mice.

The altered expression of UCP we observed in the BAT of mice may be involved in mechanisms of thermoregulation. BAT in rodents plays a major role in controlling body weight through diet-induced thermogenesis. This is primarily mediated by the uncoupling of mitochondrial respiration resulting from the marked oxidative capacity of the brown adipocytes (13,38). We hypothesized that the expression of UCP in BAT would be increased, corresponding to the increased energy expenditure and reduced adiposity that has been reported in mice fed CLA (29,39). Unexpectedly, mRNA and protein levels of UCP1 and UCP3 in BAT were significantly lower in CLA-fed mice compared to controls. One reason for these decreases could be an adaptive mechanism to compensate for increased UCP2 expression. In the BAT of UCP1-null mice, there is a fivefold elevation in the expression of UCP2 mRNA (40). Increased BAT UCP2 may be the reason that the UCP1-null mice do not have increased susceptibility to obesity (38). These observations suggest that these null mice have a compromised capacity to thermoregulate, such that they need to use other mechanisms to increase energy expenditure (38). Thus, UCP in BAT that are under control of the sympathetic nervous system (SNS) may function coordinately to enable the animal to maintain body weight and energy balance. In contrast to mice, in CLA-fed rats we observed a small but significant increase in UCP1 protein levels in BAT compared to controls. The physiological significance of this effect, however, is not clear.

Of all tissues, skeletal muscle plays the largest role in energy utilization owing to its size and has long been proposed to be the major site for adaptive thermogenesis in large mammals (12). There has been much interest recently in the UCP3 gene since its expression in skeletal muscle could potentially regulate fat metabolism and the development of obesity in humans (41). Expression of UCP in skeletal muscle, unlike BAT, is not under the control of the SNS (42). Results from *in vitro* studies in cells transfected with UCP3, as well as *ex vivo* and *in vivo*

studies in knockout and transgenic mice, suggest that UCP3 is thermogenic (43). Accumulating evidence, however, has led some investigators to conclude that UCP3 in skeletal muscle is primarily associated with the regulation of lipids as fuel substrate (42) and increased FA oxidation (44).

In the present study in mice, UCP3 was regulated differently in skeletal muscle than in BAT. We observed no changes in the mRNA levels of UCP3 in skeletal muscle isolated from mice fed CLA, but Western blot analysis showed that UCP3 protein was increased significantly, suggesting that this protein is under posttranslational control. These findings are consistent with a recent report suggesting UCP2 is regulated posttranslationally (28). In that study, while UCP2 mRNA levels remained unchanged, protein levels increased dramatically after stimulation with liposaccharide (28). Other studies that have investigated the effects of CLA on UCP have reported either that expression of UCP3 in the skeletal muscle of mice is not affected by CLA feeding (22,23) or that UCP3 mRNA levels are decreased (45). These studies, however, investigated only mRNA expression. Our results highlight the importance of analyzing both mRNA and protein levels to determine whether dietary or physiological stimuli influence these proteins at the transcriptional or translational level. Dietary CLA has been shown to increase FA oxidation in skeletal muscle (39). Our results indicate that induction of UCP3 may play a role in this effect since increased expression of UCP3 is associated with increased FA oxidation (44).

One reason for the different effects of CLA on UCP expression in mice and rats could be the known species-specific role of CLA in the activation of peroxisome proliferator-activated receptors (PPAR). CLA functions as a PPAR activator in mice (46) but in Sprague-Dawley rats it exerts little or no effect on PPAR-responsive genes. (47,48). Recent studies have shown that expression of UCP is regulated directly and indirectly by activated PPAR (49–52). Thus, it is possible that increased UCP2 expression in mice by CLA is a result of activation of PPAR.

In summary, dietary CLA caused a significant lowering of body fat accumulation in both rats and mice. In rats, however, CLA did not affect the expression of UCP in most of the tissues studied including the mammary gland, suggesting that induction of UCP is not a major mechanism responsible for fat reduction or for the known inhibitory action of CLA on mammary carcinogenesis. The alterations in UCP in mice observed in this study may be related to the previously reported effects of dietary CLA in lowering adiposity and increasing FA oxidation, and thus merit further investigation.

## ACKNOWLEDGMENTS

This research was supported by a grant from the Natural Sciences and Engineering Research Council (NSERC) with Dairy Farmers of Canada. **ABSTRACT:** By using the polymerase chain reaction approach with two degenerate primers targeting the heme-binding and the third histidine-rich motifs in microsomal carboxyl-directed desaturases, we identified a cDNA *PiD5* from *Pythium irregulare* encoding a  $\Delta 5$  desaturase. The substrate specificity of the enzyme was studied in detail by expressing *PiD5* in a yeast (*Saccharomyces cerevisiae*) mutant strain, AMY-2 $\alpha$ , where *ole1*, a  $\Delta 9$  desaturase gene, is disrupted. The result revealed that the encoded enzyme could desaturate unsaturated FA from 16 to 20 carbons beginning with  $\Delta 9$  and  $\Delta 11$  as well as  $\Delta 8$  ethylenic double bonds. Introduction of *PiD5* into *Brassica juncea* under the control of a CaMV 35S constitutive promoter resulted in accumulation of several  $\Delta 5$ -unsaturated polymethylene-interrupted FA ( $\Delta 5$ -UPIFA) including 18:2-5,9, 18:2-5,11, 18:3-5,9,12, and 18:4-5,9,12,15 in vegetative tissues. The transgenic enzyme could also desaturate the exogenously supplied homo- $\gamma$ -linolenic acid (20:3-8,11,14) to arachidonic acid (20:4-5,8,11,14). Introduction of *PiD5* into *B. juncea* and flax under the control of seed-specific promoters resulted in production of  $\Delta 5$ -UPIFA, representing more than 10% of the total FA in the seeds.

Paper no. L9061 in *Lipids* 37, 863–868 (September 2002).

Long-chain PUFA (LCPUFA) such as arachidonic acid (AA, 20:4-5,8,11,14) and EPA (20:5-5,8,11,14,17) are  $\Delta 5$  desaturated FA with multiple double bonds in the acyl chains. They are essential components of cell membranes and intermediates for the biosynthesis of various eicosanoids, a series of biologically active compounds involved in regulation and mediation of cell homeostasis and physiological activities in mammals (1). Clinical research has shown that appropriate uses of these FA can provide protection against some chronic diseases such as cardiovascular disease and arterial thrombosis and can provide some beneficial effect on arthritis, renal disorders, diabetes, and various cancers (2,3).

Biosynthesis of  $\Delta 5$ -LCPUFA occurs through sequential desaturation and chain-elongation in most eukaryotic species.

The sequence reported here (*PiD5*) has been deposited in GenBank under the accession number AF419297.

Abbreviations: AA, arachidonic acid; cyt, cytochrome; HGLA, homo- $\gamma$ -linolenic acid; LA, linoleic acid; LCPUFA, long-chain PUFA; ORF, open reading frame; PCR, polymerase chain reaction;  $\Delta 5$ -UPIFA,  $\Delta 5$ -unsaturated polymethylene-interrupted FA.

Starting with linoleic acid (LA, 18:2-9,12), biosynthesis of LCPUFA involves  $\Delta 6$  desaturation of LA to GLA (18:3-6,9,12), followed by elongation of GLA to homo- $\gamma$ -linolenic acid (HGLA, 20:3-8,11,14) and  $\Delta 5$  desaturation of HGLA to AA (20:4-5,8,11,14). The same set of desaturases and elongases can work on  $\alpha$ -linolenic acid (18:3-9,12,15), yielding the n-3 series of LCPUFA such as EPA (20:5-5,8,11,14,17).

Genes encoding  $\Delta 6$  FA desaturases have been cloned and characterized from various sources including higher plants (4), fungi (5), nematodes (6), moss (7), and mammals (8). More recently, genes encoding  $\Delta 5$  desaturase also have been identified from a slime mold (9), a nematode (10,11), *Mortierella alpina* (12,13), and humans (14,15). These studies have facilitated our understanding of the molecular mechanism underlying the biosynthesis as well as our application of this knowledge to the production of the EFA in heterologous systems.

In this report, we describe the identification of *PiD5*, a new cDNA from *Pythium irregulare* encoding a  $\Delta 5$  FA desaturase. *Pythium irregulare* is an oleaginous fungus that is unusual in that it contains a large amount of AA and EPA, both of which contain  $\Delta 5$  double bonds and show promise as dietary supplements. Expression of the desaturase in yeast and two different plants indicated that the *P. irregulare* enzyme might be useful for large-scale production of these  $\Delta 5$  FA in plants.

## MATERIALS AND METHODS

**Strains and culture conditions.** *Pythium irregulare* 10951 obtained from the American Type Culture Collection (Manassas, VA) was grown at 25°C for 6 d in a liquid medium consisting of yeast extract, 3.0 g/L; malt extract, 3 g/L; peptone, 5 g/L; glucose, 10 g/L; K<sub>2</sub>HPO<sub>4</sub>, 0.68 g/L, pH 6.0 (16). Biomass was harvested by filtration and washed three times with distilled water. The dried mass was ground with mortar and pestle into a fine powder in liquid nitrogen and stored at -70°C for use.

**Polymerase chain reaction (PCR)-based cloning.** Single-stranded cDNA was synthesized from total RNA using a First-Strand cDNA Synthesis Kit (Amersham Pharmacia Biotech, Piscataway, NJ) and used as a template for PCR amplification with two degenerate primers (the forward: GCN-RANGANCAYCCNGGNGG, and the reverse: ATNTKNG-GRAANARRTGRTG) (17).

**cDNA library construction and screening.** The mRNA was extracted from total RNA by using Dynabeads™ Oligo(dT)25 (DYNAL®; Dynal Biotech Inc., Lake Success, NY). The cDNA library was constructed and screened as described by Hong *et al* (17).

**Expression of *PiD5* in yeast (*Saccharomyces cerevisiae*).** The open reading frame (ORF) of *PiD5* was amplified by PCR using the high-fidelity *Pfu* polymerase (Stratagene, La Jolla, CA). After initial amplification, TAQ polymerase was added to the mixture to facilitate the TA cloning (PCR® 2.1; Invitrogen). Having confirmed that the PCR products were identical to the original cDNA by sequencing, the fragments were then released by BamHI-EcoRI double digestion and inserted into the yeast expression vector pYES2 (Invitrogen, Carlsbad, CA). Yeast strains InvSc2 (Invitrogen) and AMY-2 $\alpha$  (18) were transformed with the expression constructs using the lithium acetate method, and transformants were selected on minimal medium plates lacking Uracil (19). Minimal medium containing 2% galactose, either with or without 0.3 mM substrate FA in the presence of 0.1% NP-40 Tergitol (Sigma, St. Louis, MO), was inoculated with the yeast transformant cell suspension and incubated at 20°C for 3 d.

**Expression of *PiD5* in *Brassica juncea* and flax (*Linum usitatissimum*).** *Agrobacterium* transformation of *B. juncea* and flax was essentially according to our previous report (20).

**FA analysis.** Plant materials and yeast cells were harvested and washed twice with distilled water. Then 2 mL of methanolic KOH (7.5% wt/vol KOH in 95% methanol) was added to the materials and the mixture was sealed in a 12-mL glass culture tube and heated to 80°C for 60 min. Then 0.5 mL water was added and the sample was extracted twice with 2 mL hexane to remove the unsaponifiable lipids. The remaining aqueous phase was then acidified by adding 1 mL 6 N HCl and extracted twice with 2 mL hexane. The hexane phases were combined and dried under a stream of nitrogen. Next, 2 mL 3 N methanolic HCl (Supelco, Supelco Park, Bellefonte, PA) was added, and the mixture was heated at 80°C for 20 min. After cooling to room temperature, 1 mL 0.9% NaCl was added and the mixture was extracted twice with 2  $\times$  2 mL hexane.

Identity of the FA products was obtained by comparison of the retention time with standards or by GC-MS analysis of their derivatives. FA standards were purchased from Sigma (St. Louis, MO) and Nu-Chek-Prep (Elysian, MN). Fatty acyl diethylamine derivatives were prepared as described previously (17). GC-MS analysis was performed in standard EI mode using a Fisons VG TRIO 2000 mass spectrometer controlled by MassLynx version 2.0 software, coupled to a GC 8000 Series gas chromatograph. A DB-23 column (30 m  $\times$  0.25 mm i.d., 0.25  $\mu$ m film thickness; J&W Scientific, Folsom, CA) that was temperature-programmed at 180°C for 1 min, then 4°C/min to 240°C and held for 15 min, was used for the analysis (21).

## RESULTS

**Identification of *PiD5* from *P. irregulare*.** *Pythium irregulare* is an oleaginous fungus that is unusual in that it contains

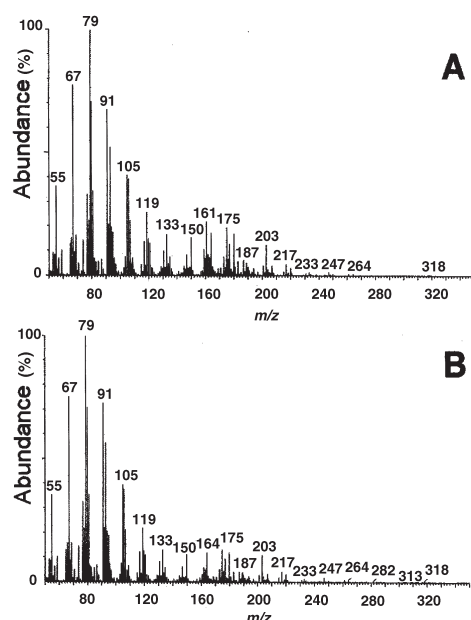

**FIG. 1.** GC analysis of FAME from yeast strain Invsc2 expressing *PiD5* with exogenous substrate homo- $\gamma$ -linolenic acid (HGLA, 20:3-8,11,14).

about 9% AA and 20% EPA. To identify genes coding for desaturases involved in the biosynthesis of these LCPUFA from *P. irregulare*, a PCR-based cloning strategy was adopted. Two degenerate primers were designed to target the heme-binding motif of cytochrome (cyt)  $b_5$ -like domain of so-called front-end desaturases (22) and the third conservative histidine motif in all microsomal desaturases, respectively. Using this strategy, we identified cDNA fragments from *P. irregulare* that encode a partial protein containing a cyt  $b_5$ -like domain in the N-terminus.

To isolate the full-length cDNA clone, the inserts were used as probes to screen a cDNA library of *P. irregulare*, which resulted in identification of several cDNA clones. Sequencing of all those clones identified a full-length cDNA that was named *PiD5*. The ORF of *PiD5* from *P. irregulare* is 1371 bp and codes for 456 amino acids (Genbank accession number AF419297). A homology search indicated *PiD5* shares high sequence similarity with the  $\Delta 5$  desaturases from *Dictyostelium discoideum* (9) and *M. alpina* (12,13). These results suggest the possible function of *PiD5* as a FA desaturase involved in AA and EPA biosynthesis.

**Expression of *PiD5* in yeast.** The *S. cerevisiae* Invsc2 was initially transformed with a plasmid, which contained the full-length ORF of the *PiD5* under the control of the galactose-inducible promoter. When the yeast transformant was induced by galactose in a medium containing HGLA (20:3-8,11,14), an extra peak was observed in the chromatogram of the FAME derived from the transformants compared with the control (Fig. 1). A comparison of the chromatogram with that of the standards revealed that the FAME had a retention time identical to AA (20:4-5,8,11,14) methyl ester. To confirm the regiochemistry of the products, the FAME was analyzed by GC-MS. The result indicated that the mass spectra of the new FA and the AA standard were identical (Fig. 2). These results

**FIG. 2.** GC-MS analysis of FAME of the new peak in Figure 1. (A) The PiD5 product; (B) the arachidonic standard (AA, 20:4-5,8,11,14).

demonstrate that PiD5 can convert HGLA into AA in yeast and indeed represents a new Δ5 desaturase from *P. irregulare*.

To study the substrate specificity of PiD5 further, we transferred the plasmid into another yeast strain, AMY-2α, where *ole1*, a Δ9 desaturase gene, is disrupted (18). The strain is unable to grow in minimal media without supplementation with monounsaturated FA. In our experiments, the strain was grown in minimal medium supplemented with 17:1(10Z), a nonsubstrate of PiD5, which enabled us to study the specificity of the enzyme toward various substrates, especially monounsaturates. A number of possible substrates including 16:1(9Z), 18:1(9Z), 18:1(11Z), 18:1(11E), 18:1(12E), 18:1(15Z), 18:2(9Z,12Z), 18:3(9Z,12Z,15Z), 20:2(11Z,14Z), and 20:3(11Z,14Z,17Z) were tested. Results indicated that PiD5 desaturated unsatu-

rated FA with Δ9 ethylenic and Δ11 ethylenic double bonds as well as the FA with a Δ8 ethylenic double bond (20:3-8,11,14). It could also desaturate *trans* FA such as 18:1(11E) and 18:1(12E).

Table 1 shows a comparison of the substrate preference of PiD5 for FA substrates tested in the yeast strain AMY-2α. As shown in Table 1, PiD5 appeared to prefer as substrate FA with a 20-carbon chain, such as 20:3(8Z,11Z,14Z), 20:3(11Z,14Z,17Z), and 20:2(11Z,14Z), whereas short-chain FA were relatively weaker substrates for the enzyme in yeast.

*Expression of PiD5 in B. juncea.* To determine whether PiD5 is functional in oilseed crops and whether its expression has any effect on their growth and development, we initially transformed *B. juncea* with a binary vector that contained PiD5 cDNA behind a constitutive promoter (a tandem cauliflower mosaic virus 35S promoter). Five independent primary transgenic plants were obtained, and the FA profile of lipids from different tissues was determined (Fig. 3). Compared with wild type, all transgenic plant tissues had an altered FA profile containing four additional peaks, which were identified as four different Δ5-unsaturated polymethylene-interrupted FA (Δ5-UPIFA), specifically, taxoleic (18:2-5,9); ephedrenic (18:2-5,11); pinolenic (18:3-5,9,12), and coniferonic acids (18:4-5,9,12,15). Thus, *B. juncea*, like yeast, can functionally express the *P. irregulare* Δ5 desaturase to convert the endogenous substrates 18:1-9, 18:1-11, 18:2-9,12, and 18:3-9,12,15 to the corresponding Δ5 desaturated FA. It appeared that roots produced the highest amount of the Δ5-UPIFA, representing more than 20% of the total FA, followed by 6% in stems and 5% in leaves.

In *B. juncea* there is no 20:3-8,11,14 substrate available, a preferred substrate for Δ5 desaturase. Thus, to examine whether the transgenic plant can produce AA, the substrate 20:3-8,11,14 was exogenously supplied. In this experiment, both wild type and transgenics were applied with an aqueous solution of sodium HGLA. It was found that exogenously applied substrates were readily taken up by plant tissues and converted into AA in transgenic plants (Fig. 4).

**FIG. 3.** FA composition of vegetative tissues (leaves, stems, and roots) expressing  $\Delta 5$  desaturase under the control of the 35S promoter. The FA levels are shown as the weight percentage of total FA in *Brassica juncea*.

Although the  $\Delta 5$ -UPIFA accumulated in all parts of the transgenic plant, there were no severe observable phenotypic changes except that the transgenic plant appeared slightly shorter than the corresponding wild type.

To produce  $\Delta 5$  desaturated FA in seeds, we transformed *B. juncea* with the construct containing *PiD5* cDNA behind a heterologous seed-specific promoter (*B. napus* napin promoter). Eight transgenic plants were produced, and the FA compositions of the primary transgenic seeds were deter-

**FIG. 4.** GC analysis of root FAME of *B. juncea* expressing *PiD5* with exogenous substrate HGLA (20:3-8,11,14). For abbreviations see Figures 1 and 3.

**FIG. 5.** Gas chromatogram of FAME prepared from seeds of *B. juncea* expressing *PiD5* under the control of the napin promoter. For abbreviation see Figure 3.

mined. FA analysis of transgenic seeds indicated that there were two new FA appearing in the gas chromatogram of transgenics compared with the wild-type control (Fig 5). These were identified as taxoleic acid (18:2-5,9) and pinolenic acid (18:3-5,9,12). Together they represent about 10% of the seed FA. Accumulation of  $\Delta 5$ -UPIFA has no significant effect on the oleic acid content compared with the untransformed control. This result is in contrast to the following result in flax transgenics expressing the same enzyme.

*Expression of PiD5 in flax.* To produce  $\Delta 5$  desaturated FA in flax seeds, we transformed flax with *PiD5* under the control of a flax seed-specific promoter (Truksa, M., and Qiu, X., unpublished data). As shown in Table 2, transgenic flax produced three  $\Delta 5$  desaturated FA: taxoleic, pinolenic, and coniferonic. Of these, taxoleic (18:2-5,9) was the most abundant and accounted for more than 9% of the total FA in an elite transgenic line, followed by coniferonic and pinolenic acids. Surprisingly, accumulation of  $\Delta 5$  desaturated FA in transgenic seeds had a significant impact on the composition of other FA, especially the oleic acid level. Accumulation of  $\Delta 5$  FA was accompanied by a huge increase in the oleic acids. The content of oleic acid in transgenic plants, on the average, reached 24.3% of the total FA, relative to the untransformed control at 17.4%.

## DISCUSSION

In this report we describe isolation of a gene encoding  $\Delta 5$  desaturase from *P. irregulare*. Expression of the gene in *B. juncea* and flax resulted in production of  $\Delta 5$ -UPIFA, where the gene was expressed.

$\Delta 5$ -UPIFA occur widely in gymnosperms but less often in angiosperms (23). These FA are unusual in that two or more methylene units ( $\text{CH}_2$ ) separate the first double bond located at position 5 from the next double bond. Because of a structure similar to that of their counterparts, the usual  $\Delta 5$  desaturated PUFA,  $\Delta 5$ -UPIFA were reported to have beneficial effects on mammals, similar to those of  $\Delta 5$  EFA (24). In this study, we introduced the full-length *PiD5* into flax and *B. juncea* under the control of a seed-specific promoter, resulting in the accumulation of  $\Delta 5$ -UPIFA in oilseeds. In transgenic flax, taxoleic acid (18:2-5,9) represented more than 9% of the total FA. These findings suggest the possibility of producing a high level of  $\Delta 5$ -UPIFA in oilseed crops, which may increase the potential uses of these FA.

An interesting observation of this study was the changes in the seed FA composition of *PiD5* transgenic flax. It appeared that accumulation of  $\Delta 5$ -UPIFA in seeds was accompanied by an increase in the oleate content. A similar phenomenon was also observed with transgenic expression of *Fad2*-related enzymes, such as *Momordica charantia* conjugase (25) and castor and lesquerella oleate hydroxylases (26,27). It had been believed that a FA modified at the  $\Delta 12$  position interferes with the *FAD2* enzyme action, resulting in accumulation of a higher amount of oleic acid. Our data revealed that modification of FA at position 5 could also result in an increase in the oleate content in flax, but production of  $\Delta 5$ -UPIFA in *B. juncea* had little effect. It is not clear why the same transgene had different effects on the level of oleic acid in flax and *B. juncea*.

Biosynthesis of  $\Delta 5$ -UPIFA in gymnosperms was believed to involve two independent  $\Delta 5$  desaturases. One is specific for unsaturated FA with a  $\Delta 9$  ethylenic double bond, the other for unsaturated FA with a  $\Delta 11$  ethylenic double bond (28). Expression of *PiD5* in yeast and *B. juncea* revealed that the enzyme could effectively work on both 18:1-9 and 18:1-11, resulting in production of two corresponding products, taxoleic and ephedrenic acid, respectively. These data indicate that the  $\Delta 5$  desaturase from *P. irregulare* is quite flexible with respect to substrate requirement.

EPA and AA are both  $\Delta 5$  EFA. They form a unique class of food and feed constituents for humans and animals. Consequently, there is an increasing interest in the production in plants of AA- or EPA-containing oil for feed supplement and infant formula fortification. In this report we demonstrate that the  $\Delta 5$  desaturase isolated from *P. irregulare* is active in oilseed crops. The enzyme, when expressed in *B. juncea*, desaturated endogenous unsaturated substrates, resulting in several  $\Delta 5$  desaturated FA, and exogenously supplied substrate HGLA, resulting in production of AA in transgenic plants. These data suggest that this enzyme may be useful for large-

scale production of the  $\Delta 5$  EFA AA and EPA in oilseed crops. However, because of the promiscuous nature of the enzyme, the challenge for the production of AA and EPA in plants will be how to reduce or eliminate the undesirable FA such as  $\Delta 5$ -UPIFA. Co-expression of a  $\Delta 12$  desaturase and others in the LCPUFA pathway including  $\Delta 6$  desaturase,  $\Delta 6$  FA elongase, and  $\Delta 5$  desaturase may be a possible solution, by which the level of undesirable precursors would be reduced.

## ACKNOWLEDGMENTS

The authors thank Drs. Ed Kenaschuk, Gordon Rowland, and Derek Pots for providing flax and *B. juncea* germplasms; Drs. Andy Mitchell and Charles Martin for providing yeast mutant strains; Stephen Ambrose for performing mass spectrometry analysis; and Darwin Reed for preparing Figure 4.

**ABSTRACT:** Alterations in the membrane structure and function of hepatocyte membranes by fumonisin B<sub>1</sub> (FB<sub>1</sub>) have been proposed to play an important role in the disruption of growth regulatory effects and hence in the cancer-promoting ability of the mycotoxin. Detailed analyses of lipids in liver microsomal fractions of rats exposed to different dietary levels of FB<sub>1</sub> over a period of 21 d indicated an increase in PC, PE, PI, and cholesterol (Chol). These changes decreased the PC/PE and increased the total phospholipid/Chol ratios. When considering FA content, the quantities of total FA increased ( $P < 0.05$ ) in the major phospholipid fractions as a result of the increased phospholipid levels. However, when considering the relative levels (mg/100 mg of the total FA) of specific FA, the monounsaturated FA (16:1n-7 and 18:1n-9) and 18:2n-6 increased ( $P < 0.05$ ), whereas the long-chain PUFA decreased ( $P < 0.05$ ) in the main phospholipid fractions. Enzyme analyses indicated that the activity of the  $\Delta 6$ -desaturase was significantly reduced in liver microsomal preparations in a dose-dependent manner. An increase in the 20:3n-6/20:4n-6 ratio also suggested a decrease in the activity of the  $\Delta 5$ -desaturase. Disruption of microsomal lipid metabolism at different levels by FB<sub>1</sub> could play an important role in the alteration of growth regulatory effects in the liver.

Paper no. L9036 in *Lipids* 37, 869–877 (September 2002).

Fumonisin B<sub>1</sub> (FB<sub>1</sub>), a naturally occurring mycotoxin produced by *Fusarium verticillioides* in corn, alters growth regulatory responses in the liver. The inhibitory effect of FB<sub>1</sub> on growth-stimulating responses *in vitro* in different cell culture systems (1,2) and *in vivo* in rat liver has been related to the cancer-promoting activity of the compound (3,4). Studies in primary rat hepatocytes indicated that FB<sub>1</sub> increased the level of PC and PE, whereas sphingomyelin (SM) decreased (5). Total cholesterol (Chol) levels were decreased, and the relative levels of 18:2n-6 and 20:4n-6 increased. Sphingolipid metabolism was disrupted *via* the inhibition of ceramide synthase (6) resulting in the accumulation of sphinganine and to some extent sphingosine. The disruptions of lipid metabolism at different levels involving phospholipid, sphingolipid, and FA biosynthesis were suggested to be key events in the cytotoxicity of the fumonisins to hepatocytes (5). Subsequent investigations in primary hepatocytes indicated that FB<sub>1</sub> inhibited the epidermal growth factor (EGF) mitogenic

Abbreviations: Chol, cholesterol; EGF, epidermal growth factor; FB<sub>1</sub>, fumonisin B<sub>1</sub>; LA, linoleic acid; PG, prostaglandin; SM, sphingomyelin; TFA, total FA; TPL, total phospholipid.

response, a common property of many cancer promoters in rat liver (1). This mitoinhibitory effect was not related to the disruption of sphingolipid metabolism; and events such as the disruption of Chol, phospholipid, and FA metabolism or combined effects seem to play a determining role. Recent findings indicated that the mitoinhibitory effect of FB<sub>1</sub> was counteracted by prostaglandin (PG) E<sub>2</sub>, suggesting that arachidonic acid (20:4n-6) metabolism is a key determinant affected by FB<sub>1</sub> (7). The modulation of FB<sub>1</sub> on 20:4n-6 and PG-induced effects on cell cycle progression and apoptosis have been reported (8,9).

When considering the FA profiles in hepatocytes exposed to FB<sub>1</sub>, it has been suggested that the rate-limiting enzyme in FA metabolism,  $\Delta 6$ -desaturase, is impaired (5). *In vivo* changes in the lipid profiles include increased Chol and PE levels and decreased SM in the liver of rats fed a dietary level of 250 mg FB<sub>1</sub>/kg for 21 d (10). A long-term feeding study in rats indicated an increased PE level at a dietary level as low as 1 ppm FB<sub>1</sub> (10). The relative level of 18:2n-6 was again significantly increased in PE, and 18:1n-9 was also markedly increased. The final FA of the n-6 pathway, 22:5n-6, was significantly decreased, indicating a disruption of the n-6 metabolic pathway, presumably owing to an impaired  $\Delta 6$ -desaturase enzyme. A similar effect was noticed in plasma PC, where the relative levels of 20:4n-6 and 22:5n-6 were reduced while 18:2n-6 accumulated.

