

# Lipids and Endothelium-Dependent Vasodilation—A Review

Lars Lind\*

Department of Medicine, Uppsala University Hospital and AstraZeneca R&D, Mölndal, Sweden

**ABSTRACT:** Studies using both *in vitro* and *in vivo* techniques have repeatedly shown that endothelium-dependent vasodilation (EDV) is impaired in different forms of experimental as well as human hypercholesterolemia. Clearly this impaired EDV can be reversed by lowering cholesterol levels by diet or medical therapy. Competitive blocking of L-arginine, changes in nitric oxide synthase activity, increased release of endothelin-1, and inactivation of nitric oxide due to superoxide ions all contribute to the impairment in EDV during dyslipidemia. The oxidation of low density lipoprotein, with its compound lysophosphatidylcholine, plays a critical role in these events. However, data on the role of triglycerides and fat-rich meals regarding EDV are not so consistent as data for cholesterol, although a view that the compositions of individual fatty acids and antioxidants are of major importance is emerging. Thus, this review shows that while impaired EDV is a general feature of hypercholesterolemia, the mechanisms involved and the therapeutic opportunities available still have to be investigated. Furthermore, discrepancies regarding the role of triglycerides and fat content in food may be explained by divergent effects of different fatty acids on the endothelium.

Paper no. L8726 in *Lipids* 37, 1–15 (January 2002).

Hypercholesterolemia has long been regarded as a major cardiovascular risk factor due to findings in epidemiological studies (1). Since the introduction of the statins, lipid lowering by these agents has had positive effects in recent years on cardiovascular morbidity and mortality (2–4).

Furchgott and Zawadzki (5) discovered in 1980 that the endothelium takes an active part in the regulation of blood flow. That the endothelium also participates in the pathogenesis of atherosclerosis was discovered later. Endothelial-derived factors contribute to maintaining a state favoring vessel patency, blood fluidity, nonadherence of circulating blood cells, and inhibition of smooth muscle cell proliferation (6–8).

In 1986, Ludmer and co-workers (9) showed that acetylcholine produced vasoconstriction in atherosclerotic coronary arteries, whereas a vasodilatory response was seen in normal arteries in humans. In fact, vasodilation was impaired in atherosclerotic-prone humans even before the development of atherosclerotic lesions could be detected with coronary angiograms (10). It was therefore suggested that an impairment

in endothelium-dependent vasodilation (EDV) could be taken as an early marker of atherosclerosis formation. Although dyslipidemia also could cause impairment in other functions of the endothelium (11), the present review will focus on the role of cholesterol, triglycerides, fatty acids, and fat intake on EDV.

## Endothelium-Derived Vasoactive Factors

*Nitric oxide (NO).* Palmer *et al.* (12) discovered that the endothelium-dependent relaxing factor, called EDRF, was identical to NO, being synthesized from the amino acid L-arginine by NO synthase (NOS) (13). NO diffuses to the smooth muscle cells in the vessels inducing formation of cGMP, which promotes vasodilation (14,15). NO is rapidly converted to metabolites, such as nitrite, nitrate, and radical forms of NO. Several analogs of L-arginine, such as N<sup>G</sup>-monomethyl-L-arginine, competitively inhibit NO production (14–16).

*Endothelin.* The main vasoconstrictive endothelin is endothelin-1 (ET-1), produced from the propeptide big ET-1 by endothelin-converting enzyme (17,18). The main vasoconstrictive endothelin receptor subtype is called ET<sub>A</sub> and is present on VSMC (19), whereas ET<sub>B</sub>-receptors, located on endothelial cells, induce vasodilation through release of NO (19–21).

*Other endothelium-derived vasoactive factors.* Apart from NO, hyperpolarizing factors (EDHF) can contribute to part of the acetylcholine-induced vasodilation (14,22,23) by opening K<sup>+</sup>-channels (24,25). Recent studies suggest that EDHF could be either a cytochrome p450-derived arachidonic acid metabolite (26,27) or the potassium ion (28). Acetylcholine could induce endothelial release of vasoconstricting factors (EDCF), such as thromboxane A<sub>2</sub> or prostaglandin H<sub>2</sub> (29–33). The endothelium could also produce other vasoactive compounds, such as the vasodilatory prostacyclin (PGI<sub>2</sub>).

## Models to Investigate EDV

*Experimental in vitro and in vivo studies.* The most widely used *in vitro* method to study EDV is to expose vessel rings mounted on a wire myograph to vasodilators, such as acetylcholine (34–70). *In vivo* studies in animals most often use acetylcholine in isolated organ preparations *in vivo* (71–78).

*Human studies of coronary circulation.* Registration of the change in vascular diameter in epicardial arteries during coronary angiography subjected to local infusion of acetylcholine is a common way to evaluate coronary EDV (79–82).

*Human forearm model.* Evaluation of the forearm blood flow response to intra-arterial infusion of vasodilator agents

Abbreviations: ADMA, asymmetric dimethylarginine; EDCF, endothelium-derived vasoconstricting factor; EDHF, endothelium-derived hyperpolarizing factor; EDV, endothelium-dependent vasodilation; ET-1, endothelin-1; HDL, high density lipoprotein; LDL, low density lipoprotein; lp(a), lipoprotein(a); LPC, lysophosphatidylcholine; LPL, lipoprotein lipase; NO, nitric oxide; NOS, nitric oxide synthase; VSMC, vascular smooth muscle cells.

by venous occlusion plethysmography is the most widely used method to study EDV in resistance arteries in humans (83–89).

**Human brachial artery ultrasound method.** High-resolution ultrasound is used to measure changes in brachial artery diameter during reactive hyperemia, flow-mediated vasodilation (90–92). Apart from these methods, the *in vitro* method has also been used for human subcutaneous small arteries (93).

### Animal Models of Hypercholesterolemia and Atherosclerosis

The most widely used model of hypercholesterolemia and atherosclerosis is the cholesterol-fed New Zealand white rabbit (34–59). Other animals, such as the rat, monkey, pig, and

the Watanabe rabbit, have also been used (60–62). In recent years, the use of knock-out mice for the apolipoprotein E or the low density lipoprotein (LDL)-receptor gene have gained in popularity (69,70).

### Effects of Hypercholesterolemia on EDV in Animal Models

Table 1 summarizes the studies in which acetylcholine has been used to induce EDV in different animal models and different types of vessels in *in vitro* experimental studies. In the vast majority of the studies evaluating the aorta, a negative effect on EDV was seen in different animals (34–50, 60–64, 69). An impaired EDV was also seen in other vessels, includ-

**TABLE 1**  
Studies in Experimental Cholesterol-Fed (CF) Animals or Inheritable Forms of Atherosclerosis Using Acetylcholine to Evaluate Endothelium-Dependent Vasodilation (EDV)<sup>a</sup>

Model	Vessel type	Effect on EDV	Reference
<i>In vitro</i>			
CF rabbit	Aorta	Negative	34–50
CF rabbit	Coronary Pulmonary artery Corpus cavernosus Carotid artery Subclavian artery	Negative	41, 51–57
CF rabbit	Femoral artery Mesenteric artery Cerebral artery Basilar artery	No effect	41, 58

CF rabbit	Kidney	No effect	75
CF pig	Kidney	Negative	76
CF monkey	Femoral artery	Negative	77
ApoE knock-out	Skin	Negative	78

<sup>a</sup>Effect on EDV denotes the influence of the animal model compared to control animals regarding EDV. LDL, low density lipoprotein; ApoE, apolipoprotein E.

ing the coronary arteries, during hypercholesterolemia (41,51–57,67,68,70). Also, *in vivo* studies using different perfused vascular beds have found that hypercholesterolemia impairs EDV (71–73,76–78). However, studies using small cerebral arteries or the renal vasculature generally have been unable to show a deleterious effect of hypercholesterolemia on EDV (41,58,61,75).

### Effects of Hypercholesterolemia on EDV in Humans

In humans, the effects of hypercholesterolemia on EDV have been even more consistent than in the experimental studies. In the 14 studies summarized in Table 2, all but one (92) showed that hypercholesterolemic subjects have an impaired EDV in different vascular beds (79–91,93). Additionally, several studies have demonstrated an inverse relationship between serum cholesterol levels and EDV in apparently healthy humans (94–98; see Fig. 1).

Thus, it can be concluded that hypercholesterolemia, both in animal models and in humans, has a deleterious effect on EDV in the majority of vascular beds studied.

### Effects of Different Types of Lipoproteins on EDV

Although native LDL reportedly induces an impairment in EDV when added to aortic preparations *in vitro* (99–101) and reduces NOS mRNA expression (102) and cGMP levels (103), oxidized LDL is more potent than the native form (104–106). A graded effect of the degree of oxidation of LDL on EDV was seen (107), confirming that oxidation of the LDL particle is essential for the endothelial effects (108–116). Also in humans, the lag phase of LDL oxidation was related to the degree of coronary EDV (117).

A major component in oxidized LDL is lysophosphatidylcholine (LPC). When aortic rings were exposed to pure LPC, a reduction in EDV similar to that with oxidized LDL was seen (109,118–123). The deleterious effect of LPC might be acting through a protein kinase-C pathway (124) and by elevated levels of phospholipase D (125). Plasma phospholipid transfer protein could abolish this impairment in EDV caused by LPC (126).

When aortic rings were exposed to high density lipoprotein (HDL) only, an impairment in EDV, similar to that of LDL, was found (100). However, when HDL was given together

**FIG. 1.** Relationship between serum cholesterol levels and endothelium-dependent vasodilation (EDV) in a sample of apparently healthy subjects (for details, see Ref. 97).

with oxidized LDL, HDL could inhibit the reduction in EDV induced by oxidized LDL (105,127) due to removal of LPC from oxidized LDL (122). Also, synthetic large “empty” phospholipid vesicles that accelerate reverse cholesterol transport improved EDV (128). In humans, a positive correlation between HDL levels and EDV has been reported (129,130).

Lipoprotein(a), especially in its oxidized form, has been reported to impair EDV (131). This effect can be reversed by adding HDL (132). In humans, lp(a) levels have been inversely related to coronary EDV and basal NO release (133–135).

### Effects of Triglycerides and Fatty Acids on EDV

Under experimental conditions, very low density lipoproteins and remnants of chylomicrons impair EDV (100,136,137). When Intralipid plus heparin was infused in humans to increase free fatty acids and triglycerides, a rapid reduction in EDV was seen (138–142). This effect was most pronounced in subjects with the BB-paraoxonase genotype (143). In the laboratory, oleic acid induced an impairment in EDV *in vitro* (144). However, later studies showed that the effect of fatty acids was not a simple one, as palmitic acid, but not stearic acid, reduced NO production in cultured cells (145). On the contrary, the two polyunsaturated fatty acids, eicosapentaenoic acid and docosahexaenoic acid, but not arachidonic acid, improved EDV (146) and NO production (147). The n-3 fatty acid supplementation in humans also improved EDV (148). We recently showed divergent effects of different fatty acids in a population study (129).

In humans with isolated hypertriglyceridemia, both an impaired (149–152) and a normal EDV have been reported (153,154). In our own population study, subjects with serum triglycerides >1.7 mmol/L showed an impaired EDV (Fig. 2) (97). As triglycerides are cleared from the circulation by lipoprotein lipase (LPL), an LPL activator improves EDV in rats (155).

**TABLE 2**  
Comparison of EDV in Human Subjects with Hypercholesterolemia (HC) and Controls Using Different Methods<sup>a</sup>

Methods	Effect of HC on EDV	Reference
Coronary	Negative	79–82
Forearm	Negative	83–89
FMD (femoral artery)	Negative	90,91
FMD (brachial artery)	No effect	92
<i>In vitro</i>	Negative	93

<sup>a</sup>FMD, flow-mediated vasodilation evaluated by ultrasound. See Table 1 for other abbreviation.

FIG. 2. Relationship between serum triglyceride levels and EDV in a sample of apparently healthy subjects (for details, see Ref. 97). See Figure 1 for abbreviation.

### Effects of a Fat-Rich Meal on EDV

Several studies (156–164), but not all (165–167), showed that meals rich in fat reduce EDV. This was not seen on low-fat diets. Antioxidant vitamins, folic acid, and red wine blunted the deleterious effects of a high-fat meal on EDV (156,157, 161). Also, food prepared in used cooking fat impaired EDV (168). A meal rich in olive oil impaired EDV only when antioxidant vitamins were not given (169), whereas an improvement was seen when hypercholesterolemic subjects were given a Mediterranean diet (170). Statin, but not fibrate, pretreatment blunted the negative effect of a high-fat meal on EDV (162).

Thus, compared to cholesterol, the effects of triglycerides and fatty acids on EDV are more complex, probably due to divergent effects of different fatty acids.

## PATHOLOGICAL CONSIDERATIONS

### Asymmetric Dimethylarginine (ADMA)

As a product of dimethylation of proteins, ADMA is formed and acts as a competitive inhibitor of NOS. ADMA levels are increased in subjects with both hypercholesterolemia (171) and isolated hypertriglyceridemia (151), and by cholesterol feeding in rabbits (172). This latter effect can be reversed by addition of L-arginine (171). The L-arginine-to-ADMA ratio is related to breakdown products of NO ( $\text{NO}_x$ ) (171), and cholesterol feeding reduces the breakdown of ADMA (173,174).

### Oxygen Free Radicals

The superoxide ion ( $\text{O}_2^-$ ) rapidly inactivates NO to form peroxynitrite ( $\text{ONOO}^-$ ) (175). Cholesterol feeding in animals increases the amount of  $\text{O}_2^-$  in vessels (176–178) and the metabolite of  $\text{ONOO}^-$ , nitrotyrosine (175). Supplementation with L-arginine, probucol, or a statin (177,179,180) reduces

this effect of cholesterol feeding on  $\text{O}_2^-$ -production. A number of antioxidants improve EDV during conditions of high cholesterol levels in humans and animal experiments (see Tables 3 and 4). However, all antioxidant interventions have not been effective in this respect. In humans, serum levels of vitamin E are directly related to EDV, whereas a marker of lipid peroxidation, plasma isoprostane 8-iso-PGF<sub>2 $\alpha$</sub> , is inversely related to EDV (181,182).

### Endothelin and Hypercholesterolemia

Elevated levels of ET-1 have been found in the circulation in hypercholesterolemic humans (183), whereas statin treatment has been shown to reduce ET-1 mRNA expression (184). Furthermore, endothelin-receptor blockade reverses the impaired EDV seen in experimental models (185,186).

### Effects of Hypercholesterolemia on NOS

Cholesterol feeding both increases caveolin binding to NOS (187) and externalizes NOS from within the caveolae (188). Dosing with tetrahydrobiopterin, a co-factor of NOS, of hypercholesterolemic subjects improved their impaired EDV within a short period of time (Table 4). Furthermore, statins may influence NOS activity directly (189,190) by an improved caveolin–NOS interaction (191).

### Endothelium-Derived Hyperpolarizing or Contracting Factors

Inhibition of cyclooxygenase improved EDV in cholesterol-fed rats, implying an importance of a prostanoid-derived EDCF during hypercholesterolemia (192). NO-dependent vasodilation was impaired in cholesterol-fed rabbits, but vasodilation mediated by EDHF was normal (193).

Thus, several factors, such as an endogenous inhibitor of NOS, effects on the enzyme itself, oxidative inactivation of NO, or an altered activity of other endothelium-derived vasoactive compounds, could be involved in the impaired EDV seen in dyslipidemia.

## EFFECTS OF INTERVENTIONS IN HYPERCHOLESTEROLEMIA

### Interventions in Animal Models

Treatment with statins in several models of hypercholesterolemia resulted in a positive effect on EDV in all (194–201) but two studies (202, 203); even then, cholesterol was not reduced (204) (Table 3). In addition, cholesterol lowering by dietary means or by cholestyramine improved EDV (205). However, the duration of hypercholesterolemia was of major importance for the effect of therapy. Once atherosclerosis had reached a certain degree, a reduction in cholesterol levels could not reverse the impairment in EDV in these models (206,207).

**TABLE 3**  
**Effects of Different Interventions on EDV in Different Animal Models<sup>a</sup>**

Intervention	Model	Type of vessel	Effect on EDV	Reference
Statins	CF rabbit, mice, monkey	Aorta	Positive	194–201
Statins	CF rabbit, Watanabe	Aorta	No effect	202,203
Statins	Watanabe	Langendorf heart	Positive	203
Cholestyramin	CF mice	Aorta	Positive	205
Dietary cholesterol-lowering	CF rabbit	Aorta	Positive	206,207
L-Arginine	CF rabbit	Aorta, hindlimb, basilar artery	Positive	202,208–214
Probucol	CF rabbit	Aorta	Positive	177,215,216
SOD	CF rabbit	Aorta	Positive and no effect	217,218
Vitamin E	CF rabbit	Aorta, carotid, Langendorf heart, perfused ear, pulse wave	Positive	208,219–226
Vitamin E	CF rabbit	Renal artery	No effect	224
Vitamin E	CF dog	Coronaries <i>in vivo</i>	Positive	227
β-Carotene	CF rabbit	Aorta	Positive	226
Tomatoes	CF rabbit	Aorta	Positive	228
NEP inhibition	CF rabbit	Aorta	Positive	229
α-Blockade	CF mice	Aorta	Positive	194
ACE-inhibition	CF rabbit	Aorta	Positive	230–232
Calcium blockers	CF rabbit	Aorta	Positive (and one no effect)	232–235
Endothelin antagonist	CF rabbit	Aorta	Positive	211
Endothelin antagonist	CF pig	Coronaries <i>in vivo</i>	Positive or no effect	236,237
Prostacyclin	CF rabbit	Langendorf heart	Positive	238
Heparin	Watanabe	Aorta	Positive	239
Cod liver oil	CF pigs	Coronaries	Positive	240
Estrogen	CF rabbit	Aorta	Positive and no effect	241,242
Estrogen	CF swine	Coronary	Positive	243

<sup>a</sup>SOD, superoxide dismutase; NEP, neuroendopeptidase; ACE, angiotensin-converting enzyme; see Table 1 for other abbreviations.

Treatment with L-arginine has been shown to improve EDV without any alterations in serum cholesterol levels (202,208–214). Also, different antioxidants or free-radical scavengers, such as probucol, superoxide dismutase, vitamin E, tomato carotenoids, and β-carotene, have positive effects on EDV in hypercholesterolemic animals (202,215–228).

**TABLE 4**  
**Effects of Different Interventions on EDV in Subjects with Hypercholesterolemia<sup>a</sup>**

Intervention	Model	Effect on EDV	Duration of treatment	Reference
Statins	Forearm	Positive	1–6 mon	246,247
Statins	FMD	Positive	6–12 wk	248–251
Statins	Coronary	Positive	5–6 mon	252,253
Statin + probucol	Coronary	Positive	12 mon	254
Statin + vitamin E	FMD	Positive	8 wk	255
Lipid-lowering drugs	Coronary, forearm, and FMD	Positive	12 mon and 12 wk	251,254,256
Cholestyramine	Coronary	Positive	6 mon	257
L-Arginine	Coronary and FMD	Positive	Acute	260,261
L-Arginine	Forearm	Positive and no effect	Acute	262,263
L-Arginine	FMD	Positive	4 wk	264
Vitamin E	FMD	Positive	4 wk	265
Vitamin E	Forearm	Positive and no effect	4 wk	266–268
Antioxidant vitamins	Forearm	No effect	4 wk	269
SOD	Forearm	No effect	Acute	270
Vitamin C	Forearm	Positive	Acute	271
Glutathione	Femoral artery	Positive	Acute	272
Folic acid	Forearm	Positive	Acute and 4 wk	273,274
Tetrahydrobiopterin	Forearm	Positive	Acute	275
ASA	Forearm	Positive	Acute	89
LDL-Apheresis	Forearm	Positive	Acute	276
Nifedipine	Forearm	Positive	6 wk	277
Estrogen	FMD	Positive	6 wk	248
Fish oil	FMD and <i>in vitro</i>	Positive	6 wk to 4 mon	93,278,279
Exercise training	Forearm	No effect	4 wk	280

<sup>a</sup>ASA, acetylic salicylic acid; LDL, low density lipoprotein; see Tables 1, 2, and 3 for other abbreviations.

Commonly used antihypertensive therapies, such as angiotensin-converting enzyme inhibition, calcium and  $\alpha$ -receptor blockade, endothelin receptor blockade, and neuroendopeptidase inhibition, all have positive effects on EDV (194,211, 229–237); a number of other drugs, such as heparin and estrogens (see Table 3) (238–245) have also exhibited this effect.

### Effects in Humans

Statins and other lipid-lowering drugs, such as cholestyramine, improve EDV in hypercholesterolemic patients after only 2 wk of treatment (246–258) in most studies (259) (Table 4). In the CARE study, EDV measured after 5 yr of treatment was related to reduction in serum cholesterol levels during that period (258).

An improvement of EDV was seen during both acute (260–263) and long-term treatment (4 wk) with L-arginine in hypercholesterolemic patients (264). Although a mixture of antioxidant vitamins or SOD produced no effects, vitamin C and E supplementation reportedly induced a positive effect on EDV (265–272) in most studies (259). A number of other interventions, including estrogen and calcium antagonists, have shown beneficial effects on EDV in hypercholesterolemic subjects (89,93,273–279). Exercise training for 4 wk, however, did not improve EDV (280).

### FUTURE ISSUES

Clearly, hypercholesterolemia impairs EDV, and lowering of cholesterol levels can reverse this condition. A publication bias may exist whereby negative studies are less likely to be published. However, several issues can be identified for future research in the field of cholesterol and EDV. Furthermore, the role of triglycerides and fatty acids deserves further investigation from the following starting points:

(i) To identify which mechanism that impairs EDV (which is associated with hypercholesterolemia and other lipids) is the major one, or whether several mechanisms act in concert.

(ii) To investigate whether supplementation with L-arginine, alone or in combination with other lipid-lowering regimens, also improves EDV during long-term treatment.

(iii) To further investigate the effect of the statins, as some statins induce vasodilation *in vitro* within minutes by a NO-dependent mechanism (189).

(iv) To identify the characteristics of the point of no return of atheroma-lesion formation, after which no major improvement in EDV can be obtained merely by lowering cholesterol levels in some animal models.

(v) To further characterize the production and metabolism of ADMA (281–283) and how these events are related to the impaired EDV seen in dyslipidemia.

(vi) To explore the future of gene therapy; for example, adenoviral gene transfer of NOS in cholesterol-fed animals improved EDV (284–286).

(vii) To consider the possibility of angiogenesis therapy in patients with coronary heart disease; the effects on EDV of

factors influencing angiogenesis should be explored. It was recently shown that basic fibroblast growth factor improved EDV in hypercholesterolemic rabbit aorta *in vitro* (287).

(viii) To investigate in more detail the action of different fatty acids on EDV in order to establish the optimal composition of lipids in food.

(ix) To establish the relevance of studying arteries in the upper limb not clinically affected by atherosclerosis as a means of revealing that impairments in EDV measured by the human forearm technique or by brachial artery ultrasound are related to atherosclerosis and an impaired EDV in the coronary circulation (288–290).

(x) Last, but not least, to investigate the use of impaired EDV as a predictor of cardiovascular events (291,292); it remains to be established that a reversal of endothelial dysfunction translates into an improved risk for cardiovascular events before EDV can be accepted as valid biomarker for atherosclerosis.

**ABSTRACT:** The seed fatty acid (FA) compositions of Abietoids (*Abies*, *Cedrus*, *Hesperopeuce*, *Keteleeria*, *Pseudolarix*, and *Tsuga*) are reviewed in the present study in conclusion to our survey of Pinaceae seed FA compositions. Many unpublished data are given. Abietoids and Pinoids (*Pinus*, *Larix*, *Picea*, and *Pseudotsuga*)—constituting the family Pinaceae—are united by the presence of several  $\Delta 5$ -olefinic acids, taxoleic (5,9-18:2), pinolenic (5,9,12-18:3), coniferonic (5,9,12,15-18:4), keteleeronic (5,11-20:2), and sciadonic (5,11,14-20:3) acids, and of 14-methyl hexadecanoic (anteiso-17:0) acid. These acids seldom occur in angiosperm seeds. The proportions of individual  $\Delta 5$ -olefinic acids, however, differ between Pinoids and Abietoids. In the first group, pinolenic acid is much greater than taxoleic acid, whereas in the second group, pinolenic acid is greater than or equal to taxoleic acid. Moreover, taxoleic acid in Abietoids is much greater than taxoleic acid in Pinoids, an apparent limit between the two subfamilies being about 4.5% of that acid relative to total FA. *Tsuga* spp. appear to be a major exception, as their seed FA compositions are much like those of species from the Pinoid group. In this respect, *Hesperopeuce mertensiana*, also known as *Tsuga mertensiana*, has little in common with Abietoids and fits the general FA pattern of Pinoids well. *Tsuga* spp. and *H. mertensiana*, from their seed FA compositions, should perhaps be separated from the Abietoid group and their taxonomic position revised. It is suggested that a “Tsugoid” subfamily be created, with seed FA in compliance with the Pinoid pattern and other botanical and immunological criteria of the Abietoid type. All Pinaceae genera, with the exception of *Pinus*, are quite homogeneous when considering their overall seed FA compositions, including  $\Delta 5$ -olefinic acids. In all cases but one (*Pinus*), variations from one species to another inside a given genus are of small amplitude. *Pinus* spp., on the other hand, have highly variable levels of  $\Delta 5$ -olefinic acids in their FA compositions, particularly when sections (e.g., *Cembroides* vs. *Pinus* sections) or subsections (e.g., *Flexiles* and *Cembrae* subsections from the section *Strobis*) are compared, although they show qualitatively the same FA patterns characteristic of

Pinoids. Multicomponent analysis of Abietoid seed FA allowed grouping of individual species into genera that coincide with the same genera otherwise characterized by more classical botanical criteria. Our studies exemplify how seed FA compositions, particularly owing to the presence of  $\Delta 5$ -olefinic acids, may be useful in sustaining and adding some precision to existing taxonomy of the major family of gymnosperms, Pinaceae.

Paper no. L8927 in *Lipids* 37, 17–26 (January 2002).

The family Pinaceae (Coniferophytina) contains a total of 12 genera: *Abies*, *Cathaya*, *Cedrus*, *Keteleeria*, *Larix*, *Nothotsuga*, *Picea*, *Pinus*, *Pseudolarix*, *Pseudotsuga*, *Tsuga*, and *Hesperopeuce* (1). Among these genera, *Pinus* is the largest and most heteromorphic genus, with *Abies* being ranked second and *Picea* third. Other genera contain considerably fewer species, some of them even being monospecific. The seed fatty acid (FA) compositions available for the most common pine species, totaling approximately one-half of extant species, were recently reviewed (2). A review on the genera *Picea*, *Larix*, and *Pseudotsuga* also appeared more recently (3). The usefulness of seed FA compositions in the taxonomy of conifers at the level of families as well as genera has been demonstrated (2–7).

The genera *Larix* and *Picea* are closely related to *Pinus*, although their relationships remain unclear. *Pinus*, *Larix*, and *Picea* are sometimes put together along with *Cathaya* and *Pseudotsuga* into a “Pinoid” group (equivalent to a subfamily), as opposed to an “Abietoid” group that embraces *Abies*, *Cedrus*, *Tsuga*, *Nothotsuga*, *Pseudolarix*, and *Keteleeria* (8). But other subfamily arrangements have been proposed, e.g., Pinoideae (*Pinus*), Laricoideae (*Larix*, *Pseudolarix*, *Cedrus*), and Abietoideae (*Abies*, *Cathaya*, *Keteleeria*, *Picea*, *Pseudotsuga*, *Tsuga*); Pinoideae (*Pinus*), Piceoideae (*Picea*), Laricoideae (*Larix*, *Cathaya*, *Pseudotsuga*), and Abietoideae (all other genera) (9); or more recently (10), Pinoideae, encompassing three tribes [Pineae (*Pinus*), Abietae (*Cathaya*, *Picea*, *Tsuga*, *Cedrus*, *Keteleeria*, and *Abies*), and Lariceae (*Larix*, *Pseudotsuga*)], and Pseudolariceae (*Pseudolarix*). Clearly, there is a lack of general agreement regarding the intergeneric relationships among Pinaceae. Here, we will review the Abietoid group as retained and immunologically de-

fined by Price *et al.* (8), thus including *Abies*, *Tsuga*, *Hesperopeuce*, *Cedrus*, *Keteleeria*, and *Pseudolarix*. *Nothotsuga* was not available from our usual tree-seed sources.

In this study, a compilation of data available for *Abies*, *Tsuga*, *Hesperopeuce*, *Cedrus*, *Keteleeria*, and *Pseudolarix* seed FA compositions is made, including numerous unpublished seed FA compositions, in particular, *Keteleeria*, for which no data were previously available. Species examined here represent approximately one-fourth of the species of the Abietoid group. Except for the seed FA compositions from *Abies* and *Cedrus* spp. that present some similarities, other genera are quite distinct one from another, with *Tsuga* in particular being quite close to Pinoids. Principal component analysis and discriminant analysis permit distinction among all Abietoid genera. This allows conclusions to be drawn on general features of the quantitative distribution of seed FA in *Abies*, *Tsuga*, *Hesperopeuce*, *Cedrus*, *Keteleeria*, and *Pseudolarix*, with emphasis on  $\Delta 5$ -unsaturated polymethylene-interrupted FA ( $\Delta 5$ -UPIFA, or  $\Delta 5$ -olefinic acids).

$\Delta 5$ -UPIFA with chain lengths  $C_{18}$  and  $C_{20}$  are characteristic of Pinaceae seed lipids but rarely occur in angiosperms. In this series of particular FA, the  $\Delta 5$ -double bond is separated from the next ethylenic bond by either two [5,9-18:2 (taxoleic), 5,9,12-18:3 (pinolenic), and 5,9,12,15-18:4 (coniferonic) acids] or four [5,11-20:2, 5,11,14-20:3 (sciadonic), and 5,11,14,17-20:4 (juniperonic) acids] methylene groups instead of only one, as in linoleic or  $\alpha$ -linolenic acids (of the methylene-interrupted type). All ethylenic bonds are in the *cis* configuration. A seventh  $\Delta 5$ -UPIFA, ephedrenic (5,11-18:2) acid, occurs in significant amounts only in *Ginkgo biloba* and *Ephedra* spp. seed lipids (11). Thus,  $\Delta 5$ -UPIFA are common constituents of seed oils from all Coniferophyte families and also some Cycadophyte families (12). In addition to seeds, these FA also occur in the leaf and wood lipids of Coniferophytes (13,14). A FA metabolically related to pinolenic acid, dihomopinolenic (7,11,14-20:3) acid, also is generally present in Pinaceae (15).

## MATERIAL AND METHODS

*Seeds, oil extraction, and fatty acid methyl ester (FAME) preparation.* The seeds analyzed here were purchased from Lawyer Nursery, Inc. (Plains, MT), F.W. Schuhmacher Co., Inc. (Sandwich, MA), Sandeman Seeds (Pulborough, Great Britain), Vilmorin S.A. (La Méniltré, France), Versepuy (Le Puy-en-Velay, France), and the National Office of Forests (ONF, Champagnole, France). Seeds were kept at 4°C until use. Lipid extraction, always performed starting with 10-g samples taken from 15  $\pm$  5 g of powdered seeds, and FAME preparation were performed as described in detail elsewhere for other gymnosperm seeds (4,6). All FAME preparations were made in duplicate and each solution was analyzed once by gas-liquid chromatography (GLC). Generally, FAME were prepared within 24 h after lipid extraction and immediately analyzed.

*Analytical GLC.* All FAME preparations were analyzed in a Carlo Erba 4130 chromatograph (Carlo Erba, Milano, Italy)

equipped with a DB-Wax column (30 m  $\times$  0.32 mm i.d., 0.5  $\mu$ m film; J&W Scientific, Folsom, CA). The oven temperature was 190°C and the inlet pressure of the carrier gas (helium) was 140 kPa. Occasionally, to confirm some identifications, a CP-Sil 88 column (50 m  $\times$  0.25 mm i.d., 0.2  $\mu$ m film; Chrompack, Middelburg, The Netherlands) was operated with temperature programming in a Carlo Erba HRGC chromatograph from 150 to 185°C at 4°C/min with H<sub>2</sub> at 100 kPa. The injector (split mode) and flame-ionization detector were maintained at 250°C for both columns. SP 4290 integrators (Spectra Physics, San Jose, CA) calculated quantitative data. In some instances, particularly to detect potential late-eluting components but also to confirm identifications, a Silar 5 CP column (50 m  $\times$  0.25 mm i.d., 0.2  $\mu$ m film; Chrompack), fitted in a Hewlett-Packard HP 5890 gas chromatograph (Avondale, PA), was used in the temperature program mode (isothermal for 1 min at 165°C; from 165 to 205°C at a rate of 1°C/min; isothermal at 205°C for 60 min). Nitrogen was the carrier gas, and the injector and detector temperatures were maintained at 230 and 260°C, respectively.

*Identification of FAME peaks.* The seed lipids from selected conifer species (15,16) or Ranunculaceae species (17) were used as sources of  $\Delta 5$ -olefinic acid methyl esters with known structures to identify FA from seed lipids by GLC, either by coinjection, comparison of the equivalent chain lengths (DB-Wax column), or retention times (CP-Sil 88 and Silar 5 CP).

*Data analysis.* Principal component analysis was performed with the program STATBOX (Grimmer, Paris, France). The classification of Abietoid spp. was performed with the program XLSTAT (copyright T. Fahmy, Paris, France). To compare the variability of interspecific seed FA compositions of Abietoid spp. and *Picea* and *Larix* spp., ascending hierarchical classifications were computed using the Ward method. This method consists of minimizing the loss of intraclass inertia at each step. The results are presented as a dendrogram (discussed below) in which the aggregation level can be interpreted as a dissimilarity index between the objects.

## RESULTS AND DISCUSSION

*Abies seed FA compositions.* Literature data on the seed FA compositions of species studied here, except for those from our Institutes (4,18), are particularly scarce. We are aware of only two papers partially describing the  $C_{18}$  unsaturated acids in fir (*A. alba*) seeds, indicating the presence of 5,9-18:2 and 5,9,12-18:3 acids characterized both by their GLC behavior (19) and their <sup>13</sup>C nuclear magnetic resonance spectra (20), but no mention of  $C_{20}$  acids was made. Although Takagi and Itabashi (21) did not analyze the seed FA of any of the genera reviewed here in their major study on gymnosperm seed lipids, Jamieson and Reid (14) reported on the leaf FA of several *Abies* and *Tsuga* species. Qualitatively, these acids were identical to those found in the leaves of other Pinaceae, i.e., *Pinus*, *Picea*, *Larix*, *Cedrus*, and *Pseudotsuga* (14).

*Abies* is the most important genus in the Abietoid group, with approximately 80 species and infraspecific taxa (Table 1). The

classification of the genus *Abies* was reviewed in 1989 by Farjon and Rushforth (22), who proposed a new classification scheme, mostly based on morphological characters. *Abies* was divided into 10 sections, some of which were further divided into subsections. Debazac (23) adopted a geographical classification. However, the differences in seed FA compositions between species were rather small, and we do not adopt either classification. Here we summarize data for 20 *Abies* spp. (Table 2). Some supplementary species were also checked, but owing to some overlap of resin components (terpenes?) in the C<sub>16</sub>–C<sub>17</sub> region, they are not reported here. However, they did not differ

appreciably in FA from other species reported here. In *Abies* spp. (Table 2), the level of total saturated acids is rather low, always less than 8–9% of total FA. These acids occur in the usual decreasing order 16:0 > 18:0 > 20:0 > 22:0, also encountered in *Tsuga*, *Cedrus*, and *Keteleeria*. In contrast to the genera reviewed earlier (*Pinus*, *Picea*, *Larix*, *Pseudotsuga*), anteiso-17:0 is higher than 0.6% in *Abies* spp., whereas the corresponding values in other genera are less than 0.4%, with the exception of *Pseudotsuga menziesii* (1.2%) (3).

The most prominent unsaturated FA in *Abies* spp. is linoleic acid, in the range of 37–46%, and values are usually

<sup>a</sup>List established according to Farjon's *World Checklist and Bibliography of Conifers* (25).

<sup>b</sup>List mostly based on tree-seed sellers' catalogs. The website <http://www.geocities.com/RainForest/Canopy> was also consulted. Abbreviations: Jap., Japanese; Mex., Mexican.

lower than those determined in *Pinus*, *Larix*, and *Picea*. Oleic acid is ranked second, varying between 20 and 35%. Here too, similar values are frequently encountered in the genus *Pinus*. The most discriminating feature is the amount of taxoleic acid, almost always higher than 4.5% (*A. procera* is an exception, with only 3.5%) and sometimes as much as 8%. A value of 4.5% is the highest encountered in *Pinus*, *Picea*, *Larix*, or *Pseudotsuga* (2,3), whereas a value of 8% is close to that presented by *Taxus baccata* seeds (24). The percentage of pinolenic acid lies within the limits of 9–17%, which on average is lower than in *Pinus*, *Picea*, *Larix*, and *Pseudotsuga* spp. This may be interpreted in terms of  $\Delta 5$ -desaturase activities, which are higher for oleic acid than for linoleic acid in *Abies* as compared to the preceding genera. With regard to the C<sub>20</sub>  $\Delta 5$ -UPIFA in *Abies* spp., 5,11-20:2 and sciadonic acid levels are not quantitatively very distinct from those occurring in *Pinus* spp. For the latter acid, the range is most often 1.7–2.7%, with only *A. procera* showing a lower value. The sums of  $\Delta 5$ -UPIFA are rather homogenous within the genus, between approximately 18 and 24% (except for *A. procera*, 16%).

*Tsuga seed FA compositions.* In addition to the species listed in Table 3, some authors [e.g., Farjon (25)] include *T. mertensiana* and its infraspecific taxa in the genus *Tsuga*, whereas other authors (1) consider it a distinct genus, *Hesperopeuce*. We have adopted the point of view that will be discussed next. Among the Abietoid genera studied here, the genus *Tsuga* is the closest to genera of the Pinoid group in its seed FA composition, with little in common with *Abies*, *Cedrus*, *Keteleeria*, or *Pseudolarix*. In a previous multicomponent analysis of conifer seed FA compositions (4), the two *Tsuga* species available at that time (as well as *P. menziesei*) were slightly set over in a bulky and stretched *Pinus* group, but were otherwise distinct from *Picea* and *Larix*. Since then, *Picea* and *Larix* spp. have been shown to constitute two clearly disjunct groups (3) with regard to their seed FA composition. *Tsuga* spp. have higher (ca. 50%) and lower (ca. 14%) average levels of linoleic and oleic acids, respectively, than most *Pinus*, *Larix*, and *Picea* species, but they are hardly distinguishable from *Pinus* spp. on the basis of their C<sub>18</sub>  $\Delta 5$ -UPIFA profiles. Within the genus, variations between species are of small amplitude, as is the case for *Picea* and *Larix* species.

<sup>a</sup>The numbers refer to species listed in Table 1.

<sup>b</sup>Some earlier chromatograms from our laboratory have been revised to take into account aiso-17:0, 11-18:1, 7,11,14-20:3 acids, and component X. Initial nomenclature (essentially that employed by tree-seed sellers) has been modified to fit recent recommendations by Farjon (25). *Abies bornmuelleriana* is retained here, although it is considered a synonym of *A. nordmanniana* ssp. *equi-trojani* by this author.

<sup>c</sup>Two isomers, 7- and 9-16:1 acids.

<sup>d</sup>14-Methylhexadecanoic acid, or anteiso-17:0.

<sup>e</sup>Unidentified component with an equivalent chain length of 19.10 on the DB-Wax column.

<sup>f</sup>Sum of Δ5-olefinic acids, including the 7,11,14-20:3 acid.

<sup>g</sup>Minor and/or unidentified fatty acids.

<sup>h</sup>Not detected or not reported.

<sup>i</sup>Trace amounts.

**Hesperopeuce seed FA composition.** The taxonomic ranking of *H. mertensiana* is rather controversial because it is sometimes considered a *Tsuga* species or even a hybrid (26). Some infrageneric taxa can be distinguished (not reported in

Table 4). A distinctive feature of *H. mertensiana* seed FA (Table 4) is the absence of α-linolenic acid, which otherwise represents 0.3–0.8% in *Tsuga* spp. Also, the proportions of linoleic and oleic acids are distinct: linoleic acid, 43.9 vs.

<sup>a</sup>List established according to Farjon's *World Checklist and Bibliography of Conifers* (25).

<sup>b</sup>List mostly based on tree-seed sellers' catalogs. The website <http://www.geocities.com/RainForest/Canopy> was also consulted.

49.7–50.8%, and oleic acid, 23.3 vs. 13.0–14.8%, in *Hesperopeuce* and *Tsuga* spp., respectively (27).

**Cedrus seed FA compositions.** The genus *Cedrus* encompasses four species (all of which are presented in this study) that are closely allied (28) and a few varieties (Table 3). In contrast to *Abies* spp., the principal unsaturated FA in *Cedrus* spp. seeds is oleic acid (41–45%), with linoleic acid representing only 23–30% (Table 4). As in *Abies*, anteiso-17:0 acid is relatively high, between 0.4 and 1%. Despite the considerable differences in the amounts of their precursors, oleic and linoleic acids, taxoleic and pinolenic acids have a distribution profile similar to that in *Abies* spp. (4.6–7.7 and 9.6–10.9%, respectively). On the other hand, the C<sub>20</sub> Δ5-UIFA are less abundant in *Cedrus* than in *Abies* seeds. In this regard, it is worth noting the particular abundance of dihomopinolenic (7,11,14–20:3) acid, the elongation metabolite of pinolenic acid; there is about twice as much in *Cedrus* than in *Abies* spp. Incidentally, the same Δ5-UIFA were present in the pollen grain lipids collected from *C. atlantica* (Wolff, R.L., unpublished observations).

**Keteleeria seed FA composition.** The genus *Keteleeria* was revised recently (29) and was shown to contain three species only (Table 3). An interesting point is the pink color of the washing upper phase during the Folch *et al.* (30) purification of lipids. Among all other Pinaceae, this was observed only for *Abies* seeds. However, no further studies of the pigment(s) were made. The prominence of oleic acid over linoleic acid is exacerbated in *Keteleeria* (Table 4), where the former acid reaches 55% but the latter acid represents only 22% of total FA. This apparently results in a higher level of taxoleic acid as compared to pinolenic acid, although both acids, in particular the latter one, are comparatively low. Also, oleic acid seems to be particularly intensively elongated and further Δ5-desaturated if one considers the exceptionally high levels of 11-20:1

(3.1%) and 5,11-20:2 (1.8%) that are reached in no other Pinaceae species. As the latter acid has no trivial name, we suggest naming it “keteleeronic” acid. The overall content of Δ5-UIFA is the lowest (*ca.* 10%) inside the Abietoid group.

In brief, considering their seed FA compositions, *Abies*, *Cedrus*, and *Keteleeria*, are justifiably grouped in the Abietoid subfamily, whereas *Tsuga* would fit the overall seed FA pattern of the Pinoid group.

**Pseudolarix seed FA composition.** *Pseudolarix* is a monospecific genus with *P. amabilis* as a single species. The main feature of its seed FA is the presence of high contents of α-linolenic and coniferonic acids, 5.2 and 1.8%, respectively (Table 4). No Pinaceae seeds analyzed thus far showed such high quantities, although some Cupressaceae species might present higher levels of coniferonic acid (4). Also, taxoleic and pinolenic acids are present in approximately equal amounts, about 7.5%, which is encountered in Pinaceae only in *C. libani* (*ca.* 10% for both C<sub>18</sub> Δ5-UIFA).

**Multicomponent analysis.** A principal component analysis was processed for species listed in Tables 2 and 4. Minor components, such as 17:0 acid, were not included in that study. In addition, the mean compositions of seed FA from *Larix* and *Picea* spp. established in a previous study (3) were included in the statistical analysis. Figure 1 shows the first two component axes, which explain 32 and 19% of the total inertia. On this plot, the different genera are quite well separated. *Abies* spp. are scattered around the mean (gravity center) at the center of the plot.

On axis 1 (horizontal), 9,12-18:2 and 5,9,12-18:3 acids can be identified as representative of *Tsuga*, *Hesperopeuce*, *Picea*, and *Larix* spp. Axis 2 (vertical) allows differentiation between these genera: 11,14-20:2 and 5,11,14-20:3 acids can particularly be associated with *Tsuga* spp. In contrast, 11-18:1 is representative of *Picea* and *Larix* spp. *Pseudolarix* and

**TABLE 4**

<sup>f</sup>Trace amounts.

<sup>g</sup>Sum of Δ5-olefinic acids, including the 7,11,14-20:3 acid.

<sup>h</sup>Minor and/or unidentified fatty acids.

*Keteleeria* spp. do not seem very different one from another. Three FA are more particularly representative of these genera: 5,11-20:2, 11-20:2, and 5,11,14-20:3 acids. *Pseudolarix* is also characterized by 16:1 and 9,12,15-18:3 acids and *Keteleeria* by 9-18:1 acid (in fact, this does not appear clearly on the first two axes). As for *Pseudolarix* and *Keteleeria* spp., *Cedrus* spp. is located on the positive direction of axis 1. Differences appear on axis 2: *Cedrus* spp. is associated with eight FA, namely 16:1, 16:0, anteiso-17:0, 18:0, 11-18:1, 9-18:1, 5,9-18:2, and 20:0 acids, which are essentially saturated and monoenoic FA.

The dendrogram in Figure 2 confirms the principal component analysis results. In particular, the importance of interspecific variability is clearly demonstrated. It is worthwhile to note the closeness between some genera. On the one hand, *Larix*, *Picea*, and *Hesperopeuce* lie in close proximity, whereas *Tsuga* spp. are only slightly dissimilar. On the other hand, *Keteleeria* spp. and *Pseudolarix* lie close to one another. The latter two genera are thus grouped together with

*Cedrus*. The intraspecific dissimilarities among *Abies* spp. are of small amplitude, as observed above.

As a first observation, it can be inferred from our data that all genera of the Pinaceae family are united by the same qualitative seed FA chromatographic profiles, including Δ5-UPIFA. However, on a quantitative basis, many differences allow distinctions between the different genera.

*Pinus* is the Pinaceae genus that presents the greatest number of species, and is also generally recognized as the most heteromorphic genus when considering botanical criteria. This also holds for *Pinus* spp. seed FA compositions, particularly when considering Δ5-UPIFA. Their sum varies from less than 0.6% (*P. monophylla*, subsection *Cembroides*) to 30% (*P. sylvestris*, subsection *Sylvestres*). Taxoleic acid always represents less than 4.5% of total FA in *Pinus* spp. seeds. In *Abies* spp., as well as in *Cedrus* spp. and *P. amabilis*, the corresponding value is practically systematically higher than 4.5%. *Tsuga* spp. and *Keteleeria* spp., on the other hand, present values similar to those found in *Pinus* spp. The highest values of tax-

**FIG. 1.** First two components of the principal component analysis based on data for Abietoid seed fatty acids summarized in Tables 2 and 4. Also plotted are the gravity centers of *Picea* and *Larix* spp. from a previous study (Ref. 3).

oleic acid presented by *Picea* and *Larix* spp. seeds also are lower than 4.6%. Thus, with regard to the percentage of taxoleic acid, *Pinus*, *Larix*, *Picea* spp., and *Pseudotsuga menziesii* (Pinoids) are united by levels less than 4.6%, a situation shared by *Tsuga* spp. and *Keteleeria* spp. (Abietoids).

If one considers pinolenic acid, *Pinus* spp. are heterogeneous and present seed FA containing a maximum of 25.3% (*P. strobus*), with the bulk of species between 14 and 23%. This is most often less than values determined for *Larix* and *Picea* spp. but similar to those found in *Tsuga* spp.

As emphasized elsewhere (3), *Picea* and *Larix* spp. display seed FA compositions that vary little from one species to another in a given genus. This apparently also holds for *Tsuga* and *Keteleeria* spp. This adds to the general recognition that all of these genera are natural groups. A particular point is that the ratio of pinolenic/taxoleic acids in Pinoids (and in *Tsuga* spp.) is always higher than that in Abietoids (results not shown). This tendency culminates in *C. libani* and in *P. amabilis*, where the ratio approaches 1.

Among botanical criteria distinguishing Pinoids from Abietoids is the presence of resin vesicles in the coat of seeds from species of the latter group but not the former one. Resin

components are extracted by the solvents used in our studies and appear as a dense region of peaks preceding palmitic acid methyl ester during GLC. This occurs when analyzing seed FA methyl esters prepared from *Abies*, *Cedrus*, and *Keteleeria* spp. seeds but not from *Tsuga* spp. seeds. Indeed, resin vesicles in the seeds from the latter genus are reported to be very small and to contain little resin.

Price *et al.* (8), Prager *et al.* (31), and Frankis (9) have constructed possible phylogenetic sequences based either on immunological characteristics and distances (8,31) or on selected botanical features (9) that are rather similar in that they both distinguish two groups more or less corresponding to Pinoids and Abietoids. However, they differ in some details. Our studies (2,3, present study) agree with such a division, with some peculiarities of *Tsuga* spp. and *H. mertensiana* seed FA that resemble Pinoids and share little in common with other Abietoids. There are two possibilities: (i) the similarity of *Tsuga* spp. and *H. mertensiana* with Pinoids is due to evolutionary convergence or (ii) *H. mertensiana* is derived through the intergeneric hybridization of *Tsuga* × *Picea* (26). Regarding the second hypothesis, *Tsuga* would in some manner be a relative to *Picea*, which would indicate a relationship between *Tsuga*

**FIG. 2.** Intra- and intergeneric dissimilarities computed from Abietoid seed fatty acid compositions summarized in Tables 3 and 4. Also plotted are the gravity centers of *Picea* and *Larix* spp. from a previous study (Ref. 3).

and *Picea* with Pinoids. To take this possibility into account, we suggest a new group, Tsugoids, encompassing *Tsuga* spp. and *H. mertensiana*, which would be between Pinoids and Abietoids.

**ABSTRACT:** Fourteen pairs of obese female monozygotic twins were recruited for a study of genetic influences on serum and adipose fatty acid (FA) composition. Following 1 wk of inpatient stabilization, fasting serum and adipose tissue obtained by surgical excision were analyzed by thin-layer and gas chromatography. Intrapair resemblances (IPR) for individual FA were assessed by Spearman rank correlation and by analysis of variance and were found in serum cholesteryl esters (CE), triglycerides (TG), and adipose TG. With two exceptions (CE linoleate and adipose eicosapentaenoate), these IPR were limited to the nonessential FA. Palmitate had significant IPR in four lipid fractions; in serum CE and adipose TG palmitate was strongly correlated with multiple measures of adiposity. In contrast to other lipid fractions, serum phosphatidylcholine (PC) FA had 12 IPR, of which 6 were essential FA including arachidonate ( $r = 0.76$ ,  $P < 0.0005$ ), eicosapentaenoate ( $r = 0.78$ ,  $P < 0.0005$ ), and docosahexaenoate ( $r = 0.86$ ,  $P < 0.0001$ ). The PC IPR could not be explained by analysis of preadmission 7-d food records. After dividing the pairs into two groups differing and nondiffering according to fat intake of individuals in the pair, there was no evidence of a gene–environment interaction between fat intake and FA composition. The IPR for nonessential FA indicate that there is active genetic control of either food choices or postabsorptive metabolic processing. The high level of IPR in the PC fraction in contrast to the other lipid fractions suggests strong genetic influence over selection of specific FA for this membrane fraction independent of diet.

Paper no. L8727 in *Lipids* 37, 27–32 (January 2002).

Beyond their function as energy substrates in the nonesterified form and as energy reserves in triglycerides (TG), individual fatty acid (FA) species possess a range of metabolically important properties. Chain length and degree of unsaturation affect the physical properties of membrane phospholipids and TG, and some members of the essential n-6 and n-3 families provide substrates for eicosanoids. In addition, enzymes involved in FA metabolism have demonstrated selectivity for specific FA. An example of this is hormone-sensitive lipase in rat adipocytes. This enzyme has been shown *in vitro* (1) and *in vivo* (2) to be

selective for release of specific FA based on their chain length, number of double bonds, and position of double bonds. This selectivity has been demonstrated in obese humans undergoing weight loss as indicated by a disproportionate decrease in  $\alpha$ -linolenate (18:3n-3) from adipose reserves (3–5). This selectivity allows specific tissue lipid fractions to maintain FA compositions that differ from those of the diet and from one another. In addition to selective release, these tissue differences could also result from selective uptake of individual fatty acids into adipose tissue (6). This effect could be achieved at any one of multiple steps in the digestion, absorption, hepatic processing, and endothelial release where interindividual variation in the processing of specific fatty acids could occur.

A number of important physiological functions are affected by the FA composition of tissue lipids, particularly the phospholipids in membranes. Odin *et al.* (7) reported variations in the rate of hepatocyte lipogenesis by varying the composition of the cell membranes in tissue culture, and Clarke and Jump (8) subsequently demonstrated that dietary fat composition directly affects FA synthase gene expression. Pelikánová *et al.* (9) and Borkman *et al.* (10) noted that variations in insulin sensitivity correlate with serum and muscle phospholipid arachidonate (20:4n-6). In addition, a relationship was found between the FA composition of child's muscle and maternal serum insulin concentration (11). These influences of phospholipid FA composition on metabolic pathways of fuel trafficking raise the potential for FA such as arachidonic acid to participate actively in the regulation of energy balance.

Genetically obese animals have been reported to have distortions in hepatic phospholipid arachidonate distribution relative to the lean genotype. The Zucker rat has reduced phospholipid arachidonate but increased cholesteryl ester compared to the lean genotype (12–14), and in the BSB mouse arachidonate is maldistributed into cholesteryl esters (15). While it is not clear if these alterations in 20:4n-6 distribution are a direct result of single or multiple genes causing their obesity, enhancing endogenous arachidonic acid production in the obese Zucker rat reduces food intake and weight gain (14,16). It remains to be determined specifically how increasing arachidonate production affects appetite in the Zucker rat or if altered arachidonate metabolism is either an important pathogenic factor or mediator in human obesity.

Studies of phenotypic variation within and between monozygotic human twins provide a powerful tool to assess genetically mediated traits (17–19). Previous human twin studies involving FA analysis have revealed intra-pair similarities in twins with schizophrenia (20) and in the branched-chain FA content of ear cerumen (21), but there have been no studies of twins selected for the phenotypic trait of obesity. To determine if genetic variation is associated with alterations in FA distribution in obese humans, we have undertaken a study of adult monozygotic twins, examining serum lipid fractions and adipose FA for variations due to diet, obesity, and genetic factors.

## MATERIALS AND METHODS

**Subjects.** Fourteen pairs of obese monozygotic premenopausal females aged  $39 \pm 1.7$  yr (mean  $\pm$  standard error, range 23–50), mean body mass index  $34.22 \pm 1.46$  kg/m<sup>2</sup> (range 24.84–59.47) were recruited for the study through the media and gave their written informed consent to participate in this study. The study was approved by the Charles University Medical Ethics Committee.

The monozygosity of the twins was established on the basis of their physical appearance, the loci of human leukocyte antigen system, and DNA of the apo B gene. The initial physician evaluation included medical history and physical examination. None of the subjects had a history of recent illness or severe cardiovascular or metabolic disease. Two pairs of twins were light smokers. None of the subjects had recently been on a diet or involved in a weight reduction regimen, and their body weight had been stable during the 6 mo prior to recruitment. Each pair had been reared together; however, with the exception of the youngest pair, they had been living apart for at least 10 yr at the time of recruitment. The initial 12 pairs were enrolled over a 15-wk period, and 2 pairs were enrolled in the following year. As part of a long-term study, four sets of twins at a time were admitted for a 1-wk inpatient baseline evaluation period in the Obesity Unit in the Fourth Department of Medicine, Charles University in Prague.

**Body composition and regional tissue distribution.** Body density was determined by the hydrostatic weighing technique, and percentage of body fat was estimated from body density by the method described by Pařízková (22) using the equation of Brozek (23). Pulmonary residual volume was determined using the helium dilution method (24). Fat mass was obtained by multiplying percentage of body fat by body weight. Anthropometric estimation of body fat was performed by measurement of 10 skinfolds according to Pařízková (22) and of 4 skinfolds according to Durnin (25). Waist and hip circumferences and sagittal abdominal diameter at the level L4/5 were measured following the standardized procedure recommended at the Airlie Conference (26).

**General test period.** After recruitment for the study but prior to the inpatient protocol, the subjects were instructed by the dietitian to record their food consumption for 7 d. These food records were evaluated by the Czech PC program

Výziva (KTS, Prague, Czech Republic), which includes more than 2000 items and evaluates 14 nutrients, minerals, and vitamins. During the 1-wk inpatient evaluation, the patients ate a diet prepared in the hospital kitchen providing daily energy intake calculated to achieve weight stability for each individual. Fat amount and compositions of the diet did not change in comparison with their previous diet. As a result, each subject's weight remained stable during this inpatient phase, and at the end of this week fasting blood was drawn for lipid fraction FA analysis. The same day AT was obtained by making a small surgical incision after lidocaine anesthesia on the abdomen about 20 mm to the left of the umbilicus, removing 300 mg of fat tissue.

**FA composition measurement.** Methanol, chloroform, dichloromethane, *n*-hexane, and *n*-heptane (analytical grade) were purchased from Lachema (Neratovice, Czech Republic), distilled before use, and checked by gas chromatography (GC). Acetic acid, sodium sulfate, sodium carbonate, and sulfuric acid were purchased from Lachema (Brno, Czech Republic). Standards of fatty acid methyl esters (FAME) were purchased from Sigma (St. Louis, MO). As a source for distilled water, Valvert drinking water (Etalle, Belgium) was used and checked as a blank sample by GC before use.

**Sample preparation.** Total lipid was extracted from 1 mL of serum and approximately 5 mg of AT by the method of Folch *et al.* (27) using dichloromethane instead of chloroform (28). Individual lipid classes—CE, TG, and phosphatidylcholine (PC)—were separated by thin-layer chromatography on silica gel with the mobile phase heptane/diethyl ether/acetic acid (80:20:3, by vol) being used for the separation of CE and TG and chloroform/methanol/water (60:30:5, by vol) for the separation of PC.

Separated CE (without isolation from the layer material) were saponified 20 h at 30°C with 2 M potassium hydroxide/methanol in darkness under nitrogen atmosphere. After cooling, samples were acidified with 2 M sulfuric acid, and lipid components (FA and sterols) were extracted twice with 2 mL of hexane and stepwise dried using a short column (20  $\times$  8 mm) of freshly activated sodium sulfate (45 min at 120°C). Combined hexane fractions were evaporated under nitrogen at 50°C. FA were separated by thin-layer chromatography on silica gel with the mobile phase heptane/diethyl ether/acetic acid (80:20:3, by vol).

**Preparation of FAME.** Isolated TG and PC were trans-methylated without previous separation from the layer material with 1 M sodium methoxide in methanol (60 min at laboratory temperature in darkness under nitrogen). Reaction mixture was neutralized by 0.5 N acetic acid. Methyl esters were extracted twice into hexane, dried by anhydrous sodium sulfate, and evaporated under nitrogen at 40°C. Samples were stored at –20°C before GC analysis. Separated FA from CE were esterified with methanol/5% sulfuric acid without previous isolation from the layer material (60 min at laboratory temperature in darkness under nitrogen). Reaction mixture was neutralized by 10% solution of sodium carbonate. Methyl esters were extracted twice into hexane, dried by anhydrous

sodium sulfate, and evaporated under nitrogen at 40°C. Samples were stored at -20°C before GC analysis.

**GC of FAME.** GC was performed with a Model 9000 gas chromatograph (Chrompack, Middelburg, The Netherlands) equipped with a capillary split/splitless injector and flame-ionization detector. The chromatograph was interfaced with an IBMPS/2 Model 30 computer and Epson LQ 550 printer (Seico Epson Corp., Japan). Chrompack integration software was used for data acquisition and handling.

Determinations of FAME were performed on a fused-silica capillary column (25 m × 0.25 mm i.d.) coated with chemically bonded CP-WAX 52 CB stationary phase (Chrompack). The

oven temperature was programmed from 150 to 230°C at 2°C/min and then kept isothermal for 10 min. The injector and detector temperatures were 250°C. The carrier gas (hydrogen) was maintained at a head pressure of 80 kPa, with a splitting ratio of 1:20.

**Statistical methods.** The data were analyzed by Spearman rank correlation. For similarity within twin pairs analysis of variance (ANOVA) was used. The intraclass correlation coefficient was computed from the between-pairs and the within-pairs least squares. Twin pairs concordant and discordant for dietary fat content were compared for intrapair differences in FA composition in individual lipid classes using ANOVA. The analysis was performed with the Statgraphics package (Manugistic Inc., Rockville, MD) on a PC microcomputer.

## RESULTS

Table 1 presents the characteristics of the subjects. Preadmission-reported intakes of selected nutrients are shown in Table 2. Proteins represent 13.5%, fats 36.5% (linoleic acid 3.29%), and carbohydrates 50% of daily energy intake. Significant intrapair resemblances (IPR) expressed as Spearman correlations were found in energy content, carbohydrates, and linoleic acid (Table 2).

The composition of FA in serum PC, CE, and TG, and in AT TG are presented in Table 3. Because linoleate is the primary substrate for the other n-6 essential FA, its correlations between diet and these lipid fractions were calculated. No correlations for the linoleic acid content in food (expressed in g/d) with percentage of linoleic acid in serum lipids and AT TG were found. To assess the contribution of varying amounts of dietary fat to intrapair differences, the FA composition in individual lipid classes examined was compared in the twins concordant and discordant in fat intake according to the baseline food records. The groups did not differ with the exception of two FA in AT TG. These were oleate (higher per-

centage in discordant than in concordant group,  $P < 0.05$ ) and docosahexaenoate (higher level in concordant group than in discordant group,  $P < 0.05$ ).

Table 4 shows IPR expressed as intra-class correlation coefficients for individual FA within the lipid fractions. In serum PC, 12 of 14 FA examined were significantly similar within pairs when compared to between pairs. In serum CE and TG, and also in AT TG, significant IPR in numerous saturated and monounsaturated FA were found. However, in the serum CE and TG fractions, only two significant IPR were found for polyunsaturates (CE, 18:2n-6, 18:3n-3,  $P < 0.05$ ).

Because of its consistent intra-pair correlations across lipid fractions, Spearman correlation coefficients were assessed for palmitoleic acid in serum CE and in AT TG vs. body weight, fat content, and some anthropometric measures of body fat content and distribution (Table 5). There were no significant correlations for palmitoleic acid in serum PC or TG against these variables, nor for palmitic acid in serum and adipose TG. Significant positive correlations also were found between myristic acid (14:0) in serum CE and adipose TG and some body composition measures (data not shown).

## DISCUSSION

The primary observation of this study was the high degree of IPR for FA in the serum PC fractions of monozygotic twins. These included nonessential FA, the essential precursor 18:3n-3 (but not 18:2n-6), and multiple anabolic products of both the n-3 and n-6 families of essential FA.

Despite the highly significant IPR in the serum PC fraction, these observations alone do not prove unequivocally that there is genetically mediated interindividual variation in membrane phospholipids in humans independent of diet. To do so would require a precisely controlled diet composition study lasting for 2 yr or longer—the duration necessary to achieve AT equilibration with dietary fat composition (29).

These cautions notwithstanding, careful evaluation of our data supports a role for genetic influence over PC FA composition. Although our analysis of the dietary intake antecedent to study enrollment lacks detailed FA intake information, and

recall methods have been shown to have limitations, our analysis of dietary variables revealed significant IPR for 18:2n-6 intake (Table 2). However, no significant correlations were found between individually reported 18:2n-6 intakes and the 18:2n-6 contents in serum and adipose FA (Table 4). Furthermore, no significant differences in FA composition of serum and AT lipids were found between pairs of twins discordant in and concordant in dietary fat intake. In this context, the fact that a very high frequency of statistically significant IPR for FA was observed in the PC fraction (Table 5), but not including 18:2n-6, argues in favor of the FA composition of this particular fraction being under genetic control. In AT TG, only oleate and docosahexaenoate were significantly different in the comparison of twin pairs concordant in and discordant in dietary fat intake, probably reflecting different dietary fat intakes of these specific FA.

Another strong point in favor of the metabolic regulation of PC FA composition being under genetic control is the fact that strong IPR were observed for PC 20:3n-6 and 22:5n-3. Both of these FA are metabolic intermediates in the pathways between dietary essential substrates (18:2n-6 and 18:3n-3) and their predominant respective pathway products (20:4n-6 and 22:6n-3; see Fig. 1). Although dietary intake of both the precursors and products can affect their proportions in serum and tissue (30,31), these intermediates are found in very low levels in common human foods. Thus, the observed IPR are attributable to metabolic similarities in FA anabolic activity and selective partitioning within twin pairs rather than to similarity in their dietary habits.

An unanticipated observation in this study was the surprisingly consistent high degree of correlation between the proportions of 16:1n-7 in serum CE and adipose TG on the one hand and multiple variables of body fatness on the other (Table 6). These strong and consistent correlations between palmitoleic acid in serum CE and adipose TG vs. body weight and anthropometric measures of body fat and AT distribution are striking, particularly for serum CE 16:1n-7 and waist circumference, which was previously validated as a measure of body fat distribution (32–34). This observation, coupled with the high degree of intra-pair resemblance in 16:1n-7 in multiple

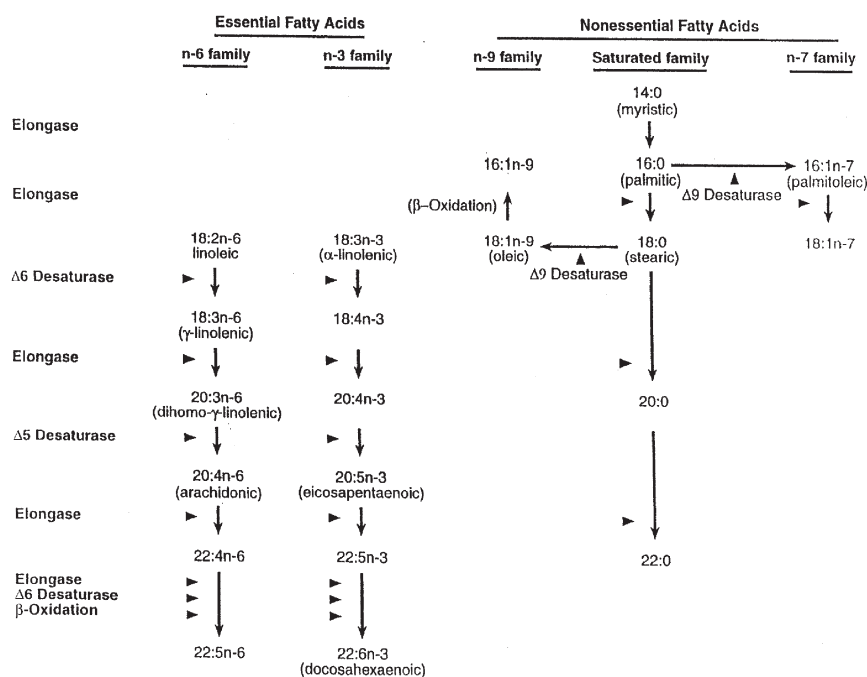

FIG. 1. Nomenclature and metabolic pathways of long-chain fatty acids.

serum and adipose TG fractions, presents a picture of 16:1n-7 as both a metabolic product under genetic control and one that is also closely linked to adiposity.

The mechanism leading to these associations is not immediately apparent. Selective release of 16:1n-7 by hormone-sensitive lipase has been observed in both rodents (1,2) and humans (3–5). However, this appears to be a relatively uniform process among individuals, and thus cannot readily explain the positive associations noted here.

A more likely process to explain the association of 16:1n-7 with adiposity is lipogenesis. Lands (35) noted that 16:1n-7 is an expected product of lipogenesis and that its content in serum CE will appropriately reflect the hepatic lipid pool. In this regard, it is noteworthy that the obese Zucker rat, a profoundly lipogenic animal, has dramatically increased proportions of 16:1n-7 in its liver TG and CE as well as in Serum CE fractions compared to lean controls fed the same diet (13). Although

Hellerstein *et al.* (36) find little evidence for hepatic lipogenesis in humans, their isotope technique is based on the quantitation of 16:0 as the primary product of lipogenesis. It is also worth noting that Aarsland *et al.* (37) published evidence for appreciable whole-body lipogenesis with carbohydrate overfeeding in humans, and they postulated that it occurs primarily in AT rather than liver. These pieces of evidence thus mesh nicely with our observed correlations between 16:1n-7 and adiposity, making 16:1n-7 in serum CE and adipose TG a candidate biomarker for processes leading to obesity.

The IPR in FA composition in obese adult identical twins clearly transcend dietary similarities, making a strong case for post-diet genetically mediated selectivity as a factor regulating tissue FA composition in humans. This pattern of IPR was most pronounced in the PC fraction, implying that the greatest effect of this selectivity, differentiating an individual from her diet, would be seen in membrane lipids. This in turn would magnify the effects of selectivity on cellular function, particularly because the PC selectivity was most pronounced among the highly unsaturated essential FA, which impart unique properties to membranes. Among the nonessential FA, there were consistent IPR for 16:1n-7 across all lipid fractions, and 16:1n-7 in serum CE and adipose TG correlated strongly with indices of adiposity. This pattern of correlations for palmitoleate suggests that it is an important product of endogenous lipogenesis, and that this shift of carbon into lipid storage pools participates directly or indirectly in the pathogenesis of obesity.

#### ACKNOWLEDGMENTS

We express our gratitude to Věra Lánská and Lubomír Poušek for statistical management and for graphical documentation of the study.

**ABSTRACT:** The ability of plant sterol esters (PSE) in salad dressing to modify plasma lipids and carotenoids was determined in 26 men and 27 women fed controlled, weight-maintaining, isocaloric diets. Diets contained typical American foods that provided 32% of energy from fat. Dressings contained 8 g (ranch) or 4 g (Italian) of fat per serving. PSE (3.6 g/d) were provided in two servings/d of one of the dressings. Diets with ranch or Italian dressing without and with PSE were fed for 3 wk/diet and crossed over randomly within dressings. Diets were adjusted to similar fat and fatty acid concentrations. Type of salad dressing did not affect plasma lipids, lipoproteins, carotenoids, or fat-soluble vitamins ( $P > 0.05$ ). Switching from a self-selected baseline diet to the control diet resulted in reduction in low density lipoprotein (LDL) cholesterol of 7.9%, a decrease in high density lipoprotein (HDL) cholesterol of 3.1%, and a decrease in triglycerides (TG) of 9.3%. Consumption of 3.6 g of PSE resulted in further decreases in LDL cholesterol (9.7%) and TG (7.3%) but no additional change in HDL cholesterol. Total plasma carotenoids decreased 9.6% with PSE. An automated stepwise procedure was developed to produce candidate mixed models relating plasma carotenoid response to PSE. These models adjusted for preintervention plasma carotenoid levels and effects of diets on blood lipids. There were significant decreases in  $\beta$ -carotene,  $\alpha$ -carotene, and  $\beta$ -cryptoxanthin (females only) not associated with changes in plasma lipids. Plasma carotenoids on all diets remained within normal ranges. We conclude that low-fat foods, such as salad dressings, are effective carriers for PSE.

Paper no. L8820 in *Lipids* 37, 33–42 (January 2002).

Although there is increased public health emphasis on maintenance of body weight and modification of lifestyle factors to reduce the risk of cardiovascular disease (CVD), elevated blood cholesterol remains of great concern and the target of both dietary recommendations (1) and drug treatments to re-

duce CVD risk. The blood cholesterol-reducing effect of plant sterols is well documented (2). However, plant sterols in natural food sources are low, ranging from 0.1 to 0.5 g/d, and therefore may not have substantial impact on cholesterol concentrations (3). Recent studies have demonstrated that plant sterol-enriched margarines lower total and low density lipoprotein (LDL) cholesterol in normocholesterolemic and mildly hypercholesterolemic subjects (4,5). Currently, such table spreads, prepared from vegetable oil and relatively high in fat (32–65%), are the major carriers for plant sterol esters (PSE) available to the public on the open market. PSE is dissolved in the fat phase of these products, termed in food technology as “fat continuous” products; that is, they are “water-in-oil” products in which water is emulsified into a continuous fat phase.

The efficacy of lower fat products as carriers of sterol esters has not been demonstrated in carefully controlled studies of blood lipids and lipoproteins. Examples of fat-based products lower in fat are salad dressings that are similar to those fed in the current study. These are “fat-in-water” products and employ the “water continuous” concept in which the fat is emulsified in a “water continuous” phase. The first objective of the present study was to determine effects of PSE in products in which fat is emulsified in a “water continuous” phase and in which the food carriers’ fat contents are reduced compared with those of margarines, the usual carriers of PSE. Indirectly, we planned to compare the efficacy of these reduced- and low-fat carriers of PSE with blood cholesterol and carotenoid effects reported for higher-fat, “fat continuous” products such as margarines.

Little is known about the effect of baseline blood lipid, fat-soluble vitamin, and carotenoid concentrations on the lipid- and carotenoid-modifying response to PSE consumption. Thus, a second objective of the current study was to examine the relationship of pretrial plasma concentrations of blood lipids and fat-soluble nutrients with the response to PSE consumption. This was achieved by including the appropriate individual pretrial variables as covariates and determining if the slopes of the control vs. PSE diets differed (i.e., if a covariate by treatment interaction was present).

## SUBJECTS AND METHODS

*Study design.* Two types of salad dressing were compared in a parallel arm design. Within each dressing (arm), there was a

randomized crossover between dressing with and without added PSE. The study cohort was divided into two groups balanced for gender, age, body mass index (BMI), and plasma total cholesterol (TC), and the groups were randomly assigned to the salad dressings. Participants consumed each diet for a period of 3 wk followed by blood sampling during the fourth week. Following the final blood sample in the first dietary period, volunteers were switched to the second diet with no washout between periods. There was no crossover between dressing types. The products were fed as part of a carefully controlled, moderately low fat, low saturated fat, weight maintenance diet. Within each dressing, a double-blind protocol was followed.

**Subjects.** The study protocol was approved by the Johns Hopkins University, School of Hygiene and Public Health, Committee on Human Research. Men and women with normal to slightly elevated blood cholesterol concentration were recruited by advertisement in the area of the Beltsville Agricultural Research Center, Beltsville, MD. Minimum eligibility criteria were based on general health, age (25–65 yr), and BMI within 85–120% of gender-specific ideal BMI specified by life insurance reference tables (6). Subjects selected for the study were required to have fasting plasma high density lipoprotein (HDL) cholesterol concentrations greater than 25 mg/dL for men and 35 mg/dL for women and fasting plasma triglyceride (TG) concentrations less than 300 mg/dL. Volunteers who reported taking lipid-lowering drugs, blood pressure medications, or dietary supplements or who had eating habits inconsistent with the study protocol (e.g., those on vegetarian or low-fat diets) were excluded. Volunteers were evaluated by a physician and determined to be in good health with no signs or symptoms of hypertension, hyperlipemia, diabetes, peripheral vascular disease, gout, liver or kidney disease, or endocrine disorders.

Women taking hormones for birth control ( $n = 2$ ) or postmenopausal hormone replacements ( $n = 3$ ) were included in the study with the requirement that they continue the same regimen (type of hormone, schedule, and dose) throughout the dietary intervention. Although smokers and nonsmokers were accepted for the study, only 5 of the 53 participants completing the study smoked. Exercise was not controlled, but subjects were encouraged to maintain their normal exercise patterns (type of exercise, duration, and frequency) throughout the study and were required to record exercise on their daily questionnaire.

**Basal diet and salad dressings.** Ranch and Italian salad dressings with PSE prepared from soybean oil were fed as part of a mixed diet (basal diet) composed of foods commonly eaten in the United States. Control ranch and Italian dressings having no added sterols but which matched the fat and fatty acid concentrations in the test dressings were fed for comparison. The fat level of both the control (–PSE) and the sterol-containing (+PSE) ranch dressing was 27%. The control and sterol-containing Italian dressings had 17 and 13% fat, respectively. The difference in fat content of the two Italian dressings as well as that between the ranch and Italian dress-

ings was balanced in the total diet by adding appropriate amounts of fat and fatty acids in other foods. Two servings, 30 g (2 tablespoons) per serving, of experimental salad dressing were fed each day. Group 1 was fed the basal diet with Italian dressing that provided 4 g of fat per serving while group 2 was fed ranch dressing that provided 8 g of fat per serving. PSE, prepared from soybean sterols, were added to each dressing so that two servings of +PSE dressing provided 3.6 g of PSE, equivalent to 2.2 g/d of free sterol. Salad dressings were prepared by Lipton (Englewood Cliffs, NJ).

**Dietary intervention.** Monday through Friday, all subjects consumed breakfast and dinner at the Beltsville Human Nutrition Research Center (BHNRC) human study facility under the supervision of a dietitian. At breakfast, each subject was provided with a carry-out lunch to be consumed that day. Snack items were included in the daily menu, and subjects were provided the option of consuming the snacks at dinner or later in the evening. One serving of the salad dressing was provided with lunch, and one serving with dinner. Meals for the weekend were packaged for home consumption and provided to the subjects, with written instructions, after dinner on Friday. Weekend menus contained the same type of foods and balance of nutrients as the weekday menus. Unlimited amounts of coffee, tea, and diet sodas were allowed, but all additives (sugar and milk) for coffee and tea were provided with the meals. Only foods provided by the Human Study Facility were allowed to be consumed during the study.

Each weekday morning, subjects were weighed before breakfast when they arrived at the facility. Energy intake was adjusted in 200-kcal increments for women and 400-kcal increments for men to maintain initial body weight. Subjects were fed the same items and the same proportions of each item relative to total dietary energy. Therefore, the relative amounts of nutrients, other than those provided by the salad dressing, were constant for all subjects. Each day, subjects completed a questionnaire detailing beverage intake, factors related to dietary compliance, exercise, medications, and illnesses. The questionnaires were routinely reviewed by a study investigator, and problems were discussed with the subject during the next meal.

**Analysis of diets.** Two composites of the 7-d menu cycle were made at two energy levels. Thus, four weekly diet composites were analyzed for dry matter, crude protein, crude fat, total dietary fiber, and ash (Corning Hazleton, Inc., Madison, WI). Fatty acid compositions of food composites were determined by gas chromatographic separation of fatty acid methyl esters. Carotenoid content of the controlled diets was estimated using data for carotenoids in foods which were compiled at BHNRC (7).

**Blood sample collection and analysis.** Baseline samples were collected on 2 d during the week immediately before initiation of the controlled feeding. Subsequently, samples were collected on two different days during the fourth week of the intervention. The subjects were randomly divided into two groups. One group had samples drawn on Monday and Wednesday and the other on Tuesday and Thursday.

Procedures for collection and processing of fasting blood samples were those described in the protocol for the Lipid Research Clinics Program (8). Plasma was harvested and stored in cryogenic vials at  $-80^{\circ}\text{C}$ . Before storage, the sample to be used for HDL cholesterol determination was precipitated by the sequential precipitation procedure of Gidez *et al.* (9). Supernatants from the HDL precipitation were stored at  $-80^{\circ}\text{C}$  for later analysis of cholesterol. Analyses for TC, TG, HDL, lipoprotein (a) [Lp(a)], and apolipoproteins were performed after the final blood collection. All samples from one subject were included in the same analytical run.

Lipid and lipoprotein analyses (TC, TG, HDL cholesterol, and apolipoproteins) were performed at the Lipid Research Clinic Laboratory, The George Washington University Medical Center, which maintains standardization with the Centers for Disease Control and Prevention, U.S. Department of Health and Human Services. Plasma TC, HDL cholesterol, and TG were determined enzymatically with commercial kits (Sigma Chemical Company, St. Louis, MO) on an Abbott VP analyzer (Abbott Laboratories, Chicago, IL). LDL cholesterol was calculated by the Friedewald equation (10). Plasma apolipoproteins A1 (Apo A1) and B (Apo B) concentrations were determined by rate nephelometry (Beckman ICS Immunochemical Analyzer; Beckman Instruments, Fullerton, CA).

Carotenoids from 0.4 mL of plasma were extracted into organic solvents containing an internal standard (11), concentrated, and analyzed by high-performance liquid chromatography (HPLC) with a Hewlett-Packard (Wilmington, DE) Series 1050 chromatograph with diode array detection. Carotenoids were separated on a reversed-phase  $\text{C}_{18}$  analytical column (Microsorb-MV; Varian Analytical Instruments, Walnut Creek, CA),  $250 \times 4.6$  mm, protected by a  $5\text{-}\mu\text{m}$  Brownlee  $\text{C}_{18}$  guard cartridge,  $30 \times 4.6$  mm, under isocratic conditions (12). The precision and accuracy of the HPLC system were verified using Standard Reference Material 968b (National Institute of Standards and Technology, Gaithersburg, MD).

*Statistical analysis.* There were a large number of independent variables, and potential interactions among them, that we wanted to consider as predictors of response to PSE consumption for each of the blood lipid, lipoprotein, and carotenoid variables. Therefore, we developed an automated stepwise model selection procedure (13), used for each of the dependent variables. Our procedure selected a mixed analysis of variance (ANOVA) model that minimized Schwartz's Bayesian information criteria (BIC) (14), where a smaller BIC corresponds to a better "fitting" model, given all the candidate independent variables. The basic within-individual covariance structure remained unchanged (that of a crossover design) while selecting the independent variables.

Models were tested in a standard stepwise approach (15). All models included an intercept term. Selection started by adding the single best independent variable or interaction term to the model. With that variable in the model, the next best variable was added. This process was repeated until no other variables could be added. After five or more independent variables were in the model, all variables currently in the

model were also tested to see if any could be removed. We used the resulting "final" model as a basis for further model development, usually by eliminating variables that changed BIC only marginally, because the resulting simpler models were easier to interpret and seemed to "fit" about as well, based on BIC.

For all dependent variables, one important predictor was the variable's pretrial value, which we refer to as baseline. This is because subjects with high posttreatment values were likely to come into the experiment with high pretreatment values, just as those with low posttreatment values came in with low pretreatment values. The baseline value of the dependent variable adjusts posttreatment scores by the variable's initial value, resulting in a more sensitive test of the treatment effects because much of the "noise" due to initial intersubject variation has been statistically removed. Since it was not initially evident to us that there would be a linear relationship between pre- and posttreatment values, we allowed for non-linearity by including a quadratic effect (the square of the baseline concentration of the dependent variable) as a candidate independent variable. In general, the quadratic effect was not included in the final model, that is, there was a linear relationship between pre- and posttreatment values.

Other candidate independent variables for both blood lipids and carotenoids included characteristics of the individual (age, sex, and BMI), pretrial plasma concentration of the dependent variable (baseline, baseline squared), design variables (period and sequence in which the diets were administered and carryover effect), and the variables of most interest, treatment and dressing. First-order interaction terms among these variables were also candidate independent variables. In addition, because carotenoids are carried by lipoproteins and concentrations may be dependent on changes in blood lipids (16), blood lipid variables were included as candidate covariates in models for carotenoids (i.e., TG, TC, LDL cholesterol, HDL cholesterol, and the sum of TG + TC).

For the carotenoids, there were 57 candidate independent variables (not including the intercept) for the routine to select from. There were fewer, 49, candidate variables for the blood lipids than for carotenoids, because blood lipid variables, other than the baseline level of the dependent variable, were not allowed into the model. For example, LDL cholesterol was not adjusted using HDL cholesterol, TC, or TG.

## RESULTS

*Subjects.* Twenty-eight men and 28 women completed the screening process and began the controlled feeding. One woman and two men withdrew for personal reasons not related to the study. Thus, 26 men and 27 women completed the feeding phase of the study. Data were analyzed statistically only for subjects who completed both feeding periods. Characteristics of these participants at baseline are presented in Table 1.

*Diets and salad dressings.* The background diets with salad dressing added were planned to be prudent, healthful diets having moderate levels of fat but lower levels of satu-

**TABLE 1**

rated fatty acids (SFA) and cholesterol, as well as higher levels of dietary fiber than reported for the average U.S. diet (17). Diets were calculated using data from the U.S. Department of Agriculture (USDA) nutrient database (18) so that total fat would be approximately 30% of energy and protein 16% of energy. Analyzed macronutrient and fatty acid compositions of the basal diet and diets with salad dressings are presented in Table 2. Analyzed compositions of diets as fed

in the study showed 32.2–32.7% of energy from fat and 15.7–16.2% from protein. The values for dietary fat are slightly lower than those reported for the U.S. diet (17). In order to avoid confounding the effect of dietary fatty acid intake on blood lipids with those of PSE, considerable effort was made to formulate diets that would vary little in the major SFA (myristic, palmitic, and stearic acids), as well as in major mono- and polyunsaturated fatty acids (oleic and linoleic

Dietary cholesterol (g/d/1000 kcal)	88	97	94	92
Dietary fiber (g/d/1000 kcal)	13	12	11	13

<sup>a</sup>Average energy intake for men was 2766 kcal/d; for women, 2163 kcal/d.<sup>b</sup>Diet composites with salad dressing included were analyzed at 2200 and 3200 kcal. Values are the average of the two composites.<sup>c</sup>Ratio of fatty acids, PUFA:MUFA:SFA = 1.3:1.4:1<sup>d</sup>Percentages of energy (en%) from salad dressing fat calculated at 2200 and 3200 kcal were, for ranch, 6.5 en% at 2200 kcal and 4.5 en% at 3200 kcal, and, for Italian, 3.3 en% at 2200 kcal and 2.2 en% at 3200 kcal.

acids). Ratios of polyunsaturated to monounsaturated to saturated fatty acids averaged 1.3:1.4:1 and were very consistent across diets. The diets averaged 12 g of dietary fiber per 1000 kcal. Mean total dietary fiber intake was 33 g/day for men and 26 g/day for women. These values are considerably higher than the average intake reported for the U.S. diet, 17.4 g/d for men and 13.7 g/d for women (17), but were constant across all diets.

**Blood lipids and lipoproteins.** As expected from documented inherent gender differences, women had higher concentrations of HDL cholesterol (+10 mg/dL) and apo A1 (+16 mg/dL) than did men but were not different from men in concentrations of LDL cholesterol and apo B. The ratio of total/HDL cholesterol was higher for men than for women,  $4.96 \pm 0.23$  vs.  $4.12 \pm 0.20$ .

The effects of type of salad dressing, gender, and gender  $\times$  dressing interaction were found to be nonsignificant ( $P > 0.05$ ) in the mixed ANOVA model; thus, data for the type of salad dressing and gender are combined. Blood lipid and lipoprotein changes due to the addition of 3.6 g PSE/d to the controlled diets are shown in Table 3. Inclusion of 3.6 g PSE/d in the controlled diet resulted in highly significant reductions ( $P < 0.005$ ) in TC [6.8% (13.8 mg/dL)], LDL cholesterol [9.8% (12.5 mg/dL)], apo B [3.3% (3.03 mg/dL)], and TG [7.3% (8.5 mg/dL)]. HDL cholesterol was unaffected by including PSE in the controlled diet ( $P = 0.33$ ). As with HDL cholesterol, apo A1 was unaffected by PSE ( $P = 0.56$ ).

The effect of PSE on the ratio of TC to HDL cholesterol depended on the ratio prior to dietary intervention, that is, there was a treatment by baseline interaction. Even so, PSE consumption always resulted in lower ratios. At a baseline ratio of 4.5, the average of the ratio at the start of the study (Table 1), the ratio decreased by 0.36 (7.5%,  $P = 0.0001$ ). At the minimum and maximum baseline ratio, the decrease was 6.9 and 7.7%, respectively. There were no significant interactions of gender or BMI with PSE effect on the ratio.

**Carotenoids.** There were no differences in the effect of PSE consumption on plasma carotenoid concentrations between Italian and ranch dressings. There were no significant interactions of gender with PSE consumption except for  $\beta$ -cryptoxanthin, where there was a significant treatment effect for females, but not for males (Table 4).

All plasma carotenoids decreased to some degree with consumption of PSE (Table 4). This general decrease in carotenoids was reflected by a 9.6% decrease ( $P < 0.0022$ ) in the sum of those carotenoids determined in our analytical procedure, i.e., total carotenoids. Among the major plasma carotenoids,  $\beta$ -carotene and  $\alpha$ -carotene decreased by 12.7 ( $P = 0.0009$ ) and 12.8% ( $P = 0.0226$ ), respectively. Lycopene decreased with consumption of PSE; however, the magnitude of the decrease varied directly with BMI (i.e., there was a significant treatment  $\times$  BMI interaction (Table 4). Estimation of the effect of BMI showed that the decrease in lycopene due to PSE became statistically significant ( $P = 0.05$ ) at BMI between 22 and 23 and ranged from 4.1  $\mu$ g/dL at BMI 22 ( $P = 0.0843$ ) to 10.9  $\mu$ g/dL at BMI 30 ( $P = 0.0001$ ). At the average BMI in this study (Table 1), the decrease in lycopene would approximate 20% of the mean lycopene concentration for the control (–PSE) treatment. Decreases in the lutein–zeaxanthin carotenoid fraction, anhydrolutein,  $\alpha$ -cryptoxanthin, and  $\beta$ -cryptoxanthin (for males only) due to PSE consumption were not statistically significant ( $P > 0.05$ ).

**Fat-soluble vitamins.** Modeling of  $\alpha$ - and  $\gamma$ -tocopherol and retinol by the same procedure and for the same covariates used for carotenoids showed no significant effects of dressing or treatment and no significant interactions of baseline concentration of the fat-soluble vitamin, gender, or BMI with dressing or treatment. The estimated means and standard errors of the estimated means (SEE) are shown in Table 4.

**Relationships of baseline subject characteristics with blood lipid and lipoprotein responses to PSE.** In Table 5 we present coefficients for independent variables entering into the model with probability values of  $\leq 0.05$  for the lipid and lipoprotein dependent variables. The coefficient for the intercept is included for completeness. There were no significant effects or interactions of type of dressing and treatment in the final model, indicating that the response to PSE consumption (treatment) was the same for both Italian and ranch dressings (Table 5). As expected, baseline concentration was a significant predictor of final concentration for all blood lipids and lipoproteins. However, there was no significant interaction of the baseline concentration with PSE (treatment effects), so the magnitude of change in the plasma lipid was the same over all baseline levels; that is, the effect of treatment on a

<sup>b</sup>There was a significant interaction of treatment (PSE) with body mass index (BMI) for lycopene; thus, LSMeans are uninformative. The decrease in lycopene due to PSE consumption was significant at BMI = 23 (-4.93 ± 2.01 µg/dL or -13.2%; *P* = 0.0181). At BMI = 30, lycopene decreased by 10.9 ± 2.10 µg/dL or 29% (*P* < 0.0001). For abbreviation see Table 2.

blood lipid or lipoprotein was independent of the baseline concentration. Because baseline was a significant indicator of the final concentration, it was included in all models. The importance of the relationship of baseline LDL cholesterol concentration to LDL cholesterol in both control and PSE diets is depicted graphically in Figure 1 for men and women.

There were no significant effects on blood lipids and lipoproteins due to gender, age, or BMI. In addition, there were no significant interactions of gender, age, or BMI with dressing or treatment, indicating that responses to dressing and PSE were also independent of these subject characteristics. Note that these relationships of blood lipids and PSE to

<sup>c</sup>NS, not significant.

**FIG. 1.** Preintervention (baseline) plasma low density lipoprotein (LDL) cholesterol concentration vs. change in LDL cholesterol in response to diets supplemented with 3.6 g/d of plant sterol esters (PSE) prepared from vegetable oil. For each participant, an arrow indicates the direction and magnitude of change from the control diet (-PSE) to the intervention diet (+PSE). Baseline concentrations for men and women were distributed similarly, as were responses to the intervention diet.

age and BMI cannot be extrapolated to a wider range than that in this study because age and BMI were selection criteria.

There was no effect of controlled diets with or without PSE on Lp(a) (data not shown).

*Relationships of baseline subject characteristics with plasma carotenoid responses to PSE, after adjusting for blood lipid changes.* In modeling responses of carotenoids to PSE, we were interested in determining if blood lipid concentrations were a determinant of carotenoid response. In addition to the independent and design variables considered for blood lipids and lipoproteins, TG, TC, LDL cholesterol, HDL cholesterol, and total plasma lipids (estimated as the sum of TG + TC) were included as candidate covariates in modeling carotenoid responses. Baseline carotenoid concentration was a significant predictor of final carotenoid concentration for all carotenoids (Table 6). As observed for blood lipids, carotenoid responses were independent of dressing at the  $P = 0.05$  level of significance. There were no significant interactions of baseline plasma carotenoid concentration with effects of dressing or treatment for any carotenoid.

After adjusting for the blood lipid covariates, baseline concentration of the dependent carotenoid variable, subject characteristics, and variables associated with study design (Table 6), there remained significant effects of PSE for total carotenoids,  $\beta$ -carotene, and  $\alpha$ -carotene. Thus, blood lipid responses to the diets do not completely determine the plasma carotenoid responses to PSE consumption.

## DISCUSSION

In this study, a large dietary trial showed that reduced-fat and low-fat salad dressings are effective carriers of PSE prepared from soybean oil. The dressings were compared within diets that were balanced for fat, fatty acids, and other nutrients. The reduction in CVD risk factors was not affected by the amount of fat in the dressing that carried the PSE. When two servings per day were fed as part of a mixed diet, the reduced-fat ranch salad dressing (8 g of fat per serving) and the low-fat Italian dressing (4 g of fat per serving), each supplemented with 1.1 g of free sterol equivalent per serving, resulted in approximately equal reductions in the major blood lipids. Each dressing was compared to a control dressing of similar fat and fatty acid composition but with no added PSE.

The effectiveness of reduced- and low-fat foods as carriers of PSE was demonstrated by highly significant reductions in blood lipid risk factors for CVD. TC and LDL cholesterol, indicators of increased risk, declined about 7% and 10%, respectively, with consumption of 3.6 g PSE/d, while HDL cholesterol, associated with reduced risk (19,20), remained unchanged. Lower ratios of TC to HDL cholesterol have been postulated to be strong, independent indicators of decreased risk for CVD (21,22). As would be expected considering the observation of major reductions in LDL cholesterol and sparing of HDL cholesterol by PSE consumption in the current study, the ratio of TC to HDL cholesterol was reduced by 6.9–7.7%, again indicating decreased risk for CVD with consumption of PSE. Increased blood TG concentrations have also been postulated as a risk factor for CVD (23). TG concentrations were reduced by 7% by PSE.

Changes in the major apolipoproteins of LDL (Apo B) and HDL (Apo A1) and changes in cholesterol associated with the corresponding lipoprotein were directionally similar. Similar changes in blood cholesterol and apolipoproteins have been shown in other studies of PSE (4,5). We did not directly determine lipoprotein particle composition. However, changes in LDL cholesterol and Apo B were directionally similar but not directly proportional. This may indicate a reduction in the cholesterol content of the lipoprotein particle as well as a reduction in the number of particles. Lp(a), similar to LDL in lipid composition and with Apo B as one major apolipoprotein but with a second major apolipoprotein referred to as Apo (a), may be a risk factor for the development of CVD (24,25). The particle has been reported to be more atherogenic than LDL (26,27). In our studies, and in those of others, Lp(a) has been altered by changes in dietary fatty acid intake. SFA tend to lower Lp(a) (28–30), whereas *trans* monounsaturated fatty acids raise Lp(a) (31,32). Although we did not expect that PSE would affect Lp(a) because the reputed action site of PSE lies ex-systemically at the level of the gastrointestinal tract (33), nonetheless it is important to know whether this highly atherogenic particle is affected by PSE in the diet before we can evaluate the overall reduction in CVD risk associated with PSE consumption. In the current study, Lp(a) was unaffected by inclusion of PSE in the diet.

<sup>f</sup>Covariates: TC, TG, LDL cholesterol, HDL cholesterol, and sum of TC and TG.

In the 1994 report of strategies for blood cholesterol reduction from the National Cholesterol Education Program (NCEP) (34), it was estimated that for every 1% reduction in cholesterol concentration, the risk of CVD decreased by an average of 2%. Application of this prediction to TC reduction observed in the present study would indicate an average reduction in risk for CVD of 28%. This is based on changes from initial (baseline) plasma TC concentrations when a moderately low-fat, low-SFA diet with 3.6 g PSE/d was consumed. This may be partitioned as 14% reduction in risk due to consumption of the reduced-SFA diet without PSE, with a further reduction of 14% due to addition of PSE to the diet. Thus PSE consumption results in a reduction in risk beyond that resulting from reduced consumption of SFA. From this, we postulate that inclusion of PSE in the diet may have benefits unrelated to saturated fat intake and that even those people unwilling to commit to changes in type or amount of fat intake may benefit significantly from consumption of food products containing PSE.

When effects of PSE consumption (and type of dressing) were modeled, baseline (preintervention) concentration of a

plasma constituent was always an important predictor of final concentration. However, there was no interaction of baseline concentrations with response to PSE for any plasma lipid or lipoprotein. This indicates that people may benefit from a reduction in CVD risk with consumption of PSE regardless of their starting blood cholesterol level. For individuals having a normal cholesterol level, regular PSE consumption may help prevent the development of elevated cholesterol often associated with aging and changes in lifestyle as we age.

Unlike plasma lipids and lipoproteins, decreases in the TC/HDL cholesterol ratio with PSE consumption was related to the ratio at entrance of the subjects into the dietary intervention. Thus, if the ratio is an independent indicator of CVD risk (19,20), people with higher ratios, and thus at higher risk, may benefit from a greater reduction in risk when they consume PSE than do those who have lower ratios.

In this investigation, we found that plasma carotenoid concentrations decreased with addition of PSE to the diet. For example, β- and α-carotene both decreased by about 13%, while lycopene decreased by about 20%. Plasma concentrations of fat-soluble nutrients such as carotenoids may be lowered by

PSE either directly by reduced absorption or indirectly through undefined mechanisms. Plasma concentrations of some, if not all, carotenoids may be related to the concentration of the plasma lipoproteins on which they are carried (16) and may decrease or increase as plasma lipoproteins change. Thus, in experimental studies, fat-soluble carotenoids and vitamins are commonly normalized to plasma lipid concentrations. This may not be appropriate, however, when both the carotenoid and the plasma lipid are dependent variables and both are subject to change with treatment.

We saw no evidence that PSE consumption affected fat-soluble vitamin absorption. However, this investigation was conducted over a relatively short time period, and results cannot be extrapolated to what might occur over longer periods. Concentrations of plasma carotenoids in this study remained well within what may be considered normal levels. Again, as for the fat-soluble vitamins, caution must be exercised in extrapolating our results to long-term effects on carotenoids. However, plasma carotenoids are strongly related to dietary intake. On diets sufficiently rich in carotenoids, we expect that plasma concentrations of carotenoids will reach a lower plateau due to PSE consumption but will remain within normal ranges. The effects of PSE on plasma carotenoid concentrations when the diet is marginal or low in carotenoids may be of more concern.

This study did not directly compare salad dressings with vegetable oil spreads, which are the common form of commercially available food carriers of PSE. However, the extent of LDL cholesterol lowering by PSE delivered by dressings in this study, averaging 17% compared with the subjects' cholesterol level at entry, and 9.7% compared with the control diet, matched what can be extrapolated from clinical studies in which PSE were delivered by spreads having a higher fat content (4,5). In theory, there should not be any difference in the *in vivo* digestion of the fat in a spread product and the fat in a dressing product despite the differences in how they are structured. Each type of product should deliver PSE to the digestive milieu. Our data clearly support this supposition.

Reduction in SFA intake remains the primary dietary goal for individuals and for the population at large to lower LDL cholesterol and reduce the risk of CVD. In the 2001 report from the NCEP on the treatment of high blood cholesterol in adults, Adult Treatment Panel III (ATP-III) (35), the recommended intake of saturated fat is less than 7% of energy with total fat intake of 25–35% of energy. Food carriers of PSE including both vegetable oil-based spreads and reduced-fat salad dressings, each having high levels of polyunsaturated fatty acids, can be incorporated in NCEP ATP-III type diets. However, dressings with lower total fat/serving may be more readily used to deliver PSE while replacing SFA. For example, two servings per day of low-fat salad dressing, such as the Italian dressing fed in this study, carrying 3.6 g of PSE, would provide about 8 g of fat and 1 g of SFA per day but would deliver PSE in amounts that significantly reduce blood cholesterol risk of CVD. For women consuming 2163 kcal per day, the average intake in this study, two servings per day of the Italian dressing added to a

diet having 30% of calories from fat would provide only 11% of the daily fat intake and 5% of the SFA recommended as the maximum SFA intake in an NCEP ATP-III type diet. Corresponding amounts for men consuming 2766 kcal per day (the average energy intake in this study) would be 9% of daily fat intake and 4% of the SFA intake. These amounts of fat are readily balanced by removal of dietary fat from other sources and would be especially beneficial if the fat replaced is animal fat or vegetable oil-containing products high in either SFA or *trans* unsaturated fatty acids.

We conclude that low-fat foods, such as reduced- and low-fat salad dressings, are effective carriers for PSE. Such reduced-fat foods can be readily included in diets low in SFA as well as diets moderately low in total fat, i.e., prudent diets, to lower blood cholesterol and reduce the risk of CVD. Furthermore, the reductions in LDL cholesterol and in the ratio of TC to HDL cholesterol are not conditioned by the plasma lipid level of the person when consumption begins. Thus, PSE addition to the diet, coupled with the primary goal of reducing saturated fat intake, may help to both prevent development of high LDL cholesterol and reduce CVD risk.

**ABSTRACT:** The purpose of this work was to study whether exercise training induces changes in the lipid profile of rat aorta and nervous system and in the *in vitro* intrinsic responsiveness of these tissues to endothelin-1 (ET-1) treatment. The exercise program performed successfully produced the characteristic metabolic alterations of the trained state. Exercise training induced a large and significant increase in the levels of both aortic ethanolamine plasmalogens (PlasEtn) and glucosylceramides. In contrast, a decrease of aortic ceramide and cholesterol levels was evoked by exercise training. ET-1 increased PlasEtn content only in sedentary animals. An exercise-induced increase in cerebellum levels of ceramides and ceramide monohexosides was found. The cerebellum ceramide content was increased by ET-1 more noticeably in sedentary rats than in trained animals. In contrast, cerebral cortex was observed to be largely insensitive to both exercise training and ET-1 treatment. It was concluded that exercise training (i) induces changes in both vascular and cerebellar lipid profiles, the former being much more pronounced than the latter, and (ii) diminishes the aortic and cerebellar sensitivity to ET-1 action.

Paper no. L8768 in *Lipids* 37, 43–52 (January 2002).

Sphingolipids and their breakdown products, ceramides, have emerged as important components of signal transduction systems (1). Ceramides play a role as secondary messengers mediating agonist action in postmitotic neuronal (2) and vascular cells (3) and are also involved in cellular proliferation, differentiation, and apoptosis phenomena (1). In addition, there is increasing experimental evidence showing that a highly complex network of interactions exists between glycerolipid and sphingolipid metabolism. We recently reported that an increase in the endogenous ceramide level elicited by sphingomyelinase (SPHase) treatment can affect choline and ethanolamine phosphoglycerides in the brain (4).

In previous studies focused on signal transduction systems, we described that sphingolipids as well as glycerolipids have a central role in the molecular mechanism of endothelin-1 (ET-1) action (5–9). ET-1 is a potent regulatory peptide gen-

erated by endothelial cells that was first isolated from cultured porcine aorta endothelial cells (10). It is now clear that ET-1 has a wide range of biological actions in both vascular and nonvascular tissues, including the nervous system (11,12). Thus, the ET-1 behavior as vasoactive peptide and neuropeptide is widely known. Therefore, the distribution and characteristics of ET-1 receptors and the signal transduction systems involved in the ET-1 molecular mechanism are being extensively studied. In this context, we reported that ET-1 is able to modulate phosphoinositide turnover and protein kinase C activity in the nervous system and in the blood-brain barrier (6–9), as well as the brain sphingolipid signal transduction system evoking ceramide production (5).

It is well known that endurance exercise training has beneficial effects on physiopathological states of the cardiovascular and nervous systems, but the molecular mechanisms involved are not completely understood. Endurance exercise causes a redistribution of tissue blood flow (13,14) and alterations in the levels of some neuropeptides (15), including those of plasma ET-1, that are augmented by exercise (13). Since aortic blood flow increases during treadmill training in the rat (16), it is conceivable that chronic exercise induces adaptive changes in the aorta, thereby contributing somehow to the modification of aortic function, as has been widely reported (17–19). In addition, there is evidence of exercise-induced changes in the nervous system (20–23), and it has been suggested that in the brain these changes might be mediated, at least in part, through neuroregulatory feedback from arterial baroreceptors to the brain (24). On the other hand, cardiovascular and neurodegenerative diseases are known to be associated with cellular apoptosis (2,3) and with oxidative stress or the vulnerability to it (25).

With this background and our interest in the molecular mechanisms involved in ET-1 actions, we have hypothesized that vascular and brain responses to ET-1 may be modified by long-term endurance exercise training. The aim of the present study was to investigate whether a long-term period of treadmill running induces alterations in the ET-1 regulatory actions on: (i) lipid second messengers, such as ceramide and diacylglycerols (DAG), considered, respectively, as being apoptotic and survival signal transducers (2), (ii) their potential lipid precursors, and (iii) ceramide monohexosides and cholesterol (CH). The study of all these lipid molecules was carried out

Abbreviations: BSS, balanced salt solution; CH, cholesterol; DAG, diacylglycerol; ET-1, endothelin-1; PlasEtn, ethanolamine plasmalogens; PtdEtn, phosphatidylethanolamine; PL, phospholipids; SPH, sphingomyelin; SPHase, sphingomyelinase; TL, total lipids; TLC, thin-layer chromatography.

because they have a causal involvement in the physiological actions of ET-1 (5) and may be involved in some beneficial effects of exercise, i.e., prevention of diseases and delay of aging, as suggested by previous evidence (25–28). In addition, differences found in the trained animals in the profile of these lipids involved in the ET-1 signal transduction systems are discussed in terms of adaptation to long-term training.

## MATERIALS AND METHODS

**Materials.** Ceramides type III from bovine brain sphingomyelin (SPH), containing primarily stearic and nervonic acids; ceramides type IV from bovine brain galactocerebrosides, containing  $\alpha$ -hydroxy fatty acids; ceramide monohexoside standards (bovine brain galactocerebrosides and human spleen glucocerebrosides); ET-1, and other standard lipids were purchased from Sigma Chemical Co. (St. Louis, MO). [ $\gamma$ - $^{32}$ P]ATP (specific activity: 3000 Ci/mmol) was obtained from Nuclear Ibérica, S.A., (Madrid, Spain) and *Escherichia coli* DAG kinase was from Calbiochem (San Diego, CA). High-performance thin-layer chromatography (TLC) plates were obtained from Merck (Darmstadt, Germany). All other reagents were of the highest analytical grade available.

**Animals and exercise training program.** Male Wistar rats (initial body weight  $150 \pm 9$  g) were obtained from Charles River (Barcelona, Spain). They were housed in an animal room at 22–24°C and given free access to commercial rat chow and tap water. The animals were adapted to an inverse 12:12 h light-dark cycle (dark period 0800 to 2000) before the beginning of the exercise regimen. Rat care and handling and all the experimental procedures employed were in accordance with internationally accepted principles concerning the care and use of laboratory animals.

Sixteen rats were randomly allotted to sedentary ( $n = 8$ ) and exercise-trained ( $n = 8$ ) groups. The rats of the trained group were exercised on a motor-driven rodent treadmill (Columbus Instruments, Columbus, OH) and performed five exercise sessions per week for 24 wk. Mild electrical stimulation was used to encourage the rats to run (grid shock  $<1$  mA). During the first 4 wk, the speed and duration of the daily exercise sessions were progressively increased until the rats were capable of running continuously for 45 min at  $25 \text{ m}\cdot\text{min}^{-1}$ . After 12 wk, the duration of the exercise sessions was increased to 60 min, and these conditions were maintained until completion of the exercise program. The selected treadmill speed corresponds to 60–70% of  $\text{VO}_{2\text{max}}$  according to the data of Brooks and White (29). During the 24-wk training period, sedentary control rats performed a single weekly exercise session for 5 min at  $15 \text{ m}\cdot\text{min}^{-1}$  to familiarize them with treadmill exercise and handling.

**Treadmill endurance test.** Two weeks before the end of the training period, a treadmill endurance exercise test was administered to all sedentary and trained rats the day before the weekly animal rest. The exercise test started with a 5 min warm-up at  $20 \text{ m}\cdot\text{min}^{-1}$  with a 5% slope after which animals ran at  $25 \text{ m}\cdot\text{min}^{-1}$  with a 5% slope until exhaustion. Rats were

judged to be exhausted when they could no longer continue at the required pace or maintain upright posture on the treadmill; at this point, they were usually unable to rapidly upright themselves when placed on their backs. Total exercise duration was recorded.

**Tissue preparation.** At the conclusion of the training program, 48 h after the final exercise training session, the rats were anesthetized with diethyl ether and killed as previously described (4), and the tissues were quickly dissected. The soleus muscles were removed, trimmed of connective tissue, weighed, fast-frozen in liquid nitrogen, and stored at  $-80^\circ\text{C}$  until further use. Aortas were removed and placed under a dissecting microscope in cold balanced salt solution (BSS) with the following composition (in mM): 135 NaCl, 4.5 KCl, 1.5  $\text{CaCl}_2$ , 0.5  $\text{MgCl}_2$ , 5.6 glucose, 10 HEPES, pH 7.4. The vessels were then cleaned of adherent fat and connective tissue with a cotton swab moistened in BSS, and the cleaned aortas were then cut into rings (4 mm long). Aortic strips were incubated as described later. Brains were removed, pial vessels and white matter were carefully discarded, and cerebral cortex and cerebellum were obtained. Slices (dimensions:  $350 \times 350 \mu\text{m}$ ) of both regions were prepared with a MacIlwain tissue chopper. They were equilibrated in BSS with 95%  $\text{O}_2/5\%$   $\text{CO}_2$  for 1 h.

To study the ET-1 effect, aorta strips and cerebral cortex and cerebellum slices from each animal were randomly divided into two portions, transferred into glass tubes containing BSS, and incubated for 30 min without or with ET-1 (final concentration  $10^{-7}$  M). These conditions have been designed to evoke physiological and biochemical alterations in aortic (30) and brain (5) intact tissue preparations. The incubation mixtures were continuously gassed with 95%  $\text{O}_2/5\%$   $\text{CO}_2$ . Reactions were stopped by removing the medium and replacing it with 0.38 mL of BSS containing 10 mM EDTA and 1 mL of chloroform/methanol/13 M HCl (100:100:1, by vol).

**Determination of citrate synthase activity in muscle homogenate.** Soleus muscle was homogenized twice for 30 s with a Polytron PT-10 at the maximum speed setting in 6.5 vol of 20 mM 3-(*N*-morpholino)propane sulfonic acid (MOPS), pH 7.0 containing 0.25 M sucrose,  $5 \text{ mg}\cdot\text{mL}^{-1}$  defatted BSA, and protease inhibitors at the following concentrations: 0.23 mM phenylmethylsulfonyl fluoride,  $100 \mu\text{g}\cdot\text{mL}^{-1}$  benzamidine, and  $0.5 \mu\text{g}\cdot\text{mL}^{-1}$  each of aprotinin, leupeptin, and pepstatin A. The resulting homogenate was diluted with 5 vol of the same buffer, filtered through two layers of cheesecloth, and used for analysis. The protein concentration of the homogenates was determined by the method of Lowry *et al.* (31).

Citrate synthase (EC 4.1.3.7) was measured in the muscle homogenates at  $37^\circ\text{C}$  as described previously (32). The assay mixture contained in a total volume of 1 mL (in mM) was as follows: 100 Tris-HCl, pH 8.1; 1 5,5'-dithiobis-(2-nitrobenzoate); 0.3 acetyl-CoA; 0.5 oxalacetate; 0.2% (wt/vol) Triton X-100, and a suitable amount of protein (60  $\mu\text{g}$ ). The reaction was started by addition of oxalacetate, and the increase in absorbance was recorded at 412 nm ( $\epsilon = 13.6 \text{ mM}^{-1}\cdot\text{cm}^{-1}$ ) in a thermostatically controlled UVIKON 930 spectrophotometer

(Kontron Instruments, Milan, Italy). The enzymatic activity was expressed in units per g of tissue wet weight ( $\mu\text{mol}\cdot\text{min}^{-1}\cdot\text{g}$  tissue wet weight $^{-1}$ ).

**Extraction of total lipids, separation of glycerolipids and sphingolipids.** Lipids were extracted by the method of Bligh and Dyer (33). The organic phases were dried under an  $\text{N}_2$  atmosphere and the total lipids were weighed and dissolved in chloroform/methanol (2:1, vol/vol). Lipids were separated by TLC.

For the sphingolipid studies, one aliquot of total lipids was subjected to alkaline hydrolysis in 0.1 M methanolic KOH at 37°C for 1 h to remove glycerolipids, as previously described (5). SPH, ceramides, and ceramide monohexosides were resolved using chloroform/methanol/water (65:25:4, by vol). Lipid standards were co-chromatographed with samples. Lipids were visualized by iodine vapors, and the bands corresponding to ceramide monohexosides and ceramides were scraped from the plates and extracted with chloroform/methanol (60:40, vol/vol) for their subsequent quantitation. SPH bands were quantitated without extraction, as described next.

**Radioenzymatic determination of ceramide and ceramide monohexoside levels.** Extracted ceramides and ceramide monohexosides were phosphorylated in the presence of DAG kinase, as described previously (34) with some modification (4). Aliquots of the dried lipids were solubilized and emulsified in 40  $\mu\text{L}$  of octyl- $\beta$ -D-glucoside/cardiolipin solution and sonicated in a bath sonicator (50–60 Hz) for 1 min. The reaction mixture containing 5  $\mu\text{g}$  of enzyme and the emulsified lipid substrate was preincubated at room temperature for 10 min, and the reaction was started by adding 10  $\mu\text{L}$  of 10 mM [ $\gamma$ - $^{32}\text{P}$ ]ATP in 20 mM imidazole buffer, pH 6.6. After incubation for 30 min at 25°C, phosphorylated derivatives of ceramides and ceramide monohexosides were extracted, fractionated by TLC, and quantitated by liquid scintillation counting (4). Calibration curves were derived using known amounts of ceramide and ceramide monohexoside.

**Radioenzymatic determination of DAG mass.** Aliquots of total lipids were phosphorylated in the presence of DAG kinase according to Preiss *et al.* (35). After DAG kinase assay, samples were fractionated by TLC (6). Spots corresponding to phosphatidic acid were visualized by autoradiography and quantitated by liquid scintillation counting. Calibration curves were derived using known quantities of 1-stearoyl,2-arachidonoyl glycerol.

**Quantitative determination of glycerophospholipids and CH. Analysis of the subclasses of ethanolamine phospholipids.** Aliquots of total lipids were dissolved in chloroform/methanol (2:1, vol/vol). For glycerophospholipid and CH studies, one aliquot of total lipid was separated using sequential one-dimensional TLC. The first system employed was chloroform/methanol/acetic acid/water (25:15:4:1.5, by vol) and the second was chloroform/methanol/acetic acid (65:2.5:4, by vol). The first system reached 4 cm from the top plate, whereas the second was developed through the plate. After development, spots were visualized by iodine vapors.

In the experiments where 1-alkenyl-2-acyl-*sn*-glycero-3-phosphoethanolamine (ethanolamine plasmalogens; PlasEtn)

were quantitated, total lipids were quantitatively split into two portions and dried under  $\text{N}_2$ . One portion was exposed to fumes from 12 M HCl in a Pyrex tray for 13 min to cleave the ether bond of the plasmalogen fraction while the 1-alkyl-2-acyl- and 1,2-diacyl-*sn*-glycero-3-phosphoethanolamine (phosphatidylethanolamine, PtdEtn) fractions remained intact. The small alkylacyl fraction was not quantitated separately. After separation by sequential one-dimensional TLC, as described previously, spots corresponding to ethanolamine phosphoglycerides, choline phosphoglycerides, and CH were scraped. Phosphorus content of glycerophospholipids and SPH was quantitated as described previously (36). In the case of ethanolamine phosphoglycerides, the untreated sample gave the total ethanolamine phosphoglyceride content, whereas the acid-resistant one gave the PtdEtn fraction level. The PlasEtn content was obtained by subtracting the latter from the former value. Identification was carried out by using respective standards. CH mass was quantitated as described previously (36).

**Statistical analysis.** All samples were individually processed and assayed in duplicate. Means  $\pm$  SD of eight independent preparations are presented. To evaluate differences between the sedentary and the exercised group, a Student's *t*-test for unpaired values was used. Measurements of lipid levels were analyzed using two-way analysis of variance to test for the two main effects (exercise training and ET-1 treatment) and for the interaction between them; a Scheffé *post hoc* analysis was performed to establish specific differences. When appropriate, effects of ET-1 in a single group were evaluated by paired *t*-testing. For all statistical analysis, significance was established at  $P < 0.05$ .

## RESULTS

**Exercise training effectiveness.** As a prerequisite of our study, we confirmed that the exercise program employed produced the characteristic effects of the endurance training. The exercise program induced several changes indicative of a trained state in male rats, as shown in Table 1. First, animal body weight was lower in the trained group compared with the sedentary group (19%,  $P < 0.05$ ), a common finding for trained male rats (37,38). Second, the results of the treadmill endurance test showed that running time until fatigue was significantly longer in trained than in control animals. Finally, the citrate synthase activity measured in the homogenates of soleus muscles of exercised rats was 60% over that of the

Effect of Exercise Training Program on Rat Body Weight, Exercise Endurance Capacity, and Skeletal Muscle Citrate Synthase Activity (CS)<sup>a</sup>

Group	Body weight (g)	Endurance time <sup>b</sup> (min)	CS activity ( $\mu\text{mol}\cdot\text{min}^{-1}\cdot\text{g}^{-1}$ )
Sedentary	625 $\pm$ 36	13 $\pm$ 6	30 $\pm$ 6
Trained	508 $\pm$ 50 <sup>c</sup>	162 $\pm$ 19 <sup>c</sup>	48 $\pm$ 5 <sup>c</sup>

<sup>a</sup>Values are means  $\pm$  SD ( $n = 8$ ).

<sup>b</sup>Endurance time is defined as the time during which the rat shows the ability to keep pace with the treadmill at 25  $\text{m}\cdot\text{min}^{-1}$  and 5% slope.

<sup>c</sup>Significant difference between sedentary and trained groups ( $P < 0.05$ ).

sedentary group, indicating that the exercise program induced the well-characterized enhancement of skeletal muscle oxidative capacity (37,38).

**Aortic responses to ET-1 treatment and exercise training.** In the ceramide radioenzymatic assay, two different molecular species of phosphorylated ceramide that showed different migration values ( $R_f$  values) in the TLC were found. The major band had an  $R_f$  value of 0.14, whereas a value of 0.32 was observed for the minor band. These bands run in parallel with the band corresponding to the phosphorylated ceramide type IV standard, which is rich in hydroxy fatty acids. The phosphorylated derivative of the ceramide type III standard (without hydroxy acids) was found to overlap to some degree with that of ceramide type IV. Therefore, it may only be concluded that aorta ceramides exist both with or without hydroxy acids. In addition, differences in the length of the fatty acid chain cannot be discarded, as it has been previously discussed (34). Figure 1 shows that ET-1 treatment did not change the level of the major ceramide species. However, the training induced a significant decrease (40%,  $P < 0.05$ ). With respect to the minor ceramide species [basal value:  $0.78 \pm 0.2$  nmol/mg total lipids (TL)], we could only observe a training-evoked slight, but not significant, decrease (30%) in their levels (data not shown).

DAG levels (basal value:  $9.1 \pm 2.5$  nmol/mg TL) remained unchanged after both ET-1 treatment and exercise-training (data not shown).

The variations exhibited by the potential phospholipid (PL) precursors of these second messengers are shown in Table 2. Neither ET-1 treatment nor exercise training produced any significant change in the levels of SPH and choline phosphoglycerides. Exercise training, but not ET-1, significantly decreased the ethanolamine phosphoglyceride level. Further separation of these PL into diacyl and alkenylacyl molecular forms gave the results shown in Figure 2. In sedentary, but not in trained animals, the basal levels of both diacyl (Fig. 2A) and plasmalogen forms (Fig. 2B) were significantly ( $P < 0.05$ ) modified by ET-1 treatment in a specific manner, since the peptide evoked a significant decrease (37%) in the level of diacyl forms and a large increase (145%) in the plasmalogen content.

**FIG. 1.** Effects of exercise training and *in vitro* endothelin-1 (ET-1) treatment on aortic ceramide levels. Data are represented as means  $\pm$  SD ( $n = 8$ ). <sup>a</sup>Significantly different from the sedentary control group at the level of  $P < 0.05$ . TL, total lipids.

<sup>b</sup>Significantly different from the sedentary control group at the level of  $P < 0.05$ .

<sup>c</sup>Significantly different from the ET-1-treated aortic strips from the sedentary group ( $P < 0.05$ ). SPH, sphingomyelin.

In the sedentary control group the plasmalogen fraction (mean value, 0.78 nmol/mg TL, Fig. 2B) made up 9% of the total ethanolamine phosphoglycerides, whereas in the trained control group this percentage was 38% (mean value of plasmalogens, 1.54 nmol/mg TL, Fig. 2B), which represents a fourfold increase. Obviously, an exercise-elicited decrease was found in the content of diacyl molecular forms, the difference being much less noticeable (91% in the control of sedentary group vs. 62% in the control of the trained group).

Figure 3 shows that ET-1 never altered the CH level and the CH/total PL molar ratio. However, aortas from trained rats

showed a significant decrease (70% under the value observed in their sedentary counterparts) in both the CH level and the CH/total PL ratio.

Previous evidence of a potential role for ceramide monohexosides in the ET-1 molecular mechanism of action (5) and in the vascular physiology (27) prompted us to evaluate potential alterations in their levels. The aortic ceramide monohexoside fraction was found to co-migrate with the glucocerebroside standard, as previously described for aortic glycosphingolipids (39). In sedentary animals, but not in trained ones, ET-1 treatment induced a slight, but not significant, increase in the ceramide monohexoside levels (Fig. 4). However, there were significantly higher ceramide monohexoside levels in aortas from trained rats compared with those of their sedentary counterparts.

**Cerebral cortex and cerebellum response to ET-1 treatment and exercise training.** Two different molecular species of ceramide were found in cerebral cortex and cerebellum as we detected in aorta. Neither ET-1 treatment nor exercise training modified ceramide levels in cerebral cortex (Table 3). In contrast, in the cerebellum, ET-1 treatment increased ( $P < 0.05$ ) the level of the ceramide species that runs more slowly in the chromatography (Fig. 5A), which was more noticeable in sedentary rats than in trained ones, i.e., 300 and 78% over their respective control value. The other ceramide species were not significantly altered by ET-1 treatment (Fig. 5B). Exercise training was found to enhance the levels of both ceramide species, 400 and 87% over their sedentary counterparts (Figs. 5 A and B, respectively).

**FIG. 4.** Exercise training-induced alterations in aorta ceramide monohexoside levels. Effect of *in vitro* ET-1 treatment. Data are represented as means  $\pm$  SD ( $n = 8$ ). <sup>a</sup>Significantly different from the sedentary control group ( $P < 0.05$ ). <sup>b</sup>Significantly different from the ET-1 treated aortas from the sedentary group ( $P < 0.05$ ). For abbreviations see Figure 1.

DAG levels in cerebral cortex (Table 3) and cerebellum (basal value:  $90.5 \pm 38$  nmol/mg TL, data not shown) were not significantly altered by ET-1 treatment or exercise training.

Tables 4 and 5 show that no significant changes were observed in the levels of cerebral cortex and cerebellum PL in response to either ET-1 treatment or exercise training except for a decrease in the cerebral cortex SPH content of sedentary animals following ET-1 treatment (53% under control value).

Table 6 shows that ET-1 evoked a decrease in the CH content (30% under control value) in cerebral cortex from trained rats, whereas in sedentary animals the peptide produced no effects. In cerebellum, the sensitivity to the ET-1 lowering effect of the CH levels was reversed, i.e., it was observed in sedentary rats, but not in trained animals. Exercise training did not give rise to any difference.

The ceramide monohexoside fraction from cerebral cortex migrated as a doublet and co-migrated with glucocerebroside standard, whereas that from cerebellum migrated slightly more slowly and showed some degree of overlapping with the galactocerebroside standard. Since cerebral cortex is not a myelinated region and shows a poor synthesis of galactocerebroside, it is likely that this lipid fraction is mainly glucosylceramide. In contrast, in the fraction from cerebellum both glucosyl and galactosylceramide are present. Figure 6 shows that levels of ceramide monohexosides in cerebral cortex (6A) and cerebellum (6B) were not modified by ET-1 treat-

duced by exercise training. This physiological condition has been described as producing beneficial adaptive changes in the cardiovascular (17–19) and nervous systems (20–23) and altering the endogenous level of ET-1 (13). In experiments where vascular tissue was studied, intact aortic strips were chosen, and when nervous system was analyzed, slices of cerebral cortex (the brain area influenced by afferent systems from working muscle and emotional processes) and cerebellum (the brain area involved in the motor processes) were used.

The training program employed in this study can be regarded as a moderate stimulus for normal rodent standards. The 6-mon training period caused a reduction in the body weight of the rats and produced an increase in exercise tolerance associated with an enhanced oxidative capacity of skeletal muscle. We selected the present conditions of treadmill

training for the following reasons. First, we previously showed that a steady-state or constant-speed protocol of the same intensity as that used in this work is more effective in enhancing exercise endurance capacity and skeletal muscle citrate synthase activity than other programs consisting of either a constant higher speed (30 m·min<sup>-1</sup>) or high-speed interval running (38). Second, it has been reported that a treadmill for rats running at 21.4 m·min<sup>-1</sup> results in a significant redistribution of tissue blood flow whereby it is greatly increased in the working muscles (40). Moreover, active muscle showed gradual increases in blood flow that were linearly related to time from 5 to 54 min of low-intensity treadmill exercise. Furthermore, ET-1 levels have been shown to increase in plasma of rats immediately after 45 min of treadmill exercise at 25 m·min<sup>-1</sup> (13). Therefore, we reasoned that chronic exposure to sessions of treadmill exercise under the conditions selected for this study (i.e., 25 m·min<sup>-1</sup> exercise intensity and 45 or 60 min duration of the sessions), would be expected not only to induce adaptations that enhance muscle perfusion, flow capacity, and oxidative metabolism but also to modify tissue responsiveness to ET-1 because the exercise sessions should have produced transient and repetitive increases in endogenous levels of the peptide in our rats. Finally, we chose a prolonged training period of 6 mon to allow for the possibility that some adaptive events require longer periods than those necessary to induce skeletal muscle adaptations (38,41).

To our knowledge, this is the first time that the aorta ceramide pattern has been described. ET-1 treatment did not elicit any significant changes in the levels of both ceramide fractions. However, we did detect a decrease in the overall ceramide level due to exercise training without significant alteration in the SPH content. Since there are conflicting results regarding the exact role of the cellular pools of SPH in

ceramide-mediated signaling (42), the possibility of the involvement of a minor pool of SPH remains open. In addition, the possibility of an accelerated glycosphingolipid biosynthesis from ceramides (as discussed below) induced by training cannot be discarded.

Evidence about the physiopathological role of vascular ceramide is controversial. Ceramide has been described to exert a vasodilatory action in *in vitro* systems (3,43). In contrast, several studies indicate that SPHase activity and ceramide-mediated cell signaling are somehow involved in the atherogenic process (3,27,28). If an increase of vascular ceramide production is a risk factor for the induction of apoptosis, the exercise-induced decrease in aortic ceramide levels reported here is consistent with the idea that exercise may protect against cardiovascular diseases. In fact, the apparent protective effect of adequate Mg<sup>2+</sup> intake on vascular function may be related to a decrease of ceramide levels in aorta smooth muscle cells (44).

The role of diacyl molecular forms of choline and ethanolamine phosphoglycerides as second messenger sources is well established. In this regard the involvement of different phospholipases in the transduction mechanism of ET-1 in aorta is well known (45). In the present experimental conditions, only ethanolamine phosphoglycerides were found to exhibit variations as a consequence of training. The alterations observed might be the result of an enhancement of their hydrolysis by a phospholipase A<sub>2</sub>, since DAG levels were unmodified.

In recent years the alkenyl-acyl molecular forms (plasmalogens) have been described to have a potential role in signal transduction systems (46,47). Thus, several plasmalogen-hydrolyzing phospholipases A<sub>2</sub> from different sources have been described to be regulated by several agonists (48,49). However, our data do not allow elucidation of the molecular mech-

anism(s) responsible for the increase of aortic PlasEtn levels induced by both ET-1 treatment and exercise training. It is interesting to point out that plasmalogens are uniquely susceptible to oxidation and have a protective role against oxidative damage within cellular membranes (25). In this respect, it has been suggested that an increase in the overall vinyl ether linkage per acyl chain in lipid extracts from cerebrovascular smooth muscle may represent a possible compensatory mechanism against lipid oxidation (50). On the contrary, aging is associated with a decline in the PlasEtn content of aortas that is more pronounced in atherogenic than in normal vessels (25). Thus, the increasing effect of exercise training on aorta PlasEtn levels observed in this work may account, at least in part, for the well-known beneficial effects of exercise on the cardiovascular system. In support of this idea, exercise has been shown to attenuate the increase in blood pressure and to reduce the lipid peroxidation in aorta of fructose-fed rats (51).

CH on its own can alter arterial smooth muscle, as indicated by observations demonstrating a correlation between CH enrichment and augmented membrane calcium permeability as well as with vasoconstrictory activity (52). Furthermore, arterial smooth muscle had increased CH levels and a high CH/total PL ratio during atherogenesis (26). In addition, antioxidant treatment has been reported to reduce the aorta CH concentration in hypercholesterolemic rabbits (53). In the present study, we did not observe any differences in the aorta CH content due to ET-1 treatment. However, a noticeable and expected reduction of CH levels induced by exercise training was found. This is another finding consistent with the hypothesis that exercise training reduces the risk of cardiovascular diseases.

The biosynthesis of complex glycosphingolipid, one of the metabolic fates of ceramides, begins with the sequential transfer of a glucose residue forming glucosylceramide followed by the addition of galactose, resulting in the synthesis of lactosylceramide. This latter step is particularly relevant in vascular metabolism. Thus, lactosylceramide has been reported to be more prevalent in atherosclerotic aorta and to induce proliferation of aortic smooth muscle cells through superoxide generation (27). Furthermore, oxidized LDL stimulate endogenous synthesis of lactosylceramide from glucosylceramide (27). In addition, a coordinated regulation of lactosylceramide and CH synthesis by LDL has been postulated (27). In this study we found that exercise evokes a notable increase in glucosylceramide levels, suggesting a deviation of ceramides toward glucosylceramide formation (see previous discussion) and/or a reduced lactosylceramide formation. This and the CH lowering effect of exercise demonstrated here constitute further evidence of the protective effect of exercise against vascular disease. The fact that ET-1 seems to evoke a slight increase in glucosylceramide levels in the sedentary group, but not in the exercised animals, supports the notion that exercise training reduces sensitivity to ET-1 action. This observation is probably related to the down-regulation and/or altered expression of ET-1 receptors secondary to the increased endogenous generation of ET-1 as it occurs during exercise (13). Accordingly, the contractile re-

sponse of coronary arteries to ET-1 is attenuated in trained animals (54,55), a fact that has been hypothesized to be the result of an altered coupling between ET-1 receptors and second messenger (phosphatidic acid) production (54).

It is interesting to note that in sedentary animals, *in vitro* ET-1 treatment elicited a small increase of aortic basal levels of glucosylceramide and a marked enhancement of those of PlasEtn, suggesting that the peptide may function as a vasoprotective agent. This potential beneficial action of ET-1 might be consistent with previous observations of vasodilatory responses to the peptide (11) and reinforces the view of the complex regulation of the vascular function by ET-1. Nevertheless, cautions must be taken when data obtained *in vitro* are extrapolated to physiopathological states. First, since the aorta ring is not in its normal biochemical environment, the response to ET-1 observed *in vitro* might somehow differ from that occurring in physiological conditions. In fact, changes in the vascular sensitivity to ET-1 are known to occur when experimental conditions are altered (56). Second, the concentration of ET-1 used ( $10^{-7}$  M) is higher than the physiological one (13); nevertheless, it is difficult to know the exact amount of the peptide that reaches discrete aorta regions since it is released in an autocrine/paracrine fashion.

Comparative analysis of the present and previous results (5) shows that the response to ET-1 within the nervous system is tissue-specifically altered with age. Thus, in sedentary adult rats, ET-1 scarcely modified the levels of sphingolipids in the cerebral cortex. In contrast, in cerebral cortex from young animals, ET-1 increased both SPHase activity and ceramide monohexoside synthesis (5). In cerebellum, ET-1 evoked an increase in the level of ceramide in adult as well as in young rats. In addition, the cerebellum response to ET-1 observed in trained animals was less noticeable than that observed in the cerebellum of their sedentary counterparts. The biochemical significance of this finding in the context of cerebellum physiology is not yet known.

As observed in aorta, exercise training induces an increase in the net levels of ceramide monohexosides in the nervous system. It has been reported that glucosylceramide synthesis is a means through which neuroepithelioma cells attempt to escape from apoptosis (57). Therefore, it is likely that the increased content of these sphingolipids (probably glucosylceramide) in the nervous system has a beneficial significance, as it occurs in the vascular tissue (27). It is clear that ceramide monohexoside levels are somehow involved in the response to exercise training.

Information exists concerning the endurance exercise-induced actions on the brain. Exercise training increases brain resistance to the damage and neurodegeneration that occurs with age (23), reduces lipid peroxidation by increasing brain antioxidant capacity (20), and enhances the velocity of the fast axonal transport of proteins and the quantity transported (58). As stated above, there is good evidence that PlasEtn are effective as ubiquitous endogenous antioxidants (25). In addition, PlasEtn are known to decline in neuronal tissues of patients with Alzheimer's disease and with age (25). In fact,

when the basal levels of PlasEtn in young animals (4) are compared with those presently observed in adult animals, a decrease of about 30% in the net content of cerebral PlasEtn with age is noted. On the other hand, the enhanced vulnerability to oxidative stress associated with aging is, at least in part, the result of higher levels of CH in brain tissue (59). However, our results demonstrate that neither PlasEtn nor CH levels from the nervous system underwent changes in response to exercise training, which is in contrast with that observed in aorta. Thus, the tissue specificity of the putative antioxidant role of the PlasEtn and CH systems appears to emerge from the present study.

Two major conclusions emerge from the present work: (i) exercise training induces tissue-specific changes in the lipid profile, the vascular tissue being much more sensitive than the nervous system is, and (ii) the sensitivity to ET-1 treatment is lower in tissues from trained animals in comparison with their sedentary counterparts. These responses likely result in a greater resistance to oxidative stress, and they may be related to adaptive mechanisms to the previously reported increase in the endogenous level of ET-1 induced by exercise (13). It must be remembered that these changes represent a response induced by an endurance exercise training that is very prolonged for the mean life span of rats, and it is not known whether the same effects would be produced by shorter training programs. In any case, our data may help to elucidate the molecular basis of the beneficial effects elicited by physical exercise in both vascular and nervous systems.

# Selective Effect of Cholesterylphosphoserine on Intracellular Cholesterol Transport

F. Cusinato and A. Bruni\*

Department of Pharmacology and Anesthesiology, University of Padova, 35131 Padova, Italy

**ABSTRACT:** Cholesteryl-3 $\beta$ -phosphoserine (CPHS) is a synthetic steroid affecting intracellular cholesterol transport. To compare CPHS with the well-known inhibitors progesterone and U18666A, we examined cholesterol transport in three human cell lines: the monocytic U-937, the endothelial ECV-304, and the lymphoid Jurkat. Under low density lipoprotein (LDL) loading, CPHS inhibited cholesterol esterification in U-937 and ECV-304 cells but not in Jurkat cells. In contrast, CPHS inhibited the mobilization of plasma membrane cholesterol induced by 25-hydroxycholesterol, brefeldin A, or sphingomyelinase in all cell lines. In cells pulse-labeled with [<sup>3</sup>H]cholesterol, CPHS decreased incorporation of cholesterol and inhibited its esterification. In prelabeled cells, CPHS promoted cholesterol efflux and enhanced the cyclodextrin-mediated removal of plasma membrane cholesterol. CPHS did not affect endogenous cholesterol synthesis nor acyl-coenzyme A:cholesterol acyltransferase activity. These data suggest that, unlike progesterone and U18666A, CPHS inhibits intracellular cholesterol transport by specifically affecting the movements of cholesterol in the plasma membrane. Owing to this restricted site of action, CPHS may help to clarify the role of the plasma membrane in cholesterol trafficking. For example, the lack of an effect of CPHS on the esterification of LDL-derived cholesterol in Jurkat cells suggests that most of the LDL-derived cholesterol in these cells is directly delivered to the endoplasmic reticulum without cycling through the plasma membrane.

Paper no. L8829 in *Lipids* 37, 53–59 (January 2002).

In eukaryotic cells, cholesterol is required for the proper functioning of plasma membranes. Together with the barrier function, cholesterol regulates the activity of membrane-bound transporters, ion channels, signaling molecules, and transport vesicles (1–3). To fulfill this function, a continuous flow of cholesterol to the plasma membrane is provided by endogenous synthesis and lipoprotein uptake. Back transport to the endoplasmic reticulum followed by esterification and an efficient system of efflux maintain cholesterol homeostasis. Certain steroids are known to influence intracellular cholesterol trafficking. For example, the role of progesterone and 3 $\beta$ -[2-(diethylamino)ethoxy]androst-5-en-17-one (U18666A) in the accumulation of low density lipoprotein (LDL)-derived cho-

lesterol in late endosomes and lysosomes, thus reproducing the phenotype of Niemann–Pick disease (4–6), has been well characterized. In addition, these steroids inhibit endogenous cholesterol synthesis (7,8). We have recently shown that a synthetic cholesteryl ester, cholesteryl-3 $\beta$ -phosphoserine (CPHS), inhibits the transport of plasma membrane cholesterol to the endoplasmic reticulum in the Jurkat lymphoid cell line (9). This observation prompted the present study aimed at establishing whether the mechanism of action of CPHS is different from that of progesterone and U18666A. Unlike the neutral progesterone and the basic U18666A, which may cross the plasma membrane, CPHS is acidic owing to the presence of a phosphoserine polar group, negatively charged at physiological pH. As has been known for many years (10), negatively charged amphiphiles may become arrested in the plasma membrane as they are repelled by the negatively charged lipids of the cytoplasmic leaflet. In agreement with this, by following the binding of fluorescent annexin V to the phosphoserine group of CPHS, we have shown that this steroid accumulates in the plasma membrane without penetrating inside the cells (9). This might indicate that the site of action of CPHS is different from that of progesterone and U18666A. Such a result would be interesting because the availability of inhibitors acting in different ways is of help in clarifying complex biological sequences such as intracellular cholesterol transport. A controversial aspect of cholesterol trafficking is the proportion of LDL-derived cholesterol that can be transported from lysosomes to the endoplasmic reticulum without cycling through the plasma membrane. This proportion might differ in the various populations of mammalian cells. To test the applicability of CPHS in the investigation of this question, we followed the intracellular cholesterol transport in three cell lines—the lymphoid Jurkat, the monocytic U-937, and the endothelial ECV-304. We selected these cells because they were previously shown to be CPHS-sensitive (9). In addition, they might be of interest as models of the cell populations involved in the formation of atherosclerotic plaque (11). Cholesterol transport was tested by the addition of LDL to cells previously incubated in the absence of lipoproteins to increase the expression of LDL receptor. The plasma membrane  $\rightarrow$  endoplasmic reticulum segment of this transport was examined in the absence of lipoproteins by the addition of cholesterol in the incubation medium (12) or by the use of agents known to mobilize plasma membrane cholesterol. In agreement with our hypothesis, the data show that CPHS affects intracellular cholesterol trafficking only when the trans-

Abbreviations: 25-OH, 25-hydroxycholesterol; ACAT, acyl-coenzyme A:cholesterol acyltransferase; BSA, bovine serum albumin; CPHS, cholesterylphosphoserine; cyclodextrin, hydroxypropyl- $\beta$ -cyclodextrin; LDL, low density lipoprotein; U18666A, 3 $\beta$ -[2-(diethylamino)ethoxy]androst-5-en-17-one.

port pathway involves the plasma membrane. In contrast, the role of progesterone and U18666A extends to inhibition of the intracellular steps of cholesterol synthesis and transport.

## MATERIALS AND METHODS

**Reagents.** The sodium salt of cholesteryl-3 $\beta$ -phospho-L-serine (a generous gift of Dr. G. Kirschner, Fidia Research Laboratories, Abano Terme, Padova, Italy) was dispersed at 1 mg/mL in 50% ethanol containing 5 mM Tris-HCl, pH 7.8, and briefly warmed at 50°C to obtain a clear solution which could be stored at 4°C for a week. The final CPHS concentration was verified by phosphorus determination. Progesterone and 25-hydroxycholesterol were obtained from Sigma (St. Louis, MO), and U18666A was obtained from Biomol (Plymouth Meeting, PA). These steroids were dissolved in ethanol. The influence of equivalent concentrations of ethanol in our tests was routinely checked. Low-density lipoproteins were prepared from human plasma, supplemented with 1 mM EDTA, by preparative ultracentrifugation ( $d$  1.019–1.063 g/mL). 25-Hydroxycholesteryl linoleate and squalene epoxides were prepared as described in References 13 and 14, respectively. Hydroxypropyl- $\beta$ -cyclodextrin (cyclodextrin) and other chemicals of reagent grade were from Sigma.

**Cell cultures.** The human cell lines used in this study were obtained from the Istituto Zooprofilattico Sperimentale della Lombardia e dell'Emilia, Brescia, Italy. The T cell line Jurkat and a strain of the monocytic cell line U-937 with a normal cholesterol metabolism (15) were used as cell suspensions maintained in RPMI 1640 medium. Adherent cultures of ECV-304 endothelial cells were maintained in M199 medium and applied as a monolayer in six-well plates. At confluence, each well contained  $400 \pm 55$   $\mu$ g of cell proteins, corresponding to  $7 \times 10^5$  cells. All media were supplemented with 10% (vol/vol) fetal calf serum (Poesys; PAA Laboratories GmbH, Linz, Austria), 2 mM L-glutamine, and antibiotics. To exclude the possibility of CPHS-induced cytotoxicity, the release of accumulated [ $^3$ H]adenine was measured (16). The spontaneous release was not changed by 10  $\mu$ M CPHS, whereas it was increased up to 7% by 20  $\mu$ M CPHS. As a cautionary limit, 10  $\mu$ M was selected as the maximal concentration to be used.

**Esterification of LDL-derived cholesterol.** To enhance LDL internalization, the cells were previously incubated in serum-free media supplemented with 5 mg/mL of bovine serum albumin (BSA) and 10  $\mu$ g/mL of transferrin. The preincubation was 48 h with the Jurkat cells and 24 h with the other cells. Jurkat and U-937 cells ( $5 \times 10^6$ ) were suspended in 1 mL of RPMI 1640 medium. Confluent monolayers of ECV-304 were incubated in 3 mL of M199. All cell cultures, supplemented with 5 mg/mL of BSA, were incubated for 4 h at 37°C in the presence of 25–50  $\mu$ g of LDL proteins. The inhibitory steroids and 5  $\mu$ Ci of [ $^3$ H]oleate (prepared at pH 7.4 in Tris buffer free of divalent cations but containing 1 mg/mL of BSA) were then added, and the incubation was continued for an additional 2–3 h. 25-Hydroxycholesterol (2.5  $\mu$ M) was

added together with the [ $^3$ H]oleate to the cultures of U-937 and ECV-304 cells. After the incubation, the cells were washed, and the lipids extracted as detailed below.

**Esterification of plasma membrane cholesterol.** Jurkat and U-937 cells ( $5 \times 10^6$ ) suspended in 1 mL of RPMI 1640 medium or confluent monolayers of ECV-304 cells in 3 mL of M199 were incubated for 2–3 h at 37°C with 5 mg/mL of BSA and 5  $\mu$ Ci of [ $^3$ H]oleate. To mobilize the plasma membrane cholesterol, cells were preincubated for 30 min with 5  $\mu$ M brefeldin A or 0.12 U of sphingomyelinase from *Bacillus cereus*. Alternatively, 2.5  $\mu$ M of 25-hydroxycholesterol was added together with the [ $^3$ H]oleate. The transport of plasma membrane cholesterol to the endoplasmic reticulum was specifically tested by measuring the incorporation and the esterification of [ $^3$ H]cholesterol in Jurkat and U-937 cells (12). Cells ( $5 \times 10^6$ ) resuspended in 1 mL of RPMI 1640 medium containing 1 mg/mL of BSA were incubated for 45 min at 37°C in the presence of 2  $\mu$ Ci of [ $^3$ H]cholesterol added in 5  $\mu$ L of ethanol. Lipids were extracted from washed cells and resolved by thin-layer chromatography.

**Extraction of plasma membrane cholesterol with cyclodextrin (17).** Suspensions of Jurkat cells ( $5 \times 10^6$ /mL of RPMI 1640 medium containing 1 mg/mL of BSA) were incubated for 15 min at room temperature with 2  $\mu$ Ci/mL of [ $^3$ H]cholesterol added in ethanol (5  $\mu$ L/mL). After centrifugation, the cells were washed twice in RPMI/BSA and resuspended in the same medium in aliquots of  $5 \times 10^6$  cells/mL. One aliquot was supplemented with cyclodextrin (2% wt/vol) and incubated for 10 min at 37°C with continuous shaking. After centrifugation, the radioactivity was measured in the supernatant and in the sediment. The other aliquots were incubated at 37°C with or without 10  $\mu$ M CPHS for the times indicated in Figure 4. After centrifugation, the supernatants were saved for the determination of CPHS-induced cholesterol efflux, and the sediments were extracted with cyclodextrin as described above. The cholesterol remaining in the final sediment after the action of cyclodextrin was extracted with chloroform/methanol to quantify the esterified fraction.

**Lipid extraction.** At the end of the above incubations, Jurkat and U-937 cells were washed, resuspended in 0.1 mL of 0.15 M NaCl, and extracted with 20 vol of chloroform/methanol (2:1, vol/vol). The lipid extract, washed twice with 0.2 vol of 0.1 M HCl, was taken to dryness and resolved with the appropriate standards in a monodimensional thin-layer chromatography system using petroleum ether/diethylether/acetic acid (90:10:1, by vol). In cases in which 25-hydroxycholesterol had been added to the cell cultures, the thin-layer plates were developed in hexane/ethyl acetate (85:15, vol/vol) to resolve the cholesteryl esters and the esters of 25-hydroxycholesterol (18). Lipid spots were visualized with iodine, scraped, and quantified by scintillation counting. The adherent ECV-304 cells were washed and detached with isopropyl alcohol (19). After transfer to glass tubes, an equal volume of petroleum ether was added to the cell suspension. The lipid extract was filtered, taken to dryness, and applied to the thin-layer chromatographic plates.

**Synthesis of cholesterol.** Cells were depleted of lipoproteins by incubation for 24 h in serum-free medium containing 5 mg/mL of BSA and 10  $\mu$ g/mL of transferrin. The cells were then incubated for 3 h at 37°C in serum-free medium containing 5 mg/mL of BSA and 10  $\mu$ Ci of [<sup>3</sup>H]acetate. After washing, the cells were collected in 0.5 mL of 0.1 M NaOH and incubated for 30 min at 37°C. A 0.5-mL volume of 1 M KOH in methanol was then added, and the samples were saponified for 1 h at 55°C. The nonsaponifiable lipids were extracted with petroleum ether and resolved by thin-layer chromatography in hexane/ethyl acetate (85:15, vol/vol). Standards of cholesterol, lanosterol, squalene, and squalene epoxides demonstrated a clear separation of these components. Desmosterol, a major final product of sterol metabolism in nonhepatic cells (20), comigrated with cholesterol.

**Subcellular acyl-coenzyme A:cholesterol acyltransferase (ACAT) activity.** Jurkat cells ( $5 \times 10^7$ ) were lysed by freezing and thawing, homogenized, and centrifuged for 10 min at 800  $\times g$  in the cold. Aliquots of the supernatant (100  $\mu$ g of protein) were mixed with 1  $\mu$ Ci of [<sup>3</sup>H]cholesterol dissolved in ethanol (1% final concentration). After 20 min at 37°C, 24  $\mu$ M of oleoyl-coenzyme A was added, and the incubation was continued for an additional 45 min at 37°C (18).

## RESULTS

After a preincubation in a lipoprotein-free medium, Jurkat cells became very active in the uptake of LDL-cholesterol, as revealed by its esterification (Fig. 1A). The LDL-induced stimulation of cholesterol esterification was detected in all experiments, although to a variable extent (mean value of  $21 \pm 14$

times the unstimulated value in 20 experiments). The inhibitory effect of CPHS was marginal and not significant ( $20.7 \pm 16\%$  in 11 experiments). In contrast, the inhibition by U18666A and progesterone was reproducible and significant (mean values of  $76.8 \pm 8.8\%$  and  $65.4 \pm 7.2\%$ , respectively).

Unlike the Jurkat cells, U-937 and ECV-304 cells showed LDL-stimulated cholesterol esterification only upon the addition of 25-hydroxycholesterol, a sterol inducing the mobilization of plasma membrane cholesterol (Fig. 1, B and C). As suggested for macrophages (21), this may reflect the large proportion of LDL-cholesterol transported to the plasma membrane in these cells and the high capacity of their plasma membranes to accommodate the newly transported cholesterol. Under this condition, LDL caused a similar stimulation of cholesterol esterification in U-937 and ECV-304 cells (a mean of  $2.9 \pm 0.9$  times the value obtained with 25-hydroxycholesterol alone in eight experiments). The LDL-induced stimulation was abolished by CPHS. Separate experiments showed that progesterone and U18666A were similarly active (data not shown).

The transport of cholesterol from the plasma membrane to the endoplasmic reticulum in the absence of LDL was studied by the addition of reagents inducing the mobilization of plasma membrane cholesterol. To this end, cells were preincubated with brefeldin A, sphingomyelinase, or 25-hydroxycholesterol. As shown in Figure 2 for U-937 cells, brefeldin A and sphingomyelinase stimulated the esterification of plasma membrane cholesterol severalfold, and their effect was inhibited by both CPHS and progesterone. U18666A was not tested in these experiments. The best results with 25-hydroxycholesterol were obtained in Jurkat cells, in which

**FIG. 1.** Esterification of low density lipoprotein (LDL)-derived cholesterol. Suspensions of Jurkat (A) and of U-937 cells (B) or monolayers of ECV-304 cells (C) were incubated for 4 h at 37°C with 25–50  $\mu$ g of LDL proteins. Inhibitory steroids and 5  $\mu$ Ci of [<sup>3</sup>H]oleate were then added, and the incubation was continued for an additional 2–3 h. 25-Hydroxycholesterol (2.5  $\mu$ M) was added together with the [<sup>3</sup>H]oleate in U-937 and ECV-304 cells. 1, Without LDL; 2, LDL; 3, LDL, 10  $\mu$ M cholesteryl-3 $\beta$ -phosphoserine (CPHS); 4, LDL, 2.5  $\mu$ M U18666A; 5, LDL, 10  $\mu$ M progesterone. Data are means  $\pm$  SEM from 11 (A) and six experiments (B,C). \* $P < 0.01$ .

**FIG. 2.** Esterification of plasma membrane cholesterol, mobilized by brefeldin A or sphingomyelinase. U-937 cells were incubated for 30 min at 37°C with 5  $\mu$ M brefeldin A (A) or 0.12 U/mL of bacterial sphingomyelinase (B). Inhibitory steroids and 5  $\mu$ Ci of [<sup>3</sup>H]oleate were then added, and the incubation was continued for an additional 2 h. 1, Cells not treated with brefeldin A or sphingomyelinase; 2, treated cells; 3, treated cells, 10  $\mu$ M CPHS; 4, treated cells, 10  $\mu$ M progesterone. Data are means  $\pm$  SEM from four or five experiments. \* $P < 0.05$ . See Figure 1 for abbreviation.

the stimulation of cholesterol esterification and the esterification of 25-hydroxycholesterol could be simultaneously tested, in accord with previous observations on hepatoma cells (18). CPHS and progesterone produced a significant inhibition of cholesterol esterification (Fig. 3A) and 25-hydroxycholesterol esterification (Fig. 3B), whereas U18666A was essentially without effect under these conditions. To confirm the action of CPHS on the esterification of plasma membrane cholesterol, we examined the esterification of [ $^3\text{H}$ ]cholesterol, added as an ethanolic solution to the incubation medium in Jurkat and U-937 cells. In these experiments, the concentration of ethanol (5  $\mu\text{L}/\text{mL}$  of RPMI 1640 medium) was critical to obtain reproducible results. After the incorporation, the added cholesterol mixed with the plasma membrane pool of cholesterol, and then it was delivered to the endoplasmic reticulum for esterification (12). In Jurkat cells, CPHS caused a dose-dependent inhibition of both cholesterol incorporation and esterification (Table 1). CPHS also decreased the percentage of incorporated cholesterol delivered for esterification, indicating a wide influence on the movements of plasma membrane cholesterol. The action of CPHS was dose-dependent with an  $\text{IC}_{50}$  (concentration at which 50% inhibition occurs) at 3  $\mu\text{M}$ . Progesterone and U18666A inhibited the esterification of cholesterol but did not affect its incorporation. Similar results were obtained in U-937 cells. The inhibition of cholesterol incorporation by CPHS suggested that this steroid might also affect its efflux. To investigate this possibility, we tested the passive cholesterol desorption from the cells, a component of cholesterol efflux (22). Jurkat cells were incubated overnight with [ $^3\text{H}$ ]cholesterol (0.2  $\mu\text{Ci}/10^6$

cells) in RPMI 1640 medium containing 5 mg/mL of BSA and 10  $\mu\text{g}/\text{mL}$  of transferrin. After this treatment, the cells showed  $33,900 \pm 7,600$  cpm/ $10^6$  cells in six experiments. Labeled cells ( $5 \times 10^6/\text{mL}$ ) were then incubated for 15 min at  $37^\circ\text{C}$  in RPMI 1640 medium containing 1 mg/mL of BSA. During this time, the passive desorption of cholesterol was  $2.5 \pm 0.6\%$  of total cpm (mean  $\pm$  SD,  $n = 6$ ). The addition of 10  $\mu\text{M}$  CPHS during the 15 min of incubation increased this value to  $4.4 \pm 1\%$  ( $P < 0.01$ ), whereas 10  $\mu\text{M}$  progesterone or 2.5  $\mu\text{M}$  U18666A was without effect.

To confirm the action of CPHS on the movements of plasma membrane cholesterol, we examined the combined effect of CPHS and cyclodextrin, a reagent that extracts cholesterol from the plasma membrane but not from intracellular sites (23,24). Owing to this property, cyclodextrin has become the agent of choice when it is necessary to monitor the arrival of intracellular cholesterol to the plasma membrane (17,25). Since cyclodextrin is more effective in cells grown in suspension and incubated with continuous shaking (23), our experiments were performed in Jurkat cells, which also yielded the most reproducible results when labeled cholesterol was added to the incubation medium. In Jurkat cells prelabeled with [ $^3\text{H}$ ]cholesterol, cyclodextrin (2% wt/vol) extracted  $67.8 \pm 3.1\%$  ( $n = 5$ ) of the incorporated cholesterol in 10 min (Fig. 4A). CPHS did not alter the effect of cyclodextrin. When 30 min of incubation preceded the addition of cyclodextrin, the fraction of extracted cholesterol decreased, indicating cholesterol migration to sites not accessible to cyclodextrin. This decrease in cyclodextrin efficiency was highly reproducible ( $P < 0.001$ ) and completely prevented by CPHS. CPHS did not change the labeled cholesterol pool remaining in the cell pellet when the preincubation was not performed but inhibited the significant increase ( $P < 0.001$ ) occurring after 30 min of preincubation. The same results were obtained when cells were preincubated for 60 and 120 min before the addition of cyclodextrin (not shown in Fig. 4A). We obtained evidence of cholesterol transfer to sites inaccessible to cyclodextrin by measuring cholesterol esterification inside the cells. In these tests, we found that esterified cholesterol became detectable after 30 min of preincubation, increasing thereafter (Fig. 4B). As expected, CPHS inhibited cholesterol esterification. During cell incubation at  $37^\circ\text{C}$  in the absence of cyclodextrin, the activating effect of CPHS on cholesterol efflux was confirmed (Fig. 4C). The action of CPHS was more manifest in the first 30 min, suggesting an induced desorption of cholesterol located in the external layer of the plasma membrane.

Next, we studied the action of inhibitory steroids on endogenous cholesterol synthesis and on ACAT activity. As reported in Figure 5 for U-937 cells, 3 h of incubation with [ $^3\text{H}$ ]acetate resulted in the labeling of cholesterol plus desmosterol ( $22.3 \pm 6.2\%$  of total cpm,  $n = 9$ ). CPHS and progesterone did not cause significant effects, whereas U18666A inhibited endogenous cholesterol synthesis by  $81.1 \pm 7.6\%$  (Fig. 5C). Progesterone caused the accumulation of lanosterol (Fig. 5B), reducing the cholesterol/lanosterol ratio from  $7.4 \pm 4.2$  to  $2.5 \pm 1.2$  (inhibition of  $64.6 \pm 10.2\%$ ,  $P < 0.05$ ). U18666A caused the accumulation of squalene epoxides (Fig. 5A) and inhibited the label-

**FIG. 3.** Esterification of plasma membrane cholesterol activated by 25-hydroxycholesterol (25-OH). Jurkat cells were incubated for 2 h at  $37^\circ\text{C}$  in RPMI 1640 medium with 5 mg/mL of bovine serum albumin (BSA), 2.5  $\mu\text{M}$  25-OH, and 5  $\mu\text{Ci}$  of [ $^3\text{H}$ ]oleate. Esters of cholesterol (A) or of 25-OH (B) were extracted and resolved by thin-layer chromatography. 1, Without 25-OH; 2, 25-OH; 3, 25-OH, 10  $\mu\text{M}$  CPHS; 4, 25-OH, 10  $\mu\text{M}$  progesterone; 5, 25-OH, 2.5  $\mu\text{M}$  U18666A. Data are means  $\pm$  SEM from five experiments. \* $P < 0.01$ . See Figure 1 for abbreviation.

**TABLE 1**  
**Cholesterol Incorporation and Esterification in Jurkat Cells<sup>a</sup>**

Added steroid	cpm/10 <sup>6</sup> cells × 10 <sup>-3</sup>		CE × 100 CE + FC
	CE	FC	
None	1.08 ± 0.10	56.1 ± 5.8	1.89 ± 0.05
2.5 μM CPHS <sup>b</sup>	0.63 ± 0.11 (40 ± 9%) <sup>c</sup>	44.9 ± 2.0 (15 ± 8%)	1.37 ± 0.21 (28 ± 6%) <sup>c</sup>
5 μM CPHS	0.41 ± 0.05 (59 ± 7%) <sup>d</sup>	37.8 ± 3.2 (27 ± 10%) <sup>c</sup>	1.05 ± 0.10 (45 ± 4%) <sup>d</sup>
10 μM CPHS	0.31 ± 0.04 (69 ± 6%) <sup>d</sup>	32.2 ± 3.2 (39 ± 10%) <sup>d</sup>	0.94 ± 0.06 (50 ± 2%) <sup>d</sup>
10 μM Progesterone	0.48 ± 0.06 (52 ± 9%) <sup>d</sup>	48.4 ± 2.8 (18 ± 10%)	0.96 ± 0.07 (49 ± 3%) <sup>d</sup>
2.5 μM U18666A	0.55 ± 0.09 (46 ± 10%) <sup>d</sup>	52.0 ± 3.9 (14 ± 8%)	1.03 ± 0.12 (46 ± 5%) <sup>d</sup>

<sup>a</sup>Jurkat cells (5 × 10<sup>6</sup>) were incubated for 45 min at 37°C in 1 mL of RPM 1640 medium containing 1 mg of bovine serum albumin, 2 μCi of [<sup>3</sup>H]cholesterol (added in 5 μL of ethanol), and the added steroid indicated. After lipid extraction, cholesteryl esters (CE) and free cholesterol (FC) were separated by thin-layer chromatography. Data are means ± SEM from 4–5 experiments (percent inhibition in parenthesis).

<sup>b</sup>CPHS, cholesteryl-3β-phosphoserine.

<sup>c</sup>P < 0.05.

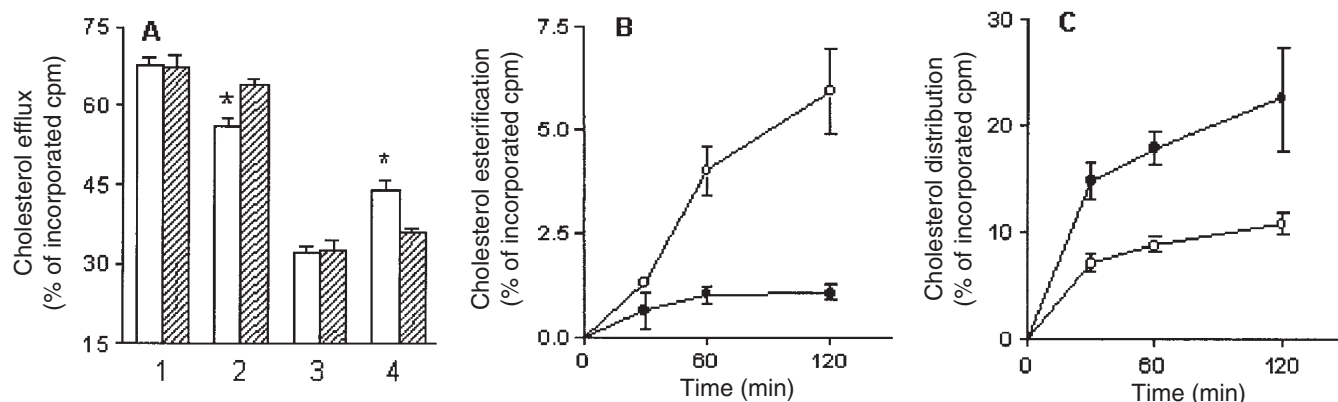

<sup>d</sup>P < 0.01.

ing of lanosterol by 74 ± 19% (Fig. 5B). CPHS did not alter the labeling of cholesterol precursors. Similar results were obtained with ECV-304 cells. In Jurkat cells, after 3 h of incubation with [<sup>3</sup>H]acetate, the label was mainly distributed in lanosterol (65.6 ± 8.1%, *n* = 3). Cholesterol/desmosterol took up 4.2 ± 2% of the label. Slow conversion of lanosterol to cholesterol was also observed in human lymphocytes (26). A clear precursor–product relationship between lanosterol and cholesterol in these cells was reached after 6 h of incubation. The high extent of labeling of lanosterol in Jurkat cells was inhibited by U18666A (inhibition of 91.2 ± 1% in three experiments, *P* < 0.01). CPHS and progesterone were without effect.

ACAT activity was tested in homogenates of Jurkat cells labeled with [<sup>3</sup>H]cholesterol. After 30 min of incubation of 1 μCi of [<sup>3</sup>H]cholesterol and 100 μg of protein with 25 μM oleoyl-coenzyme A, 1.15 ± 0.23% of cpm was recovered in cholesteryl esters (*n* = 5). The presence of 10 μM of CPHS, 10 μM progesterone, or 2.5 μM U18666A did not cause a significant change in this value.

## DISCUSSION

The results of this study show a clear difference between the newly introduced CPHS and the well-known progesterone and U18666A in the inhibition of intracellular cholesterol transport. As demonstrated by several previous studies in other cells, we confirmed with the lymphoid Jurkat, the monocytic U-937, and the endothelial ECV-304 that progesterone and U18666A inhibit the two main routes of the intracellular transport of LDL-derived cholesterol, namely, the direct route from lysosomes to the endoplasmic reticulum and the indirect route in which cholesterol is first transported from lysosomes to the plasma membrane and then from this site to the endoplasmic reticulum (4,5,19,27). Other effects of progesterone and U18666A confirmed in the present study include their inhibition of endogenous cholesterol synthesis. Progesterone influences the terminal steps of cholesterol synthesis, causing accumulation of lanosterol (7), whereas U18666A inhibits 2,3-oxidosqualene cyclase with subsequent accumulation of oxidized products of squalene and inhibition of lanos-

**FIG. 4.** Synergism between CPHS and cyclodextrin (CD). Aliquots of 5 × 10<sup>6</sup> Jurkat cells prelabeled with [<sup>3</sup>H]cholesterol (580 ± 110 cpm × 10<sup>-3</sup>) were either extracted with 2% CD in the presence or absence of 10 μM CPHS or preincubated at 37°C with or without CPHS before the extraction with CD. (A) Distribution of label in supernatants (1,2) and pellets (3,4) after the extraction with CD. 1 and 3, Without preincubation; 2 and 4, after 30 min of preincubation. The shaded bars indicate the addition of CPHS. (B) Percentage of label found in the cholesteryl ester fraction of lipid extract in cells preincubated and treated with CD. (○), Preincubation without CPHS; (●), preincubation with CPHS. (C) Percent of the incorporated cholesterol released by the cells during the preincubation in the absence (○) or in the presence of CPHS (●). Data are means ± SEM from five experiments. \**P* < 0.01. See Figure 1 for abbreviation.