It was proposed that changes in lipid metabolism in the liver, including phospho- and sphingolipids, Chol, and FA metabolism, play a determining role in the toxicological effects of the fumonisins (11,12). The interaction of these different lipid parameters is likely to be important in determining cell survival by altering cell proliferative and/or apoptotic pathways (13,14). The present study investigated lipid profiles of liver microsomal preparations of rats exposed to different dietary levels of FB<sub>1</sub> and the possible modulating effect on FA desaturation.

## MATERIALS AND METHODS

**Reagents.** [1-<sup>14</sup>C]Linoleic acid (LA; 18:2n-6) and [1-<sup>14</sup>C]-GLA (18:3n-6) were obtained from DuPont (Mechelen, Belgium). LA, GLA, NADH, ATP, nicotinamide, coenzyme A, and BHT [2,6-di-*tert*-butyl-*p*-cresol] were ordered from Sigma Chemical Corporation (St. Louis, MO). FB<sub>1</sub> was purified according to the method described by Cawood *et al.* (15) to a purity of 90–95%.

**Treatment of animals.** The Ethics Committee for Research on Animals approved this study, and it was conducted in compliance with policies and standards detailed in the South African Medical Research Council's principles and guidelines for the use of animals in biomedical research. Fischer 344 male rats were fed diets containing 10, 25, 50, 100, 250, and 500 mg FB<sub>1</sub>/kg diet over a period of 21 d, as described previously (3). Rats were terminated by decapitation and the livers collected in ice-cold saline and frozen at  $-70^{\circ}\text{C}$ .

**Preparation of microsomal preparations.** Liver homogenates were prepared by a modification of the methods described by Koba *et al.* (16) and De Antueno *et al.* (17). Liver was homogenized at  $4^{\circ}\text{C}$  with three parts of a homogenizing buffer consisting of a 0.1 M potassium phosphate buffer containing 0.25 M sucrose, 0.15 M KCl, 5 mM MgCl<sub>2</sub>, 1 mM EDTA, and 1.5 mM GSH using a Potter-Elvehjem homogenizer. The homogenate was first centrifuged at  $10,000 \times g$  for 20 min, then the supernatant was collected and centrifuged at  $105,000 \times g$  for 1 h. The microsomal pellet was resuspended in homogenizing buffer using a glass homogenizer to a level of 10 mg protein/mL and stored at  $-70^{\circ}\text{C}$ .

**Lipid analyses.** The microsomal preparations (2 mg protein/mL) were extracted with chloroform/methanol/BHT (2:1:0.01, vol/vol/%) according to the method of Smuts *et al.* (18). No lipid analyses were performed on the liver microsomal fraction of the rats fed the 500 mg FB<sub>1</sub>/kg diet. The phospholipid classes in the extracts were separated by TLC according to the method of Gilfillan *et al.* (19) using chloroform/methanol/petroleum ether/acetic acid/boric acid (40:20:30:10:1.8 g, by vol) as developing solvent. The spots corresponding with the major phospholipids were visualized under UV light and collected for phospholipid and FA analyses. Transmethylation of the FA was achieved by MeOH/H<sub>2</sub>SO<sub>4</sub> (95:5) treatment for 2 h at  $70^{\circ}\text{C}$  in glass-stoppered tubes. FAME were analyzed by GC on a Varian model 3700 gas chromatograph using fused-silica megabore DB-225 columns (J&W Scientific, Folsom, CA). The FA peaks were identified by comparison of retention times to those of a standard mixture of FFA 14:0 to 22:6 and quantified using an internal standard (17:0) and expressed as  $\mu\text{g}$  FA/mg protein.

Phospholipid analyses were carried out by the method of Itaya and Ui (20) using malachite green. The collected phospholipid fractions were digested in perchloric acid at  $170^{\circ}\text{C}$  for 2 h and diluted in an appropriate volume of H<sub>2</sub>O. Quantification was effected colorimetrically using phosphate as an external standard. The total Chol of the chloroform/methanol extracts was determined by the enzymatic iodine method using Chol oxidase and esterase enzyme preparations (18).

**$\Delta 6$ -desaturase assay.** Enzyme activity was monitored by the method of Koba *et al.* (16). Test tubes containing 0.5  $\mu\text{C}$  LA (ca. 100 nmol/mL = 100  $\mu\text{M}$ ; 20  $\mu\text{L}$  ethanol), 0.25 M sucrose, 0.15 M KCl, containing NaF (45 mM), NADH (1.0 mM), ATP (1.5 mM), CoA (0.25 mM), nicotinamide (0.5 mM), MgCl<sub>2</sub> (5 mM), GSH (1.5 mM), and 100 mM phosphate buffer (pH = 7.4) in a total incubation volume of 1 mL were preincubated at  $37^{\circ}\text{C}$  for 5 min. A 1-mL microsomal solution

(2 mg protein) was incubated separately for 5 min at  $37^{\circ}\text{C}$ , and 1 mL (2 mg protein) was added to the incubation mixture to obtain a final protein concentration of 1 mg/mL. This mixture was incubated for a further 30 min at  $37^{\circ}\text{C}$ . The assay was terminated by the addition of freshly prepared 10% KOH (1.8 N) in ethanol (2 mL), and the mixture was saponified at  $100^{\circ}\text{C}$  for 30 min. After acidifying with 0.4 mL of 11.6 N HCl (36%), the mixture was extracted with hexane ( $2 \times 5$  mL), the hexane was evaporated (N<sub>2</sub>), and the samples were transmethylated as described above. FAME were extracted with hexane/H<sub>2</sub>O ( $2 \times 2$  mL hexane + 1 mL H<sub>2</sub>O), and the hexane layer was evaporated to dryness under nitrogen. After addition of 80  $\mu\text{L}$  of hexane/chloroform (20:5, vol/vol) the methylated products were fractionated on AgNO<sub>3</sub>-TLC plates using chloroform/methanol (50:2, vol/vol) as developing solvent. For the preparation of the AgNO<sub>3</sub>-TLC plates, silica gel plates were impregnated with 10% AgNO<sub>3</sub> in acetonitrile for 15 min, dried at  $100^{\circ}\text{C}$  for 20 min, and kept desiccated in the dark prior to use. The spots were visualized under UV light after spraying with 0.1% dichlorofluorescein in chloroform/methanol (1:1 vol/vol). The spots corresponding with the substrate [ $1\text{-}^{14}\text{C}$ ]18:2n-6 (LA) and the product [ $1\text{-}^{14}\text{C}$ ]18:3n-6 (GLA) were scraped into scintillation vials; scintillation liquid was added, and the radioactivity determined. The control treatments consisted of incubations with heat-inactivated microsomes and microsomal preparations without the incubation mixture. Enzyme activity, which served to monitor the formation of GLA, was expressed as pmol GLA/min/mg protein.

**Statistical analyses.** Data were analyzed by a two-way ANOVA using the generalized linear model procedure, and Tukey's Studentized range test was used to determine whether the means differed statistically. Values were considered significant if  $P < 0.05$ .

## RESULTS

Details concerning the effects of the different dietary levels of FB<sub>1</sub> on the liver and body weight gains have been reported previously (3). In short, body weight gain was significantly reduced in rats fed the 250 mg FB<sub>1</sub>/kg diet ( $P < 0.01$ ) and markedly (although not significantly) affected in the animals that received the 100 mg FB<sub>1</sub>/kg diet.

**Chol and phospholipids.** The Chol content of the microsomes was significantly ( $P < 0.05$ ) and marginally ( $P < 0.1$ ) increased in the rats fed the 250 and 100 mg FB<sub>1</sub>/kg diets, respectively (Fig. 1A). Of the different phospholipid fractions analyzed, no significant effect on the concentration of PS was noticed as a result of the FB<sub>1</sub> treatment. In contrast, the levels of PC, PE, and PI were significantly increased ( $P < 0.05$  to  $P < 0.01$ ) in the 250 mg FB<sub>1</sub>/kg dietary group (Tables 1 and 2). In the case of PE, the concentration was also marginally ( $P < 0.1$ ) increased in the 100 mg FB<sub>1</sub>/kg dietary group. The total phospholipid (TPL) concentration was also significantly ( $P < 0.05$ ) increased from 100 mg FB<sub>1</sub>/kg, whereas it was marginally ( $P < 0.1$ ) increased at dietary levels of 10 and 50 mg FB<sub>1</sub>/kg diet (Fig. 1A). When considering the relative levels

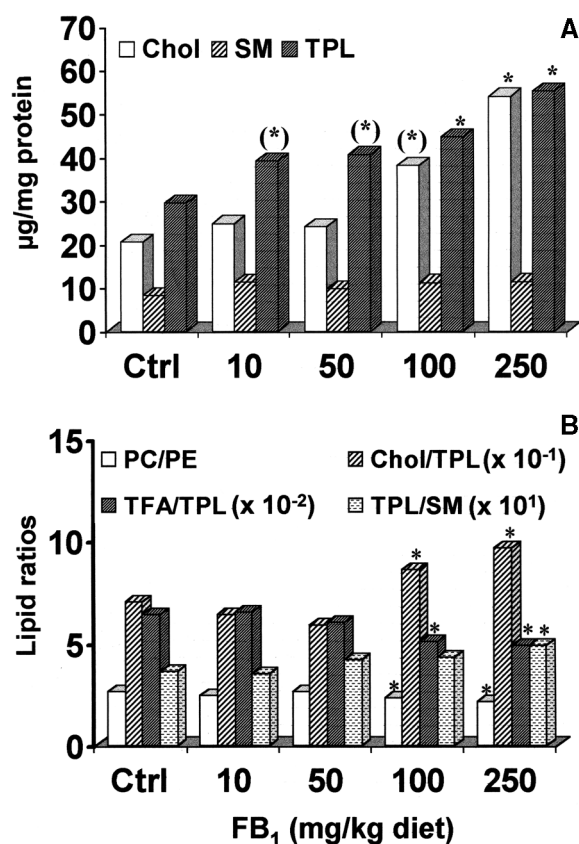

FIG. 1. (A) Effect of fumonisin B<sub>1</sub> (FB<sub>1</sub>) on the cholesterol (Chol), sphingomyelin (SM), and total phospholipid (TPL) levels in liver microsomes from rats exposed to different dietary levels over a period of 21 d. (B) Different lipid ratios that are possible factors modifying membrane fluidity. TFA, total FA. (\*) $P < 0.1$ , \*\* $P < 0.05$ .

of each phospholipid, expressed as a percentage of the TPL pool, the level of PC remained constant as PE increased marginally ( $P < 0.1$ ) and significantly ( $P < 0.05$ ) at 100 and 250 mg/kg dietary levels, respectively (Table 1). The relative levels of PI and PS significantly ( $P < 0.05$ ) decreased at the 100 and 250 mg FB<sub>1</sub>/kg dietary levels. As a result of the increase in the TPL pool, the total FA (TFA) were also increased marginally ( $P < 0.1$ ) to significantly ( $P < 0.05$ ) in the two high-dose groups, respectively. Owing to the changes in the lipid parameters of the microsomal membranes, the Chol/TPL ratio increased and the TFA/TPL and PC/PE ratios decreased in the 100 and 250 mg FB<sub>1</sub>/kg dietary groups (Fig. 1B).

**FA profiles.** The FA content, expressed as µg/mg protein, of the different phospholipids is summarized in Tables 1 and 2.

(i) **Saturated FA (16:0 and 18:0).** The total saturated fats increased significantly in the PC ( $P < 0.05$ ) and PE ( $P < 0.01$ ) phospholipid fractions in the 250 mg FB<sub>1</sub>/kg dietary group. In PC it was also significantly ( $P < 0.05$ ) increased in the 10 mg FB<sub>1</sub>/kg dietary group. Both 16:0 and 18:0 increased ( $P < 0.01$ ) in PE in the high-dose group whereas in PC only 16:0 increased significantly ( $P < 0.01$ ) in the high-dose group, and 18:0 was markedly increased in all FB<sub>1</sub>-treated groups. No changes were observed in PS and PI.

(ii) **Monounsaturated FA (16:1 and 18:1).** A marked to significant ( $P < 0.01$  to 0.05) increase in the monounsaturated

FA was noticed in all the phospholipid fractions in the livers of the two high-dose groups of rats (100 and 250 mg FB<sub>1</sub>/kg diet). In PC ( $P < 0.1$ ) and PE marked increases were also noticed at the 10 and 50 mg FB<sub>1</sub>/kg dietary levels. Both 16:1 and 18:1 contributed to the increased levels at the two high-dose levels; 18:1 was marginally ( $P < 0.1$ ) to significantly ( $P < 0.05$ ) increased in PC in all the FB<sub>1</sub>-treated groups.

(iii) **PUFA (n-6 PUFA: 18:2n-6, 20:4n-6, 22:4n-6, 22:5n-6).** LA (18:2n-6) was significantly ( $P < 0.1$  to 0.01) increased in all the phospholipid fractions in the 100 and 250 mg FB<sub>1</sub>/kg dietary groups, whereas it was markedly higher in PC and PE in the 10 and 50 mg FB<sub>1</sub>/kg groups. Arachidonic acid (20:4n-6) was significantly ( $P < 0.05$ ) increased in PC at dietary levels of 10 and 50 mg FB<sub>1</sub>/kg, but it was similar to the control levels in the two high-dose groups. No changes were observed in PS, whereas it was markedly to significantly ( $P < 0.1$  to 0.01) increased in PE and PI at all dose levels. The terminal FA in the n-6 pathway, 22:5n-6, was significantly ( $P < 0.01$ ) increased in PE at the high-dose level (250 mg FB<sub>1</sub>/kg). In PI, 22:5n-6 was significantly ( $P < 0.05$  to 0.01) increased at all the FB<sub>1</sub> dose levels. The total n-6 FA marginally to significantly increased in PC, PE, and PI at all the dose levels, whereas PS was not affected.

(iv) **PUFA (n-3 PUFA: 22:5n-3, 22:6n-3).** The level of 22:6n-3 was marginally ( $P < 0.1$ ) to significantly ( $P < 0.05$  to 0.01) increased in the PC, PE, and PI phospholipid fractions at the 10 mg FB<sub>1</sub>/kg dietary levels. At higher dietary levels it tended to mimic the level in the microsomes of the control rats despite the increase in the level of the respective phospholipid. The total n-3 FA tended to follow the same pattern in PC, PE, and PI, whereas PS was not affected.

**FA parameters.** Changes in the levels of the FA profiles presented above are related to the concentration of the respective phospholipid. As a result, PUFA were marginally ( $P < 0.1$ ) to significantly ( $P < 0.05$  to  $P < 0.01$ ) increased in the microsomal PC, PE, and PI phospholipid fractions of the FB<sub>1</sub>-treated animals. The n-6/n-3 FA ratio was also significantly ( $P < 0.05$ ) increased in PC and PE at the 100 and 250 mg FB<sub>1</sub>/kg dietary levels mainly due to an increase in the n-6 FA. The polyunsaturated/saturate FA ratio was not altered. The TFA increased markedly in the microsomes of the rats fed the 10 mg FB<sub>1</sub>/kg dietary level and significantly at the high-dose levels as a result of the increased levels of the individual phospholipids (Tables 1 and 2).

**FA desaturation.** When considering the activity of the FA  $\Delta$ -desaturases, the levels of the substrates and products of the enzyme are relevant. Since the concentration of phospholipids may vary, as in the case of the present study, the relative amount of each FA, expressed as a percentage of the TFA, needs to be considered. There was a significant increase in the relative levels of 16:1n-7, 18:1n-9, and 18:2n-6 and a significant decrease in the long-chain FA, 20:4n-6 and 22:6n-3, in PC (Fig. 2A) and PE (Fig. 2B) at a dietary level of 100 mg FB<sub>1</sub>/kg and above. The terminal FA of the n-6 metabolic pathway, 22:5n-6, significantly ( $P < 0.05$ ) decreased in both PE and PC in the 100 mg FB<sub>1</sub>/kg dietary

FIG. 2. The relative levels (% of total) of the FA in the major microsomal phospholipids PC (A) and PE (B) of the livers of rats fed different dietary levels of  $FB_1$  for 21 d. (\*) $P < 0.1$ , \* $P < 0.05$ . For abbreviation see Figure 1.

group while no decrease was noticed in the 250 mg  $FB_1$ /kg dietary group. A similar relative FA pattern was also noticed in PS and PI phospholipid fractions (data not shown). When considering specific FA ratios, using the relative concentration levels, the 18:2n-6/18:3n-6 ratio decreased significantly ( $P < 0.05$ ) in PC, whereas the 18:3n-6/20:4n-6 and 20:3n-6/20:4n-6 ratios increased significantly ( $P < 0.05$ ) in both PC and PE at the two high-dose  $FB_1$  dietary levels (Fig. 3A). No changes were observed in the 18:3n-6/20:3n-6 ratio in the PC and PE phospholipid fractions.

Enzyme analyses indicated that the conversion of  $^{14}C$ -LA to  $^{14}C$ -GLA, catalyzed by the  $\Delta 6$ -desaturase, was significantly reduced at dietary levels of 100 mg  $FB_1$  and higher (Fig. 3). The activity of the  $\Delta 5$ -desaturase was not determined.

## DISCUSSION

Lipid analyses of the livers of rats exposed to different dietary levels of  $FB_1$  indicated that the metabolism of Chol, phospholipid, FA, and sphingolipid is altered (10). The present study indicated that the phospholipids were significantly altered in the rat liver microsomal fraction due to elevated concentrations of PE, PC, and PI. When considering the relative contribution of each phospholipid to the TPL pool, PC remained constant at about

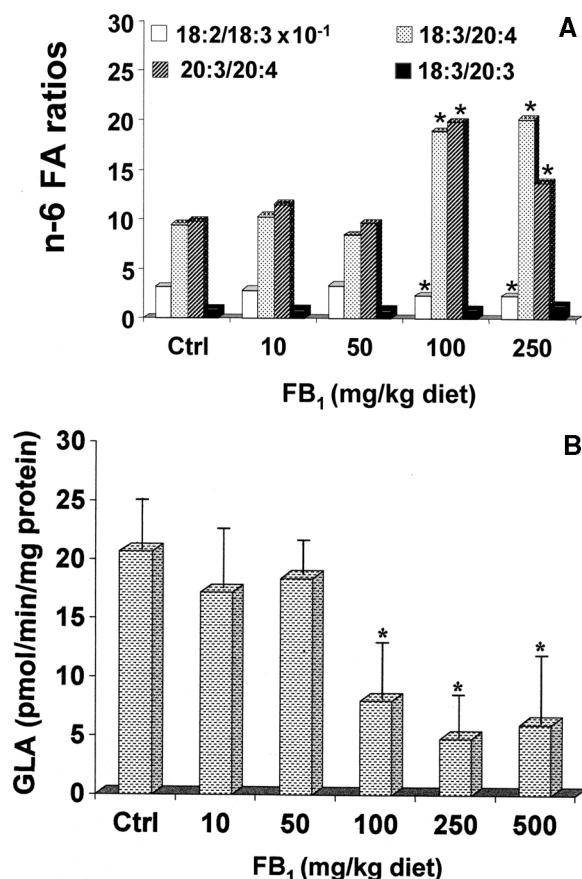

FIG. 3. Alterations of the relative FA ratios associated with changes in n-6 FA metabolism (A), and the effect of  $FB_1$  on the activity of the microsomal  $\Delta 6$ -desaturase enzyme as a function of different dietary doses fed to rats over a period of 21 d (B). Error bars represent the SD. \* $P < 0.05$ . For abbreviation see Figure 1.

60%, whereas PE increased significantly from 20 to 28%. The relative contribution of both PI and PS to the TPL pool tended to decrease, from 12 to 10% and from 4 to 2%, respectively. It appears that  $FB_1$  mainly altered the PE phospholipid compartment in rat liver microsomes, resulting in a significant decrease in the PC/PE ratio. Chol was also significantly increased (2.5 times) at the two higher dietary levels to the effect that, despite the increase in TPL, the Chol/TPL ratio increased significantly. The increase in the TPL also resulted in the increase in the TFA content. In this regard, the relative level of PUFA decreased significantly in PC, PE, and PI, and the saturated and monounsaturated FA compartment increased significantly.

The impact of these altered lipid parameters on membrane fluidity has been discussed in detail elsewhere (21). It was suggested that an increased Chol/TPL ratio decreased the PC/PE ratio, and the accumulation of the relative levels of the saturated FA together with the decrease in the long-chain PUFA could result in a more rigid microsomal membrane structure. It is not known to which extent the increase in the relative levels of the monounsaturated FA, 18:1n-9, and 18:2n-6 counteracted the impact of the other parameters in maintaining membrane fluidity. In this regard it was shown that, in persistent hepatocyte nodules, similar changes to the same lipid param-

ters were associated with an increase in fluidity (22). No changes in the concentration of the membrane sphingolipid, SM, were noticed as a result of the FB<sub>1</sub> treatment. Apparently, the disruption of sphingolipid metabolism, more specifically, the ceramide synthase by FB<sub>1</sub>, is not reflected in the microsomes. The TPL/SM ratio, however, increased significantly owing to the increase in the PC and PE concentration. As both phospholipids are involved in the synthesis of SM *via* PC:ceramide-phosphocholine and the PE:ceramide-phosphocholine transferases (23), the accumulation of PC and PE could be related to a decreased synthesis of SM owing to a reduced level of ceramide caused by the inhibition of ceramide synthase by FB<sub>1</sub>. Increased microsomal Chol is also known to induce the synthesis of SM by increasing the activities of the two phospholipid transferase enzymes (23). However, as the level of SM was not reduced, the above hypothesis does not explain the accumulation of PC and PE, and/or other mechanisms that regulate the level of SM in the microsomes may exist. Studies should be conducted on the modulating effect of FB<sub>1</sub> on Chol and phospholipid-metabolizing enzymes.

The increased TPL pool also resulted in an increase in the TFA concentrations in individual phospholipid fractions. This occurred at dietary levels as low as 10 mg FB<sub>1</sub>/kg. However, at the two higher levels the TFA/TPL ratio decreased mainly owing to an increase in TPL, whereas TFA levels did not increase to the same extent. The latter have been associated with the decrease in the relative values of PUFA, owing to the impaired  $\Delta 6$ -desaturase and/or increased lipid peroxidation induced by the hepatotoxic effects of FB<sub>1</sub> in the liver (4). Abel *et al.* (24) indicated that lipid peroxidation was significantly enhanced in rat liver microsomes after chronic feeding at a dietary level of 250 mg FB<sub>1</sub>/kg over a period of 21 d. Several other studies confirmed that FB<sub>1</sub> induces oxidation damage in membranal environments (25,26). Therefore, despite the increase in the concentration of the phospholipids, the PUFA levels, especially the relative levels of 20:4n-6 and 22:6n-3, which are prone to undergo lipid peroxidation, significantly decrease in both the PC and PE phospholipid fractions of the rats fed the high-dose FB<sub>1</sub> levels. It will not be possible to distinguish between the relative contribution of lipid peroxidation and an impaired FA desaturation toward the reduction of PUFA in the microsomes.

The activity of the  $\Delta 5$ - and  $\Delta 6$ -desaturase enzymes is affected by many factors including changes in the fluidity of the microsomal membrane (16), age (27–29), dietary status (30), different animal species, and different organs in the same species (16). Studies indicated that, with respect to dietary Chol and protein, altering the Chol/phospholipid and PC/PE ratios affects the fluidity of the microsomal membrane as well as the activity of the enzyme and hence the FA content of the microsomes (21,31). The FB<sub>1</sub>-induced alteration of FA patterns in the major phospholipid fractions in primary hepatocytes and in rat liver suggests an impaired  $\Delta 6$ -desaturase enzyme system (5,10). The present study indicates that FB<sub>1</sub> significantly decreased the activity of the  $\Delta 6$ -desaturase, resulting in the accumulation of 18:2n-6 in the major

phospholipids. When considering the 18:3n-6/20:4n-6 and 20:3n-6/20:4n-6 FA ratios, it appears that the activity of the  $\Delta 5$ -desaturase also is impaired. The increase in 18:3n-6 could explain the significant decrease in the 18:2n-6/18:3n-6 ratio, i.e., 18:3n-6 was proportionately higher than 18:2n-6. As no change was observed in the 18:3n-6/20:3n-6 ratio, it would appear that the activity of the elongase enzyme was not affected.

Whether the disruption of the activity of the FA  $\Delta$ -desaturases is related to a direct interaction with FB<sub>1</sub> or indirectly to a disruption of the membranal structure is unknown. The fact that Cawood *et al.* (32) indicated that FB<sub>1</sub> is tightly associated with hepatocyte membranes emphasizes the importance of monitoring the *in vitro* effects of FB<sub>1</sub> on the activity of the enzyme. Whatever the reason, the impairment of the FA  $\Delta$ -desaturases and the resultant disruption of FA metabolism are likely to disrupt the membrane integrity of the microsomes further. When considering the structural changes of the microsomal membranal environment, one must recognize that the activities of other important enzymes are also likely to be altered. Changes in the Chol and phospholipid membrane constituents have been shown to alter the activities of drug-metabolizing enzymes, such as cytochrome P450 (33–37). In this regard, recent studies indicated that the activity of certain isozymes of the hepatic P450 enzyme system are selectively inhibited and/or stimulated by FB<sub>1</sub> (38,39).

Structural changes with respect to Chol, phospholipids, and FA in the membrane environment of neoplastic cells have been reported to be important in the progression of these lesions into cancer (22). Membranal changes in hepatocyte nodules are associated with increased Chol and PE, resulting in an increased Chol/TPL ratio, a decrease in the PC/PE ratio, and changes in membrane fluidity. The  $\Delta 6$ -desaturase has been reported to be impaired in hepatocyte nodules and other cancerous tissue resulting in a specific FA pattern in the membranal phospholipids (22,40). The increased concentration of PE and subsequent increased level of 20:4n-6 have been implied to be important stimuli for the altered growth pattern in these lesions (22). A specific role for 20:4n-6 in the development of hepatocyte nodules has been proposed (22,41), suggesting a critical role of this FA in cancer development. Impairment of the  $\Delta 6$ -desaturase, presumably owing to structural changes in the membrane, is an early event in the genesis of hepatocyte nodules (22) and appears to be closely associated with the altered growth pattern of cancerous lesions. Recently, it was proposed that the disruption of the membrane structure by FB<sub>1</sub>, and more specifically the effect on PE and 20:4n-6 levels, could be important for the cancer-promoting ability of this compound in the liver (4,11). Addition of PG E<sub>2</sub> counteracts the mitoinhibitory effect of FB<sub>1</sub> on the EGF mitogenic response in primary hepatocytes, suggesting the disruption of 20:4n-6 metabolism (7). FB<sub>1</sub> also inhibits the effects of 20:4n-6, PG-E<sub>2</sub>, and PG-A<sub>2</sub> on apoptosis in esophageal cancer cells *in vitro* presumably related to decreased ceramide production (9).

Alterations in rat liver microsomal membrane lipid profiles and  $\Delta 6$ - and possibly  $\Delta 5$ -desaturase activity, leading to

altered FA metabolism, could have important implications regarding signaling pathways that determine cell survival and cancer development in the liver.

# The Assembly of Hepatic Very Low Density Lipoproteins: Evidence of a Role for the Golgi Apparatus

Klara Valyi-Nagy, Carla Harris, and Larry L. Swift\*

Department of Pathology, Vanderbilt University School of Medicine, Nashville, Tennessee 37232-2561

**ABSTRACT:** Previous studies from our laboratory have suggested that the assembly of lipoproteins by the liver is not completed in the rough endoplasmic reticulum but continues while the particles are *en route* to or within the Golgi apparatus. To investigate further the role of the Golgi apparatus in lipoprotein assembly, mice were injected with [<sup>3</sup>H]glycerol and killed 7.5 to 45 min after injection. Microsomes and Golgi apparatus-rich fractions were isolated from the livers and separated into membrane and content fractions. TG within microsomal and Golgi membranes were labeled, rapidly reaching peak specific activity within 7.5 min of isotope injection. The specific activity of TG in microsomal membranes decreased to approximately 40% of peak values by 45 min, whereas the specific activity of TG in the Golgi membranes decreased to approximately 30% of peak values by 45 min. To determine whether the turnover of the Golgi membrane TG pool was dependent on microsomal TG transfer protein (MTP), mice were gavaged with an MTP inhibitor, and the labeling experiments were repeated. Inhibition of MTP attenuated the turnover of newly synthesized Golgi membrane TG by approximately 50% and the turnover of microsomal membrane TG by approximately 40%. Based on the rapid turnover of the Golgi membrane TG pool and the attenuation of the turnover of this pool by MTP inhibitor, we propose that lipid is transferred from the Golgi membrane to luminal lipoproteins in an MTP-dependent manner. The results support our hypothesis that assembly of VLDL continues within the Golgi apparatus.

Paper no. L8950 in *Lipids* 37, 879–884 (September 2002).

A number of studies have suggested that the assembly of VLDL by the liver occurs *via* a two-step process (1–3). In this model, lipoprotein assembly is initiated in the rough endoplasmic reticulum (ER) with the synthesis of apolipoprotein B (apoB). The first step involves the association of apoB with phospholipids and core material, primarily cholesterol ester, to form a small HDL-like particle. In the second step additional core material, primarily TG, is added to the HDL-like particle to form a VLDL.