**FIG. 5.** Inhibition of the endogenous synthesis of cholesterol. Lipoprotein-depleted U-937 cells ( $5 \times 10^6$ ) were incubated for 3 h at 37°C in 1 mL of RPMI 1640 medium containing 5 mg of BSA, 10  $\mu$ Ci of [ $^3$ H]acetate, and the inhibitory steroids. Nonsaponifiable lipids were extracted and resolved by thin-layer chromatography. A, Squalene epoxides; B, lanosterol; C, cholesterol plus desmosterol. 1, Untreated sample; 2, 10  $\mu$ M CPHS; 3, 10  $\mu$ M progesterone; 4, 2.5  $\mu$ M of U18666A. Data are means  $\pm$  SEM from six experiments. \* $P < 0.01$ . See Figures 1 and 3 for abbreviations.

terol and cholesterol synthesis (8). In addition, we found that U18666A does not influence the mobilization of plasma membrane cholesterol promoted by 25-hydroxycholesterol nor does it inhibit the esterification of this oxysterol. The best model to detect the U18666A-induced inhibition of the plasma membrane  $\rightarrow$  endoplasmic reticulum segment of cholesterol transport has been the esterification of [ $^3$ H]cholesterol added to the incubation medium. These results are consistent with a minor influence of this steroid on the transport of cholesterol from the plasma membrane to the endoplasmic reticulum (19,28).

In comparison to progesterone and U18666A, CPHS shows a restricted area of influence. This steroid does not affect endogenous cholesterol synthesis nor ACAT activity. In addition, it shows little activity on the transport of LDL-derived cholesterol to the intracellular sites of esterification in Jurkat cells. The inhibitory activity of CPHS became apparent when we tested the esterification of LDL-derived cholesterol in U-937 and ECV-304 cells or when we specifically monitored the plasma membrane  $\rightarrow$  endoplasmic reticulum segment of cholesterol transport. The inhibition of this route has been observed in all cell lines, using several models of cholesterol transport, including the esterification of labeled cholesterol added to the incubation medium, the stimulation of cholesterol esterification by brefeldin A or sphingomyelinase in cells depleted of lipoproteins, and the 25-hydroxycholesterol-induced mobilization of plasma membrane cholesterol. Taken together, these data suggest that the plasma membrane  $\rightarrow$  endoplasmic reticulum segment of cholesterol transport is the main site of CPHS action and that this pathway is not obliga-

tory during the esterification of LDL cholesterol in Jurkat cells. In an attempt to clarify whether the CPHS-sensitive site is in the plasma membrane itself or in the postmembrane steps, we examined the action of CPHS on the movements of plasma membrane cholesterol. A first effect of CPHS observed in cells pulse-labeled with [ $^3$ H]cholesterol is the inhibition of cholesterol incorporation into the plasma membrane. In addition, CPHS activates cholesterol efflux in prelabeled cells. This action of CPHS is rapid and more manifest in the first minutes of cell incubation with the steroid. The simplest explanation of these effects is that CPHS, inserting into the plasma membrane, displaces the cholesterol contained in the exofacial leaflet of the membrane bilayer, favoring its desorption. In the external leaflet of the plasma membrane, cholesterol preferentially associates with the sphingolipids, forming the microdomains known as lipid rafts (29). In accord with a CPHS-lipid rafts interaction, our previous data demonstrate that this steroid associates with sphingomyelin and cholesterol, forming a detergent-insoluble complex (9). Alternatively or in addition, the phosphoserine group of CPHS activates the ABCA1 permease (30), thus promoting cholesterol efflux. This possibility is supported by confocal microscopy images obtained with fluorescent annexin V in Jurkat cells showing that CPHS distributes in the external cell surface, exposing its phosphoserine group to the extracellular medium (9). Additional support for the hypothesis that CPHS acts on the plasma membrane has been obtained by examining its combined effect with cyclodextrin, a cholesterol-depleting agent also acting in the plasma membrane (23,24). Confirming previous data on suspensions of mouse fibroblasts (23), we found that in Jurkat cells the addition of 2% cyclodextrin depletes  $67.8 \pm 3.1\%$  of cell cholesterol in 10 min. This high efficiency decreases after a brief preincubation of labeled cells at 37°C, indicating a rapid migration of cholesterol to sites inaccessible to cyclodextrin, and cholesterol esterification begins to be detected. The addition of CPHS inhibits cholesterol migration, thus improving the extraction by cyclodextrin and decreasing the amount of cholesterol remaining in the cells.

Owing to its selective effect on plasma membranes, CPHS may become a useful reagent for the study of the involvement of the plasma membrane in cholesterol transport in different mammalian cells. For example, we interpret the ineffectiveness of CPHS in inhibiting the esterification of LDL-derived cholesterol in Jurkat cells as indicating that in these cells most of the LDL-derived cholesterol is directly delivered to the endoplasmic reticulum, without cycling through the plasma membrane. In contrast, in U-937 and ECV-304 cells, a large proportion of LDL-derived cholesterol follows the CPHS-sensitive pathway. In accord with this, the high capacity of these cells to store LDL-derived cholesterol in the plasma membrane is indicated by the observation that the addition of 25-hydroxycholesterol is required to initiate the transfer of cholesterol to the sites of esterification in the endoplasmic reticulum. In contrast, the oxysterol is not required in Jurkat cells. Variations in cholesterol synthesis, transport, and efflux

in mammalian cells are known (2). The application of inhibitors with a defined mechanism of action may prove to be invaluable in clarifying these differences.

## ACKNOWLEDGMENTS

This work received financial support from the Italian MURST (Co-finanziamento No. 9906104773007). We are grateful to Dr. Irene Cortella (Department of Medical and Surgical Sciences, University of Padova) for her assistance in preparing the LDL.

**ABSTRACT:** The fatty acid-binding proteins are hypothesized to be involved in cellular fatty acid transport and trafficking. We established CaCo-2 cells stably transfected with intestinal fatty acid-binding protein (I-FABP) and examined how the expression of this protein may influence fatty acid metabolism. I-FABP expression was detectable in I-FABP-transfected cells, whereas parent CaCo-2 cells as well as mock-transfected cells failed to express detectable levels of I-FABP mRNA or protein at any stage of differentiation. For studies of lipid metabolism, cells were incubated with [<sup>14</sup>C]oleic acid in taurocholate micelles containing monoolein, and distribution of labeled fatty acid in cellular and secreted lipids was examined. In one transfected cell clone, expressing the highest level of I-FABP, labeled cellular triacylglycerol increased approximately twofold as compared to control cells. The level of intracellular triacylglycerol in two other I-FABP-transfected clones resembled that of control cells. However, secretion of triacylglycerol was markedly reduced in all the I-FABP-expressing cell lines. Our data suggest that increased expression of I-FABP leads to reduced triacylglycerol secretion in intestinal cells.

Paper no. L8852 in *Lipids* 37, 61–68 (January 2002).

Fatty acid-binding proteins (FABP) are small (14–15 kDa) cytosolic proteins especially abundant in tissues with active fatty acid metabolism (1–3). A role for intracellular FABP in fatty acid transport has been hypothesized for several decades, and several studies have supported this proposed function (4). The small intestine contains two different types of FABP: intestinal fatty acid-binding protein (I-FABP) (5), exclusively expressed in intestinal epithelium (6,7), and liver fatty acid-binding protein (L-FABP) (5), which is present in the liver and the intestine (8,9). It has been postulated that I-FABP, which is highly expressed in the tips of small intestine villi (2), targets the delivery of fatty acids from the brush-border membrane to specific sites of lipid metabolism, whereas L-FABP is important for the basic cellular economy of fatty

acids (10,11). The hypothesis that the two FABP in the intestine have different roles in fatty acid uptake and metabolism is supported by recent studies on lipid metabolism in mouse L-cell fibroblasts. Transfected L-cells expressing L-FABP increased fatty acid uptake and incorporated more fatty acids into phospholipids, whereas fibroblasts transfected to express I-FABP did not affect fatty acid uptake, but preferentially stimulated fatty acid incorporation into triacylglycerol as compared to control cells (11–13).

The human cell line CaCo-2 is generally considered a suitable model for enterocyte differentiation and growth regulation (14) and has been extensively used as an *in vitro* model for the investigation of intestinal lipoprotein metabolism [reviewed in (15–17)]. These cells have previously been reported to express only L-FABP (7,18–21), but the presence of endogenous I-FABP has recently been described (22–24). Furthermore, different patterns of expression and regulation have been reported for I-FABP and L-FABP in these cells (24).

Previously, cell lines transfected with I-FABP cDNA and cells that endogenously express I-FABP have provided insight on intracellular functions of I-FABP (11,13,21,25–30). With only a few exceptions (21,29), these studies have not examined the effect of I-FABP on secretion of lipids from an intact cell system. The aim of the present study was to examine synthesis and secretion of triacylglycerol in CaCo-2 cells stably transfected to express I-FABP.

## MATERIALS AND METHODS

**Materials.** [<sup>14</sup>C]oleic acid (58 Ci/mol) and [<sup>32</sup>P]dCTP were obtained from Du Pont, NEN<sup>®</sup> Research Products (Boston, MA). Bovine serum albumin (BSA) (essentially fatty acid free), oleic acid, 2-monooleoylglycerol, and sodium taurocholate were purchased from Sigma (St. Louis, MO). Silica gel F 1500 thin-layer chromatography (TLC) plates were purchased from Schleicher and Schuell (Dassel, Germany). The recombinant plasmids pJG19 and pJG418 containing cDNA encoding rat I-FABP (6) and rat L-FABP (8), respectively, were generously provided by Dr. J.I. Gordon, Washington University (St. Louis, MO).

**Cell culture.** CaCo-2 cells obtained from American Type Culture Collection (Manassas, VA) (passage 18) were grown in Dulbecco's modified Eagle's (DME) medium (4.5 g/L glucose

Abbreviations: ANOVA, analysis of variance; apoB, apolipoprotein B; BSA, bovine serum albumin; dCTP, deoxy CTP; DME, Delbecco's modified Eagle's; FABP, fatty acid-binding protein; I-FABP, intestinal fatty acid-binding protein; L-FABP, liver fatty acid-binding protein; dNTP, deoxynucleoside triphosphate; PBS, phosphate-buffered saline; PCR, polymerase chain reaction; SDS, sodium dodecyl sulfate; TLC, thin-layer chromatography.

and 3.7 g/L sodium bicarbonate) (Bio-Whittaker, Walkersville, MD) supplemented with 20% fetal calf serum (GIBCO BRL, Paisley, United Kingdom), insulin (10 µg/mL) (Sigma), L-glutamine (2 mM), penicillin (50 IU/mL), streptomycin (50 µg/mL), and 1% nonessential amino acids (Bio-Whittaker) and maintained as previously described (31).

For experiments, cells were plated at  $2 \times 10^5$  cells/cm<sup>2</sup> on the apical side of 24.5-mm diameter collagen-treated cell culture filter inserts with 3.0 µm pore size (Transwell™-COL, Costar, Cambridge, MA) and grown to 14 d postconfluence (31).

**Plasmid construction.** The recombinant plasmid pJG19 containing a 564 bp cDNA encoding rat I-FABP (6) was digested with *Dra*I and used as template in a polymerase chain reaction (PCR) amplification. The PCR was performed in a 50-µL reaction solution containing PCR buffer (50 mM KCl, 10 mM Tris-HCl pH 8.4, 1.5 mM MgCl<sub>2</sub>, and 0.001% gelatin), 25 pmol of the upstream primer 5'-CCG AAT TCA CAG CTG ACA TCA TGG CAT-3', 25 pmol of the downstream primer 5'-CCT CTA GAT CTG ACA AGG CTT GGA AGC A-3', 200 µM deoxynucleoside triphosphate (dNTP) and 1 U Taq polymerase (AmpliTaq; PerkinElmer Cetus, Norwalk, CT). The DNA was denatured at 94°C for 3 min, and the PCR mixture was subjected to 35 cycles of PCR; each cycle consisted of 1 min at 94, 55, and 72°C. The PCR product was subcloned into the plasmid vector pCR™II by means of the Original TA Cloning® Kit (Invitrogen, San Diego, CA) allowing direct insertion of a PCR product. The cDNA encoding the rat I-FABP was thereafter excised using *Eco*RI (RE site in the upper primer) and *Xba*I (RE site in the lower primer) and subcloned into the mammalian expression vector pcDNA3 (Invitrogen). Restriction enzyme analysis and DNA sequencing were used to confirm a proper insertion of the cDNA insert.

**Transfection and clone selection.** The DNA-calcium phosphate co-precipitation method (32) was used for production of stably transfected cell lines. CaCo-2 cells were plated at  $3.8 \times 10^5$  cells/100-mm dishes 24 h prior to transfection with 20 µg DNA. Cells and DNA were coincubated for 14 h at 37°C in 5% CO<sub>2</sub>. After a 10% dimethylsulfoxide shock, cultures were incubated in fresh medium for 72 h before the cells were split 1:2 and 1:4 into G418 (Geneticin®) supplemented media (0.8 mg/mL active drug) (GIBCO BRL). Medium was changed two to three times/week. From 31 d postplating, independent G418-resistant cell colonies were isolated with cloning cylinders, detached with trypsin-EDTA, and transferred to 96-well tissue culture plates. The cloned cell lines were expanded and maintained in media containing G418 (0.4 mg/mL active drug).

Several independent stably transfected cell lines expressing I-FABP were established. Mock-transfected cells, designated CaCo-2 neo, were cloned following transfection with pcDNA3 without a cDNA insert. This cell line was used as a control for the I-FABP-transfected cells to control for possible effects of G418 sulfate on the cells. The wild-type parental cell line, CaCo-2, was also included for comparison.

**mRNA isolation and Northern blot analysis.** For mRNA analysis in undifferentiated cells, the cells were grown in plastic

tissue culture flasks and harvested at confluence. For mature monolayers, cells were plated on polycarbonate filter membranes (Transwell™; Costar) and grown to 14 d postconfluence. Poly(A)<sup>+</sup> mRNA was isolated from cells using the Dynabeads mRNA Direct kit (Dyna®; Oslo, Norway). Approximately 2 µg mRNA was separated on 1% agarose gel containing 6.7% formaldehyde and transferred to nylon membrane (Hybond-N; Amersham, Buckinghamshire, United Kingdom). I-FABP and L-FABP cDNA probes were recovered from digestion of pJG19 (6) and pJG418 (8), respectively. The probes for I-FABP, L-FABP, and human β-actin (Clontech, Palo Alto, CA, USA) were labeled with [<sup>32</sup>P]dCTP by random priming according to Sambrook *et al.* (33). Membranes were prehybridized, hybridized, and washed at 65°C as described by Church and Gilbert (34). Finally, the signals were analyzed by imaging using a Phosphorimager II (Molecular Dynamics, Sunnyvale, CA) and calibrated against β-actin as an internal standard using the software ImageQuaNT (Molecular Dynamics). Before rehybridization, the membranes were stripped in 0.1% sodium dodecyl sulfate (SDS) at 95°C. The size of the mRNA was determined with reference to an RNA molecular weight marker (GIBCO BRL) that was cut off the nylon membrane before hybridization and stained with methylene blue.

**Western blot analysis.** Cells grown to 14 d postconfluence on polycarbonate filter membranes (Transwell™, Costar) were harvested by scraping into phosphate-buffered saline (PBS), and the pelleted cells were resuspended in lysis buffer [NaCl (0.1 M), Tris-HCl (20 mM, pH 7.4), ethylenediamine tetracetic acid (10 mM), Triton X-100 (1%), aprotinin (10 µg/mL), and phenylmethylsulfonyl fluoride (1 mM)] for 30 min at 4°C. Lysed cells were centrifuged (12,000 × g, 10 min) and the supernatants were collected. Total protein was measured using BSA as standard (35). Protein lysates (100 µg) were separated on 14% precast gels (Novex, San Diego, CA) by SDS-polyacrylamide gel electrophoresis (36) and transferred to PVDF membranes (NEN® Research Products) by electroblotting. Blots were probed with rabbit anti-rat I-FABP antisera and rabbit anti-rat L-FABP antisera (generously provided by Dr. J.I. Gordon), which cross-react with human I-FABP and human L-FABP, respectively (19). Antigen-antibody complexes were detected by the use of the VECTASTAIN® ABC system according to the manufacturer's instructions (Vector Laboratories, Burlingame, CA). Blots were developed by tetramethylbenzidine substrate for horseradish peroxidase. To determine the amounts of I-FABP in the various cell lysates, the filters were scanned with a laser densitometer (Molecular Dynamics). Purified recombinant rat I-FABP (Molecular Probes Europe BV, Leiden, The Netherlands) was used as a standard to estimate I-FABP protein concentrations.

**Measurement of cell-associated and secreted lipids.** Apical and basolateral media were removed and the cells were rinsed once with serum-free DME medium; unattached and damaged cells were thereby washed off. Cell monolayers were incubated in serum-free DME medium containing [1-<sup>14</sup>C]oleic acid (1 µCi/mL, 0.6 mM) and 2-monooleoylglycerol (0.3 mM) in taurocholate micelles (12 mM sodium tau-

rocholate) prepared as previously described (37). The micelles were added to the upper chamber of the cell culture system, whereas the lower chamber contained serum-free DME medium only. After incubation, the media were collected from the apical and basolateral compartments of the tissue culture inserts, and the cells were scraped off the filter membranes into PBS. Samples were taken for protein determination, using BSA as a reference protein (35).

The homogenized cell fraction was mixed with 20 vol of chloroform/methanol (2:1, vol/vol) (38). Four volumes of a 0.9% sodium chloride solution of pH 2 were added, and the mixture was allowed to separate into two phases. The organic phase was dried under a stream of nitrogen at 40°C. The residual lipid extract was redissolved in 200  $\mu$ L hexane and separated by TLC, using hexane/diethyl ether/acetic acid (80:20:1, by vol) as developing solvent. The various lipid bands were visualized by iodine vapor and cut into 8 mL liquid scintillation fluid (InstaGel II Plus, Packard Instrument, Downers Grove, IL); and the radioactivity was then quantified using a liquid scintillation counter (TRI-CARB 1900 TR, Packard Instrument).

Samples of basolateral media, devoid of cellular debris, were added to 4 vol of chloroform/methanol (2:1, vol/vol) and 2% serum as unlabeled carrier for the lipids. The water phase was reextracted once with 4 vol of chloroform/methanol (2:1, vol/vol), and the combined organic phases were further treated in the same way as for the cells.

**Statistical analysis.** All values are reported as mean  $\pm$  standard error of the mean. Comparison of different treatments was evaluated by analysis of variance (ANOVA) (StatView<sup>®</sup> 5.0, SAS Institute, Cary, NC). The analysis of variance results were *post-hoc* tested by Fisher's protected least significant difference. Statistical significance was defined as  $P < 0.05$ .

## RESULTS

**I-FABP and L-FABP expression.** Transfection of CaCo-2 cells resulted in several stably transfected cell lines expressing I-FABP (Fig. 1). Northern and Western blot analyses of differentiated cells did not show detectable levels of I-FABP mRNA or protein in parent CaCo-2 cells or mock-transfected cells (CaCo-

**FIG. 1.** Expression of intestinal fatty acid-binding protein (I-FABP) and liver fatty acid-binding protein (L-FABP) mRNA in differentiated CaCo-2 cells. Poly(A)<sup>+</sup> mRNA was isolated from transfected and nontransfected cells, and Northern blot analyses were performed with cDNA probes for I-FABP and L-FABP. (A) Lane 1, CaCo-2; lane 2, CaCo-2 neo; lanes 3–9, different clones of I-FABP transfected cells (IIB2, IIA6, IA12, IA11, IA10, IA6, IA3). The expression levels were related to  $\beta$ -actin in each sample and the relative mRNA levels are shown in (B).

**FIG. 2.** Detection of I-FABP and L-FABP protein in differentiated CaCo-2 cells. Western blot analyses of protein lysates (100  $\mu$ g) from transfected and nontransfected cells were performed using antiserum raised against rat I-FABP and rat L-FABP. Lane 1, 0.3  $\mu$ g purified rat I-FABP; lane 2, CaCo-2; lane 3, CaCo-2 neo; lane 4, clone IA6. Quantification of the I-FABP band revealed that the band from clone IA6 corresponded to approximately 0.5  $\mu$ g/mg protein. For abbreviations see Figure 1.

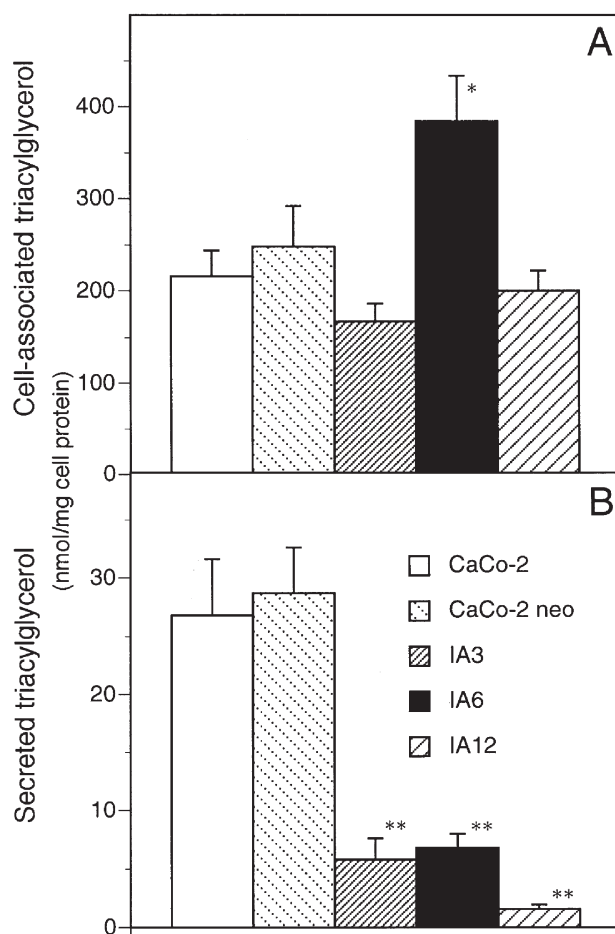

2 neo) (Figs. 1 and 2). The expression of L-FABP was already present in undifferentiated cells (data not shown), and the expression increased with differentiation, as reported earlier by several investigators (18–21,24). For the wild-type parental cell line, the relative amounts of L-FABP mRNA in 14 d postconfluent monolayers were 10 times those in undifferentiated cultures (data not shown). However, I-FABP-expressing cells showed lower levels of L-FABP mRNA than control cells (Fig. 1).

**[<sup>14</sup>C]Oleic acid esterification and distribution.** As shown in Figure 1, the different transfected clones expressed various levels of I-FABP mRNA. The effect of I-FABP on oleic acid metabolism was examined in three clones expressing different levels of I-FABP, namely, IA3, IA6, and IA12 (Fig. 3).

To study fatty acid incorporation, esterification, and secretion, cell lines were incubated up to 24 h with taurocholate micelles containing [<sup>14</sup>C]oleic acid (0.6 mM) and 2-monoacylglycerol (0.3 mM). Incorporation of labeled oleic acid into cellular triacylglycerol was significantly increased in clone IA6 as compared to the other cell lines examined (Fig. 3A). After 5 h incubation, this clone incorporated  $57 \pm 3\%$  of [<sup>14</sup>C]oleic acid into triacylglycerol, whereas nontransfected cells and mock-transfected cells incorporated  $44 \pm 4$  and  $39 \pm 4\%$ , respectively ( $P < 0.05$ ). However, the other I-FABP-expressing cell lines did not show increased incorporation into triacylglycerol (Fig. 3A). On the other hand, secretion of labeled triacylglycerol was markedly reduced in all I-FABP transfectants when compared to control cells (Fig. 3B).

The clone expressing the highest level of I-FABP, clone IA6, was studied in more detail (Table 1). Incorporation of labeled fatty acid into cellular triacylglycerol as well as total incorporation into cellular lipids was increased in this clone when compared to parent CaCo-2 cells (Table 1). However, total incorporation was not significantly different between clone IA6 and mock-transfected cells. The increased incorporation into triacylglycerol, without affecting cellular phospholipids, resulted in a twofold higher triacylglycerol/phospholipid ratio for I-FABP-expressing cells (Table 1). The levels of free [<sup>14</sup>C]oleic acid as well as the incorporation into diacylglycerol were similar in all cell lines, whereas the incorporation into cholesteryl esters was reduced both in I-FABP-expressing and mock-transfected cells (Table 1). However, the proportion of [<sup>14</sup>C]oleic acid in cholesteryl esters was less than 1% of the total incorporation into cellular lipids.

Time course experiments showed that the observed differences in cell-associated and secreted triacylglycerol between the clone IA6 and control cells were evident also after 24 h of incubation (Fig. 4).

**FIG. 3.** Incorporation of [<sup>14</sup>C]oleic acid into cell-associated (A) and secreted (B) triacylglycerol. Cell monolayers were incubated with [<sup>14</sup>C]oleic acid (0.6 mM) and 2-monoolein (0.3 mM) for 5 h. Incorporation of [<sup>14</sup>C]oleic acid into cell-associated and secreted triacylglycerol was measured as described in the Materials and Methods section. Data, given as nmol/mg cell protein, represent mean  $\pm$  standard error of the mean of 6–14 filters from 2–5 independent experiments. \*Significantly different from all other cell lines. \*\*Significantly different from controls ( $P < 0.0001$ ).

<sup>c</sup>Significantly different from CaCo-2 neo.

## DISCUSSION

In the present study, we established CaCo-2 cells stably transfected with I-FABP, and examined how the expression of this protein may influence fatty acid metabolism in intestinal cells. Our main finding was that triacylglycerol secretion was inhibited in I-FABP-transfected cells independent of the level of I-FABP expression.

Differentiated as well as undifferentiated CaCo-2 cells fail to express I-FABP when grown on plastic supports (7,20,23). However, differentiated cells grown on filter inserts have recently been shown to express I-FABP endogenously (22–24), suggesting that I-FABP expression in CaCo-2 cells may depend on culture conditions as well as maturation. Darimont *et al.* (24) reported that when collagen was present during cell differentiation on filter inserts, the expression of endogenous I-FABP, but not L-FABP, was strongly reduced. In the present study, cells for Northern and Western blot hybridization studies were differentiated on uncoated polycarbonate filters, which are not known to inhibit I-FABP expression (24). Nevertheless, parent CaCo-2 cells as well as mock-transfected cells did not show detectable levels of I-FABP mRNA or protein (Figs. 1 and 2). Also in previous studies, I-FABP protein expression was not detectable in pre- or postconfluent cells grown on filter inserts (18,19,21). The use of different antibodies as well as various culture conditions may account for

**FIG. 4.** Time course for incorporation of [<sup>14</sup>C]oleic acid into cell-associated (A) and secreted (B) triacylglycerol. Cell monolayers were incubated with [<sup>14</sup>C]oleic acid (0.6 mM) and 2-monoolein (0.3 mM) for 2, 5, and 24 h. Incorporation of [<sup>14</sup>C]oleic acid into cell-associated and secreted triacylglycerol was measured as described in the Materials and Methods section. Data represent mean ± standard error of the mean from several independent experiments. \*Significant difference as compared to the other two cell lines.

the discrepancies observed between these studies and the recent demonstrations of endogenous I-FABP expression in these cells (22–24).

Previously, cell lines transfected with I-FABP cDNA and cells that endogenously express I-FABP have provided insight on intracellular functions of I-FABP (11,13,21,25–30). Only a few of these studies were performed with cells of intestinal origin (21,28,29). In our present study, fatty acid metabolism was examined using CaCo-2 human intestinal cells stably transfected with I-FABP. We found that incorporation of [<sup>14</sup>C]oleic acid into cellular triacylglycerol was significantly increased in clone IA6, expressing the highest level of I-FABP (Table 1, Figs. 3A, 4A). However, other I-FABP transfected cell lines with lower levels of I-FABP did not show increased incorporation into cellular triacylglycerol

(Fig. 3A). The reason for the lack of dose dependence between I-FABP level and cellular triacylglycerol is not known. Because several proteins are involved in cytosolic binding of fatty acids, binding to I-FABP will account for only a minority of fatty acid transport. It appears that other factors than the level of I-FABP expression may be rate-limiting in the regulation of triacylglycerol synthesis under the conditions of cell culture.

The data from clone IA6 support the hypothesis that I-FABP may be involved in targeting long-chain fatty acids to triacylglycerol synthesis. This is in accordance with Darimont *et al.* (39), who showed that reduced incorporation of [ $^{14}\text{C}$ ]palmitic acid into triacylglycerol was accompanied by a reduced level of I-FABP in CaCo-2 cells. Our observations are also similar to results from I-FABP transfected L-cell fibroblasts (11,13) and rat intestinal epithelial cells (hBRIE 380i) (28) showing that [ $^3\text{H}$ ]oleic acid incorporation into triacylglycerol was increased in I-FABP-expressing cells. In hBRIE 380i cells, however, the increase in fatty acid incorporation into triacylglycerol was correlated to cellular differentiation in addition to I-FABP expression, leading the authors to suggest that differentiation-dependent factors other than I-FABP may play a role in long-chain fatty acid targeting (28). This is supported by studies in non-I-FABP/non-L-FABP-expressing mouse embryonic stem cells demonstrating that differentiation increased the quantity of cellular lipids, primarily triacylglycerol, whereas expression of I-FABP further enhanced triacylglycerol production (27). In our present study, experiments examining oleic acid metabolism were conducted in differentiated cells, grown to 14 d postconfluence on filter membranes. We previously showed that this stage of differentiation exhibits the most metabolically active cells, as evaluated by the degree of triacylglycerol secretion (31).

In accordance with the studies in L-cell fibroblasts (13) and hBRIE 380i cells (28), no differences were detected between cell lines in the incorporation of [ $^{14}\text{C}$ ]oleic acid into total phospholipids (Table 1). Furthermore, compared to mock-transfectants, expression of I-FABP did not increase total incorporation of labeled oleic acid into the cells (Table 1). This also confirms observations in other I-FABP-expressing cells (11,28). The suggestion that I-FABP has a passive role with respect to fatty acid uptake has been demonstrated in L-cells (11,13), in which transfection with I-FABP stimulated fatty acid esterification into triacylglycerol without increasing fatty acid uptake.

With two exceptions (21,29) previous studies on the role of I-FABP expression on fatty acid esterification have not examined secretion of lipids from an intact cell system. We show here that secretion of labeled triacylglycerol was reduced in all I-FABP-expressing cell lines as compared to control cells (Fig. 3). A recent study showed that plasma concentration of triacylglycerol was higher in Fabp $^{-/-}$  mice, indicating that the rate of dietary fat transfer into the plasma compartment was actually increased in the absence of I-FABP (40). Furthermore, a nonsignificant reduction in lipid secretion was shown in I-FABP-transfected CaCo-2 cells as com-

pared to mock-transfected cells (29). The expression of I-FABP in mock-transfected cells was similar to that previously reported by the same authors for wild type CaCo-2 cells (24). However, no data for parent CaCo-2 cells were given in this study (29). Given the clonal variability evident for these cells, it remains to be confirmed whether the metabolic activity of these mock transfected cells resembled that of wild-type cells.

In CaCo-2 cells stably transfected with two naturally occurring isoforms of I-FABP, the Thr $^{54}$ -isoforms (mutated type) increased triacylglycerol secretion relative to the Ala $^{54}$ -form (21). However, nontransfected cells secreted more triacylglycerol than either of the I-FABP-transfected cell lines (Baier, L.J., personal communication). In accordance with our study (Fig. 1), the nontransfected cells contained higher levels of L-FABP than the I-FABP expressing cells, leading the authors to suggest a coregulation between the intestinal and liver forms of this protein. However, the issue of clonal variability rather than a specific effect of I-FABP expression must also be considered. Another study in CaCo-2 cells showed different levels of L-FABP in two different cell clones transfected with I-FABP (29).

The physiological significance of the two forms of FABP in intestinal cells is unknown. Different patterns of regulation have been reported for I-FABP and L-FABP in CaCo-2 cells (24,41). Furthermore, it was shown that the total amount of FABP in these cells was not proportional to the amount of lipid transport (21). Together, these observations support the hypothesis that L-FABP and I-FABP may not affect fatty acid transport in a simple combined fashion but that the proteins may play separate roles in intracellular lipid metabolism. The contribution of L-FABP to lipid transport in I-FABP-transfected cells remains unclear. Nevertheless, the decrease in L-FABP observed in the I-FABP transfected cells may provide a mechanism for the decrease in triacylglycerol secretion observed in our study.

Consideration has been given to the possibility that newly synthesized triacylglycerol is channeled to a cytosolic storage pool and not transferred directly to lipoprotein assembly. It can be speculated that these triacylglycerol molecules might be used for secretion at a later time. It has been demonstrated that the expression of L-FABP in transfected rat (McA-RH7777) hepatoma cells inhibits the assembly and secretion of apoB100VLDL without decreasing the biosynthesis of apolipoprotein B100 (apoB100) or triacylglycerol (42). This is explained by a diversion of fatty acids from the second step in the very low density lipoprotein assembly process, thereby promoting a "late" intracellular degradation of apoB100 (42). In I-FABP-transfected CaCo-2 cells, however, preliminary data indicate that the reduced triacylglycerol secretion observed was not accompanied by decreased apoB secretion (data not shown). It seems therefore that rather than an increased degradation of apoB, dense lipid-poor particles are secreted from the cells. Interestingly, it was recently suggested that there is no coordinated regulation of FABP and apoB-containing lipoproteins (41).

Fatty acid incorporation in secreted triacylglycerol was reduced in differentiated CaCo-2 cells stably transfected with I-FABP, independent of the intracellular level of triacylglycerol. These findings need further examinations to investigate the role of I-FABP-expression on intestinal triacylglycerol secretion.

## ACKNOWLEDGEMENTS

The authors are grateful to Dr. J.I. Gordon for providing I-FABP and L-FABP cDNA and anti-rat I-FABP and L-FABP antisera. We wish to thank Mari-Ann Baltzersen and Manigeh M. Beigi for technical assistance.

**ABSTRACT:** In the starved state and during metabolic stress, free fatty acids (FFA) are the principal hepatic energy supply, undergoing  $\beta$ -oxidation. Accordingly, it appears paradoxical that FFA have been reported to increase the liver's esterification capacity by translocating the rate-limiting enzyme phosphatidic acid phosphohydrolase (PAP-1) from the cytosol to the endoplasmic reticulum. We have therefore investigated the regulation of rat liver PAP-1. Oleic acid inhibited PAP activity in all subcellular fractions, with PAP-1 activity in cytosol being the most sensitive. Inhibition was also observed with oleoyl-CoA, linoleate, and palmitate. Fatty acids and their derivatives show detergent effects at high concentrations, and such effects can lead to enzyme inhibition. Inhibition by oleate, however, was reversed by phosphatidic acid and albumin and exhibited sigmoidal kinetics. These results demonstrate that PAP-1 is reversibly inhibited by FFA and their CoA esters, which may play a role in directing hepatic FFA to  $\beta$ -oxidation during times of increased energy demand.

Paper no. L8631 in *Lipids* 37, 69–73 (January 2002).

Phosphatidic acid phosphohydrolase (PAP) catalyzes the hydrolysis of phosphatidic acid (PA) to generate *sn*-1,2-diacylglycerol (DAG), a substrate for the synthesis of a number of phospholipids, as well as a direct precursor of triacylglycerol (TAG) (1,2). Regulation of PAP activity therefore plays a crucial role in determining the rate and direction of glycerolipid synthesis with, for example, elevated levels of PAP activity being associated with alcoholic fatty liver (3). In mammalian cells, two major forms of PAP activity have been identified (4,5). PAP-1, stimulated by  $Mg^{2+}$  and inhibited by *N*-ethylmaleimide (NEM) *in vitro*, is distributed between the cytosol and endoplasmic reticulum (ER) and is regarded as the metabolic form involved in the regulation of glycerolipid synthesis. PAP-2 [for which at least three isoforms exist (2,6)] is  $Mg^{2+}$ -independent and NEM-insensitive, is found mainly in the plasma membrane and, in view of its location, is thought to be

involved principally in cell-signaling and is a member of the lipid phosphate phosphohydrolase family (6–8).

The level of PAP-1 activity expressed *in vivo* has long been considered to be regulated by the ability of the cytosolic form to translocate to the ER, where its substrate, PA, is generated *via* the acylation of glycerol-3-phosphate (reviewed in Ref. 9). Largely indirect evidence suggests that, *in vivo*, this translocation is induced by the accumulation of fatty acids, acyl-CoA esters, and PA on the ER membranes and results in the enhanced synthesis of glycerolipid (10). Such evidence has come principally from experiments that have incubated cell-free tissue homogenates with lipids prior to the preparation of cyto-solic and microsomal fractions by ultracentrifugation (5,11–15).

In addition to their putative effect on the subcellular distribution of PAP-1, some studies have reported an effect of free fatty acids (FFA) on total enzyme activity. PAP-1 activity in rat hepatocytes is apparently increased by extracellular FFA concentrations of  $\geq 2$  mM above (10,16), whereas in rat adipocytes, stimulation of lipolysis by noradrenaline leads to a rapid decrease in PAP-1 activity. This effect, which is antagonized by insulin and a  $\beta$ -adrenergic antagonist, suggests either inhibition of PAP by fatty acids or a direct hormonal effect on the enzyme, possibly *via* reversible phosphorylation, although there is no direct evidence for this covalent modification (17,18). In view of these conflicting and somewhat paradoxical data, we have further investigated the effect of fatty acids on PAP-1 activity from rat liver. We show *in vitro* that PAP-1 is directly and reversibly inhibited by both FFA and their acyl CoA esters. This regulation of PAP-1 may be important in determining the balance between  $\beta$ -oxidation and esterification in situations such as starvation and metabolic stress in which there is an increased supply of fatty acids to the liver.

## MATERIALS AND METHODS

**Materials.** Male Wistar rats (150–200 g) were obtained from Newcastle University Comparative Biology Centre (United Kingdom). They were allowed free access to food and water prior to sacrifice by cervical dislocation, after which livers were immediately removed and stored at  $-20^{\circ}\text{C}$  until use. Phosphatidic acid, 1,2-dioleoyl-*sn*-glycerol, oleic acid, linoleic acid, palmitic acid, oleoyl-CoA, bovine serum albumin (BSA) (fatty acid-free), Triton X-100, and polyethylene glycol (MW 8,000) were from Sigma Chemical (Poole, Dorset, United Kingdom).

<sup>1</sup>Current address: Faculte des Sciences et Techniques, University Cadi Ayyad, Beni-Mellal, Morocco.

Abbreviations: BSA, bovine serum albumin; DAG, diacylglycerol; DDT, dithiothreitol; ER, endoplasmic reticulum; FFA, free fatty acid; NEM, *N*-ethylmaleimide; PA, phosphatidic acid; PAP, phosphatidic acid phosphohydrolase; TAG, triacylglycerol.

*Preparation of subcellular fractions from rat liver.* Livers were suspended at 4°C in 4–5 vol of 50 mM Tris-HCl (pH 7.4) containing 0.25 M sucrose and 0.2 M DTT (buffer A) and minced with scissors before homogenization with a Teflon–glass homogenizer. The crude homogenate was then centrifuged at 4°C for 20 min at  $10,000 \times g$  and the supernatant (homogenate) collected. The pellet was resuspended in buffer A and stored at –20°C (low spin, “membrane” fraction). The homogenate was then centrifuged at  $150,000 \times g$  for 90 min at 4°C, the resulting supernatant being recentrifuged for a further 60 min at  $150,000 \times g$  to produce a cytosolic fraction. The pellets from both spins were collected and washed twice by resuspension and further centrifugation at  $150,000 \times g$  and finally resuspended in buffer A (microsomal fraction). Fractions were stored at –20°C or used immediately. A mitochondrial fraction was prepared by centrifuging crude homogenate at  $2,000 \times g$  for 15 min at 4°C. The resulting supernatant was centrifuged again at  $10,000 \times g$  for 10 min at 4°C, and the resulting pellet was resuspended in buffer A and used as crude mitochondrial fraction. Previous work in this laboratory using this methodology, coupled with marker enzymes, has shown that the low-spin “membrane” fraction contains essentially only PAP-2 and that over 80% of the PAP activity in the cytosol is due to PAP-1 (5).

For partial purification of PAP-1, cytosol was diluted in buffer A to give a final protein concentration of 6–7 mg/mL, and then solid polyethylene glycol (MW 8,000) was added (6 g per 100 mL of cytosol). The mixture was stirred for 1 h at 4°C and then centrifuged at  $5,000 \times g$  for 15 min. The precipitate (in which PAP-1 is enriched approximately 5- to 10-fold) was resuspended in buffer A. Contamination of this fraction with PAP-2 was negligible, as judged by the complete sensitivity of the activity to NEM.

*Determination of PAP activity.* Total PAP activity (*i.e.* measured in the absence of NEM) was measured at 30°C by the production of [ $^{32}$ P]P<sub>i</sub> from [ $^{32}$ P]PA, essentially as in References 5 and 19, except that Triton X-100 was omitted and the PA substrate was prepared by sonication. The standard incubation mixture (0.1 mL) contained 50 mM Tris HCl pH 7.5, 1.5 mM MgCl<sub>2</sub>, 0.1 mg/mL fatty acid-free BSA, 0.5 mM EDTA, 0.5 mM EGTA, 0.5 mM DTT, 125 mM sucrose, and 0.5 mM PA (10,000 dpm/nmol). One unit of PAP activity is defined as the release of 1 nmol of P<sub>i</sub>/min.

*Inhibition of PAP activity by fatty acids and their acyl-CoA esters.* The PAP activity of aliquots of subcellular fractions and partially purified PAP was assayed as described above except that fatty acids or their acyl-CoA esters were present in the basic assay system, and the concentration of [ $^{32}$ P]PA was reduced from 0.5 to 0.25 mM. In parallel, aliquots of the same subcellular fractions or partially purified PAP were first preincubated for 10 min at 37°C with fatty acids prior to assaying PAP activity. Palmitate and linoleate were suspended separately in buffer A containing 0.1% Triton X-100 and used as a stock solution, whereas oleate or oleoyl-CoA were directly suspended in buffer A. In all cases, the final concentration of Triton X-100 in the reaction mixture was less than 0.01%

(0.15 mM), at which levels Triton does not affect the observed activity (5). In some experiments, after the 10 min preincubation with oleate, various concentrations of BSA or PA were added to the incubations 5 min prior to the initiation of PAP assays. Kinetic data were fitted using nonlinear regression with bi-square weighting (20).

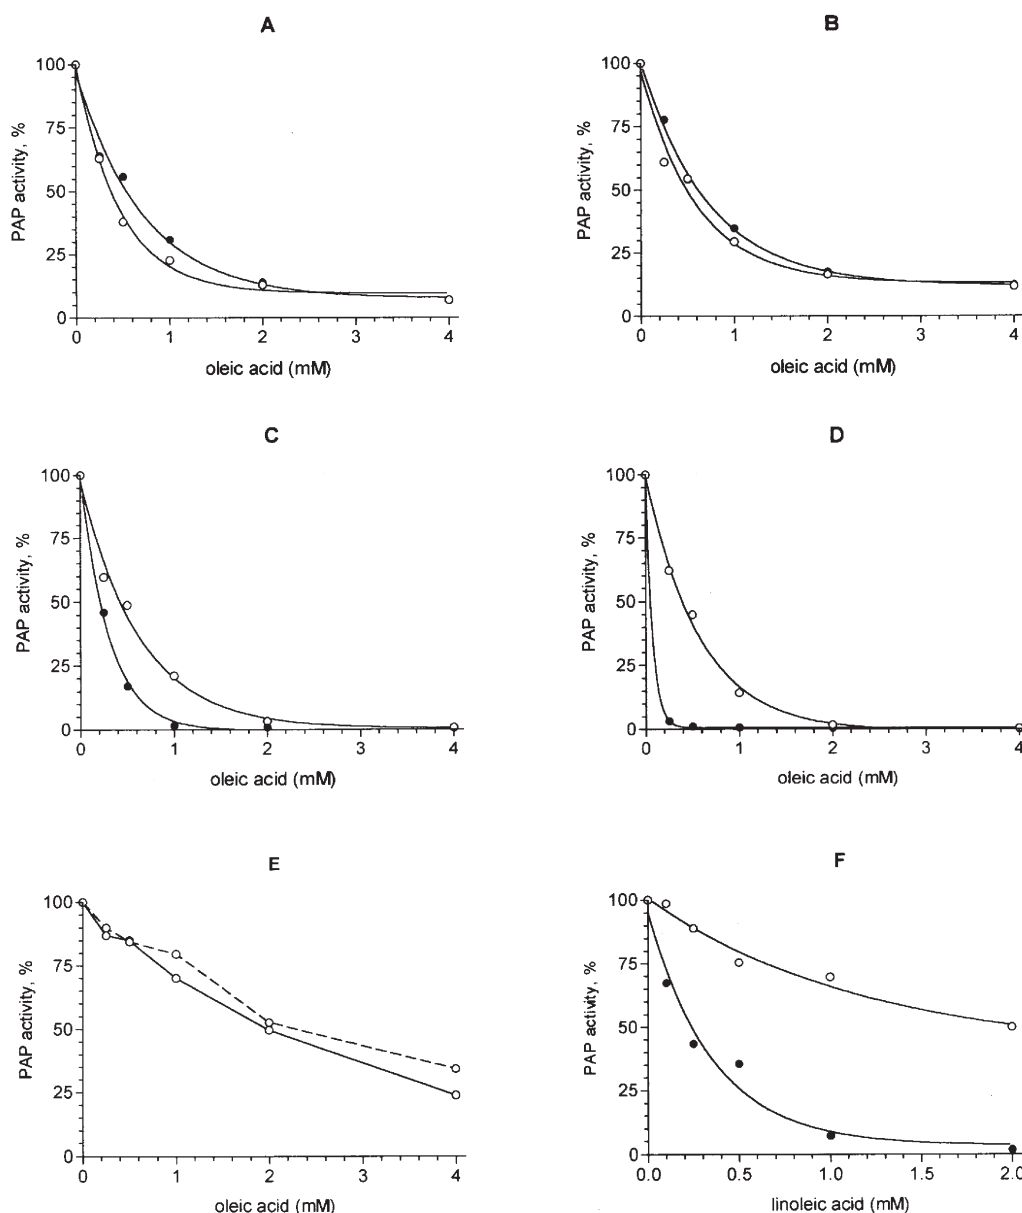

## RESULTS

Increasing concentrations of oleic acid progressively inhibited PAP activity in both the homogenate (Fig. 1A) and microsomal fractions of rat liver (Fig. 1B), which contain both PAP-1 and PAP-2, with 50% inhibition observed at approximately 0.6 mM of added fatty acid and more than 80% inhibition occurring at concentrations higher than 1.2 mM. In these fractions there was no significant increase in the inhibitory effect of oleic acid when it was present 10 min prior to initiating the assay reaction (Figs. 1A and B). PAP-1 activity in the cytosolic fraction (Fig. 1C) [which is essentially all PAP-1 (5)], or partially purified PAP-1 activity (Fig. 1D), was more sensitive to the presence of oleic acid in the reaction mixture, with 50% inhibition observed at approximately 0.4 mM and essentially 100% inhibition occurring at 2 mM oleic acid or above. Preincubation with oleic acid accentuated the inhibitory effect of oleic acid on PAP-1 activity in cytosol or partially purified PAP-1 preparations, with essentially complete inhibition observed at 1.0 and 0.5 mM, respectively. These results indicate that oleic acid is a potent inhibitor of PAP-1.

Mitochondrial and membrane-bound PAP activity [which is predominantly PAP-2 (5)] is less sensitive to the presence of oleic acid. At 1 mM oleate, PAP activity was only slightly inhibited (25% inhibition) and even at concentrations of 2–3 mM, the degree of inhibition was only 50–60% (Fig. 1E). These results suggest that PAP-1 and PAP-2 are affected to different extents by the presence of fatty acids. This is consistent with the results from the homogenate and microsomal fractions (Fig. 1A and B) in which a low level of PAP activity was maintained even at a high concentration of oleate, corresponding to the contribution of the PAP-2 isoform present in these fractions. The effect of other fatty acids and oleoyl CoA on partially purified PAP-1 was also examined. Linoleic acid inhibited this activity in a dose-dependent fashion, with increased inhibition observed following preincubation in the absence of PA (Fig. 1F).

Palmitic acid also inhibited PAP-1 activity, with 30% inhibition at 1 mM, increasing to 90% if the enzyme was preincubated in the absence of PA. The inhibitory effect of oleoyl CoA was similar to that observed with oleic acid (results not shown). The reversibility of oleate-induced inhibition of PAP-1 was investigated by addition of 3 mg/mL BSA, following preincubation of partially purified PAP-1 with 1 mM oleate but prior to assaying PAP activity. The presence of 1 mM oleate in the preincubation period reduced PAP-1 activity by about 70%. BSA completely reversed this inhibitory effect of oleate (results not shown).

To further elucidate the possible mechanism(s) of fatty acid-induced PAP-1 inhibition, we investigated the kinetics

**FIG. 1.** Effects of oleate and linoleate on the subcellular phosphatidic acid phosphohydrolase (PAP) activity in rat liver. PAP activity was measured in aliquots of homogenate (A), microsomes (B), cytosol (C), partially purified PAP (D and F), mitochondria (E, solid line), or in membrane (low spin) fraction (E, broken line) in the presence of various concentrations of oleate (A–E) or linoleate (F) as indicated. The graphs show the inhibitory effect of these fatty acids on PAP activity with (●) or without (○) preincubation for 10 min at 37°C in the absence of substrate phosphatidic acid. Similar results were obtained in five further experiments. Results are expressed as % of control (without fatty acids).

of partially purified PAP-1 activity in the absence or presence of oleic acid. The results (Fig. 2) were suggestive of  $K$ -system inhibition (21), in which the effective value of the allosteric constant  $L$  increases and saturation curves become increasingly sigmoidal as a function of the concentration of an allosteric inhibitor. The combined data fitted an allosteric model better than the alternative of simple competitive inhibition by a factor of 4.4 in residual variance. Because the deduced value of  $L$  was small ( $0.4 \pm 0.2$ ), the saturation function in the absence of oleic acid was indistinguishable from the hyperbolic function of Michaelis–Menten kinetics. The

value of  $S_{0.5}$  ( $0.13 \pm 0.02$  mM) deduced using the allosteric model did not differ significantly from the value of  $K_m$  ( $0.17 \pm 0.02$  mM) deduced for competitive inhibition, and corresponding values of maximal velocity were  $32 \pm 1$  and  $35 \pm 1$  U/mg, respectively. Both models yielded similar values of  $K_i$  ( $0.05 \pm 0.01$  and  $0.10 \pm 0.01$  mM, respectively).

## DISCUSSION

The results reported here show that fatty acids and their acyl-CoA esters are inhibitors of hepatic PAP activity, in particu-

**FIG. 2.** Effect of phosphatidic acid (PA) concentration on the initial velocity of phosphatidic phosphohydrolase-1 (PAP-1) activity in the presence of oleate. Activity of partially purified PAP (specific activity 20 U/mg) was measured as a function of PA concentrations in the absence (○) or the presence of 0.05 (□), 0.1 (△), 0.25 (▲), 0.5 (●), or 0.6 mM (◆) oleate. The data represent a typical example of five different experiments. The lines show the best fit of the combined data to a two-state allosteric model, assuming two binding sites for PA, with binding favoring the *R* state by a factor of 100, and two allosteric binding sites for oleic acid.

lar PAP-1, the form of the enzyme principally involved in glycerolipid biosynthesis. The inhibition of PAP-1 by oleate appears to involve a negative allosteric interaction, resulting in a decreased affinity for its substrate, PA, suggesting that PAP-1 could be regulated *in vivo* by the intracellular ratio of PA/fatty acids. The levels of added fatty acids and acyl CoA used in this study are consistent with those used previously in similar work (e.g., Ref. 13) but are somewhat higher than values that are normally considered to be physiological, although it should be remembered that the liver will receive high levels of fatty acids from the portal vein. Fatty acids and their derivatives show detergent effects at high concentrations and such effects can lead to enzyme inhibition. It is important to point out, however, that the inhibitory effects of fatty acids are greater at lower levels of PA (Fig. 2) and that the PA concentrations used are also higher than might be considered physiological; this is necessary in order for the enzyme activity to be detectable. The concentrations of FFA actually present in the incubations will be lower than the added amounts owing to the presence of low levels of fatty acid-free BSA, and similarly, the situation in the cell is complicated by the presence of a number of binding proteins for fatty acids and acyl CoA esters. Thus, the concentration may vary within the cytosol and in the region of different membranes. The inhibition of PAP-1 by fatty acids also offers a possible explanation for the inhibitory effect of catecholamines on PAP-1 activity reported in adipocytes, with increased levels of fatty acids and their CoA esters being responsible (17,18).

A number of studies have shown that the rate of TAG synthesis is dependent on the concentration of FFA. However, since fatty acid supply also determines the rate of  $\beta$ -oxidation, factors regulating this pathway will also affect TAG syn-

thesis. This is illustrated by the stimulation of fatty acid esterification and TAG synthesis that occurs when hepatocytes are incubated with inhibitors of  $\beta$ -oxidation (22,23). However, when cells or tissues require an increased supply of energy (e.g., during metabolic stress), fatty acids need to be preferentially directed toward  $\beta$ -oxidation rather than esterification. In the liver during conditions of stress, the increased ratio of glucagon to insulin directs incoming fatty acids (derived from adipose tissue lipolysis) toward  $\beta$ -oxidation by inhibiting acetyl-CoA carboxylase activity, leading to a reduction in malonyl CoA levels and stimulation of carnitine palmitoyl transferase, thus promoting the entry of fatty acids into mitochondria. The inhibition of PAP-1 by fatty acids and their acyl-CoA esters will further favor  $\beta$ -oxidation over esterification. Only if the liver receives an influx of fatty acids sufficient to exceed the capacity for  $\beta$ -oxidation will they then be esterified to lysophosphatidic acid and PA on the ER. The translocation induced by fatty acids in intact cells (e.g., Ref. 10) could also be an indirect effect resulting from their incorporation into newly synthesized PA, which has been shown to promote the binding of PAP-1 to microsomal and mitochondrial membranes *in vitro* (24,25). This regulation of PAP-1 metabolic expression by membrane-bound PA is similar to the regulation of the intracellular distribution of DAG kinase by DAG (26), with the substrate in each case localizing the enzyme to the membrane. In the case of PAP-1, PA would act as the signal to promote the intracellular movement of the enzyme to the membranes, contributing to increased TAG synthesis, although clearly other enzymes in the pathway such as DAG acyltransferase may play a regulatory role (reviewed in Ref. 27). In the fed state, the high ratio of insulin to glucagon will block the entry of fatty acids into the mitochondria *via* elevation of malonyl CoA levels, and they will be preferentially esterified. The subsequent increase in PA on the ER membranes will then translocate PAP-1 and overcome any fatty acid-induced inhibition of PAP-1 activity.

**ABSTRACT:** A new fatty acid, (5Z,9Z)-22-methyl-5,9-tetracosadienoic acid (**1a**), and a rare fatty acid, (5Z,9Z)-23-methyl-5,9-tetracosadienoic acid (**2a**), the predominant constituents of the free fatty acid fraction from the lipids of the sponge *Geodinella robusta*, were isolated and partly separated by reversed phase high-performance liquid chromatography, followed by multi-fold crystallization from MeOH to give **1a** and **2a** in 70% and 60% purity, respectively. These fatty acids were identified as (5Z,9Z)-22- and (5Z,9Z)-23-methyl-5,9-tetracosadienoic acids by nuclear magnetic resonance techniques, including distortionless enhancement by polarization transfer, heteronuclear multiple quantum connectivity, and correlation spectroscopy experiments, as well as from mass-spectrometric data for their methyl esters, the methyl esters of their perhydro derivatives, and their pyrrolidides. Mixtures of **1a** and **2a** showed cytotoxic activity against mouse Ehrlich carcinoma cells and a hemolytic effect on mouse erythrocytes. The sterol fraction from the same sponge was analyzed by gas-liquid chromatography-mass spectrometry, and 24-methylenecholesterol was identified as a main constituent of this fraction. The implications of the co-occurrence of membranolytic long-chain fatty acids and 24-methylenecholesterol as a main membrane sterol are discussed in terms of the phenomenon of biochemical coordination.

Paper no. L8822 in *Lipids* 37, 75–80 (January 2002).

Sponges are characterized by the wide diversity in their fatty acid composition and, in contrast with higher animals, by the presence of very long chain constituents (so-called demospongiac acids) with novel branching and unsaturation patterns. The content of demospongiac acids may approach 85% of total

fatty acids in sponge phospholipids (1–5). As a rule, C<sub>26</sub> acids, accompanied by C<sub>28</sub> and sometimes C<sub>24</sub> acids, including those of *iso* and *anteiso* structures (4,6–9), dominate in the demospongiac acids of sponges (3). Demospongiac acids with 25 carbon atoms as predominant constituents have been found only in a few cases. For example, Bergquist *et al.* (3) found a preponderance of C<sub>25</sub> acids in lipids of *Leiosella* sp. and *Ircinia novaeseelandiae*, in contradistinction to the higher concentrations of C<sub>26</sub>–C<sub>28</sub> acids in other sponges.

Usually, the demospongiac acids are found mainly as structural components of membrane phospholipids (1–9). Recently, Nemoto *et al.* (10) isolated free demospongiac acids as human DNA topoisomerase-I inhibitors from the sponge *Amphimedon* sp. and characterized them by spectral methods, including nuclear magnetic resonance (NMR) spectroscopy. The majority of unusual fatty acids with very long chains have not been isolated from the corresponding sponges but have been identified solely using gas-liquid chromatography (GLC) and GLC-mass spectrometry (MS) methods. Therefore, NMR data for many demospongiac acids have not been reported.

In the course of our continuing studies on marine natural products (11), we found that the alcoholic extract from the Far Eastern sponge *Geodinella robusta* (class Demospongiae, subclass Tetractinomorpha, order Astrophorida, family Geodiidae) showed cytotoxic activity against mouse Ehrlich carcinoma cells. Thin-layer chromatography (TLC) revealed the presence of an extraordinarily high content of free fatty acids in this extract. Bioassay-guided isolation gave a fatty acid fraction that was analyzed by GLC-MS, and C<sub>25</sub>-demospongiac acids (**1a**, **2a**) were subsequently identified as the bioactive compounds. One of these fatty acids (**1a**) has not been described previously, whereas **2a** was found by Carballeira *et al.* in several *Ircinia* species and in *Spongia tubulifera* (12). In this paper, we report the compositions of free fatty acid and free sterol fractions from the sponge *Geodinella robusta* and the isolation and structure elucidation of the demospongiac acids **1a** and **2a**, including NMR data for these compounds.

## EXPERIMENTAL PROCEDURES

**Extraction and isolation of demospongiac acids.** Specimens of *Geodinella robusta* were collected near Iturup Island (the Konservnaya Bay), Sea of Okhotsk, using scuba equipment at the depth of 5 m in August 1999. The sponges (0.25 kg dry weight) were carefully cleaned of all nonsponge debris, cut into small pieces, and immediately extracted at room temperature with ethanol for two consecutive 24-h periods. The combined extracts were concentrated *in vacuo*. The ethanol-soluble materials were dissolved in 90% ethanol (200 mL) and extracted with hexane (5 × 100 mL) to give 2.1 g of an oily residue after evaporation of the hexane extract. The material obtained was then chromatographed on a column of Sephadex LH-20 (Sigma Chemical Co., St. Louis, MO) using chloroform/ethanol (1:1, vol/vol) and rechromatographed on the same column using chloroform/ethanol (3:1, vol/vol) as the eluting solvent systems, to obtain 1.12 g of a mixture of nonpolar compounds. This mixture was separated by column chromatography on silica gel L (40–100 μm; Chemapol, Prague, Czech Republic) using petroleum ether gradually replaced with chloroform as the eluting solvent to obtain a crude fatty acid fraction (760 mg) after the removal of solvents *in vacuo*. This substance was subjected to high-performance liquid chromatography (HPLC) on an Altex (Berkeley, CA) Ultrasphere Si column (25 cm × 10 mm), eluted with hexane/ethyl acetate (5:1, vol/vol) at 2 mL/min, using a DuPont Series 8800 instrument (Boston, MA) equipped with a differential refractometer (RIDK-102). The fatty acid fraction obtained (394 mg) was subjected to HPLC on a Serva (Heidelberg, Germany) Octadecyl-Si 100 column (5 μm, 25 cm × 4.6 mm), using 96% methanol as the eluting solvent at 1 mL/min, to obtain 80.5 mg (0.03% on dry weight) of a mixture of acids **1a** and **2a** (1.5:1). Multifold crystallization of part of this mixture from methanol yielded 8.2 mg of the subfraction **I** (containing 70% acid **1a** and 30% acid **2b**) and 7.6 mg of the subfraction **II** (containing 60% acid **2a** and 40% acid **1a**).

The acids were converted to methyl esters by treatment with diazomethane. *N*-Acyl pyrrolidide derivatives were prepared by direct treatment of the methyl esters with pyrrolidine/acetic acid (10:1, vol/vol) in a capped vial (1 h, 100°C) followed by ethereal extraction from the acidified solution and purification by preparative TLC on silica gel L plates developed in CHCl<sub>3</sub>. The hydrogenations of methyl esters and *N*-acyl pyrrolidides with addition of 2H<sub>2</sub> were carried out in methanol solution using PtO<sub>2</sub> as catalyst. The β-*N*-acylglucosamides **1f** and **2f** were obtained from acids **1a** and **2a** and glucosamine by the method described elsewhere (13).

**Analysis of fatty acids.** Proton and carbon nuclear magnetic resonance (<sup>1</sup>H and <sup>13</sup>C NMR) 1D and 2D spectra of the acids were recorded using a Bruker WM-250 spectrometer (Karlsruhe, Germany) at 250 and 62.9 MHz and a Bruker DPX-300 spectrometer at 300 and 75 MHz, respectively, with tetramethylsilane as an internal standard. Proton NMR spectra of **1a** and **2a** were also obtained on a Bruker DPX-500 instrument at 500 MHz. The infrared (IR) spectrum was recorded on a Bruker "Vector 22" spectrophotometer.

**Capillary GLC.** GLC analyses of methyl esters of fatty acids were performed on a Sigma 2000 PerkinElmer chromatograph (Norwalk, CT) using an SPB-5 column [bonded; poly (5% diphenyl/95% dimethylsiloxane; 50 m × 0.32 mm)] at 260°C and on a Shimadzu Chromatograph 9A (Kyoto, Japan) with a Supelcowax 10 (Supelco, Bellefonte, PA) column (30 m × 0.32 mm) at 210°C, with helium as the carrier gas at 1 mL/min.

**GLC-MS.** GLC-MS analyses were carried out on a Hewlett-Packard 6890 GC System instrument (Palo Alto, CA) with a 5973 Mass Selective Detector, with an HP-5MS (cross-linked 5% phenyl methylsiloxane) capillary column (30 m × 250 μm × 0.25 μm) at 270°C. Helium was used as the carrier gas (1 mL/min), and the ionizing energy was 70 eV. Mass spectral and some other data of key fatty acids for this discussion are presented below.

**Methyl (5Z,9Z)-23-Methyl-5,9-tetracosadienoate (2b).** MS *m/z* (relative intensity, %): 392 (M<sup>+</sup>, 7), 360 (1), 343 (4), 318 (1), 277 (4), 264 (1), 250 (4), 181 (6), 164 (6), 154 (4), 141 (40), 121 (15), 109 (54), 96 (35), 81 (100), 67 (82), 55 (62).

**Methyl 23-Methyltetracosanoate (2c).** MS *m/z* (relative intensity, %): 396 (M<sup>+</sup>, 40), 367 (2), 353 (15), 339 (1), 311 (4), 297 (5), 199 (5), 143 (27), 129 (11), 111 (6), 87 (90), 74 (100), 57 (45).

**N-[(5Z,9Z)-23-Methyl-5,9-tetracosadienoyl]pyrrolidine (2d).** MS *m/z* (relative intensity, %): 431 (M<sup>+</sup>, 5), 420 (1.5), 388 (1), 206 (1), 194 (1), 180 (50), 152 (1.5), 140 (2), 126 (15), 113 (100), 98 (12), 85 (6), 70 (12), 55 (14).

**N-(23-Methyltetracosanoyl)pyrrolidine (2e).** MS *m/z* (relative intensity, %): 435 (M<sup>+</sup>, 5), 420 (3.5), 392 (3), 126 (20), 113 (100), 98 (10), 85 (7), 70 (12), 55 (14).

**N-[(5Z,9Z)-22-Methyl-5,9-tetracosadienoyl]/(5Z,9Z)-23-methyl-5,9-tetracosadienoyl, 1.5:1]-2-amino-α-D-glucopyranose (1f and 2f).** <sup>13</sup>C NMR (C<sub>5</sub>D<sub>5</sub>N): 11.35, 19.14, 22.5, 26.23, 27.17, 27.43, 29.36, 29.49, 29.64, 29.77, 30.09, 34.38, 36.01, 36.65, 39.00, 55.79, 63.05, 72.86, 72.29, 73.67, 92.57 (C-1), 129.34, 129.79, 129.89, 130.40 ppm.

**Isolation and analysis of free sterol fraction.** The free sterols were isolated from the fraction of nonpolar compounds (1.12 g) by preparative TLC on silica gel L (5/40 μm;

Chemapol) with the use of chloroform/ethanol (20:1, vol/vol) as the developing solvent. Treatment of the sterol mixture obtained with pyridine/acetic anhydride (1:1, vol/vol; room temperature, 24 h) yielded the sterol acetates. The sterol acetates were separated by preparative TLC on silica gel L-AgNO<sub>3</sub> plates developed with hexane/benzene (5:3, vol/vol). The isolated subfractions were then analyzed by GLC and GLC-MS as previously described (14).

**Hemolysis.** Studies involving laboratory animals were approved by an Institutional Review Board and conformed to accepted Standards. Mouse erythrocytes were washed three times by centrifugation (600 × g, 5 min) in cold Tris buffer containing 150 mM NaCl, 1 mM KCl, and 1 mM HEPES (pH 7.4). The pellet was resuspended in the same solution to a final concentration of 1%. Erythrocytes were incubated with the compounds tested for 30 min at room temperature and then centrifuged (600 × g, 5 min). Optical density of the supernatant was measured spectrophotometrically at 540 nm.

**Cytotoxicity.** Ehrlich ascites carcinoma cells were grown intraperitoneally in albino mice. Cells were harvested on the seventh day after inoculation, washed twice with cold phosphate-buffered saline using centrifugation (600 × g, 5 min), and resuspended in 199 medium (0.7 × 10<sup>6</sup> cells/mL). The cell suspension was incubated with the test compounds in a 96-well microplate at 37°C for 24 h. Then total and viable cell numbers were determined microscopically using 0.17% Trypan Blue stain (15).

## RESULTS AND DISCUSSION

The major fatty acids of the free fatty acid fraction (0.03% of dry weight of the sponge) were identified in standard fashion from GLC equivalent chain length (ECL) values and electron impact mass spectrometry (EI-MS) of methyl esters. As shown in Table 1, the fatty acid fraction contained a variety of *isolanteiso* fatty acids (87.25%) ranging from 25 to 27 carbons in length. The most abundant fatty acids of *G. robusta* were generally *ai25:2* and *i25:2* together with *ai27:2* and *ai26:2*. It is noteworthy that the fatty acids with terminal *anteiso* branching were the predominant acids and their total content was as high as 57.6%. Another peculiarity of this sponge is that the percentage of C<sub>25</sub> constituents was more than 50%. Usually, the content of C<sub>25</sub> acids is in the range of 1–10% (3); for instance, C<sub>25</sub> acids represented only 10% of phospholipid fatty acid fraction from the sponges of genus *Ircinia* (12). The fatty acids with 26 carbon atoms (about 28% of the free fatty acid fraction in *G. robusta*) are typical acids from marine sponges belonging to the class Demospongiae and usually account for 50% of total demospongiic acid mixtures (2). In contrast, C<sub>27</sub> fatty acids (18% of the free fatty acid fraction in *G. robusta*) are not as widely distributed in sponges, although *ai-5,9-27:2* acid has been found as the major fatty acid constituent (18.4%) in phospholipids from the sponge *Petrosia ficiformis* (6). Cytotoxic properties were not reported for free fatty acids. Thus, we considered the *ai25:2* and *i25:2* constituents to be interesting for structural

<sup>b</sup>Equivalent chain length; Supelcowax 10 column, 210°C.

studies and probably bioactive compounds in the sponge *G. robusta*. In fact, separation of the free fatty acid fraction by HPLC allowed us to isolate a mixture of these two acids, and it was shown that they have a potent cytotoxic action against mouse Ehrlich carcinoma cells.

The separation of *iso* and *anteiso* demospongiic acids has not yet been reported in the literature (4,6–9,12). Efforts to separate the mixture of **1a** and **2a** as free acids by HPLC procedures on a Serva Octadecyl-Si 100 column with a solvent system of 95% EtOH with 0.01 M AcONH<sub>4</sub>, 85% acetone, or MeOH with 0.1% trifluoroacetic acid or on Zorbax ODS (Kyoto, Japan), with EtOH as the eluting solvent, were unsuccessful. Similarly, separation of methyl esters of **1a** and **2a** by HPLC on an Ultrasphere-Si column in hexane/ethyl acetate (200:1, vol/vol) was not obtained. Taking into consideration the fact that reversed phase HPLC is a more available method for separation of amphiphilic compounds, we carried out the modification of isolated 5,9-25:2 demospongiic acids by the method developed in 1982 (13) to obtain β-*N*-acylglucosamides **1f** and **2f** from acids **1a** and **2a** and glucosamine. However, separation of these derivatives on an ODS column, using MeOH and acetonitrile as eluting solvents, was also unsuccessful. Nevertheless, we achieved a partial separation of compounds **1a** and **2a** by HPLC on Serva Octadecyl-Si 100, using 96% MeOH as a developing solvent, followed by multifold crystallization from MeOH. By employing this procedure, we obtained subfraction I (containing 70% **1a** and 30% of **2a**) and subfraction II (containing 60% **2a** and 40% of **1a**).

The absorption band at 1710 cm<sup>-1</sup> (CHCl<sub>3</sub>) in the infrared spectrum of **1a** and a <sup>13</sup>C NMR signal at δ 178.7 ppm (Table 2) indicated the presence of a carboxyl group (Scheme 1). A chemical shift at δ 33.2 ppm was expected and observed for the C-2 signal of the neighboring methylene group (16). The methyl ester (**1b**) had an ECL value of 25.01 on GLC and gave

<sup>b</sup>Signal assignments equivocal.

a molecular ion peak ( $M^+$ ) at  $m/z$  392. These data supported the 25:2 structure proposed for this compound. Compound **1b** was transformed into the perhydro derivative (**1c**) by catalytic hydrogenation. EI-MS of the latter compound gave a molecular ion peak at  $m/z$  396 ( $M^+$ ), confirming the presence of two double bonds in the original fatty acid. The presence of two unsaturated bonds in compound **1a** was also indicated by the <sup>1</sup>H NMR resonances at  $\delta$  5.30–5.40 (m, 4H) and by distortionless enhancement by polarization transfer <sup>13</sup>C NMR spectra, showing four CH signals at  $\delta$  128.5, 128.9, 130.5, and 130.6.

The  $\Delta^{5,9}$  unsaturation pattern was readily recognized in **1a** from the characteristic prominent peaks at  $m/z$  81 in the EI mass spectrum of the methyl ester (**1b**) and at  $m/z$  180 (C-7–C-8 cleavage) in the EI mass spectrum of the corresponding pyrrolidide (**1d**) (17). The mass spectrum of the pyrrolidide (**1d**) displayed an  $M^+$  peak at  $m/z$  431 and differences of 12 amu between homologous ions at  $m/z$  140 (C<sub>4</sub>) and  $m/z$  152

(C<sub>5</sub>), indicating a  $\Delta^5$  double bond, and between homologous ions at  $m/z$  194 (C<sub>8</sub>) and  $m/z$  206 (C<sub>9</sub>), indicating a  $\Delta^9$  double bond (6,17). Further confirmation of the double-bond positions was obtained from NMR correlation spectroscopy (COSY) experiments with consecutive COSY correlations from C-1 to C-11 clearly showing that the double bonds were located at C-5 and C-9 (Table 2). The geometry of the double bonds was established by analysis of the <sup>13</sup>C NMR chemical shifts of the neighboring carbons of the double bonds (18). It is known that carbons adjacent to *trans* double bonds have chemical shifts in the range of  $\delta$  29.5–38.0, whereas those adjacent to *cis* double bonds have values of  $\delta$  26.0–28.5. The <sup>13</sup>C NMR signals of compound **1a** were at  $\delta$  26.5 (C-4), 27.3 (C-7), 27.3 (C-8), and  $\delta$  27.4 (C-11) (Table 2), confirming the percentage of *cis* double bonds between C-5 and C-6 as well as between C-9 and C-10.

The methyl branching in **1a** was established because catalytic hydrogenation (PtO<sub>2</sub>) of methyl ester **1b** did not give a C<sub>25</sub> acid methyl ester with a normal saturated chain. Furthermore, the presence of two methyl groups in **1a** was revealed by <sup>13</sup>C NMR and <sup>1</sup>H NMR spectra. The chemical shift at 11.4 (CH<sub>3</sub>-24) shielded into a high field by the branching at the  $\beta$ -position indicated *anteiso* structure (<sup>1</sup>H NMR:  $\beta$  = 0.85, *t*,  $J$  = 6.4 Hz) while the signal at  $\delta$  19.2 (CH<sub>3</sub>-25) indicated a methyl group at C-22 (18,19). The doublet at  $\delta$  0.85 in the <sup>1</sup>H NMR spectrum and the signal at  $\delta$  34.4 (C-22) in the <sup>13</sup>C NMR spectrum (18) as well as COSY and heteronuclear multiple quantum connectivity experiments and gas–liquid chromatographic behavior of **1a** confirmed this conclusion. Moreover, EI-MS of the hydrogenated derivative of the pyrrolidide (**1e**,  $M^+$  435; Fig. 1) showed diagnostic fragments for the *ai*25:0 fatty acid (406,  $M^+$  – 29; 378,  $M^+$  – 29 – 28).

On the basis of the data discussed above, the structure of **1a** was determined as (5*Z*,9*Z*)-22-methyl-5,9-tetracosadienoic acid.

The fatty acid **2a** was easily presumed to be an isomer of **1a** by comparison of the spectral data of **1a** and **2a** (Table 2). The methyl ester (**2b**) had an ECL value of 24.82 on GLC, and EI-MS gave a molecular ion peak ( $M^+$ ) at  $m/z$  392. These data supported the C<sub>25:2</sub> structure. The positions and geometry of the double bonds as were determined for **2a** as 5*Z*,9*Z* by NMR data in the same manner as for **1a** (Table 2). The methyl branching was established based on the fact that catalytic hydrogenation (PtO<sub>2</sub>) of **2b** also did not give a methyl ester with a normal chain. The presence of two methyl groups was revealed by the signals at  $\delta$  22.6 in the <sup>13</sup>C NMR spectrum (C-24, C-25) and at  $\delta$  0.86 in the <sup>1</sup>H NMR spectrum (*d*,  $J$  = 6.6 Hz, an isopropyl group). The signal at  $\delta$  39.1 (C-22) in the <sup>13</sup>C NMR spectrum confirmed the position of methyl branching at C-23 (20,21). Mass spectrum of the tetrahydropyrrolidide (**2e**) obtained from **2a** exhibited a molecular ion peak at  $m/z$  435 (Fig. 2) and diagnostic fragmentation ions for the *iso* fatty acids at  $m/z$  420 ( $M^+$  – 15) and  $m/z$  392 ( $M^+$  – 15 – 28).

On the basis of data discussed above, the structure of **2a** was determined as (5*Z*,9*Z*)-23-methyl-5,9-tetracosadienoic acid.

The GLC-MS and  $^1\text{H}$  NMR analyses of the fraction of free sterols and the corresponding subfractions, obtained by silica gel- $\text{AgNO}_3$  preparative TLC, revealed 18 known sterols. Table 3 lists the identified sterols as well as their content (%) in the free sterol fraction and GLC relative retention times. This sterol mixture contained  $\text{C}_{26}$  (5.9%),  $\text{C}_{27}$  (21%),  $\text{C}_{28}$  (49%), and  $\text{C}_{29}$  (19%)  $\Delta^5$  sterols and stanols. The major sterol was identified as 24-methylenecholesterol (38.25%).

The demospongiac acids from the Far Eastern marine sponge *G. robusta* demonstrated potent cytotoxic activities. In fact, toxic and hemolytic effects of the mixture of the acids **1a** and **2a** (1.5:1) against mouse Ehrlich carcinoma cells and erythrocytes were observed at  $\text{ED}_{50} = 1.8$  and  $1.5 \mu\text{g/mL}$ , respectively. The sponge *G. robusta* contained 24-methylenecholesterol as the principal constituent of the free sterol fraction instead of cholesterol, a main membrane sterol of the ma-

jority of animals. Earlier, Djerassi's group (22) distinguished some sponges containing unusual additionally alkylated side chains in sterols as also having the branched demospongiac fatty acids in their membrane phospholipids. It was suggested (22) that "such an unusual feature of the membrane . . . may represent a response to stress from the sponge's biotic environment, or it may reflect a specialized requirement of certain membrane-bound enzymes for internal fluidity" (p. 645). In the course of our continued investigations on membranolytic toxins from marine organisms, we have discovered that many toxin-producing marine animals (sponges, holothurians, etc.) contain unusual sterols instead of cholesterol in their membrane free sterol fractions (23). Moreover, we confirmed by experiments that inclusion of unusual sterols instead of cholesterol into cellular membranes protects cells against membranolytic action of different marine toxins (24). We call the phenomenon, which involves the mutually conditioned presence of two different series of secondary metabolites in living organisms, "biochemical coordination" (23,24). The find-

ing of a new case where membranolytic toxins (fatty acids **1a** and **2a**) and the major sterol distinguished from cholesterol (24-methylenecholesterol) were found in the same animal (the sponge *G. robusta*) is of interest from the point of view of further studies on "biochemical coordination." Probably, 24-methylenecholesterol complements the unusual fatty acid toxicity in some unknown fashion.

## ACKNOWLEDGMENTS

We are very grateful to Drs. Ekaterina G. Lyakhova, Olga P. Moiseenko, and Mikhail V. Vysotskii for GLC analysis and MS measurements, We thank Dr. Vladimir B. Krasokhin for identification of the sponge, Dr. Nina G. Prokof'eva for performing bioassays, and Dr. Pavel A. Lukiyanov for collection of the Far Eastern sponge *G. robusta*. The research described in this publication was supported by grant no. REC-003 of the U.S. Civilian Research & Development Foundation for the Independent States of the Former Soviet Union (CRDF) and Russian Foundation of Basic Research (RFBR) grant no. 00-15-97806. The expedition on the R/V *Akademik Oparin*, during which the sponge was collected, was supported by grants DEB-9400821 and DEB-9505031 of the International Programs Divisions and Biological Science Foundation (principal investigator Theodore W. Pietscher) and of the Japan Society for the Promotion of Science (principal investigator Kunio Amaoka).

**ABSTRACT:** The lipid ester core aldehydes formed during a rapid oxidation (7.8 M *tert*-butyl hydroperoxide, 90 min at 37°C) of the triacylglycerols of purified corn and sunflower oils were isolated as dinitrophenylhydrazones by preparative thin-layer chromatography and identified by reversed-phase high-performance liquid chromatography with on-line electrospray ionization mass spectrometry and by reference to standards. A total of 113 species of triacylglycerol core aldehydes were specifically identified, accounting for 32–53% of the 2,4-dinitrophenylhydrazine (DNPH)-reactive material of high molecular weight representing 25–33% of the total oxidation products. The major core aldehyde species (50–60% of total triacylglycerol core aldehydes) were the mono(9-oxo)nonanoyl- and mono(12-oxo)-9,10-epoxy dodecenoyl- or (12-oxo)-9-hydroxy-10,11-dodecenoyl-diacylglycerols. A significant proportion of the total (9-oxo)nonanoyl and epoxidized (12-oxo)-9,10-dodecenoyl core aldehydes was found in complex combinations with hydroperoxy or hydroxy fatty acyl groups (6–10% of total triacylglycerol core aldehydes). Identified were also di(9-oxo)nonanoylmonoacylglycerols (0.5% of total) and tri(9-oxo)nonanoylglycerols (trace). The identification of the oxoacylglycerols was consistent with the products anticipated from *tert*-butyl hydroperoxide oxidation of the major species of corn and sunflower oil triacylglycerols (mainly linoleoyl esters). However, the anticipated (13-oxo)-9,11-trideca-dienoyl aldehyde-containing acylglycerols were absent because of further oxidation of the dienoic core aldehyde. A significant proportion of the unsaturated triacylglycerol core aldehydes contained *tert*-butyl groups linked to the unsaturated fatty chains *via* peroxide bridges (2–9%). The study demonstrates that rapid peroxidation with *tert*-butyl hydroperoxide constitutes an effective method for enriching natural oils and fats in triacylglycerol core aldehydes for biochemical and metabolic testing.

Paper no. L8703 in *Lipids* 37, 81–94 (January 2002).

Autoxidation of unsaturated triacylglycerols yields hydroperoxides as primary oxidation products. In the presence of divalent cations, the hydroperoxides readily undergo chain

cleavage, yielding both volatile and nonvolatile carbonyl compounds of a large variety of structural types (1,2). Whereas the volatile carbonyl compounds have been extensively studied owing to their contribution to off-flavors, color, and aroma of stored food products (3,4), the nonvolatile acylglycerol aldehyde molecules have largely been ignored (5,6). Extensive research has shown that volatile carbonyls form adducts with proteins (7–9) and some of them precipitate adverse physiological effects (9–11). The chain cleavage products remaining associated with the acylglycerol molecules, although not directly contributing to off-flavors, color, and aroma, can serve as reservoirs of potentially toxic oxidation materials as well as complexing agents. Furthermore, polar glycerolipids containing an aldehyde group are likely to remain associated with cell membranes (12) and affect their structure and function, including receptor activity. Because the nonvolatile aldehydes have been shown (13,14) to react with amino compounds as readily as the volatile aldehydes and because hydroperoxides of dietary linoleic acid esters are converted to aldehydes in the stomach before being absorbed into the body (15,16), it is essential that acylglycerol core aldehydes be available for studies on the gastrointestinal fate and metabolic consequences of ingestion of the secondary products of triacylglycerol oxidation.

As synthetic lipid ester core aldehydes are not commercially available, previous biochemical and nutritional studies have been performed with the small amounts of products generated by autoxidation of unsaturated fats and oils (17,18). Because of low yields of oxoacylglycerols, direct identification of the potential dietary precursors and the absorbed materials has been difficult, and analysts have relied on indirect tests based on various color reactions (17,18). We have previously isolated the C<sub>5</sub> and C<sub>9</sub> core aldehydes of cholesteryl esters (19,20), glycerophospholipids (19), and standard triacylglycerols (21,22) following treatment with *tert*-butyl hydroperoxide (TBHP) and have identified them by reversed-phase high-performance liquid chromatography (HPLC) with on-line electrospray ionization mass spectrometry (LC/ESI/MS) after preparation of the 2,4-dinitrophenylhydrazones (13,22). In the present study, we have used this analytical method to identify over 113 core aldehydes and their derivatives generated from corn and sunflower oil triacylglycerols by a rapid oxidation with TBHP and ferrous ions.

## MATERIALS AND METHODS

**Materials.** Corn oil (Mazola; Best Foods Canada Inc., Etobicoke, Ontario, Canada) was purchased from a local grocery store, and sunflower seed oil (Kultasula) was obtained from a Finnish manufacturer (Raision Margariini Oy, Toijala, Finland). The triacylglycerols were purified by thin-layer chromatography (TLC) as previously described (22). Reference triacylglycerols, hydroperoxytriacylglycerols, and core aldehydes were available from a previous study (22), including the oxidation products of 16:0/18:1/18:2 (21).

**Oxidation.** The oxidation was accelerated by adding 1 mL of 70% TBHP in water (7.8 M) to 10 mg of purified triacylglycerols in the presence of 10  $\mu$ M FeSO<sub>4</sub> and 100  $\mu$ L of 0.2% taurocholic acid (16). The mixture was incubated on a mechanical agitator in the dark for 1.5 h at 37°C. The reaction was stopped by diluting with 5 mL of chloroform/methanol (2:1, vol/vol) and by washing three times with water (3  $\times$  1 mL). The solvent was evaporated under nitrogen at 38°C, and the lipid residue was subjected to preparation of derivatives of 2,4-dinitrophenylhydrazine (DNPH).

**Preparation of DNPH derivatives.** The DNPH derivatives of triacylglycerol core aldehydes were obtained by adding 2 mL of freshly prepared DNPH in 1 N HCl (3.6 mg/mL) to a 6–9-mg dry sample (6). The mixture was shaken vigorously and kept in the dark at room temperature for 4 h and then overnight at 4°C. The lipids were extracted with 5 mL of chloroform/methanol (2:1, vol/vol), the chloroform phase was blown down under nitrogen, and the residue was taken up in an appropriate solvent for chromatography and MS as described below.

**TLC.** Normal-phase TLC was used to purify triacylglycerols and their oxidized derivatives. Silica gel H (E. Merck & Co., Darmstadt, Germany) plates were prepared in the laboratory, and heptane/isopropyl ether/acetic acid (60:40:4, by vol) solution was used as the mobile phase (22). The DNPH derivatives of the core aldehydes were seen as yellow bands on the chromatoplates (in daylight). The compounds were recovered from the silica gel scrapings by extraction with chloroform/methanol (2:1, vol/vol). Extracts were washed with distilled water, dried with anhydrous Na<sub>2</sub>SO<sub>4</sub>, and saved in 2-propanol.

**HPLC, LC/ESI/MS, and LC/ESI/CID/MS.** Procedures for HPLC, LC/ESI/MS, and LC with on-line ESI/collision-induced dissociation/MS (LC/ESI/CID/MS) of triacylglycerols were as described previously (21,22). The reversed-phase HPLC profiles of native corn and sunflower oil triacylglycerols were recorded with the use of a direct liquid inlet (DLI) chemical ionization (CI) mass spectrometer (Hewlett-Packard, Palo Alto, CA) as a detector, as previously described (23). For ESI/CID/MS, the capillary exit voltage was raised to 300 V to obtain fragment ions from any clearly resolved components (pseudo MS/MS) (24,25). The triacylglycerol samples were dissolved in isopropanol by heating for 2–3 min at 80°C prior to injection. Addition of chloroform to assist the dissolution of triacylglycerols was avoided as it caused distortion of peak shape and variation in retention time.

**GC/MS.** GC/MS analyses were performed using an HP5890A gas chromatograph (Hewlett-Packard, San Diego, CA) coupled to the single-quadrupole mass spectrometer described above. A fused-silica capillary column (15 m  $\times$  0.32 mm, i.d.) of the DB-1 bonded phase type (J&W Scientific, Rancho Cordova, CA) was used for the analysis with temperature programming from 200 to 300°C at 5°C/min. Spectra were recorded under electron impact (EI) (70 eV) ionization conditions.

**Peak identification and quantification.** The structures of the resolved oxoacylglycerols were established on the basis of their behavior on normal-phase TLC, reversed-phase HPLC, and LC/ESI/MS as follows. The tentative identities obtained by chromatography in relation to standards were confirmed by LC/ESI/MS, which provided high-intensity [M + 1]<sup>+</sup> and low-intensity [M – RCOOH]<sup>+</sup> ions for the underivatized oxoacylglycerols. The DNPH derivatives of the TBHP oxidation products of the oils gave [M – 1]<sup>–</sup> as the major ions on LC/ESI/MS in the negative mode. The DNPH derivatives of oxidized 16:0/18:1/18:2 were characterized by LC/ESI/CID/MS, which permitted the detection of greatly increased yields of the [M – RCOOH] ions. The data obtained with the TBHP oxidation products of 16:0/18:1/18:2 were used to assign the structures of the TBHP oxidation products of corn and sunflower oil triacylglycerols. The abundances of the major molecular ions of the core aldehydes in the TLC bands provided an estimate of the relative quantities of each component of each homologous series, which could be summed to match the estimates for the major oxoacylglycerol core aldehydes in the total negative ion profile.

## RESULTS

**Analysis of seed oils.** The molecular species composition of native corn and sunflower oil triacylglycerols was determined by reversed-phase HPLC and was found to be similar to that reported previously for commercial corn (23) and sunflower (26) seed oils. Figure 1 shows the triacylglycerol profiles of the two oils before oxidation as obtained by LC/DLI/CI/MS. Table 1 compares molecular species of triacylglycerols of corn and sunflower seed oils before oxidation. The major molecular species of triacylglycerols in both oils were 18:2/18:2/18:2 (20–22%), 18:1/18:2/18:2 (17–18%), 18:1/18:1/18:2 (12–21%), 16:0/18:2/18:2 (7–10%), 16:0/18:1/18:2 (4–9%), 18:1/18:1/18:1 (9–14%), and 18:0/18:1/18:1 (3–7%). The sunflower oil also contained minor amounts (1–5%) of 18:0/18:1/18:1, 22:1/18:1/18:2, and 22:0/18:1/18:2. The overall fatty acid composition of the original sunflower and corn oil triacylglycerols was similar to that reported previously (23,26), with linoleic (18:2), oleic (18:1), and palmitic (16:0) acids accounting for over 90% of the total, as shown in Table 2.

**Analysis of total oxidation mixtures.** Figure 2 compares the total reversed-phase HPLC elution profiles, as detected by light scattering, of corn and sunflower seed oil triacylglycerols following the TBHP treatment. The peaks corresponding to unoxidized triacylglycerols are eluted toward the end of the chromatograms and are identified by their theoretical

**FIG. 1.** Total positive ion current profiles of triacylglycerols of corn and sunflower seed oils before oxidation. Peak numbering refers to the partition number. Triacylglycerols were detected as the ammonium adducts  $[M + NH_4]^+$  in the positive ion mode. Conditions and instrumentation of reversed-phase high-performance liquid chromatography (HPLC) and mass spectrometry (MS) with direct liquid inlet (DLI) chemical ionization (CI) are described in the Materials and Methods section. Solvent gradient: 20–80% 2-propanol in methanol (0.85 mL/min) in 30 min.

**FIG. 2.** Comparison of reversed-phase HPLC elution profiles of the corn and sunflower seed oils following oxidation with *tert*-butyl hydroperoxide (TBHP) and ferrous iron. Peak numbering for residual triacylglycerols is based on partition number. Conditions of HPLC separation and light-scattering detection as in the Materials and Methods section. Solvent gradient as in Figure 1. See Figure 1 for abbreviation.

carbon number (TCN). The oxidized triacylglycerols are eluted earlier with retention times corresponding to those recorded for synthetic triacylglycerols containing epoxy, hydroperoxy, and hydroxy fatty acids in combination with unmodified fatty acids or the core aldehydes as reported previously (22). On the basis of total peak area, up to 75–80% of the original oil has been oxidized. An examination of the total oxidation mixtures by reversed-phase LC/ESI/MS in the positive ion mode gave elution profiles similar to those obtained

by HPLC with light-scattering detection (chromatograms not shown). Although the residual triacylglycerol species were readily recognized, the parts of the chromatograms containing the oxygenated triacylglycerols were too complex for identification of the molecular species of the core aldehydes. Further reversed-phase HPLC analyses of the oxidized oils were performed following conversion of the aldehyde-containing triacylglycerols into DNPH derivatives.

Figure 3 (upper panel) shows the elution profile of the DNPH derivatives of oxidized sunflower oil triacylglycerols as recorded by reversed-phase LC/ESI/MS in the negative ion mode, along with the full mass spectrum averaged over the core aldehyde elution range (4–25 min). In the negative mode, only the DNPH derivatives and the presumed DNPH polymers (0–5 min) were ionized and detected. The negative ions recorded in the early part of the chromatogram (1.5–4.6 min) were of much lower molecular mass ( $m/z$  403–513) and were attributed to the DNPH derivatives of the short-chain aldehydes and presumed DNPH derivatives produced during the oxidation of the sunflower oil triacylglycerols and were not further investigated. Similar results were obtained for the negative ion mass chromatograms of oxidized corn oil.

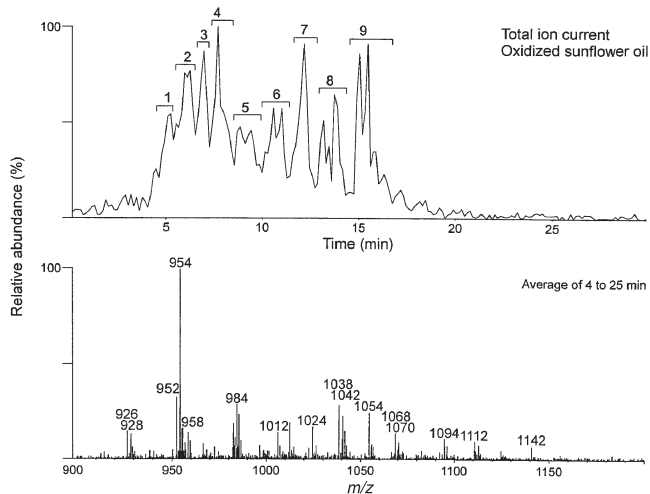

The major ions in the core aldehyde elution range (Fig. 3, lower panel) extend from  $m/z$  926 to  $m/z$  1142, the higher masses clearly exceeding those anticipated for the DNPH derivatives of the simple  $C_9$ – $C_{12:1}$  core aldehydes of sunflower

oil triacylglycerols. The major peaks or peak clusters are numbered 1–9 for reference. The major ions are tentatively identified and assigned to specific peak clusters by determining the full mass spectra associated with each peak cluster as given in Table 3. The peak clusters correspond to the polyoxygenated (clusters 1–3), dioxygenated (clusters 4 and 5), monooxygenated (cluster 6), and simple core aldehydes (clusters 7, 8, and 9) in the oxidized sunflower oil sample. The peaks were identified and quantified by ion extraction from the total negative ion current profile by the computer. All ions represent the DNPH derivatives of triacylglycerols containing at least one core aldehyde group per molecule. The peaks possess symmetrical shapes but are resolved into two or more components based on the relative proportions of the regio- and geometric isomers in the sample. The peaks belong to homologous series and may be aligned according to their TCN. Many more ions could be similarly extracted and identified on the basis of the relative retention times observed for standards or extrapolated from them.

**TABLE 3**  
The Major Ions [as 2,4-dinitrophenylhydrazine (DNPH) derivatives] in Peak Clusters of Total Ion Current Profile of *tert*-Butyl Hydroperoxide (TBHP)-Oxidized Sunflower Seed Oil<sup>a</sup>

<sup>a</sup>Ions were derivatized by DNPH. ALD, aldehyde.

**FIG. 3.** Total negative ion elution profile of the 2,4-dinitrophenylhydrazine (DNPH) derivatives of oxidized sunflower oil triacylglycerols and full mass spectrum averaged over the acylglycerol elution range. Peaks are numbered as clusters in the elution profile and identified on the basis of subsequent analyses as follows: cluster 1, trialdehydes; cluster 2, core aldehyde trihydroxides or epoxydihydroxides; cluster 3, core aldehyde dihydroxides or epoxyhydroxides; cluster 4, core aldehyde hydroperoxides or epoxyhydroxides; cluster 5, core aldehyde hydroperoxides; cluster 6, TBHP adducts of core aldehyde epoxides; cluster 7, TBHP adducts of core aldehydes; cluster 8, core aldehydes; cluster 9, core aldehydes. For identification of ions, see Tables 4–6. Conditions for liquid chromatography with on-line electrospray ionization mass spectrometry (LC/ESI/MS) as in the Materials and Methods section. See Figure 2 for abbreviations.

**TLC of DNPH derivatives.** To confirm the identification of the triacylglycerol core aldehydes, the 2,4-DNPH-treated reaction mixture was subjected to TLC prefractionation. Figure 4 shows the TLC separation of the DNPH derivatives of oxidized sunflower seed oil. The complex mixture was resolved into a total of nine yellow bands and a residual triacylglycerol band (TLC band 10), which did not absorb in daylight but possessed a weak ultraviolet absorption. The oxotriacylglycerols were resolved on the basis of overall polarity and regio- and geometric configuration of the DNPH derivatives as subsequently established by reversed-phase LC/ESI/MS of the individual TLC bands in comparison to standards.

**TLC/LC/ESI/MS of DNPH derivatives.** The structures of the triacylglycerol core aldehydes were further confirmed and the core aldehyde content quantified by examining each TLC band by reversed-phase LC/ESI/MS.

**TLC band 10.** LC/ESI/MS with positive ionization showed that TLC band 10 was made up of residual triacylglycerols along with their TBHP adducts (27).

**TLC bands 9 and 8.** The DNPH derivatives recovered from TLC bands 9 and 8 showed mainly ions with masses below

**FIG. 4.** Normal-phase thin-layer chromatography (TLC) separation of the total mixture of oxidized sunflower oil triacylglycerols following derivatization with 2,4-dinitrophenylhydrazine. TLC band 10, residual triacylglycerols; yellow TLC bands (in daylight) represent, in descending order, the following major components: 9 and 8, short-chain aldehydes; 7 and 6, simple triacylglycerol core aldehydes; 5 and 4, dioxygenated core aldehydes; 3 and 2, polyoxygenated core aldehydes; 1, trioxxygenated core aldehydes. Heptane/isopropyl ether/acetic acid (60:40:4, by vol) solution was used as a mobile phase. The compounds were recovered by extraction with chloroform/methanol 2:1 (by vol) from silica gel 60 H plates. Procedures and conditions are given in the Materials and Methods section.

600, which suggested that the major components of those bands were DNPH derivatives of the volatile short-chain aldehydes also produced by peroxidation of the sunflower oil triacylglycerols, although artifacts arising from polymerization of DNPH also were present. A typical low-molecular-weight aldehyde, hexanal, as the DNPH derivative ( $m/z$  273), was found to migrate between residual triacylglycerols and the simple core aldehyde acylglycerols in our TLC system.

**TLC bands 7 and 6.** Figure 5 shows the total ion current profile (upper panel) of TLC band 7 from oxidized sunflower seed oil, along with the full mass spectrum ( $m/z$  850–1150; lower panel) averaged over the oxotriacylglycerol elution range (2–23 min.). The complex profile of the chromatogram (upper panel of Fig. 5) is deceptive in view of the relative simplicity of the total mass spectrum (lower panel of Fig. 5), which shows major ions at  $m/z$  928, 952, 954, and 956, with minor ions at  $m/z$  876, 1014, and 1040. The peak complexity is due to the chromatographic resolution of the regio- and geometric isomers of the DNPH derivatives of the core aldehydes, which possess identical molecular masses, as shown by the mass chromatograms recorded in Figure 6 for simple core aldehyde peaks eluted over the period of 14.2–18.8 min. These peaks represent combinations of 9:0ALD (where ALD is aldehyde) with the common sunflower oil fatty acids. The major species are: 18:1/9:0ALD/18:2 ( $m/z$  952), 18:1/18:1/9:0ALD ( $m/z$  954), 16:0/18:2/9:0ALD ( $m/z$  926), 18:0/9:0ALD/18:1 ( $m/z$  956), and 16:0/18:0/9:0ALD ( $m/z$  930), and there are many minor ones. These peaks clearly represent derivatives of homologous series of sunflower oil triacylglycerols. However, some fatty acids of the core aldehydes are more saturated than the fatty acids of the typical native

**FIG. 5.** Total negative ion current profile of TLC band 7 of the DNPH derivatives of oxidized sunflower seed oil (upper panel) and the full mass spectrum (lower panel) averaged over the core aldehyde elution range (2–23 min). Peak identification and ion assignment are given in Table 4. Earlier eluted ions are attributed to hydrazones of short-chain aldehydes and artifacts from polymerization of DNPH. LC/ESI/MS conditions are as given in the Materials and Methods section. See Figures 3 and 4 for abbreviations.

**FIG. 6.** Mass chromatograms of major ions of (9-oxo)nonanoyl acylglycerols as DNPH derivatives from TLC band 7 of oxidized sunflower oil. Ion identification is given in Table 4. LC/ESI/MS conditions are as described in the Materials and Methods section. ALD, aldehyde; see Figures 3 and 4 for other abbreviations.

sunflower oil. In addition to 9:0 core aldehydes, a series of compounds was found to correspond to 8:0 core aldehydes. However, there were no masses corresponding to the 13:2 and 12:1 core aldehydes in TLC band 7 nor in TLC bands 8 and 9, which were examined in case these core aldehydes had migrated ahead of the other 9:0 core aldehydes. The peaks eluted over the range of 11–13.5 min, and clearly ahead of the simple core aldehydes, represented the TBHP adducts of the unsaturated core aldehydes. The major adduct species were: 18:1/18:2/9:0ALD, TBHP ( $m/z$  1042), 18:1/18:1/9:0ALD, TBHP ( $m/z$  1040), and 16:0/18:2/9:0ALD, TBHP ( $m/z$  1014). No adducts were seen for the saturated triacylglycerol core aldehyde species. TLC band 7 contained the bulk of the triacylglycerol core aldehydes (mainly mono-9:0) with minor amounts found also in TLC band 6 ( $m/z$  928,  $m/z$  952, and  $m/z$  956) as listed in Table 4. A total of 32 9:0 and 14 8:0 core aldehyde-containing triacylglycerols, including the TBHP adducts, were identified in both corn and sunflower oils. The identifications were consistent with the ion masses, the reversed-phase HPLC retention times of standards, as well as the TCN, and the relative proportions of the parent triacylglycerols in the original oils. The abundance of the molecular ions in the major TLC bands provided an uncalibrated quantification of the various members of each homologous series. The major TBHP adduct species also corresponded to the major species of the triacylglycerol core aldehydes: 18:1/18:2TBHP/9:0ALD DNPH ( $m/z$  1040), 18:2/18:2TBHP/9:0ALD DNPH ( $m/z$  1038), 16:0/18:2TBHP/9:0ALD DNPH ( $m/z$  1014), and others. The masses of the TBHP adducts were consistent with the presence of peroxide bridging at the sites expected to be occupied by hydroperoxyl groups, the retention times on the reversed-phase

column, and TCN, as well as with the structures of the major molecular species of residual triacylglycerols in both corn and sunflower oils. There were no significant ions corresponding to the TBHP adducts of the 12:1 core aldehydes in these bands. A similar approach was used in examining other TLC bands.

**TLC bands 5 and 4.** TLC band 5 contained the bulk of the DNPH-derivatized material. The major ions were found at  $m/z$  956, 966, 982, and 984, with minor ions at  $m/z$  1006, 1008, 1068, 1012, 1024, and 1094, indicating the presence of core aldehydes in combination with two full-length normal or oxidized-chain fatty acids in the same triacylglycerol molecule. There were indications of the presence of several homologous series of the core aldehydes. The minor peaks eluted over the time period 7.5–11.7 min represented mostly the hydroperoxides of the 9:0 core aldehydes with  $m/z$  values of 982, 958, 984, 986, 988, and 1042. In the hydroperoxides of 9:0 core aldehydes, the hydroperoxyl group was located on one of two unsaturated fatty acids bound to the triacylglycerol molecule containing the aldehyde group. The peaks eluted over the time period 11.8–13.9 min included ions with  $m/z$  values of 1000 and 1026, which could be attributed to TBHP adducts of 12:1 core aldehydes. The peaks eluted over the time period 9.3–12.7 min represent the TBHP adducts of the 12:1 core aldehyde monoepoxides with  $m/z$  values of 1092, 1094, 1068, 1070, 1096, and 1098. The peaks emerging over the time period 12.3–20.3 min represent an orderly elution sequence of the monoepoxides of 12:1 core aldehydes with  $m/z$  values of 1006, 980, 956, 1008, 982, and 1010. The sudden appearance of the 12:1 aldehydes in the epoxy triacylglycerols suggests that the epoxy group is located on the 12:1 aldehyde chain. The monoepoxides of 12:1 core aldehydes have two fatty acids and the epoxidized 12:1 aldehyde chain esterified to a parent triacylglycerol. However, the structures of epoxy compounds are shown in this paper without the loss of double bonds to indicate the original composition of core aldehydes. TLC band 4 contained the regioisomers of the epoxy core aldehydes in TLC band 5 along with the corresponding TBHP adducts (mass chromatograms not shown). The chromatographic properties and the relative quantities of the epoxides of the 12:1 core aldehydes and the corresponding TBHP adducts in TLC bands 5 and 4 are given in Table 5 in order of the reversed-phase HPLC retention times. In all instances, the relative proportions of the aldehyde derivatives corresponded to the relative proportions of the major triacylglycerols in the original oils. In the case of corn oil, some of the core aldehyde hydroperoxides were found, in part, in TLC bands 6 and 4 and in TLC bands 4 and 3. The identification of all major aldehyde hydroperoxides was consistent with ion masses and relative retention times of standards, as well as the TCN and the total acyl carbon and double-bond numbers. The molecular-ion abundances in the major TLC bands provide uncorrected estimates of the relative quantities of the various members of each homologous series.

**TLC bands 3, 2, and 1.** These minor TLC fractions represent the core aldehydes of the more highly oxygenated tri-

TABLE 4

Composition and Structure of Triacylglycerol Core Aldehydes and Peroxide Adducts in TBHP-Oxidized Corn and Sunflower Seed Oils as Determined by Reversed-Phase Liquid Chromatography with On-line Electrospray Ionization Mass Spectrometry (LC/ESI/MS) (TLC bands 6 and 7)<sup>a</sup>

acylglycerols possessing complex elution profiles (total ion currents not shown). The tentative peak identifications again were based on the TLC/HPLC behavior of synthetic standards, the specificity of the negative ion response to the DNPH derivatives, and knowledge of the general nature of the products of TBHP oxidation of standard triacylglycerols. As an example, Figure 7 shows the single ion mass chro-

matograms of major hydroxy (9-oxo)nonanoyl acylglycerols extracted from TLC band 2. Table 6 summarizes the chromatographic properties of the identified peaks along with the ion abundance recorded for each molecular species in TLC bands 3 and 2 and in the most polar minor TLC band 1. There remained significant ion abundance at  $m/z$  1040, 1056, 958, 980, 960, 982, 986, 1008, and 1012 in TLC band 3 and at  $m/z$

902, 984 1054, 1142, 1026, 944, 970, 1194, 986, 982, and 1012 in TLC band 2, for which identities consistent with the retention time, TCN, acyl carbon and double-bond numbers, and *m/z* values could not be immediately suggested.

Table 7 gives the estimated yields of the identified oxidation products for both seed oils. Depending on the mass range over which the total ion current is integrated, the overall yields of the identified aldehyde-containing triacylglycerols range from 32 to 43% of DNPH derivatives in the total oxidation mixture. The major product was the mixed acid acylglycerol containing the 9:0 monoaldehyde (44–60% of identified core aldehydes) followed by hydroperoxy (13–16% of the identified species) and mono-

epoxy aldehydes (11–12% of the identified species) and hydroperoxyepoxy aldehydes (up to 10% of the identified species). More of the TBHP adduct was obtained during the oxidation of the sunflower oil. The major ion masses correspond to the monoaldehyde esters of the 16:0/18:1/18:2 (16:0/18:1/9:0ALD DNPH, *m/z* 928), 16:0/18:2/18:0 (16:0/9:0ALD/18:0DNPH, *m/z* 930), 18:1/18:1/18:2 (18:1/18:1/9:0ALD DNPH, *m/z* 954), 18:1/18:2/18:2 (18:1/18:2/9:0ALD DNPH, *m/z* 952), and 18:0/18:1/18:2 (18:0/18:1/9:0ALD DNPH, *m/z* 956) species, which are the major triacylglycerols in corn and sunflower oils. Apparently, the linoleic acid residue in each instance was converted to the (9-oxo)nonanoate and, to a lesser extent, the

<sup>d</sup>Abundance of ion in the major TLC band.

<sup>e</sup>Core aldehyde regioisomers consistent with chromatographic and MS properties.

triacylglycerols of intermediate polarity were represented by triacylglycerols containing two core aldehyde groups (mainly TLC bands 4 and 5), whereas the least polar were the oxotriacylglycerols with a single core aldehyde group (TLC bands 6 and 7). There was partial resolution of triacylglycerols containing a single 9:0 or 12:1 core aldehyde in the primary and the secondary position. Further complications arose from a conversion of some of the aldehyde groups into acids by further oxidation. These oxidation products were seen as DNPH derivatives only when combined with another aldehyde or keto group in the same molecule (data not shown).

## DISCUSSION

TBHP is a synthetic organic hydroperoxide that is commonly employed to accelerate lipid peroxidation *in vitro*. The decomposition of the hydroperoxide to alkoxy or peroxy radicals stimulates the chain reaction of lipid peroxidation. The decomposition is aided by metal ions such as  $\text{Fe}^{2+}$  and their complexes (28). In order to increase the yield of the secondary oxidation products (e.g., core aldehydes) in the present study, the triacylglycerol peroxidation and hydroperoxide decomposition were further stimulated by elevated temperature (37°C) and the inclusion of bile salts as emulsifiers. As a result of oxidation, it was possible to obtain within 1–2 h a controlled oxidative destruction of corn and sunflower oil triacylglycerols equivalent to many months of autoxidation by thin-film exposure to air. About 90% destruction of 18:2 had occurred with relatively little loss of 18:1 as judged from the ratio of the unsaturated fatty acids to palmitic acid in the oxidized oil. The proportion of the saturated fatty acids (16:0, 18:0, 20:0, and 22:0) had proportionally increased in the oxidized corn and sunflower oil triacylglycerols along with the appearance of hydroperoxy and epoxy fatty acids (data not shown). It was, therefore, anticipated that the major triacylglycerol core aldehydes would have arisen largely from the oxidation of 18:2 and would be found in combination with palmitic and oleic acids as the DNPH derivatives of the oxotriacylglycerols.

The main mechanism for the formation of aldehydes from lipid hydroperoxides is homolytic scission ( $\beta$ -cleavage) of the two C–C bonds on either side of the hydroperoxy group (6,29) as shown in Figure 8. This reaction proceeds *via* the lipid alkoxy radical. Applying this mechanism to triacylglycerols, it would be anticipated that the cleavage of the carbon–carbon bond would result in aldehydes derived from the methyl termini of the fatty acid chains and of aldehydes still bound to the parent lipid molecule. Hydroperoxides also undergo heterolytic reactions yielding the same products as homolytic reactions. Another possible mechanism for the formation of aldehydes is the Hock–Criegee rearrangement (29,30). This acid-catalyzed carbon-to-oxygen rearrangement of hydroperoxides would be expected to yield products from linoleic acid hydroperoxide cleavage similar to those arising from homolytic scission (29).

Oxidation of methyl oleate (1–3,6), has shown that the 9-

**FIG. 8.** Postulated formation of triacylglycerol core aldehydes from linoleic acid-containing triacylglycerol. R<sub>1</sub> and R<sub>2</sub> are fatty acids esterified to a parent triacylglycerol. Positions of cleavage of the fatty acid chain of hydroperoxides are numbered 1 to 3. In oxidation by TBHP, the 9,10-epoxy derivative of the (12-oxo)dodecenoyl core aldehyde is assumed to be formed in preference to 9-hydroxy-10,11-dodecenoyl core aldehydes. Formation of the core aldehyde can take place on any *sn*-position of acylglycerol. See Figures 2 and 6 for abbreviations.

and 10-hydroperoxides are formed in amounts approximately similar to those of the 8- and 11-hydroperoxides. Therefore, the oleic acid-containing triacylglycerols would be expected to yield (8-oxo)octanoyl and (11-oxo)-9,10-undecenoyl acylglycerols, as well as (9-oxo)nonanoyl and (10-oxo)-8,9-decenoyl acylglycerols. Indeed, small amounts of (8-oxo)octanoyl-containing acylglycerols were observed. Specific masses corresponding to (10-oxo)- $\Delta^8$ -decenoyl and (11-oxo)-9,10-undecenoyl acylglycerols were not found, however. It is possible that the ions arising from the minor (11-oxo)-9,10-undecenoyl acylglycerols overlapped with those arising from the major (9-oxo)nonanoyl acylglycerols.

The major hydroperoxides arising from the oxidation of methyl linoleate are the 9-hydroperoxy and 13-hydroperoxy isomers in equal amounts (2,31). Recently, the 11-hydroperoxide of linoleic acid has been recognized as one of the primary oxidation products (32). It made up 5–10% of the abundance of 9- and 13-hydroperoxide in vitamin E-controlled autoxidation. However, in the absence of vitamin E, 11-peroxyl radicals are not stable and 9- and 13-hydroperoxides predominate (32). The core aldehydes derived from 9- and 13-hydroperoxides of linoleic acid-containing acylglycerols are expected to be 8-nonanoic acid and 9-oxononanoyl-, (12-oxo)-9,10-dodecenoyl, and (13-oxo)-9,11-tridecadienoyl acylglycerols (6,29,33,34). Figure 8 shows the proposed formation of the major core aldehydes from linoleic acid attributable to autoxidation and oxidation by TBHP. According to Frankel (33), the homolytic cleavage of the oxygen–oxygen

bond is the first step in the decomposition of unsaturated hydroperoxides (33). Decomposition proceeds with cleavage of the fatty acid chain on either side of the hydroperoxide group or by cleavage of the oxygen-carbon bond, leading to positional isomerization of the unsaturated hydroperoxides. Simple  $\beta$ -cleavage to 9- and 13-hydroperoxide would produce 9-oxo- and 12-oxo-derivatives as major core aldehydes. The formation of the (12-oxo)-9,10-dodecenoyl acylglycerols would involve another mechanism linked closely with the  $\beta$ -cleavage reaction and would depend upon an alkenyl radical formation. This 1-olefin radical could combine with a hydroxy radical to form an enol which would rearrange to an aldehyde (6,33). Esterbauer *et al.* (6) have pointed out still another possibility provided by the reaction with oxygen to form a hydroperoxide that can decompose again to the enol and then form the aldehyde. If this radical abstracted a hydrogen, it would become a core alkene, which would not be detected as the DNPH derivative unless another aldehyde group was present in the acylglycerol molecule. In the present study, there was no evidence for the presence of core aldehydes carrying short alkene chains in the acylglycerol molecules.

Acid-catalyzed cleavage of the fatty acid chain between the hydroperoxide group and the  $\alpha$ -olefinic carbon leads also to formation of the (12-oxo)-9,10-dodecenoyl acylglycerol from the 13-hydroperoxide of oxidized linoleic acid (29,30). Whereas the 9-oxononanoyl and (12-oxo)-9,10-dodecenoyl acylglycerols were readily detected, those corresponding to the (13-oxo)-9,11-tridecadienoyl acylglycerols were not found. Apparently, this unsaturated core aldehyde did not survive the oxidation and/or workup conditions. In plants, enzymatic processes resembling radical cleavage reactions take place. Gardner (34) has categorized two types of hydroperoxide lyases as heterolytic and homolytic types, found in higher plants and mushrooms, respectively. The heterolytic type of lyase catalyzes the cleavage of the fatty acid chain between the hydroperoxide group and the  $\alpha$ -olefinic carbon, resembling acid-catalyzed cleavage of the hydroperoxide. As a result of decomposition of the 13-hydroperoxide, (13-oxo)-9,11-tridecadienoyl is formed when homolytic lyase activity is present, mimicking  $\beta$ -scission.

The absence of the 12:1 aldehydes from the simple core aldehyde fractions and their appearance in the epoxy triacylglycerol fractions suggest that the epoxy group is associated with the 12:1 aldehyde chain. According to Frankel *et al.* (35) and Frankel (1,3), epoxy esters of 18:1 can arise from its reaction with hydroperoxides or from the hydroperoxides themselves. Gardner *et al.* (36) have discussed the enzymatic and nonenzymatic decomposition mechanisms for linoleic acid hydroperoxides leading to epoxide formation. The major pathways postulated for decomposition in the presence of  $\text{Fe}^{3+}$ /cysteine catalyst involved formation of an alkoxy radical by loss of OH, cyclization of the alkoxy radical to the  $\alpha$ -unsaturation, and reaction of the epoxy allylic radical either with  $\text{O}_2$  to form an epoxyhydroperoxy monoene or with OH to form the epoxyhydroxy monoene, as well as other reactions. Noordermeer *et al.* (37) have identified 9-hydroxy-(12-

oxo)-(10E)- and 11-hydroxy-(12-oxo)-(9Z)-dodecenoic acids in incubations of (12-oxo)-(9Z)-dodecenoic acid formed by a nonenzymatic process. Our results are in accordance with the findings of Noordermeer *et al.* (37), which showed that (12-oxo)dodecenoyl acylglycerols are readily further oxidized to the corresponding hydroxy, hydroperoxy, or epoxy compounds. It is possible that epoxy compounds may be formed more readily than hydroperoxy or hydroxy derivatives during TBHP oxidation. Indeed, TBHP has been employed as the oxidant for epoxidation of oleic, linoleic, linolenic, and arachidonic acids in aqueous buffers containing surfactant or in organic solvents (38). In the present study, tentative identifications were made of the diepoxides based on their migration on TLC.

The identity of the hydroperoxy linoleic and oleic acid components of the oxoacylglycerols was determined by GC-MS analysis following collection of individual HPLC peaks, hydrogenation (platinum oxide catalyst), and transmethylation with sodium methoxide. Samples were analyzed as their trimethylsilyl ether derivatives as described by Hughes *et al.* (39). In each case, the position of hydroxylation was determined from the major fragment ions formed on either side of the oxygen trimethylsilyl group. The *cis/trans* configuration of bonds was assigned on the basis of previous work. Porter *et al.* (40) had shown that the *cis/trans* isomers eluted earlier than the corresponding *trans/trans* isomers when normal-phase HPLC systems were used. According to Park *et al.* (41), the *cis/trans* isomer of the 9-hydroperoxy derivative of trilinoleoylglycerol eluted ahead of the 9-hydroperoxy *trans/trans* isomer from a reversed-phase column. However, the *trans/trans* isomer of the 13-hydroperoxy trilinoleoylglycerol eluted ahead of the corresponding *cis/trans* isomer.

In addition to core aldehydes, ketones were expected to be found among DNPH derivatives of TBHP-oxidized seed oil triacylglycerols. Because a homologous series of appropriate ions was not found, it was not possible to conclude that any isolated masses corresponding to hypothetical DNPH derivatives of ketotriacylglycerols were actually present. Individual keto compounds may have been present in our preparations, but specific identifications were not made owing to a lack of appropriate reference compounds. Possible ketotriacylglycerols could be represented by such ions as  $m/z$  1092,  $m/z$  1094, and  $m/z$  1096, which were tentatively assigned to the TBHP adducts of epoxy 12:1 aldehydes on the basis of their chromatographic behavior.

Many of the triacylglycerol core aldehydes appeared as double peaks, which were attributed to regioisomers. On the basis of previous work with standard oxotriacylglycerols (22,42), the earlier eluted peak was attributed to an aldehyde in the secondary position and the later eluted peak to an aldehyde in the primary position of the oxidized triacylglycerol molecule. A functional group in the *sn*-2 position is known to exert higher polarity than a similar group in the *sn*-1 or *sn*-3 position of the triacylglycerol molecule (22,43,44). Furthermore, each regioisomer possessed a double peak, which was

attributed to a partial resolution of the *syn/anti* isomers of the DNPH derivatives. Previous studies with DNPH derivatives of core aldehydes of known triacylglycerol structure (22) also had given two peaks, the main peak, representing 75–85% of the total, emerging ahead of the minor one, accounting for 15–25%, as estimated by reversed-phase HPLC with ultraviolet detection at 358 nm. However, a clear separation of the geometric isomers was not always obtained for the mixed triacylglycerols of the oxidized seed oils. Identification of regioisomers was complicated due to *syn/anti* isomerism of dinitrophenylhydrazones. Double peaks of DNPH derivatives have been reported to occur also in other analyses of DNPH derivatized carbonyl compounds. Kuklev *et al.* (45) have shown that the 12,13-epoxide runs ahead of the 9,10-epoxide of linoleate on adsorption TLC; this order would be reversed on reversed-phase HPLC. Likewise, 13-keto linoleate migrated ahead of 9-keto linoleate on TLC; again, the order would be reversed on reversed-phase HPLC. The nature of the solvent is known to affect the order of HPLC elution as well as the isomer ratios of these compounds (46).

The only unusual structures, although not unexpected (47), were the TBHP adducts of the unsaturated triacylglycerol core aldehydes. These compounds could have been formed in a termination reaction between a *tert*-butylhydroperoxy radical and an alkenyl radical or between a lipid hydroperoxy radical and the *tert*-butyl radical. The formation of the *tert*-butyl derivatives of the lipid hydroperoxides has a precedent in the existence of di-*tert*-butyl peroxide (40), as well as in the formation of cyclic peroxides during decomposition of linoleate hydroperoxides (31,48) and tocopherol adducts (42). Furthermore, Miyashita *et al.* (31) have demonstrated that oxygenation of methyl linoleate hydroperoxides yields dimers composed of octadecadienoate and octadecenoate moieties cross-linked through either ether or peroxy linkages across the 9- or 13-positions. Yamauchi *et al.* (49) have shown the formation of  $\alpha$ -tocopherol adducts with phosphatidylcholine peroxy radicals.

Finally, the absence of the (13-oxo)tridecadienoyl core aldehydes as oxidation products seems to be consistent with the absence of this core aldehyde also among the autoxidation products of cholesteryl linoleate (20,50) and of linoleate-containing glycerophospholipids (51). Very little work has been done on the triacylglycerol core aldehydes (21,22,42), and their structures have been assigned on the basis of the known routes of degradation of the hydroperoxides of methyl oleate and linoleate (1–3).

In conclusion, the present study demonstrates the formation of a large variety of triacylglycerol core aldehydes during a brief treatment of corn and sunflower oils, with TBHP. The identification of the high-molecular-weight aldehydes was simplified by derivatization with DNPH, normal-phase TLC isolation, and reversed-phase HPLC separation with on-line negative ion MS, which specifically detects the DNPH derivatives. By the combined application of the criteria of chemical derivatization, chromatographic, and MS behavior, it was possible to eliminate many of the uncertainties posed

by coincidental peaks and ions. The chromatographic and MS methods developed here for the characterization of the triacylglycerol core aldehydes arising from *tert*-butyl hydroperoxidation should be suitable for the identification of the core aldehydes among the autoxidation and enzymatic oxidation products of tissue triacylglycerols. This technology may also have applications in atherosclerosis research by permitting identification of aldehydic products formed during the autoxidation of low density lipoprotein (LDL), in which cholesteryl esters predominate. The study shows that rapid peroxidation with TBHP provides an effective method for enriching unsaturated vegetable oils in triacylglycerol core aldehydes for dietary and metabolic testing.

**ABSTRACT:** The role of body fat content and distribution in infants is becoming an area of increasing interest, especially as perception of its function appears to be rapidly evolving. Although a number of methods are available to estimate body fat content in adults, many are of limited use in infants, especially in the context of regional distribution and internal depots. In this study we developed and implemented a whole-body magnetic resonance imaging (MRI)-based protocol that allows fast and reproducible measurements of adipose tissue content in newborn infants, with an intra-observer variability of <2.4% and an inter-observer variability of <7%. The percentage total body fat for this cohort of infants ranged from 13.3–22.6% (mean and standard deviation: 16.6 ± 2.9%), which agrees closely with published data. Subcutaneous fat accounted for just over 89% of the total body fat, whereas internal fat corresponded to almost 11%, most of which was nonabdominal fat. There were no gender differences in total or regional body fat content. These results show that whole-body MRI can be readily applied to the study of adipose tissue content and distribution in newborn infants. Furthermore, its noninvasive nature makes it an ideal method for longitudinal and interventional studies in newborn infants.

Paper no. L8876 in *Lipids* 37, 95–100 (January 2002).

Recent advances in molecular biology are helping to redefine the role of adipose tissue (AT). This organ was originally perceived as a passive storage site for excess fat, but it is now considered a highly active, finely tuned metabolic tissue, exerting control on numerous biochemical and physiological processes in both health and disease.

Body fat content and distribution in adults influence the risk of coronary heart disease, hypertension, and type II diabetes (1). Barker *et al.* (2–4) hypothesized that infants who are small and thin at birth are at increased risk of developing cardiovascular disease and type II diabetes in adulthood. However, the relationship between body weight, fat content,

and distribution in neonates and their contribution to chronic disease in adults is unclear. This is partly due to a lack of safe and accurate methods to determine AT content and distribution in newborn infants and track changes through time.

Existing techniques for measuring body fat include underwater weighing, body water dilution, anthropometry, impedance, dual-energy x-ray absorptiometry (DXA), and total body electrical conductivity (5). Some of these techniques are clearly unsuitable for neonatal studies, for both technical and practical reasons. Several postmortem studies of fetal and infant body composition have greatly enhanced our understanding of fat deposition during *in utero* development and postnatal growth. However, the very nature of this work makes serial studies impossible (6–9). Recent developments in DXA have enabled the serial measurement of total body fat in adults and infants (10–13). An important limitation of DXA is the inability to differentiate between different fat compartments so as to quantify visceral AT, perhaps the most important AT depot in human physiology, independently of total fat mass (1,14).

Magnetic resonance imaging (MRI) scanning is a technique that is of minimal risk to the neonate and is noninvasive, capable of quantifying total and discrete AT depots, and therefore ideal for examining changes over time. MRI assessment of AT has been validated in animals (15,16), human cadavers (17), and human adults (18). MRI accurately measures AT *in vivo*, showing good agreement with the values produced by dissection and chemical analysis (15–17). Furthermore, whole-body MRI gives an unbiased measurement of the fat content, both internal and subcutaneous, for a large range of body shapes and sizes (19). To date there has been limited application of MRI to the study of AT content in neonates (20,21). Deans *et al.* (20) measured body fat content of human fetuses *in utero* at 40 wk gestation and showed significant differences in fat content between infants from healthy women and those with gestational diabetes. Olhager *et al.* (21) measured total body fat in infants aged between 19 and 107 d old and made a detailed study of the reproducibility of the image analysis. However, a drawback of both the previous MRI studies is that they did not differentiate between different AT compartments. The aim of the present study was to develop an MRI protocol that would allow for routine and noninvasive quantification of total and regional AT in newborn infants.

## SUBJECTS AND METHODS

**Subjects.** This study was approved by the Ethics Committee of the Imperial College School of Medicine and Hammer-smith Hospitals Trust, London. Parents of healthy newborn babies were approached for permission to recruit their babies. Informed parental consent was obtained.

Eight term Caucasian infants (4 males, 4 females) participated in the first phase of the study. Infants were scanned within 36 h of delivery. Anthropometric measurements were obtained at the same time.

**MRI. (i) Protocol.** All newborn infants underwent whole-body (head-to-toe) MRI using an Eclipse 1.5T Marconi Medical System scanner. The MRI sequence used in this study was adapted from a previously developed whole-body adult scanning protocol (19,22). Modification to the adult protocol took into account several factors pertinent to neonatal scanning, including signal-to-noise ratio (S/N), tissue contrast, and acoustic noise levels. A compromise between these factors and the need for good quality images led to the use of a  $T_1$ -weighted spin-echo sequence because it gives good tissue contrast, has relatively low acoustic noise, and is reasonably fast. Further reduction in scanning time was achieved by using 5-mm thick transverse images, with 5-mm gaps between slices. This method was shown to have little effect on the overall quantitation of body fat if the gaps between slices do not exceed one slice thickness (19).

S/N was maximized by using a small transmitter receiver birdcage coil (head coil, internal diameter 27 cm) instead of the conventional body coil (Fig. 1). Potential image distortions, which could compromise subsequent fat quantitation, were minimized by mapping the coil homogeneity. Phantom studies showed that the useful imaging length along the coil axis, before radiofrequency inhomogeneity results in signal

**FIG. 1.** Photograph showing the arrangement of the mobile platform (B) within the birdcage coil (A). The mobile platform allows the infant to be moved through the coil in a fast and accurate manner, without the need to remove the subject from the magnet. (See the Subjects and Methods section for more details.)

loss and imaging distortion, was limited to 20 cm. Given that the length of most infants was larger than the homogeneous area of the coil, a graduated (1 cm steps) mobile bed/platform was designed that allowed the infant to be repositioned within the coil with minimal disturbance. A photograph showing the bird-cage coil and mobile platform is shown in Figure 1.

**(ii) MRI scanning.** Infants were positioned supine during natural sleep on the platform and were swaddled to keep them as stationary as possible during the scan. We used a  $T_1$ -weighted spin-echo imaging sequence, repetition time (TR) = 600 ms, echo time (TE) = 16 ms, field of view = 24 cm, number of signals averaged = 2, and a  $256 \times 256$  matrix after phase conjugate symmetry giving a scanning time of 2.52 minutes per set of images. Twenty 5-mm thick transverse images with 5 mm gaps between slices gave 20 cm coverage. The platform was then moved 20 cms and imaging repeated. The overall scanning time was approximately 6 min. Infants were monitored using a pulse oximeter. Both a neonatal nurse and a pediatrician were present during the procedure.

**(iii) Data analysis.** Images were analyzed as previously described (19) using an image segmentation software program developed in-house that employs a threshold range and a contour-following algorithm with an interactive image editing facility. The threshold range, which isolates the AT, was computed automatically, calculated from the greyscale histogram within a contour that defined the outer boundary of subcutaneous AT and noise.

The volumes ( $\text{cm}^3$ ) of each AT compartment were determined by summing the relevant voxel counts and multiplying by the voxel dimensions in  $\text{cm}^3$ . Total body AT content was calculated by multiplying the AT volumes of each slice by the sum of the slice thickness (5 mm) and inter-slice distance (5 mm). Therefore, this analysis provides a direct measure of the volume of AT rather than the quantity of triglyceride contained within the AT. Each slice was reviewed using the interactive program that enables detection of unwanted pixels (such as milk in the stomach and bowels), which, because they contain fat, have intensity levels similar to AT. The AT depots were separated to measure pixel count in total AT, subcutaneous AT, and total internal AT. Total internal AT was subdivided into visceral and nonvisceral adipose tissue. Visceral AT content was obtained by quantifying AT in the slices from the sacrum to the slice containing the top of the liver or base of the lungs (19). Subcutaneous AT in this region of the body was termed abdominal subcutaneous AT. All other internal adipose tissue was considered nonvisceral AT.

The MRI data in liters is converted to percentage AT using the following equations:

$$\text{AT in kg} = \text{AT in liters} \times 0.9 \quad [1]$$

$$\text{Percentage AT} = (\text{AT in kg/body weight in kg}) \times 100 \quad [2]$$

The factor 0.9 in Equation 1 is the widely accepted value for the density of AT in  $\text{kg/L}$  and is required to convert the volume of adipose tissue in liters to the mass of AT in kg.

Total AT fat was calculated assuming 1 cm<sup>3</sup> of AT contains 0.66 g of fat (23; measured in infants):

$$\text{fat mass in kg} = \text{AT in liters} \times 0.66 \quad [3]$$

$$\text{total AT fat} = (\text{fat mass in kg/body weight in kg}) \times 100 \quad [4]$$

(iv) *Reproducibility measurements.* MRI studies have shown that the largest variability in the technique appears to be introduced during the data analysis stage (24). To assess the coefficient of variation (CoV) of the technique (intra-observer and inter-observer variability), whole-body images from a newborn, a 6-wk-old, and a 6-mon-old infant were analyzed by three independent observers.

*Anthropometry.* Infants' weights, lengths, and head circumferences were recorded by a single trained observer (TH). Scales used were accurate to 0.2 g (Marsden Professional Baby Scale), length was measured by using a Rollametre (Raven Equipment Ltd.), and head circumference using a measuring tape from the Child Growth Foundation.

*Statistical analysis.* All data are expressed as mean  $\pm$  standard deviation (SD). Data were tested for normality using the Shapiro–Wilk normality test. Differences between male and female infants were tested using the Student's unpaired *t*-test. Statistical analyses were performed using Unistat version 4.53. The level of significance was set at  $P < 0.05$ .

## RESULTS

Data were obtained from eight term Caucasian infants (4 males, 4 females) with a mean gestational age of  $39.1 \pm 1.6$  wk (range 36–41 wk) and a mean birth weight of  $3.5 \pm 0.5$  kg (range 2.6–4.3 kg).

The protocol for whole-body AT imaging of newborn infants developed and implemented in this study resulted in an average of 40–50 images per infant. The overall scanning time was approximately 6 min. A selection of typical images from one of these infants is shown in Figure 2. The T<sub>1</sub>-weighted imaging protocol resulted in images with high contrast between AT and other tissues, with the former appearing as high signal intensity. A three-dimensional reconstruction of the total data set is shown in Figure 3.

The reproducibility of the MRI analysis method was assessed by measuring AT content in infants with different quantities of AT. The intra-observer CoV for subcutaneous AT appears to be directly related to the relative AT content of the infant (ranging from 1–7%), with thinner babies showing the largest CoV. For internal body AT the CoV appeared to be independent of body size (*ca.* 7%). The inter-observer CoV in this study was 2.4% for subcutaneous AT and 17.6% for internal AT. To minimize inter-observer variability, all images in this study were analyzed by the same observer (ELT).

The data obtained from the MRI may be expressed as absolute values in liters, percentage AT mass, or total AT fat (i.e., correcting for the lipid content of AT). All of these values are shown in Table 1. The data in the remainder of the

**FIG. 2.** Typical magnetic resonance images obtained from a full-term newborn male infant (6 h after birth). A total of 40–50 images was normally acquired for each infant; some representative slices are shown here: (A) the brain at the low ventricular level, (B) upper cervical spine, (C) apices of lung, (D) abdomen at level of kidneys, (E) lower abdomen, (F) upper femur, (G) calf, and (H) feet. The magnetic resonance imaging protocol used in this study leads to adipose tissue appearing as high intensity compared to other tissues.

**TABLE 1**  
**Adipose Tissue and Fat Content in Newborn Infants by Magnetic Resonance Imaging<sup>a</sup>**

	Total	Subcutaneous	Internal	Subcutaneous abdominal	Visceral	Nonvisceral internal
Adipose tissue (liters)	0.9 ± 0.3 (0.5–1.5)	0.8 ± 0.3 (0.5–1.3)	0.09 ± 0.2 (0.06 ± 0.14)	0.11 ± 0.06 (0.06 ± 0.25)	0.03 ± 0.01 (0.01–0.04)	0.06 ± 0.02 (0.05–0.01)
Adipose tissue (%)	22.7 ± 4.0 (18.5–30.8)	20.3 ± 3.9 (15.9–27.8)	2.4 ± 0.6 (1.5–3.0)	3.2 ± 1.2 (1.8–5.8)	0.9 ± 0.3 (0.3–1.3)	1.5 ± 0.4 (1.1–2.1)
Total adipose tissue fat (%)	16.6 ± 2.9 (13.5–22.6)	14.9 ± 2.9 (11.7–20.4)	1.8 ± 0.4 (1.1–2.2)	2.3 ± 0.9 (1.3–4.2)	0.7 ± 0.2 (0.2–1.0)	1.1 ± 0.3 (0.8–1.6)

<sup>a</sup>Results presented as mean ± standard deviation and range.

results and discussion are expressed as total AT fat to allow ready comparison with literature values.

Total AT fat as a percentage of body weight for all eight infants studied by MRI ranged from 13.5–22.6%, with a mean value of 16.6 ± 2.9%. The percentage subcutaneous fat was 14.9 ± 2.9% (range 11.7–20.4%) and internal 1.8 ± 0.4% (range 1.1–2.2%). The ratio of internal to subcutaneous AT fat was 0.12 ± 0.03 (range 0.07–0.16). Investigating the abdomen in more detail, we found there was 2.3 ± 1.0% (range 1.3–4.2%) abdominal subcutaneous AT fat as a percentage of body weight and 0.7 ± 0.2% (range 0.2–1.0%) visceral AT fat. Most of the internal fat in infants appears to be nonabdominal and generally is found in the pelvis and limbs, as the visceral AT fat measured in this study was approximately 33% of the total internal AT fat measured. There were no significant gender differences in total body or regional AT fat content.

## DISCUSSION

The increasing interest in the potential role of AT on physiological and biochemical processes in health and disease has led to the need for accurate methodologies to assess AT content and distribution in neonates and infants. In this study we have shown that MRI allows direct and reproducible quantitation of both subcutaneous and visceral AT depots in newborn infants.

The MRI protocol developed and implemented in this study shows high reproducibility, is relatively fast, with significantly reduced acoustic noise. The images obtained with this sequence gave good contrast between AT and other tissues including muscle and internal organs. It did not, however, allow differentiation between white and brown AT depots, and all AT appeared with the same relative intensity in the MRI. The lack of contrast between brown and AT in the MR images is not surprising given that this has only been achieved in rodents using very specialized sequences and at very high field strengths (25).

At present there is no established “gold standard” technique for measuring body composition in infants with which to make a direct comparison of the MRI results obtained in the present study. Most available methods for determining AT and fat content are indirect. They utilize the measurement of different body compartments with subsequent extrapolation

in order to derive a value for AT and fat mass. MRI protocols, similar to that described in the present study, have previously been validated in both adults and animals by chemical analysis of cadaver and animal carcasses, suggesting that this non-invasive method gives an accurate measurement of body AT fat content (15–17). Moreover, these studies have demonstrated that MRI can be used to determine different AT depots, something that cannot be readily achieved with other noninvasive methods (15–17).

The relative levels of total body AT fat in newborn infants obtained in the present study (*ca.* 16.6%) compare well with those previously reported using other techniques. Widdowson (6) and Hager *et al.* (26) both reported a percentage body fat of 16% in infants using chemical analysis and whole body potassium counting, respectively. Similarly White *et al.* (7) reported an AT content of 14% by chemical dissection. Fomon *et al.* (27,28) in different studies have reported a reference infant body composition of between 11% (chemical analysis) and 14% [using a combination of anthropometry and data by Southgate and Hey (9)]. Forsum *et al.* (29), using anthropometric and skinfold measurements, showed the percentage body fat in 22 ten-day-old female infants to be 15.9% (29). Similarly, Dauncey *et al.* (30) reported a body fat content of 12% in newborn infants using anthropometry. Ziegler *et al.* (8) published body composition for the reference fetus in which the lipid content for an infant between 37–40 wk gestation was approximately 10%. This is somewhat lower than the results of both the current study and other studies using chemical analysis, but as the authors point out, the fetuses included in the study were of a relatively small size. The MRI results obtained in the present study were also similar to those reported using DXA for a similar cohort of newborn infants (15.3%, Picaud *et al.*, 10; 15.7%, Rigo *et al.*, 11; 12.8%, Butte *et al.*, 13).

In contrast to total AT fat, regional distribution of subcutaneous and internal AT fat measurements in the current study cannot be readily compared with other published data. Previous MRI studies by Deans *et al.* (20) of fetal fat content at 40 wk gestation *in utero* have found similar body fat content to that in the present study (17.2%, *cf.* 16.6%) (20). However, the authors did not appear to differentiate between internal and subcutaneous AT. Similarly, Olhager *et al.* (21) have obtained comparable measures of fat content in infants (21). Olhager *et al.* produced a percentage body fat ranging from 17.4 to 22.4%. However, their

cohort of infants covered a broad age range, 19–107 d, compared to the present study where all infants scanned were less than 36 h old. Furthermore, the authors do not provide figures for regional fat depots although they do state that 90% of the total AT volume was subcutaneous. This value is similar to that observed in the present study (89%), and as we have shown in this study, most of the internal AT is principally nonabdominal AT.

No significant gender differences in total or regional AT fat content were observed in this study. Although female infants tended to have slightly less visceral fat compared with male infants, this did not reach the level of significance. Gender differences have previously been reported, mainly in studies with a large cohort of infants (11–13,30,31). This suggests that the gender differences are relatively small. Indeed Rigo *et al.* (11) reported that on average female infants have 50 g more fat than male infants at birth, which corresponds to a difference of approximately 1.5% between male and female infants. This is well within the CoV of most techniques, including MRI, and therefore unlikely to be detected in a small cohort of infants.

Interestingly, Kabir and Forsum (23) found a gender difference in nonsubcutaneous fat, assessed by a combination of body water dilution, skinfold thickness, and ultrasonography. This should correspond to our measure of internal fat in the current study, which was not significantly different between the male and female infants studied. This may be related to the methodology used by Kabir and Forsum for their measurement of nonsubcutaneous AT. It is possible that we did not observe a difference in total AT fat content by MRI due to the small size of this study.

Another important consideration when comparing the fat measurements obtained in the present study with previously published data is the makeup of the cohort of babies. Factors such as gestational age at birth, whether the infant was an appropriate size for its gestational age, the postnatal age at which the measurement was obtained, gender, and ethnicity are all factors that are known to influence body fat content and distribution. For instance, in the present study all measurements of body composition were made within 36 h of birth, whereas many papers in the literature do not give exact ages for the infants studied but say less than 1 mon. However, we know that there is a rapid accretion of body fat within the first few weeks of postnatal life (6).

In conclusion, our preliminary studies have demonstrated MRI to be a reliable, safe method for assessing total body AT, with the advantage of visualization of different AT depots. This opens up the possibility of assessing the effects of the intrauterine environment, dietary regimes, hormonal treatments, and genetic factors on the developing infant in a fast and reproducible way.

## ACKNOWLEDGMENTS

Financial support from the Medical Research Council, Marconi Medical Systems, and Serono UK are gratefully acknowledged. The authors would also like to thank Professor Graeme Bydder, Dr. Mary Rutherford, and Dr. Gavin Hamilton for their help with this project and the babies and their parents for participating in this study.

**ABSTRACT:** A facile and efficient synthesis of the carboxyl-linked glucosides of bile acids is described. Direct esterification of unprotected bile acids with 2,3,4,6-tetra-*O*-benzyl- $\beta$ -D-glucopyranose in pyridine in the presence of 2-chloro-1,3,5-trinitrobenzene as a coupling agent afforded a mixture of the  $\alpha$ - and  $\beta$ -anomers (*ca.* 1:3) of the 1-*O*-acyl- $\beta$ -D-glucoside benzyl ethers of bile acids, which was separated effectively on a  $C_{18}$  reversed-phase chromatography column (isolated yields of  $\alpha$ - and  $\beta$ -anomers are 4–9% and 12–19%, respectively). Subsequent hydrogenolysis of the  $\alpha$ - and  $\beta$ -acyl glucoside benzyl ethers on a 10% Pd-C catalyst in acetic acid/methanol/EtOAc (1:2:2, by vol) at 35°C under atmospheric pressure gave the corresponding free esters in good yields (79–89%). Chemical specificities such as facile hydrolysis and transesterification of the acyl glucosides in various solvents were also discussed.

Paper no. L8894 in *Lipids* 37, 101–110 (January 2002).

A variety of the glycosidic conjugates of bile acids, which include  $\beta$ -D-glucuronides (1–4),  $\beta$ -D-glucosides (5–8), and  $\beta$ -D-*N*-acetylglucosaminides (9–11), have been identified in biological materials. Such glycosidation reactions are considered to be mechanisms for detoxification and elimination of such toxic and hydrophobic bile acids of lithocholic acid in patients with cholestasis. Since variations in the concentration and relative proportion of glycosidic conjugated bile acids are closely related to liver diseases, the identification, quantification, metabolism, physiological significance, and excretory route of the glycosidic conjugates are of special importance from a clinical point of view.

In conventional bile acid glycosides, a hydroxyl group in the 5 $\beta$ -steroid nucleus is attached by an ether linkage to an anomeric 1'- $\beta$ -hydroxyl group in the sugar moieties to form so-called hydroxyl-linked or ether glycosides. Meanwhile, Radomska-Pyrek *et al.* (12–15) have recently reported the simultaneous formation of a new type of glucuronide conju-

gate of short-chain ( $C_{20}$ – $C_{23}$ ) bile acid analogs,  $C_{24}$  lithocholic acid (LCA) (16), and hyodeoxycholic acid (HDCA) (17) in significant amounts by rat liver microsomal glucuronosyltransferase, together with the expected hydroxyl-linked metabolites. The novel glucuronide-conjugated bile acids, termed acyl, ester, or carboxyl-linked glucuronides, have an ester linkage between the terminal carboxyl group at C-24 in the side chain of bile acids and the 1'- $\beta$ -hydroxyl group in  $\beta$ -D-glucuronic acid. In more recent works, the occurrence of the carboxyl-linked 24-glucuronides of five common bile acids, i.e., LCA, chenodeoxycholic acid (CDCA), ursodeoxycholic acid (UDCA), deoxycholic acid (DCA), and cholic acid (CA), in incubation mixtures of rat liver microsomes and in human urine has been confirmed by Goto *et al.* (18,19). They have also revealed that LCA 24-glucuronide is easily bonded covalently with protein during incubation to give LCA-protein adduct, suggesting the presence of tissue-bound bile acids in the liver (20).

Although the carboxyl-linked 24-glycosides of bile acids in biological materials so far isolated or identified have been exclusively glucuronide conjugates, analogous glucosides and *N*-acetylglucosaminides may be also possible candidates as potential metabolites, because of the widespread occurrence of various hydroxyl-linked analogs in human biological materials. As part of our ongoing program of synthesizing new and scarce potential bile acid metabolites for use as reference standards, we have previously reported the preparation of a series of the ether glucosides of bile acids (21). In this paper, we extended our program to synthesize the  $\alpha$ - and  $\beta$ -anomers of acyl glucosides (15–28; Fig. 1) of five prominent bile acids (LCA, CDCA, UDCA, DCA, and CA) and 6-hydroxylated bile acids (HDCA and its 6 $\beta$ -epimer, murideoxycholic acid, MDCA).

## EXPERIMENTAL PROCEDURES

**Materials and methods.** LCA, DCA, and CA were purchased from Wako Pure Industries, Ltd. (Osaka, Japan). CDCA and UDCA were kindly donated by Tokyo Tanabe Co. (Tokyo, Japan). HDCA and 2-chloro-1,3,5-trinitrobenzene (CTNB) were available from Tokyo Kasei Kogyo Co., Ltd. (Tokyo, Japan). MDCA was prepared from HDCA (22). 2,3,4,6-Tetra-*O*-benzyl- $\beta$ -D-glucopyranose (TBGP) was purchased from

\*To whom correspondence should be addressed.  
E-mail: takaiida@chs.nihon-u.ac.jp

Abbreviations: CA, cholic acid; CDCA, chenodeoxycholic acid; CTNB, 2-chloro-1,3,5-trinitrobenzene; DCA, deoxycholic acid; ESI, electrospray ionization; FT, Fourier transform; HDCA, hyodeoxycholic acid; HR-MS, high-resolution mass spectra; IR, infrared; LCA, lithocholic acid; MDCA, murideoxycholic acid; NIM, negative ion mode; NMR, nuclear magnetic resonance; mp, melting points; PIM, positive ion mode; TBGP, 2,3,4,6-tetra-*O*-benzyl- $\beta$ -D-glucopyranose; UDCA, ursodeoxycholic acid.

FIG. 1. Structures of bile acid C-24 acyl glucosides and their related compounds. Bn =  $-\text{CH}_2\text{C}_6\text{H}_5$ .

Sigma Chemical Co., (St. Louis, MO). All other reagents and solvents were of analytical reagent grade and used without further purification.

Normal-phase thin-layer chromatography (TLC) of the free 1-*O*-acyl-β-D-glucosides of bile acids (**15–28**) was performed on a precoated silica gel plate (E. Merck, Darmstadt, Germany) using chloroform/methanol/acetic acid (24:6:3, by vol; solvent system A) or EtOAc/acetic acid (9:1, vol/vol; solvent system B) mixtures as the developing solvents. Reversed-phase TLC was carried out on precoated C<sub>18</sub> silica gel plates (E. Merck) using a developing mixture of methanol/water (19:1, vol/vol; solvent system C). Liquid chromatography was performed using silica gel 60 (70–230 mesh; Wako Pure Chemical Industries, Tokyo, Japan) or Cosmosil 140C<sub>18</sub>-OPN (particle size, 140 μm; Nacalai Tesque, Inc., Kyoto, Japan) as an adsorbent.

Melting points (mp) were determined on an electric hot stage and are uncorrected. Infrared (IR) spectra were obtained on a Bio-Rad FTS-7 Fourier transform IR (FTIR) spectrometer (Philadelphia, PA) using KBr tablets. <sup>1</sup>H nuclear magnetic resonance (NMR) spectra were obtained on a JEOL JNM-EX 270 FT NMR instrument (Tokyo, Japan) at 270 MHz, with CDCl<sub>3</sub>, CDCl<sub>3</sub> containing 20% dimethylsulfoxide (DMSO)-*d*<sub>6</sub> or CD<sub>3</sub>OD containing 0.1% Me<sub>4</sub>Si as the solvent; chemical shifts are expressed as δ ppm relative to Me<sub>4</sub>Si. High-resolution mass spectra (HR-MS) were obtained on a JEOL JMS-LCmate double focusing magnetic mass spectrometer equipped with an electrospray ionization (ESI) probe under the positive ion mode (PIM) [M + Na]<sup>+</sup> for benzyl ester derivatives (**1–14**) or negative ion mode (NIM) [M – H]<sup>–</sup> for free esters (**15–28**). For reference compounds, polypropylene glycol (50 ppm) in methanol for **1** and **2**, or polyethyleneglycol (50 ppm) in methanol for **3–14** was used in PIM; and sodium trifluoroacetate (200 ppm) and sodium acetate (40 ppm) in methanol for **15** and **16**, or polyethyleneglycol sulfate (50 ppm) in methanol for **17–28** was used in NIM. The apparatus

used for medium-pressure liquid chromatography consisted of a YRD-880 RI-detector (Shimamura Instruments Works, Co., Tokyo, Japan) and a chromatographic pump uf-3040S.

*General procedure for the esterification of bile acids by CTNB.* To a stirred solution of bile acid (5 mmol) and TBGP (6 mmol) in dry pyridine (12 mL) was added CTNB (5 mmol) in one portion, and the mixture was stirred at room temperature for 3 h under a stream of N<sub>2</sub> (the reaction was monitored by TLC). To the mixture was added 8% sodium hydrogencarbonate solution (70 mL), Et<sub>2</sub>O (70 mL) and then water (35 mL), and the whole mixture was stirred until a clear solution was obtained. The organic layer was washed with 5% HCl and water, dried over Drierite, and evaporated under reduced pressure. Crystallization of the residue from benzene recovered excess amounts of the starting sugar derivative. Evaporation of the combined mother liquor gave an oily residue, which was treated on a column of silica gel (70 g, 70–250 mesh) by eluting with benzene or benzene/EtOAc (7:3 to 4:1, vol/vol) mixtures containing 1% acetic acid to give the crude esterified product. Separation of the α- and β-anomeric mixtures from the resulting product was then achieved by medium-pressure liquid chromatography on a C<sub>18</sub> reversed-phase column (100 g), eluting with methanol/water mixtures (19:1 to 9:1, vol/vol) containing 1% acetic acid as a mobile phase.

(i) *Benzyl 1-O-(24-lithocholyl)-2,3,4-tri-O-benzyl-D-glucopyranose (1 and 2).* The more polar component, which eluted first, was identified as the α-anomer (**1**): this compound was found to be homogeneous according to TLC and <sup>1</sup>H NMR analyses, but failed to crystallize: The yield of this oil was 8%. The less polar component was identified as the β-anomer (**2**). Although this compound was homogeneous according to TLC and <sup>1</sup>H NMR analyses, it could not be crystallized: The yield of this oil was 19%. Spectral and HR-MS data are shown in Table 1.

(ii) *Benzyl 1-O-(24-chenodeoxycholyl)-2,3,4-tri-O-benzyl-D-glucopyranose (3 and 4).* The more polar component,

which eluted first, was identified as the  $\alpha$ -anomer (**3**): The yield of this oil was 4%. The less polar component was identified as the  $\beta$ -anomer (**4**): The yield of the oil was 12%.

(iii) *Benzyl 1-O-(24-ursodeoxycholy)-2,3,4-tri-O-benzyl-D-glucopyranose (5 and 6)*. The more polar component, which eluted first, was identified as the  $\alpha$ -anomer (**5**): The yield of this oil was 9%. The less polar component was identified as the  $\beta$ -anomer (**6**): The yield of this oil was 14%.

(iv) *Benzyl 1-O-(24-deoxycholy)-2,3,4-tri-O-benzyl-D-glucopyranose (7 and 8)*. The more polar component was identified as the  $\alpha$ -anomer (**7**): The yield of this oil was 8%. The less polar component was identified as the  $\beta$ -anomer (**8**): The yield of this oil was 16%.

(v) *Benzyl 1-O-(24-choly)-2,3,4-tri-O-benzyl-D-glucopyranose (9 and 10)*. The more polar component was identified as the  $\alpha$ -anomer (**9**): The yield of this oil was 8%. The less polar component was identified as the  $\beta$ -anomer (**10**): The yield of this oil was 16%.

(vi) *Benzyl 1-O-(24-hyodeoxycholy)-2,3,4-tri-O-benzyl-D-glucopyranose (11 and 12)*. The more polar component was identified as the  $\alpha$ -anomer (**11**): The yield of this oil was 4%. The less polar component was identified as the  $\beta$ -anomer (**12**): The yield of this oil was 16%.

(vii) *Benzyl 1-O-(24-murideoxycholy)-2,3,4-tri-O-benzyl-D-glucopyranose (13 and 14)*. The more polar component was identified as the  $\alpha$ -anomer (**13**): The yield of this oil was 4%. The less polar component was identified as the  $\beta$ -anomer (**14**): The yield of this oil was 15%.

*General procedure for the deprotection of bile acid acyl glucoside benzyl ethers.* To a magnetically stirred solution of prereduced 10% Pd-C catalyst (120 mg) with hydrogen in acetic acid/methanol/EtOAc (5 mL; 1:2:2, by vol) was added a solution of acyl glucoside benzyl ether (0.27 mmol) in the same solvent (5 mL), and the mixture was hydrogenated at 35°C for 6 h under atmospheric pressure (1 atm). After the hydrogenolysis, the catalyst was filtered off on Celite and washed four times with methanol (each 4 mL). The combined mother liquor was evaporated *in vacuo* to give an oily residue, which was crystallized directly from EtOAc.

(i) *1-O-(24-Lithocholy)- $\alpha$ -D-glucopyranose (15)*. This was recrystallized from EtOAc as a colorless amorphous solid; yield, 79%; mp, 116–119°C. TLC,  $R_f$ : 0.52 (solvent A) and 0.58 (solvent C). Spectral and HR-MS data are shown in Table 2.

(ii) *1-O-(24-Lithocholy)- $\beta$ -D-glucopyranose (16)*. This was recrystallized from EtOAc as a colorless amorphous solid; yield, 86%; mp, 123–125°C. TLC,  $R_f$ : 0.53 (solvent A) and 0.57 (solvent C).

(iii) *1-O-(24-Chenodeoxycholy)- $\alpha$ -D-glucopyranose (17)*. This was recrystallized from EtOAc as a colorless amorphous solid; yield, 86%; mp, 126–129°C. TLC,  $R_f$ : 0.34 (solvent A) and 0.66 (solvent C).

(iv) *1-O-(24-Chenodeoxycholy)- $\beta$ -D-glucopyranose (18)*. This was recrystallized from EtOAc as colorless needles; yield, 88%; mp, 120–123°C. TLC,  $R_f$ : 0.35 (solvent A) and 0.65 (solvent C).

(v) *1-O-(24-Ursodeoxycholy)- $\alpha$ -D-glucopyranose (19)*. This was recrystallized from EtOAc as a colorless amorphous solid; yield, 87%; mp, 137–140°C. TLC,  $R_f$ : 0.37 (solvent A) and 0.73 (solvent C).

(vi) *1-O-(24-Ursodeoxycholy)- $\beta$ -D-glucopyranose (20)*. This was recrystallized from EtOAc as a colorless amorphous solid; yield, 80%; mp, 141–144°C. TLC,  $R_f$ : 0.39 (solvent A) and 0.72 (solvent C).

(vii) *1-O-(24-Deoxycholy)- $\alpha$ -D-glucopyranose (21)*. This was recrystallized from EtOAc as a colorless amorphous solid; yield, 82%; mp, 134–137°C. TLC,  $R_f$ : 0.38 (solvent A) and 0.64 (solvent C).

(viii) *1-O-(24-Deoxycholy)- $\beta$ -D-glucopyranose (22)*. This was recrystallized from EtOAc as a colorless amorphous solid; yield, 89%; mp, 131–134°C. TLC,  $R_f$ : 0.39 (solvent A) and 0.63 (solvent C).

(ix) *1-O-(24-Choly)- $\alpha$ -D-glucopyranose (23)*. This was recrystallized from EtOAc as a colorless amorphous solid; yield, 80%; mp, 141–143°C. TLC,  $R_f$ : 0.19 (solvent A) and 0.71 (solvent C).

(x) *1-O-(24-Choly)- $\beta$ -D-glucopyranose (24)*. This was recrystallized from EtOAc as a colorless amorphous solid; yield, 85%; mp, 164–166°C. TLC,  $R_f$ : 0.20 (solvent A) and 0.69 (solvent C).

(xi) *1-O-(24-Hyodeoxycholy)- $\alpha$ -D-glucopyranose (25)*. This was recrystallized from EtOAc as a colorless amorphous solid; yield, 85%; mp, 133–136°C. TLC,  $R_f$ : 0.32 (solvent A) and 0.73 (solvent C).

(xii) *1-O-(24-Hyodeoxycholy)- $\beta$ -D-glucopyranose (26)*. This was recrystallized from EtOAc as a colorless amorphous solid; yield, 89%; mp, 164–166°C. TLC,  $R_f$ : 0.33 (solvent A) and 0.72 (solvent C).

(xiii) *1-O-(24-Murideoxycholy)- $\alpha$ -D-glucopyranose (27)*. This was recrystallized from EtOAc as a colorless amorphous solid; yield, 79%; mp, 108–110°C. TLC,  $R_f$ : 0.38 (solvent A) and 0.74 (solvent C).

(xiv) *1-O-(24-Murideoxycholy)- $\beta$ -D-glucopyranose (28)*. This was recrystallized from EtOAc as a colorless amorphous solid; yield, 83%; mp, 146–148°C. TLC,  $R_f$ : 0.39 (solvent A) and 0.73 (solvent C).

## RESULTS AND DISCUSSION

The instability of acyl glucosides, which are susceptible to hydrolysis and transesterification under mild conditions (see below) (17), may hamper their identification and quantitation in biological materials as well as the chemical synthesis of authentic reference compounds. Previous syntheses of acyl glucuronides have required multiple steps with several protections and deprotections, resulting in low overall yields (23–26). A feasible, shorter method, however, has recently been reported for the preparation of acyl glucuronides, all of which are produced in a condensation reaction between carboxylic acids and a protected glucuronic acid derivative in the presence of diisopropyl- (or diethyl)-azodicarboxylate and triphenylphosphine as coupling agents (27,28). By utilizing

<sup>a</sup>DMSO, dimethylsulfoxide; for other abbreviations see Table 1.

the Mitsunobu reaction, the 1-*O*-acyl-β-D-glucuronide derivatives of five common bile acids have been prepared by condensing bile acid acetates with methyl 2,3,4-tri-*O*-acetyl-D-glucopyranuronate (18). However, subsequent transformation of the resulting methyl ester-acetate derivatives of acyl glucuronides into the corresponding free ester forms was unsuccessful because of the instability of the C-24 ester linkages under alkaline hydrolysis conditions.

On the other hand, synthesis of the free 1-*O*-acyl-β-glucuronide of LCA, 1-*O*-(24-lithocholyl)-β-D-glucopyranuronic acid, has been successfully achieved in two steps by the Mitsunobu reaction of unprotected LCA with a fully benzylated derivative of glucuronic acid having a free C-1' hydroxyl group (benzyl 2,3,4-tri-*O*-benzyl-D-glucopyranuronate), followed by the hydrogenolysis of the resulting benzyl 1-*O*-(24-lithocholyl)-2,3,4-tri-*O*-benzyl-β-D-glucopyranuronate with Pd on charcoal as a catalyst (17). Subsequently, the 1-*O*-acyl-β-D-glucuronides of CDCA, UDCA, DCA, and CA have also been prepared by using a similar procedure (29).

In our synthesis of the analogous acyl glucosides of five common bile acids as well as HDCA and MDCA, we used TBGP as an alcoholic substrate. A preliminary experiment of the condensation of unprotected CDCA with TBGP by the

Mitsunobu reaction was discouraging; numerous by-products were formed, from which a mixture of the desired α- and β-anomers of the acyl glucosides benzyl ether derivative of CDCA was isolated in very low yield (6%) after tedious and repeated chromatographic purification. Similarly, the use of *N,N*-dicyclohexylcarbodiimide as a coupling agent (30) was also unsatisfactory.

However, when the mixtures of unprotected bile acids and TBGP were treated with CTNB as a condensing agent in pyridine (31), the nucleophilic acyl substitution reaction proceeded cleanly at room temperature for 3 h, *via* the activated ester intermediate of bile acid 1,3,5-trinitrobenzyl esters, to give the desired 1-*O*-acyl-D-glucoside benzyl ethers (1–14) (Fig. 2). After esterification, the reaction product was easily recovered by passage through a column of silica gel and elution with EtOAc/benzene mixtures; 1% acetic acid was added to all solvents used in the workup processes to prevent the decomposition of the resulting acyl glucosides (see below). Since each of the esterified products was a mixture of the α- and β-anomers of acyl glucoside benzyl ethers, as shown by <sup>1</sup>H NMR, they were then subjected to medium-pressure liquid chromatography on a C<sub>18</sub> reversed-phase column with elution by methanol/water mixtures. The reversed-phase

**FIG. 2.** Synthetic route to bile acid C-24 acyl glucosides. LCA, lithocholic acid; CDCA, chenodeoxycholic acid; UDCA, ursodeoxycholic acid; DCA, deoxycholic acid; CA, cholic acid; HDCA, hyodeoxycholic acid; MDCA, murideoxycholic acid.

chromatography resolved the two epimers effectively, and an  $\alpha$ -anomer (**1**, **3**, **5**, **7**, **9**, **11**, or **13**) was eluted first as a minor component (4–9% isolated yields), followed by the corresponding  $\beta$ -anomer (**2**, **4**, **6**, **8**, **10**, **12**, or **14**) as a major component (12–19% isolated yields), in an approximate  $\beta/\alpha$  ratio of 3:1, suggesting that the  $\alpha$ -anomers are more sterically unstable than the corresponding  $\beta$ -ones.

Subsequent treatment of **1–14** by hydrogenolysis in the presence of 10% Pd on charcoal as a catalyst (17,28) resulted in the complete elimination of the benzylic ether groups of a sugar moiety to form the  $\alpha$ - (**15**, **17**, **19**, **21**, **23**, **25**, or **27**) and  $\beta$ -anomers (**16**, **18**, **20**, **22**, **24**, **26**, or **28**) of free 1-*O*-acyl-D-glucosides. In our exploratory experiments, yield of the hydrogenolysis was influenced significantly by the reaction conditions. When the acyl glucoside benzyl ethers were subjected to hydrogenolysis in methanol/EtOAc mixtures (1:1, vol/vol) containing 20% acetic acid at 35°C under 1 atm, the time required for complete deprotection was only 6 h, and the yields of the resulting free acyl glucosides were 79–89%. However, when hydrogenolysis was carried out in methanol/EtOAc mixtures (1:1, vol/vol) under a positive pressure of 80 kg/cm<sup>2</sup>, the reaction took more than 24 h and yields of the desired free esters decreased steeply, probably due to the decomposition of ester linkage (see below) during the hydrogenolysis. The former procedure therefore seems to be the method of choice.

In TLC, the  $R_f$ -values observed for compounds **15–28**, which differ from one another in the number, position, and stereochemistry of hydroxyl groups in the aglycone moieties, increased in the following order in each series of the  $\alpha$ - and  $\beta$ -anomers: The acyl glucosides of CA (0.20) < HDCA (0.33) < CDCA (0.36), DCA (0.38), UDCA (0.39), MDCA (0.39) < LCA (0.53) on normal-phase TLC (solvent system A); those of LCA (0.57) < DCA (0.64), CDCA (0.65) < CA (0.70) < UDCA (0.73), HDCA (0.73), MDCA (0.74) on reversed-phase TLC (solvent system C). The TLC behaviors in each series of acyl glucosides on both the normal- and reversed-

phase TLC plates was similar to those observed for the corresponding ether glucosides (**32**). Although each pair of the corresponding  $\alpha$ - and  $\beta$ -anomers of the acyl glucosides had essentially identical mobility on TLC, they were nicely separated by medium-pressure liquid chromatography on a C<sub>18</sub> reversed-phase column, indicating that the  $\alpha$ -anomers are slightly more polar than the  $\beta$ -anomers.

Since previous workers pointed out the chemical specificity of acyl glucuronides (17), we examined the lability of the 1-*O*-acyl- $\beta$ -D-glucoside of DCA (**22**) as a representative substrate. Thus, **22** was stored at room temperature in various neutral, acidic, and alkaline solvents, and changes in the  $R_f$  values of the resulting solutions were monitored by normal-phase TLC (solvent system B). As a result, **22** ( $R_f$ , 0.22) was completely stable in acetone, acetic acid, and pyridine. However, when **22** was stored in methanol (or ethanol) containing 1% NaOH (or KOH), it was rapidly converted into the corresponding unconjugated DCA ( $R_f$ , 0.71). Interestingly, **22** was also decomposed readily within several hours on exposure in methanol (or ethanol) containing 1% HCl (or H<sub>2</sub>SO<sub>4</sub>) and gradually in a few days in the same solvent in the absence of acid. The  $R_f$  value (0.77) of the decomposed product differed from that (0.71) of the free acid of DCA, but it was in accord with that of the methyl ester derivative of DCA, clearly demonstrating the occurrence of acyl migration by transesterification. However, no intramolecular rearrangement was detected by acyl group migration of **22** to give positional isomers in which the aglycone is attached at the position of C-2', C-3', and C-4' of the  $\beta$ -D-glucoside moiety, in analogy with similar glucuronides (17). Since the carboxyl-linked glucosides of bile acids are susceptible to both hydrolysis and transesterification in alcoholic solvents, particular caution should therefore be paid in the isolation and purification processes.