The two-step model implies that assembly is completed within the ER of the cell. However, considerable evidence

suggests that the Golgi apparatus plays more than a passive role in the assembly process (4–7). For example, Bamberger and Lane (4), in studies with chick hepatocytes, concluded that assembly of TG with apoproteins occurs in the Golgi. Likewise Higgins' studies in rat liver suggested that the *trans*-Golgi regions appeared to be the major intracellular sites of assembly of apoB with TG (5). More recent studies by Stillemark *et al.* (8) suggest that assembly of apoB-48-containing VLDL is not completed in the rough ER. Pulse-chase studies combined with subcellular fractionation showed that apoB-48 VLDL did not accumulate in the rough ER, indicating either that completed apoB-48 VLDL was rapidly transferred out of the ER or that assembly steps occurred post-ER. Previous studies in our laboratory suggest a critical role for the Golgi apparatus in the assembly process. By comparing the composition of nascent VLDL ( $d < 1.006$  g/mL) recovered from the rough ER with VLDL recovered from the Golgi apparatus-rich fractions of rat livers, we concluded that an additional assembly step occurs while the particles are *en route* to the Golgi apparatus or within the Golgi apparatus (9). We estimated that up to 50% of the total VLDL TG and 30–40% of the phospholipid are added after the particle leaves the rough ER. The source of the lipid and the mechanism by which lipid is added to the particles is unknown. More recent studies in our laboratory (10) have documented size heterogeneity of nascent VLDL within the Golgi apparatus of mouse liver. We reported that approximately 50% of the apoB within the lumen of mouse liver Golgi apparatus was associated with particles recovered in the  $d$  1.006–1.210 g/mL fraction. Furthermore, using radioisotope tracer studies we found that more than 80% of the newly synthesized apoB found in the serum was recovered with the VLDL fraction. This suggested that lipid is added to the nascent particles within the Golgi apparatus before secretion.

This study was undertaken to investigate further the role of the Golgi apparatus in the assembly of VLDL by the liver. *In vivo* lipid labeling experiments with [<sup>3</sup>H]glycerol have led to the identification of a pool of newly synthesized TG within hepatic Golgi membranes. This pool, distinct from the pools in the rough and smooth ER, has a rapid turnover rate. Furthermore, the turnover of this pool is attenuated in the presence of a microsomal TG transfer protein (MTP) inhibitor. We hypothesize that this pool of TG is derived from the ER membranes and is used in the lipidation of VLDL within the Golgi apparatus in an MTP-dependent process.

## EXPERIMENTAL PROCEDURES

**Animals.** Male ICR mice (approximately 30 g) were purchased from Harlan Industries (Indianapolis, IN). The animals were maintained in the Vanderbilt University Animal Care facility on food (Wayne Lab Blox; Allied Mills, Inc., Chicago, IL) and water *ad libitum* for at least 5 but no longer than 10 d prior to the experiments. All procedures using mice were approved by the Animal Care and Use Committee at Vanderbilt University.

**Isolation of subcellular fractions.** Golgi apparatus-rich fractions were isolated from the mouse livers by the method of Swift *et al.* (10). Livers (usually three, with a total mass of 5–6 g) were minced finely with scalpels, placed in homogenizing buffer (1.5 mL/g) consisting of 0.1 M phosphate buffer, pH 7.3; 0.25 M sucrose; 1% dextran; and 0.01 M MgCl<sub>2</sub> and homogenized at a setting of 45 for 20 s using a Virtishear homogenizer. The homogenate from three livers was placed in one tube and centrifuged in an SW40 rotor at 900 × *g* for 10 min, at which point the speed was increased to 6,000 × *g* and the samples centrifuged an additional 30 min. The supernatant was discarded except when used for the isolation of microsomes (see below). Homogenizing buffer (1.7 mL) was then added to the pellet. The top one-third of the pellet was gently dislodged from the remainder of the pellet, resuspended, and layered on 8 mL of 1.2 M sucrose. The samples were centrifuged in the SW40 rotor at 3,300 × *g* for 10 min, after which the speed was increased to 13,000 × *g* for 10 min and finally increased to 83,000 × *g* for 45 min. The material banding on the 1.2 M sucrose pad was carefully removed, diluted with ice-cold distilled water, and pelleted using the SW40 rotor (6,000 × *g* for 30 min). The pellet was resuspended in 15 mM Tris and 0.154 M NaCl, pH 7.4, and the content and membrane fractions were recovered by sodium carbonate treatment followed by centrifugation as described below.

Microsomes were isolated by centrifugation of the first supernatant at 114,000 × *g* for 60 min using an SW41 rotor. The pellet was washed by resuspending it in PBS; it was then pelleted under the same conditions. The final microsomal pellet was resuspended in PBS, quick-frozen, and stored at –80°C.

Cytosolic fat was defined as the fat that floated during the initial isolation of microsomes. It was recovered from the top of the tube after tube slicing and washed in PBS under the same conditions as used for isolation.

**Separation of membrane and luminal content fractions.** Golgi and microsomal fractions were incubated on ice with an equal volume of 0.2 M sodium carbonate, pH 11.0, for 60 min (11). The final concentration of protein in the sample was approximately 0.5–1.0 mg/mL. The membranes were pelleted using an Optima TLX tabletop ultracentrifuge with a TLA 120.2 rotor (511,000 × *g*, 30 min). The supernatant was dialyzed against 0.154 M NaCl and 0.01% EDTA, pH 7.4, and was used to isolate luminal lipoproteins.

**Isolation of nascent subcellular and serum lipoprotein fractions.** The *d* < 1.006 g/mL fraction was isolated using the TLA 120.2 rotor. The samples were centrifuged for 3 h at 511,000

× *g*, and the top 250–300 μL was removed after tube slicing. The density of the infranatant was raised to 1.210 g/mL using solid KBr, and the *d* 1.006–1.210 g/mL fraction was floated by centrifuging for 4.5 h at 511,000 × *g* in the TLA 120.2 rotor. The top 250–300 μL was removed after tube slicing, and both the *d* < 1.006 and the *d* 1.006–1.210 g/mL fractions were dialyzed against 0.01% EDTA, pH 7.4, with a final change against distilled water prior to lyophilization. Serum lipoproteins were isolated at the same densities using the same conditions with the final fractions being dialyzed and lyophilized.

**Radioisotope incorporation studies.** Mice were anesthetized with ketamine/xylazine and injected *via* the retroorbital plexus with 25–30 μCi [2-<sup>3</sup>H]glycerol (16.5 Ci/mmol; NEN Life Science Products, Inc., Boston, MA). At 7.5, 15, 30, and 45 min after injection, the animals were killed by exsanguination from the inferior vena cava. The livers were removed, trimmed of excess fat and connective tissue, and rinsed. Subcellular fractions and nascent lipoproteins were isolated as described above. Aliquots of serum (100 μL) were taken for isolation of serum lipoprotein fractions as described above.

**MTP inhibitor studies.** MTP inhibitor (BMS 197636, kindly provided by R. Gregg, Bristol Myers Squibb, Princeton, NJ) was dissolved in 10% M-Pyrol (*N*-methyl-2-pyrrolidone) 80% water, 5% Cremophor EL, and 5% ethanol at a concentration of 6.25 mg/mL. The inhibitor was administered to mice by gavage (20 μg/g) 60 min prior to injection of [<sup>3</sup>H]glycerol. The remainder of the experiment was as described above. To establish the effectiveness of the MTP inhibitor, hepatic VLDL TG production rates were assessed using Triton WR1339 (12).

**Isolation of lipids.** Membrane and cytosolic fat fractions were delipidated using the method of Folch *et al.* (13). Lipoprotein fractions were delipidated using ethanol/ether (14). Neutral and polar lipids were separated using small silicic acid columns (15). Neutral lipids were separated into individual lipid classes by TLC on silica gel 60A thin-layer plates (Whatman K-6; Fisher Scientific, Atlanta, GA) with petroleum ether/ethyl ether/acetic acid (80:20:1, by vol) as the developing solvent. TG were scraped from the plate into scintillation vials. Scintillation fluid (Bio-Safe II; Research Products International Corp., Mount Prospect, IL) was added, and radioactivity was determined using a Beckman LS6800 scintillation counter.

**Analytical and enzymatic assays.** Protein was determined by the bicinchoninic acid method (Pierce, Rockford, IL), modified to eliminate interference by lipid (16) and using BSA as standard. TG were quantified using an enzymatic assay (Raichem, San Diego, CA) adapted to microtiter plates. Aliquots of the lipid fractions were dissolved in isopropanol, and 20 μL was added to each well. Water (80 μL) was added followed by 100 μL of the color reagent. Plates were incubated at 37°C for 10 min and read at 520 nm using a BioRad Model 550 microplate reader. The assay was linear from 0.5 to 10.0 μg TG. Glycerol was used as a standard.

**Statistics.** Data are presented as the mean ± SEM and were analyzed by an unpaired Student's *t*-test using GraphPad InStat (GraphPad Software, San Diego, CA).

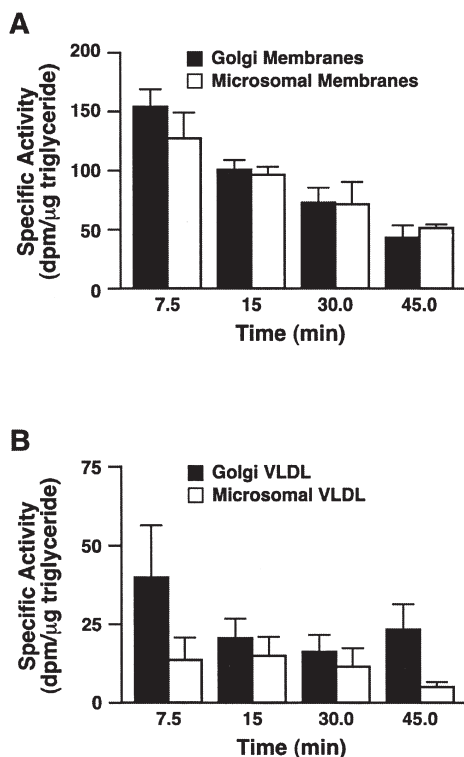

## RESULTS

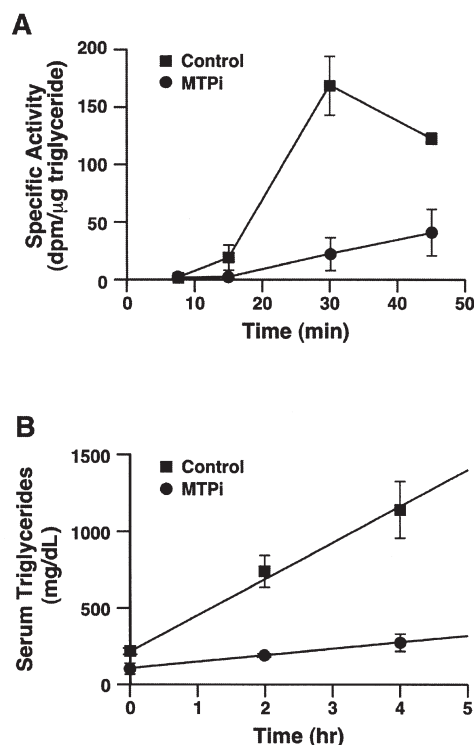

**[<sup>3</sup>H]Glycerol incorporation studies.** [<sup>3</sup>H]Glycerol was incorporated rapidly into Golgi and microsomal membrane TG, reaching peak specific activity in both membranes within 7.5 min of isotope injection (Fig. 1A). The specific activity of TG in the microsomal membranes decreased to approximately 40% of peak value by 45 min, while the specific activity of TG in Golgi membrane decreased to about 30% of peak value within the same time.

The appearance of labeled TG in Golgi VLDL followed a pattern similar to that of the TG within the Golgi membrane; however, the specific activity of Golgi VLDL TG was less than 50% of that in the Golgi membrane at each time point (Fig. 1B). The specific activity of TG in the  $d < 1.006$  g/mL lipoproteins recovered from the microsomal fraction remained relatively low with a peak near 15 to 30 min. The specific activity of the luminal TG was lower than in the membrane, similar to that observed in the Golgi. Labeled TG did not appear in the serum VLDL fraction until the 15-min time point, and increased to the 30-min time point, consistent with peak intracellular specific activity and its trafficking out of the cell (Fig. 2A).

**Incorporation of [<sup>3</sup>H]glycerol in MTP-inhibited animals.** The MTP inhibitor BMS 197636 was administered to mice

**FIG. 1.** Incorporation of [<sup>3</sup>H]glycerol into TG of mouse hepatic fractions. Mice were injected with 25–30 μCi [<sup>3</sup>H]glycerol, and hepatic fractions were isolated at different times after injection. Lipids were extracted, and TG mass and radioactivity were determined as described in the Experimental Procedures section. (A) Golgi and microsomal membranes; (B) Golgi and microsomal VLDL. Data represent the mean ± SEM. Golgi,  $n = 5$ ; microsomes,  $n = 4$ .

**FIG. 2.** Effects of the microsomal TG transfer protein (MTP) inhibitor BMS 197636 on hepatic TG production in mice. BMS 197636 was administered to mice by gavage (20 μg/g), and 60 min later [<sup>3</sup>H]glycerol was injected. The appearance of labeled TG in serum VLDL was monitored (A), and hepatic TG production was determined using the Triton method (B). Data represent the mean ± SEM. (A) Control,  $n = 3$ ; MTP inhibitor (MTPi),  $n = 3$ . (B) Control,  $n = 5$ ; MTPi,  $n = 3$ .

by gavage, and 60 min later hepatic TG production rates were determined. The MTP inhibitor decreased hepatic TG production rates by greater than 85% [ $127.4 \pm 4.7$  vs.  $17.1 \pm 5.9$  (mean ± SEM) μmol/kg/h,  $n = 3$ /group] (Fig. 2B). To verify the block in hepatic TG production, the inhibitor was given to mice and 60 min later [<sup>3</sup>H]glycerol was injected. Less than 5% of the radioactivity found in the serum VLDL of control animals was recovered in the MTP-inhibited mice, confirming the block of MTP activity and secretion of VLDL TG (Fig. 2A).

Inhibition of MTP did not affect the incorporation of newly synthesized TG into microsomal membranes, as the specific activity of the TG in these membranes at 7.5 min was identical to that found in the control (noninhibited) animals. However, inhibition of MTP did attenuate the turnover of newly synthesized TG in both the microsomal and Golgi membranes (Fig. 3). In microsomal membranes the turnover was reduced by approximately 40%, whereas in the Golgi membranes turnover was reduced nearly 50%.

The inhibitor dramatically altered the incorporation of newly synthesized TG into the cytosolic pool. In control animals the cytosolic TG pool reached peak specific activity approximately 30 min after [<sup>3</sup>H]glycerol injection (Fig. 4). In contrast, in animals given the inhibitor the specific activity of

**FIG. 3.** Effects of the MTP inhibitor BMS 197636 on turnover of newly synthesized TG in microsomal and Golgi membranes. Control mice and mice given the BMS 197636 (20  $\mu\text{g/g}$ ) were injected with [ $2\text{-}^3\text{H}$ ]glycerol, and hepatic Golgi and microsomal membranes were isolated at 7.5 and 45 min postinjection. TG mass and radioactivity were determined as described in the Experimental Procedures section, and specific activity was calculated. The specific activity of TG at 45 min is expressed as percentage of specific activity at the 7.5-min time point. Data represent the mean  $\pm$  SEM. Control,  $n = 4$ ; MTPi  $n = 3$ . \* \*\*Significantly different from control at  $P = .007$  and  $.003$ , respectively. For abbreviations see Figure 2.

the cytosolic TG reached peak value within 7.5 min, and the specific activity at this time point was identical to the specific activity at 30 min in the control animals (Fig. 4). In addition, the specific activity of the cytosolic TG in the presence of the inhibitor remained constant over the experimental period, suggesting little movement out of this pool.

**Hepatic membrane and cytosol TG content.** Golgi membranes recovered after sodium carbonate treatment and release of luminal lipoproteins contained over twice as much TG as membranes recovered from microsomal fractions ( $P = 0.0004$ ) (Table 1). Inhibition of MTP led to a significant decrease in the amount of TG in the Golgi membrane and a slight, but not significant, increase in the amount of TG in the microsomal membrane. The cytosolic TG pool increased more than 130% when MTP was inhibited. It is important to note that in these studies MTP was inhibited from 67.5 to 105 min.

## DISCUSSION

A growing body of evidence suggests that the assembly of VLDL is not completed within the ER of the cell but continues *en route* to or within the Golgi apparatus (8,10,17). Previ-

**FIG. 4.** Incorporation of [ $^3\text{H}$ ]glycerol into TG in the cytosolic pool. Control mice and mice given the MTP inhibitor (BMS 197636, 20  $\mu\text{g/g}$ ) were injected with [ $2\text{-}^3\text{H}$ ]glycerol, and hepatic cytosolic fat was isolated at various times postinjection. TG mass and radioactivity were determined, and specific activity was calculated. Data are expressed as mean  $\pm$  SEM. Control,  $n = 4$ ; MTPi,  $n = 4$ . \*Significantly different from control at  $P < .005$ . For abbreviations see Figure 2.

ous studies from our laboratory have indicated that as much as 50% of the TG and 30% of the phospholipid may be added in the Golgi apparatus of the cell (9). More recent studies from our laboratory have identified a population of apoB-containing HDL within the Golgi apparatus of mouse liver that are apparently secreted as VLDL, suggesting that neutral lipid is added within the Golgi apparatus (10). The results presented here provide additional evidence for a direct role of the Golgi apparatus in the assembly process. Our studies demonstrate the presence of a pool of newly synthesized TG within the membranes of the Golgi apparatus. Based on membrane protein, the level of TG within this membrane is greater than that in the membrane of the ER (Table 1). The turnover of TG in the Golgi membrane pool is rapid and is similar to that found with the TG in the membrane of the microsomal fraction. Furthermore, the turnover of this Golgi membrane pool is attenuated by the MTP inhibitor BMS 197636. We suggest that this pool of TG is used in the lipidation of lipoproteins within the Golgi apparatus in an MTP-dependent process.

The presence of TG within Golgi membranes is not a new finding. Hebbachi and Gibbons (18) incubated rat hepatocytes for 4 h in the presence of labeled oleate and glycerol and reported that the membranes of both *cis*- and *trans*-Golgi were more heavily labeled with TG than those of the rough or smooth ER. The *trans*-Golgi membrane had nearly twice as

**TABLE 1**  
TG Content of Hepatic Fractions<sup>a</sup>

Group	Golgi membranes (mg/mg protein)	Microsomal membranes (mg/mg protein)	Cytosol ( $\mu\text{g/g}$ liver)
Control	0.062 $\pm$ 0.007 <sup>a,b</sup>	0.027 $\pm$ 0.003 <sup>a</sup>	198.0 $\pm$ 13.0 <sup>c</sup>
MTP inhibited	0.031 $\pm$ 0.004 <sup>b</sup>	0.032 $\pm$ 0.004	461.2 $\pm$ 42.9 <sup>c</sup>

<sup>a</sup>Data represent the mean  $\pm$  SEM from eight preparations. Values with the same roman superscript are significantly different at the following  $P$  values: <sup>a</sup>0.0004; <sup>b</sup>0.0007; <sup>c</sup><0.0001.

much labeled TG per mg subcellular vesicle protein as the smooth ER membrane and almost 10 times as much as the rough ER membrane. The *cis*-Golgi membrane contained about the same amount of labeled TG as the smooth ER membrane but eight times as much as the rough ER. Our studies demonstrate that the mass of TG in the Golgi membrane per mg protein is two to three times that found in the membranes of the rough and smooth ER (Table 1). Since TG is not a structural component of membranes and since the Golgi membrane is not recognized as a major site of TG synthesis, the presence of this amount of TG within the Golgi membrane led to questions about its origins and disposition. To address these questions, kinetic studies with radioisotopic tracers were performed.

The labeling kinetics of the Golgi membrane TG were similar to those found with microsomal membranes (Fig. 1). A number of studies have shown that TG is synthesized in the ER and trafficks primarily to the cytosol, although some may enter the VLDL assembly pathway (19,20). Our results suggest that newly synthesized TG also trafficks to the Golgi membrane, yet the pathway by which this occurs is unknown. It is unlikely that the Golgi membrane TG derives from the cytosolic pool since the specific activity of the Golgi pool is higher than that of the cytosol at the early time points. Furthermore, we have been unable to document significant level of DAG acyltransferase (DGAT) activity in Golgi membranes. The presence of DGAT in the Golgi membrane might be expected if TG were transported from the cytosolic pool *via* a process of hydrolysis and subsequent re-esterification analogous to that occurring with the ER (21). It seems most likely that the transfer of membrane TG from the ER to the Golgi occurs *via* vesicular transport (22,23). Moreau *et al.* (24), using an *in vitro* transfer assay, reported that little labeled TG was transferred to the Golgi fractions (24). However, their results were collected using an *in vitro* system in which lipid transfer was less than 1% of the total lipids. Transfer *in vivo* may be quite different.

Previous studies from our laboratory (9) led us to conclude that as much 50% of the VLDL TG may be added to nascent lipoproteins in the Golgi apparatus. The finding of newly synthesized TG within the Golgi membrane led us to hypothesize that this TG serves as a pool for addition to nascent lipoproteins. The mechanism by which this TG is added to nascent Golgi lipoproteins is unknown, but there is evidence that MTP may be present in *cis*- and *trans*-Golgi fractions of liver (18,25,26). In addition, a recent study demonstrates the presence of MTP in the Golgi apparatus of rat enterocytes (27).

We then studied the effects of MTP inhibition on the synthesis of TG and distribution of newly synthesized TG within the liver. Prior to initiating these studies, we demonstrated that rates of hepatic TG output, as measured using the Triton method, were reduced by more than 85% when mice were given the inhibitor at a dose of 20  $\mu\text{g/g}$  body weight (Fig. 2B). In addition, our radioisotope incorporation studies were consistent with the Triton studies, demonstrating a marked reduction in the amount of newly synthesized TG appearing in the serum pool over the 45-min time period (Fig. 2A).

The inactivation of MTP led to a doubling of the cytosolic TG pool and a slight, albeit statistically insignificant, increase in the microsomal membrane TG pool (Table 1). In contrast, the pool of TG in the Golgi membrane was decreased by nearly 40% when MTP was inactivated. As might be predicted, inhibition of MTP blocked the entry of newly synthesized TG into the lumen of the ER (data not shown). Surprisingly, in the presence of the inhibitor the specific activity of the cytosolic TG reached its peak more rapidly than in control samples, and the specific activity of this pool remained constant over the 45-min period (Fig. 4). These data suggest that inhibition of TG transfer to the lumen of the ER leads to more rapid transfer of newly synthesized TG into the cytosolic pool. Furthermore, the fact that the specific activity of this pool remained constant over the 45-min time period suggests that the inactivation of MTP blocks the transfer of TG from the cytosol to the ER membrane. Hebbachi and Gibbons (18) reported a similar result in studies with rat hepatocytes. They suggested that MTP inhibition blocks the transfer of cytosolic TG to the ER membrane by a route that involves the luminal leaflet of the ER membrane. As noted, this would cause an accumulation of TG not only in cytosol but also in the ER membrane. It is also possible that the inhibition of MTP affects the hydrolysis of TG in the cytosolic pool or even its re-esterification within the ER membrane. The decrease in TG in the Golgi membrane in relation to the increased TG in the ER membrane is an important finding. It suggests that if Golgi membrane TG does derive from ER membranes, this process is not a simple blebbing of the ER but must involve some sorting, as suggested by Moreau *et al.* (24), and the MTP alters or inhibits the sorting or transport in some manner.

Inhibiting MTP not only decreased the TG in the Golgi membrane but also attenuated the turnover of newly synthesized Golgi membrane TG (Fig. 3), which suggests that MTP may play a role in the transfer of TG from the Golgi membrane to its contents. Hebbachi *et al.* (25) reported that inhibiting MTP with BMS 200150 resulted in a delayed removal of apoB-100 and apoB-48 from the Golgi membranes, and Hebbachi and Gibbons (18) showed a delayed removal of newly synthesized TG from the membranes of *cis*- and *trans*-Golgi. Alternatively, inhibiting MTP could block the assembly of lipoprotein in the ER, leading to a decrease in lipoproteins in the Golgi apparatus. The transfer of TG from the Golgi membrane to nascent lipoproteins within the Golgi complex would then also be blocked because of a lack of acceptor lipoproteins within the lumen. In this case, the direct involvement of MTP within the Golgi apparatus would not be required. Regardless of the mechanism, the results support a role for the Golgi apparatus in adding lipid (TG) to nascent lipoproteins. Although our studies do not permit us to differentiate between occurrences in the *cis*- or *trans*-Golgi, it is possible that the lipidation occurs early within the Golgi apparatus as suggested by Cartwright and Higgins (7). Indeed, if MTP is located within the Golgi complex by way of escape from the ER, we might expect it to be found within the *cis* Golgi elements.

These studies provide additional evidence that the Golgi apparatus participates in the assembly of nascent lipoproteins by the liver. The finding of a pool of newly synthesized TG within the Golgi membrane fraction provides a plausible mechanism by which lipid is added to nascent lipoproteins. Our finding that the inhibition of MTP attenuates the turnover of the Golgi membrane TG pool further supports the hypothesis that this pool is involved in lipoprotein assembly within the Golgi. The pathway by which TG is delivered to the Golgi membranes and the precise mechanisms by which lipid is added to the particles being formed are under study.

## ACKNOWLEDGMENTS

**ABSTRACT:** Fructose-1,6-bisphosphate (FBP) is a high-energy glycolytic intermediate that decreases the effects of ischemia; it has been used successfully in organ perfusion and preservation. How the cells utilize external FBP to increase energy production and the mechanism by which the molecule crosses the membrane bilayer are unclear. This study examined the effects of FBP on membrane bilayer permeability, membrane fluidity, phospholipid packing, and membrane potential to determine how FBP crosses the membrane bilayer. Large unilamellar vesicles composed of egg phosphatidylcholine (Egg PC) were made and incubated with 50 mM FBP spiked with <sup>14</sup>C-FBP at 30°C. Uptake of FBP was significant ( $P < 0.05$ ) and dependent on the lipid concentration, suggesting that FBP affects membrane bilayer permeability. With added calcium (10 mM), FBP uptake by lipid vesicles decreased significantly ( $P < 0.05$ ). Addition of either 5 or 50 mM FBP led to a significant increase ( $P < 0.05$ ) in Egg PC carboxyfluorescein leakage. We hypothesized that the membrane-permeabilizing effects of FBP may be due to a destabilization of the membrane bilayer. Small unilamellar vesicles composed of dipalmitoyl pC (DPPC) were made containing either diphenyl-1,3,5-hexatriene (DPH) or trimethylammonia-DPH (TMA-DPH) and the effects of FBP on the fluorescence anisotropy (FA) of the fluorescent labels examined. FBP caused a significant decrease in the FA of DPH in the liquid crystalline state of DPPC ( $P < 0.05$ ), had no effect on FA of TMA-DPH in the liquid crystalline state of DPPC, but increased the FA of TMA-DPH in the gel state of DPPC. From phase transition measurements with DPPC/DPH or TMA-DPH, we calculated the slope of the phase transition as an indicator of the cooperativity of the DPPC molecules. FBP significantly decreased the slope, suggesting a decrease in fatty acyl chain interaction ( $P < 0.05$ ). The addition of 50 mM FBP caused a significant decrease ( $P < 0.05$ ) in the liquid crystalline/gel state fluorescence ratio of merocyanine 540, indicating increased head-group packing. To determine what effects these changes would have on cellular membranes, we labeled human endothelial cells with the membrane potential probe 3,3'-dipropylthiacarbocyanine iodide (DiSC<sub>3</sub>) and then added FBP. FBP caused a significant, dose-dependent decrease in DiSC<sub>3</sub> fluorescence, indicating membrane depolarization. We suggest that FBP destabilizes membrane bilayers by decreasing fatty acyl chain interaction, leading to significant increases in

membrane permeability that allow FBP to diffuse into the cell where it can be used as a glycolytic intermediate.

Paper no. L9024 in *Lipids* 37, 885–892 (September 2002).

Fructose-1,6-bisphosphate (FBP) has been proposed to enhance ATP production during ischemia and has shown its effectiveness in certain ischemic conditions, such as hemorrhagic, cardiogenic, and endotoxin shock (1,2), extremity ischemia (3), hypoxic brain and intestine injury (4–7), coronary occlusion (8), agent-induced tissue toxicity (9–11), isolated heart perfusion (12–15), left ventricular dysfunction (16,17), and hypothermic renal and liver preservation (18,19). Results from our laboratory indicated that when FBP was added to St. Thomas solution, rat heart preservation time was also increased (20,21). It is theorized that the mechanism by which FBP exerts its effects is by a direct metabolic enhancement. During periods of prolonged ischemia, glycolysis becomes the primary mechanism for ATP production. The reasoning behind the use of FBP for tissue protection during ischemia is that if FBP could cross the membrane bilayer, FBP would bypass the two ATP-depleting steps of glycolysis and thus double glycolytic ATP production. However, there is no known receptor for FBP (22), and the two phosphate groups of FBP have classically been thought to make the molecule unlikely to cross the membrane bilayer.