<sup>1</sup>H NMR spectra provided confirmatory evidence for the structures of individual acyl glucosides (**15–28**). The resonance positions of 18-, 19-, and 21-methyl protons, as well as

methine protons at C-3, C-6, C-7, or C-12, are essentially unchanged compared to those observed for the corresponding unconjugated bile acids. An equatorial 1' $\beta$ -H signal in the  $\alpha$ -anomers (15, 17, 19, 21, 23, 25, and 27), which has a *cis* axial-equatorial relationship with adjacent axial 2' $\beta$ -H, occurs at a lower field of 6.12–6.17 ppm as a doublet with a coupling constant of 2.7–3.5 Hz (33). On the other hand, the corresponding axial 1' $\alpha$ -H signal in the  $\beta$ -anomers (16, 18, 20, 22, 24, 26, and 28) is shifted to a higher field and resonates at 5.50–5.55 ppm as a doublet with a coupling constant of 7.7–8.0 Hz owing to a *trans* diaxial relationship with 2' $\beta$ -H.

**ABSTRACT:** Dibutyrate derivatives of monoacylglycerols of oleic, petroselinic, and *cis*-vaccenic acids were prepared by diesterification of monoacylglycerols with *n*-butyryl chloride. The resulting triacylglycerols were analyzed by gas chromatography (GC) with a 65% phenyl methyl silicone capillary column and separated on the basis of both fatty acid composition and regiospecific position. The petroselinic acid derivatives eluted first, followed sequentially by the oleic and *cis*-vaccenic acid derivatives, with the *sn*-2 positional isomer eluting before the *sn*-1(3) isomer in each case. Separation of the peaks was almost baseline between petroselinic and oleic acids as well as between oleic and *cis*-vaccenic acids. To assess the accuracy of the method, mixtures of triolein, tripetroselinin, and tri-*cis*-vaccenin in various known proportions were partially deacylated with the use of ethyl magnesium bromide and derivatized and analyzed as above. The results showed that this method compares favorably to the existing methods for analysis of oleic, petroselinic, and *cis*-vaccenic fatty acids by GC with respect to peak separation and accuracy, and it also provides information on the regiospecific distribution of the fatty acids. The method was applied to basil (*Ocimum basilicum*) and coriander (*Coriandrum sativum*) seed oils. *cis*-Vaccenic, oleic, and linoleic acids were mainly distributed at the *sn*-2 position in basil seed oil, and higher proportions of linolenic, palmitic, and stearic acids were distributed at the *sn*-1(3) position than at the *sn*-2 position. In coriander seed oil, petroselinic acid was mainly distributed at the *sn*-1(3) position, and both oleic and linoleic acids were mostly located at the *sn*-2 position, whereas palmitic, stearic, and *cis*-vaccenic acids were located only at the *sn*-1(3) position.

Paper no. L8786 in *Lipids* 37, 111–116 (January 2002).

Petroselinic (*cis*-6 18:1) and *cis*-vaccenic (*cis*-11 18:1) acids are two fatty acid isomers of oleic acid (*cis*-9 18:1), differing in the position of the double bond. These isomers are major fatty acid constituents in the lipids of plants of the *Araliaceae* (1) and *Apiaceae* (formerly *Umbelliferae*) (2–9) families and are also minor constituents of seed lipids of basil (unpub-

lished results) and of other plants (10–15). Regio- and stereospecific distribution of fatty acids in oils containing petroselinic and *cis*-vaccenic acids is not well documented (16,17), attributable to the difficulties involved in the analysis of mixtures of these isomers, which tend to coelute in gas chromatography (GC) (18–21). Until recently, their analysis has been laborious and required isolation of the 18:1 isomeric fatty acids, followed by oxidative cleavage of the double bond to produce, for example, azelaic and nonanoic acids from oleic acid and adipic and lauric acids from petroselinic acid. Analytical methods allowing direct and accurate quantitative analysis by GC of mixtures of derivatized oleic, petroselinic, and *cis*-vaccenic acids were developed by Wolff and Vandamme (20,21) with isopropyl derivatives, by Thies (22) with *n*-butyl derivatives, and by Liu and Hammond (23) with 2-phenylethyl derivatives. The latter can also be analyzed by high-performance liquid chromatography (HPLC). These methods use larger ester alcohol moieties than methanol, and this results in reduced relative polarity of the esterified acid, with the double bond in the hydrocarbon moiety making the primary contribution to the polarity of the esters. Thus, the position of the polar center, i.e., the double bond, plays a significant role in the adsorption of the ester to the hydrophobic polymer coating on the chromatographic column, where the ester with the double bond at position 6 is least strongly adsorbed and should elute faster than the esters with the double bond at position 9 or 11, given that there is no difference in their vapor pressure or boiling point. This reasoning led us to hypothesize that the use of dibutyrate derivatives of monoacylglycerols (24) would permit not only the separation of the fatty acid isomers oleic, petroselinic, and vaccenic acids, but also the determination of their regiospecific distribution.

The objectives of the present work were first to evaluate the separation of dibutyrate derivatives of monoacylglycerols of oleic, petroselinic, and *cis*-vaccenic acids by GC on the basis of both fatty acid composition and regiospecific distribution; second, to determine the accuracy of this method by analyzing dibutyrate derivatives of monoacylglycerols obtained by partial deacylation of mixtures of triolein, tripetroselinin, and tri-*cis*-vaccenin in known proportions; and third, to validate the method by analyzing natural samples of basil and coriander seed oils.

## MATERIALS AND METHODS

**Materials.** Monooleoylglycerol, monopetroselinoylglycerol, monostearoylglycerol, mono-*cis*-vaccenoylglycerol, triolein, tripetroselinin, and tri-*cis*-vaccenin were purchased from Nu-Chek-Prep (Elysian, MN). Ethylmagnesium bromide (3.0 M in diethyl ether), *n*-butyryl chloride, and triethylamine were obtained from Aldrich (Milwaukee, WI).

**Oil extraction.** Mature dry seeds (10 g) of basil (*Ocimum basilicum*) (25) and of coriander (*Coriandrum sativum*), purchased from a local seed retailer, were washed and finely ground in a mortar. Oil was extracted with hexane in a Soxhlet apparatus and recovered by filtering and drying the extract over anhydrous sodium sulfate and evaporating the solvent under vacuum at 30°C on a rotary evaporator (21% yield for basil oil and 23% for coriander oil). The oils were stored under nitrogen at -35°C until further use.

**Derivatization of monoacylglycerols.** Standard monoacylglycerols (10 mg) of oleic, petroselinic, *cis*-vaccenic, and stearic acids were solubilized in dry chloroform (0.5 mL). Triethylamine (100 µL) and *n*-butyryl chloride (50 µL) were sequentially added, and the reaction mixture was held at 60°C for 20 min in a closed vial with constant stirring. After cooling to room temperature, the reaction mixture was diluted with *n*-octane (1 mL), washed sequentially with 1-mL volumes each of cold diluted hydrochloric acid (0.1 N), water, and brine (saturated aqueous solution of sodium chloride), and dried over anhydrous sodium sulfate. Aliquots (50 µL) were diluted with *n*-octane (200 µL) and analyzed by GC.

**Partial deacylation of triacylglycerols (TAG).** Mixtures of standard TAG triolein, tripetroselinin, and tri-*cis*-vaccenin in different proportions (Table 1) and basil and coriander seed oils were partially deacylated with ethylmagnesium bromide according to a literature procedure (24). After workup, the residue was solubilized in dry chloroform, derivatized with *n*-butyryl chloride as described above for standard monoacylglycerols, and analyzed by GC.

**GC of triacylglycerols.** Analysis was performed using a gas chromatograph (Hewlett-Packard Model 6890, Series II; Palo Alto, CA), equipped with a flame-ionization detector and connected to a ChemStation (Hewlett-Packard). Sample volumes (1.0 µL) in *n*-octane were injected onto a 65% phenyl methyl silicone capillary column (Restek, Bellefonte, PA; 30 m × 0.25 mm i.d., 0.10 µm film thickness) with a split ratio of 1:50. Injector and detector temperatures were set at 400°C, while the oven temperature was programmed from 190 to 300°C at 2.5°C min<sup>-1</sup> and to 360°C at 15°C min<sup>-1</sup> and held for 5 min at this temperature, for a total duration of 70 min. The linear velocity of the carrier gas (hydrogen) was 47 cm s<sup>-1</sup> at 190°C. Other chromatographic conditions used were isothermal oven temperatures from 190 to 260°C, in 5°C increments, other parameters being left unchanged. Peak areas and corrected response factors based on standards were used for quantitation. Resolution values were determined using peak base width.

**Experimental considerations.** The oil samples were crude and possibly contained components other than TAG, such as

phospholipids. These, however, do not interfere with the regiospecific analysis of TAG by the present method, which can be performed directly on the crude lipid extracts without further purification of TAG by thin-layer chromatography (TLC) or other methods (26).

## RESULTS AND DISCUSSION

**GC of TAG.** Dibutyrate derivatives of monoacylglycerols of oleic, petroselinic, and *cis*-vaccenic acids were separated by GC by both fatty acid composition and regiospecific position. The order of elution was similar to that reported for other GC methods employed in the analysis of these fatty acid isomers (20–22), with petroselinic acid derivatives eluting first, oleic acid derivatives second, and *cis*-vaccenic acid derivatives third. For each fatty acid derivative, the *sn*-2 positional isomer eluted before the *sn*-1(3) isomer (Fig. 1). The separation was nearly baseline ( $R_S = 1.28$ ) between the petroselinic and oleic acid de-

**FIG. 1.** Gas chromatograms of dibutyrate derivatives of monoacylglycerols obtained after partial deacylation of mixtures of tripetroselinin, triolein, and tri-*cis*-vaccenin by ethyl magnesium bromide, followed by derivatization with *n*-butyryl chloride. Bu, 4:0; Ps, *cis*-6 18:1; O, *cis*-9 18:1; Va, *cis*-11 18:1. Proportions of tripetroselinin/triolein/tri-*cis*-vaccenin in the initial mixtures were (A) 3:2:1, (B) 1:3:1, and (C) 1:1:1.

derivatives, and also close to baseline between the oleic and *cis*-vaccenic acid derivatives ( $R_S = 1.10$ ). The resolution of positional isomers was highest for petroselinic acid derivatives and lowest for *cis*-vaccenic acid derivatives, with  $R_S$  values of 1.37, 0.95, and 0.88 between the *sn*-2 and the *sn*-1(3) positional isomers of the petroselinic, oleic, and *cis*-vaccenic acid derivatives, respectively. However, separation between *sn*-2 and *sn*-1(3) isomers of the derivatives of the 18:1 isomers (as well as other fatty acids) depends on the quality of the column; columns with the same stationary phase can exhibit some variability in their resolution owing to variations in the polymer coating.

Analysis of dibutyrate derivatives of monoacylglycerols by this method does not require separation of glyceride species prior to derivatization because well-defined chromatographic resolution, free of overlap, of all species present in the samples is obtained with the use of proper chromatographic conditions (Fig. 2). The species included dibutyrate derivatives of monoacylglycerols, monobutyrate derivatives of diacylglycerols, TAG, and tertiary alcohols, some of which may have been partly derivatized or dehydrated during the derivatization procedure. However, we have encountered some overlapping of the elution regions for derivatives of mono- and diacylglycerols in samples containing  $C_8$  to  $C_{20}$  fatty acids, but not for individual species (data not shown).

The primary chromatographic conditions reported in the Materials and Methods section indeed allowed separation of dibutyrate derivatives of petroselinic, oleic, and *cis*-vaccenic acids. However, these conditions resulted in overlapping of petroselinic and stearic acid derivatives (Fig. 3, A1). Isothermal elution at 205°C resulted in separation of petroselinic and stearic acid derivatives, but the latter overlapped with oleic

acid derivatives (Fig. 3, A4). Although we did not succeed in obtaining acceptable separation of stearic, petroselinic, and oleic acid derivatives under a single set of chromatographic conditions, the combined chromatograms obtained under two sets of chromatographic conditions (Fig. 3, A2 and A3) made possible the quantitation of acid derivatives in a given sample. A first set of conditions resulting in overlap of petroselinic and stearic acid derivatives but resolving oleic acid derivatives, and a second set of conditions resulting in overlap of oleic and stearic acid derivatives while resolving petroselinic acid derivatives permitted accurate determination of the values of these acid derivatives in coriander seed oil (Fig. 3, B).

**Fatty acid composition of TAG mixtures.** The accuracy of the present method for the analysis of petroselinic, oleic, and *cis*-vaccenic acids in samples, and for the determination of the regiospecific distribution of these acids, was evaluated by analyzing dibutyrate derivatives of monoacylglycerols from partial deacylation of three mixtures of triolein, tripetroselinin, and tri-*cis*-vaccenin in defined proportions. The experiments were carried out in triplicate, and the results are presented in Table 1. The expected and experimental values are in good agreement for all three mixtures, although minor deviations were noted. The values for the *sn*-1(3) isomer were slightly underestimated by roughly 1% for petroselinic acid, whereas they were slightly overestimated for oleic acid. Experimental values for the *sn*-2 isomers of petroselinic and oleic acids and the *sn*-1(3) isomer of *cis*-vaccenic acid were on target. Total fatty acid compositions of the mixtures calculated from the values for the *sn*-1(3) and *sn*-2 positions were also in agreement with the expected values.

**FIG. 2.** Gas chromatogram of products resulting from partial deacylation with ethyl magnesium bromide of a 3:2:1 mixture of tripetroselinin, triolein and tri-*cis*-vaccenin, followed by derivatization with *n*-butyryl chloride. (A) Tertiary alcohols and similar compounds; (B) dibutyrate derivatives of monoacylglycerols; (C) monobutyrate derivatives of diacylglycerols; (D) triacylglycerols.

**FIG. 3.** Partial gas chromatogram of a mixture of dibutyrate derivatives of monoacylglycerols of stearic, petroselinic, oleic and *cis*-vaccenic acids under selected isothermal conditions at 250°C (A1), 230°C (A2), 210°C (A3) and 205°C (A4); and of dibutyrate derivatives of monoacylglycerols obtained after partial deacylation of coriander (*Coriandrum sativum*) seed oil under isothermal conditions at 205°C (B).  $\alpha$  and  $\beta$  refer to *sn*-1(3) and *sn*-2 positional isomers, respectively. (Derivatives of other fatty acids not shown.)

*Regiospecific analysis of basil and coriander seed oils.* The analytical method was further validated by the analysis of basil (*Ocimum basilicum*) and coriander (*Coriandrum sativum*) seed oils. The results (Table 2) showed that in basil seed oil, linolenic acid was the most abundant fatty acid in both the *sn*-1(3) and *sn*-2 positions, amounting to 55.8 and 51.3%, respectively. The results also showed that  $C_{18:1}$  isomers were mostly distributed at the *sn*-2 position, whereas the saturated fatty acids, palmitic and stearic acids, were predominantly located at the *sn*-1(3) position. In coriander seed oil, petroselinic acid was the major acid both at the *sn*-1(3) position (80.1%) and at the *sn*-2 position (40.9%). Oleic and linoleic acids were mainly distributed at the *sn*-2 position,

whereas palmitic, stearic, and *cis*-vaccenic acids were distributed only at the *sn*-1(3) position. The calculated fatty acid compositions of both seed oil TAG obtained from the results of the regiospecific analysis were in good agreement with the experimental values obtained by GC analysis of fatty acid methyl ester derivatives (25) of basil seed oil and of fatty acid isopropyl ester derivatives (20) of coriander seed oil.

We have developed a simple, fast, and accurate method for the regiospecific analysis of petroselinic, oleic, and *cis*-vaccenic acids in triacylglycerols and validated it with natural oils of basil and coriander seeds. The simplicity of the protocol more than compensates for the possibility of small errors, indicated by the analysis of known mixtures of TAG

of petroselinic, oleic, and *cis*-vaccenic acids. The existing methods for regiospecific analysis of triglycerides also have limitations with respect to accuracy, owing to additional steps in the protocols (TLC, back-calculations, etc.) (27–32). Thus, this method constitutes an improvement over the existing methods for the analysis of these acids in fats and oils: it provides a better separation of the isomers by GC and also provides information on triacylglycerol structure.

**ABSTRACT:** The present study investigated possible relationships between left ventricular mass, intima-media thickness of the carotid artery (IMT), total arterial compliance, and lipid status in a population sample of 58 apparently healthy subjects aged 20 to 69. By stepwise multiple regression analysis, including age, blood pressure, and smoking, left ventricular mass index, measured by M-mode echocardiography, increased by 13.0 g/m<sup>2</sup> for each 1 standard deviation (SD = 0.11 μM,  $r = 0.60$ ,  $P < 0.01$ ) increase in plasma malondialdehyde and 9.50 g/m<sup>2</sup> per SD increase in plasma 8-iso-prostaglandin F<sub>2α</sub> in women only (SD = 8.88 ng/L,  $r = 0.44$ ,  $P = 0.01$ ). Each 1-SD (SD = 0.27 g/L) increase in apolipoprotein B was associated with a 63 μm increase in IMT ( $r = 0.47$ ,  $P = 0.01$ ) and a 0.27 mL/min/m<sup>2</sup>/mm Hg ( $r = -0.60$ ,  $P < 0.01$ ) decrease in stroke index/pulse pressure ratio, reflecting total arterial compliance in women. In men, each 1-SD increase in the proportion of stearic acid (18:0) in serum cholesterol esters (SD = 0.12 percent units) reduced the transmitral E/A ratio, measured by Doppler echocardiography, reflecting left ventricular diastolic function, by 0.10 units ( $r = -0.29$ ,  $P < 0.05$ ). Thus, important cardiovascular characteristics, such as left ventricular mass, left ventricular diastolic function, carotid IMT, and total arterial compliance, were independently predicted by indices of lipid metabolism and peroxidation in apparently healthy subjects.

Paper no. L8762 in *Lipids* 37, 231–236 (March 2002).

Several characteristics of cardiovascular structure and function, e.g., left ventricular hypertrophy, increased intima-media thickness (IMT) of the carotid artery, and total arterial compliance, are associated with cardiovascular morbidity and mortality (1–3). IMT is regarded as an early marker of atherosclerosis and is related to coronary artery calcification (4). Left ventricular diastolic dysfunction is an early finding in hypertensive heart disease (5), but whether left ventricular

diastolic dysfunction is an independent cardiovascular risk factor has not been thoroughly investigated.

A number of epidemiologic studies have shown a strong relationship between serum cholesterol levels and coronary heart disease (CHD) (6). Moreover, high levels of LDL and nonesterified FA are associated with an increased risk of CHD (7,8). Also, saturated FA in serum, particularly palmitic acid (16:0), have been associated with an increased risk of CHD, whereas some PUFA, such as linoleic acid (18:2n-6), may be protective against CHD (9,10). Furthermore, serum levels of nonesterified FA and TG are related to relative wall thickness of the left ventricle in elderly men (11).

Lipid peroxidation has been implicated in the pathogenesis of atherosclerosis (12), CHD (13), and congestive heart failure (14–18). Indeed, oxidized LDL is found in atherosclerotic lesions (19). Oxidized LDL exerts several negative effects on the arterial wall, such as binding to scavenger receptors on macrophages, followed by internalization and formation of foam cells (20). Two biomarkers of lipid peroxidation are malondialdehyde (MDA) and 8-iso-prostaglandin F<sub>2α</sub> (8-iso-PGF<sub>2α</sub>) (21). MDA is produced as an end product by the peroxidation of FA, whereas 8-iso-PGF<sub>2α</sub> is synthesized through nonenzymatic free radical-catalyzed peroxidation of arachidonic acid (20:4n-6). Epidemiologic studies have demonstrated an inverse relationship between dietary intake of the antioxidant vitamin E and CHD, but intervention studies using vitamin E supplementation have produced a divergent picture regarding the use of this vitamin in the prevention of CHD (22–24). The antiatherosclerotic effect of vitamin E is thought to be mediated through protection of LDL from oxidation (25).

There is a significant gender difference in the incidence of cardiovascular disease, with premenopausal women at lower risk (26,27). Estrogen is considered to account for this effect, as the CHD risk in postmenopausal women approaches that of men, while estrogen replacement therapy reduces the risk of CHD.

As left ventricular hypertrophy, increased IMT of the carotid artery, and impaired arterial compliance all seem to be cardiovascular alterations commonly preceding a CHD event, we investigated whether these indices of cardiovascular structure and function are related to lipoprotein levels, plasma FA composition, biomarkers of lipid peroxidation,

Abbreviations: AVPD, atrio-ventricular valve plane displacement; CHD, coronary heart disease; EF, ejection fraction; IMT, intima-media thickness; 8-iso-PGF<sub>2α</sub>, 8-iso-prostaglandin F<sub>2α</sub>; LVEDD, left ventricular diameter in end-diastole; LVESD, left ventricular diameter in end-systole; LVMI, left ventricular mass index; MDA, malondialdehyde; PL, phospholipid; PP, pulse pressure = systolic blood pressure – diastolic blood pressure; SI, stroke index.

and antioxidants, using data from a sample of apparently healthy subjects. Owing to gender differences in risk, we also investigated whether these relationships are influenced by gender.

## MATERIALS AND METHODS

Subjects were randomly chosen from the population registry of Uppsala, Sweden. The study sample (Table 1) consisted of 58 healthy subjects, aged 20 to 69 yr. None of the subjects was on regular medication or had a history of any disease known to affect the cardiovascular system or a history of any metabolic or other chronic disease. None of the women was on contraceptive or estrogen replacement therapy. Subjects with blood pressures higher than 160/95 mm Hg, fasting hyperglycemia (>6.0 mmol/L), or pronounced hypercholesterolemia (>7.0 mmol/L) at the initiation of the investigation were not included. Blood samples for determination of lipid metabolism were collected in the morning after an overnight fast. Ultrasonographic examinations were generally performed before noon on a subsequent day. The study was approved by the Ethics Committee of Uppsala University, and informed consent was obtained from each participant.

**Echocardiography.** A comprehensive 2-D echocardiographic examination was performed with an Acuson 128 XP/10 device (Mountain View, CA) equipped with a 3.5 MHz transducer, as described previously (28). In brief, all examinations were performed with the subjects in the standard left lateral position and in expiratory apnea or quiet breathing. All recordings were stored on videotape. Two experienced persons analyzed each recording, and the mean values of the two observations were used. Five representative cardiac beats were chosen and the average of these was calculated. Left ventricular dimensions were measured with M-mode using the leading-edge to leading-edge convention. The measurements included interventricular septal thickness, posterior wall thickness, and left ventricular diameter in end-diastole (LVEDD) and end-systole (LVESD). The left ventricular ejection fraction (EF) was calculated as  $(LVEDD^3 - LVESD^3)/LVEDD^3$ . Left ventricular systolic function was also assessed by the atrio-ventricular valve plane displacement method (AVPD) (29). Left ventricular mass was calculated using the M-mode formula of Troy, according to the recommendations by the American Society of

Echocardiography (30), and indexed for body surface area (left ventricular mass index, LVMI) to adjust for body size. Intra-observer and inter-observer coefficients of variation for LVMI were 1% and 12–15%, respectively (28). Stroke index (SI) was calculated by the use of the Teichholz formula (30). The inflow over the mitral valve was measured by pulsed Doppler with the sampling volume placed between the tips of the open mitral leaflets. The maximal velocity of the early filling period (E-wave) and the filling due to atrial contraction (A-wave) were used to calculate the E/A ratio, which was used as an index of left ventricular diastolic function.

**Carotid artery intima-media thickness.** The carotid artery IMT was assessed by high-resolution B-mode ultrasonography (Acuson 128 XP/10 and a 7.5 MHz transducer) of both the right and left common carotid artery, 1–2 cm proximal to the carotid bulb. Images were focused on the far wall of the right and left common carotid artery and recorded on videotape for later analysis. All ultrasonographic images were analyzed with a computerized system (28) by one person. The mean of the far-wall IMT of the right and left common carotid artery was used. The intra-observer coefficient of variation in our laboratory was <10%.

**Arterial compliance and blood pressure.** Blood pressure was recorded with a mercury sphygmomanometer after 15 min rest in the supine position. Pulse pressure (PP) was defined as systolic blood pressure minus diastolic blood pressure. SI was calculated by the use of the Teichholz formula (30). Total arterial compliance was assessed by the SI/PP ratio. This ratio has been shown to be closely related to arterial compliance calculated by the diastolic-decay time constant using a Windkessel model (31).

**Biochemical studies.** LDL and HDL were isolated by a combination of preparative ultracentrifugation and precipitation with a sodium phosphotungstate and magnesium chloride solution. TG and cholesterol concentrations were determined enzymatically in serum and in lipoprotein fractions (Instrumentation Laboratories Company, Lexington, MA), using a Monarch apparatus. The concentrations of serum apolipoprotein A-I and apolipoprotein B were determined by immunoturbidimetry in a Monarch apparatus. FA composition of serum cholesterol esters were analyzed with GLC as described previously (32). Three tocopherols,  $\alpha$ -,  $\beta$ -, and  $\gamma$ -tocopherol, were analyzed with HPLC (33). The serum tocopherol concentration was divided by the sum of the plasma cholesterol and TG concentrations (34). MDA was determined with the thiobarbituric acid test after HPLC separation with fluorescence detection (35). Plasma 8-iso-PGF<sub>2 $\alpha$</sub>  was analyzed by a newly developed radioimmunoassay (21).

**Statistical analysis.** Data are expressed as means  $\pm$  SD unless otherwise specified. Relationships of lipid peroxidation and metabolism variables to cardiac and vascular structure and function were evaluated by linear regression analysis. Subsequently, all lipid variables with a univariate *P*-value <0.05 were entered into forward stepwise multiple regression models to search for independent determinants of cardiovascular structure and function. Age, systolic and diastolic blood

pressure, and smoking are related to most of the evaluated cardiovascular variables (36), and were included as confounders in all multiple regressions. Due to the protective effect of female gender against cardiovascular disease, gender was included as a confounder in all multiple regressions, and genders were also analyzed separately (26,27). As smoking contributes to oxidative stress, analysis was also performed after exclusion of smokers (37).  $P < 0.05$  was regarded as significant.

## RESULTS

Basic characteristics and cardiovascular and biochemical variables are given in Tables 1–4.

**Left ventricular geometry.** By multiple stepwise regression analysis, a 1-SD increase in plasma MDA level (SD = 0.13  $\mu\text{M}$ ) was associated with an increase in LVMI of 9.6  $\text{g}/\text{m}^2$  ( $r = 0.40$ ,  $P < 0.01$ ) in the total sample, independent of other confounders (age, gender, blood pressure, and smoking). When genders were analyzed separately, both MDA (13.0  $\text{g}/\text{m}^2$  per SD MDA,  $r = 0.60$ ,  $P < 0.01$ ) and the plasma 8-iso-PGF<sub>2 $\alpha$</sub>  level (9.50  $\text{g}/\text{m}^2$  per SD 8-iso-PGF<sub>2 $\alpha$</sub> ,  $r = 0.44$ ,  $P = 0.01$ ) were significant and independent predictors of LVMI in women only (Fig. 1).

**Left ventricular systolic function.** EF increased by 2.9 percent units for each 1-SD increase in the plasma 8-iso-PGF<sub>2 $\alpha$</sub>  level (SD = 8.31  $\text{ng}/\text{L}$ ,  $r = 0.38$ ,  $P < 0.01$ ), and decreased by 2.6 percent units for each 1-SD increase in the serum  $\gamma$ -tocopherol level (SD = 0.06  $\text{g}/\text{mol}$ ,  $r = -0.34$ ,  $P < 0.05$ ), independently of confounders. These relationships were only present in women when genders were analyzed separately (3.7 percent units per SD 8-iso-PGF<sub>2 $\alpha$</sub> ,  $r = 0.59$ ,  $P < 0.001$ ; and -3.5 percent units per SD  $\gamma$ -tocopherol,  $r = -0.57$ ,  $P < 0.001$  in women). There were no relationships between AVPD and markers of lipid peroxidation and metabolism in the total sample. However, when genders were analyzed separately, each 1-SD increase in the LDL/HDL ratio was associated with a 1.3-mm reduction of the AVPD ( $r = -0.48$ ,  $P < 0.05$ ) in men alone, independent of other confounders.

<sup>a</sup>Data are *n* or means ± SD.

FIG. 1. Univariate regression of left ventricular mass index (LVMI) on plasma malondialdehyde and 8-iso-prostaglandin  $F_{2\alpha}$  in women.

1 SD was associated with a decrease in the SI/PP ratio of 0.27 mL/min/m<sup>2</sup>/mm Hg ( $r = -0.60$ ,  $P < 0.01$ ), independent of confounders in women alone.

**Smoking.** The regressions of LVMI and EF on markers of lipid peroxidation and metabolism were also studied with the eight smokers excluded, as smoking contributes to lipid peroxidation. However, exclusion of smokers did not alter the relationships between LVMI and EF and circulating levels of 8-iso-PGF<sub>2α</sub>, MDA, and serum  $\gamma$ -tocopherol.

## DISCUSSION

The major findings of the present study are that in apparently healthy subjects LVMI is predicted by biomarkers of lipid peroxidation in women, whereas left ventricular diastolic function is inversely related to the proportion of stearic acid

FIG. 2. Univariate regression of the E/A ratio on the proportion of stearic acid (18:0) in the serum cholesterol ester fraction in men.

(18:0) in men. Furthermore, apolipoprotein B is a main predictor of total arterial compliance and IMT in women.

Few studies have been devoted to the relation between lipid peroxidation and left ventricular mass. Experimental models to induce left ventricular hypertrophy by pressure overload in rodents have shown increased superoxide dismutase and glutathione peroxidase activity, and lower MDA content in the myocardium (17,38). The associations between lipid peroxidation and LVMI in the present study suggest that lipid peroxidation in plasma may be of importance for growth of the left ventricle in healthy subjects.

The E/A ratio, a sensitive way to evaluate left ventricular diastolic filling, was inversely related to the saturated FA stearic acid (18:0) in serum cholesterol esters in men. This is in accordance with previous findings that supplementation with saturated FA in humans results in impaired left ventricular diastolic filling, while addition of n-3 FA has the opposite effect (39). Taken together, these data suggest that FA composition influences left ventricular diastolic performance. The underlying mechanisms may involve alterations in myocyte relaxation, as recently proposed (39), or alterations in afterload.

In the present study, left ventricular systolic performance, as evaluated by EF, was related to 8-iso-PGF<sub>2α</sub> and inversely related to the antioxidant  $\gamma$ -tocopherol. Increased levels of biomarkers of lipid peroxidation have been found in myocardial tissue in experimental heart failure (17,18), and in the circulation and pericardial fluid in humans with heart failure (14–16,40). The unexpected relations between EF, 8-iso-PGF<sub>2α</sub>, and  $\gamma$ -tocopherol in the present study may reflect the fact that all subjects were healthy and had normal left ventricular systolic function. Furthermore, left ventricular systolic function, as assessed by the AVPD method, was inversely related to the LDL/HDL ratio in men. Cardiac afterload is mainly determined by arterial compliance and blood pressure and is related to both growth and an increased contractile function of the left ventricle (41). An increased myocardial fibrosis and an increase in relative wall thickness of the left ventricle, as seen in hypertensive left ventricular hypertrophy, will result in a reduced compliance of the left ventricle, as assessed by, e.g., the E/A ratio, and subsequently in a reduced systolic performance (5). Thus, the relations of LVMI, E/A ratio, and AVPD to markers of lipid metabolism and peroxidation may in part be explained by an increase in afterload due to structural vascular changes.

Structural vascular changes, as assessed by, e.g., carotid IMT measurements, influence total arterial compliance (42). Indeed, both carotid IMT and total arterial compliance were independently related to apolipoprotein B in women in this study. Apolipoprotein B has been shown previously to be related to IMT in subjects with CHD and non-insulin-dependent diabetes mellitus (43,44). IMT is also predicted by traditional cardiovascular risk factors, such as LDL cholesterol and saturated FA (45–47). Thus, our findings further support an impact of lipoprotein metabolism on arterial distensibility and atherosclerosis also in subjects without clinical signs of atherosclerosis.

**Limitations.** The aim of the present study was to generate new hypotheses in an area of research that has previously received little attention. A number of correlations were performed and, with the chosen significance level of 5%, one correlation in 20 may be significant merely by chance. This risk is even greater when genders are analyzed separately. Therefore, these results must be interpreted with caution until reproduced by other investigators. We observed a greater impact of lipid peroxidation on left ventricular mass and of apolipoprotein B on carotid IMT and arterial compliance in women, whereas stearic acid (18:0) appears to be more predictive of left ventricular diastolic function in men. The different patterns of relations of cardiac and vascular structure and function to markers of lipid peroxidation and metabolism in men and women appear to be gender specific, although the number of male and female subjects was limited and type I errors were likely to occur. Thus, larger studies are needed to confirm the findings and gender-specific differences of this study.

In conclusion, important structural and functional changes in the heart and blood vessels are related to indices of lipid metabolism and peroxidation in apparently healthy subjects.

# Fluctuations in Human Milk Long-Chain PUFA Levels in Relation to Dietary Fish Intake

Lotte Lauritzen<sup>a,\*</sup>, Marianne H. Jørgensen<sup>b</sup>, Harald S. Hansen<sup>c</sup>, and Kim F. Michaelsen<sup>a</sup>

<sup>a</sup>Center for Advanced Food Studies, Research Department of Human Nutrition, Royal Veterinary and Agricultural University, <sup>b</sup>Department of Pediatrics, University Hospital of Copenhagen, and <sup>c</sup>Department of Pharmacology, Royal Danish School of Pharmacy, Denmark

**ABSTRACT:** Within the Danish population, milk DHA (22:6n-3) levels vary by more than a factor of 10. This paper deals with fluctuations in the milk content of 22:6n-3 and other long-chain PUFA (LCPUFA) and the acute effects of fish meals and fish oil supplements on milk levels of LCPUFA. Twelve fish-eating mothers with 4-mon-old infants provided one blood and one adipose tissue sample, and seven consecutive morning hind-milk samples with dietary records from the previous days. Another 12 lactating women were given fish oil (2–8 g) for breakfast and delivered 6–12 milk samples during the following 24 h. The mean milk 22:6n-3 content of the fish-eating mothers was  $0.57 \pm 0.28$  FA% (= percentage of total area of FAME peaks in GLC) and the day-to-day variation (SD/mean) within the individual was  $35 \pm 17\%$ . Mean milk 22:6n-3 content on mornings with no fish the day before was  $0.42 \pm 0.15$  FA%; this was increased by  $82 \pm 17\%$  ( $n = 9$ ,  $P = 0.05$ ) if the mother had eaten fatty fish. Fish oil resulted in a twofold increase in milk 22:6n-3 levels, which peaked after 10 h and lasted for 24 h. The EPA content of milk was also increased by fish meals and fish oil supplements, but these had no effect on the level of arachidonic acid. The study showed that diurnal and day-to-day fluctuations in levels of milk n-3 LCPUFA are large, which makes it difficult to assess the 22:6n-3 intake of breast-fed infants from a single milk sample. In studies of the functional outcome of dietary 22:6n-3 in breast-fed infants it is suggested also to use a measure of maternal 22:6n-3 status.

Paper no. L8890 in *Lipids* 37, 237–244 (March 2002).

Studies on formula-fed infants have indicated the beneficial effects of dietary DHA (22:6n-3) on visual acuity and cognitive development (1–5). It is therefore likely that 22:6n-3 levels in maternal milk could affect the visual and mental development of breast-fed infants. A few cross-sectional studies (6–8) and one maternal intervention trial (9) indicate that this may be the case.

In most Western populations mean 22:6n-3 levels are around 0.1–0.4% of milk FA (FA%: percentage of the total area of FAME peaks in the gas–liquid chromatogram) (10),

Abbreviations: 22:6n-3 response, area under the curve of milk 22:6n-3 vs. time (AUC, calculated by the trapezium rule), or the difference between peak and baseline levels of 22:6n-3 in milk; AUC, area under the curve of milk FA level vs. time after test meal; BMI, body mass index ( $\text{kg}/\text{m}^2$ ); FA%, percentage of the total area of FAME peaks in the chromatogram; LCPUFA, long-chain PUFA; RBC, erythrocytes.

but milk 22:6n-3 levels in populations with a high fish consumption have been found to be up to 10 times higher (11–13). Within the Danish population, milk 22:6n-3 levels vary by more than a factor of 10, and in a cross-sectional study 55% of this variation could be explained by differences in maternal fish intake (6). Many studies have shown that supplementation of lactating women with various 22:6n-3 rich oils give rise to an increase in milk 22:6n-3 levels (14–21), but few studies have looked at the day-to-day variation and the time course after 22:6n-3 supplementation.

The arachidonic acid (20:4n-6) content of human milk varies much less than the content of n-3 long-chain PUFA (LCPUFA) (22). A high maternal intake of fish and fish oil might also affect the milk content of EPA (20:5n-3) and other n-3 LCPUFA. The acids 20:5n-3 and 20:4n-6 compete with one another in many metabolic processes, and therefore 20:5n-3 might theoretically inhibit the synthesis and mammary secretion of 20:4n-6. This may be of concern since studies have indicated that the addition of n-3 LCPUFA to formula milk has a negative effect on 20:4n-6 levels in infant erythrocytes (RBC) (23–27), which could be prevented by simultaneous addition of 20:4n-6 (27).

There is a need to know in more detail how the dietary intake of fish and fish oil by the mother affects the LCPUFA supply of the breast-fed infant. We investigated day-to-day variations in LCPUFA levels of breast milk from individual women and related these to fish intake. Furthermore, maternal RBC and adipose tissue levels of 22:6n-3 were correlated with the levels of 22:6n-3 in breast milk in order to compare milk levels with biomarkers of maternal habitual fish intake. Finally, we compared the immediate effect of different doses and two kinds of fish oil supplements on milk LCPUFA levels. Our results indicate that there are considerable difficulties in assessing the dietary intake of LCPUFA in breast-fed infants.

## EXPERIMENTAL PROCEDURES

**Subjects.** Twenty-four lactating women were recruited. The only inclusion criteria were that their infants were term, normal weight for gestation, and around 4 mon of age (mean  $3.9 \pm 0.5$  mon old, range 3.1–5.3). Apart from breast milk, some infants were given tea and water, and the oldest of the infants (22.6 wk old) was given some porridge. The Scientific-Ethical Committees for Copenhagen and Frederiksberg (KF 01-299/97) approved the study protocols and all subjects gave written consent

to participate. After inclusion they were interviewed about their pregnancy, delivery, the frequency of their fish intake, and height and weight of both mothers and infants. All mothers were of normal weight [body mass index (BMI) <27 kg/m<sup>2</sup>], had an average of 1.5 (range 1–5) children, and a fish intake frequency of 3.8 ± 2.0 meals/wk.

**Design.** The mothers were divided into two groups (for a “7-d-study” and a “test-meal-study”) mainly according to their fish intake. In the 7-d-study, 12 mothers with a high fish intake (4.6 ± 1.5 meals/wk) provided one blood sample and one adipose tissue biopsy from the buttock. Every day for a week they delivered a milk sample along with a dietary record of the previous day (only food items, not quantities). The mothers were asked to collect the milk sample immediately after nursing their baby for the first time in the morning. Fish meals were classified as fatty or lean according to fat content [given in national food composition tables (28)] with a cutoff at 5 g fat/100 g fresh weight. We categorized the milk samples (fatty, lean, or no fish) according to the dietary intake of the mother the day before the sample was taken. On several days the mothers had more than one meal of fish, and in these cases the meal with the highest marine fat content was used for the categorization. For each mother, the mean FA composition was calculated for all days in each of the three categories (fatty, lean, or no fish). This way we could compare the effect of fish intake on the FA composition of the milk by a paired statistical analysis.

In the test-meal-study, the other 12 women with a lower fish intake (2.9 ± 2.5 meals/wk) were given a morning test meal containing two different doses of microencapsulated fish oil on two nonconsecutive days (see Table 1). We used two different kinds of fish oil, a standard fish oil (Dry n-3<sup>TM</sup> 18:12 from BASF Health and Nutrition A/S, Ballerup, Denmark), and a tuna oil with a low 20:5n-3 content (Dry n-3<sup>TM</sup> 5:25 from BASF Health and Nutrition A/S). All fish oil doses were supplied with 2½ dL of yogurt. Following the test meal, a hind-milk sample was expressed after each episode of nursing during the next 24 h. A single woman was given only one test meal and was asked to collect milk for a day without any intake of fish or fish oil.

**Sampling.** Milk samples (2–5 mL) were stored in the home at 5°C until they were collected no later than 30 h after expression. Aliquots (2 mL) of the milk samples were stored at –80°C with BHT (Sigma), final concentration 0.001%. All milk samples were analyzed within one year of collection. Ten to 50 mg adipose tissue biopsies were stored at –80°C

in physiological saline with 0.005% BHT. Blood samples (10 mL) were taken by venipuncture in ice-cold EDTA-conditioned tubes. RBC were separated from plasma and leukocytes immediately after sampling and washed three times in physiological saline. The isolated packed RBC were reconstituted 1:1 in physiological saline with 1 mM EDTA and 0.005% BHT and kept at –80°C until they were analyzed (maximum storage time 6½ mon).

**FA analysis.** Lipids from 1-mL aliquots of the milk samples were extracted with the Bligh and Dyer procedure (29) using 3 mL of a 1:2 mixture of chloroform/methanol followed by addition of 1 mL chloroform. Phases were separated by addition of 1 mL 0.28 N HCl and centrifugation. Lipids from 1.2 mL of reconstituted RBC were extracted using the Rose and Oklander procedure (30). Ice-cold isopropanol (6.6 mL) with 0.005% BHT was added, followed by 10 min ultrasonication and steady shaking for 50 min. Then 4.2 mL of chloroform was added and, after one more round of ultrasonication and shaking, the phases were separated by centrifugation. Lipids from 10–50 mg of adipose tissue were extracted with 4 mL of chloroform containing 0.005% BHT and phase-separated by addition of 0.8 mL of H<sub>2</sub>O and centrifugation.

The extracted lipids were reesterified with BF<sub>3</sub> in methanolic NaOH. The resulting FAME were extracted with heptane and separated by GLC on an HP-6890 (Hewlett-Packard) equipped with a 30-m SP2380 capillary column (0.32 mm i.d., 0.2 µm film thickness; Supelco, Bellefonte, PA) and an FID. The injector temperature was set at 250°C. Samples of 1 µL (1 mg FAME/40 µL) were automatically injected with a split ratio of 1:49. For the initial 3 min the oven temperature was 80°C, which was then increased to 110°C at 30°C/min, then to 208°C at 3°C/min, and finally to 240°C at 50°C/min, which was held for 10 min before cool-down and injection of a new sample (total run time 46 min). Helium was used as the carrier gas at a constant flow of 2 mL/min (pressure 10.7 psi, velocity 35 cm/s). All peaks from 12:0 to 22:6n-3, except for that of BHT, were integrated.

The FAME peaks were tentatively identified by comparison of retention times with those of known FAME mixtures (Nu-Chek-Prep Inc., Elysian, MN), a fish-oil mixture (Fish Qual; Laurodan Fine Chemicals AB, Malmö, Sweden), and the 22:5n-6 peak in a rat testis preparation. Furthermore, we verified our identification by TLC separation of FAME from one milk sample and a fish-oil sample on silver nitrate-impregnated silica gel plates in hexane/ether (85:15, vol/vol). Bands repre-

**TABLE 1**  
**Content of Test Meals<sup>a</sup>**

Test meal	Fish oil type	Fish oil (g)	No. of meals	n-3 LCPUFA (g)	20:5n-3 (g)	22:6n-3 (g)	20:4n-6 (g)
a	Standard type	2.1	4	0.7	0.37	0.25	0.03
b	Standard type	4.2	8	1.5	0.75	0.50	0.06
c	Standard type	8.3	6	2.9	1.50	1.00	0.12
e	Tuna oil	3.7	5	1.3	0.18	0.92	0.08

<sup>a</sup>Twelve women were each given two test meals (except one woman) with different doses of fish oil. The fish oil was provided microencapsulated with 2½ dL of yogurt at breakfast.

senting the different degrees of unsaturation were visualized, scraped from the TLC plates, extracted with heptane, and separated by GLC. Typically, more than 95% of the total chromatogram area was identified. Under the present GLC conditions, some FAME coelute, e.g., 20:4n-6 and 20:3n-3, but as the latter is a minor component even in fish oil (31), we assumed that this FA contributed less than 10% to the peak.

The FA composition of all samples was determined in duplicate and in a series of 8–18, each containing a blank and a reference sample. The series was rejected if major FA in the reference sample deviated by more than 2 SD from the previously established mean values. The individual sample was re-analyzed if the relative difference (difference/mean) of major FA in the duplicates was appreciably increased relative to the typical deviation for that particular FA. The interassay variation of 22:6n-3 in milk and RBC was 10 and 1.9%, respectively, and the mean interassay variation of all identified peaks with area% >0.5 was  $2.1 \pm 1.9\%$  ( $n = 14$ ) and  $5.3 \pm 3.4\%$  ( $n = 14$ ), respectively. All adipose tissue samples were analyzed in one run, and the intraassay variation of the identified FA was generally below 5%. The relative amounts of identified FA (FA%) are given as area%.

**Statistical analysis.** All results are given as mean  $\pm$  SD. The FA percentage for 22:6n-3 and other n-3 LCPUFA in milk did not agree with a Gaussian distribution, and neither did all of the 22:6n-3 responses [measured as area under the curve of milk 22:6n-3 vs. time (AUC, calculated by the trapezium rule) or as the difference between peak and baseline levels of 22:6n-3] to the test meals. Therefore, all statistical group comparisons of FA composition or 22:6n-3 levels were performed by Wilcoxon signed rank tests. Analysis of the test meal responses was performed with linear regression models on logarithmically transformed values. Mean milk 22:6n-3 levels and the 22:6n-3 levels in RBC and gluteal adipose tissue did not deviate from a Gaussian distribution; thus, correlation analyses between these parameters were done by linear regression analysis. All the statistical analyses were performed by SPSS (version 10.0, SPSS Inc., Chicago, IL).

## RESULTS

**Variations in milk 22:6n-3 levels according to fish meals.** The mean 22:6n-3 content of the breast milk of the mothers in the 7-d-study was  $0.57 \pm 0.28$  FA% ( $n = 12$  women), giving a between-person variation of 49%. The relative 22:6n-3 content of the milk from the individual women varied considerably from day to day (Fig. 1) and the mean day-to-day variation within milk from the individual woman [(CV% = (SD/mean) · 100)] was  $35 \pm 17\%$  ( $n = 12$ ).

During the experimental week the women had, altogether, 62 meals of fish [on average  $5.2 \pm 1.3$  per woman ( $n = 12$ )]. The most frequent fish meal type was lunch (35 meals), which typically included open-faced sandwiches with fatty fish. Lean fish was eaten more frequently for dinner. The milk samples were classified as described in the Experimental Procedures section. All subjects had at least one milk sample in

**FIG. 1.** Day-to-day variations in 22:6n-3 levels [peak area percentage (FA%)] in morning hind-milk samples from 12 lactating mothers of 4-month-old infants. One of the women had a milk 22:6n-3 content of 3.4 FA% after a lunch meal of herring and cod liver (outlier in the plot).

the category “lean fish” and 11 of the mothers also had at least one sample in the “fatty fish” category. During the experimental week, the mothers had on average  $2.6 \pm 1.2$  d ( $n = 12$ ) where they had no intake of fish on the previous day.

The milk 22:6n-3 level was significantly increased by maternal fish consumption (fatty or lean) on the previous day [ $0.63 \pm 0.31$  FA% compared with  $0.41 \pm 0.15$  FA% on days with no fish intake,  $n = 12$ ,  $P = 0.018$  (Wilcoxon signed rank tests)]. Thus, consumption of fish resulted in a 1.5-fold higher level of 22:6n-3 in the milk on the following morning. This increase was mainly due to intake of fatty fish, as the relative increase in milk 22:6n-3 after a day with fatty fish consumption was on average  $1.7 \pm 0.8$  times compared with no-fish levels ( $n = 11$ ). Meals of lean fish did not give rise to a significant increase in milk 22:6n-3 (Table 2). An extremely high

<sup>a</sup>Daily milk samples from 12 women were categorized according to fish intake the day before. The individual mean FA compositions in each category were calculated, and the table provides the means of all women. *P*-value for statistical comparisons with No fish (Wilcoxon): \* $P < 0.05$ , and \*\* $P < 0.01$ . SFA, saturated FA; MUFA, monounsaturated FA.

milk 22:6n-3 content (3.4 FA%) was found in one of the milk samples, which was collected the day after the mother had both herring and cod liver for lunch.

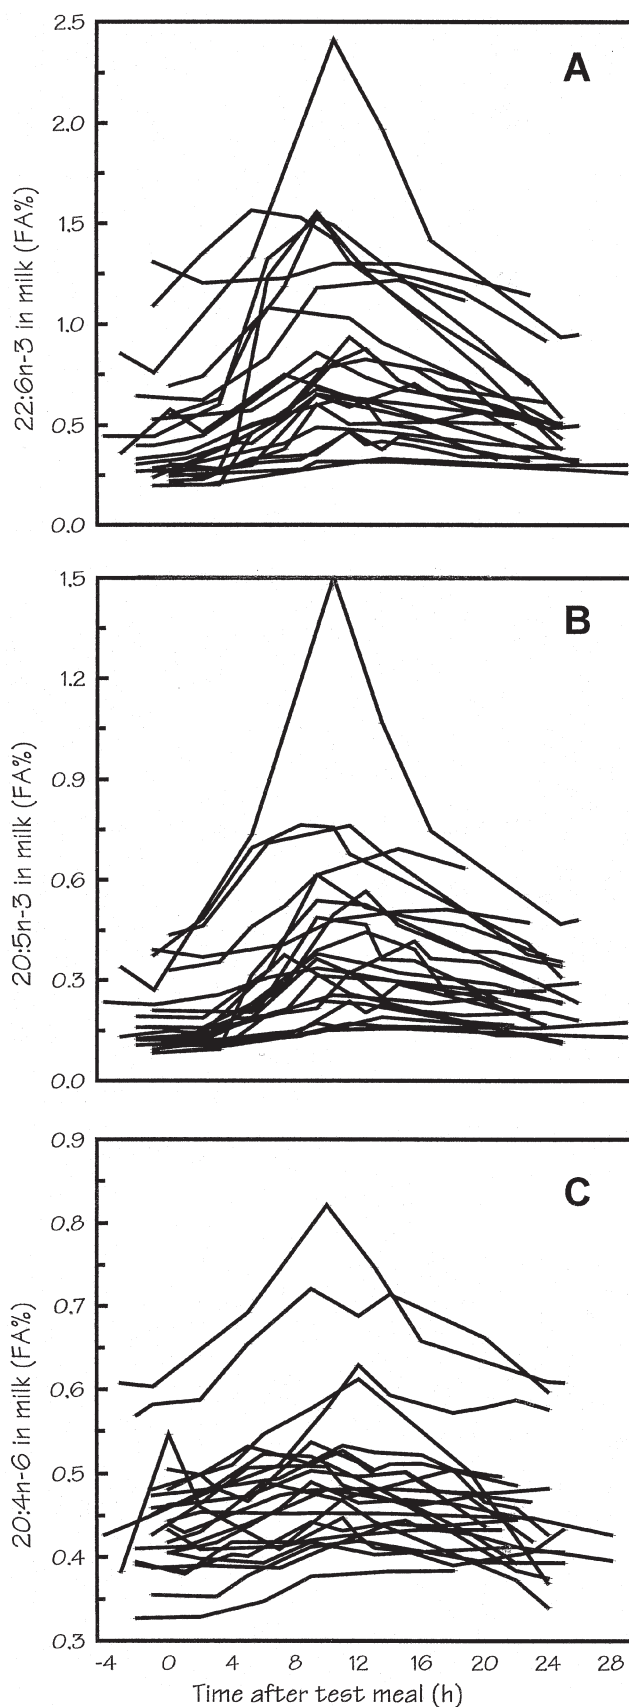

**Tissue markers of milk 22:6n-3.** The mean 22:6n-3 content of gluteal adipose tissues and RBC, two commonly used biomarkers of 22:6n-3 status, were  $0.20 \pm 0.05$  and  $6.10 \pm 0.71$  FA%, respectively. The average levels of 22:6n-3 in all seven milk samples from the same mother were significantly associated with that of RBC (Fig. 2), and also tended to be so with that of adipose tissues ( $r = 0.50$ ,  $P = 0.096$ ). The two indicators of 22:6n-3 status, RBC and adipose tissue, correlated with each other ( $r = 0.79$ ,  $P = 0.002$ ).

We also calculated correlation coefficients between the 22:6n-3 content of RBC and that of the milk for each of the 7 d. The 22:6n-3 content of the individual milk samples correlated significantly with the 22:6n-3 levels of RBC on 5 out of 7 d ( $P = 0.030$ – $0.001$ ), but on other days this association was less clear (day 3:  $P = 0.09$  and day 4:  $P = 0.52$ ). We also calculated the correlation between the 22:6n-3 status measures and the mean 22:6n-3 content of the milk on days after no fish in order to see whether maternal 22:6n-3 status was better reflected in the 22:6n-3 level of milk that was not influenced by a recent fish intake. The 22:6n-3 content of the no-fish milk samples was not significantly associated with that of RBC (Fig. 2), but correlated with that of adipose tissues ( $r = 0.69$ ,  $P = 0.012$ ).

**Effect of fish oil test meals on milk 22:6n-3.** In the test-meal study a fish oil-containing meal resulted in an acute increase in the relative 22:6n-3 content of the milk, which started after a few hours and peaked after  $10 \pm 2$  h ( $n = 23$ ) (Fig. 3A). At peak, milk 22:6n-3 reached levels  $2.3 \pm 1.1$  times higher than baseline levels (Table 3). The effect of fish oil was transient;  $23 \pm 2$  h after ingestion of the test meal the milk 22:6n-3 level

**FIG. 2.** Correlation between the levels [peak area percentage (FA%)] of 22:6n-3 in maternal erythrocytes (RBC) and milk on one individual day [here day 1 of the study ( $-\circ-$ ), on days with no prior fish consumption ( $-\circ\cdot-$ ), or as a mean of all seven days ( $-\bullet-$ ), the regression parameters of which are given in the figure]. The correlation coefficient for day 1 was  $r = 0.69$ ,  $P = 0.013$ , and for no-fish  $r = 0.51$ ,  $P = 0.09$ .

**FIG. 3.** The levels [peak area percentage (FA%)] of 22:6n-3 (A), 20:5n-3 (B), and 20:4n-6 (C) in human milk as a function of time (h) after ingestion of test meals with fish oil ( $n = 23$  test meals).

<sup>a</sup>From 12 women, hind-milk samples were collected from every lactation in 24 h following ingestion of test meals (see Table 1). The data represent mean of all fish oil responses regardless of given dose and test subject. *P*-value for comparisons with baseline (Wilcoxon): \**P* < 0.05, \*\**P* < 0.01, and \*\*\**P* < 0.001.

was almost back at starting level, being only marginally increased by 1.3 ± 0.4 times morning levels (Table 3).

The magnitude of the 22:6n-3 responses in the milk (peak relative to start concentration) after the different test meals was significantly different [Table 4, part A, *P* = 0.007 (ANOVA with logarithmically transformed values)], but a dose response was not immediately evident. There were, however, differences in the BMI of the women given the various test meals, and the starting points for milk 22:6n-3 also deviated between test meals, although not significantly. A multiple linear regression analysis (taking account of test subject, BMI, habitual fish intake frequency, and the type and

dose of fish oil) showed a highly significant dose-response relationship between the amount of 22:6n-3 given in the test meal and the resultant response (AUC) in milk 22:6n-3 (Table 5). However, the size of the 22:6n-3 response was also inversely related to the BMI of the mother (Table 5). A simple linear model of the 22:6n-3 response vs. dose of 22:6n-3/BMI explains 56% (*P* < 0.001) of the variation in the 22:6n-3 responses (data not shown).

Type of fish oil [tuna oil (e) or ordinary fish oil (a-c)] also significantly affected the milk 22:6n-3 response in the multiple regression model that controlled for the 22:6n-3 dose given (Table 5), indicating that the response to a certain dose of 22:6n-3 was larger after tuna oil than after ordinary fish oil. This was not apparent in the direct group comparison (c vs. e, Table 4, part A), but the tuna oil 22:6n-3 response was significantly larger than the fish oil response if one compares test meals with similar amounts of n-3 LCPUFA (b vs. e, *P* = 0.004).

*Milk content of 20:5n-3 and 20:4n-6.* In the 7-d-study the levels of other n-3 LCPUFA in the milk were also significantly increased if the lactating woman had fatty fish the day before the milk sample was taken as compared with the levels if she had not had fish the previous day (Table 2). The 20:5n-3 response after a fish oil test meal appears very similar to that of 22:6n-3 (Fig. 3B), with approximately the same relative increase and the same time course. All the levels of n-3 LCPUFA, as well as the ratio between n-6 and n-3 PUFA, were significantly affected at the peak of the fish oil response (Table 3).

In the test-meal-study we used two different types of fish oil: the low-20:5n-3 tuna oil and an ordinary high-20:5n-3 fish oil. As expected, the 20:5n-3 increase after tuna oil (e) was significantly lower than following the dose of fish oil that gave a

<sup>a</sup>The responses in milk LCPUFA content after fish oil test meals are expressed as relative content at peak [area% (FA%)] and area under the curve (AUC) of relative FA content vs. time (approximately 24 h). Responses were compared by ANOVA and subsequent *post hoc* tests on logarithmically transformed responses. In each column, values with different superscript letters are significantly different (*P* < 0.05). BMI, body mass index.

<sup>b</sup>Fish oil-containing test meals as specified in Table 1.

<sup>c</sup>The total AUC response corrected for the area below baseline.

**TABLE 5**  
**Influence of Individual Parameters in a Multiple Linear Regression Model for the Breast Milk 22:6n-3 Increase After Fish Oil-Containing Test Meals<sup>a</sup>**

	Unstandardized coefficients	P
22:6n-3 in test meal (g)	0.572 ± 0.155	0.002
BMI (kg/m <sup>2</sup> )	-0.059 ± 0.019	0.007
Fish oil type (a,b,c = 1; e = 2) <sup>b</sup>	0.229 ± 0.107	0.049
Frequency of fish intake (wk <sup>-1</sup> )	0.004 ± 0.003	0.147
Subject	-0.012 ± 0.010	0.247

<sup>a</sup>The 22:6n-3 increase in the milk was expressed as the logarithm of the corrected AUC response (FA%·time<sup>-1</sup>). All included variables are given in the table. The model has an overall  $r = 0.85$  (adjusted  $r^2 = 0.63 \pm 0.18$ ) and  $P = 0.001$ .

<sup>b</sup>a, b, and c represent three different test meals with standard fish oil, and e represents meals with tuna oil as specified in Table 1.

similar amount of 22:6n-3 (c). However, there was no difference between the two types of fish oil if we compared test doses of oils that supplied similar amounts of total n-3 LCPUFA (b) (Table 4, part B). A proxy for the secreted amounts (measured as AUC of FA% vs. time) showed that the increase in 20:5n-3 was  $3.7 \pm 2.6$  FA%·time<sup>-1</sup> (here in average 23 h) and that 22:6n-3 increased with  $4.5 \pm 3.5$  FA%·time<sup>-1</sup>. Since the test meals on average contained  $0.9 \pm 0.5$  g 20:5n-3 and  $0.6 \pm 0.3$  g 22:6n-3, the increase in milk 20:5n-3 per g ingested 20:5n-3 was approximately half of that for 22:6n-3, being  $5.0 \pm 3.5$  and  $9.0 \pm 6.3$  AUC/g ( $n = 23$ ), respectively.

In the 7-d-study, the fish meals did not have any negative effect on milk 20:4n-6 levels (Table 2). In the test-meal-study, milk 20:4n-6 showed a tendency toward an increase after fish oil test meals (Fig. 3C). When the results obtained from the fish oil doses were pooled, the milk 20:4n-6 levels at the peak of the responses were significantly higher than at baseline (Table 3), but no statistical differences were apparent when we compared the peak and AUC responses of 20:4n-6 after the different test meal types (Table 4, part C).

## DISCUSSION

*The time course of changes in milk n-3 LCPUFA.* In the present study we found that 22:6n-3, 22:5n-3, 20:5n-3, and total n-3 PUFA were all maximally increased 10 h after a test meal containing 2–8 g of fish oil (Fig. 3). This is in agreement with previously published time courses for n-3 LCPUFA after consumption of 1 g of fish oil (15) or 0.5 g algal oil (21), and for 16:0, 18:1n-9, and 18:2n-6 after doses of <sup>1</sup>H- or <sup>13</sup>C-labeled FA (32,33). It is also consistent with the proposed route for mammary gland fat uptake from the circulation being through the modality of chylomicrons (33). Francois *et al.* (34) found similar time courses for 18:2n-6, 22:1n-11, 18:0, and 12:0 after consumption of vegetable oil, herring oil, or cocoa butter, but after consuming 20 g menhaden oil the levels of 22:6n-3 and 20:5n-3 increased much more slowly with a peak around 24 h postingestion. In considering the large fish oil dose given in that study (34), the peak 22:6n-3 and 20:5n-3 levels in the milk were low compared to the responses with test meals with fish oil seen in the present study. The delayed

peak could theoretically be explained by the high dose of fish oil given by Francois *et al.* However, consumption of 20 g of herring oil resulted in a faster 22:1n-11 response than did 7 g (34), and we found no delay of the peak after increasing the dose of fish oil from 2 to 8 g (data not shown).

We found that the acute milk response to dietary fish oil had almost disappeared after 24 h. In many studies on the effect of daily LCPUFA supplementation, milk samples are taken 24 h after the supplement (15,19,35). Therefore, these studies may underestimate the effect of supplements on the FA composition of the milk. In this study we found that there was a significant effect of fish intake the day before milk sampling on n-3 LCPUFA levels in morning milk. The milk samples were typically taken approximately 17 h after the fish meal, which, as judged from the curves in Figure 3, seems to be a representative time with respect to the day-mean of milk 22:6n-3. This effect was primarily due to meals of fatty fish as opposed to lean fish (Table 2).

*Factors affecting 22:6n-3 milk levels.* Milk 22:6n-3 levels were significantly and dose-dependently increased after test meals with fish oil (Tables 3 and 5), which in their content of n-3 LCPUFA were comparable to that of moderate-sized fish meals [an open-faced sandwich with fatty fish or a dinner serving of codfish (28)]. We found that milk 22:6n-3 levels were negatively influenced by the BMI of the mother (Table 5), as previously reported (18,19). As milk 22:6n-3 levels are expressed relative to that of other FA (FA%) the BMI effect probably reflects increasing dilution of dietary lipids in the plasma by the endogenous lipid pool. The LCPUFA content of human milk has been shown to reflect the FA composition of maternal plasma phospholipids (17,19), which in turn is determined by dietary FA and slightly modified by hepatic metabolism and FA from internal stores. Variations in the total amount of fat ingested in the test meal and in previous and following meals probably account for many of the individual differences.

*Factors affecting 20:5n-3 milk levels.* In the present study we compared marine oils with a low and a high 20:5n-3 content in order to see whether the first oil would increase milk 22:6n-3 levels without affecting levels of 20:4n-6 and 20:5n-3. We found no difference between the 20:5n-3 responses for doses of the two fish oil types that supplied similar amounts of n-3 LCPUFA. Ordinary fish oil has a high 20:5n-3 content compared with most fish consumed in Denmark [20:5n-3/22:6n-3 = 1.5 and 0.4 (28), respectively]. Thus, at a certain 22:6n-3 response one would expect that the 20:5n-3 response to fish oil would be 3–4 times higher than that of a meal of fish. However, the 20:5n-3 and 22:6n-3 responses in the milk after fish oil and meals of fatty fish were not so different (see Tables 2 and 3). The 20:5n-3 response after fish oil test meals also appears to be lower than that of 22:6n-3, based on our estimates of the secreted amounts of these two n-3 LCPUFA. This blunting of the 20:5n-3 response does not necessarily indicate a selective mechanism for mammary secretion of 22:6n-3, but may reflect a high hepatic conversion of plasma 20:5n-3 to 22:6n-3. However, the 22:6n-3 response to tuna oil was, if anything, larger than the response

to a similar dose of 22:6n-3 from fish oil. Furthermore, it was shown in another study that dietary flaxseed oil (11 g 18:3n-3 daily for 4 wk) significantly increased maternal plasma and breast milk 18:3n-3 and 20:5n-3 but had no effect on 22:6n-3 (36). Thus, the apparent lower 20:5n-3 secretion does not appear to be due to rapid elongation and desaturation.

**Factors affecting 20:4n-6 milk levels.** The content of 20:4n-6 in human milk varies much less than the content of n-3 FA, both within the individual and among different populations (1,10,37). In the current study the day-to-day variation in milk 20:4n-6 content of 12 women was only about 8% (data not shown). Four grams of fish oil with 1 FA% of 20:4n-6 (31) would increase the maternal 20:4n-6 intake 7–40% (38,39). In agreement with other studies (14,15,17–21), our results indicate that fish meals do not have a decreasing effect on milk 20:4n-6 and that milk 20:4n-6 was significantly increased by fish oil-containing test meals.

We expected that fish oil with a high 20:5n-3 content might have a negative effect on the 20:4n-6 level of the milk. However, the 20:4n-6 level of the milk was significantly increased at the peak of the n-3 LCPUFA response after test meals with fish oil (Table 3). Although tuna oil had a lower 20:5n-3 content and a higher 20:4n-6 content than the ordinary fish oil [2.2 and 1.4 FA%, respectively (see Table 1)], it did not seem to have the same positive effect on milk 20:4n-6 levels as ordinary fish oil. The 20:4n-6 level at the peak of the tuna oil response was not higher than at time 0 (Table 4, part C). The overall significant effect that fish oil had on milk 20:4n-6 levels occurred in spite of this. Thus, we found no indication that fish oil with a low 20:5n-3 content had a protective effect on milk 20:4n-6 content compared to a standard high-20:5n-3 fish oil.

**Biomarker of infant 22:6n-3 intake.** The present results indicate that variations in milk 22:6n-3 levels within the individual woman are of the same order of magnitude as the total variation between the individuals. The average milk 22:6n-3 content in this study was in agreement with previous observations in the Danish population (6,26,40), as was the observed variation between subjects (i.e., 64%). We found a within-subject day-to-day variation of 35% and a peak effect of fish oil on milk 22:6n-3 content on the order of a factor of 2.

To assess infant 22:6n-3 intake, one would want to determine the milk 22:6n-3 content that reflects the maternal habitual fish intake. Such typical milk 22:6n-3 content will be difficult to assess accurately in a population with a variable fish intake, because of the variability in milk n-3 LCPUFA. On several days within the 7-d study there was no correlation between the 22:6n-3 content of milk and that of RBC and gluteal adipose tissues (data not shown), both of which are commonly used biomarkers of the habitual intake of n-3 LCPUFA (41–45). Thus, there is a large risk that the 22:6n-3 level in a single milk sample does not reflect the habitual intake of the breast-fed infant. We hypothesized that milk levels of 22:6n-3 on mornings with no fish consumption the previous day would represent a resting level that would reflect the overall 22:6n-3 status of the mother. However, we found that this putative resting level of milk 22:6n-3 was poorly associated with 22:6n-3 levels in maternal RBC and adipose tissues.

In this study we found that 22:6n-3 levels in milk from individual fish-eating women can vary almost as much as 22:6n-3 levels in human milk in general. Furthermore, the present study indicates that n-3 LCPUFA from the maternal diet appears faster and to a larger extent in the milk than previously realized. The acute effect of fish meals on milk n-3 LCPUFA levels is more pronounced than the effect of the overall fish intake frequency. Thus, the present study has clearly demonstrated the drawbacks of using 22:6n-3 levels in single milk samples as a measure of the dietary intake of 22:6n-3 in breast-fed infants.

## ACKNOWLEDGMENTS

We gratefully acknowledge Pediatric Nurse Lise Lotte Ingholt for assisting in collecting the data and Technician Bettina Sørensen for performing the FA analysis. This study was financed in part by FØTEK—The Danish Research and Development Program for Food and Technology and BASF Health and Nutrition A/S.

**ABSTRACT:** It is generally believed that virgin olive oil consumption has beneficial effects, but little is known about its effects postprandially on oxidant/antioxidant status. The aim of this study was to determine changes in oxidative stress biomarkers and lipid profile after a single dose of virgin olive oil and after 1 wk of daily consumption. Sixteen subjects (9 men, 7 women) ingested 50 mL of virgin olive oil in a single dose. Blood samples were collected from 0 to 24 h. Thereafter, 14 participants (8 men, 6 women) followed a 1-wk 25 mg/d virgin olive oil dietary intervention. Blood samples were collected at the end of this period. Serum TAG ( $P = 0.016$ ), plasma FA ( $P < 0.001$ ), and lipid peroxidation products in plasma ( $P < 0.001$ ) and VLDL ( $P = 0.007$ ) increased, reaching a peak at 4–6 h, and returning to baseline values at 24 h after oil ingestion. The opposite changes were observed in plasma glutathione peroxidase ( $P = 0.001$ ) and glutathione reductase (GR) ( $P = 0.042$ ). No changes in LDL lipid peroxidation or resistance to oxidation were observed postprandially. At 24 h, plasma oleic acid remained increased ( $P < 0.05$ ) and resistance of LDL to oxidation improved ( $P < 0.05$ ). After 1 wk of virgin olive oil consumption, plasma oleic acid ( $P = 0.031$ ), resistance of LDL to oxidation ( $P < 0.05$ ), and plasma GR activity ( $P = 0.005$ ) increased. These results indicate that changes in oxidant/antioxidant status occur after oral virgin olive oil. Virgin olive oil consumption could provide short-term benefits for LDL resistance to oxidation and in glutathione-related enzyme activities.

Paper no. L8901 in *Lipids* 37, 245–251 (March 2002).

Coronary heart disease (CHD) is the main cause of mortality in industrialized countries; although mortality rates vary, the Mediterranean area has among the lowest (1). The Mediterranean diet has been shown to be associated with a benefit in secondary prevention of CHD (2). The lower incidence of CHD in Mediterranean countries has been attributed to a diet rich in fruits, vegetables, legumes, and grains, in which the major fat component is olive oil. These foods contain natural antioxidants that can prevent LDL oxidation (3).

Abbreviations: Apo, apolipoprotein; CHD, coronary heart disease; GR, glutathione reductase; GSH-Px, glutathione peroxidase; MUFA, monounsaturated FA; OR, oxidation rate; SFA, saturated FA.

Evidence is increasing that dietary fat composition may influence oxidative modification of LDL (4). LDL oxidation is now widely regarded as playing an important role in the development of atherosclerosis (5). Postprandial lipemia has been recognized as a risk factor for atherosclerosis development, as it is associated with oxidative changes, including an increase in TAG-rich proteins and their remnants (6). This increase may directly damage the vascular endothelium *via* oxidative mechanisms (7). Meals rich in oxidized fats increase the oxidized lipid content of lipoproteins, and a reduction of serum paraoxonase activity after a cooked fat-rich meal has been reported (8,9).

Previous dietary intervention studies have shown that, compared to carbohydrate- or PUFA-enriched diets, monounsaturated FA (MUFA)-enriched diets reduced the LDL susceptibility to oxidation (10–13). In general, these studies utilized carefully prepared liquid-formula or solid diets highly enriched in MUFA. Whether a more realistic level of MUFA ingestion will lead to similar results is unknown.

The mechanisms underlying the apparent benefits of olive oil consumption are not completely understood. After an oral olive oil load, the magnitude of postprandial lipemia and remnant lipoprotein is reported to be lower than after ingesting butter (14), similar to that after eating a saturated fat-rich meal (15), or higher than after consuming a dose of safflower oil (16). The aim of the current study was to determine whether a bolus ingestion of virgin olive oil affected postprandial lipid peroxidation, serum antioxidant glutathione-related enzymes, and LDL oxidation resistance. The study also examined the effect on these oxidative stress markers after 1 wk of replacement of butter, margarine, or vegetable oils by crude virgin olive oil.

## MATERIALS AND METHODS

**Subjects.** Sixteen (9 men and 7 women) healthy volunteers (aged 25 to 65 yr) were recruited. The ethical committee (CEIC-IMAS) approved the protocol, and participants signed an informed consent. All volunteers were considered healthy on the basis of a physical examination and standard biochemical and hematological tests. Subjects had an average weight of  $75 \pm 13.47$  kg (men:  $83.2 \pm 4.4$ , women:  $59.7 \pm 6.11$ ) and a body mass index of  $25.6 \pm 3.1$  kg/m<sup>2</sup> (men:  $26.9 \pm 3.29$ , women:  $22.4 \pm 2.4$ ).

**Olive oil analyses.** The characteristics of the virgin olive oil used in the experiments are as follows: peroxide value (meq/kg), 9.8;  $K_{270}$  (extinction coefficient for light absorption at 270 nm), 0.10; FA (%): 16:0, 12.7; 16:1, 1.0; 18:0, 1.79; 18:1, 73.3; 18:2, 9.49; 18:3, 0.40; monounsaturated, 74.87; polyunsaturated, 9.89; saturated, 15.24; vitamin E (mg/kg), 156.20;  $\beta$ -carotene (mg/kg), 3.07; phenolic compounds (mg/kg), 253.36.

FA composition was determined by GC (17), and  $\alpha$ -tocopherol and  $\beta$ -carotene contents in olive oils were determined by RP-HPLC (18). Total phenolic content of olive oils was measured by the Folin–Ciocalteu method (19). Peroxide index and UV light absorption ( $K_{270}$ ), a measure of secondary oxidation compounds such as carbonyls (aldehydes and ketones), were determined following the analytical methods described in CEE/2568/91 of the European Union Commission (20).

**Study design.** Volunteers followed an antioxidant and olive oil-free diet for 5 d. A nutritionist instructed them on excluding several foods from their diet (coffee, tea, fruit, vegetables, wine, and olive oil). At 8 A.M. on day 5, in the fasting state, they were provided with 50 mL (44 g) of extra virgin olive oil administered in a single dose either ingested directly or with some bread. During the first postprandial 6 h, subjects abstained from food and drink with the exception of caffeine-free, low-energy drinks and water. Blood was collected at baseline (0 h) and at 2, 4, 6, 8, and 24 h after virgin olive oil administration. Thereafter, 14 participants (8 men, 6 women) followed their habitual diet for 1 wk, using the same virgin olive oil as source of crude dietary lipid. The participants' daily consumption of virgin olive oil ranged from 19 to 22 mL (17–19 g) per day (each individual was provided 25 mL/d). Blood samples were collected on day 12 of the study after a week of virgin olive oil consumption. Plasma was separated by centrifugation at  $1000 \times g$  at 4°C for 15 min.

**Dietary assessment.** Nutrient intakes were calculated from seven daily dietary records with the software *Diet Analysis Nutritionist IV* (N-Squared Computing, San Bruno, CA). The daily caloric intake of the subjects during the week of sustained olive oil ingestion ranged from 1465 to 2284 kcal (mean  $\pm$  SD,  $1748 \pm 331$  kcal) and consisted of lipids  $37.5 \pm 3\%$  (PUFA  $4.8 \pm 1.2$ , MUFA  $17.9 \pm 2.1$ , and saturated FA  $14.7 \pm 1.58\%$ ), carbohydrates  $44.2 \pm 5.1\%$ , and proteins  $18.3 \pm 2.7\%$ .

**Antioxidant enzyme activity measurements.** Glutathione peroxidase (GSH-Px) activity in plasma was measured by a modification of the Paglia and Valentine method (21) (Ransel RS 505; Randox Laboratory, Crumlin, Northern Ireland). Glutathione reductase (GR) activity in plasma was measured by glutathione reduction following the oxidation of NADPH to NADP<sup>+</sup> during the reduction of oxidized glutathione (Ransel GR 2368, Randox Laboratory) (22). Enzyme activities were measured in a Cobas Mira Plus analyzer (Hoffman-La Roche, Basel, Switzerland) at 37°C. Intra-assay CV were 3.6 and 3.5% for GSH-Px and GR, respectively. Interassay CV were 5.4 and 4.4% for GSH-Px and GR, respectively.

**Glucose, lipid, lipoprotein, and apolipoprotein (Apo) measurements.** Serum glucose, total cholesterol, HDL cholesterol,

and TAG levels were measured by standard enzymatic methods. Serum ApoA1 and ApoB were measured by immunoturbidimetric methods (Roche Diagnostics, Basel, Switzerland). LDL-cholesterol (LDL-C) was calculated by means of the Friedewald equation.

**FA measurements.** Plasma FA were directly transesterified without previous lipid extraction and measured by capillary GC (23). Intra- and interassay CV were 3.4 and 5.15%, respectively.

**Lipoprotein isolation.** Very low density lipoproteins (VLDL) and LDL isolation were performed by sequential flotation ultracentrifugation (24). Protein content was determined by the red pyrogallol method (Sigma, St. Louis, MO).

**LDL resistance to oxidation.** Conjugated diene formation after copper-mediated LDL oxidation was assessed as previously described (25). Briefly, dialyzed LDL (0.05 g protein/L) was incubated with cupric sulfate (5  $\mu$ M) in PBS at a final volume of 1 mL. Absorbance at 234 nm was continuously monitored at 2-min intervals for 5 h at 35°C. All samples from one individual were performed in the same run. For data presentation, the x-axis value corresponding to the intercept of the propagation phase tangent with the extrapolated line for the slow propagation reaction was calculated (lag time), oxidation rate (OR) was derived from the slope of the propagation phase tangent, and diene formation was calculated by the maximum increase of the absorbance at 234 nm. OR and diene formation were calculated using the molar absorbance  $\epsilon_{234\text{nm}}$  for conjugated dienes (29,500 L $\cdot$ mol<sup>-1</sup> $\cdot$ cm<sup>-1</sup>). Intra-assay CV were 3.29, 5.27, and 1.46% for lag time, OR, and diene formation, respectively.

**Lipid peroxidation measurements.** Lipid peroxidation in plasma, VLDL, and LDL was measured by the TBARS test (26) adjusted by TAG or protein content. Solutions of 1,1,3,3-tetraethoxypropane in ethanol were used as standards for the assay. Intra- and interassay CV were 4.22–4.87% and 5.89–6.87%, respectively.

**Statistical analyses.** A general linear model was used to test the best fit of the repeated measurements: linear, quadratic, or cubic. Once statistical differences among the means were observed, a *post-hoc* multiple comparison test was done for each variable separately by Tukey's test. A Bonferroni's correction was applied, so for these multiple comparisons a *P* value <0.01 was considered statistically significant. Spearman's correlation coefficients were used to assess the relationship between two continuous variables. Paired Student's *t*-test for parametric variables and Wilcoxon's test for non-parametric variables (TAG and lipid peroxides) were used to assess differences between baseline values and those obtained after 1 wk of virgin olive oil consumption. A *P* value <0.05 was considered statistically significant. These statistical analyses were performed using the SPSS statistical package (SPSS Incorporated Co., Chicago, IL).

## RESULTS

**Effects of ingesting a single dose of virgin olive oil.** Figure 1 shows the time course of plasma lipid peroxides, GSH-Px, and GR activities for 24 h after ingesting 50 mL of olive oil.

**FIG. 1.** Time course of (A) plasma lipid peroxides, (B) glutathione peroxidase (GSH-Px), and (C) glutathione reductase (GR) after ingestion of 50 mL virgin olive oil ( $n = 16$ ). \* $P < 0.005$ ; † $P < 0.01$  vs. baseline (0 h).

Plasma lipid peroxidation increased to a peak at 4–6 h, and returned to baseline at 24 h. The opposite changes were observed in plasma GSH-Px and GR activities

The time course of lipid peroxide formation in VLDL and LDL, and LDL oxidation resistance-related variables, is shown in Table 1. Lipid peroxidation in VLDL increased, reaching a peak at 6 h and returning close to baseline at 24 h, whereas no significant changes in lipid peroxidation were observed in LDL. The lag time of conjugated diene formation

in LDL increased and the OR decreased at 24 h after virgin olive oil ingestion. No statistical differences were observed in diene formation with time in LDL oxidation.

Serum TAG and plasma FA increased after ingesting 50 mL of virgin olive oil, reaching a peak at 4–6 h postprandially (Table 2). Despite the increase of oleate and the decrease of linoleate percentages in plasma ( $P < 0.001$ ) (data not shown), linoleate concentration (g/L) in plasma increased after olive oil ingestion (Table 2). At 4 h postprandial time, the concentration (g/L) of linoleic acid in plasma was directly related to plasma lipid peroxides ( $P = 0.027$ ) and inversely to plasma GSH-Px ( $P = 0.008$ ) and GR activities ( $P = 0.068$ ) (Fig. 2). No relationship was obtained among plasma oleic, or other plasma FA levels, and lipid peroxides or glutathione-related enzymes at 4–6 h of virgin olive oil ingestion. Levels of serum glucose in plasma increased from baseline ( $3.9 \pm 0.6$  mmol/L, mean  $\pm$  SD) to 2 h ( $4.4 \pm 0.8$  mmol/L, mean  $\pm$  SD) after virgin olive oil ingestion ( $P = 0.021$ ) (data not shown).

At 24 h after olive oil ingestion, plasma MUFA/PUFA ratio and oleic acid concentrations remain increased (Table 2). At this time period plasma lipid peroxides were inversely related to plasma oleic acid ( $r = -0.565$ ,  $P = 0.028$ ) and directly to linoleic acid concentrations ( $r = 0.532$ ,  $P = 0.041$ ) (data not shown).

*Effects of ingesting virgin olive oil for 1 wk.* Table 3 shows the changes in lipids, lipoproteins, FA, and oxidative stress markers after 1 wk of olive oil consumption. Consumption of virgin olive oil (19–20 mL/d) during a week led to a significant decrease in LDL-cholesterol concentration. No significant changes were observed in the total plasma FA content. An increase was observed in the oleic acid percentage and MUFA/PUFA ratio from baseline time to the end of the study. No significant changes were observed in the linoleate percentage in the evaluated times. Changes in the concentration (g/L) of the individual plasma FA were similar to those observed in their percentages. An increase in plasma GR and GSH-Px and a decrease both in the lag time and in the OR of conjugated diene formation were observed.

After 1 wk of virgin olive oil consumption, plasma linoleate/oleate ratio was directly related to plasma lipid peroxides and inversely related to plasma GR activity (Fig. 3). In comparison with data from 24 h after 50 mL olive oil ingestion, only the lag time of conjugated diene formation was slightly increased ( $P = 0.047$ ).

## DISCUSSION

This study reports the effects of both single and sustained doses of virgin olive oil on the oxidant/antioxidant balance, and on plasma TAG and FA. Plasma lipid peroxides increased, and glutathione-related enzymes decreased postprandially after 50 mL of virgin olive oil. These opposite time courses are explainable by the fact that GSH-Px, a selenium-containing enzyme requiring glutathione, besides removing reactive oxygen species (H<sub>2</sub>O<sub>2</sub>), also detoxifies lipid peroxides to nontoxic alcohols, thus acting as a chain-breaking antioxidant (27). At the same time, GR regenerates oxidized glutathione to the reduced form required by GSH-Px activity (28). A decrease in the antioxidant defenses, with an increase of lipid oxidation, is a common feature in an increased oxidative status situation (29,30).

Lipid peroxides can be generated during digestion-absorption (29,30) by alkaline pH and by the catalysts of peroxidation (i.e., transition metals with catalytic action on lipid peroxidation). Dietary ingestion of oxidized lipids is one of the sources of postprandial lipid peroxidation products (8,9). The limiting quality value indices specified by the European Union Commission for virgin olive oil are 20 meq/kg for peroxide and 0.2 for secondary carbonyl products (*K*<sub>270</sub>). Although these indices are far lower than the established limits in the virgin olive oil used in the study, the contribution of oxidized lipids from the ingested virgin olive oil to the observed postprandial oxidative stress cannot be ignored. Hyperglycemia is also a widely known cause of enhanced free radical concentration (31). Although we have not measured glucose at the earlier postprandial phase, when its peak occurs, a

moderate increase in glucose levels at 2 h postprandial state was observed. A postprandial increase in glucose and insulin has been related to oxidative stress in diabetic patients (32), but the relevance of glucose and insulin as free-radical generators in healthy individuals is unknown at present.

According to our results, postprandial VLDL are prone to oxidation after ingesting 50 mL of virgin olive oil. Postprandial TAG enrichment of VLDL is reportedly related to oxidative stress in type 2 diabetic patients (33), and postprandial remnantlike protein particles have been shown to increase intracellular oxidant content and impair endothelial function

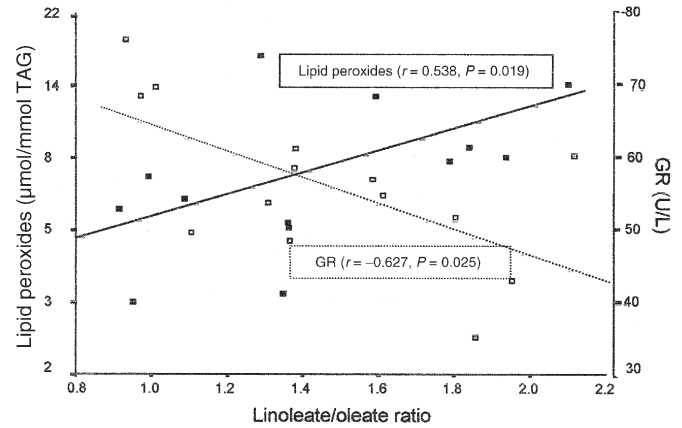

FIG. 3. Scatterplot showing the relationship between plasma linoleate/oleate ratio, plasma lipid peroxides, and glutathione reductase (GR) after 1 wk of olive oil consumption ( $n = 14$ ). TAG, triacylglycerols.

(34). After a meal rich in olive oil, the TAG in postprandial TAG-rich proteins generally reflect the composition of olive oil, although the proportion of the individual molecular species is altered by the processes leading to their formation, with an increase of linoleoyl-oleyl- and palmitoyl-oleyl-TAG (35). These results (35) are in agreement with the observed increase of oleic and linoleic acid in plasma in the postprandial state in this study. MUFA-TAG rich particles are reportedly relatively resistant to oxidation (36). However, linoleic acid is one of the most abundant and oxidizable FA (10), and its increase in plasma was related to an oxidant/antioxidant imbalance at 4 h postprandially in this study. Thus, despite the concomitant increase in the oleic acid content, the increase in linoleate content could be related to the observed oxidative stress situation postprandially.

Increased susceptibility of postprandial LDL to oxidation after a meal rich in dairy fat has been reported (37). In other studies, however, susceptibility of isolated LDL to oxidation and lipid peroxidation in LDL did not change in normal individuals after meals rich in dairy fat (38), thermally stressed cooking fat, or unheated fat (9). In the current study, the increase in lipid peroxidation in plasma and VLDL was not reflected in the resistance of isolated LDL to copper-catalyzed oxidation, nor in the lipid peroxidation products in LDL postprandially. We must point out, however, that the method of assaying lipid peroxides by TBARS assay may be insufficiently sensitive or specific (39) to detect modest differences in lipid oxidation products in LDL samples. Our results are in agreement with those of Nicolaiew *et al.* (40), who found no effect on the lag time of LDL oxidation at 6 h after virgin olive oil ingestion.

Virgin olive oil has phenolic compounds with *in vitro* antioxidant properties (24,41). We recently reported the bioavailability in humans of two characteristic olive oil phenolic compounds, tyrosol and hydroxytyrosol, from virgin olive oil in its natural form (42). The lack of changes in LDL oxidation observed in this study postprandially could be related to an increase in their antioxidant phenolic compound content. In a recent study, Bonanome *et al.* (43) reported the recovery

of tyrosol and hydroxytyrosol in all postprandial lipoprotein fractions, except in VLDL, after the ingestion of 100 g of virgin olive oil. Their findings (43) suggest that olive oil phenolic compounds are absorbed from the intestine through a pathway independent of chylomicron formation. The TAG enrichment of VLDL (6), together with a lack of phenolic compound incorporation (43), could be an explanation for the increase in VLDL lipid peroxidation observed in this study after the acute virgin olive oil ingestion.

At 24 h after olive oil ingestion, an improvement of LDL resistance to oxidation was observed, whereas plasma oleic acid and the MUFA/PUFA ratio remained elevated. At this time point, virgin olive oil was the sole source of antioxidants and oleic acid. Thus, the improvement of LDL resistance to oxidation could be related to virgin olive oil ingestion.

Concerning the 1-wk effects of sustained doses (around 20 mL/d) of virgin olive oil consumption, the increase in plasma oleic acid levels, without changes in the total FA content, confirms good compliance by the subjects and their responsiveness to the dietary intervention. Despite the short-term dietary intervention, the effects on plasma LDL-cholesterol and on susceptibility of LDL to oxidation were in line with those reported in previous dietary studies with MUFA-enriched diets (10–13) and with a lengthier (3–4 wk) dietary intervention time. One explanation for this fact could be that participants followed a washout period (4 d) with an antioxidant- and olive oil-free diet before the beginning of the study. Thus, besides virgin olive oil, other dietary antioxidant compounds could account for the increase in resistance to LDL oxidation and antioxidant enzymes. The effect of the short-term olive oil dietary intervention was reflected in a decrease of plasma linoleate/oleate ratio, this decrease being related to an apparently better plasma oxidant/antioxidant status. The protective mechanism of oleic acid-enriched diets on LDL susceptibility to oxidation has been attributed to a decrease in LDL linoleic acid content. However, recent studies on oleic acid-enriched liposomes suggest an independent protective mechanism of oleic acid on lipoprotein susceptibility to oxidation (44). The increase in glutathione-related enzymes could be attributed to a preservation of their enzymatic activities. Although little is known of the *in vivo* response of antioxidant enzymes to dietary fats or antioxidants, increased activity of GSH-Px and transferase has been reported in rabbits after olive oil supplementation (45).

To our knowledge, this is the first time that oxidative stress has been described after virgin olive oil ingestion. One limitation of this study, however, is the lack of a control group. It remains to be elucidated whether virgin olive oil ingestion affords more protection than other fat-rich meals for the postprandial oxidative stress situation. Further studies are also required to examine whether differences in the phenolic content of virgin oils could influence the postprandial oxidative stress after their ingestion.

An oxidative stress, reflected in an increase of plasma and VLDL lipid peroxidation, and a decrease in plasma GSH-Px and GR activity levels occur after an oral load of virgin olive oil. At this postprandial time, LDL seems to be protected from

oxidation. On the other hand, our results suggest that real-life moderate, sustained doses of virgin olive oil could provide benefits for the LDL resistance to oxidation and plasma glutathione-related enzyme activities.

**ABSTRACT:** A previous study has shown that the long and very long chain FA (VLCFA) content of the rat retina responds to changes in dietary n-6/n-3 ratio of the fat fed (1). The present study tested whether similar changes in these FA are associated with alterations in rhodopsin content and rhodopsin phosphorylation after light treatment. Weanling rats were fed diets containing 20% (w/w, 40% energy) fat with either high (4.8%, w/w) or low (1.2%, w/w) n-3 FA. After 6 wk of feeding, half of the animals in each group were exposed to light for 48 h at 350 lx or were kept in complete darkness. In the rod outer segment, the high n-3 diet treatment increased the level of 20:5n-3 and 22:6n-3 and reduced the levels of 20:4n-6 and 24:4n-6 in PC, PE, and PS. After the feeding of a high n-3 FA diet, total n-3 pentaenoic VLCFA from C<sub>24</sub> to C<sub>34</sub> increased in PC, whereas the n-6 tetra- and pentaenoic VLCFA decreased. No changes occurred in n-3 hexaenoic VLCFA regardless of the level of 22:6n-3 in the diet. After light exposure, animals fed a high n-3 FA diet showed reduction in 22:6n-3 as well as in n-6 and n-3 VLCFA in PC. FFA and TG fractions contained increased levels of both 20:4n-6 and 22:6n-3 after light exposure. Dark-adapted rhodopsin content and rhodopsin phosphorylation in the rod outer segment of rats fed the low n-3 FA diet were higher than in animals fed a high n-3 FA diet. After light exposure, animals fed the low n-3 FA diet lost more rhodopsin compared to animals fed the high n-3 FA diet, resulting in less phosphorylation of rhodopsin. Results indicate that the FA composition, rhodopsin content, and phosphorylation in visual cells is influenced by the dietary n-3 FA fed as well as by light exposure. The results also imply that 22:6n-3 may not be the precursor for synthesis of hexaenoic VLCFA.

Paper no. L8551 in *Lipids* 37, 253–260 (March 2002).

The role of dietary fat in determining the content of very long chain fatty acids (VLCFA, of C<sub>24</sub>–C<sub>34</sub>) has not been studied extensively in visual cells. In previous studies we demonstrated that a diet high in n-3 FA containing 22:6n-3 increased the level of 22:6n-3 and decreased 20:4n-6 and n-6 tetraenoic

VLCFA in phospholipids of the rod outer segment (ROS) (1,2). VLCFA, comprising carbon chain lengths of up to C<sub>36</sub>, are highly concentrated in PC of photoreceptors (1–4). The functional role of VLCFA in the retina has not been identified. Thus, the objective of the present study was to assess whether these diet-induced changes in photoreceptor essential FA constituents are associated with alterations in rhodopsin content or phosphorylation after light exposure.

Studies have indicated dietary modulation of n-3 FA in membrane phospholipid components of nervous tissue in the brain and retina of the chick (5), monkey (6–8), and rat (9–11). Diet-induced modulation of docosahexaenoic acid (DHA, 22:6n-3) content in the membrane appears to be associated with a change in retinal function when measured by electroretinogram or visual acuity (6,12–14). In most of these studies (6,13,14), the level of saturated and monounsaturated FA was also varied because a fat source from a single oil was used. Also, experiments were performed on n-3 FA-deficient animals made deficient by feeding an imbalanced n-6/n-3 FA diet. This extreme diet regime is not reflective of the physiological intake for neonatal animals or of infant fat intakes. Studies investigating the effect of dietary fat on individual phospholipids in visual cells in normally growing animals by feeding diets that produce a range of nutritionally balanced FA intakes are limited.

Rhodopsin is firmly embedded in the lipid bilayer in the disk of the ROS, and rhodopsin function is sensitive to specific alterations in membrane phospholipids (15,16). The function of DHA or VLCFA in phospholipids of the ROS in relation to rhodopsin function is not clear. Bush *et al.* (15) reported that rats fed safflower oil devoid of n-3 FA exhibit a slower rate of rhodopsin regeneration than animals fed soybean oil containing n-3 FA. These results suggest that the n-3 FA is important for regeneration of rhodopsin. To regenerate rhodopsin, photoactivated rhodopsin has to be phosphorylated and then dephosphorylated to rebind an 11-*cis* retinal. It is not known whether these steps are also affected by dietary n-3 FA.

Rhodopsin and its membrane environment are responsive to light (17–20). For example, animals exposed to light have a lower level of rhodopsin together with a shortened ROS

Abbreviations: LCFA, long chain fatty acids; ROS, rod outer segment; VLCFA, very long chain fatty acids.

length, a reduced number of photoreceptors, and a thinner outer nuclear layer, and they exhibit reduced rhodopsin synthesis (17–20). These changes may be partly associated with DHA, since this FA is reduced by constant illumination and bright cyclic illumination (21–23). However, the effect of light treatment on VLCFA content has not been explored. Collectively, these findings imply that altering membrane FA composition may modulate membrane functional components of photoreceptor cells after light exposure.

The present study was designed to determine whether dietary fat and light induce change in long-chain FA (LCFA) and whether VLCFA content of the ROS alters visual function in the photoreceptor cells of growing animals. The levels of polyenoic LCFA and VLCFA in individual phospholipids of the ROS after 48 h of light exposure were determined after a high or low dietary n-3 FA intake. To associate changes occurring in membrane composition with visual function, rhodopsin level and rhodopsin phosphorylation were also measured in the ROS.

## EXPERIMENTAL PROCEDURES

**Animals and diets.** This study was approved by the University of Alberta Animal Ethics Committee. Two hundred sixteen male weanling Sprague-Dawley rats were housed under cyclic light with 12-h dark and 12-h light periods. The intensity of illumination at the front of the cage was 110 lx and at the center of the cage 27 lx of cool, white fluorescent light. Animals were randomly assigned to two diet groups and fed semipurified diets (24) containing 20% (w/w) fat (40% energy as fat) of either a high (4.8% w/w of total FA) n-3 FA content providing 22:6n-3 (3.4% w/w of total FA) or a low n-3 FA content without 22:6n-3 (1.2% w/w of total FA). Shark oil was used to supply 22:6n-3 in the high n-3 diet, since it is high in content of 22:6n-3 (22%, w/w) and relatively low in 20:5n-3 (5.5%, w/w) compared to fish oils used previously (1). The fat mixture and FA composition of the diets fed are presented in Table 1 and reflect a range of dietary fat intakes typical in North America. Diets were prepared weekly, kept in the freezer, and fed to animals every other day.

After 6 wk of feeding, half of the rats in each diet group were transferred to polypropylene cages, housed in pairs, and exposed to 48 h of continuous light at the intensity of approximately 300–350 lx. This level of light intensity is equivalent to the light intensity experienced while standing in a well-lit office under the light source and is much less than 1% of the light intensity experienced when facing the sun on a clear day. The other half of the animals in each diet group were kept in complete darkness as a control. Body weight was measured weekly; the weight gain from weaning ( $54.1 \pm 4.5$  g) to 6 wk postweaning ( $374.6 \pm 30$  g) was 7.2 g per day. No effect of dietary treatment was observed on body weight or weight gain.

**Isolation of retina and ROS.** Animals were sacrificed by decapitation. All isolations were performed at 4°C. For lipid analysis, retinas were isolated either in dim red light for dark-

adapted animals or in ambient laboratory light for light-exposed groups. For analysis of rhodopsin, light-exposed animals were dark-adapted for 1 h before sacrifice in dim red light. For each sample ( $n = 1$ ), 8 retinas were pooled for the separation of the ROS for lipid analysis, and 10 retinas were pooled for measurement of ROS rhodopsin content and rhodopsin phosphorylation. The ROS was isolated by discontinuous sucrose gradient centrifugation (25). The ROS for rhodopsin analysis was resuspended with 0.5 mL of washing buffer, 50 mM Tris-acetate (pH 7.4) containing 5 mL MgCl<sub>2</sub> and 0.1 mM EDTA and then stored at -70°C.

**Lipid analysis.** Lipids were extracted from the ROS (26). Individual phospholipids were separated using silica-gel TLC H-plates as described previously (1). After recovery of the phospholipids, the silica gel containing neutral lipids was scraped into 25-mL culture tubes and eluted three times with 10 mL of chloroform/methanol (1:1, vol/vol) containing 1 ppm ethoxyquin. The eluted lipids were applied to TLC G-plates to separate neutral lipids (1). Each phospholipid and neutral lipid was recovered, and FAME were prepared with a 14% (w/w) boron trifluoride-methanol reagent (27).

**Analysis of FAME.** FAME were separated on a polar BPX70 column (25 m × 0.22 mm i.d.) using a Hewlett-Packard 5890 GLC equipped with a Vista DS 654 data system (Varian, Palo Alto, CA), as described earlier (1). With this column, the resolution of n-6 tetraenoic and pentaenoic and n-3 pentaenoic and hexaenoic VLCFA was more distinct compared to the nonpolar BP1 column used earlier (1) (Fig. 1). Degree of unsaturation and n-series of VLCFA were confirmed by GC-MS (1). The content of VLCFA obtained was not corrected for detector response factors, since pure standards for these FA are not available.

**FIG. 1.** Typical chromatograms of very long chain FA (VLCFA) of PC in the rod outer segment following diet and light treatment. FAME were separated by GLC using a polar BPX 70 column (SGE, Rose Scientific, Edmonton, Canada). Although the amount of standard is different in (A) and (B), the proportion of the FA indicated by the circle (●) in  $C_{32}$  indicates an example of the influence of diet treatment. Those indicated by the square (■) in (A) and (C) reflect light treatment: The ratio of n-3 pentaene to hexaene of  $C_{26}$ ,  $C_{28}$ , and  $C_{30}$  FA increased after light exposure. (A), High n-3 diet/dark; (B), low n-3 diet/dark; (C), high n-3 diet/light. Std, standard.

**Rhodopsin measurement.** Rhodopsin content of the ROS was determined from animals of both dietary groups that were either dark adapted or light exposed. Rhodopsin was extracted by the method of Fulton *et al.* (28), using 1% (wt/vol) octylglucoside as a detergent (29). Each extract was scanned from 270 to 700 nm using a diode-array spectrophotometer (Hewlett-Packard 8452A), and rhodopsin was quantified by difference spectroscopy at an absorption of 498 nm before and after bleaching for 480 s with a cool, white fluorescent light with the intensity of 1,000 lx at a distance of 30 cm from the cuvette. A molar extinction coefficient of 40,000 (30) was used for the calculations of rhodopsin concentration.

**Rhodopsin phosphorylation in Vitro.** Rhodopsin phosphorylation was measured by the method used by Kuhn and Wilden (31) using [ $\gamma$ - $^{32}P$ ]ATP (SA 3000 Ci/mmol; New England Nuclear-DuPont, Boston, MA) as a monitor for phosphorylation. The reaction was initiated by the onset of illumination, which was cool, white fluorescence light at 700–800 lx at a distance of 50 cm from the water bath. The resulting radiolabeled solubilized ROS membrane containing 30  $\mu$ g of protein was loaded and run on a 10-cm linear gradient (7.5% acrylamide) polyacrylamide gel (32) for 2 h at a constant current at 40 mA at  $\approx$ 150 V. The gel was dried using gel drying film (Promega, Madison, WI). Incorporation of  $^{32}P_i$  was monitored by exposing x-ray film (Kodak X-OMAT AR film) to the gel at  $-70^\circ\text{C}$

for 1.5 h. The film was developed by Kodak M35A X-Omat Processors (Rochester, NY). The resulting autoradiograms were analyzed using a scanning densitometer (Ultrosan XL, Bromma, Sweden). The area under the peak was used to quantitate labeling with  $^{32}P_i$  and was divided by the rhodopsin content loaded on the gel to express the rhodopsin phosphorylation state.

**Statistical methods.** The effect of light and diet on the FA composition of phospholipids in the ROS and on the rhodopsin content and rhodopsin phosphorylation was analyzed by a two-way ANOVA with light and diet as the main factors. The *n* number of replicates is indicated in each table and figure caption. Duncan's multiple range test (33) was used for comparison of the main factors after a significant ANOVA. All data are expressed as mean  $\pm$  SEM.

## RESULTS

**Effect of dietary fat and light on LCFA and VLCFA composition of ROS phospholipids.** Both diet and light significantly altered the FA composition of major phospholipids of the ROS in rat retina. Feeding a high 22:6n-3 diet increased the level of 22:6n-3 in PE and PS in both dark- and light-exposed animals compared to feeding a low n-3 FA diet (Table 2). This diet also increased the level of 22:6n-3 in PI of light-adapted

<sup>a</sup>Values given are means ( $n = 6$ ) ± SEM. For each  $n$ , eight retinas were pooled, except for PI ( $n = 3$ ), wherein 16 retinas were pooled. Significant effects of light and diet were analyzed by a two-way ANOVA. Values without a common roman superscript are significantly different: \* $P < 0.05$ ; \*\* $P < 0.01$ ; \*\*\* $P < 0.001$ . Significant interactions were identified only for 22:6n-3 in PE.

animals. Concomitantly, the level of 20:4n-6 decreased in all major phospholipids except PI of dark-adapted animals after feeding a high n-3 FA diet containing 22:6n-3 in comparison to feeding a low n-3 FA diet. The loss of rhodopsin from the low n-3 FA group was slightly higher than that observed for animals fed a high n-3 FA diet (59 and 51%, respectively) (Table 2). Animals fed a low n-3 FA diet containing no 22:6n-3 exhibited a significant decrease in 20:4n-6 in PE and 22:6n-3 in PS after light exposure. The level of 20:4n-6 in PI and 22:6n-3 in PE increased after light exposure.

VLCFA containing carbon chain lengths of up to C<sub>36</sub> in PC and C<sub>26</sub> in PS were also influenced by diet and light treatment (Table 3; Figs. 1 and 2). For example, in PC of dark-adapted animals, feeding a high n-3 FA diet containing 22:6n-3 increased the level of n-3 pentaenoic VLCFA of C<sub>24</sub>, C<sub>26</sub>, C<sub>30</sub>, C<sub>32</sub>, and C<sub>34</sub> carbons in chain length. This diet also decreased most of the n-6 tetraenoic VLCFA except for C<sub>30</sub> and decreased n-6 pentaenoic VLCFA of C<sub>24</sub>, C<sub>26</sub>, and C<sub>32</sub> carbons in chain length (Table 3). Hexaenoic n-3 VLCFA were not influenced by feeding a high n-3 FA diet. The high n-3 FA diet increased total n-3 pentaenoic VLCFA in PC while decreasing the n-6 tetra- and pentaenoic VLCFA (Fig. 2). In PS, the content of n-3 pentaenoic VLCFA of C<sub>24</sub> and C<sub>26</sub> and hexaenoic C<sub>26</sub> FA increased after feeding a high n-3 FA diet, whereas this diet decreased the level of n-6 tetraenes of C<sub>24</sub> and pentaenes of C<sub>24</sub> and C<sub>26</sub> carbons in chain length (Table 3).

In light-exposed animals, total n-6 tetraenoic and pentaenoic VLCFA decreased in animals fed a diet either high (46.0 and 32.5%, respectively) or low (18.4 and 47.2%, respectively) in n-3 FA (Fig. 2). Total n-3 pentaenoic and hexaenoic VLCFA also decreased in both groups fed either the high (16.9 and 14.3%) or the low (7.8 and 17.0%) n-3 FA diet. The loss of n-6 tetraenoic and pentaenoic VLCFA after light treatment was slightly greater than that of n-3 VLCFA (Fig. 2).

*Effect of dietary fat and light on FA composition of FFA and TAG fractions.* FFA and TAG fractions were also analyzed (Fig. 3) to identify the fate of 20:4n-6 and 22:6n-3 lost

from phospholipids after light treatment. In both FFA and TAG fractions, diet and light treatments influenced the level of 20:4n-6 and 22:6n-3. After consumption of the high n-3 FA diet, animals kept in the dark displayed a significant increase in 22:6n-3 content in both FFA and TAG compared to animals fed the low n-3 FA diet. In the TAG fraction, the increase in 22:6n-3 occurred concomitantly with increased levels of 20:4n-6. Exposure to light significantly increased the content of 20:4n-6 and 22:6n-3 above dark values in both dietary groups (Fig. 3).

*Effect of dietary fat and light on rhodopsin content.* Rhodopsin content of the ROS was determined in order to identify the relationship between dietary fat and retinal function. Animals fed a low n-3 FA diet exhibited a higher rhodopsin content in ROS maintained in the dark compared to ROS of animals fed the high n-3 FA (7.5 ± 0.5 nmol/mg protein and 6.1 ± 0.2 nmol/mg protein, respectively). Significant loss of rhodopsin was found after light exposure in both animal groups fed either a low or a high n-3 FA (3.1 ± 0.1 and 3.0 ± 0.3 nmol/mg protein, respectively). The loss from the low n-3 FA group was slightly higher than that observed for animals fed a high n-3 FA diet (59 and 51%, respectively).

*Effect of dietary fat and light on rhodopsin phosphorylation.* Rhodopsin phosphorylation in the ROS was analyzed *in vitro* to identify the effect of dietary fat on retinal function. Rhodopsin phosphorylation rate measured by the ratio of densitometer unit (O.D.·mm<sup>2</sup>) to rhodopsin present on the gel was altered by 1 h of incubation in continuous white light for both the dietary groups and also by the light treatment. Rhodopsin in the ROS of animals fed a low n-3 FA diet exhibited a higher phosphorylation state than that observed for animals fed the high n-3 FA diet in both dark- (59.8 ± 9.1 and 49.7 ± 8.8, respectively) and light (61.3 ± 10.1 and 53.5 ± 7.7, respectively) -exposed animals. This result, while not statistically significant, indicates that more phosphorylation of rhodopsin may have occurred following consumption of the low n-3 FA diet. After light exposure, rhodopsin from animals fed the low n-3 FA diet was phos-

<sup>a</sup>Values given are means ( $n = 6$ ) ± SEM. For each  $n$ , eight retinas were pooled. Asterisks \* indicate the significant differences between diets within each phospholipid: \* $P < 0.05$ ; \*\* $P < 0.01$ ; \*\*\* $P < 0.001$ .

<sup>b</sup>24:6n-3 in PC was also detected but not represented because its resolution time was almost the same as the standard 27:0 in the analysis.

phorylated only 2.6% more than that of dark-adapted rhodopsin, compared to 7.8% for animals fed the high n-3 FA diet.

## DISCUSSION

**Dietary fat and LCFA.** In normal growing rats, consumption of nutritionally adequate diets with a physiological change in the n-3 FA content produced considerable modification of the FA composition in photoreceptor cell membrane phospholipids. Higher n-3 FA level with addition of 22:6n-3 in the diet significantly increased membrane content of DHA in PE, PS, and PI and reduced 20:4n-6 content. This finding is in agreement with previous studies (1,10,11) and suggests that the neuronal cell is capable of replacing n-6 with n-3 FA. The replacement of n-6 with n-3 FA was more obvious in animals deficient in n-3 FA (8,34,35), perhaps owing to a significant difference in the ratio of n-6/n-3 FA diet in the control (n-6/n-3 = 7) vs. deficient diets (n-6/n-3 = 255). Changes in *de novo* synthesis and/or direct molecular replacement by deacylation–reacylation may be responsible.

PE and PS are located in the outer disk membrane monolayer (36). DHA is the major FA in these phospholipids in the

retina and ROS. In the present study, the level of DHA in the ROS was increased to 20 and 13% in PE and PS, respectively, after consumption of a diet containing a high n-3 FA content

**FIG. 2.** Effect of light on the change in level of total n-6 tetraenoic and pentaenoic and total n-3 pentaenoic and hexaenoic VLCFA (C<sub>24</sub>–C<sub>36</sub>) present in PC of the rod outer segment. The value for the percent change from dark as a result of light treatment was taken from the total mean ( $n = 6$ ) for each group from dark-adapted rats (Table 2). In both low and high n-3 FA diet groups, n-6 and n-3 VLCFA were reduced after light exposure ( $P < 0.05$ ). Diagonally lined box, low n-3 diet; open box, high n-3 diet. For abbreviation see Figure 1.

**FIG. 3.** Effect of dietary fat and light on the level of 20:4n-6 and 22:6n-3 in FFA and TAG components of the rod outer segment. The values are the mean ( $n = 3$ )  $\pm$  SEM. Sixteen retinas were pooled for each  $n$ . Values without a common letter within a lipid class were significantly different by diet and light treatment,  $P < 0.05$ . Superscripts indicate the following: x, significant effect of light ( $P < 0.003$ ); y, significant effect of diet ( $P < 0.02$ ); z, significant interaction effect ( $P < 0.003$ ). Unlike phospholipids, the levels of both 20:4n-6 and 22:6n-3 increased in the FFA and TAG after light exposure. (■), dark; (□), light.

as compared to those animals fed the low n-3 diet. DHA is the principal component of dipolyunsaturated phospholipids found in bovine and frog ROS (37–39). The relationship between FA composition in the phospholipid and an asymmetrical distribution of phospholipids in excitable membranes is not clearly established. However, this asymmetrical distribution of membrane phospholipids (36) highly enriched in 22:6n-3 may enable the optimal environment for rhodopsin conformational change induced by light exposure.

**Dietary fat and VLCFA.** The general compositional features of VLCFA in the ROS were similar to those reported earlier (1,40). The present experimental conditions identified one more series of n-6 pentaenoic VLCFA in addition to n-6 tetraenoic VLCFA. It is now clear that VLCFA are present in the ROS as either n-6 tetraenes and pentaenes or n-3 pentaenes and hexaenes.

A higher n-3 FA content in the diet significantly increased n-3 pentaenoic VLCFA in PC but not n-3 hexaenoic VLCFA. An increase in 22:6n-3 occurred in major phospholipids with no changes occurring in hexaenoic VLCFA in PC regardless of the level of 22:6n-3 in the diet. This unexpected result may imply that 22:6n-3 is not a precursor for further elongation and synthesis of hexaenoic VLCFA. Therefore, the identification of the precursors and their further metabolism to VLCFA remain to be elucidated.

The implications of altering levels of VLCFA by dietary treatment are still not known. Together with a high concentration of DHA, it is conceivable that these FA provide a suitable environment for rhodopsin since these VLCFA have a high affinity for rhodopsin (4). VLCFA may also be involved in membrane signal transduction, as recent evidence indicates the involvement of tetraenoic VLCFA in activation

of protein kinase C in rat brain (41) and  $Ca^{2+}$  modulation in human neutrophils (42).

**Light exposure on LCFA and VLCFA.** Light exposure reduced 20% of the 22:6n-3 content in PC and 5% in PS from the dark-adapted level after consumption of the high n-3 FA diet. Light-induced reduction in LCFA is mediated by phospholipase  $A_2$  (43–45). Rats raised in cyclic light at a light intensity of 800 lx from birth to 12 wk also exhibited reduced 22:6n-3 content in ROS phospholipid by 70% and reduced ROS length and rhodopsin content compared to rats raised at a light intensity of 5 lx (46). These changes on exposure to cyclic light are a form of retinal adaptation to light (46–48).

Light treatment also reduced n-3 pentaenoic and hexaenoic VLCFA in PC. This level of n-6 VLCFA was not associated with 20:4n-6 since this FA in PC was not affected by light exposure. Thus, these data suggest that VLCFA undergo a different metabolic process compared to LCFA following light exposure. VLCFA is esterified mainly in the *sn*-1 position of glycerol, whereas LCFA is esterified in the *sn*-2 position (3,49). This observation suggests that light may activate phospholipase  $A_1$ .

The present experiment demonstrated that FFA and TAG are involved in the uptake of 20:4n-6 and 22:6n-3 developed from phospholipids after light exposure for 48 h. FFA and TAG fractions contained increased levels of both 20:4n-6 and 22:6n-3 after light exposure, implying that FFA and TAG serve as sources for 20:4n-6 and 22:6n-3 to enable recycling of these essential FA after light exposure.

**Dietary fat and light on rhodopsin content and rhodopsin phosphorylation.** The present experiment demonstrated that rhodopsin content and rhodopsin phosphorylation in the ROS were higher in dark-adapted animals after consumption of a low n-3 FA diet compared to animals fed a high n-3 FA diet. The ratio of rhodopsin content (nmol/mg protein), when expressed as densitometer units, showed 20.4 and 14.6% higher phosphorylation in animals fed a low n-3 FA diet in both the dark- and light-exposed group, respectively. This implies that the enzymes involved in rhodopsin phosphorylation, rhodopsin kinase and protein kinase C, may be affected by dietary n-3 FA treatment. Light-exposed animals fed a low n-3 FA lost more rhodopsin content and had less rhodopsin phosphorylation compared to animals fed a high n-3 FA diet. It would be of interest to determine whether a low n-3 FA diet also leads to higher rhodopsin regeneration. Rhodopsin phosphorylation functioning as a turn-off mechanism to inactivate the bleached rhodopsin is a necessary step for rhodopsin restoration to the dark state. Together with the FA data, light-evoked reduction of LCFA and VLCFA seems to be associated with a reduced level of rhodopsin after light exposure.

In conclusion, it is clear that the ROS content of both LCFA and VLCFA responds to dietary fat and light exposure. It is also apparent that 22:6n-3 may not be a direct precursor for the synthesis of hexaenoic VLCFA. Light exposure induces loss of VLCFA. These compositional changes seem to be associated with rhodopsin content and rhodopsin phosphorylation since both parameters are also altered in concert by a change in exposure to light and diet n-3 FA.

**ABSTRACT:** Effects of genistein and its glycoside genistin were studied in nephritic rats with endogenous hyperlipidemia. Male Wistar rats with glomerulonephritis caused by a single intravenous injection of nephrotoxic serum were orally given 5 mg of genistein or 8 mg of genistin/d/100 g body weight for 12 d. These isoflavones suppressed nephritis-induced severe hypercholesterolemia and hypertriglyceridemia, and their hypolipidemic action was almost identical. Fecal steroid excretion was unchanged by administration of the two isoflavones. Genistein inhibited the incorporation of [1-<sup>14</sup>C]acetate into cholesterol and FA in liver slices from nephritic rats when added to an incubation buffer, whereas genistin did not. These results suggest that genistin may be hydrolyzed to genistein and that genistein itself and/or its metabolite(s) may be intracorporal entities suppressing hepatic lipid syntheses. They also suggest that the suppression of hepatic lipid synthesis may be one mechanism of the hypolipidemic action of genistein.

Paper no. L8929 in *Lipids* 37, 261–265 (March 2002).

Glomerulonephritis caused by immunological insult is often associated with apparent pathological changes of glomeruli such as glomerular cell proliferation, crescent formation, and extracellular matrix accumulation (1–4). Massive protein excretion into urine results in hypoalbuminemia (5), and secondary hyperlipidemia occurs by increased lipid and lipoprotein synthesis in the liver (6). These types of hyperlipidemia should be remedied since hyperlipidemia is believed to further the kidney dysfunction (7,8). Thus, trials to reduce hyperlipidemia have been conducted using the drug probucol (9), nutrients such as fish oil (10), and a low-protein diet (11); and all three treatments succeeded in reducing the endogenous hyperlipidemia. Besides hypolipidemic action, probucol reduced proteinuria (9), and an amino acid-fortified low soy protein diet, for instance, reduced both proteinuria and hypoalbuminemia (11).

Soybean isoflavones are known to have cancer chemopreventive (12,13) and antioxidative (13) activities, and reportedly improve cardiovascular risk factors by reducing serum

cholesterol concentrations in monkeys (14) and exogenously hypercholesterolemic rats (15). In the present study, we attempted to examine whether genistein and its glycoside genistin reduce endogenous hyperlipidemia and other symptoms in rats with glomerulonephritis.

## MATERIALS AND METHODS

**Animals and diets.** This experiment was conducted in accordance with guidelines established by the Animal Care and Use Committee at Tokyo Noko University. Male Wistar rats (3 wk of age) were obtained from Charles River Japan (Kanagawa, Japan). In an air-conditioned room with a temperature of 22 ± 2°C, a relative humidity of 60 ± 5%, and a light cycle from 8:00 A.M. to 8:00 P.M., animals were kept on a stock pellet diet (CE-2; CLEA Japan, Tokyo, Japan) for 6 d and then fed a basal 20% casein diet for another 5 d. All animals were moved on day 8 of the preliminary feeding from individual cages with wire bottoms into metabolism cages to acclimate them to these new surroundings, and to collect urine and feces. The composition of the 20% casein diet was as follows (16): 20% casein (Oriental Yeast Co., Tokyo, Japan), 5% corn oil (Hayashi Chemicals Co., Tokyo, Japan), 68.3%  $\alpha$ -cornstarch (Nihon Nosan Kogyo Co., Yokohama, Japan), 3.5% mineral mixture and 1% vitamin mixture (both AIN-76A composition; Nihon Nosan Kogyo Co.), 0.2% choline bitartrate (Wako Pure Chemical Industries, Osaka, Japan), and 2% cellulose powder (Oriental Yeast Co.). On the last day of the preliminary feedings (day 0), rats were divided into two groups of the same average body weight. One group, which received no antiserum injection, was regarded as the normal group, whereas rats of the other group were given a single intravenous injection into the tail vein of anti-rat kidney glomerular basement membrane (GBM) rabbit antiserum (0.4 mL/rat), which was produced by immunizing rabbits with the supernatant of trypsin-digested rat GBM (17,18), to induce nephritis. The following day (day 1), the animals were subcutaneously immunized with rabbit  $\gamma$ -globulin (8 mg/rat; Sigma Chemical Co., St. Louis, MO) in 0.2 mL of Freund's complete adjuvant (Wako Pure Chemical Industries) into the hind foot pads as described previously (19). On the third day after antiserum injection, nephritic rats were divided into three

Abbreviations: BA, bile acid; Ch, cholesterol; GBM, glomerular basement membrane; LPO, lipid peroxide; NS, neutral sterol; PL, phospholipid.

groups of similar average body weights and urinary protein excretion rates, and the effects of genistein and genistin (Research & Development Laboratory, Fujicco Co., Kobe, Japan) were examined. Rats of two of the nephritis groups orally received 5 mg of genistein or 8 mg of genistin/d/100 g body weight for 12 d, whereas those of the other nephritis group, designated as the control group, were similarly given vehicle alone (0.5 mL of 0.5% carboxymethylcellulose aqueous solution/d/100 g body weight). Rats of the normal group were also given vehicle alone. Oral intubation of isoflavones or vehicle was carried out once a day at 9:00–10:00 A.M. The dose of 8 mg of genistin/d/100 g body weight was chosen to examine its antinephritic action, since genistin showed a pharmacological activity in the range of the dose; the glycoside significantly suppressed bone loss in ovariectomized rats (20). The dose of 8 mg of genistin is equimolar to that of 5 mg of genistin (18.5  $\mu\text{mol}$ ). Water and diets were available *ad libitum*. Urine excreted during the preceding 24 h by the rats individually housed in metabolism cages was collected at 9:00 A.M. each day. The animals were deprived of their diets at 9:00 A.M. on day 14 and given a final administration of isoflavones or vehicle. They were allowed free access to water until they were killed, which was done 4 h later by decapitation. Blood was collected and left to clot at room temperature to obtain serum. The liver and kidney were quickly removed, washed with cold 0.9% NaCl, blotted on filter paper, and weighed.

**Lipid analyses.** Total lipids from the liver were extracted according to the procedure of Folch *et al.* (21). After aliquots of the chloroform phase had been dried, cholesterol (Ch) (22), TG (23), and phospholipid (PL) (24) were determined as previously described (10,11). The serum TG and PL levels were also determined as mentioned above. The serum total Ch and lipid peroxide (LPO, as TBARS) levels were determined using commercial kits (Wako Pure Chemical Industries).

**Measurements of serum albumin, serum urea nitrogen, and urinary protein.** Serum albumin and urea nitrogen concentrations were also measured with commercial kits (Wako Pure Chemical Industries). Urinary protein was measured by the Bradford method (Bio-Rad Protein Assay; Bio-Rad Laboratories, Richmond, CA) (25).

**Fecal steroid excretion.** Feces were collected individually for 2 d before rats were killed. Neutral sterol (NS) and bile acid (BA) were extracted according to the method of Yama-

naka *et al.* (26). NS and BA were enzymatically determined with commercial kits (Wako Pure Chemical Industries) as described (27).

**Cholesterol and FA syntheses from [ $^{14}\text{C}$ ]acetate in liver slices.** Nephritis was induced by injecting anti-GBM rabbit antiserum and immunizing rabbit  $\gamma$ -globulin to rats fed the basal 20% casein diet as described above. On the 14th day after antiserum injection, rats were killed and livers were removed from nephritic rats and sliced with a razor. From one animal, three sets of liver slices were prepared. Liver slices weighing 100–120 mg (wet weight basis) were incubated for 2 h at 37°C in 1 mL of Krebs–Ringer phosphate buffer (pH 7.4) containing 37 kBq of [ $^{14}\text{C}$ ]acetate (37 kBq/ $\mu\text{mol}$ ; NEN Research Products, Boston, MA) in the absence or presence of 1 mM genistein or genistin. These isoflavones were suspended in DMSO (Sigma Chemical Co.). Syntheses of total FA and Ch in liver slices were estimated as described previously (28,29).

**Statistical analyses.** Results were expressed as mean  $\pm$  SEM. Statistical analyses were conducted either by ANOVA followed by Tukey's Q test or by Friedman test followed by Dunn's multiple comparison test (30). A *P* value below 0.05 was considered significant.

## RESULTS

As shown in Table 1, food intake and body weight gain were decreased by nephritis induction. The oral administration of either genistein or genistin exerted no further influence on this reduction. Conversely, relative liver and kidney weights were increased by nephritis, and neither genistein nor genistin showed any further effects on this rise.

Figure 1 shows time-dependent changes in protein excretion rate into urine. The urinary protein excretion was minimal in the normal state, but the excretion rate of nephritic control animals increased approximately linearly up to day 3 and thereafter remained high up to day 14. Genistin tended to suppress the increase in protein excretion in the early stage (day 5), whereas genistein did so in the middle stage (day 10). These suppressive effects of isoflavones, however, diminished in the late stage (day 14).

As expected from severe proteinuria, serum albumin concentration significantly decreased in the nephritic control group, indicating induction of hypoalbuminemia by the

**TABLE 1**  
Effects of Genistein and Genistin on Food Intake, Body Weight Gain, Liver Weight, and Kidney Weight in Nephritic Rats<sup>a</sup>

Measurement	Normal	Nephritis		
		Control	Genistein	Genistin
Food intake (g/11 d)	222.1 $\pm$ 7.8 <sup>a</sup>	165.3 $\pm$ 11.2 <sup>b</sup>	169.4 $\pm$ 10.9 <sup>b</sup>	183.8 $\pm$ 6.8 <sup>a,b</sup>
Body weight gain (g/11 d)	84.0 $\pm$ 5.1 <sup>a</sup>	47.6 $\pm$ 6.6 <sup>b</sup>	44.3 $\pm$ 5.8 <sup>b</sup>	48.6 $\pm$ 4.6 <sup>b</sup>
Liver weight (g/100 g body weight)	4.13 $\pm$ 0.17 <sup>a</sup>	5.85 $\pm$ 0.14 <sup>b</sup>	6.16 $\pm$ 0.27 <sup>b</sup>	6.12 $\pm$ 0.22 <sup>b</sup>
Kidney weight (g/100 g body weight)	0.87 $\pm$ 0.02 <sup>a</sup>	1.43 $\pm$ 0.08 <sup>b</sup>	1.39 $\pm$ 0.08 <sup>b</sup>	1.28 $\pm$ 0.05 <sup>b</sup>

<sup>a</sup>Each value represents the mean  $\pm$  SEM for five (genistein) or six (others) rats. Values not sharing a common superscript roman letter are significantly different at *P* < 0.05 by Tukey's Q test.

FIG. 1. Effects of genistein and genistin on urinary protein excretion in nephritic rats. Each value represents the mean  $\pm$  SEM for five (genistein) or six (others) rats.

nephritis (Table 2). Genistein tended to improve, and genistin significantly improved the nephritis-induced hypoalbuminemia. Serum urea nitrogen concentration was slightly elevated by nephritis induction and decreased to normal with the administration of isoflavones, although none of the changes was significant (Table 2).

As shown in Figure 2, the serum total Ch (Fig. 2A) and TG (Fig. 2B) levels were significantly and strikingly increased by nephritis induction, indicating the occurrence of severe hypercholesterolemia and hypertriglyceridemia. The serum Ch and TG levels of nephritic rats were 5- and 21-fold, respectively, higher than those of normal rats. Genistein and genistin suppressed both the severe hypercholesterolemia and hypertriglyceridemia, although the hypotriglyceridemic activity of genistein was not significant. Likewise, the serum PL and LPO levels of the nephritic control group were significantly higher than those of the normal group (Table 2). Genistein and genistin slightly suppressed these rises, although the suppression was not significant. Liver Ch content was significantly increased by nephritis induction, but this increase was not significantly changed by treatment with the isoflavones. In contrast, neither nephritis nor isoflavones affected liver TG and PL contents (Table 2).

Changes in fecal sterol excretion are indicated in Table 3. Excretion of feces (dry weight basis) in the nephritic control group was slightly but significantly increased when compared with that in the normal group. The same tendency was observed in the excretion of NS and total steroids. Genistein and genistin exerted little influence on these four parameters.

Figure 3 depicts *in vitro* effects of genistein and genistin on lipid syntheses in the liver slices from nephritic rats. Genistein proved to significantly suppress hepatic Ch synthesis (Fig. 3A) and FA synthesis (Fig. 3B), while its glycoside genistin showed no (Fig. 3A) or weak (Fig. 3B) inhibitory effects on Ch and FA syntheses, respectively.

DISCUSSION

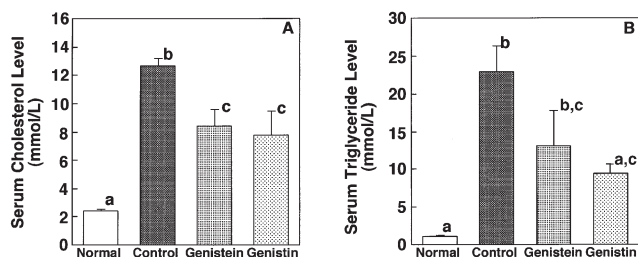

Rats with glomerulonephritis show hyperlipidemia as well as proteinuria, hypoalbuminemia, and pathological changes of glomeruli (1–4, 31). Glomerular scarring in this animal model developed and progressed as in human glomerulonephritis (17). In the present study, the effects of genistein, a potent and specific protein kinase inhibitor (32) that occurs naturally in soy foods, and its glycoside genistin were studied in nephritic rats with hyperlipidemia. These isoflavones suppressed severe hypercholesterolemia and hypertriglyceridemia in nephritic rats (Fig. 2).

Following ingestion, genistin is hydrolyzed in the large intestine by the action of bacteria to release genistein (33). Genistein is rapidly absorbed from the intestine, taken up by the liver, and excreted into bile as its glucuronide conjugate (34). These events are consistent with the fact that the hypolipidemic action of equimolar genistein and genistin was almost identical (Fig. 2). The hypocholesterolemic action of the isoflavones was not due to increased steroid excretion from the body, since excretion of neither NS nor BA into feces was enhanced by their administration (Table 3). Lipid syntheses by liver slices from nephritic rats are significantly enhanced over those from normal rats (35). Genistein inhibited the increased Ch and FA syntheses by liver slices from nephritic rats when added to the incubation buffer, whereas genistin did not (Fig. 3). Genistein reportedly inhibits the hepatocyte

growth factor-stimulated syntheses of lipids and secretion of lipoproteins in cultured rat hepatocytes (36). These previous and current *in vitro* findings suggest that genistein itself and/or its metabolite(s) may be intracorporal entities that suppress hepatic lipid syntheses and also suggest that the suppression of hepatic lipid synthesis may be one mode of the hypolipidemic action of genistein. In contrast to the present results, genistin reportedly did not reduce endogenous hypercholesterolemia and hypertriglyceridemia in ovariectomized rats at doses of 5 and 10 mg/d/100 g body weight (37). This discrepancy in genistin effect on endogenous hyperlipidemias between previous and present studies may be attributable to differences in disease models and hence to differences in mechanisms by which hyperlipidemias arise.

In addition to hypolipidemic action, genistein and genistin improved hypoalbuminemia that was induced in rats with glomerulonephritis (Table 2). However, urinary albumin excretion and hepatic albumin mRNA level were not altered by their administration (data not shown). These findings suggest that the isoflavones may increase the translational step of albumin synthesis and hence remedy hypoalbuminemia. Further studies are required to clarify the mechanisms for the remedial effect of isoflavones on hypoalbuminemia.

We demonstrated that amino acid-fortified low (8.5%) soy protein (11) and low casein (38) diets succeeded in simultaneously reducing the three major symptoms in nephritic rats, i.e., proteinuria, hypoalbuminemia, and hyperlipidemia, without causing severe protein malnutrition. Feeding fish oil, as compared with corn oil, to nephritic rats fed a 20% casein diet reduced hyperlipidemia but failed to improve proteinuria and

hypoalbuminemia (10), suggesting difficulties in the simultaneous control of proteinuria, hypoalbuminemia, and hyperlipidemia by nutrients without restricting protein intake. In the present study, genistein and genistin were demonstrated to improve two of the three symptoms simultaneously without any restriction of protein intake. Thus, isoflavone administration has the potential to mitigate protein restriction in nephritis treatment.

The doses of genistein and genistin employed in the present study seem too high to be obtained from eating soy foods in everyday life. Provided that other major isoflavones in soy foods at lower doses are also effective against nephritis, the ingestion of effective doses of isoflavones may be attainable from soy foods. Studies on dose-dependent effects of genistein, and genistin as well as on effects of other major isoflavones in soybean, daidzein and daidzin will clarify this aspect.

**ABSTRACT:** This experiment was designed to evaluate the effect of casein or ovomucin (OV) on the micellar solubility of cholesterol and the taurocholate binding capacity *in vitro*. We also evaluated the effects of casein or OV on cholesterol metabolism in rats and Caco-2 cells. OV had a significantly greater bile acid-binding capacity than that of casein *in vitro*. Micellar cholesterol solubility *in vitro* was significantly lower in the presence of OV compared to casein. The cholesterol micelles containing OV significantly suppressed cholesterol uptake by Caco-2 cells compared to the cholesterol micelles containing casein. Consistent with these *in vitro* findings, OV-feeding significantly increased the fecal excretion of bile acids or cholesterol compared with casein-feeding. Serum total cholesterol was significantly lower in rats fed OV than in those fed casein. The concentrations of total lipids in liver were significantly lower in the OV-fed group compared with the casein group. These results suggest that the suppression of cholesterol absorption by direct interaction between cholesterol mixed micelles and OV in the jejunal epithelia is part of the mechanism underlying the hypocholesterolemic action of OV. OV may also inhibit the reabsorption of bile acids in the ileum, thus lowering the serum cholesterol level.

Paper no. L8926 in *Lipids* 37, 267–272 (March 2002).

Egg protein consists of well-balanced amino acids with high biological value. However, egg is a cholesterol-rich food whose use is always strictly or carefully advocated for the prevention of hypercholesterolemia and its related diseases. As the cholesterol exists exclusively in the egg yolk, egg white is cholesterol-free. Egg intake is thought to increase serum cholesterol concentrations in experimental animals (1) and humans (2).

Egg white contains a wide variety of proteins such as ovalbumin, ovomucin (OV), ovotransferrin, and lysozyme (3,4). Several reports have indicated that the quality and quantity of dietary protein affect the serum cholesterol level (1,5–9). Only a few reports have dealt with the effect of egg white protein (EWP) on the serum cholesterol level in rats (10) and humans (11). Moreover, the mechanism by which the hypocholesterolemic effect of EWP is exerted in rats is not well understood. Although OV is one of the EWP, there is no information about the hypocholesterolemic action of OV. In earlier papers (12,13) we used cultured Caco-2 cells and found that soy protein peptic hydrolysate (SPH) directly inhibited the absorption of micellar

cholesterol. Our experimental system to evaluate cholesterol with Caco-2 cells is useful for clarifying the molecular mechanism underlying the mechanism for and effects of OV on cholesterol absorption from the small intestine. We postulate that OV-induced hypocholesterolemic action may have resulted in the inhibition of both cholesterol absorption in the intestinal epithelial cells and ileal reabsorption of bile acids. Thus, we used Caco-2 cells, rats, or *in vitro* assays to investigate the effects of the serum cholesterol-lowering action of OV.

## EXPERIMENTAL PROCEDURES

**Preparation of OV.** Fresh egg white was prepared from eggs (White Leghorn hens) according to the method of Xu *et al.* (14). OV from fresh egg white was prepared by the method of Kato *et al.* (15). Briefly, thick egg white separated from total egg white using a sieve was homogenized in a Waring blender for about 5 min and diluted with 3 vol of deionized water. The mixture was stirred for 1 h and then adjusted to pH 6.0 with 1 mol/L HCl. After the mixture stood overnight at 4°C, OV precipitated in this system and was then lyophilized.

**Chemical analyses.** Protein content was determined by the Kjeldahl method (16), with an N-to-protein conversion factor of 6.25. Lipids were extracted by using chloroform/methanol (2:1, vol/vol) and weighed. Sugar content was determined by the phenol-sulfonic acid method (17). Moisture was determined as the loss in weight after drying at 105°C for 24 h. Ash content was determined by the direct ignition method (550°C overnight). As shown in Table 1, amino acid composition was determined by the methods described previously (18). Tryptophan content was determined by the *p*-dimethyl-aminobenzaldehyde method (19,20). Casein was generously supplied by the Central Research Institute of Meiji Milk Products Co., Ltd. (Tokyo, Japan). The chemical composition of casein was as follows (g/kg): protein, 860; sugar 15; moisture, 110; lipid, 0; and ash, 15. The chemical composition of OV was as follows (g/kg): protein, 693; sugar 148; moisture, 120; lipid, 0; and ash, 39.

**Taurocholate-binding capacities.** The binding capacity of cholestyramine, casein, or OV with taurocholate was measured by the method described previously (13). The mixtures containing 1.85 kBq of tauro [carbonyl-<sup>14</sup>C]cholic acid (sodium salt) (1.89 Gbq/mmol; Amersham International, Buckinghamshire, United Kingdom), 0.1 mol/L sodium taurocholate in 5 mL of 0.1 mol/L Tris-HCl buffer (pH 7.4), and 1–500 mg binding substances [cholestyramine, casein: casein sodium (Wako Pure

Chemical, Osaka, Japan), OV] were incubated at 37°C for 2 h, and the radioactivity in the supernatant (15,000 × g for 15 min) was measured by liquid scintillation counting.

**Micellar solubility of cholesterol and taurocholate.** Micellar solubility of cholesterol and taurocholate with proteins *in vitro* was measured by the method of Ikeda *et al.* (21) with some modifications. Micellar solutions (1 mL) containing 6.6 mmol/L sodium taurocholate, 0.5 mmol/L cholesterol, 1 mmol/L oleic acid, 0.5 mol/L monoolein, 0.6 mmol/L PC, 132 mmol/L NaCl; and 15 mmol/L sodium phosphate (pH 7.4), casein sodium or OV (5 mg/mL, respectively) were prepared by sonication. Then the mixture was incubated at 37°C for 24 h and ultracentrifuged at 100,000 × g for 60 min at 37°C. The supernatant was collected for the determination of cholesterol and taurocholate as described previously (13).

**Cholesterol absorption in Caco-2 cells.** Caco-2 cells were acquired from the American Type Culture Collection (Rockville, MD). The cells were maintained DMEM supplemented with 10% FBS, 4 mmol/L L-glutamine, 50 IU/mL of penicillin, and 50 mg/L streptomycin. The cells were incubated at 37°C in a humidified atmosphere of 5% CO<sub>2</sub> in air. The monolayers became confluent 3 to 4 d after seeding at between 7 × 10<sup>5</sup> and 1.2 × 10<sup>6</sup> cells per 100-mm diameter dish, and the cells were passed at a split ratio of 4 to 8 by trypsinizing with 0.25% trypsin and 0.8 mmol/L EDTA in PBS. Monolayers were grown in 24-well plastic dishes containing 1 mL of DMEM supplemented with FBS as described previously (13), fresh medium being added every 2 d. The experiments described usually used cultures 12–15 d after plating and were performed in medium-199/Earle's (GIBCO, Grand Island, NY) containing 1 mmol/L HEPES. Cell viability, as ascertained by trypan-blue exclusion, was unaffected by any of the experimental procedures. The number of passages of the cell line ranged from 70–85.

[<sup>14</sup>C]-Labeled micellar cholesterol uptake in Caco-2 cells was measured by the method described previously (13). The

final concentration of each [<sup>14</sup>C]-labeled micellar solution (0.5 mL) was as follows: 3.7 kBq [4-<sup>14</sup>C]cholesterol (2.1 Gbq/m mol; NEN, Boston, MA), 0.1 mmol/L cholesterol, 1 mmol/L oleic acid, 0.5 mmol/L monoolein, 6.6 mmol/L sodium taurocholate, 0.6 mmol/L PC, casein sodium, and OV (2.5 mg/0.5 mL, respectively). The micellar solution was mixed by ultrasonication.

After 14 d, the cells were rinsed two times with 1 mL of PBS. A [<sup>14</sup>C]-labeled micellar solution (0.5 mL) containing casein sodium or OV was then added to the dishes, which were incubated at 37°C for 20 min in a CO<sub>2</sub> incubator. After this incubation, the cells were rinsed two times with 1 mL of PBS. The cells were finally lysed in 0.1% SDS solution, after which 7.5 mL of Aquasol-2 (NEN) was added, and the radioactivity in the cellular debris was counted to determine the amount of cholesterol absorbed into the cells. The cellular protein was determined by a commercially available kit (Bio-Rad Protein Assay; Bio-Rad, Tokyo, Japan). The amount of cholesterol absorbed into the cells was expressed as pmol/mg protein.

**Effects of OV or casein on lipid metabolism in rats (animals and diets).** Male rats of the Wistar strain (Japan SLC, Hamamatsu, Japan) were used in the present animal studies. Room temperature was maintained at 22 ± 2°C with a 12-h cycle of light (0800–2000) and dark. The approval of the Gifu University Animal Care and Use Committee was given for our animal experiments. All the rats were housed individually in metal cages and were allowed free access to food and water. After acclimation to a commercial stock diet (CE-2; Japan CLEA, Tokyo, Japan) for 3 d, 5-wk-old rats weighing 115–130 g were divided into two groups of six rats each on the basis of body weight. The composition of the basal diet recommended by the American Institute of Nutrition (22) is shown in Table 2. OV was added to the diet at a nitrogen level equivalent to that of a casein diet at the expense of carbohydrates. Each group had free access to one of the respective test diets (Table 2) containing casein or OV as the protein source for 10 d. After 24 h without food, the rats were anesthetized with

diethyl ether and killed. Blood was collected by cardiac puncture, and the liver was removed. Fecal collections (d 7–9) were completed prior to the 24-h food restriction and blood sampling. Feces were used for determining fecal steroids.

**Rat lipid analyses.** Various lipid concentrations were determined using commercially available kits as follows: serum and liver cholesterol with Monotest cholesterol (Boehringer Mannheim Yamanouchi, Tokyo, Japan); HDL-cholesterol with HDL-cholesterolase (Nissui, Tokyo, Japan); serum and liver TG with Triglycolor III (Boehringer Mannheim Yamanouchi); and serum phospholipid with Phospholipid C-Test Wako (Wako Pure Chemical, Osaka, Japan). Liver lipids were extracted by the method of Folch *et al.* (23), and total lipids were determined gravimetrically as described previously (24). Fecal acidic steroids were measured according to the method of Bruusgaard *et al.* (25) and Malchow-Moller *et al.* (26), whereas fecal neutral steroids were assayed with trimethylsilyl ether by using 1.5% OV-17 with a GC-14A instrument (Shimadzu, Kyoto, Japan) and 5  $\alpha$ -cholestane as the internal standard (27).

**Statistical analysis.** Results are expressed as mean  $\pm$  SEM. The statistical significance of differences was evaluated by Student's *t*-test (28).

## RESULTS

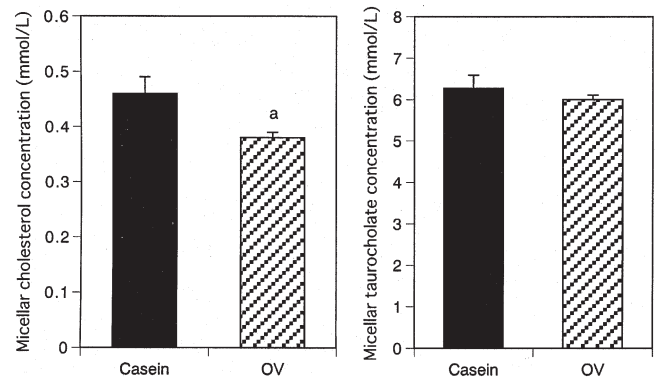

**Taurocholate binding capacities.** From 200 to 500 mg, the bile acid-binding capacity of OV was significantly greater than that of casein (Fig. 1).

**Micellar solubility of cholesterol and taurocholate.** The micellar solubility of cholesterol in the presence of OV was significantly lower than with casein. Micellar solubility of taurocholate was unchanged (Fig. 2).

**Cholesterol absorption in Caco-2 cells.** The cholesterol micelles containing OV induced a significant suppression of cholesterol absorption in Caco-2 cells compared to the cholesterol micelles containing casein (Fig. 3).

**FIG. 1.** Binding of cholestyramine (▲), casein (■), or ovomucin (●) with taurocholate. Individual values represent means of assays performed in duplicate. Error bars (SEM) are too small to show. Statistical significance compared to casein by Student's *t*-test (a,  $P < 0.05$ ).

**FIG. 2.** Effect of casein or ovomucin (OV) on micellar solubility of cholesterol and taurocholate. Each value is expressed as mean  $\pm$  SEM of three determinations. Statistical significance compared to casein by Student's *t*-test (a,  $P < 0.05$ ).

**FIG. 3.** Effect of casein or ovomucin (OV) on cholesterol absorption in Caco-2 cells. Each value is expressed as mean  $\pm$  SEM of five determinations. Statistical significance compared to casein by Student's *t*-test (a,  $P < 0.001$ ).

**Effects of OV or casein on lipid metabolism in rats.** Food intake, growth rates, and the relative liver weight were unaffected by dietary OV (Table 3). Serum total cholesterol levels in the OV groups were significantly lower than in the casein group. The HDL-cholesterol in the OV group tended to increase compared with the casein group. The proportion in the OV group of HDL-cholesterol to serum total cholesterol [(b)/(a)], which is known as the atherogenic index, was significantly higher than in the casein group. The liver total lipids level was significantly lower in the OV group than in the casein group. Fecal dry weight was unchanged by OV feeding. The fecal excretion of bile acids and cholesterol was significantly increased by OV feeding compared with casein feeding.

## DISCUSSION

In this study we found, for the first time, that hen egg OV is a hypocholesterolemic protein. OV clearly demonstrated serum

cholesterol-lowering effects compared with casein. The major differences in amino acid compositions between casein and OV are in the level of glycine and cystine (Table 1). The relationship between the serum cholesterol-lowering activity of dietary protein and the amino acid contents of protein has been reported previously (29–31). Sugiyama *et al.* (31) reported a significant negative correlation between blood cholesterol levels and the level of cystine in intact dietary proteins. Thus, as OV contains higher levels of cystine than casein, the differences in amino acids content may relate to the differences in serum cholesterol level in the present study.

The amount of OV in egg white is 3.5% (w/w) of the total EWP. Reportedly, OV, which is macromolecular and a highly glycosylated glycoprotein, has two subunits, one a protein-rich  $\alpha$ -subunit (M.W. 220 kDa) and one a carbohydrate-rich  $\beta$ -subunit (M.W. 400 kDa) (15,32). Recent studies suggest that OV exhibits both antiviral (18,33) and antitumor activities (4). All the sialic acid present in OV was described as *N*-acetylneuraminic acid (34). Previous studies (4,18,33) discussed the relationships between the *N*-acetylneuraminic acid of OV and its physiological activity. Our preliminary observations suggested that cholesterol absorption in Caco-2 cells or micellar solubility of cholesterol is unaffected by the *N*-acetylneuraminic acid *in vitro*. Whether the hypocholesterolemic action induced by OV *in vivo* is related to *N*-acetylneuraminic acid is currently being studied.

Taking dietary utilization of OV into account, OV is appropriate to use as a supplement in the diet containing an adequate protein rather than a main protein source in the diet. It is not easy to prepare a large amount of OV, which contains

only 3.5% (w/w) of the EWP. Thus, we simply added OV to the casein diet (20% casein), increasing the protein content of the diet (Table 2). We also found that the serum cholesterol level was significantly decreased in rats fed the diet containing 15% casein supplemented with 5% OV compared to that of 20% casein diet (Nagaoka, S., and Watanabe, K., unpublished results).

It has been postulated that the degree of serum cholesterol-lowering activity depends on the degree of fecal steroid excretion (acidic steroids + neutral steroids) (35). The present study demonstrated a higher fecal excretion of cholesterol (11.4% change) and acidic steroids by OV feeding (Table 3), indicating that the effect is due at least in part to an enhancement of fecal steroid excretion. Smith (36) reported that human gallbladder mucin binds to cholesterol in model bile. Thus, we speculate that an increased fecal excretion of cholesterol may be induced by the binding of cholesterol to OV in the intestine. There have been many studies on the hypocholesterolemic effects of proteins except for OV, most of which emphasized the hypothesis that a peptide with binding capacity to bile acid could inhibit the reabsorption of bile acid in the ileum and decrease the blood cholesterol level (37). These possibilities may be applicable to the case of OV on the basis of the evidence of fecal bile acid excretion (Table 3) and taurocholate-binding capacity (Fig. 1) in the present study.

Cholesterol is rendered soluble in bile salt-mixed micelles and then absorbed (38). The present study indicated that the micellar solubility of cholesterol in the presence of OV was significantly lower than with casein. Very interestingly, we found for the first time that the presence of SPH (13) or

$\beta$ -lactoglobulin tryptic hydrolysate (LTH) (39) significantly suppressed micellar solubility of cholesterol *in vitro*. Sitos-terol (21), sesamine (40), or catechin (41) also lowered the micellar solubility of cholesterol in conjunction with the serum cholesterol-lowering effects in rats. These findings, including those with OV, suggest that the suppression of micellar solubility of cholesterol induces the inhibition of cholesterol absorption in the jejunum, and this may be closely related to the lowering action of serum cholesterol. As shown in the cases of OV, LTH (39), or SPH (13), other dietary proteins or peptides may also affect such solubility.

In recent studies, monolayers of Caco-2 cell cultures were used as a model system to examine the process of lipid metabolism (42–44). For example, Field *et al.* (42) reported that Caco-2 cells, like the small intestine, had the ability to absorb micellar cholesterol and to express marker enzymes such as alkaline phosphatase as small intestinal epithelial cells. The experiments described usually used cultures 12–15 d after plating. This is optimal to determine the cholesterol uptake of the Caco-2 cell culture concomitant with the optimal expression of marker enzymes as small intestinal epithelial cells. In our previous paper (12), we found by using the Caco-2 cultured cell strain that the cholesterol micelles containing SPH (12) or LTH (39) significantly suppressed cholesterol absorption by Caco-2 cells *in vitro*. There is no information about the effects of OV on cholesterol absorption. We therefore used Caco-2 cells or rats to investigate the mechanisms of the serum cholesterol-lowering action of OV. Our experimental system to evaluate cholesterol absorption with Caco-2 cells is very useful for clarifying the molecular mechanism underlying the inhibitory effect of OV on cholesterol absorption from the small intestine, which was previously unknown. There have so far been a few experimental studies to evaluate some effects of proteins or peptides on cholesterol absorption by using cultured intestinal cells (12,13,39).

In this study, we found that OV lowers serum cholesterol levels in rats and inhibits cholesterol absorption in Caco-2 cells. The present results suggest that the suppression of cholesterol absorption by direct interaction between cholesterol-mixed micelles and OV in the jejunal epithelia is part of the mechanism of hypocholesterolemic action induced by OV. Whether OV micelles act directly to lower cholesterol absorption in rat jejunum epithelium *in vivo* is currently being studied.

There have been many studies on the hypocholesterolemic effects of proteins, most of which emphasized the hypothesis that a peptide with high bile acid-binding capacity could inhibit the reabsorption of bile acid in the ileum and decrease the blood cholesterol level (ileal effects). These possibilities may be applicable to the case of OV on the basis of the evidence of fecal bile acid excretion and bile acid-binding capacity in this study. Fecal excretion of bile acids was significantly increased by OV feeding compared with casein feeding, and the bile acid-binding capacity of OV was significantly greater than that of casein. However, our earlier studies (13,39), together with this study, suggest that the reduction of micellar solubility of cholesterol, which may cause the suppression of cholesterol absorption by

direct interaction between cholesterol-mixed micelles and OV in the jejunal epithelia, is part of the mechanism of hypocholesterolemic action induced by OV (jejunal effects). Thus, the hypocholesterolemic action of OV may involve both jejunal and ileal effects.

This study clearly indicates the hypocholesterolemic action of OV compared to casein in the animal model. Present findings concerning the hypocholesterolemic action of OV may enhance both industrial utilization of egg or egg proteins and their value for health enhancement.

**ABSTRACT:** In this manuscript we report a study of the transport of FA in L6 muscle cells. Cultured L6 cells took up labeled FA (C<sub>10</sub> to C<sub>20</sub>) as a linear function of time up to 15 min. Thereafter, the rate of uptake gradually declined although it persisted for at least 12 h after the addition of the substrate. Kinetic parameters ( $K_m$ ,  $V_m$ , and  $k_d$ ) were determined from a fitted Michaelis-Menten-type equation modified by a term for a saturable (linear) component of the measured total uptake.  $V_m$  values were different for some of the FA studied, and  $K_m$  data showed significant differences between saturated and unsaturated FA. The maximal rate of uptake was observed at pH 7.40 for decanoate, palmitate, and eicosatrienoate. Uptake was significantly influenced when the pH of the incubation medium was changed. Experiments designed to study the influence of FA/albumin molar ratio indicated that  $V_m$  was dependent on the total (bound and free) concentration of the FA. A concentrative uptake was demonstrated in short-term experiments with an apparent plateau of 20 and 40  $\mu$ M for palmitate and eicosatrienoate, respectively. A competitive inhibition was also observed between palmitate as substrate and the other FA. From our results we can postulate that the uptake of FA in L6 cells is the sum of passive diffusion plus a saturable component and that the rate of uptake is dependent on one (or more) protein structures, although their precise characteristics and functions remain to be elucidated.

Paper no. L8740 in *Lipids* 37, 273–283 (March 2002).

FA bound to albumin and serum lipoproteins represent the most suitable form in which to transport fat for its utilization. Different types of cultured cells are able to carry out the uptake and metabolism of FA. It was previously demonstrated that in cardiac myocytes the oxidation of long-chain FA is the predominant source of energy necessary for proper electrochemical function (1). As the capacity of this kind of cells to store FA in lipid pools is very limited, myocytes are dependent on a continuous supply of these substrates from the blood stream (2). The L6 rat skeletal muscle cell line would share similar metabolic characteristics with cardiac myocytes;

as a consequence, it may be a useful experimental model to investigate FA uptake.

Prior to their cellular uptake, FA must be dissociated from albumin, then they go through the plasma membrane. The driving force for this process is considered to be the concentration gradient existing across the biomembrane (1–4). Previous papers support the conclusion that transmembrane transport is governed by simple, nonfacilitated diffusion (2–6). However, it was also suggested that the plasma membrane fatty acid-binding protein (FABP), an FA transport protein, and a membrane translocase found in myocytes (2,7–11) would be involved in the FA uptake. However, the role of FABP remains a matter of discussion since transfection of L6 muscle cells with FABP-cDNA does not modify FA uptake (12). In addition, it was reported that high-affinity albumin-binding sites would participate in this process (13,14). Luiken *et al.* (2) recently discussed the idea that FA uptake in isolated cardiac myocytes would be the result of both passive and protein-mediated processes. At present no general agreement exists on this matter, and the exact mechanism of transmembrane transport of FA is still a topic of controversy. Contrary to previous results, which supported the idea of passive diffusion of FA into transformed cells (15), our findings favor a facilitated transport system operating in these skeletal muscle cells.

## MATERIALS AND METHODS

**Chemicals.** [1-<sup>14</sup>C]FA (98–99% pure, 50–60 mCi/mmol) were obtained from American Radiolabeled Chemicals, Inc. (St. Louis, MO). Unlabeled FA were provided by Nu-Chek-Prep (Elysian, MN). All acids were stored in benzene under an atmosphere of nitrogen at –20°C. Concentrations and purities were routinely checked by both gas-liquid radiochromatography and liquid-scintillation counting. Mass determinations were performed by GLC of FAME prepared in the presence of internal standards. FAME mixtures, HEPES delipidated serum albumin (BSA; fraction V from bovine), minimum essential medium Eagle (MEM) with Earle's salts, nonessential amino acids, L-glutamine, choline chloride, fetal bovine serum (FBS), Earle's balanced salts, and improved

minimal essential medium-zinc-optional (IMEM-Zo) were obtained from Sigma Chemical Co. (St. Louis, MO). All solvents were RPE grade and provided by Carlo Erba, Milano, Italy. Silicagel G-60 plates for TLC were provided by Fluka-Riedel-de Häen, Darmstadt, Germany. Other chemicals used were reagent grade and obtained from commercial sources.

**Cell culture and experimental procedure.** L6 muscle cells were grown in surface cultures in approximately 30 cm<sup>2</sup> flasks at 37°C with 5 mL MEM supplemented with 10% (vol/vol) FBS, 0.30 g/L glutamine, and 25 mM HEPES. When the cells were at the logarithmic phase of growth (approximately 72 h after seeding), the culture medium was replaced by IMEM-Zo minus linoleic acid and containing HEPES (25 mM final concentration). The cells were maintained in this medium for 24 h. Then the medium was aspirated and replaced by fresh medium at 37°C supplemented with different FA at various final concentrations. The FA were added as sodium salts bound to delipidated albumin according to Spector *et al.* (15). The uptake process was stopped following the method of Samuel *et al.* (16). After aspiration of the medium, the cells were washed twice with 5 mL of cold Earle's balanced salt solution containing 0.5% BSA. All operations were performed within 20 to 25 s. Control flasks were supplemented with defatted BSA at the same concentration used in the experimental ones. Radioactivity recovered in the last wash routinely represented 4 to 7% of the total radioactivity remaining bound to the cells. Cells were washed and then treated with 2 mL of 0.1 N NaOH and immediately shaken to produce cellular lysis. The resulting lysates were transferred to ice-cold tubes, and the culture flasks were washed twice with 1 mL each of 0.1 N NaOH. After stirring of the pooled solutions, an appropriate aliquot was directly transferred into scintillation vials containing 10 mL of ACS II Scintillation Cocktail for aqueous samples from Amersham Pharmacia Biotech (Buckinghamshire, England). A Beckman LS-5801 Liquid Scintillation Counter with 95% efficiency for <sup>14</sup>C was used. Counting of cellular-associated radioactivity by this method gives results similar to those obtained by extraction of total cellular lipids following the procedure of Folch *et al.* (17). Another aliquot of the cellular lysates was taken for protein measurement following the method of Lowry *et al.* (18). Differences in the uptake values of flasks from the same experimental group did not exceed 5%. Lipid analyses were performed on cellular pellets obtained from surface cultures of L6 cells during the logarithmic phase of growth. The attached cells were mechanically scraped off from the growing surface through the use of a rubber-tipped spatula. After centrifugation at 500 × *g* for 10 min in the cold, the pellet was washed again with 10 mL of Earle's balanced saline solution and centrifuged as described before. The final pellet was extracted according to the method of Folch *et al.* (17). Neutral and polar lipids were further isolated from the total lipid extract by silicic acid microchromatography (Bio-Rad Laboratories, Richmond, CA) according to the method of Hanahan *et al.* (19). The total amount of lipids in each fraction was determined gravimetrically (20). Samples for GLC were transesterified

and analyzed as previously described (21). Lipid analyses performed on culture medium were carried out after filtering through a 0.22 μ SM-11307 Sartorius Membranefilter (Göttingen, Germany) to remove cell debris. The filtrates were lyophilized, and the residual components extracted by the method of Folch *et al.* (17). The procedures employed for TLC analysis were described previously (22). In some experiments the initial rate of FA uptake was determined in modified incubation media. To study the effect of sodium concentration on uptake, we followed the procedure of Stremmel, Strohmeyer and Berk (23). A buffer containing 0.4 mM KH<sub>2</sub>PO<sub>4</sub>, 0.3 mM K<sub>2</sub>HPO<sub>4</sub>, and 15 mM HEPES at pH 7.40 was employed instead of IMEM-Zo medium. The desired concentration of NaCl or substitutes, such as choline chloride, KCl, CaCl<sub>2</sub>, or MgCl<sub>2</sub>, was added and, in order to perform the incubations at the same osmolarity (285 ± 5 mOsm/kg H<sub>2</sub>O), all media were checked by a Semi Micro Osmometer A-800 from Knauer GmbH (Berlin, Germany). Cell viability was assessed by the exclusion test of trypan blue (>96%) (24).

**Software and calculations.** Data are reported as the mean ± SE calculated from three or four independent analyses. The software used for statistical studies (correlation coefficient for nonlinear curve fitting, linear regressions, Student *t*-test, and ANOVA) and other calculations was Systat (version 8.0 for Windows) from SPSS Science (Chicago, IL). Data were also plotted and analyzed using Sigma Scientific Graphing Software (version 8.0) from Sigma Chemical Co. Graphics were constructed considering the amount of uncomplexed FA (UFA) in the presence of BSA. The UFA concentrations were calculated on the association constants determined by Spector *et al.* (25–27) for 12:0, 16:0, 18:0, and 18:2n-6 FA using a personal computer. In the case of the UFA, 18:3n-3 and 20:3n-6, the UFA concentrations were measured in separate experiments (in the absence of cells) by the two-phase partitioning method using heptane as the organic phase as described by Spector *et al.* (27–29). These measurements were performed with a fractional standard error among independent determinations of 2.5% or less. Uptake data were fitted to a modified hyperbolic function of the calculated UFA concentrations using the software mentioned before. During the data fitting, care was taken to find both global minima in the sum of squares and the best nonlinear regression coefficient. We found that, for all the FA studied, our results were best fitted by the following modified hyperbolic equation:

$$UT = V_m[UFA]/(K_m + [UFA]) + k_o [UFA] \quad [1]$$

where UT is the global uptake expressed in nmol FA/min/mg cellular protein, [UFA] is the UFA concentration in the presence of a specific BSA concentration (nM), *K*<sub>m</sub> is the UFA concentration at a half-maximal uptake rate (nM), *V*<sub>m</sub> is the maximal uptake rate of the saturable uptake component (nmol/min/mg cellular protein), and *k*<sub>o</sub> is the rate constant for the linear (nonsaturable) component (μL/min/mg cellular protein). The same equation can be expressed as the sum of two components, one of them with a saturable behavior

(rectangular hyperbola) and the other as an unsaturable component (a linear function of UFA concentration):

$$UT = (V_m [UFA]/(K_m + [UFA])) + k_o' [UFA] \quad [2]$$

Both equations were essentially identical to those employed by Trigatti and Gerber (14) and Stump, Fan, and Berk (30), and both of them gave statistically identical results for calculation of the kinetic parameters. Nonlinear correlation coefficients ( $R^2$ ) were within the range 0.980 to 0.997 depending on the FA studied.

## RESULTS

Owing to the significant modifications of the FA composition evoked by the culture time in complete medium (data not

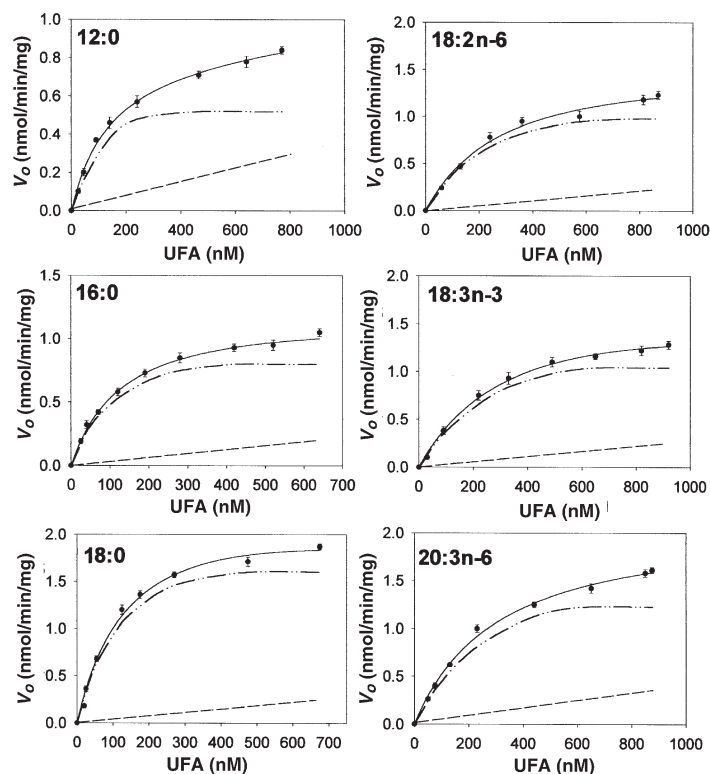

shown), the experiments described in this work were carried out using cultured monolayers of L6 muscle cells during the early logarithmic phase of growth (approximately 72 h after seeding). We chose for our experiments various FA of different chain length and degree of unsaturation. Experimental parameters such as the FA concentration, specific activities, and incubation times were determined by testing the initial rate of uptake under different assay conditions. When the time course of FA uptake was studied under physiological conditions, i.e., at exogenous concentrations of FA and albumin of 20 and 5  $\mu\text{M}$  (FA/BSA equal to 4:1), a rapid initial phase was observed for all substrates studied (Fig. 1A). This uptake was measurable within 30 s after FA addition (Figs. 1B and 1C) and linear with time for at least 15 min (Fig. 1A). Thereafter, the rate of uptake gradually declined for those FA from  $C_{14}$  to  $C_{20}$ . In contrast, the period of linear uptake was longer for

**FIG. 1.** The time course of FA uptake was determined in L6 cells using confluent monolayers of myocytes at an early logarithmic phase of growth. They were incubated in improved minimal essential medium-zinc optional (IMEM-Zo) medium with different FA (fixed initial concentration 20  $\mu\text{M}$ ) bound to delipidated albumin (FA/BSA molar ratio 4:1) and analyzed on cellular uptake at the times indicated. Samples were taken from 0 to 180 min (A) or registered during the initial 180 s at 30-s intervals (B and C). For details see Materials and Methods section. Data are the mean  $\pm$  SEM of three experiments.

shorter-chain FA ( $C_{10}$  and  $C_{12}$ ). For all the substrates studied, uptake was observed for at least 8–12 h (data not shown). It may be suggested that the fall-off in the rate of uptake could be the result of a toxic effect of the FA on the cells (3). After taking into account this possibility, the kinetic data were determined in the 0–3 min period after the FA addition. Exclusion of trypan blue was routinely performed for each determination, leading to the observation that more than 96% of cells were viable in all assays. Figure 2 shows the initial uptake rates for various FA as a function of the UFA concentration in the incubation medium calculated as mentioned in the Materials and Methods section. We chose the initial concentration of FA and BSA to obtain similar sets of UFA concentrations within the range 0 to 900 nM for each FA studied. Calculations for initial uptake rates were made from the slopes of the cumulative linear regressions curves over the first 3-min incubation period. As explained before, the uptake rates were fitted best ( $R^2$  within the range 0.980 to 0.997) by

the sum of the saturable (hyperbolic) plus nonsaturable (linear) components for all the FA studied. Computed values for the kinetic parameters obtained from these plots are presented in Table 1.  $V_m$  values varied from  $0.55 \pm 0.03$  to  $1.80 \pm 0.11$   $\text{nmol}\cdot\text{min}^{-1}\cdot\text{mg}$  cellular protein $^{-1}$ , and they were different from each other for the saturated FA studied. Results indicate that, in the case of the saturated FA,  $V_m$  values increased with the length of the carbon chain.  $V_m$  data for the UFA were very similar to each other, and these values were between those of palmitic and stearic acids. In the case of the  $K_m$  data, we also found significant differences between unsaturated FA ( $133 \pm 7$ ,  $130 \pm 8$ , and  $128 \pm 6$  nM for linoleate,  $\gamma$ -linolenate, and dihomo- $\gamma$ -linolenate, respectively) and saturated FA ( $75 \pm 4$ ,  $71 \pm 3$ , and  $68 \pm 3$  nM for  $C_{12}$ ,  $C_{16}$ , and  $C_{18}$ , respectively) (Table 1). From these kinetic parameters, it is possible to calculate the  $k_o$  constant and the percentage contribution of the uptake that is ascribed to the saturable component of the global kinetic behavior (Table 1). When the FA/BSA molar ratios

**FIG. 2.** Initial uptake rates of various [ $1\text{-}^{14}\text{C}$ ]FA as a function of the uncomplexed FA (substrate) concentration in the incubation medium. Monolayers of cultured L6 cells in IMEM-Zo medium were incubated at  $37^\circ\text{C}$  for 3 min with various concentrations of the indicated FA (fixed initial concentrations from 0 to  $500\ \mu\text{M}$ ) bound to delipidated BSA. The resultant FA/BSA molar ratios varied from 0.2:1 to 4:1. The resultant uncomplexed FA (UFA) concentrations were within the range 0 to 1000 nM; they were calculated, or experimentally determined, as indicated in the Materials and Methods section. The initial uptake rates were obtained from the linear regression slopes of the cumulative uptake curves over the initial 3-min incubation period and were fitted by a computer program to a nonlinear hyperbolic curve containing a term for nonsaturable uptake. (●), Experimentally measured total FA uptake; (—), computer-fitting of experimental data; (---), saturated uptake component; and (----), nonsaturable uptake component. Values are the means  $\pm$  SEM of three independent measurements. For abbreviation see Figure 1.