Recently, we showed that FBP can pass through membrane bilayers and cellular membranes (23). We also showed that FBP can increase the metabolism of cardiomyocytes once inside the cell (24). Several other studies have indicated that FBP can cross membrane bilayers. Hardin and Roberts (25) have shown by NMR spectroscopy of hog carotid artery segments that externally applied <sup>13</sup>C-FBP is metabolized. A similar finding was reported by Espanol *et al.* (26) using <sup>13</sup>C-FBP in neonatal rat brain slices. However, the permeability of FBP through the membrane bilayer has been questioned in several studies. For example, Roig *et al.* (27) suggested that FBP does not cross the cellular membrane but rather FBP alters potassium flux, which in turn decreases ATP demand by the cell. The decrease in potassium flux by FBP was also documented in a study by Galzigna and Rigobello (28). Clearly, there is no real consensus on how externally applied FBP can enter cells and supplement or preserve ATP levels.

The low permeability of FBP through cellular membrane bilayers is in part due to the high degree of hydration and the low solubility of FBP within the membrane interior. Thus, it is

Abbreviations: DiSC<sub>3</sub>, 3,3'-dipropylthiacarbocyanine iodide; DPH, 1,6-diphenyl-1,3,5-hexatriene; DPPC, dipalmitoylphosphatidylcholine; Egg PC, egg phosphatidylcholine; FBP, fructose-1,6-bisphosphate; MC540, merocyanine 540; TMA-DPH, 1-(4-trimethylammoniumphenyl)-1,6-phenyl-1,3,5-hexatriene *p*-toluenesulfonate.

highly unlikely under normal circumstances that FBP would readily pass through the membrane bilayer by simple diffusive mechanisms. However, if the membrane bilayer were somehow destabilized, the hydrophobic barrier of the membrane bilayer would be changed and the permeability of water-soluble compounds would increase. One intriguing finding is that FBP is a potent calcium and divalent ion chelator (29). If high extracellular concentrations of FBP could chelate the counterbalancing ions that interact with the phospholipid head groups of the membrane bilayer, then this interaction could lead to substantial changes in membrane stability. In fact, substances that affect the counterbalancing ions that stabilize membrane bilayers previously have been shown to alter membrane stability (30). Thus, FBP could potentially destabilize membrane bilayers and allow the compound to cross the membrane bilayer by simple diffusive mechanisms. The goal of the following study is to examine how FBP destabilizes membrane bilayers and what effect the destabilization has on the diffusion of the compound across the membrane bilayer into the cytosol of the cell.

## MATERIALS AND METHODS

**Materials.** Dipalmitoylphosphatidylcholine (DPPC) and egg phosphatidylcholine (Egg PC) were purchased from Avanti Polar Lipids (Alabaster, AL) and used without further purification. The fluorescent probes, 1,6-diphenyl-1,3,5-hexatriene (DPH), 1-(4-trimethylammoniumphenyl)-1-6-phenyl-1,3,5-hexatriene *p*-toluenesulfonate (TMA-DPH), merocyanine 540 (MC540), carboxyfluorescein, and 3,3'-dipropylthiadicarbocyanine iodide (DiSC<sub>3</sub>) were purchased from Molecular Probes (Eugene, OR). Fructose, fructose-1-phosphate, fructose-6-phosphate, <sup>14</sup>C-FBP, and FBP were purchased from Sigma Chemical Company (St. Louis, MO). Human umbilical vein endothelial cells and EGM culture media were purchased from BioWhittaker Corp (Walkersville, MD).

**Lipid vesicle preparation.** DPPC, dissolved in chloroform, and lipid-soluble fluorescent probes (DPH and TMA-DPH) were dried under a stream of nitrogen gas onto the side of a glass test tube. Traces of chloroform were removed by vacuum pumping for a period of 12 h. The dried lipid material was hydrated in buffer above the phase transition of DPPC at 50°C for 30 min. The hydrated lipid material was vortexed for 5 min with two glass beads to form multilamellar vesicles. For the fluorescence anisotropy studies and carboxyfluorescein leakage studies, the multilamellar vesicles were sonicated using a Branson Sonifier 450 tip-type sonicator for 4 min at a 40% duty cycle, output level 6, creating small unilamellar vesicles. For the MC540 studies of lipid packing, the lipid vesicles were extruded through 0.2 μm Nucleopore filters using an Avanti Polar Lipids Extruder. The lipids were passed through the filters 20 times to create large unilamellar vesicles.

**Carboxyfluorescein leakage.** DPPC (20 mg/mL) small unilamellar vesicles were made in the presence of 60 mM carboxyfluorescein, 30 mM KCl, and 10 mM Na<sub>2</sub>HPO<sub>4</sub>; pH 7.4. The lipid vesicles were passed down a pre-swollen Sephadex column equilibrated with 90 mM KCl, 10 mM Na<sub>2</sub>HPO<sub>4</sub>, pH

7.4, to remove nonsequestered carboxyfluorescein. The eluted vesicles were kept on ice to minimize leakage of the carboxyfluorescein until experimentation. The vesicles were injected (25 μL) into 2 mL of one of three buffers: 0.5 mM FBP/89.5 mM KCl/10 mM Na<sub>2</sub>HPO<sub>4</sub>; 5 mM FBP/85 mM KCl/10 mM Na<sub>2</sub>HPO<sub>4</sub>; 50 mM FBP/40 mM KCl/10 mM Na<sub>2</sub>HPO<sub>4</sub> (all pH 7.4) at 50°C. In some experiments the FBP was replaced with an equivalent concentration of fructose-6-phosphate, fructose-1-phosphate, or fructose. The leakage of trapped carboxyfluorescein from the vesicles was monitored for a period of 7 min using a PerkinElmer LS50B Luminescence Spectrophotometer. The excitation was at 495 nm, and the emission was followed at 520 nm. The rate of carboxyfluorescein leakage, expressed as the change in fluorescent intensity over time, is directly proportional to the leakage of the carboxyfluorescein anion through the membrane bilayer. At the conclusion of each experiment, the vesicles were lysed with 2% Triton X-100 to release the remaining trapped carboxyfluorescein, and the final fluorescence after detergent addition was measured to achieve the percent carboxyfluorescein leakage.

**Fluorescence anisotropy.** Small unilamellar vesicles of DPPC containing DPH or TMA-DPH (800:1 lipid/probe ratio) were made in the presence of either 5 mM FBP/20 mM Na<sub>2</sub>HPO<sub>4</sub>, 50 mM FBP/20 mM Na<sub>2</sub>HPO<sub>4</sub>, 5 mM fructose/20 mM Na<sub>2</sub>HPO<sub>4</sub>, or 50 mM FBP/20 mM Na<sub>2</sub>HPO<sub>4</sub>, all pH 7.4. The vesicles were placed in quartz cuvettes with a small magnetic stir bar into a PerkinElmer LS50B. The cuvette chamber was thermally controlled by use of a Haak circulating water pump. The initial temperature of the chamber was 30°C. The G-factor, or grating factor, was calculated to correct for instrumental artifacts. Fluorescence anisotropy of the DPPC/DPH or DPPC/TMA-DPH solution was determined using horizontal and vertical polarizers mounted in a PerkinElmer Fast Filter Accessory using FL WinLab software. The temperature of the lipid vesicle solution was changed every 10 min in 2°C increments until the final temperature of 50°C was obtained. The heating ramp of the Haak circulator was kept constant during the experiment to ensure that the phase transition measurements were not an artifact of heating. The slope of the phase transition of DPPC was determined from the fluorescence anisotropy measurements. This value was calculated by measuring the change in anisotropy from 35 to 45°C.

**MC540 measurements of lipid packing.** DPPC large unilamellar vesicles were made in the presence of either 50 mM FBP/20 mM Na<sub>2</sub>HPO<sub>4</sub> or 50 mM fructose/20 mM Na<sub>2</sub>HPO<sub>4</sub> pH 7.4. The lipid vesicles were injected into a solution of MC540 (10 μg/mL) buffered with 20 mM Na<sub>2</sub>HPO<sub>4</sub>, pH 7.4. The lipids and MC540 were incubated above the phase transition temperature of DPPC (50°C) for a period of 1 h. The lipid/MC540 solution was placed into a PerkinElmer LS50B Luminescence Spectrophotometer. The DPPC/MC540 solution was excited at 540 nm, and the emission of the MC540 was measured from 570 to 650 nm. The temperature of the lipid solution was varied from 25 to 55°C, and at each temperature an emission scan of the MC540 was determined. The emission of MC540 at 593 nm is considered a measure of liq-

uid-crystalline-like lipid environment, whereas the emission of MC540 at 620 nm is a measure of gel state-like environment. Thus, the ratio of MC540 emission intensities at 593 nm/620 nm is indicative of the degree of lipid packing.

**Membrane potential measurements.** Human umbilical vein endothelial cells were grown on six-well culture plates for 3 d until confluence. The cells were gently trypsinized from the dish and washed 3× in Hank's Balanced Salt Solution (pH 7.4). The endothelial cells were incubated with the membrane potential-sensitive probe DiSC<sub>3</sub> for a period of 20 min. The cells were then exposed to increasing concentrations of FBP or fructose and the fluorescence of DiSC<sub>3</sub> followed.

**Uptake of FBP by lipid vesicles.** Large unilamellar vesicles composed of Egg PC were made by lipid vesicle extrusion at 30°C. The final concentration of lipid was either 10, 1, or 0.1 mg/mL. The lipid vesicles were placed in an isosmotic solution containing 50 mM FBP spiked with 0.1 μCi <sup>14</sup>C-FBP. The vesicles were kept at 30°C by means of a circulating water bath. The vesicles and FBP were incubated for a period of 1 h, after which the vesicles were pelleted by ultracentrifugation. The pellet was washed 3× in an isosmotic buffer, and the radioactivity in the pellet was measured by liquid scintillation. In some experiments we added 10 mM calcium chloride to the FBP solution in order to examine the effects of calcium on the uptake of FBP.

**Statistical analysis.** The data in each experiment were first evaluated by ANOVA for repeated measurements using a two-factor analysis. When significant *F* values were encountered by ANOVA, the Student–Newman–Keuls' multiple-range test was used to determine which groups differed significantly from the others. Differences were considered statistically significant when *P* < 0.05. Statistical analysis was done with commercially available software (SigmaStat, Version 1.01; Jandel Corp., San Rafael, CA).

## RESULTS

In the first experiment, we examined the uptake of <sup>14</sup>C-FBP by lipid vesicles composed of Egg PC at 30°C. The vesicles were incubated with 50 mM FBP for a period of 1 h, after which the radioactivity in the vesicles was measured. Increasing the lipid concentration of Egg PC resulted in increased uptake of the FBP inside the lipid vesicles (Fig. 1). Because FBP uptake might be affected by calcium, we examined how extravesicular calcium might alter the uptake of FBP. When the FBP was supplemented with 10 mM calcium chloride, the increase in FBP uptake in the Egg PC vesicles was significantly reduced.

In the next experiment, we examined the effects of FBP on membrane permeability. Small unilamellar vesicles composed of DPPC were made with a self-quenching concentration of carboxyfluorescein. In this assay, any change in membrane permeability causes the self-quenched carboxyfluorescein to leak out of the lipid vesicle into the external milieu where the carboxyfluorescein becomes highly fluorescent. The rate of fluorescence increase over time is indicative of heightened mem-

**FIG. 1.** The uptake of fructose-1,6-bisphosphate (FBP) by lipid vesicles composed of egg phosphatidylcholine (Egg PC: 0.1, 1, and 10 mg/mL) at 30°C. Large unilamellar vesicles were made and placed in a solution containing 50 mM FBP + <sup>14</sup>C-FBP (0.1 μCi). The vesicles were then exposed to 10 mM calcium chloride to determine how excess calcium affected uptake of FBP. FBP uptake was dependent on lipid concentration, and the uptake was significantly inhibited by the addition of calcium. The results are the mean radioactivity detected in 10 different samples. \*Significantly different from Egg PC at the same lipid concentration as tested by ANOVA (*P* < 0.05). Error bars represent SD.

brane permeability. The DPPC lipid vesicles containing carboxyfluorescein were exposed to increasing concentrations of FBP, fructose-6-phosphate, fructose-1-phosphate, or fructose (Fig. 2). The addition of 0.5 mM FBP had no effect on carboxyfluorescein leakage. However, 5 and 50 mM FBP caused significant changes in membrane permeability to carboxyfluorescein. In contrast, neither fructose-6-phosphate, fructose-1-phosphate, nor fructose had any effect on DPPC membrane bilayer permeability at any concentration examined. After completion of the experiment, Triton X-100 was mixed with the vesicles to determine percent leakage. The percent leakage for the 50 mM FBP group was 9.8% after Triton application.

**FIG. 2.** FBP increases membrane permeability to carboxyfluorescein. Small unilamellar vesicles composed of dipalmitoylphosphatidylcholine (DPPC) were made in the presence of carboxyfluorescein. After removing the nonsequestered carboxyfluorescein, the vesicles were placed into cuvettes containing either FBP, fructose-1-phosphate (1-ph), fructose-6-phosphate (6-ph) or fructose (Fru) (45°C). The concentrations tested were 0.5, 5, and 50 mM, each osmotically balanced by addition of KCl. The addition of 5 and 50 mM FBP caused a significant increase in the leakage of trapped carboxyfluorescein. *dF/dT* = change in fluorescence/change in time (s). \*Significantly different from Fru, 1-ph, and 6-ph, as tested by ANOVA (*P* < 0.05). *n* = 7. Error bars represent SD. For abbreviation see Figure 1.

We hypothesized that the membrane permeability changes brought about by FBP could be the result of increased membrane fluidity (order). To examine this hypothesis, we made DPPC small unilamellar vesicles containing either DPH or TMA-DPH. DPH is a fluorescent probe that monitors membrane anisotropy changes in the fatty acyl chain region of the bilayer, whereas the amphipathic TMA-DPH measures anisotropy changes near the head group region of the bilayer. DPPC has a well-defined phase transition that occurs at 41.7°C. We measured fluorescence anisotropy of DPH in DPPC lipid vesicles from 28 to 50°C in the presence of either 50 mM FBP or 50 mM fructose (Fig. 3). The addition of FBP caused a significant decrease in membrane fluorescence anisotropy of DPH from 42 to 50°C (liquid crystalline state), indicating a more disordered lipid environment. FBP also broadened and lowered the phase transition of DPPC, which did not occur with an equimolar concentration of fructose. In contrast, fructose had no effect on DPPC membrane order within the same temperature span. We likewise examined the effects of 50 mM FBP and 50 mM fructose on DPPC membrane order using TMA-DPH (Fig. 4). Neither FBP nor fructose had any effect on the fluorescence anisotropy of TMA-DPH in the liquid crystalline state of DPPC. In the gel state of DPPC (28–40°C), FBP did cause a slight but significant increase in membrane order, which did not occur with fructose.

The slope of the phase transition, which is a measure of fatty acyl chain interaction during the main phase transition of DPPC, is derived by measuring the slope of the phase transition from 35 to 45°C. As the slope of the transition decreases, the degree of fatty acyl chain interaction decreases. From the phase transition measurements made in Figures 3 and 4, the slope of the transition was determined and plotted in Figure 5.

**FIG. 3.** FBP causes a decrease in fluorescence anisotropy of 1,6-diphenyl-1,3,5-hexatriene (DPH) in the liquid-crystalline state of DPPC. DPPC small unilamellar vesicles containing DPH were made in the presence of either 50 mM FBP, 50 mM fructose, or buffer (control). Fluorescence anisotropy measurements of DPH in DPPC were made from 28 to 50°C. The presence of FBP caused a significant decrease in the fluorescence anisotropy of DPH from 42 to 50°C. In contrast, fructose had no effect on DPH fluorescence anisotropy over the same temperature span. \*Significantly different from fructose and control as tested by ANOVA ( $P < 0.05$ ).  $n = 6$ . Error bars represent SD. For other abbreviations see Figures 1 and 2.

**FIG. 4.** FBP increases the fluorescence anisotropy of 1-(4-trimethylammoniumphenyl)-1,6-phenyl-1,3,5-hexatriene *p*-toluenesulfonate (TMA-DPH) in the gel state of DPPC. DPPC small unilamellar vesicles containing TMA-DPH were made in the presence of either 50 mM FBP, 50 mM fructose, or buffer (control). Fluorescence anisotropy of TMA-DPH in DPPC was made from 28 to 50°C. The presence of TMA-DPH caused a significant increase in the fluorescence anisotropy of TMA-DPH from 28 to 40°C. In contrast, neither fructose nor the control had any effect on the fluorescence anisotropy of TMA-DPH. \*Significantly different from fructose and control as tested by ANOVA ( $P < 0.05$ ).  $n = 6$ . Error bars represent SD. For abbreviations see Figures 1 and 2.

The presence of 50 mM FBP caused a significant decrease in the slope of the transition as measured by DPH. In contrast, 5 mM FBP had no effect on the slope of the DPPC transition. Furthermore, the slope of the phase transition as measured by TMA-DPH was unaffected by any concentration of FBP or fructose.

The changes in membrane bilayer parameters noted in Figures 2–5 suggest that the effects of FBP occur primarily in the

**FIG. 5.** The slope of the phase transition of DPPC suggests that 50 mM FBP decreases fatty acyl chain interaction. The slope of the phase transition of DPPC shown in Figures 3 and 4 was determined and is shown. The presence of 50 mM FBP decreased the slope of the transition in DPPC/DPH vesicles compared to fructose. In contrast, 50 mM FBP had no effect on the slope of the DPPC transition when monitored with TMA-DPH. Furthermore, 5 mM FBP had no effect on the slope of the phase transition. \*Significantly different from control and fructose as tested by ANOVA ( $P < 0.05$ ). Error bars represent SD. For abbreviations see Figures 1, 2, and 4.

**FIG. 6.** FBP decreases the liquid crystalline (LC)/gel ratio of merocyanine 540 (MC540) in DPPC. DPPC large unilamellar vesicles were made in the presence of 50 mM FBP, 50 mM fructose, or buffer only (control). The fluorescence of MC540 at 593 nm (liquid-crystalline-like state) and at 620 nm (gel-like state) were measured from 25 to 55°C. FBP decreased the 593 nm/620 nm ratio, indicating a more densely packed membrane. In contrast, fructose had no effect on the MC540 593 nm/620 nm ratio. \*Significantly different from fructose and control as tested by ANOVA ( $P < 0.05$ ).  $n = 10$ . Error bars represent SD. For abbreviations see Figures 1 and 2.

fatty acyl chain region. To verify this finding, we utilized the phase-sensitive fluorescent probe MC540, which undergoes a shift in its emission maxima in response to changes in membrane phase. The emission of MC540 at 593 nm is indicative of a liquid crystalline environment, whereas the emission at 620 nm is indicative of a more gel-state membrane bilayer. DPPC lipid vesicles were made in the presence of FBP or fructose, incubated with MC540, and then the fluorescence emission maxima at 593 and 620 nm were determined (Fig. 6). The fluorescence ratio of 593 nm/620 nm (liquid crystalline/gel ratio) of MC540 in DPPC from 28 to 50°C is shown. The presence of FBP caused a significant decrease in the 593 nm/620 nm ratio.

If FBP causes significant changes in membrane permeability and destabilizes the membrane bilayer, it could have drastic effects on membrane potential. To examine this hypothesis, we grew human umbilical vein endothelial cells to confluence, and then removed them from their dishes by gentle trypsinization. The cells were incubated with the fluorescent membrane potential-sensitive dye DiSC<sub>3</sub>. The endothelial cells were placed in a cuvette, FBP or fructose was added to the cells, and the fluorescence of DiSC<sub>3</sub> was measured (Fig. 7). On addition of FBP, there was a concentration-dependent decrease in DiSC<sub>3</sub> fluorescence, indicating a decrease in membrane polarization. In contrast, fructose failed to achieve the same decreases in fluorescence of the DiSC<sub>3</sub>.

## DISCUSSION

FBP is a high-energy glycolytic intermediate that has been used with good success to supplement glycolysis during prolonged periods of ischemia. The theory that substantiates the

**FIG. 7.** FBP causes a significant decrease in membrane polarization of human umbilical vein endothelial cells as measured by 3,3'-dipropylthiadicarbocyanine iodide (DiSC<sub>3</sub>). Human umbilical vein endothelial cells were grown to confluence, removed from their dish, and incubated with the membrane potential fluorescent probe DiSC<sub>3</sub>. Upon addition of FBP, there was a stepwise decrease in DiSC<sub>3</sub> fluorescence, indicating a decrease in membrane polarization. \*Significantly different from fructose and control as tested by ANOVA ( $P < 0.05$ ).  $n = 8$ . Error bars represent SD. For other abbreviation see Figure 1.

use of FBP is that if the molecule could cross the membrane bilayer, it could double glycolytic ATP production. However, there has been a controversy within the literature regarding the mechanism responsible for the movement of FBP across the membrane bilayer. Since there is no known receptor for FBP (22), it is unlikely that the molecule moves across *via* a protein channel. Several theories have been suggested to explain how FBP crosses the membrane bilayer or supplements glycolysis. These have included the use of a dicarboxylate transporter (31), hydrolysis of the phosphate groups (26), and decrease in potassium flux and thus decreased ATP demand (27). However, what makes for an interesting argument is that when <sup>13</sup>C-FBP was added to cells, <sup>13</sup>C-lactate was detected (7), and that FBP crossed the membrane bilayer of lipid vesicles (23,24). Perhaps the most confusing issue regarding how FBP crosses the membrane bilayer is the widely held biochemical theory that phosphorylated sugars such as FBP do not readily diffuse through membrane bilayers. The purpose of this study was to examine the effects of FBP on membrane bilayers. The findings from this study show that FBP destabilizes the membrane bilayer by causing loss of fatty acyl chain interaction. We theorize that the loss of fatty acyl chain interaction is likely caused by the chelating effects of FBP on membrane calcium since FBP is a known divalent chelator (18). The destabilization of the membrane bilayer decreases hydrophobic interactions leading to increased membrane permeability, allowing FBP to diffuse down its concentration gradient into the cell.

No studies to date have examined the effects of FBP on membrane bilayer properties, mainly because the assumption is that FBP cannot pass through membrane bilayers. In fact, a number of studies have ignored the idea that FBP can directly have any effect on cellular ATP levels, mainly because it is assumed that FBP cannot cross the membrane bilayer (22). For example, Bickler and Buck (32) suggest that FBP cannot

cross the membrane bilayer (although they show no evidence for this statement), but that exogenous FBP preserves ATP levels and decreases glutamate release. An earlier study by Galzigna and Rigobello (28) clearly states that the effects of FBP on proton and potassium flux "cannot, in fact, be explained on the basis of a penetration of the compound through the cell membranes, which is not possible," but affects these ions by some unknown mechanism. In support of the idea that FBP could have an effect on membrane bilayers, Hardin and Roberts (25) have shown that FBP crosses the cell membrane and is metabolized to lactate. They also theorized that FBP could cross the membrane bilayer by creating "polar discontinuities," allowing FBP to diffuse across the membrane bilayer. However, they offered no proof that would show that FBP creates polar discontinuities within the membrane bilayer, nor did they offer a mechanism to explain how FBP crosses the membrane bilayer.

When we examined the effects of FBP on the fluorescence anisotropy of DPH and TMA-DPH, we found that FBP caused some significant changes in the membrane bilayer (Figs. 3–5). Our studies indicate that FBP decreased the fluorescence anisotropy of DPH in DPPC vesicles in the liquid-crystalline state, whereas FBP had no effect on TMA-DPH fluorescence anisotropy in the liquid crystalline state of DPPC. One of the significant findings from this segment of the study was that FBP decreased the slope of the phase transition of DPPC, suggesting that DPPC fatty acyl chain interaction had decreased in the presence of FBP (Fig. 5). We also found that FBP caused the fluorescence of MC540 (a phase-sensitive fluorescent probe) to shift to a more predominant 620 nm reading (Fig. 6). This finding suggests that FBP causes the phospholipid head groups to become more condensed. One very plausible explanation of the data is that FBP causes the polar head groups to become more closely packed (MC540 data), which in turn increases the intramolecular distance between adjacent fatty acyl chains (DPH data). This drastic change in membrane structure could have significant effects on the barrier properties of the membrane bilayer to water-soluble substances such as FBP.

Cellular membrane bilayers are a complex mixture of lipids, proteins, and carbohydrates. The permeability of any substance through the membrane bilayer is a function of several different parameters including, but not limited to, M.W., lipid solubility of the agent, fatty acyl chain composition of the membrane bilayer, and the presence of integral membrane proteins. In the case of FBP, the M.W., charge, and degree of hydration would argue against the molecule passively diffusing through the membrane bilayer to any significant extent. In the case of glucose, the permeability (in the absence of any protein carrier) of the membrane bilayer to this substance is relatively small compared to more hydrophobic substances with similar M.W. (33). Thus, the long-held idea that FBP should not cross the membrane bilayer by diffusive mechanisms is substantiated by the literature. However, the idea that the permeability of the membrane bilayer to FBP should be relatively low does not take into account the chelating prop-

erties of FBP, especially when high external concentrations of FBP are utilized. Recently, it was shown that FBP could decrease the extracellular calcium concentration by up to 47% (29). Interestingly, when we exposed endothelial cells to histamine (a known intracellular calcium-elevating agent) we found an 80% decrease in intracellular calcium in the presence of 5 mM FBP (Ehringer, W.D., Chiang, B., and Chien, S., unpublished results). The chelation of calcium can have a measurable effect on cell membrane bilayer structure. For example, when extracellular calcium is elevated, nonbilayer structures can form as detected by  $^{31}\text{P}$  NMR (34). Trauble and Eibl found that only small changes in ionic environment can result in gross alterations in bilayer structure. Specifically, they found that divalent cations stabilized membrane bilayer structure. This same group has hypothesized that lowering extracellular cation levels could result in membrane destabilization, mainly because the tightly held counterbalancing ions help stabilize the membrane bilayer (35). Interestingly, removal of extracellular calcium can destabilize the membrane bilayer and cause loss of phospholipid head-group interaction (30). The loss of head-group interaction could lead to significant increases in membrane permeability as the destabilized phospholipids become less tightly packed. When we exposed lipid vesicles to FBP and extracellular calcium, we found a significant decrease in the uptake of FBP (Fig. 1). The fact that these vesicles lack any carrier protein argues strongly that the penetration of FBP into cells is likely the result of membrane destabilization, most likely due to chelation of membrane calcium. Furthermore, in the current study it was demonstrated that the uptake of FBP was increased by increasing the lipid concentration. This finding suggests that FBP alters membrane bilayer properties in proportion to the amount of lipid, which may explain how FBP can enter into cells.

One of the significant findings of this study is that FBP, a water-soluble molecule, can passively diffuse through membrane bilayers. The importance of this finding in the fields of organ preservation, tissue preservation, and ischemia needs to be addressed. The amount of FBP that can passively move through the membrane bilayers determined in the current study is relatively small (about 0.3% of the total FBP; see Fig. 1). However, the significance of the amount that is moving through when compared to the internal cellular concentration of FBP is considerable. It previously has been shown that FBP inside a cell is about 1.2  $\mu\text{M}$  (29). Thus, in our experiments with FBP we have demonstrated that as much as 75–150  $\mu\text{M}$  FBP can enter the cell. This is nearly a 60-fold increase in the normal level of FBP. For organ or tissue preservation during periods of low oxygen, this level of FBP would be more than sufficient to sustain glycolysis during low-oxygen periods. However, there appears to be a point of diminishing returns in terms of the amount of FBP that can be added, as evidenced by our membrane potential studies (Fig. 7). As the concentration of FBP is increased, there are significant changes in membrane depolarization. At doses above 10 mM FBP, the changes in membrane permeability

**FIG. 8.** Simplistic mechanism that may explain the calcium-chelating effects of FBP and the changes in membrane bilayer properties noted in the current study. Because FBP can compete with the phospholipid head groups for calcium, the head groups become stressed inward, resulting in increased head-group packing and decreased acyl chain interaction. The decrease in acyl chain group interaction leads to increased permeability to FBP. For abbreviation see Figure 1.

could result in the loss of substantial levels of intracellular ions and membrane potential.

Our findings indicate that FBP can increase acyl chain mobility in the liquid crystalline state (Fig. 3) and also increase head-group packing (Figs. 4, 6). When coupled with the ideas that the effects of FBP on membrane permeability are affected by calcium and that FBP is a known calcium chelator, the following model can be hypothesized (Fig. 8). FBP has been shown previously to chelate calcium (29). When FBP is added to cell membrane bilayers, the calcium that is used to stabilize phospholipid head groups is in direct competition with the chelating effects of FBP. In an attempt to compensate for the competition for calcium, the head groups bend inward to prevent the removal of calcium bound to the bilayer (Figs. 4, 6). This torque on the membrane head groups results in an increase in acyl chain area in the bilayer normal. Because the acyl chains are now more distant from one another, the disorder of the membrane increases, and hence the permeability increases (Figs. 1–3, 7).

The findings of the current study indicate that externally applied FBP can have dramatic effects on membrane bilayer stability. Externally applied FBP increases the fluorescence anisotropy of DPH and decreases the cooperativity of the phase transition. Since DPH mainly detects anisotropy changes in the membrane interior, it is hypothesized that fatty acyl chain interaction is decreased and the fluidity of the bilayer in this region is increased. Using the phase-sensitive fluorescent probe MC540, we have shown that FBP also causes the polar head groups of the membrane bilayer to become more closely spaced. These two pieces of data show that FBP affects membrane stability. The decrease in membrane stability in the presence of FBP allows the normally nonpermeant FBP to diffuse passively across the membrane bilayer. Once inside the cell, FBP could be used to increase glycolysis and thus decrease the effects of ischemia by doubling anaerobic ATP production.