**TABLE 1**

<sup>e</sup>Percentage contribution of the nonsaturable uptake component. UFA, uncomplexed FA; NSC, non-saturable component.

were maintained below 4:1, the linear component contributed 14 to 34% of the observed (total) uptake. The contribution observed for C<sub>18</sub> FA was of lesser extent than those from the other ones (Table 1). Within the saturated FA, the contribution of the nonsaturable uptake correlates inversely with the chain length, whereas in the case of the unsaturable FA this parameter remains almost constant (Table 1).

A series of experiments was designed to study the influence of FA/BSA molar ratio on the rate of uptake. To understand the role of BSA in the uptake of a saturated (palmitate) and an unsaturated (eicosatrienoate) FA, we performed some experiments at various concentrations of UFA in the incubation medium. The FFA concentration was selected to avoid exceeding its solubility (31,32). The incubations were performed at variable or fixed BSA concentrations (Fig. 3). In this setting, [<sup>14</sup>C]palmitate or [<sup>14</sup>C]eicosatrienoate at a fixed concentration was complexed to BSA at various concentrations or a BSA at a fixed concentration was complexed to FA at increasing concentrations producing a FA/BSA molar ratio that varied between 0.25:1 and 6:1 (Fig. 3, circles). Alternatively, the FA/BSA molar ratio was maintained constant at 6:1 as the FA concentration was increased (Fig. 3, squares). This provided various calculated UFA concentrations within the range 0 to 900 nM. Another uptake curve was obtained in the absence of BSA (Fig. 3, triangles). Results indicate a clear dependence of the uptake on the presence of BSA in the incubation medium. However, no significant differences were observed at the initial rate of uptake when the FA/BSA molar ratio was varied from 0.25:1 to 6:1. The uptake in the absence of BSA was clearly decreased with respect to that observed in the presence of the protein, and in this case, results were best fitted to a linear regression (Fig. 3, triangles).

The optimal pH for initial rates of uptake was found to be around 7.40 for decanoate, palmitate, and eicosatrienoate (Fig. 4). It is important to remark that we found maximal uptake at physiological pH for the three FA studied. Changing the pH of the incubation medium had the largest influence on the uptake of palmitate.

No differences were observed for the initial rates of uptake when using a medium supplemented with glucose (10 mM). We also found that the omission in the medium of K<sup>+</sup> (re-

placed by Na<sup>+</sup>) or Ca<sup>2+</sup> (replaced by Mg<sup>2+</sup>) had no significant influence on the rate of any of the FA studied (data not shown). However, when we examined the uptake of palmi-

**FIG. 3.** L6 cells (approximately  $3 \cdot 10^6$  cells in 4 mL final incubation volume) were incubated at 37°C with labeled palmitic (A) or eicosatrienoic (B) acid. Incubations were conducted at variable FA/BSA molar ratios (0.75:1 to 6:1) (●) or at a fixed ratio of 6:1 (■). Other curves were obtained in the absence of albumin (▲). Uptake was measured as described in the Materials and Methods section and in the legend to Figure 1. Data are the mean ± SEM of three determinations.

tate and eicosatrienoate under the effect of isosmotic  $\text{Na}^+$  substitution with different proportions of choline chloride to achieve  $285 \pm 5$  mOsm/kg  $\text{H}_2\text{O}$  in all incubation flasks, the influx of FA was significantly depressed in a nonproportional fashion (Fig. 5). A major effect was observed with complete substitution of  $\text{Na}^+$  for choline chloride added at a final concentration of approximately 135 mM. The resultant uptake values were significantly depressed within the range 0 to 50 mM  $\text{Na}^+$  compared to the values measured at 140 mM.

Table 2 shows the specific activities of labeled palmitic and eicosatrienoic acids in the medium after the incubation of the L6 cells from 1 to 5 min. The medium of each experiment was saved, and the unesterified FA were separated by TLC, methylated, and analyzed by quantitative GLC as described in the Materials and Methods section. We found no significant changes in the specific radioactivity of the FA assayed, although up to 23% of the exogenous acid was taken up by the cells. These results are in favor of a net uptake of FA rather than an exchange with FA previously present in the cells.

**FIG. 4.** Initial rates of FA uptake were determined in L6 cells incubated in IMEM-Zo medium buffered at different pH values.  $V_o$  values (nmol/min/mg of cellular protein) were determined at an FA/BSA molar ratio of 4:1 after a 3-min incubation period at 37°C. Data are the mean  $\pm$  SEM of three determinations.

We carried out another type of experiment by analyzing the composition and the concentrations of the different UFA in both the culture medium and the L6 cells. Results obtained clearly demonstrated that these cells do take up FA very efficiently from the culture medium. Moreover, a concentrative uptake could be demonstrated in short-term experiments conducted at different FA concentrations of FA under conditions where the substrates were mainly present as their unesterified form (Fig. 6). As expected, this concentrative uptake declined as the concentration of the acid increased. Apparent plateaus were reached at 20 and 40  $\mu\text{M}$  of external FA concentration for palmitate and eicosatrienoate, respectively (Fig. 6).

During FA uptake of L6 cells, a competitive inhibition takes place between palmitate as substrate and the other FA. In these experiments the initial rates of uptake for [ $1\text{-}^{14}\text{C}$ ]palmitate were determined at total concentrations of 16:0 varying from 0 to 200  $\mu\text{M}$  (UFA concentrations within the range 0 to 500 nM) with an FA/BSA molar ratio equal to 4:1, and in the simultaneous presence of different unlabeled FA as competitors added to the incubation medium at uncomplexed concentrations of 100 to 300 nM (approximately one to four times the  $K_m$  for the uptake of palmitate). Data were processed to obtain Dixon plots (21,33), and the kinetic parameters that characterized each incubation ( $V_m$  and  $K_i$ ) were calculated with the aid of the graphic software mentioned before. Dixon plots were constructed as the inverse of the initial velocities vs. inhibitor concentrations (Fig. 7). These types of kinetic analysis are frequently used to identify kinetic inhibition and to determine " $\alpha K_i$ " and " $K_i$ " values (33). The velocity equation for pure or mixed-type competitive inhibition may

**FIG. 5.** The influence of sodium ion concentration on initial uptake velocity ( $V_o$ ) of [ $1\text{-}^{14}\text{C}$ ]palmitate ( $\blacktriangle$ ) or [ $1\text{-}^{14}\text{C}$ ]eicosatrienoate ( $\bullet$ ) was studied in a buffered IMEM-Zo medium (pH 7.40) containing the indicated  $\text{Na}^+$  concentrations (as NaCl) plus sufficient choline chloride salt to achieve a total osmolarity of  $285 \pm 5$  mOsm/kg  $\text{H}_2\text{O}$  in all flasks.  $V_o$  values (nmol/min/mg of cellular protein) were determined at an FA/BSA molar ratio of 4:1 after a 3-min incubation period at 37°C. Values are the mean  $\pm$  SEM of three determinations. (\*)  $P < 0.01$  with respect to the  $V_o$  values measured at 140 mM sodium. For abbreviation see Figure 1.

5	20:3n-6	3.80 $\pm$ 0.44	23.0	2807 $\pm$ 232

<sup>a</sup>FA were incubated at 10  $\mu$ M initial concentration as albumin complexes (FA/BSA molar ratio equal to 4:1) with  $3 \cdot 10^6$  cells (approximately 3 mg of cellular protein) at the times indicated. The incubation media were saved and analyzed as described in the Materials and Methods section. Each value is the mean  $\pm$  SEM of four determinations.

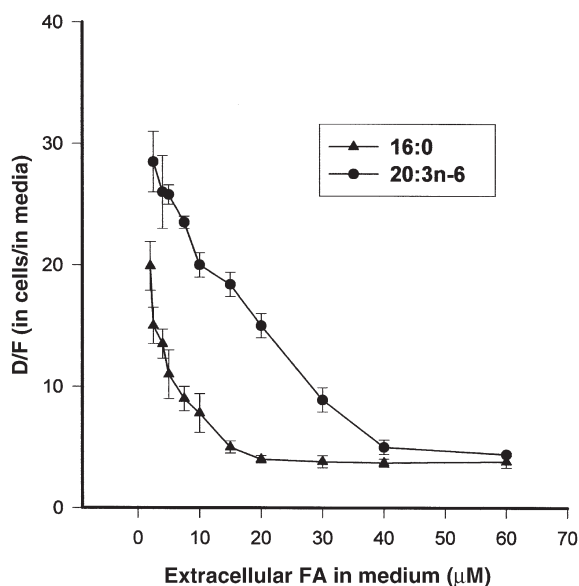

be converted into a linear form in which the varied ligand is the concentration of the FA added as competitor. The regression lines obtained at different substrate (palmitate) concentrations have positive slopes that are given by  $K_m/[S] \cdot V_m \cdot K_i$ . Since  $K_m$ ,  $[S]$ , and  $V_m$  are constants, the slopes are inversely proportional to  $K_i$ . By drawing a horizontal line at a height of  $1/V_m$ , these lines can be intercepted at the  $-[FA]$  (FA added as competitor), representing the kinetic parameter  $K_i$ . Results from Table 3 and Figure 7 indicate a competition between the FA for entry into the cells, since the presence of another FA in the incubation medium is accompanied by a decrease in palmitate uptake. The analysis of Dixon plots (Fig. 7) suggests that this inhibitory effect belongs to the type called "pure competitive" (33) with  $K_i$  values within the range 141 to 218 nM depending on the FA tested as competitor (Table 3). The values found when these FA were present either as substrates or as competitors strongly

suggest that they can interact with the same molecular system as palmitate, thus displaying a similar affinity.

## DISCUSSION

It is generally assumed that the uptake of FA by mammalian cells occurs by passive diffusion (3,4,21). Active transport of FA has been described in bacteria and yeast (34). Active transport of FA in cardiac cells from chick embryo (16) or adult rats (2) has also been suggested. In addition, other authors reported a direct involvement of BSA (13,14,35), membrane proteins (23,35,36) and various cytosolic proteins (2,35,37–45) in the uptake of FA. However, up to now, the mechanism of cellular uptake of FA has been a controversial question that probably involves both a passive and a carrier-mediated transmembrane translocation (35,46,47). In the present paper, the experimental evidence indicates that in cultured myoblastoma cells a net uptake of FA occurs through a saturable transport system. Results from Figure 2 and Table 1 clearly show that the saturable component of the FA uptake exhibits a rather high affinity for  $C_{12}$  to  $C_{20}$  FA, with different initial velocities depending on the length of the carbon chain and/or unsaturation degree. After comparing results from other laboratories—recalculated using the same units—we observed that  $V_m$  values for some of the FA studied approached previously reported rates (3,7,23), and  $K_m$  for net uptake seems to be above the physiological concentrations on non-BSA-bound FA in plasma (25,35,48,49). Stearic acid has a  $V_m$  that is almost three times greater than that of 12:0; taking into account that one million L6 cells equals *ca.* 0.8 mg of cellular protein, this value is very similar to that reported by Stremmel (7) for oleic acid in cardiomyocytes. Moreover, we found that  $K_m$  data increased significantly with chain length from  $C_{12}$  to  $C_{18}$  (Table 1) in a way similar to that suggested by DeGrella and Light (3).  $K_m$  values showed clear differences between saturated FA and UFA (Table 1). Interpretation of these results may be carried out from different points of view, but we think they, may indicate the existence of a membrane-associated transport system with appropriate capacity to meet the needs of L6 cells for FA as metabolic precursors or as a source of energy.

Transmembrane FA transport could be linked to some ATP-consuming process such as conformational changes of membrane-associated proteins, or co-transport with—for

**FIG. 6.** FA uptake was determined in L6 cells incubated in IMEM-Zo medium supplemented with various concentrations of palmitate ( $\blacktriangle$ ) or eicosa-8,11,14-trienoate ( $\bullet$ ) bound to delipidated albumin (FA/BSA molar ratio 4:1). After 4 min of incubation, radioactivity was quantified in both cells (D) and media (F) as described in the Materials and Methods section. Data are the mean  $\pm$  SEM of three analyses. For abbreviation see Figure 1.

**FIG. 7.** Competition experiments were performed in the presence of labeled palmitate (0 to 200  $\mu\text{M}$  total concentration; FA/BSA molar ratio equal to 4:1) and different unlabeled FA (12:0, 18:0, 18:2, and 20:3) as competitors at three final concentrations. Uncomplexed palmitate concentration varied from 0 to 500 nM, and the concentrations of the FA added as competitors were within the range of 100 to 300 nM (one to four times higher than the basal  $K_m$  value for palmitate). Data were processed to obtain Dixon plots, and the kinetic parameters ( $V_m$  and  $K_i$ ) were calculated through a computer software program as detailed in the Materials and Methods section. The initial velocities were calculated from the slopes of the minimal-squares linear regression plots computer-generated from the 3-min initial uptake data according to the procedure described in the text. Each value represents the mean of duplicate experiments. Inset graphics show the Michaelis–Menten-type behavior for the different sets of experimental points.

instance— $\text{Na}^+$  (23,35,50–52). Although the available data from liver and cardiac muscle cells indicate that  $\text{Na}^+$ -dependent transport of FA represents a minor portion of total uptake, previous reports from other laboratories (23,35,50,51) and the present paper (Fig. 5) indicate a direct relationship

**TABLE 3**  
Kinetic Parameters for the Uptake of Palmitate in the Presence of Various FA as Competitors<sup>a</sup>

<sup>a</sup>The kinetic parameters  $V_m$  and  $K_i$  were obtained from linear regression analysis of Dixon plots shown in Figure 7. For further details see the text. Data are expressed as the mean of duplicate experiments.

between FA uptake and sodium availability. The fact that FA uptake is facilitated specifically in the presence of  $\text{Na}^+$  suggests that L6 cells have a sodium-linked system for FA influx that may be dependent on  $\text{Na}^+/\text{K}^+$ -ATPase, similar to what had been found for the hepatocellular uptake of oleate previously reported by Stremmel *et al.* (23).

It is well-known that changing pH is a simple but potent strategy for altering the amount of FA partitioning into the biomembrane. The UFA is composed of anions and undissociated acid, but in practice, the total UFA concentration is considered to be the free anion concentration (27). This approach would be entirely valid if the pH of the medium is 7 or higher because the  $\text{p}K_a$  of FA is thought to be about 4.8 to 5.0 (27). For this reason, within the range of physiological pH values a considerable portion of total FA may be un-ionized. As reviewed by Spector (27), binding of FA to BSA is increased significantly when the pH of the medium is raised from 6.5 to 8.2. This would be reflected in the relative proportion between free and complexed FA. As discussed by

Hamilton (53), basic physical chemistry indicates that we expect an enhanced uptake of FA into cells when the pH of the medium is decreased. However, we found that decanoate, palmitate, and eicosatrienoate exhibited a maximal uptake at physiological pH (7.40) that was preceded by diminished uptake values in the pH range of 6.0 to 7.4 (Fig. 4). This fact suggests that a structure sensible to pH modification—other than the FA itself—may be involved in the uptake of the substrates. This is not the case when we assume that the uptake proceeds by passive diffusion, in which the driving force that determines the net uptake is the partition coefficient of FFA between medium and biomembrane (35,53). In the simple diffusion model, a very rapid rate of flip-flop of FA across the membrane is proposed (53). It has also been reported that the  $\text{Na}^+/\text{K}^+$  antiporter may act in response to the movement of  $\text{H}^+$  by FA flip-flop, and it may influence diffusion by local pH changes that modify the interfacial ionization of the substrate (53). Several experimental observations have described the structural changes of BSA within the pH interval we examined, including significant modifications around the physiological pH (27). Thus, BSA and/or a membrane protein could influence FA uptake by binding the substrate directly, enhancing partitioning into the membrane, or playing a role in its subsequent metabolism, for example, sequestering FA to a membrane-bound transporter. If a membrane-associated protein binds FA with high affinity in a pH-dependent manner, the rate of release from the protein will affect the rate of uptake, possibly slowing it down.

Experimental evidence from other authors indicates that only UFA enter the cells and that the rate of uptake is dependent upon the FA/BSA molar ratio, that is, upon the concentration of FFA (15,16,35,47,54). Figure 3 demonstrates that no significant differences are observed for the uptake of palmitate and eicosatrienoate at constant and variable ratios. Thus, under our experimental conditions, only the total FA concentration (bound and free) seems to be crucial for the rate of uptake. As the exogenous palmitate—or eicosatrienoate—concentrations were varied at a fixed FA/BSA ratio (Fig. 3), the uncomplexed substrate concentration, which is solely a function of the ratio (2,49,54), remained constant. Hence, the concentration of BSA in the medium was the only variable in this setting. Under these conditions, the FA uptake appeared to be saturable at increasing BSA concentration, indicating, as previously proposed by Trigatti and Gerber (14) and Glatz *et al.* (35), the possible involvement of an albumin receptor structure in the uptake mechanism. On the other hand, taking into account the high affinity of BSA for FFA, it might be assumed that these substrates cannot leave binding sites on albumin without catalysis performed by another protein. In this regard, it was reported that the rate of desorption of stearic acid from albumin may be accomplished in 70 s as determined by  $^{13}\text{C}$  NMR studies (53). This time seems to be too long compared to the time required for observing a significant uptake of FA in our experimental system (30 s) (Figs. 1B and 1C). It is evident that the presence of living cells influences the mechanism of FA desorption. We think, in conse-

quence, that the rate of spontaneous desorption is too slow to explain the uptake process without the intervention of another protein(s). The FA are maintained in a nonaggregated form by means of FA–albumin complexes as a source of substrate in transport studies (31,32). Under physiological conditions albumin is present in large quantities with respect to FA, strongly suggesting the existence of another structure that is involved in the uptake process. For this reason, we agree with other authors who postulate the presence of an albumin receptor in plasma membranes (13,14,35,53). This fact could explain the different results obtained for the FA uptake in experiments with artificial systems or cultured cells. Further support for the concept of a facilitated uptake for long-chain FA influx in L6 cells is found in Figure 6 and Table 2. We found a concentrative uptake of FA arising from the net incorporation of substrates rather than from an exchange with external FA. Moreover, the radioactivity was recovered exclusively in the methyl ester peak, indicating that the FA were not significantly metabolized and then released into the medium. The fact that L6 cells are able to take up FA in a concentrative fashion at all concentrations tested (Fig. 6) and that this uptake is dependent on sodium concentrations (Fig. 5) favors an active transport. We can assume therefore the existence of such a transport system in L6 cells for the uptake of FA. Notwithstanding, we should also keep in mind that FA-activating enzymes are present at the cytoplasmic level and in organelles. For this reason, a passive diffusion component cannot be ruled out. However, the fact that some FA do not compete with palmitate for activation but do compete for entry into cells (16) (Table 3) is a crucial argument against this possibility. Our results from competition studies are also in agreement with the hypothesis of a specific transport system operating in FA uptake. Similar values were found when FA were present either as substrates or as competitors, suggesting that they are recognized by the same protein structure (Table 3).

In conclusion, our results agree with previous reports (7,14,16,23,30,35) that postulate that the rate of entry of FA into L6 cells is determined by the sum of a diffusion-like (linear) component and a saturable (hyperbolic) component. As previously reported by Samuel *et al.* (16) for cultured cardiac cells, the contribution of passive diffusion in the total uptake of FA would account for no more than 30% of the total rate of uptake. In our experiments we found a contribution of 66 to 86% as saturable uptake (Table 1), which implies that 14 to 34% of the total uptake was evoked by passive diffusion. Thus, the importance of the saturable transport becomes evident. It is widely known that the cellular uptake of FA is a multistep process that involves a variety of membrane-associated events (3–5,7,8,14,23,30,35,37,52,53). Our results suggest the necessity of one or more protein structures to achieve these steps, although their precise function remains unknown. The physiological significance of this question is evident, since different tissues express a distinct set of proteins putatively involved in cellular uptake (2,5,8,10,11,13,14,23,35–45, 52,53). This phenomenon would explain the adaptation for

specific needs of each tissue and the central role related to FA availability and metabolism. These adaptive responses are complicated and not easily interpretable. For these reasons, we think they may not be the result of only passive (flip-flop) diffusion of FA through the plasma membranes.

## ACKNOWLEDGMENTS

The authors are grateful to Prof. Dra. María J.T. de Alaniz for stimulating discussion during the preparation of this manuscript. The helpful advice of Prof. Enrique Gustavo Bozarello regarding mathematical calculations is gratefully acknowledged. This study was supported in part by grants from CONICET, ANPCyT, Argentina.

# Platelet Phospholipids Are Differentially Protected Against Oxidative Degradation by Plasmalogens

Claude Leray, Jean-Pierre Cazenave, and Christian Gachet\*

Inserm U.311, Etablissement Français du Sang-Alsace, 67065 Strasbourg, France

**ABSTRACT:** The oxidative degradation of phospholipids in the presence and absence of plasmalogens (plasmalogen phosphatidylethanolamine: PPE) was followed by chemical analysis. Human platelet phospholipids, either intact or after removal of PPE by acid treatment, were oxidized with 28 mM 2,2'-azobis(2-amidinopropane di-HCl in Triton X-100 micelles (detergent/phospholipid 5:1, mol/mol). PPE (12% of all phospholipids, mol/mol) disappeared about three times more rapidly than glycerophospholipids, whereas sphingomyelin remained unaltered and the lysophosphatidylethanolamine (lysoPE) generated became progressively more unsaturated. After 60 min oxidation, the FA compositions of PS, PC, and PI were similar in extracts with or without plasmalogens. In contrast, diacyl phosphatidylethanolamine (DPE) became more saturated in the absence of PPE. The rate of phospholipid destruction was always unique to each class, but for all phospholipids slowed down in the presence of PPE. This protective effect increased in the order DPE < PS < PC < PI and did not seem to be simply related to the class unsaturation.  $\alpha$ -Tocopherol had no influence on the time courses of the quantities and compositions of the phospholipids, even at a molar ratio of  $\alpha$ -tocopherol to phospholipids four times higher than in platelet membranes. Thus, PPE protected phospholipids efficiently but differentially against peroxidative attack, whereas the contribution of  $\alpha$ -tocopherol appeared to be negligible even at a concentration four times greater than in platelet membranes.

Paper no. L8933 in *Lipids* 37, 285–290 (March 2002).

Several findings suggest that oxygen free radicals behave as stimulators of platelet aggregation, acting at different levels of the signal activation pathways (1,2). There is also a growing body of evidence to support the role of these active radicals in a number of pathological situations involving platelet activation, such as atherosclerosis (3) or reperfusion injury (4). Since the early demonstration of a preferential attack of "active" oxygen on the vinyl-ether linkage of plasmalogen phospholipids (5), further reports have indicated that these membrane components can play an important role in antioxidant defense (3,6,7). The most convincing systems are those employing cultured cells (8,9), LDL particles (10–12), liposomes (13–15), or micelles (12,16). The plasmalogen content of platelets is relatively high, as these compounds constitute more than half the PE pool, thus accounting for about 12% of

Abbreviations: AAPH, 2,2'-azobis(2-amidinopropane) di-HCl; DPE, diacyl phosphatidylethanolamine; lysoPE, lysophosphatidylethanolamine; PPE, plasmalogen phosphatidylethanolamine (plasmalogens); SM, sphingomyelin.

all membrane phospholipids. The contribution of choline plasmalogens nevertheless remains marginal and amounts to no more than 0.8% of the PC pool (17). Although many reports have described the susceptibility of plasmalogens to various oxidative reactions (5,9,13,14), there are no studies concerning their specific protection of phospholipids. The aim of the present work was to evaluate the protection of individual platelet phospholipids by plasmalogens during peroxidative attack by estimating their concentrations and compositions in an *in vitro* system.

## MATERIALS AND METHODS

Washed human platelets were prepared from the blood of four pools of healthy donors (18), and platelet lipids were extracted immediately (19). Tocopherols were stripped from the samples down to undetectable levels by filtering chloroform solutions onto silica gel; after eluting neutral lipids with chloroform, phospholipids were eluted with methanol. Aliquots of total phospholipids (about 9  $\mu$ g P, final concentration 600  $\mu$ M) were mixed with 3 mM Triton X-100 (12) in PBS (0.5 mL), and peroxidation was induced by addition of 2,2'-azobis(2-amidinopropane) di-HCl (AAPH) at a final concentration of 28 mM (Polysciences Inc., Eppelheim, Germany). Two micellar systems were used; in one, the phospholipids were left intact, whereas in the other plasmalogens were destroyed by vortexing chloroform solutions in the presence of 0.4 M HCl for 15 min (20). Free aldehydes were removed by filtration on a silica gel column, and phospholipids were eluted as described above. To compare the protective efficiency of plasmalogens and  $\alpha$ -tocopherol, the oxidative degradation of phospholipids was also studied after addition of  $\alpha$ -tocopherol (final concentration 2.8 or 11.2  $\mu$ M; Sigma Chemical Co., Lyon, France) before AAPH to a phospholipid suspension without plasmalogens. In these experiments, the molar ratios of phospholipids to  $\alpha$ -tocopherol were similar to those in platelet membranes (about 214:1) for 2.8  $\mu$ M or up to fourfold lower (about 54:1) for 11.2  $\mu$ M  $\alpha$ -tocopherol. After incubation at 37°C for 0, 15, 30, 45, or 60 min, phospholipids were extracted with a Folch mixture. PE, PC, PS, PI, and sphingomyelin (SM) were separated by TLC (21), and their FA compositions were analyzed by GLC after direct transmethylation with BF<sub>3</sub>/methanol reagent (21). Addition of a known amount of heptadecanoic acid as an internal standard enabled estimation of the mass of each phospholipid. DPE and PPE were quantified after elution of the PE spots

and cleavage of the vinyl bond by acid treatment (21), the lysoPE representative of PPE and the remaining DPE being separated by a second TLC run.  $\alpha$ -Tocopherol was estimated by HPLC with fluorescence detection (19).

The Mann–Whitney test was used to compare the means between experimental groups.

## RESULTS

In the present study, the phospholipid composition of the platelet samples was similar to that previously reported (21) using the same analytical procedure. The average composition of the phospholipid mixture was (mol %): PPE (14.2  $\pm$  1.1), DPE (12.3  $\pm$  0.6), PC (46.3  $\pm$  2.6), PS (12.3  $\pm$  0.5), PI (4.7  $\pm$  0.2), and SM (10.2  $\pm$  0.6).

Exposure of intact platelet phospholipids to 28 mM AAPH led to a progressive loss of diacylphospholipids, which were at 25% of their initial level after 60 min oxidation. The AAPH concentration was selected to obtain a degradation rate similar to that previously observed in brain phospholipid mixtures (16). The destruction of PPE was more rapid than that of other phospholipids, occurring mainly within the first 15 min and reaching a loss of about 75% after 60 min. Moreover, the FA

composition of the remaining PPE was significantly altered (Table 1). The new FA profile after 60 min oxidation was characterized by important increases in saturated and n-9 FA, compensated by important decreases in n-6 and n-3 PUFA of, respectively, 24 and 45%. The lysoPE generated amounted to about 7% of total diacylphospholipids, and its FA composition differed significantly from that of the small amount present at time 0 (less than 1%). The concentration of arachidonic acid was four times its value at time 0, while an increase of n-6 and n-3 PUFA compensated for a decrease of n-9 FA. The FA compositions of DPE, PS, PC, and PI at time 0 and after 60 min of oxidation in the presence or absence of plasmalogens are given in Tables 2 and 3. AAPH induced important losses of PUFA (14% for DPE and about 27% for PS, PC, and PI) in intact phospholipid extracts (with plasmalogens), compensated by increases in the concentrations of saturated and monounsaturated FA. The FA compositions of PS (Table 2), PC, and PI (Table 3) in intact extracts were similar to those in extracts without plasmalogens after 60 min oxidation. In contrast, the composition of DPE was less affected by AAPH in the presence of plasmalogens (Table 2). Thus, plasmalogens significantly reduced the losses of n-6 PUFA (13 vs. 32%,  $P < 0.01$ ) and MUFA (13 vs. 35%,  $P < 0.001$ ), whereas saturated FA

<sup>a</sup>Results are mean ± SEM ( $n = 4$ ). DPE, diacyl PE; 0, extracts at time 0 before addition of AAPH; C, control extracts with plasmalogens after 60 min oxidation; AT, acid-treated extracts (without plasmalogens) after 60 min oxidation; DBI, double bond index (number of double bonds for 100 mol FA). Other abbreviations as in legend of Table 1. The Mann-Whitney test was used to compare the means of C and AT extracts: \* $P < 0.05$ , \*\* $P < 0.01$ , \*\*\* $P < 0.001$ .

were correspondingly more abundant in extracts without plasmalogens (37%) than in intact extracts (8%) ( $P < 0.05$ ).

The time courses of the relative quantities of the phospholipids and their PUFA contents during AAPH oxidation are shown in Figure 1. In intact extracts, the rate of phospholipid destruction was constant over 1 h but differed according to the class, with only 40% of the initial DPE remaining after 60 min as compared to about 75% of PS and PI and 87% of PC. In the absence of plasmalogens, all phospholipids disappeared rapidly over the first half hour but more slowly thereafter, the destruction of DPE and PI being strongest (26–29% remaining) and that of PS and PC weakest (48–50% remaining). The time courses of the relative PUFA contents of all phospholipids were similar to those of their quantities in extracts with or without plasmalogens. In the absence of plasmalogens, the addition of  $\alpha$ -tocopherol (2.8 or 11.2  $\mu\text{M}$ ) before AAPH did not alter the time courses of the quantities and compositions of the phospholipids in the incubation mixture (data not shown). At both concentrations,  $\alpha$ -tocopherol was no longer detectable after 15 min oxidation in the presence of AAPH.

## DISCUSSION

Although the oxidative degradation of plasmalogens has been accurately described (11,14,22), their role in the protection of

diacyl phospholipids remains poorly understood. The effects of plasmalogens on the oxidative decay of total tissue phospholipids (15) or of certain specific molecular species (12,16) have been reported, but comparative effects on the degradation of individual phospholipids have not yet been described. As previously observed in various systems (14–16), there was a pronounced loss of PPE following exposure of intact platelet phospholipids to AAPH, as compared to the loss of total diacyl phospholipids. Furthermore, we observed an accumulation of lysoPE-bearing PUFA groups (50.5 ± 5.2% after 60 min). This specific destruction of PPE species having a polyunsaturated fatty acyl group esterified at the *sn*-2 position is in accordance with earlier reports (22). In contrast, an accumulation of lysoPE molecular species containing only monounsaturated fatty acyl groups was observed after oxidation of bovine brain PE (14). This discrepancy could be related to different experimental conditions and/or to the use of only PE (14) instead of a phospholipid mixture (present work). On a mass basis, the results show that plasmalogens strongly protect all diacyl phospholipids (Fig. 1). In the presence of plasmalogens (nontreated extracts), all phospholipids and their PUFA disappeared at a constant rate over a period of 1 h, whereas without plasmalogens (acid-treated extracts) the degradation proceeded more rapidly. Similar kinetics have been described by others in liposomal (15) and micellar

systems (16). Comparing the degradation rates of the different diacyl phospholipids and their PUFA over the first 30 min, we found that the protective effect of plasmalogens increased in the order DPE < PS < PC < PI. Thus, the degradation after 30 min oxidation decreased in the presence of plasmalogens by  $48 \pm 3$ ,  $66 \pm 4$ ,  $85 \pm 4$ , and  $88 \pm 5\%$  for DPE, PS, PC, and PI, respectively. Among DPE, PS, and PC, the efficiency of protection was inversely related to the double bond index (respectively,  $189 \pm 10$ ,  $147 \pm 8$ , and  $121 \pm 6$ ) or PUFA content (respectively,  $46.8 \pm 2.6$ ,  $33.0 \pm 1.7$ , and  $29.6 \pm 1.2\%$ ), the most unsaturated phospholipid (DPE) being least efficiently protected by plasmalogens. Unexpectedly, although PI is still more unsaturated than DPE, it appeared to be the most strongly protected of the diacyl phospholipids (Fig. 1).

These results demonstrate that plasmalogens participate actively in the inhibition of PUFA peroxidation and concomitantly in phospholipid degradation, the protection afforded depending on both the acyl chain unsaturation and the nature of the polar head. Interestingly, in the absence of plasmalogens the degradation rates of the four glycerophospholipids increased in the order PS < PC < DPE < PI, which is not the order of their increasing unsaturation (PC < PS < DPE < PI). Hence, if unsaturation is important for peroxidative susceptibility (23), there is also an obvious influence of the polar head group among the diacyl glycerophospholipids. Moreover, the least unsaturated phospholipid (SM) was unaffected by free

radical oxidation in our experimental system, even in the absence of plasmalogens (data not shown).

In natural membranes,  $\alpha$ -tocopherol is currently considered to be the major lipid-soluble antioxidant despite its low concentration, which approximates 1 mole for 220 moles of phospholipids, as for instance in platelets (19). The relative potency of  $\alpha$ -tocopherol as compared to plasmalogens as a protective agent against phospholipid degradation induced by peroxy radicals was evaluated by adding  $\alpha$ -tocopherol before AAPH to membrane extracts without plasmalogens. We observed that the rates of phospholipid degradation remained unchanged when using molar ratios of phospholipids to  $\alpha$ -tocopherol similar to that found in platelet membranes (214:1) or up to about fourfold lower (54:1). These unexpected results are probably at least partly due to total consumption of the added  $\alpha$ -tocopherol after 15 min oxidation. Although a significant decrease in degradation rate was previously reported (16), these authors used a higher  $\alpha$ -tocopherol amount (4:1 ratio of phospholipid to  $\alpha$ -tocopherol) and a lower AAPH concentration (2 mM) than in our experiments. Thus, in our conditions, plasmalogens appear to contribute more effectively than  $\alpha$ -tocopherol to the resistance of the unsaturated acyl chains of phospholipids to peroxidation. In spite of a scavenging activity estimated to be similar to (10) or fourfold higher (12) than that of plasmalogens, in platelet membranes only 1 mole of  $\alpha$ -tocopherol is able to compete with about 30 moles of plasmalogens

**FIG. 1.** 2,2'-Azobis(2-amidinopropane) di-HCl-mediated degradation of platelet phospholipids in the presence or absence of plasmalogens. for interaction with peroxy radicals. Any extrapolation of the present findings to biological membranes will nevertheless require further work to clarify the mechanisms responsible for the differential protection of phospholipids by plasmalogens.

**ABSTRACT:** There have been a limited number of studies investigating surfactant lipid changes in lung with trace elements. The present investigation was designed to examine the effect of moderate zinc deficiency on the lipid metabolism in rat lung. We also evaluated whether zinc deficiency, which is a widespread problem, could play a role in adult respiratory distress syndrome (ARDS). For that purpose, adult male Wistar rats were fed two diets differing in zinc concentration. The rats were divided into two groups. One group was fed a zinc-deficient diet containing 3 mg Zn/kg, and the other group received a zinc-adequate control diet with 30 mg Zn/kg according to AIN 93-M. After 2 mon of treatment, we observed that in the zinc-deficient group (i) total lipids, phospholipids, and cholesterol increased whereas TG decreased in whole lung; (ii) phospholipid (PC) concentration increased in lamellar bodies and alveolar macrophages and decreased in extracellular surfactant but did not change in microsomes; (iii) protein concentration decreased in whole lung, extracellular surfactant, lamellar bodies, and macrophages; (iv) the incorporation of [Me-<sup>14</sup>C]choline into PC (phospholipids) of lung slices increased; and (v) the activity of CTP/phosphocholine cytidyltransferase bound to the microsomes increased in the lung. These results suggest that the lipid concentration in the lung (especially the phospholipids) is modified directly or indirectly by a zinc-deficient diet. In a zinc-deficient diet, the lung changes the pattern of PC for an adaptive or recovery stage. Therefore, zinc deficiency implications are important for the design of therapies and public health interventions involving targeted zinc supplementation for high-risk groups or groups with certain diseases, such as ARDS.

Paper no. L8745 in *Lipids* 37, 291–296 (March 2002).

Serious surfactant deficiency may compromise the structural and functional integrity of the alveoli and become life threatening. An abnormal surfactant also appears to be an important characteristic of adult respiratory distress syndrome (ARDS) (1). A major early hallmark of ARDS is damage to the alveoli-capillary membrane with a concomitant increase in permeability to high-molecular-weight solutes. Surfactant changes are thought to play an important role in the pathogenesis of this condition (1,2).

Zinc deficiency (ZD) produces profound alterations in the metabolism of lipids (3,4). The effects of ZD not only depend on the type of dietary fat but also show organ-specific variations and influence the lipid metabolism in a variety of ways (3,5). Zinc-deficient rats exhibit elevated activities of lipogenic

enzymes in liver as well as elevated serum lipid concentrations (4). The effects of ZD on the FA composition of phospholipids are more pronounced in liver and plasma than in heart, testes, erythrocyte membranes, and mesentery of the small intestine (3). This might be due to the fact that the turnover rates of phospholipids in liver are higher than in other tissues (3). In ZD both pathways of PC biosynthesis in liver microsomes were significantly increased (5)

The alveolar surfaces of the lungs are lined with a lipid-protein complex called pulmonary surfactant. This material consists of approximately 90% lipids and 5–10% proteins. The surfactant lipids spread as a monolayer on the air-liquid interface.

PC is quantitatively the major component of surfactant and is undoubtedly its major surface-active component (3). *De novo* PC synthesis by type II epithelial cells from adult rats proceeds mainly *via* the CDP choline pathway (6). Dipalmitoylphosphatidylcholine may be synthesized directly *via* this pathway or by the remodeling of unsaturated PC species (7). Accumulating evidence is available from studies on a number of different cell types (6), where the enzyme cholinephosphate cytidyltransferase (CYT) catalyzes the rate-limiting step in the conversion of choline into PC. CYT (EC 2.7.7.15) is a regulatory enzyme in the synthesis of pulmonary surfactant PC *via* the Kennedy pathway (8). When CYT activity is assayed in different subcellular fractions, its greatest increase, as a function of development, is found in microsomes (9). Zimmermann *et al.* (10) speculate about the possibility that either a subcellular translocation of CYT from cytosol to microsomes or an increase in CYT gene expression is responsible for the developmental increase of *de novo* PC synthesis (10).

The lecithin/sphingomyelin ratio in amniotic fluid is used clinically as a marker of pulmonary maturation of the fetal lung and its production of surfactant (11). Zinc-deficient rats did not show an increase even at day 21 of gestation, suggesting that ZD interferes with surfactant biosynthesis in the fetal lung (11). Zinc may therefore have important implications for asthma and other inflammatory diseases, where the physical barrier is vulnerable and compromised (12).

The aim of the present study was to determine if ZD alters the metabolism of lipids in lung, in particular the synthesis of PC, the main component of the pulmonary surfactant. We also investigated whether ZD plays a role in ARDS.

## MATERIALS AND METHODS

**Chemicals and radioisotopes.** All reagents were of analytical grade. Lipid standards and protein were acquired from Sigma Chemical Co. (St. Louis, MO). Serum total lipids, cholesterol, and TG were determined by enzymatic methods using kits

from Boehringer Mannheim Diagnostics (Indianapolis, IN). [Methyl- $^{14}\text{C}$ ]phosphorylcholine (specific activity, 50 mCi/mmol) and [methyl- $^{14}\text{C}$ ]choline chloride (specific activity, 60 mCi/mol) were purchased from Dupont, New England Nuclear (Boston, MA).

**Animals and diets.** Adult male Wistar rats with an average body weight of  $200 \pm 10$  g were divided into two groups; one of them was fed a zinc-deficient diet containing 3 mg Zn/kg and the other a zinc-adequate control diet supplemented with 30 mg Zn/kg, added as  $\text{ZnCl}_2$ . All the other components of the diet remained constant. The diets were fortified with recommended amounts of vitamins and minerals according to AIN 93-M (13). The composition of the basal maintenance (semisynthetic) diet was as follows (g/kg diet): cornstarch, 465.692; casein ( $\geq 85\%$  protein), 140.000; dextrinized cornstarch, 155.000; sucrose, 100.000; fiber/cellulose, 50.000; soybean oil (containing liposoluble vitamins), 40.000; mineral mix (AIN-93M-MX), 35.000; vitamin mix (AIN-93-VX), 10.000; L-cystine, 1.800; ascorbic acid, 0.008; choline bitartrate (41% choline), 2.500. This diet had 1 mg Zn/kg dry matter. In the ZD diet, zinc was not incorporated into the mineral mix. All dietary ingredients were obtained in the purest form known with regard to zinc contamination, and newly obtained ingredients were monitored for zinc concentration.

Rats were housed individually in a controlled environment with a light-dark cycle of 14/10 h (lights on from 0600–2000) and at a temperature of 22 to 24°C. Fresh diets were given and leftover food discarded on a daily basis (20 g diet was adequate to ensure *ad libitum* feeding). Care and treatment of rats followed recommended guidelines (14). Body weights were recorded weekly.

At the end of the experimental period of 2 mon, 12 h after the last feeding all animals were sacrificed. Rats were anesthetized intraperitoneally with sodium pentobarbital (50 mg/kg, ip). The respiration of the rats was normal at all times prior to sacrifice. Blood for hematological measurements was collected into EDTA-coated vials. Blood for determination of serum zinc was collected into washed tubes, and the concentration of serum zinc was measured directly by aspirating a dilute solution (1:5, vol/vol) into the atomic absorption spectrophotometer (see below). The lungs were quickly removed, lavaged with ice-cold 0.9% saline solution, and weighed. Serum and tissue samples were stored at  $-80^\circ\text{C}$  until they were analyzed.

**Zinc analyses.** Aliquots of the diet, liver, and lung were collected without allowing any contact with metal. Each sample was wet-ashed with 16 N nitric acid as described by Clegg *et al.* (15). The zinc concentrations of the pretreated samples and the serum were quantified with a pyrolytically coated graphite tube from an atomic absorption spectrophotometer (model 5100, HGA-600 Graphite Furnace; PerkinElmer) fitted with an electrothermal atomizer and a hollow cathode lamp (PerkinElmer). A linear calibration curve was created using certified standard NIST solutions. All specimens were diluted with twice-distilled and deionized water and analyzed in duplicate. Prior to digesting the sample, different amounts of standard solution of each element were added. The recovery rate was between 98 and 99.2% for different elements.

**Isolation of extracellular pulmonary surfactant and macrophages.** In another experiment, the tracheas of anesthetized rats were cannulated and the lungs were filled with 2.5 mL ice-cold 0.15 M NaCl. Lavages containing the extracellular surfactant were then collected. This procedure was repeated nine times. The combined lavages were centrifuged at  $4^\circ\text{C}$  and  $580 \times g$  for 10 min to sediment macrophages. The resulting supernatant was centrifuged at  $198,000 \times g$  for 30 min in a Beckman ultracentrifuge LS 65 B, 65 Ty rotor to obtain the surfactant pellet (16).

**Isolation of lamellar bodies and microsomes.** After extraction of the extracellular pulmonary surfactant fraction, the lavaged lungs were used to isolate lamellar bodies and microsomes (16).

**Lipid analyses.** Lipids were extracted from total lung tissue, microsomes, lamellar bodies, extracellular surfactant, and macrophages. Total lipids were determined by dry weight. The lipids were resuspended in a hexane/isopropanol mixture (3:2, vol/vol) containing BHT as antioxidant (17). Aliquots were taken for determining phospholipids and measuring phosphorus (18) and total cholesterol (19). Other parts of the extracts were used for the separation of the different lipids on TLC plates coated with silica gel G (Merck, Darmstadt, Germany) using hexane/diethyl ether/acetic acid (80:20:1, by vol) as solvent. The lipids were detected by exposing the plates to iodine vapors. They were scraped off and used directly for determination of phospholipids (18), TG (20), and free and esterified cholesterol (19).

**Analysis of phospholipid composition.** Phospholipids were separated into component classes by TLC, using silica gel H plates and chloroform/methanol/water (65:25:4, by vol) as solvent (21). The individual phospholipids were identified and recovered as described previously and were quantified (18). The position of the phospholipids was determined using the respective standards. The results were expressed as the percentage of total phospholipid phosphorus.

**Incorporation of [Me- $^{14}\text{C}$ ]choline in lung slices.** The rate of PC synthesis in lung slices was determined by the rate of incorporation of [Me- $^{14}\text{C}$ ]choline. The lung slices (100 mg) were rapidly cut and placed into individual metabolic flasks containing DMEM (pH 7.4; GIBCO BRL). The flasks were continuously flushed with 95%  $\text{O}_2$ /5%  $\text{CO}_2$ . After the slices were preincubated for 10 min at  $37^\circ\text{C}$ , 1  $\mu\text{Ci}$ /assay [Me- $^{14}\text{C}$ ]choline was added to each flask. The incubation was stopped after 1 h by dilution with medium. After the incubation period, tissue slices were removed from the medium and the tissues were washed with ice-cold 0.9% NaCl. The tissues were homogenized, and the lipids were extracted and analyzed as described above.

**CTP:cholinephosphate CYT assay.** Lungs of control and zinc-deficient rats were used for the separation of cytosol and microsomes for enzymatic determination (22). Assay mixtures contained 20 mM Tris/succinate pH 7.8, 6 mM  $\text{MgCl}_2$ , 8 mM CTP, and 4 mM [Me- $^{14}\text{C}$ ]phosphorylcholine (specific radioactivity 1  $\mu\text{Ci}$ /assay). The reaction was started by addition of enzyme (100  $\mu\text{g}$  protein), and the assay mixture was incubated for 30 min at  $37^\circ\text{C}$ . The reaction was stopped with TCA (0.5%), and protein was removed by centrifugation ( $1000 \times g$  for 10 min). A 50  $\mu\text{L}$  sample was taken from the supernatant,

mixed with 2 nmol of unlabeled phosphorylcholine used as a carrier, and subjected to TLC on precoated silica gel H (Merck) with NaCl 0.5%/methanol/concentrated ammonia (50:50:5, by vol) used as developing solvent.

**Protein.** Protein content was determined by the method of Lowry *et al.* (23) with BSA as a standard.

**Enzyme markers.** To determine if the lamellar bodies were contaminated with microsomal, mitochondrial, or cell membranes, the activities of NADPH cytochrome c reductase (24), succinate dehydrogenase (25), and 5'-nucleotidase (26), respectively, were measured.

**Statistical analysis.** Values are expressed as mean  $\pm$  SD. Significant differences were considered at  $P < 0.05$ , as determined by Student's *t*-test.

## RESULTS

**Weight gain and zinc status of the rats.** After 8 wk of treatment, body weight gain was lower in zinc-deficient rats in comparison to controls, as previously reported by (3,4,27). The lung weight of zinc-deficient rats was also significantly lower ( $P < 0.001$ ) compared to the control (Co) (Table 1). Serum, liver, and lung zinc concentrations were significantly lower in rats fed the zinc-deficient diet compared with those of Co group (Table 2). Likewise, we found that glucose was influenced by ZD, and there was an increased level of it in plasma ( $P < 0.01$ ) (28). Other parameters, such as albumin, did not change, but globulin content fell with the zinc-deficient diet (Table 1). This was coincident with a previous report (29).

**Total lipids, cholesterol, and TG in serum and whole lung.** Total lipids and cholesterol increased and TG were not modified in the serum from the zinc-deficient rats after 2 mon of treatment. Total lipids and total free and esterified cholesterol increased, but TG decreased in whole lung of the zinc-deficient rats (Table 2).

**Phospholipid concentration in whole lung, intracellular, and extracellular compartments.** The phospholipid concentration increased in whole lung and lamellar bodies, whereas in extracellular surfactant and macrophages it decreased, but in microsomes it was not modified in the zinc-deficient group compared to the control group (Table 3).

On a percentage basis, the phospholipid composition in whole lung and other particles studied was modified after 2 mon of the zinc-deficient diet, compared to the control. In whole lung, PC and PS + PI increased; and lysophosphatidylcholine (LPC) and sphingomyelin (SPH) decreased. PE and phosphatidylglycerol (PG) did not change (Table 4). In microsomes, PS + PI increased; LPC and PE decreased; and SPH, PC, and PG did not change. In the lamellar bodies PC and PS + PI increased and LPC, SPH, PE, and PG decreased. In extracellular surfactant PS + PI increased and LPC, PC, and PE decreased, whereas SPH and PG did not change. In alveolar macrophages LPC, SPH, and PC did not change, but PS + PI, PE, and PG decreased (Table 4).

**Incorporation of [ $Me$ - $^{14}C$ ]choline into phospholipids of lung slices.** *De novo* synthesis of PC in the adult type II cell

**TABLE 1**  
**Body and Lung Weights and Serum Parameters of Male Rats<sup>a</sup>**

	Control	Zinc-deficient
Gain of body weight (g)	140 $\pm$ 24	87 $\pm$ 25 <sup>d</sup>
Lung weight (g)	1.9 $\pm$ 0.2	1.4 $\pm$ 0.1 <sup>d</sup>
Serum		
Glucose (mg/dL)	85.3 $\pm$ 5	111 $\pm$ 2 <sup>c</sup>
Total lipids (mg/dL)	350 $\pm$ 70	430 $\pm$ 160
Cholesterol (mg/dL)	49.4 $\pm$ 1.4	61.2 $\pm$ 2.6 <sup>c</sup>
TG (mg/dL)	91.1 $\pm$ 3	100 $\pm$ 9.8
Albumin (g/dL)	2.7 $\pm$ 0.02	2.9 $\pm$ 0.05
Globulin (g/dL)	4.9 $\pm$ 0.2	4.0 $\pm$ 0.5 <sup>a</sup>

<sup>a</sup>Results given as mean  $\pm$  SD;  $n = 12$  for each case. Across a row, values with different roman superscript letters indicate significant differences by analysis of Student's test: <sup>b</sup> $P < 0.05$ , <sup>c</sup> $P < 0.01$ , <sup>d</sup> $P < 0.001$ .

proceeds mainly *via* the CDP:choline pathway. The incorporation of choline in PC and SPH was modified by the zinc-deficient diet in relation to what was observed with the control diet. The incorporation of [ $Me$ - $^{14}C$ ]choline increased in PC in the zinc-deficient group compared to the control group. As well, the incorporation was significantly lower in SPH of the zinc-deficient group (Fig. 1).

**Activity of CTP:phosphocholine CYT.** The enzyme activity that takes place in the endoplasmic reticulum membranes increased in the lung of rats fed the zinc-deficient diet compared with those fed the control diet (Table 3).

**Protein concentration in whole lung, intracellular and extracellular compartments.** Proteins in whole lung, lamellar bodies, extracellular surfactant, and macrophages decreased in the zinc-deficient group, but in microsomes the proteins were similar in both cases (Table 3).

## DISCUSSION

The present study was undertaken to investigate the effect of moderate ZD in the adult rat lung. We also evaluated whether

**TABLE 2**  
**Lipids from Whole Lung and Macrophages and Zinc Concentrations in Serum, Lung, and Liver of Male Rat<sup>a</sup>**

ZD plays a role in ARDS. For this purpose, a rat model that permits the induction of moderate ZD was used. This model has the advantage that it permits long-term studies and is physiologically more relevant (3,4,30).

Suboptimal intake of dietary zinc is one of the most common nutritional problems worldwide and has been shown to exist in low-income groups, institutionalized patients, pregnant women and teenagers, and in elderly Americans (31). In our experiment, the low gain of body weight observed in the zinc-deficient group compared to the control group confirms previous results (3,4,27,29). The lower lung weight of the zinc-deficient group compared to the control group is similar to that observed in other organs, such as testes (27). The amount of food consumed by rats was similar in both diets (Table 1). This model typically consumes adequate quantities of food (1,30). In our experimental design, clinical signs such as dermatitis and alopecia were not observed.

Besides some studies of liver zinc uptake (32), very little is known about the utilization of zinc by peripheral tissues (31).

Some tissues lose zinc in order to support other tissues. For example, the zinc concentration in muscle is conserved in zinc-deficient animals, whereas zinc concentrations in bone, liver, and plasma drop (33). Our results show that in plasma, liver, and lung, the contents of zinc decreased in the zinc-deficient rats (Table 2). A reduction in plasma zinc reflects a loss of zinc from bone and liver and an increased risk for development of metabolic and clinical signs of ZD (33).

The amount of globulin (a blood plasma protein) decreased in the zinc-deficient group (Table 1). B-Lymphocyte development and antibody production, particularly immunoglobulin G, is compromised by the zinc-deficient diet (34).

Blood glucose levels increased in the zinc-deficient rats (*P* < 0.01). In ZD, the level of insulin mRNA did not change, suggesting either that translation was impaired or, more likely, that the degradation of insulin was enhanced. Another possible explanation could be an inhibition of insulin release (35).

Alveolar type II cells synthesize lipids and proteins of surfactant that are stored prior to secretion in intracellular organelles called lamellar bodies (36). The results obtained in different fractions of lungs show that ZD after 2 mon of treatment could cause changes in the synthesis, secretion, and clearance of phospholipids in surfactant.

Cholesterol is the major neutral lipid component of extracellular surfactant, and it is accepted that most cholesterol in the lung is taken up from circulating LDL or HDL (37). The increment of cholesterol in serum could be a cause of the increased cholesterol concentration observed in whole lung and macrophages in the zinc-deficient group compared to the control group. Studies utilizing isolated perfused rat lung demonstrated the uptake of lipoproteins from the perfusion medium (38).

The decreased TG concentrations observed in whole lung of the zinc-deficient group could be a consequence of a higher utilization of these as a precursor for the synthesis of phospholipids. In our laboratory we have found that the synthesis of TG decreased in lung and liver of castrated rat while the synthesis of phospholipids increased (39,40). Zinc is also known to play a major role in gene expression and protein

synthesis. The protein concentration decreased in whole lung, lamellar bodies, surfactant, and macrophages with ZD. Dietary constituents such as zinc can alter gene expression directly by interacting with regulatory components in the genome and activating or inhibiting transcription (41).

Although we observed that the protein concentration in microsomes did not change, the data were similar to those previously reported in the liver microsomes from the zinc-deficient animals (5). The enzymatic activities of PE methyltransferase, phosphatidyl-dimethylethanolamine methyltransferase, and choline phosphotransferase had a linear relationship between time and concentration of microsomal protein (5).

The lower protein concentration in the extracellular surfactant could be a consequence of its decreased secretion from lamellar bodies or decreased synthesis of specific proteins by extracellular surfactant. Specific surfactant protein-A is the major surfactant protein in regard to relative abundance as well as size, and its main known functions are support of alveolar macrophage activities and regulation of surfactant secretion (1).

The lower content of phospholipid in extracellular surfactant may be a consequence of increased recycling by alveolar type II cells or type II pneumocytes for synthesis of new surfactant (42) or decreased secretion from lamellar bodies. This change could be associated with a posttranslational change in plasma membrane proteins (43).

The macrophage, a pivotal cell in many immunologic functions, is adversely affected by ZD, which can modify intracellular killing, cytokine production, and phagocytosis (31,35). It has been reported that the amount of macrophages decrease in ZD (31,34); this is coincident with our case because the low content of phospholipids in macrophages could be a consequence of a smaller amount of these cells in extracellular surfactant in the zinc-deficient rats (Table 3).

Adult type II cells may be different from other cells because of their exceptionally high rate of uptake and choline phosphorylation and their high rate of PC synthesis, even at low substrate concentration (22). In our experiments, the rate of PC synthesis from  $[\text{Me-}^{14}\text{C}]$ choline appeared to be sensitive to ZD because the radioactivity increased 12% in PC, but in SPH it decreased 73% in relation to the control group (Fig. 1).

The amount of cholesterol would change the synthesis of PC through stimulation of CYT (44). We do not know if the increased activity of CYT observed in the lung of the zinc-deficient rats is due to a pre- or posttranslational regulation. It may be that the cholesterol concentration is an indirect cause of the increased activity of this enzyme observed in microsomes of rat lung after 2 mon of zinc-deficient diet.

In the present study, the zinc-deficient diet increases the capacity to produce surfactant phospholipids. The amount of phospholipids may be higher due to the increase in type II cells and/or an increase in specific activity of phospholipid-synthesizing enzymes (45). The alveolar epithelial damage is followed *in vivo* by an adaptive or recovery stage in which type II cells proliferate, and in this stage the capacity to produce surfactant phospholipids may be higher (45). Clejan *et al.* (46) indicated that in the liver, small intestine, and testes the synthesis of phospholipids increased in ZD. These changes may be due to the increased availability of substrates as well as to increased activities of the enzymes involved in these processes. Perhaps this situation occurs in the initial period of deficiency, which corresponds with our experimental model.

This is the first demonstration that phospholipid synthesis can be enhanced in the adult rat lung by a physiological stimulus produced by a zinc-deficient diet (*in vivo*) after 2 mon of treatment.

In moderate ZD, the lung changes the pattern of PC. In addition, we know the role of zinc in immunity and its participation in the antioxidant defense system (10). Considering all these facts, ZD implications are important to consider when designing therapies and public health interventions involving targeted zinc supplementation for high-risk groups or groups with certain diseases, such as ARDS.

## ACKNOWLEDGMENTS

# Lipid Metabolism and FA Composition in Tissues of Eurasian Perch *Perca fluviatilis* as Influenced by Dietary Fats

Xueliang Xu\* and Patrick Kestemont

Facultés Universitaires N. D. de la Paix, Unité de Recherches en Biologie des Organismes, 5000 Namur, Belgium.

**ABSTRACT:** Eurasian perch, *Perca fluviatilis*, were fed a semipurified fat-free diet for 4 wk, followed by a 16% feeding supplementation of either olive oil (OO), safflower oil (SO), linseed oil (LO), or cod liver oil (CLO) as the only lipid source in each diet for 10 wk. Significant reductions in total lipid of tissues were observed (31.4% in viscera, 66.7% in muscle, and 74.1% in liver) after feeding the fat-free diet. The SO-, LO-, and CLO-fed fish significantly increased lipid deposition in liver and viscera compared to fish fed the OO diet; however, muscle lipid levels were not significantly affected. Large amounts of dietary 18:1n-9 were incorporated directly into tissue lipids when fish were fed the OO diet. The LO diet significantly elevated 18:4n-3, 20:5n-3, 22:5n-3, and 22:6n-3 in the liver compared to fish fed OO or SO diets, and the n-3/n-6 ratio was 16 times that of the SO group, with significantly high desaturation and elongation products of 18:3n-3. These results suggest that  $\Delta 6$  and  $\Delta 5$  desaturases are highly active in Eurasian perch, and that the enzymes at this dietary n-3/n-6 ratio favor 18:3n-3 over 18:2n-6 as substrate. The SO diet significantly increased 18:3n-6, 20:3n-6, and 22:5n-6 in the liver and significantly decreased EPA and DHA. This indicates that desaturation enzymes were not specifically favoring n-3 over n-6 acids in perch lipid metabolism, and that these elongation and desaturation enzymes were influenced by n-3 and n-6 FA content in the diet. The present study indicates that high tissue content of DHA in the muscle of Eurasian perch was attributable to the greater ability for n-3 acid bioconversion.

Paper no. L8853 in *Lipids* 37, 297–304 (March 2002).

Lipid nutrition research has demonstrated that DHA, EPA, and arachidonic acid (AA) are FA essential for maintaining cell integrity and supporting life in all animals, and are now being recognized as desirable in the human diet (1–8). As n-3 and n-6 18-carbon FA are precursors of these FA, the requirements in fish are, to a large extent, associated with the ability of animals to convert the 18-carbon FA to the longer-chain highly unsaturated FA (HUFA) (9–16). The nutritive value of dietary lipid sources therefore is also closely related to the animal's ability to produce chain elongation and desaturation (17–18), and the type and amount of dietary fat have been shown to be important factors (19–21). It is generally ac-

cepted that marine fish lack one or more of the desaturation enzymes necessary to complete the chain elongation and desaturation of n-3 and n-6 acids such as linoleic acid and linolenic acid to AA, EPA, and DHA (9,11,22–25). In contrast, freshwater fish are capable of performing this conversion by chain elongation and desaturation (24,26–30). Recent interest in fish oil for animal and human nutrition has increased the demand for the world's fish oil supply. At this date, aquaculture already consumes nearly 50% of the world supply of fish oil, and with the continuous rapid growth of world aquaculture, the demand for fish oil will exceed the supply in the near future (25). It is important therefore to develop alternatives to fish oil in fish feed formulations (25). During the past three decades, although many studies on n-3 and n-6 FA nutrition and metabolism have been conducted in both marine and freshwater fish (9,11,22,23,26,28,29,31–33), limited information has been published on lipids, FA composition, and metabolism of percid fish (34–37). In fact, no study has yet addressed the influence of dietary fat source on lipid metabolism and FA composition of Eurasian perch *Perca fluviatilis*.

The purposes of the present study were to investigate the influence of different lipid sources on FA composition and metabolism in the Eurasian perch, and to evaluate the potential alternatives to fish oil in fish feed formulations.

## MATERIALS AND METHODS

**Animals and diets.** Three hundred Eurasian perch (initial mean weight 25 g) were obtained from the Tihange Fish Culture Station (University of Liège, Belgium) and were fed on a semipurified fat-free basal diet in a 1.5 × 1.5 × 1 m fiberglass tank for 4 wk. The basal diet was composed of (by wt%): casein, 47; arginine HCl, 2; blood meal, 7; cornstarch, 18.4; vitamin mix, 2; mineral mix, 2; choline chloride, 0.5; ascorbic acid, 0.2; attractants (alanine, glycine, proline, and betaine), 1; cellulose, 2; carboxymethylcellulose, 2; testing lipid source, 16. (Vitamin and mineral mixes were purchased from INVE Aquaculture NV, Dendermonde, Belgium.) After that, 240 fish were divided randomly into eight 120-L rectangular tanks (30 fish per tank) to provide duplicates of the four dietary treatments. The diets were formulated to meet the protein and lipid requirements of Eurasian perch (36–38) and contained 45% protein and 16% lipid (a cod liver oil diet served

<sup>a</sup>Total lipids were extracted from the diets as described in the Materials and Methods section. FA composition was determined by GC Trace 2000 (Thermo Quest, Carlo Erba, Italy) with on-column injection. Values were expressed as percentages of each FA over total FA identifiable. OO, olive oil; SO, sunflower oil; LO, linseed oil; CLO, cod liver oil. (—), not detected.

as the control treatment) with all ingredients identical except for the different lipid sources (Table 1). Fish were subjected to a natural photoperiod, and the water temperature during the experimental period was kept constant at 23°C. Fish were fed twice a day by hand to satiation for 10 wk. Fish were weighed in biomass at the start and finish of the experiment and at intervals of every 2 wk. Vitamin-free casein, olive oil (OO), sunflower oil (SO), linseed oil (LO), and cod liver oil (CLO) were purchased from Sigma-Aldrich (St. Louis, MO). Vitamin and mineral mixtures were purchased from INVE. An antioxidant (ethoxyquin 0.2%) was added to the oil before adding it to the basal mixture. The FA composition of each diet is presented in Table 1.

**Lipid extraction and FA analysis.** Three fish per tank were killed by a blow to the head, and liver, viscera, and muscle were dissected. Samples were stored at -80°C prior to lipid extraction. Total lipids of liver (0.5–0.8 g) and viscera (1 g) were extracted with chloroform/methanol (2:1, vol/vol) by the method of Folch *et al.* (39), and the total lipids of muscle tissues (50–100 g) were extracted with chloroform/methanol/water (2:2:1.8, by vol) by the method of Bligh and Dyer (40). BHA (0.02%) was added to chloroform/methanol as an antioxidant. The FA of total lipids were converted to methyl esters with BF<sub>3</sub>-MeOH (41), and FA were separated and quantified by GC (GC Trace, 2000; ThermoQuest, Carlo Erba, Italy) using a 30 m × 0.32 mm capillary column (FAME-Wax<sup>TM</sup>; Restek Corporation, Bellefonte, PA). Helium was used as carrier gas, and temperature programming was from 66 to 190°C at 40°C/min and then to 230°C at 2°C/min. Individual methyl esters were identified by comparison with standard fish oil (42) and quantified by the computing integrator Chrom-Card for Trace (ThermoQuest).

**Statistical analysis.** Results of replicate tanks with two different pooled samples from six fish were used for statistical analysis. Values shown in Tables 3–7 are the means ± SD, with *n* values indicating the numbers of different pooled samples per treatment. Statistical analysis was based on a one-way ANOVA processed by Duncan's multiple range test (43). The significant differences between treatments were evaluated at the 0.05 level.

## RESULTS AND DISCUSSION

Feeding fish with a fat-free diet had a pronounced effect on reducing the lipid deposition in liver, viscera, and muscle in Eurasian perch (Table 2). Total lipid content of these tissues dropped significantly, with a 31% fat reduction in the viscera, 66.7% in the muscle, and 74.1% in the liver, indicating that dietary fat is essential for building body lipids in fish. The fat-free diet also affected the FA composition of fish tissues

<sup>a</sup>Total lipids of liver, viscera and muscle are percentage by weight ± SD from three different pooled samples of six fish from duplicate tanks per treatment.

<sup>b</sup>Before feeding fat-free diet.

<sup>c</sup>After feeding fat-free diet.

<sup>d</sup>Values for initial weight and final weight are mean ± SD obtained from two biomass (25–30 fish) of duplicate tanks. Values in the same row with different superscript letters are significantly different (*P* < 0.05).

<sup>e</sup>Weight gain percent = (final weight – initial weight)/initial weight × 100%.

<sup>f</sup>Feed efficiency ratio = (g final biomass – g initial biomass + g dead fish) × (g feed supply)<sup>-1</sup>.

<sup>a</sup>Values are means ± SD obtained from two different pooled samples of six fish from duplicate tanks. Values in the same row (same tissue category) with different superscript letters are significantly different ( $P < 0.05$ ). (—), trace value ( $<0.05$ ) or not detected. SFA, saturated FA; MUFA, monounsaturated FA.

<sup>b</sup>Before feeding fat-free diet.

<sup>c</sup>After feeding fat-free diet.

(Table 3). Proportions of 18:3n-3, 18:4n-3, 20:4n-3, and total monounsaturated FA in the liver were significantly decreased, whereas DHA and total n-3 FA were significantly increased after a 4-wk fat-free diet. At the same time, 18:3n-6, 20:2n-6, 20:4n-6, and 22:4n-6 in the liver were also increased. By contrast, the FA composition of viscera and muscle remained almost unchanged after feeding the fat-free diet. The relatively high levels of HUFA (20:4n-6, 20:5n-3, and 22:6n-3) in the tissue lipids of perch fed the fat-free diet were probably the result of preferential utilization of short- and medium-chain FA as an energy source for basal maintenance, rather than an increase in the absolute content of the HUFA. AA, EPA, and especially DHA were preferentially retained in the larval lipids at the expense of other FA during the periods of starvation (44). The growth responses and feed efficiency of fish

fed four different dietary fat sources are presented in Table 2. The lowest growth rate (30%) and feed efficiency (0.86) were observed in fish fed the OO diet. LO- and SO-fed fish increased significantly in growth response (41 and 71.2%, respectively) and in improved feed efficiency (1.10 to 1.23, respectively) compared to OO fish. These results indicate that n-6 and n-3 FA may be essential for the growth of Eurasian perch. However, the highest growth rate (141.7%) and feed efficiency (1.28) were found in control fish fed the CLO diet. The differences in weight gain between the LO and the CLO fish may be attributed to the better palatability of the CLO diet.

The total lipid content of viscera, muscle, and liver of fish fed OO, SO, LO, or CLO diets is shown in Table 2. Significant differences in total lipid content of liver and viscera were

observed. The SO, LO, and CLO diets significantly increased lipid deposition in viscera as compared to the OO diet-fed fish, and the lipid content of the viscera in LO and CLO fish was significantly higher than that of the SO fish, which was comparable to or even higher than that of fish before feeding the fat-free diet, suggesting that lipid restoration in viscera was efficient compared to that of liver. The liver lipid content in LO fish was the highest among the four dietary fat treatment groups, and the lipid content of liver in CLO fish was significantly higher than that of OO diet-fed fish; however, there was no significant difference in liver lipid content between OO and SO diet-fed fish, and total lipid contents of livers from all dietary treatments were low compared to those of fish before feeding the fat-free diet, which might imply a slow restoration of liver lipids in Eurasian perch. The lipid content in muscle was not significantly affected by dietary fats and remained similar among the four treatments.

FA compositions in liver, viscera, and muscle from fish fed four different lipid sources clearly showed that significant changes were made by their responses to dietary FA (Tables 4–6). Considerable amounts of dietary FA were incorporated

into fish tissues, and extensive chain elongation and desaturation n-6 and n-3 FA were observed among the four dietary treatments. Predominant FA were 16:0, 16:1, 18:1, and 22:6n-3 in OO-fed fish, and among these FA, 18:1 was significantly increased in OO fish livers compared to those of SO, LO, and CLO fish. DHA and total n-3 FA in the livers of OO fish were significantly higher than those in SO fish, but they were significantly lower than those in LO and CLO fish, suggesting that n-3 desaturations were inhibited by the SO diet and enhanced by the LO diet.

The highest single FA was 18:2n-6 in SO-fed fish, accounting for 23.7% of total FA in the liver, 19.7% in the viscera, and 12.3% in the muscle, which was 8.5-, 4.3-, and 4.6-fold that of OO fish, 6.1-, 4.0-, and 4.0-fold that of LO fish, and 5.8-, 4.4-, and 5.9-fold that of CLO fish, respectively. These results suggest that linoleic acid is the type of FA that can be incorporated easily into all tissue lipids in Eurasian perch and stored in the lipid pool without modification. The considerable accumulations of 18:2n-6 have also been reported in liver phospholipids of gilthead bream (*Sparus aurata*) fed a diet containing soybean oil (21). The product of

<sup>a</sup>Viscera may include mostly depot TAG. Values are means ± SD obtained from two different pooled samples of six fish from duplicate tanks per treatment. Values in the same row with different superscripts are significantly different ( $P < 0.05$ ). (—), trace value ( $< 0.05$ ) or not detected. For abbreviations see Tables 2 and 3.

$\Delta 6$  desaturation and elongation of 18:2n-6, 20:3n-6, was 17-fold that of the corresponding n-3 desaturation product, 20:4n-3, indicating that the  $\Delta 6$  desaturation enzyme was also favoring 18:2n-6 as a substrate when dietary 18:3n-3 content was low. A substantially high level of 22:5n-6 (9.7-fold that of LO fish) with a low level of 20:4n-6 was found in the livers of SO fish in the present study. This indicates that the conversion of 20:3n-6 to 20:4n-6 might be reduced during SO diet feeding or that the utilization of 20:4n-6 for 22:5n-6 increased and was more rapid during the same period, leading to the accumulation of 22:5n-6 as one of the predominant metabolic products of 18:2n-6. The n-3/n-6 ratios in the tissues of fish fed the SO diet were significantly decreased compared to those of OO, LO, and CLO fish, especially in the liver. The n-3/n-6 ratio was 0.4, almost 11.3 times lower than that of OO fish, 13 times lower than that of CLO, and 15.3 times lower than that of LO fish. Significant increases in  $\Delta 6$  and  $\Delta 5$  desaturation and elongation products of 18:2n-6 were found in SO-fed fish, and a significant decrease in 22:6n-3 and total n-3 FA was observed in SO-fed fish. These signifi-

cant changes in n-3/n-6 ratio and FA composition of fish fed different dietary fats indicate that the competition and inhibition between 18:2n-6 and 18:3n-3 for further desaturation and elongation were greatly influenced by the type of dietary fat and the content of n-3 and n-6 FA in the diet. Similar changes in FA composition and n-3/n-6 ratio have also been reported for salmon, rainbow trout, and tilapia (33,45–47).

Substantial amounts of chain elongation and desaturation products of 18:3n-3, such as 18:4n-3, 20:3n-3, 20:4n-3, 20:5n-3, 22:5n-3, and 22:6n-3, were found in the liver and the viscera of fish fed the LO diet combined with few or no corresponding products of 18:2n-6. This implies that chain elongation and desaturation of 18:3n-3 were actively occurring and that desaturation enzymes at this dietary n-3/n-6 ratio probably favored 18:3n-3 over 18:2n-6 as a substrate in Eurasian perch lipid metabolism. This is in agreement with previous studies in rats (48), rainbow trout (33), and Atlantic salmon (49). FA composition of the muscle from fish fed four diets remained similar, regardless of different dietary fats. DHA content and total n-3 FA in all tissues of LO fish were

comparable to or even higher than those of control fish fed the CLO diet, indicating a high capability of converting 18-carbon n-3 acids to the longest-chain HUFA possible in Eurasian perch. Unlike in carp and other fish, linoleic acid may be incorporated to a large extent in fish tissues; a relatively low percentage of linolenic acid was found in tissues of LO-fed perch, along with high percentages of 20:5n-3 and a high level of 22:6n-3. A high dietary 18:3n-3 content with low levels of 18:3n-3 in fish tissues is clear evidence that Eurasian perch may readily catabolize 18:3n-3 in excess of their biological needs; 18:3n-3 not only serves as a precursor for chain elongation and desaturation, but also Eurasian perch metabolize it as an energy source. Consistent with our finding, Bell *et al.* (50) also reported that relatively limited amounts of 18:3n-3 were found in the phospholipids of Atlantic salmon fed an LO diet as compared to a large amount of 18:2n-6 deposition in fish fed a sunflower oil diet. The present study shows that the different characteristics of deposition and utilization between 18:3n-3 and 18:2n-6 may be the key difference in these two important FA in fish lipid metabolism. However, the essentiality of 18:3n-3 for perch and its specific

biological and physiological functions remain unclear. Evidence of a specific metabolic function for 18:3n-3 other than as a precursor of n-3 HUFA has not been published (51).

The existence and function of  $\Delta 4$  have been disputed during the past decade. Low  $\Delta 4$  desaturase activities and a possibly related product have been reported by some investigators (52–55). However, recent evidence in rainbow trout with original findings in rats has reinforced the argument of DHA synthesis in that desaturations of both PUFA of the n-3 and n-6 series through the  $\Delta 6$  and  $\Delta 5$  enzymes are used to produce 24:6n-3 and 24:5n-6, which are then chain-shortened to 22:6n-3 and 22:5n-6, respectively, by  $\beta$ -oxidation (56–57). Since only low  $\Delta 4$  desaturase activity has been reported in fish, the large amounts of DHA synthesis found in the present study most likely resulted from this peroxisomal process. However, the exact DHA synthesis process in perch awaits further investigation.

Compared to marine fish, most freshwater fish contain high levels of 18-carbon n-6 and n-3 FA, but also substantial concentrations of EPA and DHA (10,24,58). The presence of substantial amounts of DHA with relatively low EPA was also

observed in our previous studies on Eurasian perch (36). Here high concentrations of DHA and less EPA were found in all tissue lipids of LO and CLO fish, which suggests that these FA patterns are the distinguishing feature and physiological nature of Eurasian perch lipids and are probably related to the high  $\Delta 6$  and  $\Delta 5$  desaturation enzyme activities that lead to the accumulation of DHA. Therefore, active metabolic bioconversion of n-3 and n-6 FA, and n-3 and n-6 FA competition and inhibition observed in the present study are the most appropriate explanations for the similarity of DHA concentration in LO and CLO fish and for the differences in n-3 and n-6 FA composition in LO and SO fish, all of which are closely linked to the influences of their dietary fats (30).

In summary, the results of the present study with Eurasian perch confirm that the competition for the same desaturation enzyme between n-3 and n-6 FA is greatly influenced by dietary fat, and perhaps is regulated by the content of n-3 and n-6 FA in the diet. Although it contains relatively low fat in the muscle, the Eurasian perch is a potential nutritional food fish for human consumption with a high DHA content. In view of the great ability for bioconversion of n-3 and n-6 FA observed in the present study of Eurasian perch, LO is a promising alternative to fish oil in perch feed formulations in terms of DHA synthesis. However, before drawing final conclusions, more work is needed to determine to what extent LO may replace the fish oil in the diet, as well as to better understand the effects of the dietary n-3/n-6 ratio on the lipid metabolism of fish in general.

## ACKNOWLEDGMENTS

# Novel Methoxylated FA from the Caribbean Sponge *Sphaciospongia cuspidifera*

Néstor M. Carballeira\* and Johanna Alicea

Department of Chemistry, University of Puerto Rico, San Juan, Puerto Rico 00931-3346

**ABSTRACT:** The  $\Delta^6$  monoenoic methoxylated FA (6Z)-2-methoxy-6-heptadecenoic acid and (6Z)-2-methoxy-6-octadecenoic acid were identified for the first time in nature in the phospholipids from the uncommon Caribbean sponge *Sphaciospongia cuspidifera*. These findings expand the occurrence of  $\Delta^6$  2-methoxylated FA to  $C_{17}$ – $C_{18}$  chain lengths and establish a new FA biosynthetic possibility for these marine organisms. The novel methoxylated FA also could have originated from the phospholipids of a bacterium in symbiosis with the sponge.

Paper no. L8925 in *Lipids* 37, 305–308 (March 2002).

SCHEME 1

Methoxylated lipids have attracted much attention for their intriguing biological activities. Earlier work by Hallgren and collaborators with methoxy-substituted glycerol ethers from Greenland shark liver oil established their antibiotic effect against several bacterial strains, including *Streptococcus* and *Staphylococcus* (1,2). Some of these methoxy-substituted glycerol ethers also display antitumor activity against a variety of human tumors (2). Most recently, several phosphocholines possessing 2'-methoxy acyl chains, such as 1-*O*-(2'-methoxyhexadecyl)-*sn*-glycero-3-phosphocholine and 1-*O*-(2'-methoxy-4'*Z*-hexadecenyl)-*sn*-glycero-3-phosphocholine, were isolated from the sponge *Spirastrella abata* (3). These methoxylated lysophospholipids were also significantly cytotoxic against specific lines of lung, ovarian, and skin cancer cells with  $ED_{50}$  values of 4–6  $\mu\text{g/mL}$  (3).

Whereas the previous examples relate to ether lipids, some work has also been published regarding methoxylated phospholipid FA from marine sponges (4,5). For example, our group reported a whole series of  $\Delta^6$  2-methoxylated FA with  $C_{14}$ – $C_{16}$  chain lengths from the Caribbean sponge *Callyspongia fallax* (4). In addition, we showed that short-chain methoxylated FA such as (6Z)-2-methoxy-6-hexadecenoic acid display moderate antibacterial activity against Gram-positive bacteria (5). Despite these efforts, other  $\Delta^6$  2-methoxylated FA, in particular those with  $C_{17}$ – $C_{18}$  chain lengths, remain unknown. It is quite probable that these

$C_{17}$ – $C_{18}$   $\Delta^6$  2-methoxylated FA also display antimicrobial and/or antitumor activity as either FFA or bound to phospholipids. Therefore, as part of our continuing program in the isolation and characterization of novel FA from marine organisms we report the identification of the 2-methoxylated FA (6Z)-2-methoxy-6-heptadecenoic acid (1) and (6Z)-2-methoxy-6-octadecenoic acid (2) (Scheme 1) from the uncommon Caribbean sponge *Sphaciospongia cuspidifera* Lamarck (class Demospongiae, order Hadromerida, family Clionidae) (6). This finding expands the occurrence of  $\Delta^6$  2-methoxylated normal-chain FA in sponges to  $C_{14}$ – $C_{18}$  chain lengths.

## MATERIALS AND METHODS

**Instrumentation.** FAME were analyzed by direct ionization using GC–MS (Hewlett-Packard 5972A MS ChemStation) at 70 eV equipped with a 30 m  $\times$  0.25 mm special performance capillary column (HP-5MS) of polymethylsiloxane cross-linked with 5% phenyl methylpolysiloxane. The temperature program was as follows: 130°C for 1 min, increased at a rate of 3°C/min to 270°C, and maintained for 30 min at 270°C.

**Sponge collection.** *Sphaciospongia cuspidifera* Lamarck was collected from Cayo Enrique reef near La Parguera, Puerto Rico, in March 1991 at 20 m depth by scuba. A voucher specimen is stored at the Chemistry Department of the University of Puerto Rico, Río Piedras campus (6).

**Extraction and isolation of phospholipids.** The sponge (50 g) was carefully cleaned and cut into small pieces. Immediate extraction after collection with 3  $\times$  300 mL of  $\text{CHCl}_3/\text{MeOH}$  (1:1) yielded the total lipids (4 g). The neutral lipids (0.11 g), glycolipids (1.0 g), and phospholipids (1.1 g) were separated by column chromatography on Si gel (60–200 mesh) from 3 g of total lipids using the procedure of Privett *et al.* (7).

Abbreviations: DMDS, dimethyl disulfide; ECL, equivalent chain-length; FCL, fractional chain-length.

**Derivatives.** The fatty acyl components of the phospholipids were obtained as their methyl esters (0.011 g) by reaction of the phospholipids (1.07 g) with methanolic HCl followed by column chromatography. They were stored at  $-20^{\circ}\text{C}$  in hexane with BHT as antioxidant until analyzed. The methyl esters were hydrogenated in 10 mL absolute methanol with catalytic amounts of platinum oxide ( $\text{PtO}_2$ ). The double-bond positions in these compounds were determined by dimethyl disulfide (DMDS) derivatization following a procedure that was previously described (8,9).

## RESULTS AND DISCUSSION

The Caribbean sponge *S. cuspidifera* presented a typical sponge phospholipid profile with PE and PS as the two most abundant phospholipids. Acid methanolysis provided a rather complex phospholipid FA composition of around 68 identifiable FA, as shown in Table 1. FA chain lengths ranged between  $\text{C}_{10}$  and  $\text{C}_{27}$ , mainly consisting of monoenoic and dienoic FA. The monoenoic FA were particularly abundant in

this sponge; they made up around 22% of the total FA composition. However, a most interesting finding was the identification of a whole series of n-7 and n-9 monounsaturated FA with chain lengths between  $\text{C}_{18}$  and  $\text{C}_{26}$ . As expected, the most characteristic FA from *S. cuspidifera* was the (5Z,9Z)-5,9-hexacosadienoic acid, which was identified in this sponge together with other  $\Delta^{5,9}$  diunsaturated very long chain acids such as the (5Z,9Z)-5,9-tetracosadienoic acid and the (5Z,9Z)-5,9-heptacosadienoic acid (6). All of these FA were characterized as methyl esters by GC-MS, and the double bond positions in the monoenoic esters were elucidated by DMDS derivatization as well as by GC comparisons with authentic standards.

The most interesting series of FA from *S. cuspidifera* were the monounsaturated FA (6Z)-2-methoxy-5-hexadecenoic acid, (5Z)-2-methoxy-6-hexadecenoic acid, (6Z)-2-methoxy-6-heptadecenoic acid (**1**), and (6Z)-2-methoxy-6-octadecenoic acid (**2**). The methoxylated acids **1** and **2** are unprecedented in nature. The relative GC retention times of their methyl esters, the mass spectra of both the methyl esters and

<sup>a</sup>Unprecedented in nature.

the corresponding DMDS derivatives, and corroboration of these mass spectra with synthetic analogs provided the basis for their characterization (5). For example, methyl (6Z)-2-methoxy-6-heptadecenoate exhibited unusual chromatographic properties, namely, an equivalent chain length (ECL) value of 17.91, for which the fractional value is well in agreement with those reported in the literature for other  $\Delta^6$  mono-unsaturated linear chain  $\alpha$ -methoxylated methyl esters (10). The mass spectrum of methyl (6Z)-2-methoxy-6-heptadecenoate contained a molecular ion peak at  $m/z$  312 and an intense peak at  $m/z$  104, arising from a favorable McLafferty rearrangement (Table 2). The additional 30 amu, when compared with the typical base peak of saturated FAME at  $m/z$  74, could only be accounted for by a methoxy group at the 2-position. Important for the structural characterization were also the prominent fragmentation ions at  $m/z$  280 ( $M^+ - \text{MeOH}$ ),  $m/z$  253 ( $M^+ - \text{CO}_2\text{CH}_3$ ), and  $m/z$  221 ( $M^+ - \text{CO}_2\text{CH}_3 - \text{MeOH}$ ), which confirmed the  $\alpha$ -methoxylation (11). The double bond at C-6 was determined by preparing the corresponding DMDS adduct, a convenient method for the location of double bonds by mass spectrometry (8,9). For example, the mass spectrum of methyl 2-methoxy-6,7-bis(methylthio)heptadecanoate afforded a molecular ion peak at  $m/z$  406 and an  $M^+ - 59$  peak at  $m/z$  347. The double bond was readily determined to be at carbon 6 by the prominent fragmentations at  $m/z$  205 [ $\text{C}_9\text{H}_{17}\text{SO}_3$ ] $^+$  and 201 [ $\text{C}_{12}\text{H}_{25}\text{S}$ ] $^+$ , since this constitutes cleavage between carbons 6 and 7. There was also an abundant ion at  $m/z$  173 [ $\text{C}_8\text{H}_{13}\text{SO}_2$ ] $^+$  resulting from the loss

of methanol from the  $m/z$  205 fragment. Upon catalytic hydrogenation ( $\text{PtO}_2$ ), methyl (6Z)-2-methoxy-6-heptadecenoate yielded the normal-chain methyl 2-methoxyheptadecanoate as evidenced by a strong fragmentation at  $m/z$  255 ( $M^+ - 59$ ) in the mass spectrum of the latter. The experimental data thus support methyl (6Z)-2-methoxy-6-heptadecenoate as the most probable structure for this methyl ester. In a similar fashion methyl (6Z)-2-methoxy-6-octadecenoate was characterized (Table 2). A GC co-elution of methyl (6Z)-2-methoxy-6-hexadecenoate from *S. cuspidifera* with a synthetic sample confirmed a Z double bond for the natural methyl ester (5). In addition, a straight line was obtained when the retention times of the  $\alpha$ -methoxylated  $\Delta^6$ -16:1,  $\Delta^6$ -17:1, and  $\Delta^6$ -18:1 methyl esters were plotted against chain length, thus also supporting the Z double bond stereochemistry for the  $\Delta^6$ -17:1 and  $\Delta^6$ -18:1 methoxylated methyl esters.

The novel FA identified in this sponge expand the present scheme ( $2\text{-OCH}_3\text{-}n:0 \rightarrow \Delta^6$  desaturase  $\rightarrow 2\text{-OCH}_3\text{-}n:1$ ,  $n = 14\text{--}18$ ) of possible biosynthetic pathways for  $\text{C}_{14}\text{--}\text{C}_{18}$   $\alpha$ -methoxylated FA in nature. *Sphaciospongia cuspidifera* is interesting because, despite the fact that it contains a series of 2-OME- $n:1$   $\Delta^6$  FA with chain lengths between 16 and 18 carbons, it also contains a 2-OME-16:1  $\Delta^5$  FA, in addition to what was originally reported (8). With the exception of the 2-methoxyheptadecanoic acid, which has not been encountered in nature, the saturated  $\text{C}_{16}$  and  $\text{C}_{18}$  2-methoxylated FA have been reported from the phospholipids of several sponges (12). Therefore, it is logical to assume that these saturated

<sup>a</sup>DMDS, dimethyldisulfide; ECL, equivalent chain-length.

2-methoxylated FA are the biogenetic precursors of the  $\Delta^6$  monounsaturated 2-methoxylated FA. However, *S. cuspidifera* is unusual because both  $\Delta^5$  and  $\Delta^6$  desaturases operate with the methoxylated FA from this sponge, but the  $\Delta^5$  desaturation seems to be limited to  $C_{16}$  chain lengths. In any instance, the identification of small amounts (3.5%) of  $\alpha$ -methoxylated  $C_{16}$ – $C_{18}$  FA in *S. cuspidifera* suggests that these acids are probably of bacterial or endosymbiotic origin.

As to the structure of the possible phospholipids containing the methoxylated FA, we can only speculate at this point. One possibility is novel PE with  $\Delta^5$  or  $\Delta^6$   $\alpha$ -methoxylated FA at the 2-position, and a saturated nonmethoxylated FA at the 1-position, similar to the structures of the hydroxylated PE from myxobacteria (13). However, these 2-methoxylated FA could also occupy the 1-position of PC with the nonmethoxylated FA at the 2-position, analogous to the lysoPC isolated from the sponge *S. abata* (3).

# Changes in Lipid Molecular Species and Sterols of Microsomal Membranes During Aging of Potato (*Solanum tuberosum* L.) Seed-Tubers

Vladimir Zabrouskov and N. Richard Knowles\*

Department of Horticulture and Landscape Architecture, Washington State University, Pullman, Washington 99164-6414

**ABSTRACT:** Changes in sterols and the molecular species composition of polar lipids from microsomal membranes were characterized as a prerequisite to determining how lipid chemistry affects membrane susceptibility to peroxidation during aging of potato tubers. Polar lipid content of the microsomal fraction fell 17% (protein basis) as tubers aged from 2 to 38 mon at 4°C. In younger seed-tubers, PC concentration (protein basis) was the highest, followed by digalactosyldiacylglycerol (DGDG), PE, monogalactosyldiacylglycerol (MGDG), and PI. PC and PE increased 14 and 27%, respectively, whereas glycolipids fell 64 and PI 43% with advancing age. These changes resulted in PC and PE dominating the microsomal membrane lipids of 38-mon-old tubers. Nonpositional analysis of lipid molecular species across lipid pools showed an increase in 16:0/18:3, 18:3/18:3, and 18:2/18:3 (PC and PE only), and a decline in 18:2/18:2 and 16:0/18:2 (except for MGDG) with advancing tuber age. The increase in 18:3-bearing species effected a linear increase in double-bond index (DBI) of PC and PE during aging. The DBI of DGDG did not change with age; however, it fell 65% for MGDG, resulting in an overall decrease in average microsomal DBI. In addition,  $\Delta$ 5-avenasterol and stigmastanol concentrations increased 1.6- and 3.3-fold, respectively, effecting a significant increase in the sterol/phospholipid ratio with advancing tuber age. The increase in sterol/phospholipid ratio and the possibility that the increased unsaturation of microsomal membranes reflects a compensatory response to maintain optimal membrane function in light of the age-induced loss of galactolipid and PI are discussed.

Paper no. L8948 in *Lipids* 37, 309–315 (March 2002).

A decline in membrane integrity, leading to increased leakage and loss of selective permeability, is a central feature of the deterioration accompanying senescence in plants. Studies on senescing plant tissues using electron spin resonance (1), fluorescence depolarization (2), and freeze-fracture electron microscopy (3) have shown decreases in membrane fluidity, development of gel-phase domains, and increases in membrane permeability (4). Extensive phospholipid catabolism and lipid peroxidation during senescence (5) effect membrane

compositional changes (6) that include increases in sterols and sterol/phospholipid ratio (2,7), both of which are intrinsically involved in rigidification and the loss of membrane function. Furthermore, senescence-induced changes in phospholipid molecular species have been shown to increase the susceptibility of membrane lipids to enzymatic degradation (8–10).

While the relationships between lipid peroxidation and membrane deterioration during senescence have been investigated extensively, no detailed information is available on lipid catabolism in plant tissues during natural aging, as distinct from senescence, due primarily to the lack of an appropriate model system. Potato tubers are nonsenescing vegetative propagules that can maintain viability in storage for as long as 3 yr (4°C, 95% RH) and are thus well suited for studying the process of aging in plants, particularly as it relates to loss of membrane integrity and lipid catabolism. In addition to changes in plant growth potential (11), aging of seed-tubers is accompanied by increased respiration (12), decreased protein synthesis (13), increased protein catabolism (14), and oxidative stress (15).

As tuber age advances through 24 mon at 4°C, lipid peroxidation (16) contributes to a decrease in double-bond index (DBI) of total polar lipids that correlates with increased membrane permeability (17) and oxidative catabolism (15). Indeed, lipid peroxidation appears to play a pivotal role in the collective deterioration of metabolic systems during aging of seed-tubers. Using tubers transformed with sense constructs of FA desaturases, we demonstrated that high levels of linolenate in cell membranes enhanced oxidative stress and overall metabolic rate, which, in turn, accelerated aging and loss of growth potential (Zabrouskov, V., Kumar, G.N.M., Spychalla, J.P., and Knowles, N.R., unpublished data). Hence, compositional changes in lipid molecular species can render membranes more conducive to peroxidative damage. To date, detailed studies of lipid metabolism during tuber aging have been based mainly on relatively short-term durations (less than 12 mon) (18,19). Changes in lipid molecular species (vs. total esterified FA) and sterols during long-term aging of tubers, in relation to the susceptibility of membrane lipids to peroxidation and oxidative stress, are unknown.

This study characterizes the effects of age on lipid compositional changes (including sterols) in microsomal membranes of potato tubers. Molecular species analysis revealed that age-induced alterations in acyl chain composition and constituent pairing depended on lipid class. Age-induced changes to a

Abbreviations: DBI, double-bond index; DGDG, digalactosyldiacylglycerol; DHB, 2,5-dihydroxybenzoic acid; MALDI TOF MS, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry; MGDG, monogalactosyldiacylglycerol; PVP, polyvinylpyrrolidone.

given molecular species with a defined pair of acyl chains can thus be quite different from those of other species with the same pair of chains. A detailed account of these modifications is essential to gain a better understanding of the various metabolic processes that influence membrane susceptibility to deterioration during aging.

## MATERIALS AND METHODS

*Chemicals, membrane isolation, and lipid extraction.* All solvents (HPLC grade) and buffer salts were from J.T. Baker (Phillipsburg, NJ) and were used without further purification. 2,5-Dihydroxybenzoic acid (DHB) was from Aldrich Chemical Co. (Milwaukee, WI). The lipid and sterol standards were purchased from Avanti Polar Lipids (Alabaster, AL) and Supelco (Supelco Inc., Bellefonte, PA), respectively. Certified potato seed-tubers (Elite III, cv. Russet Burbank) were obtained at harvest and stored at 4°C (95% RH) for up to 38 mon.

Microsomal membranes were isolated as described by Kumar and Knowles (15), with modifications. After the appropriate storage interval, approximately 50 g of the apical third of each of three or four tubers (200 g total) was collectively homogenized with a Braun (Type 4-172, Braun Canada, Ltd., Mississauga, Ontario) hand homogenizer in 200 mL of ice-cold extraction medium. The medium (pH 7.5) contained 75 mM MOPS, 250 mM sucrose, 1 mM EDTA, 1 mM EGTA, 2.5 mM sodium bisulfite, 1.5% (wt/vol) polyvinylpyrrolidone, 1 mM *n*-propylgallate, 10 µg/mL BHT, and 1 mM DTT. The homogenate was filtered through two layers of Miracloth (Calbiochem, San Diego, CA) and the filtrate was centrifuged at 5000 × *g* for 5 min to sediment starch. The resulting supernatant was centrifuged at 10,000 × *g* for 30 min and the pellet discarded. The supernatant was then centrifuged at 105,000 × *g* for 45 min to pellet microsomal membranes. Microsomes were washed and pelleted twice (105,000 × *g*, 45 min) with washing buffer (pH 7.5), containing 5 mM MOPS, 250 mM sucrose, 1 mM EGTA, 1 mM DTT, 10 µg/mL BHT, and 10 mM KCl. The microsomal pellet was suspended in 1 mL of washing buffer and stored at -80°C until further analysis.

Lipids were extracted from microsomal membranes according to Folch *et al.* (20), and phospholipids and galactolipids were quantified with an Iatroscan (model MK-5; Iatron Labs, Tokyo, Japan). The Iatroscan couples TLC separation of analytes with FID. To separate lipid classes, approximately 1.5 µg of total lipid was spotted on a silica gel rod that was developed in chloroform/methanol/ammonium hydroxide/water (45:28:0.5:1, by vol). The rods were then processed in an Iatroscan. Hydrogen and air flow rates for the Iatroscan FID were 160 mL/min and 2 L/min, respectively. The rack speed for the silica gel rods was 30 cm/min. For analysis of FAME, lipid classes were separated by TLC (silica gel G) using chloroform/methanol/ammonium hydroxide/water (45:28:0.5:1, by vol) as the mobile phase. Lipid classes [PC, PE, PI, monogalactosyldiacylglycerol (MGDG), digalactosyldiacylglycerol (DGDG)] were eluted from the silica gel (twice)

with chloroform/methanol (1:1, vol/vol) at 55°C. Eluates were dried in a rotary evaporator and dissolved in chloroform. FAME were prepared by dissolving approximately 200 µg of lipid in 200 µL of hexane and transesterifying with 2 mL of methanol/BF<sub>3</sub> reagent (Sigma Chemical, St. Louis, MO) for 1.5 h at 90°C. After adding 1 mL of 0.088% (wt/vol) NaCl, FAME were extracted with 1 mL of hexane. FAME were separated on a 30 m × 0.25 mm × 0.25 µm INNOWax capillary column (Agilent Technologies, Wilmington, DE) and quantified using an HP 6890 GC (Agilent Technologies). The oven temperature was initially 160°C for 1 min and then increased (8°C/min) to 233°C. Injection volume was 1 µL, and the injector and detector temperatures were 240 and 250°C, respectively. Helium was the carrier gas at 1.7 mL/min.

*Nonpositional analysis of lipid molecular species.* PC and PE were digested to their corresponding DAG with phospholipase C in preparation for molecular species analysis by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) (21). MGDG and DGDG were left intact for this analysis. DHB in acetone (0.5 M) was used as the matrix. The lipids in chloroform were mixed (1:5 vol/vol) with the matrix solution; and 1 µL, containing 30 to 100 ng of lipid, was applied to the sample plate. MALDI spectra were obtained using a PerSpective Biosystems (Framingham, MA) Voyager DE-RP time-of-flight mass spectrometer equipped with a nitrogen laser (337 nm). All spectra were the average of 256 laser shots. The laser was adjusted to one-third of maximum power, depositing approximately 100 µJ per laser pulse. The applied potential was 25,000 V, and a focusing guide wire was held at a potential of 0.1% of the accelerating voltage. A delay time of 100 ns was used between the time of the laser pulse and application of the accelerating voltage. The instrument was set in the reflector mode and spectra were acquired from 0 to 5000 *m/z*. A spectrum for each sample was acquired from two wells, and the results were averaged. Spectra of standard PC were used to calibrate the instrument. FAME data were used to determine certain isomeric abundances within the isobaric mix of particular molecular species (such as 18:1/18:2 and 18:0/18:3). Where FAME data were insufficient to deduce isomeric abundances (as in the case of DGDG and MGDG), the molecular species are presented as an isomeric mix.

*Sterol analysis.* Sterols were analyzed as described by Toivo *et al.* (22) with an acid hydrolysis step to account for glycosylated moieties. Microsomal lipids (0.25 to 1 mg in chloroform) were spiked with 20 µg of 5- $\alpha$ -cholestane as an internal standard, dried under N<sub>2</sub>, and dissolved in 10 mL of 1 M HCl in denatured ethanol (90%, Baker). The lipids were incubated for 1 h at 65°C in a dry bath. Samples were then cooled to room temperature prior to the sequential addition of 0.9 mL of 60% (wt/vol) aqueous KOH and 5 mL of 2.84% (wt/vol) KOH in denatured alcohol. After being shaken for 1 min, the mixture was incubated for 1 h at 65°C in a dry bath, cooled, and transferred to 50-mL plastic tubes with 8 mL of water (HPLC grade). Sterols were extracted with 10 mL of hexane (three times). The extracts were combined and dried in

a rotary evaporator (40°C). The underivatized free sterols were solubilized in 200  $\mu$ L of chloroform and 1  $\mu$ L was injected into a GC (HP 6890) equipped with a 15 m  $\times$  0.25 mm  $\times$  1  $\mu$ m DB-5MS column (J&W Scientific, Folsom, CA). Separation and quantification of sterols was accomplished in isothermal mode (285°C), and injector and detector temperatures were 300°C. The identity of sterols was confirmed based on retention times of authentic standards and GC-MS. Microsomal protein was quantified according to Bradford (23), following solubilization of the membranes in 0.05% (w/w) Triton X-100.

Concentrations of microsomal lipids and sterols were expressed on a protein basis to reflect the dynamics outside the particular lipid pool. Microsomal protein declined with age (~25% from 2 to 38 mon), thus contributing to the trends characterized in this study. However, the majority of age-induced changes in lipid molecular species were far greater than what could be attributed to changes in protein. Hence, in most cases, the trends shown on a protein basis were also evident on a mole percent basis.

**Experimental design.** The study was conducted as a randomized complete block design with four seed-tuber ages (2, 14, 26, and 38 mon of storage at 4°C) replicated three times. Variation attributable to age was partitioned in ANOVA. Treatment means are reported  $\pm$  SE.

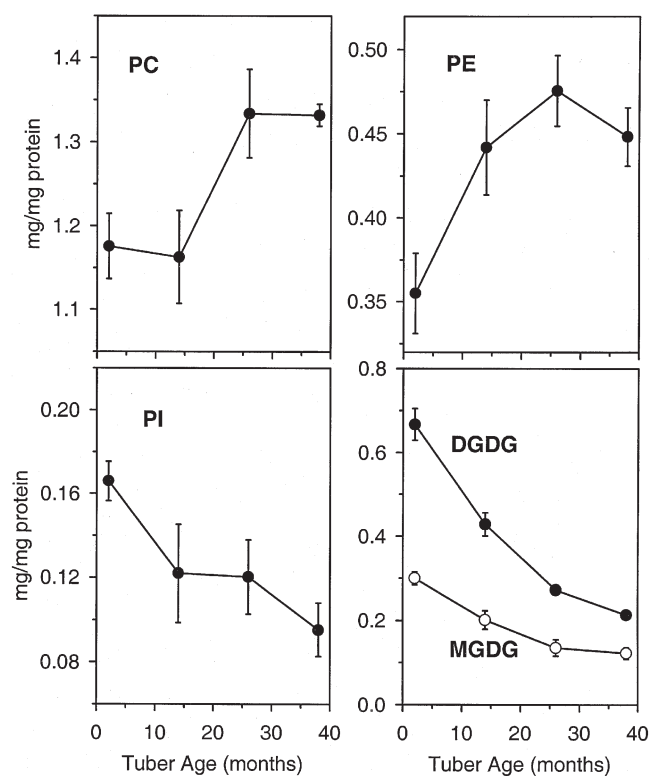

## RESULTS

The concentration of total polar lipids in microsomal membranes fell 17% (protein basis) as tuber age advanced from 2 to 38 mon (Fig. 1). In 2-mon-old tubers, PC accounted for 45%, DGDG 25%, PE 13%, MGDG 11%, and PI 6% of total polar lipid. The concentrations of PC and PE increased 14 and 27%, respectively, whereas glycolipids (DGDG and MGDG) fell 65% and PI 43% with advancing age (Fig. 1). These age-induced changes resulted in PC and PE dominating the microsomal lipids of 38-mon-old tubers, where they accounted for 60.3 and 20.4% of polar lipid, respectively.

Four major (16:0/18:2, 18:2/18:2, 18:2/18:3, and 16:0/18:3) and three relatively minor molecular species (18:0/18:2, 18:1/18:2, and 18:3/18:3) were identified within the PC pool (Fig. 2). Near-linear increases in PC 16:0/18:3, 18:2/18:3, 18:3/18:3, and 18:1/18:2 ranged from 1.7- to 8.5-fold through 38 mon of storage, reflecting a major effect of age on increased unsaturation. On the other hand, PC 16:0/18:2, 18:2/18:2, and 18:0/18:2 declined with advancing age, the greatest decline occurring over the initial 13 mon of storage.

PE had the same molecular species profile as PC; however, aging induced changes that differed from those of PC (Fig. 3). The greatest increases in PE 16:0/18:3, 18:2/18:3, 18:3/18:3, and 18:1/18:2 occurred during the initial 13 mon of storage. Furthermore, PE 16:0/18:2 and 18:2/18:2 remained relatively constant through the entire 38-mon storage period. These changes effected an overall increase in the level of PE, elevating it from third- to second-most abundant polar lipid in microsomal membranes as tubers aged through 38 mon.

DGDG had three major (16:0/18:2, 18:2/18:3, isobaric mix

**FIG. 1.** Age-induced changes in the concentrations of phospho- and galactolipids in microsomal membranes from potato tubers. DGDG, digalactosyldiacylglycerol; MGDG, monogalactosyldiacylglycerol. Error bars indicate SE.

of 18:2/18:2 + 18:1/18:3) and four minor (16:0/18:3, 18:3/18:3, isobaric mix of 18:0/18:2 + 18:1/18:1, 18:1/18:2 + 18:0/18:3) molecular species (Fig. 4). Except for 16:0/18:3, which remained constant with age, all molecular species declined proportionally during aging, resulting in a 65% drop in DGDG concentration of microsomal membranes and no change in the DBI of this pool.

Three major (18:2/18:3, 18:3/18:3, isobaric mix of 18:2/18:2 + 18:1/18:3) and four minor (16:0/18:2, 16:0/18:3, isobaric mix of 18:1/18:2 + 18:0/18:3, and 18:0/18:2 + 18:1/18:1) molecular species made up the initial MGDG pool at 2 mon (Fig. 5). Similar to DGDG, the concentrations of several MGDG molecular species (16:0/18:2, 18:2/18:3, 18:3/18:3, 18:2/18:2 + 18:1/18:3) fell with advancing age, while 16:0/18:3 increased from undetectable levels in 2-mon-old tubers to 5.4  $\mu$ g/mg protein in 38-mon-old tubers. Unlike DGDG, these changes defined a 65% drop in DBI, reflecting a significant loss of relative unsaturation in the MGDG fraction of membranes during aging. Moreover, this age-induced drop in unsaturation of MGDG offset increases in the DBI of PC and PE, resulting in an overall decline in DBI of polar lipids in the microsomal membrane fraction.

The total sterol fraction of microsomal membranes from potato tubers contained  $\Delta$ 5-avenasterol,  $\beta$ -sitosterol, stigmasterol, and cholesterol, in order of decreasing concentration (Fig. 6A). Concentrations of  $\Delta$ 5-avenasterol and stigmasterol increased 1.6- and 3.3-fold, respectively, as tuber age advanced

to 38 mon, while  $\beta$ -sitosterol and cholesterol remained relatively constant. These changes resulted in a 57% increase in total sterol concentration over the aging interval (Fig. 6B). The sterol/phospholipid ratio also increased (41%) as tuber age advanced from 2 to 26 mon, stabilizing thereafter (Fig. 6B, inset).

## DISCUSSION

This study provides the first comprehensive characterization of changes in lipid composition of microsomal membranes during natural aging of potato tubers over their entire storage life. Results indicate that head group and FA composition of polar lipids are important determinants of the susceptibility of individual lipid species to age-induced metabolism. Specific mono- and digalactolipid molecular species (16:0/18:2, 18:2/18:2 + 18:1/18:3, 18:2/18:3, 18:3/18:3) were catabolized to a much greater extent than other species (16:0/18:3, 18:1/18:2 + 18:0/18:3) during aging, resulting in a decline of the entire galactolipid fraction. This likely reflects the deterioration of amyloplasts and could explain the progressive sweetening that occurs during aging (16). Differential susceptibility of microsomal membrane lipids to breakdown has also been reported during floral senescence (10), the process of which culminates in death of the flower. In this regard, it is worth reiterating that potato tubers do not undergo senescence. As natural vegetative propagules, potato tubers are suitably adapted for maximal longevity and thus are ideal for

FIG. 5. Age-induced changes in the molecular species of MGDG in microsomal membranes from potato tubers. For abbreviation see Figure 1. Error bars indicate SE.

assessing the effects of age, as distinct from senescence, on membrane structure and function in herbaceous plants.

In contrast to galactolipids, unsaturated molecular species of PC and PE increased in microsomal membranes from tubers with advancing age, likely reflecting increases in the activities of 18:1 and 18:2 FA desaturases. Increases in  $\Delta 9$ -desaturase mRNA levels have been demonstrated during floral senescence (24). These changes, however, appear contradictory to the general increase in saturation of microsomal

membranes that accompanies senescence of flowers (24). Like senescing tissues, the mechanisms by which the molecular species composition of various lipid pools within potato tubers changed during aging are no doubt complex, involving the concerted actions of FA desaturases and membrane re-tailoring enzymes (lipases, acyltransferase, acyl CoA synthetase, etc.).

Although the fluidity of microsomal membranes often decreases during senescence (26), associations between fluidity, unsaturation, and desaturase activity remain speculative. Thompson and Martin (27) proposed that desaturases are activated when membrane fluidity drops below a threshold level. By using synthetic lipid bilayers, it was demonstrated that the physical properties of membranes cannot be predicted based solely on their overall FA profiles. Intramolecular positioning of acyl chains is an important factor determining the fluidity of membranes (28,29). A number of other factors have also been shown to affect membrane fluidity, including sterol content, sterol-to-phospholipid ratio, and lipid-to-protein ratio (30). Increase in sterol/phospholipid ratio leads to membrane rigidification (25) and is diagnostic of microsomal and plasma membrane deterioration during senescence (7). Stigmasterol has a disordering effect on artificial membranes (31) and has been shown to increase in the plasma membranes of mung bean hypocotyls during senescence (32). Moreover, an increase in the stigmasterol/sitosterol ratio has been proposed as a marker of physiologically older tissue (33). Thus, consistent with senescence, tuber aging resulted in an increase in sterol/phospholipid and stigmasterol/sitosterol ratios. In contrast to senescence (10), however, substantial increases in the major phospholipids of microsomal membranes were observed during tuber aging.

In addition to being developmentally linked (8–10,25), changes to membrane lipids are a common adaptive response of plants to various environmental stresses (27), such as temperature. Indeed, the early increases in 18:3-bearing species of potato tuber may simply reflect an adaptive response to maintain membrane fluidity at low temperature. Similar initial increases in phospholipid unsaturation in tubers during short-term storage have been reported (19). Moreover, increased unsaturation during acclimation of tubers to cold over the first weeks of storage is consistent with cold acclimation responses in other plants (27,34). Continued increases in 18:3 content of various PC and PE molecular species (18:3/18:3, 18:2/18:3, 16:0/18:3) beyond 13 mon, however, were unexpected. These latter increases may reflect a compensatory response to the age-induced loss of PI and increase in sterol content of membranes, thus characterizing age-specific effects on glycerolipid metabolism.

An increase in unsaturation alone does not necessarily translate into an increase in overall membrane fluidity. Previous studies on heart mitochondrial lipids of aging rats demonstrated that, despite age-related increases in unsaturation, there was an apparent decrease in membrane fluidity (35). The decrease was attributed to age-induced accumulation of peroxidized lipids in the lipid bilayer that greatly affected

FIG. 6. Changes in the concentrations of individual (A) and total (B) sterols in microsomal membranes from potato tubers. Inset shows sterol/phospholipid (PL) ratio (µg/mg). Error bars indicate SE.

membrane architecture and thus membrane biophysical properties, including fluidity. These results were confirmed in a later study using artificial liposomes, where decreases in microfluidity, lateral diffusion, and liposome size were associated with peroxidation of PUFA in the lipid bilayer (36). Because unsaturated FA are more susceptible to free radical attack, their increase with age would only serve to magnify lipid oxidative damage. Indeed, products of lipid peroxidation accumulate in tubers during aging, despite a decrease in lipolytic activity (16). Additionally, older tubers have leakier membranes (17; Zabrouskov, V., Kumar, G.N.M., Spsychalla, P., and Knowles, N.R., unpublished data), reflecting age-induced increases in membrane permeability. Hence, maintaining membrane fluidity through increased unsaturation appears to be a response to maintain membrane function during aging of potatoes. However, increases in PUFA content are also likely to be detrimental by rendering membranes more susceptible to nonenzymatic and possibly enzymatic degradation, thus compromising membrane functional properties, including fluidity. While older tubers have lower lipoxigenase and lipolytic acylhydrolase activities (16; Zabrouskov, V., Kumar, G.N.M., Spsychalla, J.P., and Knowles, N.R., unpublished data), the role of lipolytic enzymes in the age-induced catabolism of tuber lipids remains unresolved, owing to the fact that lipases exhibit preferences for various phospholipid molecular species (8–10), resulting in their differential susceptibility to enzymatically mediated degradation. The genuine lipolytic potential within different ages of tubers therefore will depend on the phospholipid molecular species that are characteristic for a particular tuber age.

Thus, changes in molecular species of microsomal membranes during tuber aging are consistent with previous work demonstrating age-induced declines in membrane integrity and increases in lipid peroxidation, all of which contribute to oxidative stress and loss of growth potential. Our results provide a base for further studies to establish the impact of age-related changes in molecular species on (i) susceptibility of membrane lipids to enzymatic degradation and (ii) the physical parameters of membranes in relation to their architecture and function.

In summary, aging effected differential changes in the molecular species of lipids in microsomal membranes from potato that were dependent on the particular lipid class (or pool). The modifications were characterized by increases in 18:3/18:3 and 18:2/18:3 species of PC and PE, lower galactolipid content and unsaturation owing to decreases in 16:0/18:2, 18:2/18:2 + 18:1/18:3, 18:2/18:3, and 18:3/18:3 and an increase in 16:0/18:3 species, and higher sterols content and sterol/phospholipid ratio. These alterations in membrane lipid chemistry are consistent with previous studies showing a decline in membrane integrity, increased susceptibility of membranes to lipid peroxidation, and the development of oxidative stress during aging of potato tubers.

# Selective (*R*)-3-Hydroxylation of FA by *Stenotrophomonas maltophilia*

Kerstin Weil<sup>a</sup>, Patrick Gruber<sup>a</sup>, Frank Heckel<sup>a</sup>, Dag Harmsen<sup>b</sup>, and Peter Schreier<sup>a,\*</sup>

<sup>a</sup>Lehrstuhl für Lebensmittelchemie and <sup>b</sup>Institut für Hygiene und Mikrobiologie, Universität Würzburg, D-97074 Würzburg, Germany

**ABSTRACT:** Soil samples were screened for microorganisms selectively transforming FA. One of the isolated strains was identified as the bacterium *Stenotrophomonas maltophilia* by its phenotypic features and genotypic characterization by sequencing the ribosomal RNA gene. Using linoleic acid as substrate resulted in the formation of two major compounds. After liquid chromatographic isolation and separation, their structures were elucidated by HPLC–tandem MS, GC–MS, and NMR techniques to be 3-hydroxy-Z6-dodecenoic acid and 3-hydroxy-Z5,Z8-tetradecadienoic acid. In additional experiments, other FA, such as  $\alpha$ -linolenic, oleic, palmitoleic, myristoleic, and *cis*-vaccenic acids, were converted to 3-hydroxylated metabolites of shorter chain lengths as well. Determination of the enantiomeric composition revealed highly enriched (*R*)-hydroxylation (88–98% enantiomeric excess).

Paper no. L8827 in *Lipids* 37, 317–323 (March 2002).

Long-chain hydroxy FA and other oxygenated FA derivatives (oxylipins) are widely distributed in both the animal and plant kingdoms and exert different biological actions (1,2). During the last decade, knowledge has accumulated regarding the biosynthesis of oxylipins by fungi and related organisms (3). A large number of unsaturated hydroxy FA, which are formed by lipoxygenase, dioxygenase, or cytochrome P450-mediated pathways, have been found in various fungal species (4–6). Bacterial conversions of unsaturated FA have been exploited, too. For instance, oleic acid and linoleic acid were transformed to the corresponding 10-hydroxy and 10-keto FA by hydratases from *Flavobacterium* sp. DS5 (7) and *Nocardia cholesterolicum* (8). In addition, oleic acid was converted to 7,10-dihydroxy-E8-octadecenoic acid via a 10-hydroxy-Z8-octadecenoic acid as intermediate by *Pseudomonas aeruginosa* PR3 (9). 12,13,17-Trihydroxy-Z9-octadecenoic acid was produced from linoleic acid by a Gram-positive strain identified as *Clavibacter* sp. ALA2 (10). Other trihydroxy acids, such as 9,12,13-trihydroxy-10-octadecenoic acid and 9,12,13-trihydroxy-10,15-octadecadienoic acid, as well as epoxy unsaturated FA have been found in some rice cultivars (11). Finally, several cytochrome P450 enzymes have been isolated from different strains of *Bacillus megaterium* and characterized.

They are capable of catalyzing the  $\omega$ -1,  $\omega$ -2, and  $\omega$ -3 hydroxylation of long-chain FA, amides, and alcohols (12,13).

In this report, we describe the biotransformation of linoleic acid and other unsaturated FA into (*R*)-3-hydroxylated metabolites of shorter chain length by a *Stenotrophomonas maltophilia* strain isolated from topsoil.

## MATERIALS AND METHODS

**Isolation procedure and bacterial growth.** Microorganisms were isolated from a soil sample taken in the Würzburg University area. The bacterial cultures were maintained on plate count agar (Creatogen Biosciences GmbH, Augsburg, Germany).

**Phenotypic characterization of the microorganism.** Phenotypic characterization of the isolated strain was carried out by investigations concerning appearance (microscopic study including Gram stain) and behavior (optimal growth temperature) of the bacteria. Sensitivity against antibiotics (ampicillin, piperacillin, imipenem, meropenem, cefotaxime, cefotiam, gentamicin, amikacin, cotrimoxazol, ofloxacin) was tested by means of an agar diffusion test. In addition, classification using the commercially available test-stripe APIZYM 20 NE (bioMérieux Deutschland GmbH, Nürtingen, Germany) was done. Enzyme assays were performed according to Smibert and Krieg (14).

**Preparation, amplification, and sequencing of bacterial ribosomal RNA gene.** The preparation of intact bacterial cells for the PCR was performed as described (15). Briefly, cells were cultivated in Luria Bertani broth, centrifuged, washed with 1 M NaCl, resuspended in TE buffer (10 mM Tris, 1 mM EDTA, pH 7.6), and diluted in TE buffer to an optical density of 1.0 at 600 nm. A 1- $\mu$ L aliquot of each cell suspension was used for the PCR.

Partial-length small subunit ribosomal RNA gene (16S) was amplified using PCR with primers 27f and 342r (16), one of which was biotinylated in each of two reciprocal reactions. Single-stranded DNA were sequenced with internal primers by using the Taq-cycle DyeDeoxy™ Terminator method combined with a 373A automatic sequencer (ABI Division of PerkinElmer, Weiterstadt, Germany). For all newly determined nucleotide sequences (variable region V1–V3 of the 16S-rRNA), data were obtained for both DNA strands; sequences from primer regions were not included in the analysis. Finally, a homology search with the sequence data against the European Molecular Biology Laboratory (EMBL) database was performed (17).

**Materials and chemicals.** Linoleic,  $\alpha$ -linolenic, oleic, and Z5-dodecenoic acids were obtained from Aldrich (Sigma-Aldrich Chemie GmbH, Deisenhofen, Germany). Palmitoleic and myristoleic acids were acquired from Sigma (Sigma-Aldrich Chemie GmbH, Deisenhofen, Germany). *cis*-Vaccenic acid was purchased from ICN (ICN Pharmaceuticals, Inc., Cosa Mesa, CA). Reagents and solvents were of analytical or HPLC grade. As rotary shaker, a GFL 3031 (Gesellschaft für Labortechnik mbH, Burgwedel, Germany) was used. A Wolf SanoClav-MCN autoclave (Wolf, Geisslingen, Germany) was employed for sterilization, and a laminar AirFlow bench was used for sterile work (NuAire Inc., Plymouth, MN). A Beckman J2-21 centrifuge was applied for cell separations (Beckman, Fullerton, CA).

**Biotransformation and product isolation.** Liquid minimal medium (100 mL), prepared according to Dworkin and Foster (18), with an additional trace-element solution (5 mL/L) (19) was autoclaved, and glucose (5 g/L) was added under sterile conditions. The culture used to inoculate the liquid medium was taken from freshly grown plates with an inoculating loop. The liquid culture was allowed to grow for about 23 h at 30°C in a rotary shaker at 120 rpm until 100 mg of the FA was added under sterile conditions. After further incubation for 18 h under the same conditions, the culture was worked up by sonication of the bacterial broth for 15 min and centrifugation at 15,000  $\times$  g for 20 min. The supernatant (approximately 100 mL), adjusted to pH 3 by adding 2 mL of HCl (10%), was extracted three times each with 50 mL diethyl ether. The combined extract was dried over Na<sub>2</sub>SO<sub>4</sub> and, after filtration, the solvent was removed under reduced pressure (rotary evaporator). For subsequent HPLC analysis, the residue was dissolved in 5 mL of methanol/water mixture (1:1, vol/vol).

For the isolation and purification of the transformation products, the combined extract obtained from eight conversions was applied onto a glass column (10  $\times$  2 cm) filled with RP18 (octadecyl reversed phase) material (40–63  $\mu$ m particle size; Merck KGaA, Darmstadt, Germany). Separation was carried out by employing a gradient composed of mobile phase A (water/0.05% formic acid) and B (acetonitrile). The share of solvent B increased from 40 to 100% in 5% steps using 100-mL fractions. Fractions (12 mL) were collected and analyzed by analytical HPLC. Fractions containing the target compounds were combined and lyophilized. Yields of transformation products ranged from 10 to 15%.

**Derivatization of products.** Methylation with diazomethane was performed by a standard procedure (20).

**HPLC.** Analytical separation was carried out on a Eurospher 100 C-18 column (250  $\times$  4 mm, 5  $\mu$ m particle size; Knauer, Berlin, Germany) using a flow rate of 1 mL/min, employing a Knauer HPLC pump MaxiStar coupled to (i) a Knauer multi-wavelength UV/visible detector (234 nm) and (ii) an ELSD (Sedere, Alfortville Cedex, France) kept at 40°C and 2.2 bar compressed air. Data acquisition was achieved using Eurochrom 2000 software (Knauer). The following gradient was applied: solvent A (water/0.05% formic acid), solvent B (acetonitrile): 0–30 min, 5–80% B, 30–40 min, 80–100% B, 40–45 min, 100% B.

**HPLC–tandem mass spectrometry (HPLC–MS/MS).** Analysis of the isolated products was performed using a triple-stage quadrupole TSQ 7000 HPLC–MS/MS system (Finnigan MAT, Bremen, Germany) using electrospray ionization (ESI) in either the positive or the negative mode. ESI capillary voltage was set to 4 kV (positive mode) and 3 kV (negative mode), respectively. The temperature of the heated capillary was 250°C. Nitrogen served both as sheath (60 psi) and auxiliary gas (10 L/min). Positive and negative ions were detected by scanning from 150 to 400 u with a total scan duration of 1.0 s for a single full spectrum. MS/MS experiments were performed at a collision gas pressure of 1.8 mTorr argon and a collision-induced dissociation offset voltage of –12 eV scanning a mass range of 20 to 280 u within 2.0 s. Data acquisition and evaluation were carried out on a Personal DECstation 5000/33 (Digital Equipment, Unterföhring, Germany) and ICIS 8.1 software (Finnigan MAT).

**High-resolution GC–MS (HRGC–MS).** After methylation of the isolated compounds with diazomethane, HRGC–MS analysis was performed using a Fisons MD 800 mass spectrometer coupled to a Fisons GC 8000 with split injector (1:20). The system was equipped with the Mass Lab software (version 1.3) (Fisons, Mainz-Kastel, Germany). A J&W DB Wax fused-silica capillary column (30 m  $\times$  0.25 mm i.d., 0.25  $\mu$ m film thickness; J&W Scientific, Folsom, CA) was employed. The temperature program was 3 min isothermal at 50°C and then increased at 4°C/min to 240°C using a flow rate of 1.5 mL/min helium. The MS operating parameters were as follows: ionization voltage 70 eV (electron impact ionization), ion source and interface temperatures 210 and 250°C, respectively.

**Multidimensional GC (MDGC).** A double-oven MDGC system consisting of two Fisons GC 8000 apparatus was used (Fisons, Mainz-Kastel, Germany). Split injection (1:10) and FID detection in ovens 1 and 2 were employed. Preseparation was achieved in oven 1 on a J&W DB Wax fused-silica capillary column (30 m  $\times$  0.25 mm i.d., 0.25  $\mu$ m film thickness; J&W Scientific). In oven 2, a chiral fused-silica capillary column was connected to the precolumn by a moving column–stream switching system. As chiral phase, a 2,3-*O*-diethyl-6-*O*-*tert*-butyldimethyl-silyl- $\beta$ -cyclodextrin column (MEGA, Milano, Italy) was employed for the separation of the 3-hydroxy acid methyl esters. Helium was used as the carrier gas (1.9 mL/min).

**NMR.** <sup>1</sup>H and <sup>13</sup>C NMR spectra were recorded on a Bruker WM 400 spectrometer (Bruker, Ettlingen, Germany) with CDCl<sub>3</sub> (Merck KGaA) as solvent and are reported in ppm ( $\delta$ ) relative to CDCl<sub>3</sub> as internal reference; coupling constants (*J*) are given in Hertz (Hz).

## RESULTS

*Phenotypic characterization of the microorganism.* With linoleic acid as substrate, different soil samples were investigated in order to detect microorganisms selectively degrading FA. Of the bacteria screened, one culture, isolated from a humid soil sample, converted the exogenous substrate to more polar compounds at greater than a trace amount. This strain was a Gram-negative, nonfermentative rod ( $0.5 \times 2 \mu\text{m}$ ) that exhibited optimal growth at  $30^\circ\text{C}$ . The following reactions of the commercially available test-stripe APIZYM 20 NE showed positive results: existence of urease,  $\beta$ -glucosidase, protease, and  $\beta$ -galactosidase as well as assimilation of glucose, arabinose, mannose, mannitol, *N*-acetylglucosamine, maltose, capric acid, malic acid, and citric acid. Checks concerning aminopeptidase, catalase, and DNase were positive, whereas no oxidase activity could be detected. The isolated strain was very resistant to antibiotics. Only two antibiotic substances, i.e., cotrimoxazol and oflocacin, inhibited the bacterial growth. Comparison of these data with those of known strains revealed that the strain belongs to the genus

*Stenotrophomonas* and has 99% similarity to the species *S. maltophilia*.

**Genotypic identification of the bacterial strain.** To confirm the phenotypic characterization, the isolated strain was subjected to sequencing of the first 300 base pairs of its small subunit ribosomal RNA gene (16S) by means of the Taq-cycle-DyeDeoxy™-terminator technique. The resulting nucleotide sequences were compared with the sequence data of the EMBL database, which disclosed that a *Pseudomonas* sp. had been isolated. Prior to its second reclassification in 1993, *S. maltophilia* had been named *Pseudomonas maltophilia* and before that *Xanthomonas maltophilia* (25,26).

**Structure determination of the biotransformation products of linoleic acid.** HPLC analysis of the extract obtained by incubation of linoleic acid with the *S. maltophilia* strain showed two major products **1** and **2** (Fig. 1). Their isolation was performed by liquid chromatography. Fractions containing the target compounds (HPLC control) were combined. Lyophilization revealed two colorless, oily liquids.

The identification of **1** and **2** was carried out by HPLC–MS/MS analysis. In the full scan mode, the spectrum of compound **1** displayed pseudomolecular ions at  $m/z$  232 [ $M + NH_4$ ]<sup>+</sup> and  $m/z$  237 [ $M + Na$ ]<sup>+</sup>. Fragmentation of the ammonium adduct ion (Fig. 2A) revealed characteristic ions at  $m/z$  215, 197, and 179, which are caused by subsequent elimination of the ammonium as well as one and two water molecules. The other prominent signals at  $m/z$  155 and 137 are due to a cleavage of the molecule and following splitting-off of water. Analogously, the spectrum of compound **2** revealed pseudomolecular ions at  $m/z$  258 [ $M + NH_4$ ]<sup>+</sup> and  $m/z$  263 [ $M + Na$ ]<sup>+</sup>. The product ion spectrum (Fig. 2B) showed fragments at  $m/z$  241, 223, 205, 181, and 163 due to dissociation processes similar to that of product **1**.

In addition, HRGC–MS analysis was carried out after methylation of **1** and **2** with diazomethane. Both compounds exhibited a characteristic signal at  $m/z$  103 [ $C_4H_7O_3$ ], which is indicative of a hydroxylation at the C-3 position as induced by an  $\alpha$ -cleavage of the molecule. Further fragments were caused by decomposition of the carbon chain, mainly next to the double bonds. The molecular ion of the methyl esters of **1** and **2** at

**FIG. 1.** RP-HPLC separation (ELSD detection) of the extract obtained after incubation of linoleic acid with *Stenotrophomonas maltophilia* strain isolated from topsoil: **1**: 3-hydroxy-Z6-dodecenoic acid; **2**: 3-hydroxy-Z5,Z8-tetradecadienoic acid.

**FIG. 2.** HPLC–electrospray-tandem mass spectrometry product ion spectra of compounds **1** (A) and **2** (B); precursor ions  $m/z$  232 and 258 [ $M + NH_4$ ]<sup>+</sup>, respectively (positive mode, collision-induced dissociation offset voltage –12 eV, 1.8 mTorr argon as collision gas).

$m/z$  254 and 228, respectively, as well as fragments of  $m/z$  236 and 210 corresponding to [ $M - H_2O$ ] were also observed.

Structural elucidation of **1** and **2** was completed by recording different 1D and 2D NMR spectra (*cf.* Materials and Methods section). On the basis of the received results, products **1** and **2** were identified as 3-hydroxy-Z6-dodecenoic acid and 3-hydroxy-Z5,Z8-tetradecadienoic acid, respectively.

**Substrate specificity.** To elucidate the scope of substrate acceptability, various other FA were fed to *S. maltophilia* (*cf.* Materials and Methods section). Product separation and structure elucidation was performed as mentioned above for linoleic acid. Figure 3 summarizes the substrates used (including linoleic acid) and their biotransformation products observed (for spectroscopic data, see the Materials and Methods section).

**Stereochemistry of biotransformation products.** Analysis of the enantiomeric distribution of the methylated 3-hydroxylated products **1** to **7** by MDGC revealed ratios ranging from 99:1 to 94:6% (*cf.* Fig. 3). Stereochemical evaluation was carried out by MDGC after transformation of the 3-hydroxylated microbial products into the corresponding saturated 1,3-diols by hydrogenation and subsequent reduction of the carboxylic function with  $LiAlH_4$  (27) and comparison with reference data. A racemic reference substance was synthesized by aldol addition with methyl acetate and subsequent hydrogenation, followed by reduction of the methyl ester with  $LiAlH_4$  (27). Enantioselective synthesis of (*S*)-dodecane-1,3-diol was carried out by asymmetric epoxidation under Sharpless conditions (28) and treatment of the epoxide formed with sodium bis(2-methoxy-ethoxy)aluminum (Red-Al) (29).

FIG. 3. Substrates fed to *Stenotrophomonas maltophilia* and main products formed after an incubation time of 18 h (percentage of total transformation and enantiomeric composition given).

In addition, circular dichroism (CD) spectroscopy (30) was employed. The details of the configurational assignment including synthesis of the reference compounds as well as MDGC analysis and CD spectroscopy are reported elsewhere (31). Both methods revealed highly enriched (*R*)-configured 3-hydroxy derivatives for all substrates under study.

## DISCUSSION

The capability of producing (*R*)-3-hydroxylated FA metabolites is not restricted to *S. maltophilia* alone. In 1967, the occurrence of (*R*)-3-hydroxy palmitic acid and related saturated compounds was reported in yeasts such as *Rhodotorula graminis* (32) and *Saccharomyces malanga* (33). Medium-chain 3-hydroxy FA are present in the glycolipids of the smut fungi *Ustilago zaeae* and *U. nuda* (34). Similar data have been found for the yeast *Dipodascopsis uninucleata* (22) and the soil fungus *Mucor genevensis* (35). In these organisms, 3-hydroxylated FA appear to be implicated in the regulation of vegetative growth and sexual reproduction within the life cycle. A recent immunofluorescence microscopic study using an antibody that exhibited group-specificity toward (*R*)-3-hydroxy-oxylipins revealed that in *D. uninucleata* (*R*)-hydroxylated compounds occur selectively in the gametangia, in asci as well as between the released ascospores (36).

The biosynthetic pathway to the (*R*)-3-hydroxy enoic FA remains to be elucidated. From the structural identification of the FA derivatives formed after incubation with *S. maltophilia*, it is evident that during transformation of the admitted substrate the carbon chain remained unchanged from the  $\omega$ -end. Only even-numbered products were detected. Owing to these observations, FA degradation by  $\beta$ -oxidation is assumed. While during "normal"  $\beta$ -oxidation an intermediary (*S*)-3-hydroxyacyl-CoA is formed as the major metabolite of the enoyl-CoA hydratase-catalyzed reaction, we have clearly demonstrated that *S. maltophilia* converts different FA into (*R*)-3-hydroxylated products of shorter chain length. Thus, as a metabolic route to (*R*)-3-hydroxy FA a reaction sequence analogous to  $\beta$ -oxidation is conceivable; however, the sequence would imply the occurrence of a 2-enoyl CoA hydratase with opposite stereochemistry. The occurrence of such enzymes has already been demonstrated in microorganisms. Recently, an (*R*)-specific *trans*-2,3-enoylacyl-CoA hydratase has been isolated and characterized from *Rhodospirillum rubrum* (37).

## ACKNOWLEDGMENTS

This work was supported by the Deutsche Forschungsgemeinschaft, Bonn (SFB 347 "Selective Reactions of Metal-Activated Molecules") and Fond der Chemischen Industrie. Dr. Matthias Grüne and Elfriede Ruckdeschl are thanked for the measurement of NMR spectra.

# Saturated and Unsaturated Anteiso-C<sub>19</sub> Acids in the Seed Lipids from *Hesperopeuce mertensiana* (Pinaceae)

Frédéric Destailats<sup>a</sup>, Robert L. Wolff<sup>b,\*</sup>, and Paul Angers<sup>a</sup>

<sup>a</sup>Department of Food Science and Nutrition, and Dairy Research Center (STELA), Université Laval, Sainte Foy, Québec, Canada, G1K 7P4, and <sup>b</sup>Institut des Science et Techniques des Aliments de Bordeaux, Université Bordeaux 1, Talence, France

**ABSTRACT:** Minor uncommon FA from *Hesperopeuce mertensiana* (a gymnosperm species of the Pinaceae family) seed oil were characterized through a combination of silver ion TLC of their FAME, and GLC coupled with MS of their picolinyl derivatives. These uncommon components have the structures 16-methyloctadecanoic (anteiso-19:0), 16-methyl-*cis*-9-octadecenoic (anteiso-19:1), and 16-methyl-*cis*-9,*cis*-12-octadecadienoic (anteiso-19:2) acids. These branched C<sub>19</sub> acids were identified earlier in the wood of *Picea abies*, which would indicate that such acids could be widespread, though minor, components of Pinaceae lipids.

Paper no. L8953 in *Lipids* 37, 325–328 (March 2002).

It is generally admitted that branched (br) FA, mostly with iso- and anteiso- structures, are characteristic of animal fats, particularly ruminant fats. On the other hand, it is also widely recognized that these acids do not, or very rarely, occur in the plant kingdom. In fact, this is a simplistic point of view. Gymnosperms, which are one of the most prominent elements of the extant flora, do indeed contain br-FA, i.e., br-15:0 and br-17:0 acids, in their leaves (1), anteiso-17:0 acid in their seeds (2), and several saturated and unsaturated anteiso-C<sub>19</sub> acids in their wood (3).

We had some indications that sustained the possibility of the presence of anteiso-C<sub>19</sub> acids in the seed lipids from Pinaceae. First of all, Plattner *et al.* (4) characterized such uncommon FA in the seed lipids from *Larix leptolepis* (= *L. kaempferi*) by MS coupled with GLC. Second, analyses by GLC of fractions isolated by silver ion TLC (Ag-TLC) from FAME prepared from *L. decidua* indicated the presence of some unidentified peaks in the C<sub>19</sub> acid region (5). In one particular case, that of *Hesperopeuce mertensiana*, 1.7% of seed FA had not been identified in a previous study (6).

We report here on the GLC–MS characterization of these uncommon FA prepared from *H. mertensiana* seeds in the form of their picolinyl esters (7). Globally, they are similar to the br-C<sub>19</sub> acids characterized by Ekman in the wood of *Picea abies* (3), although present in minute amounts, which would indicate that they are more widespread in conifers than considered thus far.

## MATERIALS AND METHODS

**Sample.** The seed oil prepared from *H. mertensiana* was available from an earlier investigation, and details of its source, extraction, and FA composition are given elsewhere (6).

**GLC of FAME.** Methylation of O-acetylated FA (ca. 10 mg in 2 mL hexane) was carried out in a sealed tube with 0.4 N sodium methoxide in methanol (0.5 mL). Analyses of the FAME were performed with a Hewlett-Packard gas chromatograph, model 5890 Series II, equipped with an FID and connected to a computer with a Hewlett-Packard ChemStation (Hewlett-Packard, Palo Alto, CA). Samples in hexane (1.0 µL) were injected onto an open tubular DB-225 capillary column (30 m × 0.25 mm i.d., 0.25 µm film thickness; J&W, Folsom, CA). The injector and detector temperatures were maintained at 250°C, while the oven temperature was 190°C isothermal. Hydrogen was the carrier gas, with a head pressure of 140 kPa.

**Fractionation of FAME by Ag-TLC.** FAME were fractionated by TLC on silica gel plates impregnated with AgNO<sub>3</sub>. The plates were immersed in a 5% AgNO<sub>3</sub> solution in acetonitrile for 15 min in the dark and activated at 100°C for 1 h. Fractionation was performed according to number and configuration of double bonds, using a mixture of hexane and diethyl ether (80:20, vol/vol) as developing solvent. At the end of the chromatographic runs, the plates were sprayed with a solution of 2',7'-dichlorofluorescein and viewed under UV light. The bands corresponding to saturated, monounsaturated, diunsaturated, and triunsaturated FA were separately scraped off and transferred into test tubes, and methanol (1.5 mL), hexane (2 mL), and an aqueous solution of NaCl (5% wt/vol, 1.5 mL) were successively added with thorough mixing after each addition. After standing for ca. 1 min, the hexane phase was withdrawn, the solvent was evaporated under a stream of nitrogen, and the residue was redissolved in dry methylene chloride (1 mL) prior to further derivatization.

**Picolinyl ester preparation.** Picolinyl esters were prepared from fractionated FAME according to Destailats and Angers (8). A solution of potassium *tert*-butoxide in THF (100 µL, 1.0 M; Aldrich Chemicals, Milwaukee, WI) was added to 3-pyridylcarbinol (200 µL; Aldrich Chemicals). After homogenization, the FAME solutions (1 mL) were added to the reagent, and the mixtures were held at 40°C for 15 min in a closed vial. After cooling to room temperature, the reaction mixture was washed with distilled water (1 mL) and the organic phase was withdrawn, dried over anhydrous sodium sulfate, and filtered before analysis.

Abbreviations: Ag-TLC, silver ion TLC; amu, atomic mass unit; br, branched.

**GLC-MS analysis.** FA picolinyl esters were analyzed by GLC-MS (Hewlett-Packard model 6890 Series II gas chromatograph attached to an Agilent model 5973N selective quadrupole mass detector; Palo Alto, CA) under an ionization voltage of 70 eV at 250°C, and connected to a computer with a Hewlett-Packard ChemStation. The injector, in split mode (25:1), and the interface temperatures were maintained at 230°C, and He was used as carrier gas under constant flow (1 mL min<sup>-1</sup>). GLC separation was performed on a BPX-70 capillary column (SGE, Melbourne, Australia; 60 m × 0.25 mm i.d., 0.25 μm film thickness) with an oven temperature of 200°C isothermal for 10 min, increased to 240°C at 5°C min<sup>-1</sup>, isothermal at this temperature for 20 min, and then increased to 260°C at 5°C min<sup>-1</sup>, for a total run time of 47 min.

## RESULTS

Picolinyl ester derivatives, prepared from FAME separated by Ag-TLC and under mild reaction conditions (8), were used to achieve structural determination of presumably C<sub>19</sub> FA. The mass spectra of three uncommon FA found in *H. mertensiana* seed oil are given in Figure 1.

A first spectrum (Fig. 1A) shows a molecular ion at  $m/z = 389$ , characteristic of a saturated C<sub>19</sub> structure. Loss of carbon-16 and its associated methyl group resulted in two distinctive ion fragments at  $m/z = 360$  and 332. Further fragmentation produced ions of  $m/z$  ranging from 164 to 332, with successive increments of 14 atomic mass units (amu), thus confirming the saturated structure of anteiso-19:0 (16-methyl stearic) acid (7). A second mass spectrum (Fig. 1B) indicates a monounsaturated C<sub>19</sub> structure, with a molecular ion at  $m/z = 387$ . A fragmentation pattern similar to that observed for anteiso-19:0 acid (ion fragments at  $m/z = 358$  and 330) attributable to loss of carbon-16 and its associated methyl group, confirms the anteiso-structure of this FA (16-methyl 18:1). A Δ9 location for the double bond on the hydrocarbon chain was deduced from a 26 amu gap (-C<sub>2</sub>H<sub>2</sub>) between ion fragments at  $m/z = 234$  and 260, characteristic of vinylic fragmentations between carbon atoms C<sub>8</sub>-C<sub>9</sub> and C<sub>10</sub>-C<sub>11</sub>, respectively (7). Moreover, ion fragments at  $m/z = 220$  and 274, resulting from allylic fragmentation, confirmed this position. This FA (as FAME) co-eluted with oleic (*cis*-9 18:1) acid in Ag-TLC fractionation, indicating a similar double bond configuration, and thus completing determination of the 16-methyl-*cis*-9 18:1 (anteiso-19:1) acid structure.

Finally, the spectrum given in Figure 1C resembles that of anteiso-19:1 acid, but the molecular ion at  $m/z = 385$  rather indicates a dienoic acid. Indeed, the spectrum gave diagnostic ions of a monomethylene-interrupted double bond system at  $m/z = 234$ , 260, 274, and 300, indicating ethylenic bonds at positions 9 and 12. Moreover, this compound co-eluted with linoleic (*cis*-9,*cis*-12 18:2) acid in Ag-TLC, indicative of an all-*cis* double bond system. Typical anteiso- fragmentation resulted in ions at  $m/z = 328$  and 356, and completed structure elucidation of this 16-methyl-*cis*-9,*cis*-12 18:2 (anteiso-19:2) acid.

## DISCUSSION

We have shown that *H. mertensiana* seed lipids contain several anteiso-C<sub>19</sub> acids, all of which were earlier characterized in the wood of *P. abies* (3). However, we could not positively identify the anteiso-5,9,12 19:3 present in *P. abies* wood (3). To which extent these findings apply to other Pinaceae seed oils needs further investigation, as no intensive research of these FA was made during our systematic studies of gymnosperm seed lipids. However, *H. mertensiana* and *Picea* spp. are generally not recognized as close relatives. The first species belongs to the Abietoid group, whereas *Picea* spp. belongs to the Pinoid group [this classification is based on botanical as well as immunological observations (9)]. We recently suggested that a Tsugoid group be created (9), considering the closeness of the seed FA compositions of *Tsuga* spp. and *H. mertensiana* on the one hand, and of *Larix*, *Picea*, and most *Pinus* spp. on the other hand, which consistently differed from other Abietoid seed FA.

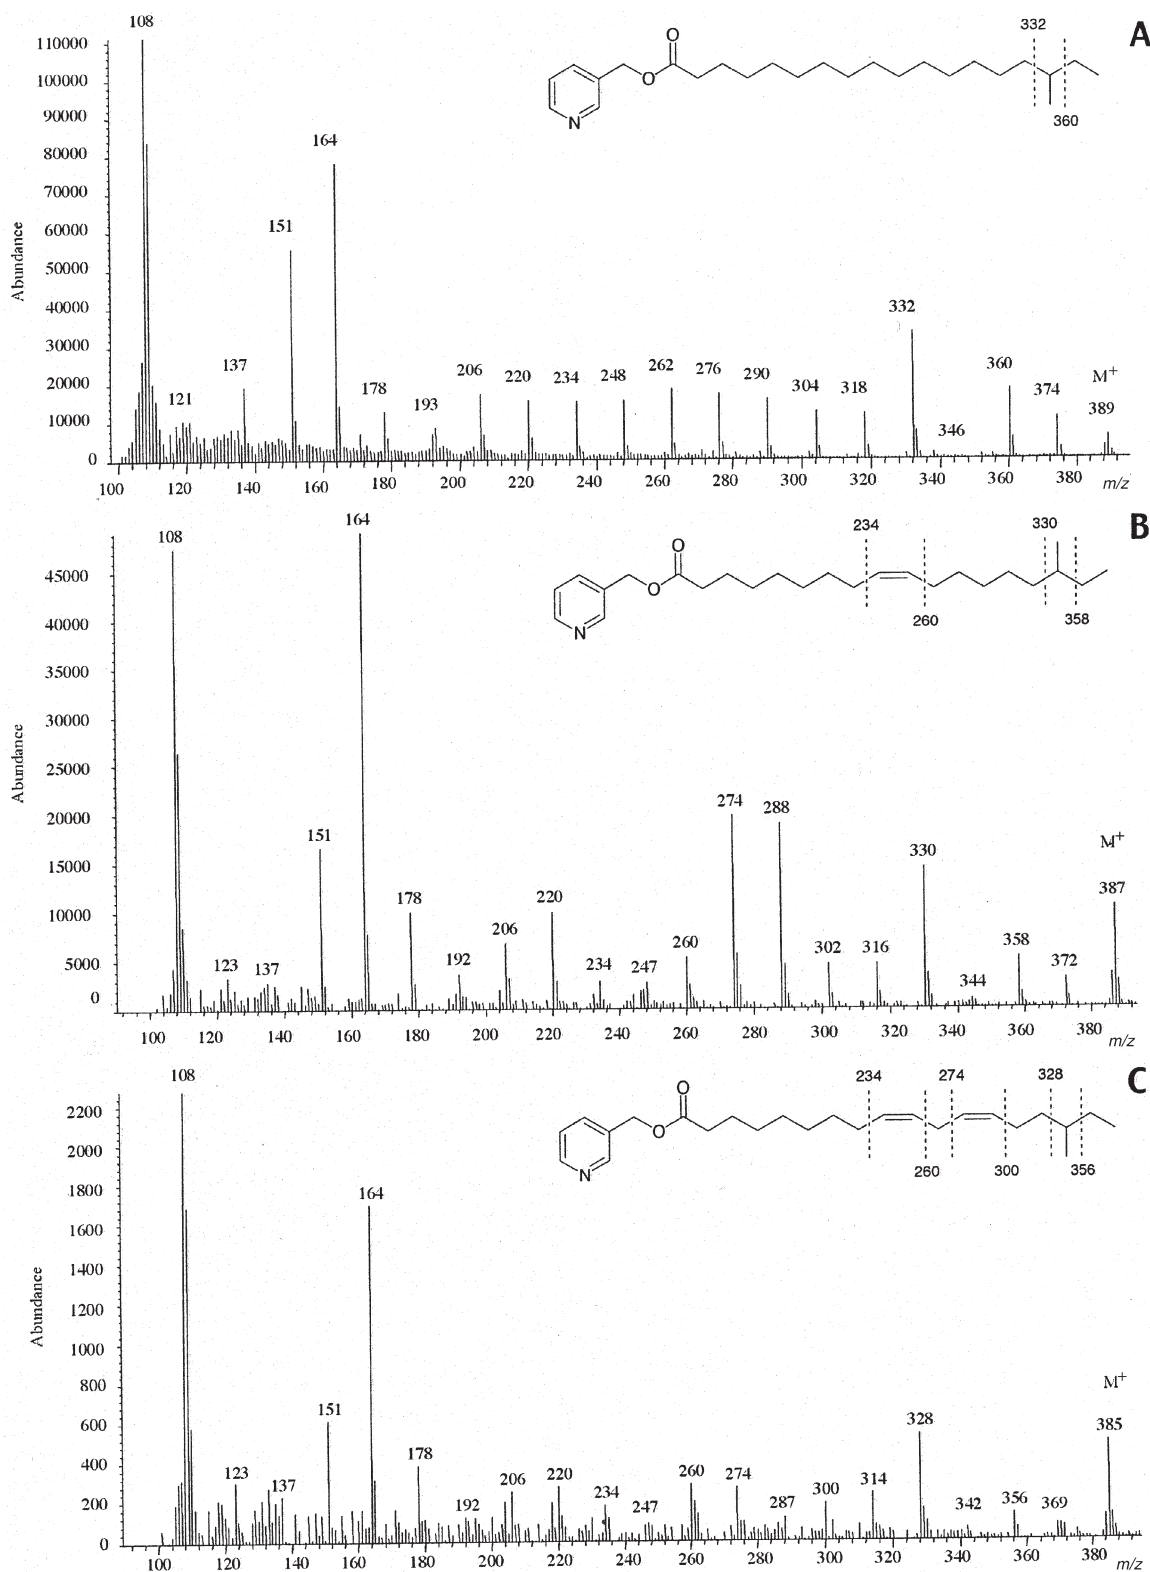

From a quantitative point of view, the anteiso-C<sub>19</sub> acids remain of minor significance (anteiso-19:0, 0.14% of total FA, anteiso-19:1, 0.14%, and anteiso-19:2, 0.05%), and some of them are hindered in chromatograms by other FA of considerably higher levels, but this may vary with the GLC column used. As such, structures of minor FA still remain to be determined. Whatever the distribution of these FA in the seeds of Pinaceae, they do not alter our conclusions reported in three recent reviews for that family (5,9,10). The metabolic origin of br-FA in Pinaceae, however, remains unknown, except that they occur in their leaf, wood, and seed lipids.

## ACKNOWLEDGMENTS

We acknowledge financial support from the Natural Sciences and Engineering Council of Canada, and the Conseil de Recherches en Pêche et en Agroalimentaire du Québec (CORPAQ). The authors are also grateful to the Fondation de l'Université Laval for a Ph.D. award to Frédéric Destailats.

# Distribution of Medium-Chain FA in Different Lipid Classes After Administration of Specific Structured TAG in Rats

Huiling Mu\* and Carl-Erik Høy

BioCentrum-DTU and Center for Advanced Food Studies, Technical University of Denmark, DK-2800 Lyngby, Denmark

**ABSTRACT:** Structured TAG (STAG) containing medium-chain FA (MCFA) in the *sn*-1,3 positions and essential FA in the *sn*-2 position were synthesized by lipase-catalyzed acidolysis. In our previous studies we found that part of the MCFA from STAG could be absorbed in the small intestine; however, it was unclear how they were absorbed. In order to get a better understanding of the metabolism of STAG to improve future design and application of STAG, in the present study lymph lipids collected after feeding STAG were fractionated into different classes and the FA composition of each lipid class was studied by GC after methylation to FAME. Caprylic acid was detected in the fraction of TAG only after administration of 1,3-dioctanoyl-2-linoleyl-*sn*-glycerol (8:0/18:2/8:0), whereas lauric acid was detected in TAG, DAG, and FFA as well as phospholipids after administration of 1,3-didodecanoyl-2-linoleyl-*sn*-glycerol (12:0/18:2/12:0). We conclude that the enterocyte has the ability to reacylate the MCFA into TAG and that the intestinal absorption of MCFA from STAG mainly occurs by resynthesis of TAG. Caprylic acid from STAG is not incorporated into phospholipids, whereas lauric acid from STAG can be incorporated into phospholipids.

Paper no. L8934 in *Lipids* 37, 329–331 (March 2002).

Medium-chain TAG (MCT) provide the advantage of being rapidly digested and thus rapidly providing energy. Therefore, they have been used in clinical nutrition for patients suffering from malabsorption. However, these patients also suffer from a lack of essential FA, a problem that is not solved by using MCT. New lipase-catalyzed acidolysis makes it possible to synthesize structured TAG (STAG) containing medium-chain FA (MCFA) in the *sn*-1,3 positions and essential FA in the *sn*-2 position (1). The absorption of essential FA from these STAG was better in comparison with that from conventional long-chain TAG (2).

To study the effect of chain length of MCFA on the absorption of long-chain FA (LCFA) and the distribution of MCFA between the portal vein and lymphatics in rats with normal fat absorption, we studied the lymphatic transport of FA from specific STAG containing different MCFA varying from caprylic acid (8:0) to lauric acid (12:0) in *sn*-1,3 positions and linoleic acid in the *sn*-2 position. Earlier we found that the chain length of the MCFA in the primary positions of

STAG did not affect the maximal intestinal absorption of LCFA in the *sn*-2 position, whereas the distribution of FA between the lymphatics and the portal vein reflected the chain length of the FA (3). Even though several studies on the absorption of STAG have been reported (4–7), the absorption pathway is still unclear and the intestinal absorption of MCFA from MLM (medium-long-medium)-type STAG is not well understood. A better understanding of the metabolism of STAG may help in the future design and application of STAG. Therefore, lymph lipids collected after feeding STAG were fractionated into different classes, and the FA composition of each lipid class was studied by GC after methylation to FA methyl esters (FAME). The primary target of this study was to find out in which lipid fraction the MCFA exist and whether the distribution of MCFA in different lipid classes changes with the variation in chain length of the MCFA. Therefore, one baseline fraction of lymph and the lymph fractions with maximal absorption of MCFA after administration of different STAG were studied.

## EXPERIMENTAL PROCEDURES

**STAG.** The STAG were synthesized by lipase-catalyzed inter-esterification of safflower oil (Róco, Copenhagen, Denmark) and MCFA (Sigma Chemical Co., St. Louis, MO) in a packed-bed reactor (1). The individual STAG were purified by preparative HPLC (3). The composition of the purified STAG was determined by GC after methylation with 2 M KOH in methanol and Grignard degradation (8). The purity of 8:0/18:2/8:0 and 12:0/18:2/12:0 was 94 and 87%, respectively.

**Animal experiments.** Animal experiments were approved by the Danish Animal Experiments Inspectorate. Male albino Wistar rats were used in the study. More details about surgery and lymph collection have been described previously (3). The lymph FA composition was studied and reported previously (3). The lymph used in this study was collected during the maximal absorption of MCFA after administration of STAG 8:0/18:2/8:0, 12:0/18:2/12:0, or maximal absorption of linoleic acid after administration of safflower oil.

**Analytical procedure.** The lymph from all six rats was pooled together for each group and 200  $\mu$ L lymph, together with internal standards of PC 15:0, DAG 15:0, FFA 15:0, and TAG 15:0, were extracted with chloroform and methanol. After washing with water, drying with anhydrous sodium sulfate, and evaporating under nitrogen, the residues were redissolved in 150  $\mu$ L chloroform/methanol (95:5, vol/vol). The

Abbreviations: LCFA, long-chain FA; MCFA, medium-chain FA; MCT, medium-chain TAG; STAG, structured triacylglycerol.

total lipids from the lymph samples were separated into different lipid classes on a silica TLC plate (art. 5721; Merck, Darmstadt, Germany), which was developed in a closed chamber with hexane/diethyl ether/acetic acid (80:20:1, by vol). Following visualization by spraying with 2,7-dichlorofluorescein (0.2% in ethanol), TAG, FFA, DAG, and phospholipids were scraped off and methylated to FAME catalyzed with  $\text{BF}_3$ . The FAME of each lipid fraction were analyzed on an HP 6890 gas chromatograph (Hewlett-Packard, Waldbronn, Germany) equipped with a capillary column (SP-2380, 60 m  $\times$  0.25 mm i.d.; Supelco Inc., Bellefonte, PA). Oven temperature was programmed from 70°C (2 min) to 200°C at a rate of 15°C/min and then to 230°C at a rate of 1.5°C/min and held for 20 min. An FID was used at 300°C, and the injector temperature was 260°C. The injector was used in split mode with a ratio 1:20. The carrier gas was helium with a column flow of 2 mL/min. The FA were identified by comparing the retention time with standards of known FA composition.

**Statistical methods.** The statistical program InStat (GraphPad Software Inc., San Diego, CA) was used in the statistical evaluation. A one-way ANOVA was applied to analyze differences among different lymph groups. The Tukey–Kramer multiple comparisons test was used to evaluate statistical significance.

## RESULTS AND DISCUSSION

Caprylic acid was detected only in lymph TAG after administration of the STAG 8:0/18:2/8:0, whereas lauric acid was also detected in other lipid fractions, i.e., phospholipids, FFA, and DAG, after administration of 12:0/18:2/12:0 (Table 1). A significantly higher level of lauric acid than caprylic acid ( $P < 0.001$ ) was

detected in lymph TAG, partly because the caprylic acid was preferably transported *via* the portal vein and partly because of the low activity of acyl-transferase toward caprylic acid. The relatively high level of oleic acid in lymph lipids after administration of the STAG 8:0/18:2/8:0 may have been due to a greater endogenous contribution when most of the caprylic acid was transported *via* the portal vein.

The distribution of linoleic acid in different lymph lipids was similar after administration of the two STAG and safflower oil (Fig. 1), except that more linoleic acid was detected in DAG after administration of the STAG ( $P < 0.01$ ). When the total FA distributions of different lipid classes were compared, the level of phospholipids was higher ( $P < 0.05$ ) after administration of 8:0/18:2/8:0 than the others (Fig. 2), which may reflect the formation of smaller chylomicrons. It has been reported previously that the number of chylomicrons and the production of apolipoprotein are not changed after a diet containing lipids, but the chylomicron size is increased (9). Since most of the absorbed caprylic acid was transported *via* the portal vein, the chylomicron size decreased, which may have required more phospholipid molecules to form the surface and consequently resulted in more secretion of phospholipids from bile. Comparing the FA profile of lymph phospholipids after administration of the STAG and safflower oil, the levels of palmitic acid ( $P < 0.05$ ) and arachidonic acid ( $P < 0.01$ ) were higher after administration of 8:0/18:2/8:0 than 12:0/18:2/12:0 and safflower oil. Since the major FA of bile phospholipids are palmitic acid (35.7%), stearic acid (6.2%), oleic acid (6.1%), linoleic acid (31.0%), and arachidonic acid (8.3%) (Fruekilde, M.-B., and Høy, C.E., unpublished results), the relatively high levels of palmitic and arachidonic acids in lymph phospholipids after administration of 8:0/18:2/8:0 may have resulted from the contribution of bile phospholipids.

**FIG. 1.** The distribution of linoleic acid (wt%) in different lipid fractions of lymph after intragastric administration of specific structured TAG (STAG) 8:0/18:2/8:0 and 12:0/18:2/12:0. PL, phospholipids.

**FIG. 2.** The distribution of total FA (wt%) in different lipid fractions of lymph after intragastric administration of specific STAG 8:0/18:2/8:0, 12:0/18:2/12:0, and safflower oil. For abbreviations see Figure 1.

In summary, this study provides evidence that caprylic acid is not incorporated into phospholipids and that the intestinal absorption of caprylic acid from STAG mainly occurs by resynthesis of TAG. Lauric acid from the STAG can be incorporated into phospholipids.

#### ACKNOWLEDGMENTS

We thank Jannie Agersten for her technical assistance, Maj-Britt Fruekilde for providing the FA composition of bile phospholipids, and the Center for Advanced Food Studies (LMC) for financial support.

## Habitual Fish Intake Is Associated with Decreased LDL Susceptibility to *ex vivo* Oxidation

**ABSTRACT:** A sample of 101 free-living individuals eating their habitual diets had fish consumptions ranging from less than one serving per week to over five servings per week. Statistically significant positive correlations were found between the amounts of EPA (20:5), DHA (22:6), and total n-3 PUFA ingested with the diet and their amounts in serum and in the phospholipid and cholesterol ester fractions of isolated LDL. No statistically significant correlations were observed between the intake and the serum or LDL amounts of any other FA [total n-6 PUFA, linoleic acid (18:2), arachidonic acid (20:4), monounsaturated FA, or saturated FA]. The increase in serum n-3 PUFA did not affect the Trolox-equivalent antioxidant capacity of serum (1.18 ± 0.17 mmol/L). When isolated LDL were subjected to Cu<sup>2+</sup>-induced *ex vivo* oxidation, a statistically significant but negative correlation was found between intake of n-3 PUFA and the rate of appearance of conjugated dienes as well as with the total amount of conjugated dienes. In contrast, intake of n-6 PUFA showed a significant and positive correlation with these two oxidation parameters. The observed results suggest that 22:6 but not 20:5 could have a possible protective effect, whereas perhaps 20:4 and 18:2 could have a prooxidant effect.

a high dietary intake of fish and high plasma levels of n-3 PUFA. Parkinson *et al.* (3) compared the habitual diets of Alaskan Eskimos with those of a nonnative population used as control and related the amount of n-3 PUFA ingested to plasma n-3 PUFA levels. Similar conclusions have been reached in other studies carried out in Finland (4) and the Madeira Islands (5) by comparing the serum amounts of n-3 PUFA among populations with different dietary habits and lifestyles. Likewise, a number of other workers administering very high levels of dietary supplements (mostly in the form of oil capsules) to volunteer individuals on low-fish diets have obtained similar results with n-3 PUFA in total plasma (6–14), particularly in plasma phospholipids and cholesteryl esters (6,14–23). However, few studies have been done comparing individuals with similar lifestyles consuming their habitual diets ranging from less than one serving of fish per week to up to five or more servings per week (23–28). Likewise, the relation between the increase in lipoprotein n-3 PUFA and fish intake has been documented in cases where fish oil supplements were given (8,10,15,29–34) or in groups of people with extreme dietary habits (35). But the relationship of habitual diets with different amounts of fish on the levels of n-3 PUFA in plasma and in lipoprotein lipids in free-living individuals has not been well documented.

Dietary FA potentially can modify LDL oxidation by changing its FA composition. PUFA are the most susceptible to oxidation (36), and diets enriched with n-6 PUFA result in increased LDL oxidation in humans (19,37–42). The peroxidation of PUFA in LDL has been linked to atherosclerosis (43–45). Fish is high in n-3 PUFA, primarily EPA (20:5) and DHA (22:6), both of which are highly susceptible to oxidation (36,46). Several studies have shown that diet supplementation with n-3 PUFA increased LDL oxidation in healthy subjects (19,31,47) and hypertriglyceridemic patients (10,29). This result was also reported in a small group of people who habitually consume very large amounts of fish (35). By contrast, in other diet intervention studies with high doses of n-3 PUFA, the susceptibility of LDL to oxidation did not change (30,32) or decreased (34). However, we are not aware of any study with free-living individuals who consumed a variety of diets with no supplements in which oxidation of LDL was studied.

The purpose of this work was to study the correlation between a wide range of dietary fish intake (mostly white, lean fish) in a large number of healthy, free-living individuals, their serum and LDL levels of n-3 and n-6 PUFA, and the susceptibility of these PUFA to *ex vivo* oxidation. To assess the antioxidant capacity of LDL, the following indices of oxidizability were used: conjugated dienes (total amount, rate at which they increased, and length of the lag phase), TBARS, and the reaction with trinitrobenzene sulfonic acid (TNBS) after oxidation with  $\text{CuSO}_4$ . Total antioxidant capacity of serum was also determined because literature data are contradictory: Some studies show that fish oil supplements do not affect serum oxidation (4,13,16,22,29), whereas others show an increase in serum oxidation (7,21).

## EXPERIMENTAL PROCEDURES

**Subjects.** The study was carried out with a sample of the cohort of participants from the province of Gipuzkoa (Basque country, Spain) participating in the EPIC (European Prospective Investigation in Cancer and Nutrition) project among nine European countries (48,49). Each participant agreed in writing to the study. The sample consisted of 120 randomly selected healthy individuals of both sexes aged 35–65 with fish intakes ranging from less than one serving per week to five or more servings per week. Subjects were divided into the following four categories of fish intake according to their dietary habits: occasional consumers,  $\leq 31.0$  g/d; low consumers, 31.1–64.0 g/d; moderate consumers, 64.1–115.0 g/d; and high consumers,  $>115.0$  g/d.

**Dietary habits.** Information on daily dietary intake over the previous year was obtained by a personal interview with

each individual (conducted by trained interviewers) using the method of dietetic history with a computerized questionnaire, especially designed and validated by the EPIC Group of Spain (50–52), as described in a previous study (53). Energy and nutrient intake were estimated from Food Composition Tables (54) using a computerized database designed for the EPIC project. The intake of the major FA was calculated from specific Spanish food-composition tables (55–57).

Fish consumption ranged from 0 to 250.70 g/d among the final sample of 101 free-living individuals (46 men and 55 women). Fish, FA, and antioxidant vitamin intakes of grouped individuals according to habitual fish consumption are shown in Table 1. The group of high consumers had an intake of n-3 PUFA 2.2-fold higher than the occasional consumers. The average amount of 20:5 and 22:6 consumed was 6.0- and 4.5-fold higher, respectively, in the high consumer group than for occasional consumers. Saturated FA, monounsaturated FA (MUFA), n-6 PUFA, antioxidant vitamins, and total calorie intake were not significantly different among groups of consumers. Statistically significant differences were found only for the intake of n-3 PUFA ( $P > 0.001$ ) but not for that of n-6 PUFA, MUFA, and saturated FA. The total amount of dietary 20:5 and 22:6 intake in the high-consumer individuals (0.30 and 0.90 g/d, respectively) was comparable to that of other fish diets (4–6,23,24)

**Reagents.** All reagents were purchased from Sigma-Aldrich (Madrid, Spain) and were analytical reagent grade or better. Solvents (highest grade available) were purchased from Teknochroma (Barcelona, Spain) and were not redistilled before use.

**Blood samples.** A fasting blood sample from each individual was collected during a second personal interview. Plasma, serum, and other fractions were separated immediately and

kept at  $-180^{\circ}\text{C}$  in liquid nitrogen until analyzed. Serum was used for all analyses reported herein. Samples were analyzed without knowing their identity. A 0.1-mL serum aliquot for the Trolox (a water-soluble vitamin E analog) equivalent antioxidant capacity (TEAC), as oxidizability measurement in total serum, was sealed under nitrogen and kept at  $-80^{\circ}\text{C}$  for up to 2 d.

Lipoproteins were separated by ultracentrifugation on a NaBr density gradient as described by Kelly and Kruski (58). The NaBr (containing 0.05% EDTA) gradient was prepared in a Buchler Auto DensiFlow (Buchler Instruments, Fort Lee, NJ), and the ultracentrifugation was carried out in a Beckman L8-M ultracentrifuge with a SW 40 Ti rotor (Beckman Instruments, Palo Alto, CA) for 24 h at  $110,000 \times g$  and  $14^{\circ}\text{C}$ . The yellow-orange band corresponding to the LDL was collected. A 100- $\mu\text{L}$  aliquot was used to determine the total protein concentration (59). BHT (1%) was added to a 0.5-mL aliquot, and this sample was stored at  $-80^{\circ}\text{C}$  until the lipid analysis was done. The remainder was used immediately for lipoprotein oxidizability measurements.

**Lipid analysis.** Total serum FA were quantitated as FAME following the method of Lepage and Roy (60) as modified by Matorras *et al.* (61). Briefly, 2.0 mL toluene/methanol (1:4 vol/vol) containing 10  $\mu\text{g}$  *n*-heptadecanoic acid as internal standard was added to 100  $\mu\text{L}$  serum in a stoppered glass tube. After mixing, 200  $\mu\text{L}$  acetyl chloride was added, and the tube was incubated overnight (16–18 h) at  $60^{\circ}\text{C}$ . Then 500  $\mu\text{L}$  *n*-heptane containing 250  $\mu\text{g}$  BHT and 3.0 mL 10% potassium carbonate was added. The tube was centrifuged to separate the phases, and the upper phase was transferred to a glass vial. The solvent was evaporated under a stream of nitrogen on a sand bath at  $35^{\circ}\text{C}$ , and the residue was dissolved in 50  $\mu\text{L}$  *n*-heptane.

FAME were separated by capillary GC on a 30-m capillary SP-2330 column (0.32 mm internal diameter, 0.20 mm film thickness). The chromatograph was from Hewlett-Packard (model 5890 series II, Palo Alto, CA), equipped with an FID, split-splitless injector, automatic sampler, and work station. The carrier gas (He) flow through the column was 0.95 mL/min. Oven temperature was programmed from 80 (1 min) to  $140^{\circ}\text{C}$  at  $50^{\circ}\text{C}/\text{min}$  and to  $190^{\circ}\text{C}$  at  $5^{\circ}\text{C}/\text{min}$ . After 5 min at  $190^{\circ}\text{C}$ , the temperature was increased to  $215^{\circ}\text{C}$  at  $5^{\circ}\text{C}/\text{min}$  and held at  $215^{\circ}\text{C}$  for 8 min. Injector and detector temperatures were  $250^{\circ}\text{C}$ , and the split-splitless valve was set at 1:10. Serum samples were extracted in duplicate, and each sample was injected twice into the gas chromatograph.

LDL lipids were extracted and lipid classes were separated by TLC on silica gel plates as described (62,63). Phospholipids and cholesterol esters were recovered and derivatized, and the resulting FAME were quantitated as described above.

**Oxidizability measurements.** The TEAC value of serum was determined using a commercially available kit (catalog no. NX2332; Randox, Crumlin, United Kingdom), based on the method of Miller *et al.* (64).

**Oxidizability measurements in LDL.** The antioxidant capacity of LDL was evaluated by three different methods: con-

jugated dienes after oxidation with  $\text{CuSO}_4$ , TBARS, and the reaction with TNBS. Total amount of conjugated dienes, the rate of diene appearance, and the length of the lag phase for the oxidation of these dienes were determined by the modified method of Puhl *et al.* (65) as follows: an aliquot of LDL containing 50  $\mu\text{g}$  protein/mL, PBS (0.15 M NaCl, 0.01 M phosphate buffer, pH 7.4), and 5  $\mu\text{M}$   $\text{CuSO}_4$  was incubated at  $30^{\circ}\text{C}$  in a spectrophotometric cuvette, and the increase in absorbance at 234 nm was recorded during 4 h. To determine TBARS the method described by Kleinveld *et al.* (66) was used. After oxidizing LDL aliquots as described above at  $30^{\circ}\text{C}$  for 3 h, 0.1 mL EDTA (6.7 mg/mL) and 0.1 mL TCA (100%) were added. The mixture was centrifuged at  $7,500 \times g$  for 15 min. To 0.5 mL of the supernatant was added 1.0 mL thiobarbituric acid (TBA: 0.67%), and the mixture was incubated in a double boiler for 15 min. Absorbance at 532 nm was read after the samples had cooled. Results are expressed as equivalents of malondialdehyde generated by the acid hydrolysis of 1,1,3,3-tetramethoxypropane. The oxidation of the protein fraction of LDL was determined according to the method of Steinbrecher (67) for the  $\epsilon$ -amino group of lysine residues. Aliquots of LDL were oxidized as described above for 6 h. The reaction was stopped by the introduction of 0.1 mL EDTA (6.7 mg/mL), and 1.0 mL  $\text{NaHCO}_3$  (4%) and 50  $\mu\text{L}$  TNBS were added. The mixture was incubated at  $37^{\circ}\text{C}$  for 1 h. Then 0.1 mL 1 M HCl and 0.1 mL SDS (10%) were added, and the absorbance was read at 340 nm. The value obtained was compared to that of the nonoxidized (but otherwise identically treated) LDL aliquot.

**Statistical analysis.** Statistical treatment of the data (SPSS Statistical Software, Chicago, IL) was done for a final sample of 101 individuals due to the loss of some samples during analytical manipulations. Results are presented as mean  $\pm$  SD. One-way ANOVA were done to compare the intake and FA composition of serum and LDL among the groups of occasional ( $\leq 31.0$  g/d), low (31.1–64.0 g/d), moderate (64.1–115.0 g/d), and high ( $> 115.0$  g/d) fish consumers. The influence of fish intake on the FA composition of serum and LDL was studied by simple linear regression analysis. Multiple linear regression analysis was used to study the influence of PUFA intake and LDL FA composition (independent variables) on the oxidation parameters of serum and LDL (dependent variables). In this analysis  $r$  represents the value of the multiple correlation coefficient for all variables and  $\beta$  represents the direction and value of the regression coefficient of each independent variable. Statistical significance was considered to be  $P < 0.05$  for all results.

## RESULTS AND DISCUSSION

**FA in serum and LDL.** The amounts of unsaturated FA present in serum and in LDL phospholipid and cholesterol esters are listed in Tables 2 and 3, respectively. Statistically significant differences among consumer groups were observed only for the percentage of *n*-3 PUFA in serum ( $P < 0.001$ ) and in LDL phospholipids ( $P < 0.01$ ) and cholesterol esters ( $P < 0.001$ ).

**TABLE 2**

<sup>b</sup>NS, not significantly different values among fish consumption groups, where significant differences are taken as  $P < 0.05$ .

Fish intake was positively correlated with the values of n-3 PUFA in serum ( $P < 0.001$ ), 20:5, 22:6, and total n-3 PUFA (Table 4). The same was true for phospholipids and cholesterol esters of isolated LDL (Table 5). No statistically significant differences were observed in the correlations between fish intake and the amounts of the other FA, n-6 PUFA (total, linoleic, or arachidonic acids), MUFA, or saturated FA, either in total serum lipids or in those of isolated LDL. This result is consistent with the fact that the dietary intake of these FA was essentially identical ( $P > 0.05$ ) for all subjects. In diet intervention studies in which subjects have been given large amounts of n-3 PUFA, other authors have shown that n-3 PUFA in total serum (9,17,23) or LDL (33) can be used as serum markers of fish intake. Our results are in agreement with this observation even though in our study only a small fraction of the subjects (10%) would have ingested amounts of n-3 PUFA ( $\geq 2.5$  g/d) similar to the lower value of the

dietary supplements given in those studies (2.5–7.7 g/d). The correlation between intake of n-3 PUFA and their serum concentrations agrees with published studies of fish intake (23–28).

*Serum and LDL oxidizability.* Total antioxidant capacity of serum samples was measured with the Randox commercial reagent kit developed after the method of Miller *et al.* (64). Average values obtained for the TEAC measurements of all serum samples were  $1.18 \pm 0.17$  mmol/L (range: 0.65–1.74). The observed increase in total serum n-3 PUFA levels with fish intake did not affect the total antioxidant capacity of serum. These observations are similar to those of other investigators who showed that dietary supplements of either fish oil or n-3 PUFA have no effect on oxidation of serum lipids, both in humans (4,13,16,29) and in rats (68). This could be explained by the relatively high vegetable and fruit intake (the average was 616 g, or 7.7 servings per day) in all individuals (69), which would

provide a number of low M.W. antioxidants. It is known that the presence of antioxidant compounds in serum such as albumin, urate, ascorbate, bilirubin, or  $\alpha$ -tocopherol can stop the appearance and propagation of free radicals (64). Thus, even though the level of serum n-3 PUFA increased significantly with fish intake, no differences were observed in the susceptibility to oxidation of serum samples from individuals with widely different fish intakes.

Isolated LDL fractions were subjected to Cu<sup>2+</sup>-induced oxidation *ex vivo*, and the following lipid oxidation parameters were measured: duration of the lag phase, rate of conjugated diene production, total diene concentration, and TBARS. In addition, the percentage of nonoxidized protein (TNBS) was also measured. Intake of n-3 and n-6 PUFA was significantly correlated with the rate of conjugated diene appearance (*P* < 0.05) and the total diene concentration (*P* < 0.05) (Table 6). The average rate of conjugated diene production (propagation rate) was 17.63  $\pm$  5.33 nmol·min<sup>-1</sup>·mg protein<sup>-1</sup> (range: 7.73–37.90 nmol·min<sup>-1</sup>·mg protein<sup>-1</sup>), and the average amount of conjugated dienes was 518.19  $\pm$  111.34 nmol·mg

<sup>a</sup>*r*, multiple correlation coefficient for all variables;  $\beta$ , regression coefficient for each independent variable; NS, no statistically significant correlation, where significance is taken as *P* < 0.05.

protein<sup>-1</sup> (range: 229.91–849.91 nmol·mg protein<sup>-1</sup>). These two parameters negatively correlated with n-3 PUFA intake, indicating that higher amounts of these highly unsaturated FA gave lower propagation rates and, therefore, lower conjugated diene concentrations. Thus, the increased levels of n-3 PUFA present in LDL as a result of higher dietary fish intakes did not result in higher LDL *ex vivo* oxidizability. In contrast, intake of n-6 PUFA presented a positive correlation with these two lipid oxidation parameters (*P* < 0.05). As expected, the intake of saturated FA and MUFA showed no statistically significant correlation with any of the LDL oxidation parameters measured. The average duration of the lag phase was 70  $\pm$  12 min (range: 38–102 min), and the TBARS measurements gave an average value of 86.08  $\pm$  16.96 nmol·mg protein<sup>-1</sup> (range: 45.38–136.32 nmol·mg protein<sup>-1</sup>). The observed differences in LDL lipid composition as a result of the different fish intakes did not significantly affect these parameters of lipid oxidation. Other investigators, directing diet intervention studies in which subjects were given higher amounts of n-3 PUFA than the majority of subjects herein ingested, have shown that a decrease in the lag phase and an increase in the TBARS value was related to the prooxidant effect of fish oil and n-3 PUFA (10,19,29,31,35,47). In contrast, other investigators have not found any effect of dietary supplements containing fish oil or n-3 PUFA on these LDL lipid peroxidation parameters (30,32,34).

The percentage of nonoxidized protein (TNBS measurements) was 54.29  $\pm$  12.14 (range: 22.40–87.42). The lack of significant differences in these values indicated that the observed differences in lipid composition did not affect the oxidizability of the protein composition of LDL as a result of the oxidation of the lipid components.

The increase in total n-3 PUFA in LDL phospholipids and cholesterol esters was negatively correlated ( $P < 0.01$  and  $P < 0.001$ , respectively) with the propagation rate of  $\text{Cu}^{2+}$ -induced oxidation, whereas total n-6 PUFA showed a statistically significant positive correlation ( $P < 0.05$  and  $P < 0.001$ , respectively) (Table 7). Of the two major n-3 PUFA, only the amount of 22:6 showed a statistically significant but negative correlation with the rate of appearance of conjugated dienes, both in the cholesterol ester ( $P < 0.05$ ) and phospholipid ( $P < 0.001$ ) fractions of the LDL (Table 8), indicating that as the percentage of this FA in the corresponding fraction in the

LDL increased, the formation of conjugated dienes decreased (Table 8). This unexpected protective effect of total n-3 PUFA, and of 22:6 in particular, has also been observed by some authors in LDL isolated from humans (31), nonhuman primates (70), and Yucatan minipigs (71). In these studies, propagation rates decreased in the presence of higher amounts of n-3 PUFA. In contrast, in cholesterol esters it was the percentage of linoleic acid and not that of arachidonic acid that correlated positively with the rate of propagation ( $P < 0.01$ ) as well as with the total conjugated diene concentration ( $P < 0.05$ ), in agreement with results from other studies

<sup>a</sup>For footnotes see Table 6.

(41,42). We have also observed that the amount of arachidonic acid is positively correlated with an increase in the value of TBARS, for phospholipids ( $P < 0.001$ ) and cholesterol esters ( $P < 0.01$ ), and a decrease in the duration of the lag phase for phospholipids and cholesterol esters ( $P < 0.001$ ) (Table 8), both of which would be consistent with the prooxidant effect of n-6 PUFA.

Thomas *et al.* (72) showed that the rate of conjugated diene appearance during peroxidation of LDL was similar when LDL were enriched with n-3 PUFA or MUFA, but it was considerably higher when LDL were enriched with n-6 PUFA. Furthermore, Frankel *et al.* (30) showed that, after intake of fish oil supplements, the PUFA composition of LDL as well as the oxidation products is modified, although these changes taken together do not affect the susceptibility to *ex vivo* peroxidation of LDL. *In vitro* studies with PUFA in aqueous micelles indicate that n-3 PUFA have greater resistance to oxidation than n-6 PUFA (46,73,74).

As a consequence of an habitually higher fish intake the percentage of n-3 PUFA increased significantly in serum and in LDL, but this increase did not result in a loss of serum antioxidant capacity or in an increase in susceptibility toward  $\text{Cu}^{2+}$ -induced oxidation in LDL. Furthermore, these FA, particularly 22:6, appear to confer some antioxidative character because of a decrease in the propagation velocity of the lipid peroxidation.

**ABSTRACT:** The present study compared the effect of dietary conjugated linolenic acid (CLNA) on body fat and serum and liver lipid levels with that of CLA in rats. FFA rich in linoleic acid,  $\alpha$ -linolenic acid, CLA, or CLNA were used as experimental fats. Male Sprague–Dawley rats (4 wk old) were fed purified diets containing 1% of one of these experimental fats. After 4 wk of feeding, adipose tissue weights, serum and liver lipid concentrations, serum tumor necrosis factor (TNF)- $\alpha$  and leptin levels, and hepatic  $\beta$ -oxidation activities were measured. Compared with linoleic acid, CLA and, more potently, CLNA were found to reduce perirenal adipose tissue weight. The same trend was observed in the weight of epididymal adipose tissue. CLNA, but not CLA, was found to significantly increase serum and liver TG concentrations. Serum FFA concentration was also increased in the CLNA group more than in the other groups. The activity of  $\beta$ -oxidation in liver mitochondria and peroxisomes was significantly higher in the CLNA group than in the other groups. Thus, the amount of liver TG exceeded the ability of hepatic  $\beta$ -oxidation. Significant positive correlation was found between the adipose tissue weights and serum leptin levels in all animals (vs. perirenal:  $r = 0.557$ ,  $P < 0.001$ ; vs. epididymal:  $r = 0.405$ ,  $P < 0.05$ ). A less significant correlation was found between adipose tissue weights and serum TNF- $\alpha$  level (vs. perirenal:  $r = 0.069$ ,  $P > 0.1$ ; vs. epididymal:  $r = 0.382$ ,  $P < 0.05$ ). Although the mechanism for the specific effect of CLNA is not clear at present, these findings indicate that in rats CLNA modulated the body fat and TG metabolism differently from CLA.

Paper no. L8937 in *Lipids* 37, 343–350 (April 2002).

CLA is a FA that has 18 carbons and one conjugated double bond, including multiple positional and geometric isomers (9*c*, 11*t*; 10*t*, 12*c*; etc.), and is exclusively found in a trace amount

Abbreviations: CLNA, conjugated linolenic acid; CPT, carnitine palmitoyl-transferase; DTNB, 5,5-dithiobis-(2-nitrobenzoic acid); LA, linoleic acid; LNA,  $\alpha$ -linolenic acid; PPAR, peroxisome proliferator-activated receptor; TNF, tumor necrosis factor; UCP, uncoupling protein.

in ruminant meats and dairy products (1,2). CLA has been shown to reduce body fat in rodents (3,4) and humans, although results were not always unequivocal (5–9). The exact mechanism of the anti-obese effect of CLA is not clear. Animal studies showed that it could be attributed in part to a decrease in the activity of lipoprotein lipase (10–12), an increase in lipolysis in adipocytes (10), or a moderate increase in FA oxidation in adipose tissue (10), muscle (10), and liver (13). Compared with linoleic acid (LA), CLA has been shown to lower plasma concentrations of cholesterol and TG and regress established atheroma in rabbits (14,15), whereas it increases liver TG concentrations in mice (16,17) but not in rats (13,18). It has been demonstrated that more highly unsaturated FA, such as LA metabolites, are more hypocholesterolemic than LA (19). Similar to LA, CLA is thought to be metabolized to conjugated eicosatrienoic or eicosatetraenoic acids through desaturation and elongation in rats (20,21). From these backgrounds, it is of interest to know how a more highly unsaturated conjugated FA affects lipid metabolism.

CLNA is one of the more highly unsaturated forms of conjugated FA and possibly includes multiple positional (8, 10, 12; 9, 11, 13; etc.) and geometric (*cis* and *trans*) isomers. CLNA occurs abundantly in some specific seed oils, such as karela oil (22), tung oil (23,24), and pomegranate oil (24). There is evidence showing that karela oil, as compared with linseed oil [rich in  $\alpha$ -linolenic acid (ALA)], increased the serum cholesterol and TG concentrations in rats fed a high-fat diet (20% fat containing 10% CLNA) (22). Igarashi and Miyazawa showed that CLNA, but not CLA, exhibited cytotoxic effects on some lines of human tumor cells (23). They also reported that conjugated eicosapentaenoic and docosahexaenoic acids with conjugated trienoic structures exhibited the strongest cytotoxic effect on human tumor cells, possibly due to the induction of apoptosis of the cells through lipid peroxidation (25). From these observations, feeding of CLNA with conjugated trienoic structure was expected to affect lipid metabolism more than was CLA. To date, no additional

evidence is available to show the biological effects of CLNA. The objective of the present study using a rat model was to examine how CLNA affects body fat mass, and serum and liver lipids.

## MATERIALS AND METHODS

**Experimental fats.** Experimental fats used in the present study were FFA that were rich in LA, LNA, CLA, and CLNA, all supplied by Rinoru Oil Mills Co., Ltd. (Tokyo, Japan). LA- and LNA-rich FA were derived from safflower oil and perilla oil, respectively, and from them CLA- and CLNA-rich FA were prepared by alkaline isomerization. The FA profile was measured as described previously (26). Briefly, approximately 25 mg of the FFA sample was methylated with 2 mL of BF<sub>3</sub>-methanol at 40°C for 10 min. FAME were analyzed by GLC with a J&W DB-23 capillary column (30 m × 0.25 mm i.d.; Agilent Technologies, Palo Alto, CA). The FA profile of the experimental fats is shown in Table 1. For the confirmation of CLNA analysis, we observed two peaks for conjugated diene and six peaks for conjugated triene by HPLC (27) monitoring at 234 and 268 nm, respectively (23). It was confirmed by GC/MS that the former peaks contained 18:3 and 18:2 and the latter peaks contained 18:3. Although CLNA contained 18:3 conjugated diene and triene, the identification of individual components awaits further study.

**Animals and diets.** Thirty-two male weanling Sprague-Dawley rats (4 wk old) purchased from SEAC Yoshitomi Co. (Fukuoka, Japan) were acclimatized for 3 d in a room maintained at 21–23°C with a 12-h light–dark cycle. Animals were randomly assigned to four groups of eight animals each according to the experimental fats: LA, ALN, CLA, and CLNA. Diets were prepared according to the AIN-93G formula (28) and contained (by wt %) casein 20; soybean oil 6; experimental fat 1; cornstarch 39.7; dextrinized cornstarch 13.2; sucrose 10; cellulose 5; mineral mixture (AIN-93G-MX) 3.5; vitamin mixture (AIN-93-VX) 1; L-cystine 0.3; choline bitartrate 0.25; and *t*-butylhydroquinone 0.0014. Animals were maintained on their respective diets *ad libitum* for 4 wk. During the feeding period, body weight and food consumption were recorded every other day. After 16 h of food deprivation, animals were anesthetized with diethyl ether, and blood was collected from the abdominal aorta. Serum was separated by centrifugation. The liver and other tissues, including perirenal and epididymal white adipose tissues and interscapular brown adipose tissue, were excised and weighed.

**Serum and liver lipid analysis.** Serum total and HDL cholesterol were measured using commercial assay kits (Cholesterol CII-test Wako; Wako Pure Chemical Industries, Osaka, Japan; and HDL-C2; Daiichi Pure Chemicals, Tokyo, Japan). Serum phospholipid, TG, FFA, and TBARS were also measured using commercial assay kits (Phospholipid B-, Triglyceride G-, NEFA-, and Lipid Peroxide-Test Wako; Wako Pure Chemical Industries).

Total liver lipids were extracted by the method of Folch *et al.* (29). The concentrations of liver cholesterol, phospholipid, and TG were measured by the methods of Ide *et al.* (30), Rouser *et al.* (31), and Fletcher (32), respectively.

**Preparation of liver mitochondria/peroxisomes.** An aliquot of liver was homogenized in 7 vol of a 0.25-M sucrose solution. The homogenate was centrifuged at 1,000 × *g* for 10 min at 4°C. The supernatant was centrifuged at 16,000 × *g* for 20 min to sediment mitochondria/peroxisomes. The pellet was suspended in a solution containing 0.3 M mannitol, 10 mM HEPES, and 0.1 mM EGTA. The suspension was stored at –80°C until used for the measurement of carnitine palmitoyltransferase (CPT) and peroxisomal β-oxidation activities. The protein content of the suspension was measured by the method of Lowry *et al.* (33).

**Measurement of CPT activity.** The activity of CPT was measured spectrophotometrically by monitoring the release of CoA-SH from palmitoyl-CoA using 5,5-dithiobis-(2-nitrobenzoic acid) (DTNB) (34). The carnitine-dependent reaction was initiated by addition of enzyme (sample suspension) to the reaction cuvette containing 58 mM Tris HCl (pH 8.0), 1.25 mM EDTA, 0.1% Triton X-100, 0.25 mM DTNB, 37.5 mM palmitoyl-CoA, and 1.25 mM L-carnitine. The reaction compartment was thermostated at 27°C. The reaction was followed at 412 nm. The carnitine-independent reaction was conducted by an identical procedure without L-carnitine. The difference between L-carnitine-dependent and -independent reaction rates was regarded as CPT activity. Data were expressed as nmol CoA/min/mg protein.

**Measurement of peroxisomal β-oxidation.** The peroxisomal β-oxidation was measured spectrophotometrically by monitoring the reduction of NAD to NADH in the presence of palmitoyl-CoA (35). The reaction was initiated by the addition of enzyme (sample suspension) to the reaction cuvette containing 50 mM Tris HCl (pH 8.0), 20 mM NAD, 0.33 M DTT, 1.5% BSA, 2% Triton X-100, 10 mM CoA, 1 mM FAD, 100 mM KCN, and 5 mM palmitoyl-CoA. The reaction compartment

was thermostated at 37°C. The reaction rate was followed at 340 nm. Data were expressed as nmol NAD reduced/min/mg protein.

**Serum concentration of tumor necrosis factor (TNF)- $\alpha$  and leptin.** The concentration of serum TNF- $\alpha$  and leptin was measured by ELISA using a commercial kit (Rat TNF- $\alpha$  ELISA YK 040 and Rat Leptin ELISA YK 050; Yanaihara Institute Inc., Shizuoka, Japan).

**Measurement of uncoupling protein (UCP) 1 of brown adipose tissue by western blotting.** An aliquot of brown adipose tissue was homogenized in PBS containing 0.5% sodium deoxycholate, 0.1% SDS, 2 mM EDTA, 1% NP-40 (Sigma, St. Louis, MO), 5 mg/mL phenylmethylsulfonyl fluoride, and 2 mg/mL aprotinin. The homogenate was centrifuged at 10,000  $\times$  g for 10 min at 4°C. The supernatant was used for the following measurements. The protein concentration was determined using a commercial kit (BCA Protein Assay Reagent; Pierce Chemical Co., Rockford, IL). The sample (50 mg protein/lane) was electrophoresed using SDS polyacrylamide gel (12%) transferred to nitrocellulose membrane. UCP 1 was probed with rabbit anti-rat UCP 1 antibody at 4°C for 16 h (2000 times diluted solution), which was kindly provided by Dr. Teruo Kawada (Kyoto University, Kyoto, Japan). Then the membrane was reacted with goat anti-rabbit IgG POD (peroxidase) conjugated (secondary antibody; ICN Pharmaceuticals, Aurora, OH) at 37°C for 1 h. Detected protein was visualized using equivalent chain length western blotting detection reagents (Amersham Pharmacia Biotech, Buckinghamshire, England), and the bands were quantitated using NIH (National Institutes of Health) Image. The amount of  $\beta$ -actin was also measured by western blotting and anti-rat  $\beta$ -actin clone AC-15 (3000  $\times$  dilution; Sigma) and anti-mouse IgG HRP conjugated (3000  $\times$  dilution; ICN) were used as primary and secondary antibodies. Values of UCP 1 were divided by those of  $\beta$ -actin to be normalized.

**Statistical analysis.** Results were expressed as means and pooled SE unless otherwise indicated. All data were analyzed by a one-way ANOVA followed by the Tukey–Kramer test to determine the dietary fat-dependent difference. All analyses were performed with SuperANOVA software (Abacus Concepts, Berkeley, CA).

## RESULTS

**Body weight gain, food intake, and tissue weights.** During 4 wk of feeding, food intake tended to be higher in rats fed LNA and CLA than in those fed LA and CLNA (Table 2). The relative weight of perirenal adipose tissue was significantly lower in rats fed CLA and CLNA than in those fed LA, and it tended to be lower in the CLNA group than in the CLA group. This trend also was observed in the weight of epididymal adipose tissue. The relative liver weight was significantly heavier in rats fed CLNA than in those fed other fats. This trend also was observed in the relative heart weight.

**Serum and liver lipid concentrations.** The concentration of serum cholesterol was significantly lower in the CLNA group than in the LA group (Table 3). Although CLA exhibited the same trend as CLNA, the cholesterol-lowering effect against LA was not statistically significant. The concentration of HDL-cholesterol was significantly lower in rats fed CLNA than in those fed other fats. As a result, the ratio of HDL/total cholesterol was significantly lower in the CLNA group than in the LNA group (data not shown). The serum TG concentration of the CLNA group was more than twice that of the LA, LNA, and CLA groups. The serum FFA concentration of the CLNA group was significantly higher than that of the other groups. The serum TBARS value, an index of the potential for lipid peroxidation, was significantly higher in rats fed CLNA than in those fed CLA. However, there was no significant difference in this value between the other groups.

Effects of different dietary fats on the liver lipid concentrations are shown in Table 3. The concentration of liver cholesterol was significantly higher in rats fed the LNA diet than in those fed other fats. The TG concentration of the CLNA group was approximately twice that of the other three groups.

***β-Oxidation activity in liver mitochondria and peroxisomes.*** The β-oxidation activity was examined in liver mitochondria and peroxisomes. The activity of CPT, a key enzyme in the FA oxidation pathway, was measured as an index of liver mitochondrial β-oxidation. Since freezing–thawing mitochondria inactivates CPT I but not CPT II (36), the CPT activity measured in the present study most likely represented CPT II activity (37). As shown in Figure 1A, CPT II activity was 7 μmol/mg protein in rats fed LA. The activity was increased 20% by either LNA or CLA and 57% by CLNA. The activity in rats fed CLNA was significantly higher than that in animals fed other fats. On the other hand, relative to LA, peroxisomal β-oxidation, measured using palmitoyl-CoA as a substrate, was increased threefold by CLNA but was unaffected by the other dietary treatments (Fig. 1B).

***Serum concentration of TNF-α and leptin.*** As shown in Figure 2A, the serum concentration of TNF-α was significantly higher in rats fed LNA, CLA, and CLNA than in those fed LA. The concentration of serum leptin tended to be higher in rats fed LNA than in those fed LA (Fig. 2B). The leptin concentration of CLA-fed rats tended to be lower, whereas the leptin concentration of CLNA-fed rats was significantly lower than that of LNA-fed rats.

The correlations between serum TNF-α or leptin concentrations and adipose tissue weight are shown in Figure 3. A positive correlation was observed between the serum TNF-α concentration and epididymal but not perirenal adipose tissue (Fig. 3A). On the other hand, serum leptin exhibited a significant positive correlation with weights of both perirenal and epididymal adipose tissues (Fig. 3B).

***UCP 1 level of brown adipose tissue.*** NIH-imaged UCP 1 levels normalized by β-actin were  $1.36 \pm 0.12$ ,  $1.40 \pm 0.10$ ,  $1.33 \pm 0.13$ , and  $1.35 \pm 0.12$  for the LA, LNA, CLA, and CLNA groups (mean ± SE), respectively. No statistically significant difference was observed.

## DISCUSSION

The present study examined how dietary CLNA affects body fat mass and serum and liver lipid levels in rats. The effect of dietary CLNA was compared with that of CLA, LNA, and LA. In agreement with the earlier findings using mice as an experi-

**FIG. 1.** Effect of conjugated linolenic acid (CLNA) on liver mitochondrial (A) and peroxisomal (B) β-oxidation activity. LA, linoleic acid; LNA, α-linolenic acid; CPT, carnitine palmitoyltransferase. All data are expressed as mean ± SE of eight rats. Values not sharing a common letter (a,b) are significantly different at  $P < 0.05$ .

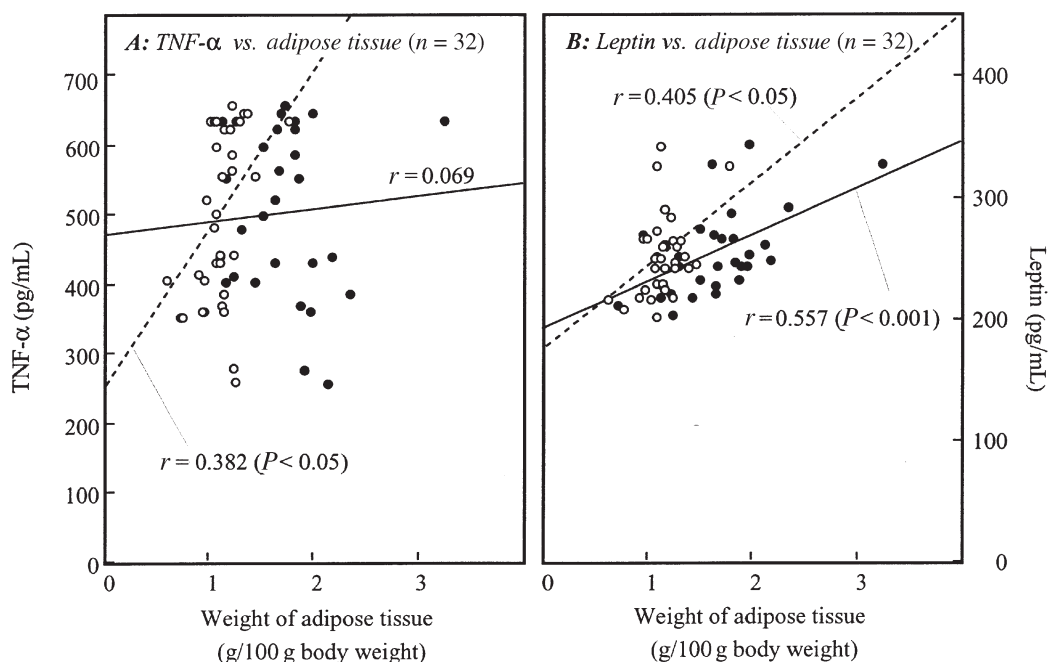

**FIG. 2.** Effect of CLNA on tumor necrosis factor (TNF)- $\alpha$  (A) and leptin (B) concentrations in serum. For other abbreviations see Figure 1. All data are expressed as mean  $\pm$  SE of 8 rats. Values not sharing a common letter (a,b) are significantly different at  $P < 0.05$ .

mental animal (3,4), feeding of CLA reduced the perirenal adipose tissue weight more than LA did. However, the difference between LNA and CLA was not statistically significant. On the other hand, feeding of CLNA reduced the weight of perirenal adipose tissue significantly more than LA and LNA did. This suggests that the body fat-reducing effect of CLNA is at least comparable to or even stronger than that of CLA under the experimental conditions described in the present study.

Serum lipid concentration was modified by dietary CLNA.

The concentration of serum TG increased 2.5-fold in rats fed CLNA as compared with the animals fed LA, LNA, or CLA. Since serum TG was normally associated with lipoproteins (38), one may expect that the increase in serum TG concentration might cause an increase in serum cholesterol concentration. However, serum cholesterol concentration was significantly lower in rats fed CLNA than in those fed LA. Serum phospholipid concentration was comparable among the groups. Since the rats were fasted for 16 h prior to collection of blood, this elevated level of TG in rats fed CLNA in the present study might be indicative of an inability to clear VLDL, possibly due to an inhibition of lipoprotein lipase activity (10–12). It is plausible that the increase in the serum concentration of TBARS (Table 3) and the whitish color of the serum may be responsible for the hypertriglyceridemia caused by CLNA. Dhar *et al.* (22) reported that karela oil containing CLNA increased the serum concentration of cholesterol and TG, whereas it tended to decrease the liver TG. The difference in the dietary level of experimental fat and the type of FA molecule may be the cause of the discrepancy. The dietary level of the experimental fat was 20% (as karela oil) in their report, whereas it was only 1% (as CLNA) in the present study. Also, karela oil contains mainly 9*c*, 11*t*, 13*t*-18:3 (39), whereas the CLNA used in the present study was a mixture of conjugated diene and triene, which possibly contains multiple positional and geometric isomers. In the present study, adipose tissue did not grow as rapidly in rats fed CLNA or CLA. In an early report, Park *et al.* (10) suggested that CLA reduced the body fat through a reduction of fat deposition and an increase of lipolysis in adipocytes. It was demonstrated that 10*t*, 12*c*-18:2 but

**FIG. 3.** Correlation between TNF- $\alpha$  concentration and adipose tissue weight (A) and leptin concentration and adipose tissue weight (B). ●, Perirenal adipose tissue; ○, epididymal adipose tissue. —, vs. perirenal adipose tissue; ----, vs. epididymal adipose tissue. For abbreviation see Figure 2.

not 9*c*,11*t*- and 9*t*,11*c*-isomers inhibited lipoprotein lipase activity (12) and depressed the concentration of intracellular TG in 3T3-L1 preadipocytes (11,12). As shown in Table 1, CLA contained 33% of 10*t*,12*c*-18:2, whereas CLNA contained 15% of this isomer, and 32 and 17% of conjugated 18:3 with diene and triene structures (Table 1). Therefore, conjugated diene and/or triene isomers of 18:3 may reduce the fat deposition more efficiently than CLA. Moreover, feeding of CLNA, but not CLA, increased the serum concentration of FFA significantly more than that of LA and LNA, suggesting that CLNA may increase FA mobilization from the adipose tissues.

Previous studies have established that adipocytokines, such as leptin and TNF- $\alpha$  secreted from adipocytes, can modulate the amount of adipose tissue (40). Therefore, the correlation between these adipocytokine levels and adipose tissue weights was investigated to clarify which adipocytokine was more closely related to the adipose tissue weights (Fig. 3). As a result, serum leptin level was found to exhibit a significant positive correlation with the weight of perirenal and epididymal adipose tissues. Adipose tissue weight was related to serum leptin concentration more than to TNF- $\alpha$  concentration (40). Relative to the group fed LA, TNF- $\alpha$  levels were elevated by LNA, CLA, and CLNA to a similar extent (Fig. 2). An early report in animals showed that TNF- $\alpha$  decreased the synthesis of lipoprotein lipase in adipose tissue but increased the activity of lipoprotein lipase in liver (41). TNF- $\alpha$  was reported to decrease peroxisome proliferator-activated receptor (PPAR)- $\gamma$  mRNA level in 3T3-L1 preadipocytes (42). PPAR- $\gamma$  is known to play an important role for the differentiation of adipocytes (43,44). Recently, studies in obese women showed that PPAR- $\gamma$  mRNA levels in adipose tissue were positively associated with the serum concentrations of HDL-cholesterol (45,46). Serum HDL-cholesterol concentrations were also shown to exhibit a positive correlation with leptin mRNA levels in adipose tissue (45). In the present study, serum leptin concentration exhibited a significant positive correlation with serum HDL-cholesterol ( $r = 0.596$ ,  $n = 32$ ,  $P < 0.001$ , data not shown). Also, serum leptin and HDL-cholesterol levels were the lowest in the CLNA group. This could be one explanation why CLA and, more potently, CLNA decreased the weight of white adipose tissues as compared with the corresponding nonconjugated FA, even under the equally high concentration of serum TNF- $\alpha$ . In the present study, the level of UCP 1 was also measured, which is a thermogenic uncoupling protein and expresses exclusively in brown adipose tissue (47). Although TNF- $\alpha$  was reported to increase UCP 1 level of brown adipose tissue (48), the effect of dietary fat on the UCP1 level was not clear in the present study.

CLA and CLNA also affected differently the concentration of liver TG. CLA tended to suppress the liver TG concentration as compared with LA or LNA (Table 3) without affecting the liver weight (Table 2). The liver mitochondrial CPT II activity and peroxisomal  $\beta$ -oxidation activity tended to be higher in rats fed CLA than in those fed LA (Fig. 1). The

increase in  $\beta$ -oxidation activity may cause a decreased concentration of TG in the liver. In contrast to CLA, CLNA increased liver TG concentration twofold as compared with LA or LNA. This may be one reason why the liver weight was significantly increased only by CLNA (Table 2). Also, CLNA, as compared with other FA significantly enhanced the activities of both liver mitochondrial and peroxisomal  $\beta$ -oxidation (Fig. 1). Peroxisomal  $\beta$ -oxidation in particular increased 3–3.5-fold in CLNA-fed rats as compared with other groups of animals. It was reported that an enhancement of hepatic  $\beta$ -oxidation was regulated through activation of PPAR- $\alpha$  in the liver (49). Moya-Camarena *et al.* (50) demonstrated, using a rat hepatoma cell line, that CLA is an activator of PPAR- $\alpha$ . Also, feeding of the prototypical peroxisome proliferator Wy-14,643 (0.01 wt% in the diet) increased hepatic total lipid content and mRNA level of acyl CoA oxidase, the first step enzyme of peroxisomal  $\beta$ -oxidation in rats (51), consistent with the phenomena observed in rats fed the CLNA diet in the present study. Therefore, it was suggested that CLNA feeding affected hepatic lipid metabolism much more potently than did CLA. It seems likely that the accumulation of liver TG in the CLNA group may have resulted from a situation in which the amount of FA influx exceeded the ability of FA to oxidize in liver, even though the  $\beta$ -oxidation activity was considerably enhanced in these animals.

CLNA feeding resulted in a net reduction in adipose tissue weight. This effect was more potent than with CLA. Also, serum and liver TG concentrations were increased more than twofold by CLNA in contrast to CLA. The adipose tissue weight-reducing effect of CLNA may be related to a decrease either in TG deposition from circulation and/or in lipolysis in adipose tissues. Although the underlying mechanism is not clear at the moment, these findings indicate that CLNA modulates the body fat and TG metabolism differently from CLA in rats. Studies with a more purified form of CLNA are necessary before definite conclusions are drawn. Also, studies on the individual isomers of CLNA are important for future research. Some specific seed oils containing CLNA will be useful for this purpose.

<sup>a</sup>Department of Food and Nutrition, Sugiyama Jogakuen University, Nagoya 464-8662, Japan, and <sup>b</sup>Laboratory of Nutrition Chemistry, Department of Bioscience and Biotechnology, Faculty of Agriculture, Graduate School Kyushu University, Fukuoka 812-8581, Japan

**ABSTRACT:** We have shown that sesame lignans added to rat diet resulted in significantly greater plasma and tissue concentrations of  $\alpha$ - and  $\gamma$ -tocopherol concentrations in supplemented rats than in rats without supplementation. In the present studies we examined whether sesaminol, a sesame lignan, enhances tocotrienol concentrations in plasma and tissues of rats fed diets containing a tocotrienol-rich fraction of palm oil (T-mix). In Experiment 1, effects of sesaminol on tocotrienol concentrations in plasma, liver, and kidney were evaluated in rats fed diets containing 20 mg/kg of T-mix (20T) and 50 mg/kg of T-mix (50T) with or without 0.1% sesaminol. Although the T-mix contained 23%  $\alpha$ -tocopherol, 22%  $\alpha$ -tocotrienol, and 34%  $\gamma$ -tocotrienol,  $\alpha$ -tocopherol constituted most or all of the vitamin E in plasma and tissue (from 97% in kidney to 100% in plasma), with no or very little  $\alpha$ -tocotrienol and no  $\gamma$ -tocotrienol at all. Addition of sesaminol to the T-mix resulted in significantly higher plasma, liver, and kidney  $\alpha$ -tocopherol concentrations compared to values for T-mix alone. Further, T-mix with sesaminol resulted in significantly higher  $\alpha$ -tocotrienol concentrations in kidney, although the concentration was very low. In Experiment 2, we examined whether sesaminol caused enhanced absorption of  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol in a dosage regimen supplying T-mix and sesaminol on alternating days and observed significantly higher levels of  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol in rats fed sesaminol, even without simultaneous intake, compared to those in rats without sesaminol. In Experiment 3,  $\alpha$ -tocopherol was supplied to the stomach with and without sesaminol, and  $\alpha$ -tocopherol concentrations in the lymph fluid were measured.  $\alpha$ -Tocopherol concentrations were not different between groups. These results indicated that sesaminol produced markedly higher  $\alpha$ -tocopherol concentrations in plasma and tissue and significantly greater  $\alpha$ -tocotrienol concentrations in kidney and various other tissues, but the concentrations of  $\alpha$ -tocotrienol were extremely low compared to those of  $\alpha$ -tocopherol (Exps. 1 and 2). However, the sesaminol-induced increases of  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol concentrations in plasma and tissue were not caused by their enhanced absorption since sesaminol did not enhance their absorption.

Abbreviations: AIN, American Institute of Nutrition;  $\alpha$ -CEHC, 2,5,7,8-tetramethyl-2 (2'-carboxyethyl)-6-hydroxychroman;  $\gamma$ -CEHC, 2,7,8-trimethyl-2 (2'-carboxyethyl)-6-hydroxychroman; T-mix, tocotrienol-rich fraction from palm oil containing  $\alpha$ -tocopherol; Toc, tocopherol; Toc3, tocotrienol;  $\alpha$ -TTP,  $\alpha$ -tocopherol transfer protein.

Sesame seed has long been used as a health food for its purported anti-aging effects, but it contains only  $\gamma$ -tocopherol and negligible amounts of  $\alpha$ -tocopherol, which suggests low physiological vitamin E activity. However, sesame seed contains substantial amounts of the characteristic lignans sesamin and sesaminol. In earlier experiments we found that sesame seed and its lignans produced elevated levels of  $\alpha$ - and  $\gamma$ -tocopherol concentrations in plasma and tissue (1–3). Subsequently, we investigated the mechanisms by which sesame lignans caused higher tocopherol concentration in rats. In a previous paper (4), we examined whether the secretion of tocopherols into bile was suppressed by sesame seed feeding. However, we found that concentrations of  $\alpha$ - or  $\gamma$ -tocopherol in bile showed a good correlation with concentrations of  $\alpha$ - or  $\gamma$ -tocopherol in liver. We concluded that suppression of tocopherol secretion into bile did not cause higher tocopherol levels in the rat body. Thus, as a further possibility, we decided to examine whether sesame lignans enhance absorption of tocopherols. In the present experiments we used a tocotrienol-rich palm oil fraction as a dietary source of vitamin E, since some papers have shown that tocotrienols concentrated in palm oil exhibit stronger functions than  $\alpha$ -tocopherol as antioxidants and antitumor agents (5–7). If sesame lignans produce higher tocotrienol concentrations in *in vivo* tests, tocotrienols with sesame lignans might show stronger effects than tocotrienol alone. Therefore, in the first experiment of the present series we attempted to determine whether sesame lignans produced higher tocotrienol concentrations following the use of sesaminol and a tocotrienol-rich fraction of palm oil containing some  $\alpha$ -tocopherol (T-mix). In these experiments we sought to determine whether sesaminol acted at the site of absorption and whether enhanced absorption of vitamin E was dependent on sesaminol being supplemented simultaneously with T-mix. In Experiment 2, we examined the effect of sesaminol on vitamin E concentrations in plasma and tissues of rats when given in a regimen that provided T-mix and sesaminol on alternating days. In Experiment 3, we measured the direct effects of sesaminol on  $\alpha$ -tocopherol concentrations in lymph fluid after  $\alpha$ -tocopherol had been supplied into the rat stomach with and without sesaminol.

## MATERIALS AND METHODS

**Materials.**  $\alpha$ -Tocopherol,  $\gamma$ -tocopherol, and vitamin E homologs used for biochemical analysis were gifts of Eisai Co.

(Tokyo, Japan). Pure  $\alpha$ -tocotrienol,  $\gamma$ -tocotrienol, and tocotrienol-rich palm oil fraction (T-mix) were gifts of Lion Corporation (Tokyo, Japan). Sesaminol (30% ethanol solution; 74.5% purity as solid) was donated by Takemoto Oil & Fat Co. (Aichi, Japan). Vitamin E-stripped corn oil was purchased from Funahashi Nogyo Co. (Chiba, Japan). A vitamin E-free vitamin mixture and a mineral mixture were both made according to AIN-76 formulation (8) by Nihon Nosan Kogyo (Yokohama, Japan). Solvents used for chromatography were HPLC grade from Katayama Chemicals Co., Ltd. (Osaka, Japan). Thiobarbituric acid was purchased from Merck (Darmstadt, Germany). All reagents for the measurement of pyruvate kinase (EC 2.7.1.40) activity were purchased from Boehringer-Mannheim Yamanouchi (Tokyo, Japan). All other chemicals were of analytical grade.

**Animals and diets.** Three-week-old male Wistar strain rats (Japan SLC Inc., Shizuoka, Japan) were housed individually in stainless-steel wire-mesh cages at 24.5°C and 55% RH, with a 12-h light/dark cycle in Experiments 1 and 2. Rats were maintained in accordance with the Guidelines for Animal Experimentation of Nagoya University. Rats were allowed free access to a nonpurified diet for 3–5 d and given an experimental diet for 8 wk. The experimental diets in Experiments 1 and 2 were in accordance with AIN-76 formulation (8) and consisted of 20% protein, 10% fat, vitamins excluding vitamin E, and minerals, as shown in Table 1. In Experiment 3, 8-wk-old male Sprague-Dawley rats (Seiwa Experimental Animals, Fukuoka, Japan) weighing 280–320 g were given *ad libitum* a commercial nonpurified diet (type NMF; Oriental Yeast Co., Tokyo, Japan) and drinking water. Rats were maintained in accordance with the

Guidelines for Animal Experimentation of Kyushu University.

In Experiment 1, effects of sesaminol on tocotrienol concentrations in plasma, liver, and kidney were evaluated in rats fed diets containing 20 mg/kg T-mix (20T) and 50 mg/kg T-mix (50T) with or without 0.1% sesaminol. We set up the vitamin E-free diet as a vitamin E-deficient control, 50 mg  $\alpha$ -tocopherol diet as a vitamin E-sufficient control, and 20T and 50T diets with or without sesaminol. Although the 20T diet was a vitamin E-insufficient diet, we anticipated more pronounced effects of sesaminol in this diet because sesaminol caused greater changes in a low  $\alpha$ -tocopherol diet than a normal vitamin E diet in our previous study (3). To examine the extent to which tocotrienols affected vitamin E activity in the 50T diet, this diet was compared to a 50 mg  $\alpha$ -tocopherol diet. 20T and 50T diets contained, respectively, 4.6 and 11.5 mg  $\alpha$ -tocopherol, 4.4 and 11.0 mg  $\alpha$ -tocotrienol (Toc3), 1 and 2.5 mg  $\beta$ -Toc3, 6.8 and 17.0 mg  $\gamma$ -Toc3, and 2 and 5 mg  $\delta$ -Toc3. Thirty-six rats were randomly divided into six groups and fed the diets shown in Table 1 for 8 wk.

Addition of sesaminol to 20T produced higher concentrations of  $\alpha$ -tocopherol in plasma and tissue than were found with 20T alone (Experiment 1). In Experiment 2, to clarify the mechanism by which sesaminol induced higher  $\alpha$ -tocopherol concentrations, we investigated whether sesaminol would cause enhanced absorption of  $\alpha$ -tocopherol. We thought that enhanced absorption would take place when  $\alpha$ -tocopherol and sesaminol were present at the absorption site at the same time. Group 1 was fed a diet containing 20T throughout; group 2 was fed a diet containing 40T and a vitamin E-free diet on alternating days, with a diet containing 40T on the final day

<sup>c</sup>30% Ethanol solution, 78% purity as solid. The sesaminol-dissolving ethanol was canceled by reducing cornstarch.

(40T/-E/40T); group 3 was fed the same diet as group 2 except for a vitamin E-free diet on the final day (-E/40T/-E); group 4 was fed a diet containing 40T and a vitamin E-free with sesaminol diet on alternating days, with a diet containing 40T on the final day (40T/S/40T); and group 5 was fed the same diet as group 4 except for a vitamin E-free with sesaminol diet on the final day (S/40T/S). The rationale for the dietary groups was as follows: To ensure that all rats consumed nearly the same amount of T-mix as the animals in group 1, rats were fed a diet containing twice the amount T-mix on one day and a vitamin E-free diet or a vitamin E-free with sesaminol diet on the other day. Since we thought there might be a difference in  $\alpha$ -tocopherol concentration in rats fed 40T and rats fed vitamin E-free diet on the final day, we omitted T-mix for the two groups (groups 3 and 5) on the last day. After being on experiment for 8 wk, the animals were sacrificed.

In Experiment 1, we determined tocopherol and tocotrienol concentrations in plasma, liver, and kidney as well as TBARS in liver, red blood cell hemolysis, and plasma pyruvate kinase activity as indices of vitamin E status. In Experiment 2, only tocopherol and tocotrienol concentrations in plasma and tissues were determined. After 8 wk of feeding and 24 h of fasting, rats were anesthetized with Nembutal, and blood samples were drawn from the heart using heparinized needles and syringes. The tissues were excised after the liver had been perfused with physiological saline. A hemolysis test of red blood cells was conducted immediately after collection of blood samples. Plasma was prepared, and measurements of pyruvate kinase activity were made within 7 h after the rats were killed. The remaining plasma and tissues were kept at  $-80^{\circ}\text{C}$  until analysis. Tocopherol and tocotrienol concentrations in plasma and tissue as well as TBARS in liver were determined.

In Experiment 3, to obtain more direct evidence of  $\alpha$ -tocopherol absorption, we examined  $\alpha$ -tocopherol concentrations in the lymph fluid of rats supplied  $\alpha$ -tocopherol with and without sesaminol into the stomach. Sixteen rats were anesthetized with Nembutal; then an indwelling catheter was placed in the stomach and a cannula in the left thoracic lymphatic channel. Lymph fluid collections were performed according to the method described by Ikeda *et al.* (9). After administration of 3 mL of a test emulsion contained 200 mg sodium taurocholate, 50 mg FA-free albumin, 200 mg triolein, and 10 mg  $\alpha$ -tocopherol with or without 100 mg sesaminol, lymph fluid was collected for 24 h in four tubes containing EDTA, three tubes collected at 3-h intervals during the first 0–9 h, and one tube collected for 15 h during the latter 9–24 h.

*Analysis of samples.* Analytical procedures were essentially the same as described by Yamashita *et al.* (4). Tocopherol and tocotrienol concentrations in plasma and tissue were analyzed by HPLC according to the method of Ueda and Igarashi (10). Lymph fluid was treated in the same manner as plasma. Instrumentation used for HPLC was a Shimadzu Model LC-9A (Shimadzu, Kyoto, Japan) with a Shimadzu RF-535 fluorescence detector (excitation, 298 nm; emission, 325 nm). The analytical column used was a Develosil 60-5 (4.6 mm i.d.  $\times$  250 mm; Nomura Chemical, Aichi, Japan).

The mobile phase was hexane containing 1% (vol/vol) dioxan and 0.2% (vol/vol) isopropyl alcohol (99:1, vol/vol), and the flow rate was 1 mL/min. Lipid peroxides in liver were determined as TBARS by the thiobarbituric acid colorimetric method of Ohkawa *et al.* (11). Oxidative hemolysis of red blood cells was measured using dialuric acid (12). Plasma pyruvate kinase activity was determined according to the method described by Gutmann and Bernt (13).

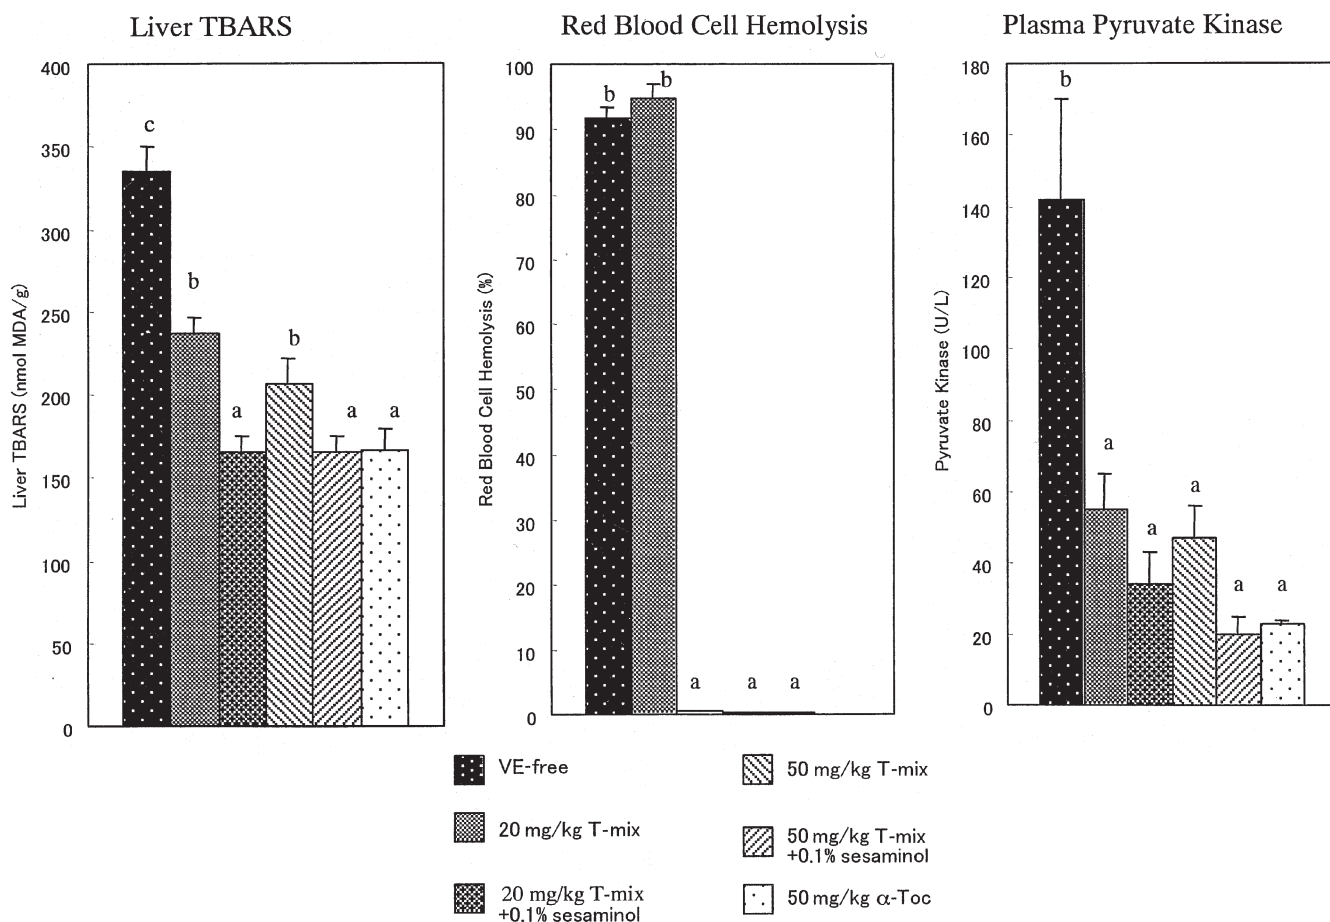

*Statistical analysis.* Data are expressed as mean  $\pm$  SEM. Experiments 1 and 2 were analyzed by using one-way ANOVA in SPSS Base 9.0 (Chicago, IL). When one-way ANOVA revealed  $P < 0.05$ , the data were further analyzed using Duncan's multiple comparisons test (14). Experiment 3 was performed by using Student's *t*-test to compare the effect with and without sesaminol. Differences were considered statistically significant at  $P < 0.05$ .

## RESULTS

In Experiment 1, the diets exhibited no significant effect on food intake or animal growth except for liver weight. As in our previous studies (1–3), we observed significantly greater liver weights (107–110%) in rats fed sesaminol-containing diets. We determined liver TBARS concentrations, red blood cell hemolysis, and plasma pyruvate kinase activity as vitamin E status indices. As shown in Figure 1, liver TBARS were significantly lower in the 20T and 50T groups than in the vitamin E-free group. The addition of sesaminol to the 20T and 50T diets significantly suppressed liver TBARS, and these values were nearly the same as those in the 50 mg  $\alpha$ -tocopherol control diet. Red blood cell hemolysis in the 20T group showed the same high value as in the vitamin E-free group, but the other groups showed almost no hemolysis. Plasma pyruvate kinase activity showed significantly higher activity in the vitamin E-free group than the other groups. Although the activities in the other groups were not statistically different, all groups showed similar patterns with respect to liver TBARS.

$\alpha$ -Tocopherol concentrations in plasma, liver, and kidney are shown in Figure 2. In spite of the greater intake of tocotrienol, vitamin E analogs detected were nearly all  $\alpha$ -tocopherol, with a very small amount of  $\alpha$ -tocotrienol. We could not detect  $\gamma$ -tocotrienol in the plasma, liver, or kidney. The groups receiving sesaminol had significantly higher  $\alpha$ -tocopherol concentrations than those receiving T-mix alone. In the kidney, supplementation of sesaminol to T-mix resulted in significantly higher concentrations of  $\alpha$ -tocotrienol compared to groups receiving T-mix alone, although the concentrations were extremely low compared to  $\alpha$ -tocopherol. Plasma  $\alpha$ -tocopherol, kidney  $\alpha$ -tocopherol, and kidney tocotrienol concentrations were not significantly different between the groups receiving 20T with sesaminol and 50T alone.

In Experiment 2, we investigated whether sesaminol enhanced the absorption of  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol in rats fed a T-mix-containing diet. We examined whether sesaminol induced higher  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol concentrations in plasma and tissue if rats were not fed sesaminol concurrently with T-mix. Plasma and tissue con-

**FIG. 1.** Effect of sesaminol on TBARS in liver, red blood cell hemolysis, and plasma pyruvate kinase activity. Thirty-six rats were divided into six groups and fed experimental diets for 8 wk. The experimental diets consisted of vitamin E-free (VE-free) as vitamin E-deficient control; 20 mg/kg of tocotrienol-rich palm oil (T-mix); 20 mg T-mix + 0.1% sesaminol; 50 mg T-mix; 50 mg T-mix + 0.1% sesaminol; and 50 mg  $\alpha$ -tocopherol ( $\alpha$ -Toc) as a vitamin E-sufficient control. The 20 and 50 mg/kg T-mix diets contained, respectively, 4.6 and 11.5 mg  $\alpha$ -Toc, 4.4 and 11.0 mg  $\alpha$ -tocotrienol ( $\alpha$ -Toc3), 1 and 2.5 mg  $\beta$ -Toc3, 6.8 and 17.0 mg  $\gamma$ -Toc3, and 2 and 5 mg  $\delta$ -Toc3. Values are means  $\pm$  SE of six rats. Values not sharing the same superscript letter are significantly different at  $P < 0.05$ . Abbreviation: MDA, malondialdehyde.

centrations of  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol are shown in Table 2. All rats consumed nearly the same amounts of  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol, and much larger amounts of  $\gamma$ -tocotrienol. In spite of these facts, almost all vitamin E detected in the plasma and tissue was  $\alpha$ -tocopherol. Small amounts of  $\alpha$ -tocotrienol were detected, but  $\gamma$ -tocotrienol was not detected in the plasma and tissue. Plasma and tissue concentrations of  $\alpha$ -tocopherol were below normal since rats were fed low vitamin E diets for 8 wk. In groups that received sesaminol on alternate days with 40T, significantly higher plasma and tissue concentrations of  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol were observed. We detected very low concentrations of  $\alpha$ -tocotrienol in plasma and tissue, but there were differences in the ratios of  $\alpha$ -tocotrienol to  $\alpha$ -tocopherol in plasma and tissue. The ratios in plasma and tissue were high in sesaminol-fed groups, and those in liver and plasma were extremely low compared to those in kidney, adrenal, and testes. There were no significant differences in  $\alpha$ -tocopherol or  $\alpha$ -tocotrienol concentrations between groups 2 and 3, or groups 4 and 5, that is, between groups that were fed 40T and vitamin E-free diets on the final day except for concentrations of

$\alpha$ -tocopherol in liver and plasma and  $\alpha$ -tocotrienol in liver, testes, and lung.

In Experiment 3, we determined the  $\alpha$ -tocopherol recovered in the lymph fluid of rats intragastrically administered a test emulsion containing 10 mg  $\alpha$ -tocopherol with or without sesaminol. Lymph flow rate was linear during the experiments, and it was  $160.6 \pm 17.4$  and  $162.2 \pm 8.0$  mL for 24 h in rats given  $\alpha$ -tocopherol and  $\alpha$ -tocopherol with sesaminol, respectively. There was no significant difference between the groups. The results are shown as the percentage of  $\alpha$ -tocopherol in lymph fluid recovered over the experimental period from the 10 mg administered intragastrically, and as  $\alpha$ -tocopherol concentrations in lymph fluid collected at each interval. As shown in Figure 3, lymphatic recovery of  $\alpha$ -tocopherol was not enhanced by sesaminol.

## DISCUSSION

As shown in Figure 2, despite feeding with a mixture of  $\alpha$ -tocopherol,  $\alpha$ -tocotrienol and  $\gamma$ -tocotrienol, most of the vitamin E detected in plasma, liver, and kidney was  $\alpha$ -tocopherol;

a very slight concentration of  $\alpha$ -tocotrienol was found, but  $\gamma$ -tocotrienol was not found. These results agree with the tissue concentrations of tocopherols and tocotrienol in humans and hamsters found by Hayes *et al.* (15) and in humans by Mensink *et al.* (16). It is generally thought that discrimination between the structural forms of vitamin E in hepatic  $\alpha$ -tocopherol transfer protein ( $\alpha$ -TTP) caused these results (17–19). The addition of sesaminol to diets containing T-mix caused significantly higher concentrations of  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol in plasma and tissue, but most vitamin E detected was still  $\alpha$ -tocopherol (90–99%). Liver  $\alpha$ -tocopherol concentration in the 20T with sesaminol group was lower than in the 50T group. However, liver TBARS concentration in the 20T with sesaminol group was lower than in the 50T (Fig. 1). This result could not be explained by the  $\alpha$ -tocopherol concentration, because the  $\alpha$ -tocopherol concentration in 50T was higher than in 20T with sesaminol. There are reports that sesaminol itself exhibits strong antioxidative activity *in vitro* and *in vivo* (20–22). Sesaminol might have contributed to the lower TBARS concentration in the 20T or 50T with sesaminol groups. Since the 20T diet contained insufficient vitamin E, hemolysis in this diet group had the same high level as in the vitamin E-free group. It is well known that hemolysis does not occur in proportion to the concentration of vitamin E in red blood cells but occurs below a certain critical concentration (12,23). We observed substantial hemolysis in animals consuming 20T, but not in 50T diets. Addition of sesaminol to 20T completely suppressed hemolysis. Plasma pyruvate kinase activity did not exhibit significant differences among groups except for vitamin E-free animals, but all groups showed similar patterns with respect to liver TBARS. These results indicated that sesaminol improved vitamin E indices in rats receiving 20T or 50T diets by promoting significantly higher  $\alpha$ -tocopherol concentrations and by possibly acting as antioxidant.

A further concern is how sesaminol produced higher  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol concentrations *in vivo*. In a previous paper (4), we examined whether the secretion of tocopherol into the bile was suppressed with sesame seed feeding. However, we could not observe suppressed secretion of tocopherol into the bile in rats fed sesame seed. According to past studies, no discrimination exists among vitamin E analogs during absorption (24–26), but Hayes *et al.* (15) reported lower absorption of tocotrienols and Ikeda *et al.* (9) enhanced absorption of  $\alpha$ -tocotrienol. Further, Hirose *et al.* (27) reported sesamin, the main sesame lignan, suppressed cholesterol absorption. Therefore, we hypothesized that vitamin E absorption might be enhanced by sesaminol, and in Experiments 2 and 3, we examined the effect of sesaminol on absorption of vitamin E. Using a total of five groups in Experiment 2, we examined whether there were higher concentrations of vitamin E in plasma and tissue of rats fed sesaminol and T-mix on alternate days, not concurrently. As shown in Table 2, we observed significantly higher concentrations of  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol in groups 4 and 5, fed sesaminol, than in groups 1, 2, and 3, not fed sesaminol. Even if rats were fed sesaminol 24 h after T-mix, sesaminol showed an effect similar to that

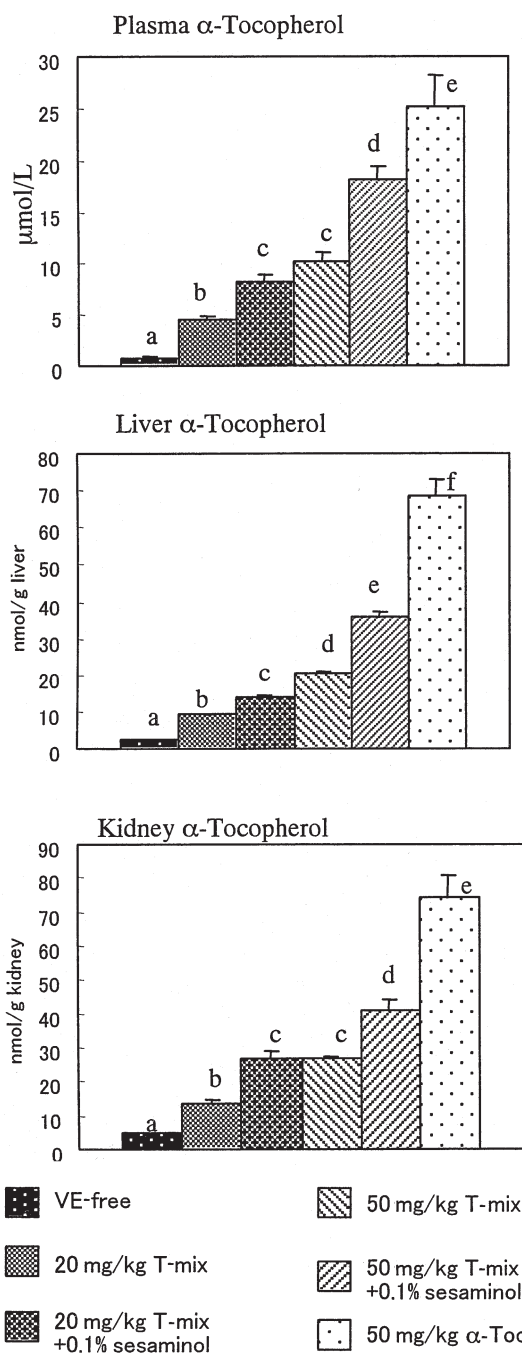

FIG. 2. Effect of sesaminol on  $\alpha$ -tocopherol concentrations in the plasma, liver, and kidney of rats fed diets containing 20 and 50 mg/kg T-mix. Values are means  $\pm$  SE of six rats. Values not sharing the same superscript letter are significantly different at  $P < 0.05$ . For abbreviations see Figure 1.

found with rats that were fed sesaminol and T-mix simultaneously in Experiment 1. These results indicated that the higher vitamin E concentrations with sesaminol were not caused by enhanced vitamin E absorption. Further, we knew that vitamin E concentrations *in vivo* did not significantly change 24 or 48 h after T-mix had been supplied because there were almost no significant differences in groups 2 and 3 or groups 4 and 5. In addition to Experiment 2, we found more direct evidence that

sesaminol did not enhance the absorption of  $\alpha$ -tocopherol in Experiment 3, in which  $\alpha$ -tocopherol was supplied to the stomach with and without sesaminol, and  $\alpha$ -tocopherol concentration was determined in the lymph fluid (Fig. 3). Because enhanced absorption was not observed in rats fed sesaminol, we must consider other potential mechanisms by which sesaminol may enhance  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol concentrations. As mentioned previously, sesaminol has strong antioxidative properties. Therefore, the antioxidative activity of sesaminol may act to produce a sparing effect on vitamin E, or to promote the recycling of vitamin E, as it does with vitamin C. To clarify such mechanisms, it might be fruitful to investigate the contributions of antioxidative activity in sesaminol to vitamin E concentrations.

There was organ specificity in the accumulation of tocotrienol (Table 2), since ratios of tocotrienol to tocopherol were low in liver and plasma compared to kidney, adrenal, testes, and lung. Addition of sesaminol to T-mix resulted in significantly higher ratios in all tissues and plasma. We could not determine why sesaminol produced the higher ratio of tocotrienol to tocopherol. Although the concentrations of tocotrienols were extremely low in plasma and tissue examined

in the present experiments, Podda *et al.* (28) reported significant presence of tocotrienols in skin of hairless mice, and Hayes *et al.* (15) reported substantial amounts of tocotrienols in adipose tissue of hamsters. We have also observed considerable quantities of  $\alpha$ - and  $\gamma$ -tocotrienols in the skin of rats and mice (29) and in adipose tissues of rats (30) fed diets containing the same T-mix as in the present experiment. At the present time, we are inclined to think that the skin and adipose tissue are unique tissues in which substantial amounts of tocotrienols exist in spite of the simultaneous presence of  $\alpha$ -tocopherol. These facts suggest that tocotrienols exhibit tissue specificity in acting as vitamin E.

Recently, Parker *et al.* (31) reported that the metabolism of  $\gamma$ -tocopherol to  $\gamma$ -carboxyethylhydroxy chroman ( $\gamma$ -CEHC) was inhibited by sesamin in rat primary hepatocytes. Possibly, the catabolism of  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol to  $\alpha$ -CEHC is inhibited by sesaminol in the present experiments. Inhibition of tocopherol and tocotrienol catabolism by sesame lignans is the most likely cause of higher concentrations of tocopherols and tocotrienols in plasma and tissue. However, the concentrations of  $\alpha$ -tocotrienol were extremely small compared to those of  $\alpha$ -tocopherol. We need to consider the

**FIG. 3.** (A) Lymphatic recovery of  $\alpha$ -tocopherol in rats intragastrically administered a test emulsion containing  $\alpha$ -tocopherol with and without sesaminol, and (B)  $\alpha$ -tocopherol concentration in lymph fluid after administration of  $\alpha$ -tocopherol collected over 24 h at each time interval. The test emulsion contained 200 mg sodium taurocholate, 50 mg FA-free albumin, 200 mg triolein, and 10 mg  $\alpha$ -tocopherol with or without 100 mg sesaminol. An asterisk (\*) indicates significant difference between control and sesaminol groups,  $P < 0.01$  by Student's *t*-test.

contribution of  $\alpha$ -TTP and the modulated affinity of vitamin E to  $\alpha$ -TTP by sesame lignans, and will pursue this possibility in future research.

In the present studies we observed that sesaminol induced significantly higher concentrations of  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol in rats fed diets containing palm oil extracts rich in  $\alpha$ -tocopherol,  $\alpha$ -tocotrienol, and  $\gamma$ -tocotrienol than in controls, and further, that sesaminol may have acted as an antioxidant *in vivo*. The results of Experiments 2 and 3 indicated that the higher concentrations of  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol induced by sesaminol were not caused by their enhanced absorption.

**ABSTRACT:** Although it is well known that dietary lipids affect the course of glomerulonephritis in rats and humans, the precise mechanisms involved have not been fully elucidated. The aim of this study was to investigate the effects of different types of dietary lipids (fish oil and vegetable oil) on daunomycin (DM)-induced nephropathy in mice fed on soybean oil (SO) or cod liver oil (CLO). Urinary protein excretion, serum albumin, creatinine, total cholesterol, and TG were measured, and glomerular histological changes were evaluated. Antioxidant enzymes were also measured, along with the levels of lipid peroxide, GSH, thromboxane (Tx) B<sub>2</sub>, and 6-keto prostaglandin F<sub>1α</sub> in renal cortical tissue. Dietary CLO significantly reduced urinary albumin excretion and ameliorated the histological changes induced by DM. The increase of tissue lipid peroxide levels seen in SO-fed mice was suppressed in CLO-fed mice, whereas CLO-fed mice showed higher GSH levels than SO-fed mice throughout the experiment. In addition, renal tissue GSH peroxidase activity was significantly higher at 72 h after DM injection in CLO-DM mice than in SO-DM mice. Both renal cortical TxB<sub>2</sub> and 6-keto PGF<sub>1α</sub> levels were significantly lower in CLO-DM mice than in SO-DM mice. These results suggest that inhibition of oxidative damage by dietary CLO played an important role in the prevention of DM nephropathy in this mouse model. The effect of CLO was closely associated with the inhibition of Tx synthesis.

Paper no. L8896 in *Lipids* 37, 359–366 (April 2002).

Daunomycin (DM), an anthracycline compound, induces nephropathy and massive proteinuria in rats and mice after a single injection (1,2). Although two well-known biological mediators, eicosanoids and reactive oxygen species (ROS), have been suggested to cause the nephrotoxicity of anthracyclines (3–6), the exact mechanisms underlying anthracycline nephropathy have not been fully established.

Abbreviations: AA, arachidonic acid; ADR, adriamycin; AOE, antioxidant enzyme; CLO, cod liver oil; CyA, cyclosporin A; DM, daunomycin; DMTU, dimethylthiourea; FO, fish oil; GSH-Px, glutathione peroxidase; PG, prostaglandin; PL, phospholipase; ROS, reactive oxygen species; SO, soybean oil; SOD, superoxide dismutase; Tx, thromboxane.

Remuzzi *et al.* (3) demonstrated that glomerular thromboxane (Tx)A<sub>2</sub> production was increased at 14 and 30 d after a single injection of adriamycin (ADR) in rats, whereas administration of selective Tx synthetase inhibitors for 14 to 18 d after ADR injection caused a significant reduction of proteinuria. Accordingly, increased Tx production was thought to be responsible for proteinuria by altering glomerular basement membrane permeability to protein, but why the generation of TxA<sub>2</sub> increased in ADR nephropathy was not clarified. Milner *et al.* (4) found that dimethylthiourea (DMTU), a hydroxyl radical scavenger, prevented glomerular injury in rats with ADR nephropathy, and Okasora *et al.* (5) demonstrated that administration of superoxide dismutase (SOD) together with ADR suppressed the development of proteinuria in rats.

We previously reported the existence of differences in the nephrotoxicity of DM among several strains of inbred mice (2). We found that A/J and BALB/c mice were sensitive to DM, whereas C57BL/6J, DAB-2, and B10D2/o mice were resistant. Using DM-sensitive A/J mice and DM-resistant C57BL/6J mice, we also found that DM nephropathy seemed to be mediated by ROS and that intrinsic antioxidant enzymes (AOE), including SOD and glutathione peroxidase (GSH-Px), apparently play an important role in modulating the sensitivity to DM (6).

Recently, fish oil (FO) supplementation has been reported to improve renal damage when compared to vegetable oil supplementation in rats with ADR nephropathy (7,8). Ito *et al.* (7) reported that the beneficial effect of FO was related to reduced glomerular production of TxA<sub>2</sub> and a decrease of circulating lipids, and Barcelli *et al.* (8) found that FO decreased the production of TxB<sub>2</sub>, prostaglandin (PG)E<sub>2</sub>, and 6-keto-PGF<sub>1α</sub> in isolated glomeruli. However, there has been no investigation of the effect of FO on oxidative renal damage mediated by ROS, even though this is thought to be one of the major factors in anthracycline nephropathy (4–6).

Soybean oil (SO) is the usual dietary lipid source in standard laboratory chow, and injection of DM causes severe nephropathy in standard chow-fed A/J mice (2,6). In the present study, we used SO for the control and cod liver oil (CLO) for the experimental dietary lipid. Although we did not compare a typical control diet with the FO diet, it was thought to be meaningful to clarify the effects of these lipids on DM

nephropathy. Accordingly, we investigated (i) the effects of two different dietary lipids (SO and CLO) on DM nephropathy in mice and (ii) how dietary lipids modified oxidative damage, AOE activity, and eicosanoid production in renal tissue during the course of DM nephropathy.

## MATERIALS AND METHODS

**Animals and diets.** Inbred male A/J mice were bred in our laboratory. They had free access to standard laboratory chow and water. After weaning at 4 wk of age, they were allocated to two indicated isocaloric diets containing 7% SO or 6% CLO plus 1% SO. The reason for the 1% SO supplement to the latter diet was to supply EFA. The composition of diets after the addition of fat was: cornstarch 40.5% w/w, casein 25% w/w,  $\alpha$ -starch 10% w/w, cellulose powder 8% w/w, fat 7% w/w (two different types as mentioned above), minerals 3.5% w/w, granulated sugar 5% w/w, and vitamins 1% w/w (Oriental Yeast Co. Ltd., Tokyo, Japan). FA composition varied between SO and CLO as described in Table 1. The contents of antioxidants in the SO and CLO diets were analyzed at the Japan Food Research Laboratories and were found to be almost identical between the two diets, i.e., vitamin E of 74 and 70 mg/kg, and vitamin C of 56 and 58 mg/kg in the SO and CLO diets, respectively. And the content of selenium, which is a substrate of GSH-Px, was also identical, i.e., 0.16 and 0.15 mg/kg in SO and CLO diets, respectively. Diets were kept at 4°C in airtight bags and provided daily to minimize autoxidation of dietary lipids. Paired feeding was applied, with the amount of daily diet adjusted to the lower food consumptions of the two groups throughout the experiment. Since the SO-fed mice ate their food more quickly than the CLO-fed mice, the food receptacle in the SO-fed group was not refilled until the CLO-fed group had finished their ration. Food consumption was 7 g/mouse/d and yielded a calorie intake of almost 28 kcal/mouse/d in both groups at the time of saline or DM injection.

**Study design.** Mice were pair-fed for 10 wk, i.e., 8 wk before and 2 wk after DM injection, and body weights were recorded weekly. Eight weeks after the diets had started, mice

were injected with DM, 20 mg/kg body weight, or a vehicle (saline) through the tail vein, and they were divided into four groups, i.e., SO-DM: DM-injected mice with SO diet; SO-C: saline-injected mice with SO diet; CLO-DM: DM-injected mice with CLO diet; CLO-C: saline-injected mice with CLO diet. Before and 7 and 14 d after injection, 24-h urine samples were collected in the metabolic cages. Fifteen days after injection, mice were anesthetized with diethyl ether and blood was obtained *via* a cardiac puncture. Blood samples were assayed for albumin, creatinine, total cholesterol, and TG concentrations. After blood sampling, the kidneys were removed and fixed in 10% neutral buffered formalin solution for histological study. This study was approved by the research committees in the Shizuoka University School of Nursing and the Hamamatsu University School of Medicine.

**Analytical methods.** (i) *Serum and urine.* The urinary concentration of albumin was measured with a radial immunodiffusion method using rabbit anti-mouse albumin serum (9). Twenty-four-hour urine samples were collected in a small plastic tube. Urine volumes were less than 2 mL both in the basal state and after the onset of nephritis. All samples were diluted to 2 mL with saline solution and applied to immunodiffusion. The protein concentration in the tissue homogenate was determined by the method of Lowry *et al.* (10) with crystalline bovine albumin used as the standard. Serum concentrations of albumin and creatinine were measured with the bromocresol green method and Jaffe's reaction, respectively, using a Hitachi 736 autoanalyzer (Hitachi, Ltd., Tokyo, Japan). TG and cholesterol were measured by enzymatic methods on a Hitachi autoanalyzer.

(ii) *Morphological studies.* Formalin-fixed renal tissue was stained with periodic acid-Schiff. Mesangial matrix expansion, ballooning of the glomerular epithelial cells, and intracapillary thrombi are the characteristics of DM-induced glomerulopathy. These glomerular morphological changes were evaluated in all four groups 15 d after DM or saline injection. (i) Mesangial matrix expansion was graded from 0 to 4: Grade 1 represented minimal expansion involved in less than 25% of tufts, and grade 4, severe expansion in almost all tuft areas, while intermediate scores were assigned arbitrarily according to the severity and extent. The mean scores of 20 glomeruli per mouse, were calculated and five mice in each group were evaluated. (ii) One hundred glomeruli per mouse were used to estimate the ballooning change. If at least one epithelial ballooning was seen in a glomerulus, it was estimated as positive. The total positive glomerular numbers of 100 glomeruli were counted in five mice from each group. (iii) Intracapillary thrombus formation was evaluated in the same way as the epithelial ballooning. A positive grading means that the glomerulus had at least one thrombus in its tufts. The positive glomerular numbers of 100 glomeruli were counted in five mice from each group.

(iii) *Tissue preparation.* For the measurements of lipid peroxide and AOE (SOD, catalase, and GSH-Px) and reduced GSH content in the renal cortex, 8 to 11 mice from each group (mentioned before) were sacrificed before and 24 and 72 h

**TABLE 1**  
**FA Composition of Lipids**

FA	Oil (%)	
	Soybean	Cod liver
14:1	—	4.7
16:0	10.3	12.4
16:1	0.1	7.2
18:0	3.8	2.2
18:1 (oleic)	24.3	18.5
18:2 (linoleic)	52.7	1.0
18:3 ( $\alpha$ -linoleic)	7.9	0.6
20:0	0.3	6.5
20:4 (arachidonic)	—	0.6
20:5 (EPA)	—	11.6
22:0	0.4	10.6
22:6 (DHA)	—	10.2

after injection with DM or saline. The kidneys were perfused with cold saline. The renal cortical tissues were collected and frozen in liquid nitrogen. Tissue samples were stored at  $-85^{\circ}\text{C}$  until the analyses.

Renal cortical  $\text{TxB}_2$  (a stable metabolite of  $\text{TxA}_2$ ) and 6-keto  $\text{PGF}_{1\alpha}$  (a stable metabolite of  $\text{PGL}_2$ ) contents were measured 24 and 72 h after DM injection. Five mice from each group were sacrificed at the indicated times. Kidneys were perfused with 5 mL of ice-cold saline containing EDTA (10 mM) and indomethacin (0.1 mM), as used in the previous paper (11). The renal cortical tissue was immediately excised and stored at  $-85^{\circ}\text{C}$  until the analyses.

**Lipid peroxide measurement.** Tissue lipid peroxide content was determined as described previously (6). Cortical tissue (15–20 mg) in each tissue sample was used for the assay, and the fluorescence intensity of the *n*-butanol layer was measured using a spectrofluorometer FP-777 (Japan Spectroscopic Co., Ltd., Tokyo, Japan). The set wavelengths were excitation at 515 nm and emission at 535 nm, and 0.1–1.0 nmol of 1,1,3,3-tetramethoxypropane solution was used as the standard. Data are expressed as nmol/mg protein.

**Measurement of AOE activities and GSH content.** SOD, catalase, and GSH-Px activities and GSH content in the cortical tissue were measured as described before (6). SOD activity was expressed as units of nitrite per mg of protein. Catalase activity was calculated as *K*, the rate constant of a first-order reaction,  $\text{s}^{-1}/\text{mg}$  protein, and GSH-Px activity was expressed as nanomoles of NADPH oxidized to NADP per minute per milligram of protein, using the extinction coefficient of NADPH at 340 nm,  $6.22 \times 10^3 \text{ mol}^{-1} \text{ cm}^{-1}$ . The content of GSH was expressed as nanomoles per milligram of protein.

**Measurement of  $\text{TxB}_2$  and 6-keto  $\text{PGF}_{1\alpha}$ .** About 30 mg of renal cortical tissue was homogenized in 3 mL of 95% ethanol at  $4^{\circ}\text{C}$  and then centrifuged at  $600 \times g$  for 10 min. Then the supernatant was used for measurements of arachidonic acid (AA) metabolites by radioimmunoassay methods ( $^{125}\text{I}$ - $\text{TxB}_2$  and  $^{125}\text{I}$ -6-keto  $\text{PGF}_{1\alpha}$  kit; Daiichi RI, Tokyo, Japan) as used in the previous paper (11). Data are expressed as pg/mg protein.

**Statistics.** Results are presented as mean  $\pm$  SEM. Differences between groups were determined by ANOVA and two-tailed Student's *t*-test. A level of  $P < 0.05$  was accepted as significant.

## RESULTS

**Effect of dietary lipids on body weight.** The body weights in the two diet groups (10 mice in each group) are shown in Table 2. No significant difference was observed at various intervals under paired feeding.

**Effect of dietary lipids on urinary albumin excretion and serum parameters.** Urinary albumin excretion is shown in Figure 1. The basal urinary albumin excretion was less than 0.1 mg/d in both dietary groups. A significant increase in urinary albumin was observed in the SO-DM mice 1 wk after DM injection. Two weeks after injection, a further elevation

**TABLE 2**  
Effect of Dietary FA Substitution on Body Weight<sup>a</sup>

Age (wk)	Body weights (g)	
	Soybean oil diet	Cod liver oil diet
4	15.1 $\pm$ 0.48	15.6 $\pm$ 0.52
6	19.4 $\pm$ 0.51	21.0 $\pm$ 0.94
8	21.9 $\pm$ 0.41	23.0 $\pm$ 0.68
10	24.7 $\pm$ 0.75	25.2 $\pm$ 1.02
12	26.0 $\pm$ 0.73	25.6 $\pm$ 1.02

<sup>a</sup>The temporal change in body weight of soybean oil-fed and cod liver oil-fed mice from day of weaning to the day of injection. Data are expressed as mean  $\pm$  SEM ( $n = 10$  for each diet group).

of albumin excretion was observed in this group. The CLO-DM mice did not show a significant increase in albuminuria on day 7. Thereafter, the albuminuria on day 14 in CLO-DM mice significantly increased when compared to control mice (CLO-C), but it was significantly lower than that in SO-DM mice ( $1.51 \pm 0.86$  vs.  $5.41 \pm 1.76$  mg/d,  $P < 0.05$ ).

Serum parameters on day 15 are presented in Table 3. The serum creatinine and TG levels were not different among the four groups. Serum albumin levels significantly decreased in SO-DM mice compared to the other three groups. In contrast, they were not significantly decreased by DM injection in CLO-DM mice. The total cholesterol level was significantly higher in SO-DM mice. The cholesterol levels were low in CLO-fed mice compared to SO-fed mice. Although the total cholesterol levels increased in CLO-DM mice after DM injection, they were still lower than the SO control mice (SO-C).

**FIG. 1.** Urinary albumin excretion in SO-DM (■) and CLO-DM (●) mice after DM injection. Data are expressed as mean  $\pm$  SEM ( $n = 10$ ). Urinary albumin excretions in SO-fed mice and CLO-fed mice with saline injection (SO-C and CLO-C) are under 0.1 mg/d through the experimental period. \* $P < 0.05$  and \*\* $P < 0.01$  vs. pretreatment value in the same group; <sup>#</sup> $P < 0.05$  vs. CLO-DM at the same time point. **TABLE 3**  
**Effect of Dietary Oils and Daunomycin (DM) Injection on Serum Parameters<sup>a</sup>**

Parameter	Group			
	SO-C	SO-DM	CLO-C	CLO-DM
Albumin (g/dL)	3.53 ± 0.09	2.58 ± 0.41 <sup>a</sup>	3.50 ± 0.06	3.26 ± 0.25 <sup>c</sup>
Creatinine (mg/dL)	0.33 ± 0.02	0.35 ± 0.03	0.36 ± 0.02	0.33 ± 0.02
Total cholesterol (mg/dL)	112.2 ± 5.36	152.5 ± 16.65 <sup>b</sup>	67.8 ± 2.24 <sup>b</sup>	107.8 ± 10.91 <sup>c,d</sup>
TG (mg/dL)	76.8 ± 11.5	87.6 ± 11.8	60.2 ± 6.2	52.3 ± 6.0 <sup>d</sup>

<sup>a</sup>SO-C, saline-injected mice fed soybean oil (SO) diet; SO-DM, DM-injected mice fed SO diet; CLO-C, saline-injected mice fed cod liver oil (CLO) diet; CLO-DM, DM-injected mice fed CLO diet. Five to eight mice from each group were killed on day 15. Values are expressed as mean ± SEM. <sup>a</sup>*P* < 0.01 vs. SO-C; <sup>b</sup>*P* < 0.05 vs. SO-C; <sup>c</sup>*P* < 0.05 vs. SO-DM; <sup>d</sup>*P* < 0.05 vs. CLO-C.

**Morphological studies.** DM-induced histological changes in SO-fed and CLO-fed mice are shown in Figure 2. The degrees of expansion of the mesangial matrix, glomerular epithelial cell ballooning, and glomerular intracapillary thrombus were almost completely suppressed by CLO supplementation (Fig. 3).

**Lipid peroxide content in the renal tissue.** The basal lipid peroxide levels in renal cortical tissues were not different in either diet group (Fig. 4A). In SO-DM, a significant increase in peroxide levels was observed 72 h after DM injection. No significant increase in lipid peroxide level was evident in CLO-DM over 72 h after DM injection.

**GSH content in the renal tissue.** The basal GSH content was 1.4-fold higher in CLO-fed mice (CLO-C and CLO-DM) than in SO-fed mice (SO-C and SO-DM) (Fig. 4B). After DM injection, a significant decrease in GSH content was observed in both DM-treated groups (SO-DM and CLO-DM). However, the levels of GSH were consistently higher in CLO-DM than in SO-DM over 72 h after DM injection.

**Antioxidant enzyme activity in the renal tissue.** The basal levels of tissue antioxidant enzymes (SOD, catalase, and GSH-Px) activities were not different between the two diet groups (Table 4). After DM treatment, SOD activity increased transiently, but not significantly, in both diet groups (SO-DM and CLO-DM) after 24 h and returned to the basal levels after 72 h. Catalase activity at the basal level was almost the same in both diet groups. The activity decreased significantly in SO-DM at 72 h after DM injection. No marked change in catalase activity was found in the CLO-fed groups. Tissue GSH-Px activity in CLO-fed mice was higher than that in SO-fed mice in the basal state, although not significantly. The activity in CLO-DM mice increased after DM injection. The GSH-Px activity transiently increased after 24 h in SO-DM mice, but not significantly, and decreased below the basal level after 72 h. Consequently, the activities in SO-DM and CLO-DM after 72 h were significantly different.

**TxB<sub>2</sub> and 6-keto PGF<sub>1α</sub> in the renal cortical tissue.** Tissue eicosanoids 24 and 72 h after DM or saline injection are shown in Table 5. The tissue TxB<sub>2</sub> levels in the saline control groups (SO-C and CLO-C) were not significantly different

between the two diets. Acceleration of the production of tissue TxB<sub>2</sub> was found 72 h after DM injection in SO-DM mice. On the contrary, in CLO-DM mice, significant elevation of tissue Tx synthesis was not found over 72 h after DM injection.

Tissue 6-keto PGF<sub>1α</sub> increased 72 h after DM injection in SO-DM mice, although the increase was not statistically

**FIG. 2.** Morphological changes in DM-induced nephropathy (periodic acid-Schiff stain). (a) Mesangial matrix expansion, glomerular epithelial ballooning (arrow), and intracapillary thrombus (arrowhead) are seen in SO-DM at 2 wk after DM injection. (b) Histological changes in CLO-DM at 2 wk after DM injection. For abbreviations see Figure 1.

FIG. 3. Morphological study. (A) The mesangial matrix expansion score; (B) the number of glomeruli with epithelial ballooning per 100 glomeruli; (C) the number of glomeruli with intracapillary thrombi per 100 glomeruli. \*\* $P < 0.01$ ; NS, statistically not significant. For abbreviations see Figure 1.

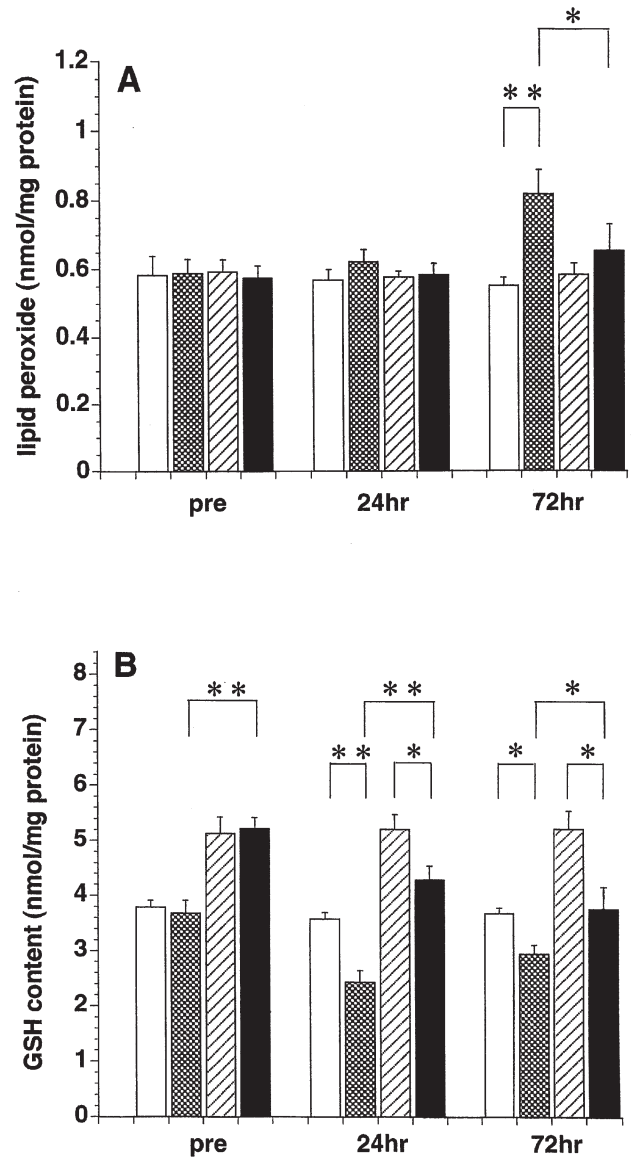

FIG. 4. (A) Lipid peroxide levels in the renal cortical tissue; (B) GSH content in the renal cortical tissue. Eight to 11 mice were sacrificed at specified intervals, and data are expressed as mean  $\pm$  SEM. Open bars: The values of SO-C; cross-hatched bars: SO-DM; diagonally lined bars: CLO-C; and solid bars: CLO-DM. \* $P < 0.05$ , \*\* $P < 0.01$ . For abbreviations see Figure 1.

significant compared to the saline control group (SO-C). No increase in 6-keto  $\text{PGF}_{1\alpha}$  levels was found in CLO-DM mice after DM injection. When compared 72 h after DM injection, a significant difference in tissue 6-keto  $\text{PGF}_{1\alpha}$  was found between SO-DM and CLO-DM mice.

## DISCUSSION

In the present study, dietary lipids dramatically modified the course of DM nephropathy in mice. Replacement of SO with CLO in the diet effectively ameliorated renal injury induced by the injection of DM. The characteristic histological changes of DM nephropathy, i.e., mesangial expansion,

<sup>a</sup>Eight to 11 mice from each group were sacrificed at specified intervals, and values are expressed as mean ± SEM. Units are: SOD, nitrite units/mg protein; catalase,  $k \times 10^{-2}$ /s/mg protein; GSH-Px,  $10^4$  nmol/min/mg protein. Statistics: <sup>a</sup> $P < 0.05$  vs. 24-h value in SO-DM; <sup>b</sup> $P < 0.01$  vs. pre value in SO-DM; <sup>c</sup> $P < 0.01$  vs. 72-h value in SO-DM. SOD, superoxide dismutase; GSH-Px, glutathione peroxidase; for other abbreviations see Table 3.

epithelial ballooning, and intracapillary thrombus formation, were decreased by dietary CLO to levels similar to those seen in saline control mice. Albuminuria was increased slightly at 14 d in CLO-DM mice, but the increase was significantly suppressed, by 30%, in SO-DM mice. These effects of CLO were associated with the suppression of lipid peroxide, a high tissue GSH content, and an increase of GSH-Px activity, as well as with suppression of renal cortical  $\text{TxB}_2$  and 6-keto  $\text{PGF}_{1\alpha}$  production in the early period after DM injection.

The main differences between SO and CLO are in the ratio and type of PUFA. SO contains about 60% PUFA, whereas CLO contains about 35% PUFA. In SO, PUFA are mainly n-6 FA (linoleic acid), whereas PUFA in CLO are n-3 FA, i.e., EPA and DHA. There are two possible explanations for why these differences of dietary FA composition modified the course of DM nephropathy. One is the inhibition of Tx and PG production, and the other is that oxidative damage to renal tissue was reduced by CLO supplementation.

There are two possible explanations for the prevention of Tx production by CLO. One is that EPA and DHA can compete with AA as a substrate for cyclooxygenase, resulting in the formation of trienoic eicosanoids ( $\text{TxA}_3$  and  $\text{PGI}_3$ ) that

are less biologically active than dienoic prostanoids ( $\text{TxA}_2$  and  $\text{PGI}_2$ ), as suggested in previous reports (7,8). The other possibility is that factors promoting Tx biosynthesis may be inhibited by dietary CLO supplementation. Angiotensin II, arginine-vasopressin, platelet-activating factor, interleukin-1, and ROS (13) are known to stimulate Tx synthesis. In the present study, we did not investigate whether any of these factors were modified by dietary CLO supplementation, apart from ROS, so it is difficult to speculate about this issue. As a result of the inhibition of Tx production, basement membrane permeability to protein might be decreased, and consequently albuminuria would decrease. In addition, Tx and PG are important factors that influence renal vascular resistance and/or arterial blood pressure (13). Therefore, a possibility exists that the effects of CLO might occur through eicosanoid-mediated alterations of glomerular hemodynamics, but we did not investigate these parameters in the present study.

Regarding lipid peroxidation in the kidneys, the high content of PUFA in SO appears to enhance the susceptibility of the mice ingesting SO to lipid peroxidation, and the high GSH content of renal tissue from mice on a CLO diet may also have been an important factor in preventing oxidative tissue

**TABLE 5**

<sup>a</sup>Five mice from each group were sacrificed at specified intervals. Values are expressed as mean ± SEM. Statistics: <sup>a</sup> $P < 0.01$  vs. 72 h value in SO-C; <sup>b</sup> $P < 0.01$  vs. 72 h value in CLO-DM; <sup>c</sup> $P < 0.05$  vs. 24 h value in SO-DM.  $\text{TxB}_2$ , thromboxane  $\text{B}_2$ ;  $\text{PGF}_{1\alpha}$ , prostaglandin  $\text{F}_{1\alpha}$ ; for other abbreviations see Table 3.

damage. GSH acts directly as a hydroxyl radical scavenger, and it is also a substrate for GSH-Px, an enzyme that metabolizes hydrogen peroxide. The GSH and GSH-Px system maintains a favorable redox status in cells and confers resistance to oxidative damage. The high renal tissue GSH content might have enhanced the tissue redox potential, thus leading to less lipid peroxidation in CLO-fed mice. This is the second study, to our knowledge, to indicate that FO supplementation increases the GSH content of renal tissue. Milner *et al.* (14) showed that FO supplementation increased the renal GSH content in a rat model of ADR nephropathy, but they did not clarify the mechanism involved. Outside the kidney, Ibrahim *et al.* (15) have reported elevation of the GSH content in the mouse liver by dietary FO. Because unsaturated and unstable long-chain n-3 FA are more susceptible to oxidation than n-6 FA, the increased GSH content of renal cortical tissue may have been a response to increased oxidative stress. The precise mechanism by which CLO supplementation caused GSH to increase still needs to be clarified.

With respect to enhanced GSH-Px activity, the findings of Chandrasekar and Fernandes (16) may be pertinent. They reported that FO increased the renal expression of mRNA for SOD, catalase, and GSH-Px when compared with the levels found in corn oil-fed control mice, and that treatment with FO delayed the onset and progression of renal disease in lupus-prone NZB/NZW F1 female mice. In the present study, although GSH-Px activity was only significantly elevated at 72 h after DM injection in CLO-DM mice, the pretreatment values found in both CLO-DM and CLO-C mice were higher than those seen in SO-fed mice. The higher GSH-Px activity in CLO-fed mice may have reflected upregulation of its mRNA in renal tissue.

We also need to take into account the direct relationship between ROS and eicosanoid production. An *in vitro* experiment by Baud *et al.* (17) provided clear evidence that the production of TxB<sub>2</sub> and 6-keto PGF<sub>1α</sub> in isolated rat glomeruli was increased twofold by stimulation with ROS, which caused activation of membrane phospholipase (PL) A<sub>2</sub> and led glomerular Tx production to increase as a consequence of the enhanced availability of AA. An increase of lipid peroxidation as a result of stimulation by ROS has also been suggested to increase the susceptibility of membrane lipids to PLA<sub>2</sub>. But few studies have evaluated the relationship between ROS and eicosanoid production in an *in vivo* model of renal injury. Shibouta *et al.* (18) reported the simultaneous enhancement of the production of renal cortical TxA<sub>2</sub>, leukotrienes, and malondialdehyde in rats with puromycin nephrosis, and Parra *et al.* (19) found that glomerular TxB<sub>2</sub> and ROS syntheses were simultaneously increased in rats with cyclosporin A (CyA) nephrotoxicity. Interestingly, the administration of vitamin E (a free radical scavenger) prevented an increase in glomerular TxB<sub>2</sub> production in these rats, suggesting that the increase of TxB<sub>2</sub> synthesis depended on the overproduction of ROS.

In the case of DM nephropathy, the initial stimulus that induces nephropathy is the injection of DM. After being

injected, DM is converted to a semiquinone radical and promotes the free radical cascade (20). DM nephropathy can be prevented by administration of SOD or DMTU (6), and it was ameliorated along with the inhibition of enhanced lipid peroxidation by dietary CLO supplementation in the present study. Thus, scavenging of ROS may be the primary effect of CLO supplementation. ROS produced after injection of DM may act on cell membrane PUFA, and lipid peroxide that is produced as a result may be rapidly metabolized by the enhanced GSH-GSHPx system in mice receiving dietary CLO. The inhibitory effect of CLO supplementation on TxB<sub>2</sub> production in DM nephropathy may occur *via* a mechanism similar to that shown in rat CyA nephropathy, i.e., the increase of TxB<sub>2</sub> synthesis was inhibited by blocking the overproduction of ROS through CLO supplementation.

We studied the effects of dietary CLO compared with SO, not necessarily the beneficial effects of FO in general. This study could not distinguish between the beneficial effect of CLO, the adverse effect of SO, or a combination of the two. A further study is needed to clarify the relative beneficial or unfavorable effects of FO and vegetable oil. By using several diets that differ in only one FA, we could further extend our understanding of the interaction between PUFA and renal injury.

Dietary CLO supplementation could significantly reduce DM-induced glomerular injury when compared to that in SO-fed mice. The mechanisms linking ROS and eicosanoids during the progression of DM nephropathy have not been fully clarified, but the effect of CLO supplementation was probably due to modification of oxidative damage as well as alteration of eicosanoid production. The effect of CLO may be possibly related to an enhanced redox potential (a high GSH level and increased GSH-Px activity), together with the suppression of TxB<sub>2</sub> production in renal tissue.

**ABSTRACT:** Peroxisomal proliferator-activated receptors (PPAR) are a FA-response system involved in diverse cellular responses. FA regulate PPAR activity and modulate PPAR mRNA abundance. Increasing evidence indicates that PUFA are required for optimal neuronal development and function. To gain insight into the mechanism for nutrition-induced impairment of neuronal development and function we investigated the effect of chronic n-3 FA deficiency on PPAR mRNA levels in rat brain and ocular tissues. Rats were fed for three generations a diet designed to reduce DHA levels in tissues, and the abundance of PPAR $\alpha$  and PPAR $\beta$  transcripts was measured by hybridization with specific probes. Chronic consumption of the  $\alpha$ -linolenic acid (LNA)-insufficient diet caused a remarkable modification in DHA content in membrane phospholipids. The results reported here indicate that PPAR $\alpha$  mRNA levels did not exhibit significant variation in ocular, hepatic, or nervous tissues from rats fed the experimental diet. In contrast, PPAR $\beta$  mRNA normalized to  $\beta$ -actin mRNA was 21% higher in ocular tissue from F3 generation rats consuming the LNA-deficient diet but was independent of diet in hepatic and nervous tissues. The absolute abundance of PPAR $\beta$  transcripts showed a 17% increase in ocular tissue from rats consuming the LNA-deficient diet (F3 generation). The biological significance of the reported changes in PPAR $\beta$  mRNA in ocular tissue remains to be determined.

Paper no. L8931 in *Lipids* 37, 367–374 (April 2002).

FA are one of the main energy substrates for most mammalian species. In addition, FA serve as components of membrane phospholipids, precursors for the synthesis of molecules involved in cellular signaling, and modulators of gene expression (1–3). An inadequate FA balance, particularly a deficit of long-chain PUFA, is associated with reduced fetal growth and impaired neurodevelopment and nerve transmission in animal models (4–6). Furthermore, dietary studies in humans indicate that PUFA status affects sensory and cognitive development in premature and term infants (7–10).

Investigations over the past decades support the involvement of peroxisome proliferator activated-receptors (PPAR)

in many of the physiological responses to FA. PPAR are ligand-dependent transcription factors, initially recognized as mediators of FA effects on lipid metabolism, controlling gene expression for  $\beta$ -oxidation and lipid biosynthesis. Lately, it became apparent that PPAR not only participate in the regulation of FA oxidation and lipogenesis but also play a role in a wide array of cellular responses, including inflammation, thermogenesis, and cell differentiation (3,11,12).

Three PPAR isoforms encoded by individual genes, namely,  $\alpha$ ,  $\beta$  and  $\gamma$ , have been described. These isoforms display a tissue-selective pattern of expression (13). PPAR $\alpha$  is expressed in liver, brown adipose tissue, skeletal muscle, kidney, and adrenal glands. PPAR $\gamma$  is mainly expressed in white adipose tissue and, to a lesser extent, in spleen, gut, and the immune system. PPAR $\beta$  displays a broad pattern of expression with relatively higher levels in skeletal muscle, testis, placenta, and neuronal tissues (i.e., cerebellum, oligodendrocytes) (14–17). The presence of both PPAR $\alpha$  and PPAR $\beta$  transcripts has been reported both in outer and inner layers of rat retina (13). Regarding PPAR function, the  $\alpha$  isoform appears primarily to regulate the transcription of several FA-metabolizing enzymes in hepatic mitochondria and peroxisomes. PPAR $\gamma$  is implicated in the control of lipogenesis, regulating the maturation of preadipocytes and the accumulation of lipid droplets in the cytoplasm of fat cells (18,19). The physiological role of PPAR $\beta$  remains unclear, although it reportedly regulates acylCoA synthetase 2 in rat brain cultures (20), but it also seems to participate in early differentiation of adipocyte precursor cells (21). Furthermore, PPAR $\beta$ -null mice display alterations in development, epidermal cell proliferation, myelination of the corpus callosum, and lipid metabolism (22). Recently, PPAR $\beta$  has also been implicated in colorectal cancer (23), in bone resorption (24), and in the stimulation of reverse cholesterol transport (25).

PPAR activity is mainly controlled by ligand binding (26). Different FA and their derivatives (such as conjugated FA, eicosanoids, and prostaglandins) are able to activate PPAR isoforms (2,26). Among FA, DHA has been reported as a potent PPAR activator (27). FA activation of PPAR $\alpha$  seems to account for many of the short-term effects of dietary fat on gene expression in liver, at least in rodents. However, there is increasing evidence that under different nutritional states, not

Abbreviations: DPAn-6, docosapentaenoate; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; LA, linoleic acid; LNA,  $\alpha$ -linolenic acid; PPAR, peroxisome proliferator-activated receptor; RXR, retinoic acid receptor.

only PPAR activity but also its mRNA abundance are modified. After feeding, PPAR $\gamma$  increases in adipose tissue in response to sterol regulatory element binding protein 1 (28,29), thus stimulating uptake of FA and their conversion to TG, whereas, PPAR $\gamma$  diminishes in murine liver during fasting periods (28). Starvation causes a decrease in PPAR $\alpha$  mRNA levels in liver (30). In contrast, fasting results in high expression of PPAR $\alpha$  (30,31), increasing the ketonemia and thus providing fuel for different tissues. The recently identified fasting-induced adipose factor gene (FIAF) seems to be a target for the PPAR $\alpha$ -mediated response to fasting (32).

This work addresses the effect of long-term n-3 FA deficiency on the abundance of PPAR mRNA in rat tissues. Rats were chronically fed diets sufficient in linoleic acid (LA: 18:2n-6) but low or adequate in  $\alpha$ -linolenic acid (LNA: 18:3n-3). Consumption of diets containing oils low in LNA significantly reduced DHA (22:6n-3) content in F2 generation rat brain and liver FA. PPAR $\alpha$  and PPAR $\beta$  mRNA levels were analyzed in nervous, ocular, and hepatic tissues from F2 and F3 generation rats. Our results show a moderate increase in PPAR $\beta$  mRNA in ocular tissues from rats with an inadequate dietary supply of n-3 FA. In contrast, levels of neither PPAR $\alpha$  mRNA in all three tissues nor PPAR $\beta$  mRNA in hepatic or nervous tissues were significantly modified.

## MATERIALS AND METHODS

**Diets.** Diets based on the AIN93 diet (33) were designed to contain 10% total lipids and either deficient or adequate amounts of LNA (34). The experimental diets were composed of (in g/100 g diet): 20 vitamin-free casein, 60 carbohydrates (15 cornstarch, 10 sucrose, 20 dextrose, and 15 maltose-dextrin), 10 cellulose vitamins/minerals, and 10 lipids. Safflower oil was used to provide an adequate amount of LA (18:2n-6), and flaxseed oil was the source of LNA (18:3n-3) in the LNA-sufficient diet. The LNA-deficient diet contained 8.1 g/100 g of hydrogenated coconut oil (abundant in lauric and myristic acids) and 1.9 g/100 g of safflower oil. The LNA-adequate diet contained 7.75 g/100 g of hydrogenated coconut oil, 1.77 g/100 g of safflower oil, and 0.48 g/100 g of flaxseed. Fatty acyl composition analysis of the diets showed that 18:3n-3 was 3.1 and 0.04% of total FA in the LNA-sufficient and the LNA-deficient diet, respectively (34).

**Experimental design.** Female Long-Evans rats (Charles River, Portage, MI) were randomly divided into two groups of 12 rats each and reared on n-3 adequate or deficient diets beginning at 21 d of life. These females (F1 generation) were mated with chow-fed males and similarly, F2 generation females were mated with chow-fed males. Their male offspring (F2 and F3 generations) were weaned to the diet of the dam and maintained on this diet until sacrifice at 12 wk of age. No obvious differences in reproduction efficiency or pup size were observed in this study between dietary groups. Animals were killed by decapitation and the tissues rapidly excised and stored at  $-80^{\circ}\text{C}$  until analysis. Cerebellum, liver, and whole eyeballs were collected from the F2 and F3 generation

rats. All animal procedures were approved by the NIAAA Animal Care and Use Committee, NIH.

**FA analysis.** FA composition was determined in rat brain and liver. Lipids were extracted in the presence of tricosanoic acid (23:0) as internal standard (35). FA were transmethylated and analyzed by GC (36). The identification of individual FA was based on the retention time, and their content was expressed as a weight percentage of total FA (37).

**Slot blot analysis.** Frozen tissue samples (approximately 100 mg) were ground in a prechilled mortar. Total RNA was extracted with guanidine isothiocyanate/phenol (TRIZOL reagent; GIBCO BRL, Bethesda, MD) according to the manufacturer's instructions, precipitated in ethanol, and stored at  $-80^{\circ}\text{C}$ . Before use, samples were resuspended in diethyl pyrocarbonate-treated doubly distilled water and incubated for 45 min at  $37^{\circ}\text{C}$  with 0.03 units of RNase-free RQ1 DNase (Promega Corp., Madison, WI) per microgram of RNA.

Total RNA (0.5 to 1  $\mu\text{g}$ ) was denatured at  $68^{\circ}\text{C}$  in 0.21 M sodium citrate, 0.021 M sodium chloride, pH 7.0, 69% deionized formamide, 9% formaldehyde, and transferred to nitrocellulose membranes (Schleicher & Schuell GmbH, Dassel, Germany) by filtration under negative pressure. RNA was fixed to membranes using a UV cross linker (Stratagene, La Jolla, CA) and hybridized with  $^{32}\text{P}$ -labeled cDNA probes for PPAR $\alpha$ , PPAR $\beta$ , glyceraldehyde-3-phosphate dehydrogenase (GAPDH), or  $\beta$ -actin. Probes for PPAR $\alpha$ , PPAR $\beta$ , GAPDH, and  $\beta$ -actin transcripts were obtained by reverse transcription-PCR using primers specific for the corresponding cDNA sequences available on databases (PPAR $\alpha$ , Genebank accession # M88592; PPAR $\beta$ , Genebank accession # U40064;  $\beta$ -actin, Genebank accession # V01217; GAPDH Genebank accession # X02231 X00972). PCR-amplified fragments, cloned into pCR II (Invitrogen, Carlsbad, CA) or pBluescript (Stratagene) vectors, constituted nucleotides 1030 to 1775 of PPAR $\alpha$  cDNA, nucleotides 86 to 392 of PPAR $\beta$  cDNA, nucleotides 1253 to 2381 of  $\beta$ -actin gene, and nucleotides 87 to 626 of GAPDH cDNA. The identity of cloned fragments was confirmed by direct cDNA sequencing. The specificity of all probes used in slot blot hybridizations was verified by Northern analysis. Unique bands of the predicted size were observed in autoradiograms. Hybridization with nonlimiting amounts of radioactive probes was carried out for 24 h at  $42^{\circ}\text{C}$  in 0.02 M sodium phosphate buffer, pH 6.5, containing  $6\times$  SSC (0.9 M sodium chloride, 0.09 M sodium citrate pH 7.0),  $5\times$  Denhardt's solution (0.1% wt/vol polyvinylpyrrolidone, 0.1% wt/vol Ficoll type 400, 0.1% wt/vol BSA), 5% wt/vol dextran sulfate in formamide, 0.1 mg/mL denatured salmon sperm DNA, and  $^{32}\text{P}$ -labeled probes. Labeling of the probes was carried out by the PCR Radioactive Labeling System (GIBCO BRL) and  $\alpha$ - $^{32}\text{P}$ -dCTP (111 TBq/mmol, 370 MBq/mL; NEN Life Science Products, Inc., Boston, MA). Membranes were washed with a solution containing  $0.2\times$  SSC (0.015 M sodium chloride, 0.0015 M sodium citrate, pH 7.0), and 0.1% SDS at 60, 63, or  $68^{\circ}\text{C}$  for PPAR $\beta$ , PPAR $\alpha$ , or  $\beta$ -actin and GAPDH, respectively. Membranes were exposed to X-ray films using intensifying screens, and densitometric analysis of autoradio-

grams was carried out with a Bio-Rad GS-670 image densitometer. PPAR signal intensities for each tissue in individual animals were standardized with those of the reference mRNA measured in parallel. The mean  $\pm$  SD of two experiments was determined for each dietary group. Hybridizations to mRNA from different tissues were carried out independently. To compare PPAR mRNA abundance among samples and experiments,  $\beta$ -actin and GAPDH mRNA were used as an internal reference. Thus, results for PPAR $\alpha$  and PPAR $\beta$  mRNA were expressed relative to  $\beta$ -actin and GAPDH mRNA.

*Statistical analysis.* Statistical differences between the mean values of dietary groups were assessed by the two-tailed unpaired *t*-test and were considered significantly different at  $P < 0.05$ .

## RESULTS

*Effect of diet on FA composition.* Analysis of liver and brain lipids from rats fed LNA-deficient or LNA-adequate diets shows significant differences in FA composition (Table 1), particularly in DHA, which accounts for over 99 and 85% of total n-3 FA in brain and liver, respectively. A fivefold lower level of DHA was found in brain and an 11-fold DHA decrease in liver from rats fed the LNA-deficient diet. A concomitant compensatory increase in 22-carbon n-6 FA, particularly in docosapentaenoate (DPA $n$ -6, 22:5n-6) and, to a lesser extent, in 22:4n-6 was detected in the lipids of hepatic and nervous tissue. Thus, the total n-6 to n-3 ratio increased almost 10-fold in brain lipids and 14-fold in liver lipids.

<sup>b</sup>NA, not available; ND, not detectable; LNA,  $\alpha$ -linolenic acid; LA, linoleic acid. Values may not equal 100% due to unidentified peaks.

Changes in lipid composition were not evaluated in ocular tissue because the whole sample was used for mRNA quantification, and other studies show that retinal responses are similar to those of brain with respect to DHA loss and replacement with DPAn-6 (4,38,39).

**Effect of diets on PPAR mRNA abundance.** GAPDH and  $\beta$ -actin transcripts are widely accepted as reference genes for expression analysis. Because changes in either GAPDH or  $\beta$ -actin mRNA levels have been reported under some experimental conditions (40–42), the abundance of both transcripts was evaluated in the tissues analyzed here (Table 2). Data are expressed as the mean value of  $\beta$ -actin and GAPDH mRNAs in tissues from rats fed the LNA-deficient diet and as a percentage of the value obtained from the LNA-adequate group. GAPDH mRNA levels in different tissues were independent of the dietary supply of LNA, except for a 10% decrease in nervous tissue in F3 generation rats fed the LNA-deficient diet. In addition, significantly lower levels of  $\beta$ -actin mRNA were detected in ocular (10%), nervous (20%), and hepatic (42%) tissues from F2 generation rats fed the LNA-deficient diet as compared to those that consumed the LNA-adequate diet. Therefore, data normalized to  $\beta$ -actin mRNA in all tissues from F2 generation rats and to GAPDH mRNA in nervous tissue (F3 generation) were not included for analysis. In addition, a lower level (37%) of  $\beta$ -actin transcripts was also found in liver from F3 generation rats. However, this difference was not statistically significant, probably owing to variability within the group.

The abundance of PPAR mRNA in nervous and ocular tissues was evaluated and expressed relative to both  $\beta$ -actin and GAPDH mRNA levels in the same tissue, as pointed out in the Materials and Methods section (Tables 3 and 4). Analysis of mRNA in hepatic tissue was included as a control, because of reported high levels of PPAR $\alpha$  mRNA expression. As shown in Table 3, most of the differences detected in the relative abundance of PPAR $\alpha$  mRNA in ocular, nervous, and hepatic tissue from F2 and F3 generation rats fed LNA-deficient or LNA-adequate diets were not statistically significant. PPAR $\alpha$  mRNA abundance normalized to  $\beta$ -actin mRNA was 61% higher in hepatic tissue from F3 generation rats consuming the LNA-deficient diet than that measured in rats fed the LNA-adequate diet. However, the latter could be explained,

at least in part, by the lower  $\beta$ -actin mRNA measured in hepatic tissue from these rats (Table 2). This is confirmed when results are examined relative to GAPDH mRNA. In this case, PPAR $\alpha$  levels do not significantly differ in the liver samples. As illustrated in Table 4, PPAR $\beta$  mRNA abundance also displayed significantly higher levels when expressed relative to  $\beta$ -actin mRNA but not to GAPDH mRNA.

The results of the PPAR $\beta$  mRNA abundance determination in nervous and hepatic tissues shown in Table 4 indicate no significant changes, except a 51% increment in PPAR $\beta$  mRNA normalized to  $\beta$ -actin mRNA in the F3 generation (possibly influenced by the decrease observed in  $\beta$ -actin transcripts in liver). In ocular tissue, significantly higher PPAR $\beta$  mRNA abundance relative to  $\beta$ -actin transcripts (21%) was found in F3 generation rats from the LNA-deficient group (Table 4). It is likely that the increase in the normalized PPAR $\beta$  level in ocular tissue arises mainly from a moderately higher absolute abundance of PPAR $\beta$  mRNA (17%) in the rats consuming the n-3-deficient diet (Table 4).

## DISCUSSION

Effects of dietary FA at the level of gene expression are part of an adaptive metabolic response to the amount and type of fat. These are mediated, at least in part, by the PPAR system. Although the activity of PPAR isoforms is mainly regulated by ligand binding and phosphorylation status, control at the transcriptional level is also apparent. Changes in the abundance of PPAR $\alpha$ , which influences the expression of enzymes for FA oxidation, have been detected in liver during fasting periods, with a concomitant increase in the level of PPAR $\alpha$  mRNA (31). Moreover, food intake increases PPAR $\gamma$  mRNA levels, whereas PPAR $\gamma$  abundance decreases during fasting periods (28). Changes in PPAR $\alpha$  mRNA levels in response to total dietary fat intake and to FA composition have also been documented. Feeding rats a diet rich in LNA for 12 wk after weaning caused a decrease in PPAR $\alpha$  mRNA abundance in the epididymal fat pads (43). In contrast, an increased expression of PPAR $\alpha$  mRNA in rat liver was observed in 5-wk-old rats fed a high-fat diet (250 g/kg of either coconut oil or olive oil or safflower oil) over a 4-wk period (44).

<sup>c</sup>The mean value of PPAR $\alpha$  mRNA relative to  $\beta$ -actin or to GAPDH mRNA for the LNA-deficient diet was expressed as percentage of the value for the group fed the LNA-adequate diet. PPAR $\alpha$ , peroxisome proliferator-activated receptor  $\alpha$ ; for other abbreviations see Tables 1 and 2.

The effect of high- and low-fat diets on PPAR $\alpha$  mRNA abundance in kidney of 3-wk-old rats also has been investigated previously (45). In this study, pups were kept on a low-fat diet (less than 1% fat) from day 16 to 21; then a group was placed on a high-fat diet (supplemented with 25% coconut oil) for 24 h. Despite marked changes in the mRNA levels for enzymes involved in  $\beta$ -oxidation in the kidney cortex, the authors reported no significant modification of PPAR $\alpha$  mRNA abundance, suggesting that modulation of the expression of the PPAR $\alpha$  gene is not involved in this physiological response to a high-fat diet. A diet high in fat causes a small increase in PPAR $\gamma$  in rat adipose tissue (28). However, the infusion of lipids (Intralipid) in humans results in a marked increase in subcutaneous adipose tissue PPAR $\gamma$  mRNA (46). Considering the PPAR $\beta$  ligand-binding profile (26), it is likely that FA are physiological regulators of its activity as a transcription factor. However, information regarding the regulation of PPAR $\beta$  gene expression is not yet available.

Many investigations support the role of n-3 FA, particularly DHA, on the development and function of the nervous system in humans (4,38,47,48), particularly in the visual system (7,10,47). High DHA levels are found in the inner membranes of photoreceptor outer segments, in certain brain areas,

and in specific neuronal cell types. Dietary n-3 FA deficiency alters rat retinal function (49). Moreover, DHA promotes differentiation of developing photoreceptors in culture (50). Interestingly, PPAR $\beta$  mRNA is more prominent than other PPAR isoforms in many areas of the rat adult brain (15) and its level is particularly high during embryonic development (51). Expression of PPAR $\beta$  is also abundant in differentiating oligodendrocytes, cells involved in myelin sheath formation (16). Consistently, PPAR $\beta$  null mice show alterations in myelination of the corpus callosum and in lipid metabolism (22). As in other cell types, it likely that PPAR transcriptional activity is modulated by FA in neuronal cells although their PPAR-responsive genes have not been identified.

The purpose of this study was to explore whether long-term modification of FA intake, specifically n-3 FA deficiency, affects the abundance of PPAR $\alpha$  and  $\beta$  mRNA in neural tissues. It is well known that the content and composition of dietary lipids can alter FA composition in biological membranes (38,39,52–54). These studies demonstrate that when two or more generations of animals are maintained on an n-3-deficient diet, a marked modification of the FA composition in the nervous system occurs. Therefore, in the present study, rats were fed the experimental diet for three gener-

<sup>a</sup>Because hybridization assays to mRNA from different tissues were carried out independently (see Materials and Methods section), the comparison of absolute PPAR $\beta$  mRNA values should be restricted to the same tissue.

<sup>b</sup>Data are mean  $\pm$  SD. In parentheses are the number of samples. <sup>c</sup>Statistically significant differences: <sup>d</sup> $P = 0.001$ , <sup>e</sup> $P = 0.005$ , <sup>f</sup> $P = 0.004$ , <sup>g</sup> $P = 0.03$ , <sup>h</sup> $P = 0.02$ , and <sup>i</sup> $P = 0.02$ .

<sup>c</sup>The mean value of PPAR $\beta$  mRNA relative to  $\beta$ -actin or to GAPDH mRNA for the LNA-deficient diet was expressed as a percentage of the value for the group fed the LNA-adequate diet. For abbreviations see Tables 1–3.

ations. The effects of the diet deficient in LNA were compared to those of a diet providing adequate levels of this FA. One would expect that n-3 FA deficiency would resemble genetic diseases associated with impaired DHA synthesis, which preferentially affect the function of excitable tissues such as brain, retina, and muscle (55,56). Despite no apparent differences in body or brain weight, siblings of these rats that consumed the n-3-deficient diet showed poorer performance in spatial and olfactory-cued learning tests than those that received the control diet (33,57,58). As shown here, long-term inadequate dietary provision of n-3 fat sources results in a remarkable decrease in DHA in rat brain phospholipids (five-fold) and in liver (11-fold), and a concomitant increase in DPAn-6 FA (>20-fold).

In the present study, quantitation of PPAR mRNA in hepatic, ocular, and nervous tissues from rats fed the LNA-deficient or -adequate diet was referred to both  $\beta$ -actin and GAPDH mRNA abundance. Results shown here indicate that reference transcripts did not differ significantly in most tissues from rats consuming the LNA-deficient diet. However,  $\beta$ -actin mRNA levels in the F2 but not in the F3 generation were consistently lower in the LNA-deficient rats for all three tissue types analyzed here. In addition, GAPDH mRNA was also significantly lower in nervous tissue of F3 generation rats fed the LNA-deficient diet. We do not have a clear explanation for the apparent selective decrease in  $\beta$ -actin mRNA. As a matter of speculation, we propose that the expression of  $\beta$ -actin and GAPDH genes is sensitive, to a different extent, to an undefined factor that is dissimilarly present in F2 vs. F3 generation rats fed the LNA-deficient diet. Therefore, taking into account the results discussed above, PPAR data normalized to  $\beta$ -actin mRNA (F2 generation) and GAPDH mRNA (F3 generation, nervous tissue) were excluded from the analysis.

Our findings indicate that the marked decrease in DHA levels in tissues did not correlate with substantial changes in the level of PPAR $\alpha$  or PPAR $\beta$  transcripts in rat liver or brain. We found a modest increase in the abundance of PPAR $\beta$  mRNA in ocular tissues from rats consuming the LNA-deficient diet compared to those fed the LNA-adequate diet. In F3 generation rats, the PPAR $\beta$  mRNA level was 17% higher, and PPAR $\beta$  mRNA normalized to  $\beta$ -actin showed a 21% increase in ocular tissues from the n-3 FA deficient group.

Given that the biological activity of PPAR transcription factors is primarily controlled by ligand binding, the functional relevance of an increment in the abundance of the corresponding transcripts remains a matter of speculation. Considering that the precise function of PPAR $\beta$  has not been determined, the theoretical outcome of an eventual increase in PPAR $\beta$  protein (as a consequence of higher mRNA levels) could be inferred from emerging information that supports the role of PPAR $\beta$  as a dietary lipid sensor and modulator of lipid homeostasis. Reportedly, PPAR $\beta$ -null mice have reduced adipose tissue depots. Moreover, the advent of a selective PPAR $\beta$  ligand has provided evidence for its role as a regulator of the expression of the gene encoding the ABCA1 reverse cholesterol transporter (25). Therefore, changes in PPAR $\beta$

mRNA absolute abundance in ocular tissue could hypothetically stimulate the efflux of cholesterol from cells. However, modulation of other cellular pathways cannot be excluded.

Our results indicate that PPAR gene expression is moderately sensitive to long-term n-3 FA deficiency in the whole-body experimental model tested here. The dietary intervention in this study is highly specific to the n-3 FA series, preserving the total amount of fat as well as the amount of n-6 FA. The response to this dietary intervention conceivably includes mechanisms other than the transcriptional control of PPAR genes. It is possible that the consequences of dietary intake of n-3 FA primarily involve modulation of the activity rather than amount of PPAR. In addition, other transcription factors may be involved in the response to n-3 deficiency. Recent experiments using cell lines show that DHA is a potent activator of the transcriptional activity of 9-*cis* retinoic acid receptor (RXR) isoforms. Moreover, the reported effect was highly specific to DHA in comparison to other C<sub>22</sub>, C<sub>20</sub>, and C<sub>18</sub> unsaturated FA (59). Given the fact that RXR responsiveness to DHA is affected by heterodimerization and that PPAR and RXR are common partners, it is possible that DHA deficiency alters cellular pathways under the transcriptional control of both RXR and PPAR or other heterodimerization partners.

# Dietary Cholesterol Modulates $\Delta 6$ and $\Delta 9$ Desaturase mRNAs and Enzymatic Activity in Rats Fed a Low-EFA Diet

Rodolfo R. Brenner\*, Ana M. Bernasconi, María S. González, and Omar J. Rimoldi

Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), CONICET-UNLP,  
Facultad de Ciencias Médicas, 1900-La Plata, Argentina

**ABSTRACT:** The effects of a 1% addition of cholesterol to a diet low in EFA on FA desaturases were examined. The administration of cholesterol markedly increased the esterified cholesterol content in microsomes and total liver lipids from the first day, whereas the proportion of free cholesterol remained unaltered throughout the treatment. An excellent homeostasis in the free cholesterol content was apparently evoked by the acyl-CoA cholesterol acyltransferase. The cholesterol esters were mainly oleate, palmitate, and stearate, and the addition of cholesterol increased the relative proportions of cholesterol palmitoleate and oleate. The addition of cholesterol to a low-EFA diet induced, as in animals fed a high-EFA diet, a marked increase in liver stearoyl-CoA desaturase-1 mRNA and enzyme activity. This increased activity apparently evoked a similar enhancement of palmitoleic and oleic acids in total and microsomal liver lipids. The cholesterol-rich diet depressed the liver  $\Delta 6$  and  $\Delta 5$  desaturase activity. However, the abundance of  $\Delta 6$  desaturase mRNA was not modified throughout the treatment. This indicates that the depressive effect is evoked at a step beyond that controlled by the mRNA level. The depression of both enzymatic activities was consistent with the decrease in the percentages of arachidonic acid and DHA in total and microsomal liver lipids. Taken together, these results indicate that through its modulating effect on the desaturases, dietary cholesterol may lead an animal or human fed low-EFA diet to a true deficiency by the decreased synthesis of the highly polyunsaturated acids derived from linoleic and  $\alpha$ -linolenic acids.

Paper no. L8938 in *Lipids* 37, 375–383 (April 2002).

Very early research in the 1960s (1,2) showed, by the measurement of parameters used then, that feeding cholesterol to animals with a suboptimal EFA intake led to an exacerbation of the signs of EFA deficiency. The real biological effects of EFA deficiency are mainly due to a decrease in the highly polyunsaturated acids of the n-6 and n-3 families and not to linoleic or  $\alpha$ -linolenic acids. It has repeatedly been shown in later publications that administration of dietary cholesterol to

E-mail: rbrenner@atlas.med.unlp.edu.ar

Abbreviations: HPTLC, high-performance thin-layer chromatography; Ptd-Cho, phosphatidylcholine; SCD, stearoyl-CoA desaturase; SREBP, sterol regulatory element binding protein.

rats evokes not only its incorporation into the cell but also an increase in liver  $\Delta 9$  desaturase activity and a decrease in  $\Delta 6$  and  $\Delta 5$  desaturase activities, followed by important changes in the FA composition of cell phospholipids (3–8).

These effects of cholesterol were shown in rats fed diets rich in linoleic acid, and they provoked a decrease in the polyunsaturated acids as arachidonic acid was synthesized in the animal from dietary linoleic acid. Therefore, enhancing the effects of EFA deficiency evoked by cholesterol might be the consequence of the depression of  $\Delta 5$  and  $\Delta 6$  desaturases.

However, a linoleic acid-rich diet causes a depressive effect on the  $\Delta 9$  desaturase gene expression (9). In addition, Clarke's group (10) showed not only that the addition of linoleic acid to a fat-free diet depressed the hepatic  $\Delta 6$  desaturase activity, but also that this depression was paralleled by a reduction in the corresponding  $\Delta 6$  desaturase mRNA. The same authors (11) also found that a diet containing 10% safflower seed oil depressed the hepatic mRNA of  $\Delta 5$  desaturase compared to that of rats fed a fat-free diet or a diet containing triolein. In addition to these results, we have repeatedly shown in our laboratory, as well as in a recent review (12), that, in general, hormones (except insulin) evoke effects on the  $\Delta 9$  desaturase that are antagonistic to those found for both  $\Delta 6$  and  $\Delta 5$  desaturation activities, indicating different mechanisms of regulation. Therefore, we consider it necessary to prove definitively if—in a diet low in EFA that already enhances  $\Delta 9$ ,  $\Delta 6$ , and  $\Delta 5$  desaturation of FA—the addition of 1% cholesterol is still able to modify activities and even push animals to a true EFA deficiency. Moreover, in spite of the enhancing effect of a high-cholesterol, EFA-rich diet on the abundance of stearoyl-CoA desaturase-1 (SCD-1) mRNA in rat liver shown by Landau *et al.* (7), the effect of a high-cholesterol diet on the  $\Delta 6$  desaturase mRNA level has not yet been investigated.

All these results prompted us to investigate at different times the simultaneous effect of a diet low in EFA and one containing 1% cholesterol on the incorporation of cholesterol into total liver cells and microsomes; the  $\Delta 9$ ,  $\Delta 6$ , and  $\Delta 5$  desaturation activities; and the abundance of  $\Delta 9$  and  $\Delta 6$  desaturase mRNA. The total FA composition of liver cells and microsomes, as well as the distribution of cholesterol and cholesterol esters and their FA composition, was also checked.

We found that dietary cholesterol was incorporated into liver microsomes and total liver cells, increasing the cholesterol ester fraction but not the relative ratio of free cholesterol. Dietary cholesterol evoked an increase in  $\Delta 9$  desaturase mRNA that correlated with the enzymatic activity. However, it did not modify the abundance of  $\Delta 6$  desaturase mRNA but decreased the enzymatic activities of both  $\Delta 6$  and  $\Delta 5$  desaturases. The FA composition of microsomes, total liver lipids, and cholesterol esters followed the enzymatic activity changes rather well and showed a drastic decrease in highly polyunsaturated acids.

## MATERIALS AND METHODS

**Materials.** [1- $^{14}$ C]Stearic acid (56 mCi/mmol, 98% radiochemically pure) and [1- $^{14}$ C]linoleic acid (55 mCi/mmol, 99% radiochemically pure) were purchased from Amersham Life Science (Amersham, England). [1- $^{14}$ C]Eicosa-8,11,14-trienoic acid (52 mCi/mmol, 98% radiochemically pure) was provided by New England Nuclear (Boston, MA). Unlabeled FA were provided by Nu-Chek-Prep (Elysian, MN). Cofactors used for enzymatic reactions were obtained from Sigma Chemical Co. (St. Louis, MO). Solvents for HPLC were purchased from Carlo Erba (Milan, Italy).

Rat SCD-1 ( $\Delta 9$  desaturase) cDNA was a kind gift from Dr. Juris Tsunehiro Ozols (Department of Biochemistry, University of Connecticut, Central Health, Farmington, CT), and rat  $\Delta 6$  desaturase cDNA was a kind gift from Dr. T. Aki (Department of Molecular Biotechnology, Hiroshima University, Higashi-Hiroshima, Japan). Restriction enzymes and other DNA nuclei-modifying enzymes were obtained from Promega (Madison, WI). All plasmid DNA were isolated by SDS-NaOH methods (13).

**Animals and diets.** Animal care and handling were in accordance with internationally accepted principles concerning the care and use of laboratory animals. Forty male Wistar rats were fed for 10 d after weaning with a control diet low in EFA composed of 62 wt% starch, 22.6 wt% delipidated casein, 9.4 wt% cacao butter, 2 wt% vitamins (14), and 4 wt% minerals (14). The FA composition of the food was 32.2 wt% 16:0, 0.6 wt% 16:1, 28.7 wt% 18:0, 34.0 wt% 18:1, and 4.5 wt% 18:2; cholesterol was not detected. After this time, 20 animals were kept on the control low-EFA diet, whereas the other 20 animals were fed the same diet as the control with the addition of 1 wt% cholesterol. Lots of five animals from each group were sacrificed by decapitation without anesthesia and exsanguinated on days 1, 3, 7, and 21. The liver from each animal was rapidly excised and placed in an ice-cold homogenizing solution (1:3 wt/vol) composed of 0.25 M sucrose, 0.15 M KCl, 0.1 mM EDTA, 1.41 mM *N*-acetyl cysteine, 5 mM  $\text{MgCl}_2$ , and 62 mM phosphate buffer (pH 7.4). Microsomes were obtained by differential ultracentrifugation at  $100,000 \times g$  (Beckman Ultracentrifuge) as described elsewhere (15). They were stored at  $-80^\circ\text{C}$ .

Protein concentration was measured according to the procedure of Lowry *et al.* (16).

**Lipid analysis.** Lipids were extracted from total liver and microsomes according to the procedure of Folch *et al.* (17). Total lipid content was measured by aliquot evaporation to constant weight. Total phosphorus was determined by the method of Chen *et al.* (18).

Free and esterified cholesterol were measured in total homogenate and microsomal liver lipids. They were separated by TLC on Whatman high-performance thin-layer chromatography (HPTLC) plates of  $20 \times 10$  cm (Linear-K preadsorbent strip), using hexane/ethyl ether/acetic acid (80:20:1, by vol). Cholesterol and esterified cholesterol spots were visualized by the ferric chloride method of Lowry (19). They were quantified by comparison to curves constructed using commercial standards (1–5  $\mu\text{g}$ ). After staining, the plates were scanned and the densitometric quantitation was performed using 1D Image Analysis Software (Kodak, Rochester, NY) from multiple exposures. The cholesterol esters separated by TLC were saponified with alcoholic KOH, and the FA were separated and methylated with  $\text{BF}_3$  at  $64^\circ\text{C}$  for 1 h.

FA composition of the cholesterol esters, microsomal liver lipids, and total lipids of liver, adrenals, and testicles were analyzed by GLC of their methyl esters in a Hewlett-Packard HP 6890 apparatus. They were injected into an Omega Wax 250 (Supelco, Bellefonte, PA) capillary column of 30 m, 0.25 mm i.d., and 0.25  $\mu\text{m}$  film. The temperature was programmed to obtain a linear increase of  $3^\circ\text{C}/\text{min}$  from 175 to  $230^\circ\text{C}$ . The chromatographic peaks were identified by comparison of their retention times with those of standards.

**FA desaturation assays.**  $\Delta 9$ ,  $\Delta 6$ , and  $\Delta 5$  desaturations were estimated in hepatic microsomes using as substrates 50  $\mu\text{M}$  [1- $^{14}$ C]stearic acid, 33  $\mu\text{M}$  [1- $^{14}$ C]linoleic acid, and 50  $\mu\text{M}$  [1- $^{14}$ C]eicosa-8,11,14-trienoic acid, respectively. The acids were incubated with 2.5, 2.0, and 1.95 mg of microsomal protein, respectively, in a final volume of 1.5 mL at  $36^\circ\text{C}$  (3). The reaction mixture consisted of 0.25 M sucrose, 0.15 M KCl, 1.41 mM *N*-acetyl-L-cysteine, 40 mM NaF, 60  $\mu\text{M}$  CoA (sodium salt), 1.3 mM ATP, 0.87 mM NADH, 5 mM  $\text{MgCl}_2$ , and 40 mM potassium phosphate buffer (pH 7.4). After 1 min preincubation at  $36^\circ\text{C}$ , the reaction was started by addition of microsomal protein, and the mixture was incubated in open tubes for 15 min in a thermoregulated shaking water bath. The desaturation reaction was stopped with 10% (wt/vol) KOH in ethanol followed by saponification. The extracted FFA were dissolved in methanol/water/acetic acid (85:15:0.2, by vol) and fractionated by RP-HPLC (20). Separations were performed on an Econosil  $\text{C}_{18}$  10- $\mu\text{m}$  particle size reversed-phase column ( $250 \times 4.6$  mm) (Alltech Associates, Inc., Deerfield, IL) coupled to a guard column (10  $\times$  4 mm), and filled with pellicular  $\text{C}_{18}$ , using a mobile phase (methanol/water/acetic acid, 90:10:0.2, by vol) at a flow rate of 1 mL/min and a Merck-Hitachi L-6200 solvent delivery system (Darmstadt, Germany). The column eluate was monitored by a UV spectrometer at 205 nm for FA identification on the basis of retention times. Radioactivity associated with FA was measured by a Radiomatic Instrument (Tampa, FL) Flo-One Beta flow-through liquid scintillation counter fitted with a

0.5-mL cell. Ultima Flo-M scintillation cocktail (Packard Instruments, Downers Grove, IL) was used at a rate of 3 mL/min.

**Northern blots of Δ9 and Δ6 desaturase mRNA.** Total liver RNA of the different animals tested was isolated with a Wizard RNA Isolation System (Promega) according to the manufacturer's instructions. Twenty micrograms of total RNA was size-fractionated on a 1% formaldehyde gel and then transferred to a Zeta-Probe nylon membrane (Bio-Rad, Richmond, CA). The Δ9 and Δ6 desaturase and β-actin probes were prepared by incorporating [<sup>32</sup>P]dCTP by random prime labeling. Northern blot hybridization analyses were performed as described by Sambrook *et al.* (13). The autoradiographic signal for Δ9 and Δ6 desaturase mRNA was quantified from multiple exposures using 1D Image Analysis Software (Kodak). They were normalized to mRNA for β-actin, with all mRNA probed on the same gel.

**Statistical analysis.** Data in the tables are expressed as mean ± SD. They were analyzed using ANOVA (Instat v.2.0 Graph Pad Software, San Diego, CA) to identify time and diet effects and their interactions. When effects were identified as significant (*P* < 0.05), Tukey's *post-hoc* tests were utilized to identify significant effects of diet at particular time points or significant effects of time on a particular diet.

**RESULTS**

**Effect of dietary cholesterol on free cholesterol and cholesterol ester content in liver homogenate and microsomes.** Dietary cholesterol has repeatedly been shown to be incorporated into liver (3–5,7). In the present experiment, the same is shown in total liver and liver microsomes (Table 1). However, the incorporation of cholesterol apparently did not increase the lipid content of the liver microsomes since the lipid/protein ratio of these organelles was steadily maintained at 0.52 mg/mg throughout the 21 d of the experiment. Nevertheless, the total lipid content of total liver increased due to cholesterol incorporation. In the control rats the lipid/protein ratio

(by wt) was maintained at 0.22 throughout the 21 d, whereas it increased in the cholesterol-treated animals from 0.22 to 0.37 on day 7 and to 0.50 on day 21.

When we compared the extent to which the relative cholesterol increase in the lipid fraction was due to the free or esterified form, we found that in cytosol and microsomes the increase was due to cholesterol esters but not to free cholesterol.

In total liver homogenate (Table 1) the percentage of free cholesterol in the lipids compared to the control animals was not increased and remained unmodified on days 1, 7, and 21 after cholesterol administration. However, the percentage of cholesterol ester in the same lipids was very significantly increased as early as 24 h after cholesterol administration and was progressively enhanced on days 7 and 21. In spite of that, the amounts of both cholesterol forms increased in the cell because the total lipids increased.

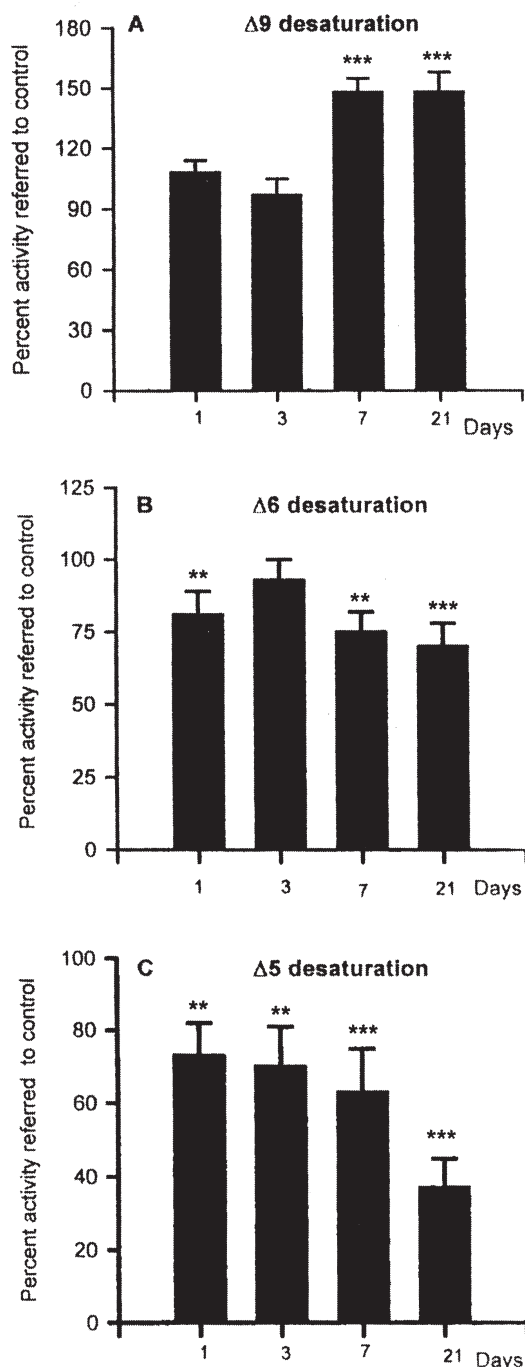

Similarly, in rat liver microsomal lipids (Table 1), although no modification of the free cholesterol was shown compared to the control animals on days 1, 7, and 21, a very significant increase in cholesterol esters was also found after 24 h of treatment. In microsomes the higher level of esters was maintained on the following days, at least up to the end of the experiment (21 d). Since the lipid/protein ratio was maintained in the microsomes, only the cholesterol ester fraction was quantitatively increased.

**Effect of dietary cholesterol on liver Δ9 desaturation activity and the abundance of mRNA.** The liver Δ9 desaturation activity for the conversion of stearic acid to oleic acid is shown in Figure 1. After 24 h of cholesterol feeding, no significant change in Δ9 desaturation activity was shown. After 7 d, it reached significance compared to the activity of control animals. These results are similar to results from experiments (3–5,7) in which a different diet rich in EFA was administered. An EFA-rich diet is known to depress Δ9 desaturation activity (21). Therefore, in spite of these differential effects of low-EFA and EFA-sufficient diets on the liver Δ9 desaturation activity, the addition of cholesterol evoked a relative activation of the reaction.

**TABLE 1**  
**Free and Esterified Cholesterol (wt%) of Total Lipids<sup>a</sup>**

Treatment	Time						
	1 d		7 d		21 d

<sup>a</sup>Results are the mean ± SD (*n* = 5 animals) expressed as weight percentage of total lipids. Different roman superscript letters indicate significant differences between this value and that in the group headed by the same letter. \*\*\**P* < 0.001, \*\**P* < 0.01, \**P* < 0.05.

**FIG. 1.** Relative FA desaturation activities in cholesterol-treated rats.  $\Delta 9$ ,  $\Delta 6$ , and  $\Delta 5$  desaturation in EFA-deficient rats during cholesterol supplementation (at 1, 3, 7, and 21 d) using liver microsomes. Microsomal protein was incubated with (A) [ $1\text{-}^{14}\text{C}$ ]stearic acid; (B) [ $1\text{-}^{14}\text{C}$ ]linoleic acid, or (C) [ $1\text{-}^{14}\text{C}$ ]eicosatrienoic acid. The assay mixture contained 60  $\mu\text{M}$  CoA, 1.3 mM ATP, 0.45 mM NADH, 5 mM  $\text{MgCl}_2$  in 40 mM potassium phosphate buffer, 0.25 M sucrose, 0.15 M KCl, 1.41 mM *N*-acetyl-L-cysteine, and 40 mM NaF; final pH: 7.0. Data are expressed as a percentage of the control group at each time point and represent means  $\pm$  SD ( $n = 4$ ). Control enzymatic activities (nmol product/min-mg protein) on day 1 were (A)  $0.407 \pm 0.048$ ; (B)  $0.668 \pm 0.031$ ; and (C)  $1.165 \pm 0.201$ . Symbols above columns indicate statistically significant differences from values of control groups: \*\*\* $P < 0.001$ ; \*\* $P < 0.01$  using the Student's *t*-test (Excel Microsoft).

**FIG. 2.** Effect of a cholesterol-rich diet on the levels of liver, stearoyl-CoA desaturase-1 (SCD-1), and  $\Delta 6$  desaturase mRNA. Total liver mRNA from control and cholesterol-fed animals at the periods indicated were electrophoresed on a 1% agarose-formaldehyde gel, blotted to nylon membrane, and probed with  $^{32}\text{P}$ -random primed cDNA. mRNA levels of SCD-1 and  $\Delta 6$  desaturases were compared to  $\beta$ -actin signals.

The relative abundance of SCD-1 mRNA in the livers of rats fed the cholesterol diet was significantly higher than in the livers of animals fed the low-EFA diet alone (Fig. 2). A 1.5-fold increase compared to the controls was evident 24 h after feeding the cholesterol diet, and it apparently reached a steady state on the following days at approximately twofold. It is important to note that this enhancement is evoked by the cholesterol diet independent of any apparent EFA deficiency effect known to induce the SCD-1 mRNA (22).

However, we have to remark that the relatively significant increase in the  $\Delta 9$  desaturation activity evoked by cholesterol in this experiment was shown only after 7 d of treatment (Fig. 1), whereas the relative increase in liver SCD-1 mRNA was already shown in the first 24 h (Fig. 2).

*Effect of dietary cholesterol on liver  $\Delta 6$  and  $\Delta 5$  desaturation activities and level of  $\Delta 6$  desaturase mRNA.* The activities of microsomal liver  $\Delta 6$  and  $\Delta 5$  desaturations of linoleic and eicosatrienoic n-6 acids, respectively, in rats fed a low-EFA control diet and the same diet plus 1% cholesterol are shown in Figure 1. As expected, the relative activities of both reactions are depressed to some extent by the addition of dietary cholesterol.

On this occasion we also measured the abundance of  $\Delta 6$  desaturase mRNA in liver cells by Northern blot analysis (Fig. 2). Two transcripts of mRNA  $\Delta 6$  desaturase were found. It is important to remark that Cho *et al.* (11) also found two transcripts of this enzyme, a major one of 3.8 kb and a minor one of 1.9 kb in rat liver and similar ones in mouse. Both mRNA transcripts, the major one and the minor one (see Fig. 2), are not significantly altered when compared to control animals by the effect of cholesterol addition to the diet as measured after 1, 3, 7, and 21 d of treatment. From these data, the depressive effect of cholesterol-rich diets on the  $\Delta 6$  desaturation

activity cannot be attributed to a decrease in the enzyme mRNA level.

*Effect of dietary cholesterol on the FA composition of liver lipids, microsomes, and cholesterol esters.* (i) The effect of the cholesterol-rich and low-EFA diets on the FA composition of total liver lipids is shown in Table 2. In control animals, the effect of the low-EFA and high-oleic content of the diet is shown by the high proportions of oleic acid that were maintained up to 21 d and by the presence of a significant level of eicosa-5-8,11-trienoic acid of the n-9 series. Unexpectedly, the proportion of the latter decreased from 8.43 to 3.82% during the experiment from day 1 to 21 of control diet feeding. The already low proportions of linoleic acid, arachidonic acid, and DHA evoked by the low-EFA diet were not further decreased for the additional 21 d of the experiment.

The addition of 1% cholesterol to the control diet evoked the expected effects, increasing progressively and significantly the proportions of palmitoleic and, especially, oleic acids. It did not modify the level of 20:3n-9 found in control rats, nor did it modify the percentage of linoleic acid for 21 d. Rather, it decreased significantly and progressively the proportions of arachidonic acid and DHA.

(ii) The effect of the control diet, low in EFA, on the microsomal FA (Table 3) also showed, as in total liver lipids, a high level of oleic acid, approximately threefold higher than in the Leikin and Brenner (3) experiment, in which corn oil was administered. It also evoked a high level of 20:3n-9 acid, typical of EFA deficiency, but as in total liver lipids, a progressive decrease in this acid was shown during the 21-d experiment. No significant changes were observed during this time on the already low levels of linoleic acid, arachidonic acid, and DHA, which were half the amounts found with a high-EFA diet (3).

An analysis of the effect of the cholesterol-rich diet over time on the comparative FA composition of rat liver microsomes (Table 3) followed the same general pattern as that of the total liver lipids. An increase in palmitoleic and oleic acids (the main components) was shown, and this increase became very significant on day 7. As in total liver lipids, no relatively significant decrease occurred in the percentage of 20:3n-9.

Linoleic acid, a minor component, was modified very little; arachidonic acid, a major component, decreased significantly and progressively; and DHA, a minor component, was not significantly altered.

<sup>a</sup>Only principal FA were considered. Data are presented as mean ± SD ( $n = 5$  animals). Different roman superscript letters indicate significant differences between this value and that in the group headed by the same letter. \*\*\* $P < 0.001$ , \*\* $P < 0.01$ , \* $P < 0.05$ .

(iii) The FA composition of cholesterol esters of total liver lipids is shown in Table 4. In these lipids, the predominant FA were 16:0, 18:1n-9, and 18:0. They had very little arachidonic and eicosatrienoic n-9 acids, and DHA was not detected.

The addition of cholesterol to the diet provoked an increase in cholesteryl palmitoleate from the first 24 h. Cholesteryl oleate also increased rapidly and doubled after 7 d, reaching a value of  $\cong 61\%$ , which was maintained for 21 d. Cholesteryl stearate, linoleate, and arachidonate were also reduced after 24 h.

(iv) In liver control microsomes (Table 4) the predominant cholesterol esters were 16:0 > 18:1n-9 > 18:0. However, the percentage of cholesteryl palmitate increased somewhat with time, whereas the oleate ester remained unaltered. The percentage of cholesteryl linoleate was higher than that in total liver cholesterol esters, but it decreased rapidly up to the experimental time of 21 d. No arachidonate was detected.

The addition of cholesterol to the diet did not significantly modify the relative microsomal percentage of cholesteryl palmitate, palmitoleate, and stearate; it increased cholesteryl oleate after the first 24 h of cholesterol administration and somewhat decreased linoleate esters.

The relative proportion of cholesterol esters, in both total liver and liver microsomes followed the pattern of saturated and monounsaturated amounts found in total liver and microsomal lipids rather well, but the percentage of polyunsaturated acid cholesterol esters was either markedly diminished or undetected, as shown for arachidonate in total liver.

To compare the effect of the diets on the FA composition of liver lipids with other organs, the FA of testes and adrenals were analyzed for the same time periods. The relative compositions of neither testes nor adrenal FA were significantly altered by the cholesterol diet throughout the 21-d experiment. The low-EFA diet evoked only a reduced increase of 20:3n-9 acid in both tissues (data not shown).

## DISCUSSION

*Incorporation of cholesterol into liver lipids.* Ingested cholesterol has repeatedly been shown to be incorporated into ani-

mal tissues, especially in liver (3–8). Table 1 confirms these results in our rats and shows a significant incorporation into liver microsomes and total cellular homogenate as early as 24 h after ingestion. However, these tables also show that the true relative increase of cholesterol in microsomal and total liver lipids was evoked in the cholesterol ester fraction and not in the free cholesterol. The relative increase of microsomal cholesterol esters was found after 24 h, and similar figures were maintained throughout time, showing that the esterification of any incorporated cholesterol is immediate and that the homeostasis of microsomal free cholesterol is very efficient. The same efficient homeostasis of free cholesterol is also shown in total liver homogenate, which does not modify the steady and similar relative values in the lipids of control and cholesterol-treated rats from 24 h up to at least 21 d (Table 1). The cholesterol provided by the cholesterol-rich diet is also especially derived in total cells to the cholesterol ester fraction, which in this case increased 10-fold after 21 d of treatment. It offered excellent protection in the cell cytosol against the deleterious effect of the high free cholesterol contents.

This homeostasis is undoubtedly evoked by the ACAT enzymes. In rodents (mice) two ACAT with approximately 40% identity have been cloned, ACAT-1, whose liver activity in these animals is doubtful, and ACAT-2, recently recognized, which is apparently active in the lives of mice (23,24). These enzymes are mainly located in the cell endoplasmic reticulum, and the mechanism of action in cholesterol homeostasis (24) is interpreted in the following way. In cholesterol-loaded cells and when cholesterol is added to the microsomes, cholesterol esterification is activated and increased (24). Therefore, the endoplasmic reticulum ACAT esterifies the added cholesterol (24) and only some controlled amount of it; in accordance with our results in Table 1, it accumulates in this organelle. The excess is removed from the endoplasmic reticulum, increasing the amount of cholesterol esters in other parts of the cell such as cytosol, storing it harmlessly in cytosolic droplets (25), or exporting it as lipoproteins (24,26). This mechanism is in accordance with the results in Table 1, which also show

an increased accumulation with time of cholesterol esters in extramicrosomal places.

The FA compositions of cholesterol esters in liver cellular homogenate and microsomes of control rats (Table 4) showed typical and similar patterns evoked mainly by the specificity of ACAT fatty acyl-CoA in choosing FA provided by the diet, provided by the cellular lipids, and specifically synthesized in accordance with the corresponding activities of  $\Delta 9$ ,  $\Delta 6$ , and  $\Delta 5$  desaturases. The most abundant esters found were the oleate, palmitate, and stearate (Table 4), which were also the predominant FA in the food. Linoleic acid, a lesser component in the food and liver lipids, appeared as a minor component of total liver cholesterol esters and a little higher in the microsomal esters. However, in either control or treated animals, the percentage of cholesteryl linoleate significantly decreased with time for the 21 d of the experiment. These results may be easily explained as an effect of EFA deficiency in the diet. Arachidonic acid cholesterol ester was a very minor component in total liver and was below detection limits in microsomes.

The typical composition of the cholesterol esters found (Table 4) is in accordance with the known fatty acyl-CoA specificity of rodent ACAT-2, which does not practically accept arachidonyl-CoA (23), whereas ACAT-1 has a broader spectrum that also includes arachidonyl-CoA (24). Moreover, it has been shown (24) that in ACAT-1 knockout mice (ACAT-1  $-/-$ ) livers, no problem exists in the synthesis of large amounts of cholesterol esters.

The addition of cholesterol to the diet evoked significant increases in total liver (Table 4) of cholesterol esters of palmitoleic and oleic acids and decreases in palmitate and stearate. These results are in accordance with the evoked increases in SCD-1 mRNA (Fig. 2) and  $\Delta 9$  desaturation activity (Fig. 1). Moreover, Miyazaki *et al.* (27) already proved that the activation of SCD-1 is specifically responsible for the increase in the relative proportion of cholesterol oleate. In an earlier work, Miyazaki *et al.* (28) showed that oleate and palmitoleate, which arise in rodents from SCD-activity, are the preferred substrates for ACAT synthesis of cholesterol esters. In addition, they concluded that the regulation of liver SCD-1 activity plays an important role in the mechanisms of cellular cholesterol homeostasis. In the present experiment, the increases in cholesterol esters of oleic and palmitoleic acids in liver are shown to be produced together with relative increases in SCD-1 mRNA (Fig. 2).

*Effect of cholesterol on the  $\Delta 9$  desaturase activity and corresponding levels of mRNA.* It has repeatedly been shown that the addition of 1% cholesterol to an EFA-rich diet evokes a relatively higher activity of the liver  $\Delta 9$  desaturation (3–5,7) of both palmitic and stearic acids and SCD-1 mRNA (7). In the present research, the addition of cholesterol shows a similar effect but in animals fed a low-EFA diet. However, the increase in liver SCD-1 mRNA was immediate (24 h), whereas the enzymatic activity was only significantly enhanced on day 7 (Fig. 1A).

At present, we know that from the three genes of  $\Delta 9$  desaturase characterized in rodents, SCD-1, SCD-2 (22), and SCD-3 (29,30), only SCD-1 is regularly expressed in liver, and it is the one we measured. SCD-2 apparently can only be expressed in liver by a very strong stimulus (31), which is not the present case.

Our results confirm those of Landau *et al.* (7) for animals fed a high-EFA diet and show that the effect of dietary cholesterol on the activation of the SCD-1 is evoked first by an increase in its mRNA and afterward, with some retardation and less pronounced, by the enzymatic activity independent of the EFA content of the diet. Therefore, these effects supplement possible activating effects evoked by low-EFA diets. However, we do not yet envisage a clear mechanism that would explain the way this activation is produced.

The possible role of the sterol regulatory element-binding proteins (SREBP) in this dietary cholesterol-enhancing effect of the enzyme activity is not yet understood (8) when compared to the findings of Shimomura *et al.* (31) and the Goldstein group, which showed an SREBP-dependent depression in cell cultures (32). This problem was thoroughly discussed by Ntambi (22) without reaching a definitive conclusion.

*Effect of cholesterol on the  $\Delta 6$  and  $\Delta 5$  desaturation activities and the level of  $\Delta 6$  desaturase mRNA.* Results displayed in Figure 1 show that cholesterol-treated rats fed a low-EFA diet have lower liver  $\Delta 6$  and  $\Delta 5$  FA desaturation activities than control rats. They confirm similar experiments (3–5) done with rats receiving a high-EFA diet and explain the depression found in some of the n-6 and n-3 PUFA (mainly the 20:4n-6) of those animals (Tables 2 and 3).

One of the possible mechanisms by which dietary cholesterol might modulate the  $\Delta 6$  desaturation activity is through the depression of  $\Delta 6$  desaturase mRNA. The present experimental data displayed in Figure 2 discard this possibility and reject the suggestion that it could be evoked either through a mechanism depressing the enzyme mRNA transcription or any other mechanism that could alter its abundance of mRNA. Therefore, cholesterol downregulation of rat liver  $\Delta 6$  desaturation activity must be ascribed to an effect produced at a later step than that of mRNA.

In spite of the fact that our studies on the effect of cholesterol on the abundance of  $\Delta 5$  desaturase mRNA in rats are still in progress, we expect that a result similar to that found for the  $\Delta 6$  desaturase will be found due to the extreme similarity in the activity regulation in animals (33). Besides, Clarke's group (11) showed that, in addition to the great similarity of the cDNA of both enzymes, it is very possible that the transcription of  $\Delta 5$  and  $\Delta 6$  desaturase genes may be coordinately governed by regulatory sequences within the 11,000-bp region that is common for both genes.

Another possible mechanism suggested to explain the way in which cholesterol could depress  $\Delta 6$  and  $\Delta 5$  desaturation is by a modification of the biophysical properties of microsomal lipid environment in which the desaturation systems are embedded (3,4). This suggestion has not been proved, in spite

of the fact that Leikin and Shinitzky (34,35) isolated from microsomes by hydrostatic pressure a lipid fraction constituted by PtdCho and cholesterol that included a  $\Delta 6$  desaturation system constituted by the NADH-cytochrome  $b_5$  reductase, cytochrome  $b_5$ , and the  $\Delta 6$  desaturase. Moreover, *in vitro* incorporation of free cholesterol into isolated rat liver microsomes provokes just the opposite effect, enhancing both  $\Delta 6$  and  $\Delta 5$  desaturation (36). Therefore, another mechanism, different from these genetic and biophysical ones, must be sought. Cholesterol would appear to modulate  $\Delta 6$  and  $\Delta 5$  desaturase activities by a mechanism different from that of  $\Delta 9$  desaturase.