# Comparison of the Oxidizability of Various Glycerophospholipids in Bilayers by the Oxygen Uptake Method

Ryouta Maeba\*, Youltuz Yusuf, Hiroyuki Shimasaki, and Nobuo Ueta

Department of Biochemistry, Teikyo University School of Medicine, Tokyo 173-8605, Japan

**ABSTRACT:** The aims of this study were twofold: develop a convenient and rapid procedure for assessing the oxidizability of small quantities of glycerophospholipids in bilayers by the oxygen uptake method, and determine and compare the oxidizability of various glycerophospholipids in bilayers. Our purpose was to elucidate phospholipid oxidation characteristics in membranes. The quantitative autoxidation kinetics of dilinoleoyl phosphatidylcholine (DLPC) (18:2/18:2) was studied in large unilamellar vesicles (LUV) in aqueous dispersions with water-soluble initiator—2,2'-azobis(2-amidinopropane) dihydrochloride—and inhibitor 2-carboxy-2,5,7,8-tetramethyl-6-chromanol. The kinetic data indicated a high efficiency of free radical production, resulting in shortening of measuring time; the very low kinetic chain length, particularly in the induction period, suggested the possibility of including large errors in the kinetics data. Nevertheless, the autoxidation of DLPC obeyed the classic rate law:  $R_p = k_p[\text{LH}]R_i^{1/2}/(2k_t)^{1/2}$  (where  $R_p$  = rate of oxygen consumption,  $k_p$  = rate constant for chain propagation,  $[\text{LH}]$  = substrate concentration;  $R_i^{1/2}$  = square root of rate of chain initiation, and  $2k_t$  = rate constant for chain termination) in a mixed bilayer system with saturated dimyristoyl PC (14:0/14:0), which provided precise and reproducible data. Therefore, the system was used to assess the relative oxidizability of each glycerophospholipid DLPC (18:2/18:2), dilinolenoyl PC (18:3/18:3), 1-palmitoyl-2-linoleoyl PC (16:0/18:2), 1-palmitoyl-2-arachidonoyl PC (16:0/20:4), 1-palmitoyl-2-docosahexaenoyl PC (16:0/22:6), and dilinoleoyl PE (18:2/18:2) in bilayers. The results suggested that the oxidizability of glycerophospholipid in bilayers is substantially influenced by the number of intramolecular oxidizable acyl chains and the content of bis-allylic hydrogen in a structured environment, and showed deviation of the rate law for autoxidation in PC and PE mixed LUV, which possibly was due to non-homogeneous phospholipid distribution in vesicles.

Paper no. L9000 in *Lipids* 37, 893–900 (September 2002).

Lipid peroxidation mediated by free radicals *in vivo* has attracted growing attention because of its potential contribution to various diseases and the aging process (1). Oxidation in

Abbreviations: AAPH, 2,2'-azobis(2-amidinopropane) dihydrochloride; DLPE, dilinoleoyl phosphatidylethanolamine; DLnPC, dilinolenoyl phosphatidylcholine; DLPC, dilinoleoyl phosphatidylcholine; DMPC, dimyristoyl phosphatidylcholine; DOPE, dioleoyl phosphatidylethanolamine; kcl, kinetic chain length;  $[\text{LH}]$ , substrate concentrations; LUV, large unilamellar vesicles; PAPC, 1-palmitoyl-2-arachidonoyl phosphatidylcholine; PDPC, 1-palmitoyl-2-docosahexaenoyl phosphatidylcholine; PLPC, 1-palmitoyl-2-linoleoyl phosphatidylcholine; Trolox, 2-carboxy-2,5,7,8-tetramethyl-6-chromanol.

biomembranes is one of the critical events leading to biomembrane dysfunction. Biomembranes basically consist of phospholipid bilayers; therefore, proper assessment of the oxidizability of phospholipid in bilayers is essential in understanding the oxidation of biomembranes. Among the available methods for assessing oxidizability, the oxygen uptake method is considered to be the most reliable and accurate.

Several investigators (2,3) have used the oxygen uptake method to determine the oxidizability of PC in vesicles as model membranes. In their quantitative kinetic studies on autoxidation, the kinetics of autoxidation in heterogeneous systems of bilayers and micelles has been shown to follow the classical rate law for autoxidation given by Equation 1 (4) as well as in homogeneous solution (5,6):

$$-d[\text{O}_2]/dt = R_p = k_p[\text{LH}]R_i^{1/2}/(2k_t)^{1/2} \quad [1]$$

where  $R_p$  is the rate of oxygen consumption;  $R_i$ , the rate of chain initiation;  $[\text{LH}]$ , the concentration of substrate; and  $k_p$  and  $2k_t$ , the rate constants for chain propagation and termination, respectively. The ratio of these rate constants,  $k_p/(2k_t)^{1/2}$ , is referred to as the susceptibility of a substrate to undergo autoxidation, that is, oxidizability. To allow quantitative studies on the kinetics of autoxidation, the rate of chain initiation  $R_i$  must be controlled and measurable. This is generally achieved by using thermally labile azo initiators (A–N=N–A), which decompose to give two radicals at a known and constant rate (7). The rate of initiation,  $R_i$ , is generally determined by the induction period method with a chain-breaking antioxidant as indicated by Equation 2:

$$R_i = n[\text{IH}]/t_{\text{inh}} \quad [2]$$

where IH is the antioxidant,  $t_{\text{inh}}$  the induction period produced by the addition of the antioxidant, and  $n$  the stoichiometric number of radicals trapped by each antioxidant. Since  $[\text{LH}]$  is known and  $R_p$  and  $R_i$  are determined experimentally, oxidizability,  $k_p/(2k_t)^{1/2}$ , can be calculated from Equation 3:

$$k_p/(2k_t)^{1/2} = R_p/[\text{LH}]R_i^{1/2} \quad [3]$$

Quantitative kinetic measurements can be made by using either water-soluble or lipid-soluble initiators with water-soluble or lipid-soluble inhibitors (8). Although the use of lipid-soluble initiator and inhibitor is the most reasonable for measuring the rate of initiation in the lipid phase, it is often

inconvenient and time-consuming. That is, (i) since it is sometimes difficult to incorporate the lipid-soluble initiator and inhibitor into vesicles in amounts that are known *a priori* by calculation, it is necessary to check their concentrations in some way after preparation of the vesicles. (ii) It is sometimes difficult to measure the induction period exactly, because the thermally labile initiator easily initiates autoxidation during preparation and pre-incubation of vesicles. (iii) Measurement with a lipid-soluble initiator is often more time-consuming than that with a water-soluble one because of the extremely low efficiency of free radical production in the lipid phase and the limited concentration of lipid-soluble initiator in vesicles. Accordingly, it was considered that water-soluble compounds that do not need to be incorporated into vesicles provide some advantages for measurement.

In the present study, a convenient procedure for assessing the oxidizability of glycerophospholipids in bilayers in a short experimental time and using a small quantity of test lipid was developed; the kinetic measurement was carried out on large unilamellar vesicles (LUV), which are more suitable model membranes for free radical oxidation *in vivo*, in the presence of the water-soluble initiator 2,2'-azobis(2-amidino-propane) dihydrochloride (AAPH) and the inhibitor 2-carboxy-2,5,7,8-tetramethyl-6-chromanol (Trolox) at a low molar ratio of substrate to initiator. The oxidizability values for each glycerophospholipid—dilinoleoyl phosphatidylcholine (DLPC; 18:2/18:2), dilinolenoyl phosphatidylcholine (DLnPC; 18:3/18:3), 1-palmitoyl-2-linoleoyl phosphatidylcholine (PLPC; 16:0/18:2), 1-palmitoyl-2-arachidonoyl phosphatidylcholine (PAPC; 16:0/20:4), 1-palmitoyl-2-docosa-hexaenoyl phosphatidylcholine (PDPC; 16:0/22:6), and dilinoleoyl phosphatidylethanolamine (DLPE; 18:2/18:2)—were determined, and their relationships to the peroxidation index were established in order to elucidate the characteristics of phospholipid oxidation in membranes.

## EXPERIMENTAL PROCEDURES

**Materials.** PLPC, PAPC, and PDPC were purchased from Sigma Chemicals (St. Louis, MO). DLPC and DLnPC were obtained from Doosan Serdary Research Laboratories (Englewood Cliffs, NJ). Dimyristoyl phosphatidylcholine (DMPC; 14:0/14:0) and dioleoyl phosphatidylethanolamine (DOPE, 18:1/18:1) were purchased from Nichiyu Liposome Co., Inc. (Tokyo, Japan). DLPE was obtained from Avanti Polar Lipids, Inc. AAPH was obtained from Wako Pure Chemical Industries (Osaka, Japan). Trolox was purchased from Aldrich Chemicals (Milwaukee, WI).

**Preparation of LUV.** Mixtures of saturated and unsaturated glycerophospholipids were dissolved in chloroform at a specified molar ratio. The solvent was evaporated completely in a stream of nitrogen ( $N_2$ ) gas. The dried lipids were dispersed in PBS (10 mM, pH 7.4) kept at 40°C (above the phase transition temperature for all lipids used) in the presence of 0.1 mM EDTA (Wako) in a vortex mixer to yield multilamellar vesicles. LUV were prepared from the multilamellar vesicles

with an extruder (Lipex Biomembranes Inc., Vancouver, Canada) as described previously (9). The concentration of phospholipids in the lipid dispersions and constituent molar ratio of phospholipids in vesicles was checked by TLC separation and phosphorus analysis for phospholipids after preparation of vesicles by extrusion.

**Autoxidation procedures.** Autoxidation of LUV was initiated with the water-soluble azo radical initiator AAPH, and oxygen consumption was measured in the aqueous dispersion. The rate of chain initiation  $R_i$  was determined by the induction period method with the water-soluble phenolic antioxidant Trolox. The dissolved oxygen in the reaction solvent was monitored with a Galvani-type oxygen electrode (MD-1000; Iijima Electronics Corp., Tokyo, Japan). The oxygen concentration was set at 0  $\mu$ M with the meter in water containing 5% sodium bisulfite (Wako) and at 220  $\mu$ M in water saturated with air at 37°C. Trolox (0.05–0.1  $\mu$ mol) was dissolved in ethanol (5  $\mu$ L) and added to the aqueous dispersion as an antioxidant before mixing the LUV with AAPH. In a typical experiment, 1.9 mL of a PBS dispersion of the appropriate LUV kept at 37°C was mixed with 0.35 mL of AAPH in PBS and put in a reaction vessel connected to an oxygen electrode. The reaction mixture was maintained at 37°C and stirred with a magnetic stirrer while measurements were taken.

## RESULTS

The kinetics of the autoxidation of DLPC in LUV in aqueous dispersions were measured by using variable amounts of vesicles, AAPH, and Trolox (Table 1). From the slope of the straight line obtained by plotting the induction period,  $t_{inh}$ , as a function of [Trolox]/[AAPH] (Fig. 1), the stoichiometric number of radicals trapped by Trolox,  $n$ , was found to be 1.8. This value is slightly lower than 2, the theoretical value for water-soluble vitamin E analog Trolox, which is known to trap two peroxy radicals. By using an  $n$  value of 1.8,  $R_i$  and the efficiency of free radical production,  $e$ , were calculated from Equations 2 and 4, respectively, where the concentrations of initiator, AAPH, and inhibitor, Trolox, are expressed in the lipid phase and  $2k_i$  for AAPH is taken as  $1.36 \times 10^{-6} s^{-1}$  at 37°C (10).

$$e = R_i / 2k_i [AAPH] \quad [4]$$

The kinetic chain length,  $kcl$ , is the number of substrate molecules oxidized per initiating radical and can be obtained from Equation 5:

$$kcl = (R_p \text{ or } R_{inh}) / R_i \quad [5]$$

where  $R_{inh}$  is the rate of oxygen consumption during the induction period.

The  $e$  values obtained, 0.71–1.00, show that free radicals were generated at very high efficiency, whereas the very low  $kcl$  values indicate insufficient progress of radical chain reactions in the present oxidizing system (Tables 1, 2). The effects

<sup>a</sup>Abbreviations: DLPC, dilinoleoyl phosphatidylcholine; LUV, large unilamellar vesicle; DMPC, dimyristoyl phosphatidylcholine; AAPH, 2,2'-azobis(2-amidinopropane) dihydrochloride; Trolox, 2-carboxy-2,5,7,8-tetramethyl-6-chromanol; kcl, kinetic chain length.

<sup>b</sup>The concentrations in the reaction solvent.

<sup>c</sup>The  $n$  value was taken as 1.8.

<sup>d</sup>The concentrations were calculated as per lipid volume, which was estimated by assuming that the density of phospholipid is 0.8.

<sup>e</sup>The  $k_i$  for AAPH was taken as  $6.8 \times 10^{-7} \text{s}^{-1}$ .

of the amounts of AAPH, Trolox, and vesicles on the kinetics data were explored by comparing the correlations between  $R_p$  and  $R_i^{1/2}$  (Figs. 2A–C). Measurements under a fixed concentration of Trolox (Fig. 2C) provided greater coefficient values,  $r_2 > 0.97$ , than those obtained under a fixed concentra-

**FIG. 1.** Plots of the induction period,  $t_{inh}$ , against  $[\text{Trolox}]/[\text{AAPH}]$  in the autoxidation kinetics of DLPC in LUV.  $y = 1.798x - 0.2069$ ,  $r^2 = 0.9805$ . Data from Table 1. Trolox, 2-carboxy-2,5,7,8-tetramethyl-6-chromanol; AAPH, 2,2'-azobis(2-amidinopropane) dihydrochloride; DLPC, dilinoleoyl phosphatidylcholine; LUV, large unilamellar vesicle.

tion of AAPH,  $r_2 > 0.90$  (Fig. 2B), or vesicles,  $r_2 > 0.91$  (Fig. 2A). Moreover, the  $R_p/R_i^{1/2}$  ratio was found to be influenced most by variation in the amount of Trolox (Fig. 2C). These results show that the measurement should be carried out with a fixed concentration of Trolox to obtain a more precise value. Therefore, the measurement was carried out hereafter with variable amounts of vesicles under fixed concentrations of AAPH and Trolox.

The oxidizability of DLPC in bilayers was determined by using three different mixed vesicles composed of various concentrations of oxidizable DLPC with an inert saturated DMPC (Table 2), because the concentration of substrate, [LH], for DLPC LUV composed of a single phospholipid shows a constant value independent of the amount of vesicles in the reaction solvent (11). Plots of  $R_p$  against  $R_i^{1/2}$  for each mixed LUV gave straight lines with  $r_2 > 0.96$  (Fig. 3A), which is evidence for a constant  $R_p/R_i^{1/2}$  ratio in each mixed LUV containing DLPC as an oxidizable substrate, at identical concentrations. A plot of  $R_p/R_i^{1/2}$  against [LH] gave an excellent linear correlation ( $r_2 = 0.99$ ) (Fig. 3B). The slope of the straight line obtained,  $R_p/[LH]R_i^{1/2} = 2.1 \cdot 10^{-2} (\text{Ms})^{-1/2}$ , corresponds to the oxidizability value for DLPC in bilayers. The

<sup>f</sup>The rate of oxygen consumption in the absence of oxidizable substrate, which was estimated from the intercept value,  $5.95 \times 10^{-3}$  (M/s)<sup>1/2</sup>, in Figure 3B.

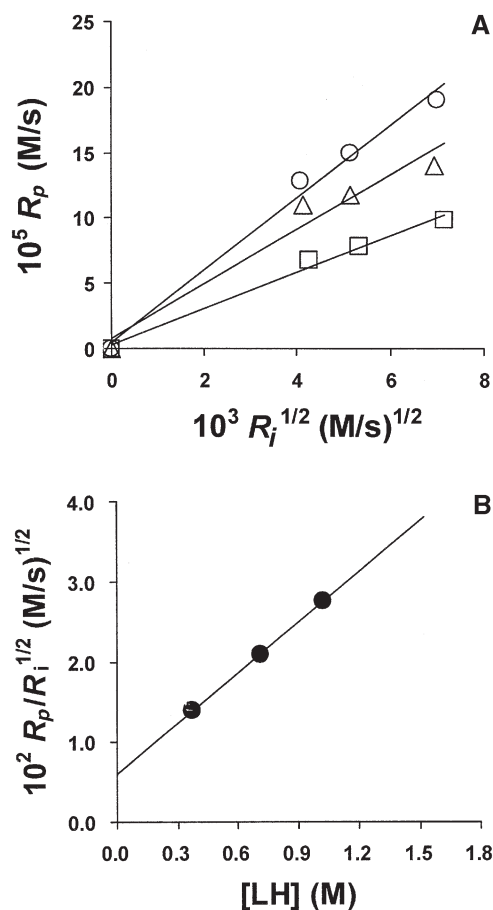

**FIG. 2.** Plots of the rate of oxygen consumption,  $R_p$ , against the square root of the rate of radical initiation,  $R_i^{1/2}$ , in the autoxidation kinetics of DLPC in LUV. The correlation between  $R_p$  and  $R_i^{1/2}$  was analyzed with the data measured under conditions of a fixed concentration of vesicles (A) or AAPH (B) or Trolox (C). (A)  $\circ$ : 1.28 mM DLPC,  $y = 3.1227x - 0.9952$ ,  $r^2 = 0.918$ ;  $\triangle$ : 2.14 and 2.56 mM DLPC,  $y = 3.3073x - 0.9596$ ,  $r^2 = 0.9231$ ;  $\square$ : 4.05 and 5.05 mM DLPC,  $y = 3.4527x - 1.0769$ ,  $r^2 = 0.9378$ ;  $\diamond$ : 6.76 mM DLPC,  $y = 3.2037x - 0.3513$ ,  $r^2 = 0.98$ . (B)  $\circ$ : 23.3 mM AAPH,  $y = 2.8052x - 0.1645$ ,  $r^2 = 0.9079$ ;  $\triangle$ : 38.9 mM AAPH,  $y = 3.0196x + 0.1717$ ,  $r^2 = 0.9222$ ;  $\square$ : 58.3 mM AAPH,  $y = 3.0658x + 0.5018$ ,  $r^2 = 0.9277$ . (C)  $\circ$ : 22.2  $\mu$ M Trolox,  $y = 3.4376x - 0.1401$ ,  $r^2 = 0.9847$ ;  $\triangle$ : 33.3  $\mu$ M Trolox,  $y = 3.141x - 0.479$ ,  $r^2 = 0.9718$ ;  $\square$ : 44.4  $\mu$ M Trolox,  $y = 2.6962x - 0.1149$ ,  $r^2 = 0.9762$ . Data and abbreviations from Table 1.

intercept, the  $R_p/R_i^{1/2}$  value when [LH] is zero (Fig. 3B), represents the ratio of the rate of oxygen consumption in the absence of the oxidizable substrate,  $R_{p0}$ , to the  $R_i^{1/2}$  value. Therefore, the rate of oxygen consumption involved in lipid peroxidation was corrected by subtracting each  $R_{p0}$  value, estimated from the intercept value,  $5.95 \cdot 10^{-3}$

(M/s)<sup>1/2</sup>, from the measured rate,  $R_p$  (Table 2). Plots of  $R_p - R_{p0}$  for each mixed LUV against  $R_i^{1/2}$  also gave straight lines with  $r_2 > 0.92$  (Fig. 4A). A plot of  $(R_p - R_{p0})/R_i^{1/2}$  against [LH] provided a straight line passing through zero (Fig. 4B). The slope of the straight line,  $(R_p - R_{p0})/[LH]R_i^{1/2} = 2.1 \cdot 10^{-2}$  (Ms)<sup>-1/2</sup>, was exactly equal to the value for

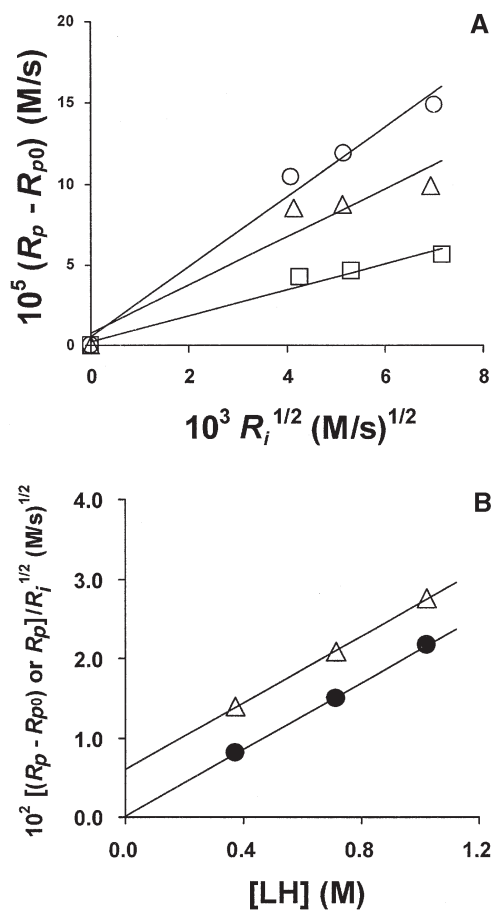

**FIG. 3.** Autoxidation kinetics of DLPC in mixed LUV with DMPC: (A) Plots of the rate of oxygen consumption,  $R_p$ , against the rate of radical initiation,  $R_i^{1/2}$ .  $\circ$ : [1.023] DLPC,  $y = 2.7599x + 0.5024$ ,  $r^2 = 0.9898$ ;  $\triangle$ : [0.714] DLPC,  $y = 2.0893x + 0.7332$ ,  $r^2 = 0.9601$ ;  $\square$ : [0.374] DLPC,  $y = 1.3948x + 0.2594$ ,  $r^2 = 0.9894$ . The kinetics data are shown in Table 2. (B) Plots of the ratio,  $R_p/R_i^{1/2}$ , obtained from Figure 3A, against [LH] in the autoxidation kinetics of DLPC in mixed LUV with DMPC. The concentration of substrate, [LH], is expressed as moles DLPC per liter of total lipid volume of vesicles and was changed by altering the relative amounts of DLPC and DMPC in vesicles.  $y = 2.1101x + 0.5952$ ,  $r^2 = 0.9998$ . DMPC, dimyristoyl phosphatidylcholine; for other abbreviations see Figure 1.

$R_p/[LH]R_i^{1/2}$ , which suggests that it may be unnecessary to correct the rate of oxygen consumption to obtain the oxidizability value. This inference was confirmed in all measurements for determination of the oxidizability of other glycerophospholipids (data not shown). Accordingly, the oxidizability values have been indicated using the uncorrected measured rates of oxygen consumption.

The oxidizability values for each glycerophospholipid were determined by using a mixed bilayer system with an inert saturated phospholipid. These are summarized in Table 3. The oxidizability values for PLPC, DLPC, and DLnPC were strongly correlated with their peroxidation indexes (Fig. 5A), but there was no linear correlation between the oxidizability value and peroxidation index among PC having a single oxidizable fatty acyl chain at the *sn*-2 position, such as PLPC, PAPC, and PDPC (Fig. 5B).

**FIG. 4.** Autoxidation kinetics of DLPC in mixed LUV with DMPC. (A) Plots of the corrected rate of oxygen consumption,  $R_p - R_{p0}$ , against the square root of the rate of radical initiation,  $R_i^{1/2}$ . The rates of oxygen consumption in the absence of oxidizable substrate,  $R_{p0}$ , are referred to in Table 2.  $\circ$ : [1.023] DLPC,  $y = 2.1645x + 0.5047$ ,  $r^2 = 0.9835$ ;  $\triangle$ : [0.714] DLPC,  $y = 1.4946x + 0.7332$ ,  $r^2 = 0.9248$ ;  $\square$ : [0.374] DLPC,  $y = 0.7992x + 0.2609$ ,  $r^2 = 0.9679$ . (B) Plots of the ratios,  $R_p/R_i^{1/2}$ , obtained from Figure 3A, and  $(R_p - R_{p0})/R_i^{1/2}$ , obtained from Figure 4A, against [LH] in the autoxidation kinetics of DLPC in mixed LUV with DMPC.  $\triangle$ :  $R_p/R_i^{1/2}$ ,  $y = 2.1101x + 0.5952$ ,  $r^2 = 0.9998$ ;  $\bullet$ :  $(R_p - R_{p0})/R_i^{1/2}$ ,  $y = 2.096x + 0.0081$ ,  $r^2 = 0.9997$ . For abbreviations see Figures 1 and 3.

The application of PC and PE mixed LUV to the determination of oxidizability was explored by measuring the oxidizability of DLPC in mixed LUV with DOPE instead of DMPC as an inert saturated phospholipid. Although  $r_2$  values between  $R_p$  and  $R_i^{1/2}$  were more than 0.98 in the autoxidations of each mixed LUV (Fig. 6A), plots of the  $R_p/R_i^{1/2}$  ratio against [LH] provided a curved line with a height at around 0.8 of [LH] (Fig. 6B). To confirm this phenomenon, the oxidizability of DLPE was measured in mixed LUV with DMPC. Although there were good correlations between  $R_p$  and  $R_i^{1/2}$  ( $r_2 > 0.98$ ) in each mixed LUV (Fig. 7A), plots of  $R_p/R_i^{1/2}$  against [LH] gave no linear correlation; again, the  $R_p/R_i^{1/2}$  value was beside the straight line over an [LH] value of 0.6 (Fig. 7B). The apparent oxidizability values of DLPC and DLPE were estimated as  $4.7 \times 10^{-2}$  and  $4.8 \times 10^{-2}$  (Ms) $^{-1/2}$ , respectively, from the slope of the straight

<sup>a</sup>Abbreviations: DOPE, dioleoyl phosphatidylethanolamine; DLPE, dilinoleoyl phosphatidylethanolamine; PLPC, 1-palmitoyl-2-linoleoyl phosphatidylcholine; DlnPC, dilinolenoyl phosphatidylcholine; PAPC, 1-palmitoyl-2-arachidonoyl phosphatidylcholine; PDPC, 1-palmitoyl-2-docosahexaenoyl phosphatidylcholine. For other abbreviations see Table 1.

<sup>b</sup>The coefficient of correlation,  $r^2$ , was calculated based on the number of experiments (in parentheses).

<sup>c</sup>Peroxidation index (PI) was calculated according to the following equation: PI = (% dienoic  $\times$  1) + (% trienoic  $\times$  2) + (% tetraenoic  $\times$  3) + (% pentaenoic  $\times$  4) + (% hexaenoic  $\times$  5).

lines obtained by plotting  $R_p/R_i^{1/2}$  against [LH] within the range for which the correlation is linear (Figs. 6B, 7B).

## DISCUSSION

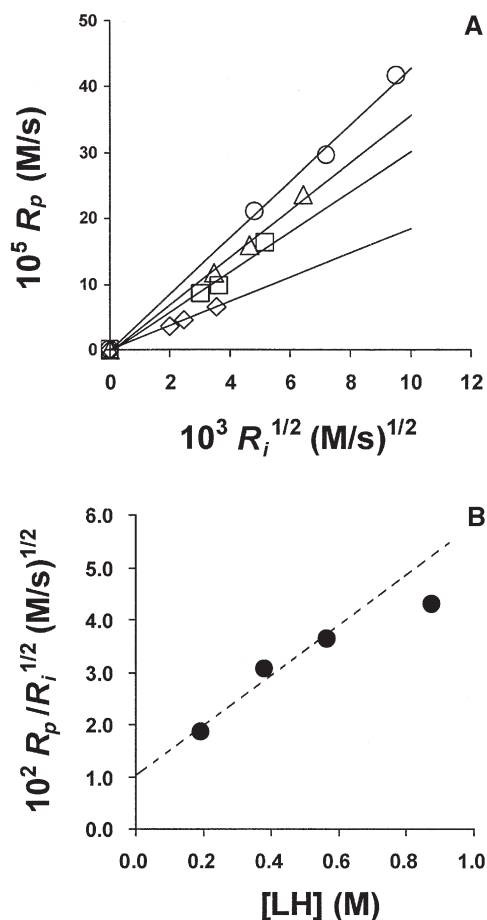

The present procedure, which used a water-soluble radical initiator and unilamellar vesicles with a small quantity of substrate, brought about a remarkable increase in the efficiency of free radical production ( $e > 0.6$  through all the experiments), resulting in shorter completion times (the dissolved oxygen was completely consumed in the reaction solvent within about 1 h). This oxidizing system is characterized by very low  $k_{cl}$  values, particularly in the induction period (Tables 1, 2), which indicates that possibly the initiating azo peroxy radicals are

trapped by the water-soluble inhibitor in the aqueous phase. This can lead to very large errors in determining the  $R_i$  for their lipid phase. It is quite possible that initiating azo peroxy radicals react with each other in the aqueous phase to terminate the initiating reaction, which also results in considerable errors in measuring both the  $R_i$  and  $R_p$  for their lipid phase. Accordingly, it was suggested that the present system may not be appropriate for determining an absolute oxidizability value for glycerophospholipids in bilayers.

Nevertheless, the kinetics data for autoxidation of DLPC, obtained in the mixed bilayer system with an inert saturated DMPC, were confirmed to follow the classical rate law closely for autoxidation,  $R_p = k_p[\text{LH}]R_i^{1/2}/(2k_t)^{1/2}$  (Figs. 3A,B). Furthermore, a combination of unilamellar vesicles and water-soluble initiator and inhibitor was found to give a clear induction period, which results in more precise and reproducible data. Therefore, the procedure was considered to be useful in assessing the relative oxidizability of glycerophospholipids in bilayers in identical systems.