**FA composition of liver lipids.** The FA composition found in total liver and microsomal lipids (Tables 2 and 3) of control rats fed a low-EFA diet agrees with the well-known effect of this type of diet, i.e., depression of mainly the linoleic and arachidonic acid proportions and an increase in oleic acid, and specifically 20:3n-9, in animal tissues. These changes are evoked by the decreased exogenous supply of linoleic and  $\alpha$ -linolenic acids. On one hand, they activate oleic acid biosynthesis (9) and, on the other hand, as shown previously (37), they decrease the very active competition of linoleic and  $\alpha$ -linolenic acids with oleic acid for the  $\Delta 6$  desaturase that catalyzes and regulates the conversion of oleic acid to 20:3n-9. However, we cannot explain why the level of 20:3n-9 is not increased, or at least maintained, in control animals (Tables 2 and 3) for the additional 21 d of the experiment in which they were fed the same low-EFA diet.

It is apparent that administration of cholesterol provokes, in both total liver and microsomal lipids, and independent of the FA composition of the diet, an increase in palmitoleic and oleic acids that, as has been shown in similar experiments (3–8), must be attributed to the increase in  $\Delta 9$  desaturation activity. It is also apparently preceded by an increase in liver SCD-1 mRNA (Fig. 2).

The depression of  $\Delta 6$  and  $\Delta 5$  desaturation activity produced by the cholesterol-rich diet (Fig. 1) would explain, as in other experiments (3–6,8), the decrease in arachidonic acid in both total liver and microsomal lipids and DHA only in total liver lipids (Tables 2 and 3). Moreover Bernasconi *et al.* (8) showed that the administration of cholesterol to rats fed an EFA-rich diet specifically depressed the 18:0/20:4 and 16:0/20:4 PC molecular species and increased the 18:1-containing species.

Another important conclusion that may be deduced from these results is that a cholesterol-rich diet evokes an additional EFA deficiency effect on an already EFA-deficient or, even more important from a nutritional point of view, on an EFA-limited diet. This effect is mainly due not to a decrease in linoleic acid, but to an important decrease in the synthesis and amount of the highly polyunsaturated acids, arachidonic acid and DHA. These two acids, as is well known, are the main effectors among the EFA that control very important physiological functions in animal tissues.

Therefore, another important new finding shown here is that in animals or humans receiving diets near the limit of EFA necessity, the addition of cholesterol to these diets may push them into a true EFA deficiency.

## ACKNOWLEDGMENTS

This study was supported by a grant from CONICET, Argentina. The authors are very grateful to Dr. Tsunehiro Aki from Japan and to Dr. Juri Ozols from the United States for providing the cDNA of rat  $\Delta 6$  and  $\Delta 9$  desaturases, respectively, and to Mrs. L. Hernández for her technical assistance.

**ABSTRACT:** It has been reported that apoptosis is a significant contributor to myocardial cell death as a result of reperfusion injury. However, whether the extent of cardiomyocyte apoptosis following ischemia and reperfusion varies in different pathophysiological backgrounds is still uncertain. In this study, we examined whether hypercholesterolemia increases the extent of myocardial reperfusion injury by aggravating cardiomyocyte apoptosis and the effects of hypercholesterolemia on the expression of Bcl-2 and Bax proteins and the activation of caspase-3. Twenty-eight male New Zealand white rabbits were fed standard chow (control,  $n = 14$ ) or chow supplemented with 1% cholesterol (hypercholesterolemic,  $n = 14$ ) for 8 wk. Anesthetized rabbits were then subjected to 30 min of left circumflex artery occlusion followed by 4 h of reperfusion. Apoptosis was identified as "DNA ladders" by gel electrophoresis and confirmed histologically using the terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling (TUNEL) assay. The infarct size (% of risk region) was significantly greater in hypercholesterolemic rabbits than in controls ( $39 \pm 6$  vs.  $23 \pm 2\%$ ,  $P = 0.02$ ). Very few TUNEL-positive cardiomyocytes could be identified in the nonischemic regions in both groups, consistent with an absence of DNA laddering. In contrast, TUNEL-positive cardiomyocytes were significantly displayed in the ischemic, nonnecrotic myocardium, and DNA ladder occurred in all animals. The percentage of TUNEL-positive cardiomyocytes in the ischemic nonnecrotic myocardium was significantly higher in hypercholesterolemic rabbits compared with controls ( $40 \pm 5$  vs.  $17 \pm 1\%$ ,  $P < 0.001$ ). Western blot analysis showed that, in the nonischemic myocardium, hypercholesterolemic rabbits exhibited an approximately 50% increase in the expression of Bcl-2 ( $P < 0.05$ ), but not Bax, than control rabbits. However, compared with controls, hypercholesterolemic rabbits exhibited a more pronounced decrease in the expression of Bcl-2 ( $42 \pm 4$  vs.  $26 \pm 2\%$ ,  $P < 0.01$ ) and a similar extent of increase in the expression of Bax in the ischemic myocardium. Furthermore, hypercholesterolemic rabbits were associated with a markedly increased activation of caspase-3 within the ischemic myocardium compared to con-

trol rabbits. This study demonstrates that although hypercholesterolemia is associated with an increased myocardial Bcl-2/Bax ratio at baseline, it still significantly exacerbates cardiac reperfusion injury, not only by increasing the infarct size but also by increasing the extent of cardiomyocyte apoptosis.

Paper no. L8833 in *Lipids* 37, 385–394 (April 2002).

Timely reperfusion of jeopardized myocardium by thrombolytic therapy or angioplasty is now the standard of care in patients with acute myocardial infarction (1). However, the process of reperfusion, although beneficial in terms of myocardial salvage, has been shown to be injurious to the ischemic myocardium as well (2). Although reperfusion-related cardiomyocyte deaths are traditionally assumed to be necrotic, recent studies have demonstrated that a substantial proportion of cardiomyocyte deaths are actually apoptotic following ischemia and reperfusion (3–6). Under experimental conditions, 10–15% of cardiomyocytes rendered ischemic and reperfused were recognized as apoptotic by using the *in situ* terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling (TUNEL) assay (7). Moreover, in acute myocardial infarction in humans, 12% of cardiomyocytes were TUNEL-positive in the border zone of infarction (8). Nevertheless, whether the extent of cardiomyocyte apoptosis following ischemia and reperfusion varies in different pathophysiological background (e.g., hypercholesterolemia and hypertension) remains to be elucidated.

Hypercholesterolemia and ensuing atherosclerosis have been implicated in the pathophysiology of coronary artery disease (9–11). It is noteworthy that, in the Scandinavian Simvastatin Survival Study, the mortality rate of definite myocardial infarction in the placebo group was 28% higher than that in the simvastatin group (10). This finding indicates that hypercholesterolemia may have an adverse effect on the evolution of myocardial infarction, possibly by aggravating the severity of reperfusion injury. Moreover, we previously demonstrated that the detrimental effect of hypercholesterolemia on postinfarct left ventricular ejection fraction is independent of the patency rate of infarct-related artery and the infarct size estimated by serum cardiac enzyme changes (12). Because cardiomyocyte apoptosis, which could not be evaluated by conventional serum

cardiac enzyme changes (13), affects myocardial mechanics by reducing the force-generating capacity of the muscle, we speculated that hypercholesterolemia may increase the magnitude of cardiomyocyte apoptosis following ischemia and reperfusion and thereby aggravate the extent of postinfarct left ventricular systolic dysfunction.

Despite previous experiments that have uniformly shown that hypercholesterolemia results in larger infarct size in hearts exposed to ischemia and reperfusion (14–16), two recent studies demonstrated that prolonged exposure to hypercholesterolemia (over 5 wk) protects the heart from reperfusion injury (17,18). Hence, the effects of prolonged hypercholesterolemia on reperfusion injury after myocardial ischemia still deserve further investigation.

In the present study, we examined whether prolonged hypercholesterolemia (8 wk) increases the extent of experimental myocardial reperfusion injury by aggravating cardiomyocyte apoptosis. Although a large number of genes have been reported to be involved in the regulation of apoptotic cell death, the antiapoptotic Bcl-2 and proapoptotic Bax play major roles in regulating myocardial apoptosis following ischemia and reperfusion (19). Furthermore, apoptotic cell death is mediated by a family of aspartate-specific cysteine proteases known as caspases. Of the 14 caspases characterized, caspase-3 plays a critical role in cardiomyocyte apoptosis and represents the final common pathway of the caspase cascade (7). We thus determined the effects of hypercholesterolemia on the expression of Bcl-2 and Bax and the activation of caspase-3 in both ischemic and nonischemic myocardium to identify the underlying molecular mechanisms induced by hypercholesterolemia.

## MATERIALS AND METHODS

**Animals and diet.** Adult male New Zealand white rabbits (2.4–2.8 kg) were housed in individual cages in environmentally controlled rooms (12 h light-dark cycle, relative humidity  $50 \pm 5\%$ , and  $20 \pm 1^\circ\text{C}$ ). Twenty-eight rabbits were randomly assigned to two different dietary groups: Animals in the control group ( $n = 14$ ) were fed standard rabbit pellets (Purina 5321, St. Louis, MO), whereas those in the cholesterol-fed group ( $n = 14$ ) received a diet enriched with 1% cholesterol and 10% coconut oil added to the standard Purina rabbit pellets for a total of 8 wk. At the end of the 8-wk feeding period, the rabbits were studied. The animals had free access to water. Blood samples were taken to determine plasma levels of cholesterol and TG just before the administration of the diet and at the end of the 8-wk feeding period. All experiments were performed in accordance with the *Guide for the Care and Use of Laboratory Animals* (NIH Publication No. 85-23, revised 1996). The experimental protocol was approved by the Institutional Animal Care and Use Committee.

**Surgical procedures.** After 12 h of fasting, the rabbits were anesthetized with pentobarbital (25 mg/kg i.v.), and anesthesia was maintained during the experiment by intravenous injection of small amounts of pentobarbital (5 mg/kg), sufficient to abolish the corneal reflex. An intratracheal tube was

inserted through a midline incision, and all rabbits were given intermittent positive-pressure ventilation *via* a Harvard small animal respirator (Harvard Apparatus). The respirator was adjusted to maintain arterial blood gases within the physiological range. The standard limb leads of the electrocardiogram were monitored during the experiment. A polyethylene catheter was inserted through the right femoral artery and positioned in the abdominal aorta for blood gas and arterial pressure monitoring (Gould Instruments, Essex, United Kingdom). A midline sternotomy was performed, and the heart was exposed after the pericardium was incised. A 5-0 silk suture on a small curved needle was passed through the myocardium beneath the major marginal branch of the left circumflex coronary artery located on the dorsal surface of the heart, 10 to 12 mm from its origin. A reversible tie was subsequently made and loosely placed on the myocardial surface. After a 20-min stabilization period after thoracotomy, myocardial ischemia was initiated by complete ligation of the marginal coronary artery. Myocardial ischemia was confirmed by ST-segment elevation on the electrocardiogram and regional cyanosis of the myocardial surface. The ligature was released after 30 min of ischemia, and the ischemic myocardium was reperfused for 4 h. Reperfusion was confirmed by myocardial blush over the risk area after the ligature was released. We eliminated from analysis the rabbits that did not complete the experiment.

**Determination of area at risk and infarct size.** At the end of the reperfusion period, the marginal coronary artery was again occluded through ligation of the tie that remained at the site of previous occlusion. Immediately after ligation, 5 mL of 1% Evans blue dye (Sigma, St. Louis, MO) was injected directly into the left atrial cavity to delineate the area of the left ventricular myocardium perfused by patent coronary arteries. The area-at-risk was thus determined by negative staining. The heart was then rapidly removed and placed in ice-cold 0.9% saline, and the atria, right ventricle, and great vessels were removed. The left ventricle was sliced into sections 2 mm thick parallel to the atrioventricular groove. The unstained portion of the myocardium (i.e., the area-at-risk) was separated from the stained portion (i.e., the nonischemic area). The unstained portion was subsequently sliced into 1-mm thick sections and counterstained with 10 mL of 1% solution of the 2,3,5-triphenyltetrazolium chloride (TTC) (Sigma) in 20 mM PBS, pH 7.4 at  $37^\circ\text{C}$  for 15 min to detect the presence of coenzyme and dehydrogenase. The necrotic portion of the myocardium, which did not stain, was separated from the stained portion (i.e., ischemic but nonnecrotic area). The nonischemic portion was also counterstained with TTC as done for the ischemic portion to avoid the possible confounding effect of TTC staining on apoptosis and Western blotting analyses. All three portions of the left ventricular myocardium (i.e., nonischemic, ischemic nonnecrotic, and ischemic necrotic) were weighed individually. The results were expressed as the percentage of the infarct (ischemic necrotic) area to the area-at-risk or the total left ventricular mass. The individual portions of the myocardium were further sectioned into  $1 \times 1$  mm transmural

myocardial columns and either fixed in 10% buffered formalin for *in situ* nick end labeling or rapidly frozen in liquid nitrogen and stored at  $-70^{\circ}\text{C}$  for DNA and protein isolation. The entire procedure took approximately 25 min to complete. Because differences in this additional time may affect comparability of the results of apoptosis and Western blotting analyses, we carefully monitored the entire procedure to ensure that the time taken for processing both ischemic and nonischemic myocardia was the same.

**DNA laddering.** Frozen tissue samples (20–30 mg each) were minced in 600  $\mu\text{L}$  of lysis buffer (Puregene DNA Isolation Kit, Minneapolis, MN) and quickly homogenized on ice. The tissue was digested with 150  $\mu\text{g}/\text{mL}$  of proteinase K at  $55^{\circ}\text{C}$  for 16 h and incubated with RNase A at  $37^{\circ}\text{C}$  for 2 h. After incubation, tissues were precipitated and centrifuged at 14,000 rpm for 10 min. The DNA in supernatants was extracted with phenol/chloroform and precipitated with isopropanol. After centrifugation at 14,000 rpm for 30 min, the resulting DNA pellets were washed with 70% ethanol and dissolved in TE buffer (10 mM Tris and 1 mM EDTA). The concentration and purity of DNA were determined by measurement of the optical density at 260 nm and the ratio of optical density at 260 nm to that at 280 nm.

To augment the detection of DNA laddering, we employed a terminal deoxynucleotidyl transferase labeling reaction prior to electrophoretic analysis. Briefly, 2  $\mu\text{g}$  of isolated DNA was added into a reaction mixture containing 60 EU/mL terminal deoxynucleotidyl transferase (Boehringer Mannheim, Mannheim, Germany) and 6 nmol/mL biotinylated dUTP (Boehringer Mannheim). After 15 min incubation at  $37^{\circ}\text{C}$ , the biotin-labeled DNA was precipitated with ethanol, resuspended in TE buffer, and separated by electrophoresis on a 1.8% agarose gel. The electrophoretically separated DNA was subsequently transferred onto a nylon membrane (Millipore, Bedford, MA) and detected by the Biotin Detection Kit (KPL Laboratory, Gaithersburg, MD) using a chemiluminescent substrate and exposure on an X-ray film.

**In situ nick end labeling.** The TUNEL protocol was performed with the use of a FragEL DNA fragment detection kit (Oncogene, Cambridge, MA) according to the manufacturer's instructions with minor modifications. Briefly, the fixed transmural ventricular slices were embedded in paraffin, and 4- $\mu\text{m}$  thick sections were deparaffinized by washing in xylene and a descending ethanol series. Subsequently, the tissue sections were stripped of proteins through incubation with 20  $\mu\text{g}/\text{mL}$  proteinase K for 15 min at room temperature. The slides were incubated with 3% hydrogen peroxide for 5 min to allow inactivation of endogenous peroxidase and then incubated for 90 min at  $37^{\circ}\text{C}$  with terminal deoxynucleotidyl transferase and biotinylated dUTP to label the 3'-OH ends of DNA. After the end labeling, the slides were coated with streptavidin-conjugated peroxidase for 30 min at room temperature and visualized with the use of chromogen 3,3'-diaminobenzidine and hydrogen peroxide. Counterstaining was performed with methyl green. Using this method, each cardiomyocyte could be defined, and TUNEL-positive or -negative nuclei were stained dark brown or light green, respectively, under light microscopy. When the

TUNEL method was performed, positive controls were always included. As a positive control, sections of heart tissue were exposed to DNase I for 20 min before nick end labeling.

Cardiomyocytes from six separate sections that were picked randomly from three of the transmural slices of both nonischemic and ischemic nonnecrotic portions of the left ventricular myocardium were analyzed per animal. In each section, cardiomyocytes with counterstained nuclei were counted in 20 random high-power fields ( $\times 400$ ) from the endocardial to epicardial portion and the index of apoptosis was determined (i.e., number of apoptotic myocytes/total number of myocytes  $\times 100$ ). TUNEL-positive cardiomyocytes were carefully distinguished from TUNEL-positive noncardiomyocytes, such as macrophages. This evaluation was carried out independently by two persons who were unaware of the experimental protocol.

**Western blots.** For immunoblot assays of Bcl-2 and Bax proteins, tissue samples (80–100 mg) were homogenized in a lysis buffer (2%  $\beta$ -mercaptoethanol, 10 mM Tris, pH 7.4, 140 mM NaCl, 1 mM phenylmethylsulfonyl fluoride, 10  $\mu\text{g}/\text{mL}$  leupeptin, 10  $\mu\text{g}/\text{mL}$  pepstatin, 10  $\mu\text{g}/\text{mL}$  aprotinin, 1% NP-40, and 0.5% deoxycholic acid). After centrifugation at 14,000 rpm for 20 min, protein concentration was determined by the method of Lowry *et al.* (20), using BSA as the standard. Aliquots containing 50  $\mu\text{g}$  protein were resuspended in the same volume of 2 $\times$  sample buffer (20%  $\beta$ -mercaptoethanol, 4% SDS, 20% glycerol, 0.0125% bromophenol blue, and 0.125 mM Tris, pH 6.4), and they were boiled for 5 min. Proteins were then size-fractionated on 12% polyacrylamide gels by electrophoresis using a Mini-Protean II Dual Stab Cell (Bio-Rad, Hercules, CA), and they were electrotransferred to PVDF membranes (Millipore) by a semidry blotting system (3 mA/cm<sup>2</sup> for 45 min in a buffer consisting of 48 mM Tris, 39 mM glycine, 0.037% SDS, and 20% methanol). Nonspecific binding was blocked with 5% nonfat dry milk in PBS for 3 h. Then membranes were incubated with specific antibodies overnight at  $4^{\circ}\text{C}$ . For Bcl-2 detection, a mouse monoclonal anti-rat Bcl-2 antibody (PharMingen, San Diego, CA) was used at 1:500 in the blocking solution; for Bax immunodetection, a mouse monoclonal anti-rat Bax antibody (PharMingen) was used at 1:500 in the blocking solution. After washing, Bcl-2 and Bax-bound antibodies were detected by alkaline phosphatase-conjugated anti-mouse IgG (Promega, Madison, WI) at 1:5000 in PBS. The immunoreactivity on the membranes was detected by treatment with nitro blue tetrazolium/5-bromo-4-chloro-3-indolyl-phosphate (Promega). For negative controls, membranes were incubated with normal goat serum without specific antibodies. The specificity of the bands was checked by preabsorbing anti-Bcl-2 and anti-Bax with the corresponding synthetic peptides. The density of each protein band was quantified by the National Institutes of Health (NIH) Image software and then calculated as the ratio of Bcl-2 or Bax to glyceraldehyde-3-phosphate dehydrogenase (GAPDH). The values for each sample were presented in percentage of control (nonischemic tissue of rabbits fed with standard diets) on the same gel.

**Caspase activity assay.** In a separate series of experiments, both normally fed and cholesterol-fed rabbits were subjected to 30-min ischemia followed by 4-h reperfusion. After rabbits were euthanized by pentobarbital overdose, the hearts were excised and the ischemic and nonischemic portions of the left ventricular myocardium were separately dissected. Tissues were homogenized by a Polytron homogenizer in ice-cold lysis buffer and centrifuged at 14,000 rpm for 30 min. Homogenates (100  $\mu$ g of protein) were applied for the measurement of caspase activity by CasPACE assay system (Promega) according to the instructions. Briefly, the fluorogenic substrates for caspase-3 are labeled with fluorochrome 7-amino-4-methyl coumarin (AMC). The substrates produce a blue fluorescence that can be detected by exposure to UV light at 360 nm. AMC is released from the substrates upon cleavage by caspase-3. Free AMC produces a yellow-green fluorescence that is measured by a fluorometer at 460 nm. Fluorescent units were converted to pmol AMC using a standard curve generated with free AMC. The values for each sample were then normalized by the value of the control (non-ischemic myocardium of control rabbits).

**Statistics.** Results are presented as mean  $\pm$  SEM computed from the average measurements obtained from each group of rabbits. Student's *t*-test or two-way ANOVA followed by Scheffé's *post hoc* test was used to assess the statistical significance of variations observed between groups where appropriate. A value of  $P < 0.05$  was accepted as statistically significant.

## RESULTS

**Characteristics and mortality.** Table 1 summarizes plasma cholesterol and TG levels and body weight in rabbits before and after 8 wk of normal diet or cholesterol-enriched diet feeding. Rabbits in both groups began the dietary regimen with equivalent plasma total cholesterol and TG concentrations. Plasma total cholesterol and TG levels were markedly increased in cholesterol-fed rabbits by the end of the 8-wk feeding period. All rabbits exhibited a similar weight gain

<sup>a</sup>HR, heart rate; MABP, mean arterial blood pressure.

throughout the 8-wk feeding period. Four cholesterol-fed rabbits died of ventricular fibrillation (two during reperfusion and two during coronary occlusion), whereas only one rabbit in the control group died during reperfusion. However, the difference in mortality rate between both groups (29% in the cholesterol-fed group vs. 7% in the control group) did not reach statistical significance ( $P = 0.15$ ), which might be limited by the small sample size.

**Hemodynamic data.** There was no significant difference in heart rate between control and cholesterol-fed groups either before or after ischemia and reperfusion. In contrast, mean arterial blood pressure was decreased in cholesterol-fed rabbits compared to control, though not statistically significantly, both before and after ischemia and reperfusion (Table 2). During the 30-min period of ischemia, both control and cholesterol-fed rabbits showed a comparable degree of decrease in blood pressure, which then slightly elevated during the reperfusion period.

**Myocardial infarct size after ischemia and reperfusion.** In order to determine the effect of hypercholesterolemia on myocardial vulnerability following ischemia and reperfusion, we measured the amount of infarct (necrotic) tissue either as a percentage of area-at-risk or as a percentage of total left ventricle (Fig. 1). There was no significant difference in area-at-risk as a percentage of total left ventricular mass, indicating a comparable

**FIG. 1.** Tissue wet weights of area-at-risk (AR) as a percentage of the total left ventricular wet weight (LV) (left), infarct tissue (area of necrosis, AN) as a percent of the AR (middle), and AN as a percent of the total LV (right) for both groups of rabbits that underwent myocardial ischemia and reperfusion. The infarct size (% of risk region) was significantly greater in cholesterol-fed rabbits than in controls (39  $\pm$  6 vs. 23  $\pm$  2%,  $P = 0.02$ ). Error bars indicate  $\pm$ SEM.

degree of jeopardy had occurred in both groups. However, the infarct size, whether expressed as a percentage of area-at-risk or as a percentage of total left ventricle, was greater by approximately 70% in cholesterol-fed rabbits than in normally fed rabbits ( $P = 0.002$ ). Thus, hypercholesterolemia did have a detrimental effect on myocardial vulnerability following ischemia and reperfusion.

**DNA fragmentation (DNA ladder) in hearts subjected to ischemia and reperfusion.** Myocardial DNA fragmentation in the nonischemic, ischemic but nonnecrotic, and necrotic (TTC unstained) areas in both groups is shown in Figure 2. DNA ladders were not detected in the nonischemic left ventricles of either normally fed or cholesterol-fed rabbits (lanes 1 and 4, respectively). Typical nucleosomal DNA ladders indicative of apoptosis were clearly demonstrated in myocardial specimens sampled from the ischemic, nonnecrotic left ventricles of both normally fed and cholesterol-fed rabbits (lanes 2 and 5, respectively). The intensity of the ladders was more pronounced in cholesterol-fed rabbits. In specimens sampled from the necrotic (TTC unstained) myocardium, patterns of background smear, a hallmark of necrosis, were evident in both normally fed and cholesterol-fed rabbits (lanes 3 and 6). DNA laddering was also present in specimens from the necrotic myocardium. Likewise, the intensity of the ladders and background smear in the necrotic samples was also more prominent in cholesterol-fed rabbits.

**In situ determination of apoptosis in ischemic-reperfused myocardium.** Heart tissue from the nonischemic area exhibited very low levels of staining for TUNEL in both normally

**FIG. 2.** DNA laddering. Laddering represents multiples of 180-bp internucleosomal DNA fragments and corroborates histological evidence of apoptosis. DNA was extracted from the myocardium of normally fed rabbits (lanes 1–3) and of cholesterol-fed rabbits (lanes 4–6). Lanes 1 and 4 are from the nonischemic zones. Lanes 2 and 5 are from the ischemic, nonnecrotic zones. Lanes 3 and 6 are from the necrotic (infarcted) zones. Lane M is 100-bp ladder marker. The figure is representative of at least six separate experiments.

fed ( $0.3 \pm 0.1\%$ ) and cholesterol-fed ( $0.4 \pm 0.1\%$ ) rabbits (Figs. 3A and 3B, respectively), consistent with an absence of DNA laddering. In contrast, significant numbers of cardiomyocyte nuclei from the ischemic nonnecrotic myocardium were stained positively for TUNEL in both groups (Figs. 3C–F). The positive TUNEL staining was primarily confined to the cardiomyocytes, which could be easily distinguished from other nonmyocytes by their morphology. Furthermore, apoptotic myocytes were localized to a greater degree in the subendocardial area and were individually dispersed among otherwise normal cardiomyocytes (Figs. 3C and 3D). The percentage of TUNEL-positive cardiomyocytes in the ischemic nonnecrotic myocardium in cholesterol-fed rabbits was significantly higher than that in normally fed rabbits ( $40.3 \pm 4.7$  vs.  $17.1 \pm 1.4\%$ ;  $P < 0.001$ ) (Fig. 4). This finding is consistent with a more pronounced DNA laddering in the ischemic myocardium of cholesterol-fed rabbits than control. Because DNA degradation occurred nonspecifically in necrotic myocardium, and this might also be stained by TUNEL, the extent of cardiomyocyte apoptosis in the necrotic areas was thus not assessed.

The percentage of TUNEL-positive cardiomyocytes in myocardium from sham-operated control rabbits ( $0.3 \pm 0.1\%$ ) was similar to that in the nonischemic myocardium of both control and cholesterol-fed rabbits. This finding demonstrates that both TTC staining and the additional time for processing the myocardium did not affect the analyses of apoptosis.

**Expression of Bcl-2 and Bax proteins after ischemia and reperfusion.** The expression of Bcl-2 and Bax proteins was analyzed by Western blot analysis, as illustrated in Figure 5. Densitometrically, the amount of Bcl-2 expressed in the nonischemic area was approximately 50% higher ( $P < 0.05$ ) in cholesterol-fed rabbits than in normally fed rabbits. However, there was no significant difference in the expression of Bax between both groups in the nonischemic area. Furthermore, for rabbits in both groups, the expression of Bcl-2 and Bax in the nonischemic myocardium was similar to that in sham-operated rabbits (data not shown). This finding suggests that myocardial ischemia and reperfusion did not affect the expression of Bcl-2 and Bax in the nonischemic myocardium. Therefore, the expression of both Bcl-2 and Bax in the nonischemic myocardium could be viewed as a reflection of baseline myocardial status.

Compared with that in the nonischemic myocardium, the expression of Bcl-2 in the ischemic myocardium increased by  $34 \pm 3\%$ , whereas the expression of Bax decreased by  $22 \pm 2\%$ . Changes of the amount of Bax expressed following ischemia and reperfusion were similar between both groups. However, compared with normally fed rabbits, cholesterol-fed rabbits were associated with more pronounced decrease in the expression of Bcl-2 in the ischemic myocardium ( $42 \pm 4$  vs.  $26 \pm 2\%$ ;  $P < 0.01$ ). Furthermore, changes of the expression of both Bcl-2 and Bax proteins became significant 2 h after reperfusion, which was earlier than the development of cardiomyocyte apoptosis as assessed by DNA ladder formation (data not shown).

**Caspase-3 activity after ischemia and reperfusion.** For normally fed rabbits, there was a 1.8-fold increase in cas-

**FIG. 3.** Paraffin sections stained with terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling (TUNEL) and methyl green in the nonischemic zones (A, normally fed rabbits; B, cholesterol-fed rabbits), subendocardium of the ischemic zones (C, normally fed rabbits; D, cholesterol-fed rabbits), and subepicardium of the ischemic zones (E, normally fed rabbits; F, cholesterol-fed rabbits) are presented (200 $\times$  magnification). The apoptotic cardiomyocyte is detected by the brown nuclear staining in contrast to the methyl green-stained normal cardiomyocyte nucleus. Figures are representative of at least six separate experiments.

pase-3 activity in the ischemic myocardium compared with that in the nonischemic myocardium (Fig. 6). However, for cholesterol-fed rabbits, there was a much greater increase (2.5-fold) in caspase-3 activity in the ischemic myocardium compared with that in the nonischemic myocardium. Caspase-3 activity in the nonischemic myocardium was similar between normally fed and cholesterol-fed rabbits. Like Bcl-2 and Bax, caspase-3 activity was markedly increased 2 h after reperfusion (data not shown).

## DISCUSSION

This study shows, for the first time, that long-term (8 wk) hypercholesterolemia significantly increases the extent of cardiomyocyte apoptosis as well as infarct size following exper-

imental myocardial ischemia and reperfusion. In the nonischemic myocardium, hypercholesterolemia increases the expression of anti-apoptotic Bcl-2 protein but not pro-apoptotic Bax protein. However, in the ischemic-reperfused myocardium, hypercholesterolemic rabbits exhibited a more pronounced decrease in the expression of Bcl-2, a similar extent of increase in the expression of Bax, and a significantly increased activation of caspase-3. These findings may partly explain why hypercholesterolemia is associated with greater cardiomyocyte apoptosis after ischemia and reperfusion.

Although there are several studies showing that cardiomyocyte apoptosis is a significant contributor to myocardial cell death following ischemia and reperfusion (3–8), it is still not known whether the severity of reperfusion-related cardiomyocyte apoptosis varies in patients with different

**FIG. 4.** Percentage of cardiomyocyte nuclei stained positive for TUNEL in the nonischemic (left) and ischemic nonnecrotic (right) areas from both normally fed and cholesterol-fed rabbits. The percentage of TUNEL-positive cardiomyocytes in the ischemic nonnecrotic myocardium in cholesterol-fed rabbits was significantly higher than that in normally fed rabbits ( $40.3 \pm 4.7\%$  vs.  $17.1 \pm 1.4\%$ ;  $P < 0.001$ ). Error bars indicate  $\pm$ SEM. For abbreviation see Figure 3.

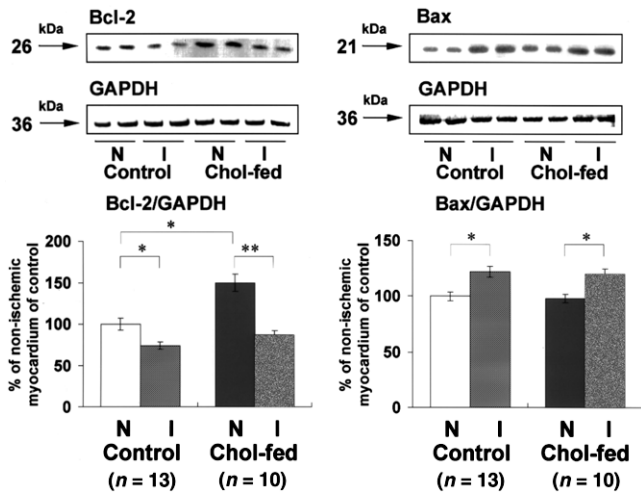

co-morbid conditions. The present study is the first to demonstrate that hypercholesterolemia is associated with a more than twofold increase in the number of cardiomyocytes undergoing apoptosis following experimental ischemia and reperfusion in the ischemic nonnecrotic myocardium. In this study, we defined apoptosis by two conventional methods, DNA laddering by agarose gel electrophoresis and histochemical visualization of nuclear DNA fragments by the

**FIG. 6.** Caspase-3 activity in the nonischemic (N) and ischemic (I) myocardium. Caspase-3 activity was measured by the ability of tissue homogenates to cleave DEVD-fluorochrome 7-amino-4-methyl coumarin (AMC). The values for each sample are presented in percentage of control (nonischemic myocardium of control rabbits). For control rabbits, there was a 1.8-fold increase in caspase-3 activity in the ischemic myocardium compared with that in the nonischemic myocardium. However, for cholesterol-fed rabbits, there was a much greater 2.5-fold increase in caspase-3 activity in the ischemic myocardium compared with that in the nonischemic myocardium. Caspase-3 activity in the nonischemic myocardium was similar between control and cholesterol-fed rabbits. \* $P < 0.05$ , \*\* $P < 0.001$ . Error bars indicate  $\pm$ SEM.

TUNEL staining. While TUNEL staining has been criticized for lack of specificity when used in tissue where necrosis occurs along with apoptotic cell death (21), recent studies have demonstrated that in areas where necrotic cells are not present to any significant amount, good correlation is found between the TUNEL test and other more sophisticated methods (22,23). We herein assessed the magnitude of cardiomyocyte apoptosis only in ischemic areas without evidence of necrosis, confirmed by the absence of background smear on agarose gel electrophoresis. Previous studies examining the effects of ischemia-reperfusion on cardiomyocyte apoptosis by TUNEL staining often included both necrotic and non-necrotic areas (3,6,24). However, the extent of cardiomyocyte apoptosis following ischemia and reperfusion in normocholesterolemic rabbits reported here agrees with most previous studies with this methodological flaw (7). Although DNA laddering may be due to noncardiomyocyte apoptosis, we demonstrated that most TUNEL-positive cells had typical morphological features of cardiomyocytes. This observation is consistent with recent reports that showed that DNA fragmentation on gel electrophoresis was essentially associated with cardiomyocyte apoptosis (3,6).

Adult cardiomyocytes are terminally differentiated cells and thought to have, at best, a very limited capacity for self-renewal (25). Viewed from this perspective, death of a significant number of cardiomyocytes, by either necrosis or apoptosis, can have lasting adverse consequences on overall cardiac performance. Because postinfarct left ventricular systolic function is the most important determinant of long-term

**FIG. 5.** Expression of Bcl-2 and Bax proteins was visualized in the nonischemic (N) and ischemic nonnecrotic (I) myocardium by Western blot analysis. The ratio of Bcl-2 or Bax band density to glyceraldehyde-3-phosphate dehydrogenase (GAPDH) band density was calculated and then normalized by the value of control (nonischemic myocardium of control rabbits). In the nonischemic myocardium, cholesterol-fed rabbits exhibited an approximately 50% increase in the expression of Bcl-2 ( $P < 0.05$ ), but not Bax, than control rabbits. However, compared with control, cholesterol-fed rabbits exhibited a more pronounced decrease in the expression of Bcl-2 ( $42 \pm 4$  vs.  $26 \pm 2\%$ ,  $P < 0.01$ ) and a similar extent of increase in the expression of Bax in the ischemic myocardium. Figures are representative of at least six separate experiments. \* $P < 0.05$ , \*\* $P < 0.001$ . Error bars indicate  $\pm$  SEM.

survival in patients with myocardial infarction, our observation that hypercholesterolemia increases the extent of cardiomyocyte apoptosis as well as infarct size following ischemia and reperfusion is consistent with the clinical phenomenon that hypercholesterolemic patients treated with lipid-lowering drugs had a better prognosis after sustaining a myocardial infarction than those treated with placebo, even in the current reperfusion era (10,12). Moreover, because cardiac enzymes are released only when cardiomyocytes break down and cardiomyocytes typically rupture during necrosis but not apoptosis (13), evaluation of infarct size by cardiac enzyme values may underestimate the severity of myocardial infarction, especially in patients with predisposing conditions that may aggravate the magnitude of apoptosis. This explains our previous observation that the deleterious effect of dyslipidemia on postinfarct left ventricular systolic function was independent of the size of myocardial infarction estimated by cardiac enzyme changes (12).

In view of the markedly increased activation of caspase-3 and the significant contribution of cardiomyocyte apoptosis as a result of reperfusion injury, it is speculated that anti-apoptotic interventions, such as caspase inhibitors, may reduce myocardial reperfusion injury by attenuating cardiomyocyte apoptosis within the ischemic myocardium. Despite several studies that have demonstrated that *in vivo* administration of various caspase inhibitors is effective in reducing the extent of apoptosis, their effect on infarct size reduction was still controversial (24,26). One possible reason is that because the apoptotic cardiomyocytes are mostly scattered, not grouped together, in the ischemic myocardium as shown in the present and other studies (3,5,6,24,26), evaluation of infarct size by the traditional TTC staining at the gross examination may underestimate the impact of apoptosis inhibition, which was evident at the histological examination. Since the magnitude of cardiomyocyte apoptosis doubled in hypercholesterolemic rabbits, we speculated that caspase inhibitors might have a greater protective effect on myocardial ischemia-reperfusion injury in animals with underlying hypercholesterolemia. Further investigations are needed to test this hypothesis.

Compared with normally fed rabbits, rabbits in the cholesterol-fed group had a higher mortality rate following myocardial ischemia and reperfusion. Because rabbits dying in the procedure might have had a greater extent of cardiomyocyte apoptosis as well as larger infarct size, our observation may underestimate the impact of hypercholesterolemia on reperfusion-related cardiac injuries. This may also explain why mice fed a cholesterol-enriched diet for 12 wk had a significantly decreased infarct size following ischemia and reperfusion than normocholesterolemic mice in one recent study (17).

The multigene family of Bcl-2-like proteins, some of which, such as Bcl-2 itself, inhibit apoptosis and others, such as Bax, that promote apoptosis, is one of the best-known regulators of the apoptotic process (19). The ratio of Bcl-2 to Bax, the so-called death-switch, is often used as an indicator of

apoptosis. An increase in this ratio is used to signify attenuation of the apoptotic process, whereas a decrease in this ratio is used to signify exacerbation of the apoptotic process. In this study, compared with normally fed rabbits, the expression of Bcl-2 was significantly upregulated in the nonischemic myocardium of hypercholesterolemic rabbits, whereas the expression of Bax was similar between both groups. This intriguing finding indicates that hypercholesterolemia may render the myocardium more resistant to pro-apoptotic stimuli by increasing the Bcl-2/Bax ratio. Although we did not perform immunohistochemical staining to ensure the exact origin of both Bcl-2 and Bax proteins, several studies demonstrated that the expression of both Bcl-2 and Bax primarily originates from cardiomyocytes (6,27). It is still not known whether hypercholesterolemia has a direct effect on the expression of Bcl-2 and Bax in cardiomyocytes. However, prolonged hypercholesterolemia may confer to the heart a relatively oxygen-deprived milieu by leading to coronary atherosclerosis and subsequent depressed pump function, as manifested by decreased mean arterial blood pressure at baseline in cholesterol-fed rabbits in the present and other studies (17,18). Hence, we speculated that hypercholesterolemia may cause the heart to develop a preconditioning-like response and thereby upregulate the expression of Bcl-2. In keeping with our observation, one study reported that ischemic preconditioning was associated with upregulation of Bcl-2 in rats (28). Furthermore, in explanted failed human hearts, Olivetti *et al.* (29) reported a near doubling of the expression of Bcl-2 without changes in the expression of Bax. This preconditioning-like effect of hypercholesterolemia also explains why isolated perfused heart of the cholesterol-fed rabbits, in the absence of invading activated inflammatory cells, was more resistant to ischemia-reperfusion injury in one recent study (18).

Although cholesterol-fed rabbits were associated with an increased Bcl-2/Bax ratio in the nonischemic myocardium, these rabbits also exhibited a more pronounced decrease in the expression of Bcl-2 and a similar extent of increase in the expression of Bax in the ischemic myocardium compared with normally fed rabbits. This finding is in accordance with our observation that hypercholesterolemia increased cardiomyocyte apoptosis following ischemia and reperfusion. Several studies demonstrated that hypercholesterolemia is associated with massive generation of oxygen-derived free radicals (30), increased interactions between circulating leukocytes and the endothelium (31,32), impaired anticoagulant mechanisms (15), and underdevelopment of collateral circulation following ischemia and reperfusion (33). These adverse effects may offset the cardioprotective action conferred by an increased Bcl-2/Bax ratio and thus render the heart more susceptible to the ischemia-reperfusion insult.

*Limitations.* First, some other members of the Bcl-2 family, such as Bcl-x and Bax, may also be involved in regulation of apoptosis (19). However, these proteins were not measured in the present study. Second, it has been reported that infiltrated inflammatory cells express high levels of Bax (34). Because immunohistochemical staining was not done in the

present study, we cannot exclude the possibility that the increased Bax expression following ischemia and reperfusion may be partly due to invading activated inflammatory cells, such as neutrophils. Nevertheless, although several previous studies demonstrated that the number of neutrophils accumulated in the ischemic myocardium was significantly higher in cholesterol-fed rabbits than in normally fed ones (32), the increase in Bax expression in the ischemic myocardium was similar between both groups in this study. Hence, the contribution of inflammatory cells to the increase in Bax expression may be small. Third, because the positive TUNEL has been observed in necrotic cells as well as apoptotic cells, we cannot accurately assess the extent of cardiomyocyte apoptosis in the necrotic myocardium. Further studies using the more specific Taq polymerase-based *in situ* ligation assay may resolve this problem (7).

**Clinical implications.** In this study, we demonstrated that although hypercholesterolemia is associated with an increased myocardial Bcl-2/Bax ratio at baseline, diet-induced hypercholesterolemia significantly exacerbates cardiac reperfusion injury, not only by increasing the infarct size but also by increasing the extent of cardiomyocyte apoptosis. The increased extent of cardiomyocyte apoptosis may adversely influence the left ventricular remodeling process and subsequently lead to poor prognosis. Because the magnitude of reperfusion-related cardiomyocyte apoptosis is significantly greater in hypercholesterolemic rabbits, we speculated that the administration of anti-apoptotic agents following the establishment of successful revascularization might provide additional benefits in salvaging the ischemic myocardium.

# Effect of SMP-500, a Novel ACAT Inhibitor, on Hepatic Cholesterol Disposition in Rats

Katsuhisa Ioriya\*, Takeshi Nishimura, and Naohito Ohashi

Research Division, Sumitomo Pharmaceuticals Co., Ltd., Osaka, Japan

**ABSTRACT:** The effects of SMP-500, a novel ACAT inhibitor, on serum lipid levels, hepatic lipid secretion rate, and hepatic lipid disposition in rats were studied to clarify its lipid-lowering action. SMP-500 reduced the serum cholesterol level in a dose-dependent manner in rats fed a hypercholesterolemic diet. SMP-500 also reduced hepatic free cholesterol content in addition to hepatic total and esterified cholesterol contents. Biliary concentrations of cholesterol and bile acid were increased by SMP-500; however, the bile flow and lithogenic index were not affected. SMP-500 increased cholesterol 7 $\alpha$ -hydroxylase mRNA level. Therefore, it is suggested that the increase in concentrations of cholesterol and bile acid in bile is due to both the increase of bile acid production through the increase of cholesterol 7 $\alpha$ -hydroxylase and the decrease of hepatic free cholesterol content. An inhibitory effect of SMP-500 both on the cholesterol secretion and on the TG secretion from liver was observed. SMP-500 reduced the serum TG level in sucrose-fed rats. From these results, one may hypothesize that the suppression of hepatic VLDL secretion probably plays an important role on both cholesterol- and TG-lowering effects of SMP-500.

Paper no. L8923 in *Lipids* 37, 395–400 (April 2002).

Hypercholesterolemia and cardiovascular disease are major health problems in many industrialized countries. One therapeutic approach for reducing hypercholesterolemia is to inhibit enzymes essential for cholesterol metabolism. ACAT is a primary enzyme responsible for the intracellular esterification of cholesterol (1). ACAT plays important roles in physiological processes. In the small intestine, ACAT facilitates the absorption of exogenous cholesterol, which is incorporated into chylomicrons (2,3). In liver, ACAT also plays an important role in the assembly of VLDL, which is secreted into blood (4–6). Under pathological states, ACAT is presumed to play a crucial role in foam cell formation of macrophages in the arterial wall, a characteristic feature of atherosclerotic lesions (7–9).

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; HC, high-cholesterol; LI, lithogenic index; MC, methyl cellulose; RT-PCR, reverse transcription-PCR; SMP-500, *N*-(2,6-bis(1-methylethyl)phenyl)-*N'*-(1-butyl-1,2-dihydro-2-oxo-4-(3-(3-pyridylmethoxy)phenyl)-1,8-naphthyridin-3-yl)-urea nitrate.

Therefore, an ACAT inhibitor is expected to lower serum cholesterol through suppression of intestinal cholesterol absorption and hepatic VLDL secretion and to prevent atherosclerosis through the inhibition of foam cell formation of macrophages (10,11). Several ACAT inhibitors have been synthesized, and their pharmacological activities have been evaluated in animals and humans (12–19).

Recently, we reported a novel ACAT inhibitor, SMP-500, that can potently inhibit ACAT and cause cholesterol lowering in hyperlipidemic and normolipidemic animals (20). Interestingly, SMP-500 reduced hepatic free cholesterol contents. That data suggested that SMP-500 directly facilitates the mobilization of cholesterol from liver.

Rats can be made hypercholesterolemic when cholesterol is fed in combination with lipophilic bile salts (21). Rats also have a high activity of cholesterol 7 $\alpha$ -hydroxylase, the major rate-limiting enzyme in bile acid biosynthesis from free cholesterol (22–24). Therefore, the rat is a good animal model for the study of cholesterol disposition from liver. In this study, to clarify the role of SMP-500 in liver, we investigated the effect of SMP-500 on both disposition and secretion of hepatic cholesterol in rats, and the lowering effect of SMP-500 on serum TG and serum cholesterol.

## EXPERIMENTAL PROCEDURES

**Materials.** SMP-500, *N*-(2,6-bis(1-methylethyl)phenyl)-*N'*-(1-butyl-1,2-dihydro-2-oxo-4-(3-(3-pyridylmethoxy)phenyl)-1,8-naphthyridin-3-yl)-urea nitrate, was synthesized at the Research Division, Sumitomo Pharmaceuticals Co. Ltd., Osaka, Japan.

**Animals.** SD rats (SLC Japan, Hamamatu, Japan) were individually housed in metal cages in a room with controlled temperature (23  $\pm$  3°C), relative humidity (50  $\pm$  20%), and light (12/12 h light/dark cycle). They had free access to water and a stock diet, CE-2 (Clea Japan Inc., Tokyo). All procedures related to the use of animals in these studies were reviewed and approved by the Institutional Animal Care and Use Committee at Sumitomo Pharmaceuticals Research Division.

**Cholesterol-lowering effect.** SD rats were fed either CE-2 diet containing 1.5% cholesterol, 0.5% cholic acid, 5.5% peanut oil [high-cholesterol (HC) diet] (25) or CE-2 (normal group), and started on the HC diet at the same time as SMP-500. SMP-500 was suspended in 0.5% methylcellulose (MC) and administered by gavage to the HC diet-fed rats once a day

for 6 d. In control and normal groups, 0.5% MC solution was administered. On the day after the final administration, rats were anesthetized with diethylether. Blood samples were collected from the orbital sinus using a capillary tube. Serum concentrations of total and HDL cholesterol were measured by enzymatic methods using commercial kits (Wako Pure Chemical Industries, Ltd., Osaka, Japan). The non-HDL cholesterol level was calculated as the difference between the HDL cholesterol level and the total cholesterol level. After collecting the blood samples from the rats, laparotomy was performed to remove the liver, which was immediately frozen in liquid nitrogen. Lipids of these samples were extracted with chloroform/methanol mixture according to the method of Folch *et al.* (26). The amounts of total and free cholesterol were measured by the method of Kunitomo *et al.* (27). The esterified cholesterol was calculated as the difference between the free and the total cholesterol.

**Bile flow and biliary cholesterol secretion.** SMP-500 was suspended in 0.5% MC and administered by gavage to HC diet-fed rats once a day for 6 d. On the day after the final administration, rats were fitted with a cannula on the bile duct, and bile was collected for 1 h under anesthesia (50 mg/kg; Nembutal®, Abbot Laboratories, IL). The serum total cholesterol level and biliary total bile acid, cholesterol and phospholipid were measured with enzymatic methods using commercial kits, as described above. The lithogenic index (LI), expressed as the cholesterol saturation of bile, was calculated by the method of Admirand and Small (28).

**Lipid secretion rate.** The effect of SMP-500 on the rate of lipid secretion from liver was determined by measuring the plasma cholesterol and TG levels after intravenous administration of Triton WR-1339 to rats (29). SMP-500 was suspended in 0.5% MC and administered by gavage to normal diet-fed rats once a day for 3 d. After the second administration, rats were fasted. On the next day, 1 h after the final administration, 400 mg/kg Triton WR-1339, as a 10% solution in 0.9% NaCl, was administered intravenously *via* the tail vein under diethylether anesthesia. Two hours later, rats were anesthetized with diethylether, and blood samples were collected from the orbital sinus and supplemented with 1 mg/mL of EDTA. The plasma VLDL fraction was then isolated by ultracentrifugation (30), and VLDL-cholesterol and VLDL-TG levels were measured by enzymatic methods using commercial kits, as described above.

**TG-lowering effect in sucrose-fed rats.** Rats were fed a high-sucrose diet (High Sucrose AIN-76A; Purina, St. Louis, MO) (25) for 2 wk, and orally administered SMP-500 suspended in 0.5% MC, once a day for 6 d utilizing the same diet. On the day after the final administration, rats were anesthetized with diethylether. Blood samples were collected from the orbital sinus of nonfasted rats, and the serum TG levels were measured by enzymatic methods using commercial kits, as described above.

**Cholesterol 7 $\alpha$ -hydroxylase mRNA level in HepG2 cells.**  $\beta$ -VLDL was isolated from rabbit plasma by ultracentrifugation (30). HepG2 cells were purchased from the American Type

Culture Collection (Manassas, VA), and cultured in DMEM/F-12 (GIBCO, Grand Island, NY) containing 10% FCS (GIBCO), 100 units/mL penicillin, and 100  $\mu$ g/mL streptomycin in a humidified incubator (5% CO<sub>2</sub>) at 37°C. Cells were grown to confluence and then the medium was changed to a fresh medium containing 10% lipoprotein-deficient serum and  $\beta$ -VLDL (200  $\mu$ g/mL) with or without SMP-500, followed by incubation for 24 h. SMP-500 was dissolved in DMSO, and the final concentration of DMSO in the medium was 0.1% (vol/vol). Isolation of total RNA and real-time quantitative reverse transcription (RT)-PCR were performed as described previously (31). Total RNA was isolated from HepG2 cells using TRIzol reagent (Life Technologies, Inc., Rockville, MD). The mRNA for cholesterol 7 $\alpha$ -hydroxylase was measured by real-time quantitative RT-PCR using a PE Applied Biosystems prism model 7700 sequence detection instrument (Applied Biosystems, Foster, CA). The sequences of forward and reverse primers as designed by Primer Express (PE ABI) were 5'-GCGCATGTTTCTCAATGACACT-3' and 5'-CGCTGAATGTGTTTGCTT-3', respectively. The TaqMan<sup>TM</sup> fluorogenic probe used was 5'-6FAM-ATGATCTGGAGAAGGCCAA-GACACACCTC-TAMRA-3'. Cholesterol 7 $\alpha$ -hydroxylase mRNA levels were corrected for  $\beta$ -actin RNA, which was measured using a kit (PE ABI, P/N 401846) from PerkinElmer as per the manufacturer's protocol.

**Statistical analysis.** Data were expressed as mean  $\pm$  SEM. Differences among the groups were determined by Dunnett's multiple comparisons test. Student's *t*-test was also used to compare data between two groups. Differences were considered statistically significant when the *P*-value was less than 0.05.

## RESULTS

SMP-500 was administered by gavage once a day to rats fed a HC diet for 6 d. The serum total cholesterol level markedly increased during feeding with the HC diet in the control groups to approximately 3.2-fold in comparison to the value of the normal diet group (HC diet group: 207  $\pm$  26 mg/dL, normal diet group: 64  $\pm$  4 mg/dL) (Fig. 1). The increased amount of total cholesterol level was due to an increase in the non-HDL cholesterol level. SMP-500 significantly reduced the serum total and non-HDL cholesterol levels in a dose-dependent manner at doses of 10 mg/kg/d or higher (Fig. 1). Compared with HC-fed controls, serum total cholesterol level was reduced by 35 and 66% and non-HDL cholesterol level was reduced 41 and 77% in animals administered SMP-500 at 10 and 30 mg/kg/d, respectively. The total cholesterol content in liver from the HC diet group was approximately nine times higher than that of the normal group (HC diet group: 23.1  $\pm$  0.7 mg/g tissue, normal diet group: 2.5  $\pm$  0.1 mg/g tissue) (Fig. 2A). The increase in the hepatic total cholesterol content was mainly due to an increase in the hepatic cholesteryl ester content. SMP-500 markedly reduced the hepatic total and esterified cholesterol content (Figs. 2A, 2B) and significantly reduced the hepatic free cholesterol content (Fig. 2C).

SMP-500 was administered by gavage once a day to rats fed

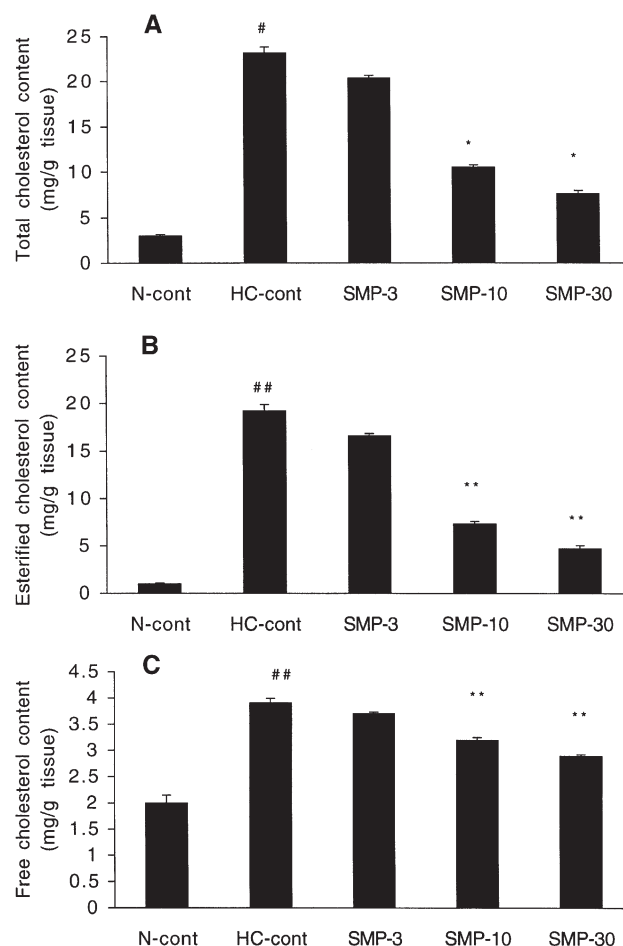

**FIG. 1.** Effect of SMP-500 on serum cholesterol levels in hypercholesterolemic rats. SMP-500 was administered by gavage to the high-cholesterol (HC) diet-fed rats once a day at doses of 3, 10, and 30 mg/kg/d for 6 d. Each point represents the mean  $\pm$  SEM ( $n = 6$ ). SMP-500, *N*-(2,6-bis(1-methylethyl)-phenyl)-*N'*-(1-butyl-1,2-dihydro-2-oxo-4(3-(3-pyridylmethoxy)phenyl)-1,8-naphthyridin-3-yl)-urea nitrate; N-cont, normal diet control; HC-cont, HC diet-fed control; SMP-3, 10, and 30, SMP-500 at doses of 3, 10 and 30 mg/kg/d, respectively; \* $P < 0.05$ ; \*\* $P < 0.01$ , significantly different from HC-cont using Dunnett's multiple comparisons test. ## $P < 0.01$ , significantly different from N-cont using Student's *t*-test.

the HC diet for 6 d. On the day after the final administration, rats were anesthetized with sodium pentobarbital, the bile duct was cannulated, and the bile was collected for 1 h. The concentrations of both biliary cholesterol and bile acid in collected bile were increased, whereas the concentration of biliary phospholipid was not affected by SMP-500 (Table 1). However, the total bile efflux and the LI were not affected by SMP-500 (Table 1).

SMP-500 was administered by gavage to normal diet-fed rats once a day for 3 d. One hour after the final administration of SMP-500, Triton WR-1339 (400 mg/kg) was intravenously injected to determine its effect on lipid secretion from the liver into blood. Two hours later, the cholesterol and TG levels in the plasma VLDL fraction had increased. In the plasma VLDL fraction, the increased cholesterol level was  $72 \pm 4$  mg/dL/2 h and that of TG was  $729 \pm 28$  mg/dL/2 h. SMP-500 decreased the cholesterol influx into the plasma at doses of 10 mg/kg or more and the TG influx into the plasma at a dose of 30 mg/kg (Fig. 3). The reduction in cholesterol influx into the plasma was 18 and 29% and in TG influx into the plasma 8 and 18% at doses of 10 and 30 mg/kg/d, respectively.

Rats were fed a high-sucrose diet for 2 wk, and further fed the same diet while being administered SMP-500 suspended in 0.5% MC once a day for 6 d. The serum TG level in this

**FIG. 2.** Effect of SMP-500 on the hepatic total (A), esterified (B), and free cholesterol (C) content in rats. SMP-500 was administered by gavage to the HC diet-fed rats once a day for 6 d. Each column represents the mean  $\pm$  SEM ( $n = 6$ ). For abbreviations see Figure 1. \*\* $P < 0.01$ , significantly different from HC-cont using Dunnett's multiple comparisons test; ## $P < 0.01$ , significantly different from N-cont using Student's *t*-test.

model increased from approximately 190 to 350 mg/dL after feeding rats the high-sucrose diet in the first 2 wk and that in the control group increased from  $350 \pm 28$  mg/dL to  $403 \pm 38$  mg/dL throughout the period of administration of SMP-500 or vehicle. SMP-500 significantly reduced the serum TG level in a dose-dependent manner (Fig. 4). The reduction in the serum TG levels were 8, 18, and 29% at doses of 10, 30, and 100 mg/kg/d, respectively.

To investigate the mechanism for the increase of bile acid concentration in bile induced by SMP-500, the mRNA for cholesterol 7 $\alpha$ -hydroxylase was measured by real-time quantitative RT-PCR in HepG2 cells. Treatment with SMP-500 for 24 h increased cholesterol 7 $\alpha$ -hydroxylase mRNA level approximately 1.3-fold compared with control cells (Fig. 5).

## DISCUSSION

Recently, we reported a novel ACAT inhibitor, SMP-500, that can potentially inhibit ACAT and cause cholesterol lowering in

<sup>a</sup>Each value represents the mean  $\pm$  SEM ( $n = 12$ ). SMP-500 was orally administered to high-cholesterol (HC) diet-fed rats once a day for 6 d. On the day after final administration, bile was collected from the bile duct for an hour under anesthesia. The lithogenic index (LI) was calculated by the method of Admirand and Small (28). \* $P < 0.05$ , \*\* $P < 0.01$ , significant difference from HC control by Dunnett's multiple comparison test.

<sup>b</sup>SMP-10 and 30, SMP-500 at doses of 10 and 30 mg/kg/d, respectively; STC, serum total cholesterol; TBA, total bile acid; PL, phospholipid; SMP-500, *N*-(2,6-bis(1-methylethyl)phenyl)-*N'*-(1-butyl-1,2-dihydro-2-oxo-4-(3-(3-pyridylmethoxy)phenyl)-1,8-naphthyridin-3-yl)-urea nitrate.

mice, rabbits, and hamsters (20). Interestingly, SMP-500 reduced hepatic free cholesterol contents. These data suggested that SMP-500 directly facilitates the mobilization of chole-

sterol from liver. In this article, we investigated the effect of SMP-500 on both the component in bile and VLDL secretion in rats to clarify its role in liver. In rats fed a HC diet, SMP-500 strongly reduced the serum total cholesterol levels. The hypocholesterolemic effect of SMP-500 was due to a reduction in non-HDL cholesterol level. SMP-500 reduced the hepatic free cholesterol content as well as the hepatic total and esterified cholesterol contents. These data were consistent with the results obtained by using other animals in our previous studies (20).

First, the bile efflux and the biliary secretions of bile acid and cholesterol were measured. The biliary concentrations of cholesterol and bile acid were increased by SMP-500, although the bile efflux and the LI were not affected. These data suggested that SMP-500 facilitated hepatic cholesterol removal through increases in bile acid production and chole-

**FIG. 3.** Effect of SMP-500 on cholesterol influx (A) and TG influx (B) into plasma in rats. Rats fed a normal diet were administered SMP-500 by gavage once a day for 3 d. One hour after the final administration, they were intravenously injected with Triton-WR1339, and the plasma lipid levels were measured before and 2 h after injection. The difference in the plasma lipid levels is expressed as the lipid secretion from liver. All data represent the mean  $\pm$  SEM ( $n = 6$ ). \* $P < 0.05$ , significant difference from control using Dunnett's multiple comparisons test. For abbreviation see Figure 1.

**FIG. 4.** Effect of SMP-500 on serum TG levels in sucrose-fed rats. Rats were fed a sucrose diet for 2 wk, and further fed sucrose and administered SMP-500 by gavage once a day for 7 d. All data represent the mean  $\pm$  SEM ( $n = 6$ ). \* $P < 0.05$ ; \*\* $P < 0.01$ , significant difference from control using Dunnett's multiple comparisons test. For abbreviation see Figure 1.

**FIG. 5.** Effect of SMP-500 on cholesterol 7 $\alpha$ -hydroxylase mRNA level in HepG2 cells. Cells were incubated for 24 h in medium containing 10% lipoprotein-deficient serum and  $\beta$ -VLDL (200  $\mu$ g/mL) with or without SMP-500. Cholesterol 7 $\alpha$ -hydroxylase mRNA level was measured by real-time quantitative reverse transcription-PCR. Cholesterol 7 $\alpha$ -hydroxylase mRNA levels were corrected for  $\beta$ -actin RNA. All values are expressed as a percentage of mRNA level in control cells and represent the mean  $\pm$  SEM ( $n = 6$ ). \* $P < 0.05$ ; \*\* $P < 0.01$ , significant difference from control using Dunnett's multiple comparisons test. For abbreviation see Figure 1.

terol influx into the bile. The treatment of SMP-500 in HepG2 cells for 24 h increased cholesterol 7 $\alpha$ -hydroxylase mRNA level compared with the control. It has been reported that CI-1011 (32) and HL-004 (33) facilitate bile acid production through an increase of cholesterol 7 $\alpha$ -hydroxylase activity and mRNA level. The inhibition of hepatic ACAT activity causes a change in the metabolic pathway of cholesterol by increasing the supply of free cholesterol as a substrate. Free cholesterol is also reported to be an inducer of cholesterol 7  $\alpha$ -hydroxylase (24,34,35), resulting in an enhanced production of bile acids (21,22,36). These processes are common in several species, such as rats or humans (37,38). SMP-500 is thought to have a similar effect on cholesterol 7  $\alpha$ -hydroxylase. As a result, SMP-500 reduced the hepatic free cholesterol content. CI-1011 and HL-004 (two other ACAT inhibitors), however, did not change the hepatic free cholesterol content, although they were thought to facilitate bile acid production through a temporary increase in free cholesterol (32,33). SMP-500 increased the concentration of cholesterol in bile and, on the other hand, CI-1011 and HL-004 had no effect. The decrease of hepatic free cholesterol by SMP-500 may be due to this effect.

ACAT also plays an important role in the assembly of VLDL (4–6). VLDL-cholesterol and TG influx into plasma was measured using the Triton model to investigate the effect of SMP-500 on VLDL secretion. As expected, an inhibitory effect of SMP-500 on cholesterol influx into plasma was observed. This effect by SMP-500 is also involved in its cholesterol-lowering effect. In addition, the inhibitory effect of SMP-500 on TG influx into plasma was shown. It has been reported that some ACAT inhibitors reduce serum TG level (25,39–41). These reports indicate that a reduction of serum TG depends on the suppression of VLDL secretion by hepatic

ACAT inhibition and that a reduction of serum cholesterol depends on both the inhibition of cholesterol absorption and the suppression of VLDL secretion. These mechanisms may also be involved in the observed effects of SMP-500, although further studies will be necessary for clarifying this mechanism.

In this study, we demonstrated that SMP-500 dose-dependently reduces serum cholesterol level in rats. We clarified that SMP-500 facilitated hepatic cholesterol clearance through increases in bile acid that were due to the increase in cholesterol 7 $\alpha$ -hydroxylase mRNA level and cholesterol concentration in the bile and to suppressed VLDL-cholesterol secretion that was involved in the hypocholesterolemic effect of this compound. In addition, SMP-500 reduced serum TG level. These results suggest that SMP-500 may have therapeutic potential for both hypercholesterolemia and hypertriglyceridemia.

# Synthesis and Phospholipase C Inhibitory Activity of D609 Diastereomers

Albert González-Roura, Josefina Casas, and Amadeu Llebaria\*

Research Unit on BioActive Molecules (RUBAM), Department of Biological Organic Chemistry, IIQAB-CSIC, 08034-Barcelona, Spain

**ABSTRACT:** The potassium xanthate D609 is widely accepted as a selective inhibitor of PC-specific phospholipase C (PC-PLC). The tricyclo[5.2.1.0<sup>2,6</sup>]decane skeleton present in D609 can lead to four diastereomeric pairs, but the diastereoselectivity of PC-PLC inhibition has never been reported. In this article, the synthesis of racemic D609 diastereomers and that of other xanthates, as well as their inhibitory effect on PC-PLC is reported. All xanthates obtained were competitive inhibitors of PC-PLC from *Bacillus cereus* (PLC*Bc*). No significant differences were found in the activity of D609 diastereomers ( $K_i$  13–17  $\mu\text{M}$ ), suggesting the absence of a diastereochemical control of the enzyme by xanthate inhibitors. This result was confirmed after obtaining other potassium xanthates differing from D609 in the aliphatic chain. Among them, the potassium *O*-*n*-decenylxanthate was the most active inhibitor of PLC*Bc* ( $K_i$  10  $\mu\text{M}$ ). These data indicate that the essential structural requirements for PLC*Bc* *in vitro* inhibition by xanthates are the presence of a Zn-chelating dithiocarbonate head and a sufficiently hydrophobic aliphatic moiety.

Paper no. L8955 in *Lipids* 37, 401–406 (April 2002).

PC-specific phospholipase C (PC-PLC) is a crucial enzyme in lipid metabolism that hydrolyzes PC into phosphorylcholine and DAG and has been implicated in the cellular signal transduction cascade (1). Among different biological effects, the tricyclic potassium xanthate D609 (Fig. 1) is a potent inhibitor of PC-PLC (2). The inhibitory effect is selective for PC-PLC as compared to other phospholipases (3), which has made D609 a universally accepted pharmacological tool to assess the involvement of a PC-PLC enzyme in a given cellular process. However, a few reports show that D609 can also inhibit the enzymes of the sphingomyelin cycle, namely, sphingomyelinases and sphingomyelin synthase (4,5). The effect on sphingomyelin synthase is especially critical, since this enzyme catalyzes the transfer of phosphorylcholine from PC to ceramide to give sphingomyelin and DAG. At this point, it is worth mentioning that the possible differential ef-

D609

FIG. 1. Chemical structure of D609.

fects of D609 diastereomers and other xanthates on PC-PLC have not been reported; in addition, the exact diastereomeric composition of the commercially available D609 inhibitor is not specified. Therefore, we were interested in determining the effect of the different D609 diastereomers and other xanthates on lipid-metabolizing enzymes, since some discrepancies existing in the literature might arise from different D609 diastereomers or its mixtures used in the experimentation. The use of structurally simpler xanthates, without stereogenic centers, avoids misleading and controversial results arising from the use of stereochemically different tools.

In this article we describe the synthesis of a series of xanthates and the preparation of D609 diastereomers in racemic form, as well as their evaluation as inhibitors of the PC-PLC of *Bacillus cereus* (PLC*Bc*). This commercially available enzyme is currently accepted as a surrogate of the elusive mammalian PC-PLC, both enzymes having antigenic similarities (6). The structure and mechanism of PLC*Bc* are well known (7–12), and several inhibitors other than D609 have been disclosed for this enzyme (13,14).

## EXPERIMENTAL PROCEDURES

**Materials and methods.** FTIR spectra are reported in  $\text{cm}^{-1}$ .  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra were obtained in  $\text{CDCl}_3$ ,  $\text{CD}_3\text{OD}$ , DMSO, or  $\text{D}_2\text{O}$  solutions at 200 or 300 MHz for  $^1\text{H}$  and 50 or 75 MHz for  $^{13}\text{C}$ . Chemical shifts are reported in  $\delta$  units, parts per million (ppm) relative to the singlet at 7.24 ppm of  $\text{CDCl}_3$  for  $^1\text{H}$  and ppm relative to the center line of a triplet at 77.0 ppm of  $\text{CDCl}_3$  for  $^{13}\text{C}$ . Electrospray (ESP) mass spectra in negative mode were obtained by HPLC–MS using acetonitrile/water (1:1) at 0.5 mL/min as mobile phase. Solvents were distilled prior to use and dried by standard methods. Ketone **9** and the mixture of alcohols **10** are commercial products

Abbreviations: DAG, diacylglycerol; ESP, electrospray; PC-PLC, phosphatidylcholine-specific phospholipase C; PLC*Bc*, PC-PLC from *Bacillus cereus*.

(TCD-keton A and TCD-alcohol E, respectively) and were obtained from Celanese Chemicals Europe GmbH (Oberhausen, Germany). Racemic diastereomeric alcohols **5–8** were obtained following described procedures: *O*-*exo*,*C*-*exo* **5** (15); *O*-*endo*,*C*-*exo* alcohol **6** (16,17); *O*-*exo*,*C*-*endo* **7** (18); and *O*-*endo*,*C*-*endo* **8** (15,17,18) and characterized by comparison with reported spectroscopic data (17).

**Determination of CMC.** The CMC of xanthates and PC were determined in 96-well microtiter plates by dye-binding with Coomassie brilliant Blue G-250 (19). Using this method, CMC of 1,2-dihexanoyl-*sn*-glycero-3-phosphocholine was determined to be 6.23 mM.

**General procedure for the synthesis of potassium xanthates (1–4, 14–17).** The alcohol (1.1 eq) was slowly added to a solution of *t*-BuOK (1 eq.) in anhyd. THF (3 mL/mmol) at 0°C under nitrogen. Carbon disulfide (1.1 eq) was added dropwise, and the solution was stirred for 4 h at this temperature. The reaction mixture was diluted with ether (15 mL/mmol) and concentrated to give the crude product. The residue was washed with ether and dried to give the corresponding potassium xanthate as a white powder.

Mass spectrum (ESP<sup>-</sup>): *m/z* 275 (M – K, base peak), 199 (alcohol fragment). CMC: 4.16 mM.

**Enzymatic assays.** Inhibition studies were performed *in vitro* using commercially available PLCβc. Quantification of the enzymatic activity was performed following an indirect method described by Hergenrother and Martin (20). Briefly, 1,2-dihexanoyl-*sn*-glycero-3-phosphocholine (2 mM final concentration) was incubated with PC-PLC in the absence or presence of inhibitors (0–2 mM, final concentration) at 37°C in 96-well plates, and after 1.5 min the reaction was quenched with Tris-HCl 2M, pH 8. A molybdenum blue complex with the phosphate produced after alkaline phosphatase hydrolysis of phosphorylcholine was formed and read with a microplate reader. All assays were performed at least in triplicate. The IC<sub>50</sub> values were determined by plotting percent activity vs. log[I], using at least five different inhibitor concentrations (0.0003–1 mM). As indicated previously, CMC values of tested xanthates ranged from 2.6 to >10 mM; therefore, all assays were performed below the CMC of substrate and inhibitors.

Kinetic parameters for more active inhibitors were determined by Lineweaver–Burke plots of assays performed with the corresponding xanthate derivative (10 μM) and five different substrate concentrations (0.6–5 mM). *K<sub>i</sub>* values were calculated with the following equation:

$$K_i = K_m[I]/(K_{m,app} - K_m) \quad [1]$$

## RESULTS AND DISCUSSION

**Synthesis.** The classical approach to the synthesis of xanthates is based on the reaction of the corresponding sodium or potassium alcoholate with carbon disulfide. Therefore, the prepara-

SCHEME 1

tion of racemic tricyclic xanthates **1–4** required the synthesis of diastereomeric alcohols **5–8** (Fig. 2). This was accomplished as detailed in Scheme 1. The alcohols **5** and **6**, displaying an *exo* cyclopentane group, were obtained from commercially available ketone **9** and a mixture of regioisomeric alcohols **10**, respectively. After reduction of ketone **9**, pure *O-endo,C-exo* alcohol **6** was obtained in 31% isolated yield after chromatography to separate it from the *O-exo,C-exo* epimeric alcohol **5**, which was a minor product of this reaction. Complete chromatographic separation of **5** from **6** proved unfeasible, but catalytic hydrogenation of double bonds in **10** directly gave high-purity *O-exo,C-exo* alcohol **5** in almost quantitative yield.

The alcohols **7** and **8** having an *endo* cyclopentane attached to the norbornene skeleton were obtained from *endo*-dicyclopentadiene **11** following reported procedures. Thus, olefin regioselective acetoxymercuration-demercuration sequence on *endo*-dicyclopentadiene with *in situ* hydrolysis of the resulting acetate afforded a mixture of regioisomeric racemic alcohols **12**. After catalytic hydrogenation the desired *O-exo,C-endo* isomer **7** was obtained in 74% yield over two steps. The racemic epimeric alcohol **8** was obtained by oxidation of **7** to the corresponding tricyclic ketone **13** followed by NaBH<sub>4</sub> reduction to give the *O-endo,C-endo* alcohol **8** in 62% yield after two steps.

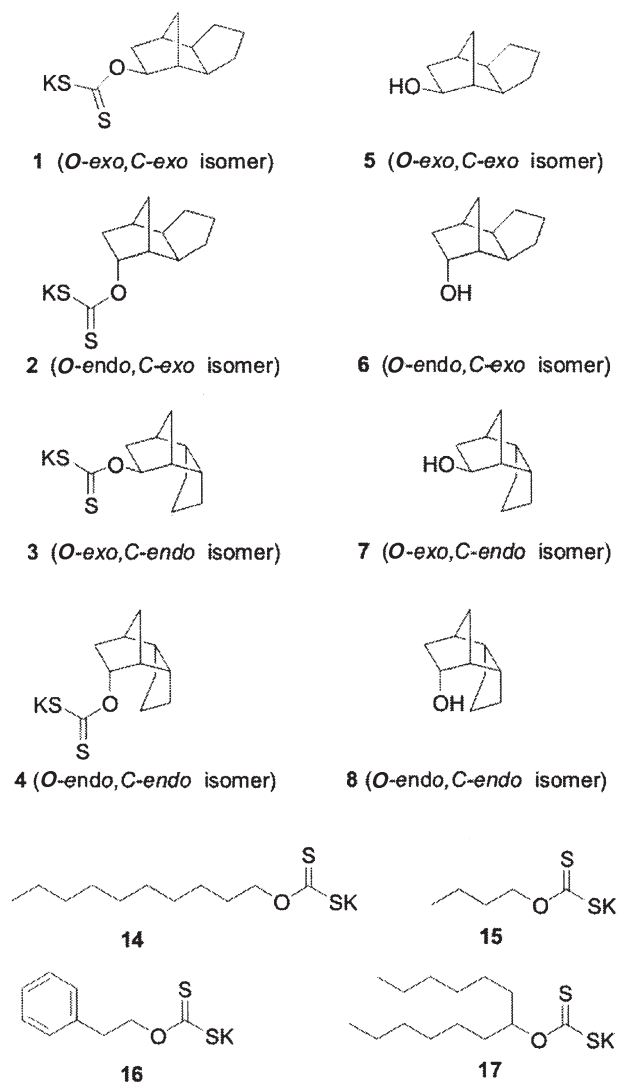

FIG. 2. Tested xanthates and D609 alcohol precursors.

With racemic diastereomeric alcohols **4–8** in hand, the corresponding xanthates were synthesized by reaction with carbon disulfide in the presence of an equivalent of potassium *t*-butoxide in THF. This method was also employed to synthesize the xanthates **14** (from *n*-decanol), **15** (from *n*-butanol), **16** (from 2-phenylethanol), and **17** (from 7-tridecanol) also required for this study (Fig. 2).

**Inhibition studies.** Enzymatic assays were performed on commercial PLCBc using the method described by Hergenrother and Martin (20). This is based on a colorimetric determination of phosphate after alkaline phosphatase hydrolysis of the phosphorylcholine produced by PLCBc-catalyzed hydrolysis of PC.

To check the reliability of the colorimetric method for testing xanthate derivatives as inhibitors of PC-PLC, we performed experiments aimed to exclude a possible effect of xanthates on alkaline phosphatase. We found that all xanthates at 1 or 2 mM concentration did not affect the enzymatic activity of

alkaline phosphatase in the assay conditions (45–450  $\mu\text{M}$  phosphorylcholine and 6 U/mL of enzyme, 2 h at 37°C).

Kinetic parameters calculated for PLCBc with 1,2-dihexanoyl-*sn*-glycero-3-phosphocholine ( $V_{\text{max}}$ : 2600  $\pm$  670  $\mu\text{M}/\text{min}\cdot\text{mg}$  and  $K_m$ : 2.6  $\pm$  0.14 mM,  $n = 5$ ) were close to those described in the literature using this substrate (20). Therefore, a substrate concentration of 2 mM was chosen to test the activity of alcohol **5** and the different synthesized xanthates. Among these compounds only alcohol **5** was inactive, this indicating that the presence of the oxygen-bonded dithiocarbonate group is essential for inhibitory activity.

All tested xanthates exhibited a dose-dependent inhibition (Fig. 3 and Table 1) of PLCBc with different degrees of activity. Among the four D609 diastereomers analyzed, compounds with a *C-exo* configuration (**1–2**) showed slightly lower  $\text{IC}_{50}$  values than the corresponding *C-endo* isomers (**3–4**). In addition to xanthates bearing a tricyclo[5.2.1.0<sup>2,6</sup>]decane skeleton, the xanthate **14**, derived from *n*-decanol, also showed a remarkable inhibitory activity on PLCBc. Therefore, the presence of a tricyclic system as hydrophobic moiety in xanthates does not seem to be an essential structural requirement for *in vitro* PLCBc inhibition. Other xanthates resulted in less active inhibitors. Thus, potassium *O-n*-butylxanthate **15**, potassium *O-2*-phenylethylxanthate **16**, or potassium *O-7*-tridecylxanthate **17** differ in the length of the hydrophobic chains attached to the dithiocarbonate group, which must be the reason for their different PC-PLC inhibitory activities. The  $\text{IC}_{50}$  values obtained decrease in parallel to the increase on the hydrophobicity of xanthate aliphatic chain. This effect is especially noteworthy in the case of *n*-butanol-derived xanthate, which was found to be the least active xanthate used in this study. These results are in agreement with the low inhibitory activity reported for potassium *O*-ethylxanthate (46% inhibition at 0.63 mM) (3). The use of xanthate **17** derived from a secondary alcohol containing a double hydrophobic chain or the presence of a phenylethyl

FIG. 3. Dose-dependent inhibition of phosphatidylcholine/specific phospholipase C of *Bacillus cereus* by different xanthate derivatives. Compounds (**1**: *O-exo,C-exo* isomer D609, **15**: potassium *n*-butylxanthate, **17**: *O-7*-tridecylxanthate) were incubated with 2 mM of PC for 1.5 min at 37°C.

group on compound **16** did not result in a significant improvement as compared to the compounds with a single chain and did not reach the inhibitory effect of D609.

Inhibition parameters for the most active xanthates were also calculated. Lineweaver–Burke plots obtained for xanthate **14** (Fig. 4) were very similar to those achieved with xanthates **1–4**. The curves obtained in the absence and in the presence of inhibitor cross in the ordinate axis, indicating a competitive type of inhibition of PC-PLC by all compounds. Calculated inhibition constants were comparable (10–17  $\mu\text{M}$ , Table 1), and similar to that reported for D609 using dipalmitoyl PC or *p*-nitrophenylphosphatidylcholine as substrate (3).

The results described show the absence of substantial differences in the activity of D609 diastereomers, suggesting the lack of a diastereochemical control of the enzyme by this family of inhibitors. In addition, simple straight-chain xanthates with sufficient lipophilic chains inhibit PLCBc even more potently than D609. This result confirms the lack of selectivity of this enzyme for the hydrocarbon chain present in xanthates. In this context, it has been described that PLCBc presents a shallow cleft for docking the phospholipid substrate, with a minimum acyl chain length being required for good enzymatic activity (12,21).

Although different types of enzymes are reported to be inhibited by xanthates, the mechanisms of inhibition are differ-

FIG. 4. Lineweaver–Burke plot for the phosphatidylcholine specific phospholipase C of *Bacillus cereus* inhibition by potassium *O-n*-decylxanthate (**14**). [I] = 0 (■) and 10  $\mu\text{M}$  (●).

ent. Thus, the xanthate derivative of cholesterol exhibited a good inhibitory activity of Cdc25A phosphatase, an enzyme involved in the regulation of the G1/S transition of the cell cycle, and the xanthate group would surrogate the phosphate moiety in a cysteinyl-phosphate enzyme intermediate formed during the reaction course (22). On the other hand, different xanthates, including D609, were found to be specific mechanism-based inactivators of cytochrome P450 2B1 and 2B6, and the inactivation is caused by covalent binding of a reactive xanthate intermediate to the apoprotein (23). Contrary to the results reported in the present paper for the inhibition of PC-PLC, reported  $K_i$  values for the inactivation of P-450 2B1 were not strongly dependent on the length of the aliphatic chain substituent. Concerning the effects of D609 on sphingomyelin synthase, the almost complete absence of structural, mechanistic, and biochemical data for this enzyme (24) precluded any hypothesis on the mechanism of inhibition by D609. In regard to PC-PLC inhibition by xanthates, our results and previously published data indicate that active xanthates are competitive inhibitors, suggesting that they have affinity for the PC binding site. Different experimental evidences indicate that the three zinc ions are present in the active center of PC-PLC, which are essential for full activity, and are involved in substrate binding and activation of the phosphate moiety toward nucleophilic attack through charge neutralization. An active site base-activated water molecule acts as the nucleophilic species (10). Xanthate derivatives that have the appropriate lipophilic chain would fit in the active center of PC-PLC, and the dithiocarbonate group could act as a surrogate of the phosphate group and presumably would bond to active-site Zn ions in view of the charge and metal coordinating ability of the sulfur atoms present in this group.

The *in vitro* inhibitory activity of a series xanthates on PLC $\beta$ c indicated that the essential structural requirements are the presence of a sufficiently hydrophobic aliphatic chain and a dithiocarbonate head group.

# FA Composition of Heart and Skeletal Muscle During Embryonic Development of the King Penguin

Frederic Decrock<sup>a</sup>, René Groscolas<sup>a</sup>, and Brian K. Speake<sup>b,\*</sup>

<sup>a</sup>Centre d'Ecologie et Physiologie Energétiques, Centre National de la Recherche Scientifique, Associé à l'Université Louis Pasteur, 67087 Strasbourg, France, and <sup>b</sup>Lipid Laboratory, Avian Science Research Centre, Scottish Agricultural College, Ayr KA6 5HW, United Kingdom

**ABSTRACT:** Since the yolk lipids of the king penguin (*Aptenodytes patagonicus*) naturally contain the highest concentrations of DHA and EPA yet reported for the eggs of any avian species, the effects of this (n-3)-rich yolk on the FA profiles of the embryonic heart and skeletal muscle were investigated. The concentrations (mg/g wet tissue) of phospholipid (PL) in the developing heart and leg muscle of the penguin doubled between days 27 and 55 from the beginning of egg incubation (i.e., from the halfway stage of embryonic development to 2 d posthatch), whereas no net increase occurred in pectoral muscle. During this period, the concentration of TAG in heart decreased by half but increased two- and sixfold in leg and pectoral muscle, respectively. The most notable change in cholesteryl ester concentration occurred in pectoral muscle, increasing ninefold between days 27 and 55. Arachidonic acid (ARA) was the major polyunsaturate in PL of the penguin's heart, where it formed about 20% (w/w) of FA at day 55. At the equivalent developmental stage, the heart PL of the chicken contained a 1.3-fold greater proportion of ARA, contained a fifth less DHA, and was almost devoid of EPA, whereas the latter FA was a significant component (7% of FA) of penguin heart PL. Similarly, in PL of leg and pectoral muscle, the chicken displayed about 1.4-fold more ARA, up to 50% less DHA, and far less EPA in comparison with the penguin. Thus, although ARA-rich PL profiles are achieved in the heart and muscle of the penguin embryo, these profiles are significantly affected by the high n-3 content of the yolk.

Paper no. L8884 in *Lipids* 37, 407–415 (April 2002).

During development of the avian embryo, FA derived from yolk lipids are distributed to the growing tissues where they are used for energy metabolism, membrane biogenesis, and the formation of fat stores (1). As a result of the selective uptake and incorporation of certain PUFA, the phospholipids (PL) of the various embryonic tissues display highly distinctive FA profiles (1). Particular attention has been focused on the high proportions of DHA (22:6n-3) in the PL of the embryonic brain and retina, largely because this n-3 polyunsatu-

rate is believed to perform essential roles during neuronal differentiation (2–4). However, the development and subsequent functioning of the embryonic heart and skeletal muscles are also dependent on lipid-related events. For example, the early stages of skeletal myogenesis, characterized by the proliferation of myoblasts and their subsequent fusion to form multinucleate myotubes, are dependent on high rates of PL metabolism associated with membrane rearrangements (5–7). Also, studies in mammals have demonstrated that the proportion of C<sub>20-22</sub> polyunsaturates and the n-3/n-6 ratio in muscle PL are positively correlated with the tissue's sensitivity to insulin and that inadequacies in the provision of certain PUFA during development could contribute to insulin resistance (8,9). Most notably, investigations using mammalian cardiomyocytes have revealed a central role for PL-derived arachidonic acid (ARA, 20:4n-6) in the signal transduction mechanisms that regulate the heart beat (10,11). Moreover, DHA and EPA (20:5n-3) have been shown to exert powerful antiarrhythmic effects on heart cells by modulating membrane ion channels (12,13). In addition, the intramyocellular TAG of both heart and skeletal muscle could function as an important energy reserve during development (14,15).

Given the regulatory roles of C<sub>20-22</sub> polyunsaturates of both the n-6 and n-3 series in cardiac and skeletal muscle (8–13), the avian embryo may require the provision of these FA from the yolk in adequate amounts and in the appropriate n-3/n-6 ratio to support the functional differentiation of these tissues. For a particular avian species, major distortions of the yolk's polyunsaturate profile away from that which is normally encountered by the embryo, as achieved by altering the diet of the hen, could conceivably result in impairments of myocellular function. If so, this is analogous to the well-studied consequences of n-3 or n-6 deprivation during development on the subsequent performance of the brain and retina (16,17). However, different avian species utilize a variety of dietary modes resulting in a great diversity of species-specific yolk FA compositions (18,19). For those species whose eggs naturally contain a great excess of n-3 over n-6 FA, or vice versa, the embryo could possibly express adaptations to ensure that a more balanced spectrum of polyunsaturates is delivered/incorporated into the muscle cells. Alternatively, the lipid-dependent regulatory mechanisms in the developing heart and skeletal muscle of such species may possess sufficient

Abbreviations: ARA, arachidonic acid; CE, cholesteryl ester; PL, phospholipid.

flexibility to accommodate the excess of one or the other type of polyunsaturate.

The eggs of some piscivorous birds provide an extreme case since their yolks are exceptionally enriched with DHA and EPA due to the large amounts of these FA in the fish they eat (20–22). For example, the n-3/n-6 ratio of the yolk lipids of the king penguin (*Aptenodytes patagonicus*) is 3.0 compared with only 0.1 in eggs of the chicken (20,21). We recently described the rearrangements in FA composition that occur as lipids are transferred from the yolk of the king penguin to the embryonic plasma and liver (21). In the present work, and based on comparison with the chicken, we show how the (n-3)-rich yolk of the king penguin affects the FA profiles of lipids of the developing heart and skeletal muscle in this species.

## MATERIALS AND METHODS

### *The penguin colony, egg incubation, and tissue collection.*

The breeding colony of king penguins (Crozet Archipelago, South Indian Ocean), the natural incubation of eggs in the wild, and the sampling of eggs for the collection of embryonic tissues (during the austral summer of 1998/1999) were described in detail previously (21). In brief, eggs in the range of 280–320 g were removed from the incubating parent after 27, 33, 40, and 47 d of development. Hatching occurs after  $53 \pm 1$  d in this species but began about 3 d earlier (23,24). Additionally, some eggs in which hatching had commenced were transferred from the parent to a laboratory incubator maintained at 37.5°C and 100% relative humidity until the chicks were completely hatched. These were either sampled immediately on hatching or were maintained for 2 d and provided with drinking water but no food. The reason for not obtaining newly hatched and 2-d posthatch chicks directly from the colony is that parents commence feeding their chicks before they have fully emerged from the shell. The FA composition of this food (myctophid fishes) differs from that of the yolk (21) and would therefore interfere with any assessment of yolk-to-muscle lipid transfer. Unfed newly hatched chicks rely on the residual contents of the internalized yolk sac for their source of nutrients (1). Embryos and chicks were sacrificed by decapitation and hearts and muscles were dissected and immediately stored frozen at –20°C. Samples were maintained at –20°C during air transport to Britain, where they were stored at –80°C for up to 6 mon prior to analysis. The use of fewer than 60 eggs to generate samples for the present work and for a related study (21) had negligible impact on the local population of 30,000 breeding pairs given that natural mortality is several thousand eggs and chicks per year.

*Incubation of chicken eggs.* Fertile eggs of the domestic chicken (Ross 1 broiler-breeder strain) were obtained from a commercial hatchery. The laying hens were provided with a standard commercial diet in which 18:2n-6 and 18:3n-3, formed about 44 and 6% (w/w) respectively, of total FA but ARA and DHA were present only in trace amounts (less than 0.5%), and EPA was not detected. The proportions (wt% of total FA) of

18:2n-6, 18:3n-3, ARA, EPA, and DHA in the total lipids of the unincubated eggs were 15.3, 0.6, 1.5, 0.1, and 1.4%, respectively, consistent with the well-established FA composition of chicken eggs (1,2,25). This contrasts markedly with eggs of the king penguin, where the proportions of 18:2n-6, 18:3n-3, ARA, EPA, and DHA in total lipids were 1.9, 0.1, 1.6, 3.0, and 5.9%, respectively (21). Eggs were incubated at 37.8°C and 60% relative humidity in a benchtop incubator (Brinsea Products, Banwell, United Kingdom). Hatching occurred after 21 d and the chicks were maintained for 2 d with drinking water but no food provided. After sacrifice by decapitation, heart and muscle samples were dissected and stored at –80°C for up to 1 mon prior to analysis.

*Lipid analysis.* The methodology for lipid and FA analysis was previously described in detail (21,26). In brief, total lipids were extracted from samples of heart and skeletal muscle using the modified Folch method (27), lipid classes were separated by TLC on silica gel G using a solvent system of hexane/diethyl ether/formic acid (80:20:1, by vol), and, following exhaustive elution of the identified bands from the silica (26), the isolated PL, TAG, and cholesteryl ester (CE) were subjected to transmethylation. The resultant FAME were analyzed by GLC using a Carbowax capillary column (30 m  $\times$  0.25 mm, film thickness 0.25  $\mu$ m; Alltech, Carnforth, United Kingdom) in a CP9001 Instrument (Chrompack, Middleburg, The Netherlands) with peak integration and data analysis performed by an EZ Chrom Data Analysis System (Scientific Software, San Ramon, CA). Peaks were quantified with reference to a 19:0 standard and identified by comparison with standard FAME (Sigma, Poole, United Kingdom). FA compositions are expressed as wt%. Since minor FA (<0.2%) were not included in the tables, the sum of the presented values is less than 100%. The amounts of the lipid classes were calculated from the FA mass derived from each class together with the acyl group contribution to the M.W. of these compounds. Free cholesterol was determined using an enzymatic/colorimetric assay kit (Boehringer, Lewes, United Kingdom).

*Data analysis.* Results are expressed as mean  $\pm$  SE of values from  $n = 4$ –8 embryos or chicks. Comparison of FA compositions between two developmental stages or between penguin and chicken utilized the unpaired two-tailed Student's *t*-test after arcsine transformation of percentage values. Tissue lipid class concentrations throughout development were compared by one-way ANOVA and *post-hoc* Bonferroni tests.

## RESULTS

*Concentrations of lipid classes in heart and skeletal muscle during development of the king penguin.* Developmental changes in the tissue concentrations of PL, TAG, and CE (expressed as mg/g wet tissue) are shown in Figures 1–3. The concentration of PL in the heart of the king penguin increased by almost twofold ( $P < 0.001$ ) between day 27 of embryonic development (i.e., the halfway stage of the embryonic period) and 2 d posthatch (Fig. 1). It should be noted that the

**FIG. 1.** Concentrations (mg/g wet tissue) of phospholipid (●), TAG (○), and cholesteryl ester (▲) in the heart of the king penguin during development. Values are means of  $n = 8$  (days 27 and 33), 6 (day 40), and 4 (days 47, 53, and 55) with SE indicated by error bars.

**FIG. 2.** Concentrations (mg/g wet tissue) of phospholipid (●), TAG (○), and cholesteryl ester (▲) in leg muscle of the king penguin during development. Values are means ( $n = 4$ ) with SE indicated by error bars.

concentration of PL in the heart at the time of hatching was approximately twice as high as in the two skeletal muscle sites (Fig. 1 vs. Figs. 2 and 3). The concentration of TAG in the heart of the day 27 embryo was less than half of the value for PL at that stage and decreased by 67% ( $P < 0.01$ ) throughout the latter half of the embryonic period. Thus, by the time of hatching, the concentration of PL in the heart was 12.5 times greater than that of TAG. At day 27, CE was a relatively minor component of the heart lipids (less than a third of the PL content), but its concentration had increased by 1.8-fold ( $P < 0.02$ ) at 2 d posthatch.

PL was the major lipid class of leg muscle throughout development and its concentration increased twofold ( $P < 0.001$ ) between day 27 of embryonic life and day 2 after hatching; the apparent abrupt rise between hatching and 2 d posthatch did not reach statistical significance (Fig. 2). The concentration of TAG in this tissue also doubled ( $P < 0.001$ ) during this same period. After a decrease of 50% ( $P < 0.01$ ) between days 27 and 33, the concentration of CE was restored to its initial value by the time of hatching.

In contrast with heart and leg muscle, the concentration of PL in pectoral muscle did not undergo a net increase during this period; instead it decreased by 30% ( $P < 0.001$ ) between days 27 and 33 with the original concentration being restored by the time of hatching (Fig. 3). On the other hand, the concentrations of TAG and CE in pectoral muscle increased during development, the latter continuously so that its concentration at 2 d posthatch was 9.0 times greater ( $P < 0.001$ ) than at day 27, and the former peaked at day 47 when its concentration was 8.8 times higher ( $P < 0.01$ ) than at day 27.

*FA profiles of heart lipids during development of the king penguin.* To illustrate developmental change, the FA profiles of heart lipids at 27 and 55 days of incubation were compared, the latter time point representing day 2 after hatching. These

times represent the earliest and latest developmental stages that were sampled. ARA was the main polyunsaturate of the heart PL (Table 1), and substantial proportions of EPA and DHA were also present; however, 18:2n-6 was a very minor FA and no 18:3n-3 was detected. Between days 27 and 55, the proportions of 16:0 and 22:5n-3 in PL decreased, whereas those of 18:0, 18:1n-9, and 18:2n-6 increased; however, the most striking change was a reduction in the proportion of DHA to less than half its day 27 value.

At day 27, the most notable feature of the heart's TAG was the very high proportion of DHA. By day 55, however, the proportion of DHA had decreased by two-thirds, accompanied by a major increase in the contribution of 18:1n-9 and lesser

**FIG. 3.** Concentrations (mg/g wet tissue) of phospholipid (●), TAG (○), and cholesterol ester (▲) in pectoral muscle of the king penguin during development. Values are means ( $n = 4$ ) with SE indicated by error bars.

<sup>e</sup>*P* < 0.001; comparison with day 27.

increases in the proportions of 16:0 and 16:1n-7. DHA was the major polyunsaturate of heart CE at day 27; it was still the major polyunsaturate at day 55 although its proportion was much lower than at day 27. The other main difference during development was the 1.3-fold increase in the proportion of 18:1n-9 in CE.

*FA profiles of leg muscle lipids during development of the king penguin.* DHA was the main polyunsaturate of the PL fraction of leg muscle (Table 2) at both time points although its proportion had decreased by a quarter at the latter stage, commensurate with increased contributions from ARA and EPA. Also, the proportion of 18:0 in PL increased 1.3-fold

over this period. DHA was also the main polyunsaturate of the TAG fraction at both stages, even though its proportion had decreased by more than a third at day 55. Reductions in the contributions from ARA and EPA were also evident at the latter stage. A major increase in the proportion of 16:0, an increase in that of 18:1n-9, and a reduced contribution from 18:0 also occurred during development. Again, DHA was the predominant polyunsaturate of CE at both stages although its proportion decreased by more than half during development. The proportion of ARA was also lower at the later stage, and there was an increased contribution from 18:1n-9.

<sup>e</sup> $P < 0.001$ ; comparison with day 27.

*FA profiles of pectoral muscle lipids during development of the king penguin.* DHA, the major polyunsaturate of pectoral muscle PL (Table 3), decreased by a fifth between the two stages, commensurate with an increased proportion of ARA. A decrease in the proportion of 16:0 in PL during development was balanced by an increased contribution from 18:0. DHA was again the major PUFA of the TAG fraction, with no significant decrease during development; the proportions of 18:0 and EPA were lower at day 55, whereas the proportion of 18:1n-9 was higher. In CE, DHA was also the main polyunsaturate, although its proportion decreased by half during development; the contributions of ARA and EPA were also less at the later stage, whereas the proportion of 18:1n-9 increased 1.3-fold during development, and that of 16:0 decreased slightly.

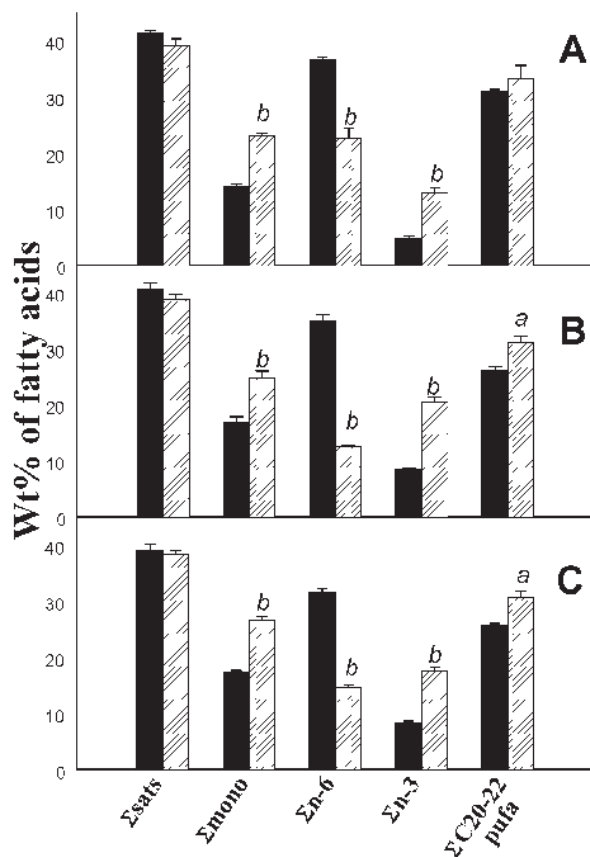

Data (not shown) from intermediate stages indicate that, for heart, leg, and pectoral muscle, the differences in FA composition between days 27 and 55 reflect continuous trends during this period.

*Comparison with the chicken.* The FA profiles of the PL fraction of the heart, leg, and pectoral muscle of the newly hatched chicken were compared (Figs. 4 and 5) with the equivalent values for the penguin at the same developmental stage (i.e., 2 d posthatch). The PL fraction was chosen since it is the main structural and functional lipid of the cell membranes. For all three tissues, the proportions of total saturates (16:0 plus 18:0) in PL did not differ between the two avian species (Fig. 5). The heart PL of the chicken displayed only half the proportion of 18:1n-9 but nearly five times as much 18:2n-6 compared with the values for the penguin; also, a 1.3-fold greater contribution from ARA in the chicken was counterbalanced by a near-absence of EPA and a lower (by a fifth) proportion of DHA (Fig. 4A). The heart PL of the chicken

**FIG. 4.** Proportions (wt% of total FA) of unsaturated FA in phospholipid of heart (A), leg muscle (B), and pectoral muscle (C) in the chicken (filled bars) and king penguin (diagonally lined bars), both at 2 d posthatch. Values are mean ( $n = 8$  and 4 for chicken and penguin, respectively) with SE indicated by error bars. <sup>a</sup> $P < 0.05$ ; <sup>b</sup> $P < 0.001$ ; comparison with chicken.

**FIG. 5.** Composite parameters (wt% of total FA) for phospholipid FA of heart (A), leg muscle (B), and pectoral muscle (C) of the chicken (filled bars) and king penguin (diagonally lined bars), both at 2 d posthatch. Abbreviations: sats, saturated FA; mono, monounsaturated FA; pufa, polyunsaturated FA. Values are means ( $n = 8$  and  $4$  for chicken and penguin, respectively) with SE indicated by error bars. <sup>a</sup> $P < 0.05$ ; <sup>b</sup> $P < 0.001$ ; comparison with chicken.

contained lower proportions of total monounsaturates and n-3 polyunsaturates but more n-6 polyunsaturates than that of the penguin, whereas the contributions of total  $C_{20-22}$  polyunsaturates did not differ between the two species (Fig. 5A). The n-6/n-3 ratio in heart PL was 7.6 for the chicken compared with only 1.8 for the penguin.

Compared with the penguin, the leg muscle PL of the chicken contained a much greater (10.2-fold) proportion of 18:2n-6 and commensurately less 18:1n-9; the contribution from ARA was 1.5 times greater in the chicken tissue, but again, EPA was almost absent and the proportion of DHA was about a third lower than in the PL of the penguin leg muscle (Fig. 4B). Thus, the leg muscle PL of the chicken was characterized by lower proportions of total monounsaturates and n-3 polyunsaturates but a higher proportion of n-6 polyunsaturates than were present in the corresponding penguin samples; the total contribution of  $C_{20-22}$  polyunsaturates was also slightly less in the case of the chicken (Fig. 5B). The n-6/n-3 ratio in leg muscle PL was 4.2 for the chicken compared with only 0.6 for the penguin.

The pectoral muscle PL of the chicken contained almost

nine times the proportion of 18:2n-6 but a lower (by a third) proportion of 18:1n-9, than that of the penguin; the contribution from ARA was 1.4 times greater in the chicken tissue, but EPA was a very minor FA and the proportion of DHA was little more than half the value for the penguin (Fig. 4C). Consequently, the contributions of total monounsaturates, n-3 polyunsaturates, and total  $C_{20-22}$  polyunsaturates were lower and that of total n-6 polyunsaturates was higher in the case of the chicken tissue (Fig. 5C). The n-6/n-3 ratio in pectoral muscle PL was 3.8 for the chicken but only 0.8 for the penguin.

## DISCUSSION

*Concentrations of lipid classes in heart and skeletal muscle during development of the king penguin.* The increased concentrations of PL in heart and leg muscle that were observed during the second half of the penguin's embryonic period may reflect the proliferation of myoblasts and subsequently, during myogenic differentiation, the formation of membranous structures, such as the sarcoplasmic reticulum and transverse tubules. In the chicken, the phase of skeletal myoblast proliferation is largely confined to the first half of embryonic development; cell fusion to form multinucleate myotubes occurs around the middle period, and myotube maturation proceeds throughout the final trimester (7). If skeletal myogenesis in the leg of the king penguin employs a similar ontogeny, then the second half of embryonic development, as studied here, is largely characterized by the stages of myoblast fusion and myotube maturation, with any cell division limited to the beginning of this period.

In contrast to the results for heart and leg muscle, the concentration of PL in the pectoral muscle of the penguin did not display a net increase over the same developmental period. This may relate to differences in the rates of maturation between the different muscle sites, such as leg muscle developing in advance of pectoral muscle. We have no quantitative data on this point, but on dissection, the pectoral muscle of the newly hatched penguin chick was markedly underdeveloped compared to leg muscle and to the situation in the adult (Decrock, F., and Groscolas, R., unpublished observations). Such observations are consistent with the fact that, at the beginning of posthatch life, the king penguin's main form of locomotion is walking; it is only later (at 1 yr of age) that it needs a powerful pectoral muscle for swimming (24).

Studies on mammalian skeletal muscle have demonstrated that intramyocellular TAG represents a dynamic energy store that accumulates particularly during periods of high fat intake and is utilized during or just after exercise (28–30). Mobilization of this TAG is catalyzed by intramuscular hormone-sensitive lipase, which is activated by adrenergic stimulation and muscle contraction (14,31). The changing concentration of TAG in the pectoral muscle of the developing king penguin may be consistent with such a role, increasing continuously and substantially (8.8-fold) between days 27 and 47 of egg incubation [a time of rapid provision of yolk-derived lipid to

the embryo (21)] followed by a 35% decrease, which, although not reaching statistical significance, could indicate mobilization of TAG to provide energy for this muscle during the hatching period. In leg muscle, the concentration of TAG increased 2.5-fold between day 27 and hatching, although the pattern of change was not continuous and the 20% decrease within 2 d posthatch did not reach significance. These findings provisionally suggest that TAG is deposited in the skeletal muscle of the developing penguin at a time when the embryo is replete with lipid and that it functions as a reserve of energy, possibly to assist with the demands of the hatching and early posthatch periods. Mobilization of the embryo's TAG stores for energy during hatching is suggested by observations that between days 49 and 54 the total lipid content of the king penguin embryo/chick decreased by 22%, and subcutaneous adipose tissue decreased by 35% (Groscolas, R., and Decrock, F., unpublished data).

By contrast, TAG did not accumulate in the heart of the embryonic king penguin; in fact, the concentration of this lipid in the heart decreased as development progressed. In mammals, myocardial TAG exists in a dynamic state, capable of providing as much as 40% of the energy needs of the beating heart while being rapidly resynthesized to minimize depletion (15). The net decrease in the heart's TAG content throughout the second half of the penguin's embryonic period, despite the intensive transfer of lipid from yolk to embryo, may reflect the substantial use of myocardial TAG as an energy source for the working heart during development.

A consequence of the transfer of lipids from yolk to the avian embryo is the formation in the plasma of CE-rich lipoprotein remnants, which are mainly taken up by the liver (1). However, in the chicken embryo, skeletal muscle is also a significant site for the disposal of plasma CE (32). This would also appear to be the case during the development of the king penguin, particularly in the pectoral muscle where the concentration of CE increased continuously from day 27 of egg incubation to day 2 after hatching.

*Effect of the (n-3)-rich yolk of the king penguin on the FA profiles of embryonic muscle.* The FA composition of the initial yolk of the king penguin (21) forms a dramatic contrast with that of the domestic chicken. Since the chicken's diet was almost devoid of ARA and DHA, the presence of these long-chain polyunsaturates in the chicken's egg is most likely due to desaturation/elongation of dietary 18:2n-6 and 18:3n-3 in the liver of the hen (1,25). In the total yolk lipid, the penguin eggs contained 4.2 times the proportion of DHA and 6.4 times the proportion of C<sub>20-22</sub> n-3 FA in the chicken eggs used in this study. The proportion of ARA was similar for the two species, whereas the chicken yolks displayed an eightfold greater proportion of 18:2n-6. Consequently, the n-3/n-6 ratio of the yolk was 3.0 for the penguin but only 0.1 for the chicken.

An aim of the present work was to evaluate the impact of such disparities on the FA profiles of the developing heart and muscle. Despite the preponderance of C<sub>20-22</sub> n-3 FA in the yolk of the king penguin, the PL of the developing heart of

this species contained ARA as the main polyunsaturate, consistent with an essential role for this n-6 FA in the regulation of cardiomyocyte contraction (10,11). The characteristic fatty acyl profile of the penguin eggs was not, however, without effect on the heart's PL composition since the proportion of ARA was less than in the chicken's heart at the same developmental stage, whereas in the heart of the penguin the contribution from DHA was slightly higher and that of EPA was far more pronounced. It is notable that the total proportion of C<sub>20</sub> polyunsaturates (i.e., ARA plus EPA) in the posthatch heart PL, at  $26.8 \pm 2.7\%$  and  $25.4 \pm 0.2\%$  for the penguin and chicken, respectively, did not differ significantly between the two species. Thus, it is feasible that in the penguin's cardiomyocytes EPA makes a contribution to the signaling functions that in other species are performed entirely by ARA.

Similarly, the skeletal muscle PL of the posthatch king penguin displayed less ARA, more DHA, and far more EPA than the equivalent chicken samples. Nevertheless, the proportions of total C<sub>20</sub> polyunsaturates were again very similar for the two species. Thus, in leg muscle PL, ARA plus EPA formed  $16.8 \pm 0.6$  and  $16.3 \pm 0.6\%$  for the penguin and chicken, respectively, the equivalent values for pectoral muscle being  $15.4 \pm 0.5$  and  $16.5 \pm 0.1\%$ . In neither case were these summed proportions significantly different between the two species. Again, this may imply that some of the regulatory functions normally attributable to ARA have, in the penguin's skeletal muscle, been partly delegated to EPA.

These findings suggest that the PL FA profiles of the developing heart and skeletal muscle of the king penguin represent a compromise between the tissue-specific requirements for particular polyunsaturates (i.e., those that have a defined role in the function and regulation of myocytes) and the pattern of FA that are supplied from the yolk. Thus, the typical "high-ARA" profile of heart PL is upheld in the penguin embryo but in a modified form in which the contribution from n-3 FA is greater than in other avian species (1,33). However, the variation in functional maturity between tissues of the precocial chicken and the semialtricial penguin at the time of hatching (34) should also be considered as a possible contributory factor to the differences in tissue FA profiles.

A consistent finding was that the proportion of DHA in penguin muscle PL was high at day 27 of incubation but then decreased significantly during the second half of the embryonic period; in the case of the two skeletal muscle sites, this was accompanied by a significant increase in the proportion of ARA. The biological relevance of these changes in polyunsaturate composition is not clear but could relate to maturation-dependent modifications in membrane fluidity or lipid-mediated regulatory mechanisms. It is also unclear whether the decreases in the proportion of DHA in myocellular TAG and CE that occurred during the second half of embryonic life are related in some way to the functions of these lipids in the maturing muscle.

The FA composition of the food (myctophid fishes) that is supplied to the newly hatched king penguin by its parents differs from that of the yolk in several respects (21,22). As a

result, the hatchling will consume higher proportions of EPA, DHA, and long-chain (C<sub>20-22</sub>) monounsaturates and a lower proportion of ARA than the embryo (21). The consequences of this nutritional transition on the FA profiles and physiology of the cardiac and skeletal muscles during the posthatch period remain to be investigated.

The king penguin, whose eggs exhibit the highest proportion of C<sub>20-22</sub> n-3 FA yet reported for any bird (21), provides an extreme example to assess the relationship between the FA composition of the yolk and that of embryonic tissues such as the heart, which in most species is dominated by ARA (1,33). The data suggest that the esterification reactions involved in the synthesis of heart PL display a high degree of selectivity in the penguin embryo to sustain a "high-ARA" profile despite the predominance of n-3 FA in the lipids supplied from the yolk. This profile is, however, modified by the presence of higher proportions of EPA and DHA than are found in the heart PL of other species (1,33). In the penguin embryo, the FA-dependent signal transduction cascades that regulate cardiac function (10,11) are presumably adapted to accommodate this modified composition, possibly by employing EPA as well as ARA in these roles. A similar argument may apply to any regulatory roles of n-6 and n-3 polyunsaturates in the developing skeletal muscle.

## ACKNOWLEDGMENTS

We are grateful to Institut Français pour la Recherche et la Technologie Polaires (Program 119) and to the Scottish Executive Rural Affairs Department for financial support. Logistical support was provided by Terres Australes et Antarctiques Françaises. The project was approved by the ethical committee of the Institut Français pour la Recherche et la Technologie Polaires and conformed to the Agreed Measures for the Conservation of Antarctic and Subantarctic Fauna.

# Cloning and Molecular Characterization of the $\Delta 6$ -Desaturase from Two *Echium* Plant Species: Production of GLA by Heterologous Expression in Yeast and Tobacco

Federico García-Maroto<sup>a</sup>, José A. Garrido-Cárdenas<sup>a</sup>, Juan Rodríguez-Ruiz<sup>b</sup>, Miguel Vilches-Ferrón<sup>b</sup>, Ana C. Adam<sup>c</sup>, Julio Polaina<sup>c</sup>, and Diego López Alonso<sup>b,\*</sup>

Departamentos de <sup>a</sup>Bioquímica and <sup>b</sup>Biología Aplicada, Facultad de Ciencias Experimentales, Universidad de Almería, E-04120 Almería, Spain, and <sup>c</sup>Instituto de Agroquímica y Tecnología de Alimentos, Consejo Superior de Investigaciones Científicas, E-46100 Burjassot, Valencia, Spain

**ABSTRACT:** The synthesis of GLA ( $\Delta 6,9,12$ -18:3) is carried out in a number of plant taxa by introducing a double bond at the  $\Delta 6$  position of its precursor, linoleic acid ( $\Delta 9,12$ -18:2), through a reaction catalyzed by a  $\Delta 6$ -desaturase enzyme. We have cloned genes encoding the  $\Delta 6$ -desaturase (D6DES) from two different Macaronesian *Echium* species, *E. pitardii* and *E. gentianoides* (Boraginaceae), which are characterized by the accumulation of high amounts of GLA in their seeds. The *Echium* D6DES genes encode proteins of 438 amino acids bearing the prototypical cytochrome b<sub>5</sub> domain at the N-terminus. Cladistic analysis of desaturases from higher plants groups the *Echium* D6DES proteins together with other  $\Delta 6$ -desaturases in a different cluster from that of the highly related  $\Delta 8$ -desaturases. Expression analysis carried out in *E. pitardii* shows a positive correlation between the D6DES transcript level and GLA accumulation in different tissues of the plant. Although a ubiquitous expression in all organs is observed, the transcript is particularly abundant in developing fruits, whereas a much lower level is present in mature leaves. Functional characterization of the D6DES gene from *E. gentianoides* has been achieved by heterologous expression in tobacco plants and in the yeast *Saccharomyces cerevisiae*. In both cases, overexpression of the gene led to the synthesis of GLA. Biotechnological application of these results can be envisaged as an initial step toward the generation of transgenic oleaginous plants producing GLA.

Paper no. L8951 in *Lipids* 37, 417–426 (April 2002).

GLA ( $\Delta 6,9,12$ -18:3) is recognized as an EFA in human nutrition. Its deficiency causes several health disorders, and it has also been claimed that its administration prevents some diseases (1–3). In particular, GLA has been shown to improve skin function in elderly people (4), attenuate body fat accumulation (5), and have a selective tumoricidal action over human gliomas (6,7).

GLA is synthesized from linoleic acid ( $\Delta 9,12$ -18:2, LA) by the activity of the enzyme  $\Delta 6$ -desaturase (D6DES) that introduces a new double bond into the  $\Delta 6$  carbon (8). The same

enzyme is able to introduce a  $\Delta 6$  desaturation into  $\alpha$ -linolenic acid ( $\Delta 9,12,15$ -18:3, ALA), producing octadecatetraenoic acid ( $\Delta 6,9,12,15$ -18:4, OTA) (9). Although present in humans, D6DES activity is apparently too low to provide enough GLA to satisfy body needs. Therefore, GLA has interest as an essential nutrient and as a component of some pharmaceutical products and functional foods.

GLA is currently marketed from seeds of a few plant species, e.g., evening primrose (*Oenothera biennis*), common borage (*Borago officinalis*), and black currant (*Ribes nigrum*). However, current sources have been recognized as inadequate for the continuous demand of an expanding market (10–12), since they are not oil-rich plants, and their agronomic practices are not as well developed as for other crops. Therefore, attempts have been made to find alternative sources (13). In this sense, GLA production from genetically modified organisms, including oilseed plants, has been suggested as a possible alternative (13–16). Initial attempts at overexpression of D6DES genes in heterologous systems have emphasized the importance of the gene origin and host organism. For instance, functional expression of the D6DES gene from a cyanobacterium was very inefficient when performed in a higher plant, tobacco (15), whereas performance of the *Borago* D6DES was much better in the same host plant (17). Therefore, D6DES genes from higher plants seem to be a better choice (instead of those from fungi or cyanobacteria) when used as transgenes in oilseed crops.

A group of endemic Macaronesian plants from the genus *Echium* (Boraginaceae) were recently identified as among the richest sources of GLA found in nature (18). Among them, *E. gentianoides* showed an exceptional GLA content in the seed, 28% of total FA (19), which makes this species an interesting source of the D6DES gene. However, *E. gentianoides* is a perennial shrub whose flowering takes about 2–3 yr in its natural habitat, a major problem when a study of gene expression in floral tissues and developing fruits is intended. To overcome this problem, a closely related species, *E. pitardii*, was also used in our studies to perform a molecular characterization of the D6DES gene. Although somewhat less efficient in GLA seed accumulation (22%), *E. pitardii* has the advantage of an annual life cycle that is completed in about 4 mon in the laboratory.

Abbreviations: ALA,  $\alpha$ -linolenic acid; CaMV, cauliflower mosaic virus; DIG, digoxigenin; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; IPCR, inverse polymerase chain reaction; LA, linoleic acid; MS, mass spectrometry; OTA, octadecatetraenoic acid; PCR, polymerase chain reaction.

In this work, we obtained the genomic sequences for the  $\Delta 6$ -desaturase genes of *E. gentianoides* (*EGD6DES*) and *E. pitardii* (*EPD6DES*). A molecular characterization of these genes, including the expression pattern analysis, was performed. Functionality of the putative *D6DES* product was proved by heterologous expression of *EGD6DES* in tobacco *calli* and in the yeast *Saccharomyces cerevisiae*. In transgenic tobacco *calli* the synthesis of GLA and OTA was achieved from the endogenous substrates LA and ALA, respectively, whereas GLA production in the yeast took place from exogenously incorporated LA. These results pave the way for the generation of oilseed plants overexpressing the *EGD6DES* gene.

## MATERIALS AND METHODS

**Plant material.** Seeds from *E. gentianoides* Webb ex Coincy and *E. pitardii* A. Chev. were collected in their natural habitats at the Macaronesian island of La Palma (Canary Islands) during the summers of 1999 and 2000. Tobacco plants, *Nicotiana tabacum* var. Wisconsin 38, were used for transformation experiments. All plants were grown at 25°C under controlled conditions in growth cabinets with a 16 h light/8 h dark photoperiod.

**Microbial strains.** *Agrobacterium tumefaciens* LBA4404 (20) was used as a vector for plant transformation. The *S. cerevisiae* strain used in this work was Sc340: *MATa ade1 leu2 ura3 his3::P<sub>GAL10</sub>-GAL4-URA3* (21,22). Cloning procedures in *Escherichia coli* were carried out with strain DH5 $\alpha$  as the host.

**Cloning and sequence analysis of the *D6DES* genes.** Cloning of the *D6DES* gene from *EGD6DES* was achieved by polymerase chain reaction (PCR) amplification of a partial sequence, followed by bi-directional genomic walking through inverse PCR (IPCR). Initially, a 550 bp PCR fragment corresponding to amino acid positions 187 to 369 (Fig. 1) was obtained by using the degenerate oligonucleotides BO-1 [5'-AT(A/C)AG(T/C)AT(T/C)GGTTGGTG-GAA(A/G)TGG-3'] and BO-2 [5'-AATCCACC(A/G)TG-(A/G)AACCA(A/G)TCCAT-3'] as primers and genomic DNA from *E. gentianoides* as a template, following standard PCR protocols. The product was cloned into the pGEM-T-Easy® vector (Promega, Madison, WI) and the sequences for several clones were obtained from both strands by the dideoxy method using a PerkinElmer (Foster City, CA) ABI-377 DNA automated sequencer. Two sequences were obtained that were identified as corresponding to the putative  $\Delta 6$ -desaturase and the highly related  $\Delta 8$ -desaturase, based on the comparison to the orthologous genes from *B. officinalis*. From the *D6DES* partial sequence, two nested upstream primers, GE-1 (5'-GAGGTGAGCGAGCTAAACA ACTTG-3') and GE-2 (5'-AACATATTGACCCTAGCGGAACA-3'), and two nested downstream primers, GE-3 (5'-CTCGGTGACTGGAATGCAACAAG-3') and GE-4 (5'-CGGCGAGT-GTTTATGTTGGTCAG-3'), were designed to perform the IPCR essentially as described (23). The DNA was digested with one of the enzymes *Hind*III or *Ssp*I and subjected to circularization followed by two nested rounds of PCR amplification. Suitable fragments were analyzed and sequenced as de-

scribed before. With this approach, we obtained about 2.5 kbp of genomic sequence, comprising 120 bp upstream of the initiation ATG and some 1.1 kbp downstream of the stop codon.

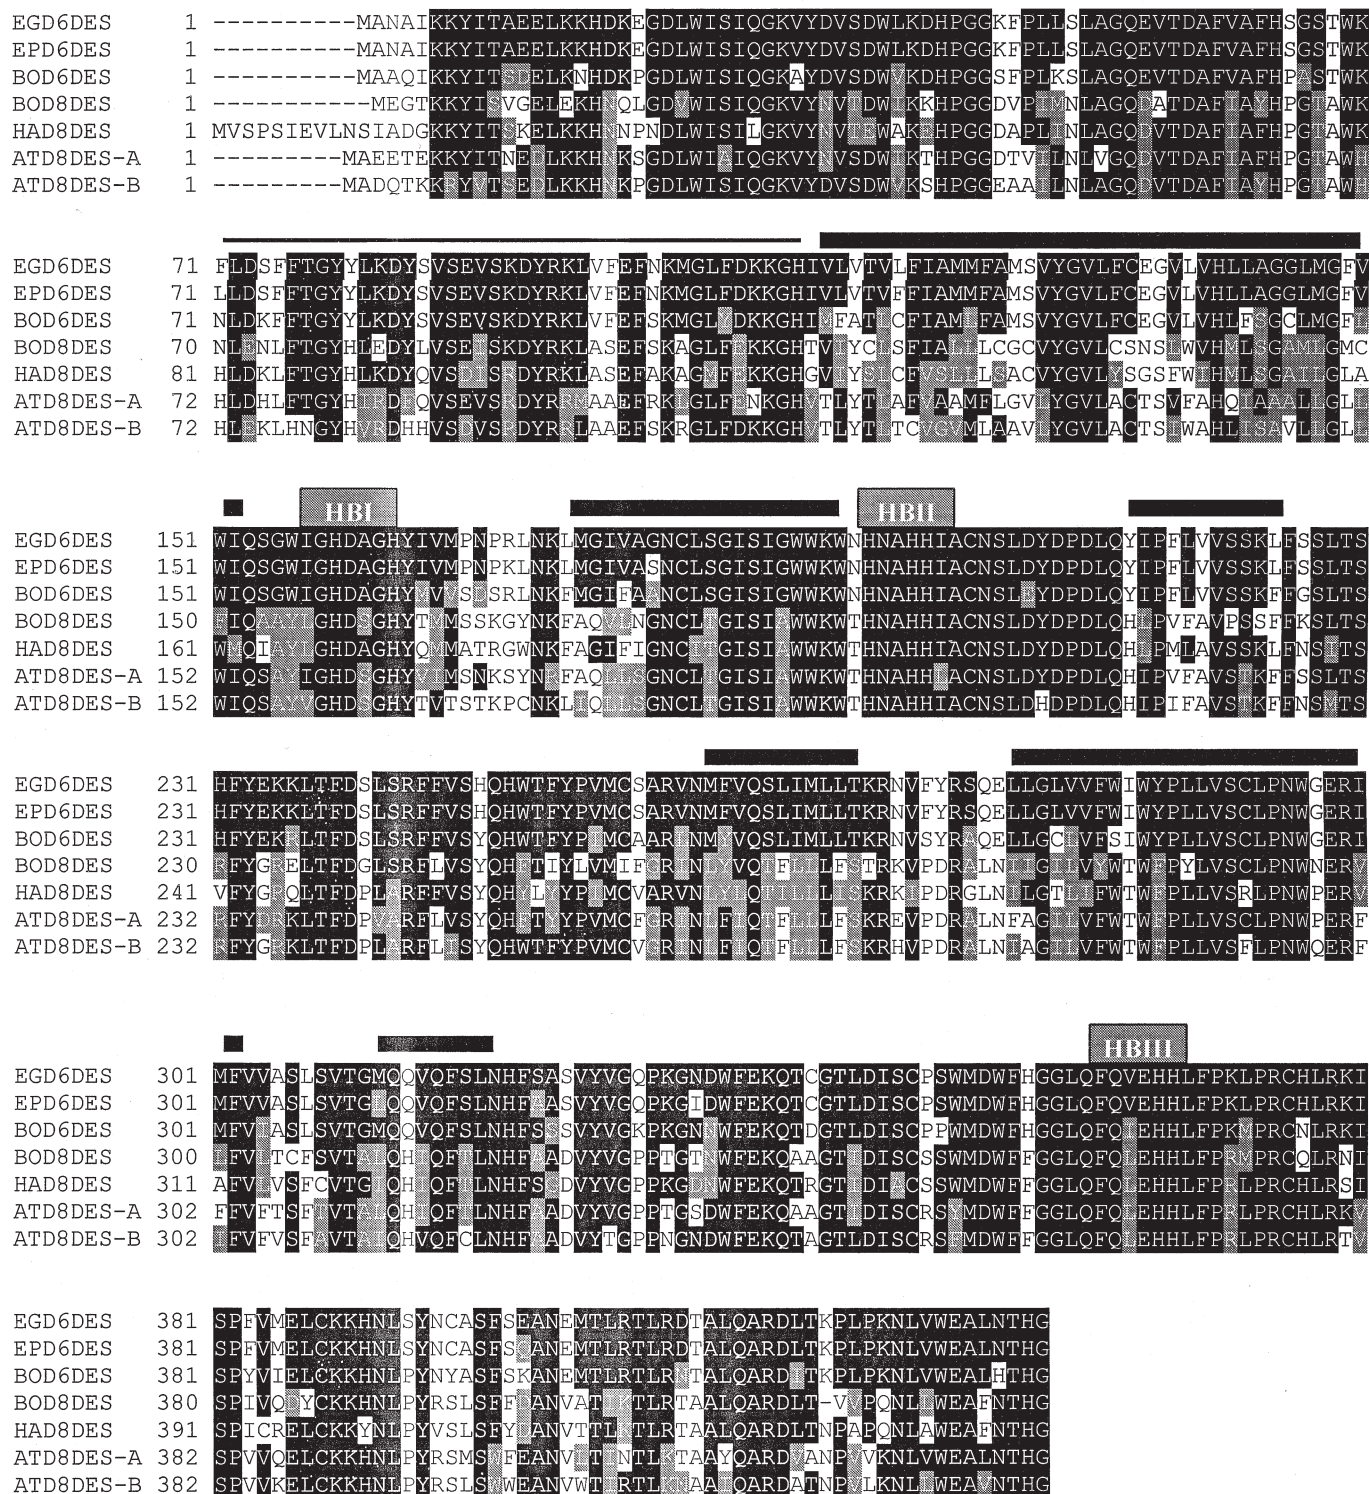

A genomic DNA fragment containing the whole coding sequence (besides 36 and 97 bp of the 5'- and 3'-untranslated regions, respectively) for *EGD6DES* was obtained by PCR amplification using suitable upstream GE-5 (5'-TGGATCACCAAA-CACAGTAGTAAG-3') and downstream GE-6 (5'-TCCAACA-AGTAGAACCAATGCAAG-3') primers and a reading-proof polymerase (AccuTaq®, Sigma). The fragment was cloned and sequenced as indicated. Similarly, a whole genomic clone for the *D6DES* gene from *EPD6DES* was obtained by PCR on genomic DNA, using the same GE-5 and GE-6 flanking primers.

**Cladistic analysis.** Alignment of amino acid sequences for desaturase proteins was done using the program Clustal X v.1.7 (24) (European Molecular Biology Laboratory, Heidelberg, Germany) with the default settings. For the selected sequences in Figure 1, the alignment was visualized using the Boxshade v. 3.21 program (European Molecular Biology Laboratory). The whole alignment output was used to generate a phylogenetic tree (Fig. 2) based on the neighbor-joining algorithm of Saitou and Nei (25) with the following parameters: The whole amino acid sequence of the protein was considered, positions with gaps were not excluded, and distances were not corrected for multiple substitutions. Bootstrap values over 1,000 replicates were also calculated using the same program. The resulting phenogram was drawn using the program TreeView (University of Glasgow, Glasgow, United Kingdom) (26).

**Southern and Northern blot analysis.** Genomic DNA was isolated from *Echium* seedlings by a cetyltrimethylammonium bromide-based extraction procedure (27). DNA (about 3  $\mu$ g) was restricted with the appropriate restriction enzymes, separated on a 0.8% agarose gel, and transferred by capillarity onto Hybond® N+ nylon membranes (Amersham, Buckinghamshire, United Kingdom). Filters were fixed by baking, prehybridized at 42°C for 5 h in the 50% formamide/High SDS buffer recommended by the digoxigenin (DIG) manufacturer (Boehringer-Mannheim, Mannheim, Germany), and hybridized at the same temperature and same buffer solution (stringent conditions), containing the DIG-labeled *EGD6DES* specific probe at 25 ng/mL. High stringency washes were performed twice at 65°C during 15 min in buffer containing 0.5  $\times$  SSC (1  $\times$  SSC = 150 mM NaCl, 15 mM sodium citrate, pH 7.0) and 0.1% SDS, and the luminogenic substrate CSPD® (Boehringer-Mannheim) was used for detection following the instructions provided with the DIG detection kit. Images were obtained by exposure of Biomax ML® films (Kodak, Rochester, NY) for 10–25 min and final developing by standard procedures. The *EGD6DES* probe was obtained by random primed labeling from a PCR fragment (Fig. 3) generated with primers GE-4 and GE-6, corresponding to the last 115 amino acids of the protein and about 100 bp of the 3'-untranslated region. Probe specificity was previously confirmed by the absence of cross-hybridization under the same conditions with a highly homologous  $\Delta 8$ -desaturase fragment from *Echium* (not shown).

Cytochrome b<sub>5</sub>

**FIG. 1.** Sequence comparison between *Echium* D6DES and related D6DES and D8DES proteins from higher plants. The amino acid sequences of  $\Delta 6$ -desaturases of *E. gentianoides* (EGD6DES, acc. no. AY055117), *E. pitardii* (EPD6DES, AY055118), *Borago officinalis* (BOD6DES, U79010), and  $\Delta 8$ -desaturases from *B. officinalis* (BOD8DES, AF133728), *Helianthus annuus* (HAD8DES, S68358), and *Arabidopsis thaliana* (ATD8DES-A, AAC62885.1; and ATD8DES-B, CAB71088.1) are aligned by using the Clustal X (v1.7) software (European Molecular Biology Laboratory, Heidelberg, Germany). The Boxshade program (European Molecular Biology Laboratory) is used to highlight the homology between protein sequences. Shading is applied when there is agreement for a fraction of sequences above 0.5. Amino acids identical to EGD6DES are enclosed in black boxes and similar residues are in grey boxes. The N-terminal cytochrome-b<sub>5</sub> domain, as well as the position of the three characteristic histidine boxes (HBI to HBIII), are also indicated. Putative transmembrane regions of EPD6DES predicted by the TMPRED software (48) are marked with thick black bars.

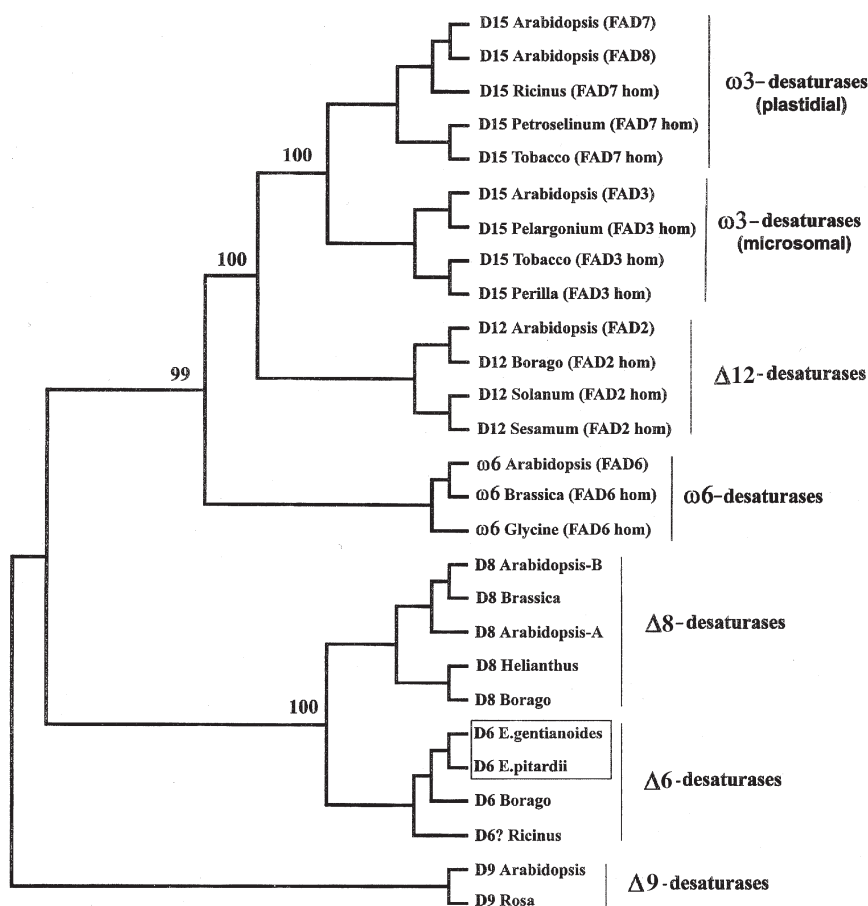

FIG. 2. Neighbor-joining tree illustrating relationships among *Echium* D6DES proteins and other desaturases from dicot species. Amino acid sequences were analyzed as described in the Materials and Methods section. EGD6DES and EPD6DES proteins reported in this paper are indicated enclosed by a square. The tree was rooted using  $\Delta 9$ -desaturases as the outgroup. Bootstrap values are expressed as percentages (over 1000 replicates) at relevant nodes.

Total RNA was extracted from different tissues of *E. pitardii* plants grown to maturity following the method of Chang *et al.* (28). About 5  $\mu$ g per lane of total RNA was loaded onto an agarose/formaldehyde gel, electrophoretically separated, and transferred to Hybond-N+ membranes. Filters were hybridized at 50°C (stringent conditions) as described for Southern analysis using the same *EGD6DES* specific probe. Stringent washes, accomplished at 68°C, and detection of the DIG labeled probe were as indicated before. As a control, the filters were rehybridized with a 900 bp cDNA probe from tobacco, which encodes part of the cytosolic glyceraldehyde-3-phosphate dehydrogenase gene (29). In this case, hybridization was done in the same conditions, but the final washes were performed at 65°C.

**Tobacco transformation and generation of calli.** A full DNA genomic fragment encoding the whole EGD6DES protein and part of the 5' and 3'-untranslated regions was obtained by PCR as indicated before. The fragment was sequenced to check for the absence of PCR mutations and cloned in the sense orientation at the polylinker of the transcriptional fusion vector pJIT60 (30) between a 35S CaMV promoter containing a duplicate enhancer sequence and

appropriate termination-polyadenylation signals. The *KpnI-XhoI* "cassette" containing the transcriptional fusion was liberated and cloned into the pBIN19 binary vector (31), and the resulting construct was used to transform the *A. tumefaciens* LBA4404 strain. Tobacco leaf disc transformation was achieved essentially as described by Horsch *et al.* (32). The *calli* were obtained by incubation of tobacco leaf disks in Murashige-Skoog medium containing 30 g/L glucose, 0.1 mg/L 6-benzylamino-purine, 1 mg/L  $\alpha$ -naphthalene acetic acid, 100 mg/L kanamycin, 500 mg/L cefotaxime, and 1 mL/L vitamins (stock solution from Sigma). Incubation was performed in petri dishes kept in growth chambers at 25°C under a 12L/12D photoperiod regime.

**Yeast transformation.** *Saccharomyces cerevisiae* Sc340 strain was transformed by the procedure of Ito *et al.* (33) with plasmid pYexD6D. This plasmid was constructed by cloning the *E. gentianoides* D6DES gene under control of the *CYC-GAL* hybrid promoter of expression vector pEMBLyex4 (34). Transformant colonies were selected by complementation of the *leu2d* marker. Yeast-transformed clones were grown for about 48 h at 30°C in standard minimal medium supplemented with the auxotrophic requirement of the strain. The

**FIG. 3.** Genomic structure of the *D6DES* gene of *Echium gentianoides*. (A) Restriction map of the *EGD6DES* genomic sequence reconstructed by inverse polymerase chain reaction. Enzyme symbols are stated below. Position of the *EGD6DES*-specific probe is indicated by a bar. (B) Southern blot analysis of *EGD6DES* in *E. gentianoides*. DNA was digested with *Hind*III (H3), *Hind*II (H2), *Rsa*I (R), *Dra*I (D), *Hae*III (H), or *Vsp*I (V) restriction endonucleases, and hybridization was performed under stringent conditions, as described in the Materials and Methods section, using the *EGD6DES*-specific probe (Fig. 3B). Size markers (kbp) positions are indicated.

cells were collected by centrifugation and transferred to a medium suited for the induction of the *GAL* promoter, which contained 1% yeast extract, 2% peptone, 0.5% glucose, and 1% galactose. The induction medium also contained 25  $\mu$ M of the GLA precursor LA (final concentration) prepared in Tergitol (1% final concentration). The transformant cells were incubated in the induction medium at 20°C and samples were taken for analysis after 24 and 48 h.

**FA analysis.** The biomass (tobacco *calli* or yeast) was previously lyophilized. Simultaneous lipid extraction and generation of FAME were performed as described elsewhere (35). For some experiments, fresh tobacco *calli* were directly analyzed following the same method. FA composition was determined by GLC as in (35). GC-MS analysis was carried out using a Varian (Palo Alto, CA) 3400 gas chromatograph-Saturn 3 ion trap mass spectrometer operating at an ionization voltage of 70 eV with a scan range of 60–650 Da. The mass spectra of the relevant peaks were compared to those of standards processed by the same equipment.

## RESULTS

**Cloning of genes encoding the  $\Delta$ 6-desaturase from *Echium* plants.** The complete genomic sequence for the *D6DES* gene of *E. gentianoides* was obtained by PCR amplification of a partial sequence fragment, followed by walking in both directions by IPCR (see the Materials and Methods section).

Degenerated primers corresponding to highly conserved motifs (ISIGWWKW, and MDWFHGG) of  $\Delta$ 6- and  $\Delta$ 8-desaturases (Fig. 1) were used to amplify from the genomic DNA of *E. gentianoides* a 550 bp PCR fragment that was subsequently cloned in a T-vector. Several clones were sequenced, allowing the identification of putative  $\Delta$ 6- and  $\Delta$ 8-desaturase sequences based on the comparison to the *Borago* orthologues. From the partial *D6DES* sequence, gene-specific primers were designed that allowed the obtaining of several IPCR clones and the assemblage of a 2.5 kbp genomic sequence containing the whole coding region. Finally, genomic fragments comprising the coding sequence of genes from *EGD6DES* and *EPD6DES* were obtained by PCR amplification on genomic DNA using flanking primers derived from the *E. gentianoides* sequence. None of these genes contained intervening sequences showing 98% of identity at the DNA level. The two genes presented very similar open reading frames encoding proteins of the same length, 438 amino acids (Fig. 1). The *Echium* proteins shared a high similarity, with only seven amino acid changes (three of them conservative). Both proteins are highly homologous to  $\Delta$ 6- and  $\Delta$ 8-plant desaturases (Fig. 1). They exhibit the prototypical cytochrome  $b_5$  domain at the N-terminus, as reported for other  $\Delta$ 6- and  $\Delta$ 8-desaturases (36). In addition, three Histidine boxes, the third one conforming to the characteristic consensus QXXHH of these desaturases, are found at the corresponding positions. Putative trans-membrane regions are predicted to occur

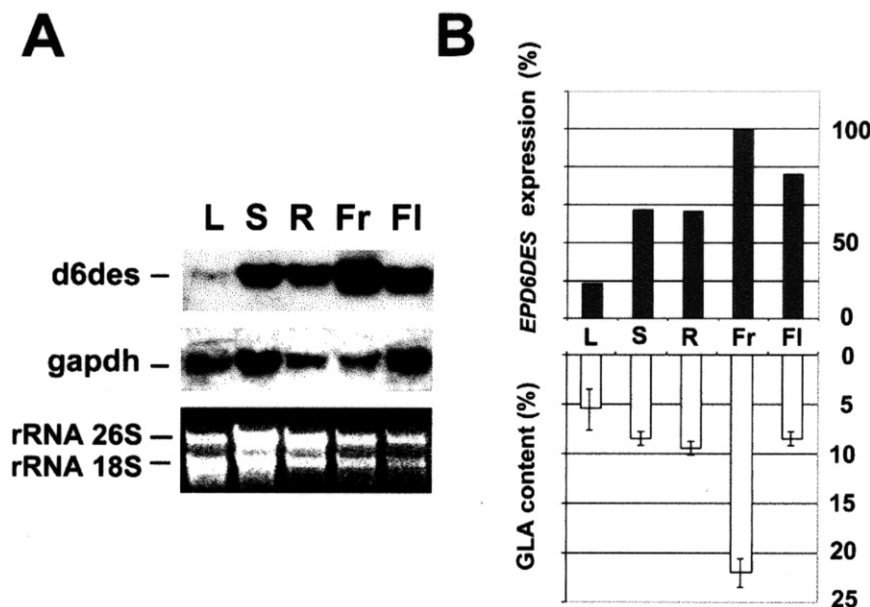

(Fig. 1) according to their location as membrane-bound proteins. Protein BLAST search revealed the highest homology to D6DES of *B. officinalis*, sharing 85% of identical residues with EGD6DES. Clustering analysis including representative members of the different desaturase classes shows a clear grouping of the two *Echium* proteins with the D6DES of *Borago* and a still uncharacterized protein from *Ricinus* (acc. no. AF005096). These proteins make up a separate clade (supported by a 100% bootstrap value) to that of the highly related  $\Delta 8$ -desaturases. This provides evidence for the identification of the *Echium* gene products as  $\Delta 6$ -desaturases.

**Genomic organization and expression analysis of the *Echium*  $\Delta 6$ -desaturase.** Genomic structure and organization of the *D6DES* gene in *Echium* was investigated by Southern blot analysis. Genomic DNA from *E. gentianoides* was digested with six different restriction enzymes followed by hybridization with a *EGD6DES* specific probe (see the Materials and Methods section) under stringent conditions. Single hybridization bands were obtained with five enzymes that do not cut within the probe (Fig. 3B), thus indicating that the *EGD6DES* gene is represented in the haploid genome by a single copy. Moreover, sizes for the hybridization fragments comprising the coding region are in agreement with the genomic sequence assembled by IPCR walking (Fig. 3A), thus confirming that the *D6DES* genes do not possess introns.

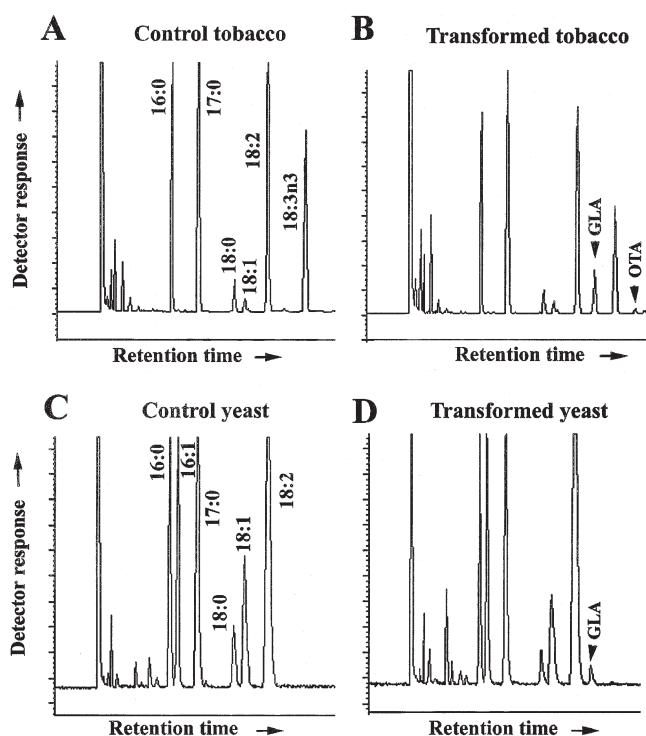

Similar results were obtained from Southern analysis in *E. pitardii* (results not shown).

The expression pattern of the *D6DES* was analyzed by Northern blot on total RNA from different tissues of *E. pitardii*. Hybridization with the *EGD6DES* specific probe under stringent conditions resulted in relatively strong hybridization signals for samples corresponding to stems, roots, flowers, and developing fruits, this latter tissue giving the highest intensity. Conversely, the *EPD6DES* RNA was found at a comparative low level in the leaves (Fig. 4A). In the same experiment expression of the housekeeping gene *GAPDH* served as a positive hybridization control. The relative transcript levels (normalized in base to RNA loading) of *EPD6DES* showed a good correlation with the GLA content determined for the different tissues (Fig. 4B). This might be an indication that in *Echium* plants the GLA content in a given tissue might be primarily governed by the steady-state level of the *D6DES* mRNA.

**Functional analysis of the *Echium*  $\Delta 6$ -desaturase by heterologous expression in tobacco calli.** In order to demonstrate that the *Echium* genes actually encode enzymes with a  $\Delta 6$ -desaturase activity, we have introduced *via Agrobacterium* the complete *EGD6DES* gene under the control of a constitutive 35S CaMV double promoter in tobacco, a plant that does not accumulate GLA. The phospholipid-bound LA, which is

**FIG. 4.** Expression analysis of the *EPD6DES* gene. (A) Northern experiment of the *D6DES* of *Echium pitardii*. Equivalent amounts of total RNA from leaves (L), stems (S), roots (R), developing fruits (Fr), and developing flowers (F) were hybridized with the *EGD6DES*-specific probe (Fig. 3A) under high-stringency conditions, as indicated in the Materials and Methods section. The expression pattern of the cytosolic glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*), a constitutive gene used as a control, is shown below beside the ethidium bromide staining of the gel. The *GAPDH* probe was obtained from tobacco. (B) Comparison of the GLA content and *D6DES* expression in different tissues of *E. pitardii*. Relative *D6DES* expression (above), normalized in base to RNA loading, is expressed as a percentage over the maximum level attained in developing fruits. GLA content is shown (below) as a percentage of total FA. These data were determined in triplicate as described in the Materials and Methods section, and the mean values beside their SE intervals are indicated in the figure.

**FIG. 5.** Identification by GC of GLA in tobacco and yeast transformed with the *Echium D6DES* gene. FAME of total lipids of tobacco *calli* (A,B) and *Saccharomyces cerevisiae* (sc340) grown under inductive conditions in the presence of the linolenic acid substrate (C,D). (A) Control tobacco *calli* transformed with the pBIN19 vector alone. (B) Tobacco *calli* transformed with the *EGD6DES* gene under control of the CaMV constitutive promoter. (C) Control yeast transformed with the pEMBLyex4 vector alone. (D) Yeast transformed with the *EGD6DES* gene under control of the  $P_{CYC-GAL}$  inducible promoter. Positions of the additional peaks (GLA and OTA) are indicated by arrows. Heptadecanoic acid (17:0) is included in the analysis as an internal standard. OTA, octadecatetraenoic acid.

the main substrate for D6DES, is present at a high level in tobacco tissues. Therefore, synthesis of GLA was expected in the transformed plants. To speed-up the assay, *calli* derived from leaf discs were analyzed for FA composition. As a negative control tobacco *calli* transformed with the pBIN19 vector alone was used. A total of 22 *calli* samples representing individual transformation events were screened for both the control and 35S::*EGD6DES* constructs. In all transgenic samples harboring *EGD6DES*, the presence of an additional peak with a retention time corresponding to GLA was apparent (Fig. 5B), as compared to the control (Fig. 5A). Further identification of this compound as GLA was achieved by GC-MS using the pure GLA-methyl ester as a standard (data not shown). The mass spectra of the unknown and GLA standard were identical. In this experiment, GLA was found in variable amounts ranging in the different samples from 1.9 to 11.8% on total FA (Table 1). This variation should be attributed to positional effects of the T-DNA insertion in each individual *callus*. The presence of a second additional peak corresponding to the OTA was also observed in a number of transgenic samples (Figs. 5A and 5B). Identification by GC-MS of the new peak was

<sup>a</sup>Control experiment correspond to *calli* transformed with the empty vector pBIN19.

<sup>b</sup>Contributions of individual FA are expressed as percentage of total FA. Total FA are calculated as percentage of the dry callus weight.

<sup>c</sup>The results are from the analysis of 10 individual *calli*. LA, linoleic acid; ALA,  $\alpha$ -linolenic acid; OTA, octadecatetraenoic acid.

achieved by comparison with the OTA standard (data not shown). Again this compound was expected to be produced by the D6DES activity using the endogenous ALA as a substrate. It is noteworthy that, when detected, the amount of OTA was consistently lower than GLA (Table 1).

*Functional expression of the Δ6-desaturase from Echium in the yeast S. cerevisiae.* The complete coding region of *EGD6DES* (see the Materials and Methods section) was cloned in the yeast expression vector pEMBLyex4 under control of the  $P_{CYC-GAL}$  promoter inducible by galactose. The resulting plasmid (pYexD6D) was used to transform *S. cerevisiae* strain Sc340. This strain carries a construction in which the *GAL4* gene under control of the  $P_{GAL10}$  promoter is located at the site that interrupts the *HIS3* gene. *GAL4* encoded an enhancer protein that triggers the expression of genes activated by galactose. The *GAL4* protein is present in the cell in very low amounts. Therefore, the Sc340 construction amplifies the expression of genes placed under control of *GAL* promoters (21,22). The transformed yeast strains were cultured under inductive conditions in the presence of LA provided as exogenous substrate. This FA is not synthesized by the yeast, but it is efficiently incorporated, reaching about 70% of the total FA in the cell under our experimental conditions. Extracts of yeast cells transformed with the *EGD6DES* gene showed a peak not present in the extracts of control cultures transformed with the vector alone (Figs. 5C and 5D). The retention time in GC experiments coincides with that of GLA, and the identity of the compound was confirmed by GC-MS analysis (not shown). In this case, GLA accumulation reached a maximum of 1.5% of total FA.

## DISCUSSION

*Functional characterization of the Echium D6DES gene.* Here we provide evidence for the identification of the gene products *EGD6DES* and *EPD6DES* as functional  $\Delta 6$ -desaturases. First, a high similarity of their protein sequences was found with other previously characterized D6DES, mainly *B.*

*officinalis*, a species belonging to the same family of plants. However, as it has been pointed out (11), sequence similarity among desaturases should be considered cautiously before assigning a particular function to an unknown protein. For example, a sunflower desaturase, showing a high homology to the *Borago* D6DES (BOD6DES), was identified as a  $\Delta 8$ -desaturase active on sphingolipids rather than on glycerolipids (37). This is further supported by directed mutagenesis experiments in which few amino acid changes in a desaturase resulted in drastic alterations in the substrate specificity regarding acyl chain length and desaturation position (38). Nevertheless, clustering analysis of desaturases from higher plants separates with a high reliability the group integrated by BOD6DES and the *Echium* desaturases from that of the  $\Delta 8$ -desaturases, thus indicating that the *Echium* products are likely to be  $\Delta 6$ -desaturases.

To obtain a direct proof for the activity of the putative *Echium* desaturases we overexpressed the *EGD6DES* gene in tobacco *calli*. FA composition of these undifferentiated cells is similar to that of nonphotosynthetic tissues, such as the root, where a higher amount of LA (45%) relative to ALA (26%) is found (39). These compounds were previously shown to act as substrates of D6DES enzymes, giving rise to GLA and OTA, respectively (9,40). Both products were detected in transformed *calli*, thus demonstrating the ability of the *Echium* enzyme to desaturate the  $\Delta 6$  position of FA containing previous double bonds at  $\Delta 9$  and  $\Delta 12$  carbons. These results also indicate that the activity of a single D6DES enzyme is enough to synthesize both GLA and OTA.

The activity of EGD6DES has been further analyzed by heterologous expression in a yeast system. As expected, desaturation of exogenously provided LA was observed in transformed cells. A similar experiment has been carried out with the D6DES from the fungus *Mortierella alpina* (13). In this case  $\Delta 6$ -desaturation of the endogenous 16:1n-7 and 18:1n-9 was observed in transformed yeast that were not supplemented with LA. Accumulation of 16:2n-7 has also been reported by yeast expression of the *Borago* D6DES (41). However, in our experiments we did not detect the accumulation of such compounds. This discrepancy could be attributed to differences in the experimental conditions, or it might reflect a different behavior of the D6DES from those organisms.

*Gene structure and expression analysis of the Echium D6DES gene.* We have shown that the *D6DES* of *Echium* do not contain introns. The same seems to be true for the *Borago D6DES* and the *D8DES* from *Echium* and *Borago*, since partial sequences obtained by genomic PCR also present continuous open reading frames (results not shown). Moreover, the whole coding sequences of the two *D8DES* genes (F2A19.180; At2g46210) present in the *Arabidopsis* genome are also contained within single exons. This is in contrast to the gene structure of D6DES from other organisms such as the moss *Physcomitrella* (42), the worm *Caenorhabditis* (43), and *Homo* (44), where a number of introns interrupt both the desaturase and cytochrome  $b_5$  domains. Although we cannot exclude the existence in *Echium* of an additional version of

the *D6DES* gene containing introns, this is not supported by Southern analyses since they do not reveal the presence of further loci. It seems likely therefore that loss of introns of the *D6DES* gene may have occurred during evolution of higher plants, followed, at least in Boraginaceae species, by high divergence or loss of the interrupted gene. Loss of introns has been well documented in a number of instances, with retroposition as the most direct mechanism (revised in 45). The fact that *D8DES* genes are also continuous suggests that the retroposition event took place before the duplication and further divergence of the *D6DES/D8DES* lineages.

We have also studied the expression of the *D6DES* gene in different tissues of *E. pitardii*. High relative levels of D6DES transcript is found in all tissues of the plant except in leaves of mature plants, where it is barely detectable. This correlates with the accumulation of GLA in those tissues, as the synthesis of this compound in the mature leaves is about five times below that of the developing fruits. The lower GLA level in the leaves has also been reported in other plants (46,47), and competition between the D6DES and the  $\omega 3$ -desaturase for the same substrate (LA) to give either GLA or ALA, respectively, was suggested as the cause (9). It is likely that this competition has its origin at the transcriptional level. This correlation suggests that, at least in *Echium*, the steady-state level of the D6DES transcript might be the limiting factor in the accumulation of GLA in the different tissues.

## ACKNOWLEDGMENTS

We are indebted to Dr. Edgar B. Cahoon for helpful suggestions about this work. We are also grateful to Drs. Antonio Valverde and Amadeo Rodriguez for their help in the GC-MS analyses and to Jerónimo Pérez and Juan Carlos Gázquez for providing facilities and technical assistance in greenhouse plant culture. This work was supported by an UAL-CAJAMAR research project and by the Plan Andaluz de Investigación (PAI-III, CVI-279).

# Biosynthesis of New Divinyl Ether Oxylinins in *Ranunculus* Plants

Mats Hamberg\*

Department of Medical Biochemistry and Biophysics, Division of Physiological Chemistry II,  
Karolinska Institutet, S-171 77 Stockholm, Sweden

**ABSTRACT:** [1-<sup>14</sup>C]Linolenic acid was incubated with homogenates of leaves from the aquatic plants *Ranunculus lingua* (greater spearwort) or *R. peltatus* (pond water-crowfoot). Analysis by reversed-phase high-performance liquid radiochromatography demonstrated the formation of a new divinyl ether FA, i.e., 12-[1'(E),3'(Z)-hexadienyloxy]-9(Z),11(Z)-dodecadienoic acid [11(Z)-etherolenic acid] as well as a smaller proportion of ω5(Z)-etherolenic acid previously identified in terrestrial *Ranunculus* plants. The same divinyl ethers were formed upon incubation of 13(S)-hydroperoxy-9(Z),11(E),15(Z)-octadecatrienoic acid, a lipoxygenase metabolite of linolenic acid, whereas the isomeric hydroperoxide, 9(S)-hydroperoxy-10(E),12(Z),15(Z)-octadecatrienoic acid, was not converted into divinyl ethers in *R. lingua* or *R. peltatus*. Incubation of [1-<sup>14</sup>C]linoleic acid or 13(S)-hydroperoxy-9(Z),11(E)-octadecadienoic acid produced the divinyl ether 12-[1'(E)-hexenyloxy]-9(Z),11(Z)-dodecadienoic acid [11(Z)-etheroleic acid] and a smaller amount of ω5(Z)-etheroleic acid. The experiments demonstrated the existence in *R. lingua* and *R. peltatus* of a divinyl ether synthase distinct from those previously encountered in higher plants and algae.

Paper no. L8992 in *Lipids* 37, 427–433 (April 2002).

The divinyl ether synthase pathway of FA hydroperoxide metabolism was discovered by Galliard and Phillips, who in 1972 described the structures and biosynthesis of colneleic and colnelenic acids (1). These two divinyl ether FA were formed from the 9(S)-hydroperoxide derivatives of linoleic and linolenic acids, respectively, in homogenates of potato tubers (1), and were later identified also in preparations of tomato roots (2) and potato leaves (3). The enzyme responsible, i.e., divinyl ether synthase, is a membrane-bound P-450 protein, and the gene encoding it was recently cloned (4). Studies using other plant tissues have shown that hydroperoxides generated by 13-lipoxygenase activity can also serve as precursors of divinyl ethers. Evidence for this was first provided by Proteau and Gerwick (5), who isolated 12-[1'(Z),3'(Z)-hexadienyloxy]-6(Z),9(Z),11(E)-dodecatrienoic acid and 12-[1'(Z),3'(Z)-hexadienyloxy]-9(Z),11(E)-dodecadienoic acid [ω5(Z)-etherolenic acid] from the brown alga

\*E-mail: Mats.Hamberg@mbb.ki.se

Abbreviations and trivial names: Colneleic acid, 9-[1'(E),3'(Z)-nonadienyloxy]-8(E)-nonenoic acid; colnelenic acid, 9-[1'(E),3'(Z),6'(Z)-nonatrienyloxy]-8(E)-nonenoic acid; etheroleic acid, 12-[1'(E)-hexenyloxy]-9(Z),11(E)-dodecadienoic acid; etherolenic acid, 12-[1'(E),3'(Z)-hexadienyloxy]-9(Z),11(E)-dodecadienoic acid; 9-H(P)OD, 9-hydro(pero)xy-10(E),12(Z)-octadecadienoic acid; 13 H(P)OD, 13-hydro(pero)xy-9(Z),11(E)-octadecadienoic acid; 9-H(P)OT, 9 hydro(pero)xy-10(E),12(Z),15(Z)-octadecatrienoic acid; 13-H(P)OT, 13-hydro(pero)xy-9(Z),11(E),15(Z)-octadecatrienoic acid.

*Laminaria sinclairii*, compounds presumably derived from the 13-hydroperoxides of stearidonic and linolenic acids, respectively. Subsequently, Grechkin *et al.* (6) obtained 12-[1'(E),3'(Z)-hexadienyloxy]-9(Z),11(E)-dodecadienoic acid (etherolenic acid) and 12-[1'(E)-hexenyloxy]-9(Z),11(E)-dodecadienoic acid (etheroleic acid) following incubation of the 13(S)-hydroperoxides of linolenic and linoleic acids, respectively, with an extract of garlic bulbs. Hamberg (7) isolated the 1'(Z) isomers of these divinyl ethers, i.e., ω5(Z)-etherolenic acid and ω5(Z)-etheroleic acid, following incubation of the 13-hydroperoxides with leaves from *Ranunculus* plants.

The present study reports the structures of additional divinyl ethers, i.e., the 11(Z) isomers of etheroleic and etherolenic acids, and their biosynthesis in leaves from two aquatic *Ranunculus* plants.

## EXPERIMENTAL PROCEDURES

**Plant materials.** Specimens of greater spearwort (*R. lingua* L.) and pond water-crowfoot (*R. peltatus* L.) were collected in freshwater lakes in the Stockholm area in 1999. Leaves were either used directly or shock-frozen in liquid nitrogen and stored at -80°C.

**FA, FA hydroperoxides, and divinyl ethers.** Linoleic and linolenic acids were purchased from Nu-Chek-Prep (Elysian, MN). [1-<sup>14</sup>C]Linolenic acid (DuPont NEN, Boston, MA) was mixed with unlabeled material and purified by SiO<sub>2</sub> chromatography to afford a specimen having a specific radioactivity of 5.5 kBq/μmol. The FA hydroperoxides used in the present work, i.e., 9(S)-hydroperoxy-10(E),12(Z),15(Z)-octadecatrienoic acid [9(S)-HPOT], 13(S)-hydroperoxy-9(Z),11(E),15(Z)-octadecatrienoic acid [13(S)-HPOT], 9(S)-hydroperoxy-10(E),12(Z)-octadecadienoic acid [9(S)-HPOD], and 13(S)-hydroperoxy-9(Z),11(E)-octadecadienoic acid [13(S)-HPOD] were purchased from Larodan Fine Chemicals (Malmö, Sweden). From the same source were also obtained [17,17,18,18,18-<sup>2</sup>H<sub>5</sub>]linolenic acid, 12-oxo-10,15(Z)-phytodienoic acid as well as the divinyl ether FA used, i.e., colneleic, colnelenic, etheroleic, etherolenic, ω5(Z)-etheroleic, and ω5(Z)-etherolenic acids.

**Enzyme preparations.** Leaves of *R. lingua* or *R. peltatus* were minced and homogenized at 0°C in 0.1 M potassium phosphate buffer pH 6.7 (5:1, vol/wt) using an Ultra-Turrax homogenizer. The homogenate was filtered through gauze, and the filtrate was used in incubations carried out on a small scale. Centrifugation of the whole homogenate at 1100 × g for 15 min provided a low-speed particulate fraction, and further centrifu-

gation of the supernatant at  $105,000 \times g$  for 60 min provided a high-speed particulate fraction. The two particulate fractions, which both contained divinyl ether synthase activity, were re-suspended in volumes of phosphate buffer equal to those of the corresponding supernatants and used in large-scale incubations.

**Incubations on a small scale and treatments.** [ $1\text{-}^{14}\text{C}$ ]-Linolenic acid, [ $1\text{-}^{14}\text{C}$ ]linoleic acid, or hydroperoxides (300  $\mu\text{M}$ ) were stirred with the whole homogenate preparations from *R. lingua* or *R. peltatus* (2–15 mL) at 23°C for 20 min. The mixtures were acidified to pH 4 and rapidly extracted with 2 vol of diethyl ether. Material obtained after evaporation of the solvent was dissolved in 3 mL of 2-propanol/chloroform (1:2, vol/vol) and subjected to solid-phase extraction using an aminopropyl column (0.5 g; Supelco, Bellefonte, PA). After rinsing with 5 mL of the same solvent mixture, acidic components were eluted with 10 mL of diethyl ether/acetic acid (98:2, vol/vol). The material obtained was subjected to RP-HPLC radiochromatography using a column of Nucleosil 100-5  $\text{C}_{18}$  (250  $\times$  4.6 mm) (Macherey-Nagel, Düren, Germany) and a solvent system composed of acetonitrile/water/acetic acid (60:40:0.02, by vol). The flow rate was 1.5 mL/min, and the detector was set at 210 nm.

**Preparation of compound 4.** Crystalline compound 4, which was needed for structural and chromatographic studies, was prepared in the following way. Suspensions of the low-speed and high-speed particulate fractions obtained from 26 g of leaves of *R. lingua* were separately stirred at 23°C for 20 min with 300  $\mu\text{M}$  13(*S*)-HPOT. The mixtures were pooled, acidified to pH 4, and extracted with two portions of diethyl ether. The residue remaining after evaporation of the solvent was dissolved in 12 mL of 2-propanol/chloroform (1:2, vol/vol) and subjected to solid-phase extraction (four columns). Material obtained from five such batches was subjected to RP-HPLC using a column of Nucleosil  $\text{C}_{18}$  100-7 (250  $\times$  10 mm) and a solvent system of acetonitrile/water/acetic acid (60:40:0.02, by vol) to afford 4.5 mg of pure compound 4 (168–177 mL effluent; yield, 4%). The low yield was caused mainly by the strong hydroperoxide lyase activity in the tissue used, which diverted the main part of the incubated hydroperoxide into 12-oxo-9(*Z*)-dodecenoic acid and 3(*Z*)-hexenal. Crystallization of compound 4 from hexane at  $-25^\circ\text{C}$  afforded white crystals, m.p. 66–67°C. When carrying out the m.p. determinations, it was noted that further heating of melted samples led to the development of a faint odor of 3(*Z*)-hexenal, suggesting the presence of a 1,3-hexadienyloxy partial structure in compound 4.

**Preparation of methyl [17,17,18,18,18- $^2\text{H}_5$ ] $\omega$ 5(*Z*)-etherolenate.** [17,17,18,18,18- $^2\text{H}_5$ ]13(*S*)-HPOT (18 mg) was prepared by incubation of [17,17,18,18,18- $^2\text{H}_5$ ]linolenic acid with soybean lipoxygenase followed by purification by open-column  $\text{SiO}_2$  chromatography. The hydroperoxide (300  $\mu\text{M}$ ) was incubated with a suspension of the  $105,000 \times g$  particulate fraction from a homogenate of 40 g of leaves of *R. acris* as described earlier (7). Purification by RP-HPLC and  $\text{SiO}_2$  chromatography and methyl esterification by treatment with diazomethane afforded 6 mg of the title compound. Analysis

by GC-MS showed a single peak and a mass spectrum displaying a molecular ion at  $m/z$  311. The isotopic purity was 95%.

**Chemical, chromatographic, and instrumental methods.** Detailed descriptions of the methodology used for isolation and structural analysis are given or referred to in a previous study on hydroperoxide metabolism in terrestrial *Ranunculus* plants (7).

## RESULTS

**Isolation of oxidation products of linolenic acid.** [ $1\text{-}^{14}\text{C}$ ]-Linolenic acid (300  $\mu\text{M}$ ) was stirred at 23°C for 20 min with a whole homogenate preparation (10 mL) of *R. lingua*. Material obtained following extraction with diethyl ether and solid-phase extraction was subjected to RP-HPLC radiochromatography. Four major products were observed, i.e., compounds 1 (6% of the recovered radioactivity), 2 (5%), 3 (1%; 34.0 mL effluent), and 4 (10%; 35.8 mL effluent). Compound 1 was identified as 12-oxo-10,15(*Z*)-phytodienoic acid by UV spectroscopy and GC-MS using the authentic compound as reference (*cf.* Ref. 7). In a similar way, compound 2 was found to be identical to 13(*S*)-HOT. Compound 3 was spectroscopically and chromatographically indistinguishable from 12-[1'(*Z*),3'(*Z*)-hexadienyloxy]-9(*Z*),11(*E*)-dodecadienoic acid [ $\omega$ 5(*Z*)-etherolenic acid] recently isolated following incubation of linolenic acid with preparations of *R. acris* or other terrestrial *Ranunculus* plants (7). Compound 4 was a new divinyl ether oxylipin, and its structure was determined as described below. Incubation of [ $1\text{-}^{14}\text{C}$ ]linolenic acid with a whole homogenate preparation from *R. peltatus*, another aquatic *Ranunculus* plant, produced compounds 1 (16% of the recovered radioactivity), 3 (15%), and 4 (52%) as the main products.

**Structure of compound 4.** Compound 4 showed strong UV absorption with  $\lambda_{\text{max}}$  (EtOH) = 267 nm,  $\epsilon$  = 41,600 [reference:  $\omega$ 5(*Z*)-etherolenic acid,  $\lambda_{\text{max}}$  (EtOH) = 267 nm,  $\epsilon$  = 41,200], suggesting a dibutadienyl ether structure (Table 1). The FTIR spectrum (film) of the methyl ester of compound 4 showed bands at 1740 (ester C=O), 1646 (C=C), 1595 (C=C), 1165 (C–O–C), and 910  $\text{cm}^{-1}$  (*trans*-substituted vinyl ether). The mass spectrum of the methyl ester of compound 4 showed prominent ions at  $m/z$  306 (23%;  $\text{M}^+$ ), 277 (2;  $\text{M}^+ - 29$ ; loss of  $\cdot\text{C}_2\text{H}_5$ ), 275 (3;  $\text{M}^+ - 31$ ; loss of  $\cdot\text{OCH}_3$ ), 245 [4%;  $\text{M}^+ - (29 + 32)$ ], 217 (2), 199 (3), 163 [9%;  $\text{M}^+ - 143$ ; loss of  $\cdot(\text{CH}_2)_6\text{-COOCH}_3$ ], 149 (21), 131 (27), 107 (31), 81 (100), and 55 (98). Catalytic hydrogenation of the methyl ester of compound 4 provided an octahydro derivative, the mass spectrum of which showed ions at  $m/z$  314 (0.1%;  $\text{M}^+$ ), 283 (2%;  $\text{M}^+ - 31$ ; loss of  $\cdot\text{OCH}_3$ ), 229 [18%;  $\text{M}^+ - 85$ ; loss of  $\cdot(\text{CH}_2)_5\text{-CH}_3$ ], 214 [15%;  $\text{M}^+ - 100$ ; loss of  $\text{-OHC-(CH}_2)_4\text{-CH}_3$ ], 197 [49%;  $\text{M}^+ - (85 + 32)$ ], 143 {27%; [( $\text{CH}_2)_6\text{-COOCH}_3$ ] $^+$ }, 129 {11%; [( $\text{CH}_2)_5\text{-COOCH}_3$ ] $^+$ }, 97 {31%; [( $\text{CH}_2)_4\text{-CH=C=O}$ ] $^+$ }, 87 {59%; [( $\text{CH}_2)_2\text{-COOCH}_3$ ] $^+$ }, 74 {69%; [ $\text{CH}_2\text{=C(OH)-OCH}_3$ ] $^+$ }, and 55 (100). Oxidative ozonolysis performed on the methyl ester of compound 4 produced monomethyl azelate as the major nonvolatile fragment. Collectively, these data indicated that compound 4 possessed a

<sup>b</sup>UV spectra were recorded on the free acids dissolved in 99.5% ethanol.

<sup>c</sup>Straight-phase HPLC was performed on the methyl esters using a column of Nucleosil 50-5 and a solvent system of ethyl acetate/hexane (8:992, vol/vol) at a flow rate of 1.0 mL/min. The detector was set at 250 nm.

<sup>d</sup>Capillary electrophoresis. Data from Reference 8.

<sup>e</sup>GLC was performed on the methyl esters using a methyl silicone capillary column (25 m) at 230°C. The C-values indicate the retention times relative to those of standards of saturated FAME.

<sup>f</sup>Partial degradation on the capillary column.

9,11-dodecadienoate moiety linked to a 1,3-hexadienyl group by an ether oxygen, i.e., a skeletal structure identical to that of etherolenic acid (**6**) and  $\omega$ 5(Z)-etherolenic acid (**7**). The distinguishing feature of compound **4**, i.e., the geometrical configuration of the double bond system, was established by NMR analysis of the methyl ester.

Eight of the deshielded signals due to the eight olefinic

protons of compound **4** were observed (Table 2, Fig. 1C). Correlation of the signals with the different protons was achieved by spin-spin decoupling experiments and by using the NMR spectra of methyl etherolenate (**6**) and methyl  $\omega$ 5(Z)-etherolenate (**7**) as references. The signals centered at 5.41 and 6.33 ppm were due to the protons at C-9 and C-10, respectively, whereas the signals at 5.82 and 5.31 ppm were due to the protons at C-3' and C-4', respectively. As shown by the values of  $J_{9,10}$  and  $J_{3',4'}$  (11.1 and 10.6 Hz, respectively), both the  $\Delta^9$  and  $\Delta^{3'}$  double bonds had the *Z* geometrical configuration. Earlier work on divinyl ether FA and on other vinyl ether compounds, such as ethyl propenyl ether (5-7,9,10), showed that the coupling constants of protons across *Z* and *E* vinyl ether double bonds have values of 6-7 and 11-12 Hz, respectively. As seen in Table 2, the  $J_{11,12}$  determined for the signals of the vinylic protons at C-11 (5.49 ppm) and C-12 (6.20 ppm) was 6.2 Hz, thus demonstrating that the  $\Delta^{11}$  double bond had the *Z* configuration. In the same way, the coupling constant of the vinylic protons of the  $\Delta^{1'}$  double bond (signals centered at 6.59 and 6.06 ppm) was 11.9 Hz. This showed that the  $\Delta^{1'}$  double bond had the *E* geometrical configuration. On the basis of the data presented, compound **4** was identified as 12-[1'(E),3'(Z)-hexadienyloxy]-9(Z),11(Z)-dodecadienoic acid [11(Z)-etherolenic acid] (Scheme 1).

Compound **4** and  $\omega$ 5(Z)-etherolenic acid differed only with respect to their alternative placements of their *E,Z*-butadienyl ether and *Z,Z*-butadienyl ether partial structures (Scheme 1), and accordingly, their NMR spectra were virtually identical (Figs. 1A and 1C). Therefore, the NMR signal assignments made for compound **4** were in part based on those previously made for  $\omega$ 5(Z)-etherolenic acid (**7**). It was deemed important to confirm the correctness of the latter

assignments in an independent way. To this end, an NMR analysis of [17,17,18,18,18- $^2\text{H}_5$ ] $\omega 5(Z)$ -etherolenic acid prepared by incubation of [17,17,18,18,18- $^2\text{H}_5$ ]**13(S)**-HPOT

**SCHEME 1**

with *R. acris* (cf. Ref. 7) was performed. As expected, the NMR spectrum of the methyl ester of this compound lacked signals due to the methyl protons and the 5' protons. Importantly, the multiplet at 5.41 ppm ascribed to the 4' protons of unlabeled  $\omega 5(Z)$ -etherolenic acid (**7**) simplified to a doublet (5.41 ppm;  $J_{3',4'} = 10.9$  Hz) (Fig. 1B), thus confirming that the spin system 1'–4' corresponded to the Z,Z-butadienyl moiety as previously concluded (**7**). By means of exclusion, this experiment gave independent proof for the location at C-9 to C-12 of the corresponding moiety of compound **4**.

**Incubation of 13(S)-HPOT.** [1- $^{14}\text{C}$ ]**13(S)**-HPOT (300  $\mu\text{M}$ ) was stirred at 23°C for 20 min with a whole homogenate preparation (10 mL) of *R. lingua* or *R. peltatus*, and the materials obtained following extraction with diethyl ether and solid-phase extraction were subjected to RP-HPLC radiochromatography. The pattern of radioactive products was similar to that observed following incubation of [1- $^{14}\text{C}$ ]linolenic acid; however, the amount of compound **3** [ $\omega 5(Z)$ -etherolenic acid] relative to that of compound **4** was higher and more variable. Thus, the ratio of compound **3**/compound **4** observed with linolenic acid

incubated with *R. lingua* was 1:10, whereas 13(*S*)-HPOT incubated with the same plant gave ratios of up to 50:50.

**Incubation of linoleic acid and 13(*S*)-HPOD.** Incubation of [ $1\text{-}^{14}\text{C}$ ]linoleic acid (300  $\mu\text{M}$ ) as described above led to the formation of two divinyl ethers, i.e., compound **5** and compound **6** in proportions 20:80. Compound **5** was found to be identical to 12-[1'(*Z*)-hexenyloxy]-9(*Z*),11(*E*)-dodecadienoic acid [ $\omega 5$ (*Z*)-etheroleic acid], a compound previously obtained from linoleic acid incubated with an enzyme preparation from *R. acris* and other terrestrial *Ranunculus* plants (7). The structure of compound **6**, the major divinyl ether formed from linoleic acid, was determined as described below. Incubation of 13(*S*)-HPOD with whole homogenate preparations of *R. lingua* or *R. peltatus* provided the same divinyl ethers as those formed from linoleic acid although in proportions 40:60 (compound **5**/compound **6**).

**Structure of compound 6.** The UV spectrum of **6** showed  $\lambda_{\text{max}}$  (EtOH) = 253 nm (Table 1), and the FTIR spectrum (film) of the methyl ester showed absorption bands at 1741 (ester carbonyl), 1647 (C=C), 1601 (C=C), 1158 (C-O-C), and 933 and 916  $\text{cm}^{-1}$  (*trans*-substituted vinyl ether). The mass spectrum showed prominent ions at  $m/z$  308 (31%;  $\text{M}^+$ ), 277 (2%;  $\text{M}^+ - 31$ ; loss of  $\cdot\text{OCH}_3$ ), 251 [3%;  $\text{M}^+ - 57$ ; loss of  $\cdot(\text{CH}_2)_3\text{-CH}_3$ ], 219 [2%;  $\text{M}^+ - (57 + 32)$ ], 177 (13), 165 [20%;  $\text{M}^+ - 143$ ; loss of  $\cdot(\text{CH}_2)_6\text{-COOCH}_3$ ], 159 (14), 135 (25), 81 (60), 67 (70), and 55 (100). Catalytic hydrogenation of **6** produced a derivative identical to that formed from **4** upon the same treatment (see above). Oxidative ozonolysis performed on the methyl ester of **6** yielded monomethyl azelate as the main product. The data mentioned indicated the presence in **6** of a tri-unsaturated ether partial structure spanning from C-9 to C-14. NMR spectroscopy showed six groups of signals due to olefinic protons (Table 2). The protons at the  $\Delta^9$  double bonds gave rise to signals at 5.35 and 6.34 ppm. The value of  $J_{9,10}$  (11.1 Hz) demonstrated that this double bond had the *Z* geometrical configuration. The signals at 5.42 and 6.14 ppm were due to the protons at the  $\Delta^{11}$  double bond. The observed  $J_{11,12}$  (6.2 Hz) was in agreement with a vinyl ether double bond having the *Z* configuration. In the same way, the  $\Delta^{1'}$  double bond was assigned the *E* configuration based on the  $J_{1',2'}$  (12.1 Hz) measured from the signals at 6.30 and 5.13 ppm (protons at C-1' and C-2', respectively). On the basis of these results, compound **6** was assigned the structure 12-[1'(*E*)-hexenyloxy]-9(*Z*),11(*Z*)-dodecadienoic acid [11(*Z*)-etheroleic acid]. This compound was obtained earlier as a minor by-product in the biosynthesis of etheroleic acid from 13(*S*)-HPOD using a crude enzyme preparation from garlic bulbs (10).

**Incubations of 9(*S*)-HPOT, 9(*S*)-HPOD, and  $\omega 5$ (*Z*)-etherolenic acid.** Incubation of 9(*S*)-HPOT (300  $\mu\text{M}$ ) with the whole homogenate preparations of *R. lingua* or *R. peltatus* did not result in the formation of divinyl ethers. The compounds observed were identified as unconverted hydroperoxide accompanied by smaller amounts of 9(*S*)-HOT and 9-oxo-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid. Incubation of 9(*S*)-HPOD likewise produced small amounts of 9-HOD and

9-oxo-10(*E*),12(*Z*)-octadecadienoic acid but no divinyl ethers. Incubation of  $\omega 5$ (*Z*)-etherolenic acid did not lead to conversion into other compounds, thus excluding the presence of isomerase(s) catalyzing interconversion of divinyl ether isomers in the preparations used.

**Chromatographic separation of divinyl ether FA.** As seen in Table 1, straight-phase HPLC allowed separation of the methyl esters of etherolenic and etheroleic acids from their corresponding  $\omega 5$ (*Z*) and 11(*Z*) isomers. Furthermore, complete resolution of the divinyl ether isomers could be effected by capillary electrophoresis (8). Also GLC was useful for identification and separation of divinyl ethers, although the methyl ester of etherolenic acid was inseparable from its  $\omega 5$ (*Z*) isomer.

## DISCUSSION

In a previous study, leaves of terrestrial *Ranunculus* plants were shown to metabolize linolenic acid and 13(*S*)-HPOT extensively into a single crystalline divinyl ether FA identified as  $\omega 5$ (*Z*)-etherolenic acid (7). The present study describes the formation of a higher-melting form of this divinyl ether in leaves from two aquatic *Ranunculus* plants, i.e., greater spearwort (*R. lingua*) and pond water-crowfoot (*R. peltatus*). The new divinyl ether, compound **4**, was separable from previously recognized divinyl ether FA by chromatographic methods (Table 1) but gave results similar to those of  $\omega 5$ (*Z*)-etherolenic acid when analyzed by UV and FTIR spectroscopy as well as MS. NMR spectrometry performed on the methyl ester of compound **4** and using the methyl esters of  $\omega 5$ (*Z*)-etherolenic acid and [ $17,17,18,18,18\text{-}^2\text{H}_5$ ] $\omega 5$ (*Z*)-etherolenic acid as references (Fig. 1) demonstrated the presence in compound **4** of a *Z,Z*-butadienyl structure located in the 9–12 position and an *E,Z*-butadienyl structure located in the 13–16 position. Accordingly, compound **4** was identified as the 11(*Z*) isomer of etherolenic acid (Scheme 1). Linoleic acid and 13(*S*)-HPOD were metabolized in an analogous way to produce compound **6** [11(*Z*)-etheroleic acid] as the main divinyl ether product.

The finding that biosynthesis of divinyl ethers from linolenic and linoleic acids in *R. lingua* and *R. peltatus* was accompanied by the formation of smaller amounts of 12-oxo-10,15(*Z*)-phytodienoic acid, 13-HOT, and 13-HOD demonstrated the presence of 13-lipoxygenase activity in the preparations used. This fact, coupled with the result that 13(*S*)-HPOT and 13(*S*)-HPOD served as efficient precursors of divinyl ethers, indicated that a two-step pathway involving 13-lipoxygenase and divinyl ether synthase was responsible for biosynthesis of divinyl ethers in the plants studied (Fig. 2). Divinyl ether synthases emerge as a group of isoenzymes catalyzing the conversion of FA hydroperoxides into regioisomeric and stereoisomeric divinyl ethers. One such enzyme, i.e., the one catalyzing the conversion of 9(*S*)-HPOD into colnelic acid, has been found to be a cytochrome P-450, protein and the gene encoding it has been cloned (4).

Conversion of 13-hydroperoxides into 11(*Z*)-etheroleic and 11(*Z*)-etherolenic acids by divinyl ether synthase in *R. lingua* and *R. peltatus* is remarkable in the sense that it

**FIG. 2.** Biosynthesis of isomeric divinyl ethers from 13(*S*)-hydroperoxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid [13(*S*)-HPOT]. DES, divinyl ether synthase; ELn, etherolenic acid; see Figure 1 for other abbreviations.

involves a thermodynamically unfavorable  $E \rightarrow Z$  isomerization of the  $\Delta^{11}$  double bond (Fig. 2). An epoxide carbocation has been proposed to serve as an enzyme-bound intermediate in the biosynthesis of divinyl ethers (10–12), and a basic amino acid residue in the active site of divinyl ether synthases has been proposed to effect the stereoselective removal of a proton from the noncharged carbon  $\alpha$  to the epoxide (11,12). It can be speculated that the active sites of the divinyl ether synthase isoenzymes catalyzing the biosynthesis of etherolenic, 11(*Z*)-etherolenic, and  $\omega 5$ (*Z*)-etherolenic acids show subtle differences with respect to the positioning of amino acid residues needed for binding and further conversion of the epoxide carbocation intermediate. This may force the intermediate to adopt different conformations by rotation of the 11,12 and 13,14 single bonds to provide conformers that serve as precursors of the different geometrical isomers of etherolenic acid (Fig. 2).

The function of divinyl ether FA in plants is not well-established. A role in plant–pathogen interactions is suggested by the antifungal properties of colnelic and colnelenic acids (3) and by the pathogen-induced formation of these compounds in potato leaves (3) or in cell cultures from potato (13).

#### ACKNOWLEDGMENTS

Gunvor Hamberg is thanked for expert technical assistance and for collection and identification of the plant materials used. The author is greatly indebted to Professor Per-Erik Jansson and Reine Eserstam (Clinical Research Center, Huddinge University Hospital,

Stockholm) for their help with the NMR analyses. This work was supported by Vesical Co., Stockholm, Sweden, and by the Swedish Council for Forestry and Agricultural Research (project 980.0897/00).

# Evidence for [1,5] Sigmatropic Rearrangements of CLA in Heated Oils

Frédéric Destailats and Paul Angers\*

Department of Food Science and Nutrition, and Dairy Research Center (STELA),  
Université Laval, Sainte-Foy, Québec, Canada, G1K 7P4

**ABSTRACT:** Linoleic acid was heated at 200°C under helium. Analysis of degradation products by GC on a long polar open tubular capillary column showed the presence of CLA isomers. The identified mono *trans* CLA isomers were *cis*-9,*trans*-11, *trans*-9,*cis*-11, *trans*-10,*cis*-12, *cis*-10,*trans*-12, *trans*-8,*cis*-10, and *cis*-11,*trans*-13 18:2 acids. Oils containing different levels of linoleic acid (peanut, sesame seed, and safflower seed oils) were also heat treated, resulting in similar CLA distributions. Elution order was confirmed using *cis*-9,*trans*-11 and *trans*-10,*cis*-12 acid methyl esters standards and their respective configuration isomers (*trans*-9,*cis*-11, *cis*-10,*trans*-12), obtained after mild selenium-catalyzed isomerization. These results indicated that two conjugated mono *trans* isomers of 18:2 acid, *cis*-8,*trans*-10 and *trans*-11,*cis*-13 18:2 were absent from the series, thus strongly suggesting that some constraints were preventing their formation. By heating pure methyl rumenate (*cis*-9,*trans*-11 18:2) under similar conditions, isomerization resulted principally in a nearly equimolar mixture of methyl rumenate and *trans*-8,*cis*-10 18:2. Similarly, the methyl ester of *trans*-10,*cis*-12 18:2 acid was partially transformed into *cis*-11,*trans*-13 18:2 acid. Respective geometrical isomers were also formed in trace amounts. A concerted pericyclic isomerization mechanism, a [1,5] sigmatropic rearrangement, is proposed that limits the conjugated system to isomerization from a *cis*-*trans* acid to a *trans*-*cis* acid, and vice versa. This mechanism is consistent with undetected *cis*-8,*trans*-10 and *trans*-11,*cis*-13 18:2 isomers in heated oils containing linoleic acid.

Paper no. L8962 in *Lipids* 37, 435–438 (April 2002).

During the last decade, more than 600 scientific articles have been published on analysis, physiology, nutrition, and technological implications of CLA. These conjugated FA are naturally present in milk fat and in the meat of ruminants and may result in beneficial health effects, which have recently been reviewed (1). CLA, especially all-*trans*-9,11-18:2 and -10,12-18:2 acid isomers, are also found in trace amounts in processed materials such as partially hydrogenated oils (2). Juanéda *et al.* (3) showed that CLA had been formed in frying oils collected from restaurants. Their structures have been determined by a combination of GC and silver ion HPLC. The formed CLA consisted mainly of *trans*-9,*trans*-11, *trans*-10,*trans*-12, *cis*-9,*trans*-11, *trans*-10,*cis*-12, *trans*-8,*cis*-10, *cis*-11,*trans*-13 18:2 acids, and minor amounts of *cis*-9,*cis*-11, *cis*-10,*cis*-12, and *cis*-11,*cis*-13 18:2 acids. Indeed, occurrence of CLA in heat-treated sunflower

seed oil, high in linoleic (*cis*-9,*cis*-12 18:2) acid, has been demonstrated by Sébédio *et al.* (4), who observed the presence of similar isomers. Obviously, some constraints prevented the formation of two conjugated mono *trans* isomers of 18:2 acid in heated oils, *cis*-8,*trans*-10 and *trans*-11,*cis*-13 18:2, which were absent from the series.

In this study, successive experiments were performed to identify reaction mechanisms causing the formation of *trans*-8,*cis*-10 and *cis*-11,*trans*-13 18:2 acids in heated oil, while preventing the formation of their respective *cis*-8,*trans*-10 and *trans*-11,*cis*-13 18:2 configuration isomers. Comprehensive chemical observations are a prerequisite step to further interpretations of chemical behavior of CLA.

## MATERIALS AND METHODS

**Samples and reagents.** Linoleic (*cis*-9,*cis*-12 18:2), *cis*-9,*trans*-11 (rumenic), and *trans*-10,*cis*-12 18:2 acid methyl esters were purchased from Nu-Chek-Prep (Elysian, MN). *n*-Hexadecane, *n*-hexane, selenium metal (-100 mesh, 99.999%), and silver nitrate were obtained from Aldrich Chemicals (Milwaukee, WI). Peanut, sesame seed, and safflower seed oils were purchased from a local store.

**Heat treatment.** Methyl linoleate (50  $\mu$ L) was heated under helium in a sealed glass vial for 120 h at 200°C in the oven of a 5890A gas chromatograph (Hewlett-Packard, Palo Alto, CA). Methyl rumenate (25  $\mu$ L) and methyl *trans*-10,*cis*-12 18:2 (25  $\mu$ L) acids were diluted in hexadecane (500  $\mu$ L) and separately heated under helium at 200°C for 13 h in the same apparatus. After cooling to room temperature, samples were diluted with *n*-hexane (*ca.* 1 mL) prior to GLC analysis. Oils of peanuts, sesame seeds, and safflower seeds (25 mL each) were heated at 200°C in open 50-mL flasks. Samples were collected after 18 h of heat treatment and transesterified (5) prior to analysis. All experiments were performed in duplicate.

**Fractionation of FAME by Ag-TLC.** Methylation of FA from heated oil samples was carried out in sealed tubes with 0.4 N sodium methoxide in methanol. FAME from heated oils were fractionated according to number and configuration of double bonds by TLC on silica gel plates (20  $\times$  20 cm) impregnated with AgNO<sub>3</sub>. The plates were immersed in a 5% AgNO<sub>3</sub> solution in acetonitrile for 15 min in the dark, and activated at 100°C for 1 h. The developing solvent was a mixture of hexane and diethyl ether (80:20, vol/vol). At the end of the chromatographic runs, the plates were sprayed with a solution of 2',7'-dichlorofluorescein and then viewed under UV light. The bands

\*To whom correspondence should be addressed at Department of Food Science and Nutrition, Université Laval, Sainte-Foy (Québec) Canada G1K 7P4. E-mail: paul.angers@aln.ulaval.ca

corresponding to monounsaturated FA, which also contained the CLA isomers, were scraped off and transferred into test tubes. Methanol (1.5 mL), hexane (2 mL), and a 5% (wt/vol) aqueous solution of NaCl (1.5 mL) were successively added to the silica gels. Thorough mixing followed each addition. After standing for *ca.* 1 min, the hexane phase was withdrawn and concentrated under a stream of dry nitrogen before analysis.

**Synthesis of CLA isomers.** Configurational isomers of methyl-9,11-linoleate were synthesized using a modified literature procedure (6): to a stirred solution of methyl rumenate (100  $\mu$ L) in anhydrous hexadecane (0.5 mL), contained in a flame-dried flask under inert atmosphere (He), selenium (7 mg) was added. After 20 h at 120°C, under constant stirring, the solution was cooled to room temperature, filtered, diluted in hexane (*ca.* 2 mL), and analyzed by GC. The reaction products consisted of a mixture of methyl *trans*-9,*trans*-11 (**12**), *trans*-9,*cis*-11 (**5**), *cis*-9,*trans*-11 (**2**), and *cis*-9,*cis*-11 (**9**) linoleate. A similar experiment on methyl *trans*-10,*cis*-12 (**7**) linoleate yielded the corresponding configurational isomers methyl *trans*-10,*trans*-12 (**11**), *trans*-10,*cis*-12 (**7**), *cis*-10,*trans*-12 (**4**), and *cis*-10,*cis*-12 (**10**) linoleate.

**FAME analysis.** Analysis of conjugated methyl linoleate isomers was performed on a 6890 Series II gas chromatograph (Hewlett-Packard), equipped with a fused-silica BPX-70 capillary column (equivalent to 70% cyanopropyl; 120 m  $\times$  0.25 mm i.d., 0.25  $\mu$ m film thickness; SGE, Melbourne, Australia), and connected to a ChemStation (Hewlett-Packard). Injection (split mode) and detection (flame-ionization) were performed at 250°C. Oven temperature programming was 60°C isothermal for 1 min, increased to 170°C at

20°C min<sup>-1</sup>, and held isothermal for 40 min at 170°C (3). The inlet pressure of the carrier gas (H<sub>2</sub>) was 300 kPa at 170°C. Identification of individual *cis-trans* CLA isomers was achieved based on literature data (3,5,7,8), and confirmed with both commercially available and synthesized standards.

## RESULTS AND DISCUSSION

**Identification of individual *cis-trans* CLA isomers.** Structural determination of configurational CLA isomers presents some difficulties and may be confusing for closely related structural pairs. Analysis of individual CLA isomers has been achieved both by silver-ion HPLC (2,3,5,8,9), and by GC under appropriate eluting conditions using long polar open tubular capillary columns (3,5,7,8). We analyzed 18:2 conjugated isomers by GC on a 120-m highly polar BPX-70 column coated with 70% cyanoalkylpolysiloxane equivalent polymer. Separations were performed under temperature programming mode according to literature (3) and required high pressure (300 kPa at 170°C) to prevent excessive diffusion and to optimize run time. Elution order for mono *trans* 9,11 and 10,12 CLA was confirmed by using commercial rumenic (**2**) and *trans*-10,*cis*-12 (**7**) acid methyl esters standards, and their respective configuration isomers, *trans*-9,*cis*-11 (**5**) and *cis*-10,*trans*-12 (**4**), were obtained by isomerization of **2** and **7**, respectively, under mild conditions, using selenium metal as catalyst (6). Corresponding gas chromatograms are presented in Figure 1.

**CLA isomers from heated methyl linoleate and vegetable oils.** Methyl linoleate was heat treated at 200°C for 120 h under helium to ensure the formation of isomeric CLA. Similarly,

**FIG. 1.** Gas chromatogram of all configurational isomers of (A) methyl 9,11-linoleate and (B) methyl 10,12-linoleate, for confirmation of elution order of methyl *trans*-9,*cis*-11 (**5**) and *cis*-10,*trans*-12 (**4**) linoleate isomers. Isomers **5**, **9** (methyl *cis*-9,*cis*-11 linoleate), and **12** (methyl *trans*-9,*trans*-11 linoleate) were synthesized from **2** (methyl rumenate) by selenium-catalyzed isomerization. Similarly, isomers **4**, **10** (methyl *cis*-10,*cis*-12 linoleate), and **11** (methyl *trans*-10,*trans*-12 linoleate) were prepared from **7** (methyl *trans*-10,*cis*-12 linoleate). Analysis was performed on a 120-m BPX-70 capillary column (see Materials and Methods section for details).

**FIG. 2.** Gas chromatogram region of (A) methyl CLA isomers from heated methyl linoleate, and (B) details of mono *trans* methyl CLA isomers from heated samples of methyl linoleate, safflower seed oil, peanut oil, sesame seed oil, methyl rumenate **2** (*cis*-9,*trans*-11 18:2), and methyl ester of *trans*-10,*cis*-12 18:2 acid **7**. Analysis was performed on a 120 m BPX-70 capillary column (see Materials and Methods section for details). Identification of CLA isomers is **2** (*cis*-9,*trans*-11), **3** (*trans*-8,*cis*-10), **4** (*cis*-10,*trans*-12), **5** (*trans*-9,*cis*-11), **6** (*cis*-11,*trans*-13), and **7** (*trans*-10,*cis*-12). Arrows in panel A indicate respective location for peaks of undetected **1** (*cis*-8,*trans*-10) and **8** (*trans*-11,*cis*-13) 18:2 isomers.

refined vegetable oils containing different levels of linoleic acid—peanut (28%), sesame seed (44%), and safflower seed (70%) oils—were heated at 200°C for 18 h in open flasks, in order to partly simulate oxygen uptake during the frying process. Respective CLA levels of 0.10, 0.25, and 1.1% were obtained. After methylation of heated oils, FAME were fractionated by Ag-TLC to achieve concentration of CLA isomers while removing saturated FA that elute within the CLA pattern on GC. A chromatogram exhibiting the *cis,trans* and *trans,cis* CLA elution zone (Fig. 2) shows distribution of mono *trans* CLA isomers from heated methyl linoleate and vegetable oils. They consisted of **2** *cis*-9,*trans*-11, **3** *trans*-8,*cis*-10, **4** *cis*-10,*trans*-12, **5** *trans*-9,*cis*-11, **6** *cis*-11,*trans*-13, and **7** *trans*-10,*cis*-12 18:2 acids. Relative CLA isomer distribution was identical for methyl linoleate and for peanut, sesame seed, and safflower seed oils. It was also similar to those from frying oils (3). As expected, two CLA isomers, **1** *cis*-8,*trans*-10 and **8** *trans*-11,*cis*-13 18:2 acids, were not detected in products from heat-treated methyl linoleate and vegetable oils.

**Evidence of [1,5] sigmatropic rearrangement.** The question that arises from the absence of **1** and **8** in the products from heated linoleic acid derivatives is, why? Obviously, a concerted mechanism, sensitive to steric or configurational factors, such as an internal pericyclic rearrangement of conjugated double bonds, must prevail. Indeed, sigmatropic

rearrangements are sensitive to such factors and thus have been extensively used in organic synthesis (10,11). To verify this hypothesis, methyl rumenate **2** was heated at 200°C under helium for 13 h. Owing to configuration constraints that would prevent the formation of mono *trans* isomer **1** in a [1,5] sigmatropic rearrangement, only mono *trans* isomer **3** should be formed (Fig. 3). Indeed, the resulting products of heat treatment of **2** were composed in quasi equal proportions of **2** and **3** (Fig. 2). Geometrical all-*cis* and all-*trans* isomers were also formed in small amounts. Sigmatropic rearrangement resulting in shift of the double bonds leading to 10,12 CLA isomers was not observed again as a result of unfavorable steric factors and configurations. Similarly, heat treatment of **7** resulted mainly in the formation of **6** (Figs. 2,3). These results suggested the establishment of an equilibrium between *cis,trans* and *trans,cis* systems in CLA that is in agreement with a [1,5] sigmatropic rearrangement (10). In the present case, the intramolecular process involved sigmatropic migration of an allylic hydrogen. This resulted in a shift of one carbon position for the conjugated system and imposed geometrical configurations for the two double bonds. In particular, the *cis* configurations in **3** and **6** were imposed by the cyclic geometry of the pericyclic mechanism, and the *trans* configurations, by steric factors. In addition, the process also prevented the formation of **1** and **8** CLA isomers, which were not detected in heated

**FIG. 3.** [1,5] Sigmatropic rearrangement of **2** (*cis*-9,*trans*-11 18:2) into **3** (*trans*-8,*cis*-10 18:2) and **7** (*trans*-10,*cis*-12 18:2) into **6** (*cis*-11,*trans*-13 18:2) acid isomers. Geometrical constraints prevent isomerization of **2** into **1** (*cis*-8,*trans*-10 18:2) and **7** into **8** (*trans*-11,*cis*-13 18:2) acid isomers.

linoleic acid derivatives (Fig. 2). Very likely, a [1,5] sigmatropic rearrangement may also occur between **4** and **5** acids, whose presence gives some clues on the formation of CLA from linoleic acid. Indeed, the formation of CLA very likely proceeds also through a concerted mechanism that results in abstraction of active hydrogen at C-11 by C-9 or C-13 (12). Moreover, the presence of **4** and **5** suggests that geometrical isomerization may also occur during this process, resulting in a mixture of all configuration isomers of 9,11 and 10,12 CLA. Further heat treatment then causes mono *trans* CLA to rearrange through a [1,5] sigmatropic mechanism, thus completing logical links between the three *cis,trans* and the three *trans,cis* CLA isomers found in heated vegetable oils.

# Issues Concerning the Monitoring of Statin Therapy in Hypercholesterolemic Subjects with High Plasma Lipoprotein(a) Levels

Angelo M. Scanu<sup>a,b,\*</sup> and Janet Hinman<sup>a</sup>

Departments of <sup>a</sup>Medicine and <sup>b</sup>Biochemistry and Molecular Biology, University of Chicago, Chicago, Illinois 60637

**ABSTRACT:** Most studies on the topic have shown that statin therapy decreases plasma LDL levels but not those of lipoprotein(a) [Lp(a)]. This specificity of action, although previously noted, has not been systematically investigated. In the current study we approached this problem by monitoring LDL- and Lp(a) cholesterol in 80 hypercholesterolemic subjects with high Lp(a) levels, at entry and 8 mon after initiation of statin therapy. We found that commonly used direct and indirect LDL cholesterol assays gave an LDL cholesterol value that comprised both true LDL- and Lp(a) cholesterol. We estimated these two analytes from the values of Lp(a) protein determined by ELISA and from knowledge of the Lp(a) chemical composition, complemented by data from immunochemical and ultracentrifugal analyses. Statin therapy, while not affecting plasma Lp(a) protein levels ( $21.7 \pm 10.4$ , before, and  $22.0 \pm 10.1$  mg/dL, after), caused a decrease in the estimated or true LDL cholesterol ( $P < 0.0001$ ) to values in some cases as low as 10 mg/dL. This drop in true LDL was validated by the decrease in the LDL band in the ultracentrifugation profiles, and its magnitude was proportional to the degree of total cholesterol lowering and to the pretreatment true LDL/Lp(a) cholesterol weight ratio. We conclude that true LDL but not Lp(a) cholesterol is affected by statin therapy and that this specific response cannot be monitored by current LDL cholesterol assays and must, rather, rely on estimates of these two analytes.

Paper no. L8996 in *Lipids* 37, 439–444 (May 2002).

Lipoprotein(a) [Lp(a)] is an LDL variant in which apolipoprotein B-100 (apoB-100) is linked by a single disulfide bond to apolipoprotein(a), [apo(a)], the characteristic glycoprotein of Lp(a) (1). As a consequence of this linkage, Lp(a) acquires metabolic properties that differ from those of LDL; among them is the inability to be taken up and degraded *via* the LDL receptor pathway (2,3). This impaired mechanism has been attributed to the failure of statins to lower the plasma levels of Lp(a) significantly, in contrast to LDL (4). The difference in metabolic behavior and pharmacological response of these two lipoproteins is not routinely recognized when statins or other hypolipidemic agents are used to treat subjects with high plasma Lp(a) levels (5). A main reason for this lack of recognition is the reliance placed on LDL cholesterol assays

that measure both LDL and Lp(a) cholesterol (6). The metabolic consequences and clinical magnitude of the different responses of LDL and Lp(a) to statins have not been clearly established. In the present study we investigated 80 hypercholesterolemic subjects on statin therapy who had both high plasma LDL and Lp(a) levels, and we also determined the LDL, Lp(a), and HDL distribution by physical, chemical, and immunochemical methods both at entry and after 8 mon at completion of the study. Furthermore, we examined the performance of direct and indirect assays for total LDL cholesterol and estimated this value by subtracting the amount contributed by Lp(a) from the total cholesterol. We report here that statin treatment can cause a significant depletion of plasma LDL but not of Lp(a), thus causing an unusually high Lp(a)/LDL profile that, if unrecognized, introduces a confounder in monitoring hypercholesterolemic subjects with high Lp(a).

## MATERIALS AND METHODS

**Human subjects.** The 80 subjects were chosen from the patient population seen in the Lipid Clinic of the University of Chicago, presenting with either a personal or a family history of plasma lipid abnormalities with or without an established atherosclerotic cardiovascular disease assessed by the occurrence of one or more episodes of myocardial infarction, positive thallium stress test, and/or coronary angiography. The characteristics of the subjects studied are summarized in Table 1. All of them at entry had a significant elevation of plasma total cholesterol (above 200 mg/dL), LDL cholesterol (above 100 mg/dL), apoB-100 (above 100 mg/dL), and Lp(a) protein (above 10 mg/dL). The plasma TG did not exceed the 300 mg/dL level, thus permitting the application of the Friedewald *et al.* formula (7).

**Study plan.** At entry each subject was examined for plasma levels of total and LDL cholesterol, apoB-100, Lp(a) protein, and Lp(a) cholesterol, HDL cholesterol, and apolipoproteins A-1 (apoA-1) along with a lipoprotein profile obtained by isopycnic density gradient ultracentrifugation. In addition, genotyping and phenotyping of apo(a) and genotyping of apolipoprotein E (apoE) were also conducted. The same analyses, except for genotyping, were carried out after 8 mon during which time the patients were under statin treatment. The statins used were: atorvastatin (Pfizer, New York, NY), cerivastatin (Bayer, New Haven, CT), pravastatin (Bristol-Meyers Squibb, Princeton, NJ) and simvastatin (Merck, West

Point, PA) (Table 2). Their choice and dosage were individualized according to clinical presentation, degree of hypercholesterolemia, and drug response. At the beginning of the study and during the course of the therapy each subject received nutritional and exercise counseling.

**Blood collection.** All subjects gave informed consent according to a protocol approved by the Institutional Review Advisory Board of the University of Chicago. The subjects fasted overnight before blood was withdrawn from the antecubital vein. The blood was collected into EDTA-containing tubes that were centrifuged within 30 min of collection. Following addition of an antiproteolytic cocktail (8), the plasma was either examined immediately or stored at 4°C in airtight containers until use within no more than 2 d.

**Laboratory analyses.** Total plasma cholesterol, TG, and HDL cholesterol were determined in a Vitros DT60 II System (Ortho Clinical Diagnostics, Rochester, NY) following the instructions by the manufacturer. Validation of the results was obtained from the College of American Pathologists (Northfield, IL). In all cases, the total LDL cholesterol was calculated according to the formula of Friedewald *et al.* (7). For comparative purposes, in 10 randomly selected subjects we also determined the total LDL cholesterol by direct assays, using each of the two following procedures: (i) Sigma Diagnostic procedure #353 (Sigma, St. Louis, MO), which utilizes latex beads coated with affinity-purified goat polyclonal antisera to specific human apolipoproteins to remove HDL and VLDL from the plasma sample; (ii) Sigma Diagnostic EZ LDL<sup>TM</sup> Homogeneous Method, in which, as a first step, an enzyme is used to bind to LDL cholesterol, rendering it unreactive and, as a second step, the enzyme is removed, thus permitting the colorimetric measurement of LDL cholesterol. The techniques

were carried out according to the manufacturer's instructions. In all cases, Lp(a), in terms of protein, was determined by ELISA as described by Fless *et al.* (9). Lp(a) cholesterol was estimated by multiplying the Lp(a) protein value by 1.7, a factor obtained from the average protein/total cholesterol weight ratio of six Lp(a) preparations differing in density (10). We estimated LDL cholesterol (est-LDL) by subtracting Lp(a) cholesterol from total LDL cholesterol. ApoB was determined by ELISA as previously described (11) and apoA-I by an ELISA developed in our laboratory using monospecific polyclonal antibodies raised in the rabbit utilizing reference materials kindly provided by Dr. Santica Marcovina of the Northwest Lipid Research Laboratories (Seattle, WA). Genotyping of apo(a) was carried out according to Lackner *et al.* (12) and that of apoE according to Hixson and Vernier (13). Phenotyping of apo(a) was conducted as previously described (14). All subjects had two alleles that ranged between 60 and 140 kb. Two apo(a)-size isoforms were present in the plasma; however, except for those cases in whom the two isoforms differed by 2–3 kringsles, the smaller sizes (12–15 kringsles) were the dominant ones. Creatine kinase (CK) and liver function tests were carried out at 4-mon intervals in the General Clinical Chemistry Laboratory of the University of Chicago.

**Isopycnic density gradient ultracentrifugation.** This was carried out according to an updated version (14) of a previously described technique (15). In brief, a nonlinear salt gradient was constructed to maximize the separation of LDL, Lp(a), and HDL classes. VLDL remained at the top of the tube. This discontinuous gradient was centrifuged in a swinging bucket rotor, SW40 (Beckman, Palo Alto, CA) at 284,000 × *g* for 50 h. At the end of the run, the effluent emerging from the top of the tube was monitored at 280 nm in a UA-5 ISCO absorbance monitor (Isco, Lincoln, NE) and recorded on a chart with a chart speed of 60 cm/h and a pump flow rate of 1 mL/cm. Density calibration was carried out as reported previously (14) by measuring the densities of each collected gradient fraction (0.9 mL) using a Mettler/Paar Precision Density Meter Model DMA 02C, and the distribution of Lp(a) was determined throughout the profile by ELISA. The subjects selected for the study had plasma levels of Lp(a) protein above

**TABLE 2**  
**Statin Regimen for the 8-mon Study**

Statin	Number of subjects	Dose (mg/d)
Atorvastatin	48	10–80
Simvastatin	17	20–40
Cerivastatin	8	0.2–0.4
Pravastatin	7	20–40

10 mg/dL, which permitted detection of a peak in the density gradient profile. In preliminary studies, we also established that in the hypertriglyceridemic subjects less than 1% of the total plasma apo(a) was present in the low-density portion of the gradient containing the TG-rich particles.

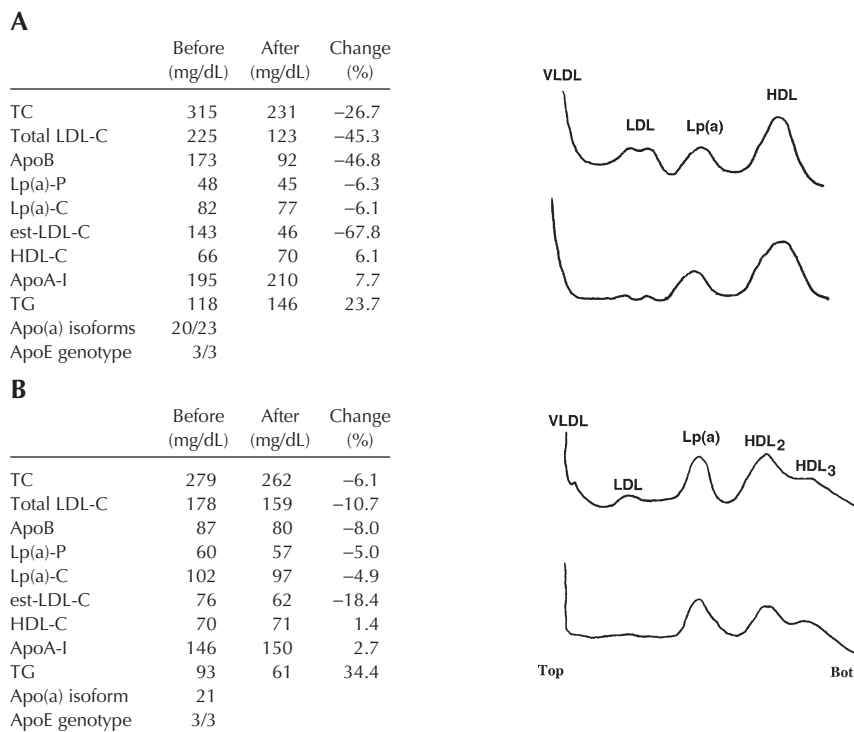

**Electrophoresis and immunoblotting.** For apo(a) phenotyping, the electrophoretic analyses were carried out on SDS-PAGE (4% polyacrylamide) on a Novex system (Novex, San Diego, CA) as previously described (16). Following electroblotting, the Immobilon blots were blocked in PBS containing 5% dry powdered milk and 0.3% Tween 20, followed by incubation with a specific anti-Lp(a) antibody prepared in the laboratory as previously described (16). M.W. markers representing apo(a) recombinants of a defined number of kringles were obtained from Dr. Eduardo Angles Cano (INSERM U 143, Paris, France).

**Statistical analyses.** The changes of the various parameters following statin treatment were determined by the paired two-tailed *t*-test. Because of the potential skewed distribution of

some of the parameters, particularly Lp(a) protein and Lp(a) cholesterol, all data were also examined by the Wilcoxon rank-sum test. We considered values of  $P < 0.05$  as significant.

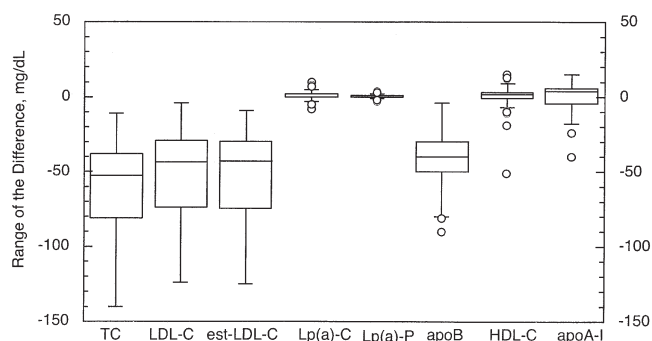

## RESULTS

In the 10 subjects used in the comparative studies, the mean total LDL cholesterol value  $\pm$  SD ( $126.7 \pm 67.2$  mg/dL) obtained by the formula of Friedewald *et al.* was in close agreement with the mean values  $\pm$  SD obtained by the Sigma 353 and EZ direct assays,  $132.2 \pm 63.2$  and  $133.2 \pm 66.5$  mg/dL, respectively. Since the formula of Friedewald *et al.* previously has been shown to provide the combined values of LDL cholesterol and Lp(a) cholesterol (6), it is apparent from our results that commonly used LDL cholesterol assays jointly measure both parameters. Figure 1 shows the lipoprotein and apolipoprotein values obtained in two representative subjects before and 8 mon after continual statin therapy. The subject in panel A exhibited a marked change in total cholesterol,

**FIG. 1.** Single spin profiles in two subjects before and after statin therapy. (A) This subject experienced a marked change in plasma total and est-LDL cholesterol and a modest change in Lp(a) protein while on atorvastatin, 20 mg daily. The marked drop in "true" LDL and apoB is reflected by the single spin profile (lower pattern) in which the double LDL peak is markedly reduced while the bands corresponding to Lp(a) and HDL remained essentially unchanged in keeping with the chemical and immunochemical data. (B) This subject had, at entry, a very high plasma level of Lp(a) protein indicating that a high percentage of the plasma cholesterol was carried by Lp(a). The hypocholesterolemic response elicited by cerivastatin 0.4 mg daily involved only est-LDL, as reflected by the chemical and ultracentrifugal data. Also in this case, chemical, immunochemical, and ultracentrifugal results showed little change in Lp(a) and HDL. In all cases the ultracentrifugal profiles were continuously recorded at 280 nm. The vertical axis represents optical density readings and the horizontal axis the gradient from top to bottom. TC, total cholesterol; LDL-C, total LDL cholesterol; est-LDL-C, estimated LDL cholesterol; Lp(a)-C, Lp(a) cholesterol; Lp(a)-P, Lp(a) protein; HDL-C, HDL cholesterol; apoB and apoA-I, apolipoproteins B and A-I; Lp(a), lipoprotein(a).

**FIG. 2.** Box plot of the range of difference of each parameter before and after statin treatment. Each box encloses 50% of the data with the median value of the parameter displayed as a line. The top and bottom of each box marks the  $\pm 25\%$  limit of the parameter studied. The lines extending from the top and bottom of each box mark the minimal and maximal values within the data set that fall within the acceptable range. Any outlier outside of this range is displayed as an individual point. For abbreviations see Figure 1.

LDL cholesterol, apoB, and est-LDL cholesterol, whereas there was comparatively little change in Lp(a) protein and Lp(a) cholesterol. In keeping with the chemical and immunochemical findings, the ultracentrifugal lipoprotein profiles showed that, after statin therapy (lower profiles), there was a marked reduction of the two LDL bands with little change in the Lp(a) and HDL bands. For the subject in panel B (Fig. 1), about 58% of the total LDL cholesterol (178 mg/dL) at entry, was in Lp(a) (102 mg/dL). Again, statin therapy had little effect on Lp(a) protein and Lp(a) cholesterol, as also reflected by the ultracentrifugation profiles. Both subjects in Figure 1, who differed in their apo(a), had the same apoE genotype, E3/3. In the 80 subjects, the effects on the various parameters of statin therapy are summarized in Figure 2. Major changes are evident for total cholesterol, LDL cholesterol, est-LDL cholesterol and apoB. The statistical analyses of the data (Table 3) using the paired *t*-test indicated that all these changes were highly significant. On the other hand, for Lp(a) protein and Lp(a) cholesterol, the mean change and the 95% confidence interval values after statin therapy were in each case very small, indicating that despite the *P* values, the changes were of either little or no biological relevance. The

Wilcoxon treatment of the data gave results comparable to those obtained with the paired *t*-test. Taken together, our results indicate that, whenever present, the drop in total plasma cholesterol occurred at the expense of the est-LDL cholesterol or true LDL cholesterol.

The statins were well tolerated with no evidence of side effects. The liver function tests and CK values remained within normal limits.

## DISCUSSION

The results of the current studies show that in hypercholesterolemic subjects with high plasma Lp(a) levels, statin treatment causes a decrease of total plasma LDL at the expense of the LDL component without a significant effect on Lp(a). This specificity in response could not be identified by either the indirect Friedewald *et al.* method or by the two direct "LDL cholesterol" assays, since all of them measured the total LDL cholesterol, i.e., the sum of LDL- and Lp(a) cholesterol. These results are in agreement with the ultracentrifugation-based  $\beta$  quantification data also shown to measure total LDL cholesterol (6). We believe that this is also likely to apply to any method that makes use of reagents reacting with apoB-100. Based on experimental findings in the current study, which was aimed at developing an understanding of the magnitude of the statin effect on true LDL- and Lp(a) cholesterol, we estimated those parameters based on the Lp(a) protein values and the data on the chemical composition of Lp(a) (see the Materials and Methods section for details) In our work, we used the factor 1.7 to estimate Lp(a) cholesterol from the Lp(a) protein ELISA data. However, this factor may not be universally applicable owing to the wide interindividual variation in Lp(a) in terms of apo(a) size, lipid content, and composition. From our own data and those in the literature, the protein-to-total cholesterol weight ratio may vary from 1.3 to 2 and in extreme cases 2.5 (5). Our conclusion that the statin effect is at the expense of true LDL was corroborated by both the density gradient ultracentrifugal profiles and the apoB-100 data. We attempted to compare the estimated Lp(a) cholesterol values with those obtained by the direct Lp(a) cholesterol assay of Seman *et al.* (17) utilizing a

commercial kit developed by Genzyme. Unfortunately, we were unable to arrive at a credible comparison because the number of available observations is limited by the fact that the kit has been removed from the market. An ultracentrifugation method, VAP (Atherotec, Birmingham, AL), has been proposed for simultaneously determining the cholesterol distribution among the main plasma lipoproteins. However, this approach suffers from the fact that both LDL and Lp(a) are highly heterogeneous in density (14), causing overlaps among these species and thus difficulties in making unequivocal lipoprotein assignments in the absence of appropriate apolipoprotein markers.

From our studies it is apparent that statin therapy, by specifically lowering the plasma LDL levels, leaves a residual statin-resistant hypercholesterolemia mainly sustained by Lp(a), the magnitude of which depends on pretreatment plasma LDL cholesterol and the LDL/Lp(a) cholesterol ratio. This specificity in response supports the notion that LDL and Lp(a) have distinct metabolic pathways (3,4). Moreover, the fact that the drop in plasma LDL involved the whole lipoprotein particle, as was shown by the chemical, immunochemical, and ultracentrifugal data, provides evidence that the LDL particles were removed *in toto* via the LDL receptor pathway.

The treatment with statins of hypercholesterolemic subjects with high plasma Lp(a) levels was prompted by the notion that decreasing the plasma LDL levels reduces the cardiovascular pathogenic potential of Lp(a) (18). Of note, the safety limit for the hypocholesterolemic effect of hypolipidemic agents has not been established. This situation cannot be compared with hypo- $\beta$ - and  $\alpha$ - $\beta$ -lipoproteinemia since these disorders are genetically determined and characterized by very low to absent plasma levels of LDL and apoB-100 (19), however, with little or no Lp(a)/apo(a) (3), and thus they are not directly comparable to the statin-induced LDL-deficient/high Lp(a) phenotype. Concerns about plasma cholesterol lowering have been raised because of reports associating plasma cholesterol levels with mood changes (20,21), depression and suicide attempts (22–25), and violent crime (26). However, the threshold of plasma cholesterol associated with these pathologies has not been uniformly established nor has the type of lipoprotein accounting for the cholesterol lowering been determined. In this study, statins caused an important drop in true LDL but did not significantly affect the levels of Lp(a) and HDL. Thus, in this unique scenario, we may speculate that the potentially harmful lowering of LDL may be functionally compensated by the cholesterol contained in either Lp(a) or HDL, or both. This would be in keeping with the lack of psychological problems reported in extensive statin trials, which likely included subjects of the type examined in the current study.

Atorvastatin, cerivastatin, simvastatin, and pravastatin, the four statins represented in this study, all exhibited similar behavior at the doses used by significantly lowering the plasma levels of true LDL while not affecting those of Lp(a). Thus, this appears to represent a class effect. A main message from our studies is that when hypercholesterolemic subjects with

elevated plasma levels of Lp(a) are treated with statins, the currently available assays that measure total LDL-cholesterol cannot be used to monitor compliance with the National Cholesterol Education Program III (NCEP III) guidelines (27) and therapeutic response. Recently, the two-step non-HDL cholesterol assay has been suggested as a better tool for cardiovascular risk and treatment assessment (28) and a better predictor (29) than the three-step LDL cholesterol assays. Although this approach clearly deserves further evaluation, the fact that the non-HDL cholesterol includes Lp(a) among the atherogenic lipoproteins requires attention.

## ACKNOWLEDGMENTS

Celina Edelstein provided invaluable assistance during the preparation of the manuscript and Ditta Pfaffinger, critical technical help. We are grateful to Drs. Theodore Karrison and Dezheng Huo of our Department of Health Studies for advice in the statistical analyses. Supported by the National Heart, Lung, and Blood Institute grants HL 63115 and 63209.

**ABSTRACT:** Treatments with high doses of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors may induce the expression of sterol regulatory element binding protein (SREBP)-target genes, causing different effects from those attributed to the reduction of hepatic cholesterol content. The aim of this study was to investigate the effects of high doses of statins on the key enzymes involved in VLDL production in normolipidemic rats. To examine whether the effects caused by statin treatment are a consequence of HMG-CoA reductase inhibition, we tested the effect of atorvastatin on these enzymes in mevalonate-fed rats. Atorvastatin and simvastatin enhanced not only HMG-CoA reductase but also the expression of the SREBP-2 gene itself. As a result of the overexpression of SREBP-2 caused by the statin treatment, genes regulated basically by SREBP-1, as FA synthase and acetyl-coenzyme A carboxylase, were also induced and their mRNA levels increased. DAG acyltransferase and microsomal TG transfer protein mRNA levels as well as phosphatidate phosphohydrolase activity were increased by both statins. Simvastatin raised liver cholesterol content, ACAT mRNA levels, and CTP:phosphocholine cytidyltransferase activity, whereas it reduced liver DAG and phospholipid content. Mevalonate feeding reversed all changes induced by the atorvastatin treatment. These results show that treatment with high doses of statins induces key enzymes controlling rat liver lipid synthesis and VLDL assembly, probably as a result of SREBP-2 overexpression. Despite the induction of the key enzymes involved in VLDL production, both statins markedly reduced plasma TG levels, suggesting that different mechanisms may be involved in the hypotriglyceridemic effect of statins at high or low doses.

Paper no. L8856 in *Lipids* 37, 445–454 (May 2002).

Inhibitors of the rate-limiting step in cholesterol biosynthesis, 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, are efficient drugs used to lower plasma cholesterol levels (1). However, their ability to reduce TG concentrations depends on the baseline TG levels and on the potency and efficacy of the statin used (2–4). Daily doses of HMG-CoA reduc-

tase inhibitors used for the treatment of hyperlipidemias are progressively increasing in order to achieve optimal control of plasma lipid levels. However, it is still unknown whether the mechanisms involved in the hypolipidemic action are the same at high doses of statins or whether different effects may be responsible for the lipid-lowering activity of these drugs.

HMG-CoA reductase inhibitors have been shown to lower apolipoprotein B (apoB) concentrations in several animal models by decreasing hepatic VLDL apoB secretion into plasma, but not all studies have been consistent with this concept (5,6). Although the HMG-CoA reductase inhibitors have similar pharmacodynamic properties, they differ in their pharmacokinetic behavior. Therefore, the differences in apoB secretion observed *in vivo* among reported studies may, in part, pertain to the type and especially the dose of HMG-CoA reductase inhibitor administered (7). It has been proposed that inhibition of HMG-CoA reductase could limit the availability of cholesterol for VLDL production and decrease hepatic VLDL secretion, with the subsequent lowering of plasma TG (6,8). Nevertheless, the decrease in the cellular cholesterol content elicited by drug treatment not only limits cholesterol availability but also leads to the activation of the sterol regulatory element binding proteins (SREBP), membrane-bound transcription factors that transcriptionally regulate multiple genes involved in cholesterol metabolism and TG synthesis (9).

The role of SREBP in lipoprotein production has not yet been elucidated. However, it has been reported that SREBP-1 and SREBP-2 bind to the microsomal TG transfer protein (MTP) promoter (10). Furthermore, data obtained from transfected cells suggest that lipogenesis and the assembly and secretion of apoB-containing lipoproteins might be coordinately regulated by SREBP (11). We hypothesized that the effects of statins on VLDL production and secretion may differ depending on the dose used. Thus, treatments with high doses of HMG-CoA reductase inhibitors may induce an intense stimulus in the expression of SREBP-target genes, causing different effects from those attributed to the reduction of hepatic cholesterol content.

Both adequate supply of lipids and functional MTP are required for efficient formation of apoB-containing lipoproteins (12). Here we investigate the effect of high doses of atorvastatin and simvastatin on MTP and key enzymes involved in hepatic lipid synthesis in normolipidemic rats, an animal model widely used to study the hypotriglyceridemic effect of

statins. In addition, we have studied whether the effects caused by statin treatment are a consequence of HMG-CoA reductase inhibition by determining the effect of atorvastatin on these enzymes in mevalonate-fed rats.

## METHODS

**Animals and treatments.** Male Sprague–Dawley rats (Harlan, France) were maintained with water and food *ad libitum* at constant humidity and temperature with a light/dark cycle of 12 h. The animals (average weight  $207 \pm 11$  g) were randomized into three groups and fed a standard diet (Panlab, Barcelona, Spain) or the same diet supplemented with atorvastatin or simvastatin (0.1% w/w) for 3 d.

A subgroup of 12 animals was randomized into three groups of treatment: control, mevalonate, and atorvastatin-mevalonate groups. The control group was fed a standard diet (Panlab); mevalonate and atorvastatin-mevalonate groups were fed the same diet supplemented with mevalonate (0.1% w/w) or atorvastatin (0.1% w/w) plus mevalonate (0.1% w/w), respectively. Animals were treated for 3 d and killed by decapitation between 9 and 10 A.M. at the beginning of the light period. Treatment diets were prepared as described in Alegret *et al.* (13). Mevalonate was supplied by Sigma-Aldrich (St. Louis, MO), atorvastatin calcium was supplied by Pfizer S.A. (Madrid, Spain), and the simvastatin lactone form was a generous gift from Merck (Barcelona, Spain).

Golden Syrian hamsters (Harlan, France) weighing 35–40 g were maintained in the same conditions described above. All procedures were conducted in accordance with the principles and guidelines established by the University of Barcelona Bioethics Committee as stated in Law 5/1995, 21st July, from the Generalitat de Catalunya.

**Sample preparation.** Rat liver homogenate and subcellular fractions were obtained as described previously (14) and stored at  $-80^{\circ}\text{C}$  until needed. The protein concentration of each fraction was determined by the method of Bradford (15). Between 10 and 100 mg of liver tissue of each rat was immediately frozen in liquid  $\text{N}_2$  and used for the extraction of total RNA with the Ultraspec™ (Biotechx, Houston, TX) reagent, following the instructions provided by the manufacturer. Blood samples were collected at the time of death in heparinized tubes; plasma was obtained by centrifugation and stored at  $-80^{\circ}\text{C}$  until needed.

**Lipid analysis.** Plasma total cholesterol, TG, and phospholipid concentrations were measured with the Boehringer-Mannheim GmbH (Mannheim, Germany) colorimetric tests (Monotest Cholesterol-CHODPAP No. 290319, Peridochrom-Triglyceride-GPO-PAP No. 701882, and MPR2 No. 691844 phospholipid, respectively). VLDL and LDL from plasma samples were precipitated by using reagent No. 543004, also from Boehringer-Mannheim GmbH, and HDL-cholesterol concentration was determined in the supernatant.

Liver lipid was extracted and measured as described previously (14). DAG concentration was measured with the Amersham-Pharmacia-Biotech-Europe GmbH (Freiburg, Germany) radioactive test (DAG reagents system RPN 200).

**Enzyme assays.** HMG-CoA reductase, phosphatidate phosphohydrolase (PAP), and CTP:phosphocholine cytidyltransferase (CT) activities were determined as described previously (14). DAG acyltransferase (DGAT) activity was measured as described previously (13). MTP activity was assayed by the commercial kit WAK-MTP-100 (Wak-Chemie Medical GmbH, Bad Homburg, Germany), following the instructions provided by the manufacturer.

**Immunoblot analysis.** Crude nuclear extract from livers was prepared, and immunoblot analysis for endogenous SREBP-2 was performed as described previously (16,17).

**mRNA analysis.** (i) *Reverse transcription PCR (RT-PCR).* Relative levels of specific mRNA were assessed by RT-PCR, as described previously (18). To check the absence of contamination, negative controls were included in each experiment. Preliminary experiments were carried out to establish conditions for exponential amplification of all the genes studied, calculating the range of cycle numbers at which a linear relationship was detected between input RNA and final product. For each primer set, an increasing number of PCR cycles with otherwise fixed conditions were performed to determine the optimal number of cycles to be used. The same procedure was followed for RNA concentration (19). Adenosyl phosphoribosyl transferase (APRT) was used as an internal control and was coamplified with target sequences in the same tube, except for SREBP-2 and FA synthase (FAS). These sequences were amplified in parallel with APRT in separate tubes and in duplicate. The number of cycles was 26 for ACAT-1, 24 for DGAT, 22 for HMG-CoA reductase, 21 for CT, 30 for SREBP-2, 23 for acetyl-CoA reductase (ACC), and 18 for FAS. Twenty-three cycles were used for APRT when it was amplified separately. Primer sequences and resulting PCR products are listed in Table 1. Five microliters of each PCR reaction mixture was subjected to electrophoresis in 5% polyacrylamide gel in  $1 \times$  TBE (Tris-borate-EDTA). Gels were dried, autoradiographed on RX-OMAT S Kodak film (Rochester, NY), and quantified by image analysis (Vilbert Lourmat Imaging, Scientific and Technical Services, University of Barcelona). The mRNA levels were always expressed as a ratio relative to APRT mRNA levels.

(ii) *Northern blot analysis.* Rat MTP cDNA was cloned by RT-PCR amplification. First-strand cDNA was reverse transcribed from hamster liver total RNA (1  $\mu\text{g}$ ) by using SuperScript™ II from GIBCO BRL Life Technologies (Paisley, United Kingdom). The cDNA was amplified by PCR using sense (forward) and antisense (reverse) primers designed from the hamster MTP cDNA sequence (GenBank accession number: X59657). Sense and antisense primers were designed at 29 to 49 bp (5'-GGG AAG GCT GGT CTT CAC GGT-3') and at 456 to 476 bp (5'-TGG TTT CCA GGC CAG CTT TCA-3'), respectively, relative to the translation start site. The PCR was conducted for 34 cycles, and PCR products were fractionated on 1% agarose gels, and DNA fragments of the appropriate size (448 bp) were excised and purified by Jetsorb, Gel Extraction Kit (GenoMed, Bad Oeynthausen, Germany). These cDNA probes were  $^{32}\text{P}$ -labeled

<sup>a</sup>DGAT, diacylglycerol acyltransferase; HMG-CoA Rd, 3-hydroxy-3-methylglutaryl-coenzyme A reductase; SREBP, sterol regulatory element binding protein; CT, CTP:phosphocholine cytidyltransferase; ACC, acetyl-CoA carboxylase; FAS, FA synthase; APRT, adenosyl phosphoribosyl transferase.

by a Random Priming Mix™ procedure from Promega-Boehringer Ingelheim (Heidelberg, Germany).

Twenty micrograms of total rat liver RNA was denatured and electrophoresed in 1% agarose gel and transferred to nylon membrane filter (Zeta-Probe; Bio-Rad, Barcelona, Spain). The filter was hybridized using ExpressHyb™ solution (Clontech Laboratories Inc., Palo Alto, CA) according to the instructions of the manufacturer and exposed to Kodak X-OMAT X-ray film at -80°C (20). mRNA levels were evaluated by densitometric scanning of the autoradiograph as described above and corrected for the amount of APRT using a cDNA probe.

**Statistics.** The results are the mean ± SEM of *n* experiments assayed in duplicate. Significant differences were established by an ANOVA test, using the computer program GraphPad InStat™ (GraphPad Software v2.03, San Diego, CA). When the number of animals was too small or the variance was not homogeneous, a nonparametric test was performed (Kruskal-Wallis test). When significant variations were found, the Student-Newman-Keuls multiple comparisons test was performed. Linear correlation between variables was calculated by using the above-mentioned program. Level of statistical analysis was set at *P* < 0.05.

## RESULTS

**Plasma and liver lipid.** Statin administration reduced plasma TG without affecting cholesterol and phospholipid levels (Table 2). Mevalonate feeding did not affect plasma lipid values, but reversed all the modifications induced by the atorvastatin treatment (Table 3).

In contrast to atorvastatin, the simvastatin treatment increased liver free cholesterol and decreased phospholipid and DAG concentration (20, 41, and 35% vs. control, respectively).

TG content was not significantly modified by statin administration (Table 2). Mevalonate feeding raised liver free cholesterol, TG, and phospholipid content (2.6-, 3.4-, and 2.3-fold vs.

**TABLE 2**  
**Effect of Atorvastatin (ATV) and Simvastatin (SVT) Treatment on Plasma and Liver Lipid Levels<sup>a</sup>**

	Control	ATV	SVT
Plasma

<sup>a</sup>Data are the mean ± SEM (*n* = 4) and are expressed as mg/dL of plasma or 10<sup>-3</sup> mg/mg of liver postnuclear supernatant protein. \**P* < 0.05. MVL, mevalonate; ATVMVL, atorvastatin-mevalonate.

control, respectively). These changes were blunted when animals were fed with both atorvastatin and mevalonate (Table 3).

**SREBP-2 and enzyme involved in cholesterol synthesis and esterification.** Atorvastatin and simvastatin treatments raised the mRNA levels of SREBP-2 (Fig. 1A). The increase in SREBP-2 mRNA levels is a consequence of SREBP-2 activation, as the SREBP-2 gene is a target gene of itself (21). Therefore, the nuclear form of SREBP-2 (active form) should increase after statin treatment. We checked this issue in a small subgroup of animals and, as expected, the nuclear form of SREBP-2 was increased by statin treatment ( $0.83 \pm 0.12$  and  $2.07 \pm 0.50$  (arbitrary units), respectively, for control and simvastatin groups ( $n = 4$ ;  $P < 0.05$ ). Statin treatment also increased mRNA levels of HMG-CoA reductase (Fig. 1B), whereas ACAT mRNA levels were only increased by simvastatin (1.54-fold induction vs. control group; Fig. 2). Despite statins being competitive inhibitors of HMG-CoA reductase, when microsomal HMG-CoA reductase activity from livers of statin-treated animals was measured, an increase in enzyme activity was detected because the inhibitors had been removed from the microsomes when samples were obtained (22). Accordingly, both statins enhanced microsomal HMG-CoA reductase activity ( $0.192 \pm 0.0512$ ,  $1.31 \pm 0.074$ , and  $2.65 \pm 0.083$  nmol/min/mg, for the control, atorvastatin, and simvastatin groups ( $n = 6$ ), respectively;  $P < 0.001$ ). Although atorvastatin was more potent than simvastatin in increasing mRNA levels (16- and 8-fold, respectively, relative to control), HMG-CoA reductase activity was lower in atorvastatin than in simvastatin-treated animals, given that this drug is more difficult to remove from microsomes than other HMG-CoA reductase inhibitors (23).

Mevalonate feeding downregulated SREBP-2 and HMG-CoA reductase. mRNA levels were reduced 50 and 56% vs. the control group, respectively, whereas HMG-CoA reductase activity decreased 88% vs. the control (Table 4). Even in the presence of mevalonate, atorvastatin increased mRNA levels of both genes and HMG-CoA reductase activity relative to the mevalonate group, achieving values similar to control group (Figs. 1C,D, Table 4).

**Enzyme involved in FA synthesis.** Atorvastatin and simvastatin treatment increased the mRNA levels of FAS and ACC (2.5- and 1.4-fold induction vs. control group, respectively; Figs. 3A,B). Mevalonate feeding did not affect mRNA levels of FA biosynthetic enzymes but reversed the changes induced by atorvastatin treatment in the mRNA levels of these genes (Table 4).

**Enzyme involved in TG synthesis.** As shown in Figure 4A, PAP activity was markedly increased by simvastatin and atorvastatin administration (3.7- and 3.4-fold induction vs. the control value, respectively). mRNA levels of DGAT were enhanced by statin treatment (Fig. 4B). As a result DGAT activity was also increased ( $17.9 \pm 1.48$ ,  $25.1 \pm 0.84$ , and  $20.8 \pm 0.35$  nmol/min/mg for the control, atorvastatin, and simvastatin groups ( $n = 4$ ), respectively;  $P < 0.05$ ). Mevalonate feeding did not modify significantly the PAP activity (Table 4) or the DGAT mRNA levels (data not shown) but blocked the increase in enzyme activity caused by atorvastatin.

**TABLE 4**  
Effect of ATV Treatment on Enzymes Involved in Hepatic Lipid Synthesis and VLDL Assembly in MVL-Fed Rats<sup>a</sup>

	Control	MVL	ATVMVL
HMG-CoA Rd (activity)	$0.185 \pm 0.029$	$0.0225 \pm 0.005^a$	$0.23 \pm 0.067^c$
FAS (mRNA)	$0.434 \pm 0.037$	$0.461 \pm 0.077$	$0.369 \pm 0.029$
ACC (mRNA)	$1.155 \pm 0.052$	$1.345 \pm 0.085$	$1.332 \pm 0.141$
PAP (activity)	$0.662 \pm 0.047$	$0.680 \pm 0.071$	$0.607 \pm 0.026$
CT (mRNA)	$0.545 \pm 0.172$	$0.762 \pm 0.092^a$	$0.718 \pm 0.025$
CT (activity)	$624.5 \pm 32.7$	$912.8 \pm 63.5^a$	$826.8 \pm 25.1$
MTP (mRNA)	$0.327 \pm 0.029$	$0.405 \pm 0.006$	$0.382 \pm 0.017$
MTP (activity)	$208 \pm 13$	$249 \pm 50$	$263 \pm 33$

<sup>a</sup>Data are the mean  $\pm$  SEM ( $n = 4$ ) and are expressed as pmol/min/mg (HMG-CoA Rd); nmol/min/mg (PAP activity); fluorescence arbitrary units/h/mg (MTP activity) and arbitrary units (mRNA). PAP, phosphatidate phosphohydrolase; MTP, microsomal TG transfer protein. For other abbreviations see Tables 1 and 3. <sup>a</sup>Values significantly different from control ( $P < 0.05$ ). <sup>c</sup>Values significantly different from MVL ( $P < 0.05$ ).

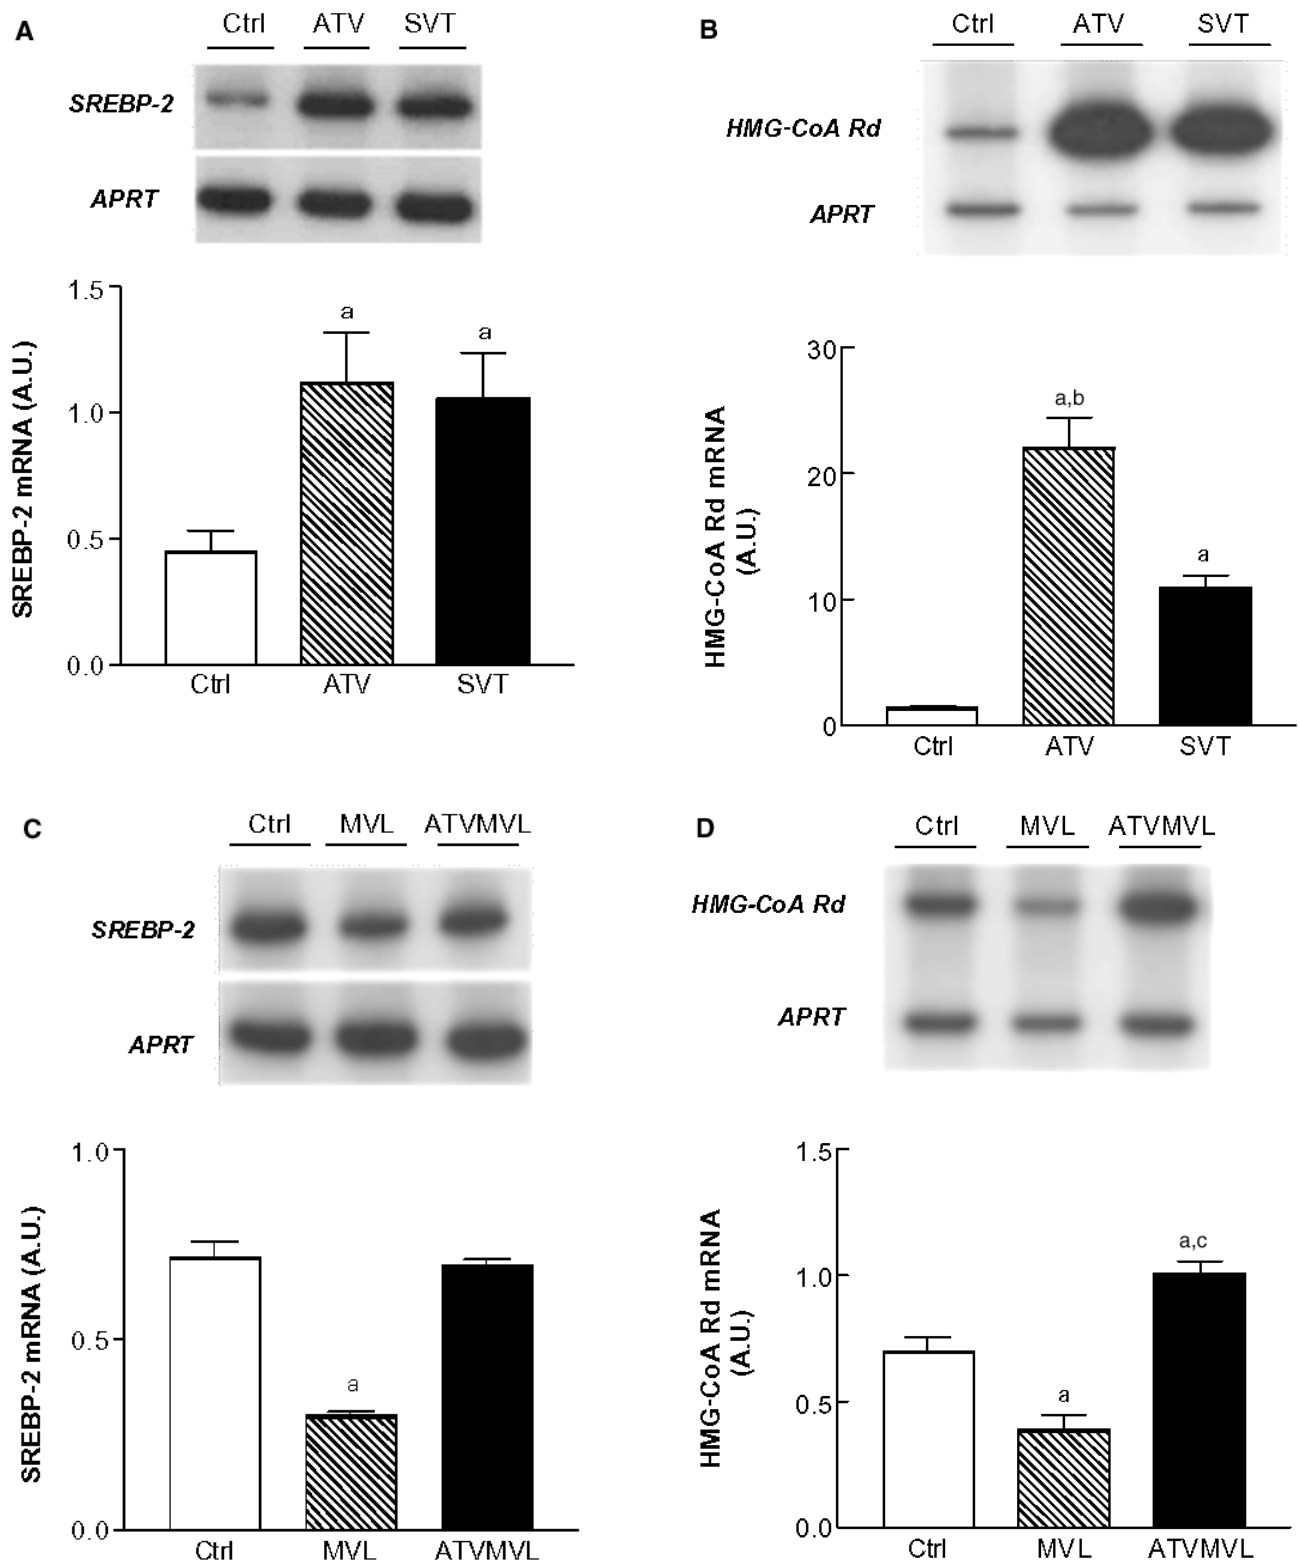

**Enzyme involved in phospholipid synthesis.** Figure 5 shows the effect of statin administration on CT. After atorvastatin treatment no significant changes were observed. In contrast, simvastatin increased the enzyme activity (1.4-fold vs. control value) without significantly affecting mRNA levels ( $0.78 \pm 0.014$ ,  $0.85 \pm 0.15$ , and  $0.96 \pm 0.11$  for the control, atorvastatin, and simvastatin groups ( $n = 6$ ), respectively). When animals were fed with a diet supplemented with mevalonate, mRNA levels and CT activity rose relative to the control group (1.4- and 1.5-fold, respectively) (Table 4).

**Enzyme involved in lipoprotein assembly.** Statin administration increased mRNA levels of MTP, the enzyme that catalyzes the transference of hepatic lipid to apoB, although this increase was statistically significant only for atorvastatin (Fig. 6). Neither atorvastatin nor simvastatin affected MTP activity [ $306 \pm 9.9$ ,  $381 \pm 23$ , and  $346 \pm 40$  for the control, simvastatin, and atorvastatin group ( $n = 6$ ), respectively]. Further, mevalonate feeding did not affect MTP mRNA levels or enzyme activity but blocked the increase in the mRNA levels caused by atorvastatin (Table 4).

## DISCUSSION

HMG-CoA reductase inhibitors deplete cellular cholesterol causing SREBP activation and enhancing the expression of SREBP-2 target genes, as HMG-CoA reductase or LDL receptors. However, SREBP have been shown to regulate many other enzymes involved in hepatic lipid synthesis and VLDL assembly (9). In the present study, we have focused on the effects of high doses of atorvastatin and simvastatin on key enzymes involved in VLDL production in normolipidemic rats.

Atorvastatin and simvastatin not only induce HMG-CoA reductase but also raise mRNA levels of SREBP-2 (Fig. 1). Generally, despite the induction of HMG-CoA reductase, HMG-CoA reductase activity and cholesterol synthesis remain inhibited, while statins present inside the hepatocyte and plasma cholesterol levels decrease. However, it is well established that HMG-CoA reductase inhibitors do not lower

**FIG. 1.** Effect of statin treatment on mRNA levels of sterol regulatory element binding protein-2 (SREBP-2) and 3-hydroxy-3-methylglutaryl-CoA reductase (HMG-CoA Rd) in normolipidemic rats (A,B) and mevalonate-fed rats (C,D). Total liver RNA was subjected to reverse transcription PCR (RT-PCR), and adenosyl phosphoribosyl transferase (APRT) was used as a reference gene to normalize mRNA levels of SREBP-2 (A,C) and HMG-CoA Rd (B,D). Bars represent the mean  $\pm$  SEM of the values obtained from six (A,B) or four (C,D) animals in each treatment group. A representative autoradiography of a RT-PCR assay for one animal of each treatment group is shown in the upper part of the figures. Ctrl, control; ATV, atorvastatin; SVT, simvastatin; MVL, mevalonate; ATVMVL, atorvastatin-mevalonate. <sup>a</sup>Values significantly different from control ( $P < 0.05$ ); <sup>b</sup>significant differences between values from ATV and SVT groups ( $P < 0.05$ ); <sup>c</sup>values significantly different from MVL ( $P < 0.05$ ).

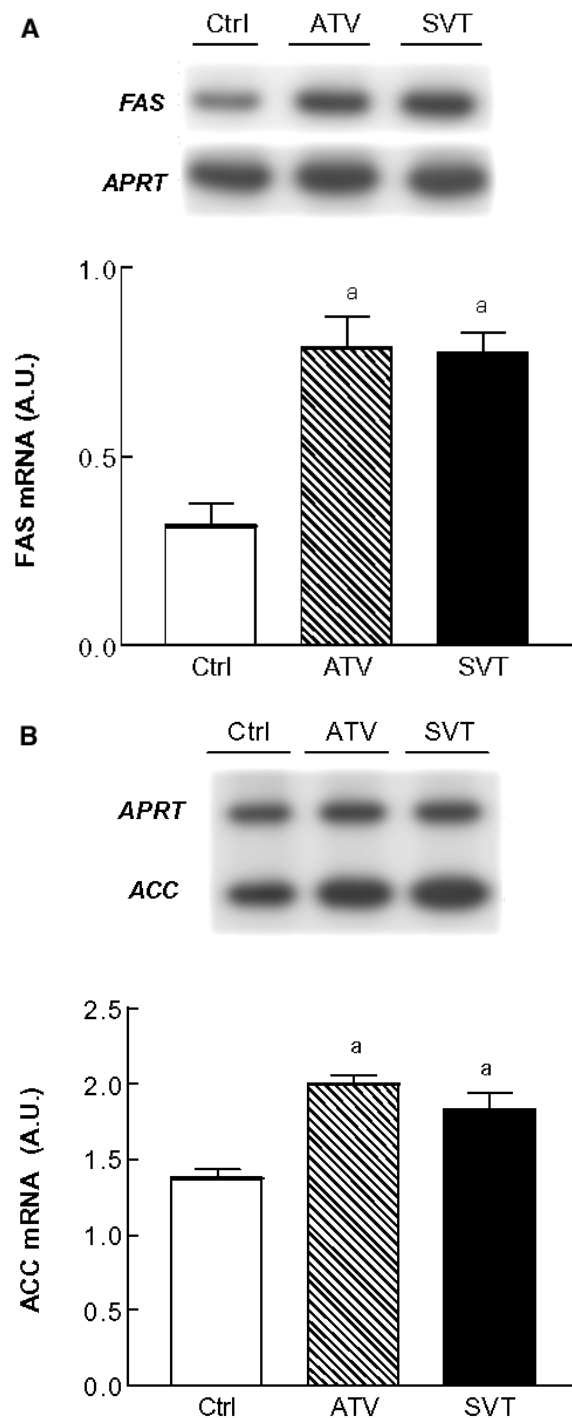

**FIG. 2.** Effect of statin treatment on mRNA levels of ACAT in normolipidemic rats. APRT-normalized mRNA levels of ACAT as measured by RT-PCR. Bars represent the mean  $\pm$  SEM of the values obtained from six animals in each treatment group: Ctrl, ATV, and SVT. For abbreviations see Figure 1. <sup>a</sup>Values significantly different from control ( $P < 0.05$ ).

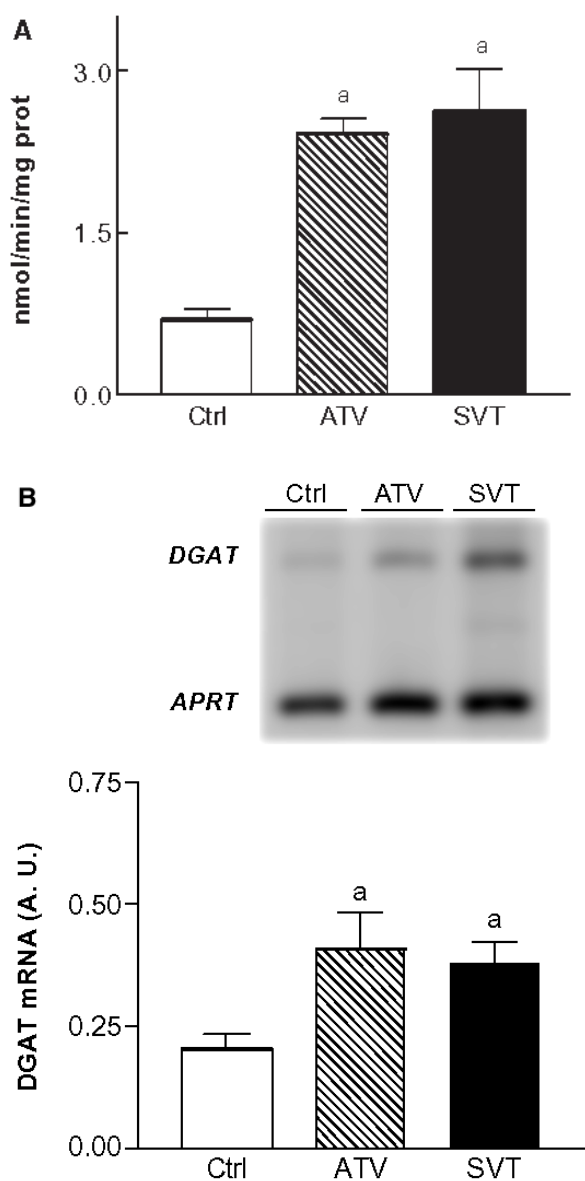

plasma cholesterol in rats, as HDL is the main transporter of rat plasma cholesterol (8). In fact, the great activation of SREBP elicited by treatment with high doses of statins may cause a superinduction of HMG-CoA reductase, which can compensate for the inhibitory effect of the drug and increase hepatic cholesterol (24). This effect depends on the dose, the potency, and the duration of action of the compound used. Thus, in the present study, simvastatin, but not atorvastatin, increased liver cholesterol content (Table 2). This difference may be attributable to the longer duration of action of atorvastatin, which maintains its inhibitory effect on HMG-CoA reductase for more than 24 h (2). This increase in hepatic cholesterol content was associated with higher ACAT mRNA levels. We cannot ensure that both effects are related, as little is known about the regulation of ACAT expression. However, it has been described that a high-fat, high-cholesterol diet causes an increase in ACAT mRNA levels in rabbit liver (25). Therefore, the increase in mRNA levels could be addressed to eliminate the excess of cholesterol produced by the simvastatin treatment (26).

Treatment with atorvastatin and simvastatin markedly reduced plasma TG levels. Although the mechanism underlying their TG-lowering effect is still unclear, low doses of statins may reduce apoB secretion in normolipidemic rats and other animal models (6,8). TG availability has been shown to be one of the major factors in the posttranslational regulation of apoB secretion (27,28). The effect of statins on TG synthesis has been tested in cell culture and animal models. These results show that low doses of statins affect neither the rate of TG synthesis nor the activity of key enzymes involved in the biosynthetic pathway (13,14,29,30). However, in the present study, the main enzymes involved in FA and TG synthesis were induced by treatment with high doses of atorvastatin and simvastatin. It is interesting to point out that the genes involved in FA synthesis are selectively activated by SREBP-1, but at high levels of expression, SREBP-2 also activates the enzyme cascade required for FA synthesis (31,32). Therefore,

**FIG. 3.** Effect of statin treatment on mRNA levels of FA synthase (FAS) and acetyl-CoA carboxylase (ACC) in normolipidemic rats. APRT-normalized mRNA levels of FAS (A) and ACC (B) as measured by RT-PCR. Bars represent the mean  $\pm$  SEM of the values obtained from six animals in each treatment group. A representative autoradiograph is shown in the upper part of each figure, with signals corresponding to FAS or ACC and the reference gene, APRT, for one Ctrl, one ATV-, and one SVT-treated rat. For abbreviations see Figure 1. <sup>a</sup>Values significantly different from control ( $P < 0.001$ ).

the increase in the mRNA levels of FAS and ACC may be attributed to the overexpression of SREBP-2 induced by the administration of high doses of statins. Thus, while low doses

**FIG. 4.** Effect of statin treatment on mRNA levels of diacylglycerol acyltransferase (DGAT) and phosphatidate phosphohydrolase (PAP) activity in normolipidemic rats. (A) PAP activity. The results are the mean  $\pm$  SEM of the values obtained from six animals in each treatment group. (B) APRT-normalized mRNA levels of DGAT as measured by RT-PCR. Bars represent the mean  $\pm$  SEM of the values obtained from six animals in each treatment group. A representative autoradiograph is shown in the upper part of each figure, with signals corresponding to DGAT and the reference gene, APRT, for one Ctrl, one ATV- and one SVT-treated rat. For abbreviations see Figure 1. <sup>a</sup>Values significantly different from control ( $P < 0.05$ ).

of statins induce only SREBP-2 target-genes, such as HMG-CoA reductase, high doses of statins cause such great activation of SREBP-2 that SREBP-1 target genes, such as FAS and ACC, are also induced by drug treatment.

DGAT and PAP may also be transcriptionally regulated by SREBP, as other enzymes involved in glycerolipid synthesis (33). Nevertheless, we cannot discard the notion that the induction of these enzymes was due to FA activation (34–36). Thus,

**FIG. 5.** Effect of ATV and SVT treatment on CTP:phosphocholine cytidyltransferase (CT) activity in normolipidemic rats. The results are the mean  $\pm$  SEM of the values obtained from six animals in each treatment group. For abbreviations see Figure 1. <sup>a</sup>Values significantly different from Ctrl ( $P < 0.01$ ). <sup>b</sup>Significant differences between values from ATV and SVT groups ( $P < 0.01$ ).

in the present study we have shown a concomitant increase in FAS mRNA levels, DGAT activities, and PAP activities. Given that others have shown that the increase in FAS mRNA parallels the relative increase in FA synthesis measured *in vivo*

**FIG. 6.** Effect of statin treatment on mRNA levels of microsomal TG transfer protein (MTP) in normolipidemic rats. Total liver RNA was subjected to electrophoresis and blot hybridization with the MTP <sup>32</sup>P-labeled probe and with a control <sup>32</sup>P probe directed against APRT. The mRNA levels were calculated after correction for loading differences with APRT. Bars represent the mean  $\pm$  SEM of the values obtained from six animals in each treatment group. A representative autoradiograph is shown in the upper part of the figure, with signals corresponding to MTP and the reference gene, APRT, for one Ctrl, one ATV-, and one SVT-treated rat. For abbreviations see Figure 1. <sup>a</sup>Values significantly different from control ( $P < 0.05$ ).

(9,32), the changes in DGAT and PAP found in the present study might be secondary to the induction of FA synthesis. In this sense, it is interesting to point out that we have found an almost 50% direct correlation between mRNA levels of FAS and PAP activity ( $n = 18$ ;  $r^2 = 0.470$ ;  $P = 0.0017$ ).

PAP is the branch point between TG and phospholipid synthesis and catalyzes the production of DAG. Despite the induction of FA and TG biosynthetic enzymes, hepatic TG content was unaffected by atorvastatin and simvastatin. Instead, DAG and phospholipid contents were decreased by the simvastatin treatment. It has been reported that statins increase biliary cholesterol and phospholipid secretion in rats owing to the induction of hepatic synthesis of cholesterol (24,37). From our results we can deduce that the DAG produced by PAP is shunted to the synthesis of phospholipids in order to supply enough phospholipid to eliminate the excess of cholesterol synthesized. The balance between cholesterol, TG, and phospholipid synthesis was maintained after atorvastatin treatment without changes in liver content of cholesterol, TG, DAG, or phospholipid. However, simvastatin caused a greater increase in cholesterol synthesis, probably because of its shorter duration of action. As a consequence, the DAG supply was not sufficient to sustain phospholipid synthesis for biliary cholesterol secretion, and the liver cholesterol content rose while the DAG and phospholipid contents decreased (Table 2).

Phospholipid synthesis is mainly regulated by CT activity, the rate-limiting enzyme of PC synthesis (38). The effects of statins on CT activity are not clear, and they seem to depend on the type of compound and experimental model used (13,14). In the present study, no change in CT activity was observed after the atorvastatin treatment. However, the simvastatin treatment caused an increase in this enzyme activity and a decrease in liver phospholipid content. The decrease of liver phospholipid caused by simvastatin (Table 2) may activate the translocation of CT (39,40), explaining the increase in the enzyme activity shown in the present study (Fig. 5). Although CT translocation is also activated by FA and DAG in cultured cells (40), we can discard the view that the increase in CT activity caused by simvastatin was a consequence of FA or DAG activation, since atorvastatin also enhanced FA synthesis and PAP activity without modifying CT activity.

MTP plays a pivotal role in VLDL assembly by mediating the transfer of hepatic lipid to nascent apoB (12). The effect of statins on MTP has not been tested in animal models. In the present study, treatment with high doses of atorvastatin and simvastatin caused an increase in MTP mRNA levels (Fig. 6), as a result of HMG-CoA reductase inhibition, although the enzyme activity was unaffected by drug treatment. This divergence is not surprising because of the long half-life of MTP (4.4 d) (41), which it makes difficult to observe a rise in MTP activity subsequent to a 1.4-fold increase in the mRNA levels. Transcriptional regulation of MTP has not been fully elucidated, but both SREBP and FA seem to control MTP expression (10,42,43). Horton *et al.* (31) showed a fourfold increase in MTP mRNA levels in SREBP-2

transgenic mice. Therefore, the increase in MTP mRNA levels observed in the present study might be a consequence of SREBP-2 overexpression, although we cannot discern whether MTP induction is a result of direct SREBP or FA activation.

Despite the induction of the key enzymes involved in lipid synthesis and lipoprotein assembly, plasma cholesterol was unchanged and TG levels were reduced by statin treatment. These results suggest the following: (i) apoB secretion is not enhanced in the present study. Nevertheless, given that treatment with high doses of lovastatin for 7 d raised plasma cholesterol levels (24), we cannot discard the view that longer treatment periods with high doses of statins may increase apoB secretion in normolipidemic rats. (ii) The blockage of apoB secretion does not seem to be one of the mechanisms involved in the TG-lowering effect of statins at high doses in normolipidemic rats. It has been reported that statins reduce cholesterol availability for apoB secretion, and this effect depends on the extent of HMG-CoA reductase inhibition (7). However, the reduction of plasma TG levels observed in the present study is difficult to explain by this mechanism, especially for simvastatin, because the induction of HMG-CoA reductase caused by high doses of this drug can overcome its inhibitory effect and increase hepatic cholesterol content (Table 2). Although the aim of this study was not to investigate the mechanisms involved in the hypotriglyceridemic effect of statins, we can speculate that the decrease in plasma TG levels observed in this study might be due to an induction of lipoprotein lipase by SREBP (44,45).

In summary, we have shown that treatment with high doses of statins induces key enzymes controlling rat liver lipid synthesis and VLDL assembly. High doses of atorvastatin and simvastatin induce not only SREBP-2 target genes involved in cholesterol synthesis as SREBP-2 or HMG-CoA reductase, but also SREBP-1 target genes, as FAS or ACC. PAP, DGAT, and MTP were also induced by the statin treatment as a result of SREBP or FA activation. After the atorvastatin treatment, the balance between hepatic cholesterol, TG, and phospholipid synthesis was maintained without changes in liver lipid content. In contrast, simvastatin increased liver cholesterol and reduced DAG and phospholipid content. Despite the induction of the key enzymes involved in VLDL production, both statins markedly reduced plasma TG levels, suggesting that different mechanisms may be involved in the hypotriglyceridemic effect of statins at high or low doses in normolipidemic rats.

**ABSTRACT:** Oxidized cholesterol in the diet have been shown to exacerbate arterial cholesterol deposition and the development of atherosclerosis in animal models. Dietary oxidized cholesterol are absorbed through the intestine and incorporated into lymph chylomicrons. The aim of this study was to investigate the effect of oxidized cholesterol on the metabolism of nascent chylomicrons *in vivo*. It was shown that oxidized cholesterol markedly delay the clearance of chylomicrons from plasma compared to rats given TG alone. However, there was no difference in the clearance of chylomicrons containing oxidized cholesterol vs. purified cholesterol, although the presence of oxysterols did appear to exacerbate the removal of these particles from circulation. The impaired clearance of chylomicrons containing oxidized cholesterol was not due to impaired lipolysis and slower conversion to the remnant form. Moreover, the incorporation of oxidized cholesterol did not alter the hepatic or splenic uptake of chylomicrons compared to chylomicrons isolated from rats given purified cholesterol or TG alone. Collectively, the results of this study suggest that the exacerbated delay in clearance of chylomicron remnants enriched with oxysterols may be due to impaired uptake by tissues other than the liver and spleen. Apolipoprotein (apo) analysis showed that oxysterol incorporation reduced the apoE content and altered the apoC phenotype of chylomicrons, which may have an impact on the removal of chylomicron remnants from plasma. In conclusion, dietary oxysterols appear to have the potential to adversely affect chylomicron metabolism. Therefore, further investigations in humans are required to determine whether dietary oxidized cholesterol found in cholesterol-rich processed foods delay the clearance of postprandial remnants, which may contribute to and exacerbate the development of atherosclerosis.

Paper no. L8972 in *Lipids* 37, 455–462 (May 2002).

The onset of atherosclerosis is marked by the accumulation of cholesterol and oxidized cholesterol in the arterial wall (1,2). The oxidized cholesterol content of early foam cells and fatty streaks closely resembles the oxidized cholesterol found in cholesterol-rich processed foods (3–8). We and others have shown that dietary oxidized cholesterol are absorbed from the intestine and incorporated into lymph chylomicrons (9,10). In humans, absorption of oxidized cholesterol from cholesterol-rich processed foods results in increased circulating levels of

cholesterol oxidation products in plasma lipoproteins (11,12). Early studies showed that feeding oxidized cholesterol resulted in focal arterial damage and fibrous lesions in rat and rabbit models (13–15). More recently we have shown that short-term feeding of oxidized cholesterol to rabbits result in a marked increase in aortic cholesterol concentration compared to rabbits fed purified cholesterol (16). Longer-term feeding of oxidized cholesterol to rabbits has shown that these sterols accelerate and exacerbate the development of atherosclerotic lesions (17,18). Epidemiological evidence also suggests oxysterols are proatherogenic, because the consumption of ghee, which is rich in oxysterols, has been associated with an increased incidence of coronary heart disease (19). Given postprandial lipoproteins transport dietary oxidized cholesterol to the circulation, and chylomicron remnants penetrate and are retained by the arterial wall (20), it has been proposed that dietary lipids may be a potential source of early lesion oxidized cholesterol (9,16).

The consumption of dietary cholesterol has been associated with delayed clearance and accumulation of chylomicron remnants in plasma (21,22). The consumption of cholesterol may often include cholesterol-rich processed foods that contain oxidized cholesterol products (3). The absorption and incorporation of oxidized cholesterol into lymph chylomicrons may modulate the metabolism and tissue uptake of these particles. We have previously shown that chylomicrons enriched with oxysterols have an increased size due to a greater content of cholesterol and TG in these particles compared to rats given purified cholesterol (9). The size of chylomicrons can influence their kinetics, with larger chylomicrons having delayed clearance from plasma compared to smaller chylomicrons (23). Furthermore, increasing the cholesterol content can further delay the clearance of chylomicrons (21,24).

Like cholesterol, oxidized cholesterol products appear to affect chylomicron metabolism. Mortimer and co-workers (25) reported that the inclusion of the oxidized cholesterol 7 $\alpha$ -hydroxycholesterol, 7 $\beta$ -hydroxycholesterol, 25-hydroxycholesterol, and 3-ketocholesterol into chylomicron-like lipid emulsions retarded plasma clearance. However, the effects of dietary oxidized cholesterol products on chylomicron composition and metabolism remain unclear.

The normal metabolism of chylomicrons involves the rapid conversion to chylomicron remnants by the action of endothelial lipases. Lipoprotein lipase (LPL) requires apolipoprotein CII (apoCII) to catalyze the hydrolysis of TG and

Abbreviations: apoB<sub>48</sub>, -B-100, -C, -CII, -CIII, -E, apolipoproteins B<sub>48</sub>, B-100, C, CII, CIII, E; HL, hepatic lipase; LPL, lipoprotein lipase.

is responsible for approximately 70% of chylomicron TG lipolysis. Chylomicron remnants are subsequently removed from circulation primarily by the liver *via* the apoB<sub>100</sub>/E receptor. The processes of lipolysis and high-affinity uptake of chylomicrons are critically regulated by the size, lipid composition, and apolipoprotein composition of the particles (26,27). Given that dietary oxidized cholesterols increase the cholesterol content and size of chylomicrons, it was hypothesized that these sterols may modulate the clearance of chylomicrons from plasma. Therefore, the objective of this study was to investigate the effect of oxidized cholesterol on chylomicron metabolism *in vivo*. The mechanism of how oxysterols may alter chylomicron metabolism was studied by determining the effect of oxysterols on apolipoprotein composition, lipolysis, and receptor-mediated uptake processes.

## MATERIALS AND METHODS

**Materials.** Cholesterol (>99% purity) and triolein (>99% purity) were purchased from Sigma (St. Louis, MO). Cholesterol (catalog no. TR13015; Trace Scientific, Melbourne, Australia) and TG (Wako, Osaka, Japan) were determined colorimetrically. Bis(trimethylsilyl)-trifluoroacetamide was purchased from Sigma. Radiolabeled lipids, [<sup>14</sup>C]palmitate and [<sup>3</sup>H]cholesterol, were purchased from Amersham Pharmacia Pty. Ltd. (Piscataway, NJ).

**Preparation of lipid emulsions.** The purified and autooxidized cholesterol emulsions were prepared as previously described (9). Briefly, aliquots of radiolabeled TG ([<sup>14</sup>C]palmitate) and cholesterol ([<sup>3</sup>H]cholesterol) were placed into a glass vial, and the solvent was evaporated under N<sub>2</sub>. The pure or heat-treated cholesterol (50 mg) predissolved in chloroform and triolein (600 mg) was added, and the solvent was evaporated under N<sub>2</sub> in a water bath at 37°C for both cholesterol treatments. The control treatment consisted of triolein (600 mg) alone. The GC-MS analysis of the purified cholesterol emulsion showed 99.9% purity. The GC-MS analysis of the oxidized cholesterol emulsion was cholesterol (69.3%), 7β-hydroxycholesterol (6.9%), 5α,6α-epoxycholesterol (4.8%), 5β,6β-epoxycholesterol (4.83%), 7-ketocholesterol (8.6%), 6-hydroxycholesterol (1.0%), cholest-4-ene-3-one (0.4%), 4,6-cholestadiene-3-one (1.4%), cholestane-3,6-dione (1.0%), and unknown oxysterols (1.5%) (9).

**Chylomicron isolation.** The isolation of lymph chylomicrons has been described previously (9,28). Approval for experimental procedures was obtained from the University of Western Australia Ethics Committee, and procedures followed recommendations of the National Health and Medical Research Council of Australia. Briefly, 300 g male Wistar nonfasted rats were anesthetized with phenobarbital (0.05 mg/kg), and the superior mesenteric lymph duct was cannulated and the duodenum cannulated *via* a gastrostomy. The triolein vehicle alone (control) and cholesterol emulsions (50 mg autooxidized cholesterol or purified cholesterol) were administered *via* the gastric cannula. Chylomicrons were then isolated from lymph by density ultracentrifugation as previ-

ously described (29). Chylomicron cholesterol and TG were measured, and oxysterol analysis was done by GC-MS as reported previously (9,30,31). The size of chylomicrons was also determined using an automated particle sizer.

**Kinetic studies with radiolabeled chylomicrons.** Nonfasted recipient male Wistar rats weighing 300 ± 10 g were anesthetized with ketamine/xylazine (2:1, 1 mL/kg), and the right carotid artery and left jugular vein were cannulated as reported previously (28). Chylomicrons were injected into the external jugular vein at a dose of 7–10 mg of TG in 0.4–0.5 mL, and blood samples were taken from the carotid artery into heparinized tubes after injection of doubly labeled chylomicrons. At the end of the clearance study, rats were given a lethal dose of phenobarbital *via* the jugular vein, and the liver and spleen were removed. Blood volume was calculated as 4% of body weight (28). The radioactivity of plasma and tissues was measured using a Wallac 1410 Liquid Scintillation Counter in dual-label mode with autoquench correction (28).

**Chylomicron TG lipolysis with postheparin plasma lipases.** The lipoprotein TG lipolysis studies were carried out *in vitro* using techniques previously described (32). The enzyme activities of LPL and hepatic lipase (HL) were determined for chylomicrons isolated from rats given the triolein vehicle alone (control), autooxidized cholesterol, or purified cholesterol. The assay quantitates the [<sup>14</sup>C]FFA after liberation from chylomicron TG ([<sup>14</sup>C]palmitate) by the action of LPL and HL. TG hydrolysis was expressed as the appearance of radiolabeled FA released (μmol FA/mL/h) (32).

**Preparation of chylomicron remnants.** Chylomicron remnants were generated in functionally hepatectomized rats as previously described (33). Briefly, male Wistar rats were anesthetized with ketamine/xylazine (1 mL/kg) and a hepatectomy was performed. Chylomicrons isolated from the control, autooxidized cholesterol, and purified cholesterol-treated donor rats were infused into the femoral vein. After 30 min blood was taken from the abdominal aorta, and chylomicron remnants were isolated by density ultracentrifugation as previously described (29).

**Apolipoprotein analysis.** Chylomicrons and chylomicron remnants were delipidated according to the method of Herbert *et al.* (34). Chylomicrons and chylomicron remnant apolipoproteins were separated by SDS-PAGE and by isoelectric focusing to separate the isoforms of the apolipoproteins as described previously (32). Chylomicrons and chylomicron remnants were pooled from each treatment group to ensure there was sufficient protein after delipidation of samples for visualization and quantitation of apolipoproteins. The area of apolipoprotein bands was standardized to apoB<sub>48</sub> to enable determination of apolipoprotein changes per particle, as one chylomicron contains one apoB<sub>48</sub>.

**Statistical analysis.** The chylomicron kinetics, organ uptake, and rates of lipolytic activity were compared between treatments by one-way ANOVA with a Bonferroni correction for multiple comparisons testing for significance at α = 0.05 (GraphPad InStat, San Diego, CA). Chylomicron TG and cholesterol clearance from plasma were determined as the area above the curve (GraphPad Prism 1.00).

**RESULTS**

Chylomicrons isolated from rats given oxysterols were approximately 100 nm larger compared to those from purified cholesterol and control animals owing to increased TG and cholesterol incorporation (Table 1). In the postprandial phase (2–4 h) there was an increase in size as well as changes in chylomicron composition compared to fasted chylomicrons in all treatment groups due to absorption of lipid from the infusate. Therefore, for the kinetic studies, chylomicrons isolated *in vivo* during this period were pooled.

The metabolism of chylomicrons is a twofold process involving lipolysis of chylomicron TG to form cholesteryl ester-rich remnant particles and rapid removal of chylomicron remnants from circulation primarily by the liver *via* receptor-mediated processes. The clearance from plasma of chylomicron cholesteryl ester represents the uptake of chylomicron remnants by tissues and organs and is predominantly an indicator of high-affinity uptake *via* hepatic receptors. The clearance from plasma of cholesterol in chylomicrons containing oxysterols and purified cholesterol is shown in Figure 1. The clearance of chylomicron remnants was reduced by approximately 33%, based on the greater percentage of cholesteryl ester radioactivity remaining in plasma (area below the curve,  $1569.2 \pm 87.22$ ) compared to control chylomicrons ( $1067.6 \pm 179.52$ ,  $P = 0.014$ ). Chylomicrons isolated from rats given purified cholesterol also had delayed clearance, which was intermediate compared to control and oxidized cholesterol-containing chylomicrons, but the removal of these particles was not significantly different from that of the other two treatment groups ( $1334.77 \pm 152.10$ ). In all three groups studied, chylomicron clearance from plasma was characterized by a rapid phase (0–5 min) followed by a slower metabolic rate (5–30 min), which is consistent with previous studies on chylomicron metabolism *in vivo* (23,26,28,33). The rate of clearance of chylomicrons isolated from oxysterol-fed rats was reduced by approximately 10% compared to the purified and control

**FIG. 1.** The clearance from plasma of chylomicron cholesteryl ester is shown as a percentage of the dose of radioactive <sup>3</sup>H-cholesterol ester injected. Chylomicrons were isolated from lymph-cannulated rats given an infusate of either oxidized cholesterol or purified cholesterol in a vehicle of triolein or triolein (control) alone *via* a gastric cannula. Chylomicrons were then injected into the external jugular vein of recipient conscious rats. Data are mean  $\pm$  SEM ( $n = 9$ ),  $P < 0.05$ . \*The chylomicrons containing oxidized cholesterol products had a significantly delayed clearance from the plasma compared to the control ( $P = 0.014$ ) but not the purified cholesterol containing chylomicrons.

chylomicrons during the initial rapid phase but was similar in the slower phase of catabolism.

The clearance of chylomicron TG from plasma for chylomicrons containing oxysterols, purified cholesterol, and control particles is shown in Figure 2. The plasma clearance profile observed for chylomicron TG typifies the initial rapid phase, in which chylomicrons bind to endothelial lipases on infusion of particles into the circulation, and the slower phase, which represents release of chylomicrons from lipases and subsequent particle uptake (23,28,33). Both oxysterol and purified cholesterol incorporation into chylomicrons resulted in a similar and delayed TG clearance from plasma compared to chylomicrons containing TG alone (area below the curve, oxysterols  $948.3 \pm 76.71$ ,  $P = 0.0068$ ; purified cholesterol  $904.89 \pm 97.31$ ,  $P = 0.0025$ ; controls  $489.8 \pm 129.88$ ). The impaired TG clearance was marked in the first 5 min after chylomicron infusion in which both the oxidized and purified cholesterol-containing chylomicrons had only 50% of the TG cleared compared to 75% in the control.

There was no significant difference in the hepatic uptake of chylomicrons as a consequence of oxysterol or cholesterol

<sup>d</sup>The major oxysterols in the oxidized cholesterol chylomicrons include 7 $\beta$ -hydroxycholesterol, 5 $\alpha$ ,6 $\alpha$ -epoxycholesterol, 5 $\beta$ ,6 $\beta$ -epoxycholesterol, and 7-ketocholesterol.

**FIG. 2.** The clearance from plasma of chylomicron TG is shown as a percentage of the dose of radioactive  $^{14}\text{C}$ -TG injected. See Figure 1 for experimental procedures. Chylomicrons were then injected into the carotid artery of conscious recipient rats. Data are mean  $\pm$  SEM ( $n = 9$ ),  $P < 0.05$ . \*There was no difference in the plasma clearance of TG between chylomicrons containing oxidized cholesterol or purified cholesterol. Chylomicrons containing both oxidized and purified cholesterol had a significant delay in clearance of TG compared to the control ( $P = 0.0068$  and  $P = 0.0025$ , respectively).

feeding as shown in Table 2. The splenic uptake of chylomicrons is representative of the reticuloendothelial system and was shown to be similar for chylomicrons isolated from rats given oxysterols or purified cholesterol.

To elucidate whether the delayed clearance of chylomicrons containing oxysterols or purified cholesterol was a con-

sequence of impaired remnant formation, the lipolytic process was assessed using the *in vivo* lipolytic index and by measuring lipase-mediated hydrolysis *in vitro*. The rate of chylomicron remnant formation can be estimated by the difference in TG clearance (lipolysis plus particle uptake) and cholesteryl ester clearance (particle uptake alone) and is called the lipolytic index (34,35). The delayed clearance of chylomicrons containing oxysterols did not appear to be due to slower remnant formation. Rather, the chylomicrons containing oxysterols had a higher mean lipolytic index (area above the curve,  $620.88 \pm 64.67$ ), but this was not significantly greater than either the control or purified cholesterol chylomicrons (area above the curve,  $577.80 \pm 251.99$  and  $429.88 \pm 64.67$ , respectively).

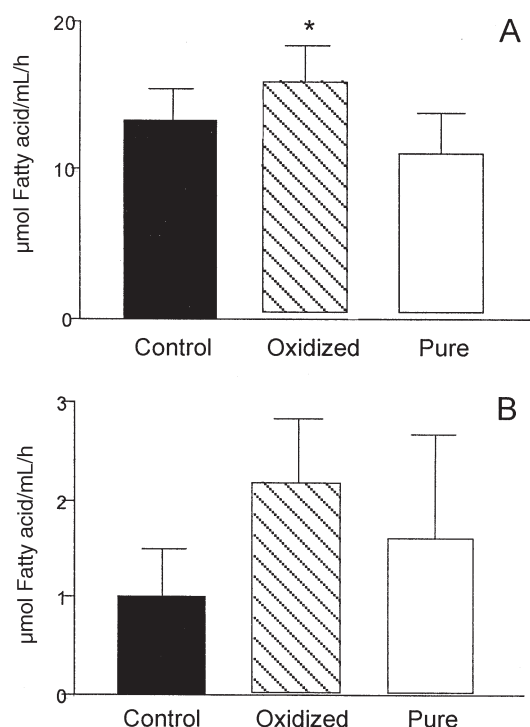

To further explore changes in the lipolytic process, the extent of lipolysis of chylomicron TG was measured to assess the activity of lipases. Chylomicrons used for the *in vitro* lipolysis measurements were isolated from rats given lipid emulsions containing oxidized cholesterol, purified cholesterol, or TG alone (control). In chylomicrons containing oxysterols, the total lipolysis of TG substrate was greater compared to the purified cholesterol-containing chylomicrons and control chylomicrons by 30 and 20%, respectively. The increase in rate of substrate lipolysis in chylomicrons containing oxysterols was attributable to LPL, which account for 90% of chylomicron TG cleavage (Fig. 3A). Chylomicron TG lipolysis occurred at a faster rate in rats fed oxysterols ( $15.85 \pm 2.39 \mu\text{mol FA/mL/h}$ ) compared to control and purified cholesterol-fed rats ( $11.14 \pm 2.72 \mu\text{mol FA/mL/h}$ ,  $P = 0.048$ , and  $13.24 \pm 2.15 \mu\text{mol FA/mL/h}$ ,  $P = 0.041$ ). HL accounted for a small increase in substrate lipolysis in the chylomicrons containing oxysterols, but this was not significant compared to the other chylomicrons, as shown in Figure 3B.

The apolipoprotein complement of chylomicrons and chylomicron remnants is critical in the regulation of their metabolism because the apolipoproteins serve as cofactors for lipases and ligands for receptors. The apolipoproteins of chylomicrons and chylomicron remnants are shown in Table 3. The ratio of total apoE/apoC was approximately 60% lower in chylomicrons isolated from rats given oxidized (0.115) and purified cholesterol (0.121) compared to controls (0.305), as shown in Table 3. Oxysterol incorporation into chylomicrons also reduced the mass of apoE by 38% per particle (as normal-

<sup>a</sup>Nascent chylomicrons were isolated from rats given infusates of either oxidized cholesterol or purified cholesterol in a vehicle of triolein or triolein (control) alone *via* a gastric cannula. Chylomicrons were then injected into the external jugular of conscious recipient rats, and arterial blood was sampled to monitor the clearance of chylomicrons from plasma. Following the final arterial blood sample at 30 min, rats were sacrificed and the liver and spleen removed.

**FIG. 3.** The rate of lipoprotein lipase activity (A), and hepatic lipase (B) in postheparin plasma of chylomicron TG isolated from rats given oxidized ( $n = 4$ ) or purified ( $n = 4$ ) cholesterol in a vehicle of triolein and vehicle alone (control,  $n = 4$ ). TG substrate hydrolysis was expressed as the appearance of radiolabeled FA released ( $\mu\text{mol FA/mL/h}$ ). \*The rate of lipase activity in oxidized cholesterol postheparin plasma was significantly different compared to that of purified cholesterol and control ( $P < 0.05$ ).

ized for apoB<sub>48</sub>) compared to 21% for purified cholesterol-containing chylomicrons (see Table 3). The decreased apoE content was subsequently confirmed in posthydrolyzed remnants enriched with oxysterols and purified cholesterol, in which they had an 18 and 12% lower apoE per particle, respectively, compared to control chylomicron remnants. The chylomicron remnants from oxysterol-fed rats also contained a greater amount of apoC compared to the control and purified cholesterol chylomicron remnants, which expressed only

traces of this apolipoprotein. Further to the changes in total apoE content, the apoE isoform expression was also altered in chylomicrons derived from oxidized cholesterol, showing half the apoE<sub>4</sub> (4% of total apoC and apoE) compared to the control (8%) or purified cholesterol chylomicron (9%), as shown in Table 3. In addition, the chylomicron apoC isoforms CIII<sub>1+2</sub> and CIII<sub>3</sub> were also shown to be elevated in oxysterol-fed rats.

**DISCUSSION**

We proposed that oxidized cholesterol incorporation into lymph chylomicrons may modulate chylomicron metabolism based on previous observations showing that oxidized cholesterol alter chylomicron structure and composition (9). The results reported here are the first experiments using *in vivo*-synthesized lymph chylomicrons isolated after intestinal absorption of oxidized cholesterol and purified cholesterol to study the kinetics of these particles *in vivo*. It has been demonstrated in this study that cholesterol enrichment of lymph chylomicrons retards the clearance of chylomicrons from circulation. Moreover, oxidized cholesterol exacerbate the reduced clearance of chylomicron remnants from circulation compared to purified cholesterol.

The kinetics of both oxidized cholesterol- and purified cholesterol-enriched chylomicrons displayed a biphasic mode of clearance with an initial rapid phase followed by a slower rate of clearance, which is consistent with the established catabolism of chylomicrons *in vivo* (26,28). The initial, rapid phase is indicative of the binding of chylomicrons to endothelial lipases. The second, slower phase primarily represents sequestration of particles onto extracellular matrices, and the internalization of chylomicrons and remnants *via* receptor-mediated processes by the liver and other tissues. Chylomicrons isolated from rats given oxidized cholesterol showed a moderate impairment of tissue uptake as reflected in the decreased removal from plasma of the chylomicron cholesterol ester, but this was not significantly different from the purified cholesterol-containing chylomicrons. Similarly, chylomicrons isolated from rats given purified cholesterol displayed impaired removal from plasma but to a lesser degree than

those animals given oxysterols. The delay in removal of chylomicrons containing oxidized cholesterol was particularly evident in the initial phase of clearance compared to both the control and purified cholesterol containing chylomicrons. Therefore, these results suggest that oxidized cholesterol may impair the initial binding or interaction of particles with extracellular matrices and receptors that enable rapid sequestration and removal of chylomicrons from the circulation.

TG clearance from the plasma is normally indicative of the extent of lipolysis, which is obligatory for chylomicron remnant formation and thereafter for uptake by tissues, predominantly the liver. The clearance of chylomicron TG from plasma was found to be impaired in both the oxidized cholesterol- and purified cholesterol-enriched particles. The delayed clearance of chylomicrons isolated from rats given oxidized cholesterol was not a result of delayed conversion to the remnant form because lipolysis *in vivo* did not appear to be impaired. Rather, the *in vitro* lipolytic studies showed that chylomicrons isolated from rats given oxidized cholesterol had increased TG lipolysis compared to control and purified cholesterol-containing chylomicrons.

The lipolysis of chylomicron TG is regulated by the apolipoprotein complement of the particles. The ratio and mass of apolipoproteins play a key role in determining the lipolytic rate. ApoCII is an important cofactor for the action of LPL, whereas apoCIII and apoE inhibit LPL activity (35,36). Interestingly, both the oxidized cholesterol- and purified cholesterol-containing chylomicrons had a reduced total apoE/C ratio, which is consistent with the finding that chylomicrons enriched with oxidized cholesterol had increased LPL TG hydrolysis. In the purified cholesterol-containing chylomicrons, no effect on LPL activity was observed. A lower apoE/C ratio has been associated with larger particle size (37) and may account for the preferential hydrolysis of the larger TG-enriched particles isolated from rats given oxidized cholesterol.

The inhibitory action of apoCIII may have influenced the complete lipolysis of oxidized cholesterol-containing chylomicron remnants, however, which is necessary for the internalization of particles by tissues (38). The hydrolysis of TG from larger chylomicron particles has previously been shown in the rat model to be relatively incomplete compared to smaller particles (23). However, the size of particles does not appear to inhibit the sequestration of particles by the liver (23). Chylomicrons that are partially hydrolyzed have reduced binding affinity for uptake by receptor-mediated pathways and may require further hydrolysis by hepatic lipases before actual internalization by hepatocytes (27).

ApoE is associated with the sequestration and uptake of chylomicron remnants by tissues. The confirmation of apoE has been reported to be altered by the particle size of lipoproteins, whereby as the particle size of TG-rich lipoproteins increases, the  $\alpha$ -helical conformation of apoE unfolds, which is unfavorable in terms of the interaction of particles with the apoB-100/E receptor at least (37). Hence, the greater size of chylomicrons containing oxidized cholesterol may prevent

the apoE-associated uptake of these particles by tissues other than the liver. Particle size can also alter the molecular order of lipid constituents, which may affect the conformation of apoE (39). The hydroxyl, epoxide, and keto groups associated with oxysterols may disturb the order of lipid packing in the chylomicrons, as observed in phospholipid bilayer models (40). In the chylomicrons containing oxidized cholesterol, this may affect particle surface structure, apoE conformation, and interaction with apoE ligands. However, it should be noted that the removal of larger particles from circulation is thought to be less dependent on interaction with the apoB-100/E receptor specifically and more reliant on other mechanisms of sequestration, including interaction with extracellular matrices and other receptor proteins (37).

Collectively, the findings of this study suggest that the impaired clearance of chylomicrons containing oxidized cholesterol may be associated with extra-hepatic tissues. The hepatic sequestration of chylomicrons enriched with oxysterols was not altered compared to the control or purified cholesterol-containing chylomicrons. The splenic uptake of chylomicrons rich in oxidized cholesterol showed that these particles were not preferentially removed by the reticuloendothelial system. However, splenic uptake does only account for less than 2% of chylomicron remnant uptake. The impaired uptake of chylomicrons enriched with oxidized sterols by tissues other than the liver and spleen warrants further investigation. However, it would appear that the delayed clearance of these particles may be due to a combined effect of the observed reduction in apoE and elevated apoCIII content, and potential effects on complete lipolysis, receptor-mediated, and nonspecific mechanisms of removal of these particles from plasma.

The impaired clearance of chylomicrons containing oxidized cholesterol and the associated accumulation in plasma of these particles may be mechanisms whereby oxidized cholesterol exacerbate cholesterol deposition in the arterial wall and the development of atherosclerosis in animal models (16–18) and perhaps humans (19). The accumulation of chylomicron remnants in plasma results in increased delivery and retention of these particles by the arterial wall leading to accelerated lesion development, as evidenced in type III hyperlipoproteinemia (41) and familial hypercholesterolemia (42). Indeed, in animal models of impaired chylomicron remnant and LDL clearance, such as apoE- and LDL-receptor-deficient mice, feeding diets containing oxidized cholesterol leads to accelerated atherosclerotic lesion development compared to mice fed cholesterol alone (43). Rong and coworkers (44) have shown that repeated arterial exposure of emulsions containing oxidized cholesterol results in vascular injury and enhanced permeability of the arterial endothelium to macromolecules in the rabbit model. Modulation of vascular integrity and permeability by dietary oxysterols may further influence the uptake of cholesterol-rich remnant particles such as postprandial remnants and LDL into the arterial wall (44).

In summary, the impaired removal of oxidized cholesterol-containing chylomicrons from plasma appears to be associated with modulation of the size and apolipoprotein composition of

chylomicrons upon incorporation of dietary-derived oxidized cholesterol into these particles. Although further investigations in humans are required, the results of this study suggest that the consumption of cholesterol-rich processed foods may adversely modulate postprandial metabolism with the potential to exacerbate the development of cardiovascular disease.

**ABSTRACT:** Consumption of dietary oil, *viz.*, corn, fish, coconut, or olive, induced the secretion of surfactant-like particles (SLP) in rat intestine. These lipoprotein particles differ in (i) levels of alkaline phosphatase activity, (ii) lipid composition, and (iii) FA composition in response to feeding of different oils. The secreted particles had similar buoyancy (1.07–1.08 g/mL) and cholesterol/phospholipid molar ratios (0.61–0.72) except that feeding coconut oil to rats produced SLP with a low (0.18) cholesterol/phospholipid molar ratio compared to control animals. It is concluded from these observations that feeding different oils induces the secretion of lipoprotein particles in rat intestine with different chemical compositions.

Paper no. L8629 in *Lipids* 37, 463–468 (May 2002).

Fat feeding increases intestinal alkaline phosphatase (IAP) in serum, but the mechanism responsible for this phenomenon is unclear. The role of surfactant-like particles (SLP) has been implicated in the delivery of this membrane-bound enzyme into lumen and serum (1). These particles, secreted by enterocytes, exhibit morphologic and surface-active properties resembling pulmonary surfactants and are enriched for IAP and PC (2). Chemical analysis of SLP revealed that they consist of four to six major proteins having molecular sizes of the order of 30–120 kDa (3). These lipoprotein particles were associated with fat droplets and have been implicated in transepithelial transport of TAG (4) in rat intestine. Previous studies on the characterization of SLP have been based on corn oil feeding (3). However, feeding different dietary fats induces different changes in chemical composition of the brush border membrane (BBM) in rat intestine (5). Changing the saturation of dietary fats produces substantial differences in the FA composition of the membranes of intact viable cells and tissues (6,7). Changes in the FA composition of membranous proteins may be responsible for altered enzyme activities, as many enterocyte plasma membrane enzymes are in-

trinsic proteins whose activities depend on the fluidity and physical state of the membrane lipids (8,9). Therefore, the objectives of this study were to determine (i) whether the choice of dietary oil affects the quality and quantity of SLP production in rat intestine and (ii) whether the lipid and enzyme activity profile of these lipoprotein membranes varied under these conditions.

## MATERIALS AND METHODS

Adult male Wistar rats (150–170 g) were used. The animals were obtained from Central Animal Facility of Panjab University, Chandigarh, and were maintained on a commercial rat pellet diet (Hindustan Lever Ltd., India) with free access to water until they attained the required weight. All procedures done on animals were approved by the Ethical Committee Board of Panjab University, Chandigarh, India. Animals were divided into five groups and were fed corn (group 2), fish (group 3), coconut (group 4), or olive (group 5) oil. Rats were fasted overnight with free access to water. On the following day, animals were given 2.0 mL of the respective oil intragastrically *via* an infant feeding tube and were killed 5 h after fat feeding. Animals in the control group received saline alone (group 1).

**Tissue sampling.** Animals were sacrificed under ether anesthesia. Blood was collected by introducing a needle in the left ventricle of the heart, and perfusion was done with 0.9% saline until the liver was blanched to minimize contamination of tissue samples with blood. Blood samples were then incubated at 37°C for 30 min and then centrifuged at 5,000 × *g* for 15 min at 4°C to separate serum. Serum was then frozen at –20°C in aliquots until further analysis. Starting from the ligament of Treitz, 20 cm of proximal intestine was removed. The intestine was opened longitudinally, and the mucosal surface was lightly scraped using Whatman no. 3 paper and suspended in solution A [5mM Tris (hydroxymethyl) amino methane buffer, pH 7.4, containing 5 mM CaCl<sub>2</sub>] as described by Eliakim *et al.* (2).

**Gradient centrifugation.** SLP were isolated from the light mucosal scrapings by passing them through a gradient that separated membrane-bound phosphatase (density 1.07–1.08

Abbreviations: BBM, brush border membrane; Chl, cholesterol; IAP, intestinal alkaline phosphatase; LPC, lysophosphatidylcholine; PL, phospholipid; SLP, surfactant-like particle.

g/L) from free IAP (density 1.057 g/L). The mucosal scrapings from each of the five groups were fractionated on continuous NaBr gradients (0.49–1.46 M in solution A) as described for the isolation of human lung surfactant (10). A visible white band of density 1.07–1.08 g/L was formed against clear solution after centrifugation at  $100,000 \times g$  for 16 h at 5°C using an SW-41 rotor (Beckman Instruments). These conditions were identical to those used by Eliakim *et al.* (2) to isolate rat intestinal SLP. One-milliliter fractions were removed from the top of the gradient by siphoning and used for biochemical analyses. Fractions 3 and 4, exhibiting maximal IAP activity, were pooled from several gradients, dialyzed, and concentrated using an Amicon filter (XM-10) assembly (Millipore Corp., Bedford, MA).

**Enzyme assays.** Alkaline phosphatase activity was assayed by the method of Bergmeyer (11). Disaccharidases were determined by the method of Dahlqvist (12). Protein was determined by the method of Lowry *et al.* (13) using BSA as the standard.

**Lipid extraction and analysis.** Total lipids from SLP were extracted by the method of Folch *et al.* (14). Various phospholipid (PL) fractions were estimated following the method of Marinetti (15). Total cholesterol (Chl) was determined by the method of Zlatkis *et al.* (16). TG were estimated by the method of Van Handel *et al.* (17).

**TLC.** PL were fractionated by TLC using  $\text{CHCl}_3/\text{CH}_3\text{OH}/7\text{N NH}_3$  (65:25:4, by vol) as the resolving solvent and quantified. Synthetic PL (Sigma Chemical Co., St. Louis, MO) were used as standards in parallel lanes.

Individual spots were identified by exposing the plates to iodine vapors in a glass chamber. Yellowish-brown spots seen were scraped off the plates, and PL were estimated as described by Marinetti (15). Individual PL fractions were determined as percentage of the total PL.

**FA analysis.** FA from total lipid extract were methylated using boron trifluoride/methanol reagent as described by Metcalfe and Schmitz (18). FA were analyzed by GC–MS (Shimadzu QP-5000) using a DB 23 capillary column (J&W Scientific, Folsom, CA; 30 m length, 0.25 mm i.d.). FAME were detected by GC with an FID, followed by mass determination. The carrier gas used was helium at a pressure of 72.3 kPa.

**Statistical analysis.** Statistical analysis of the data was done using Student's *t*-test and two-way ANOVA. Values having  $P < 0.05$  were considered to be statistically significant.

**BCIP staining.** Purified SLP proteins (100  $\mu\text{g}$ ) were separated on 10% polyacrylamide-SDS gels under nondenaturing conditions and stained with 5-bromo-4-chloro-3-indolyl phosphate (BCIP) for the detection of alkaline phosphatase activity in the gels. The gels were incubated in BCIP (1 mg/mL in 50 mM Tris-HCl, pH 7.6) solution at 37°C. After the bands of desired intensity were visible, the reaction was stopped by transferring the gel to 10% acetic acid and then the gel was rinsed in distilled water and dried.

**Western blotting.** SLP (100  $\mu\text{g}$  protein) from rats fed fats 5 h previously were subjected to electrophoresis under denatur-

ing conditions in 10% polyacrylamide-SDS gels, and Western blotting was performed as described (3). Briefly, the proteins were transferred onto an Immobilon P membrane (Millipore) at 30 volts for 16 h at 4°C. Anti-SLP (1:1000) was used as primary antibody, and color was developed using peroxidase-linked secondary anti-immunoglobulin, 2,4-diaminobenzene, and  $\text{H}_2\text{O}_2$ .

## RESULTS

The activity profile of IAP in various NaBr gradient fractions after centrifugation of light scrapings from intestine of control and fat-fed rats is shown in Figure 1. As expected from Eliakim *et al.* (2), the activity of IAP peaked in fraction 3, corresponding to a density of 1.07–1.08 g/L. However, the level of IAP activity varied considerably in animals fed different oils. It followed the pattern olive oil > fish oil > corn oil > coconut oil > saline-treated animals.

Although IAP constitutes the major enzyme in SLP, it also contains small amounts of various brush border enzymes (2). Thus, the activities of various disaccharidases in purified SLP were also analyzed and expressed on a protein basis. These results are shown in Table 1. SLP from olive oil-fed animals showed a threefold increase in IAP activity ( $P < 0.001$ ) as compared to the controls, whereas the increases in enzyme activity induced by corn oil or fish oil feeding were 1.6- ( $P < 0.001$ ) and 1.3-fold ( $P < 0.01$ ), respectively. IAP activity in SLP was slightly increased upon coconut oil treatment ( $P < 0.05$ ) compared to control rats. Thus, specific activities of AP were as maximal in animals fed olive oil, followed by corn oil, fish oil, and coconut oil with respect to control animals. Sucrase, lactase, and trehalase activities in SLP either declined

**FIG. 1.** Profile of alkaline phosphatase (AP) activity in NaBr gradient fractions of intestinal scrapings from rats fed dietary oils. Crude surfactant-like particle (SLP) scrapings were applied on NaBr gradient and centrifuged at  $100,000 \times g$  for 16 h at 4°C. One-milliliter fractions were subsequently collected for AP estimation.

**TABLE 1**  
Effect of Feeding Different Oils to Rats on Various Enzymes in Purified Surfactant-Like Particles in Intestine<sup>a</sup>

Treatment	AP	Sucrase	Trehalase	Lactase
	(nmol/min/mg protein)			
Saline	2.60 ± 0.07	0.14 ± 0.01	0.13 ± 0.01	11.91 ± 1.01
Corn oil	4.26 ± 0.08 <sup>c</sup>	0.11 ± 0.02	0.02 ± 0.01 <sup>c</sup>	4.28 ± 0.61 <sup>c</sup>
Fish oil	3.46 ± 0.04 <sup>b</sup>	0.13 ± 0.03	0.04 ± 0.01 <sup>c</sup>	6.92 ± 0.90 <sup>c</sup>
Coconut oil	2.78 ± 0.06 <sup>a</sup>	0.08 ± 0.02 <sup>b</sup>	0.05 ± 0.01 <sup>c</sup>	3.90 ± 0.29 <sup>c</sup>
Olive oil	7.58 ± 0.10 <sup>c</sup>	0.07 ± 0.01 <sup>c</sup>	0.03 ± 0.01 <sup>c</sup>	2.53 ± 0.31 <sup>c</sup>

<sup>a</sup>Values are mean ± SD (*n* = 5). <sup>b</sup>*P* < 0.05; <sup>c</sup>*P* < 0.01; <sup>c</sup>*P* < 0.001 compared to the controls.

or remained unaltered upon oil feeding to the animals, compared to the control group.

The role of SLP in IAP transport has been described (19); thus, IAP activity was also determined in serum after fat feeding (Table 2). Serum AP activity was increased 4.3-fold (*P* < 0.001) after feeding olive oil as compared to the controls, whereas a 3.5-fold increase in the enzyme activity was observed in fish oil- and corn oil-fed animals (*P* < 0.001). Serum from coconut oil-fed animals showed 3.0-fold increase in AP activity as compared to the control animals (*P* < 0.001). Serum from olive oil-fed animals exhibited significantly higher activity compared to corn oil-fed rats (*P* < 0.001). Total TG levels were also elevated in serum after feeding of different fats to rats, compared to control group (Table 2).

Data on the lipid composition of SLP (Table 3) revealed that PL content was significantly enhanced in corn, fish, or olive oil-fed rats (*P* < 0.001) but was unaffected by coconut oil feeding to rats compared to controls. Corn or olive oil feeding enhanced total Chl (*P* < 0.001), but coconut oil feeding significantly reduced the Chl content of SLP in rat (76%, *P* < 0.001). The Chl/PL molar ratio was essentially unaffected and varied between 0.61 and 0.68 in SLP isolated from intestines of rats fed different oils. However, animals given coconut oil had a considerably lower Chl/PL molar ratio (0.18). Thus, the PL and Chl contents of SLP secreted by gut are modified by feeding different oils.

As shown in Table 4, PL composition of SLP also showed considerable variations in response to feeding of different oils to rats. In all four experimental groups examined, PS was not detected in isolated SLP. However, PC and lysophosphatidylcholine (LPC) constituted 60–80% of the PL of SLP except in the coconut oil-fed group, which contained 86% of PC, whereas LPC was only 4%. Sphingomyelin content of SLP from corn

oil- or coconut oil-fed animals decreased compared to the control group (*P* < 0.001). All the oil-fed rats except those given coconut oil showed an appreciable increase in PE content of SLP.

The FA composition of SLP showed that feeding different dietary fats also modified the fatty acyl group composition of membranous SLP lipids (Table 5). In the control group, the major FA was palmitic acid (91%); only 9% was stearic acid. Feeding corn oil reduced palmitic acid to 63%; other FA detected included oleic (27%) stearic (8%), and myristic (2%). Feeding animals with fish oil produced SLP with 81% palmitic and 14% oleic acid; stearic acid content (5%) was low compared to that in corn oil-fed animals. SLP from olive oil-fed rats had 64% palmitic and 36% palmitoleic acid. In SLP from coconut oil-fed animals, palmitic acid constituted about 92% while the remaining 8% was stearic and myristic acids.

Since IAP constitutes the major marker of SLP produced by the gut, activity of the enzyme in nondenaturing SDS-PAGE gel was also analyzed under various experimental conditions. Figure 2 shows the BCIP staining of SLP preparations from animals fed different oils. Feeding of olive oil (lane 3) resulted in the maximal IAP activity (121%) compared to the control (lane 1), followed by fish oil (lane 5; 85%), corn oil (lane 2; 30%) and coconut oil (lane 4; 25%).

Western blot analysis of SLP proteins from animals fed different oils showed six to eight protein bands, but four major proteins of molecular sizes 116, 99, 66, and 35 kDa were quite conspicuous in SLP isolated from corn-, fish-, coconut-, or olive oil-fed animals (Fig. 3). Relative densities obtained from the scan of various protein bands in SLP from animals fed different oils are shown in Figure 3A. Feeding of different oils induced different proteins. Olive oil feeding maximally induced 116 kDa protein compared to other

**TABLE 2**  
Effect of Feeding Different Oils on Serum AP Activity (nmol/mL) and Total TG Levels (mg/dL) in Rats<sup>a</sup>

<sup>a</sup>Values are mean ± SD (*n* = 3). <sup>a</sup>*P* < 0.05; <sup>b</sup>*P* < 0.01; <sup>c</sup>*P* < 0.001 compared to the controls. ND, not detected; LPC, lysophosphatidylcholine; SM, sphingomyelin; for other abbreviations see Table 3.

groups. Feeding coconut oil maximally induced a 99-kDa protein, whereas corn oil feeding induced a 66-kDa protein. The 35-kDa protein was maximally induced in rats fed fish oil. However, the 35-kDa protein was reduced below the control level in SLP from coconut oil-fed rats. Thus, different oils induced various proteins in SLP to different extents in rat intestine.

## DISCUSSION

These results indicate that different dietary fats induced the secretion of SLP in rats with different (i) chemical composition, (ii) IAP activity, and (iii) qualitatively similar but quantitatively varying protein patterns as revealed by SDS-PAGE gels. However, the isolated SLP exhibited similar buoyant density (1.07–1.08 g/L) and Chl/PL molar ratios in response to feeding corn, fish, and olive oil to rats. These findings are essentially similar those of Eliakim *et al.* (2). Among the different oils studied, feeding olive oil induced maximal production of IAP-rich SLP. Animals fed coconut oil showed a slight increase in IAP activity compared to the controls but coconut oil had a minimal effect among the four oils studied.

The observed changes in IAP activity were further confirmed by analysis of IAP activity in SLP run on SDS-PAGE under nonreduced conditions, as determined by staining with BCIP for IAP activity. These findings indicate differential effects of dietary fats on the production of SLP in the rat intestine having different enzyme and chemical compositions. These results could be related to different levels and degrees of saturation of these oils (20). Kaur *et al.* (5) found changes in chemical composition of BBM in rat intestine in response to different fats. Similar changes also occur in SLP secreted by the intestine upon feeding different oils. These may affect the stability and turnover rate of the particle proteins in the intestine.

**TABLE 5**  
Effect of Dietary Oils on the FA Composition (percentage of total FA content) of Surfactant-like Particles Secreted by Rat Intestine<sup>a</sup>

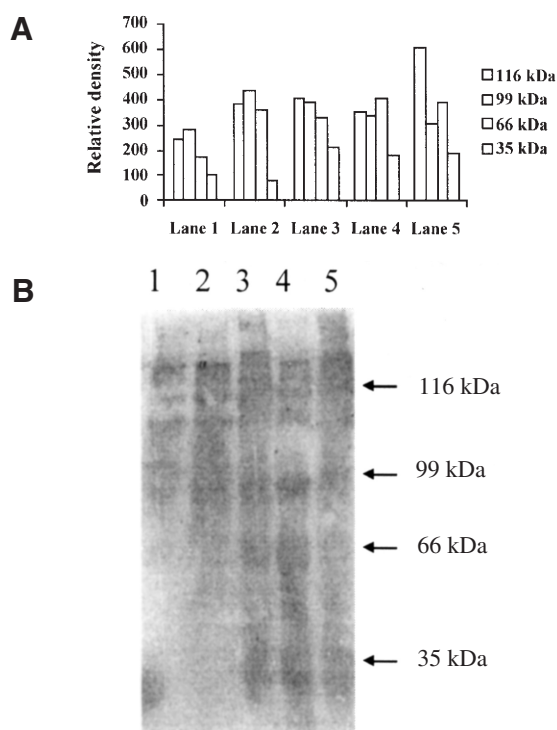

Treatment	14:0	16:0	16:1	18:0	18:1
Saline	—	91.10	—	8.90	—
Corn oil	1.87	62.69	—	8.51	26.93
Fish oil	—	81.01	—	5.34	13.65
Coconut oil	2.21	92.18	—	5.61	—
Olive oil	—	63.96	36.04	—	—

<sup>a</sup>Values are mean of two observations.

Changes in enzyme activities in response to different dietary oils also may be due to changes in the lipid microenvironment of SLP, which are accompanied by shifts in transition temperatures and values of energies of activation (21). In the present data changes in lipid composition of SLP with different dietary fats are evident. Differences in the orientation of these enzymes in the lipid milieu may also be responsible for the differential effects in particle proteins seen with various oils (22,23). Also, much higher IAP/sucrase ratios of SLP (18–108) were observed in different experimental groups as compared to the reported value of 0.99 in BBM by Young *et al.* (24), thus indicating highly enriched IAP in these particles as compared

**FIG. 2.** (A) BCIP staining of AP activity in SLP proteins separated on polyacrylamide gel electrophoresis (PAGE) from rats fed dietary oils (100 µg). Protein was applied in each lane on 10% acrylamide gel under nonreducing conditions. The gel was stained for AP by transferring the gel in 1 mg/mL BCIP in 50 mM Tris-HCl, pH 7.6, and the reaction was stopped with 10% acetic acid. (B) Relative densities of AP bands identified by BCIP staining of SLP proteins on PAGE as determined by densitometric scanning (lane 1—control, lane 2—corn oil, lane 3—olive oil, lane 4—coconut oil, lane 5—fish oil). BCIP, 5-bromo-4-chloro-3-indolyl phosphate; for other abbreviations see Figure 1.

**FIG. 3.** (A) Western blot analysis of SLP isolated from intestinal scrapings in rats fed different dietary oils. Protein (100  $\mu$ g) was subjected to PAGE, and anti-SLP (1:1000) was used as described in the Materials and Methods section. (B) Scan of protein bands identified by Western blotting of SLP isolated from rat intestine (lane 1—control, lane 2—coconut oil, lane 3—fish oil, lane 4—corn oil, lane 5—olive oil). The bands were scanned by densitometry, and the relative density of the various bands was obtained in the form of peaks. The area under each peak was determined to obtain the intensity of the protein band.

to brush borders. Similar results have been reported by DeSchryver-Kecsckemeti *et al.* (25). The maximal ratio (108) was observed in our work in SLP from olive oil-fed animals, thus indicating maximal induction of SLP in this group.

The increase in alkaline phosphatase activity observed in serum upon feeding dietary oils (except for coconut oil) is in agreement with the role of SLP as a vehicle that delivers IAP into the serum and also to the lumen (25). A marked increase in the levels of total TG in serum may be due to association of SLP with TAG transport (4). The lipid composition of SLP was considerably modified in response to fat feeding, which was quite distinct from the response reported for BBM. This further suggested that these lipoprotein particles are not derived from the underlying plasma membrane but constitute a distinct membranous entity (2) and thus may have distinct regulation.

PL and Chl contents increased in response to feeding different oils containing unsaturated FA, *viz.*, corn, fish, and olive oils. The PL content of SLP remained unaltered, while the amount of Chl was decreased in response to feeding coconut oil. These changes are presumably related to the saturation index of the dietary fat. The decrease in Chl/PL molar ratio in SLP from coconut oil-fed animals seems similar to that ob-

served by Brasitus *et al.* (26) and Wahnon *et al.* (27) in BBM, who reported an increase in Chl/PL molar ratio in animals maintained on a PUFA-rich diet as compared to those on a saturated fat-rich diet. This may represent a compensatory response to the diet. Mahmood *et al.* (3) reported a Chl/PL ratio of 1.49 for BBM and 0.68 for SLP. In the present study SLP had Chl/PL molar ratios of 0.61–0.68 except for coconut oil, which had a ratio of 0.18, thus indicating the distinct nature of these structures from underlying BBM. Furthermore, a different composition was observed for SLP at the level of individual PL fractions and FA composition as compared to BBM. PS was undetectable, and major phospholipids were PC and LPC as reported earlier by Eliakim *et al.* (2). Coconut oil feeding enhanced PC up to 86% but appreciably decreased other PL. It has been shown in animal models and cultured cells that the uptake of LPC leads to an increase in the transport of TAG (28). In this context the observed decrease of LPC in SLP of coconut oil-fed animals might affect their ability to transport TAG. The functional role in the gut of such changes in PL composition of SLP, however, remains to be identified.

FA in SLP from coconut oil-fed animals were entirely saturated, 92% being 16:0 and the rest being 14:0 and 18:0. However, SLP from unsaturated oil-fed animals had 63–81% palmitic acid (16:0). Other FA, including unsaturated ones, were found. Corn oil had 27% of 18:1, fish oil had 14% of 18:1, and olive oil had 36% of 16:1. Thus, the saturation index declined in response to feeding unsaturated fats to animals. These findings may suggest that the FA composition of the secreted SLP membranes is derived from *de novo* synthesis. Regulation of release of FA by decreasing the rate of esterification or secretion or both in response to dietary n-3 FA by enterocytes has been reported by Murthy *et al.* (29). Also  $\Delta^9$ - $\Delta^6$ -desaturase activities have been demonstrated in intestinal mucosa of rats (30) and in the human CaCo-2 cell line (31). Intestinal desaturases, unlike their counterparts in liver, did not respond to changes in dietary levels of n-3 FA. SLP contains proteins that are distinct and thus may be related to fat metabolism (32).

Feeding of dietary fats, *viz.*, olive, fish, and corn oil, induced formation of SLP in the rat intestine with different lipid and IAP activity. As determined by IAP assay, feeding olive oil produced greater amounts of SLP than feeding corn oil. Composition of these particles varied with type of fat given to rats. Considerable changes were observed in Chl and PL contents of SLP from coconut oil-fed animals. Thus, induction of SLP in response to a high-fat diet may be related to the degree of saturation/unsaturation and type of fat consumed by the animals. The physiological significance of these observations needs to be established.

#### ACKNOWLEDGMENTS

We are grateful to Prof. David H. Alpers of Washington University School of Medicine (St. Louis, MO) for providing the rat SLP antibody used in these experiments. Seema Kalra was the recipient of a research fellowship from the Council of Scientific and Industrial Research (New Delhi, India).

<sup>a</sup>Cell Biology B, Biomedical Center B11, Lund University, S-221 84 Lund, Sweden, and <sup>b</sup>Institute of Medicine, Lund University Hospital, S-221 85 Lund, Sweden

**ABSTRACT:** Dietary sphingomyelin (SM) may have regulatory effects on cell proliferation and tumorigenesis in the colon. Alkaline sphingomyelinase (SMase) is the major enzyme responsible for hydrolysis of SM in the gut. Previously we purified the enzyme and showed that the presence of glycerophospholipids inhibited SM hydrolysis induced by alkaline SMase *in vitro*. In the present work, we studied the effects of TG, DG, FA, ceramide, and cholesterol on SM hydrolysis catalyzed by purified alkaline SMase. The results showed that both TG (triolein and tristearin) and DG (1,2-dioleoyl-*sn*-glycerol and 1,2-distearoyl-*rac*-glycerol) inhibited the activity of alkaline SMase. 1-Monooleoyl-*rac*-glycerol, 1-monostearoyl-*rac*-glycerol, stearic acid, oleic acid, linoleic acid, linolenic acid, and arachidonic acid stimulated the activity of alkaline SMase at 0.4–0.8 mM concentrations but inhibited the enzyme at higher concentrations. There was no difference between the effects induced by saturated and unsaturated FA. A short-chain FA such as lauric acid had a stronger stimulatory effect at low concentrations and weaker inhibitory effect at high concentrations than long-chain FA. Choosing linoleic acid as an example, we found that FA had similar effects on both alkaline SMase and neutral SMase. Cholesterol and ceramide when mixed with FA to increase its solubility in bile salt micelles inhibited SMase activity. In conclusion, glycerides, FA, ceramide, and cholesterol influence SM hydrolysis catalyzed by intestinal alkaline SMase. The presence of lipids in the diet may thus influence the course of SM digestion in the gut and thereby the exposure of colon to SM metabolites.

Paper no. L8978 in *Lipids* 37, 469–474 (May 2002).

Sphingomyelin (SM) is an important constituent of most cell membranes and is present in many dietary products including milk, meat, egg, and fish (1–3). Digestion of SM in the gut may have implications in colonic tumorigenesis. Recent studies have shown that when SM was given to mice treated with dimethylhydrazine, the number of colonic aberrant crypt foci was reduced by 70% (4). Dietary SM also reduced the proportion of malignant carcinomas to benign adenomas in di-

methylhydrazine-treated mice (5). We previously found that the activities of sphingomyelinase (SMase) in human colonic adenoma, carcinoma, and adenomatous polyposis were significantly decreased, indicating a potential chemopreventive effect of SMase on colon cancer (6,7).

Several types of SMase that are responsible for the catabolism of SM in different organs and cellular locations have been identified (8,9). In the intestinal tract, there is a specific SMase termed alkaline SMase, which is present in both intestinal mucosa and lumen, with peak activity in the middle of small intestine (10,11). Animal studies have shown that digestion of dietary SM occurs mainly in the middle and lower part of the small intestine where alkaline SMase is abundant, indicating an important role of the enzyme for the digestion of SM in the gut (12).

Digestion and absorption of dietary SM is characterized as a slow and incomplete process (12–14). The factors that influence the activity of alkaline SMase in the intestinal tract are still unclear. In our previous study, we found that other phospholipids, including PC, PI, PE, PS, and some of their metabolites had an inhibitory effect on SM hydrolysis induced by intestinal alkaline SMase (15). In this paper, we examined the effects of the major dietary lipids in the gut, i.e., TG, its hydrolysis products, and cholesterol on the hydrolysis of SM *in vitro* as catalyzed by purified rat intestinal alkaline SMase.

## MATERIALS AND METHODS

**Materials.** Triolein, tristearin, lauric acid, palmitic acid, arachidic acid, and arachidonic acid were purchased from Labora Chemicon (Stockholm, Sweden). 1,2-Dioleoyl-*sn*-glycerol, 1,2-distearoyl-*rac*-glycerol, 1-monooleoyl-*rac*-glycerol, 1-monostearoyl-*rac*-glycerol, stearic acid, oleic acid, linoleic acid, linolenic acid, and arachidonic acid, cholesterol, ceramide, and taurocholate (TC) were from Sigma-Aldrich AB (Stockholm, Sweden). Rat intestinal alkaline SMase was purified from rat intestinal mucosa as described previously (16), and bacterial neutral SMase was purchased from Sigma-Aldrich AB. SM was purified from bovine milk and was provided by Lena Nyberg of Skane Dairies' Association of Sweden. The purified SM was labeled with

Abbreviations: SM, sphingomyelin; [<sup>14</sup>C-SM], <sup>14</sup>C-choline-labeled sphingomyelin; SMase, sphingomyelinase; TC, taurocholate.

$^{14}\text{C}$ -choline [ $^{14}\text{C}$ -SM] according to the method of Stoffel (17), with its specific activity being 56  $\mu\text{Ci}/\text{mg}$ .

**Preparation of TG, FA, ceramide, and cholesterol solution.** Glycerides, FFA, ceramide, and cholesterol were dissolved in chloroform/methanol (2:1) as 1 mg/mL stock solutions and stored at  $-20^\circ\text{C}$ . At the beginning of each experiment, lipids of different amounts were added to the test tubes and dried under a blowing stream of nitrogen. The lipids were then suspended in bile salt containing buffers after sonication, and their effects on SM hydrolysis were examined as described below.

**Assay of SM hydrolysis by alkaline and neutral SMase.** The assay of SM hydrolysis induced by alkaline SMase has been described previously (18). Briefly, to each test tube with the lipids tested was added 75  $\mu\text{L}$  of assay buffer containing 30 mM Tris, 0.15 M NaCl, 2 mM EDTA, 10 mM TC, pH 9.0, followed by sonication for 10 s. Five microliters of purified rat intestinal alkaline SMase (5 ng) in 20 mM Tris buffer, pH 8.2, was then added, and the reaction was started by the addition of 10,000 dpm [ $^{14}\text{C}$ -SM] in 20  $\mu\text{L}$  0.15 M NaCl solution containing 10 mM TC. The incubation was performed at  $37^\circ\text{C}$  for 30 min and then stopped by adding 0.4 mL chloroform/methanol (2:1). Phase partitioning was obtained by centrifugation at  $6,000 \times g$  for 3 s and a 100  $\mu\text{L}$  aliquot of the upper phase containing the cleaved  $^{14}\text{C}$ -phosphocholine was taken for liquid scintillation counting. As for the assay of SM hydrolysis induced by neutral SMase, a similar procedure was performed except for the assay buffer, which contained 30 mM Tris-HCl, 0.15 M NaCl, 4 mM  $\text{MgCl}_2$ , and 10 mM TC, pH 7.4.

**Statistical analysis.** The data were expressed as mean  $\pm$  SEM. Two-way ANOVA and Student's *t*-test were used when available to compare the differences between two groups.  $P < 0.05$  was considered statistically significant.

## RESULTS

**Inhibitory effect of TG and TG metabolites on alkaline SMase activity.** As shown in Figure 1 (panels A and B), the presence of TG and DG reduced SM hydrolysis induced by rat intestinal alkaline SMase in a dose-dependent manner. The effect of tristearin was stronger than that of triolein, and that of distearin was slightly stronger than that of diolein. The effects of monoolein and monostearin are more or less biphasic, stimulating SM hydrolysis at low concentrations but inhibiting it at high concentrations (panel C).

**Effects of FA on the activity of alkaline SMase.** The effects of stearic, oleic, linoleic, and linolenic acids on the activity of alkaline SMase are shown in Figure 2. All of these  $\text{C}_{18}$  FA showed stimulatory effects, with peak effect at concentrations around 0.4 to 0.8 mM. The stimulatory effect decreased when the concentration was over 0.8 mM, and the inhibitory effect became evident when the concentration reached 3.2 mM. Oleic acid was the most effective, whereas linolenic acid was the least effective acid tested in stimulating SM hydrolysis by alkaline SMase.

The effects of FA on alkaline SMase with carbon chain length are shown in Figure 3. When the efficacies of lauric

**FIG. 1.** Effects of TG, DG, and MG on intestinal alkaline sphingomyelinase (SMase) activity. Different amounts of TG and partial glycerides dissolved in chloroform/methanol (2:1) were added to the test tubes and dried under nitrogen. Alkaline SMase assay buffer (pH 9.0) was added, followed by sonication for 10 s. Alkaline SMase and  $^{14}\text{C}$ -choline-labeled sphingomyelinase were then added, and the enzyme activity was measured. The activity in the absence of any glycerolipids was taken as 100%. The specific activity in the enzyme preparation is about 160 nmol/h/mL. Results are mean  $\pm$  SE obtained from three experiments. The differences between triolein and tristearin and between diolein and distearin are statistically significant ( $P < 0.05$ , ANOVA test).

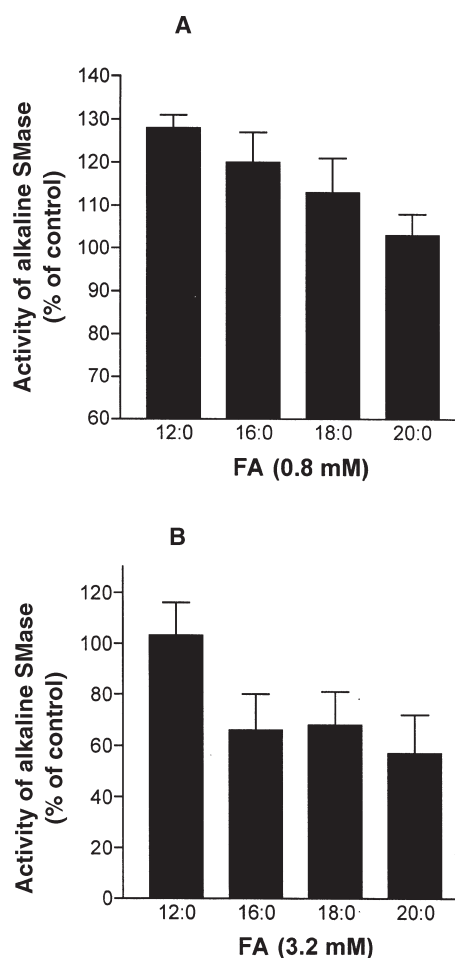

**FIG. 2.** Effects of stearic acid, oleic acid, linoleic acid, and linolenic acid on the activity of alkaline SMase. Different amounts of FA were added in the test tubes and dried by nitrogen, followed by adding the assay buffer and sonication. The reaction was started by adding alkaline SMase and  $^{14}\text{C}$ -choline-labeled sphingomyelin [ $^{14}\text{C}$ -SM]. The activity of the enzyme was determined, and the activity in the absence of any FA was regarded as 100%. The results are means from three experiments. For other abbreviation see Figure 1.

acid (12:0), palmitic acid (16:0), stearic acid (18:0), and arachidic acid (20:0) were compared at 0.8 mM, the stimulatory effect of FA was found to decrease with increasing carbon chain length (panel A). At a concentration of 3.2 mM (Fig. 3B), palmitic, stearic, and arachidic acids all reduced the activity to same extent (about 50%), whereas lauric acid inhibited the activity of this enzyme only slightly.

**Effects of arachidonic acid on alkaline SMase activity.** It has been reported previously that arachidonic acid activates membrane-bound neutral SMase (19). We studied the *in vitro* effect of arachidonic acid on the activity of alkaline SMase. As shown in Figure 4, arachidonic acid dose-dependently stimulated the activity of alkaline SMase up to 0.8 mM and inhibited it at higher concentrations. At a concentration of 3.2 mM, the activity of alkaline SMase fell to about 50% of the control.

**Comparison of the effects of FA on alkaline and neutral SMase activities.** To find out whether the effect of FA on alkaline SMase was specific, we compared the effect of linoleic acid on the activity of alkaline SMase at pH 9.0 and the activity of neutral SMase at pH 7.4. Linoleic acid was found to have similar biphasic effects on both alkaline and neutral SMase (Fig. 5). However, the dose-dependent curve for neutral SMase shifted to the right, and the extent of changes was greater than those for alkaline SMase, indicating neutral SMase is more sensitive than alkaline SMase in response to the FA.

**Effect of cholesterol and ceramide on the activity of alkaline SMase.** Owing to the low solubility of cholesterol and ceramide in pure TC micelles, their effects on SM hydrolysis cannot be studied in ways similar to those used for other lipids.

**FIG. 3.** Effects of FA with different chain lengths on the activity of alkaline SMase. Lauric acid, palmitic acid, stearic acid, and arachidic acid at 0.8 (A) and 3.2 mM (B) final concentration were mixed with [ $^{14}\text{C}$ -SM] and alkaline SMase in the assay buffer. The activity of the alkaline SMase was determined, and the activity in the absence of any FA was taken as 100%. The results are mean  $\pm$  SE obtained from three experiments. For abbreviations see Figures 1 and 2.

However, the solubility can be increased in mixed TC-FFA micelles. We therefore mixed 0.4 mM linoleic acid with different amounts of cholesterol or ceramide and examined the effects of the ratio of cholesterol or ceramide, to linoleic acids on alkaline SMase activity. As shown in Figure 6, both cholesterol and ceramide inhibited the hydrolysis of SM in the presence of linoleic acid. The maximal inhibitory effect for cholesterol was at a ratio of cholesterol/linoleic acid about 1:1, and that for ceramide at a ratio of ceramide/linoleic acid about 2:1.