Barclay *et al.* (12) and Yamamoto *et al.* (13) have reported that oxidizability values,  $k_p/(2k_t)^{1/2}$ , for DLPC in bilayers of  $4.6 \times 10^{-2}$  and  $9.2 \times 10^{-2}$  (Ms)<sup>-1/2</sup>. The value for DLPC obtained in the present procedure,  $2.1 \times 10^{-2}$  (Ms)<sup>-1/2</sup>, was less than half, but was within the same order of magnitude of these values despite possibly including large errors in the kinetics data. The errors in the rate of oxygen consumption may be neutralized by using a mixed bilayer system with inert saturated phospholipids as shown in Fig. 4B. But the rate of chain initiation,  $R_i$ , determined by the induction period method would give a large error in the oxidizability value, because the actual amount of initiating radicals involved in lipid peroxidation, in other words,  $R_i$ , is deduced to be smaller than the value estimated from the equation:  $R_i = n [\text{Trolox}]/t_{\text{inh}}$ . This overestimation of the  $R_i$  value may result in an oxidizability value lower than the true value.

The relative oxidizability values of various glycerophospholipids in bilayers have been determined in the system. The values of PLPC, DLPC, and DLnPC were linearly correlated with their peroxidation indexes, calculated on the basis of the numbers of bis-allylic hydrogens in the lipid molecules (Fig. 5A). There was no linear correlation between oxidizability and the peroxidation index among PC having a single oxidizable fatty acyl chain at the *sn*-2 position, such as PLPC, PAPC, and PDPC (Fig. 5B). The accuracy of our results cannot be confirmed, because the oxidizability values determined by the oxygen uptake method of other PC containing more unsaturated FA such as arachidonic acid (20:4) and docosahexaenic acid (22:6) have not been reported, and their relationships to the peroxidation index have not been discussed.

In a homogeneous solution, the existence of a positive relationship between the bis-allylic hydrogen number in the lipid molecule and the oxidizability is well known (14). In heterogeneous systems, the oxidizability in bilayers has been shown to depend on the bis-allylic hydrogen content by using multilamellar liposomes (15) or intact cells (16). On the other hand, the oxidizabilities of PUFA in aqueous micelles are inversely proportional to the bis-allylic hydrogen number (17,18). Interestingly, that molecular species of PC substantially affect oxidation kinetics has been shown by comparing the oxidizabilities of soybean PC and egg yolk PC in homogeneous solutions and in unilamellar vesicles (19,20). Our result with unilamellar vesicles appears to agree with their observations, because soybean PC contains mainly DLPC, whereas major molecular species of egg yolk PC have a single oxidizable acyl chain at the *sn*-2 position and an inert saturated acyl chain at the *sn*-1 position. This phenomenon may be explained in terms of "arm to arm autoxidation" theory (21), which is used to describe the increase in apparent oxidizability of glyceryl trilinoleate caused by decreasing its concentration in the reaction solvent (14).

When the oxidizability was measured with PC and PE mixed vesicles, there was no linear correlation between  $R_p/R_i^{1/2}$  and [LH] despite the excellent correlation between  $R_p$  and  $R_i^{1/2}$  ( $r_2 > 0.98$ ) for each mixed LUV (Figs. 6 and 7). This indicates the possibility of nonhomogeneous

distributions of PC and PE in unilamellar vesicles as observed in biomembranes (22), because the autoxidation reactions obey the rate law even in each mixed LUV. This causes an increase in the local concentration of oxidizable phospholipid in vesicles and so results in an increase in the apparent oxidizability of test lipid in bilayers. This inference may be supported by the greater oxidizability values for DLPC and DLPE determined in PC and PE mixed LUV,  $4.7 \times 10^{-2}$  and  $4.8 \times 10^{-2} \text{ (Ms)}^{-1/2}$ , respectively, than the value for DLPC determined in mixed vesicles with DMPC.

The present study describes a convenient and rapid procedure that would be useful in assessing the relative oxidizability of glycerophospholipids in bilayers. The results suggest that the oxidizability of phospholipids in bilayers is substantially influenced by the number of intramolecular oxidizable acyl chains, in addition to the content of bis-allylic hydrogen in a structured environment, and show deviation of the rate law for autoxidation in PC and PE mixed vesicles, possibly due to inhomogeneous phospholipid distribution in vesicles.

**ABSTRACT:** Increased mean platelet volume (MPV) has been suggested as an independent risk factor for acute myocardial infarction and the increased reactivity of large platelets. The aim of this study was to investigate the correlation between platelet phospholipid (PL) PUFA composition and MPV in 139 free-living healthy men ages 20–55 yr (vegans,  $n = 18$ ; ovo-lacto vegetarians,  $n = 43$ ; moderate meat-eaters,  $n = 60$ ; and high meat-eaters,  $n = 18$ ). Each subject completed a semiquantitative Food Frequency Questionnaire and gave a blood sample. Platelet PL FA composition and MPV were determined by standard methods. MPV was significantly greater in the vegans than in the ovo-lacto vegetarian, moderate, or high meat-eater groups ( $P < 0.01$ ). Both vegan and ovo-lacto vegetarian groups had significantly higher platelet PL 18:2n-6 and 22:4n-6, and lower 20:5n-3 and 22:6n-3 compared with the moderate and high meat-eater groups. The vegans demonstrated a significant reduction in 20:4n-6 and 22:5n-3 compared with the ovo-lacto vegetarian, high meat-eater, and moderate meat-eater groups. Bivariate analysis results showed that MPV was significantly positively correlated with platelet PL 18:2n-6 ( $P = 0.048$ ) and negatively correlated with 20:3n-6 ( $P = 0.02$ ), 20:5n-3 ( $P = 0.005$ ), and 22:5n-3 ( $P < 0.0001$ ), respectively. In a multiple linear regression analysis, after controlling for potential confounding factors such as dietary group, age, exercise, body mass index, and dietary polyunsaturated and saturated fat, cholesterol, carbohydrate, and fiber intake, the MPV was still strongly negatively correlated with platelet PL 20:3n-6 ( $P = 0.003$ ) and 22:5n-3 ( $P = 0.001$ ). The present data suggest that 22:5n-3 and 20:3n-6 may play a role in the structural function of the platelet membrane.

Paper no. L8755 in *Lipids* 37, 901–906 (September 2002).

Evidence from case control studies has indicated that an increased mean platelet volume (MPV) is an independent risk factor for acute myocardial infarction (MI) (1) and for acute and/or nonacute cerebral ischemia (2). Large platelets, in such cases, have been shown to have increased reactivity, leading to the potential for thrombus formation.

The major role of platelets is in maintaining vascular integrity and minimizing blood loss. The process is regulated

by a complex dynamic balance between factors released from both the endothelium and platelets, including prostacyclin (which inhibits platelet aggregation) and thromboxane (which potentiates aggregation). Platelets normally circulate in a quiescent disk-shaped state, but as they become activated, changes occur that cause them to undergo a disk-to-sphere transformation with the development of pseudopodia (3). This shape change leads to an increase in platelet size, as measured by MPV, and platelet aggregation is enhanced (4,5).

Flow cytometry techniques have demonstrated that this greater reactivity of larger platelets is associated with an increased exposure of fibrinogen receptors and the release of platelet granule contents (6). Platelet activation may be measured using more sophisticated tests of platelet function, such as platelet aggregation and release by platelet aggregometry, or by measurement of immunological markers of activation using flow cytometry. These techniques are time-consuming and labor-intensive, whereas measurement of platelet size (MPV) may be a useful rapid index of platelet activation in circumstances where production or loss is not impaired (7).

Dietary intervention and epidemiological studies have reported that increased levels of n-3 PUFA, relative to n-6 PUFA, in the platelet membrane may provide a protective effect against thrombus formation *via* reduced thromboxane A<sub>2</sub> formation (8). The consumption of purified 20:5n-3 ethyl esters (900 or 1800 mg/d) has been shown to decrease MPV significantly in patients with thrombotic or atherosclerotic diseases (9). Changes in the proportions of eicosapentaenoic and arachidonic acids of platelets have been reported to influence the structure, function, and fluidity (order) of the platelet membrane *via* eicosanoid metabolism (10); to bind to platelet membrane proteins *via* thioester bonds in place of saturated FA; and to modulate hydrophobic protein–membrane lipid and protein–protein interactions (11,12). However, there are no data in the literature on the correlation between the platelet phospholipid (PL) individual FA and MPV in either human or animal studies.

The aim of this study was to investigate the correlation between the composition of individual FA in platelet PL and MPV. We collected Food Frequency Questionnaires (FFQ) and blood samples from four groups of healthy men (vegans,  $n = 18$ ; ovo-lacto vegetarians,  $n = 43$ ; moderate meat-eaters,  $n = 60$ ; and high meat-eaters,  $n = 18$ ) ages 20–55 yr with widely varying intakes of long-chain PUFA. We hypothesized that the long-term intake of long-chain n-3 PUFA from their habitual diet would be negatively correlated with the MPV.

## METHODS

**Subjects.** This study formed part of a large project investigating the association between diet and cardiovascular risk factors in Australian men (13). The project was approved by the Human Research Ethics Committee of RMIT University. One hundred thirty-nine healthy male nonsmokers between 20 and 50 yr of age were recruited through advertisements in university newsletters and local newspapers, and all subjects gave written informed consent for participation in the study. The exclusion criteria for this study were: evidence of cardiovascular disease (CVD), hypertension, renal disease, hyperlipemia, hematological disorders, diabetes, a family history of CVD, excess alcohol intake, and drug therapy. Subjects were asked to complete an FFQ (14) and were given detailed instructions on how to complete it. Each completed FFQ was checked by the same dietician. According to their habitual dietary intake (based on the FFQ), the subjects were divided into high meat-eaters ( $n = 18$ ), moderate meat-eaters ( $n = 60$ ), ovolacto vegetarians ( $n = 43$ ), and vegans ( $n = 18$ ). A high meat-eater was defined as someone consuming  $\geq 280$  g raw meat per day, and a moderate meat-eater was defined as one who consumed  $< 280$  g per day. A vegan was defined as someone who ate meat, eggs, and dairy products less than six times per year. An ovolacto vegetarian was defined as someone who ate meat no more than six times per year but consumed eggs and dairy products freely. For the subjects to be classified into these categories, they had to have been practicing their diets for at least 6 mon prior to the study.

**Dietary intake.** The dietary intake data of each subject were assessed using the FFQ and calculated using Diet/1 Version 4 software (Xyris Software, Pty. Ltd., Highgate Hill, QLD, Australia) with the NUTTAB 95 database based on Composition of Foods, Australia.

**Blood specimen collections.** Subjects came to the Medical Centre of RMIT University in the morning following an overnight fast. They were allowed to sit relaxed for 10 min, and then venous blood was drawn into CTAD (citrate, theophylline, adenosine, and dipyridamole) and citrate vacuum tubes with 21-gauge needles. After blood collection, the sub-

jects' weight, height, and blood pressure were measured. Two CTAD tubes of whole blood were spun at  $100 \times g$  for 10 min. Platelet-rich plasma (PRP) was removed, and platelets were isolated from PRP using the method of Castaldi and Smith (15).

**MPV.** MPV of citrate-preserved whole blood was measured on a Coulter STKR analyzer (Coulter Electronics Inc., Hialeah, FL).

**Platelet PL FA.** Total lipids of platelets were extracted with solvents, the platelet PL fraction was separated by TLC, and FAME of the platelet PL fraction were prepared and separated by GLC as described previously (16).

**Statistical analyses.** Data analyses were performed using a StatView software program (Abacus Concepts Inc., Berkeley, CA). An ANOVA was used to establish whether differences existed between the dietary groups for each parameter. If a significant difference was found, a further multiple comparison test was performed using Fisher's *post-hoc* tests to determine differences between each pair of dietary groups (13). Linear regressions were used to determine the relationship between MPV and platelet PL FA composition. Bivariate analyses were initially used to assess the relationship between MPV and platelet PL composition of individual FA, and dietary intake of micro- and macronutrients. In the multivariate linear regression analysis, MPV was used as a dependent variable, and platelet PL FA compositions were used as independent variables. Dietary intakes of PUFA, saturated fat, cholesterol, carbohydrate, and fiber were used as covariates and controlled for the following factors: exercise, dietary group, age, and body mass index (BMI) (17). The values are reported as mean  $\pm$  SD in Tables 1 and 2 and mean  $\pm$  SEM in Figure 1 unless otherwise specified. *P* values were two-sided, and  $< 0.05$  was considered significant.

## RESULTS

Table 1 reports the physiological characteristics and daily dietary intake of the four dietary groups. The mean BMI was significantly greater in both the high and moderate meat-eater groups than in both the ovolacto vegetarian and vegan groups.

**TABLE 1**

<sup>a</sup>E, energy; CHO, carbohydrate; SFA, saturated FA; MUFA, monounsaturated FA; BMI, body mass index. Significance of differences for <sup>a</sup>high meat-eaters, <sup>b</sup>moderate meat-eaters, <sup>c</sup>ovolacto vegetarians: \* $P < 0.05$ , \*\* $P < 0.01$ , \*\*\* $P < 0.001$ .

The median age (range) was 35 yr (21 to 50) for the high meat-eater group, 38 (21 to 55) for the moderate meat-eater group, 31 (22 to 54) for the ovo-lacto vegetarian group, and 31 (22 to 50) for the vegan group. Energy intake was significantly higher in high meat-eaters than in the other three dietary groups. However, the energy sources were quite different between the four dietary groups. Protein, total fat, saturated FA (SFA), and monounsaturated FA (MUFA) as percentage of energy showed a significant decreasing tendency from high meat-eaters to moderate meat-eaters to ovo-lacto vegetarians and vegans. However, PUFA as percentage of energy was significantly increased from high meat-eaters to moderate meat-eaters to ovo-lacto vegetarians and vegans. Vegans do not eat dairy products and meats, and their fat intake was derived mostly from seeds, nuts, avocados, and vegetable oils. Cholesterol intake showed a significant decreasing tendency from high meat-eaters to moderate meat-eaters to ovo-lacto vegetarians to vegans. The small amount of cholesterol in the vegan diet was derived from egg-containing pastry.

There was a tendency for the MPV to increase from high meat-eaters to moderate meat-eaters to ovo-lacto vegetarians to vegans, and it was significantly greater in the vegan group than in the other three groups (Fig. 1).

Platelet PL PUFA compositions are shown in Table 2. There was no significant correlation between MPV and individual platelet SFA and MUFA, so only platelet PUFA data (% of total FA) are reported. The proportions of platelet PL 18:2n-6 and 22:4n-6 were significantly higher in both the ovo-lacto vegetarian and the vegan groups than in both the high and the moderate meat-eater groups. There was a significant tendency for 20:4n-6, 20:5n-3, and 22:6n-3 to decrease from the high and the moderate meat-eater groups to ovo-lacto vegetarian to vegan groups. The proportion of 22:5n-3 in the vegan group was significantly lower compared with other three dietary groups.

Bivariate analysis results showed that MPV was positively correlated with platelet PL 18:2n-6 ( $P = 0.048$ ) and negatively correlated with platelet PL 20:3n-6 ( $P = 0.02$ ), 20:5n-3

FIG. 1. Mean platelet volume (MPV) of four dietary groups. Lowercase a and b indicate a difference between dietary groups. Error bars represent mean  $\pm$  SEM.

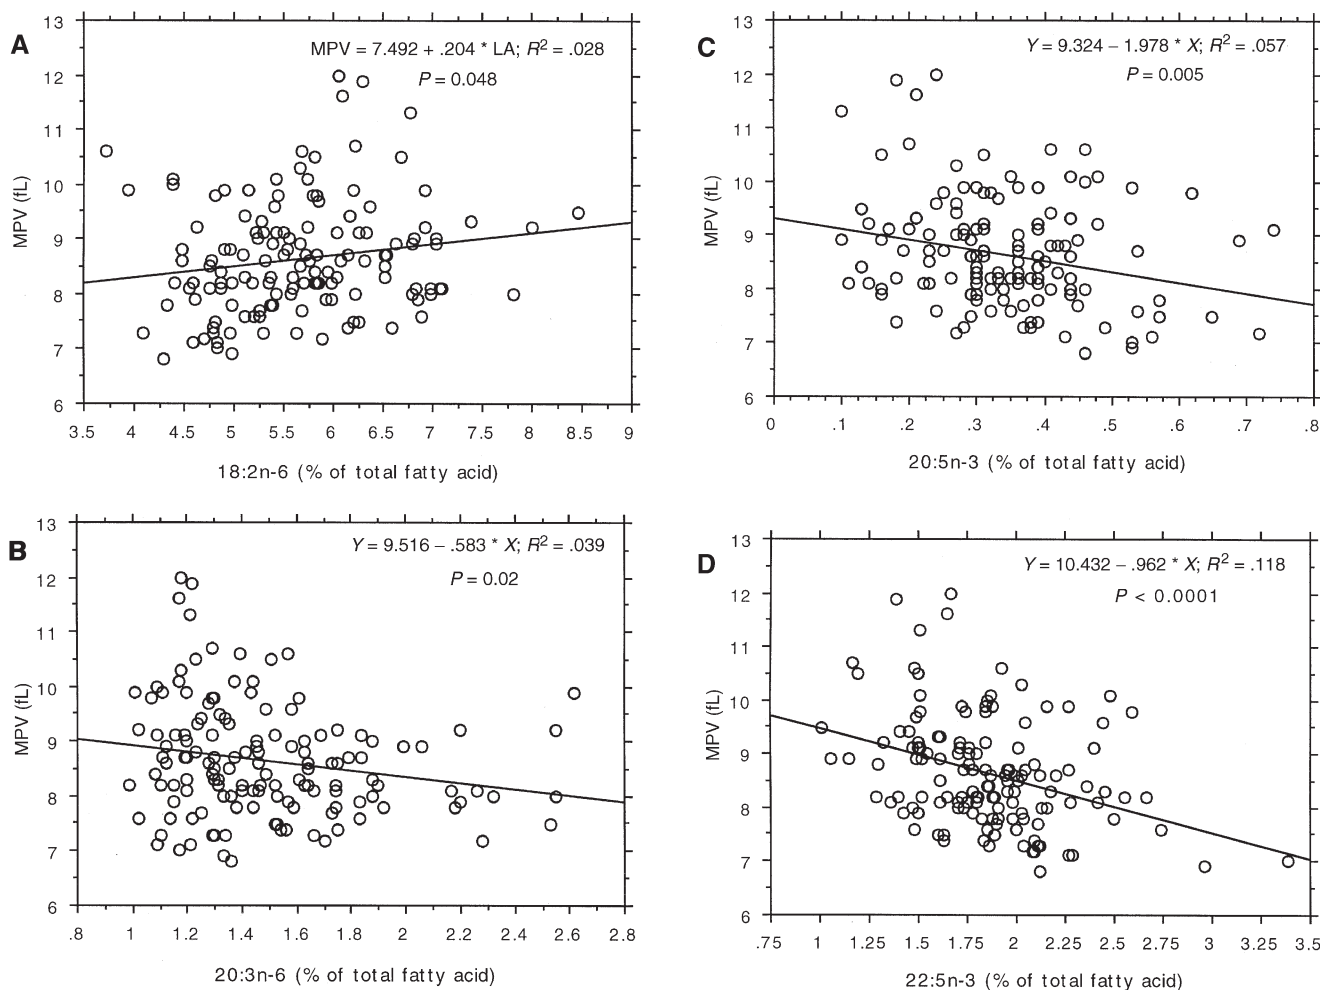

( $P = 0.005$ ), and 22:5n-3 ( $P < 0.0001$ ), respectively (Figs. 2 A–D). There was a significant negative correlation between MPV and platelet count ( $P < 0.001$ ). MPV was also positively correlated with dietary intake of carbohydrates ( $P = 0.043$ ), PUFA ( $P = 0.0146$ ), and fiber ( $P = 0.002$ ) and negatively correlated with dietary intake of SFA ( $P = 0.003$ ) and cholesterol ( $P = 0.002$ ).

Table 3 shows the results of the multiple linear regression, in which MPV was used as the dependent variable and platelet PL 22:5n-3, 18:2n-6, 20:3n-6, and 20:5n-3 were the independent variables. After controlling for confounding factors such as dietary group, age, BMI, dietary total saturated fat, total PUFA, cholesterol, carbohydrate, and fiber intake, the MPV was still strongly positively correlated with platelet PL 22:5n-3 ( $P = 0.0012$ ) and 20:3n-6 ( $P = 0.0034$ ).

Exercise (h/d)	-0.058	0.120
Dietary group	0.207	0.247

<sup>a</sup>Std. Coeff., standardized regression coefficients; for other abbreviations see Table 1.

pothesized that the long-term intake of long-chain n-3 PUFA from the habitual diet would be negatively correlated with MPV, based on evidence from previous studies suggesting that n-3 PUFA reduce platelet aggregability (18,19).

In this study, the MPV was significantly positively correlated with platelet PL 18:2n-6 and negatively correlated with 20:3n-6, 20:5n-3, and 22:5n-3 in the bivariate analysis. In the multiple linear regression, after controlling for the confounding factors such as BMI, exercise, age, dietary groups, dietary intake of carbohydrates, fiber, cholesterol, PUFA, and SFA, the MPV was still significantly negatively correlated with platelet PL 20:3n-6 and 22:5n-3 ( $P < 0.01$ ). This result suggests that if it were possible to increase the levels of these particular PUFA in platelet membranes, this increase might be associated with a reduced MPV as discussed later. In the quiescent disk-like state associated with lower MPV values, platelets are less likely to be involved in thrombotic conditions (18) since they are not subject to activating stimuli that cause shape and behavioral changes. Although the main function of platelets is to arrest bleeding, they also have been implicated in the initiation and development of arterial thrombosis in circumstances where inappropriate activation occurs (19).

Reports of the effect of dietary intervention with n-3 PUFA on the MPV have been inconsistent. For example, the MPV showed a significant decrease when the diets of 34 patients (26 men and 8 women), ages 42 to 86 yr, with thrombotic or arteriosclerotic diseases were supplemented with 900 or 1800 mg of purified eicosapentaenoic acid ethyl ester for 12 wk (9). In contrast, the MPV showed significant increases when healthy subjects, ages 16 to 69 yr, consumed 15 mL of cod liver oil/olive oil (1:1, vol/vol) ( $n = 40$ ) and whale oil ( $n = 38$ ) daily for 12 wk (20); when 9 healthy men, ages 31 to 65 yr, consumed a salmon diet for 40 d (21); and when the diets of 34 healthy subjects (20 men and 14 women), ages 20 to 40 yr, were supplemented with 25 mL cod liver oil per day for 8 wk (22). The mean MPV was significantly reduced from 8.3 to 7.7 fL when 10 healthy men, ages 32 to 40 yr, consumed a high stearic acid diet (8% of energy), compared with a low stearic acid diet (2% of energy), for 40 d (23). In a similar study, the MPV decreased significantly from 8.9 to 8.4 fL when 13 healthy men, ages 20 to 55 yr, consumed a diet high in stearic acid (19.4 g/d) for 4 wk, compared with a baseline diet (7.3 g stearic acid/d); the latter was associated with an increase in the proportion of stearic acid (from 20.1 to 24.6%) in platelet PL (24). Platelet membrane 20:3n-6 was reported to decrease significantly ( $P < 0.01$ ) and MPV to increase significantly in postmenopausal women ( $n = 38$ ) who were given hormone replacement therapy for 6 wk (25).

MPV is influenced by body weight and physical exercise. MPV was shown to increase with age in a population study of 1065 subjects who ranged in age from 0 to 75 yr (27). The lightest subpopulation had the lowest MPV (26). MPV was shown to increase in obese patients who undertook weight loss therapy with either a hypocaloric diet or a nutritionally complete very low caloric diet for 40 wk (28). MPV also decreased significantly in 60 male and 18 female healthy subjects after 18 to 20 mon of physical exercise (29).

As discussed above, increased MPV in some cases is not necessarily a risk factor for CVD. As reported by others (30–32), we also found that MPV was significantly negatively correlated with platelet counts in healthy subjects. This indicates that in healthy subjects when MPV goes up, platelet count goes down to maintain a physiological platelet mass (33). Furthermore, the results of platelet size and shape studies carried out in patients with CVD cannot necessarily be extrapolated to healthy subjects. Results from the present study suggest that 22:5n-3 and 20:3n-6 play a role in the structural function of platelet membranes.

The results from this paper suggest that two PUFA found in platelets (20:3n-6 and 22:5n-3) may influence platelets by reducing their reactivity. The effects of these two PUFA on platelet function have rarely been studied, although they occur in platelets at about the same levels as 20:5n-3, perhaps because 22:5n-3 has only recently become available as a pure standard. Two reports, however, indicate that 22:5n-3 does influence platelet function. First, Careaga and Sprecher (34) reported that 22:5n-3 inhibited synthesis of both thromboxane  $B_2$  and 5,8,10-heptadecatrienoic acid from arachidonic

acid. They also reported that 12-hydroxy-5,8,10,14-eicosatetraenoic acid (12-HETE) synthesis increased due to substrate shunting to the lipoxygenase pathway when platelets were incubated with a high concentration of 22:5n-3 (20  $\mu$ M) and increasing levels of [ $1-^{14}C$ ]20:4n-6 (34). Second, Akiba *et al.* (35) reported that 22:5n-3, compared with 20:5n-3 or 22:6n-3, exhibited the most potent activity for inhibiting thromboxane  $A_2$  formation and for accelerating 12-HETE production by intact rabbit platelets. These authors suggested the effects may have been responsible for the marked inhibition of platelet aggregation by 22:5n-3. Oelz *et al.* (36) fed a large amount of 20:3n-6 to rabbits, and although considerable amounts of prostaglandin (PG)  $E_1$  and  $PGE_2$  were produced by their aggregating platelets, no changes in response to agonist ADP, collagen, and arachidonic acid were detected.

In conclusion, the data from this study support the need for further research on the role of different PUFA on platelet function using purified FA and various *ex vivo* techniques to probe the possible mechanisms of the action of PUFA on the platelet.

## ACKNOWLEDGMENT

This study was supported by a grant from the Meat Research Corporation of Australia, and an RMIT postgraduate scholarship for D.L. We acknowledge Neil Mann, Leeann Johnson, They Ng, Maureen Francis, Fiona Kelly, Lavinia Abedin, Alisa Wilson, and Sirithon Nakkote for their assistance in various aspects of the original large project.

**ABSTRACT:** Long-chain *N*-acylethanolamines (NAE), including the endocannabinoid, anandamide, accumulate in mammalian tissues under a variety of pathological conditions. They have also been shown to inhibit the growth of various cancer cell lines *in vitro*. Here, we report the presence, in widely differing amounts (3.88–254.46 pmol/μmol lipid P), of NAE and their precursor phospholipids in various human tumors and some adjacent unaffected tissues. Anandamide ranged from 1.5 to 48% of total NAE, and incubation of tissue homogenates suggested possible NAE biosynthesis by both the established transacylation-phosphodiesterase pathway *via N*-acyl PE and by direct *N*-acylation of ethanolamine.

Paper no. L9090 in *Lipids* 37, 907–912 (September 2002).

Long-chain *N*-acylethanolamines (NAE) and their precursors, *N*-acylethanolamine phospholipids (*N*-acyl PE), are ubiquitous constituents of mammalian cells, tissues, and certain body fluids. They can accumulate *post mortem* and under pathological conditions involving membrane degeneration (reviewed in Refs. 1,2). Relatively high amounts of these lipids have been identified in membranes of undifferentiated murine neuroblastoma C1300 N18 cells, but not after differentiation of these cells (3). Whereas the signaling activity of the major saturated and monounsaturated NAE has only recently become of interest (4,5), their polyunsaturated analogs, especially anandamide (20:4n-6 NAE), have received much more attention since they have been identified as endogenous cannabinoid receptor agonists (6; reviewed in Refs. 7,8). Because  $\Delta^9$ -tetrahydrocannabinol and other cannabinoids have been shown to inhibit the growth of various cancer cell lines and certain malignant tumors (9, reviewed in Ref. 10), the endocannabinoid, anandamide, was also tested for its potential antiproliferative effects. A dose-dependent anti-proliferative effect was observed in human breast cancer cells, but several other tumor cell lines were not similarly affected (11). The effect of anandamide was mediated by CB1-like cannabinoid receptors; inhibition occurred in the G1/S phase of the cell cycle and appeared to be due to

inhibition of prolactin-induced cell proliferation (11–13). Interestingly, the proliferative effect of nerve growth factor was also blocked by CB1 cannabinoid receptor agonists (13). The effect of anandamide was found to be enhanced by 16:0 NAE, which was shown to inhibit the expression of FA amide hydrolase (FAAH; 14). At this time it remains unclear what role anandamide and other cellular NAE may play in tumor cell proliferation *in vivo*.

Although it might be assumed that NAE, including anandamide, are present in human tumors, data regarding the presence of NAE in human neoplasms are not available. Such data are necessary before a possible correlation between NAE-mediated cell signaling and the malignant properties of human tumors can be postulated. In this communication, we report for the first time the levels and composition of NAE and their precursor phospholipids in a variety of human tumors, compared with adjacent normal tissues, obtained as surgical waste following surgery.