## DISCUSSION

The present study examined the role of glycerides, FA, and cholesterol on SM hydrolysis induced by purified intestinal alkaline SMase. Our results demonstrate that TG, DG, ceramide, and cholesterol have inhibitory effects on hydrolysis of SM, whereas MG and FA have biphasic effects, stimulating it at low concentrations and inhibiting it at higher concentrations. When

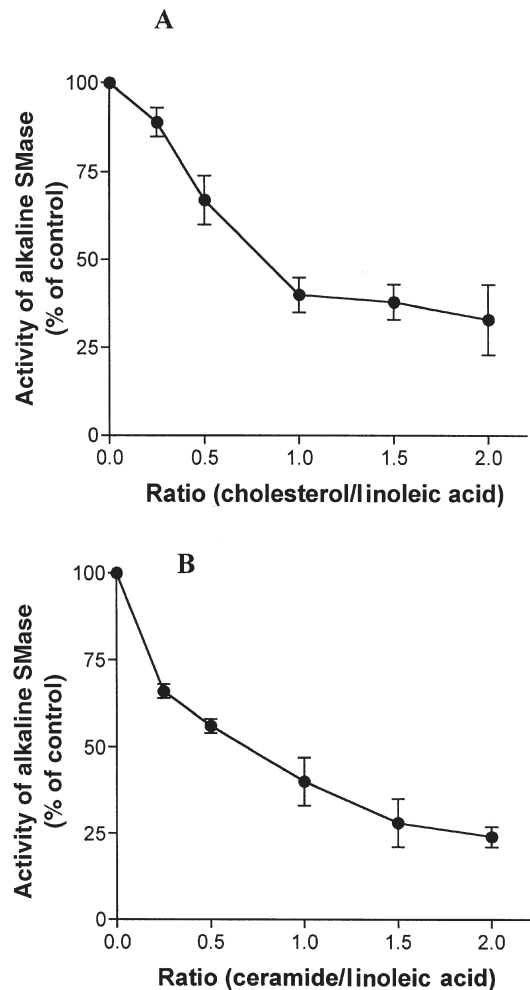

**FIG. 4.** Effect of arachidonic acid on the activity of alkaline SMase. Different amounts of arachidonic acid were added to the test tubes and dried by nitrogen. The assay buffer was added followed by sonication. Alkaline SMase activity was determined and the activity in the absence of arachidonic acid was taken as 100%. The results are mean  $\pm$  SE obtained from three separate experiments. For abbreviation see Figure 1.

the effects of FA with different chain lengths were compared, a medium-chain FA (12:0, lauric acid) was more effective than the 16–20 carbon FA in stimulating alkaline SMase at 0.8 mM concentration, and was less effective in inhibiting the enzyme

**FIG. 5.** Comparison of the effects of linoleic acid on the activity of alkaline SMase (K-SMase) and neutral SMase (N-SMase). Different amounts of linoleic acid were added in the tubes and dried under nitrogen. Neutral assay buffer (pH 7.4) and alkaline assay buffer (pH 9.0) were added, respectively, followed by sonication. After adding neutral and alkaline SMase, respectively, the reaction was started by adding 10,000 dpm [ $^{14}$ C-SM]. The activities of neutral and alkaline SMase were determined, and the activities in the absence of linoleic acid were taken as 100%. The results (mean  $\pm$  SEM) were obtained from three separate experiments. \* $P < 0.05$ , \*\* $P < 0.05$ , and \*\*\* $P < 0.05$ , compared with K-SMase of the same concentration. For abbreviations see Figures 1 and 2.

**FIG. 6.** Effect of cholesterol (A) and ceramide (B) on the activities of alkaline SMase. Linoleic acid (final concentration 0.4 mM) was mixed with different amounts of cholesterol or ceramide and dried under nitrogen. The assay buffer was added followed by sonication. The alkaline SMase was assayed in the assay buffer. Activity in the absence of cholesterol or ceramide was taken as 100%. The results (mean  $\pm$  SEM) were obtained from three separate experiments. For abbreviation see Figure 1.

at 3.2 mM concentration. Arachidonic acid stimulated alkaline SMase, similar to what was previously reported for neutral SMase in cultured cells (19).

Lipid hydrolysis in the intestinal tract depends on the sequential interactions of various lipolytic enzymes, substrates, and products present in the gut. For example, hydrolysis of Intralipid (an intravenous lipid emulsion) is significantly enhanced by short- and medium-chain FA produced by gastric lipase (20), and hydrolysis of the FA ester at position 2 of glycerophospholipids by phospholipase  $A_2$  accelerates the hydrolysis of TG in a similar emulsion (21). Whereas the concerted actions among gastric lipase, bile-salt stimulated lipase, pancreatic lipase  $A_2$ , and classic pancreatic lipase have been intensively studied, little is known about the influence of other lipases and lipolytic products on hydrolysis of SM. Digestion of SM in the gut is drawing more attention recently, as it may have implica-

tions in intestinal tumorigenesis and atherosclerosis (23,24). Therefore, to study the influence of lipids on SM hydrolysis not only is of nutritional importance but also has clinical implications.

Although the intestinal lumen contains SMase and ceramidase, not all of the ingested SM is hydrolyzed and absorbed (12–14). The rate-limiting factors for SM hydrolysis have not been clarified, although the localization of the alkaline SMase, the high concentration of bile salts, and the relatively low pH in the gut may be implicated (18). We recently demonstrated that glycerophospholipids and their metabolites had an inhibitory effect on the activity of alkaline SMase activity *in vitro* (15). In the present *in vitro* study, we extended our previous study by showing that TG and DG inhibit SM hydrolysis catalyzed by alkaline SMase. It appears that before digestion and absorption of both dietary TG and the phospholipids, SM hydrolysis in the intestinal tract cannot be effective until both dietary TG and phospholipids are digested and absorbed. As for cholesterol, an earlier *in vivo* experiment showed that feeding cholesterol together with SM inhibited digestion and absorption of SM in the rat intestinal tract (25). In the present study, we examined the possibility that cholesterol in the presence of 0.4 mM linoleic acid would facilitate the solubilization of cholesterol in the micelles and found that cholesterol caused significant inhibition of the SM hydrolysis. Similar to cholesterol, ceramide also reduced SM hydrolysis caused by alkaline SMase. As the absorption of ceramide is slow and ceramide can be identified along the intestinal tract including the colon, it may exert inhibitory roles along the gut. However, in the gut, hydrolysis of ceramide is catalyzed by neutral ceramidase, whose distribution in the intestine is parallel to that of alkaline SMase (26). Thus, intestinal neutral ceramidase could play a role in limiting the inhibitory effects of ceramide on alkaline SMase activity.

The mechanism by which TG, partial glycerides, FA, and cholesterol influence SM hydrolysis catalyzed by alkaline SMase may be related to their effects on the physical form of the substrate or on the enzyme. The finding that linoleic acid had similar effects on the activity of both intestinal alkaline SMase and bacterial neutral SMase indicated that the effects of FA were not enzyme-specific. The presence of glycerides and FA could change the size, surface charge, or the conformational structure of the mixed micelles formed by bile salts and SM. The solubility limit of MG and FA such as oleate in 10-mM TC solution can reach over 10 mM (27,28). The addition of glycerides to the micelle may influence the affinity of this enzyme for its substrate or change the diffusion intensity, thus facilitating or interfering with the hydrolysis of SM.

The solubility of cholesterol in a bulk system containing TC and SM is low (29). Even in the presence of oleate and 10 mM TC, its solubility limit is only about 0.4 mM (27). When the concentration of cholesterol reached 0.4 mM, with a ratio of linoleic acid to cholesterol of 1:1 in this study, more cholesterol could not be incorporated into micelles. This may explain why no further inhibition of the SM hydrolysis was seen at higher cholesterol concentrations.

On the basis of the present study and earlier studies both *in vivo* and *in vitro*, we postulate that the rate of hydrolysis of dietary SM in the upper part of the small intestine is low because of the low level of alkaline SMase (11) and the presence of TG, partial glycerides, and glycerophospholipids that tend to inhibit SM hydrolysis. In the middle and lower parts of the small intestine, the alkaline SMase levels are higher, and most of the glycerolipids have been hydrolyzed and absorbed; thus, the inhibitory effects of other lipids on SM hydrolysis become less effective. As a consequence, digestion of dietary SM occurs mainly in this part of small intestine (12). However, endogenous and dietary cholesterol still remain in the gut lumen and may decrease the rate of SM hydrolysis in this part of the intestine. Although the physiological concentrations of these lipids in different parts of the intestine are unknown, it is reasonable to suspect that the inhibitors of alkaline SMase are present along the whole length of the small intestine. The presence of multiple inhibitors, on one hand, results in a low rate of SM digestion, and on the other hand, results in the exposure of the colon to intact SM and its hydrolytic products such as ceramide. This may have implications for the antitumorigenic effect of SM metabolism in the colon.

# Albumin Stimulates Lysophosphatidic Acid Acyltransferase Activity in T-Lymphocyte Membranes

Christopher A. Jolly\* and Latha Kannan

The University of Texas at Austin, Austin, Texas 78712

**ABSTRACT:** Phosphatidic acid (PtdOH) and lysophosphatidic acid (lysoPtdOH) have been shown to enhance T-lymphocyte function. However, the FA preference and influence of acyl-CoA binding proteins on lysoPtdOH and PtdOH biosynthesis are not known. Therefore, we determined glycerol-3-phosphate acyltransferase (GPAT) and lysophosphatidic acid acyltransferase (LAT) activity in rat T-lymphocyte and liver membrane preparations in the presence of palmitoyl-CoA and oleoyl-CoA with or without BSA. We found two different properties of GPAT and LAT in whole T-lymphocyte membrane preparations relative to liver. First, T-lymphocyte basal GPAT and LAT activities were similar, whereas in liver membranes LAT activity was 10-fold higher than GPAT. Second, T-lymphocyte LAT, but not GPAT, activity was inducible (fivefold) by the addition of albumin in the presence of palmitoyl-CoA but not oleoyl-CoA. In contrast, albumin stimulated GPAT, but not LAT, activity in liver membranes in the presence of palmitoyl-CoA. These results show, for the first time, that T-lymphocyte LAT activity can be increased by the presence of an acyl-CoA binding protein, which may indicate a new important control mechanism for regulating intracellular lysoPtdOH and PtdOH levels in T-lymphocytes.

Paper no. L8922 in *Lipids* 37, 475–480 (May 2002).

Phosphatidic acid (PtdOH) is a key intermediate in generating most glycerophospholipids (1) and can serve directly as a lipid signaling molecule (2). For example, PtdOH has been shown to stimulate raf-1 kinase activity (3,4) and increase intracellular calcium levels (2). Recently, lysophosphatidic acid (lysoPtdOH) has also been shown to be a potent mitogen involved in mediating the effects of several hormones such as epidermal growth factor (5). PtdOH is synthesized *de novo* by the sequential acylation of glycerol-3-phosphate to lysoPtdOH then to PtdOH *via* glycerol-3-phosphate acyltransferase (GPAT) and lysophosphatidic acid acyltransferase (LAT), respectively. GPAT is thought to be the rate-limiting enzyme in PtdOH formation, as liver GPAT activity is approximately 10-fold less than that of LAT (6,7). Furthermore, several recent studies have shown that liver GPAT, but not LAT, activity can be enhanced in membrane preparations

*in vitro* using proteins that bind the substrate acyl-CoA, including albumin (6,8–11).

T-lymphocytes are key immune regulatory cells influencing both the type and extent of immune response. Both PtdOH and lysoPtdOH have been implicated in regulating the response of T-lymphocytes to various mitogens, including cytokines (12). Several recent lines of evidence have further added to the potentially critical role of PtdOH and/or lysoPtdOH in T-lymphocyte function by showing that the LAT gene is located in the same chromosomal region as the major histocompatibility complex III gene (13), that lysoPtdOH stimulates T-lymphocyte migration (14), and that the addition of exogenous lysoPtdOH can enhance T-lymphocyte proliferation (15,16) and wound healing (17). On the other hand, PtdOH generation has been linked to the function of interleukin-2 (18), which is a potent autocrine and paracrine T-lymphocyte growth factor. The increased PtdOH production may be important in lowering cyclic AMP levels, which are antimitogenic in T-lymphocytes (19).

Although PtdOH and lysoPtdOH have been implicated as important regulators of T-lymphocyte function, the relative activities of GPAT and LAT and their ability to incorporate saturated vs. unsaturated FA and the influence of proteins that bind acyl-CoA have not been examined in T-lymphocytes. Therefore, we examined GPAT and LAT activities in T-lymphocyte and liver whole-membrane preparations and determined the influence of palmitic vs. oleic acid containing acyl-CoA in the presence or absence of albumin on PtdOH biosynthesis. Herein, we find different properties of GPAT and LAT in T-lymphocytes relative to liver, which may play an important role in lysoPtdOH- and PtdOH-dependent functions in T-lymphocytes.

## MATERIALS AND METHODS

**Materials.** ESA-free BSA, palmitoyl-CoA, and oleoyl-CoA were purchased from Sigma (St. Louis, MO). The [<sup>14</sup>C]palmitoyl-CoA and [<sup>14</sup>C]oleoyl-CoA were purchased from NEN Life Sciences (Boston, MA).

**T-lymphocyte isolation and membrane preparation.** Male, 3-mon-old Sprague–Dawley rat splenic T-lymphocytes were isolated as described by the manufacturer using negative selection Immulan columns (Biotex, Inc., Houston, TX). All animal procedures were approved by the University of Texas Animal Use and Care Committee. Negative selection prevents the confounding variable of perturbing T-lymphocyte receptors,

Abbreviations: ACBP, acyl CoA binding protein; GPAT, glycerol-3-phosphate acyltransferase; LAT, lysophosphatidic acid acyltransferase; L-FABP, liver FA binding protein; lysoPtdOH, lysophosphatidic acid; PtdCho, phosphatidylcholine; PtdIns, phosphatidylinositol; PtdOH, phosphatidic acid; PtdSer, phosphatidylserine; Spm, sphingomyelin.

as with positive selection, and of potentially altering intracellular metabolism. T-lymphocytes were counted and viability (>92%) was determined by trypan blue exclusion (20). We routinely obtain approximately 90% pure T-lymphocytes using this technique. Whole-membrane preparations from liver and purified T-lymphocytes were prepared essentially as described previously (21). Briefly, T-lymphocytes and liver membranes were homogenized and passed through a syringe to disrupt cells in a buffer containing 300 mM mannitol, 15 mM Tris, 5 mM EGTA, and 0.1 mM PMSF. The supernatant was centrifuged at  $48,000 \times g$  for 30 min, and the pellet was resuspended in cold reaction buffer. Protein concentrations were determined using the BioRad Protein Assay.

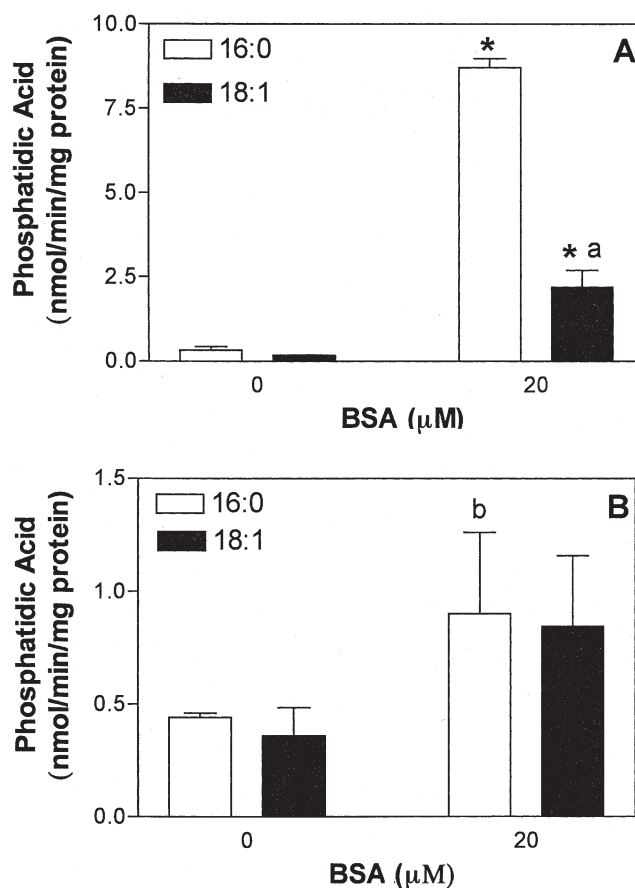

**PtdOH biosynthesis.** Phosphatidic acid biosynthesis was carried out essentially as described previously (8) using 10  $\mu$ g of membrane protein incubated for 30 min at 37°C with the following modifications: Twenty micromolar essential fatty acid-free BSA and 40  $\mu$ M [ $^{14}$ C]palmitoyl-CoA or [ $^{14}$ C]oleoyl-CoA was used. Both palmitoyl-CoA and oleoyl-CoA were chosen, because we had used the two acyl-CoA in liver and wished to remain consistent with our previously published observations (8,22). Purified bovine albumin was chosen rather than rat albumin for consistency with previously published observations (11). Preliminary experiments were carried out to determine the optimal concentration (20  $\mu$ M) of albumin to use. The first reaction used glycerol-3-phosphate as the substrate and measured GPAT activity. The second reaction involved the substitution of glycerol-3-phosphate with lysoPtdOH to determine LAT activity. Individual phospholipids were separated by TLC using Silica Gel 60 plates with a solvent system containing chloroform/methanol/acetic acid/ddH<sub>2</sub>O (50:37.5:3.5:0.5, vol/vol). The bands corresponding to PtdOH, as determined by simultaneously running an authentic standard, were scraped and counted by scintillation counting. GPAT activity was determined by multiplying the cpm by two (two radiolabeled FA incorporated into PtdOH from glycerol-3-phosphate) then dividing by the specific activity of the [ $^{14}$ C]acyl-CoA solution to obtain nmol of synthesized PtdOH. The nmol of PtdOH formed was then divided by the incubation time (30 min) and the amount of membrane protein used in the reaction (0.010 mg) to obtain nmol/min/mg protein. For LAT activity, the calculation was the same except that the cpm value was not multiplied by two, as only one radiolabeled FA was incorporated per PtdOH molecule using lysoPtdOH as substrate.

**Phospholipid FA transacylation.** The GPAT assay was carried out as described previously (6) except that isolated T-lymphocyte membranes were incubated in the presence or absence of 20  $\mu$ M EFA-free BSA with either [ $^{14}$ C]palmitoyl-CoA or [ $^{14}$ C]oleoyl-CoA. Following phospholipid subclass isolation by TLC, the bands corresponding to phosphatidylcholine (PtdCho), phosphatidylinositol (PtdIns), phosphatidylserine (PtdSer), and sphingomyelin (Spm) were identified using authentic standards, scraped, and counted by scintillation counting. Incorporation of radiolabeled FA was calculated as described above for the LAT assay and expressed as nmol/min/mg protein.

**Statistical analysis.** Data were analyzed with the unpaired Student's *t*-test using GraphPad Prism software (San Diego, CA). A *P* value less than 0.05 was considered significantly different.

## RESULTS

**PtdOH biosynthesis.** To assess the PtdOH biosynthetic capability of T-lymphocytes, liver whole-membrane preparations were used in parallel as a control. Liver membranes were chosen as the control because the influence of multiple acyl-CoA binding proteins on PtdOH biosynthesis has previously been shown (10,11). Additionally, using liver membranes allowed the researchers to determine whether the albumin effects were similar in different cell populations, such as the T-lymphocyte. Figure 1 shows that basal GPAT activity was similar between

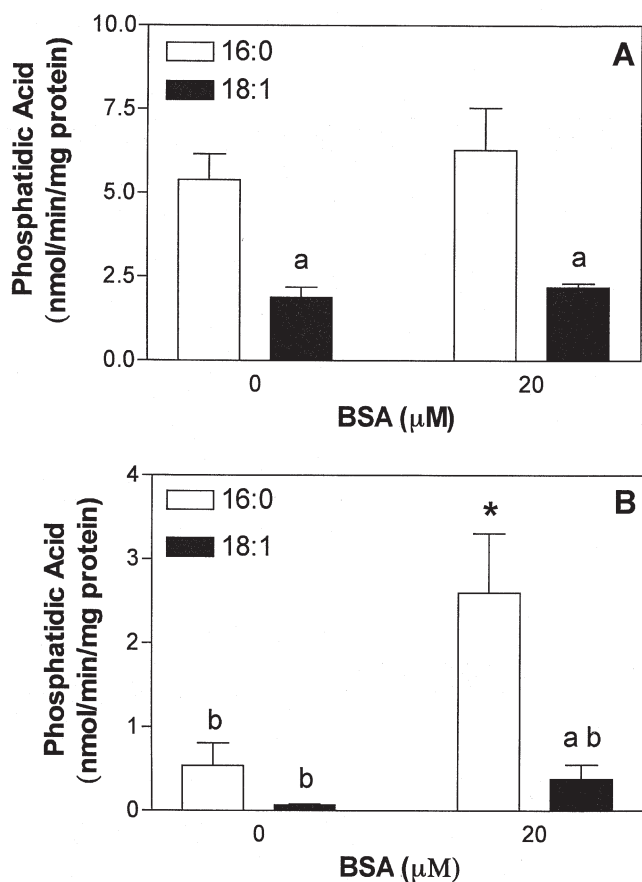

**FIG. 1.** Glycerol-3-phosphate acyltransferase activity is marginally induced by albumin in T-lymphocyte membranes. Whole membranes from liver (A) and T-lymphocytes (B) were isolated as described in the Materials and Methods section. Reactions were carried out in the presence of glycerol-3-phosphate, with or without albumin, and palmitoyl-CoA (open bars) or oleoyl-CoA (solid bars). Values represent the mean  $\pm$  SEM of 3–4 separate animals. Bars with an asterisk are significantly different ( $P < 0.05$ ) compared to the bars with the same acyl-CoA and no albumin stimulation. The bar with the roman letter a is significantly different ( $P < 0.05$ ) between palmitoyl-CoA and oleoyl-CoA within the no-albumin or with-albumin groups. The bar in panel B with a roman letter b is significantly different ( $P < 0.05$ ) from the corresponding bar in panel A.

T-lymphocyte and liver membranes in the presence of palmitoyl-CoA or oleoyl-CoA. Similar to previous observations, addition of albumin stimulated liver membrane GPAT activity 25- and 13-fold in the presence of palmitoyl-CoA and oleoyl-CoA, respectively (Fig. 1A), whereas albumin did not have a significant effect in T-lymphocyte membranes in the presence of either palmitoyl-CoA or oleoyl-CoA (Fig. 1B).

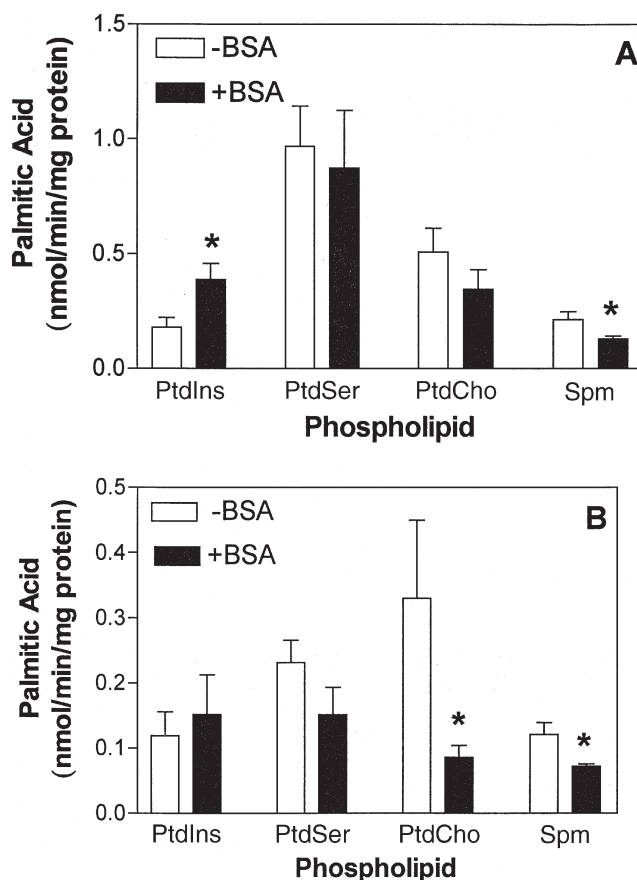

Figure 2A shows that basal liver membrane LAT activity is threefold higher in the presence of palmitoyl-CoA compared to oleoyl-CoA. The LAT activity was 17- and 11-fold higher than GPAT activity in the presence of palmitoyl-CoA and oleoyl-CoA, respectively. The LAT activity in T-lymphocyte membranes was similar to that of GPAT in the presence of palmitoyl-CoA (Fig. 2B). Interestingly, basal LAT activity in the presence of oleoyl-CoA was approximately sixfold less than the GPAT activity. Liver membrane LAT activity was 10- and 29-fold higher compared to the T-lymphocyte for palmi-

toyl-CoA and oleoyl-CoA, respectively. Albumin did not significantly induce liver membrane LAT activity in the presence of either palmitoyl-CoA or oleoyl-CoA (Fig. 2A). However, albumin significantly induced T-lymphocyte LAT activity fivefold in the presence of either palmitoyl-CoA or oleoyl-CoA (Fig. 2B). Even in the presence of albumin, T-lymphocyte LAT activity was only approximately 50 and 20% that of basal liver membrane LAT activity in the presence of palmitoyl-CoA and oleoyl-CoA, respectively.

*Phospholipid FA transacylation.* The FA composition of phospholipids can also be influenced by the nonenzymic transacylation of FA into preexisting phospholipids in addition to PtdOH biosynthesis (9). Therefore, the influence of albumin on the incorporation of palmitoyl-CoA into liver and T-lymphocyte membrane phospholipid subclasses was determined and is shown in Figure 3. Incorporation of palmitic acid into PtdSer was greater than into PtdIns, PtdCho, or Spm in liver membranes (Fig. 3A), whereas in the T-lymphocytes palmitic acid was incorporated primarily into PtdSer and

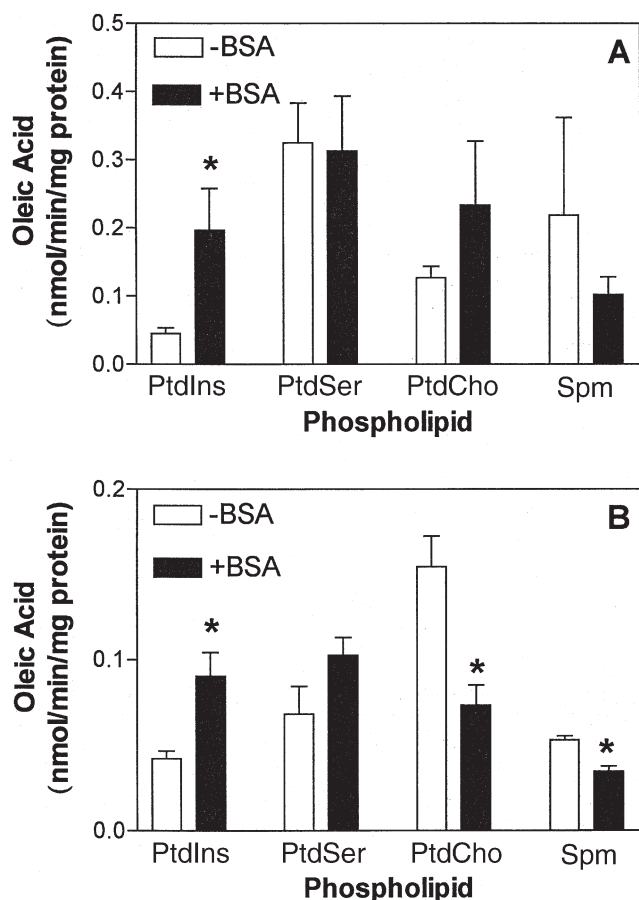

**FIG. 2.** Lysophosphatidic acid acyltransferase activity is low in T-lymphocyte membranes and enhanced by albumin. Whole membranes from liver (A) and T-lymphocytes (B) were isolated as described in Figure 1. Reactions were carried out in the presence of lysophosphatidic acid, with or without albumin, and palmitoyl-CoA (open bars) or oleoyl-CoA (solid bars). Values represent the mean ± SEM of 3–4 separate animals. Bars with an asterisk are significantly different ( $P < 0.05$ ) compared to the bars with the same acyl-CoA and no albumin stimulation. Bars with the roman letter a are significantly different ( $P < 0.05$ ) between palmitoyl-CoA and oleoyl-CoA within the no-albumin or with-albumin groups. Bars in panel B with a roman letter b are significantly different ( $P < 0.05$ ) from the corresponding bar in panel A.

**FIG. 3.** Palmitic acid transacylation into phosphatidylcholine (PtdCho) is reduced by albumin in T-lymphocyte membranes. Whole membranes from liver (A) and T-lymphocytes (B) were isolated, and reactions were carried out as described in Figure 1 in the presence of palmitoyl-CoA with (solid bars) or without (open bars) albumin. Values represent the mean ± SEM of 3–4 separate animals. Bars with an asterisk are significantly different ( $P < 0.05$ ) compared to the unstimulated bars with the same acyl-CoA. PtdIns, phosphatidylinositol; PtdSer, phosphatidylserine; Spm, sphingomyelin.

**FIG. 4.** Oleic acid transacylation into PtdIns is enhanced by albumin. Whole membranes from liver (A) and T-lymphocytes (B) were isolated and reactions were carried out as described in Figure 1 in the presence of oleoyl-CoA with (solid bars) or without (open bars) albumin. Values represent the mean  $\pm$  SEM of 3–4 separate animals. Bars with an asterisk are significantly different ( $P < 0.05$ ) compared to the bars with the same acyl-CoA and no albumin stimulation. For abbreviations see Figure 3.

PtdCho and, to a lesser extent, into PtdIns and Spm (Fig. 3B). The addition of albumin significantly reduced the incorporation of palmitic acid into Spm in both liver and T-lymphocyte membranes. In contrast, albumin significantly reduced the incorporation of palmitic acid into PtdCho in T-lymphocyte membranes but did not have a significant effect in liver membranes. Furthermore, albumin significantly enhanced palmitic acid incorporation into liver PtdIns by twofold while having no effect in T-lymphocyte membranes.

Similar to palmitic acid, oleic acid was preferentially incorporated into PtdSer compared to PtdIns, PtdCho, and Spm in liver membranes (Fig. 4A). In contrast, oleic acid was preferentially incorporated into PtdCho in T-lymphocyte membranes (Fig. 4B). Addition of albumin significantly enhanced the incorporation of oleic acid into PtdIns in liver membranes while not significantly influencing the other phospholipid subclasses examined (Fig. 4A). Similar effects of albumin were seen in T-lymphocytes except that oleic acid incorporation into PtdCho was reduced by 50% (Fig. 4B).

## DISCUSSION

Although albumin is always present physiologically, it was important to perform the assays in the absence of albumin to determine the relative contribution of albumin vs. the enzyme itself on cellular GPAT and LAT activity as well as on acyl-CoA preference. The most striking observation presented in this investigation was the increase in LAT activity in T-lymphocyte membranes in the presence of albumin, whereas GPAT activity was not significantly affected. In contrast, liver membrane GPAT and not LAT activity was induced by the addition of albumin. The reason for this difference is unknown but may be related to the expression of different LAT isoforms in spleen and liver. Recently, two LAT isoforms ( $\alpha$  and  $\beta$ ) have been cloned. The  $\beta$  isoform was primarily located in liver and muscle, whereas the  $\alpha$  isoform was found in all tissues tested including spleen (12). However, other factors such as membrane composition cannot be ruled out. Our results in the liver showed that basal GPAT activity was approximately 25-fold less than LAT activity and were similar to those published previously (6). However, the 25-fold induction of GPAT activity with albumin was twice as high as that reported by Jolly *et al.* (6). The reason for this discrepancy is most likely due to the use of whole-membrane preparations in this study rather than isolated microsomes as reported previously. Both GPAT and LAT are located in several organelles, including mitochondria and microsomes (7); thus, the inclusion of all organelles in a membrane preparation may result in higher PtdOH biosynthetic capacity. We chose to examine PtdOH biosynthesis in whole membrane preparations to determine the total biosynthetic capability of T-lymphocytes, since multiple organelles may be involved under *in vivo* conditions. The lower basal activity of LAT in T-lymphocytes is significant given the recent results showing that the substrate lysoPtdOH is a potent T-lymphocyte mitogen (15,16). Thus, the lower basal LAT activity as compared to that of liver would prevent lysoPtdOH from being quickly converted to PtdOH prior to exerting its biological activity. However, showing that LAT activity is inducible, as we found for albumin addition, indicates that potential mechanism(s) exist which can quickly eliminate lysoPtdOH when necessary. Furthermore, this suggests a novel biological function for proteins that bind acyl-CoA (i.e., remove lysoPtdOH).

The exact mechanism(s) by which albumin stimulates GPAT in liver membranes and LAT in T-lymphocyte membranes is not known. Enhanced activity due to a potential contaminant in the albumin preparation is not likely, because a multitude of other highly purified proteins that bind acyl-CoA can enhance GPAT activity in membrane preparations (10). Similarly, the preference of albumin in stimulating LAT activity in the presence of palmitoyl-CoA, but not oleoyl-CoA, is not known. However, several possibilities exist, including the preference for albumin to extract (i.e., solubilize) palmitoyl-CoA over oleoyl-CoA from membranes, preferably preventing the hydrolysis of palmitoyl-CoA to palmitate and coenzyme or by direct interaction of albumin with the LAT

enzyme. Future studies examining the influence of other proteins that bind acyl-CoA are needed to elucidate the potential mechanism(s) by which albumin stimulates PtdOH biosynthesis, as different acyl-CoA binding proteins have different numbers of acyl-CoA binding sites and vary in their affinity for acyl-CoA. However, this will be difficult, because most proteins that bind acyl-CoA are not commercially available in a highly purified form, requiring the proteins to be purified by individual investigators. It is tempting to speculate, however, that the mechanism involves direct interaction between the enzyme and acyl-CoA-bound albumin. This speculation is derived from two recent reports. First, it has been shown that acyl-CoA bound to acyl-CoA binding protein (ACBP) is preferred over free acyl-CoA to enhance carnitinepalmitoyl-acyltransferase activity in mitochondria (23). Second, both liver FA binding protein (L-FABP) and ACBP can stimulate PtdOH biosynthesis to a similar degree in the presence of oleoyl-CoA, even though L-FABP has two acyl-CoA binding sites and ACBP has only one (6). Whereas these studies examined the influence of albumin on GPAT and LAT in unstimulated T-lymphocytes, determining whether T-lymphocyte activation using mitogens may somehow change the ability of albumin or other acyl-CoA binding proteins to influence PtdOH biosynthesis requires further investigation.

The transacylation of palmitic and oleic acids into phospholipid subclasses also differed between liver and T-lymphocyte membranes. Oleic acid was preferentially incorporated into PtdCho in T-lymphocytes, whereas PtdSer appeared to be the major site of incorporation in liver. Additionally, albumin enhanced the incorporation of oleic acid into PtdIns both in liver and T-lymphocyte membranes and reduced palmitic acid incorporation in T-lymphocyte membrane PtdCho. This is significant because both PtdIns and PtdCho are important sources of DAG, which activates protein kinase C and is an important signal for appropriate T-lymphocyte proliferation (24,25). Furthermore, DAG containing unsaturated FA are thought to be more potent activators of protein kinase C.

# Comparison of the Effects of Dietary $\alpha$ -Linolenic, Stearidonic, and Eicosapentaenoic Acids on Production of Inflammatory Mediators in Mice

Kenji Ishihara<sup>a,\*</sup>, Wataru Komatsu<sup>b</sup>, Hiroaki Saito<sup>a</sup>, and Kazuki Shinohara<sup>c</sup>

<sup>a</sup>Functional Biochemistry Section, Marine Biochemistry Division, National Research Institute of Fisheries Science, Yokohama 236-8648, Japan, <sup>b</sup>Department of Food and Nutrition, Toita Women's College, Hachioji 193-0802, Japan, and <sup>c</sup>Food Function Division, National Food Research Institute, Tsukuba 305-8642, Japan

**ABSTRACT:** The effects of dietary stearidonic acid (18:4n-3) on inflammatory mediator release in whole blood and splenocytes was investigated in Balb/c mice, and the effects were compared with those of two other n-3 PUFA:  $\alpha$ -linolenic acid (18:3n-3) and EPA (20:5n-3). TAG mixtures containing 10% of 18:4n-3, 18:3n-3, or 20:5n-3 as the respective sole n-3 PUFA were enzymatically synthesized. Diets containing synthesized TAG mixtures were fed to Balb/c mice for 3 wk. The release of prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) and tumor necrosis factor (TNF) were measured in whole blood and splenocytes stimulated with lipopolysaccharide. In whole blood, the production of TNF was suppressed by all dietary n-3 PUFA (18:3n-3, 18:4n-3, and 20:5n-3) as compared with the control diet, which contained TAG prepared from safflower oil. PGE<sub>2</sub> production was not significantly changed. Differences among the n-3 PUFA (18:3n-3, 18:4n-3, and 20:5n-3) were not observed. In splenocytes, PGE<sub>2</sub> production was suppressed by dietary n-3 PUFA, but TNF production was not. GC analysis of plasma and splenocyte FA profiles showed an increase in the levels of 20:4n-3, 20:5n-3, and 22:6n-3 in mice fed the diet containing 18:4n-3.

Paper no. L8944 in *Lipids* 37, 481–486 (May 2002).

Since the discovery of a low incidence of heart disease in Eskimos by Dyerberg *et al.* (1–3), the nutritional, physiological, and pharmacological effects of n-3 PUFA on humans have been recognized. Many studies showed vegetable and fish oils rich in n-3 PUFA, such as EPA (20:5n-3), DHA (22:6n-3) and  $\alpha$ -linolenic acid (18:3n-3), to have beneficial effects on pathophysiological states such as coronary heart disease, hyperlipidemia, and inflammation, and the contribution of these PUFA to the beneficial effects has been studied (4,5).

The major n-3 PUFA in seafood are 20:5n-3 and 22:6n-3. In addition to these, some seafoods contain various n-3 PUFA such as hexadecatetraenoic acid (16:4n-3), stearidonic acid (18:4n-3), and tetracosahexaenoic acid (24:6n-3) (6,7). We have studied the physiological activities of these FA *in vitro*

Presented in part at the 17th International Congress of Nutrition, October 27–31, 2001, Wien, Austria.

Abbreviations: LPS, lipopolysaccharide; PGE<sub>2</sub>, prostaglandin E<sub>2</sub>; TNF, tumor necrosis factor.

and found a suppressing effect of these PUFA on eicosanoid production (8,9).

Stearidonic acid (18:4n-3) is an intermediate in the metabolism from 18:3n-3 to longer n-3 PUFA (10). Stearidonic acid is contained in significant amounts in fish oils (11), in plant oils (12,13), and in edible algae (7). *In vivo* metabolism of 18:4n-3 has been studied in rats (10) and mice (14). Iritani *et al.* (15) showed a suppressive effect of 18:4n-3 on liver lipogenic enzyme activity in rats. Recently, Hansen Petrik *et al.* (16) reported that dietary 18:4n-3 strongly suppressed tumorigenesis in Apc<sup>Min/+</sup> mice and that the suppression was correlated with the inhibition of prostaglandin (PG) biosynthesis. Thus, interest in the nutritional and physiological activity of 18:4n-3 is increasing.

Dietary oils containing n-3 PUFA have anti-inflammatory activity in animals and humans (4,5,17). In this work, we studied the effect of dietary 18:4n-3 on inflammatory mediator release from the whole blood and splenocytes in mice (to assess the anti-inflammatory effect of 18:4n-3) and compared this effect with that of other common n-3 PUFA (18:3n-3 and 20:5n-3). We measured prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) and tumor necrosis factor (TNF) release. Both are well known as mediators of inflammation, and both play important roles in many pathological processes (18–22). PGE<sub>2</sub> also has been reported to be closely related to intestinal carcinogenesis in Apc<sup>Min/+</sup> mice (23), and TNF has been considered to act as an internal promoter of carcinogenesis (18). This study gives information about not only anti-inflammatory but also the anticarcinogenic effects of dietary 18:4n-3.

## EXPERIMENTAL PROCEDURES

**Animals and diets.** Twenty-eight male Balb/c mice (3 wk of age, Tokyo Experimental Animals, Tokyo, Japan) were housed individually in stainless steel cages and fed a commercial pellet diet (CE-2; Japan CLEA, Tokyo, Japan) for 3 d before starting the experimental diets. Mice were maintained in an air-conditioned room (temperature: 20–22°C; relative humidity: 55–65%; lighting: 0700–1900). All animal procedures were in accordance with the National Research Institute of Fisheries Science guidelines for the ethical treatment of laboratory animals. The mice were divided into four dietary groups (seven mice/group): control, 18:3n-3, 18:4n-3,

and 20:5n-3. Each group was fed the experimental diet *ad libitum* for 3 wk. This period and dose of PUFA were based on the study of Yamazaki *et al.* (10). They studied the incorporation and metabolism of dietary 18:4n-3 in rats and found that feeding for 3 wk at a dose of 1% of the diet significantly affected tissue FA profiles.

The composition of the experimental diet was as follows (g/kg diet): casein, 230; cornstarch, 410; sucrose, 200; AIN-76 mineral mixture, 35; AIN-76 vitamin mixture, 10; cellulose powder, 20; maltodextrin, 20; DL-methionine, 3; choline bitartrate, 2; test oil, 100. Sucrose was purchased from Maruha Corp. (Tokyo, Japan). DL-Methionine and choline bitartrate were from Wako Pure Chemical Industry (Osaka, Japan). Maltodextrin was a generous gift from Matsutani Chemical Industry (Hyogo, Japan). The test oils were prepared as described below.

**Preparation of test oils.** Stearidonic acid (purity > 95%) was purified from the brown alga *Undaria pinnatifida* as previously described (24).  $\alpha$ -Linolenic acid was obtained from Wako Pure Chemical Industry. EPA was generously donated by Nissui Corp. (Tokyo, Japan). Safflower oil (Ajinomoto Corp., Tokyo, Japan) was saponified in ethanolic-KOH, and FFA were extracted as previously described (24). TAG containing n-3 PUFA were enzymatically synthesized essentially according to the method of Kosugi and Azuma (25). Briefly, the n-3 FA and safflower FFA were mixed 1:1 (w/w); 20 g of the FFA mixture was then added along with 1.8 g of glycerol (approximate molecular ratio, 3:1) and 1.3 g of Novozyme 435 (kind gift from Novozymes Japan, Chiba, Japan). The mixture was reacted at 60°C under vacuum conditions (~10 Torr) on a magnetic stirrer (500 rpm) for 24 h. After the reaction, lipid was extracted by the method of Folch *et al.* (26), and TAG were purified by Florisil column chromatography using hexane/diethyl ether (7:3, vol/vol) as solvent. Purified TAG were diluted with safflower oil and purified by the same method as that for synthesized TAG to give a composition of n-3 PUFA at 10% (w/w), and DL- $\alpha$ -tocopherol was added to the mixture at a level of 0.2% (w/w). The FA composition of the test oils is shown in Table 1. With this method, we obtained TAG which contained 18:3n-3, 18:4n-3, or 20:5n-3 as almost the sole n-3 PUFA. This allowed us to evaluate the effect of single dietary n-3 PUFA.

**Measurement of inflammatory mediator release in whole blood.** Inflammatory mediator release in whole blood was assayed essentially according to the report of Di Santo *et al.* (27). At the end of the experimental period, mice were fasted for 5 h and anesthetized with i.p. injection of Nembutal (1 mL/kg body weight; Dainippon Pharmaceutical, Osaka, Japan). Whole blood was collected from heart in a syringe that contained 7 U of heparin/0.1 mL of saline. Aliquots (100  $\mu$ L) of whole blood were dispensed into a 96-well microtiter plate to which was added 10  $\mu$ L of PBS containing 0.1  $\mu$ g of lipopolysaccharide (LPS, from *Escherichia coli* O26:B6; Wako Pure Chemical Industry). Six hours later, blood was recovered and plasma was collected after centrifugation at 1,000  $\times$  g for 15 min. Plasma TNF activity was measured as cytotoxicity against L929 fibroblasts as described by Komatsu *et al.* (28). Plasma PGE<sub>2</sub>

**TABLE 1**  
**FA Composition of Test Oils<sup>a</sup>**

FA	Dietary group			
	Control	18:3n-3	18:4n-3	20:5n-3
	g/100 g total FA			
14:0	0.1	0.0	0.1	0.1
16:0	4.6	4.0	4.4	4.1
16:1n-7	0.2	0.2	0.2	0.2
18:0	1.8	1.6	1.6	1.6
18:1n-9	75.5	66.2	66.3	67.9
18:2n-6	16.9	17.1	14.9	15.2
18:3n-6	0.0	0.0	0.1	0.0
18:3n-3	0.3	10.2	0.6	0.2
18:4n-3	0.0	0.0	10.0	0.0
20:0	0.4	0.3	0.3	0.3

20:1n-7	0.1	0.1	0.1	0.1
20:4n-6	0.0	0.0	0.3	0.0
20:5n-3	0.0	0.0	0.7	10.0

<sup>a</sup>Test oils were synthesized as described in the Experimental Procedures section.

concentration was measured with PGE<sub>2</sub> enzyme immunoassay kit (Cayman Chemical Company, Ann Arbor, MI; cross-reactivity: PGE<sub>2</sub> 100%, PGE<sub>3</sub> 43%, PGE<sub>1</sub> 18.7%, 6-keto PGF<sub>1 $\alpha$</sub>  1%, PGD<sub>2</sub> <0.01%). In a preliminary experiment, PGE<sub>2</sub> production in whole blood incubated without LPS was less than 5% of that incubated with LPS.

**Measurement of inflammatory mediator release by splenocytes.** The spleen was excised and splenocytes were isolated as described by Hayek *et al.* (29) and suspended in RPMI-1640 medium supplemented with 5% FCS (Biological Industry Inc., Beit Haemek, Israel). Splenocyte suspension was seeded into 24-well plates (10<sup>6</sup> cells/0.5 mL/well). Following the preincubation for 2 h, splenocytes were stimulated by adding of 50  $\mu$ L of PBS containing 0.5  $\mu$ g of LPS (final concentration: 1  $\mu$ g/mL). This concentration of LPS was confirmed to fully stimulate splenocyte TNF production (data not shown). After 6 h stimulation, the supernatant was collected, and TNF activity and PGE<sub>2</sub> concentration were measured as detailed above. Cellular protein content was measured with Bio-Rad protein assay reagent (Bio-Rad Laboratory, Hercules, CA).

**FA analysis.** Lipids of plasma and splenocytes were extracted by the method of Folch *et al.* (26). Total lipids of plasma and splenocytes were methyl-esterified and analyzed by GC using the previously reported method (9).

**Statistical analysis.** Statistical analyses were done using StatPartner version 3 (NEC software, Tokyo, Japan). Data obtained in this report were analyzed by one-way ANOVA. If significant, data were further analyzed by Duncan's multiple range test. Significance level was set at  $P < 0.05$ .

## RESULTS

**Growth, food intake, and relative organ weight.** Initial body weight, body weight gain, total food intake, and relative liver weight were not different among the dietary groups (Table 2).

**TABLE 2**  
**Initial Body Weight, Body Weight Gain, Total Food Intake, and Relative Weight of Liver<sup>a</sup>**

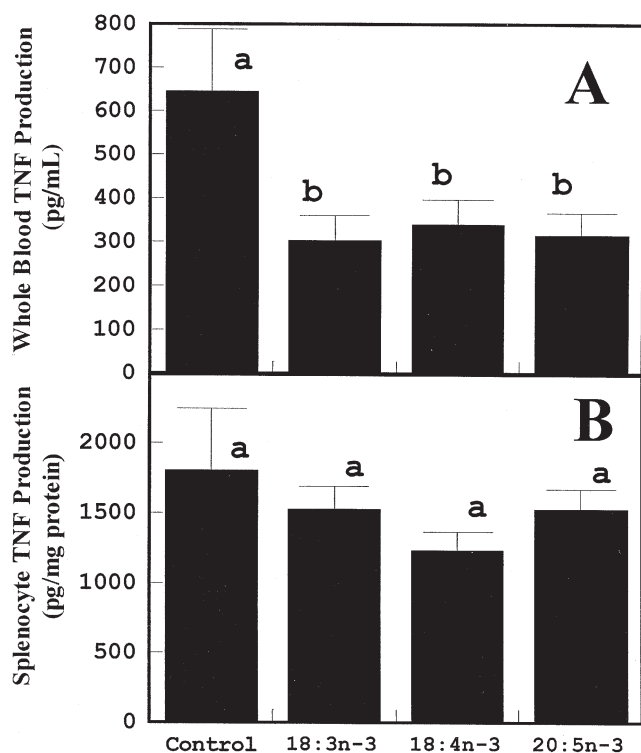

Diet group	Initial body weight (g)	Body weight gain (g/3 wk)	Total food intake (g/3 wk)	Relative liver weight (% of body weight)
Control	18.0 ± 0.3	5.5 ± 0.4	83.2 ± 1.4	4.03 ± 0.09
18:3n-3	18.0 ± 0.3	5.1 ± 0.1	79.2 ± 1.9	4.08 ± 0.12
18:4n-3	18.0 ± 0.3	5.3 ± 0.4	79.7 ± 1.9	3.64 ± 0.18
20:5n-3	17.9 ± 0.4	5.5 ± 0.3	86.0 ± 2.0	3.74 ± 0.10

<sup>a</sup>Data are expressed as the mean ± SEM of seven mice. Data were analyzed by one-way ANOVA, and no significant differences were observed ( $P > 0.05$ ).

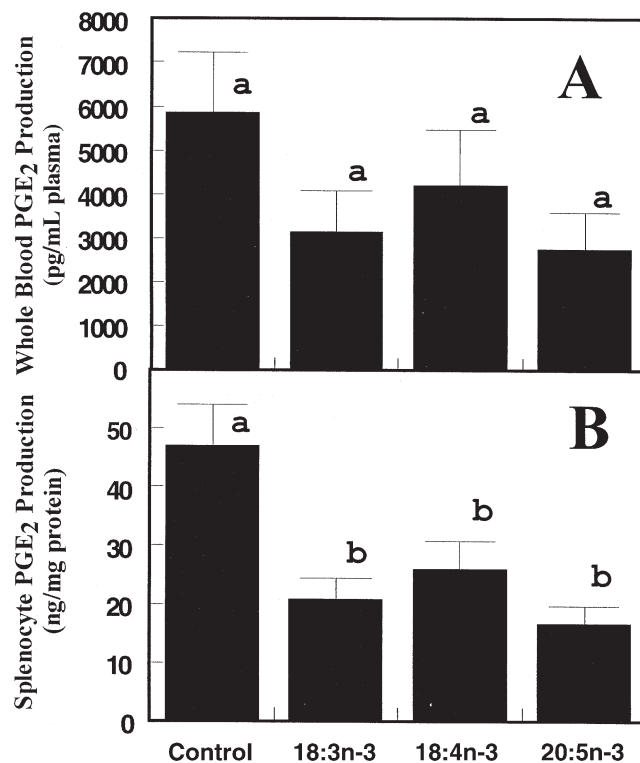

**TNF production in whole blood and splenocytes.** TNF production in whole blood was significantly decreased by dietary n-3 PUFA compared to the control group (59% for 18:3n-3, 59% for 18:4n-3, and 61% for 20:5n-3, Fig. 1A). There was no difference among the dietary n-3 PUFA. In splenocytes (Fig. 1B), no significant difference was found between the dietary groups, but there was a tendency for TNF production to be reduced by dietary n-3 PUFA.

**PGE<sub>2</sub> release in whole blood and splenocytes.** PGE<sub>2</sub> synthesis in whole blood and splenocytes is shown in Figure 2. Splenocyte PGE<sub>2</sub> synthesis was significantly suppressed in n-3 PUFA-fed mice (56, 45, and 64% compared to the control in 18:3n-3, 18:4n-3, and 20:5n-3 fed groups, respectively). There was no difference among the dietary n-3 PUFA. Whole blood PGE<sub>2</sub> production revealed the same trend as for splenocytes, but it was not significant.

**FA profile.** FA profiles of the total lipid of plasma and splenocytes were analyzed (Fig. 3). The proportion of arachidonic acid (20:4n-6) was decreased in serum and splenocytes by dietary n-3 PUFA. Dietary 20:5n-3 more effectively decreased the composition of 20:4n-6 than 18:4n-3 and 18:3n-3. The influence of dietary n-3 PUFA on the composition of n-3 PUFA differed between plasma and splenocytes (Fig. 3). In plasma, dietary n-3 PUFA increased the composition of 22:6n-3 to the same extent. Dietary 18:3n-3 only increased 22:6n-3, but 18:4n-3 and 20:5n-3 increased the composition of 18:4n-3 and 20:5n-3 as well as 22:6n-3 (Fig. 3A). In splenocytes, the 22:6n-3 level was raised only by dietary 18:4n-3. Dietary 18:3n-3 did not change the levels of n-3 PUFA significantly. Dietary 18:4n-3 elevated the proportion of 18:4n-3, 20:4n-3, 20:5n-3, 22:5n-3, and 22:6n-3. EPA increased 20:5n-3 and 22:5n-3 (Fig. 3B).

**FIG. 1.** Tumor necrosis factor (TNF) production from whole blood (A) and splenocytes (B) in mice fed n-3 PUFA. Vertical bars indicate SEM of seven mice. Values not sharing a common letter are significantly different at  $P < 0.05$  by Duncan's multiple range test.

**FIG. 2.** Prostaglandin (PG) E<sub>2</sub> production from whole blood (A) and splenocytes (B) in mice fed n-3 PUFA. Vertical bars indicate SEM of seven mice. Values not sharing a common letter are significantly different at  $P < 0.05$  by Duncan's multiple range test.

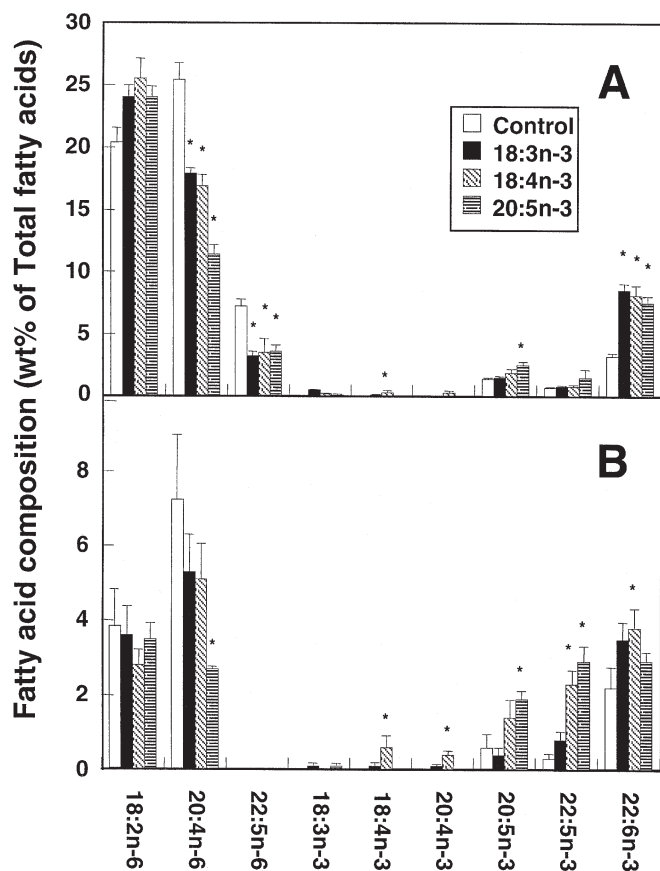

FIG. 3. n-6 and n-3 PUFA composition of total lipid in serum (A) and splenocytes (B) in mice fed n-3 PUFA. Vertical bars indicate SEM of seven mice. Asterisk (\*) indicates significant difference from control by Duncan's multiple range test.

## DISCUSSION

In this study, we synthesized TAG that contained 18:4n-3 as the almost sole n-3 PUFA by using the lipase reaction reported by Kosugi and Azuma (25). TAG containing 18:3n-3 and 20:5n-3 were also synthesized. This allowed us to investigate the nutritional effect of dietary 18:4n-3 while avoiding influences of the chemical form of the FA and the co-occurrence of other PUFA. Several reports describe nutritional studies of diets containing 18:4n-3 (10,12,14–16). Some of these studies used black currant seed oil, which has a high percentage composition of  $\gamma$ -linolenic acid (18:3n-6) and 18:3n-3, and a relatively low percentage composition of 18:4n-3. Yamazaki *et al.* (10) and Huang *et al.* (14) studied the metabolic uptake of 18:4n-3 by using pure 18:4n-3 ethyl ester although digestion and absorption of FA reportedly differ between the ethyl ester form and the TAG form (30). Therefore, this is the first report studying nutritional effects of 18:4n-3 as a sole n-3 PUFA and in TAG form. The method used in this report for preparing the test oils may be applicable to the nutritional study of other FA.

In this study, we examined the effect of dietary 18:4n-3 on the release of inflammatory mediators (TNF and PGE<sub>2</sub>) in whole blood and splenocytes in response to LPS *ex vivo*.

These mediators are known to be produced and play important roles in the inflammation process (19). LPS is a component of gram-negative bacterial cell walls and induces many inflammatory reactions and leads to the production of inflammatory mediators when administered into animals (31). Thus, inflammatory mediator release in response to LPS exposure *ex vivo* will reflect the intensity of inflammatory response in the animal. Dietary n-3 PUFA are known to reveal beneficial effects *via* suppressing the production of these mediators in inflammation and other disease models (20–22).

Eicosanoids (PG and leukotrienes) are synthesized from 20:4n-6. n-3 PUFA such as 18:3n-3, 20:5n-3, and 22:6n-3 can suppress their synthesis (17). Hansen Petrik *et al.* (16) measured PG levels in the small intestine of mice fed diets supplemented with various FA ethyl esters. They showed that dietary n-3 PUFA (18:3n-3, 18:4n-3, 20:5n-3, and 22:6n-3) decreased the PGE<sub>2</sub> level, and the decrement did not differ among the n-3 PUFA. This result is in agreement with our results. However, Kockmann *et al.* (32) reported that the inhibition of the production of cyclooxygenase pathway products by 18:4n-3 in isolated human platelets *in vitro* was less than the inhibitory activity of 20:5n-3. In our unpublished results, 18:4n-3 had only a weaker inhibitory activity than 20:5n-3 on PGE<sub>2</sub> synthesis in cultured murine macrophage cell line. Thus, suppressive activity of dietary 18:4n-3 on PGE<sub>2</sub> synthesis may be exerted not only by 18:4n-3 itself but also by its metabolites, such as 20:5n-3 and 22:6n-3. In this study, metabolism of 18:4n-3 to 20:5n-3 and 22:6n-3 was observed in plasma and splenocytes (Fig. 3). In whole blood, the effect of n-3 PUFA on PGE<sub>2</sub> production was not significant but was similar to that of splenocytes. However, FA profiles of serum and splenocytes were different (Fig. 3). The reasons for the difference in response of PGE<sub>2</sub> production to dietary n-3 PUFA is not clear. There might be real FA pools, not reflected in the FA profile of total lipids that influence PGE<sub>2</sub> production.

Calder (21) and Blok *et al.* (22) reviewed reports of studies of the effect of dietary n-3 PUFA on inflammatory cytokine production in animals *ex vivo*. In their reviews, there are reports showing inconsistent results: decreasing, no, and increasing effects of dietary n-3 PUFA on cytokine production. Most human *ex vivo* and animal *in vivo* studies revealed a suppression of cytokine production by dietary n-3 PUFA (21,22). Blok *et al.* (22) and Calder (21) suggested the detailed conditions of the experiments (cell type used, methods of stimulation, incubation time, etc.) may have produced the contradictory results. Most of the studies that have shown an enhancing effect of n-3 PUFA on cytokine production used peritoneal macrophages as cytokine sources. In this study, a significant suppression of TNF production was observed in whole blood. From these results, it is suggested that interactions of different types of cells are required for the expression of a suppressive effect on cytokine production of dietary n-3 PUFA. The experiment that used thioglycolate-elicited macrophages showed an inhibition of cytokine production by dietary n-3 PUFA. In this case, it was possible that these macrophages had interactions with other cells during stimulation with thioglycolate *in vivo*. Our present results

showed suppression of TNF production by dietary n-3 PUFA in whole blood but not in splenocytes. Whole blood is a complex system and consists of many types of cells; on the other hand, the isolated splenocyte system is relatively simple. Thus, cellular interactions in both systems seem to be different. It might explain the difference in the effect of n-3 PUFA on TNF production in the two systems. Hansen Petrik *et al.* (16) revealed an anticarcinogenic activity of dietary n-3 PUFA, and the activity of 18:4n-3 and 20:5n-3 was stronger than that of 18:3n-3 and 22:6n-3. They suggested their activity was in part due to the suppression of PGE<sub>2</sub> synthesis. It was reported that TNF could act as an endogenous tumor promoter (18). Thus, the possibility is suggested that dietary 18:4n-3 may exert its anticarcinogenic effect not only by suppression of PGE<sub>2</sub> synthesis but also by the suppression of TNF production.

Stearidonic acid (18:4n-3) is a  $\Delta$ 6-desaturase metabolite of 18:3n-3.  $\Delta$ 6-Desaturation is known as a rate-limiting step of the metabolism of 18:3n-3 to longer n-3 PUFA (10). Thus, 18:4n-3 is expected to be more readily metabolized than 18:3n-3. This was reported in mouse liver and intestine lipids (14,16) and in rat liver and plasma lipids (10). In the present results, we found 18:4n-3 was metabolized more readily than 18:3n-3 only in splenocytes. The reason is not clear. Differences in the chemical form of PUFA, tissue enzyme activities, and co-occurring FA may influence the metabolism of n-3 PUFA. Dietary n-3 PUFA reduced the 20:4n-6 concentration in serum and splenocytes (Fig. 3). EPA reduced the level of arachidonic acid (20:4n-6) more effectively than 18:3n-3 and 18:4n-3. Arachidonic acid is a precursor of PG biosynthesis. PG are known to influence cytokine production, inflammation reaction, and carcinogenesis (16,17,19–22). Tissue 20:4n-6 level has been shown to influence PG biosynthesis (16,17,23). Thus, dietary n-3 PUFA may be important due to their ability to reduce tissue level of 20:4n-6.

In this study, we compared the effects of dietary 18:3n-3, 18:4n-3, and 20:5n-3 on the production of TNF and PGE<sub>2</sub> in mice and found that all three n-3 PUFA had suppressive activity on the production of TNF in whole blood and PGE<sub>2</sub> in splenocytes. Differences in activity among dietary groups were not observed. However, differences in the rate of incorporation and metabolism of n-3 PUFA were suggested in some tissues. Therefore, it is possible that the differences in the activity of n-3 PUFA will be found in some physiological functions.

## ACKNOWLEDGMENT

We thank Dr. Kazuhiko Hata (Central Research Institute, Nissui Corporation) for providing us 20:5n-3 ethyl ester, Novozymes Japan Ltd. for giving us Novozyme 435, and Matsunami Chemical Industry for the donation of maltodextrin. We thank Kazuhiko Yamamoto for his skillful technical assistance.

# Peroxisome Proliferator-Activated Receptor $\alpha,\gamma$ Coagonist LY465608 Inhibits Macrophage Activation and Atherosclerosis in Apolipoprotein E Knockout Mice

Steven H. Zuckerman\*, Raymond F. Kauffman, and Glenn F. Evans

Division of Cardiovascular Research, Lilly Research Laboratories, Indianapolis, Indiana 46285

**ABSTRACT:** The apolipoprotein E (apoE) knockout mouse has provided an approach to the investigation of the effect of both cellular and humoral processes on atherosclerotic lesion progression. In the present study, pharmacologic modulation of both interferon gamma (IFN $\gamma$ )-inducible macrophage effector functions, and atherosclerotic lesions in the apoE knockout mouse were investigated using the peroxisome proliferator-activated receptor (PPAR)  $\alpha,\gamma$  coagonist LY465608. LY465608 inhibited, in a concentration-dependent manner, IFN $\gamma$  induction of both nitric oxide synthesis and the  $\beta$  2 integrin CD11a in elicited peritoneal macrophages from apoE knockout mice. Similar effects were observed *ex vivo* following 10 d of treating mice with 10 mg/kg of LY465608. Treatment of apoE knockout mice for 18 wk with LY465608 resulted in a statistically significant 2.5-fold reduction in atherosclerotic lesion area in en face aorta preparations. These effects were apparent in the absence of any reduction in total serum cholesterol or in lipoprotein distribution. Finally, treatment of apoE knockout mice with established atherosclerotic disease resulted in a modest but not statistically significant decrease in aortic lesional surface area. These results demonstrate the utility of PPAR coagonists in reducing the progression of the atherosclerotic lesion.

Paper no. L8986 in *Lipids* 37, 487–494 (May 2002).

Novel therapeutic approaches to the prevention and mitigation of atherosclerotic disease include strategies in which more specific interventions toward the inflammatory response are being considered. The macrophage is involved in all aspects of the pathobiology of the atherosclerotic lesion and mediates its effects through both cellular and humoral processes including the elaboration of cytokines and oxidants (1–3). Macrophage activation has been observed within the atheroma and is believed to be due to the autocrine and

paracrine effects of cytokines as well as to the binding and ingestion of oxidized LDL (4–6). Interferon  $\gamma$  (IFN $\gamma$ ) represents one such macrophage-activating cytokine whose effects on apolipoprotein (apoE) secretion, ABC-1 and ACAT expression, cholesterol efflux, and metalloprotease production could contribute to the pathology associated with atherosclerosis (7–12). Inhibiting IFN $\gamma$  signaling, for example, by crossing apoE knockout (KO) mice with mice lacking the IFN $\gamma$  receptor, results in reduced atherosclerosis (13). These *in vivo* results suggest that pharmacologic agents that inhibit macrophage activation through IFN $\gamma$  signaling could be useful in slowing or reversing lesion progression.

The peroxisome proliferator-activated receptors (PPAR) represent nuclear receptors that function as ligand-activated transcription factors. PPAR subtypes include PPAR $\alpha$ , PPAR $\delta$ , and PPAR $\gamma$ ; upon ligand activation, PPAR form heterodimeric structures with the retinoid X receptor to bind to and activate specific gene transcription through PPAR response elements (14–16). Anti-inflammatory effects both *in vitro* and *in vivo* have been reported for both PPAR $\alpha$ - and PPAR $\gamma$ -specific agonists (17–21). PPAR $\gamma$  agonists, for example, have been reported to inhibit IFN $\gamma$ -induced inducible nitric oxide synthetase (iNOS) activity, gelatinase, and scavenger receptor activity *in vitro* in mouse macrophages, matrix metalloprotease 9 (MMP 9) activity in human monocyte-derived macrophages, and both phorbol ester and lipopolysaccharide induction of tumor necrosis factor (TNF) and interleukin 6 (IL-6) production (17,22–25). PPAR $\gamma$  agonists also have been reported to increase both scavenger receptor class B type I (SR-BI) and CD36 expression in macrophages, thereby contributing to the process of reverse cholesterol transport (26–30).

Similarly, PPAR $\alpha$  agonists also have been reported to have anti-inflammatory effects including inhibiting the production of MMP 9 activity, IL-6 and endothelin-1 secretion, and cyclooxygenase 2 and iNOS expression (19–21). PPAR activation appears to inhibit inflammatory processes by antagonizing both nuclear factor  $\kappa$ B (NF- $\kappa$ B) and activator protein-1 (AP-1) pathways (20,21,31). Therefore, it would be expected that PPAR $\alpha$  or  $\gamma$  agonists should be beneficial in preclinical models of atherosclerosis. To this extent, the recent reports demonstrating that activation of the retinoid X receptor

Abbreviations: ABC-1, ATB-binding cassette transporter-1; AP-1, activator protein-1; apo, apolipoprotein; CD11a, integrin  $\alpha_L$ ; CD11b, integrin  $\alpha_M$ ; CD36, member of the scavenger receptor family; CMC, carboxymethylcellulose; FITC, fluorescein isothiocyanate; FPLC, fast protein liquid chromatography; IFN $\gamma$ , interferon  $\gamma$ ; IL, interleukin; iNOS, inducible nitric oxide synthetase; KO, knockout; LDLR, LDL receptor; LY465608, 2-[4-[2-(2-biphenyl-4-yl-5-methyl-oxazol-4-yl)-ethoxy]-phenoxy]-2-methyl-propionic acid; MMP 9, matrix metalloprotease 9; NF- $\kappa$ B, nuclear factor  $\kappa$ B; PPAR, peroxisome proliferator-activated receptor; SR-BI, scavenger receptor class B, type I; TNF, tumor necrosis factor.

through the administration of rexinoids or a PPAR $\alpha,\gamma$  coagonist reduced lesion development in the apoE KO mouse (32) suggest the utility of this approach. Separate studies with the PPAR $\gamma$  agonist troglitazone, rosiglitazone, or GW7845 also reported reductions in lesional areas in both apoE and LDL receptor KO mice as well as increases in CD36 and lipoprotein lipase message (33–35).

LY465608 (2-[4-[2-(2-biphenyl-4-yl-5-methyl-oxazol-4-yl)-ethoxy]-phenoxy]-2-methyl-propionic acid) represents a new class of PPAR $\alpha,\gamma$  coagonists in which the pharmacophores of known PPAR $\gamma$  and PPAR $\alpha$  selective agents were combined into a single compound. IC<sub>50</sub> values for human PPAR $\alpha,\gamma$  of 174 and 548 nM, respectively, were determined (36). Cotransfection studies demonstrated that this compound is an effective agonist against both receptors as well as the mouse PPAR $\alpha$ . The specificity of this compound was also determined in transfection studies where it was demonstrated that the  $K_i$  for retinoid and rexinoid receptors, glucocorticoid, and thyroid receptors was greater than 10  $\mu$ M. Finally, this compound has been demonstrated to lower both plasma glucose and TG levels in a diabetic mouse model at 30 mg/kg (36). These results as well as the nuclear receptor specificity of LY465608 suggested a potential therapeutic role for this PPAR coagonist in reducing atherosclerosis in the apoE KO mouse.

The present study was initiated to evaluate the impact of LY465608 on macrophage effector functions *in vitro* systematically, to evaluate its effects on macrophage responses to IFN $\gamma$  *ex vivo*, and to determine whether there would be any beneficial effect on lesion development and/or progression. LY465608 was demonstrated both *in vitro* and *ex vivo* to inhibit the ability of IFN $\gamma$  to induce both iNOS and CD11a expression. Furthermore, when administered at the initiation of exposure of apoE KO mice to an atherogenic diet, LY465608 significantly reduced the extent of atherosclerotic lesion development. Finally, similar studies were performed on older apoE KO mice with established lesions to determine whether a similar beneficial effect could be observed in lesional surface area. These latter results, however, failed to achieve statistical significance. Collectively, the results provide further evidence for the therapeutic value of a PPAR coagonist in the treatment of atherosclerosis in a model in which a vascular effect is observed in the absence of a significant beneficial impact on serum lipoprotein profiles.

## MATERIALS AND METHODS

**Macrophage cultures and reagents.** Peritoneal macrophages were obtained from thymoglobulin-primed apoE KO mice (C57BL/6Tac-Apo<sup>tm1Unc</sup>N11, male; Taconic Laboratories, Germantown, NY) and maintained in culture in RPMI 1640 supplemented with 2% FCS (Hyclone Laboratories, Logan, UT). Macrophages were activated with the designated concentrations of recombinant murine IFN $\gamma$  (BioSource International, Camarillo, CA) for 48 h, and supernatants were quantified for nitrites and cells processed for flow cytometry. LY465608 at final concentrations between 1 nM and 10  $\mu$ M

were added to the macrophage cultures at the time of IFN $\gamma$  addition.

**Flow cytometry and nitric oxide measurements.** Following 48 h of stimulation with IFN $\gamma$ , macrophage cultures were stained with a phycoerythrin-conjugated antibody against CD11a (integrin  $\alpha$ L) or fluorescein isothiocyanate (FITC)-conjugated antibody against CD11b (integrin  $\alpha$ M) (Pharmin-gen, San Diego, CA). All flow cytometry experiments were evaluated on 10,000 individual cells gated for macrophages based on their forward and side light-scatter profiles. The mean fluorescence intensity was measured using a Becton Dickinson FacSort with Cellquest software (Becton Dickinson, San Jose, CA). Supernatants were quantified for nitric oxide levels using the Griess reaction as previously described (30). The optic density change at 10 min was measured at 550 nm and converted to micromoles of nitrites based on a sodium nitrite standard curve.

**Atherosclerosis model.** Male apoE KO mice were shifted to a high-fat diet (21% milkfat, 0.15% cholesterol; Harlan Teklad, Madison, WI) and were dosed orally by gavage with 10 mg/kg of LY465608 [prepared in 1% carboxymethylcellulose (CMC) plus 1% Tween 80] daily. Mice were treated with LY465608, 10 mg/kg/d, for 18 wk starting at 8 wk of age when they were shifted to a high-fat diet. At the end of the 18 wk of treatment both vehicle and LY465608 mice were evaluated for lipoprotein profiles and atherosclerotic lesions. In studies designed to investigate the effect of LY465608 on established lesions, mice were maintained on the high-fat diet for 16 wk and then treated for an additional 12 wk with 10 mg/kg LY465608 prior to sacrifice. The control animals in all experiments were dosed with the CMC vehicle. All animal studies were in compliance with institutional guidelines.

**Lesion analysis.** At sacrifice, animals were prepared for en face aorta evaluation by cutting the aorta below the bifurcation in the lower abdomen as previously described (37). Briefly, the aortas were perfused with PBS, cleaned of external fat, opened, flattened on a microscope slide, and covered with a coverglass. All samples were fixed in 4% formalin and kept at 4°C in humidified chambers until imaging. Samples were visualized using a Microtek ScanMaker 9600 XL (Microtek Lab, Inc., Redondo Beach, CA) and Adobe Photoshop LE (Adobe Systems, San Jose, CA). The images were analyzed using a custom-written macro (Mike Esterman, Jeff Hanson, Lilly Research Labs) in Image Pro Plus (Media Cybernetics, L.P., Silver Spring, MD) that uses the threshold tool to select lesion sites based on image intensity contrasted to the normal translucent arterial wall. Lesion area and total aortic area were expressed in square mm. Approximately 45 mm square of total aortic surface was evaluated per aorta for lesion quantification.

**Serum cholesterol and lipoprotein analysis.** Total serum cholesterol levels were measured using the Cholesterol CII kit from Wako Pure Chemicals (Richmond, VA). Sera from each group at the designated times were pooled, and 25–100  $\mu$ L aliquots were resolved by fast protein liquid chromatography (FPLC; Pharmacia, Bromma, Sweden) using tandem-linked Superose

6 columns as previously described (38). Total cholesterol was quantified enzymatically (Wako Chemicals USA, Richmond, VA) from 100- $\mu$ L aliquots of the FPLC fractions. The relative amount of cholesterol within each peak was determined by area quantification under the curves using the appropriate baseline modifications from the FPLC cholesterol tracings. Serum TG levels were measured by enzymatic assay (Sigma Chemicals, St. Louis, MO).

**Statistics.** Statistical analysis was performed by unpaired (two-tailed) *t*-test. Values are reported as means  $\pm$  SD. The 95% confidence limit was taken as significant ( $P < 0.05$ ). Additional statistical analysis was by a Dunnett's multiple comparisons test. Analysis of the lesion area data was performed using chi square and Tukey's biweight function robust method as well as by a Mann-Whitney U test, a nonparametric test.

## RESULTS

Activation of primary peritoneal macrophages with IFN $\gamma$  results in an increase in macrophage effector functions including the generation of nitric oxide through the induction of iNOS and the upregulation of the  $\beta$  2 integrin CD11a. Consistent with previous studies using the less-specific PPAR $\gamma$  agonist 15-deoxy- $\Delta^{12,14}$ -prostaglandin J<sub>2</sub> (30), 100 nM LY465608 resulted in a significant reduction both in nitric oxide production (Fig. 1A) and in CD11a induction (Fig. 1B) at all concentrations of IFN $\gamma$  used for macrophage activation. In contrast, CD11b, which is already expressed on the macrophage surface, was only significantly modulated by LY465608 at the highest IFN $\gamma$  concentration (Fig. 1C). The effects of the coagonist were concentration dependent, with significant effects apparent at 100 nM for both iNOS activity (Fig. 2A) and CD11a induction without any effect on CD11b expression until the highest concentration of 10  $\mu$ M (Fig. 2B). These results suggested that a PPAR $\alpha,\gamma$  coagonist was able to mitigate the macrophage effector functions induced by IFN $\gamma$ .

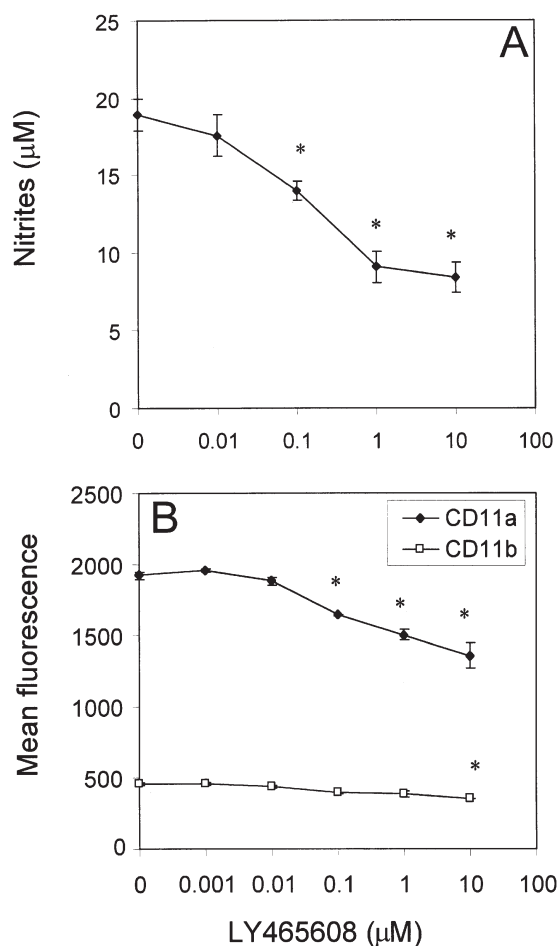

To determine whether a similar impact on macrophage effector functions could be demonstrated *in vivo*, apoE KO mice on standard laboratory chow were dosed at 10 mg/kg orally with LY465608 for up to 10 d. At day 10, elicited macrophages were harvested and stimulated *in vitro* with varying concentrations of IFN $\gamma$  for an additional 48 h. In comparison with the vehicle group, elicited macrophages from LY465608-treated mice showed a reduced induction of CD11a at both optimal (500 units/mL) and suboptimal (50 units/mL) concentrations of IFN $\gamma$  (Fig. 3A), and at optimal IFN $\gamma$  concentrations, they showed an approximate 50% reduction in nitric oxide formation (Fig. 3B). There was also, in the LY465608-treated animals, an overall increase in total serum cholesterol; in the control cholesterol was  $412 \pm 89$  vs. coagonist  $591 \pm 186$  mg/dL. This increase in the coagonist group was statistically significant by a two-tailed unpaired *t*-test ( $P < 0.03$ ).

The demonstration *ex vivo* that LY465608 was able to modulate IFN $\gamma$ -mediated macrophage effector functions

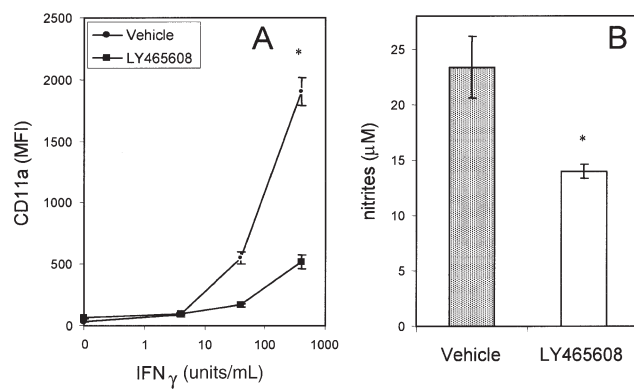

**FIG. 1.** Effects of LY465608 (2-[4-[2-(2-biphenyl-4-yl-5-methyl-oxazol-4-yl)-ethoxy]-phenoxy]-2-methyl-propionic acid) on interferon  $\gamma$  (IFN $\gamma$ )-mediated induction of nitric oxide and CD11a in murine peritoneal macrophages. Macrophages from apoE KO mice were treated *in vitro* in triplicate, with 0–500 units/mL IFN $\gamma$  with or without 100 nM LY465608 for 40–60 h. Cell supernatants were assayed for nitrites (A), and cells for the membrane integrins CD11a (B) and CD11b (C) by flow cytometry measuring the mean fluorescence intensity (MFI). Brackets represent the standard deviation of the mean from triplicate cultures. The difference between the untreated and LY465608-treated macrophages was significant by a two-tailed unpaired Student's *t* test at  $P < 0.05$  (#),  $P < 0.01$  (\*), or  $P < 0.001$  (+). A standard two-way ANOVA was also performed, followed by a Bonferroni adjusted multiple comparison of treated vs. untreated at each IFN $\gamma$  concentration. Significance was at the  $P < 0.001$  (+,\*) or  $P < 0.05$  (#) levels.

**FIG. 2.** LY465608 in a concentration-dependent manner inhibited nitric oxide and CD11a induction by IFN $\gamma$ . Triplicate cultures of macrophages were treated with 1 nM to 10  $\mu$ M LY465608 with 200 units/mL IFN $\gamma$ . After 48 h incubation, supernatants were assayed for nitrites (A), and cells were evaluated for expression of CD11a and CD11b (B). \*Difference from the control was significant by a two-tailed unpaired Student's *t*-test ( $P < 0.01$ ). A one-way ANOVA analysis was also performed, followed by a Dunnett's multiple comparison of each concentration of LY465608 compared to vehicle. Significance was also at the  $P < 0.01$  level. For abbreviations see Figure 1.

suggested it could have a favorable impact on atherosclerotic disease progression in the apoE KO mouse. Accordingly, mice were treated with LY465608, 10 mg/kg/d, for 18 wk starting at 8 wk of age, when they were shifted to a high-fat diet. At the end of the 18 wk of treatment, both vehicle and LY465608 mice were evaluated for cholesterol and lipoprotein profiles, and quantitation of aortic lesions was performed on the en face preparations. As demonstrated (Fig. 4A), LY465608 treatment reduced the rate of weight gain compared to the vehicle group. This decrease in weight gain was not due to a reduction in food consumption, which remained relatively constant in both groups through the duration of the study (approximately 25 g/mouse/wk). Interestingly, the LY465608-treated animals had a statistically significant ( $P < 0.01$ ) increase in serum cholesterol relative to the vehicle group at sacrifice ( $996 \pm 217$  vs.  $808 \pm 208$  mg/dL) which

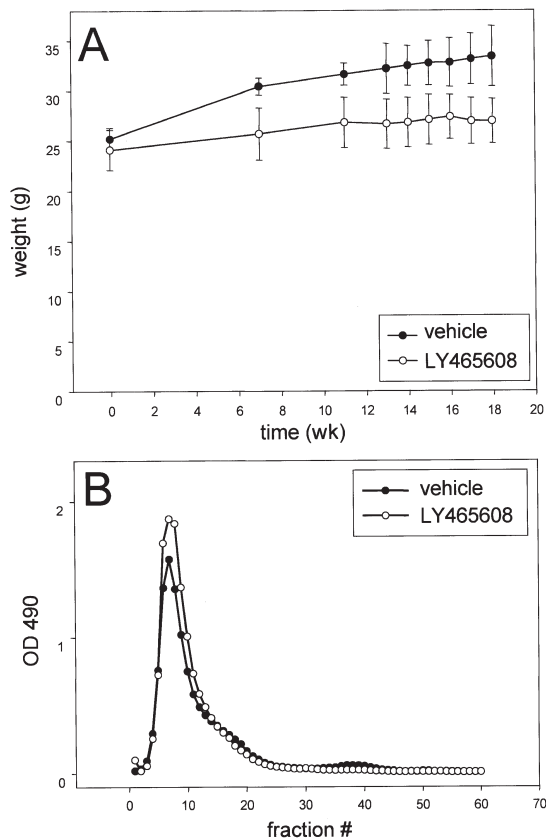

**FIG. 3.** Ex vivo effects of LY465608 on murine peritoneal macrophages. ApoE KO mice were dosed orally for 10 d with LY465608 or vehicle alone; and elicited peritoneal macrophages were collected, plated in 24-well plates, and evaluated for IFN $\gamma$ -induced CD11a expression (A) and nitric oxide production (B). CD11a expression was measured following induction of macrophages with varying concentrations of IFN $\gamma$  (5, 50, and 500 units/mL) and for nitric oxide production at 500 units/mL of IFN $\gamma$ . Macrophages were not exposed to exogenous LY465608 during the 48–72 h *in vitro* phase of the experiment. Cells from three animals for each treatment were pooled before plating. Representative experiment of five; brackets indicate the SD of the mean. \*Difference from the control was significant by a two-tailed unpaired Student's *t*-test ( $P < 0.01$ ). For abbreviations see Figures 1 and 2.

was evident in the VLDL peak of the lipoprotein profile (Fig. 4B). Serum TG were reduced in the LY465608 group ( $521 \pm 191$  vs.  $591 \pm 217$  mg/dL); however, this reduction was not statistically significant.

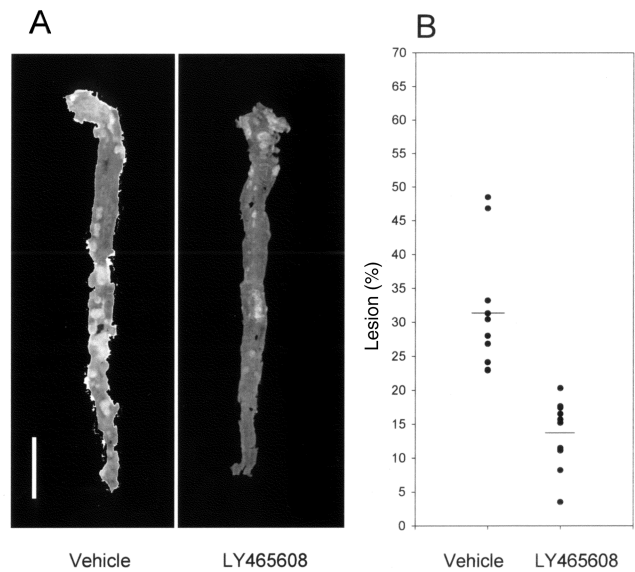

Although there were no significant reductions in the VLDL or LDL lipoproteins, and in fact there was a consistent increase in the former, there were significant reductions in aortic lesions in the LY465608-treated animals. En face evaluation of the lesion distribution revealed that the atherosclerotic lesions were primarily localized to the aortic arch and the surfaces around the bifurcations. Representative aortas en face (Fig. 5A) clearly demonstrate a decrease in the lesion surface area in the LY465608-treated animals that was statistically significant and apparent when the lesion distribution for each animal was quantified (Fig. 5B). The mean lesion area in the vehicle group was  $31.5 \pm 9.2$  vs.  $13.5 \pm 4.9\%$ , and this difference was significant ( $P < 0.0001$ ). Furthermore, the vehicle group had 8 of 9 animals with  $>25\%$  lesion area, whereas the LY465608 group had 0 of 10 animals with greater than 25% of the surface area containing lesions. These results demonstrate a significant reduction in lesion progression when apoE KO mice were treated with LY465608 at the time that they were shifted to the high-fat atherogenic diet.

To determine whether the PPAR coagonist LY465608 could have a similar effect in apoE KO mice with established lesions, a final series of experiments was performed in which mice were allowed to consume the high-fat diet for 16 wk. Following 16 wk on diet, mice were randomized to receive either LY465608 at 10 mg/kg or vehicle and were continued on diet and treatments for an additional 12 wk prior to

**FIG. 4.** Effect of LY465608 on weight gain and serum cholesterol profile. ApoE KO mice, 10 per group, were placed on “western” high-fat diets and dosed with LY465608 or the vehicle for 18 wk. Body weights and food consumption were measured weekly. Body weights (A) and total serum cholesterol fast protein liquid chromatography profile (B) were determined on pooled serum samples at the termination of the study. Brackets represent the SD of the mean. The difference in weight between the vehicle- and LY465608-treated mice was significant by a two-tailed unpaired Student’s *t*-test ( $P < 0.01$ ) by 6 wk treatment and remained so through the remainder of the study. The changes in weight were also analyzed by a repeated measures ANOVA, and the LY465608 group was compared to vehicle at each week using a Bonferroni adjusted multiple comparison test. By this analysis significance after week 0 was  $P < 0.0001$ . OD, optical density; for other abbreviations see Figure 1.

sacrifice. As demonstrated (Fig. 6A), apoE KO mice treated with the PPAR coagonist demonstrated a significant reduction in weight, which was apparent by 2 wk. As in the previous study, this reduction in weight gain was not due to a decrease in food consumption. Furthermore, serum cholesterol levels between the two groups were indistinguishable ( $1517 \pm 503$  vehicle and  $1518 \pm 590$  mg/dL for LY465608) as were the lipoprotein profiles, which consisted primarily of a VLDL fraction with an LDL shoulder (data not shown). There was, however, a significant increase in serum TG in the LY465608 animals  $884 \pm 442$  vs.  $418 \pm 130$  mg/dL ( $P < 0.003$ ). Quantification of lesion surface area revealed that 11 of 15 animals treated with LY465608 had less than 25% lesion area compared to the vehicle group with 6 of 15. The chi-squared test for the significance of this change in ratio, however, did not achieve statistical significance ( $P < 0.065$ ). Although there

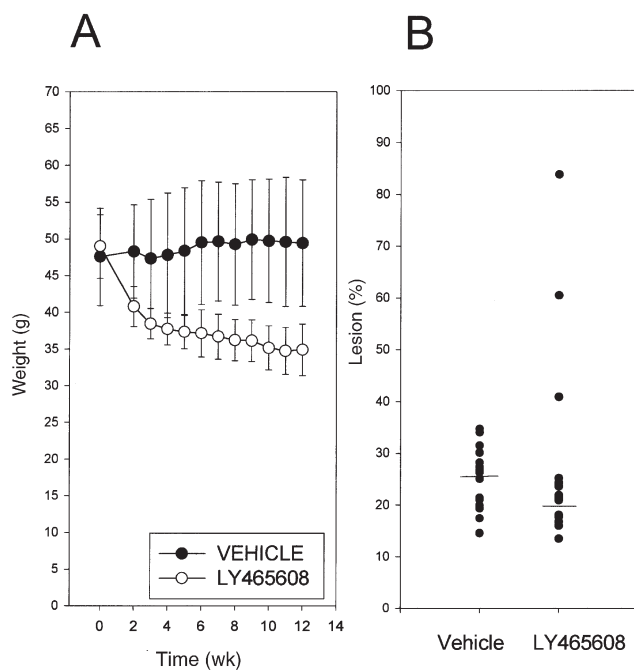

**FIG. 5.** Effect of LY465608 on aortic lesion formation in apoE KO mice on “western” diet. Mice at 8 wk of age were placed on a high-fat diet and randomized to vehicle or 10 mg/kg LY465608 groups. After 18 additional weeks on the diet the animals were sacrificed, and the aortas were dissected and placed on microscope slides. Representative en face images of the aorta from control and LY465608-treated aortas (A) and the percentage of the aortic surface area covered with lesions are presented for each animal ( $n = 10$  per group) (B). Note reduction in the lesion surface area from the LY465608-treated animals. This difference was significant by a two-tailed unpaired Student’s *t*-test ( $P < 0.0001$ ). Scale bar represents 5 millimeters.

appeared to be a nonsignificant reduction in lesion area in this study on established lesions, there was one animal in the LY465608 group that had greater than 80% of the aortic surface area covered with lesion. Whereas this animal did have other problems detected at autopsy, i.e., fluid in the lungs, there was no apparent reason to treat this animal as an outlier and hence it was included in the data set. These results, however, do suggest that intervention fairly late in the process of lesion development can in fact reduce further increases in lesion accumulation through effects independent of serum cholesterol levels or lipoprotein profiles.

## DISCUSSION

PPAR $\alpha$ , $\gamma$  agonists as well as coagonists are clearly demonstrating additional biologic responses beyond HDL elevation and insulin sensitization that would suggest a broader therapeutic role in the management of chronic inflammatory diseases (39–42). To explore these potential roles further, the PPAR $\alpha$ , $\gamma$  coagonist LY465608 was evaluated in a model of atherosclerosis where HDL represents a minor component of the lipoprotein profile and where insulin sensitivity is not recognized as part of the disease process. The apoE KO model represents such a model and is characterized by extremely high serum cholesterol (>1000 mg/dL when placed on a high-fat diet), primarily carried on VLDL and remnant particles, and significant lesions throughout the aortas (43).

**FIG. 6.** Therapeutic intervention with LY465608 on mice after 16 wk on a high-fat diet. ApoE KO mice were placed on the “western” diet for 16 wk and then randomized ( $n = 15$  per group) to receive LY465608 orally at 10 mg/kg or vehicle alone for an additional 12 wk. The high-fat diet was continued during this treatment phase. Weight (A) and food consumption were monitored weekly. At the termination of the experiment, the aortic surface area covered with atherosclerotic lesions was quantified and the distribution was presented for each animal (B). The difference in weight between the two groups was significant by a two-tailed unpaired Student’s  $t$ -test ( $P < 0.01$ ) as early as 2 wk on LY465608. The changes in weight were also analyzed by a repeated measures ANOVA, and the LY465608 group was compared to vehicle at each week using a Bonferroni adjusted multiple comparison test. By this analysis, significance after week 0 was  $P < 0.01$ . (B) Robust mean estimates are presented (horizontal bars) and were 26.3% in the vehicle and 21.6% for the LY465608 group. The chi-squared test for the significance of the difference in lesion surface area did not achieve statistical significance ( $P < 0.065$ ).

The present study was designed to determine whether LY465608 treatment *in vitro* would mitigate the macrophage response to IFN $\gamma$  using both iNOS and CD11a induction as indicators of macrophage activation. These two parameters can be linked to the pathology associated within the atherosclerotic lesion by inducing oxidant stress with the former and by promoting macrophage adherence and migration through the  $\beta 2$  integrin pathway with the latter (44,45). The results of this study demonstrated a direct inhibitory effect of this coagonist on these parameters of macrophage activation. Furthermore, similar effects were also apparent *ex vivo* when apoE KO mice were pretreated with LY465608 for 10 d prior to harvesting elicited macrophages and subjecting them to *in vitro* stimulation with IFN $\gamma$ . In additional studies, 4–5 d of oral treatment with LY465608 exhibited similar *ex vivo* results (data not shown).

The ability of the coagonist to influence these effector functions suggested that LY465608 should favorably reduce

atherosclerotic lesion progression, and, in fact, lesional surface area was reduced 2.5-fold in the experimental group. The extent of lesion reduction in the apoE KO mouse compares favorably with similar studies recently reported for the PPAR $\gamma$  agonist troglitazone (35), with troglitazone, rosiglitazone, or GW7845 in the LDL receptor KO (33, 34), and with a retinoid X receptor agonist LG100364 (32). This latter study reported a lesser effect on lesion reduction with the PPAR coagonist GW2331, and still lesser efficacy with the PPAR $\gamma$  agonist rosiglitazone.

Although the results in reducing total lesional area were similar across these studies, some differences were observed. In the present study we detected a reduction in weight gain with chronic administration without an impact on food consumption. These effects were consistent with PPAR $\alpha$  activity of the coagonist, as PPAR $\alpha$  agonists have been reported to reduce body weight increase in other rodent models (46,47). It is, however, noteworthy that in one study troglitazone did reduce total body weight in the LDL receptor (LDLR) KO mice fed a high-fat diet (34). Chen *et al.* (35) reported a doubling in HDL cholesterol but no effect on total cholesterol or TG, whereas Claudel *et al.* (32) reported increases in total serum cholesterol and TG, primarily in the VLDL and remnant peak. In the present study we did not detect any increase in HDL cholesterol but did observe a significant increase in total cholesterol, through the VLDL and remnant peak, but no increase in serum TG as seen in the second study which had been designed to evaluate the effect of LY465608 on lesion development.

Finally, to reflect the clinical situation more closely, we designed studies to determine whether LY465608 would have an effect on established lesions rather than initiating treatment at the time of exposure to the atherogenic diet. Accordingly, apoE KO mice were maintained on the atherogenic diet for 16 wk prior to initiating treatment with LY465608 for an additional 12 wk. These results, although failing to achieve statistical significance, did suggest reduced lesional surface areas in the LY465608 group when compared to the controls. This represents, to the best of our knowledge, the first study in which intervention with a potential anti-atherosclerotic compound was evaluated in apoE KO mice with established lesions. Whereas the precise mechanism(s) by which PPAR coagonists may limit the development of new lesions and affect established lesional mass remains unclear, it is likely to involve the inhibition of both NF- $\kappa$ B and AP-1 dependent transcriptional pathways (20,21). PPAR expression within atherosclerotic lesions in monocytes, macrophages, foam cells, and smooth muscle and endothelial cells provides a pathway for limiting lesion progression (45). PPAR $\alpha$  agonists, for example, reportedly induce apoptosis of TNF-activated macrophages and limit monocyte recruitment in early lesions by inhibiting TNF induction of vascular cell adhesion molecule expression, presumably by serving as negative regulators of NF- $\kappa$ B (48,49). One such mechanism of inhibiting NF- $\kappa$ B activation is through the induction of I $\kappa$ B $\alpha$  by PPAR $\alpha$  agonists and thus keeping the NF- $\kappa$ B complex inactive within

the cytoplasm (21). However, whereas many of the NF- $\kappa$ B and AP-1 dependent regulated genes are thought to be proinflammatory, such as MMP-9, IL-6, and TNF, there is some evidence that PPAR agonists may have confounding effects on lesion development. Lee *et al.* (50), for example, reported that the PPAR $\alpha$  agonist Wy14643 stimulated the synthesis of IL-8 and monocyte chemoattractant protein-1 in human aortic endothelial cells, whereas the PPAR $\gamma$  agonist troglitazone suppressed production of these chemokines. Furthermore, although PPAR agonists have been reported to upregulate CD36 and consequently the uptake of oxidized LDL (28,29), further studies have implicated a PPAR $\gamma$  pathway for promoting cholesterol efflux through the increase in ABC-1 expression *via* induction (26). These authors further demonstrated that PPAR $\gamma$ -null bone marrow cells transplanted into LDLR KO mice resulted in significant increases in atherosclerotic lesion mass. Collectively, these studies suggest that PPAR coagonists should favorably affect atherosclerotic disease through anti-inflammatory processes as well as by stimulating reverse cholesterol transport.

The results of the *in vitro* and *in vivo* studies clearly demonstrate that the PPAR coagonist LY465608 can favorably affect atherosclerotic disease progression through processes unrelated to changes in serum lipoprotein profiles. These data demonstrate a clear role and direction for the next generation of agents to treat atherosclerosis, namely, targeting the vascular component.

## ACKNOWLEDGMENTS

The authors wish to acknowledge Dr. Mary K. Peters for providing LY465608, and Mark Farman for statistical support. The technical assistance of Pat Forlor, Jack Cochran, Phyllis A. Cross, Brian K. McKenney, Martin S. Cramer, Richard L. Tielking, Courtney Burch, Kat Andrzejewski, and Renee L. Grubbs is also gratefully acknowledged.

**ABSTRACT:** The peroxisomal proliferator-activated receptor  $\beta$  ( $\delta$ ) (PPAR $\beta$ ) is a nuclear hormone receptor that is ubiquitously expressed and that regulates the transcription of genes involved in lipid metabolism. A homozygous PPAR $\beta$ -null mouse has been developed in which the ligand-binding domain of the PPAR $\beta$  receptor is disrupted. Analysis of brains from these animals shows that female null mice have 24 and 17% increases in plasmalogen ethanolamine and phosphatidylserine and a 9% decrease in the level of phosphatidylinositol when compared to controls. The phospholipid changes found in female null mice were associated with increased levels of esterified 18:1n-9, 20:1n-9, 20:4n-6, and 22:5n-3 FA in plasmalogen ethanolamine, 20:1n-9 in phosphatidylinositol, and 18:0, 18:1n-9, 18:3n-6, 20:1n-9, and 20:4n-6 in phosphatidylserine. Increased levels of esterified 18:1n-9, 18:2n-6, 18:3n-6, and 20:1n-9 were also found in the phosphatidylethanolamine fraction despite its cellular content remaining unchanged. Brain phospholipid content in male PPAR $\beta$ -null mice did not differ from controls, but increased levels of 20:1n-9 in the phosphatidylinositol and 18:1n-9 in the phosphatidylserine fractions were observed. No changes were found in the content of brain cholesterol, TAG, and FFA in either female or male PPAR $\beta$ -null mice. These data suggest that PPAR $\beta$  is involved in maintaining FA and phospholipid levels in adult female mouse brain and provide strong evidence that suggests a role for PPAR $\beta$  in brain peroxisomal acyl-CoA utilization.

Paper no. L8920 in *Lipids* 37, 495–500 (May 2002).

The peroxisome proliferator-activated receptors (PPAR) are regulatory transcriptional factors that constitute a subfamily of nuclear hormone receptors that are classified into three types:  $\alpha$ ,  $\beta$  (also called  $\delta$  or nuc 1), and  $\gamma$  (1). PPAR maintain lipid homeostasis by regulating the expression of enzymes involved in peroxisomal and mitochondrial  $\beta$ -oxidation, FA mobilization, and adipocyte differentiation in response to differential ligand activation and gene expression (1).

Abbreviations: ACS-2, acyl-CoA synthetases 2; CerPCho, sphingomyelin; plasmalogen, 1-*O*-alk-1'-enyl-2-acyl-*sn*-glycero-3-phosphocholine; plasmalogen ethanolamine, 1-*O*-alk-1'-enyl-2-acyl-*sn*-glycero-3-phosphoethanolamine; phosphatidylcholine, 1,2-diacyl-*sn*-glycero-3-phosphocholine; phosphatidylethanolamine, 1,2-diacyl-*sn*-glycero-3-phosphoethanolamine; phosphatidylinositol, 1,2-diacyl-*sn*-glycero-3-phosphoinositol; phosphatidylserine, 1,2-diacyl-*sn*-glycero-3-phosphoserine; PPAR, peroxisomal proliferator-activated receptors.

Although the functions of both PPAR $\alpha$  and  $\gamma$  are well documented, the role of PPAR $\beta$  remains elusive. It has been shown that PPAR $\beta$  can modulate the expression of brain acyl-CoA synthetases 2 (ACS-2) in reaggregated brain cell culture (2), which suggests that the activation of this nuclear transcription factor can affect the utilization of FA by modulating the levels of acyl-CoA. However, the expression of ACS-2 is not altered by the targeted disruption of PPAR $\beta$  in the adult mouse (3). That the first three committed steps in ether phospholipid metabolism occur in the peroxisome (4), and acyl-CoA synthase-2 mRNA expression is unaffected by the absence of PPAR $\beta$ , suggest that the decreased myelin content found in the female PPAR $\beta$ -null mice (3) may be the result of altered peroxisomal acyl-CoA utilization. To begin to examine this idea, phospholipid and FA composition of brains from PPAR $\beta$ -null mice were determined. Since female PPAR $\beta$ -null mice exhibited a more pronounced constitutive phenotype, it was hypothesized that female PPAR $\beta$ -null mice might also show significant alterations in brain phospholipid composition.

Whereas most of the functions known to occur in peroxisomes involve lipid metabolism, the  $\beta$ -oxidation of FA and the biosynthesis of ether phospholipids are central to their role (5,6). In the peroxisome, unsaturated FA are converted into coenzyme A (CoA) esters by peroxisomal acyl-CoA synthetases unique to this organelle (7) and then  $\beta$ -oxidized into acetyl-CoA and shorter FA, or are oxidized to fatty alcohol (Fig. 1). The preliminary steps of ether phospholipid biosynthesis also occur in the peroxisome and involve the formation of both fatty alcohol and acyl-dihydroxyacetone phosphate (Fig. 1). Studies using liver peroxisomes show that lignoceric acid, and not hexadecanol or hexadecanoic acid, is the principal source of the 1-*O*-alkyl group found in ether phospholipids (8) and suggest that the formation of fatty alcohol is coupled to peroxisomal  $\beta$ -oxidation. That the activity of fatty alcohol:NAD<sup>+</sup> oxidoreductase is inhibited by palmitoyl-CoA and NADH in a concentration-dependent manner suggests that the utilization of acyl-CoA in the peroxisome can regulate fatty alcohol levels by inhibiting the oxidation of peroxisomal FA (Fig. 1) (9).

However, the involvement of PPAR $\beta$  and its influence on peroxisomal gene products that modulate peroxisomal FA and ether phospholipid metabolism in brain are uncertain. Therefore, to assess the potential role of PPAR $\beta$  in the maintenance

**FIG. 1.** The utilization of FA and acyl-CoA in the peroxisome showing the balance between peroxisomal  $\beta$ -oxidation and ether phospholipid biosynthesis. Outlined are the initial and committed steps and cofactors involved in the utilization of peroxisomal FA and acyl-CoA. Reactions involved in the formation of acyl-CoA from FA, the initial step in peroxisomal  $\beta$ -oxidation of acyl-CoA, the reduction of acyl-CoA to fatty alcohol, the initial step in the formation of ether phospholipid, and the oxidation of fatty alcohol to FA are represented. The dashed line represents the postulated inhibition of fatty alcohol: $\text{NAD}^+$  oxidoreductase by acyl-CoA (9). Acyl-DHAP, acyl-dihydroxyacetone phosphate.

of brain FA and ether phospholipid synthesis, we performed analyses of brains from PPAR $\beta$ -null mice. We found that distinct membrane phospholipid changes occur in the female PPAR $\beta$ -null mouse that are associated with increased levels plasmeneylethanolamine and phosphatidylserine, decreased levels of phosphatidylinositol, and altered levels of esterified FA. These data suggest that PPAR $\beta$  is involved in the maintenance of brain FA and phospholipid levels in adult female mouse brain and provide strong evidence that suggests a role for PPAR $\beta$  in brain peroxisomal acyl-CoA utilization.

## EXPERIMENTAL PROCEDURES

Phospholipid, neutral lipid, and FAME standards were purchased from Nu-Chek-Prep (Elysian, MN), TLC plates were from Analtech (Deerfield, IL), and HPLC-grade *n*-hexane and 2-propanol were from EM Science (Gibbstown, NJ). Reagent-grade chloroform, methanol, and other chemicals were from Mallinckrodt (Paris, KY). All samples and extracts

were stored in *n*-hexane/2-propanol (3:2, vol/vol) + 5.5%  $\text{H}_2\text{O}$  under  $\text{N}_2$  at  $-80^\circ\text{C}$ .

**Tissue and extraction.** The homozygous wild-type control and PPAR $\beta$ -null mice used for this work have been described previously (3) and were maintained in accordance with the National Institutes of Health Guidelines for the Care and Use of Laboratory Animals (NIH Publication No. 80-23). Brains from female and male control and PPAR $\beta$ -null mice between the ages of 9 and 12 mon were snap-frozen following cervical dislocation. Whole frozen brains were extracted using *n*-hexane/2-propanol (3:2, vol/vol) in a glass Tenbroeck homogenizer as previously described (10).

**Phospholipid and neutral lipid separation.** Standards and samples in chloroform were applied to  $20 \times 20$  cm Whatman silica gel 60A LK6 TLC plates and separated as previously described (11). Bands corresponding to ethanolamine glycerophospholipids, phosphatidylinositol, phosphatidylserine, choline glycerophospholipids, sphingomyelin, and neutral lipids were scraped from the TLC plate and stored. The

ethanolamine and choline glycerophospholipid fractions were extracted off the silica gel using *n*-hexane/2-propanol (3:2, vol/vol) + 5.5% H<sub>2</sub>O, combined, and concentrated under N<sub>2</sub> at 55°C. The glycerophospholipid fractions were subjected to mild acid hydrolysis to cleave the vinyl ether linkage of the plasmalogens and the phosphatidylethanolamine; lysoplasmylethanolamine, phosphatidylcholine, and lysoplasmylethanolamine fractions were purified using HPLC (12). Half of the samples were used to quantify FA and other half were used to assay for lipid phosphorus (13).

**Neutral lipid separation.** The neutral lipid fractions were extracted from the silica gel by using *n*-hexane/2-propanol (3:2, vol/vol) + 5.5% H<sub>2</sub>O, concentrated under N<sub>2</sub> at 55°C, and dissolved in *n*-hexane/2-propanol/acetic acid (98.7:1.2:0.1, by vol). The individual neutral lipid fractions were separated by HPLC (14) using a Selectosil 5 $\mu$  silica column (250  $\times$  4.6 mm; Phenomenex, Torrance, CA). Fractions corresponding to cholesterol, TAG, and FFA were collected in separate screw-top test tubes and stored at -80°C. The esterified FA in the TAG and the FFA were quantified by GC. Cholesterol was quantified by colorimetric assay (15).

**Methylation of esterified FA and FFA.** The esterified FA found in the different phospholipids and the TAG fractions were methylated using 0.5 M methanolic KOH at 37°C for 30 min. The reaction was stopped with methylformate, and the FAME were extracted using *n*-hexane. The FFA and esterified FA in the sphingomyelin fractions were methylated using 2% sulfuric acid in toluene/methanol (1:1, vol/vol) at 65°C for 2 h. The reaction was stopped with H<sub>2</sub>O, and the FAME were extracted in petroleum ether. The FAME were quantified by GC.

**GC of FAME.** FAME were separated using a gas chromatograph (Trace 2000; ThermoQuest, Houston, TX) equipped with a capillary column (30 m  $\times$  0.32 mm i.d.; SP 2330, Supelco, Bellefonte, PA) and an FID. Methyl heptadecanoate was used as an internal standard, and the individual FA were quantified by peak area analysis. The flow rate of the helium carrier gas was constant and set at 2.5 mL·min<sup>-1</sup>. Injection and detection ports were set at 250°C. Sample runs were initiated at 90°C with a temperature gradient to 230°C over 20.0 min. FAME standards were used to establish the relative retention times and concentration factors. The detector response was linear, with correlation coefficients of 0.998 or greater within the sample concentration range for all FA standards of differing chain length and degree of saturation.

**Data and statistics.** Unpaired *t*-tests were performed on the averaged means using the GraphPad InStat® statistical program (GraphPad, San Diego, CA). Unpaired *t*-tests were used to test the statistical significance between control and PPAR $\beta$ -null female and male groups. Statistical significance was taken as  $P \leq 0.05$ .

## RESULTS

**Brain phospholipid levels.** Table 1 shows the brain phospholipid composition of female and male control and PPAR $\beta$ -null mice along with statistical comparisons. The levels of plasmenyl-

CerPCho	3.4 $\pm$ 0.4	3.2 $\pm$ 0.1	3.1 $\pm$ 0.1	3.6 $\pm$ 1.0
Total	52.6 $\pm$ 4.9	57.0 $\pm$ 3.3	49.2 $\pm$ 4.9	54.5 $\pm$ 4.3

<sup>a</sup>Values represent the mean  $\pm$  SD in units of  $\mu$ mol·g brain<sup>-1</sup> ( $n = 5$ ). \* $P < 0.02$ ; \*\* $P < 0.01$ . PPAR $\beta$ , peroxisomal proliferator-activated receptor  $\beta$ ; PtdEtn, phosphatidylethanolamine; PlsEtn, plasmenylethanolamine; PtdIns, phosphatidylinositol; PtdSer, phosphatidylserine; PtdCho, phosphatidylcholine; PlsCho, plasmenylcholine; CerPCho, sphingomyelin.

ethanolamine and phosphatidylserine were significantly increased from 7.4  $\pm$  1.3 to 9.8  $\pm$  0.7 and 5.8  $\pm$  0.6 to 7.0  $\pm$  0.5  $\mu$ mol·g brain<sup>-1</sup> in female PPAR $\beta$ -null mice as compared to controls, respectively. The level of phosphatidylinositol also decreased in female PPAR $\beta$ -null mice from 2.2  $\pm$  0.1 to 2.0  $\pm$  0.1  $\mu$ mol·g brain<sup>-1</sup>. No changes in the amount of total brain phospholipid were detected in either genotype of female or male mice. The changes in the female PPAR $\beta$ -null mice represent an increase of 24 and 14% in the levels of plasmenylethanolamine and phosphatidylserine, respectively, and a 9% decrease in the level of phosphatidylinositol. No changes were found in the phospholipid composition of male PPAR $\beta$ -null mice. The compositional changes in the female PPAR $\beta$ -null mouse brains show that there is a significant mole percentage increase of plasmenylethanolamine and a subsequent decrease in the percentages of phosphatidylinositol and phosphatidylcholine (data not shown). Consistent with the phospholipid levels, the male PPAR $\beta$ -null mice had no apparent change in the composition of brain phospholipid as compared to controls.

**FA composition of the phospholipid classes.** Tables 2–6 show the esterified FA composition of the brain phospholipid classes in units of nmol·g brain<sup>-1</sup> with statistical comparisons. As expected, there were large increases in the levels of esteri-

fied FA in the plasmeneylethanolamine and phosphatidylserine phospholipids of female PPAR $\beta$ -null mice. These changes were associated with increased levels of 18:1n-9, 20:1n-9, 20:4n-6, and 22:5n-3 FA in plasmeneylethanolamine (Table 3) and increased levels of 18:0, 18:1n-9, 18:3n-6, 20:1n-9, and 20:4n-6 in phosphatidylserine (Table 5). A significant increase in 18:1n-9 was also found in the phosphatidylserine fraction of male PPAR $\beta$ -null mice. Both female and male PPAR $\beta$ -null mice had significant increases in the level of 20:1n-9 in the phosphatidylinositol fraction (Table 4), despite

<sup>a</sup>Values represent the mean  $\pm$  SD in units of nmol-g brain<sup>-1</sup> ( $n = 5$ ). \* $P < 0.05$ ; \*\* $P < 0.01$ . For abbreviations see Table 1.

the fact that the female PPAR $\beta$ -null mice had a 9% decrease in the amount of this phospholipid. Analysis of the female PPAR $\beta$ -null mouse brain phosphatidylethanolamine fraction also revealed significant increases in the levels of 18:1n-9, 18:n-6, 18:3n-6, and 20:1n-9 with no changes in the male phosphatidylethanolamine fraction (Table 2) or the female and male phosphatidylcholine, plasmeneylcholine, and sphingomyelin fractions (data not shown).

**Brain cholesterol, TAG, and FFA.** Analysis of brain neutral lipids shows that the absence of a functional PPAR $\beta$  did not affect the levels of total brain cholesterol, TAG, FFA, or the cholesterol to phospholipid ratio in both female and male PPAR $\beta$ -null mice (Table 7).

## DISCUSSION

In this study we found that the female PPAR $\beta$ -null mouse brain, consistent with the constitutive phenotype, showed elevated levels of plasmeneylethanolamine and phosphatidylserine and decreased levels of phosphatidylinositol. However, no changes were found in the phospholipid content in the male PPAR $\beta$ -null mouse brain. Analysis of the esterified FA content in the membrane phospholipids showed an overall trend toward increased levels of esterified long-chain n-9 and n-6 FA with a more pronounced phenotype being present in the female null mouse. The PPAR $\beta$ -null mouse phenotype showed no changes in the levels of cellular cholesterol or TAG in either female or male mice.

These data suggest that PPAR $\beta$  is involved in maintaining FA and phospholipid levels in adult mouse brain that result in distinct gender-related differences when PPAR $\beta$  is disrupted. Although the presence of gender-related differences in lipid metabolism is not unusual, the molecular basis responsible for this phenomenon is not completely understood. It is known that circulating levels of estrogen can modulate the fasting activity of both TAG lipase and neutral cholesteryl ester hydrolase activity, alter lipoprotein metabolism at subcellular sites in the liver, and increase the plasma clearance of LDL and HDL (16). The hepatic uptake of long-chain FA from plasma is also nearly twofold faster for females than males in both humans (17,18) and rats (19–21) because of gender-related differences in intra-

cellular FA transport and binding proteins (22) and in the larger sinusoidal volume (23). However, the metabolic rates for [<sup>3</sup>H]palmitate utilization in female and male liver are similar, as determined by using the traditional multiple-indicator dilution model to measure apparent influx, efflux, and cytoplasmic diffusion constants (23). Thus, whereas the plasma clearance rate of palmitate in female is faster, the rate of metabolism is not. Therefore, the altered phospholipid and FA composition found in the female PPAR $\beta$ -null mouse may be due to both the gender-related alterations in metabolism and a disruption in the transport and utilization of brain FA.

Indeed, the altered brain FA and phospholipid composition found in the PPAR $\beta$ -null female mice can be the result of several mechanisms. However, the presence of increased amounts of esterified long-chain FA is indicative of either reduced oxidation or increased metabolism. Increased levels of brain plasmenylethanolamine, coupled with the fact that the first committed steps in ether phospholipid synthesis occur in the peroxisome, suggest that PPAR $\beta$  may function to modulate the enzymes involved in peroxisomal FA and acyl-CoA metabolism (Fig. 1). Because the rate-limiting and committed step in ether phospholipid metabolism is the formation of the fatty alcohol (24), accumulation of PUFA and acyl-CoA may indirectly influence the levels of ether phospholipid by increasing the levels of the committed substrate, fatty alcohol (Fig. 1). Although FA transport may be affected in the female PPAR $\beta$ -null mouse, it is more likely that the increased levels of plasmenylethanolamine found in the female PPAR $\beta$ -null mouse brain are due to altered peroxisomal FA and acyl-CoA utilization.

In the female PPAR $\beta$ -null mouse, there were multiple changes in both brain phospholipid and esterified FA, which suggest that PPAR $\beta$  may play a role in maintaining membrane structure and may influence bulk membrane dynamics. However, the cholesterol to phospholipid ratio, an indicator of bulk membrane dynamic changes (25,26), in both female and male PPAR $\beta$ -null mice did not differ significantly from the controls owing to the lack of significant differences in the levels of total brain cholesterol and total brain phospholipid. Although the female PPAR $\beta$ -null mouse displayed multiple changes in membrane phospholipid and FA content, gross changes in membrane dynamics were not present. However, the chain length and degree of saturation of esterified FA do participate in membrane organization (27–29) and are important in the proper function of membrane-bound protein (30).

Even though bulk membrane dynamic changes were not present in the PPAR $\beta$ -null mice, alterations in the FA composition could affect the physical properties of the membrane in terms of the rate and range of acyl chain motion, lateral diffusion of lipid and proteins, as well as alterations in protein–lipid interactions (25,31). The increased levels of esterified n-9 and n-6 FA in the PPAR $\beta$ -null mice, despite a lack of bulk membrane dynamic changes, can alter the membrane phase transition and hence influence brain function.

In this regard, the displacement of acylated proteins from membrane rafts, which are specialized regions within the plasma membrane that contain high levels of plasmenylethanolamine, phosphatidylserine, and phosphatidylinositol and are important to intracellular signaling and vesicular trafficking (32–35), are dependent on phospholipid and FA composition (33,36). The formation of these lipid rafts is also involved in signal transduction and is thought to influence the turnover of inositol-containing phospholipids (37). Therefore, alteration in the phospholipid and FA composition of lipid rafts not only can influence protein–lipid interactions but also may influence the turnover of inositol-containing phospholipid. Therefore, the increase in 20:1n-9 in phosphatidylinositol despite its overall decrease in brain may be a result of changes in the turnover rate of inositol-containing phospholipid due to altered membrane dynamics and, indirectly, to the loss of PPAR $\beta$  function.

These data suggest that PPAR $\beta$  is involved in maintaining FA and phospholipid levels in adult mouse brain that result in distinct gender-related differences when PPAR $\beta$  is disrupted. The alterations in the levels of brain plasmenylethanolamine and the changes in esterified FA composition provide strong evidence of a role for PPAR $\beta$  in brain peroxisomal acyl-CoA utilization. However, further studies are needed to identify target genes of PPAR $\beta$ , how they regulate the gender-related lipid changes found in PPAR $\beta$ -null mice, the influence PPAR $\beta$  has on peroxisomal acyl-CoA utilization, and its effect on ether phospholipid metabolism in the brain.

**ABSTRACT:** We previously showed that a 48-h intravenous lipid infusion in rats induces pancreatic  $\beta$ -cell hypersensitivity to catecholamines. Our aim was to study the lipid-related changes that may account for such hypersensitivity in pancreatic islets. We show here that a 48-h increase in plasma FFA alters the binding characteristics of  $\beta$ -cell  $\alpha_2$  adrenoceptors in rats. Lipid infusion decreases pancreatic norepinephrine (NE) turnover rate by 28%, reflecting a reduction of pancreatic NE stores. Following lipid infusion, the density of  $\alpha_2$  adrenoceptor binding sites is significantly lower and receptor affinity higher, both in islet homogenates (by three- and fivefold, respectively) and isolated whole  $\beta$ -cells (by two- and sixfold, respectively). These changes correlate with the elevated insulin response to glucose found in lipid-infused rats. We also found a modification of islet phospholipid content, particularly in phosphoethanolamine species containing infused FA such as palmitate, oleate, stearate, and linoleate. This may account for the modifications in receptor affinity. These results suggest that hyperlipidemia-associated pathologies such as diabetes and obesity not only may result from alterations of metabolic pathways but also may be a consequence of early modifications in nervous firing rates and signal transduction pathways.

Paper no. L8993 in *Lipids* 37, 501–506 (May 2002).

Among the many signals modulating islet insulin response to glucose, the autonomic nervous system plays a determinant role (reviewed in Refs. 1,2). Acetylcholine, released by parasympathetic neurons, has a potentiating effect on glucose-induced insulin secretion (GIIS), as opposed to the inhibiting effect of the sympathetic neurotransmitter, norepinephrine (NE) (3). In a previous study, we showed that a 48-h increase in plasma FFA concentration in rats lowers sympathetic nervous activity and leads to increased  $\beta$ -cell responsiveness to glucose with no concomitant alteration of either basal glycemia or insulinemia (4). Changes in sympathetic activity have been associated with dyslipidemia in both humans (5–7) and rats (8,9).

Abbreviations: ESI, electrospray ionization; FACS, fluorescence-activated cell sorting; FAD, flavin adenine dinucleotide; GIIS, glucose-induced insulin secretion; IL, Intralipid; KRBH buffer, Krebs-Ringer-bicarbonate-Hepes; NE, norepinephrine; POPE, palmitoyl-oleoyl-PE; RT-PCR, reverse transcription-PCR; [<sup>3</sup>H]RX821002, 2-(2-methoxy-1,4-benzodioxan-2-yl)-2-imidazole, a benzodioxane derivative that exhibits high affinity for  $\alpha_2$ -adrenergic receptors; TM buffer, Tris-HCl/MgCl<sub>2</sub> buffer.

Taken together, these results suggest that the sympathetic nervous system may have a determinant role in lipid-associated metabolic diseases such as type 2 diabetes and obesity.

In both rats and humans, catecholaminergic inhibition of insulin secretion is mediated by  $\alpha_{2A}$  adrenergic receptors (3), which are the predominant forms of  $\beta$ -cell adrenoceptors. Paradoxically, we found that  $\beta$ -cell sensitivity to oxymetazoline, a relatively selective  $\alpha_{2A}$ -adrenoceptor agonist, was elevated by lipid infusion (4). Thus, the aim of our study was to identify the mechanisms implicated in this  $\beta$ -cell hypersensitivity. We show here that hyperlipidemia alters the binding characteristics of  $\beta$ -cell  $\alpha_2$  adrenoceptors; the density of  $\alpha_2$  adrenoceptor binding sites is significantly lowered and receptor affinity is increased after lipid infusion. As there is no difference in mRNA levels, the reduced number of receptors may result from lipid-related posttranslational modifications. The changes in islet phospholipid composition and in pancreatic NE content may account for the higher receptor affinity. These results suggest that hyperlipidemia-associated pathologies such as diabetes and obesity not only may result from alterations of metabolic pathways but also may be a consequence of early modifications in nervous firing rates and signal transduction pathways.

## EXPERIMENTAL PROCEDURES

**Animal experiments.** All rats were treated in accordance with the European Community guidelines, and the experimentation was approved by our local institution. Male Wistar rats weighing 240–270 g were used. They were allowed free access to standard laboratory chow pellets (UAR, Villemoisson-sur-Orge, France) and water.

Operations were performed under pentobarbital anesthesia (50 mg/kg intraperitoneally; Sanofi, Libourne, France). For intravenous infusion, a catheter was implanted in the right atrium *via* the jugular vein. Rats were infused either with a 20% TG emulsion (Intralipid KabiVitrum 2,000 kcal/L, Stockholm, Sweden) mixed with heparin 20 U/mL (IL rats) or with a saline/heparin solution as described previously (4). The percentage composition of the 20% Intralipid emulsion was: 10 palmitate, 4 stearate, 23 oleate, 53 linoleate, and 8 linolenate.

**Hormone and substrate concentrations.** Blood samples obtained from caudal vessels were used for measurement of

substrate (FFA, TG, glucose) and insulin concentrations. Glucose was measured using a glucose monitor (Roche Diagnostic, Meylan, France). Enzymatic assay kits were used to determine plasma FFA (NEFA C; Wako Chemical, Marburg, Germany) and TG and glycerol concentrations (Boehringer Mannheim Biochemica, Mannheim, Germany). Insulin was measured by radioimmunoassay (DiaSorin, Antony, France). Plasma and organ NE levels were determined by HPLC with C<sub>18</sub> reversed-phase material (150 × 2 mm Beckman column packed with Ultrasphere ODS C (Beckman/Altex, San Antonio, TX; 18.5 μm average particle size) and electrochemical detection (Kontron 402) after alumina extraction. Calibration curves were made with spiked plasma or homogenate. Recoveries were calculated on the basis of peak heights measured by an integrator (Shimadzu System, Yakanike, Japan).

**In vivo GIIS studies.** After 48 h of infusion, a single injection of glucose (0.5 mg/kg) was administered in rats *via* the intracardiac catheter. Blood samples were collected before and 1, 3, 5, 10, 15, 20, and 30 min after glucose injection. Plasma was obtained after centrifugation, and glucose concentration was immediately determined using a glucose monitor (Boehringer). The remaining plasma was stored at -20°C until insulin assay.

**Pancreatic NE turnover.** We used the synthesis inhibition method by Brodie *et al.* (10). Two hours after lights on, rats were injected with  $\alpha$ -methyl-DL-*p*-tyrosine, a tyrosine hydroxylase inhibitor (250 mg/kg *i.p.*; Sigma Chemical). Three hours after injection, one group of rats (T<sub>3</sub>h) was killed, and the pancreata were rapidly removed and frozen in liquid nitrogen. The other group (T<sub>6</sub>h) received an additional 125 mg/kg *i.p.* of  $\alpha$ -methyl-DL-*p*-tyrosine. These rats were killed 3 h later and the pancreata were also removed and frozen. Rats from a third group (T<sub>0</sub>h) were not injected with the inhibitor, and they were killed at the beginning of the experiment.

**Pancreatic islet and  $\beta$ -cell isolation.** Islets of Langerhans were isolated after collagenase digestion of the pancreas as previously described (11). For cellular dissociation, the isolated islets were pooled in 15 mL chelation saline buffer (PBS, 5 mM EGTA) and incubated for 5–6 min at 37°C in buffer supplemented with 0.1 mg/mL trypsin (Difco, Draveil, France), with occasional mixing with a Pasteur pipette. The digestion was stopped by adding cold KRBH buffer (Krebs-Ringer-bicarbonate-Hepes; 140 mM NaCl, 3.6 mM KCl, 0.5 mM NaH<sub>2</sub>PO<sub>4</sub>, 0.5 mM MgSO<sub>4</sub>, 2 mM NaHCO<sub>3</sub>, 1.5 mM CaCl<sub>2</sub>, 10 mM Hepes, 5.6 mM glucose, 0.5% BSA). The isolated islet cells were washed twice in cold KRBH buffer. This procedure yielded on average 0.5 × 10<sup>6</sup> islet cells per pancreas. Islets and sorted  $\beta$ -cells were used either for binding experiments or for RNA extraction.

**Fluorescence-activated cell sorting (FACS).** Islet cells were sorted using a FACSTAR Plus (Becton Dickinson, San Jose, CA). An argon laser (model 163, Spectra Physics, Mountain View, CA) illuminated the cells at 488 nm. An interference filter detected the light emitted at 510–540 nm, which was taken as the flavin adenine nucleotide (FAD) cell content. The discrimination between  $\beta$ -cells and non- $\beta$ -cells was done using autofluorescence for FAD (FL-1) and cell size (forward size scatter).  $\beta$ -Cells displayed a 50% higher FAD content (12) and

were 50% larger (13) than non- $\beta$ -cells. Cell sorting was done using Normal-R mode, ensuring 90% purity with a 2 drop-envelope. The quality of the sorting was verified by a subsequent cell FACS analysis of a sample of the purified cells.

**Radioligand binding studies.**  $\alpha_2$ -Adrenergic receptors were quantified by radioligand binding using [<sup>3</sup>H]RX821002 [2-(2-methoxy-1,4-benzodioxan-2-yl)-2-imidazoline; 59 Ci/mmol; Amersham, Saclay, France], a benzodioxane derivative that exhibits high affinity for  $\alpha_2$ -adrenergic receptors, either on freshly isolated and sonicated islets of Langerhans or on whole pancreatic  $\beta$ -cells. In the first case, 600 to 800 freshly isolated islets were resuspended in 2.6 mL of TM buffer (50 mM Tris-HCl, 5 mM MgCl<sub>2</sub>, pH 7.5), and sonicated for 5 s. Total binding was measured by incubating 75 to 100 μg of islet homogenate proteins [as determined by the method of Lowry *et al.* (14)] with increasing concentrations of [<sup>3</sup>H]RX821002, in a total volume of 400 μL of TM buffer. After a 1-h incubation at 25°C, bound radioligand was separated from free radioligand by rapid filtration over glass fiber filters (Millipore) under vacuum and was measured in a Packard Tri-Carb 460C liquid scintillation system. Nonspecific binding was measured using 10<sup>-4</sup> M epinephrine (Sigma). On whole pancreatic  $\beta$ -cells, the study was carried out as above, with 20,000 to 30,000 cells per tube and 2 h incubation at 4°C. Data from binding experiments were analyzed using a nonlinear curve-fitting GraphPad Prism® program (GraphPad Software, San Diego, CA).

**Competitive standard RNA synthesis for quantitative PCR.** For a precise quantitation of  $\alpha_{2A}$  adrenoceptor RNA, we synthesized a 219 bp standard RNA containing the same sequence as the rat  $\alpha_{2A}$  adrenoceptor RNA from positions 196 to 396, plus a 3' end constituted of the 487 to 506  $\alpha_{2A}$  adrenoceptor RNA sequence. Hence, the standard RNA has the same, but shorter, sequence as the target RNA and can still be amplified with the same primers. Total cellular RNA (250 ng) was reverse-transcribed and amplified using One-Step RT-PCR Kit (Qiagen, Courtaboeuf, France) with the following primers: 5'-AAT TCT AAT ACG ACT CAC TAT AGG GAG AAG CGC CCC AGA ACC TCT TCC T-3' (forward) and 5'-AGT GGC GGG AAG GAG ATG ACG TAG CGG TCA AGG CTG ATG G-3' (reverse). Forty microliters of the 248bp cDNA PCR product was transcribed *in vitro* in a 100-μL reaction volume and incubated for 2 h at 37°C, using T7 RNA polymerase according to the manufacturer's instructions (Roche-Boehringer Mannheim, Mannheim, Germany). At the end of the reaction, T7 RNA polymerase was heat-inactivated (5 min, 65°C), and the transcription product was treated with 100 U of DNase I–RNase free for 15 min at 37°C. Standard RNA was purified using Qiagen's RNeasy® Mini Kit, with an on-column DNase digestion. Standard RNA solution was tested for contamination by cDNA in a PCR assay.

**Reverse transcription-PCR (RT-PCR) assay.** Total cellular RNA from frozen cells were extracted using the method of Chomczynski and Sacchi (15). The primers used for the  $\alpha_{2A}$  adrenergic receptor subtype were chosen as described in (16): 5'-GCG CCC CAG AAC CTC TTC CT-3' (forward) and 5'-AGT GGC GGG AAG GAG ATG AC-3' (reverse) and

provided amplification of a 311-bp fragment, from positions 196 to 506. In each reaction, 200 ng of total cellular RNA was co-reverse transcribed and amplified with 10<sup>5</sup> to 10<sup>8</sup> standard RNA molecules in a single reaction using One-Step RT-PCR Kit (Qiagen) including a hot start PCR, in 27 cycles of 1 min denaturation at 94°C, 1 min annealing at 60°C, and 1 min extension at 72°C. Negative controls were performed by omitting RNA from the RT-PCR reaction. Band intensities were quantified by densitometry using National Institutes of Health Image software. The logarithmic value of the ratio of standard RNA to α<sub>2A</sub> adrenergic receptor RNA was plotted against the logarithmic value of standard RNA molecule number. Thus, an equimolar point was determined where the starting number of α<sub>2A</sub> adrenergic receptor RNA equaled the starting number of standard RNA molecules (logarithmic value of the ratio equals 0).

**Electrospray ionization (ESI) MS.** ESI/MS analyses were performed on a Finnigan (San Jose, CA) TSQ-7000 triple stage quadrupole mass spectrometer equipped with an electrospray ion source and controlled by Finnigan ICIS software operated on a DEC alpha station (computer). Phospholipids were dissolved in methanol/chloroform (9:1, vol/vol) at final concentrations of about 1–5 pmol/μL. To facilitate formation of anionic species for negative ion analyses and to form lithiated adducts of PC for positive ion analyses, methanolic LiOH (0.1 μM/μL) was added to a final concentration of 2–5 nmol/μL (17,18). Samples were infused (1 μL/min) into the ESI source with a Harvard syringe pump. The electrospray needle and the skimmer were at ground potential, and the electrospray chamber and the entrance of the glass capillary were at 4.5 kV. The heated capillary temperature was 250°C. For collisionally activated dissociation and tandem MS, precursor ions were selected in the first quadrupole (Q1) and collided with Ar (2.3 mtorr) in the rf (radio frequency)-only second quadrupole (Q2) using a collision energy of 30–35 eV, and mass-analyzed in the third quadrupole (Q3). Both the Q1 and Q3 were tuned to unit resolution, and the mass spectra were obtained in the profile mode. Typically, a 1-min period of signal averaging was employed for scanned spectra, and 1 to 10 min was employed for tandem mass spectra. The product-ion spectra of the [M + Li]<sup>+</sup> ion of PC and the [M – H]<sup>–</sup> ions of PE and PI were used for the structural assignments of the phospholipid species (19,20).

**Statistics.** Results are given as means ± SEM. Statistical analyses were performed using ANOVA. Results from binding experiments were statistically analyzed using the Mann–Whitney U test.

**RESULTS**

**Plasma FFA, TG, glycerol, and catecholamine concentrations.** As shown in Table 1, after a 48-h intravenous lipid infusion, there was a fourfold increase in plasma FFA concentration as well as a twofold increase in plasma glycerol. As heparin was infused with the intralipid emulsion, thus stimulating lipoprotein-lipase activity, the level of TG remained similar to that of control rats throughout the lipid infusion. There was a 60% reduction in plasma NE in IL rats as compared to control rats. Plasma glucose and insulin were similar in all rats.

**TABLE 1**  
**Time Course of Plasma TG, FFA, Glycerol, and NE Concentrations During Lipid Intravenous Infusion<sup>a</sup>**

	Infusion time (h)		
	0	24	48
TG (mg/L)	0.92 ± 0.11	1.04 ± 0.16	1.10 ± 0.31
FFA (μM)	311 ± 35	1012 ± 173**	1222 ± 119**
Glycerol (μM)	0.32 ± 0.06	0.61 ± 0.10**	0.68 ± 0.29**
NE (ng/L)	1.53 ± 0.12	1.17 ± 0.10*	0.63 ± 0.07**

<sup>a</sup>Values are mean ± SEM. \*P < 0.05; \*\*P < 0.01, significantly different from time 0. NE, norepinephrine.

**Effect of lipid infusion on in vivo GIIS.** The *in vivo* time course of plasma insulin concentrations are depicted in Figure 1. At time 0, plasma insulin was similar in both groups. After glucose injection, insulin level was significantly higher at all time points in lipid-infused compared to control rats. Changes in glucose concentration were similar in both groups (data not shown).

**Pancreatic NE turnover.** We found a significant reduction of the endogenous pancreatic stores (control: 419 ± 3 ng; IL: 293 ± 4 ng; Table 2) as well as a 28% decrease in turnover rate of NE in the pancreas of IL rats as compared to control rats (control: 63.2 ± 0.5 ng/h; IL: 45.5 ± 0.6 ng/h), with no significant changes in NE half-life.

**Islet and β-cell α<sub>2</sub> adrenoceptor binding characteristics.** The 48-h intravenous lipid infusion resulted in a threefold decrease in sonicated islet α<sub>2</sub> adrenoceptor number (control: 38.8 ± 7.6 fmol/mg of proteins vs. 13.9 ± 2.2 fmol/mg of proteins in IL rats; Fig. 2A) and a twofold decrease in whole β-cell binding sites number (control: 112.3 ± 26.8 fmol/10<sup>6</sup> cells; IL: 61.3 ± 10.9 fmol/10<sup>6</sup> cells; Fig. 3A). The dissociation constant (K<sub>d</sub>) is significantly reduced in IL rats compared to controls, thus reflecting a higher affinity, as measured on islet homogenates (control: 2.53 ± 0.41 nM; IL: 0.51 ± 0.19 nM; Fig. 2B) as well as on whole isolated β-cells (control: 1.22 ± 0.37 nM; IL: 0.24 ± 0.08 nM; Fig. 3B).

**β-Cell α<sub>2A</sub> adrenoceptor mRNA concentration.** Using competitive quantitative RT-PCR, we found no difference in the concentration of α<sub>2A</sub> adrenoceptor mRNA between IL and control rats (data not shown).

**FIG 1.** Time course of plasma insulin during glucose-induced insulin secretion after intravenous lipid infusion. Control rats (○) and IL (●) rats. Values are mean ± SEM. \*\*\*P < 0.001, significantly different from control rats. IL, Intralipid-infused, where IL is supplied by KabiVitrum (Stockholm, Sweden).

**TABLE 2**  
Pancreatic NE Levels ( $NE_0$ ), Fractional Turnover Constants ( $k$ ), and Turnover Rates<sup>a</sup> (TR)

	$NE_0$ (ng)	$k$ ( $h^{-1}$ )	TR (ng/h)
Control	419 ± 3	0.151	63.2 ± 0.5
IL	293 ± 4**	0.156	45.5 ± 0.6**

<sup>a</sup>Values are mean ± SEM. \*\* $P < 0.01$ , significantly different from control rats. IL, Intralipid-infused rats. Intralipid source: KabiVitrum (Stockholm, Sweden).

**Islet phospholipid composition.** There was no significant difference in PC and PI relative intensities in islets of IL rats compared to controls (data not shown). In PE species, we found a significant 47% elevation in the relative intensity of palmitoyl-oleoyl-PE (POPE: 16:0/18:1 and 18:1/16:0; control rats: 8.8 ± 1.3%; IL rats: 16.5 ± 1.3%, Fig. 4) and a 28% increase in stearyl-linoleyl-PE (18:0/18:2; control rats: 24 ± 0.9%; IL rats: 33.5 ± 3.2%, Fig. 4).

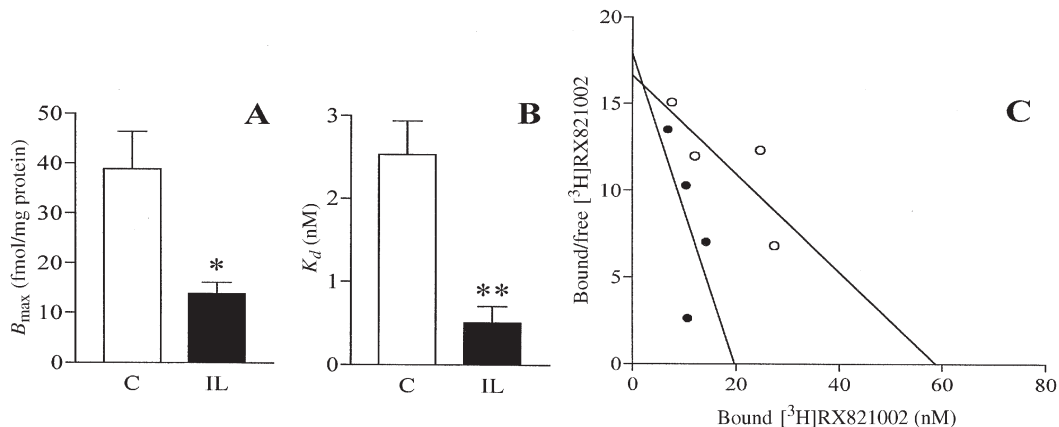

## DISCUSSION

Our aim was to understand how lipids induced islet catecholamine hypersensitivity. In this study, we report that a

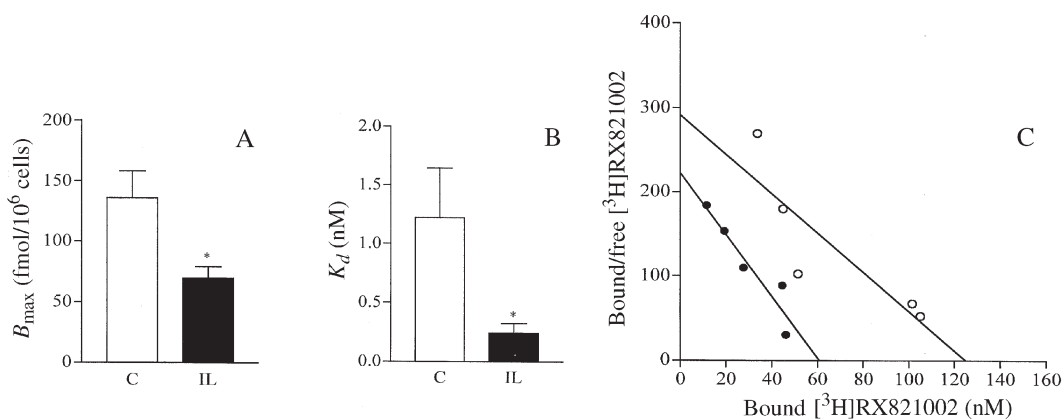

48-h increase in plasma FFA alters the binding characteristics of  $\beta$ -cell  $\alpha_2$  adrenoceptors.

We confirmed that a 48-h lipid infusion leads to an increased GIIS (4). We had previously established that this was partly the result of a reduced sympathetic nervous activity, as measured at the cervical sympathetic ganglion level (4). Consequently, plasma NE concentrations were significantly lower in IL rats, reflecting changes in global sympathetic nervous activity. To assess local changes in sympathetic firing rates, we measured pancreatic NE turnover rate and found a 28% reduction following lipid infusion. Thus, the attenuation in sympathetic activity was also found at the level of the pancreas, concordant with the increased GIIS in IL rats (4). A similar reduction in pancreatic NE turnover was described in diet-induced and genetically obese rats (8,21–23), suggesting that changes in pancreatic catecholamine content may therefore be a consequence of the main metabolic abnormality related to obesity, i.e., chronic elevation of plasma FFA concentration.

Using radioligand binding assay, we showed that hyperlipidemia induced a fivefold decrease in  $\beta$ -cell  $\alpha_2$  adrenoceptor dissociation constant ( $K_d$ ), reflecting an enhanced affinity for the radioligand. Because  $\alpha_{2A}$  adrenoceptors are the pre-

**FIG. 2.** Islet  $\alpha_2$  adrenoceptor characteristics after intravenous lipid infusion. (A) Maximal binding; (B) dissociation constant ( $K_d$ ); (C) Scatchard representation: control (C) rats (○) and IL rats (●). Values are mean ± SEM. \* $P < 0.05$ ; \*\* $P < 0.01$ , significantly different from control rats. [<sup>3</sup>H]RX821002, a benzodioxane derivative that exhibits high affinity for  $\alpha_2$ -adrenergic receptors; for other abbreviation see Figure 1.

**FIG. 3.**  $\beta$ -Cell  $\alpha_2$  adrenoceptor characteristics after intravenous lipid infusion. (A) Maximal binding; (B) dissociation constant ( $K_d$ ); (C) Scatchard representation: C rats (○) and IL rats (●). Values are mean ± SEM. \* $P < 0.05$ , significantly different from control rats. For abbreviations see Figures 1 and 2.

**FIG. 4.** Islet phospholipid composition after intravenous infusion. Percentage of relative intensity of *m/z* 700 (16:0/18:1 and 18:1/16:0) and 742 (18:0/18:2) PE species in isolated islets from C (open bars) and IL rats (solid bars). Values are mean ± SEM. \**P* < 0.05, \*\**P* < 0.01, significantly different from controls.

dominant form of β-cell α<sub>2</sub> adrenoceptors, this result could also account for the islet hypersensitivity to oxymetazoline in IL rats (4). Other studies have demonstrated that hyperlipidemia is associated with a higher adrenoceptor sensitivity (24). The lower pancreatic NE stores may account for the higher β-cell α<sub>2A</sub> adrenoceptor affinity in IL rats, since ligand depletion stabilizes high-affinity forms of the receptor, as shown in ventromedial hypothalamic nucleus-lesioned rats (25). However, we cannot exclude a direct effect of FFA on the pancreatic β-cell, as shown in other cell types (24). High extracellular lipid levels can alter the FA profile of membranes, changing membrane fluidity, as shown both *in vivo* (26) and *in vitro* (27). It is established that changes in receptor lipid environment change G-protein-coupled receptor ligand affinity (28), and this may be enhanced in adrenoceptors where the ligand binding site is a hydrophobic region located inside the plasma membrane. Our evidence suggests that intravenous lipid infusion changes islet phospholipid content. Particularly, we found an increase in phosphoethanolamine species containing infused FA such as palmitate (10% of the infused emulsion), oleate (23%), stearate (4%), and linoleate (53%). Such changes may be partly responsible for the increased β-cells' α<sub>2A</sub> adrenoceptor affinity in hyperlipidemic rats.

Another important result in our study is the threefold decrease in the number of islet α<sub>2</sub> adrenoceptor binding sites in IL rats, as compared to controls. The α<sub>2A</sub> adrenoceptor being the predominant α<sub>2</sub> subtype in pancreatic β-cells (29), these changes likely reflect modifications in islet α<sub>2A</sub> adrenoceptors. We measured α<sub>2</sub> adrenoceptor binding sites on whole β-cells and found a similar decrease. The lower number of α<sub>2A</sub> adrenoceptors was particularly surprising considering the reduction in pancreatic NE content in these rats, which, in normal physiological states, is coupled to an upregulation of adrenoceptors (30). However, several other studies have described a similar defect in α<sub>2</sub> adrenoceptor regulation in response to NE release in obesity-related states (21,31,32). Par-

ticularly, Levin (21,31) found that in hypothalamic nuclei of obesity-prone rats, both α<sub>2</sub> adrenoceptor number and NE turnover were decreased when compared to obesity-resistant rats.

The α<sub>2A</sub> adrenoceptor mRNA concentration in isolated β-cells is not attenuated in IL rats, as shown using quantitative competitive RT-PCR. Thus, we conclude that lipids affect islet adrenoceptor density by acting at the posttranslational level. One hypothesis is receptor palmitoylation, which is a dynamic process regulating α<sub>2A</sub> adrenoceptor function (33). In favor of this hypothesis, we found that IL rat islets display a higher islet POPE content, reflecting a greater palmitate availability for receptor palmitoylation. α<sub>2A</sub> adrenoceptors contain a potential site for palmitoylation, i.e., Cys 442, in the carboxyterminal region. It is now established that α<sub>2A</sub> adrenoceptor downregulation is palmitoylation-dependent (34). Receptor downregulation may thus occur in response to lower catecholamine levels than in controls, resulting in a reduced α<sub>2A</sub> adrenoceptor number with no concomitant increase in NE pancreatic content. These results, although preliminary, suggest that hyperlipidemia may alter β-cell signal transduction pathways, explaining the defective islet response to regulators such as NE, as described in other hyperlipidemic models (21,31).

Lower pancreatic sympathetic output and α<sub>2A</sub> adrenoceptor number may account for enhanced GIIS in IL rats. In addition, the higher α<sub>2A</sub> adrenoceptor affinity may explain the pancreatic hypersensitivity to oxymetazoline. As shown in humans in the very early stages of obesity, sympathetic tone is low and, as reported here, may be associated with islet hypersensitivity to catecholamine (35). Later, if the sympathetic tone were to increase, as is the case in obese individuals, such a hypersensitivity would become deleterious for pancreatic function and would account for the abnormal GIIS in obese, prediabetic subjects. The lipid-related changes in islet catecholamine receptor and metabolism reported here provide new insights into the perturbations of islet responsiveness to glucose due to chronic elevation of FFA concentration.

## ACKNOWLEDGEMENTS

We would like to thank Géraldine Bienvenu (INSERM U515, Paris, France; director: Professor Yves le Bouc) and the rest of the staff for their helpful technical support.

**ABSTRACT:** Separation of phospholipid classes in lipid extracts from the scallop *Pecten maximus*, the Pacific oyster *Crassostrea gigas*, and the blue mussel *Mytilus edulis* was conducted using HPLC. An isolated polar lipid fraction was found to contain a very high level of DHA, up to 80 mol% of the total FA. MS with electrospray ionization in the positive-ion mode, tandem MS (MS-MS) and multidimensional NMR spectroscopy were used to analyze the detailed chemical structure of this polar lipid fraction. The isolated fraction contained exclusively cardiolipin (CL) molecules, predominantly in a form with four docosahexaenoyl chains (Do<sub>4</sub>CL). To the best of our knowledge, this is the first time that such a CL form has been analytically characterized and described in these three bivalve species. This tetradocosahexaenoic CL is presumed to reflect a specific adaptation in bivalves that enhances the structural and functional mechanisms of biomembranes in response to variations in environmental conditions (temperature, salinity, emersion).

Paper no. L8989 in *Lipids* 37, 507–514 (May 2002).

In a previous study, we described a polar lipid fraction containing a high amount of DHA (22:6n-3) ester residue from the scallop *Pecten maximus* (1). By analyzing the polar lipid composition of larvae and male and female gonads of *P. maximus*, the specific composition of this fraction was confirmed (2–4). It was also demonstrated that though the 22:6n-3 level changed slightly with dietary modification (2,3), the overall

22:6n-3 FA molar percentage was maintained between 60 and 90 mol% of the total FA of the fraction. However, based on the retention times of standards obtained from the HPLC, the isolated fraction, initially designated as GLY, was not directly related to any of the less common phospholipid classes [PA, phosphatidylglycerol (PG); cardiolipin (CL), and glycolipids] that eluted nearby (1). Furthermore, attempts using HPLC and high-performance TLC (HPTLC), methods commonly utilized for lipid identification (5,6), produced contradictory results and failed to clearly identify this DHA-rich lipid class. As this point, we propose two hypotheses: (i) marine bivalves contain an unidentified polar lipid class, and (ii) the high DHA content of this lipid class changes the chromatographic retention time, thus leading to a previous mistaken identification. To clearly elucidate the molecular structure of this compound, further purification and use of conventional spectroscopic methods are required. MS is usually used in combination with NMR spectroscopy to determine molecular structure of purified unknown compounds (7,8). The recent development of “soft” ionization techniques for MS, such as electrospray ionization (ESI), provides the advantage of characterizing a wider variety of biological compounds including phospholipids (9,10). Particularly, the negative-ion mode ESI–MS system gives information about the molecular weight of the acyl constituents (10). Additionally, the positive-ion mode ESI+/MS is known to provide more information on the nature of the glycerol backbone (9). NMR has also been proven to be a valuable additional approach for the determination of structure and configuration of the core of some glycolipids and phospholipids (11,12). The present paper reports (i) the isolation and characterization of a previously described DHA-rich lipid fraction employing HPLC, HPTLC, and GC, and (ii) the determination of the structure and purity of this DHA-rich compound by the combination of ESI+/MS and ESI+/tandem MS (ESI+/MS-MS) in the positive-ion mode with NMR. The putative functions of this phospholipid in marine bivalves are also discussed.

## MATERIALS AND METHODS

**Materials.** Mammalian CL standard (MamCL) [CL from bovine heart, with four linoleoyl chains (L<sub>4</sub>CL) content

Abbreviations: CL, cardiolipin, common name of diphosphatidylglycerol; DQF-COSY, double-quantum filter correlated spectroscopy; DG, diacylglycerol; DGDG, digalactosyldiacylglycerols; DorCL, docosahexaenoic-rich cardiolipin fraction; Do<sub>4</sub>CL, 1',3'-bis[1,2-didocosahexaenoyl-*sn*-glycero-3-phospho]-glycerol, cardiolipin with four docosahexaenoyl chains; also named tetradocosahexaenoic cardiolipin; Do<sub>3</sub>PCL, cardiolipin with three docosahexaenoyl and one palmitoyl chains; ESI, electrospray ionization; HMQC, heteronuclear multiple quantum coherence; HPTLC, high-performance thin-layer chromatography; L<sub>4</sub>CL, 1',3'-bis[1,2-dilinoleoyl-*sn*-glycero-3-phospho]-*rac*-glycerol, cardiolipin with four linoleoyl chains; M<sub>2</sub>PG, 1,2-dimyristoyl-*sn*-glycero-3-phosphoglycerol; M<sub>4</sub>CL, 1',3'-bis[1,2-dimyristoyl-*sn*-glycero-3-phospho]-*rac*-glycerol; MamCL, mammalian cardiolipin standard; MGDG monogalactosyldiacylglycerols; MS-MS, tandem MS; O<sub>2</sub>PA, 1,2-dioleoyl-*sn*-glycero-3-phosphoric acid; O<sub>4</sub>CL, 1',3'-bis[1,2-dioleoyl-*sn*-glycero-3-phospho]-*rac*-glycerol; P<sub>2</sub>PA, 1,2-dipalmitoyl-*sn*-glycero-3-phosphoric acid; PG, phosphatidylglycerol; SAPG, 1-stearoyl-2-arachidonoyl-*sn*-glycero-3-phosphoglycerol; TOF, time of flight.

>98%, sodium salt]; phosphatidic acids [di-oleic ( $O_2PA$ ) and di-palmitic ( $P_2PA$ )]; phosphatidylglycerols (PG) [stearic-arachidonic (SAPG) and dimyristic ( $M_2PG$ )]; glycolipid standards [monogalactosyldiacylglycerols (MGDG) and digalactosyldiacylglycerols (DGDG) (from whole wheat flour)] and PE (from bovine brain) were obtained from Sigma (St. Quentin Fallavier, France). CL standards (sodium salts) with four oleoyl ( $O_4CL$ ) and four myristoyl chains ( $M_4CL$ ) were obtained from Avanti Polar Lipids (Alabaster, AL). Boron trifluoride ( $BF_3$ , 10% by wt in methanol) was obtained from Supelco (St. Quentin Fallavier, France). Other described reagents and solvents were purchased from Merck (Darmstadt, Germany).

**Sample preparation and lipid extraction.** Adult *P. maximus* scallops were collected from the Bay of Brest in September 2000. The muscles of 10 individual scallops were removed and homogenized with a Danguomeau homogenizer at  $-180^\circ C$ . Lipid extraction was conducted on muscle homogenates according to the method described by Folch *et al.* (13). The organic phase containing total lipids was washed twice by addition of methanol/water as described by Nelson (14). Then 0.01 wt% BHT (antioxidant) was added, and the extract was stored at  $-20^\circ C$  under nitrogen. Total lipids were also extracted from whole body tissues of Pacific oyster (*Crassostrea gigas*) and blue mussel (*Mytilus edulis*) as indicated above (four individuals of each species collected from the Bay of Best in September 2000, were pooled and homogenized).

**Separation of polar lipids by silica gel microcolumn.** An aliquot of the lipid extracts was evaporated to dryness, and lipids were recovered with three washings of 500  $\mu L$  of  $CHCl_3/MeOH$  (98:2, vol/vol) and deposited at the top of a silica gel microcolumn [30  $\times$  5 mm i.d., packed with Kieselgel 60 (70–230 mesh, Merck) previously heated at  $450^\circ C$  and deactivated with 5 wt%  $H_2O$ ] (15). Neutral lipids were eluted with 10 mL of  $CHCl_3/MeOH$  (98:2, vol/vol). The polar lipid fraction was recovered with 15 mL of MeOH and stored at  $-20^\circ C$  for later phospholipid class separation by HPLC and FA composition analysis by GC.

**Isolation of DHA-rich CL fraction (DorCL) by silica gel liquid chromatography (LC) column.** To obtain high quantities of the DorCL fraction, an aliquot of *P. maximus* muscle lipid extract was evaporated to dryness, recovered with three washings of 1 mL of  $CHCl_3/MeOH$  (98:2, vol/vol), and deposited at the top of a silica gel column (40  $\times$  25 mm i.d., same packing as the one described above). The neutral lipids were first eluted with 160 mL of  $CHCl_3/MeOH$  (98:2, vol/vol), and then 160 mL of acetone was passed through the column to elute glycolipids. The DorCL fraction was recovered by rinsing the column with 160 mL of  $CHCl_3/MeOH$  (90:10, vol/vol). An aliquot of this isolated fraction was taken to determine the purity by HPLC and GC. The rest was further analyzed using NMR and MS.

**Separation of phospholipid classes and FA analysis.** Separation of the phospholipid classes was achieved, based on the method previously described (1), on a Waters (Milford, MA) HPLC system (UV detection at 206 nm). For a better identifi-

cation within the low-polarity phospholipid area, this method was modified as follows. Only the diol column (OH-bound silica gel column, Lichrosorb Diol 5  $\mu m$ , 250  $\times$  4 mm i.d.; Merck) was employed, and a binary mobile phase was used. A linear gradient of 15 min was performed from 100% solvent A (acetonitrile) to an 8:2 ratio of solvent A and solvent B (acetonitrile/methanol/phosphoric acid, 93:5:1.5, by vol). This solvent ratio was maintained for 5 min, and followed by a linear gradient to 100% solvent B in 10 min. The column was maintained on solvent B for 30 min, and then switched to 100% solvent A during 15 min to reactivate the column. Solvent flow rate was 1 mL/min. The DorCL fraction was identified, collected, and analyzed for FA composition using GC after transesterification ( $MeOH/BF_3$ ) (4).

**Characterization of DorCL isolated from LC by HPTLC.** HPTLC (Silica gel 60, 10  $\times$  10 cm; Merck) was pre-run with a mixture of hexane/diethyl ether (1:1, vol/vol). The plate was then dried and activated for 1 h at  $160^\circ C$ . First, the isolated DorCL fraction and phospholipid standards (SAPG, MamCL, PE, DGDG, and MGDG) were dissolved in chloroform/methanol (2:1, vol/vol), then deposited in separate lanes of the plate and developed with the solvent system methyl acetate/isopropanol/chloroform/methanol/3 M KCl (10:10:10:4:3.6, by vol). Second, to evidence the possible influence of the FA chain unsaturation on the chromatographic behaviors of CL and PG, equivalent concentrations of DorCL and lipid standards ( $M_4CL$ ,  $O_4CL$ , MamCL, SAPG,  $M_2PG$ ) were converted into a single salt form by dissolving them, in a solution of chloroform/methanol/1 M  $CaCl_2$  (65:25:3 by vol), before spotting them onto HPTLC plates. This approach eliminated the influence due to the cations with which acidic phospholipids are associated (5). Then they were developed using a solvent system containing the same cation (chloroform/methanol/0.5 M  $CaCl_2$ ; 65:40:4, by vol) to prevent any ion exchange during chromatography (5). To visualize the lipid bands, HPTLC plates were charred 20 min at  $160^\circ C$  after dipping in a solution containing 8% (by vol) orthophosphoric acid and 3% (by wt) cupric sulfate.

**ESI-MS.** ESI-MS analyses were performed on a high-resolution tandem mass spectrometer ZABSpec TOF (Micromass, Manchester, United Kingdom) with an EBE time of flight (TOF) geometry equipped with a micro-ESI source. High-resolution masses were obtained from ions of a known internal standard, polyethyleneglycol, added to the sample before injection. Mass measurement accuracy was usually less than 5 ppm. Mass spectra were obtained in the positive mode over the  $m/z$  range of 100 to 3,000 (ESI accelerating potential: +4.0 kV). All samples were dissolved in chloroform/methanol (1:1, vol/vol). This solvent mixture was found to give stable electrospray conditions and optimal parent quasi-molecular ion peaks. Samples were then continuously injected into the system at a flow rate of 10  $\mu L/min$  (0.3  $\mu L/min$  in nanospray mode) by a syringe pump. MS/MS of cardiolipins after ESI was obtained by passage of the mass-selected precursor ion in the TOF analyzer. Kinetic energy of ions before collision was 500 eV, and dissociation was induced through collision activation with methane gas.

**NMR spectroscopy.** All NMR analyzes were conducted on a Bruker DRX-500 Avance Spectrometer (Wissembourg, France) equipped with a triple inverse 5-mm  $^1\text{H}/\{^1\text{H}\}/^{13}\text{C}$  gradient probehead. The probe temperature was 298°K. Prior to analysis, lipid samples (DorCL and standards) were dissolved in  $\text{CDCl}_3/\text{CD}_3\text{OD}$  (1:2.5, vol/vol), except for MGDG, which was dissolved in  $\text{CDCl}_3$ . All samples were warmed and sonicated at about 30°C for about 5 min. 2-D NMR spectra were acquired with nonspinning samples with deuterium frequency locking.  $^1\text{H}$ - $^1\text{H}$  double-quantum filter correlated spectroscopy (DQF-COSY) and heteronuclear multiple quantum coherence (HMQC) were employed to assign signals and were performed according to standard pulse sequences with a delay of 60 ms. DQF-COSY and HMQC measurements on DorCL in the area 3.5–4.5 ppm were recorded by collecting 512 (F2)  $\times$  200 (F1) data points zero-filled to 512 (F1) using spectral width of 500 Hz (500 MHz) with a repetition time of 2 s.  $^1\text{H}$  and  $^{13}\text{C}$  NMR chemical shifts were expressed in ppm by reference to tetramethylsilane as external standard.

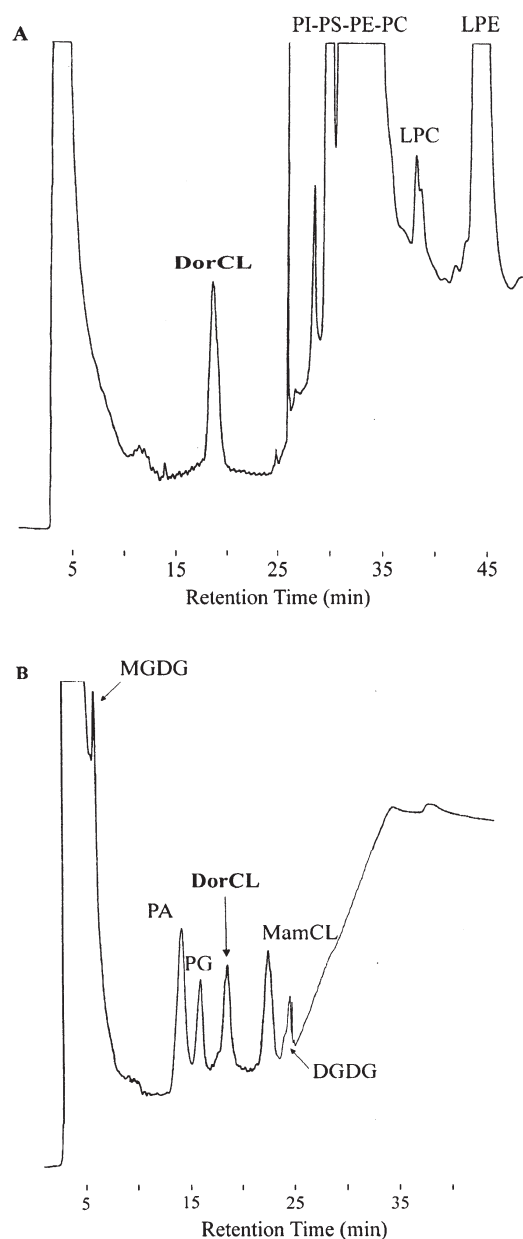

## RESULTS

**Analyzes of phospholipid classes by HPLC.** The previously unidentified DorCL peak eluted first, before all the identified phospholipid classes (Fig. 1A). Similar elution patterns were obtained when polar lipid fractions from the other two bivalve species, *C. gigas* and *M. edulis*, were analyzed. When the isolated DorCL fraction was co-injected with commercial phospholipid and glycolipid standards of similar polarity ( $\text{O}_2\text{PA}$ , SAPG, MamCL, MGDG, DGDG), it was eluted between the mammalian cardiolipin (MamCL) and PG (Fig. 1B).

**Analyzes of phospholipid classes by HPTLC.** HPTLC analysis of DorCL fraction together with the foregoing lipid standards also showed that the DorCL fraction had an  $R_f$  value 0.5 different from those lipid standards [SAPG (0.42); MamCL (0.45); PE (0.47); DGDG (0.57); MGDG (0.88)] (Fig. 2A). When the DorCL fraction and lipid standards (PG and CL with different unsaturation of acyl chains) were all converted to a single salt form prior to HPTLC analyses, results (Fig. 2B) revealed that elution differences existed between the CL standards and DorCL fraction, whereas SAPG and  $\text{M}_2\text{PG}$  were eluted together.

**FA composition of DorCL.** GC analysis of FAME derived from the isolated DorCL fraction of the three bivalve species showed a FA profile with 83–94 mol% of 22:6n-3 (DHA) (Table 1). Three other FA, 16:0, 22:5n-3 and 20:5n-3, are important minor components. The DorCL class contributed 0.6 to 1.0 mol% of the total phospholipids. In terms of polar lipids, 6.2 to 13.6 mol% of the total DHA content was found in the DorCL fraction.

**Isolation of DorCL by LC.** The proportion 90:10 (chloroform/methanol, vol/vol) was found to be the best solvent mixture to isolate the DorCL fraction for mass production. Although the controls [phospholipid standards: PA ( $\text{P}_2\text{PA}$ ,  $\text{O}_2\text{PA}$ ), PG ( $\text{M}_2\text{PG}$ , SAPG), and CL ( $\text{M}_4\text{CL}$ ,  $\text{O}_4\text{CL}$ , MamCL)] were found to elute using this solvent mixture, for all the

**FIG. 1.** HPLC separations of phospholipid classes. (A) Polar lipid extract of *Pecten maximus* muscle. (B) Co-injection of the isolated DHA-rich cardiolipin (DorCL) with standards of acidic phospholipids. Chromatographic conditions used are indicated in Materials and Methods section. LPC and LPE = 2-acyl-*sn*-glycero-3-phosphorylcholine and 2-acyl-*sn*-glycero-3-phosphorylethanolamine (resulting principally from the hydrolysis of plasmalogens by the mobile acid phase used); MGDG, monogalactosyldiacylglycerol; PA, phosphatidic acid; PG, phosphatidylglycerol; MamCL, mammalian cardiolipin standard; DGDG, digalactosyldiacylglycerol.