## MATERIALS AND METHODS

**Materials.** Anonymized samples of both malignant and adjacent benign human tissues were obtained following surgery and were placed on dry ice and kept frozen at  $-80^{\circ}\text{C}$  until analysis and/or incubation.

**Lipid extraction and fractionation.** The frozen tissues were weighed (typically 0.5–2.0 g), cut into small pieces, and homogenized with a Tissumizer (Tekmar, Cincinnati, OH) in 10 mL of ice-cold methanol; then 20 mL of chloroform was added and the mixture was homogenized again. The homogenate was transferred to a large screw-capped glass tube and 7.5 mL of 2.5% aqueous NaCl was added in order to separate phases (15). After centrifugation, the lower chloroform phase was transferred to a glass screw-capped tube, blown to dryness with  $\text{N}_2$ , and the residue redissolved in chloroform. Aliquots were taken for the determination of lipid phosphorus (16).

Internal standards of *N*-heptadecanoyl PE (0.6 μg) and deuterated NAE (16:0, 17:0, 18:0, 18:1, 18:2, and 20:4  $d_4$  NAE, 0.1 μg each) were added before the lipid extract (up to 3 μmol lipid P in chloroform) was applied to a 100 mg silica solidphase extraction (SPE) cartridge (Alltech). After elution of the neutral lipids with 4 mL of chloroform, NAE was eluted with 4 mL chloroform/methanol (98:2, vol/vol) and *N*-acyl PE with chloroform/methanol (8:2, vol/vol).

Abbreviations: *N*-acyl PE, *N*-acylphosphatidylethanolamine (possibly consisting of 1,2-diacyl, 1-*O*-alkyl-2-acyl, and 1-*O*-alk-1'-enyl-2-acyl-glycerol subclasses); FAAH, fatty acid amide hydrolase; NAE, *N*-acylethanolamine; SPE, solid-phase extraction.

**Assay of *N*-acyl PE and NAE.** Both *N*-acyl PE and NAE were derivatized and analyzed by GC-MS as described in detail previously (17). Briefly, the NAE fraction containing deuterated internal standards was converted to *t*-butyldimethylsilyl ethers and analyzed with a Hewlett-Packard 5890 gas chromatograph equipped with a 5972 mass selective detector and 7673 autosampler. The HP5MS column, 30 m by 0.25 mm i.d. (Hewlett-Packard, Palo Alto, CA), was programmed from 150 to 280°C at 50°C per min. The M – 57 ions were monitored in selected ion monitoring mode.

NAE derived from *N*-acyl PE by phospholipase D hydrolysis was isolated by SPE and processed as described above.

**Preparation and incubation of tissue.** Several tumors and one normal tissue sample were homogenized (Tissumizer) in 40 mM Hepes, pH 7.4. Aliquots of 0.5 mL, representing about 100 mg wet weight, were incubated in this buffer at 37°C for 1 h in the presence of either Ca<sup>2+</sup> or ethanolamine, 5 mM each, and lipids were then extracted and analyzed as described above.

## RESULTS

**Levels and compositions of *N*-acyl PE and NAE in human tumors and normal tissues.** Samples of human tumors and adjacent normal tissues were kept frozen until they were extracted and analyzed for *N*-acyl PE and NAE content. As summarized in Table 1, all tissues contained measurable amounts of both lipids. In general, tumor tissues contained

higher amounts of phospholipid on a wet weight basis than adjacent normal tissues. Hence, on a wet weight basis, tumor tissues contained substantially higher levels of both *N*-acyl PE and NAE, whereas NAE levels were either higher or lower than those of normal tissues when normalized to total phospholipid. Even on a phospholipid basis *N*-acyl PE levels in tumors were generally higher, with the notable exception of the malignant lymphoma of the terminal ileum (Table 1). This tumor had the lowest *N*-acyl PE level (30.92 pmol/μmol P), whereas a prostatic adenocarcinoma had the highest (381.09 pmol/μmol P).

The compositions (mol%) of the amide-linked FA of both *N*-acyl PE and NAE derived from the same tumor and benign tissues are listed in Table 2. The six *N*-acyl groups assayed represent the majority, but small amounts of other (polyunsaturated) FA may also have been present. As observed previously with animal tissues, 16:0 NAE was the main constituent of both NAE and the amide-linked FA of *N*-acyl PE. Interestingly, anandamide (20:4n-6 NAE) was relatively high in prostate, especially in prostate tumors, whereas the corresponding amide-linked arachidonate was low in the *N*-acyl PE of these tissues. Conversely, carcinoma of the bladder and soft tissue malignant fibrous histiocytoma, as well as adjacent normal skeletal muscle, exhibited relatively high *N*-arachidonate levels in *N*-acyl PE but low percentages of anandamide among NAE.

Assays of additional human tumors (Table 3) confirmed that they contained wide ranges of *N*-acyl PE, from 11.37

<sup>a</sup>For abbreviations see Table 1.

pmol/ $\mu$ mol P in a lymph node metastatic melanoma to 1756.82 pmol/ $\mu$ mol P in a bladder carcinoma. These tumors also contained the lowest and highest levels of NAE, 3.88 and 254.46 pmol/ $\mu$ mol P, respectively. As a percentage of total amide-linked FA, 20:4n-6 ranged from 3.1 to 24.6% in *N*-acyl PE and from 1.5 to 48.0% in NAE.

*Generation of N-acyl PE and NAE in human tumors and normal tissues.* Although it is now generally accepted that NAE, including anandamide, are synthesized *via* *N*-acyl PE through the Ca<sup>2+</sup>-dependent transacylation-phosphodiesterase pathway (7,8), there is evidence that direct N-acylation of ethanolamine also occurs *in vitro* and in intact cells (17) in the presence of ethanolamine. Because the condensation of FA and ethanolamine could be selective for arachidonate, we tested preparations of human tumors and normal tissues for their capacity to synthesize *N*-acyl PE and NAE in the presence of Ca<sup>2+</sup> or ethanolamine. As shown in Figure 1, incubation in the presence of Ca<sup>2+</sup> resulted in the expected (but relatively minor) increases in *N*-acyl PE and NAE levels, whereas NAE levels were elevated dramatically in the presence of ethanolamine. In the case of a carcinoma of the bladder, NAE was increased about 47-fold over its level in unincubated tissue.

These data suggest that both transacylase and phospholipase D activity were present in these tissues, as in all other mammalian tissues examined so far (7,8), and that condensation of ethanolamine with endogenous FA occurred as well. Interestingly, this N-acylation of ethanolamine showed a

preference for arachidonate in both a bladder tumor and benign bladder tissue, leading to both an absolute (172-fold) and relative (from 4 to 15.2%) increase in anandamide (data not shown). Other tissues did not exhibit this effect. Whether such condensation reactions are relevant *in vivo* depends on the amounts of ethanolamine present in these tissues.

## DISCUSSION

We have shown here that malignant human tumors contain widely varying levels of *N*-acyl PE and NAE, whose compositions also varied widely. In most cases, cancer tissues contained substantially higher concentrations of these lipids than adjacent benign tissue, when normalized to wet weight, since most tumors also contained higher levels of phospholipids (Table 1). Such higher contents of phospholipids in tumors have been previously documented and suggested for use in the diagnosis of several types of cancer and for evaluating the efficacy of treatment (18–21). On a phospholipid basis, by far the highest levels of both *N*-acyl PE and NAE (1756 and 254 pmol/ $\mu$ mol lipid P, respectively) were seen in an invasive, grade 3 squamous cell carcinoma of the bladder (Table 3). In other cancers, *N*-acyl PE levels ranged from less than 20 to over 300 pmol/ $\mu$ mol P. NAE levels, which are commonly lower than those of *N*-acyl PE in the same tissue (1,8), ranged from less than 1 to over 60 pmol/ $\mu$ mol P (Tables 1 and 3). The concentration of the endocannabinoid anandamide (20:4n-6 NAE) was highest in prostate cancer (reaching 24

**FIG. 1.** Levels of total *N*-acylethanolamine (NAE) and *N*-acylphosphatidylethanolamine (*N*-acyl PE) in homogenates of tumor and normal tissues before incubation (a) or after incubation for 60 min in the presence of either 5 mM  $\text{Ca}^{2+}$  (b) or 5 mM ethanolamine (c).

pmol/ $\mu\text{mol P}$ ), where it also represented the highest percentage (48%) of NAE.

Because *N*-acyl PE is the direct precursor of NAE, including anandamide, the percentage distribution of their amide-linked FA tends to be similar (1,7,8). This was also the case with many of the human tumors and benign tissues analyzed. However, it is interesting to note that the percentage of the anandamide precursor, *N*-arachidonoyl PE, rather than of anandamide itself, was very high in breast cancer tissues (up to 25%). This may be relevant in view of the growth-inhibitory action of anandamide observed with human breast cancer cells (11–13). Although the turnover rates of *N*-acyl PE and NAE in these tumors are not yet known, they were shown to be very high in macrophages (22). In such a case, the high proportion of *N*-arachidonoyl PE could be an important source for the continuous production of anandamide in mammary tumors. Conversely, the very high percentage of anandamide in prostate cancer was not matched by an equally high percentage of *N*-arachidonoyl groups in its *N*-acyl PE precursor. These data are reminiscent of similar relationships seen in peri-implantation mouse uterus where anandamide was found to reach extremely high levels without a correspondingly high concentration of *N*-arachidonoyl PE (23).

Although the phospholipase D that hydrolyzes *N*-acyl PE to NAE does not exhibit any substrate selectivity with respect to *N*-acyl groups, anandamide could be formed under certain conditions by an alternative pathway. The FAAH that hydrolyzes NAE to FA and ethanolamine is known to act in reverse in the presence of high substrate concentrations (24–26). This reaction was shown to occur in intact cells in the presence of exogenous ethanolamine (22). Whether human tumors, such as prostate adenocarcinoma (Table 3), can produce significant concentrations of arachidonic acid and ethanolamine for selective anandamide production by this pathway remains to be investigated.

The data presented here were acquired over several years by a method that has been found to be highly accurate and

well reproducible. At this time, no comparable data are available in the literature. A recent study of NAE in human brain tumor (meningioma) and normal human brain, as well as neuroblastoma and lymphoma cells (27), reported levels several orders of magnitude higher (e.g., 50 nmol/g tissue of anandamide) than those reported by us and others. However, these data (27) must be accepted with caution because the internal standards were added to aqueous homogenates, which were subsequently centrifuged to obtain the membranes to be analyzed. The internal standards may have been discarded with the supernatants, resulting in a considerable overestimation of the compounds of interest. Thus, our present data represent the first reliable information on the presence of NAE and *N*-acyl PE in human cancer and will form the basis for further study on their potential role in carcinogenesis.

**ABSTRACT:** Dolichol (D) levels increase dramatically in older tissue. An understanding of the exchangeability of D between tissues may be essential in order to understand the mechanism of the abnormal accumulation associated with aging. The question was investigated by the use of organ transplantation. D-poor hearts donated by 3-mon-old and D-rich by 22-mon-old male Lewis rats were transplanted heterotopically in 3-mon-old syngenic recipients, whose peripheral tissues and liver were poor in D. Native and transplanted hearts were taken 7 and 21 d after surgery. Native hearts of 3-mon- and 22-mon-old male Lewis rats served as control. D concentration and quantity were higher in older than in younger native hearts as expected. In the transplanted hearts, the quantity of D was unchanged, irrespective of the age of the donor and of the time of transplantation, whereas D concentration increased because of the remarkable disuse atrophy. No changes in D were observed in recipients' tissues. It is concluded that dolichol is not redistributed *via* circulation from the transplanted heart to the tissues and liver of the younger recipient.

Paper no. L9038 in *Lipids* 37, 913–916 (September 2002).

Dolichol is a long-chain polyisoprenoid widely distributed in the biological membranes of experimental systems and human tissues (1–3). Metabolism and functions of dolichol are largely unknown. Synthesis of dolichol has been demonstrated *in vitro* and *in vivo* in many tissues, but no enzymatic pathway for dolichol catabolism has been described so far (4). In view of the total dolichol content of the body, of the half-life of total body dolichol, and of the dolichol content in the extracellular space, it was concluded that the dolichol in tissues probably derives from biosynthesis in those tissues and that relocation of dolichol *via* circulation cannot be prominent *in vivo* (4,5). However, more recent evidence in a patient with abetalipoproteinemia reopened this question and invited the suggestion that the HDL-associated dolichols in serum could possibly be taken up at least in part and carried by HDL from peripheral tissues (6).

We thought that the clarification of the role of exchange between tissues in the metabolism of tissue dolichol might be essential in order to understand the mechanism underlying the

well-known, dramatic accumulation of dolichol in older animal tissues (7–10), and that transplantation experiments of older dolichol-rich tissues into younger recipients could give an answer to the question. In this research we report on the levels of dolichol in the heart of younger and older rat donors transplanted in younger recipients, and show that there is no net redistribution of dolichol from the old heart to the younger tissues.

## MATERIALS AND METHODS

**Animals.** Groups of male 2-mon-old rats of the Sprague-Dawley and Lewis strain were purchased from Harlan Italy (Corezzano, Italy) and maintained on a standard laboratory food (TEKLAD, Harlan) and water *ad libitum*. Rats were sacrificed 7 and 20 d after surgery; the grafted and the native hearts and kidney, liver, and extensor digitorum longus and soleus muscle were excised and weighed; and samples were taken for the extraction of lipid and the assay of cholesterol and dolichol by HPLC. Specimens for electron microscopy were taken from the left ventricular papillary muscle, and a quantitative analysis of ultracellular components (mitochondria, sarcoplasm, myofibrils, and dense bodies) was performed by morphometric techniques (11).

**Experimental model.** Three groups of Lewis rats were used. The first group consisted of age-matched heterotopic heart transplantation (HHTx) specimens in which donors and recipients were 3 mon old. The second group consisted of age-mismatched HHTx specimens in which the heart was taken from donors of 22 mon of age and transplanted into recipients of 3 mon of age. Hearts from the donor group (3-mon- or 22-mon-old rats) were excised under diethylether anesthesia and implanted into 3-mon-old Lewis anesthetized recipients heterotopically according to the Ono and Lindsay procedure (12). The beating activity of heart grafts was checked by daily palpation.

**Extraction and HPLC assay of cholesterol and dolichol.** The minced tissue (about 0.25 g) was hydrolyzed in 0.5 mL 0.25% pyrogallol in methanol and 0.5 mL 60% KOH at 100°C for 30 min; the mixture was extracted twice with diethyl ether/petroleum ether (1:1, vol/vol). The pooled extracts were washed with methanol/water (1:1, vol/vol) and dried under nitrogen. Cholesterol and isoprenoids were assayed by reversed-phase HPLC as described (13). The sensitivity of the method allowed us to measure a minimum of 50 ng chole-

Abbreviation: HHTx, heterotopic heart transplantation.

terol and 1.7 ng of total dolichol. Calibration curves of total peak height against quantity injected were linear in the 0.05–15  $\mu\text{g}$  (cholesterol) and in the 1.7–1000 ng (dolichol) range. Recovery of dolichol was determined by addition of internal standards to samples (10) and was 95%. Data are given as mg cholesterol and as  $\mu\text{g}$  dolichol in the organ and per g wet tissue.

**Statistical analysis.** The ANOVA test was used to evaluate differences among multiple conditions. Values of  $P > 0.05$  were considered not to be significant.

**Materials.** All reagents were of the highest quality commercially obtainable.

**FIG. 1.** Effect of transplantation on the accumulation of dolichol and cholesterol in the heart tissues of Lewis rats. Means  $\pm$  SEM of at least five cases are given. Open columns: quantity of dolichol ( $\mu\text{g}$ ) and cholesterol (mg) in the organ; solid columns, concentration of dolichol ( $\mu\text{g/g}$ ) and cholesterol (mg/g) in the heart tissue. (A) Native hearts; (B) passive hearts, 7 d after transplantation; (C) passive hearts, 20 d after transplantation. Statistical analysis (ANOVA) showed that the effects of age on dolichol quantity and concentration and on cholesterol quantity were significant ( $P < .01$  all); the effects of transplantation on the quantity of both lipids were not significant, and those on the concentration were significant (dolichol:  $P < .01$ ; cholesterol:  $P < .01$ ).

## RESULTS

Preliminary experiments on Sprague-Dawley rats showed that the levels of dolichol exhibited a similar, six- to sevenfold increase and that cholesterol levels did not change significantly with increasing age in several transplantable organs (14). The HHTx was considered to be the most suitable experimental model to investigate how much dolichol can be transferred between tissues because the liver and kidney may release part of their dolichol into bile and urine, respectively (2,5). The Lewis rat is the preferred rat strain for HHTx because of anatomy.

Figure 1 shows that, in the Lewis rat, the levels of dolichol in the older native hearts were almost fivefold higher than in younger native hearts, whereas the concentrations of cholesterol did not increase significantly with increasing age; that the quantities of dolichol and cholesterol in both the younger and the older transplanted hearts were not affected by organ transplantation (the slight decrease in the quantity of cholesterol was not significant); and that concentrations of the lipids increased significantly because of the remarkable disuse atrophy of the nonvolume-loaded HHTx. Atrophy was more rapid in the hearts from the older rats (Fig. 2). No changes in cholesterol and dolichol were found in the tissue of several recipients.

Disuse atrophy resulted in a significant increase in dolichol concentration in both younger and older HHTx. A morphometric quantitation of cell organelles in native and atrophic transplanted hearts showed that the volume density of mitochondria decreased substantially in transplanted younger and older hearts, whereas the volume density of the sarcoplasmic reticulum did not change significantly and the volume density of dense bodies increased (Fig. 3). The changes in the

**FIG. 2.** Heart weight of donor and recipient rats of the Lewis strain. Means  $\pm$  SEM of at least five cases are given. (A) Native hearts; (B) passive hearts, 7 d after transplantation; (C) passive hearts, 20 d after transplantation. Statistical analysis (ANOVA) showed that the effect of age ( $P < .01$ ) and of transplantation ( $P < .01$ ) and interaction age  $\times$  transplantation ( $P < .05$ ) were all significant.

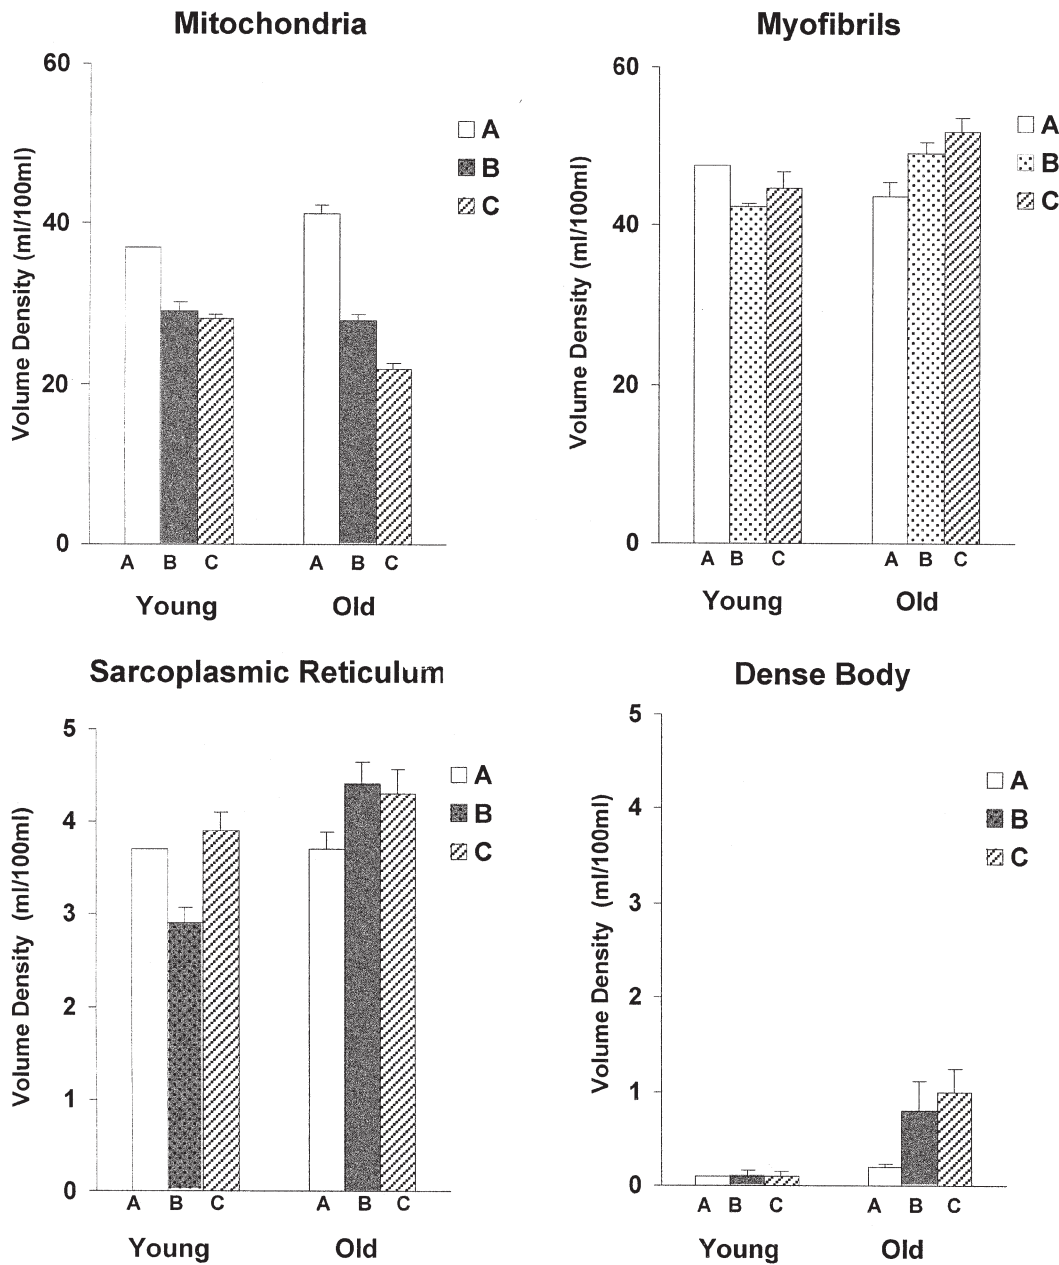

FIG. 3. Volume density of mitochondria, myofibrils, sarcoplasmic reticulum and dense body in the heart tissues of Lewis rats. Means  $\pm$  SEM of at least five cases are given. (A) Native hearts; (B) passive hearts, 7 d after transplantation; (C) passive hearts, 20 d after transplantation. Statistical analysis (ANOVA) showed that the effects of transplantation on mitochondria ( $P < .05$ ) and myofibrils ( $P < .05$ ) were significant both in younger and older heterotopic heart transplantation (HHTx); the effect on sarcoplasmic reticulum was not significant; and the effect on dense bodies was significant in older HHTx ( $P < .05$ ).

volume density of myofibrils were less than 10–20% but reached statistical significance.

## DISCUSSION

The transplanted hearts were volume-unloaded and became atrophic (15,16) but retained contractility. The faster loss of weight of the older HHTx might be attributed to a regression of the age-related hypertrophy of the left cardiomyocytes compensating for age-related cardiomyocyte loss (16). No

signs of underperfusion were visible in the cardiomyocytes of younger and older transplanted hearts by using the electron microscope. The concentrations of dolichol and cholesterol in younger native hearts were very close to those reported by Kalèn *et al.* (8) in young, adult, and mature male Sprague-Dawley rats. The present data show that dolichol accumulation continues until very old age in older native hearts. A major new finding is that the quantity of dolichol in the younger and older HHTx is similar to that in the native hearts of corresponding age, in spite of the loss of weight, and that

the quantity of dolichol in older HHTx, which is much larger than that in the tissues of the recipient rat, does not decrease with increased time post-transplantation. In conclusion, these results confirm that dolichol is not lost or transferred from the transplanted organ to the peripheral tissues or to the liver *via* circulation (4) and provide evidence that accumulation of dolichol in older tissues may be the consequence of an alteration of dolichol metabolism in those tissues. An age-dependent alteration in 3-hydroxy 3-methylglutaryl CoA reductase activity was reported in rat liver (17).

The increase in the concentration of cholesterol and dolichol in the atrophic HHTx may not necessarily imply a dramatic change in membrane composition. Shrinking of organelles and cytomembranes during atrophy is the consequence of autophagy and lysosomal degradation (18); indigestible lipids (like cholesterol and dolichol) in the degraded organelles and membranes may stay in the cells for a long time stored in the lysosomal compartment (residual bodies), which are enlarged (see also Refs. 18,19). In view of the way cells handle cholesterol, the small decrease in the quantity of this lipid in HHTx might have a physiological meaning (20).

#### ACKNOWLEDGMENTS

This work was cofunded by the Italian Ministry of University and Scientific Research. E. Bergamini is indebted to the Italian Consiglio Nazionale delle Ricerche for approval of the project (year 1995) even though the project could not be funded because of administrative delays.

# Simultaneous Determination by GC-MS of Epoxy and Hydroxy FA as Their Methoxy Derivatives

R. Wilson\* and K. Lyall

Cardiovascular Research Unit, University of Edinburgh, Edinburgh EH8 9XF, Scotland, United Kingdom

**ABSTRACT:** We report on a capillary GC-MS method for the quantitative analysis of hydroxy and epoxy FA. Catalytic hydrogenation of lipid extracts produces stable saturated lipids. Saponification followed by methylation with boron trifluoride in the presence of methanol converts FA to methyl esters and epoxy groups to methoxy-hydroxy groups. These compounds are purified from nonoxidized methyl esters using solid phase extraction. Derivatization of the hydroxy group using tetramethylammonium hydroxide forms methoxy and vicinal dimethoxy FAME. When subjected to EI-MS, fragmentation gives two characteristic ion fragments for each epoxy and hydroxy positional isomer. Quantitative measurements were achieved using uniformly labeled hydroxy and epoxy  $^{13}\text{C}$  FA as internal standards. Epoxy and hydroxy FA were identified in both plasma and adipose tissue of men, and the levels of hydroxy and epoxy in these tissues were related. The levels of hydroxy isomers were typical of oxidation of linoleic acid, whereas epoxy isomers were characteristic of oxidation of oleic acid.

Paper no. L9071 in *Lipids* 37, 917-924 (September 2002).

Free radical damage of cellular components is believed to lead to the development of disease (1). Reactive oxygen species are formed during normal metabolic process and when homeostatic mechanisms are disrupted, damage occurs (2,3). Oxidative damage to lipids is one form of damage, but elucidating the involvement of lipid peroxidation in disease requires sensitive and specific techniques (4,5). Hydroperoxy FA are primary products of free radical damage but are short-lived and difficult to measure directly (5). The use of surrogate markers of lipid peroxidation (5) and their association with disease are now well documented (1). GC-MS provides unequivocal identification of metabolites and has become increasingly popular for the quantitative analysis of markers of lipid peroxidation in biological material (5-10). Epoxy FA are also formed during normal metabolic processes in the body (11-13) and, like hydroperoxy FA or their hydroxy derivatives, epoxy FA exhibit biological and toxicological behavior (1-3,5,11-13). The use of GC-MS for the quantitative analysis of epoxy FA is limited by the instability of the epoxy group at elevated temperatures. Although the mass spectrum gives limited structural information (14,15), the formation of

chlorohydrin adducts facilitates the identification of the epoxy group (15). Epoxy FA have been analyzed directly by GC-MS using less harsh on-column injection techniques (16,17) or by HPLC with MS detection (18). As intermediates in biosynthetic pathways, epoxy FA derived from arachidonic acid have been studied intensively (12,13,16-18). The identification of biologically active epoxy FA derived from linoleic acid has increased the interest in these compounds (11). Epoxy FA derived from  $\text{C}_{18}$  FA have been identified in blood, plasma, and urine from human volunteers (19-21), but that GC-MS technique requires reductive deuteration to discriminate epoxy from endogenous hydroxy FA (20,21). Although hydroxy and epoxy FA have been identified in heart tissue in pigs, quantitative measurements are limited (22). We previously described a GC-MS technique for the quantitative analysis of hydroxy FA from biological samples (23). In the present paper we describe a quantitative GC-MS method that simultaneously determines both epoxy and hydroxy FA in biological tissues.

## MATERIALS

All solvents were HPLC grade from Rathburn Chemicals (Walkerburn, Scotland). Platinum(IV) oxide was from Fluka (Gillingham, Dorset, United Kingdom). Tetramethylammonium hydroxide (TMAH) in methanol (25%, w/w), chloroperoxy benzoic acid, and deuterium gas were from Sigma-Aldrich (Gillingham, Dorset, United Kingdom). The suitability of boron trifluoride in methanol (14%, w/w) must be checked, as certain batches gave blanks with high 12-hydroxy and 9,10-epoxy. Uniformly labeled [ $^{13}\text{C}$ ]oleic acid was obtained from Nippon Sanso Europe GmbH (Plaisir, France). 10,13-Nonadecadienoate (19:2) methyl ester was from Nu-Chek-Prep (Elysian, MN) and other FAME were from Sigma-Aldrich (Poole, Dorset, United Kingdom). Solid-phase extraction (SPE) silica columns (500 mg) were obtained from IST (Hengoed, Mid-Glamorgan, United Kingdom). Hydroxy internal standards were synthesized from  $^{13}\text{C}$ -oleic methyl ester as detailed previously (23). Epoxy internal standards were synthesized from  $^{13}\text{C}$ -oleic methyl ester as detailed in *Lipid Analysis* (24). Citrated plasma collected in a clinical polyvinyl chloride (PVC) bag was obtained from the local blood transfusion service. To the plasma was added EDTA to a final concentration of 1.6 mg/mL. Aliquots of 1.2 mL were added to 1.5-mL Eppendorf tubes and then stored at  $-70^\circ\text{C}$ .

## METHODS

**Extraction of lipids from plasma.** Lipids were extracted from EDTA plasma as described previously (23). Briefly, to 10 mL dichloromethane/methanol (2:1, vol/vol) was added 100  $\mu$ L of standard (containing 1  $\mu$ g each of hydroxy and epoxy  $^{13}$ C-standard in chloroform), 100  $\mu$ L FA standard (containing 200  $\mu$ g 19:2 in methanol), 0.5 mL plasma, and 2 mL saline (0.88%, w/w). The samples were vortexed and then centrifuged at  $500 \times g$  for 5 min to separate the layers. The lower dichloromethane layer was transferred into a clean 7-mL screw-capped tube, and solvent was removed under argon at 35°C using a Techne DB3 3A Dri-Block apparatus (Duxford, Cambridge, United Kingdom). Dried lipid was immediately hydrogenated as described below.

**Hydrogenation (deuteration) and saponification.** Platinum catalyst was added to a solution of methanol/toluene (1:1, vol/vol) to give 5 mg of platinum catalyst per mL of solvent. The solvent was shaken to suspend the catalyst, and 1 mL was added to the dried plasma lipid. For adipose tissue, approximately 20 mg was teased with forceps to disrupt the tissue prior to addition of the platinum. The tube was purged with hydrogen for 20 s and capped using a Teflon seal. The tubes were then shaken at room temperature for 15 min on a Desaga shaker. Hydrogenation was rapid and quantitative. Hydrogenolysis is a side reaction that occurs during hydrogenation using active catalysts, such as platinum, leading to products other than those desired (25). In other experiments, hydroxy and epoxy standards were hydrogenated and products were determined by GC with FID detection. No major hydrogenolysis of epoxy or hydroxy standards was observed in these experiments.

Deuterium scrambling is a recognized phenomenon that occurs with active catalysts such as platinum (25,26); therefore, the amount of the deuterated isomers was not determined. In experiments to confirm the number of double bonds, cyclohexane was used as solvent and processed as follows to minimize deuterium scrambling. The tubes were purged with deuterium for 20 s and then shaken for 5 min to saturate the solvent with deuterium. The catalyst was added and the tube was again purged with deuterium and shaken for 5 min.

Hydrogenated lipid was then saponified (23,24) to release FA. To the tube was added 2 mL KOH (1 M) in methanol/water (95:5, vol/vol), and the sample was heated at 70°C for 30 min. After cooling, the sample was transferred to an 18-mL Quick-Fit tube to which 2 mL water and 3 mL hexane/ether (1:1, vol/vol) were added. The sample was vortexed and centrifuged if necessary at  $500 \times g$  for 2 min to separate the layers. The upper organic layer containing cholesterol was discarded, and the procedure was repeated using 3 mL hexane/ether (1:1, vol/vol). The sample was acidified with 0.5 mL HCl (5 M) and FA were recovered by extracting the aqueous layer twice using 3 mL hexane/ether (1:1, vol/vol). The extracts were pooled into a 7-mL screw-capped tube and solvent was removed under argon.

**Methylation and derivatization of epoxy groups.** To the

tube were added 0.5 mL toluene and 2 mL boron trifluoride in methanol (14%, w/w), and the sample was heated at 60°C for 10 min. After cooling, 2 mL water and 3 mL hexane/ether (1:1, vol/vol) were added, and the sample was vortexed and then centrifuged at  $500 \times g$  for 2 min to separate the layers. The upper organic layer was transferred to a clean tube, and the procedure was repeated by adding 3 mL hexane/ether (1:1, vol/vol). Solvent was removed under argon. During this procedure FA were methylated and epoxy groups were quantitatively converted into methoxy-hydroxy groups.

**Purification of methoxy and hydroxy FAME.** Because 9,10-epoxy stearate is found in plastic sources, the silica SPE columns were prewashed with chloroform to remove potential contaminants. Columns were air dried and then activated at 100°C for 20 min. Methoxy- and hydroxy-containing FAME were separated from saturated FAME as described previously (23). The SPE columns were conditioned using 5 mL hexane/ethyl acetate (98:2, vol/vol). The sample was transferred to the SPE column using  $2 \times 250 \mu$ L hexane/ethyl acetate (95:5, vol/vol) and nonoxidized saturated FAME were eluted using 5 mL hexane/ethyl acetate (95:5, vol/vol). Methoxy and hydroxy FAME were retained on the column and were then eluted using 5 mL hexane/ethyl acetate (50:50, by vol) and collected in 7-mL screw-capped tubes. Solvent was removed under argon.

**GC-MS.** The isolated FAME were transferred to vials using 250  $\mu$ L methanol/dichloromethane (1:1, vol/vol) containing TMAH (1%, w/w). This reagent methylates by pyrolysis in hot injection ports and converts hydroxy to methoxy FAME and methoxy-hydroxy FAME to vicinal dimethoxy FAME. Samples were analyzed using a Hewlett-Packard 6890 series II gas chromatograph equipped with a 5973 AMS mass spectrometer and a 6890 autosampler. For analysis, 2- $\mu$ L volumes were injected into a split/splitless injector set at 260°C under splitless mode. Analysis was performed using a 30 m  $\times$  0.25 mm i.d.  $\times$  0.25  $\mu$ m HP 5MS fused-silica capillary column (Hewlett-Packard, Cheadle Heath, United Kingdom) and the following temperature program: 3 min at 100°C, 25°C/min to 170°C, 2°C/min to 260°C, 5 min at 260°C. While the temperature was maintained at 260°C, two blank solutions of TMAH were injected at 5-min intervals to flush through the system. Helium, as carrier gas, was maintained at a constant flow rate of 0.9 mL/min.

EI (70 KeV)-MS of methoxy FAME produced two major ions with fragmentation on either side of the methoxy group. EI (70 KeV)-MS of vicinal dimethoxy FAME also gave two major ions with fragmentation occurring between the adjacent methoxy groups (Fig. 2C). Fragmentation of derivatized monoepoxy FA was similar to that of hydroxy FA; thus, both compounds were quantified simultaneously. A total of 23 ions were monitored for determination of hydroxy and epoxy isomers, with a dwell time of 30 ms and a cycle time of 0.96 cycle/s (Table 1). For each isomer, five-point dilution calibration curves were prepared. The abundance of the ion fragment representing the methoxy carboxylic methyl ester part of the molecule was used to calculate amounts (Fig. 2C).

<sup>a</sup>The above table gives the major ions from the fragmentation of methoxy and vicinal dimethoxy isomers derived from hydroxy and epoxy FA. The target ion representing the methoxy carboxylic methyl ester part of the molecule was used for the quantification. Relative retention times (RRT) are given in relation to the <sup>13</sup>C<sub>18</sub> 9-methoxy internal standard.

<sup>b</sup>The ion ratio (abundance of the target ion divided by that of the qualifier ion) was calculated from a scan chromatogram using standards.

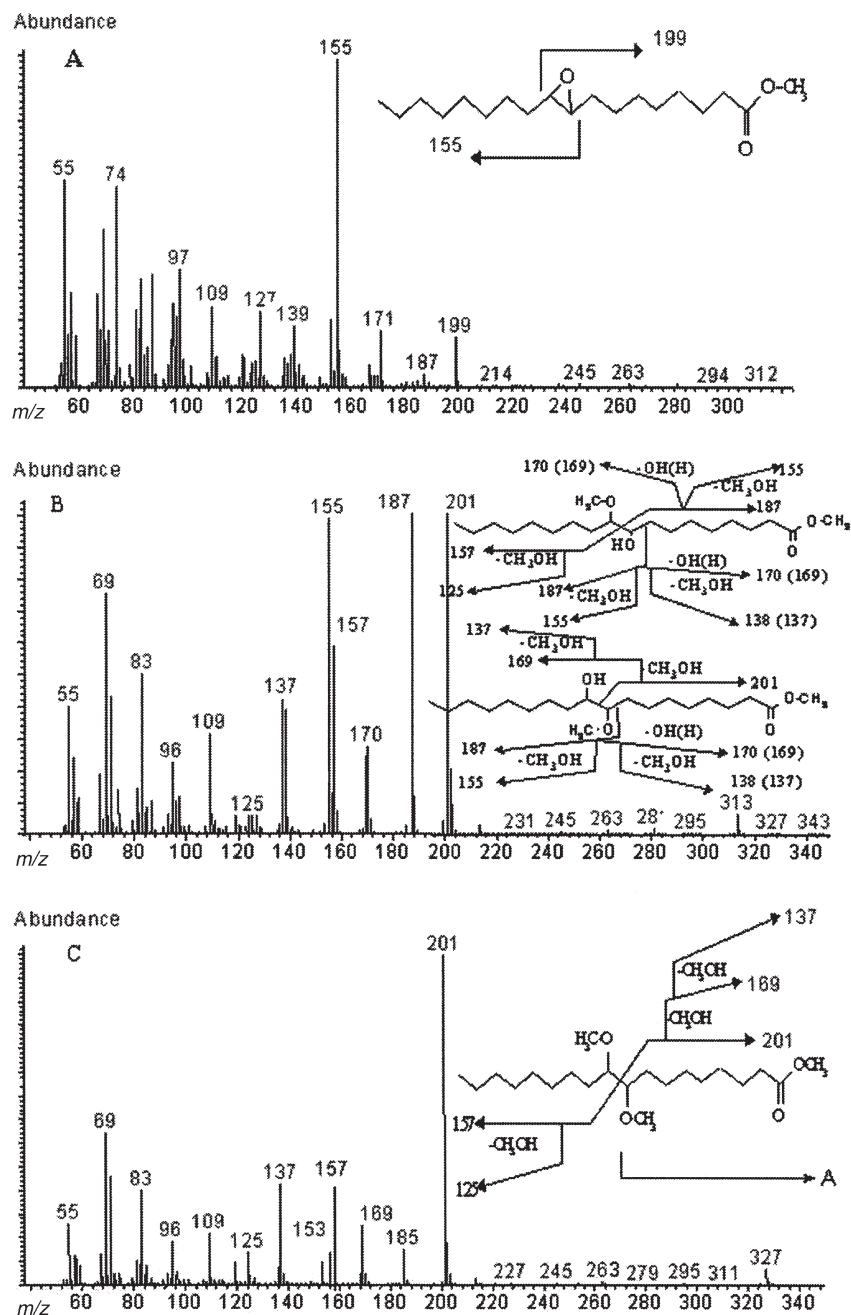

## RESULTS

The chromatographic separation of the methoxy and dimethoxy isomers is shown in Figure 1. The 8-, 9-, 10-, and 11-methoxy C<sub>18</sub> isomers were not resolved; the 12- and 13-methoxy C<sub>18</sub> were partially resolved, and the 15- and 16-methoxy C<sub>18</sub> are baseline resolved. The 9,10-dimethoxy C<sub>18</sub> was resolved from the 12,13-dimethoxy and 15,16-dimethoxy C<sub>18</sub> isomers. The 10-methoxy C<sub>19</sub> was partially resolved from

**FIG. 1.** Chromatogram of methoxy and dimethoxy isomers. A sample containing hydroxy and epoxy isomers was analyzed as detailed in the Methods section. The above figure shows the chromatographic separation of the methoxy and dimethoxy isomers. The 8-, 9-, 10-, and 11-methoxy (#) are not resolved, nor are the 12,13-dimethoxy C<sub>18</sub> and 14-methoxy C<sub>19</sub> (\*). However, the ions for each isomer are unique; therefore, these isomers can be determined by MS.

the 9,10-dimethoxy C<sub>18</sub>, whereas the 14-methoxy C<sub>19</sub> and the 12,13-dimethoxy C<sub>18</sub> were not resolved. The ions for these co-eluting isomers were unique; therefore, each could be determined by MS. The mass spectrum of 9,10-epoxy stearate was typical of that recorded in the literature (Fig. 2A). The interpretation of the mass spectra was relatively simple, with cleavage on either side of the epoxy group. Epoxy FAME, however, exhibited some degradation at high temperatures, giving multiple peaks, and it was considered necessary to convert epoxy FAME into derivatives that were stable in the hot injection port liner. Treatment with boron trifluoride in methanol converted the epoxy group to a vicinal hydroxy-methoxy group, and two isomers were formed. The two isomers from 9,10-epoxy stearate were not chromatographically resolved, whereas those from 15,16-epoxy stearate were baseline resolved (not shown) under the chromatographic conditions used. These compounds were stable at 260°C in the hot injection port liner. The mass spectra of these compounds were complex because of the loss of methoxy, hydroxy, and water (Fig. 2B). It was possible, however, to elucidate the structure of the two isomers from the mass spectrum (Fig. 2B). For the 9-hydroxy-10-methoxy isomer, fragmentation between these groups gave ions 157 and 187, and  $\alpha$ -fragmentation to the hydroxy group gave ion 187. Typical losses of CH<sub>3</sub>OH (32 amu), OH (17 amu), or H<sub>2</sub>O (18 amu) were identified, giving ions 170 (187 – 17), 169 (187 – 18), 155 (187 – 32), 138 (170 – 32), 137 (169 – 32), and 125 (157 – 32). For the 9-methoxy-10-hydroxy isomer, fragmentation between these groups gave ion 201 only, and  $\alpha$ -fragmentation

**FIG. 2.** Mass spectrum of 9,10-epoxy stearate and its derivatives. Figure A is the mass spectrum of 9,10-epoxy stearate. Conversion to hydroxy and methoxy stearate gives a simplified spectrum, and the fragments produced confirm the structure of the two isomers (Fig. B). However, the mass spectrum is further simplified, and for the dimethoxy derivative two ions, ions 201 and 157, can be used to identify and quantify 9,10-epoxy stearate (Fig. C). In this example the major ion fragment A, representing the methoxy carboxylic methyl ester, is used for quantification.

to the methoxy group gave ion 187. Typical losses of  $\text{CH}_3\text{OH}$  (32 amu), OH (17 amu), or  $\text{H}_2\text{O}$  (18 amu) were identified, giving ions 169 (201 – 32), 170 (187 – 17), 169 (187 – 18), 155 (187 – 32), 138 (170 – 32), and 137 (169 – 32). Derivatization of the vicinal hydroxy–methoxy FAME using TMAH produced a single chromatographic peak of vicinal dimethoxy FAME but, more importantly, the mass spectrum was simplified and

easily interpreted (Fig. 2C). Major fragmentation occurred between the vicinal dimethoxy groups; and the two major ion fragments formed, 201 and 157, could be used to identify and quantify the 9,10-epoxy isomer.

The precision of the method was assessed using quality control (QC) plasma, the biological material containing the least amount of lipid (1.5 mg/mL). The quantification of

U-<sup>13</sup>C-labeled 10-hydroxy methyl stearate using U-<sup>13</sup>C-labeled 9-hydroxy methyl stearate as the internal standard gave a CV of 2.7%. For 8-, 9-, 10-, 11-, 12-, and 13-hydroxy isomers, the CV of quantification was between 10 and 15% ( $n = 84$ ). It should be noted that the value of the minor isomers decreased as the mass spectrometer became dirty through sample analysis; this was reflected in the higher CV of 37 and 53% for the 15- and 16-hydroxy isomers, respectively. The 16-hydroxy isomer value decreased from 0.042 to 0.014  $\mu\text{M}$  over a 6-mon time period, but the major component values were unchanged. At this point the mass spectrometer source was cleaned. The limit of detection was 0.01  $\mu\text{M}$ . The analysis of blank samples gave values for individual hydroxy isomers of less than 0.01  $\mu\text{M}$ . It should be noted that a high 12-hydroxy was associated with certain batches of boron trifluoride. With this exception, the quantification of hydroxy isomers was the same using diazomethane or boron trifluoride (not shown). The within-batch CV of QC total plasma hydroxy was of 6.7% ( $n = 10$ ) and the between-batch CV was 10.1% ( $n = 84$ ). The 10-hydroxy and 14-hydroxy isomers derived from oxidation of the added 19:2 were constant during a 6-mon period,  $0.020 \pm 0.005 \mu\text{M}$ , and during this time no sample failed acceptable QC criteria. These values were not greater than when 19:2 was hydrogenated directly, so correction for oxidation of during-sample processing was not necessary. The 15,16-epoxy isomer was not detected in this QC plasma, and the 12,13-epoxy isomer was found at levels similar to the 15-hydroxy isomer. The within-batch CV of analysis of QC plasma epoxy was of 8.5% and the between-batch CV was 13.8%. The 9,10-epoxy isomer was found in plastic sources and should be avoided to obtain low blanks. Injection port septa also gave rise to contamination, and Teflon-coated septa or Merlin Microseal septa gave the best results. Under these conditions, blank samples gave values of around 0.03  $\mu\text{M}$  for the 9,10-epoxy isomer and less than 0.01  $\mu\text{M}$  for the 12,13-epoxy isomer.

Treatment of plasma samples with deuterium increased the mass of the hydroxy isomers proportional to the number of double bonds. This was clearly evident for the 9-hydroxy and 13-hydroxy isomers where the mass increased by 4 amu (from 171 to 175 and from 257 to 261 amu, respectively), indicating that these fragments contained two double bonds. However, little or no increase in mass was observed for the major 9,10-epoxy isomer; thus, this epoxy isomer contained no additional double bonds. Treatment of adipose tissue samples with deuterium increased the mass of the hydroxy isomers proportional to the number of double bonds. It was evident that the 12,13-epoxy isomer contained one double bond, as the mass of the fragment containing the double bond increased by 2 amu (from 243 to 245 amu). Yet there was little evidence for a similar increase in mass for the 9,10-epoxy isomer. Thus, in adipose tissue the 9,10-epoxy isomer contained no additional double bonds.

Epoxy FA and hydroxy FA were identified in the plasma of 19 men (Table 2). The 9,10-epoxy isomer was present at a higher concentration than either the 12,13-epoxy isomer or

**TABLE 2**  
**Hydroxy and Epoxy Isomers in Plasma of Man<sup>a</sup>**

Hydroxy isomer	Amount ( $\mu\text{M}$ )	Amount ( $\mu\text{M}$ )	Epoxy isomer
8-	$0.067 \pm 0.003$		
9-	$0.209 \pm 0.011$		
10-	$0.132 \pm 0.004$	$0.260 \pm 0.040$	9,10-
11-	$0.112 \pm 0.005$		
12-	$0.082 \pm 0.004$	$0.080 \pm 0.004$	12,13-
13-	$0.122 \pm 0.006$		
15-	$0.050 \pm 0.001$	$0.034 \pm 0.006$	15,16-
16-	$0.018 \pm 0.001$		
Total	$0.792 \pm 0.041$	$0.374 \pm 0.025$	Total

<sup>a</sup>Hydroxy and epoxy isomers in the plasma of 19 men were determined as described in the Methods section. Values are mean  $\pm$  SEM.

the 15,16-epoxy isomer (Table 2). The 9-, 10-, 11-, 12-, and 13-hydroxy isomers were all major products, and the pattern of hydroxy isomers was typical of oxidation of plasma unsaturated FA, in particular linoleic acid. The level of total hydroxy was related to the level of total epoxy ( $r = 0.52$ ,  $P < 0.001$ ), and this was also reflected in that the major 9,10-epoxy isomer was related to the sum of the 9-hydroxy and 10-hydroxy isomers ( $r = 0.57$ ,  $P < 0.001$ ). In these men hydroxy FA were, on average, 1.7-fold greater in concentration compared to epoxy FA. In contrast, the level of 9,10-epoxy isomer in QC plasma ( $0.752 \pm 0.023 \mu\text{M}$ ) was similar in magnitude to the level of total hydroxy isomers ( $0.720 \pm 0.031$ ).

Epoxy FA and hydroxy FA were identified in adipose tissue of the same 19 men (Table 3). Similar to that in plasma, the 9,10-epoxy isomer was present in substantially higher concentrations than either the 12,13-epoxy isomer or the 15,16-epoxy isomer (Table 3). In adipose tissue there was, on average, 4.8-fold more hydroxy than epoxy FA, with 9-, 10-, 11-, 12-, and 13-hydroxy isomers all being major products. In contrast to plasma, the 11-hydroxy isomer was the major product in adipose tissue. The levels of total hydroxy were significantly related to the levels of total epoxy ( $r = 0.65$ ,  $P < 0.005$ ), and this was reflected in the fact that the 9,10-epoxy isomer was significantly related to the sum of the 9- and 10-hydroxy isomers ( $r = 0.53$ ,  $P < 0.02$ ). It should be noted that

**TABLE 3**

16-	$1.26 \pm 0.05$		
Total	$112.9 \pm 10.4$	$23.31 \pm 3.45$	Total

<sup>a</sup>Adipose tissue from 19 men was analyzed for hydroxy and epoxy isomers as described in the Methods section.

<sup>b</sup>Values are  $\mu\text{g}$  hydroxy per g wet weight adipose tissue (mean  $\pm$  SEM).

although a weak correlation was found between plasma and adipose hydroxy isomers ( $r = 0.35$ ,  $P = 0.14$ ), there was no correlation between plasma and adipose epoxy FA ( $r = 0.12$ ,  $P = 0.60$ ). We found that the CV of adipose tissue tended to be greater than that of plasma samples from the same men. An accurate wet weight contributed to the increased error, but unlike plasma, small samples of adipose tissue were not homogeneous. Thus, adipose analyzed from a large adipose sample from a single individual gave a CV of 17% for total hydroxy ( $n = 10$ ).

## DISCUSSION

Hydroxy FA are derived directly from hydroperoxy FA and are stable end products of the body's defense mechanisms to the free radical attack (2,3). Linoleic acid is the major PUFA within the body (27). We therefore used hydroxy FA derived from linoleic acid as a surrogate measure of free radical oxidative damage (23,28). Hydroxy FA have been used as a surrogate measurement of hydroperoxy FA in biological systems in many studies (1–10). Hydrogenation is an essential step in many methods because it not only stabilizes the hydroperoxy group early in the analytical procedure (as a hydroxy group) but through elimination of double bonds also prevents further oxidation during sample workup. These methods cannot distinguish between hydroperoxy and hydroxy FA (5). The hydrogenation step described in the present paper is excellent, as demonstrated in that oxidation products derived from the added 19:2 were consistently low throughout the period of analysis and thus no autoxidation occurred during sample processing.

Methylation of FA using diazomethane, as in the original method (23), does not open up the epoxy group. Hence, FA containing monoepoxy groups were not retained on the SPE column and could not be measured. In addition to producing methyl esters, boron trifluoride in methanol opens up the epoxy group to form hydroxy-methoxy groups (14), and these compounds are retained on the SPE columns. Derivatization of hydroxy groups with TMAH improves both the chromatography and fragmentation of the hydroxy and epoxy FA esters. Two main ions are formed, and each unique ion pair defines the position of oxidation of the original carbon-carbon double bond. The method can be used to monitor and quantify all hydroxy and epoxy isomers of  $C_{18}$  FA and also measure and quantify hydroxy and epoxy isomers of  $C_{20}$  and  $C_{22}$  FA. However, in plasma and adipose tissue, the two tissues routinely sampled in human studies, the 9-, 10-, 11-, 12-, and 13-hydroxy  $C_{18}$  isomers and the 9,10-epoxy  $C_{18}$  isomer are the most abundant, and these isomers would routinely be quantified. The 9,10-epoxy isomer would, of course, be indistinguishable from the 9,10-dihydroxy isomer. However, little 9,10-dihydroxy is detected in plasma, and in samples with a high 9,10-dihydroxy concentration then measurement with and without boron trifluoride treatment would be required.

It has long been assumed that oxidized lipids are poorly absorbed (29), but it has recently been shown that hydroxy

and epoxy FA present in oils and foods are absorbed from the diet (28,30). Although consumption of oxidized fat increased the levels of hydroxy and epoxy FA during postprandial lipemia, the absorbed fat did not contribute to fasting plasma levels of oxidized lipids some 24 h later (28,30). Thus, fasting plasma hydroxy and epoxy FA may give reliable measurements of free radical damage occurring within the body. In the present study, the total fasting hydroxy FA level was  $0.792 \pm 0.041 \mu\text{mol/L}$ . It is important to note that the hydroxy FA levels are similar to the direct measurement of plasma hydroperoxy levels using other techniques (31,32). The 9- and 13-hydroxy isomers are typical of free radical oxidation of linoleic acid, and the use of deuterium confirmed that the 9- and 13-hydroxy isomers were indeed derived from linoleic acid. The 9,10-epoxy isomer was a major component in both plasma and adipose tissue and was from oleic acid. High levels of 9,10-epoxy stearate were found in blood (19), and later 9,10-epoxy octadeca-12-enoate and 12,13-epoxy octadeca-9-enoate, epoxy isomers derived from linoleic acid (20), were identified by the same researchers (20). That method, in which the epoxy group was chemically reduced to hydroxy groups, did not readily distinguish between epoxy and endogenous hydroxy FA isomers. It is possible that the high levels of 9-hydroxy and 13-hydroxy isomers in plasma were identified as epoxy isomers in those studies (20). Diffusion of epoxy FA from plastic sources into foods is now documented (33). However, there is no indication that the 9,10-epoxy stearate found in blood collected in clinical PVC bags in this and other studies (19,20) is due to a similar process. It is important to note that a plasma pool collected using glass syringes and glass tubes gave epoxy values similar to that collected using normal procedures ( $0.112 \pm 0.12$  vs.  $0.120 \pm 0.15$ ,  $n = 3$ ).

PUFA can be oxygenated by cytochrome P450 (13). This ubiquitous enzyme catalyzes the oxygenation of xenobiotics through epoxidation and hydroxylation reactions, often to detoxify these compounds, but it can also oxygenate endogenous lipids (13). Arachidonic acid, as a precursor of eicosanoids, has been studied intensively, but linoleic acid and other  $C_{18}$  FA are substrates for cytochrome P450 (11–13,34). A major hydroxylation product of cytochrome P450 is the 11-hydroxy isomer derived from linoleic acid (13). It is interesting to note that, of the two monoperoxides of linoleic acid, the rate of conversion to the 9,10-isomer is more than three times higher than the 12,13-isomer by liver (11) or soybean microsomes (34). Oleic acid is also readily oxidized to 9,10-epoxy by soybean microsomes in a mechanism consistent with hydroperoxy linoleic acid acting as an oxygen donor rather than by a free peroxy radical mechanism (34). Oxidized lipids have been detected in diseased heart tissue in pigs (22) and in humans (35), and their amounts increased with time of ischemia (22). These compounds were absent (22) or lower in concentration (35) in healthy heart tissue. Measurements were semiquantitative, but the identification of 9,10-epoxy stearate and leukotoxins (the 9,10-epoxy octadeca-12-enoate and 12,13-epoxy octadeca-9-enoate, isomers derived from

linoleic acid) led these investigators to conclude that they originated from enzymatic oxidation rather than from lipid peroxidation (35). Interestingly, in adipose tissue the 11-hydroxy isomer, a potential product of cytochrome P450 (13), was the largest component. The 9,10-epoxy isomer identified in the present study contained no additional double bonds and therefore was from the oxidation of oleic acid rather than linoleic acid. However, the present technique could not determine the stereochemistry of the isomers. Techniques to determine the stereochemistry, which might differentiate between free radical and enzymatic sources of oxygenated metabolites, have recently been reviewed (25). The origin of the 11-hydroxy and 9,10-epoxy isomer in plasma and adipose tissue requires further investigation, but it is interesting to speculate that these two products are formed enzymatically rather than from a free radical mechanism.

With the increased interest in the biological effects of epoxy FA derived from linoleic acid (11–13), there is a need for quantitative measurements. This paper describes a GC–MS technique for the quantitative analysis of hydroxy and epoxy FA derived from biological samples. The method is accurate and gives good consistency, both within batch and between batches. The method described shows good sensitivity, with 0.5 mL plasma and 20 mg adipose tissue being sufficient to measure hydroxy and epoxy isomers. Our method is a major advance over that currently available in the literature. The synthesis of hydroxy and epoxy FA from U-<sup>13</sup>C-labeled oleic acid permitted accurate quantitation. The hydrogenation step is fast and effective with no oxidation during sample preparation. Purification of hydroxy and epoxy FAME from the bulk of nonoxidized material eliminates chromatographic interference and maintains MS sensitivity for prolonged periods. Derivatization of hydroxy groups improves EI–MS readings, permitting ease of identification and simultaneous quantification of all hydroxy and epoxy isomers. Measurement of multiple isomers rather than a single ion, as in negative ion techniques, can distinguish between isomers derived from enzymatic sources and those from free radical oxidation, thus facilitating interpretation of the data.

## ACKNOWLEDGMENTS

This study was supported by a LINK Agro Food Programme grant (AFQ112). We wish to thank the Ministry of Agriculture, Food and Fisheries and the members of the Link management group—Nestlé UK Ltd., Roche Products Ltd., and Van den Bergh Foods Ltd.—for their support. R.W. was funded by EU grant (Generale Study QLRT-1999-02111). This study was also supported by an equipment grant for the purchase of the mass spectrometer from the Wellcome Foundation and the Scottish Chest, Heart and Stroke Association.
